Library of Congress Cataloging-in-Publication Data

Names: Ohshima, Hiroyuki, 1944– editor.
Title: Encyclopedia of biocolloid and biointerface science / edited by Hiroyuki Ohshima.
Description: Hoboken, New Jersey : John Wiley & Sons, Inc., 2016– | Includes index.
Identifiers: LCCN 2016004182 | ISBN 9781118542767 (set) | ISBN 9781118542682 (cloth : v. 1)
Subjects: LCSH: Biocolloids–Encyclopedias. | Biological interfaces–Encyclopedias. | Surface chemistry–Encyclopedias.
Classification: LCC QD549 .E53 2016 | DDC 547/.134503–dc23 LC record available at http://lccn.loc.gov/2016004182

CONTENTS

List of Contributors **xxiii**

Preface **xxix**

A

Aerogel

1 Studies On Biocompatible Surface-Active Silica Aerogel and Polyurethane−Siloxane Cross-Linked Structures for Various Surfaces **1**
K. Seeni Meera, R. Murali Sankar, S. N. Jaisankar, and Asit Baran Mandal

1.1 Introduction, 1
1.1.1 Silica Aerogel, 1
1.1.2 Ionic Liquids, 2
1.1.3 Polyurethane–Siloxane Cross-Linked Structures, 2
1.2 Experimental Section, 3
1.2.1 Preparation of Silica Aerogel Using Choline Formate, 3
1.2.2 Preparation of Polyurethane–Siloxane Cross-Linked Films, 3
1.2.3 Characterization, 4
1.3 Results and Discussion, 5
1.3.1 Results of Surface-Active Silica Aerogel, 5
1.3.2 Results of Polyurethane–Siloxane Cross-Linked Structures, 8
1.4 Conclusions, 12
Acknowledgment, 14
References, 14

Anesthetics

2 Interaction of Anesthetics with Globular Proteins **17**
Makoto Nishimoto, Michio Yamanaka, and Hitoshi Matsuki

2.1 Introduction, 17
2.2 Anesthetic Effect on FFL, 18
2.3 Anesthetic Effect on Mgb, Lys, and BSA, 22
2.4 Intrinsic Interaction Mode of an Anesthetic with Proteins, 29

2.5 Conclusions, 32
Acknowledgments, 33
References, 33

3 Lipid Monolayer and Interaction with Anesthetics 36
Yasushi Yamamoto and Keijiro Taga

3.1 Introduction, 36
3.2 Monolayer Formation, 36
3.2.1 Dipalmitoyl Phosphatidyl Choline (DPPC), 37
3.2.2 Dimyristoyl Phosphatidyl Choline (DMPC), 39
3.2.3 Cholesterol, 40
3.2.4 DPPC and Cholesterol Mixture, 41
3.2.5 Usefulness of Dropping Method, 44
3.3 Interaction between Lipid Monolayer and Anesthetics, 44
3.3.1 Quartz Crystal Oscillator (QCO) Method, 45
3.3.2 Apparatuses and Procedure, 46
3.3.3 Time Course of Frequency (QCM) and Resistance (QCI), 48
3.3.4 Concentration Dependence of Frequency (QCM) and Resistance (QCI), 49
3.3.5 True Anesthesia Phenomenon, 56
Acknowledgment, 56
References, 57

Atomic Force Microscopy

4 Atomic Force Microscopy for Measuring Interaction Forces in Biological Materials and Cells 59
Naoyuki Ishida, Yasuyuki Kusaka, Tomonori Fukasawa, and Hiroyuki Shinto

4.1 Introduction, 59
4.2 Measurement of Interaction Forces Using AFM, 60
4.3 Interaction of Model Membranes, 61
4.4 Interaction of Proteins, 62
4.5 Interaction of Cells, 63
4.6 Concluding Remarks, 65
References, 65

B

Bacterial Interaction

5 Bacterial Interactions 68
Masanori Toyofuku, Yosuke Tashiro, Tomohiro Inaba, and Nobuhiko Nomura

5.1 Introduction, 68
5.2 Gram-Positive and Gram-Negative Bacteria, 68
5.3 Cell–Cell Communication in Bacteria, 69
5.3.1 Cell–Cell Communication in Gram-Negative Bacteria, 69
5.3.2 Cell–Cell Communication in Gram-Positive Bacteria, 71
5.3.3 A Common Language for Gram-Negative and Gram-Positive Bacteria: AI-2, 71
5.4 Membrane Vesicles, 72
5.4.1 Components of MVs, 72
5.4.2 Biological Roles of MVs, 73

5.4.3 Surface Characteristics of MVs, 73
5.4.4 Future Perspectives in MV Research, 74
5.5 Biofilm Formation, 74
5.5.1 Surface-Attached Biofilms, 75
5.5.2 Bacterial Aggregates, 76
5.6 Concluding Remarks, 77
References, 77

Biocompatible Polymer

6 2D and 3D Biocompatible Polymers for Biomedical Devices 82
Masaru Tanaka

6.1 Introduction, 82
6.2 Biocompatible Polymeric Biomaterials, 82
6.3 Protein Adsorption on Polymeric Biomaterials, 83
6.4 Water Structure of Polymers, 84
6.5 3D Polymer Surfaces for Tissue Engineering, 85
6.6 Methods of 3D Polymer Fabrication, 86
6.6.1 Top–Down Fabrication, 86
6.6.2 Bottom–Up Fabrication, 86
6.7 Control of Cell Adhesion and Functions, 88
6.8 Conclusions and Perspectives, 90
Acknowledgments, 91
References, 91

Biofilm

7 Biofilm 94
Hisao Morisaki

7.1 Introduction, 94
7.2 Formation Process of Biofilm, 94
7.3 Biofilm Constituents, 95
7.3.1 Substratum Surface, 95
7.3.2 Biofilm Microbes, 96
7.3.3 Extracellular Polymeric Substances (EPSs), 97
7.3.4 Interstitial Water among EPSs, 98
7.4 Biofilm and Surrounding Environment, 99
7.4.1 Influence of Surrounding Environment on Biofilm, 99
7.4.2 Influence of Biofilm on Surrounding Environment, 99
7.5 Present and Prospective Biofilm Research, 100
References, 101

Bioflotation

8 Use of Microorganisms for Complex ORE Beneficiation: Bioflotation as an Example 108
Akira Otsuki

8.1 Introduction, 108
8.2 Characterization of Complex Ores, 108
8.2.1 Mineral Analysis in Dry State, 108
8.2.2 Mineral/Particle Analysis in Water, 109
8.2.3 Mixture of Complementary Analyses, 111

8.2.4 Refractory Gold Ore Beneficiation, 111
8.2.5 Sulfide Flotation Using a Microorganism as a Flotation Reagent, 111
8.3 Summary, 116
References, 116

Biofouling

9 Biofouling **118**
Kazuho Nakamura

9.1 Definition of Biofouling, 118
9.2 Formation of Biofilms, 118
9.3 Biofouling in Industries, 118
9.3.1 Biofouling in Heat Exchangers, 119
9.3.2 Biofouling of Medical Devices, 119
9.3.3 Biofilms in Wastewater Treatment Processes, 120
9.3.4 Biofouling in Membrane Processes, 121
References, 121

Bio-inspired Microemulsion

10 Bioinspired Microemulsions and Their Strategic Pharmacological Perspectives **122**
Soumik Bardhan, Kaushik Kundu, Gulmi Chakraborty, Bidyut K. Paul, Satya P. Moulik, and Swapan K. Saha

10.1 Introduction, 122
10.2 A Brief Outline of Microemulsion Systems, 123
10.2.1 Types of Microemulsion Systems, 124
10.2.2 Role of Surfactant in Formation of Microemulsions, 124
10.2.3 Role of Cosurfactant in Formation of Microemulsions, 124
10.2.4 Role of Oil in Formation of Microemulsions, 125
10.2.5 Solubilization in Microemulsions, 125
10.2.6 Characterization of Microemulsions, 125
10.2.7 Stability of Microemulsions, 125
10.3 Design Strategy for Bioinspired Microemulsion Systems, 126
10.3.1 Selection of Ingredients, 126
10.3.2 Types of Bioinspired Microemulsions, 127
10.3.3 Decisive Factors for Pharmaceutical Applications, 129
10.4 Recent Advances in Bioinspired Microemulsions in Pharmaceutical Science, 129
10.4.1 Microemulsions as in Vitro Drug Delivery Systems, 129
10.4.2 Microemulsions as in Vivo Drug Delivery Systems, 131
10.4.3 Microemulsions in Cancer Therapy, 132
10.4.4 Microemulsions in Biotechnology, 133
10.4.5 Antimicrobial Activity of Microemulsions, 134
10.4.6 Biocompatible Ionic Liquid Microemulsions in Drug Delivery and Biotechnology, 135
10.4.7 Patents in Microemulsion Drug Delivery Systems, 136
10.5 Biocompatibility and Toxicity Issues, 137
10.6 Future Outlook, 138
Acknowledgment, 138
References, 138

Biomaterial

11 Development of Nonfouling Biomaterials **145**

Ruey-Yug Tsay and Toyoko Imae

11.1 Introduction, 145
11.2 Why Nonfouling is Relevant in Biomaterials, 145
11.2.1 Antithrombogenesis and Anti-inflammatory Response, 145
11.2.2 Host Response to Biomaterials, 146
11.2.3 Antibacterial Property, 147
11.3 Protein Adsorption and Material Properties, 148
11.3.1 Adsorption Mechanism of Protein, 148
11.3.2 Protein–Surface Interactions, 148
11.3.3 Surface Hydration, 149
11.3.4 Strategies for Nonfouling Design, 149
11.4 Nonfouling Biomaterials, 150
11.4.1 Surface Immobilization Techniques, 151
11.4.2 Nonionic Hydrophilic Materials, 153
11.4.3 Zwitterionic Materials, 154
11.4.4 Amphiphilic Materials, 156
11.5 Conclusions and Future Perspectives, 157
References, 157

12 Surface Characterization of Silver and Fe_3O_4 Nanoparticles Incorporated into Collagen-based Scaffolds as Biomaterials for Tissue Regeneration: State-of-the-Art and Future Perspectives **161**

Abhishek Mandal, N. Chandrasekaran, Amitava Mukherjee, and Thothapalli P. Sastry

12.1 Introduction, 161
12.2 Structural Information, 163
12.2.1 SDS-PAGE Analysis, 163
12.2.2 Circular Dichroism (CD) Studies, 164
12.2.3 Differential Scanning Calorimetry (DSC), 165
12.2.4 X-Ray Diffraction (XRD), 166
12.3 Chemical Information, 167
12.3.1 Fourier Transform Infrared (FT-IR) Spectroscopy, 167
12.3.2 X-Ray Photoelectron Spectroscopy (XPS), 168
12.4 Morphological Information, 171
12.4.1 Scanning Electron Microscopy (SEM), 171
12.4.2 Atomic Force Microscopy (AFM), 173
12.5 Conclusions and Future Perspectives, 175
Acknowledgment, 175
References, 175

Biomimetics

13 Biomimetic Polymer Aggregates: Self-Assembly Induced by Chemical Reactions **181**

Eri Yoshida

13.1 Introduction, 181
13.2 Self-Assembly Induced by Electron Transfer, 181
13.2.1 Oxidation-Induced Self-Assembly, 182
13.2.2 Reduction-Induced Self-Assembly, 184
13.2.3 Disproportionation-Induced Self-Assembly, 184

13.3 Self-Assembly Induced by Irreversible Photoreactions, 186
13.3.1 Photolysis-Induced Self-Assembly, 188
13.3.2 Photo-Claisen Rearrangement-Induced Self-Assembly, 189
13.3.3 Photoelectron Transfer–Induced Self-Assembly, 190
13.4 Conclusions, 191
References, 191

14 Molecular Interaction in Biomimetics and Biosystems: Chirality and Confinement at Nanodimension 195
Nilashis Nandi and Saheb Dutta

14.1 Introduction, 195
14.2 Methods of Theoretical Calculation, 198
14.3 Chiral Discrimination in Biomimetic Monolayers, 198
14.4 Experimental Studies on Chiral Discrimination in Peptide Synthesis and Aminoacylation Reaction, 199
14.5 Computational Analysis of Chiral Discrimination in Aminoacylation Reaction, 202
14.6 Computational Studies of the Chiral Discrimination in Peptide Bond Formation Reaction, 204
14.7 Concluding Remarks, 206
Acknowledgments, 207
References, 207

Biosensing

15 Softinterface on Biosensing 211
Yukichi Horiguchi and Yukio Nagasaki

15.1 Introduction, 211
15.2 Advantages of Suppressing the Nonspecific Adsorption on a Surface by PEGylation, 212
15.3 Peg Chain Behavior on Surfaces, 212
15.4 Functionalization of PEG End for PEGylation on Surface, 214
15.5 Hybrid Immobilization of PEG with Ligand Molecules, 215
15.6 Conclusion, 217
References, 217

Bioseparation

16 Bioseparation Using Thermoresponsive Polymers 220
Kenichi Nagase and Teruo Okano

16.1 Introduction, 220
16.2 Thermoresponsive Chromatography with Hydrophobic Interactions, 220
16.3 Thermoresponsive Chromatography with Electrostatic Interactions, 222
16.4 Thermoresponsive Chromatography Using Volume Exclusion Effect of PIPAAm, 224
16.5 Thermoresponsive Chromatography for High-Speed Separation, 226
16.6 Thermally Modulated Cell Separation Using PIPAAm, 227
16.7 Conclusions, 228
Acknowledgment, 229
References, 229

Biosurfactant

17 Biosurfactants **231**
Etsuo Kokufuta

17.1 Introduction, 231
17.2 Classification, 231
17.3 Chemical and Physical Properties, 239
17.4 Applications, 242
References, 243

Blood-brain Barrier

18 Structure and Regulation of the Blood–Brain Barrier **244**
Yung-Chih Kuo, Chin-Lung Lee, and Jyh-Ping Hsu

18.1 Introduction, 244
18.2 Cellular System of the BBB, 244
18.2.1 Tight Junctions, 244
18.2.2 Neurovascular Unit, 245
18.2.3 BMECs, 245
18.2.4 Astrocytes, 245
18.2.5 Pericytes, 246
18.3 In Vitro BBB Model, 246
18.3.1 Primary Culture, 247
18.3.2 Coculture, 247
18.4 ABC Transporters in the BBB, 247
18.4.1 Mechanism of ABC Transporters, 247
18.5 Secreted Factors for BBB Regulation: Mechanism and Inhibitor, 247
18.5.1 TGFβ1, 248
18.5.2 VEGF, 248
18.5.3 MMP-9, 248
18.6 Nanoparticles for Delivering Pharmaceuticals Across the BBB, 248
Acknowledgments, 250
Abbreviations, 250
References, 250

Boron Tracedrug

19 Boron Tracedrugs as Theranostic Agents for Neutron Dynamic Therapy **255**
Hitoshi Hori and Hiroshi Terada

19.1 The Real Crisis for Twenty-First-Century Medicinal Chemists in Pharmaceutical Industries and Academia, 255
19.2 Boron Tracedrugs as a Challenge to Traditional Drug Design Methodology, 255
19.3 Boron Tracedrugs for Neutron Dynamic Therapy (NDT), as Physician-Friendly Tools, 257
19.4 Conclusions, 258
Acknowledgment, 259
References, 259

C

Carbohydrate

20 Carbohydrates as Biocolloids in Nanoscience **260**
Zaheer Khan, Shokit Hussain, Ommer Bashir, and Shaeel Ahmed Al-Thabaiti

20.1 Introduction, 260
20.2 Types of Biocolloids, 261
20.3 Properties, 262
20.4 Carbohydrates in Nanoscience, 262
References, 265

Cartilage

21 High-Strength Poly(Vinyl Alcohol) Hydrogels for Artificial Cartilage **269**
Atsushi Suzuki and Teruo Murakami

21.1 Introduction, 269
21.2 Fundamental Properties of Physical PVA Gels, 270
21.2.1 Network Structure: Swelling Ratio and Crystallinity, 270
21.2.2 Conditions for Starting Raw Materials, 271
21.3 Typical Examples of Physical PVA gels: Preparations and Mechanical Properties, 272
21.3.1 Swelling Ratio and Compression Stress, 273
21.3.2 Tearing Energy by a Trouser Tear Test, 274
21.3.3 Dynamic Friction Coefficient and Wear Ratio, 274
21.4 Mechanical Strengthening and Future Visions, 276
Acknowledgment, 277
References, 277

22 Superior Tribological Behaviors of Articular Cartilage and Artificial Hydrogel Cartilage **278**
Teruo Murakami and Atsushi Suzuki

22.1 Introduction, 278
22.2 Various Lubrication Modes in Natural Synovial Joints, 278
22.3 Biphasic Lubrication in Natural Synovial Joints, 280
22.4 Boundary Lubrication in Natural Synovial Joints, 282
22.5 Lubrication Modes in Artificial Joints, 284
22.6 Frictional Behaviors of Artificial Hydrogel Cartilage, 285
22.6.1 Artificial Cartilage, 285
22.6.2 Articular Cartilage, 286
22.7 Biphasic Finite-Element Analyses for Artificial Hydrogel Cartilage, 286
22.8 Boundary Lubrication in Freeze-Thawing PVA Hydrogel, 287
22.9 Superior Tribological Behavior of Artificial Hydrogel Cartilage, 288
22.10 Conclusion, 289
Acknowledgment, 289
References, 289

Cell Mimicking Vesicle

23 Self-Assembled Cell-Mimicking Vesicles Composed of Amphiphilic Molecules: Structure and Applications **292**
Swati De and Ranju Prasad Mandal

23.1 Introduction, 292

23.2 Principles of Vesicle Formation, 292
23.2.1 Parameters, 292
23.3 Classical Vesicles, 295
23.3.1 Classification, 295
23.3.2 Dynamic Processes Occurring in Vesicles, 295
23.3.3 Formation of Vesicles, 296
23.4 Novel Vesicular Systems–Going Beyond Lipids, 300
23.4.1 Niosomes, 301
23.4.2 Ethosomes, 301
23.4.3 Transferosomes, 301
23.4.4 Sphingosomes, 301
23.4.5 Pharmacosomes, 302
23.4.6 e-Liposomes, 302
23.4.7 Polymerosomes, 302
23.4.8 Catansomes, 302
23.5 Vesicle Characterization Techniques, 303
23.5.1 Morphology, 303
23.5.2 Size Distribution, 303
23.5.3 Membrane Thickness, Lamellarity, and Fluidity, 303
23.5.4 Zeta-Potential and Surface Properties, 304
23.5.5 Stability, 304
23.5.6 Entrapment Efficiency, 304
23.5.7 In Vitro Release Study, 304
23.5.8 pH Sensitivity Assessment, 304
23.6 Applications of Vesicles, 304
23.6.1 Drug Delivery, 304
23.6.2 Cosmetic Applications, 305
23.6.3 As Self-Assembled Nanoreactors, 305
23.6.4 As Organized Assemblies for Fluorescence-Based Studies, 306
23.7 Future Perspectives and Directions of Research on Vesicles, 307
Acknowledgments, 307
References, 308

Cell Regulation

24 Integrin-Dependent Cell Regulation and its Clinical Application 313
Takuya Iyoda, Takuya Matsunaga, and Fumio Fukai

24.1 Introduction, 313
24.2 Inactivation of β1-Integrin by FNIII14 Increases Chemosensitivity of Acute Myelogenous Leukemia (AML) Cells, 314
24.3 Forced Adhesion to Fibronectin Through Sustained Activation of β1-Integrin by TNIIIA2 Caused Apoptosis in Hematopoietic Tumor Cells, 317
24.4 TNIIIA2-Induced Activation of β1-Integrin Enhances Intracellular Drug Accumulation in Hematopoietic Tumor Cells, 318
24.5 TNIIIA2-Mediated β1-Integrin Activation Accelerates Erythroid Differentiation of Hematopoetic Tumor Cells, 320
24.6 TNIIIA2-Mediated β1-Integrin Activation Leads Deregulated Hyperproliferation to Nontransformed Fibroblastic Cells, 320
24.7 Concluding Remarks, 321
References, 323

Chitosan

25 Depth Profile of Kr^+-Irradiated Chitosan **325**
Kazunaka Endo

25.1 Introduction, 325
25.2 Computational Method, 325
25.3 Experimental Method, 326
25.4 Results and Discussion, 326
25.4.1 Raman Shift Spectral Analysis, 327
25.4.2 Valence Band X-Ray Photoelectron Spectral Analysis, 328
25.5 Conclusion, 329
References, 330

26 Electronic Structure of Chitosan **331**
Kazunaka Endo

26.1 Introduction, 331
26.2 Experimental Method, 331
26.3 Theoretical Background, 332
26.3.1 NMR Chemical Shielding Tensor, 332
26.3.2 XPS, 332
26.4 Calculations, 332
26.4.1 NMR Chemical Shielding Tensor, 332
26.4.2 XPS, 333
26.5 Results and Discussion, 333
26.5.1 ^{13}C-NMR Chemical Shielding Tensor, 333
26.5.2 XPS, 336
26.6 Conclusion, 337
References, 338

Collagen Matrix

27 Aligned Fibrillar Collagen Matrices **340**
Ralf Zimmermann, Jens Friedrichs, Babette Lanfer, Uwe Freudenberg, and Carsten Werner

27.1 Introduction, 340
27.2 Shear Flow Deposition of Collagen Matrices, 341
27.2.1 Fibers in Shear Flow, 341
27.2.2 Experimental Approach, 341
27.2.3 Possible Mechanism of Fibril Alignment, 347
27.2.4 Comparison with Other Methods, 347
27.3 Collagen Self-Alignment on Mica, 347
27.3.1 Directing Collagen Self-Assembly into Ultrathin Matrices, 347
27.3.2 Adjusting the Collagen Matrix Density by pH Change, 348
27.3.3 Role of Electrolytes in Determining Final Collagen Matrices, 349
27.3.4 Structural Features of Self-Assembled Collagen Fibrils Resembling in Vivo Fibrils, 349
27.3.5 Reshaping Collagen Matrices on Nanoscale, 349
27.3.6 Collagen Matrices Showing Enhanced Stability after Maturation, 350
27.3.7 Insight into Collagen Self-Assembly through Time-Lapse AFM, 350
27.4 Summary, 352
Acknowledgment, 352
References, 352

Colloidal Crystallization

28 Colloidal Crystallization **355**

Tsuneo Okubo

28.1 Introduction, 355
28.2 Preparation and Characterization of Biological and Synthetic Colloidal Particles, 356
28.2.1 Biological Colloidal Particles, 356
28.2.2 Polymer Colloidal Particles, 356
28.2.3 Inorganic Colloidal Particles, 357
28.2.4 Basic Characteristics of Colloidal Particles, 358
28.3 Why Crystal Structures Form, 358
28.4 Morphology and Phase Diagram of Colloidal Single Crystals, 359
28.5 Lattice Structure of Colloidal Crystals, 360
28.6 Alloy Crystals of Colloidal Mixtures, 361
28.7 Colloidal Crystallization Kinetics, 361
28.8 Static and Dynamic Light Scattering and Small-Angle Neutron Scattering, 362
28.9 Structural Relaxation Times of Colloidal Crystals, 363
28.10 Rigidity of Colloidal Crystals, 364
28.11 Viscosity and Viscoelasticity of Colloidal Crystals, 365
28.12 External Field Effects on Colloidal Crystals, 365
28.13 Colloidal Crystallization in Microgravity, 367
28.14 Two-Dimensional Colloidal Crystals, 367
28.15 Biological Colloidal Crystals, 368
28.16 New Colloidal Crystal Systems, 368
28.17 Miscellaneous, 369
28.18 Application of Colloidal Crystals, 369
28.19 Concluding Remarks, 370
References, 370

D

Dielectric Property

29 Dielectric Properties of Biological Macromolecules and Biomolecule–Water Interfaces **380**

Brandon Campbell, Lin Li, and Emil Alexov

29.1 Background, 380
29.2 Macromolecular Dynamics and Its Effect on the Macromolecular Interior and Molecular Surface, 381
29.2.1 Thermal Fluctuations of Atoms, Amino or Nucleic Acids, or Entire Domains, 381
29.2.2 Conformational Changes Induced by Macromolecular Function, 381
29.2.3 Intrinsically Disordered Macromolecules, 382
29.2.4 Conformational Changes Caused by a Change in Environment Due to pH or Salt Concentration, 383
29.3 Water Molecule Dynamics and Its Effect on Protein Interior and Molecular Surface, 383
29.4 Modeling Macromolecular Interior and Macromolecule–Water Interfaces, 384
29.5 Role of Ions, 384

29.6 Dielectric Properties of Biological Macromolecules and Biomolecule–Water Interfaces, 384
29.7 Concluding Remarks, 386
Acknowledgments, 386
References, 386

Drug Delivery

30 NMR of Drug Delivery Coupled with Lipid Membrane Dynamics 391
Emiko Okamura

30.1 Introduction, 391
30.2 Dynamics of Membranes as a Platform of Vital Functions, 391
30.2.1 Diffusion, 392
30.2.2 Protrusion, 394
30.3 Drug Delivery Related to Membrane Dynamics, 394
30.3.1 Diffusion of Drugs in the Membrane, 395
30.3.2 Kinetics of Membrane Binding and Dissociation, 396
30.3.3 Thermodynamic Stability, 399
30.3.4 Dynamic Binding Probability, 399
30.3.5 Effect of Cholesterol, 400
30.4 Concluding Remarks and Future Perspectives, 400
Acknowledgments, 401
References, 401

31 Stimulus-Responsive Intelligent Drug Delivery System Based on Hydroxyapatite-Related Materials 403
Makoto Otsuka

31.1 Introduction, 403
31.2 Slow Drug Release from Self-Setting Apatite Cements, 403
31.3 Effect of Calcium Level on in Vitro Drug Release from Apatite Cement, 404
31.4 Calcium-Level-Responsive Drug Release of Apatite Cements Containing Antiosteoporosis Drug in Healthy and Diseased Rats and Therapeutic Effects, 404
31.5 Drug Delivery System Containing VK2 Based on Self-Setting Apatite/Collagen Composite Cements (AC), 406
31.6 Biodegradation of the AC Block with Interconnecting Pores as a Skeletal Bone Cell Scaffold, 407
31.7 Drug Release from Biodegradable Apatite/Collagen Composite Cements with Interconnective Macropores, 408
31.8 In Vitro Bone Cell Activity–Responsive Drug Release from Biodegradable Apatite/Collagen Bone Cell Scaffold with Interconnective Macropores, 408
31.9 In Vivo Bone Cell Activity–Responsive Deoxyribonucleic Acid (DNA) Release from Injectable Self-Setting Apatite Cement and Application to Gene Therapy, 409
Acknowledgments, 411
References, 411

Drying Structure

32 Drying Structure 412
Tsuneo Okubo

32.1 Introduction, 412

32.2 Convectional Patterns, 413
32.3 Sedimentation Patterns, 416
32.4 Drying Patterns of Colloidal Dispersions and Colloidal Crystals, 417
32.5 Drying Patterns of Polymer Gel Spheres, 419
32.6 Drying Patterns of Synthetic and Biological Polymers, 421
32.7 Drying Patterns of Ionic and Neutral Surfactants, 423
32.8 Drying Patterns of Simple Electrolytes, 424
32.9 Drying Patterns of Other Solutes, 424
32.10 Transferring Information on Solutions and Suspensions Toward the Drying Patterns, 424
32.11 Miscellaneous, 426
32.12 Concluding Remarks, 426
References, 427

E

Electrophoretic Mobility

33 Electrophoretic Mobility of Colloidal Particles 430
Hiroyuki Ohshima

33.1 Introduction, 430
33.2 Smoluchowski's, Hückel's, and Henry's Equations, 430
33.3 General Theory of the Electrophoretic Mobility of Spherical Hard Particles, 431
33.4 Relaxation Effect, 433
33.5 Electrophoretic Mobility of Soft Particles, 435
References, 437

Electrostatic Interaction

34 Electrostatic Interaction Between Colloidal Particles 439
Hiroyuki Ohshima

34.1 Introduction, 439
34.2 Interaction Between Hard Particles, 439
34.2.1 Interaction between Two Parallel Plates: Low-Potential Case, 439
34.2.2 Derjaguin's Approximation for Calculation of Interactions between Two Spheres or Cylinders, 440
34.2.3 Low-Potential Case, 440
34.2.4 Linear Superposition Approximation: Arbitrary Potential Case, 441
34.3 Interaction Between Soft Particles, 443
34.4 Interaction Between Two Soft Particles After Contact, 444
34.4.1 Two-Stage Model, 444
34.4.2 Three-Stage Model, 446
34.5 Electrostatic Interaction Between Two Interpenetrating Soft Particles, 448
34.5.1 Linearized Poisson–Boltzmann Equations for Two Interacting Charged Porous Spheres, 448
References, 449

Emulsion

35 Physicochemical Properties and Clinical Applications Of Surfactant-Free Emulsions Prepared with Electrolytic Reduction Ion Water (ERI) 451
Ken-ichi Shimokawa and Fumiyoshi Ishii

35.1 Introduction, 451

35.2 Preparation and Physicochemical Properties of Surfactant-Free Emulsions Prepared with ERI Containing Magnesium Aluminum Silicate, 453
35.3 Effects of Electrolytic Reduction Ion Water (ERI) Lotion Prepared with Surfactant-Free Emulsions on Burn Wound Healing (Case Report), 456
References, 457

Enzyme Membrane

36 Steady-State Coupling in Enzyme Membrane 459
Kazuo Nomura

36.1 Introduction, 459
36.2 Theoretical Background, 459
36.3 Results and Discussion, 462
36.3.1 Membrane Permeation across the Ionomer Membrane, 462
36.3.2 Immobilization of Enzyme, 463
36.3.3 Hydrolysis of 4-Nitrophenylphosphate across Immobilized Enzyme Membrane, 463
36.3.4 Degree of Coupling between Reaction Rate and Diffusional Flux in the Enzyme Membrane System, 464
36.3.5 Quantity of Immobilized Acid Phosphatase, 466
References, 468

Exosome

37 Evaluation of Zeta-Potential of Individual Exosomes Secreted from Biological Cells Using a Microcapillary Electrophoresis Chip 469
Takanori Akagi and Takanori Ichiki

37.1 Introduction, 469
37.2 Exosome Preparation, 469
37.3 Electrophoresis System for Exosomes, 470
37.4 Relation Between Zeta-Potentials of Exosomes and Their Originating Cells, 470
37.5 Effect of Sialidase on the Zeta-Potential of Exosomes, 472
37.6 Conclusion, 473
References, 473

F

Flocculation Dynamics

38 Flocculation Dynamics on the Basis of Collision-Limited Analysis 474
Yasuhisa Adachi

38.1 Introduction, 474
38.2 Population Balance Equation, 474
38.3 Brownian Coagulation, 475
38.3.1 Collision Process under Brownian Motion, 475
38.3.2 Smoluchowski Solution, 476
38.3.3 Self-Similar Solution, 477
38.3.4 Effect of Fractal Structure of Flocs on Flocculation Rate, 478
38.4 Coagulation in Shear Flow, 479
38.4.1 Collision Frequency in Shear Field, 479

38.4.2 Interaction between Colloid Particles in Laminar Shear Flow, 480
38.4.3 Effect of Formation of Floc Structure on Shear Coagulation Rate, 480
38.5 Initial Stage of Bridging Flocculation in a Turbulent Mixing, 481
38.5.1 Schematic Picture of Flocculation with Polymer Flocculants in a Practical System, 481
38.5.2 Collision Process in Turbulent Flow, 481
38.5.3 Historical Review of Concept of Nonequilibrium Flocculation, 483
38.5.4 Initial-Stage Dynamics of Bridging Flocculation of PSL Particles Induced by Polyelectrolytes under High Ionic Strength, 484
38.6 Conclusion and Future Perspectives, 485
Acknowledgment, 485
References, 485

G

Gel

39 Anisotropic Gel Formation Induced by Dialysis **487**
Toshiaki Dobashi and Takao Yamamoto

39.1 Introduction, 487
39.2 Dialysis-Induced Gelation, 487
39.2.1 Boundary Conditions, 487
39.2.2 Birefringence of Dialysis-Induced Gel, 488
39.2.3 Trigger for Gelation, 489
39.2.4 Dynamics of Gelation, 489
39.3 Theoretical Treatment of Analysis of Dialysis-Induced Gelation, 489
39.3.1 Dynamics of Gelation Induced by a Cross-Linking Agent, 490
39.3.2 Dynamics of Gelation Induced by pH Change, 493
39.3.3 Dynamics of Gelation Accompanied by Transition in Mechanism, 496
39.3.4 Dynamics of Gelation Induced by Dual Mechanisms, 496
39.4 Applications of Dialysis-Induced Anisotropic Gels, 497
References, 497

40 Gels **498**
Etsuo Kokufuta

40.1 Introduction, 498
40.2 Outline of Volume Phase Transition (VPT), 498
40.3 Theories of VPT, 500
40.4 Understanding VPT at the Molecular Level, 503
40.5 Effects of Distribution of Ionic or Hydrophilic Monomer Units Within the Network, 505
40.6 Effects of COIL-TO-HELIX Transition in Polypeptide Gels, 507
40.7 Effects of Surfactant Binding, 507
40.8 Network Inhomogeneity and Swelling–Shrinking Kinetics, 510
40.9 Microgels, 511
40.10 Conclusions, 512
References, 512

41 Gel Crystals **514**
Tsuneo Okubo

41.1 Introduction, 514
41.2 Gel Spheres used for Type I Gel Crystals, 517

41.3 Phase Diagram and Morphology of Type I Gel Crystals, 518
41.4 Lattice Structure of Type I Gel Crystals, 519
41.5 Kinetics of Type I Gel Crystallization, 521
41.6 Role of Electrical Double Layers on Type I Gel Crystallization, 522
41.7 Rigidity of Type I Gel Crystals, 523
41.8 Type II Gel Crystals, 524
41.9 Type III Gel Crystals, 524
41.10 Type III Gel Crystallization of Gel Agglomerates During Dryness, 524
41.11 Conclusions and Future Perspectives, 524
References, 526

Gemini Surfactant

42 Oleic Acid-Based Surfactants as Cost-Effective Gemini Surfactants 529
Kenichi Sakai and Masahiko Abe

42.1 Introduction, 529
42.2 Syntheses and Molecular Structures, 529
42.3 Dilute Aqueous Solution Properties, 530
42.4 Temperature–Concentration Phase Behavior with Water, 533
42.5 Characterizing Insoluble Monolayer Films Formed at the Air–Water Interface, 535
42.6 Adsorption Characteristics at Solid–Aqueous Solution Interfaces, 535
42.7 Concluding Remarks, 537
References, 537

43 Synthesis and Properties of Heterocyclic Cationic Gemini Surfactants 539
Avinash Bhadani, Sukhprit Singh, Hideki Sakai, and Masahiko Abe

43.1 Introduction, 539
43.2 Pyridinium Gemini Surfactants, 539
43.3 Imidazolium Gemini Surfactants, 547
43.4 Pyrrolidinium Gemini Surfactants, 552
43.5 Piperidinium Gemini Surfactants, 552
References, 553

H

Hydrogel

44 Functional Hydrogel Microspheres 554
Daisuke Suzuki, Takuma Kureha, and Koji Horigome

44.1 Introduction, 554
44.2 Microgel Synthesis, 554
44.3 Microgel Characterization, 556
44.4 Functional Microgels, 558
44.4.1 Hybrid Microgels, 558
44.4.2 Janus Microgels, 558
44.4.3 Oscillating Microgels, 560
44.5 Concluding Remarks, 567
References, 567

Hydrophilic-Lipophilic Balance

45 Hydrophilic–Lipophilic Balance (HLB): Classical Indexation and Novel Indexation of Surfactant **570**

Yuji Yamashita and Kazutami Sakamoto

45.1 Introduction, 570
45.2 Calculations of HLB Number, 570
45.3 Practical Side of HLB Theory, 572
45.4 Evaluation of Hydrophilicity and Lipophilicity, 572
45.5 TLC Evaluation of Amino Acid-Derived Surfactants, 573
45.6 Conclusions, 574
References, 574

LIST OF CONTRIBUTORS

Masahiko Abe, Department of Pure and Applied Chemistry, Faculty of Science and Technology, Tokyo University of Science, Chiba, Japan

Yasuhisa Adachi, Faculty of Life and Environmental Science, University of Tsukuba, Ibaraki, Japan

Silvia Ahualli, Department of Applied Physics, School of Sciences, Campus Fuentenueva, University of Granada, Granada, Spain

Takanori Akagi, Department of Bioengineering, Graduate School of Engineering, University of Tokyo, Bunkyo-ku, Tokyo, Japan

Md. Sayem Alam, Council of Scientific and Industrial Research (CSIR)—Central Leather Research Institute (CLRI), Industrial Chemistry Laboratory, Adyar, Chennai, India

Emil Alexov, Computational Biophysics and Bioinformatics, Physics Department, Clemson University, Clemson, South Carolina, United States

Shaeel Ahmed Al-Thabaiti, Department of Chemistry, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia

S. Angayarkanny, CSIR—Central Leather Research Institute (CLRI), Adyar, Chennai, India

Stefano Angioletti-Uberti, Department of Physics, Humboldt University Berlin, Berlin, Germany

Kenji Aramaki, Graduate School of Environment and Information Sciences, Yokohama National University, Hodogaya-ku, Yokohama, Japan

Makoto Aratono, Department of Chemistry, Faculty of Sciences, Kyushu University, Higashi-ku, Fukuoka, Japan

Rajat Banerjee, Department of Biotechnology and Dr. B.C. Guha Centre for Genetic Engineering and Biotechnology, University of Calcutta, Kolkata, India

Victor Banerjee, Department of Chemistry, Laboratory of Protein Chemistry, Bose Institute, Kolkata, West Bengal, India

Soumik Bardhan, Department of Chemistry, University of North Bengal, Darjeeling, India

Ommer Bashir, Department of Chemistry, Jamia Millia Islamia, Jamia Nagar, New Delhi, India

Geetha Baskar, CSIR—Central Leather Research Institute (CLRI), Adyar, Chennai, India

Avinash Bhadani, Department of Pure and Applied Chemistry, Faculty of Science and Technology, Tokyo University of Science, Noda, Chiba, Japan

Marian Brestic, Institute of Soil and Water Conservation, Northwest A&F University, Yangling, China and Department of Plant Physiology, Slovak Agricultural University, Nitra, Slovak Republic

Brandon Campbell, Computational Biophysics and Bioinformatics, Physics Department, Clemson University, Clemson, South Carolina, United States

Félix Carrique, Department of Applied Physics II, School of Sciences, Campus Teatinos, University of Málaga, Málaga, Spain

Gulmi Chakraborty, Department of Chemistry, University of North Bengal, Darjeeling, India

N. Chandrasekaran, Centre for Nano-Biotechnology, School of Bio-Sciences and Technology, VIT University, Vellore 632014, Tamil Nadu, India

Sudeshna M. Chatterjea, Department of Biotechnology and Dr. B.C. Guha Centre for Genetic Engineering and Biotechnology, University of Calcutta, Kolkata, West Bengal, India

Aritra Chowdhury, School of Chemistry, University of Manchester, Manchester, United Kingdom

K.P. Das, Department of Chemistry, Bose Institute, Kolkata, West Bengal, India

Swati De, Department of Chemistry, University of Kalyani, Kalyani, West Bengal, India

Ángel V. Delgado, Department of Applied Physics, School of Sciences, Campus Fuentenueva, University of Granada, Granada, Spain

Kabir-ud-Din, Department of Applied Chemistry, Aligarh Muslim University, Aligarh, India

Toshiaki Dobashi, Graduate School of Science and Technology, Gunma University, Gunma, Japan

Saheb Dutta, Department of Chemistry, University of Kalyani, Kalyani, West Bengal, India

Kazunaka Endo, Division of Colloid and Interface Science, Research Institute for Science and Technology, Tokyo University of Science, Kagurazaka, Shinjuku-ku, Tokyo, Japan

Dotchi Exerowa, Institute of Physical Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria

Jens Friedrichs, Leibniz Institute of Polymer Research Dresden, Max Bergmann Center of Biomaterials Dresden, Dresden, Germany

Uwe Freudenberg, Leibniz Institute of Polymer Research Dresden, Max Bergmann Center of Biomaterials Dresden, Hohe Strasse 6, D-01069 Dresden, Germany; Technische Universität Dresden, Center for Regenerative Therapies Dresden, Tatzberg 47, 01307 Dresden, Germany

Keiji Fujimoto, The Center for Chemical Biology, School of Fundamental Science and Technology, Graduate School of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama, Japan

Fumio Fukai, Department of Molecular Patho-Physiology, Faculty of Pharmaceutical Sciences, Center for Drug Delivery Research, and Center for Physical Pharmacology, Research Institutes for Science and Technology, Tokyo University of Science, Noda, Chiba, Japan

Tomonori Fukasawa, Department of Chemical Engineering, Hiroshima University, Japan

Yuuka Fukui, The Center for Chemical Biology, School of Fundamental Science and Technology, Graduate School of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama, Japan

Makoto Gemmei-Ide, Department of Applied Chemistry, Graduate School of Science and Engineering, University of Toyama, Toyama, Japan

Masaki Goto, Department of Life System, Institute of Technology and Science, The University of Tokushima, Tokushima, Japan

Christof Gutsche, Department of Experimental Physics I, Leipzig University, Leipzig, Germany

Yusuke Hattori, Research Institute of Pharmaceutical Sciences, Musashino University, Shin machi, Nishitokyo, Tokyo, Japan

Hitoshi Hori, Department of Pharmacology, Faculty of Pharmaceutical Sciences, Niigata University of Pharmacy and Applied Life Sciences, Niigata, Japan and NDT Research Institute, Tokushima, Japan

Koji Horigome, Graduate School of Textile Science & Technology, Shinshu University, Ueda, Nagano, Japan

Li-Hsien Yeh, Department of Chemical and Materials Engineering, National Yunlin University of Science and Technology, Yunlin, Taiwan

Shoko Yokoyama, School of Pharmaceutical Sciences, Kyushu University of Health and Welfare, Miyazaki, Japan

Eri Yoshida, Department of Environmental and Life Sciences, Toyohashi University of Technology, Tempaku-cho, Toyohashi, Aichi, Japan

Zoya Zaheer, Department of Chemistry, Aligarh Muslim University, Aligarh, Uttar Pradesh, India

Ralf Zimmermann, Leibniz Institute of Polymer Research Dresden, Max Bergmann Center of Biomaterials Dresden, Dresden, Germany

PREFACE

The principal aim of this encyclopedia is to provide a physicochemical tool for interpreting various biological phenomena in terms of a language of colloid and interface science. The present book concentrates on subjects in the field of biocolloid and biointerface science, since there are already excellent encyclopedias on colloid and interface science available in the literature. This field is the youngest—but is becoming a very important—branch in the area in colloid and interface science. Actually, however, colloid and interface science has been closely related to biological science. Colloids, or more specifically, colloidal particles with diameters ranging from 1 to 1000 nm, which are one of the major subjects in colloid and interface science, can be found quite often in biological systems as biocolloids such as biological cells. Surfactant molecules, which are also one of the most important subjects in colloid and interface science, adsorb at interfaces between two immiscible media (e.g., water and oil), forming micelles and vesicles, which are a prototype of living cells. The Derjaguin–Landau–Verwey–Overbeek (DLVO) theory explains well the stability of colloidal suspensions in terms of the electrostatic and van der Waals interactions between the particles. In their book *Theory of Stability of Lyophobic Colloids*, Evert Verwey and Jan Overbeek, two of the founders of DLVO theory, stated that an ordered structure formed by tobacco mosaic viruses can be explained via DLVO theory.

This encyclopedia consists of 71 topics, which are ordered alphabetically. Each topic contains 1–4 review articles, so that there are a total of 89 review articles.

Finally, I would like to gratefully acknowledge the assistance provided by Ms. Anita Lekhwani, Senior Acquisitions Editor at John Wiley and Sons.

CONTENTS

List of Contributors **xxi**

Preface **xxvii**

I

Insulin

46 Insulin Fibrillation and Role of Peptides and Small Molecules in its Inhibition Process **575**

Victor Banerjee and K.P. Das

46.1 Introduction, 575
46.1.1 Protein Fibrillation, 575
46.1.2 Diseases Associated with Protein Fibrillation, 575
46.1.3 Fibrillation of Insulin, 576
46.2 Prevention of Insulin Fibrillation, 580
46.2.1 General Strategies to Prevent Insulin Fibrillation, 580
46.2.2 Peptide-Based Inhibitors of Insulin Fibrillation, 580
46.2.3 Small Molecule Inhibitors of Insulin Fibrillation, 585
46.3 Summary and Conclusion, 588
References, 588

Interfacial Water

47 Interfacial Water Between Charge-Neutralized Polymer and Liquid Water **592**

Hiromi Kitano and Makoto Gemmei-Ide

47.1 Introduction, 592
47.2 Polymer Film Systems, 592
47.3 Zwitterionic Polymer Brush System, 595
47.4 Amphoteric Polymer Brush System, 596
47.5 Conclusion, 596
References, 596

L

Langmuir Monolayer Interaction

48 Langmuir Monolayer Interaction of Perfluorooctylated Long-Chain Alcohols With Biomembrane Constituents **597**
Hiromichi Nakahara and Osamu Shibata

48.1 Introduction, 597
48.2 Thermal Properties of *F*8*Hm*OH, 597
48.3 Langmuir Monolayer Behavior of *F*8*Hm*OH, 598
48.4 Binary Monolayers of DPPC and *F*8*Hm*OH, 599
48.4.1 The π–A and ΔV–A Isotherms, 599
48.4.2 Excess Gibbs Free Energy, 599
48.4.3 Two-Dimensional Phase Diagram, 601
48.4.4 Brewster Angle Microscopy (BAM), 602
48.4.5 Fluorescence Microscopy (FM), 603
48.4.6 Atomic Force microscopy (AFM), 604
48.5 Miscibility of *F*8*Hm*OH With Lipids, 605
48.6 Conclusions and Perspectives, 606
References, 606

Latex

49 Affinity Latex **609**
Haruma Kawaguchi

49.1 Introduction, 609
49.1.1 Bioseparation, 609
49.1.2 Affinity Chromatography, 609
49.2 Immunolatex, 610
49.3 Materials Composing Affinity Latex, 610
49.3.1 Latex Particle as a Ligand Carrier, 610
49.3.2 Procedure for Binding Ligands to a Latex Particle Surface, 610
49.3.3 Binding Site of Ligand Molecule, 611
49.4 Comparison Between Affinity Column Chromatography and Affinity Latex, 611
49.5 Features of Affinity Latex, 611
49.5.1 Specific Base Sequence ssDNA-Carrying Affinity Latex, 611
49.5.2 Speedy Recovery of Target-Capturing Affinity Particles, 612
49.6 Novel Affinity Latex, 613
49.6.1 Capture and Cutting Affinity Latex, 613
49.6.2 Affinity Latex for the Detection of Telomerase, 613
49.7 Concluding Remarks and Future Prospects, 613
References, 613

50 Latex Diagnosis **614**
Haruma Kawaguchi

50.1 Introduction, 614
50.2 Materials Composing Immunolatex, 614
50.2.1 Antigen and Antibody, 614
50.2.2 Latex Particle, 614
50.3 Design of Immnolatex, 614
50.3.1 Hemagglutination, 614
50.3.2 Use of Latex Particle as Carrier of Immunocomponents, 615
50.3.3 Improvement of Immunolatex in Terms of Sensitization Mode, 615

50.4 Measurement of Agglutination, 616
50.4.1 Patterns of Agglutination Test, 616
50.4.2 Antigen Excess Zone, 617
50.5 Latex Diagnostics Independent from Agglutination, 617
50.6 Multiplex Assay Using Affinity Latex, 618
50.7 Concluding Remarks and Future Prospects, 618
References, 618

Light Scattering

51 Light Scattering and Electrophoretic Light Scattering of Biopolymers 619
Etsuo Kokufuta

51.1 Introduction, 619
51.2 Static Light Scattering, 619
51.3 Dynamic Light Scattering, 620
51.4 Electrophoretic Light Scattering, 623
51.5 Discussion and Conclusion, 624
References, 627

Line Tension

52 Impact of Line Tension on Colloidal Systems 628
Hiroki Matsubara, Takanori Takiue, and Makoto Aratono

52.1 Introduction, 628
52.2 Domains in Langmuir Monolayers, 628
52.3 Modification of Domain Line Tension, 630
52.4 Vesicles, 631
52.5 Line Tension at Wetting Transitions, 633
52.6 Particles at Liquid Surfaces, 636
52.7 Foam Films, 637
52.8 Summary, 639
References, 639

Lipid

53 Liquid Structures and Properties of Lipids 642
Makio Iwahashi

53.1 Introduction, 642
53.2 Comparison of Alcohols with Their Corresponding Fatty Acids in Their Aggregated Structures and Properties, 642
53.2.1 Density and Molar Volume, 642
53.2.2 Viscosity of Fatty Acids and Alcohols, 643
53.3 Aggregation Number of Alcohol and Stability of Fatty Acid Dimer, 645
53.3.1 Effect of Molecular Structure on Aggregation Number of Alcohol in CCl_4 and in Its Pure Liquid, 645
53.3.2 Stability of Fatty-Acid Dimers in CCl_4 and in the Pure Liquid State (Melt), 646
53.4 Intra- or Intermolecular Movements of Lipids, 647
53.4.1 Segmental Movements (Intramolecular Movements), 647
53.4.2 Intermolecular (Transfer) Movements and Apparent Hydrodynamic Radius for Alkane, Alcohol, Fatty Acid, and Fatty-Acid Ester, 649

53.5 Liquid Structures of Fatty Acids, 650
53.5.1 Fatty Acid Having a Longer Hydrocarbon Chain, 650
53.5.2 Fatty Acid Having a Medium Hydrocarbon Chain, 651
53.6 Effect of Cholesterol and Other Additives on the Cluster Structure and Properties of Oleic Acid, 652
53.7 Aggregated Structures and Properties of Acylglycerols, 655
53.7.1 Triacylglycerols, 655
53.7.2 Diacylglycerols, 655
53.7.3 Monoacylglycerol, 655
53.8 New Application of Fatty-Acid Esters, 656
53.8.1 Application of Fatty-Acid Ester as Insulating Oil in Transformers, 656
53.8.2 An Application of Fatty-Acid Ester for Hepatoma Operation Using a Microcatheter, 656
References, 658

Lipid Bilayer Membrane

54 Birefringence in Lipid Bilayer Membranes 661
Kiyoshi Mishima

54.1 Introduction, 661
54.2 Birefringence in Uniaxial Crystals, 661
54.3 Birefringence in Lipid Bilayers, 663
54.4 Interference with Birefringent Materials, 664
54.5 Birefringence Techniques for Analyzing Lipid Bilayer Membranes, 666
54.5.1 Dual-Polarization Interferometry (DPI), 667
54.5.2 Optical Waveguide Lightmode Spectroscopy (OWLS), 668
54.5.3 Coupled Plasmon–Waveguide Resonance (CPWR), 668
54.5.4 Polarized Transmitted Light Spectroscopy (PTL), 669
References, 672

Lipid Monolayer

55 Surface States of Lipid Monolayers Containing Gangliosides 674
Shoko Yokoyama

55.1 Introduction, 674
55.2 Experimental Materials, 674
55.3 Measurement of Surface Pressure, 674
55.4 Preparation of LB Film, 675
55.5 AFM Observation, 675
55.6 Results and Discussion, 675
55.6.1 Single System of Ganglioside Monolayer, 675
55.6.2 Binary System of Ganglioside–Phospholipid, 675
55.6.3 Ternary System of Ganglioside/DPPC/DOPC, 676
55.6.4 Ternary System of Ganglioside/DPPC/Chol, 679
55.6.5 Quaternary System of Ganglioside/DPPC/DOPC/Chol, 680
55.6.6 Five-Component System of Gangliosides/DPPC/DOPC/Chol, 681
55.7 Conclusion, 683
References, 683

Liponano-capsule

56 Liponanocapsule: A Nanocapsule Built From a Liposomal Template 684
Yuuka Fukui and Keiji Fujimoto

56.1 Introduction, 684
56.2 Multilayer Coating to Produce *Liponanocapsule*, 685
56.3 Release Behavior of Liponanocapsules, 685
56.4 Interaction of Liponano Capsules with Cells, 686
56.5 Assembly of Liponanocapsules to Create Freestanding Bioscaffold, 686
56.6 Coating with Minerals to Prepare Organic–Inorganic Hybrid Liponanocapsule, 687
56.7 Conclusions, 688
References, 688

M

Magnetic Suspension

57 Physical Phenomena of Magnetic Suspensions for Application to Bioengineering 690
Akira Satoh

57.1 Introduction, 690
57.2 Simulation Methods for Colloidal Suspensions, 691
57.2.1 Monte Carlo Method, 691
57.2.2 Brownian Dynamics Method for Axisymmetric Particles, 692
57.3 Surface Modification, 693
57.3.1 Magnetic Spherical Particle System, 693
57.3.2 Rodlike Particle System, 695
57.3.3 Disklike Particle System, 696
57.4 Sedimentation, 699
57.4.1 Introductory Remarks, 699
57.4.2 Particle Model and Simulation Method, 700
57.4.3 Results and Discussion, 700
57.5 Conclusion, 701
References, 702

Membrane Electrode

58 Ion-Sensing Membrane Electrodes in Study of Surfactant–Biopolymer Interaction 704
Sudeshna M. Chatterjea, Koustubh Panda, and Satya P. Moulik

58.1 Introduction, 704
58.2 Development of Surfactant Ion-Selective Electrodes (SISEs), 705
58.2.1 Liquid Membrane Electrodes (LMEs), 705
58.2.2 PVC-Based ISEs, 706
58.3 Study of Surfactant Biopolymer Systems Using SISEs, 710
58.3.1 Interactions between Ionic Surfactants and Biopolymers, 711
58.3.2 Kinetic Studies of Surfactant–Biopolymer Interactions Using SISEs, 714
58.4 Conclusion, 714
Acknowledgment, 715
References, 715

Membrane Potential

59 Membrane Potential as a Function of Dielectric Constant **721**
Akihiko Tanioka and Hidetoshi Matsumoto

59.1 Introduction, 721
59.2 Theoretical Background, 722
59.2.1 Donnan Potential, 722
59.2.2 Membrane Diffusion Potential, 723
59.2.3 Mean Activity Coefficient in Mixed Solvent–Salt Systems, 723
59.2.4 Membrane Potential, 723
59.2.5 Effective Membrane Charge Density, 723
59.2.6 Permeability Coefficient, 725
59.2.7 Mobility of Ions in a Membrane, 725
59.3 Materials and Experimental Procedures, 726
59.3.1 Materials, 726
59.3.2 Potentiometric Titration and Measurement of Equilibrium Water Content, 727
59.3.3 Membrane Potential Measurements, 727
59.3.4 Measurement of Modified Degree of Hydration, 727
59.3.5 Measurement of Permeability Coefficient, 727
59.4 Results and Discussion, 728
59.4.1 Organic Solution System, 728
59.4.2 Low-Water-Content System, 731
References, 734

Micellar Protein Alpha-crystalline

60 Biophysical Studies of a Micellar Protein α-Crystallin by Fluorescence Methods **737**
Aritra Chowdhury, Rajat Banerjee, and K.P. Das

60.1 α-Crystallin, 737
60.2 A Brief Introduction to Fluorescence in Proteins, 737
60.3 Challenges in Determining α-Crystallin Structure and Preliminary Structural Models Based on Micellar Architecture, 738
60.4 Hydrophobicity of α-Crystallin and Its Chaperone Function, 738
60.5 Effect of Temperature on Chaperone Function of α-Crystallin, 740
60.6 Identification of Chaperone Sites of α-Crystallin Using Hydrophobic Fluorophores, 741
60.7 Substrate Conformation Recognized by α-Crystallin: Comparison with Other Chaperones, 741
60.8 Subunit Exchange of α-Crystallin and Its Diverse Role, 743
60.9 Oligomeric Assembly and Unfolding of α-Crystallin, 746
60.10 Summary and Conclusions, 750
References, 751

Muscle Contraction

61 Modeling Muscle Contraction Mechanism in Accordance with Sliding-Filament Theory **753**
Toshio Mitsui and Hiroyuki Ohshima

61.1 Introduction, 753
61.2 Muscle Structures and the Sliding-Filament Theory, 753

61.3 Thermodynamic Relationship that any Models Based on Sliding-Filament Theory Should Fulfill, 754
61.3.1 Work Done by One Crossbridge Using ATP Hydrolysis energy, 755
61.3.2 Relation between p and T in Sliding-Filament Theory, 755
61.3.3 Thermodynamic Relationship, 756
61.3.4 Values of D/r Estimated from Literature Data, 757
61.4 Difficulties of the Power Stroke Model, 757
61.4.1 Difficulty Concerning Magnitude of r, 757
61.4.2 Values of r and D Estimated from Experimental Data, 757
61.5 Requirements for any Models Based on Sliding-Filament Theory, 758
61.6 Construction of a New Model, 758
61.6.1 Formation of Complex MA_3 by a Myosin Head and Three Actin Molecules, 758
61.6.2 Molecular Model for MA_3, 759
61.6.3 Cooperative Interaction among Crossbridges, 759
61.6.4 Chemical Reactions and Energy Liberation Associated with Force Production, 762
61.6.5 Role of Thermal Fluctuations, 763
61.7 Characteristics of the Model That are Helpful for Numerical Calculations, 763
61.7.1 Relation between p and T, 763
61.7.2 Cyclic Force Generation and Parameter y_c, 763
61.8 Comparison of Calculation Results with Experimental Data, 764
61.8.1 Existence Probability of Myosin Molecule in Wells in MA_3, 764
61.8.2 Steady Filament Sliding, 764
61.8.3 Transition Phenomena, 766
61.9 Summary and Discussion, 768
61.9.1 Requirements for Models, 768
61.9.2 Discussion, 769
References, 769

N

Nanocarrier

62 Nanocarriers of Functional Materials From Amino Acid Surfactants 771
Geetha Baskar, S. Angayarkanny, and Asit Baran Mandal

62.1 Introduction, 771
62.2 Self-Assembly and Aggregated Structures, 772
62.2.1 Self-Aggregated Structure Formation in Simple Amphiphiles, 772
62.2.2 Different Chemical Architectures in Surfactants, 773
62.3 Polymeric Amphiphiles, 774
62.3.1 Architectures and Formation of Self-Aggregated Structures in Polymeric Amphiphiles, 774
62.3.2 Self-Organisation in Graft Polymers and Other Polymeric Amphiphiles, 774
62.4 Amino Acid Surfactants, 775
62.4.1 Highlights of Unique Characteristics of Amino Acid Surfactants, 775
62.4.2 Types of Amino Acid Surfactants, 775
62.4.3 Self-Assembled Structure Formation in Amino Acid Surfactants, 776
62.4.4 Polymeric Amphiphiles from Amino Acids, 777
62.5 Polymeric Nanocarriers in Pharmaceutical and Other Applications, 778
62.5.1 Polymeric Nanoparticles, 779
62.5.2 Amino Acid Templates for Synthesis of Nanoparticles, 779

62.6 Summary, 780
Acknowledgments, 780
References, 780

Nanocolloid

63 Syntheses of Metallic Nanocolloids and the Quenching Abilities of Reactive Oxygen Species **784**
Yukihide Shiraishi and Naoki Toshima

63.1 Introduction, 784
63.2 Monometallic Nanocolloids, 785
63.2.1 Preparation of Monometallic Nanocolloids, 785
63.2.2 Characterization of Metallic Nanocolloids, 786
63.2.3 Application to Reactive Oxygen Species (ROS) Scavengers by Monometallic Nanocolloids, 786
63.3 Bimetallic Nanocolloids, 787
63.3.1 Preparation of Bimetallic Nanocolloids, 787
63.3.2 Application to ROS Species Scavengers by Bimetallic Nanocolloids, 788
Acknowledgments, 789
References, 789

Nanocomposite

64 Silver and Gold Nanocomposites: Amino Acid Sidechain Effect on Morphology **790**
Zoya Zaheer and Rafiuddin

64.1 Introduction, 790
64.2 Role of Sidechain, 791
64.3 Mechanism in the Formation of Silver Nanoparticles, 792
References, 796

Nanogel

65 Nanogel, an Internally Networked Poly(Amino Acid) Nanoparticle for pH-Responsive Delivery **799**
Jong-Duk Kim and Chan Woo Park

65.1 Introduction, 799
65.1.1 pH Sensitivity of Nanogels, 799
65.1.2 Modified Poly(amino acid)s, 800
65.2 Preparation of Poly(Amino Acid) Nanogels, 801
65.2.1 Physical Association, 801
65.2.2 Chemical Cross-Linking of Poly(amino acid)s, 801
65.2.3 Morphology of Nanogels prepared from Amphiphilic Polymers, 804
65.3 Structure and Characteristics of Nanogel, 805
65.3.1 Shape and Size, 805
65.3.2 Internal Structure, 806
65.3.3 Swelling of Nanogel, 808
65.4 pH-Responsive Nanogels, 808
65.4.1 pH-Sensitive Property of Nanogels, 808
65.4.2 pH-Responsive Release of Payloads from Nanogels, 809

65.5 Conclusions, 810
References, 810

Nanoparticle

66 Strategies of Metal Nanoparticles for Nanobiology 812
Daisuke Matsukuma and Hidenori Otsuka

66.1 Introduction, 812
66.2 Metal Nanoparticles, 812
66.2.1 Basic Key Aspects of Metal Nanoparticles for Nanobiology, 813
66.2.2 Noble Metal Nanoparticle, 813
66.2.3 Quantum Dots, 813
66.2.4 Magnetic Nanoparticles, 814
66.3 Bioconjugation of Metal Nanoparticles for Nanobiology, 814
66.4 Surface Modification of Metal Nanoparticles by Functional Polymers, 815
66.4.1 Natural Polymer Coating of Nanoparticles, 815
66.4.2 Synthetic Polymer Coating of Nanoparticles, 815
66.4.3 Structural Regulated Copolymer for Coating Agent, 816
66.5 Reducing Polymers Act as Dispersants for Nanoparticles, 817
66.6 Conclusion, 818
References, 818

O

On-chip Electrophoresis

67 On-Chip Electrophoresis for Evaluating Zeta-Potential of Nanoliposomes 821
Takanori Akagi and Takanori Ichiki

67.1 Introduction, 821
67.2 Nanoliposome Preparation, 821
67.3 Zeta-Potential Measurement System, 822
67.4 Calculation of Zeta-Potential of Liposomes, 822
67.5 Capillary Electrophoresis of Liposomes, 823
67.6 Conclusion, 824
References, 824

P

Phase Separation

68 Phase Separation in Phospholipid Bilayers Induced by Cholesterol 825
Nobutake Tamai, Masaki Goto, and Hitoshi Matsuki

68.1 Introduction, 825
68.2 Historical Background, 826
68.3 Solid–Liquid Phase Diagrams of Binary Mixtures, 827
68.4 Phase Transitions of C*n*PC–Cholesterol Binary Bilayers, 829
68.4.1 Prodan Fluorescence Spectra of Pure and Cholesterol-Containing CnPC Bilayers, 829
68.4.2 Characterization of Phase Transitions of CnPC–Cholesterol Binary Bilayers by DSC, 830
68.5 Phase Diagrams of C*n*PC–Cholesterol Binary Bilayers, 833

68.6 Acyl Chain Length Dependence of Characteristic Cholesterol Compositions, 836
68.7 Summary, 838
References, 838

69 Phase Separation Phenomena in Drug Systems 841
Andleeb Z. Naqvi and Kabir-ud-Din

69.1 Introduction, 841
69.2 Drug-DDS Interactions: Effect of Temperature on Solution, 842
69.2.1 Effect of pH/Concentration, 844
69.2.2 Effect of Electrolytes, 845
69.2.3 Effect of Urea/Thiourea, 846
69.2.4 Effect of Alcohols, 847
69.2.5 Effect of Amines, 848
69.2.6 Effect of Amino Acids, 848
69.2.7 Effect of Sugars, 849
69.2.8 Effect of Polymers, 850
69.2.9 Effect of Surfactants, 850
69.2.10 Effect of Fatty Acids (Sodium Salts), 852
69.2.11 Effect of Bile Salts, 852
69.2.12 Effect of Hydrotropes, 853
69.2.13 Effect of Cyclodextrins, 853
69.2.14 Effect of Phospholipids, 854
References, 854

Phosphatidylcholine

70 Bilayer Imaging of Phosphatidylcholines by High-Pressure Fluorometry 860
Masaki Goto, Nobutake Tamai, and Hitoshi Matsuki

70.1 Introduction, 860
70.2 Prodan Fluorescence Spectra, 860
70.2.1 Fluorescence Measurements, 860
70.2.2 Location of Prodan Distributed in PC Bilayer Membranes, 861
70.3 Factors Affecting the Packing State in the PC Bilayer, 862
70.3.1 Effect of Acyl Chain Length, 862
70.3.2 Effect of Vesicle Size, 863
70.3.3 Effect of Acyl Chain Asymmetry, 865
70.4 Packing State in the L_c Phase, 866
70.5 Conclusions, 868
Acknowledgments, 868
References, 868

Plant-responding Mechanism

71 Physiological and Molecular Aspects of Mechanisms Involved in Plant Response to Salt Stress 870
Xiaoli Tang, Xingmin Mu, Hongbo Shao, Hongyan Wang, and Marian Brestic

71.1 Introduction, 870
71.2 Growth and Photosynthesis, 871
71.3 Osmotic Stress Effects and Tolerance, 872
71.4 Ion Toxicity and Ion Homeostasis, 872
71.5 Oxidative Stress and Antioxidant Defense Responses, 875

71.6 Phytohormone in Salt Stress, 876
71.7 Conclusions, 876
Acknowledgments, 878
References, 878

Pulmonary Surfactant

72 Interfacial Phenomena of Pulmonary Surfactant Preparations 885
Hiromichi Nakahara, Sannamu Lee, and Osamu Shibata

72.1 Introduction, 885
72.2 Isotherm Behavior of the Lipids and Peptide, 886
72.3 Interaction Between the Lipids and Peptide, 888
72.4 Hysteresis in $\pi-A$ and $\Delta V-A$ Isotherms, 890
72.5 Morphological Phase Behavior, 891
72.5.1 Fluorescence Microscopy (FM), 891
72.5.2 Atomic Force Microscopy (AFM), 892
72.6 Polarized ATR-FTIR Spectra, 894
72.7 PM-IRRAS Spectra at the Air–Water Interface, 895
72.7.1 The in situ PM-IRRAS Spectra in the Amide Region, 895
72.7.2 Secondary Structure Transformation of Hel 13–5, 897
72.7.3 Lipid Stretching Vibration Modes, 898
72.8 Conclusions, 901
References, 902

73 Using Thin Liquid Film for Study of Pulmonary Surfactants 905
Dotchi Exerowa, Roumen Todorov, and Dimo Platikanov

73.1 Introduction, 905
73.2 Experimental Technique, 905
73.3 Physicochemical Properties Studied by the Thin Liquid Film Method, 907
73.4 Pulmonary Surfactants, 909
73.5 Method for Lung Maturity Assessment, 909
73.6 Foam Films from Pulmonary Surfactant and Its Components, 910
73.7 Thin Liquid Wetting Films from Pulmonary Surfactant Solutions, 912
73.8 Conclusion, 913
References, 913

R

Receptor-ligand Interaction

74 Probing Receptor–Ligand Interactions on a *Single* Molecule Level Using Optical Tweezers 915
Tim Stangner, Carolin Wagner, Christof Gutsche, Konstanze Stangner, David Singer, Stefano Angioletti-Uberti, and Friedrich Kremer

74.1 Introduction, 915
74.2 Methodology, 916
74.2.1 The Setup, 916
74.2.2 Trapping Basics and Force Calculation, 917
74.2.3 Position Detection in Three Dimensions, 917
74.2.4 Other Methods for Characterizing Receptor–Ligand Interactions, 920

74.3 Theoretical Description of Receptor–Ligand Interactions, 921
74.3.1 An Ideal Bond, 921
74.3.2 Force-Induced Bond Rupture: The Dudko—Hummer–Szabo Model, 922
74.4 Case Studies, 923
74.4.1 Measurement Procedure, 923
74.4.2 Ensuring Single Binding Events and Specificity, 924
74.4.3 Reducing the Data Variance in Dynamic Force Spectroscopy Measurements Using Presorted Particles, 924
74.4.4 Dynamic Force Spectroscopy on the Binding of Monoclonal Antibodies and τ-Peptides, 926
74.4.5 Determining the Specificity of a Monoclonal Antibody Using Dynamic Force Spectroscopy, 927
74.5 Conclusion, 929
References, 929

S

Soft Particle

75 AC Electrokinetics of Concentrated Suspensions of Soft and Hairy Nanoparticles: Model and Experiments 933
Silvia Ahualli, Ángel V. Delgado, Félix Carrique, and María Luisa Jiménez

75.1 Introduction, 933
75.2 Basic Equations, 934
75.2.1 General Overview and Notation Used, 934
75.2.2 The Case of Grafted Polymer: Spherical Polyelectrolyte Brushes (SPBs), 937
75.2.3 Expressions for Electrophoretic Mobility and Permittivity of the Suspension, 937
75.3 Some Predictions, 938
75.3.1 Soft Particles, 938
75.3.2 Brushlike Particles, 939
75.4 Experimental Verification, 941
75.4.1 Soft Particles, 941
75.4.2 Polyelectrolyte Brushes, 941
75.5 Conclusion, 943
Acknowledgment, 944
References, 944

76 Electrophoretic Behavior of pH-Regulated Soft Biocolloids 946
Li-Hsien Yeh and Jyh-Ping Hsu

76.1 Introduction, 946
76.2 Theoretical Model, 947
76.2.1 General Electrokinetic Equations, 947
76.2.2 Boundary Conditions, 948
76.2.3 Forces Acting on a Soft Particle, 948
76.2.4 Perturbation Approach, 949
76.3 Electrophoresis of a pH-Regulated Soft Biocolloid, 950
76.3.1 Governing Equations, 951
76.3.2 Boundary Conditions, 952
76.3.3 Solution Procedure, 952

76.3.4 Model Validation by Experimental Data, 953
76.3.5 Electrokinetics of a pH-Regulated Soft Biocolloid, 955
76.4 Summary, 956
76.5 Notations, 957
Greek Letters, 958
Superscripts, 959
Subscripts, 959
Prefix, 959
References, 959

77 Electrophoretic Mobility of Soft Particles 961
Kimiko Makino and Hiroyuki Ohshima

77.1 Introduction, 961
77.2 Electrophoretic Mobility of Hard Particles, 961
77.3 Electrophoretic Mobility of Soft Particles, 962
77.4 Analysis of Electrophoretic Mobility of Soft Particles, 965
77.4.1 RAW117 Lymphosarcoma Cells and Their Variants, 965
77.4.2 Poly(*N*-isopropylacrylamide) Hydrogel–Coated Latex, 966
77.5 Electrophoresis of Nonuniformly Charged Soft Particles, 967
References, 968

78 Potential Distribution Around a Hard Particle and a Soft Particle 970
Hiroyuki Ohshima

78.1 Introduction, 970
78.2 Hard Particles, 970
78.3 Soft Particles, 974
78.4 Discrete-Charge Effect, 975
References, 978

Soil

79 Soil Interfacial Electrical Phenomena 979
Munehide Ishiguro

79.1 Introduction, 979
79.2 Ion Transport in Soils, 979
79.2.1 Influence of Electric Charge on Ion Transport, 979
79.2.2 Influence of Selectivity Coefficient, Distribution Ratio, and Peclet Number on Ion Transport, 982
79.3 Soil Dispersion and Flocculation, 983
79.4 Influence of Dispersion on Soil Permeability, 985
79.5 Surfactant Adsorption, 988
79.6 Ion Exclusion and Salt Sieving, 991
References, 992

Solid-water Interface

80 Pharmaceutical Solid–Water Interface Phenomena Measured by Near-Infrared Spectroscopy 994
Yusuke Hattori and Makoto Otsuka

80.1 Introduction, 994
80.2 Exploration of Interface Phenomena Using Near-Infrared Spectroscopy, 995

80.2.1 Initial Dissolution of Compressed Solids, 996
80.2.2 Hydration and Swelling of Disintegrating Agents: Two-Dimensional Correlation Spectroscopy (2DCOS), 998
80.3 Conclusion, 1001
References, 1002

Stability

81 Colloid Stability of Biocolloidal Dispersions 1004
Tharwat Tadros

81.1 Introduction, 1004
81.2 Kinetic Stability of Biocolloidal Dispersion Systems and General Stabilization Mechanisms, 1004
81.2.1 Electrostatic Stabilization, 1004
81.2.2 Steric Stabilization, 1006
81.3 Nanoemulsions, 1007
81.3.1 Preparation of Nanoemulsions, 1008
81.3.2 Steric Stabilisation and Role of Adsorbed Layer Thickness, 1008
81.3.3 Ostwald Ripening, 1009
81.4 Nanobiodegradable Dispersions, 1010
81.5 Liposomes and Vesicles in Pharmaceuticals, 1011
References, 1013

82 Stability Ratio and Early-Stage Aggregation Kinetics of Colloidal Dispersions 1014
Hiroyuki Ohshima

82.1 Introduction, 1014
82.2 DLVO Theory of Colloid Stability and the Stability Ratio, 1014
82.3 Approximate Analytic Expressions for the Stability Ratio W, 1016
82.4 Rate Equations for Early-Stage Aggregation Kinetics of Colloidal Particles, 1017
82.5 Approximate Solution to the Rate Equation, 1018
References, 1019

Surfactant

83 Catanionic Surfactants: Novel Surrogates of Phospholipids 1020
Kausik Manna and Amiya Kumar Panda

83.1 Introduction, 1020
83.2 Classifications, 1021
83.3 Preparation and Isolation, 1029
83.3.1 Extraction Method, 1029
83.3.2 Precipitation Method, 1029
83.3.3 Ion Exchange Method, 1029
83.3.4 Evaporation Method, 1029
83.3.5 Proton Exchange Method, 1029
83.4 Characterization of Isolated IPA, 1029
83.4.1 ^{1}H-NMR Spectroscopy, 1029
83.4.2 FT-IR Spectroscopy, 1030
83.4.3 X-Ray Diffraction Study, 1030

83.5 Properties, 1031
83.5.1 Properties of Catanionic Surfactants as Functions of Composition and Concentration, 1031
83.5.2 Properties of Isolated IPA, 1035
83.6 Catanionic Micelles, 1036
83.7 Catanionic Vesicles: Catanosomes, 1037
83.7.1 Preparation Methods, 1037
83.7.2 Stability of Catanosomes, 1038
83.8 Applications of IPA/Catanionic Surfactants, 1039
83.8.1 Drug Delivery, 1039
83.8.2 Templates for Nanomaterial Synthesis, 1040
83.9 Challenges and Future Perspectives, 1041
References, 1041

84 Phase Behavior of Natural-Sourced Surfactant Systems 1044
Kenji Aramaki

84.1 Introduction, 1044
84.2 Sugar-Based Surfactants, 1044
84.3 Glycerol-Based Surfactants, 1046
References, 1050

85 Surfactants and Biosurfactants 1051
Youichi Takata

85.1 Introduction, 1051
85.2 General Surfactants, 1051
85.2.1 Hydrophobic Group, 1051
85.2.2 Hydrophilic Group, 1052
85.2.3 Novel Surfactants, 1053
85.3 Biosurfactants, 1054
References, 1055

Surface Active Drug

86 Effect of Additives on Self-Association and Clouding Phenomena of Various Surface-Active Drugs 1056
Md. Sayem Alam and Asit Baran Mandal

86.1 Introduction, 1056
86.2 Surface Properties, Self-Association, and Mixed Micellization of Surface-Active Drugs with and Without Additives, 1059
86.3 Effect of Additives on Clouding Behavior of Amphiphilic Drug Solutions, 1062
86.3.1 Effect of pH, 1062
86.3.2 Effect of Electrolytes, 1062
86.3.3 Effect of Surfactants, 1064
86.3.4 Effect of Additives at Different Fixed pHs, 1064
86.3.5 Effect of Additives at Different Fixed Drug Concentrations, 1064
86.4 Thermodynamics at CP, 1065
86.4.1 Effect of Surfactants, 1066
86.5 Conclusions, 1067
Acknowledgment, 1067
References, 1067

T

Thermodynamic Analysis of Partial Molar Volume

87 Thermodynamic Analysis of Partial Molar Volume in Biocolloidal Systems **1071**

Michio Yamanaka, Hideyuki Maekawa, Tamaki Yasui, and Hitoshi Matsuki

87.1 Introduction, 1071
87.2 Definition of Partial Molar Volume and Elementary Thermodynamic Equations of the Volume Behavior of Solutions, 1072
87.3 Partial Molar Volumes in a Protein–Ligand System, 1073
87.4 Partial Molar Volume in Mixed Membrane Systems, 1079
87.4.1 Binary Mixtures of Water-Insoluble Lipids, 1082
87.4.2 Binary Mixtures of a Water-Insoluble Lipid and a Water-Soluble Substance, 1083
Acknowledgments, 1086
References, 1086

V

Van der Waals Interaction

88 Van Der Waals Interaction Between Colloidal Particles **1087**

Hiroyuki Ohshima

88.1 Introduction, 1087
88.2 Van Der Waals Interaction Between Two Molecules, 1087
88.3 Van Der Waals Interaction Between Two Colloidal Particles, 1088
88.4 Various Geometries, 1088
88.4.1 A Molecule and a Plate, 1088
88.4.2 Two Parallel Plates, 1089
88.4.3 A Molecule and a Sphere, 1089
88.4.4 Two Spheres, 1089
88.4.5 A Molecule and a Rod, 1090
88.4.6 Two Parallel Rods, 1090
88.4.7 A Molecule and a Cylinder, 1090
88.4.8 Two Parallel Cylinders, 1090
88.4.9 Two Crossed Cylinders, 1091
88.4.10 Two Parallel Rings, 1091
88.4.11 Two Parallel Torus-Shaped Particles, 1091
88.4.12 Two Particles Immersed in a Medium, 1092
88.4.13 Two Parallel Plates Covered with Surface Layers, 1093
References, 1093

Wormlike Micelle

89 Wormlike Micelles with Nonionic Surfactants **1095**

Rekha Goswami Shrestha, Kenji Aramaki, Hideki Sakai, and Masahiko Abe

89.1 Introduction, 1095
89.2 Wormlike Micelles in Nonionic Surfactants, 1097
89.3 Conclusion, 1102
References, 1102

Index **1105**

LIST OF CONTRIBUTORS

Masahiko Abe, Department of Pure and Applied Chemistry, Faculty of Science and Technology, Tokyo University of Science, Chiba, Japan

Yasuhisa Adachi, Faculty of Life and Environmental Science, University of Tsukuba, Ibaraki, Japan

Silvia Ahualli, Department of Applied Physics, School of Sciences, Campus Fuentenueva, University of Granada, Granada, Spain

Takanori Akagi, Department of Bioengineering, Graduate School of Engineering, University of Tokyo, Bunkyo-ku, Tokyo, Japan

Md. Sayem Alam, Council of Scientific and Industrial Research (CSIR)—Central Leather Research Institute (CLRI), Industrial Chemistry Laboratory, Adyar, Chennai, India

Emil Alexov, Computational Biophysics and Bioinformatics, Physics Department, Clemson University, Clemson, South Carolina, United States

Shaeel Ahmed Al-Thabaiti, Department of Chemistry, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia

S. Angayarkanny, CSIR—Central Leather Research Institute (CLRI), Adyar, Chennai, India

Stefano Angioletti-Uberti, Department of Physics, Humboldt University Berlin, Berlin, Germany

Kenji Aramaki, Graduate School of Environment and Information Sciences, Yokohama National University, Hodogaya-ku, Yokohama, Japan

Makoto Aratono, Department of Chemistry, Faculty of Sciences, Kyushu University, Higashi-ku, Fukuoka, Japan

Rajat Banerjee, Department of Biotechnology and Dr. B.C. Guha Centre for Genetic Engineering and Biotechnology, University of Calcutta, Kolkata, India

Victor Banerjee, Department of Chemistry, Laboratory of Protein Chemistry, Bose Institute, Kolkata, West Bengal, India

Soumik Bardhan, Department of Chemistry, University of North Bengal, Darjeeling, India

Ommer Bashir, Department of Chemistry, Jamia Millia Islamia, Jamia Nagar, New Delhi, India

Geetha Baskar, CSIR—Central Leather Research Institute (CLRI), Adyar, Chennai, India

Avinash Bhadani, Department of Pure and Applied Chemistry, Faculty of Science and Technology, Tokyo University of Science, Noda, Chiba, Japan

Marian Brestic, Institute of Soil and Water Conservation, Northwest A&F University, Yangling, China and Department of Plant Physiology, Slovak Agricultural University, Nitra, Slovak Republic

Brandon Campbell, Computational Biophysics and Bioinformatics, Physics Department, Clemson University, Clemson, South Carolina, United States

Félix Carrique, Department of Applied Physics II, School of Sciences, Campus Teatinos, University of Málaga, Málaga, Spain

Gulmi Chakraborty, Department of Chemistry, University of North Bengal, Darjeeling, India

N. Chandrasekaran, Centre for Nano-Biotechnology, School of Bio-Sciences and Technology, VIT University, Vellore 632014, Tamil Nadu, India

Sudeshna M. Chatterjea, Department of Biotechnology and Dr. B.C. Guha Centre for Genetic Engineering and Biotechnology, University of Calcutta, Kolkata, West Bengal, India

Aritra Chowdhury, School of Chemistry, University of Manchester, Manchester, United Kingdom

K.P. Das, Department of Chemistry, Bose Institute, Kolkata, West Bengal, India

Swati De, Department of Chemistry, University of Kalyani, Kalyani, West Bengal, India

Ángel V. Delgado, Department of Applied Physics, School of Sciences, Campus Fuentenueva, University of Granada, Granada, Spain

Kabir-ud-Din, Department of Applied Chemistry, Aligarh Muslim University, Aligarh, India

Toshiaki Dobashi, Graduate School of Science and Technology, Gunma University, Gunma, Japan

Saheb Dutta, Department of Chemistry, University of Kalyani, Kalyani, West Bengal, India

Kazunaka Endo, Division of Colloid and Interface Science, Research Institute for Science and Technology, Tokyo University of Science, Kagurazaka, Shinjuku-ku, Tokyo, Japan

Dotchi Exerowa, Institute of Physical Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria

PREFACE

The principal aim of this encyclopedia is to provide a physicochemical tool for interpreting various biological phenomena in terms of a language of colloid and interface science. The present book concentrates on subjects in the field of biocolloid and biointerface science, since there are already excellent encyclopedias on colloid and interface science available in the literature. This field is the youngest—but is becoming a very important—branch in the area in colloid and interface science. Actually, however, colloid and interface science has been closely related to biological science. Colloids, or more specifically, colloidal particles with diameters ranging from 1 to 1000 nm, which are one of the major subjects in colloid and interface science, can be found quite often in biological systems as biocolloids such as biological cells. Surfactant molecules, which are also one of the most important subjects in colloid and interface science, adsorb at interfaces between two immiscible media (e.g., water and oil), forming micelles and vesicles, which are a prototype of living cells. The Derjaguin–Landau–Verwey–Overbeek (DLVO) theory explains well the stability of colloidal suspensions in terms of the electrostatic and van der Waals interactions between the particles. In their book *Theory of Stability of Lyophobic Colloids*, Evert Verwey and Jan Overbeek, two of the founders of DLVO theory, stated that an ordered structure formed by tobacco mosaic viruses can be explained via DLVO theory.

This encyclopedia consists of 71 topics, which are ordered alphabetically. Each topic contains 1–4 review articles, so that there are a total of 89 review articles.

Finally, I would like to gratefully acknowledge the assistance provided by Ms. Anita Lekhwani, Senior Acquisitions Editor at John Wiley and Sons.

1.1 INTRODUCTION

Nanomaterials are one of the important classes of materials having unique properties. Several methods have been recommended in the literature for the preparation of nanomaterials. The important wet chemical method to prepare nanocrystalline and nanostructured amorphous materials is the sol-gel approach [1]. The term *sol-gel* was introduced by Thomas Graham (Scottish chemist, 1864) during his extensive study on the properties of silicic acid and some other colloids [2]. The sol-gel method is a room-temperature process, which requires very mild synthetic conditions to prepare porous glasslike materials and ceramics. The main advantages of using the sol-gel approach for preparing nanomaterials are low temperature and pressure processing conditions, mild solvents, easily available metallorganic precursors, and easy processing versatility of the prepared colloidal silica [3]. These porous materials have wide applications in optical sensors, biomolecule encapsulation, separation and chromatographic techniques, catalysis, hybrid coatings, controlled release, adsorption, and other processes [4, 5].

1.1.1 Silica Aerogel

The most important material to be prepared using sol-gel approach is aerogel. *Aerogels* are a new class of interesting materials prepared using metal alkoxide precursors in slightly acidic or basic medium. They have several unique properties, such as large pores, high surface area, low density, and low thermal conductivity [6]. The most widely synthesized and studied aerogel is silica aerogel, which is obtained primarily from silicon alkoxide precursor [tetraethylorthosilicate (TEOS) and tetramethylorthosilicate (TMOS)] by employing the sol-gel approach. This unique class of material finds several applications in catalysis, adsorbents, optical sensors, drug delivery systems, thermal insulations, and chemical separations [7–9]. Apart from its chemical and mechanical behavioral advantages, it has the important activity of biocompatibility. The biocompatibility of silica aerogel finds application as a biochip for molecular recognition of nucleotide acids and antigens [10, 11], entrapment of membrane proteins [12], in situ protein entrapment [13], and virus detection [14]. The sol-gel-processed silica aerogel have several unique properties and various applications. However, they have a disadvantage of matrix shrinkage as well as gel network collapse during the long-term aging process [15]. To overcome this hurdle, some superior drying techniques have been employed, namely, supercritical drying, freeze drying, ambient pressure drying, the use of drying control chemical additives (DCCAs; e.g., formamide, *N*-methylformamide, *N*-*N*'-dimethylformamide, acetamide, glycerol and oxalic acid),

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

and drying in organic solvents [16, 17]. Most of the drying techniques employed to prepare aerogel require vigorous conditions such as high temperature and pressure and use of organic solvents. During the drying process, the evaporation of solvent results in shrinkage and collapse of the gel network, which can be avoided by using novel solvents with low vapor pressure. The fact that these solvents do not exert any external pressure on the walls of the silica aerogel surface and thereby retain the gel network structure is of current interest.

1.1.2 Ionic Liquids

In the recent past, a new class of solvent called *ionic liquids* (ILs) received much attention in preparing nanomaterials due to their exceptional physical and chemical properties. They have several interesting properties, including low vapor pressure, high polarity, high ionic conductivity, and thermal stability [18]. Because of these favorable conditions and excellent properties, ionic liquids could be used to prepare silica aerogel. The use of ILs as solvent during the sol-gel process could provide control over the structure, pore size, and distribution of the resultant aerogel [19]. Ionic liquids avoid the shrinkage and matrix collapse often observed during long-term aging as well as the drying process [9]. The risky supercritical drying process was eliminated with the use of ionic liquid {1-ethyl-3-methylimidazolium bis[(trifluoromethyl)sulfonyl]amide} during the preparation of silica aerogel in one study [20]. More recently, another team [21] used ionic liquids based on 1-butyl-3-methylimidazolium tetrafluoroborate and 1-butyl-3-methylpyridinium tetrafluoroborate salts for the preparation of silica aerogel, and they achieved control over the pore size of xerogel as well as aerogel. ILs are used for the preparation of silica nanoparticles as well as bulk aerogel [22, 23]. Most of the ILs used for the synthesis of these types of nanomaterials are based mainly on the imidazolium, pyridinium, phosphonium, and other organic salts.

At present, ionic liquids containing components (cations and anions) with widely studied biological and toxicological properties are of interest. One of these is choline, which is an important cation having several metabolic activities in the human body. Choline cation–based ionic liquids containing a number of anions such as formate, acetate, dihydrogen phosphate, aminoacetate, and levulinate have been reported [24]. Choline-based ILs have been reported to have the ability to retain the stability and structure of proteins [25]. Based on the merits of choline based ILs, we have chosen choline formate ionic liquid for the preparation of biocompatible silica aerogel. Our approach is to prepare mesoporous surface-active silica aerogel using a biocompatible ionic liquid and study its effect on the surface properties as well as biocompatibility.

1.1.3 Polyurethane–Siloxane Cross-Linked Structures

Polyurethanes (PUs) are reported to have very promising applications due to their excellent properties and environmental suitability. Various polyurethanes are available to meet the specific requirement of applications such as coatings, elastomers, foams, adhesives, fibers, paints, resins, and development of liquid crystal [26, 27]. PUs offer a wide variety of improved properties such as high thermal stability, mechanical flexibility, barrier properties, hardness, and chemical resistance. More recently, we have reported [28] thermoplastic interpenetrating polymer networks (IPNs) based mainly on polyurethane ionomers and poly(vinyl chloride) with different concentrations of calcinated clay filler, which exhibit as tough films with better miscibility, and thermal stability. These IPNs may find application in the area of damping field for footwear and allied products [28]. Very recently, another group. [29] reported that surface modified and medicated polyurethane sheets could be used as insole material in footwear for athletic shoes, which avoids foot odor and other foot problems. Most of the PU systems can be synthesized by using polyol/diol with diisocyanates. The main concern associated with the use of conventional polyol/diol for the polyurethane preparation is environmental, due to the depletion of petroleum resources and environmental risks. These petrochemical products have increased the threat to the environment and also concomitantly have discharged into the natural environment, creating global environmental pollution problems [30]. More recently, researchers have focused on the use of natural resources for the preparation of polyurethanes, thermosets, interpenetrating networks, elastomers, coatings, and other compounds [31, 32]. Among different oils derived from plants and animals, castor oil (CO) is an important one as it contains hydroxyl groups in 90% of the fatty acid chain [33]. This hydroxyl group is used to react with diisocyanates to obtain PUs. Several studies utilizing the hydroxyl functionality of CO to obtain PUs have been reported [34–37].

In the recent past, the combination of polyurethane and siloxane has represented an important advancement in combining the mechanical properties of polyurethanes and biostability of the siloxane unit [38]. Siloxane linkages are used mainly to alter the surface energy and wettability of the materials surface, and these linkages also provide high thermal stability to the PUs [39]. Polyurethane–siloxane copolymers exhibit superior flexibility, resistance to humidity, acid–base solvents, and thermal stability compared to conventional PUs [40]. Often, siloxane linkages are introduced in to the PU matrix through cross-linking. The cross-linking resulted mainly from Si−O−Si linkage via sol-gel hydrolysis and condensation of the alkoxysilane moiety, which attached to the PU matrix [41]. One group of investigators [42] reported that siloxane cross-linked polyether urethane elastomers have inflammatory

response with controlled biodegradation with relatively short time. Siloxane- coated polymer systems possessing hydrophobicity are reported to have higher protein adsorption over the hydrophilic surface [43]. Another group. [44] reported that cross-linked polyurethane-*block*-poly(trifluoropropylmethyl)siloxane elastomers may find very good application in the field of biomedicine. Novel poly(*N*-vinylpyrrolidone)-grafted poly(dimethylsiloxane) surfaces were prepared by the grafting technique, exhibiting antibiofouling properties with long-term stability [45]. Recently, cross-linked hybrid materials have been obtained by forming stronger covalent bonds between organic and inorganic compounds [46]. The most commonly used organic moiety is polyurethane, and the inorganic part is siloxane linkage, which can be coupled by using different silane coupling agents: 3-aminopropyltrimethoxysilane (APTMS), 3-aminopropyltriethoxysilane (APTES), 3-glycidyloxypropyltriethoxysilane (GPTES), 3-glycidyloxypropyltrimethoxysilane (GPTMS), and 3-isocyanatopropyltriethoxysilane (ICPTES). The main goal of this work is to prepare biorenewable castor oil–based polyurethane–siloxane cross-linked film structures and elaborate studies of physicochemical properties using various structural, thermal, surface, and morphological techniques.

1.2 EXPERIMENTAL SECTION

1.2.1 Preparation of Silica Aerogel Using Choline Formate [47]

Silica aerogel was prepared using tetraethylorthosilicate precursor, formic acid catalyst, and biocompatible ionic liquid (choline formate). Choline formate was synthesized by following the reported procedure [24]. The formic acid–catalyzed sol-gel silica aerogel was prepared using a modified method following the procedure in the literature as follows [5,20] Tetraethylorthosilicate, formic acid, and choline formate were mixed in a ratio of 1:2:1 under magnetic stirring at room temperature in a bottle. The silica sol formed within 3 h after mixing of the precursor, catalyst, and ionic liquid. The mixture gelled overnight and was allowed to age at room temperature for 3 weeks. The bottle was closed with parafilm, and small holes were drilled for the evaporation of solvent formed during the aging process. A white transparent silica aerogel was obtained after 3 weeks of aging. The ionic liquid entrapped in the gel matrix was removed by Soxhlet extraction overnight using ethanol as solvent. The solvent was then freeze-dried to remove the frozen ethanol present in the gel. The gel in wet condition (presence of IL) was labeled as SAGIW, and the dried gel was labeled as SAGID. In addition, we prepared a transparent gel without ionic liquid, which was labeled as SAG (Fig. 1.1a; shrinkage indicated by red arrow). Gel shrinkage during the aging process was high in the case of SAG, whereas the shrinkage reduced for gel in wet conditions (SAGIW; Fig. 1.1b).

1.2.2 Preparation of Polyurethane–Siloxane Cross-Linked Films [48]

Castor oil polyurethane–siloxane cross-linked films were prepared using a convenient two- step process. In the first step, polyurethane prepolymer was synthesized, and the second step involved the attachment of silane moiety followed by hydrolysis and condensation to form cross-linked structures. Polyurethane prepolymer was prepared in a three-necked round-bottomed flask fitted with a condenser, nitrogen (N_2) gas inlet, and addition funnel. Then 2.796 g of castor oil

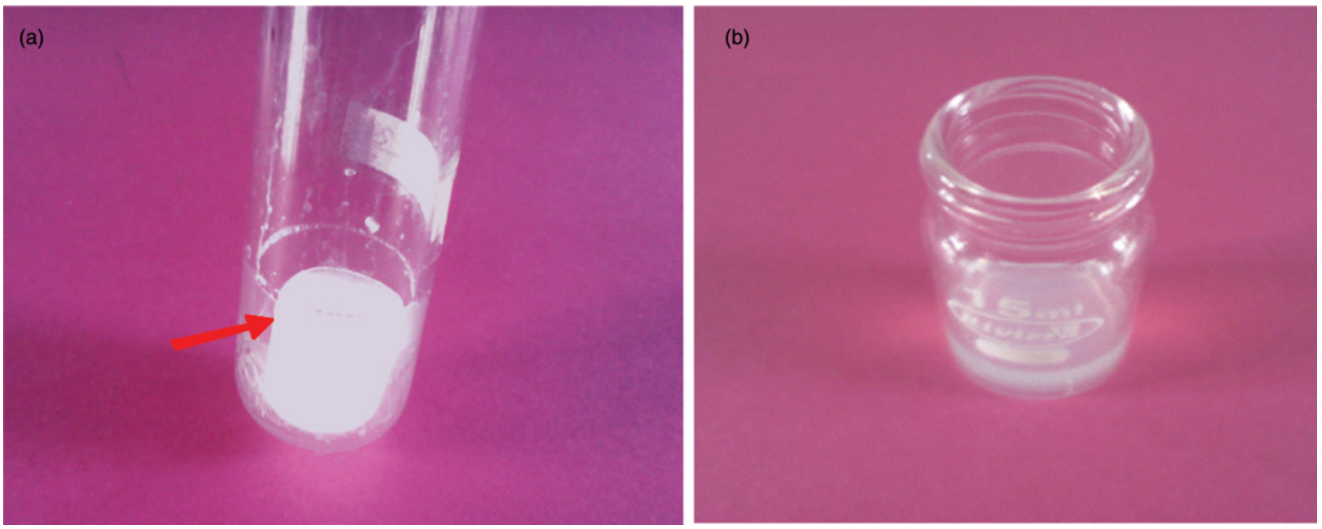

FIGURE 1.1 Image of gel prepared (a) without IL (SAG) and (b) with IL (SAGIW).

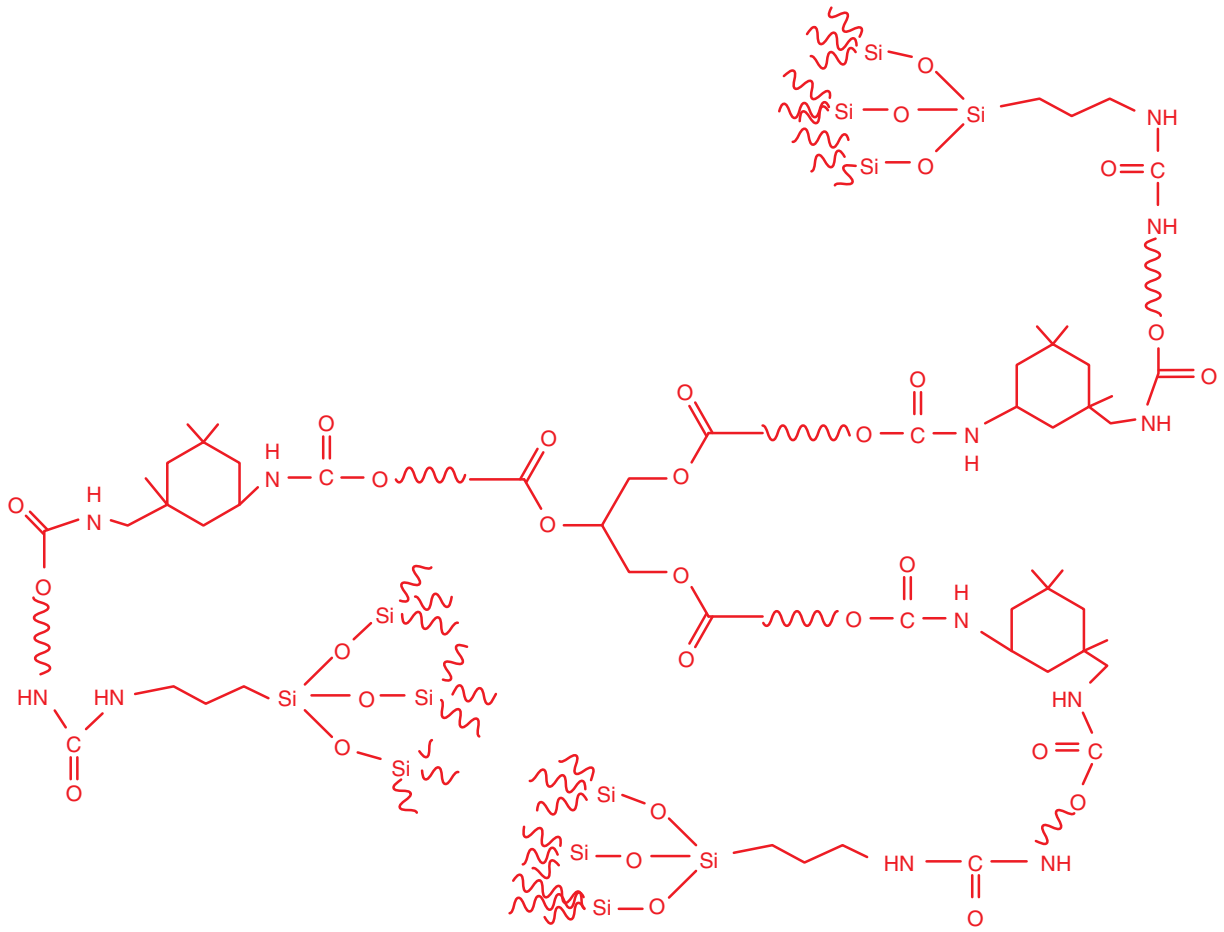

FIGURE 1.2 Scheme showing castor oil polyurethane–siloxane structures [48].

was poured into the reaction vessel and dissolved in 10 mL of chloroform and heated to 70°C with magnetic stirring. The required amount of isophorone diisocyanate (IPDI) was introduced into the reaction vessel dropwise under magnetic stirring, and dibutyltindilaurate (0.001%) catalyst was added also in dropwise fashion. The reaction further continued for 4 h to obtain PU prepolymer solution. To the PU prepolymer solution, a different ratio of 3-aminopropyltrimethoxysilane was added and heated at 70°C for another 4 h and was mold-casted to obtain polyurethane–siloxane cross-linked films. The PU cross-linked structures were obtained as transparent films. The sample codes and compositions are depicted in Table 1.1, and the polyurethane–siloxane cross-linked structures are shown in Fig. 1.2.

1.2.3 Characterization

1.2.3.1 Characterization of Silica Aerogel. Fourier transform infrared (FT-IR) spectra of the gel samples were recorded on a Perkin–Elmer FT-IR spectrometer over a range from 4000 to 400 cm^{-1}. Rheological measurements of the gel samples were performed using a MCR52 rheometer (Anton Paar Inc., USA). Thermogravimetric analyses were done using TG Analyzer-Model Q50 (TA Instruments, USA), under N_2 atmosphere with a heating rate of 20°C/min over a temperature range of 30–800°C. Differential scanning calorimetric analyses were conducted in DSC-Model Q200 (TA Instruments, USA) at a heating rate of 10 °C/min over the range from −70 to 300°C under N_2 flow. The morphology of the aerogel samples was examined using a FEI Quanta 200 (USA) environmental scanning electron microscope. The

TABLE 1.1 Codes and Compositions of Polyurethane–Siloxane Cross-Linked Film Structure

	Compositions (g)			
Codes	CO	IPDI	APTMS	Thickness (mm)
PU-0.0	2.796	2.152	–	0.87 ± 0.05

PU-1.5			2.457	1.08 ± 0.05

reduction of live cells during MTT assay was monitored using a synergy HT-1 microreader at 570 nm.

1.2.3.2 Characterization of Polyurethane–Siloxane Cross-Linked Film Structures. Thicknesses of the PU films were measured using Mitutoyo absolute thickness cage (ID-C1012EBS; Mitutoyo Corp., Japan), and the values reported were averages of 10 values taken at different sites on the films. The formation of polyurethane was monitored using attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy on ABB MB 3000 (Canada), by keeping the film samples on ZnSe surface. The solution state ^{1}H-NMR spectra were used to confirm the formation of polyurethane–siloxane cross-linked structure and spectra taken in a JEOL 500-MHz NMR spectrometer by using deuterated chloroform ($CHCl_3$-d_1) solvent. The solid-state NMR spectra (^{29}Si CP/MAS) for the polyurethane films were carried out using a Bruker Avance 400 spectrometer (Germany), over a range from −150 to 150 ppm. Contact-angle studies were carried out using a contact-angle meter (Holmarc Opto Mechatronics Pvt. Ltd., India). The optical properties of polyurethane films were recorded using a Varian Cary 50 Bio (USA) UV–visible spectrophotometer. Moisture sorption isotherm analysis was performed using moisture sorption analyzer, Q5000 SA (TA Instruments, USA). The adsorption–desorption behavior was noticed over a time interval ranging from 0 to 3000 min. The morphology of the polyurethane films was observed using a Quanta 200 FEG (USA) scanning electron microscope. The surface roughness and topography were analyzed using Atomic Force Microscopy (AFM). Agilent Technologies (USA) 5500 scanning probe microscope instrument in tapping mode.

1.3 RESULTS AND DISCUSSION

1.3.1 Results of Surface-Active Silica Aerogel

1.3.1.1 FT-IR Spectra. The FT-IR spectra of prepared gels are shown in Fig. 1.3. In the FT-IR spectra, the region 3200–3700 cm^{-1} is the characteristic O−H stretching vibration of the Si−OH groups present in the surface of aerogel.

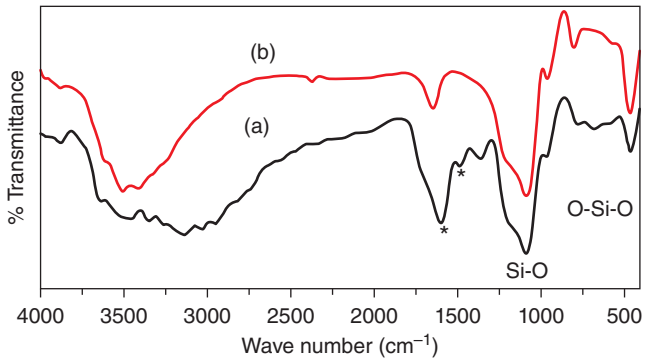

FIGURE 1.3 FT-IR spectra of (a) SAGIW, and (b) SAGID.

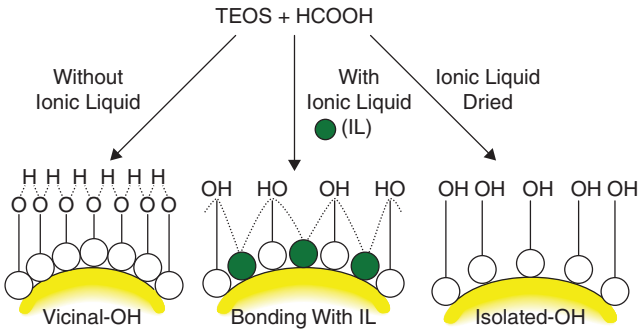

FIGURE 1.4 Schematic representation of –OH groups on silica aerogel surface.

The peak at 1088 cm^{-1} is due to the presence of Si−O stretching vibration ($\nu_{Si\text{-}O}$) and also two peaks observed at around 460 and 790 cm^{-1} are the characteristics of O−Si−O vibration. Importantly, two peaks marked with asterisks in the spectrum (Fig. 1.3a) are the characteristics of ionic liquid (peaks at 1595 cm^{-1} and 1482 cm^{-1} are characteristic C=O of formate ion), which are invisiible in Fig. 1.3b because of the removal of ionic liquid by Soxhlet extraction and freezing. In the case of gel prepared with IL, a negative bandshift at 769 cm^{-1} corresponding to O−Si−O was observed as a result of the physical confinement and interaction between silica gel and IL [49].

The −OH groups present on the surface of silica gel schematically represented in Fig. 1.4. The gel prepared without ionic liquid (SAG) contains vicinal hydroxyl groups (3438 cm^{-1}) on the surface of silica gel, whereas gel prepared with ionic liquid (in wet condition, SAGIW) contains a hydroxyl group bonded with ionic liquid, which shifts the peak position from 3438 to 3475 cm^{-1}. The ionic liquid (i.e., choline formate) shows a −OH peak at 3421 cm^{-1}. Once the ionic liquid is removed from the gel matrix (SAGID), a free hydroxyl group appears on the surface of the gel at 3510 cm^{-1} [50]. These free hydroxyl groups can be further functionalized to get desired functionalities on the surface of the aerogel.

1.3.1.2 Rheological Studies. The rheological measurements of the aerogels showed elastic properties (Fig. 1.5). The storage modulus (G′) of gel with IL increased beyond that of the loss modulus (G″) with respect to the variation of angular frequency from 100 to 0.1 rad/s (data not shown). On the other hand, the complex viscosity (η^*) of gel with IL also shows improved viscosity (Fig. 1.5b). The gelation temperature was increased from 65 to 115°C for SAG and SAGIW, respectively. This shows that the presence of IL plays a major role in improving the viscosity and elastic properties of silica aerogel. Gel prepared with ionic liquid shows viscoelastic properties, which means that the presence of ionic liquid favors more formation of large number of interconnected silica network in colloidal gel [51].

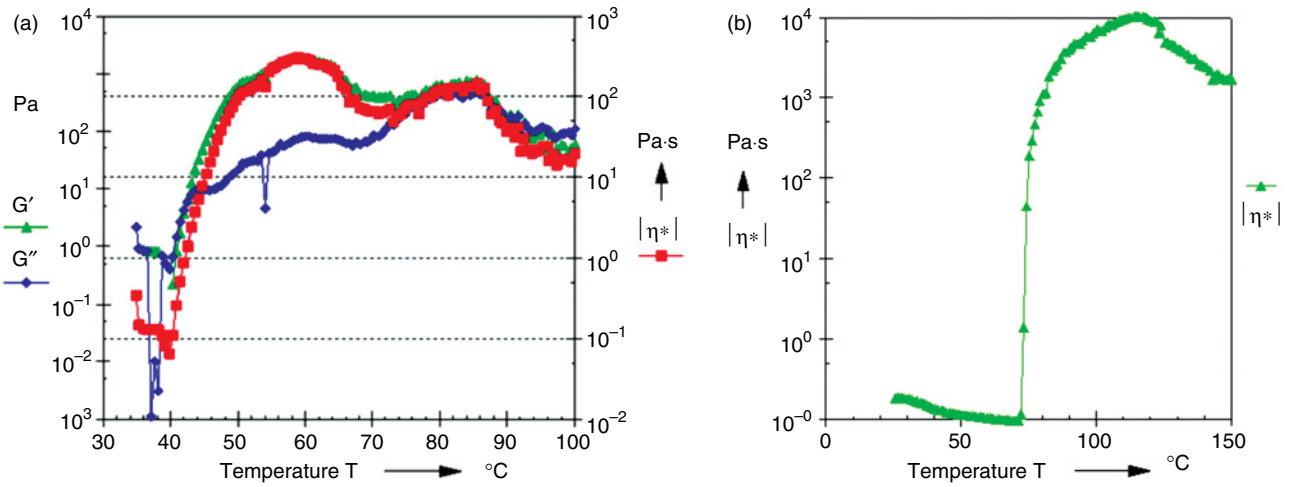

FIGURE 1.5 Rheological behaviors of (a) silica aerogel and (b) silica aerogel with IL.

1.3.1.3 Thermal Properties of Gels. Thermal studies (TGA and DSC) were conducted for the prepared gels and the data presented in Table 1.2. TGA results show that all the gel samples possess weight loss up to 100°C, due to the elimination of water and alcohol formed during the sol-gel process [52]. In the case of SAGIW, a new degradation was observed at 190°C. This corresponds to the degradation of IL presence in the gel matrix, which degrades at 190°C. A similar type of degradation was not obtained for SAGID, which confirms the removal of IL from the pores of the gel by solvent extraction and freeze drying. Furthermore, weight loss behavior at 100°C clearly shows that the presence of IL improves the thermal stability of the gel. In the presence of IL, the percent weight loss at 100°C decreased from 72.1% to 11.8% for SAG and SAGIW, respectively.

Although DSC studies reveal that SAG and SAGID give single endothermic peaks at 147.7 and 141.6°C, respectively, SAGIW yields two endothermic peaks at 140.6°C and 241.3°C. The appearance of new peak in DSC for SAGIW corresponds to the presence of IL in the pores of the gel matrix. The ionic liquid (choline formate) gives two peaks at 148.2°C and 176.5°C. In the case of SAGIW, the second melting peak shifted to 241.3°C, which may be due to the confinement IL in the pores of the gel [53]. This confinement of IL in the pores of the gel plays a crucial role in shifting the melting behavior and controlling the pore volume as well as surface hydroxyl group on the gel surface (Fig. 1.4).

1.3.1.4 Morphology of the Gels. The morphologies of the gels were examined using scanning electron microscopy, and the micrographs are depicted in Fig. 1.6. The gel prepared without ionic liquid shows very dense network structure (Fig. 1.6a). One group of investigators. [21] reported an interconnected network structure of silica particles for aerogels and xerogels made with ionic liquid. SAGIW shows an agglomerated silica particle with network structure due to the presence of ionic liquid (Fig. 1.6b). The increase in size of the silica particle (∼40 nm) was observed for the aerogel prepared with ionic liquid, whereas a smaller size (∼20 nm) was observed for the aerogel prepared without ionic liquid in another study [52]. In the case of SAGID, the structure becomes more porous due to the removal of IL from the gel matrix by solvent extraction (Fig. 1.6c). SEM studies show that the presence of IL yields a network structure of silica particles.

1.3.1.5 Biocompatibility of the Prepared Gels. Biocompatibility of IL and gel samples were tested by following a standard MTT (3-[4,5-dimethyltriazol-2-y1]-2,5-diphenyltetrazolium bromide) assay method [54] using

TABLE 1.2 Thermal Properties of IL and Gels

	TGA		DSC			
Codes	Weight loss at 100°C (%)	Residue (%)	T_{m1} (°C)	ΔH_1 (J/g)	T_{m2} (°C)	ΔH_2 (J/g)
CF	24.2	0.03	148.2	60.4	176.5	37.8
SAG	72.1	22.5	147.7	640.7	–	–
SAGIW	11.8	33.5	140.6	467.4	241.3	372.4
SAGID	25.3	68.9	141.6	630.3	–	–

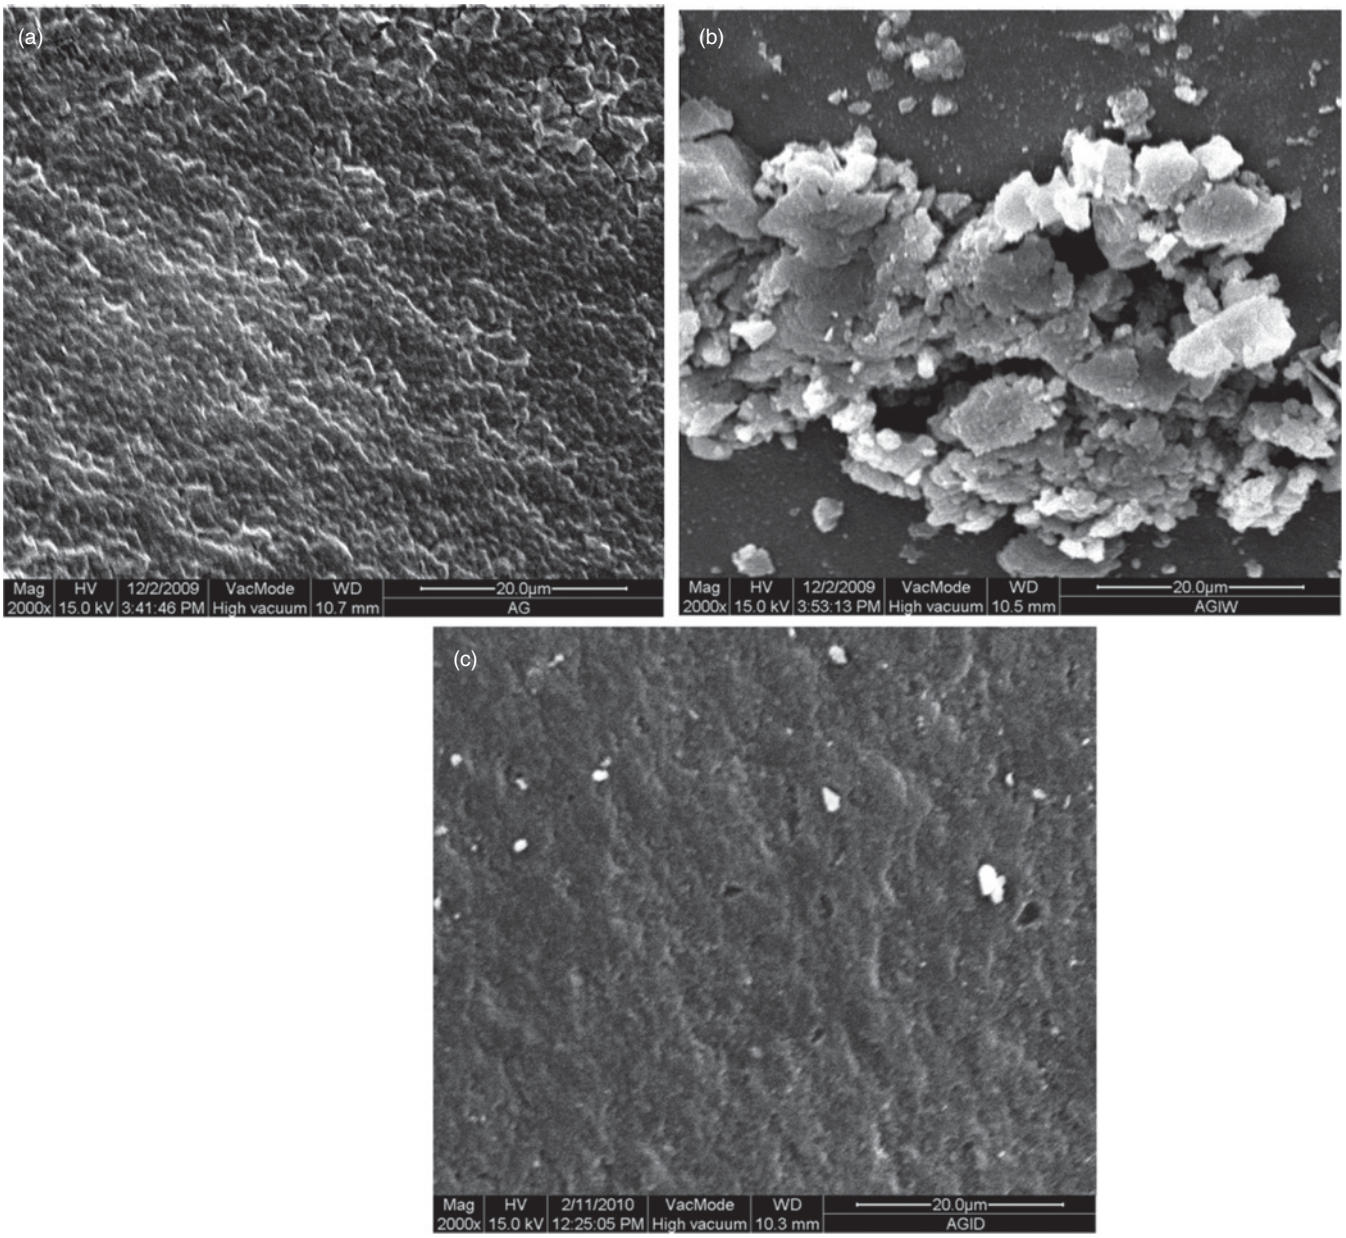

FIGURE 1.6 SEM micrographs of (a) SAG, (b) SAGIW, and (c) SAGID (2000×).

3T3-L1 cells and the obtained results compared with the control. The cell viability of the samples were tested for 24, 48, and 72 h with different concentration of gel samples (viz., 20, 40, 60, 80, and 100 mg), and the results are depicted in Figs. 1.7–1.9. In all the concentrations, the cell viability of IL and gels were high. In the case of SAGIW, the cell viability was around 120% for 20 and 40 mg of samples at 24, 48, and 72 h. The cell viability of gel sample prepared with IL shows very good results at higher concentration (60, 80, and 100 mg) for all the time durations. These results show that the presence and confinement of IL (choline formate) in the pores of gel increases and enhances the cell viability and proliferation of the prepared aerogel [55]. The percent cell viability of IL and gel samples was calculated using the following equation [56]:

$$\text{Cell viability (\%)} = \frac{A_t}{A_c} \times 100 \tag{1.1}$$

where A_t and A_c are absorbance values of treated and control cells, respectively.

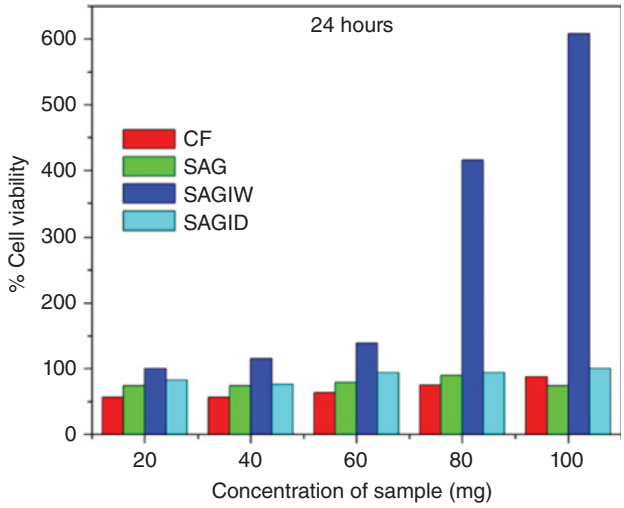

FIGURE 1.7 The MTT assay of IL and gels at 24 h.

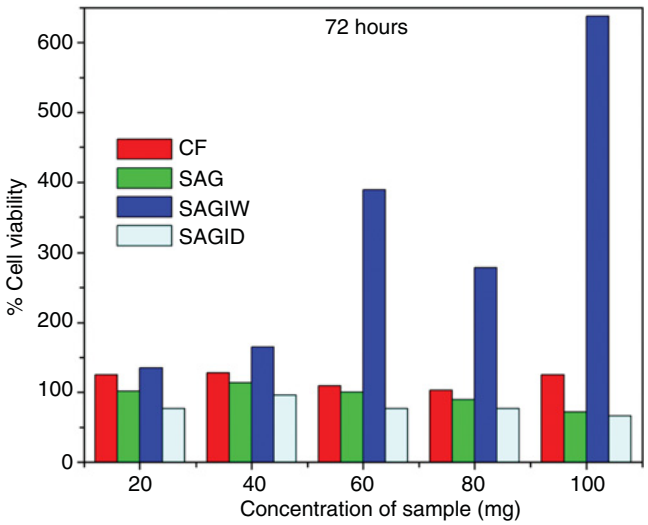

FIGURE 1.9 The MTT assay of IL and gels at 72 h.

1.3.2 Results of Polyurethane–Siloxane Cross-Linked Structures

1.3.2.1 ATR-FT-IR Spectra. The formation of PU and siloxane structure was evidenced from the ATR-FT-IR spectra, shown in Fig. 1.10. Control castor oil polyurethane shows all the characteristic peaks such as C=O, N−H, and −NCO peaks. The free −NCO peak appeared at 2259 cm^{-1}, but completely disappeared in the case of polyurethane–siloxane systems [57]. Control polyurethane (PU-0.0) contains only a urethane peak, whereas siloxane cross-linked samples show a new peak at 1637 cm^{-1} corresponds to a urea peak formed by the attachment of NH_2 group present in silane moiety to the free −NCO of polyurethane prepolymer [58]. Further, two new peaks were observed for the cross-linked systems at 772 and 1094 cm^{-1} corresponding to O−Si−O and Si−O stretching vibrations, respectively. These results confirm the attachment of silane moiety as well as their cross-linkage. In addition to this, the introduction of siloxane shifts the peak position of characteristic N−H, urethane C−O, urea C−O, and Si−O peaks and also the intensity of the respective peaks increased. These results clearly give an idea about the formation of polyurethane, attachment of silane moiety, and cross-linking of siloxane groups in the polyurethane–siloxane cross-linked films.

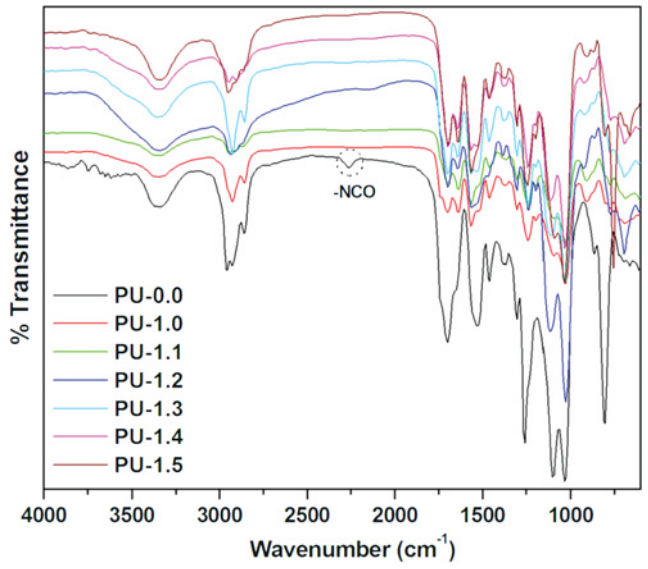

FIGURE 1.10 The ATR-FT-IR spectra for polyurethane–siloxane films.

TABLE 1.3 Chemical Shift Values for ^{1}H-NMR Spectra of Polyurethane–Siloxane Structures

Castor oil [59, 60] δ (ppm)	Castor oil polyurethane prepolymer δ (ppm)	Castor oil polyurethane-siloxane δ (ppm)
4.06–4.28 (m), $-CH_2$ of glycerol moiety	New peaks in addition to castor oil peaks	New peaks in addition to castor oil peaks
5.18–5.24 (m), −CH of glycerol moiety		7.08–7.12, urethane N−H
2.23–2.29 (t), CH_2 attached to ester −C−O	Urethane peak appears at 7.0–7.05	5.89, urea N−H
1.35–1.63, $-CH_2$ chain		3.06, $-CH_2$ next to urea N−H [61]
1.96–2.04, $-CH_2$ attached to C=C on aliphatic side		4.60–4.76, −C−H attached to N−H of urethane
2.13–2.19, $-CH_2$ attached to C=C on −OH side		1.39 and 1.52, CH_2 of APTMS
3.51–3.60 (m), C−H attached to −OH		
0.80–0.87, terminal $-CH_3$		5.0, Si−OH
5.26–5.53 (m), −CH=CH − [62]		

1.3.2.2 ^{1}H-NMR Spectra. The formation and structure of CO polyurethane–siloxane cross-linked film structure was identified and confirmed using solution-state ^{1}H-NMR spectra, and their corresponding chemical shift values are given in Table 1.3. The ^{1}H-NMR spectrum of castor oil polyurethane–siloxane gives all the characteristic peaks of CO. In addition to CO peaks, some new peaks appeared in the ^{1}H-NMR spectrum of polyurethane–siloxane. The appearance of urethane N−H and urea N−H confirms the formation of polyurethane and attachment of silane moiety to PU chain. Furthermore, two new peaks appeared in the range of 1.3–1.6 ppm, which are the characteristic peaks of APTMS. The appearance of a new broad peak at around 5.0 ppm provides evidence for the formation of Si−OH groups. The ^{1}H-NMR spectrum of castor oil PU prepolymer gives only urethane peak (not urea peak), which shows that the urea formation occurs in the second stage of the reaction (after adding APTMS).

1.3.2.3 Solid-State ^{29}Si-NMR Spectra. The formation and cross-linking of siloxane groups in polyurethane– siloxane cross-linked structure occurred through hydrolysis and condensation of Si−OCH_3 groups present in the APTMS moiety. In order to ensure a clearer understanding of the cross-linking, the hydrolysis and condensation of polyurethane–siloxane films were analyzed by using ^{29}Si CP/MAS NMR spectroscopy. Control polyurethane (PU-0.0) doesn't have any silica moiety on its chain, whereas polyurethane–siloxane cross-linked structures contain siloxane linkages. The polyurethane–siloxane structure contains three hydrolyzed (Si−O−Si) and one nonhydrolyzed ($-Si-CH_2-CH_2-CH_2-NH_2$) parts, which are designated as Q (Q^1, Q^2, and Q^3) and T (T^3) terminologies, respectively in ^{29}Si CP/MAS NMR [63, 64]. In case of PU-1.0, ^{29}Si NMR spectra give all the four characteristic peaks (Q^1, Q^2, Q^3, and T^3) ranging from −75 to 100 ppm. This shows that the lower concentration of silane results in a mixed Si environment. Further, increasing the concentration of silane from 1.0 to 1.4 yields three peaks corresponding to Q^2, Q^3, and T^3 ranging from −78 to −98 ppm [65]. The higher concentration of silane (1.5) results in only two peaks (Q^3 and T^3) at −82.4 and −98.7 ppm, which confirms the occurrence of complete cross-linking in polyurethane–siloxane cross-linked systems (PU-1.5). The increase in silane ratio provides a similar kind of Si environment with complete cross-linking in the polyurethane–siloxane system. The major peaks of Q^3 and T^3 play a vital role in forming the complete network structure. ^{29}Si CP/MAS NMR spectra provide a clear picture about the cross-linking state of silica species present in the polyurethane–siloxane system.

1.3.2.4 Contact-Angle Studies. The surface behavior of polyurethane–siloxane films was studied using static contact-angle measurements by placing water (polar) and hexadecane (dispersive) droplets over the film surface. Control PU (PU-0.0) exhibits relatively hydrophilic behavior for water droplets (θ=74.0°; see Fig. 1.11). The introduction of siloxane linkage to the PU chain provides hydrophobicity to the PU surface. In the case of PU-1.5, a higher concentration of

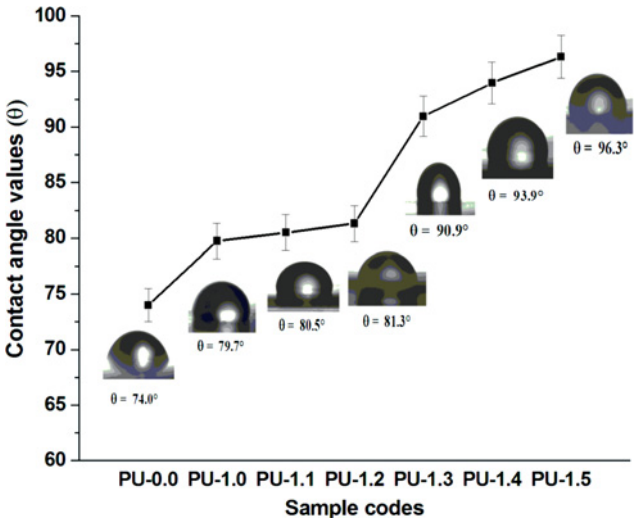

FIGURE 1.11 Contact-angle values for polyurethane–siloxane cross-linked films on a water droplet at 25°C.

silane ratio results in an increment of approximately 23° in the water contact angle (polar component), which proves that siloxane linkage provides hydrophobicity to the film surface. The siloxane linkage present in the PU film surface easily migrates to the surface and imparts antiwettability to the PU surface [66,67]. However, in the case of hexadecane droplets (dispersive component), the contact-angle value decreased from 8.9° to 6.5° for PU-0.0 to PU-1.5, respectively. Overall, this results in decrease of total surface free energy of polyurethane surface from 37.6 (PU-0.0) to 29.7 mJ/m^2 (PU-1.5). The introduction of siloxane helps to ensure a hydrophobic surface with low surface free energy. The low-free-energy surface resulted from the incorporation of siloxane linkages having low surface tension present on the surface of PU films [68]. The chemical modification of cellulose acetate with siloxane cross-linking results in increased contact angle, which provides water repellance to the surface [69].

1.3.2.5 UV–Visible Spectra. The UV–visible absorbance spectra for the prepared polyurethane–siloxane films are given in Fig. 1.12. The incorporation of siloxane cross-linking influenced the absorbance of PU films. All the film samples show very good absorbance in the range of 200–350 nm, whereas in the range of 350–800 nm the absorbance decreased. That means the transmittance of the polyurethane–siloxane films increased in the range of 350–800 nm with increasing concentration of silane ratio from 0.0 to 1.2. Further, increasing the concentration of silane from 1.3 to 1.5 slightly decreased the absorbance of the polyurethane films. Polyurethane films containing a silane ratio of 1.2 show very good transmittance in the range of 350–500 nm. The transparency of the polyurethane–siloxane

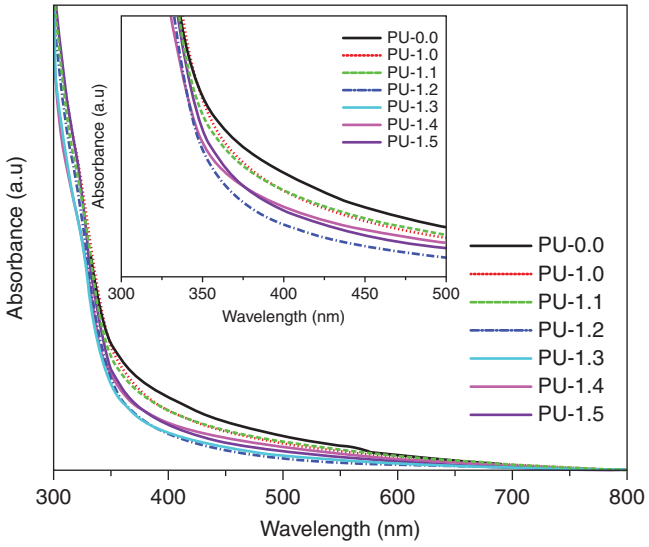

FIGURE 1.12 UV–visible spectra of castor oil polyurethane–siloxane films.

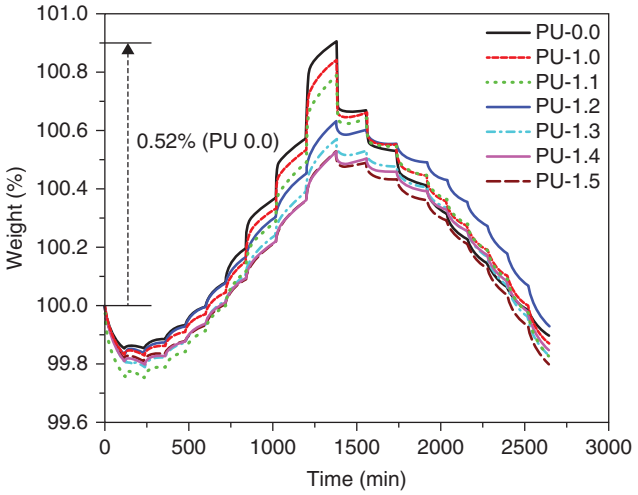

FIGURE 1.13 Time-dependent moisture sorption behavior of polyurethane–siloxane films.

films can be altered by changing the concentration of the silane content. In general, all the polyurethane films show very good transmittance in the visible range, which help us to find applications in the development of leather coatings, transparent coatings, lens, optical fiber, and so on [70,71].

1.3.2.6 Moisture Sorption. The moisture sorption property of polyurethane–siloxane cross-linked film samples were analyzed using a moisture sorption isotherm over a long time duration (2700 min) and are shown in Fig. 1.13. Sorption phenomena occurred up to 1400 min, followed by the occurrence of desorption phenomena until 2700 min. The maximum weight gain during sorption for PU-0.0 sample is 0.91%. In the case of siloxane cross-linked films, the maximum weight gain was found to be 0.83%, 0.78%, 0.62%, 0.57%, 0.53%, and 0.52% for PU-1.0, PU-1.1, PU-1.2, PU -1.3, PU-1.4, and PU-1.5, respectively (Table 1.4). This clearly indicates that the control polyurethane sample shows a slightly hydrophilic characteristic due to the presence of free –OH and –NCO groups, which contributes to its hydrophilicity. The maximum weight gain during sorption decreased

TABLE 1.4 Moisture Sorption Behavior of Polyurethane–Siloxane Films

Codes	Moisture sorption weight (%)
PU-0.0	0.91
PU-1.0	0.83
PU-1.1	0.78
PU-1.2	0.62
PU-1.3	0.57
PU-1.4	0.53
PU-1.5	0.52

with increasing silane content, thus demonstrating that the siloxane cross-linking imparts hydrophobicity to the films [72, 73]. The increased hydrophobicity with respect to silane ratio was already evidenced from contact-angle measurements (Fig. 1.11). The decreased moisture sorption capacity was observed in another study [74] for cellulose–siloxane cross-linked polyester materials.

1.3.2.7 SEM Images. The surface morphology of the polyurethane films was investigated using SEM micrographs and is depicted in Fig. 1.14. In the case of control polyurethane PU 0.0, the surface was almost uniform (Fig. 1.14a). However, siloxane cross-linked film samples exhibit slightly phase-separated structures. In case of PU-1.0, small domains were observed, which originated mainly from within siloxane domains (Fig. 1.14b). Microphase separation with domain structure has been reported for siloxane-modified poly(IPDI-PTMO) copolymers [75]. SEM images of polydimethylsiloxane–polyurethane dispersion (PDMS-PUD) shows a very smooth and uniform surface, whereas block and random PDMS-PUD film samples exhibit better microphase separation with improved tensile properties such as tensile strength and tensile modulus [76].

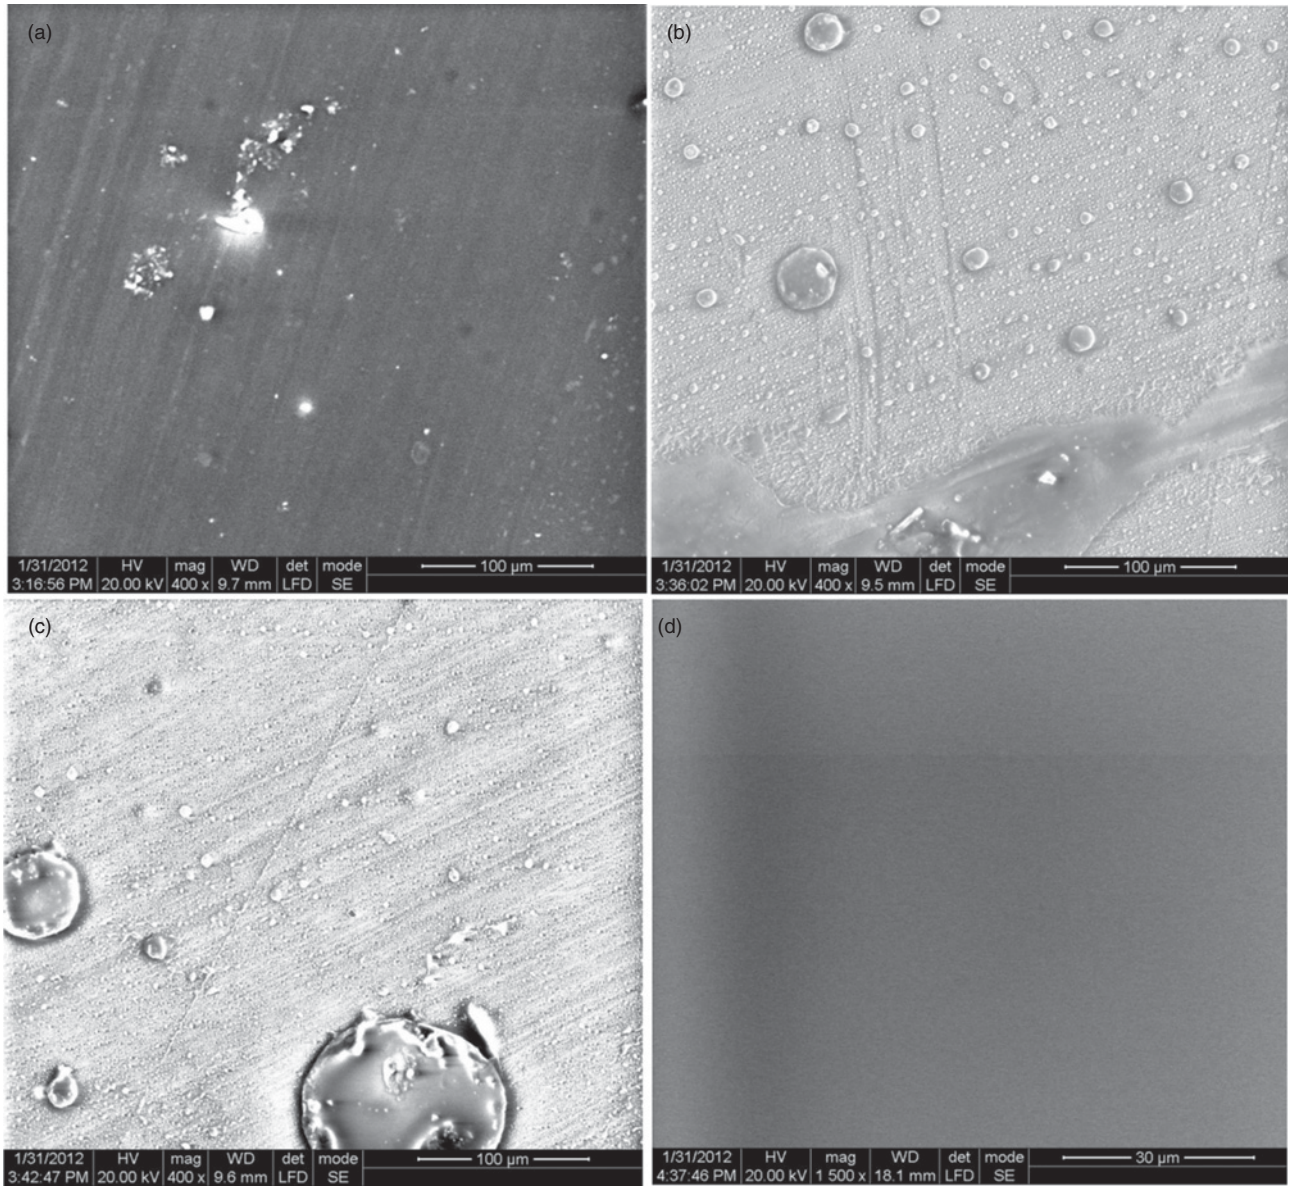

FIGURE 1.14 SEM images of polyurethane–siloxane cross-linked films: (a) PU-0.0 (400×); (b) PU 1.0 (400×); (c) PU 1.1 (400×); (d) PU 1.4 (1500×).

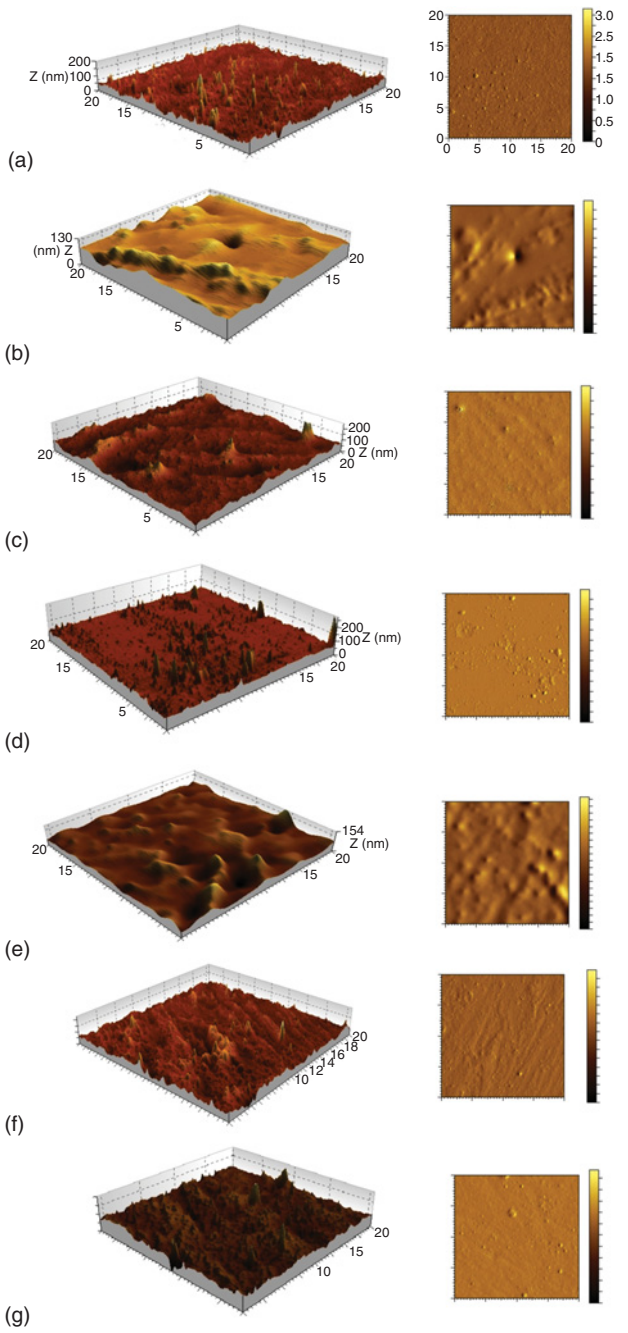

FIGURE 1.15 AFM images of polyurethane films.

1.3.2.8 AFM Studies. The surface roughness as well as topography of the polyurethane films was analyzed using atomic force microscopy, and the images are presented in Fig. 1.15. The incorporation of siloxane cross-linking greatly influences the surface roughness of the film surface. Control polyurethane PU-0.0 shows an irregular surface with a surface roughness value of 13.4 nm (Fig. 1.15a). The incorporation of siloxane cross-linking transforms the surface into a smoothed surface. In the case of higher silane ratios (PU-1.5), the roughness value decreased to 4.7 nm (Table 1.5). This clearly indicates that the introduction of siloxane cross-linking provides smoothness to the film surface. This is due mainly to the presence of siloxane linkages on the surface of polyurethane films, which increases the hydrophobicity of the film surface (Fig. 1.11). The increased contact angle induces the surface to acquire low surface free energy; the roughness profile images are given in Fig. 1.16 The presence of siloxane group gives some relatively dark and light parts, indicating that microphase separation was observed with lower siloxane content (Fig. 1.15c) [48, 77]. Siloxane groups tend to stratify during the formation of film structure and also allow to complete the hydrolysis and condensation of silane moiety, which result in a smoothed surface with low surface free energy [78]. A similar observation has been reported [79] for polyurethane dispersions modified with dihydroxylpropyl terminated siloxane oligomer. The presence of siloxane groups on the polyurethane film surface is schematically represented in Fig. 1.17. This siloxane group covers the surface of polyurethane films, which is responsible for the increased water contact angle with low surface energy. The covering of siloxane group over polyurethane surface reduces the surface roughness and forms a uniform surface [80].

TABLE 1.5 Root-Mean-Square (RMS) Surface Roughness Values of Polyurethane Films [48]

Codes	RMS surface roughness R_q (nm)
PU-0.0	13.4
PU-1.0	13.3
PU-1.1	12.2
PU-1.2	8.2
PU-1.3	7.7
PU-1.4	6.9
PU-1.5	4.7

1.4 CONCLUSIONS

A new class of sol-gel-derived silica aerogel was developed using ionic liquid, with choline formate as pore-forming agent. The presence of ionic liquid in the sol-gel matrix increases the aging time, thereby avoiding collapse of the gel structure. Ionic liquid plays a vital role in controlling the surface behavior of hydroxyl groups. Further, removal of ionic liquid from the gel matrix leaves a free hydroxyl group, which can be further functionalized for some other potential applications. Rheological studies reveal the viscoelastic nature of the prepared gels. Thermal studies clearly show that the presence of ionic liquid greatly influenced the degradation as well as melting behavior of

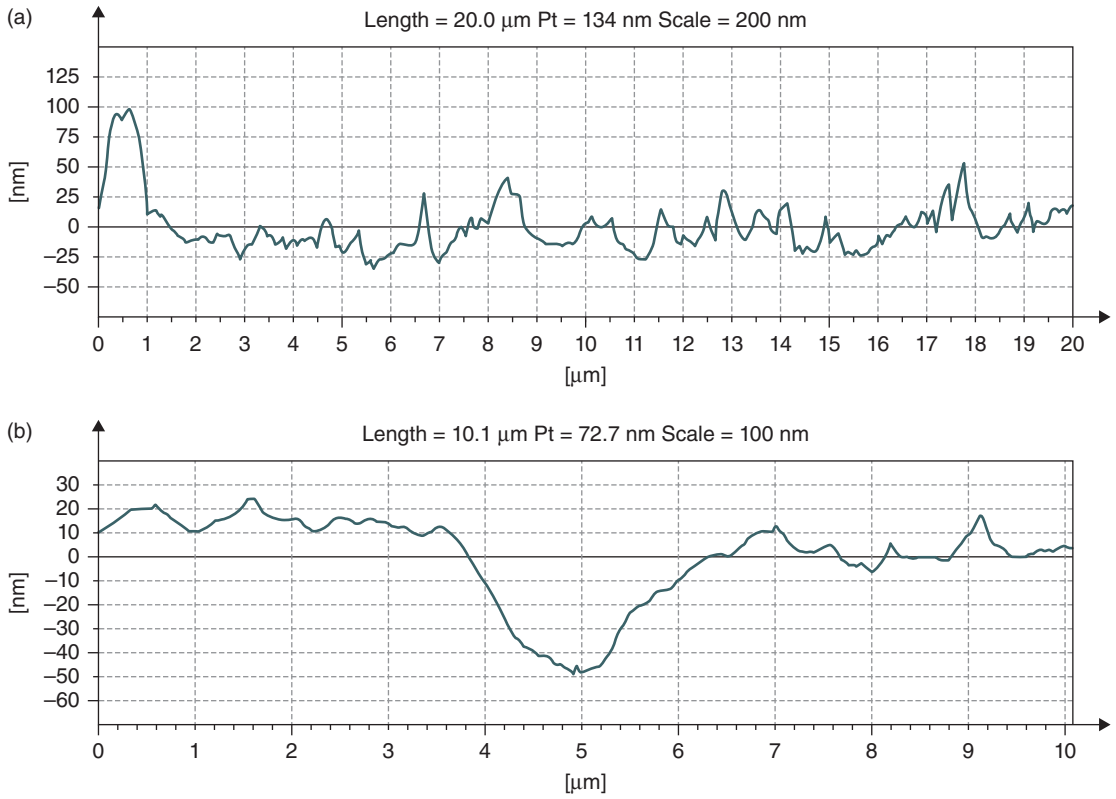

FIGURE 1.16 Surface roughness profile for the PU–siloxane films: (a) PU-0.0; (b) PU-1.5

the gels. The role of ionic liquid on the morphology of silica aerogel was observed using the SEM technique. Furthermore, biocompatibility studies clearly indicate that choline formate ionic liquid enhanced the cell viability as well as proliferation of the aerogels. Higher cell viability was observed irrespective of the concentration of the gel and time duration for the prepared aerogel samples with ionic liquid. These studies clearly indicate that the prepared silica aerogel could be used for the encapsulation of biomolecules such as proteins, enzymes, and other substances for longer time duration, which could help retain their conformational stability.

We adopted a similar sol-gel strategy to prepare polyurethane–siloxane cross-linked film structure. The polyurethane was prepared using a biorenewable castor oil as a polyol, and the siloxane moiety was introduced by coupling the silane agent on to the polyurethane prepolymer. Structural, surface, and morphological properties of the polyurethane–siloxane cross-linked films were extensively studied using ATR-FT-IR, solution ^{1}H NMR, solid-state ^{29}Si CP/MAS NMR, contact-angle, moisture sorption, UV–visible, SEM, and AFM techniques. The ATR-FT-IR spectra confirmed the formation of polyurethane prepolymer, attachment of silane moiety, and siloxane cross-linking. The confirmation of polyurethane formation as well as silane attached to polyurethane prepolymer moiety was analyzed using solution ^{1}H-NMR studies. The cross-linking state of silane moiety on increasing the silane concentration from 1.0 to 1.5 was monitored using solid-state ^{29}Si-NMR spectra. The surface behavior of the film surface was studied using contact-angle measurements, which proves the hydrophobicity of the cross-linked films. Furthermore, adsorption behavior of the films shows that the polyurethane surface has a hydrophobic character. UV–visible studies provide information about the transmittance of the polyurethane films. AFM studies shows that the surface roughness of the films decreased from 13.4 to 4.7 nm for PU-0.0 and PU-1.5, respectively. These hydrophobic polyurethane surfaces may be used for the development of leather coatings, lens, and other materials.

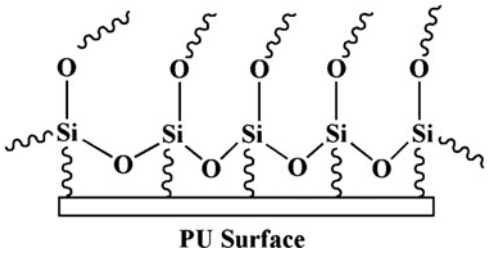

FIGURE 1.17 Schematic representation of siloxane groups on PU surface.

Overall, the study shows that these kinds of sol-gel-derived surface-active silica aerogel and biorenewable castor

oil–based polyurethane–siloxane cross-linked hydrophobic surfaces may find potential applications in the area of development of biomaterials and further widen the scope in the material science.

2.1 INTRODUCTION

It is well known that organic compounds with a small and simple structure such as ethers and alcohols induce anesthetic action. More than 150 years have passed since the phenomenon of anesthesia was discovered; however, the action mechanisms still have not been clarified thus far. There are some common characteristics in anesthetic action as follows:

1. *No Structural Specificity of Anesthetics*. Most volatile organic liquids exhibit anesthetic potency, although they cannot be clinically used because of the strong toxicity. Laughing gas (nitrous oxide) and inactive-gas xenon also have anesthetic potency. Figure 2.1 shows various molecular structures of anesthetics. Such molecular diversity undoubtedly indicates that functional groups needed for the anesthetic action cannot be determined.
2. *High Effective Anesthetic Concentration*. The EC_{50} (the concentration needed for 50% drug action) values of anesthetics take values of mM (M = mol dm^{-3}) order while those of receptor-binding drugs take values of from nM order to μM order, indicating that they are more than 1000 times larger than the latter.
3. *Pressure Reversal of Anesthesia.* These phenomena were first reported in anesthetic experiments of luminous bacteria [1, 2]; subsequently, they were [3] also confirmed in swimming experiments of tadpoles that pressure antagonisms the anesthetic action.
4. *Cutoff Phenomenon*. The anesthetic effect of organic compounds such as alcohols vanishes suddenly beyond a certain chain length [4, 5].

These characteristics of anesthetic action distinctly describe that the action is quite different from that of most drugs biochemically or physiologically oriented and closely related to fields of not only medical science but also natural science such as colloid and surface chemistry and biophysical chemistry.

Studies of anesthetic mechanisms go back to one rule proposed by Meyer and Overton [6, 7] at the beginning of twentieth century. They described that there exists an excellent correlation between olive oil/water partition coefficients of anesthetics and the anesthetic potency. Because biological membranes provide similar hydrophobic environments with moderate hydrophilicity to olive oil, it was believed that the anesthetic action is produced by a certain amount of an anesthetic incorporated into the membrane; that is, the Meyer−Overton rule suggested that the location of anesthetic action is the membrane. There has been a repeated dispute between two theories in studies of anesthetic mechanisms since the proposal of the Meyer−Overton rule. One theory is that nonspecific binding of the anesthetics into the membranes changes the membrane properties such as fluidity and phase state, and the secondary effect by anesthetics

into the membrane proteins causes anesthesia [8–10]. This is called a *lipid hypothesis* and flourished up to the mid-1980s, but the lipid hypothesis suffers from several criticism [11]: effects of stereoisomers [12, 13] and nonimmobilizers [14,15], low-temperature enhancement of anesthesia [16,17], and cutoff phenomenon [4, 5]. In addition to the backlash of the lipid hypothesis, the rapid development of protein and genetic engineering brought about the prosperity of another theory called a *protein hypothesis*, explaining that anesthesia is caused by the specific binding of anesthetics into several signal receptor proteins in the membrane [18–20]. The protein hypothesis has became popular until now; hence, more recent anesthetic studies concentrate on examinations of specific interactions between anesthetics and various kinds of proteins for the purpose of the identification of anesthetic binding sites in these proteins.

Some water-soluble globular proteins with a relatively simple structure have been used as model proteins for anesthetic studies. However, It has been reported in these model protein systems that the action of anesthetics on proteins varies depending on the kinds of the proteins, namely, the anesthetic sensitivity among the proteins is different from one another. This became a hindrance to the understanding of interaction modes between anesthetics and proteins. Recently, other investigators [21, 22] and we [23–25] have shown that the essential interaction modes of anesthetics to proteins can be revealed by comparing them with the interaction modes of substrates or substrate analogs, what is called specific or competitive binders, to the proteins. In this chapter, comparative studies of interaction modes of anesthetic and specific binders performed on several model globular protein systems are reviewed. At first, a comparative study on a luminescence enzyme firefly luciferase (FFL), which was reported as an anesthetic-specific protein for the first time in 1984 [26], is discussed. Next, studies using several globular proteins, which were also considered to be other anesthetic-specific proteins until now, an oxygen transporter myoglobin (Mgb), a hydrolytic enzyme of polysaccharide lysozyme (Lys), and a carrier enzyme in blood plasma bovine serum albumin (BSA), are demonstrated. Finally, we describe the reason for the diversity of anesthetic sensitivity among proteins by recent our idea of anesthetic–protein interactions.

2.2 ANESTHETIC EFFECT ON FFL

Most enzymes require anesthetic concentrations higher than the clinical level to show significant effects. However, FFL is uniquely sensitive to anesthetic actions; therefore, this enzyme has been used as a lipid-free protein model for the study on the anesthetic interaction with proteins. One investigator [27] first reported that FFL is highly sensitive to anesthetics about 50 years ago. Subclinical concentrations of inhalation anesthetics inhibited partially purified cell-free FFL from Japanese species (*Luciola cruciata*). Later, the authors of a report [28] on the temperature dependence of the anesthetic effects on partially purified American FFL (*Photinus pyralis*) concluded that anesthetics inhibited FFL by reversibly denaturing the structure into the less active unfolded form. On the other hand, another team [26, 29] reported that anesthetics and alcohols inhibited FFL in competition with the substrate luciferin. A controversy of anesthetic mechanism between the above investigators continued in late 1990s. Although the final conclusion has not yet been settled at present, for reasons mentioned in the introduction, now their idea for the anesthetic effect on FFL has been widely recognized as evidence for the specificity of anesthetic action and the paper was regarded as a milestone in the protein hypothesis [30].

The FFL protein is globular, with a molecular weight of 62 kDa, and emits a flash of light when mixed with luciferin and ATP in the presence of oxygen. The initial flash of light is followed by a weak light intensity with a slow decline continuing for hours. The reaction sequence of light emission was clarified [31–33] as follows:

$$E + LH_2 + ATP \Leftrightarrow E \bullet LH_2 \bullet AMP + PP_i \quad (2.1)$$

$$E \bullet LH_2 \bullet AMP + O_2 \Rightarrow E \bullet L_{ox} \bullet AMP + CO_2 + \text{light} \quad (2.2)$$

$$E \bullet L_{ox} \bullet AMP \Rightarrow E + L_{ox} + AMP \quad (2.3)$$

where E is the FFL, LH_2 is the reduced form of luciferin, L_{ox} is oxiluciferin, and PP_i is inorganic pyrophosphate. Initial reaction of FFL is to activate luciferin by ATP to form acyl-AMP between carboxyl moiety of luciferin and phosphate moiety of AMP, releasing PPi [Eq. (2.1)]. More recently, other studies [21,22] have revealed that long-chain fatty acids

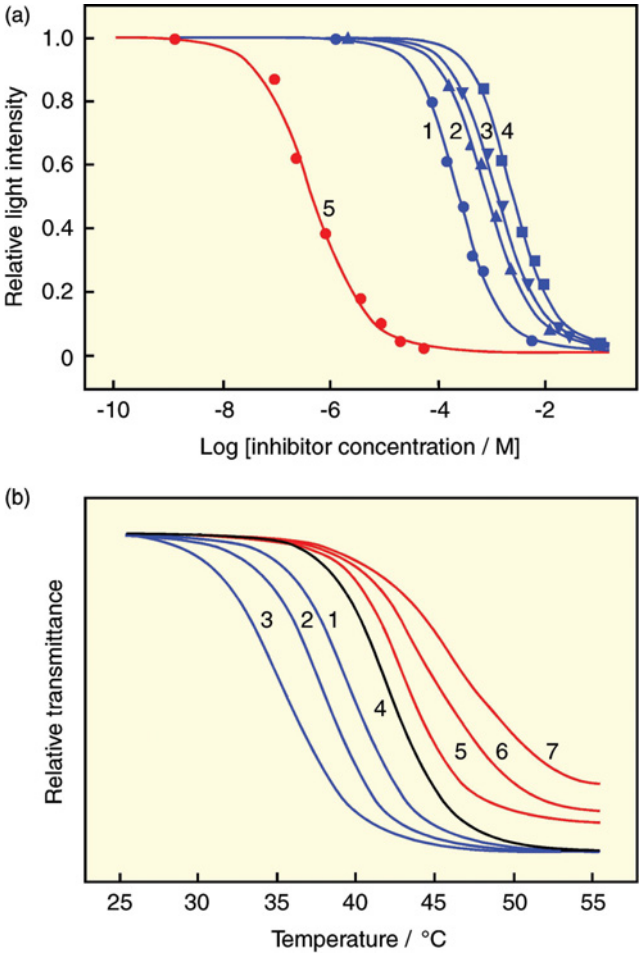

FIGURE 2.2 (a) Dose–response curves of inhalation anesthetics and myristic acid on light intensity of FFL: (1) halothane; (2) isoflurane; (3) enflurane; (4) chloroform; (5) myristic acid. such as myristic and palmitic acids inhibit FFL luminescence greater than do alcohols or anesthetics and that they are strong luciferin competitors. The acylation of AMP by carboxylates is often the initial step in activating the carboxylates in many biochemical reactions. Fatty acids are activated by ATP to form acyl-AMP and release PPi during β-oxidation by acyl-coenzyme A (acyl-CoA) synthetases [34] as follows

$$\text{R–COOH} + \text{ATP} \Leftrightarrow \text{R–COO} \bullet \text{AMP} + \text{PP}_\text{i} \quad (2.4)$$

$$\text{R–COO} \bullet \text{AMP} + \text{CoA} \Leftrightarrow \text{R–COO} \bullet \text{CoA} + \text{AMP} \quad (2.5)$$

where R−COOH is a fatty acid. The reaction is identical to the initial interaction of luciferin with ATP in Eq. (2.1). The homology between FFL and acyl-CoA synthetases has been

TABLE 2.1 Effects of Inhalation Anesthetics and Fatty Acids on FFL

Ligand	IC_{50} (μM)	n^a	$\Delta T_{1/2}$ (μM)^b	log P^c
Anesthetics

mentioned [35, 36]. Long-chain fatty acids bind luciferin recognition sites with high affinity by the negative charge of the carboxyl moiety. Therefore, the inhibition modes of anesthetics are different from fatty acids. Here we review several experimental results obtained by comparative studies on FFL−ligand interactions [21, 22, 37−40].

Figure 2.2a shows the dose-response curves of FFL light intensity measured at steady-state conditions when inhalation anesthetics or myristic acid, were added. The values of concentrations needed for 50% inhibition (IC_{50}) are shown for anesthetics and fatty acids in Table 2.1, respectively. The IC_{50} values for anesthetics are in mM ranges, while that of myristic acid is in μM range. Despite almost three orders of magnitude difference in IC_{50} values, the octanol/water partition coefficients are similar: myristic acid 199 [41], halothane 199, enflurane 126, and chloroform 93 [42]. The slopes of the dose-response curves of ligands are related to the Hill coefficients, n, of ligands, and the n values were calculated by the equation at constant temperature and pressure

$$\ln[(I_1/I_2 - 1)] = n \ln[I] + \text{constant} \quad (2.6)$$

where I_1 and I_2 are the intensity without the inhibitor and that with the inhibitor and $[I]$ is the inhibitor concentration, respectively. The calculated n values of inhalation anesthetics exceed one while that of myristic acid is below one. The n value does not necessarily indicate that n molecules of anesthetics bind to the protein. The derivation assumes a highly cooperative reaction between enzyme, E, and ligand, L, where only two species are present, E and EL_n. The intermediate n species, EL_1, EL_2,…, EL_{n-1}, are not counted. When the Hill number exceeds one, at least two

ligand molecules bind to one enzyme molecule cooperatively. The above results mean that inhalation anesthetics interact cooperatively with multiple hydrophobic pockets while the binding sites of myristic acid are limited.

The change in thermal denaturation temperature of a protein by ligand binding gives useful information regarding the ligand effect on structural stability of the protein. If the denaturation is irreversible, the thermal denaturation can be estimated by the ratio between the folded native fraction and the irreversibly denatured fraction. We found that the FFL solution suddenly becomes turbid at the denaturation temperature. The irreversibly denatured fraction was measured by the turbidity. Since the transition temperature varies by the protein concentration and scan rate because of the irreversibility [21], the ligand effects on the transition were compared at a fixed protein concentration and scan rate by using the temperature at which the denaturation was half completed ($T_{1/2}$). Figure 2.2b shows the thermal transmittance tracings of the effects of isoflurane and myristic acid together with a control with no ligand (thick curve). In the case of anesthetics, they are effective at mM range. At μM range, anesthetics show no effect. By contrast, myristic acid increases $T_{1/2}$ dose-dependently at μM range. The anesthetic concentrations that decreased $T_{1/2}$ by 1.0°C and the myristic acid one that increased $T_{1/2}$ by 1.0°C are also shown in Table 2.1. We can understand that the $T_{1/2}$ data are well correlated with the IC_{50} values.

A similar competitive effect of myristic acid with luciferin was observed in the fatty-acid homologs with the carbon number of ≥10 [22] as given in Table 2.1. On the other hand, during the FFL study, we observed that the inhibitory potency of fatty acids on FFL suddenly decreases at the certain carbon chain length. This is the similar cutoff phenomenon of the anesthetic potency observed in the series of homologous alcohols [4, 5, 43]. In the alcohol series, however, the longer alcohols lose their potency unlike the FFL inhibition by fatty acids. Here we compared the effects of butyric acid (C4), hexanoic acid (C6), and octanoic acid (C8) with those of the longer-chain fatty acids on the steady-state luminescence intensity and the thermal denaturation temperature of FFL [37]. We immediately notice from Table 2.1 that there is a sudden discontinuous change from μM to mM at C10–C8. The IC_{50} values change a 220-fold from C10 to C8. In contrast to this, the change in IC_{50} from C12 to C10 is only 11-fold. The dose–response curves of the three fatty acids are shown in Fig. 2.3a. The obtained dose–response curves are not parallel. This is unusual because the dose–response curves of similar compounds such as 1-alkanol series and those of the fatty acids with a longer acyl chain than C10 are parallel [22,24]. Therefore, a large change in shape among the curves shown in Fig. 2.4 means that the Hill numbers change from less than one at C8 to more than one at C6. The result reveals that the binding number suddenly increases when the carbon chain length becomes shorter than C8; that is, the

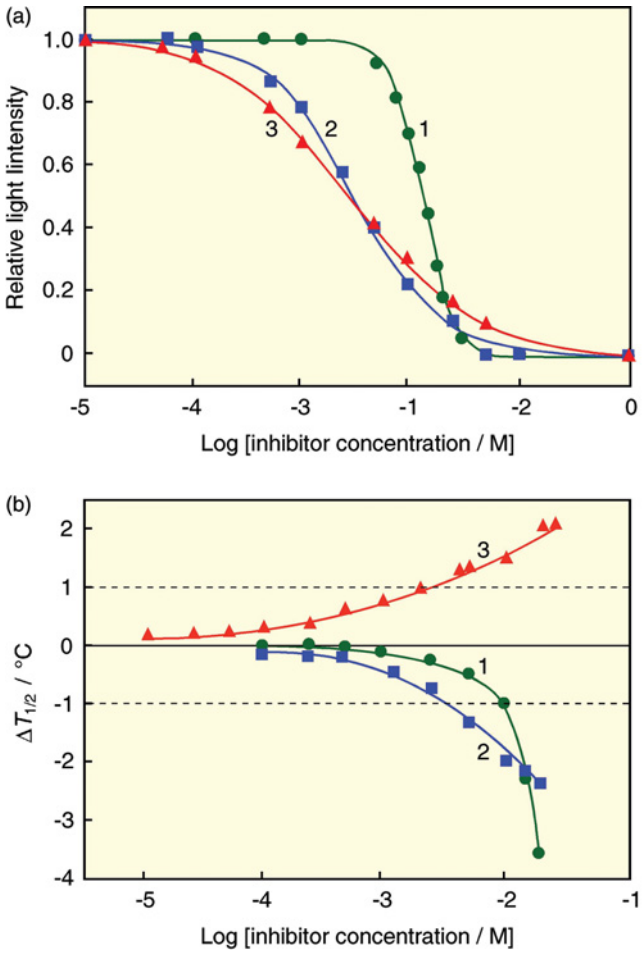

FIGURE 2.3 (a) Dose–response curves of short-chain fatty acids on light intensity of FFL (1) butyric acid (C4), (2) hexanoic acid (C6), and (3) octanoic acid (C8). The light intensity is expressed by the fraction of the control light intensity without ligands. (b) Dose-dependent effects of short-chain fatty acids on thermal denaturation temperature of FFL: (1) C4; (2) C6; (3) C8. Broken lines indicate the lines of denaturation-temperature change of 1.0°C.

binding mode changes from noncooperative limited number of binding sites to highly cooperative multiple binding sites. Further, a more dramatic change was observed with the transition temperature. The dose-dependent effects of C8, C6, and C4 on the thermal denaturation temperature are shown in Fig. 2.3b. The fatty acids with a longer acyl chain than C10 increase the denaturation temperature, whereas those with a chain shorter than C8 decrease the temperature. The latter mode is identical to that of anesthetics and alcohols. The concentration that changed the transition temperature 1.0°C (negative or positive) increases a 332-fold from C10 to C8. The change from C12 to C10 is only 3.2-fold.

The above results show that there are two modes in the action of fatty acids on luciferase. The action mode of fatty acids switches from specific to nonspecific when the carbon

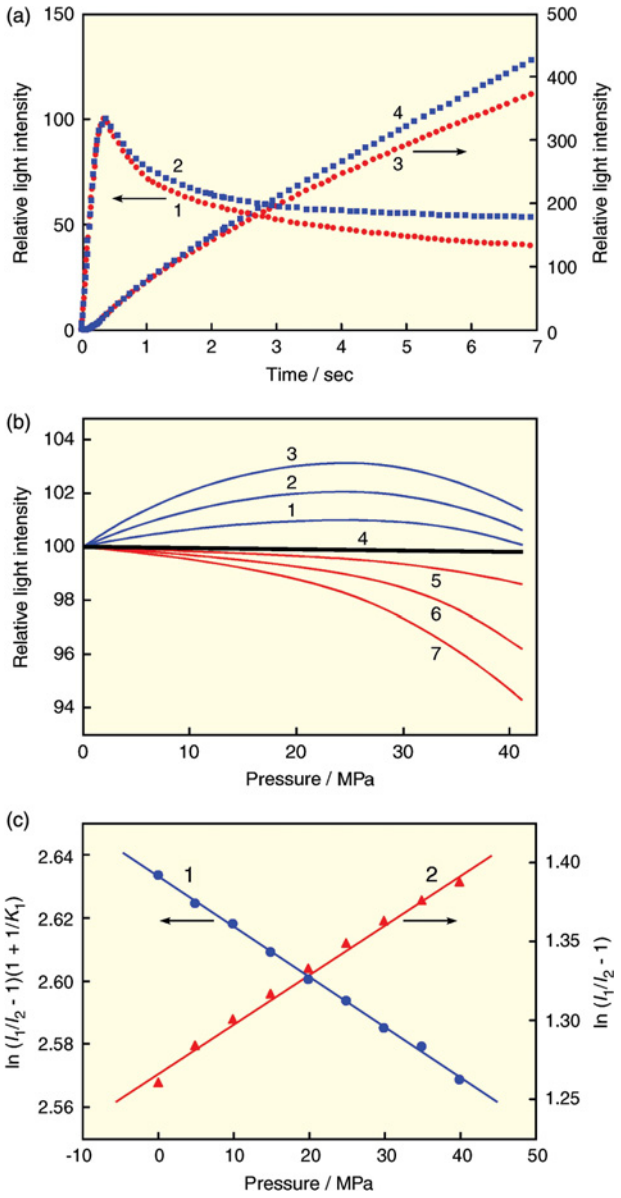

FIGURE 2.4 (a) Stopped-flow tracings of the effect of 1-octanol (0.7 mM) on the light intensity of FFL (initial flash intensity): (1) 0.1 MPa, (2) 12 MPa, and the integral of the tracings (steady-state intensity): (3) 0.1 MPa, (4) 12 MPa. (b) Effect of hydrostatic pressure on the steady-state light intensity of FFL in the presence of halothane and myristic acid at 19.1°C: (1) halothane concentration 0.1 mM; (2) 0.5; (3) 1.0; (4) control without ligands; (5) myristic acid concentration 0.5 μM; (6) 2.5; (7) 5.0. The relative light intensity is taken as the values at ambient pressure as 100. (c) Johnson–Eyring plots for anesthetic and specific-binder inhibition at 25°C: (1) 0.5 mM halothane; (2) 2.5 μM myristic acid.

chain length is reduced below C8. Another author [44, 45] proposed the induced-fit model where the ligands that bind to the substrate binding sites induce the protein structure to a high-energy native state. Another investigator [46] proposed the rate process model where anesthetics and alcohols bind nonspecifically to proteins and reversibly unfold the protein into a less active state by releasing the surface-bound water molecules. Fatty acids with a longer acyl chain than C10 are high-affinity specific binders and follow the induced-fit model. On the other hand, because of the strong hydrophobicity of the luciferin binding site [32], fatty acids with a chain shorter than C8 are apparently excluded from the luciferin binding site and they are low-affinity nonspecific denaturants and follow the rate process model. These results contradict the general consensus that the size of the receptor cavity discriminates specific binders.

The antagonizing effect of high pressure against anesthesia is well known. The pressure reversal of anesthesia has been generally accepted as a standard feature of anesthetic actions. There was a controversy about the anesthetic effect on FFL under high pressure. Another team [47] reported that application of high pressure does not affect the initial flash intensity (i.e., the initial peak heights) of FFL. In contrast, another group [38, 48] reported that high pressure decreases the steady-state light intensity at low temperatures but increases it at high temperatures and that the discrepancy between them is caused by the difference in the choice of parameters to represent the reaction velocity: initial flash intensity versus steady-state light intensity. Figure 4(a) demonstrates the stopped-flow tracings of the light intensity at 25°C in presence of 0.7 mM 1-octanol at ambient pressure and at 12 MPa, respectively, to compare the pressure effects on the initial flash intensity and the steady-state light intensity. The light intensity decays rapidly and the weak light lasts for hours. The initial flash is a transient event and is not in a steady state. We can understand that the flash intensity does not change with the application of hydrostatic pressure in the presence or absence of 1-octanol, but the tailings are different. On the other hand, the steady state is represented by the slope of the linear part of the integral of the light output. It is evident that high pressure increases the steady-state light intensity when the light intensity is integrated with respect to time. The rapid reaction kinetics of the transition state theory [49] shows the initial peak intensity approximately corresponds to the total amount of active enzyme and is unrelated to the reaction rate. Anesthetics inhibit the initial flash intensity by decreasing the amount of the active enzyme by reversibly unfolding the enzyme into the less active state, whereas pressure affects the steady-state light intensity by changing the reaction rates.

Here let us compare the effect of high pressure up to 40 MPa on the light inhibition of an anesthetic (halothane) and a fatty acid (myristic acid) under the steady-state condition, which can be obtained by eliminating the initial peak with addition of pyrophosphate [31, 39, 48]. The temperature scan of the steady-state light intensity of FFL showed that the maximum light intensity is observed at 19.1°C. When pressurized at the temperature that gives maximum light, hydrostatic pressure does not show any effect in the absence of

inhibitory ligands. Figure 2.4b shows the pressure effect on the steady-state light intensity in the presence of ligands at 19.1°C [39]. Here the pressure effect on the light intensity of the ligand-bound FFL is expressed against the light intensity at ambient pressure in the presence of inhibitors as reference states (controls). When halothane is added, pressure increases the light intensity with a maximum effect at about 25 MPa, and then further increase of pressure decreases the light intensity to the control. It is also noticed that pressure increases the light intensity with increasing the halothane concentration. In contrast to the observed effect of halothane, application of hydrostatic pressure in the presence of myristic acid decreases the light intensity monotonously and there is no minimum on the intensity curve. The myristic acid concentration synergizes the pressure effect in direct opposition to the case of halothane. From the pressure effects on the light intensities of the control and the ligand-bound FFL, the volume changes of the host protein (ΔV) were estimated. The Johnson−Eyring rate−process model calculates the volume change by plotting the logarithm of the ratio between the ligand-induced decrement of the light intensity and the control light intensity against the applied pressure [39, 50]

$$\ln[(I_1/I_2 - 1)(1 + 1/K_1)] = -p\Delta V/RT + \text{constant, for anesthetics} \quad (2.7)$$

$$\ln[(I_1/I_2 - 1)] = -p\Delta V/RT + \text{constant, for specific binders} \quad (2.8)$$

where K_1 is the equilibrium constant between the unfolded inactive fraction and the native fraction of the enzyme. Results of the Johnson−Eyring plots of 0.5 mM halothane and 2.5 μM myristic acid at 25°C are demonstrated in Fig. 2.4c. Here the light intensity curves at 25°C in Figs. 2.3 and 2.4 in Ref. 52 were used for data analysis. From the slope values of these curves, the ΔV values of FFL were estimated to be +3.94 cm^3 mol^{-1} for halothane and –7.66 cm^3 mol^{-1} for myristic acid, respectively. These results show that there are distinct differences between these ligands in their response to high pressure, that is, the effect of myristic acid is unambiguously the reverse of that of halothane.

The three-dimensional (3D) molecular structure of FFL (*Photinus pyrali*) in the absence of substrates (luciferin and ATP) was established in 1996 [51]. The enzyme takes an "open" conformation with a large solvent exposed cleft between a large *N*-terminal domain and a smaller *C*-terminal domain (Fig. 2.5a), which was constructed from PDB data (1LCI). The same team [52] also identified anesthetic binding sites on FFL without substrates from X-ray crystallography (Fig. 2.5b) constructed from 1BA3 that two bromoform molecules lie close to one another and bind within pockets in the large *N*-terminal domain: one is bound in a luciferin binding pocket, whereas the other is bound to a pocket accessible from the external surface of the enzyme. Another group [53] determined the FFL (*Luciola cruciata*) structure in the presence of substrates (Fig. 2.5c) constructed from 2D1R. They revealed that the enzyme takes a "closed" conformation, which involves a rigid-body bending of the *C* domain toward the the *N* domain and a ∼90° counterclockwise rotation of the *C* domain relative to the *N* domain, and luciferin and ATP bind closer to the domain interface and the cleft. This is a typical example of the induced-fit model. These facts clearly indicate that the binding of anesthetics to FFL hardly induces any change in structure, while there is a significant structural change in binding of the substrates. Concerning fatty-acid binding to FFL, other investigators [54] reported that FFL has a catalytic activity to synthesize fatty acyl-CoA via fatty acyl−adenylate as an intermediate from fatty acid in the presence of ATP, Mg^{2+}, and CoA. This is because that FFL belongs to adenylate-forming superfamily of enzymes and can produce an intermediate of acyl−adenylate (luciferyl-AMP) similar to fatty acyl−adenylate (fatty acyl-AMP) as seen in Eqs. (2.1) and (2.4) [55−57]. More recently, the structures of long-chain fatty acyl-CoA synthetase (LC-FACS) and its complexes with substrates (Fig. 2.5d,e) constructed from 1ULT and 1V26 have been reported [58]. The structure of LC-FACS in the absence of the substrates (fatty acid and ATP) is markedly similar to that of FFL under the same conditions, and surprisingly, the enzyme changes the conformation from "open" to "closed" by the large structural change between a large *N*-terminal domain and a smaller *C*-terminal domain, due to the substrate binding. The situation is essentially identical to the case of the substrate binding to FFL. Judging from the structural information with the experimental results as mentioned above, we can conclude that fatty acids, which compete with luciferin, stabilize the FFL conformation against thermal perturbation and decrease the FFL volume, indicating that they are a specific binder characterized by high affinity and small binding numbers. On the contrary, anesthetics, which do not compete with the substrate, destabilize the FFL conformation and increase the FFL volume, indicating that they are a nonspecific binder characterized by low affinity and large binding numbers.

2.3 ANESTHETIC EFFECT ON Mgb, Lys, AND BSA

An idea that anesthetics reduce the protein stability, namely, the promotion of protein unfolding, has found general acceptance and holds the anesthetic effect on FFL. However, in more recent reports [59], an opposite effect by anesthetics has been found on BSA, and this attracted a great deal of attention. The authors observed that the thermal denaturation temperature of BSA elevates by adding halothane and pointed out that halothane stabilizes the BSA structure. They explained that this stabilization is caused by the specific

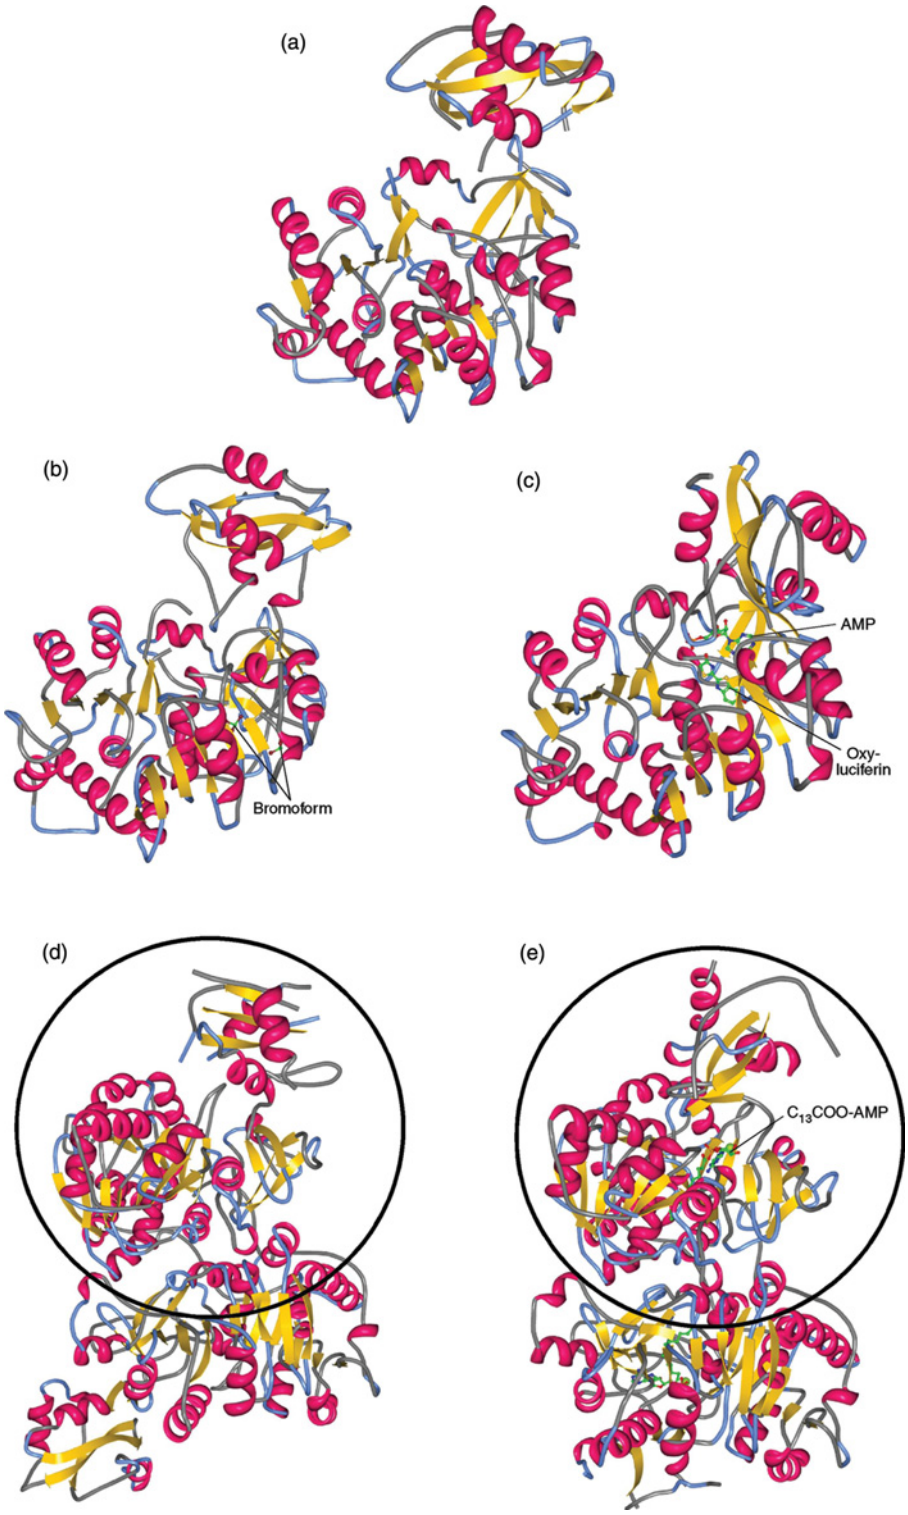

FIGURE 2.5 Structures of FFL and LC-FACS dimer complexed with ligands: (a) FFL without ligands; (b) FFL with bromoform; (c) FFL with AMP and oxyluciferin; (d) LC-FACS dimer without ligands; (e) LC-FACS dimer with C13COO-AMP. LC-FACS monomer is surrounded by a circle, and the ligand in each site is represented by ball-and-stick models. These figures were prepared from PDB data (1LCI, 1BA3, 2D1R, 1ULT, and 1V26) by using MBT Protein Workshop.

binding of halothane to the binding sites of native BSA. Another group [60] investigated the volume behavior of BSA in the absence and presence of medium-chain alcohol octanol and elucidated that the volume change of BSA-octanol binding is large negative, indicating that octanol decreases the BSA volume. These results form a great contrast to the destabilization (unfolding) of FFL by the addition of anesthetics, which was described in the preceding section. Further, investgtigators [61] have also observed that the effects of halothane on other globular proteins such as Mgb and Lys are markedly different from each other. The above findings suggest that an anesthetic acts on a protein in different ways depending on the kinds of the proteins, and this diversity of anesthetic sensitivity among proteins makes it difficult to systematically understand the mode of the interaction between an anesthetic and proteins. To clarify the intrinsic binding mode of anesthetics on globular proteins, we have recently performed a comparative study of ligand interactions on Mgb, Lys, and BSA from three viewpoints [23,25]: (1) comparison of interaction modes of anesthetics to the proteins to those of substrates or substrate analogs, (2) comparison between thermal and volume changes by ligand binding, and (3) comparison of the obtained macroscopic data with the structural data from X-ray crystallography.

The thermal changes of the proteins by anesthetic binding were estimated comparatively by differential scanning calorimetry (DSC). The DSC thermograms of Mgb, Lys, and BSA solutions in the absence and presence of halothane are demonstrated in Fig. 2.6, respectively. The effect of halothane on the thermal denaturation for all proteins appears at concentrations of mM range, however, the extent of the effect varies. The endothermic peak of Mgb shifts to a lower-temperature region with increasing halothane concentration, while Lys shows only a slight peak shift to a lower-temperature region with the concentration. On the contrary, the peak of BSA conversely shifts to a higher-temperature region with increasing halothane concentration. In Fig. 2.7, the denaturation temperatures (T_D) and denaturation enthalpy (ΔH_D) obtained for Mgb, Lys, and BSA at pH 7.0 are plotted against halothane concentration, respectively. For Mgb, the T_D value is depressed and the ΔH_D value decreases with increasing halothane concentration. The depression of T_D and the decrease in ΔH_D means that the binding of halothane to Mgb reduces the thermal stability of the native Mgb; in other words, halothane unfolds the structures as observed in the case of FFL [21]. On the other hand, the variation in the T_D and ΔH_D values of Lys is considerably small although both values decrease only slightly with increasing halothane concentration, which indicates that halothane produces little effect on the unfolding of Lys structures. In contrast to the cases of Mgb and Lys, the T_D and ΔH_D values for BSA increase with increasing halothane concentration, implying that halothane brings about the thermal stabilization of the native BSA by folding the structure. The

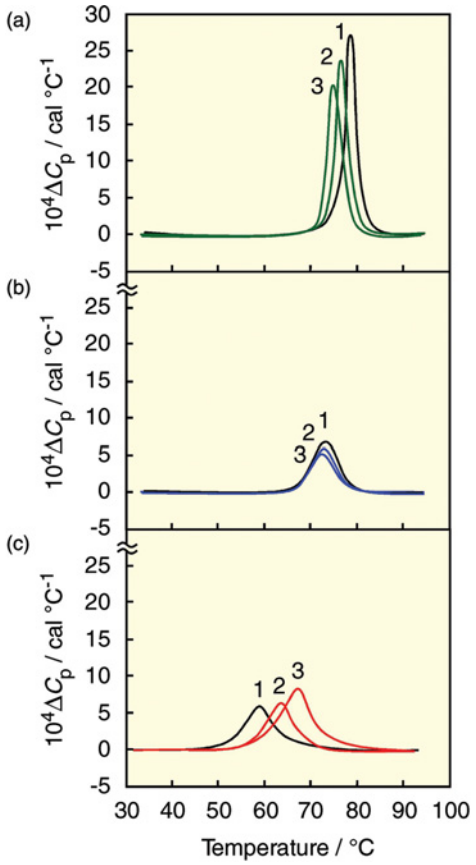

FIGURE 2.6 DSC thermograms of protein solutions at pH 7.0 in the absence and presence of halothane: (a) Mgb, (1) 0 mmol kg^{-1}, (2) 7.9, (3) 16.9; (b) Lys, (1) 0 mmol kg^{-1}, (2) 4.9, (3) 12.1; (c) BSA, (1) 0 mmol kg^{-1}, (2) 5.0, (3) 10.0.

corresponding results for the proteins at other pH levels exhibited a similar behavior for all the proteins [23,62,63].

The abovementioned anesthetic effect on the thermal change of the proteins was compared with that of their specific binders (substrates). The DSC thermograms of Lys solutions in the absence and presence of *N*-acetyl-D-glucosamine (NAG) are shown in Fig. 2.8 together with those of BSA solutions in the absence and presence of palmitic acid. Here NAG and palmitic acid are substrates of Lys and BSA, respectively. The endothermic peak of Lys shifts only slightly with the addition of NAG, while a greater peak shift is caused by the addition of palmitic acid for BSA. The effect of NAG on the T_D and ΔH_D values of Lys and that of palmitic acid on those values of BSA are shown in Fig. 2.9, respectively. The T_D and ΔH_D values of Lys increase very slightly with increasing NAG concentration unlike the case of halothane. In the case of BSA, peculiar behavior is observed for T_D with increasing palmitic acid concentration in the μM range, not mM range: there exists a bimodal increase in T_D, which is originated from the appearance of a new endothermic peak at a higher temperature. The ΔH_D value (total enthalpy of

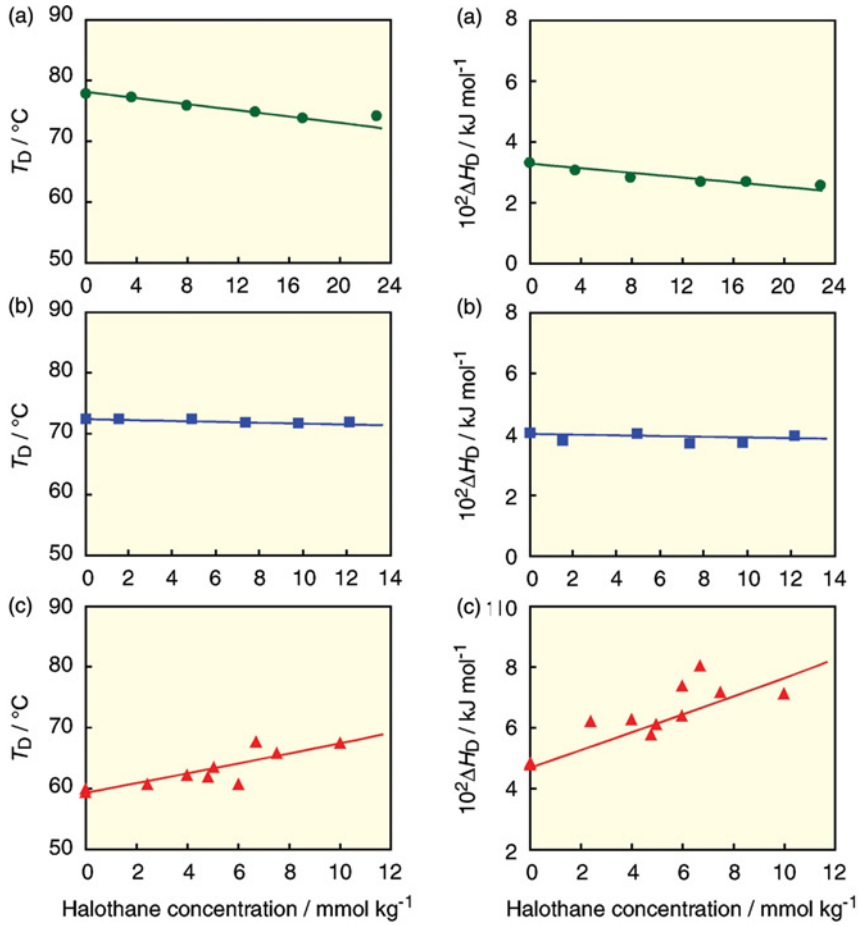

FIGURE 2.7 Thermal denaturation temperatures and enthalpies of proteins at pH 7.0 as a function of halothane concentration: (a) Mgb; (b) Lys; (c) BSA.

the two peaks) greatly increases with palmitic acid concentration. We can say from these results that the mode of the interaction between a specific binder and the protein is also different depending on the kinds of proteins, and also that the specific binder essentially produces the stabilization of the protein structure. The effect of the specific binder is in distinct contrast to that of halothane when considering their much lower effective concentrations.

Ligands affect not only the thermal behavior of a protein but also the volume behavior. Pressure study on FFL definitely suggests that pressure reversal of anesthesia is closely related to the volume change of proteins by binding of ligands. A comparative study of ligand effects on the volume behavior of Mgb, Lys, and BSA by using viscometry was performed [23, 25]. The pH dependence on the reduced viscosity (η_{red}) values of three kinds of protein solutions in the absence of halothane is shown in Fig. 2.10 by open symbols, respectively. The η_{red} values of the Mgb and BSA solutions are almost constant irrespective of pH values, while those of the Lys solution increase in the weak alkaline pH region. The η_{red} values of the three protein solutions in the presence of halothane at various pHs are also presented in Fig. 2.10 by closed symbols. Here the halothane concentration of 5.0 mmol kg^{-1} was adopted in the measurements considering the change in the thermal behavior of the proteins induced by halothane (Fig. 2.7). The changes in the η_{red} values of the protein solutions by the addition of halothane are different from one another: the η_{red} values of the Mgb, Lys, and BSA solutions in the presence of halothane become respectively larger, slightly larger and smaller than those in the absence of halothane at all pHs measured. The variation in the η_{red} value with halothane suggests that the volume of the protein in the solution changes by the addition of halothane, that is, that halothane causes a volume expansion of Mgb and a slight volume expansion of Lys, but a volume shrinkage of BSA.

The effect of the specific binder on the protein volume in the solution was investigated in the same way. The η_{red} values of the Lys solution in the absence and presence of NAG are plotted against pH together with those of BSA in the absence and presence of palmitic acid in Fig. 2.11. Here the NAG concentration of 690 μmol kg^{-1} and the palmitic acid concentration of 150 μmol kg^{-1} were selected by taking

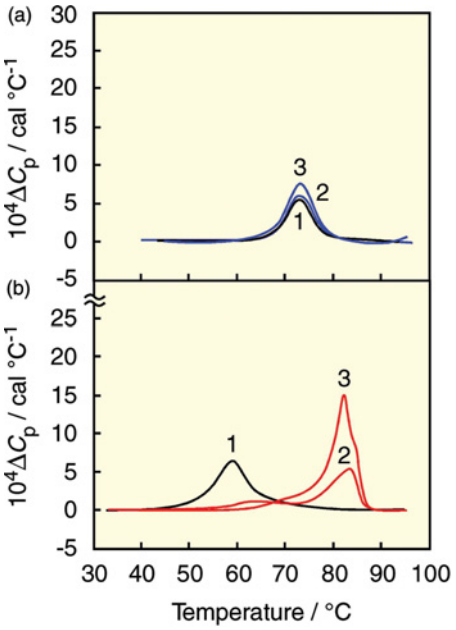

FIGURE 2.8 DSC thermograms of protein solutions at pH 7.0 in the absence and presence of specific binders: (a) Lys, (1) 0 μmol kg^{-1}, (2) 159, (3) 359; (b) BSA, (1) 0 μmol kg^{-1}, (2) 100, (3) 200. Here the binders of Lys and BSA are NAG and palmitic acid, respectively.

account of their effective concentrations (Fig. 2.9). The η_{red} values of the Lys solution in the presence of NAG are almost the same as those in the absence of NAG. The invariance of the η_{red} value suggests that the structural change of Lys by the NAG binding is not large enough to affect the volume. On the other hand, the η_{red} values of the BSA solution in the presence of palmitic acid become larger than those in the absence of palmitic acid, indicating that the BSA volume in the solution expands by the addition of palmitic acid. It is noteworthy that although the thermal behavior of BSA by halothane and palmitic acid (Figs. 2.7 and 2.9) is consistent with the direction of folding of the BSA structure, the volume expansion of BSA by palmitic acid is apparently the direction of unfolding of the structure in contrast to the volume shrinkage caused by halothane.

Mgb, Lys, and BSA are generally regarded as globular proteins. Hence, by assuming that the protein molecule is a hard-sphere particle, we roughly estimated the percentage of the volume change of the protein by the addition of the ligand. The viscosity of a dispersion of hard-sphere particles in homogeneous medium at a low concentration is expressed by Einstein's equation as

$$\eta_{red} = 2.5(v/V)C \tag{2.9}$$

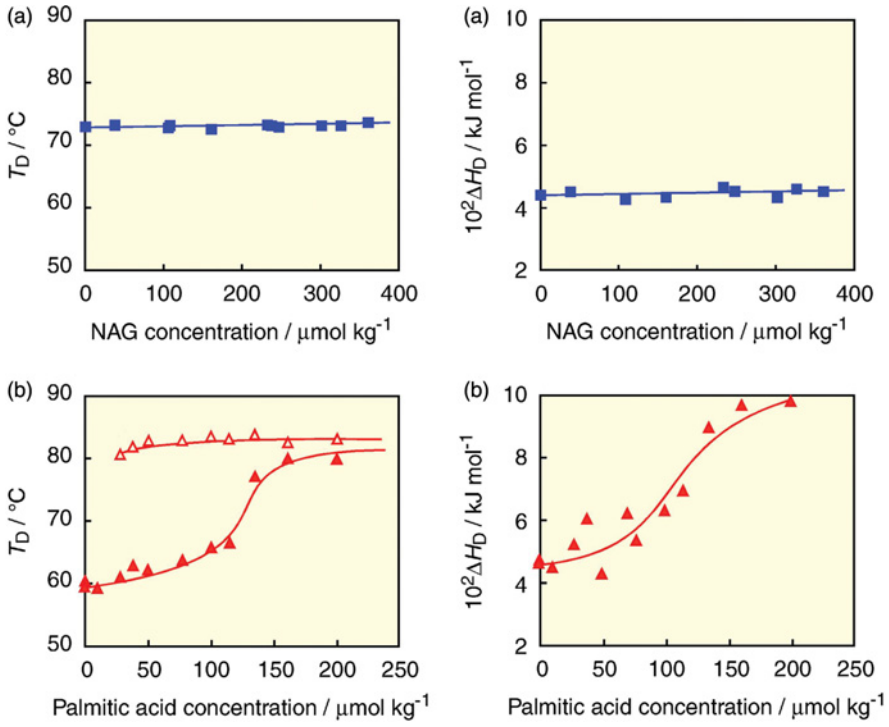

FIGURE 2.9 Thermal denaturation temperatures and enthalpies of proteins at pH 7.0 as a function of specific binder concentrations: (a) Lys; (b) BSA. For BSA, temperatures of low- and high-temperature denaturation are shown and total enthalpies of denaturation are given.

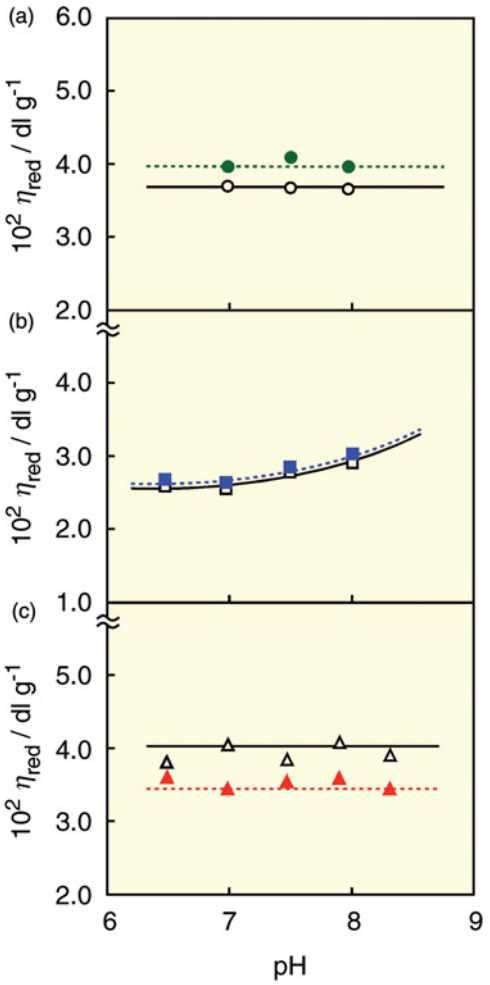

FIGURE 2.10 Reduced viscosity of protein solutions as a function of pH in the absence and presence of halothane: (a) Mgb; (b) Lys; (c) BSA. The solid and broken were obtained from a least-squares method.

where v and V are the volume of all the hard-sphere particles in the dispersion and the total volume of the system, respectively, and C is the concentration of a protein in units of g dL^{-1}. For nonspherical particles, although the numerical coefficient of v/V is larger than 2.5, it should be constant for any given shape provided the shear rate is sufficiently low. The percentage can be given by the following equation derived by use of Eq. (2.9)

$$[v(\mathrm{P}+\mathrm{L})/v(\mathrm{P})-1]^{*}100 = [\eta_{red}(\mathrm{P}+\mathrm{L})/\eta_{red}(\mathrm{P})-1]^{*}100 \qquad (2.10)$$

where $v(\mathrm{P}+\mathrm{L})$ and $v(\mathrm{P})$ are the volumes occupied by all the protein molecules in the solutions in the presence and absence of the ligand, respectively, and $\eta_{red}(\mathrm{P}+\mathrm{L})$ and $\eta_{red}(\mathrm{P})$ are

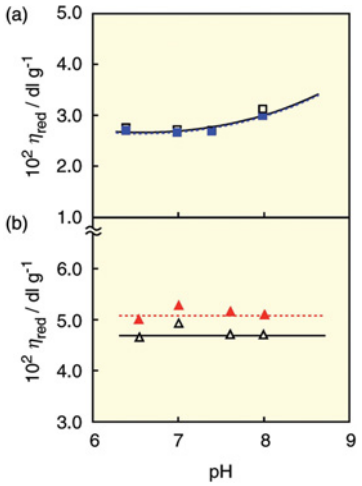

FIGURE 2.11 Reduced viscosity of protein solutions as a function of pH in the absence and presence of specific binders: (a) Lys; (b) BSA. The open and closed circles correspond to the results for protein solutions in the absence and presence of specific binders. The concentrations of NAG and palmitic acid are 690 and 150 μmol kg^{-1}, respectively. The solid and broken lines were obtained from a least-squares method.

the reduced viscosities of the protein solutions in the same situation. The calculated volume change for each protein by the addition of 5 mmol kg^{-1} halothane at pH 7.0 was 7.7% for Mgb, 1.3% for Lys, and –14.7% for BSA. With regard to the specific binders, we obtained the values of –0.72 % for Lys at the NAG concentration of 690 μmol kg^{-1} and pH 7.0, and 10.4 % for BSA at the palmitic acid concentration of 150 μmol kg^{-1} and pH 7.0. It can be said that the volume behavior of proteins is affected in different manners by the specific binder as well as the anesthetic.

For serum albumin, the structural data of several albumin complexed with ligands (anesthetics and substrates) are available from the Protein Data Bank. Let us consider the thermal and volume changes of BSA by the binding of ligands in reference to the structure. The determination of the first high-resolution crystal structure of human serum albumin (HSA) was from X-ray structural analysis in 1992 [64]. The binding sites of anesthetics and fatty acids in HSA have been recently determined by Bhattacharya et al. [65, 66], respectively. Since BSA has a very similar primary structure to HSA and forms almost the same tertiary structure as HSA [67], it is conceivable that the binding sites of halothane and palmitic acid in BSA are virtually the same as those in HSA. HSA has 585 amino acid residues (BSA: 583 residues) and consists of three homologous α-helical domains (I, II, and III). Each domain contains ten helices and is divided into six-helix and four-helix subdomains (A and B). Figure 2.12 demonstrates the structures of HSA, HSA complexed with halothane, palmitic acid, or halothane and myristic acid, respectively, which are constructed by use of PDB

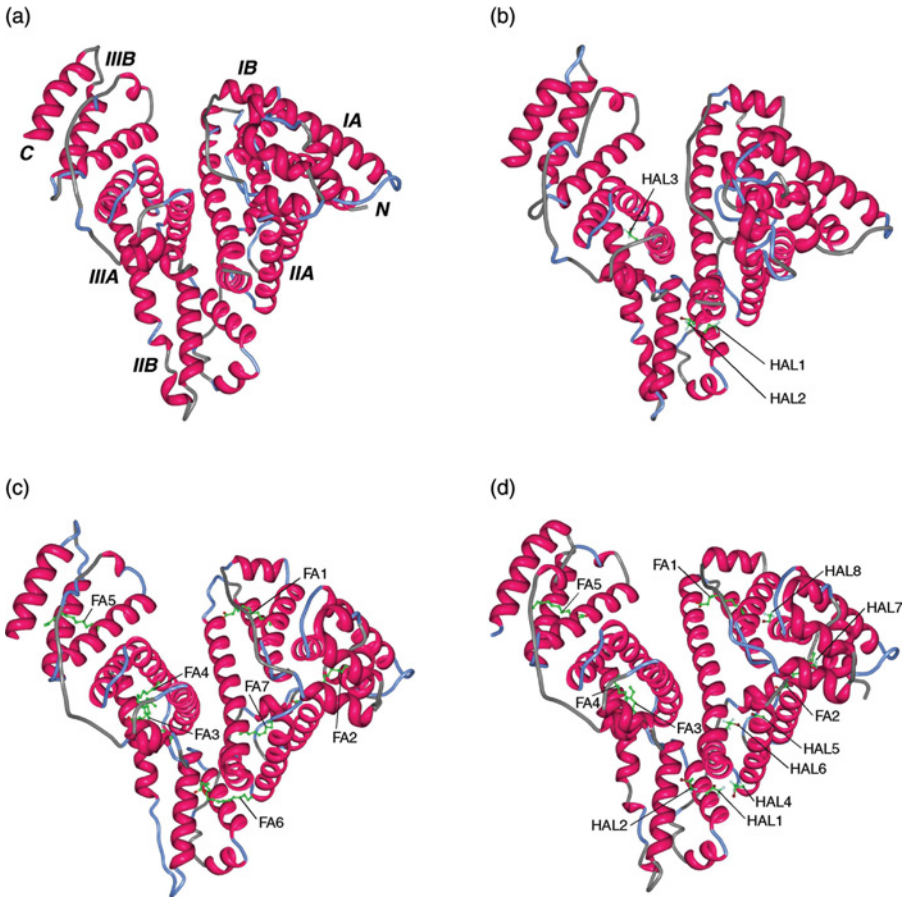

FIGURE 2.12 Structures of HSA complexed with ligands: (a) HSA without ligands; (b) HSA with halothane; (c) HSA with palmitic acid; (d) HSA with halothane and myristic acid. Three domains, I, II, and III, with subdomains A and B in each domain, are shown in figure (a) schematically. The ligand in each site is represented by ball-and-stick models. In part (d), the fatty-acid-binding site FA3 prevents the binding of halothane to the site (HAL3). These figures were prepared from PDB data (1BM0, 1E7B, 1E7H, and 1E7C) by using MBT Protein Workshop.

data (1BM0, 1E7B, 1E7H, and 1E7C). Halothane binds at three discrete sites on HSA in the clinically relevant concentration range (around 15% of the saturated vapor pressure): two sites at the interface between subdomains IIA and IIB (HAL1 and HAL2) and one site in subdomain IIIA (HAL3). The binding of halothane to HSA causes only very minor changes in local structure. On the other hand, palmitic acid binds at seven discrete sites on HSA: one site in subdomain IB (FA1), one at the interface between subdomains IA and IIA (FA2), two in IIIA (FA3 and FA4), one in IIIB (FA5), one at the interface between IIA and IIB (FA6), and one IIA (FA7). Unlike the case of halothane, the binding of palmitic acid to HSA causes the conformational changes among three domains as described below. Furthermore, at high halothane concentrations (around 60% of the saturated vapor pressure) in the presence of myristic acid, there exist seven halothane-binding sites on HSA together with five myristic acid-binding sites. These halothane-binding sites are amphiphilic pockets and clefts preformed on HSA, and all reside at the location of fatty-acid-binding sites.

The above structural data were compared with the thermal results. The effective concentration of halothane on BSA is significantly different from that of palmitic acid. Because we used the overall concentrations to express the ligand concentrations, the binding and free concentrations between BSA and ligand at equilibrium cannot be determined. However, it is useful to compare the molar ratio of ligand to BSA by use of the overall concentration. The molar ratio of effective halothane concentrations of 5 and 10 mmol kg^{-1} correspond to 165 and 330 moles per 1 mol of BSA, while that of effective palmitic acid concentrations of 100 and 200 μmol kg^{-1} correspond to 3.3 and 6.6 mol, respectively. The structurally determined binding numbers of halothane and palmitic acid are not very different from each other. However, in the molar ratio of both ligands, 50−100 times greater ratio of halothane compared with that of palmitic acid is necessary for the

appearance of ligand actions; in other words, the greater numbers of halothane molecules are required for the appearance of the ligand action on BSA whereas palmitic acid suffices for several molecules. Comparing the molar ratio of both ligands at the effective concentrations with the structural data of HSA complexed with ligands, the ratio of halothane is not consistent with the binding numbers on HSA, whereas that of palmitic acid is in good agreement with the numbers. This fact suggests that there is an only slightly observable anesthetic effect on BSA even if the halothane concentration corresponding to the binding numbers determined from X-ray analysis as the overall concentration is added to the BSA solution. Considering the fact that the molar ratio of halothane at the effective concentration is much larger than the concentration of binding number, there are undoubtedly a lot of free halothane molecules in the BSA solution at the concentration. Therefore, we can conclude that halothane is an essentially nonspecific binder to BSA and affects BSA by the nonspecific solvent effect in the higher concentration range. In contrast with the case of halothane, the binding mode of palmitic acid is quite different. The consistency of molar ratio and structural data exhibits that the overall concentration of palmitic acid added can be substantially regarded as the binding concentration, and then there is almost no free plamitic acid in the BSA solution. Further, it should be noted that the molar ratio of BSA to palmitic acid at optimal stabilization is very close to the maximum binding number 7 determined from X-ray analysis. We can thus conclude that palmitic acid is a specific binder to BSA and stabilizes the BSA structure at the transition state in the lower concentration range.

Moreover, it was revealed from the structures of HSA/fatty-acid complexes that binding of fatty acids to HSA produces a distinct conformational change [66,68,69]: fatty-acid binding causes domains I and III to be displaced to the left, opening up the central crevice and increasing the width of the molecule from 80 to 90 Å. The rotation of domain I relative to domain II is stabilized by the fatty-acid binding at FA2 to the interface between subdomain IA and IIA. More recent studies of ^{13}C NMR [70] and molecular dynamic simulation [71] exhibited that fatty acid binding sites FA2, FA4, and FA5 are identified as high-affinity sites, with sites FA1, FA3, FA6, and FA7 as low-affinity sites. Therefore, a few molecules of palmitic acid occupy the binding site of BSA, probably high-affinity sites, including at the interface of subdomains IA and IIA (FA2); the conformational change of BSA from a native state to a transition state occurs; and the structure of BSA becomes thermally stable. An abrupt change in the thermal behavior in the vicinity of the molar ratio of 4 shown in Fig. 2.7 may be in good agreement with the above behavior. Further increase in palmitic-acid concentration increases stabilization, and when seven molecules of palmitic acid occupy all the binding sites, the maximum stabilization effect appears. Concerning the volume behavior of BSA in the presence of palmitic acid, we may say simultaneously that the conformational change due to the binding of palmitic acid produces an increase in volume of BSA, although the thermal stabilization seems to contradict the volume expansion because both trends are apparently mutually inverse to each other in terms of the folding-related stabilization. This behavior is in accord with the fact revealed from the drug-binding study on HSA by X-ray structural analysis [72] that the binding of fatty acids increases the volume of drug site 1 (a preformed binding pocket within the core of subdomain IIA). We speculate that the transformation may be accompanied with a volume increase. This stabilization mechanism of palmitic acid forms a striking contrast to that of halothane.

In contrast to this, almost no change in thermal and volume behavior of Lys is caused by the binding of NAG to Lys (rigorously speaking, very slight thermal stabilization and volume shrinkage). Because it is known that a hexamer of NAG binds at the binding site within Lys [73, 75], the monomers of NAG can also bind at the same sites [73, 74]. However, the DSC measurements revealed that the stabilization of the Lys structure by the binding of NAG is extremely small. Therefore, the binding of NAG does not induce so large a structural change of Lys as to affect its thermal and volume behavior. It was reported from the X-ray structural analysis [73] that oligomers of NAG bind in the cleft of active sites of Lys and cause the induced-fit type interaction. The monomer binds in subsite C with 4 hydrogen bonds and 30 van der Waals contacts and the interaction increases in proportion to oligomerization of NAG. Then, the structural change of Lys by the binding of the monomer of NAG seems to be considerably small as compared with the binding of other oligomers like dimer and trimer. Gekko et al. [76] have shown that the change in partial specific volume and partial adiabatic compressibility of Lys by the binding of the monomer of NAG is smaller than those of the dimer and trimer. One possible reason why the binding of the monomer of NAG to Lys does not produce the detectable structural change accompanied by the stabilization is the imperfect packing in the binding site in addition to the rigid structure of Lys, as mentioned below.

2.4 INTRINSIC INTERACTION MODE OF AN ANESTHETIC WITH PROTEINS

We showed by comparative studies of ligand−protein interaction that the mode of the interaction between an anesthetic and a protein is markedly different from that between a specific binder and a protein. On the other hand, the interaction mode is also remarkably different depending on the kinds of proteins. What is the cause of the difference in ligand sensitivity among globular proteins? We speculate that the difference in anesthetic sensitivity among globular proteins is attributable to two factors: (1) the magnitude of the hydrophilicity on the protein surface, namely, the balance

TABLE 2.2 Properties Related to Hydrophilicity on Protein Surface

Protein	Molecular weight (kDa)	Hydropathy value	H_ϕ[a]	P[b]
Mgb	17.8	−280.1	1038	1.09
Lys	14.3	−210.8	893	1.04
BSA	66.3	−1235.1	990	1.23

[a]The total hydrophobicity divided by the number of residues (cal/residue).
[b]Polarity parameter of Bigelow.

between the hyrophilicity and hydrophobicity on the surface, and (2) the rigidity of the protein structure, that is, whether the protein is hard or soft.

Although it is difficult to quantify the hydrophilicity of the protein surface directly, we can qualitatively infer the hydrophilicity of the protein surface from several parameters determined on the basis of the primary structure of the protein. Table 2.2 lists the values of hydropathy index [77], hydrophobic energy [78] and polarity parameter [79] for Mgb, Lys, and BSA. As the hydrophilicity of a protein becomes large, the hydropathy index and the hydrophobic energy decrease while the polarity parameter increases. From these values, the hydrophilicity of the proteins is Mgb ≈ Lys < BSA but the difference between Mgb and Lys cannot be distinguished. The surface hydrophilicity of a protein is closely related to the solubility of the protein in a buffer solution, or the protein crystallization in the solution. In other words, the more hydrophilic the protein surface is, the larger the concentration at which the crystallization occurs becomes. Therefore, we selected the crystallization concentrations of these proteins as the index of the surface hydrophilicity. Since it is known that the protein crystallization is remarkably dependent on solution conditions such as kinds of solvent and added salts, pH, and so on, we determined the crystallization concentrations under the same buffer condition (0.1 M and pH 7.0). The results of the solubility measurements are given in Fig. 2.13. Although

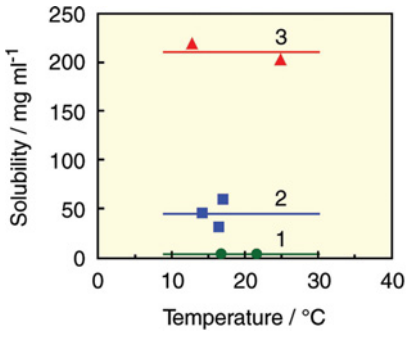

FIGURE 2.13 Solubility of proteins as a function of temperature: (1) Mgb; (2) Lys; (3) BSA. Here all solubilities were determined at the same solution condition: 0.1 M phosphate buffer, pH 7.0.

the solubilities of these proteins are almost constant in the temperature range measured, a pronounced difference in solubility among the proteins is found: the solubility is large for Lys (∼40 mg mL^{-1}) and very large for BSA (ca. 210 mg mL^{-1}) while remarkably small for Mgb (∼4 mg mL^{-1}). Taking into account the above parameters and the solubility for the proteins, we elucidated that the surface hydrophilicity increases in the order of Mgb < Lys < BSA. Regarding FFL, although there are no available data for the hydrophilicity, it seems to have similar hydrophilicity to Mgb, judging from the fact that the solubility of FFL in a Gly-Gly buffer is considerably low.

Inhalation anesthetics are amphiphilic molecules, and the hydrophobicity is relatively large as is seen from the solubility in water [80]. Since almost all the globular proteins are water-soluble, unlike membrane proteins, the proteins used in this study are fundamentally hydrophilic. The difference in the halothane sensitivity of the proteins is closely related to the interaction mode of a hydrophilic protein with an amphiphilic ligand, and the magnitude of the hydrophilicity is one of the determinants of the sensitivity. Proteins maintain the structural integrity by the balance between hydrophilic and hydrophobic interactions on the protein surface surrounded by water. This means that the extensive hydrogen bonding capability of water essentially dominates the behavior of a protein. Anesthetics act in the protein/water interface region and thus interrupt the interaction between proteins and water. They decrease the restrictive force of water (hydrophobic hydration) and loosen the structure for a protein with predominantly hydrophobic residues on the surface. To the contrary, they decrease the attractive force of water (electrostriction) and tighten the structure for a protein with predominantly hydrophilic residues at the surface.

The circumstances around the protein molecule are identical to those for polymer chains in a poor or a good solvent that is often dealt with in general polymer science. Water is repulsive to hydrophobic solutes and act as a poor solvent, but is strongly attractive to hydrophilic solutes and becomes a good solvent. A polymer chain tends to expand in a good solvent while it is inclined to shrink in a poor solvent. Adding a high concentration of an anesthetic can induce a local change of the nature of the solvent in the vicinities around the protein molecules from pure water to a mixed solvent of water and the anesthetic. Such a microscopic mixed-solvent environment produces an effect as a good solvent for a protein with relatively low hydrophobicity, and then they are expected to unfold. As for a protein with large hydrophilicity, on the other hand, such an environment has an effect as a poor solvent, and then the protein is conversely expected to fold. We call this effect a *microscopic solvent effect*. Therefore, the anesthetic effect on proteins may vary according to the difference in the hydrophilic and hydrophobic balance of the protein−water interface. It can be said from the thermal and volume behavior of FFL, Mgb, Lys, and BSA in the presence

of an anesthetic that the former microscopic solvent effect is predominant for FFL and Mgb while the latter solvent effect is predominant for BSA. In the case of Lys, the intermediate situation may be expected to hold and probably another factor mentioned in the next section greatly contributes to the structural stability.

We think that another factor that determines the anesthetic sensitivity of globular proteins is the rigidity of the protein structure. The rigidity of a protein can be estimated from its compressibility in the aqueous solution. Another research group [81−83] have measured the sound velocities and the densities for dozens of aqueous globular protein solutions to determine the adiabatic compressibilities of the proteins in water. They clarified the correlation between the compressibility and several factors affecting the compressibility, such as molecular size, hydrophobicity, and secondary structure, and categorized each of them as a hard or a soft protein. The adiabatic and the isothermal compressibilities of Mgb, Lys, and BSA at 25°C [82] are summarized in Table 2.3 together with other molecular properties of the proteins, such as partial specific volume, fraction of α-helix and β-sheet, and numbers of S-S bond. We immediately notice that the compressibility values of Mgb and BSA are large, while the value of Lys is as low as about half of the values of BSA and Mgb. The compressibility values suggest that Mgb and BSA are fairly soft proteins, while Lys is a rather hard protein, and hence, the rigidity of the structure for the proteins increases in the order of BSA $\approx$ Mgb $<$ Lys. For FFL, the compressibility value has not yet been determined for the enzyme; however, considering the large structural change by the binding of substrates, the rigidity of the structure is expected to be a relatively soft protein.

It is understandable from the secondary structures of the proteins in Table 2.3 that Mgb and BSA contain high percentages of α-helical structures in comparison with Lys. High-pressure studies on volume properties of peptides [84−86] have proved that the compressibility of α-helix or β-sheet itself is negligibly small: they have very hard structures. However, an increase in the α-helix content in a whole protein molecule may cause the insufficient packing between an α-helix and another α-helix or its surrounding hydrophobic region due to its bulky structure, which, in turn, causes the number and the size of cavities to increase. As a result, higher content of α-helix generally tends to soften the protein structure, that is, the α-helix-rich proteins are highly compressible [82]. Therefore, the large variation of Mgb (expansion by unfolding) and BSA (shrinkage by folding) by nonspecific microscopic solvent effect of halothane may result from their soft structures, due to the large α-helical content. It has been reported in the molecular simulation study [87] that the inside of α-helix of Mgb is difficult to compress; however, cavities between α-helices are easily compressed. In contrast to Mgb and BSA, Lys with low α-helix content shows very low sensitivity to halothane. This is also explainable from the same viewpoint: the low halothane sensitivity is probably attributable to the hard structure of the Lys molecule.

As mentioned above, the anesthetic sensitivity of globular proteins is closely correlated with the hydrophilicity of the protein surface and the rigidity of the protein structure. On the basis of the above idea, we can roughly classify the globular proteins into four categories as follows: (1) a protein with large hydrophilicity and soft structure, (2) a protein with small hydrophilicity and soft structure, (3) a protein with large hydrophilicity and hard structure, and (4) a protein with small hydrophilicity and hard structure. From the surface hydrophilicity and the structural rigidity of the present proteins, we can say that FFL and Mgb belong to category 2, Lys belongs to category 3, and BSA belongs to category 1, respectively. Figure 2.14 demonstrates the classification of the proteins schematically. Here FFL is omitted from the figure since the relative position cannot be determined in the figure due to the paucity of property data. These findings imply that the effect of an anesthetic is remarkable for a soft protein, and the degree of hydrophilicity of the protein surface determines the direction of the structural change, that is, folding or unfolding. On the other hand, in the case of a hard protein, the effect of an anesthetic is appreciably small even though the structure of the protein shifted to a folded or an unfolded state depending on the surface hydrophilicity.

The volume information obtained from anesthetic binding on proteins indicates that volumes of FFL and Mgb expand, a volume of Lys slightly expands while a volume of BSA

TABLE 2.3 Properties Related to Rigidity of Protein Structure

Protein	v^{0a} (mL g^{-1})	Fraction (%) of α-Helix	Fraction (%) of β-Sheet	S–S bond[b]	$\beta_S\times10^{12c}$ (cm^2 dyn^{-1})	$\beta_T\times10^{12d}$ (cm^2 dyn^{-1})
Mgb	0.747	77	2	0	8.9	13.1
Lys	0.712	29	16	4	4.6	7.7
BSA	0.735	70	15	17	10.5	14.6

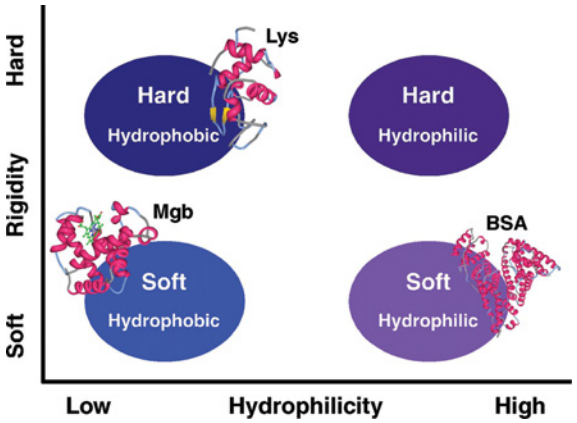

FIGURE 2.14 Schematic representation of the correlation between rigidity of protein structure and hydrophilicity of protein surface. Scales in abscissa and ordinate are depicted relatively in arbitrary units. The protein structures were obtained from the PDB, sperm whale Mgb (1MBN), hen egg Lys (2LYZ), and HSA (1BM0), respectively, and HSA was used instead of BSA.

shrinks by the addition of halothane. The behavior of the volume changes for the proteins well corresponds to that of the structural changes (i.e., unfolding, slight unfolding and folding) expected from the changes in the thermal stability that turbidity and DSC measurements have revealed. Thus, it is interesting to consider the correlation between the volumetric results and the pressure reversal of anesthesia. The standard volume change (ΔV^0) associated with the binding of an anesthetic to a protein can be written as

$$\Delta V^0 = -RT(\partial \ln K/\partial p)_T \tag{2.11}$$

where K is the binding constant between the anesthetic and the protein, and R is a gas constant. Since the ΔV^0 value can be approximately regarded as equal to the ΔV value, the sign of the ΔV value determines whether the number of the anesthetic molecules being bound to the protein will increase or decrease with increasing pressure. The positive ΔV value means the antagonism of the binding by pressure, while the negative value does the synergism of the binding. When considering the pressure antagonism occurs only in the case of the positive ΔV value, it turns out that FFL and Mgb is suitable as a model protein for anesthetic mechanism, and Lys and BSA are not suitable. Especially, BSA may not be involved with the anesthetic mechanism [60]. Therefore, we can conclude that it is reasonable to use proteins belonging to category (2) as model proteins of anesthetic action such as FFL and Mgb.

2.5 CONCLUSIONS

The effect of an anesthetic on globular proteins is different depending on the kinds of the proteins. Hence, it seems that the interaction mode of an anesthetic with proteins is quite complicated at first sight. However, comparing the effect with that of a substrate or a specific binder, the intrinsic interaction mode of the anesthetic with the proteins becomes clear. Taking into account the Meyer–Overton rule, we propose here that the intrinsic interaction mode between an anesthetic and a water-soluble globular protein can be systematically interpreted by considering the following four factors: (1) hydrophobicity of an anesthetic, (2) hydrophilicity of a protein surface, (3) rigidity of a protein structure, and (4) molar ratio of an anesthetic to a protein at the effective concentration. When considering that the effective concentrations of anesthetics is larger than those of specific binders and also that a protein surface and a protein structure are relevant to the interaction mode, the binding to a protein by the nonspecific weak interaction such as a microscopic solvent effect may be an intrinsic interaction mode of an anesthetic, which forms a pronounced contrast to the modes of specific binders of which the binding numbers are exactly determined from physicochemical measurements as the X-ray structural analysis of the protein.

The volume change of a protein by ligand binding provides us with useful information regarding the interaction between ligands and a protein because the ligand binding to a protein is sensitively reflected in the protein volume. The volume change of the protein is closely related to the pressure antagonism of anesthesia and one of key factors to elucidate the anesthetic mechanism. Volume studies of proteins [88–90] showed that the volume change of a protein associated with the unfolding is attributable to the volume changes of hydrated water on the protein surface and that of cavity in the protein. These determinants have almost the same meaning as the hydrophilicity of a protein surface and the rigidity of the protein structure, respectively. We expect that the anesthetic–protein interactions should also be considered in detail from the viewpoint of cavity and hydrated water in the future.

Finally, we focus here on anesthetic–protein interactions, but the location of anesthetic action is biological membranes. The anesthetic effect on lipid membranes cannot be neglected. Although the protein hypothesis only emphasizes the anesthetic–protein interactions and refutes the involvement in lipid membranes for anesthetic mechanism, anesthetics affect almost all proteins and lipid membranes. We recently investigated the ligand effect on phospholipid bilayer membranes by means of a comparative study similar to that described here and showed [91] that the interaction modes of an anesthetic, saturated and unsaturated fatty acids with dipalmitoylphosphatidylcholine (DPPC) bilayer membranes are markedly different from one another. This study proved that the DPPC bilayer membranes have high ability to recognize kinds of ligand molecules as well as proteins and can discriminate among them with specific interaction by the membrane states. Considering the anesthetic

sensitivity of lipid membranes and the fact that the ratio of proteins to lipids in real nerve membranes is about 2:8, we cannot eliminate the lipid membranes for the mechanism. Furthermore, we are now thinking that the anesthetic effect on lipid membranes may also be explained similarly to that on proteins: (1) hydrophobicity of an anesthetic, (2) hydrophilicity of a membrane surface, (3) rigidity of a membrane structure, and (4) molar ratio of an anesthetic to a lipid at the effective concentration. Here, in lipid membranes, the hydrophilicity and rigidity are closely related to the membrane states and lipid molecular structures. The hydrated crystalline or gel state has small hydrophilicity with a hard structure, while the liquid crystalline state has large hydrophilicity with a soft structure. Additionally, lipid ingredients in membranes such as saturated or unsaturated lipids and neutral or acidic lipids also affect the factors mentioned above. Because the anesthetic activities exhibit common characteristics and the anesthetic sensitivity between proteins and lipid membranes can be interpreted similarly, we can say that the action is essentially physical and nonspecific, not chemical and specific.

LIPID MONOLAYER AND INTERACTION WITH ANESTHETICS

YASUSHI YAMAMOTO AND KEIJIRO TAGA

Department of Life and Materials Engineering, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya, Japan

3.1 INTRODUCTION

Surfactant (or *surface-active agent*) is a general term referring to compounds in which the hydrophobic moieties compatible with oil (alkyl chain) and the hydrophilic moieties compatible with water coexist in one molecule by a chemical bond (covalent bond). This molecule is also called an *amphiphilic molecule* as it possesses both hydrophobicity and hydrophilicity; therefore, it forms various aggregations such as micelles, vesicles (liposomes), an emulsion, a monolayer, or bilayers, in the water phase and/or on the various interfaces. Extensive investigations on the properties of these aggregations have been performed not only from an industrial perspective such as cleaning, emulsification, and dispersion, but also from a biological perspective on the biomembranes of various composition and functions [1–3].

The monolayer on the water surface, using the above surfactant, points to a monomolecular layer whose molecules arrange two-dimensionally on the water surface, orienting hydrophobic alkyl chains toward the air phase and also hydrophilic moieties toward the water phase. It is possible to form a stable flat film (ultraorganic thin film) comparatively easily on the monomolecular level and also to control the number of monolayer molecules arbitrarily. The monolayer is found in industrially applications such as a nano-level insulator, frictional reduction film, and organic thin-film device applied electronically, by moving the monolayer on the substrate. From the biological perspective, it is also possible to regard it as a half of the biomembrane. Therefore, the monolayer is selected as a biomembrane model; it is applied to investigate cellular functions such as membrane structure, transmission of compounds into and/or out of membrane, interaction with substances, and molecular recognition [1–3].

In this chapter, we focus on the developing monolayer on the water surface (Langmuir monolayer), using a lipid of the biomembrane model substance. We will describe the method of monolayer formation and investigations on monolayer properties, as well as interactions between the monolayer and anesthetics.

3.2 MONOLAYER FORMATION

Benjamin Franklin was the first scientist to observe the monolayer. He was interested in a phenomenon that a *wake* (water) created by a ship or boat sailing became smoothly by throwing way the water that had been polluted with cooking oil. He also observed that when about one-teaspoonful of the oil was dropped on the pond side, the oil spread in a $\sim$1000 m^2 area and the amplitude of the wave in the pond quickly subsided (this is termed the *formation of calm*). These observations were published by the British Royal Association (Royal Society) in 1773 [4]. Thus, the manner in which monolayer molecules float on the water surface, followed by formation of the monolayer, is now called the *dropping method*. This method consists in dropping volatile solution droplets, including monolayer molecules, continuously (one by one) on the water surface, resulting in formation of the monolayer by spreading the molecules throughout the water surface. By using this method, the spontaneous monolayer, in which the monolayer molecules are maintained in their most comfortable state, is formed on the water surface.

A more systematic study of monolayers was performed by Agnes L. W. Pockels, who was interested in spreading of an oil stain in water. She noticed how the oil stain spread on the washing water surface in her kitchen, using handmade equipment with a movable partitioning board, and she observed how the area of a soap monolayer of the stain changed on contact with the water. Pockels' experimental result was published in 1892 through Lord Rayleigh of the Royal Society [5]. Later, the foundation of the present monolayer technology was further developed by Irving Langmuir [6, 7]. Thus, the manner in which monolayer molecules float on the water surface, followed by subsequent formation of the monolayer by squeezing (compressing) it using a partitioning board, is now called the *compression method*. This method consists in dropping small aliquots of the fixed volatile solution on the water surface, resulting in formation of the monolayer by squeezing the partition board horizontally, or by compressing the monolayer molecules. This is the main method for monolayer formation at present. This is also currently applied by forming a high-density monolayer on the water surface by compressing monolayer molecules using an artificial power supply and the partitioning board.

Here, we will describe the formation process and the properties of various lipid monolayers that are formed by the dropping method that enable formation of the flexible monolayer, compared with the corresponding monolayers formed by the compression method. Three processes are applied in the formation of a flexible monolayer by the dropping method: (1) concentration of the dropping solution including monolayer sample (0.5–1.0 mM), (2) dropping volume per time (1.0 μL by microsyringe), and (3) dropping time interval per time (>1 min for the droplet to spread sufficiently on the water surface; droplet spreading is checked as the constant value of surface tension after dropping by the recorder). Process 3 continue until the monolayer was formed, and the monolayer formation was confirmed by the formation of a lens on the water surface. The lens did not spread (move), so the surface tension value didn't change. With the dropping method, many dropping volumes and times are needed for monolayer formation. However, the above process would enable us to form the spontaneous monolayer in which molecules maintain comfortable (equilibrium) states. Therefore, the flexible monolayer, incorporating the interaction between hydrophilic groups in monolayer and water molecules sufficiently, is formed on the water surface. Those monolayers would also be suitable for model membranes.

3.2.1 Dipalmitoyl Phosphatidyl Choline (DPPC)

Dipalmitoyl phosphatidyl choline (DPPC) is a typical phospholipid, composed of two palmitc acids (C16) and a phosphatidyl choline group. DPPC is one of the main components in the biomembrane and possesses many biological

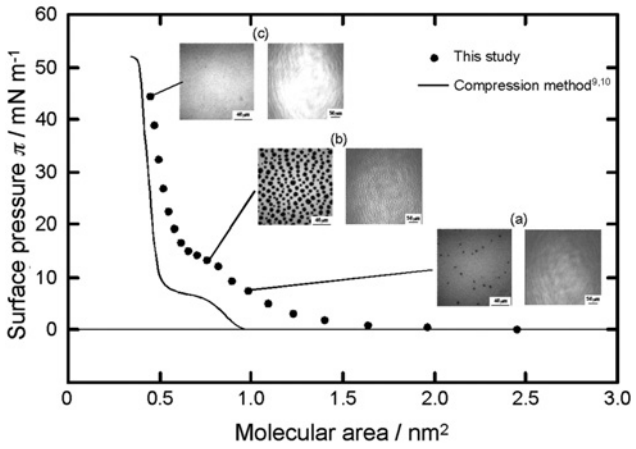

FIGURE 3.1 Surface pressure versus molecular area (π–A) isotherm curve of DPPC monolayer at 26°C. Solid circles (•) indicate dropping method; solid lines, compression method.

characteristics such as formability and flexibility of membrane; therefore, DPPC has been widely used and researched for the elucidation of various biofunctions as biomembrane model substances [8].

Figure 3.1 shows the surface pressure versus molecular area (π–A) isotherm curve of DPPC monolayer at 26°C using the dropping method [indicated by solid circles (•)] together with a typical π–A isotherm curve using the compression method (solid lines) [9, 10]. Chloroform is used as a spreading solvent for DPPC monolayer formation. The horizontal axis (abscissa) represents the molecular area calculated from molecular values in the dropping volume, and the vertical axis (ordinate) represents the surface pressure at which enough time had passed after infusion of the DPPC-chloroform droplet to allow the pressure value to become constant.

Many isotherm studies on the DPPC monolayer using the compression method have shown that the DPPC monolayer forms the following three states; a liquid-expand (LE) state at low surface pressure, a liquid-condensed (LC) state at higher surface pressure, and a LE-LC transition state (plateau range) at a surface pressure of approximately 8 mN/m (indicated by solid lines in Fig. 3.1) [11]. In the LE state, cylinderlike alkyl chains in DPPC molecules [8, 12] lie on the water surface and/or remain in mutually open state. In the LC state, alkyl chains interact with each other and rise to the water surface.

The π–A isotherm curve obtained by the dropping method (solid circles) presented a curve shape [13] different from than that obtained using the compression method (solid line) [9, 10]. The surface pressure increased gradually from about 1.7 nm^2 molecular area and after an unclear, small plateau range (LE-LC transition state, around 12 mN/m), increased up to 42 mN/m.

Two remarkable points are shown in Figure 3.1: (1) *the maximum pressure in the π–A isotherm curve observed*; the

pressure value obtained by the dropping method (42 mN/m) is lower than that due to the compression method (~50 mN/m), and (2) *the limiting molecular area* (A_0). A_0 obtained by the dropping method is 0.65 ± 0.05 nm^2/molecule (~40 mN/m), and this value is approximately 30 % larger than that obtained by the compression method (0.48 nm^2/molecule). These results indicate that the DPPC monolayer obtained by the dropping method is in a *semi-expanded state* and has a *flexible and fluid structure*, similar to the fluidity-rich biomembrane.

In the case of dropping method, a sufficient time interval is maintained between the introduction of different, consecutive droplets on the water surface. This time interval enables DPPC molecules to spread throughout and reach equilibrium state on the water surface. Dropping in succession also results in disentanglement of the unbalanced domain of DPPC molecules, due to redissolution of the domain by the spreading of the solution (DPPC-chloroform). Consequently, DPPC are expected to disperse over the entire water surface and begin to form the monolayer. In a DPPC molecule, the redissolution causes the hydrophobic alkyl chains in the DPPC molecule to open freely in three dimensions, thereby facilitating the intermolecular interactions (hydrophobic interaction) between DPPC molecules. Using the dropping method, the DPPC monolayer passed through the monolayer-forming process in which the priority was given to the intermolecular interaction by alkyl chains in DPPC molecules. This corresponds to an increase in the surface pressure (decrease in the surface tension) at the initial stage in DPPC monolayer formation. Actually, all measurements showed the curve beginning with an initial dispersion of 1.4–1.8 nm^2 molecular area. After the LE-LC transition, two alkyl chains in one DPPC molecule interacted with each other and the alkyl chains in the DPPC molecules rose to the water surface; these results were also observed using the compression method. In this case, the DPPC molecules might have become compatible with water molecules under the special conditions of the dropping method. Therefore, the hydrophilic group of DPPC molecules and water molecules would structure and maintain themselves in the most comfortable (highest-equilibrium) hydrogen-bonding network (hydrophilic interaction) [14]. This is quite different from the scenario obtained using the compression method; the compression collapses the hydrogen-bonding network, and the hydrophilic groups of DPPC molecules and the alkyl chains continue to be compressed, resulting inthe high-density state. This finding is consistent with the assumption that the range of LE-LC transition obtained using the compression method is wider than that using the dropping method. An increase in the dropping volume of solution (increase in DPPC molecule) promotes monolayer growth and hence a higher density finally resulting incompletion of the DPPC monolayer. In the general monolayer formation obtained using the compression method, the interactions between hydrophobic alkyl chains and between hydrophilic groups are very important factors, and such interactions promote the formation of high-density monolayer. In the DPPC monolayer using the dropping method, the hydrophilic interaction between the hydrophilic group of DPPC molecules and water molecules would be maintained and consequently prevent condensation of hydrophobic alkyl chains (hydrophobic interaction) in DPPC molecules. Semi-expanded DPPC monolayer would be formed on the water surface [15], compared to the condensed DPPC monolayer using the compression method. Such a hydrophilic interaction would ultimately control the formation process of DPPC monolayer obtained by the dropping method.

The inset images in Fig. 3.1 show fluorescence microscopy (FM) and Brewster angle microscopy (BAM) images at three surface pressures: (a) 8 mN/m, (b) 12 mN/m, and (c) 42 mN/m). The left images are FM, and the right BAM. On the FM measurement, FM probes (Rh-DMPE) of 0.1 mol% are included in the monolayer. The DPPC monolayer of each surface pressure value is moved on the surface-treated (piranha solution) cover glass with a scooping-up motion [16] and observed by FM. On the BAM measurement, the DPPC monolayer formed at each surface pressure is directly observed in situ by BAM.

In the compression method, the molecular area of 1.2 nm^2 shows zero surface pressure (gaseous monolayer), and both FM and BAM images are homogeneous in dark contrast [17–19]. In the dropping method, on the other hand, that area maintains 8 mN/m surface pressure, and the corresponding images are slightly bright [13]. This indicates that DPPC molecules are already forming a LE-state monolayer with a molecular area of 1.2 nm^2. At the surface pressure of 12 mN/m (b), both FM and BAM images are shown inbright contrast and indicated a LE-LC transition. A remarkable point is the appearance of images. The hole-type LE domain (in dark contrast) appeared in the whole LC phase, thereby indicating a coexistence state. This is completely opposite to the island-type conformation reported with the compression method [17–19], at which small and very bright condensed LC domains disperse in a continuous background of the darker LE phase. Those images (b) would correspond to the π–A isotherm curve that showed unclear LE-LC transition in Fig. 3.1; FM and BAM images also indicate that a flexible and fluid-structured DPPC monolayer is being formed on the water surface. At the surface pressure of 42 mN/m (c), both FM and BAM images became homogeneously bright with the completion of LC-type phase and fluidic DPPC monolayer. The FM needs some additional action for the observation such as mixing of FM probes to DPPC molecules and scooping up the monolayer on the substrate such as a cover glass. However, such actions are not influenced by the formation of DPPC monolayer, and semi-expanded and flexible monolayer is maintained even on the glass, from direct BAM observation [13].

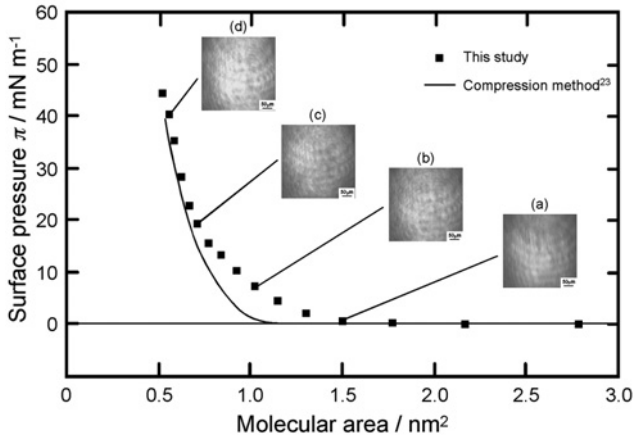

FIGURE 3.2 Surface pressure versus molecular area (π–A) isotherm curve of DMPC monolayer at 26°C. Solid squares (■) indicate dropping method, solid lines, compression method.

It was found that the DPPC monolayer obtained by the dropping method traced a unique monolayer formation process, different from that obtained by the compression method. The comfortable (equilibrium) state between hydrophilic groups of DPPC molecules and water molecules, compared to the interactive state between hydrophobic alkyl chains in DPPC molecules, would lead to the appearance of semi-expanded and flexible DPPC monolayer.

3.2.2 Dimyristoyl Phosphatidyl Choline (DMPC)

Dimyristoyl phosphatidyl choline (DMPC) is also a typical phospholipid as well as DPPC, and composed of two myrisitc acids (C14) and a phosphatidyl choline group. DMPC is one of the components in the biomembrane. DMPC also transforms its state from gel (solid) to a liquid–crystal phase at 24°C (transition temperature); many studies on the phase state of DMPC have been performed relating with biofunctions [8, 20–22].

Figure 3.2 shows the surface pressure versus molecular area (π–A) isotherm curve of DMPC monolayer at 26°C, using the dropping method [solid squares (■)] together with a typical π–A isotherm curve using the compression method (solid lines) [23]. The horizontal axis (abscissa) represents the molecular area calculated from molecular values for the dropping volume, and the vertical axis (ordinate) represents the surface pressure (see also Fig. 3.1).

Many isotherm studies for DMPC monolayer using the compression method have shown that DMPC monolayer forms only one state, a LE state [11]. Therefore, the surface pressure increased gradually from 1.1 nm^2 of molecular area and the pressure increased gradually and monotonously up to 36 mN/m (solid line). In the LE state, two alkyl chains were disordered partially at 26°C. The structure includes a *gauche*-type conformation and a disturbed state; these chains possess expandability, and the cross-sectional area would be larger than that of the hydrophilic group.

The π–A isotherm curve obtained by the dropping method (solid squares) also presented a typical LE state [24]. Therefore, the surface pressure increased gradually from about 1.4 nm^2 molecular area, and increased monotonously up to 43 mN/m. The shape of curve is smooth and similar to that obtained by the compression method (solid line). The limiting molecular A_0 is 0.80 ± 0.05 nm^2/molecule (~40 mN/m), and the value is quite similar to that obtained by the compression method reported previously [0.78 nm^2/molecule (~40 mN/m)].

As well as in the case of DPPC, both sufficient dropping-time interval and the dropwise succession obtained by the dropping method result in dispersal of DMPC molecules over the entire water surface and commencement of the monolayer formation. This corresponds to the increase in surface pressure from the initial stage by the preferential intermolecular interaction of the alkyl chains in DMPC molecules. An increase in the dropping volume of solution (i.e., increase in DMPC molecule) promotes growth of the monolayer and increases the density, as in the case of DPPC. However, partially disordered alkyl chains do not occur in the DPPC-like phase transition, and the molecules also maintain their structure. This is different from the case of DPPC monolayer using the dropping method, where hydrophilic interaction between the hydrophilic group of DPPC molecules and water molecules is dominant. Therefore, the expanding DMPC monolayer forms on the water surface and maintain the expanding state (disordered alkyl chains) of DMPC molecules, and ultimately leading to completion of the DMPC monolayer [15]. This corresponds to the shape of the π–A isotherm curve, which increases gradually and monotonously. The partially disordered alkyl chains that possess larger molecular space than that of hydrophilic group, control the formation process of DMPC monolayer; the differences in the π–A curve between the compression and dropping methods would not appear to be significant. On such the DMPC monolayer, the limiting molecular area A_0 of DMPC monolayer is certainly larger than that of DPPC monolayer; nevertheless, both DMPC and DPPC possess the same hydrophilic group (phosphatidyl choline group). In other words, this indicates that the alkyl chains in DMPC are partially disordered and those in DPPC are cylinderlike at 26°C, as mentioned above.

The π–A isotherm curve of DMPC obtained by the dropping method showed the initial curve starting at higher density (more to the left, about 1.4 nm^2) than that of DPPC (about 1.7 nm^2; see Fig. 3.1). As mentioned above, alkyl chains in DPPC molecules are cylinderlike and the DPPC molecule itself possesses rigidity. In the initial stage of DPPC monolayer formation, the repulsion between DPPC molecules is comparatively large because of its rigidity; therefore, the curve would result in a surface pressure value at lower

molecular density. On the other hand, the DMPC molecule itself possesses expandability because of the partially disordered alkyl chains in DMPC molecule. This expandability may absorb the repulsion energy between DMPC molecules. In other words, the disordered structure of DMPC alkyl chains is somewhat deformable; therefore, the curve may show the surface pressure value at a density higher than that of DPPC.

The inset images in Fig. 3.2 show BAM images at four surface pressures: (a) 1 mN/m, (b) 8 mN/m, (c) 19 mN/m, and (d) 38 mN/m). On the BAM measurement, their treatments are as same as those shown in the Fig. 3.1 insets.

At quite a low surface pressure of 1 mN/m (a), the whole image is shown in slight bright contrast. This indicates that DMPC molecules are beginning to form an expanding monolayer at less than 1 mN/m. As indicated by an increase in surface pressure (8 and 19 mN/m; see Fig. 3.1b, c), the image became brighter but did not result in any morphology change in DPPC molecules (Fig. 3.1b, right); therefore, the DMPC monolayer continued to form homogeneously. At 38 mN/m (Fig. 3.1d), the image became still brighter and consequently the homogeneous DMPC monolayer was formed and completed on the water surface. Such a gradual increase in brightness corresponds to the gradual increase in the surface pressure on the π–A isotherm curve. The brightness of image at 38 mN/m (Fig. 3.1d) was not greater than that of DPPC (Fig. 3.1c, right). On the BAM, thickness and refractive index of monolayer on the water surface is closely related to the brightness [25–27]. DMPC monolayer forms an expandable structure, which also fluctuates on the water surface. Such characteristics of DMPC monolayer would change the refractive index and might also weaken the reflected BAM light compared to the DPPC monolayer.

It was found that the DMPC monolayer obtained by the dropping method traced a monolayer formation process similar to that obtained by the compression method. The comfortable (equilibrium) state of partially disordered alkyl chains in DMPC molecules at 26°C would lead to the appearance of expandable DMPC monolayer, even though hydrophilic DMPC molecules and water molecules maintain equilibrium and interact with each other. Such a partially disordered hydrophobic structure may not be dependent on the pattern of monolayer formation. This is quite different from the DPPC monolayer whose molecules possess cylinderlike alkyl chain structures at 26°C.

3.2.3 Cholesterol

Cholesterol (Chol) is classified under the steroid group, and is composed of a steroid skeleton and hydroxyl group (–OH). Chol is one of the main components in the biomembrane and also the important organic compound in connection with various biological phenomena. Chol is distributed widely in the living body; many studies on biofunctional aspects

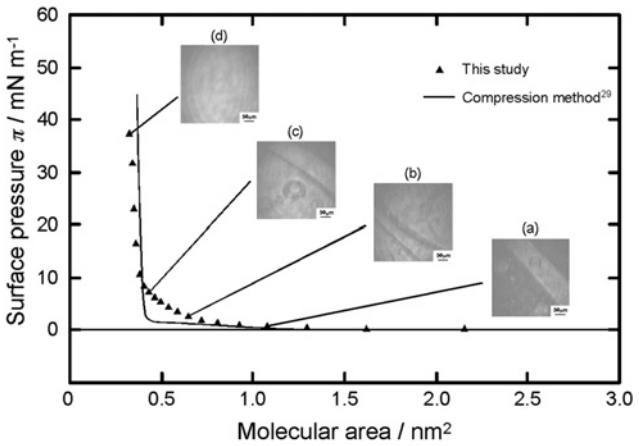

FIGURE 3.3 Surface pressure versus molecular area (π–A) isotherm curve of Chol monolayer at 26°C. Solid triangles (▲) indicate dropping method; solid lines, compression method.

such as its usefulness and toxicity have been performed [8, 14, 28].

Figure 3.3 shows the surface pressure versus molecular area (π–A) isotherm curve of Chol monolayer at 26°C, using the dropping method [solid triangles (▲)] together with a typical π–A isotherm curve using the compression method (solid lines) [29]. The horizontal axis (abscissa) represents the molecular area calculated from molecular values in the dropping volume, and the vertical axis (ordinate) represents surface pressure (see also Fig. 3.1).

Many isotherm studies on the Chol monolayer using the compression method have shown that this monolayer forms only one state, a condensed (solid) state [11]. Therefore, the surface pressure shows extremely gradual increase from 0.6 nm^2 of molecular area (< 2 mN/m) and sudden and steep increase to 40 mN/m at less than 0.45 nm^2. The shape of the π–A isotherm curve is very sharp, similar to a titration curve, and does not change its shape at various temperature (20–40°C). In the condensed state, the Chol molecules orient almost vertically to the water surface and are found in a vertical high-density stacking conformation [30].

The π–A isotherm curve obtained by the dropping method (solid triangles) presented a condensed-type state. Therefore, the surface pressure increased gradually from about 1.0 nm^2 of molecular area and monotonously until about 10 mN/m, and after that increased steeply up to 37 mN/m. The limiting molecular area A_0 is 0.41 ± 0.02 nm^2/molecule (~36 mN/m), and the value is quite similar to that obtained by the compression method reported previously (0.40 nm^2/molecule (~40 mN/m) [23]. On the other hand, the π–A isotherm curve was slightly different from that obtained by the compression method; initially the curve showed only a gradual increase and also a larger molecular area compared to that obtained by the compression method.

As in the case of DPPC, both sufficient dropping-time-interval and the the successive dropping, obtained by the dropping method, supply the dispersion of Chol molecules over the entire water surface, accompanied by the beginning of monolayer formation. This corresponds to the increase in the surface pressure from the initial stage by the preferential intermolecular interaction of steroid skeleton in Chol molecules. An increase in the dropping volume of solution (increase in Chol molecule) strongly promotes the hydrophobic interaction between steroid skeletons in Chol molecules because of its stacking characteristics; thus Chol molecules would form a condensed monolayer on the water surface. This corresponds to the steep increase in the π–A isotherm curve to >10 mN/m. The small hydrophilic group (–OH) may also originate in such formation process of Chol monolayer. This is different from the scenario obtained by the compression method. In the latter method, after the dropwise addition of several aliquots of the condensed aggregates (island-type), dispersion of Chol molecules already appeared partially on the water because of the strong hydrophobic steroid skeleton interaction between these molecules. The compression only gathers those condensed islands on the water surface and forms Chol monolayer of only a solid-type condensed state and, thereby, a steep increase in the π–A isotherm curve. On the other hand, using the dropping method, the Chol monolayer undergoes a liquid-type expanding state, leading to the formation of a condensed state. Although both moieties are the same condensed states at the completion of monolayer, the degrees of uniformity may differ.

Inset images in Fig. 3.3 show BAM images at four surface pressures: (a) 1 mN/m, (b) 3 mN/m, (c) 8 mN/m, and (d) 36 mN/m. On the BAM measurement, the pressures are treated the same as those shown in the Fig. 3.1 insets.

At a relatively low surface pressure (1 mN/m), the image showed the existing line- and circle-type domain states. This indicates that aggregates of Chol molecules already exist on the water surface and begin to form an expanding monolayer at 1 mN/m. As indicated by an increase in surface pressure (3 and 8 mN/m), a number of those domains increased and the domains also enlarged gradually. The brightness of those images also increased. Chol molecules themselves possess high condensation forces and continue to form the monolayer. At 36 mN/m, those domains obtained at ≤8 mN/m disappeared and subsequently the image manifested a homogeneous state. The brightness of the image increased beyond that at 8 mN/m; the homogeneous Chol monolayer was formed and completed on the water surface. Brightness of the image at 36 mN/m (Fig. 3.3d) did not increase beyond that of completed DPPC and DMPC monolayers (Fig. 3.1c right and Fig. 3.2d). Chol molecules are smaller than DPPC and DMPC molecules, and their molecular length is nearly half that of DPPC and DMPC molecules. A size-dependent characteristic such as this would change the refractive index and also might weaken the reflected BAM light compared to the completed DPPC and DMPC monolayer.

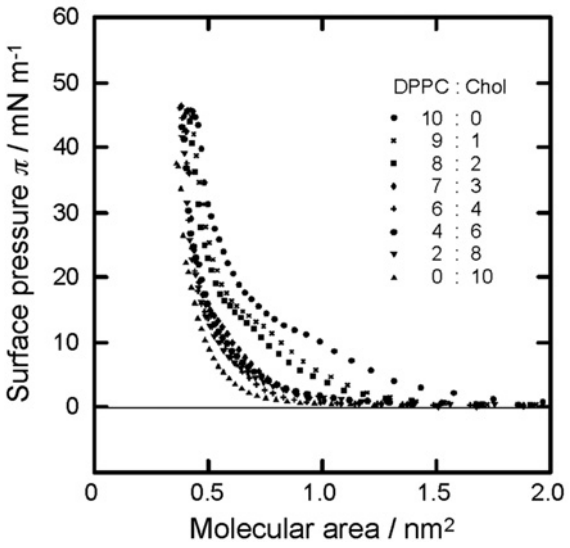

FIGURE 3.4 Surface pressure versus molecular area (π–A) isotherm curve of various DPPC–Chol mixed monolayer at 26°C. Mole fraction of Chol: 0.0, 0.1, 0.2, 0.3, 0.4, 0.6, 0.8, 1.0 from the right π–A isotherm curve.

It was found that the Chol monolayer obtained by the dropping method traced a slightly different monolayer formation process compared to that obtained by the compression method. Sufficient spreading-time interval and the continuous dropping may improve the spreading state at the initial stage of monolayer formation. The strong hydrophobic interaction between steroid skeletons ultimately leads to the formation of a condensed Chol monolayer, similar to that obtained by the compression method.

3.2.4 DPPC and Cholesterol Mixture

Figure 3.4 shows the surface pressure versus molecular area (π–A) isotherm curves of various DPPC-Chol mixed monolayers at 26°C, using the dropping method. Mole fractions of Chol are 0.0, 0.1, 0.2, 0.3, 0.4, 0.6, 0.8, and 1.0. The horizontal axis (abscissa) represents the molecular area calculated from mixed molecular values, and the vertical axis (ordinate) represents surface pressure (see also Fig. 3.1). The curves of 0.0 [pure DPPC (•)] and 1.0 [pure Chol (▲)] are as almost the same as those in Figs. 3.1 and 3.3.

The curves of DPPC-Chol mixed monolayer shift to the left relative to those of the pure DPPC monolayer, as inedicated by an increase in the mole fraction of Chol, and approach the pure Chol monolayer [31]. The unclear small plateau range observed in the pure DPPC monolayer (LE-LC transition) becomes narrower and its surface pressure also decreases, and then completely disappear at >0.3 mole

fraction of Chol. The shape of curves with >0.3 mole fraction of Chol is closely similar to that of pure Chol monolayer. This tendency is also similar to that obtained by the compression method [9, 10, 32, 33]. These observations indicate that Chol molecules strongly influence the DPPC monolayer (condensation effect of Chol) even using the dropping method, and at >0.3 mole fraction of Chol the condensed mixed monolayers form on the water surface. Therefore, the mixed monolayer with <0.3 mole fraction of Chol forms LC-type phase and with >0.3 mole fraction of Chol, the condensed phase.

The mean limiting molecular area of DPPC-Chol mixed monolayer obtained by the dropping method can be compared to that of the ideal mixed monolayer, which is calculated from each A_0 of pure DPPC and Chol monolayer. The excess area A_{ex} can be obtained by using the following equation [9, 10]

$$A_{\text{ex}} = A_{DC} - (X_D A_D + X_C A_C)$$

where A_{DC} is the mean limiting molecular area of the mixed monolayer, A_D and A_C are the limiting molecular area of each pure DPPC and Chol, respectively, and x_D and x_C are the mole fractions of the DPPC and Chol components.

Figure 3.5 shows the dependence of the Chol mole fraction on A_{ex}. The horizontal axis (abscissa) represents the mole fraction of Chol, and the vertical axis (ordinate) represents the excess area A_{ex}. Figure 3.5 also shows typical Chol mole fraction dependences of A_{ex} on previously reported data obtained by the compression method; those data were recalculated by the original calculation method based on those π–A isotherm curves [9, 10, 32, 33]. The present study of the shape of Chol dependence is similar to that of previous data; therefore, the

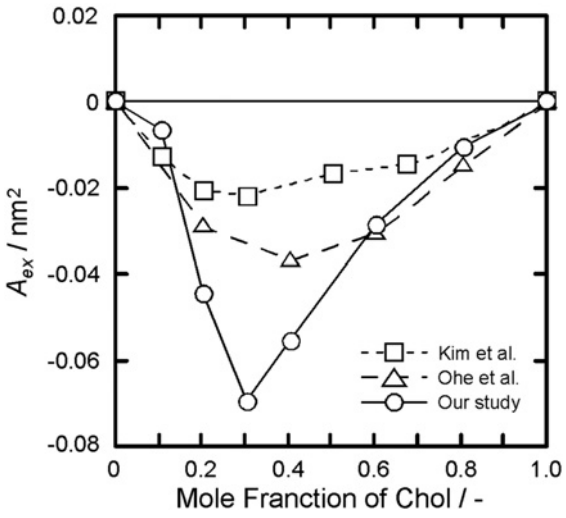

FIGURE 3.5 Chol mole fraction dependence of the excess area A_{ex}. Solid lines indicate dropping method, dashed and dotted lines, compression method.

addition of Chol in the DPPC monolayer showed a negative deviation from the ideal line, and the extreme value is at the ~0.3 mole fraction of Chol. These findings indicate again that Chol molecules cause condensation of the DPPC monolayer at various Chol mole fractions. The present A_{ex} is about twice those of previous data, ranging within $x_C = 0.2$–0.4.

As mentioned in Section 3.2.1, the DPPC monolayer obtained by the dropping method has a fluidic structure, where the hydrophilic interaction between phosphatidyl choline groups in DPPC molecules and water molecules predominates in the hydrophobic alkyl chain interactions between DPPC molecules. Such a state is quite different from that found using the compression method, where intermolecular interaction (hydrophilic and hydrophobic interaction) between DPPC molecules occurs because of the effect of artificial force exerted by the movable partitioning board. The fluidic, loose structure of alkyl chains in the present DPPC monolayer would be a strongly causative factor in the high-condensation effect of Chol; therefore, the easily inserted hydrophobic Chol molecules in DPPC molecules strongly attract weakly interacting alkyl chains in DPPC molecules. Such an attractive force may also collapse the hydrogen-bonding network structured by the hydrophilic interaction between hydrophilic groups of DPPC molecules and water molecules. The present negative large A_{ex} obtained by the addition of Chol indicates that the fluidic pure DPPC monolayer obtained by the dropping method certainly forms on the water surface.

Figure 3.6 shows FM and BAM images on DPPC-Chol mixed monolayer of the 0.2 mole fraction of Chol at various surface pressures (1, 4, 11, and 43 mN/m).Upper images are FM, and lower ones are BAM. The FM (upper) and BAM (lower) images shown in Fig. 3.6 indicate that their treatments are the as same as those shown in in the Fig. 3.1 insets.

At quite a low surface pressure (1 mN/m), the FM image shows a bright state and the irregular spot-type pattern is partially revealed in the image (this pattern could not be detected in the BAM image). The brightness of both FM and BAM images is higher than that of the pure DPPC monolayer at 1 mN/m (not shown). Therefore, Chol molecules assemble DPPC molecules at 1 mN/m, and the mixed monolayer is already formed as the aggregate of DPPC molecules by Chol (condensing state) on the water surface. These findings correspond to the π–A isotherm curve at the 0.2 mole fraction of Chol (Fig. 3.4), which shifts to the left by the condensation effect of Chol. At 4 mN/m, the unique image is obtained in the FM; the image showed the plural dark-spot-type pattern and the size is smaller than that of pure DPPC monolayer at 12 mN/m (insetin Fig. 3.1b, left). Compared to the pure DPPC monolayer, such a spot-type pattern is revealed at 8 mN/m lower surface pressure (4 mN/m); therefore, the LE-LC transition of mixed monolayer of the 0.2 mole fraction of Chol occurred at about 4 mN/m. Such an image was also observed in the BAM, but it was indistinct because of the low

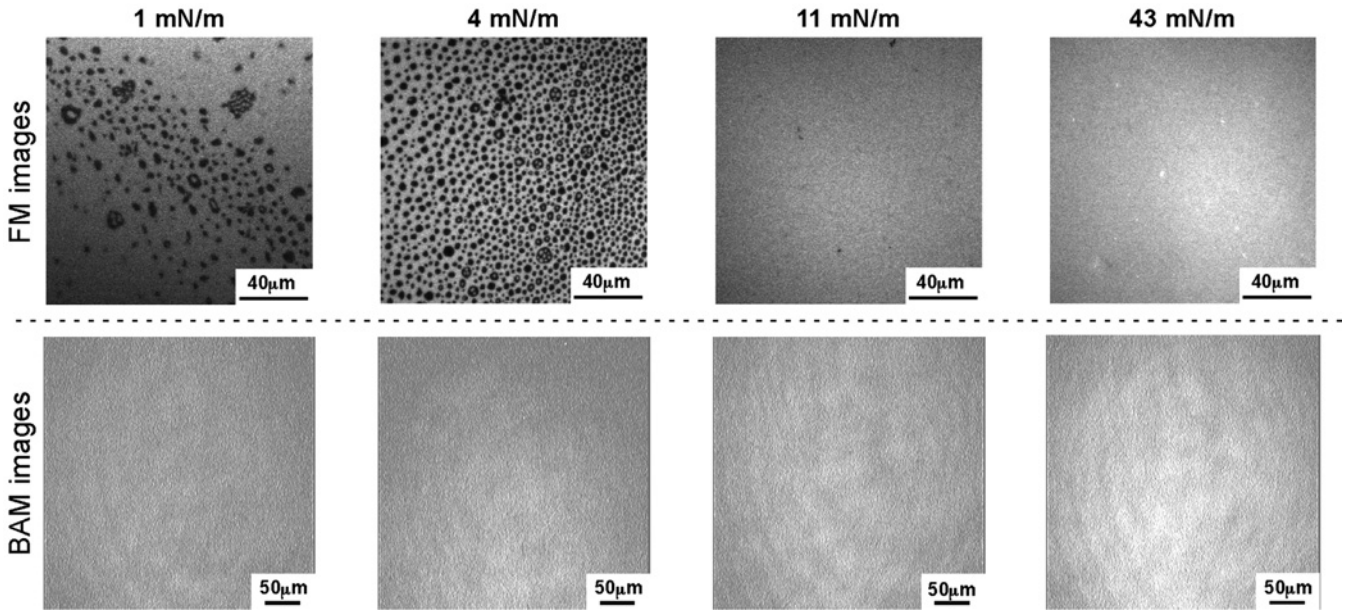

FIGURE 3.6 FM and BAM images on DPPC–Chol mixed monolayer of 0.2 mol fraction of Chol at various surface pressures (1, 4, 11, and 43 mN/m). Upper: FM images; lower: BAM images.

resolution of BAM. The brightness of both FM and BAM at 4 mN/m was greater than that of pure DPPC monolayer at 4 mN/m (not shown), as well as in the case of 1 mN/m. The mixture with Chol and DPPC molecules strengthens the hydrophobic interaction between hydrophobic alkyl chains in DPPC molecules and also relatively weakens the hydrophilic interaction between hydrophilic groups of DPPC molecules and water molecules; therefore, the difficult-to-spread DPPC-Chol mixture would reassemble and form the condensed mixed monolayer on the water surface. This corresponds to a decrease in the size of the dark spot compared to the pure DPPC monolayer. Actually, several island-type aggregates exist in the dark spot, and they are similar to the transition state by the compression method [17–19]. At 11 mN/m, the dark-spot-type pattern of both FM and BAM observed at 4 mN/m disappeared and subsequently those images became homogeneously bright. On the FM image, the brightness is approximately same as that of the bright part observed at 4 mN/m. After the end of the LE-LC transition at the previously observed 4 mN/m caused by Chol molecules, the condensed mixed monolayer is continuously formed on the water surface. This corresponds to the continuous increase in π–A isotherm curve at the 0.2 mole fraction of Chol (Fig. 3.4). At 43 mN/m, a further homogeneous image was observed at both FM and BAM, and the brightness was greater than that observed at 11 mN/m; the formation of homogeneous mixed monolayer was completed. Compared to the pure DPPC completed monolayer, the brightness of BAM was somewhat darker (Fig. 3.1c right). The mixing of Chol would change the mean monolayer thickness of the mixed monolayer compared to the pure DPPC monolayer, The surface roughness would also increase, and consequently a change in the refractive index, and might also weaken the reflected BAM light compared to the pure DPPC monolayer. As shown in the πA isotherm curve, FM and BAM images also revealed that the DPPC-Chol mixed monolayer at the 0.2 mole fraction of Chol forms higher condensed monolayer than the pure DPPC monolayer on the water surface, by the Chol condensation effect.

Figure 3.7 shows BAM images on the DPPC-Chol mixed monolayer of the 0.3 mole fraction of Chol at various surface pressures (1, 4, 11, and 43 mN/m). On the BAM measurement, their treatments are the same as those shown in the insets in Fig. 3.1.

Those images of the mixed monolayer of Chol 0.3 were quite different from those of pure DPPC monolayer (Fig. 3.1 insets) and Chol 0.2 (Fig. 3.4). Therefore, at quite a low surface pressure (1 mN/m), the image showed the existed line- and circle-type domain state. It was indeed the same as that of the following pure Chol monolayer (1 mN/m; Fig. 3.6) at which Chol molecules form a condensed monolayer from quite a low surface pressure. This indicates that the condensed aggregates of DPPC and Chol molecules were already visible on the water surface at 1 mN/m. According to an increase in surface pressure (4 and 11 mN/m), a number of those domains increased and those domains also enlarged gradually. The brightness of the image also increased. As was the case at 1 mN/m, those morphology changes were the same as those of the following pure Chol monolayer (3, 8 mN/m; Fig. 3.6). At 43 mN/m, those domains obtained at 11 mN/m disappeared and subsequently the image exhibited a homogeneous state. The brightness of the image increased

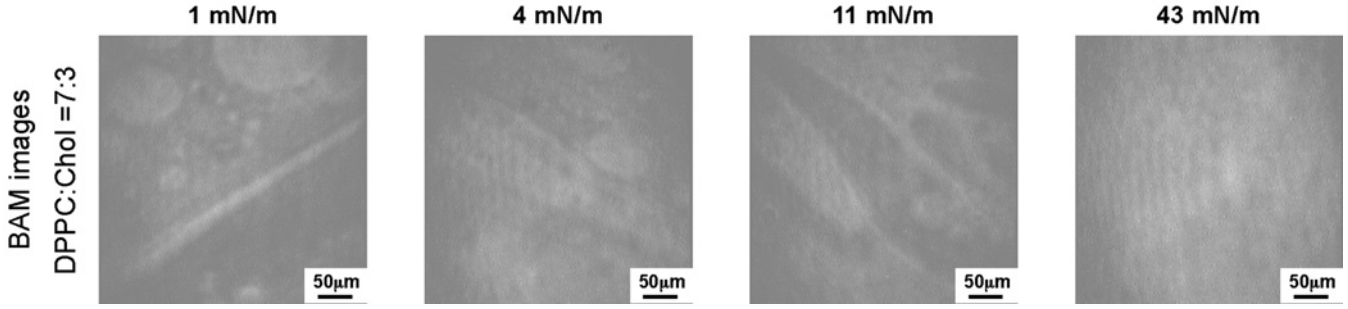

FIGURE 3.7 BAM images on DPPC–Chol mixed monolayer of 0.3 mol fraction of Chol at various surface pressures (1, 4, 11, and 43 mN/m).

beyond that at 11 mN/m and was also similar to that of the 0.2 mole fraction of Chol. As was the case at 1, 4, and 11 mN/m, it was the pure Chol-type morphology change (Fig. 3.3). This indicates that the mixed monolayer at the 0.3 mole fraction of Chol forms Chol-type condensed monolayer and forms on the water surface from the initial stage (low surface pressure) of its monolayer formation. These findings also correspond to the result that the shape of π–A isotherm curve of Chol 0.3 is quite similar to that of pure Chol monolayer (Fig. 3.4), and the condensation rate shows a maximum value at the 0.3 mole fraction Chol (Fig. 3.5). In other words, the pure DPPC monolayer obtained by the dropping method forms flexible monolayer, which is influenced easily on the condensation effect of Chol.

It was found that the DPPC monolayer obtained by the dropping method is strongly affected by the condensation effect of Chol; from the π–A isotherm curve, the excess area A_{ex} was about twice larger than that obtained by the compression method in the range from 0.2 to 0.4 mole fraction of Chol. Both FM and BAM images also supported the condensation effect of Chol; more than the 0.3 mole fraction of the Chol DPPC-Chol mixed monolayer showed Chol-type condensed state. It is known that the condensation effect of Chol also occurs at the DPPC-Chol mixed monolayer formed by the compression method. The present DPPC monolayer obtained by the dropping method certainly forms fluidic state, and hydrophilic groups of DPPC molecules and water molecules retain equilibrium while interacting with each other. Therefore, the monolayer would be strongly affected by the condensation effect of Chol.

3.2.5 Usefulness of Dropping Method

It is interesting that the influence on the monolayer formation by the dropping method differs among DPPC, DMPC, and Chol; DPPC molecules form fluidic and flexible monolayer, DMPC expanding monolayer, and Chol condensed monolayer. In the compression method, DPPC and Chol form condensed monolayer, and DMPC expanding monolayer. Recent research on a phosphatidyl ethanolamine (PE) series also showed such influence; dimyristoyl-PE (DMPE) molecules form fluidic and flexible monolayer, whereas dipalmitoyl-PE (DPPE) molecules form condensed monolayer. With the compression method, both DMPE and DPPE form condensed monolayer. The dropping method may be directly capable of forming reflected the original properties of molecules themselves, such as flexibility or rigidity, dispersion or aggregation, on the water surface. In other words, the monolayer formed by the dropping method would supply the suitable measurement field for the elucidation of membrane function at the present when the membrane flexibility attracts attention in the functional revelation of biomembrane.

3.3 INTERACTION BETWEEN LIPID MONOLAYER AND ANESTHETICS

Biomembranes have fundamental fluid structures as represented by the *fluid mosaic model* proposed by two researhers [34], which buries functional proteins in lipid bilayers composed of various kinds of phospholipids [28]. At the fluidic field of membrane, intermolecular interactions such as hydrogen bonding, hydrophobic interactions, and van der Waals interactions play an important role in various cellular functions, for example, the construction of tertiary structures of protein, the hybridization of DNA, the molecular recognition of membranes, and the transport of nutrition and various medicines [28, 35, 36], as mentioned in Section 3.1.

An anesthesia phenomenon would also belong to the same category as the above interaction, at the point of the interaction between a biomembrane and an anesthetic [37–43]. Anesthetics do not have a common molecular structure; various molecules, such as those of alcohol, diethyl ether, chloroform, and dinitrogen monoxide, and even familiar gas molecules of CO_2, N_2, and Xe, cause the anesthesia phenomenon. At the present, some halogenated compounds, called *halothane*, *enflurane*, *isoflurane*, and *sevoflurane*, are used as anesthetic drugs. The anesthesia phenomenon occurs at the high concentration of millimolar order (mM) in body fluid different from general medicine [nanomolar

order (nM)], and the effect naturally shows reversibility depending on the medication concentration. An anesthetic strength (anesthetic potency) is also known to show temperature dependence; diethyl ether and alcohol weaken the anesthetic potency at a low temperature, whereas chloroform and halogenated compounds strengthen this potency.

Although some anesthetic theories (lipid theory, protein theory, etc.) have been suggested since Meyer and Overton proposed the *lipoid hypothesis* [44, 45], it would probably, be clear that the anesthesia phenomenon is a *physisorption phnomenon*, in which an anesthetic aggregation acts indirectly on a biomembrane interface, according to the above various experimental and clinical findings [38–40, 46, 47]. The details of anesthesia theory and its mechanism are entrusted to another chapter on anesthesia, so we will discuss the action mechanism of anesthetics to the lipid monolayer on the water surface and the correlation with the mechanism and anesthesia phenomenon, describing the principle of measurement technique and the contents of the apparatuses actually used.

3.3.1 Quartz Crystal Oscillator (QCO) Method

Among various interface chemistry techniques, we adopted a quartz crystal oscillator (QCO) method to investigate the interaction between membrane and anesthetic. The QCO method is now a useful and powerful tool for investigating various physicochemical properties, including interfacial phenomena [48, 49].

The QCO apparatus was originally used as a quartz crystal microbalance (QCM) that could detect a mass change in the nanogram-order level [50]. The QCM method has been applied to a gas adsorption measurement in gas phases to monitor the thickness of a vacuum evaporation device [51, 52]. In one study, where the QCM was used for quantitative analysis of cyanide ion in liquid phases, the QCO was shown to have a stable resonance frequency in liquid phases [53]. That pioneering work was preceded by many extensive experimental methods. Another team investigated the adsorbtion of oxygen on the Au surface (electrode of QCO) in perchloric acid solution, and reported that the adsorption process of oxygen proceeded via a three-step reaction sequence from the analysis of mass change [54]. Another group also investigated the cation selectivity on ITO/Au surface (electrode of QCO) modified by a Prussian blue (PB) thin film in propylene carbonate solution, and reported that the selectivity coefficient of Na^+ versus Li^+ on the PB film was about 15 [55]. More recently, another group performed systematic studies of nanogram-order detection on the molecular recognition (chemical adsorption and desorption) using DNA strands and lipid monolayers [56–64]. Those studies were characterized by the use of an oscillator surface modified by the functional film and/or biomembrane and the detection as the mass change on such adsorption processes.

In the QCM method, the resonance frequency of the QCO changes because of the adsorption of substances on the QCO surface. The relation between the resonance frequency and the adsorbed mass is shown according to the following proportional equation [50]

$$\Delta f = -2f_0^2 \Delta m / A(\rho_q \mu_q)^{1/2}$$

where Δf is the measured frequency change (Hz), f_0 is the resonance frequency of the oscillator, Δm is the mass change (g), A is the electrode area (cm^2), ρ_q is the density of quartz (2.648 g/cm^3), and μ_q is the shear modulus (2.947×10^{11} dyn/cm^2). For example, using a 6-MHz AT-cut QCO, the change in 1 Hz of QCO corresponds to 12.2 ng/cm^2; therefore, QCM can detect the volume down to the nanogram level.

These quantitative analyses are based on the above Sauerbrey equation [50]. On the other hand, it has been also reported that the resonance frequency changes in response to a change in not only in mass but also in properties such as density, viscosity, and elasticity of adsorbed substance. This indicates that the Sauerbrey equation is not always applicable to the measurements, especially in liquid phases. Later, another new QCO method, termed the *quartz crystal impedance* (QCI) method, was proposed by several authors [65–68]. The QCI method is now used as a powerful tool for detecting the viscosity/elasticity of adsorbed layers independently of mass of adsorbed layers on the QCO. Yet another team investigated the adsorbed mass and the viscosity change about the action of DNA on the –OH-modified QCO electrode, and reported that the viscosity on the QCO electrode also changed with the adsorption, immobilization, and hybridization of DNA, as well as its mass change [69]. Another group also investigated the temperature dependence of Langmuir–Blodgett (LB) films (1,3-dioctadecyl-*rac*-glycer-2-ol) adsorbed on the QCO, and reported that the phase transition of LB films caused the viscosity change of LB films themselves [70]. Recently another group performed detailed analyses of the molecular properties such as adsorption, precipitation, and denaturation of proteins using piezoelectric QCI system [71–73].

In the QCI method, the mechanical oscillation of QCO is exchanged with the electrical equivalent circuit, including resistance R_1, capacitance C_1, inductance L_1, and capacitance C_0 as shown in Fig. 3.8a, according to the theory of electro-mechano-acoustical analogy [52, 65–68, 74, 75]. In the circuit, R_1, C_1, and L_1 correspond to the viscosity, elasticity, and mass of the oscillating body (quartz plate, electrode, and adsorbed layer), respectively. C_0 is the capacitance between the two electrodes on the QCO. The admittance Y of the circuit is expressed by the following equation

$$Y = 1/(R_1 + 1/j\omega C_1 + j\omega L_1) + j\omega C_0$$

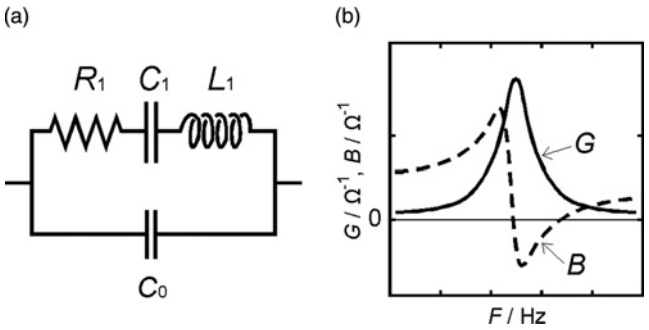

FIGURE 3.8 (a) Electrical equivalent circuit for an AT-cut QCO (R_1 = resistance; C_1 = capacitance; L_1 = inductance; C_0 = capacitance) for QCO; (b) conductance (G) and susceptance (B) spectra of an AT-cut QCO.

This equation is also converted using the conductance G and the susceptance B, which are real and imaginary parts of Y, respectively. R_1, C_1, L_1, and C_0 are calculated using the following equations from analysis of the above G and B obtained by an impedance analyzer at scanned frequency (Fig. 3.8b):

$$R_1 = 1/G_{\max}$$
$$C_1 = 1/L_1 \left(2\pi f_{G_{\max}}\right)^2$$
$$L_1 = 1/2\pi \left(f_{B_{\min}} - f_{B_{\max}}\right)$$
$$C_0 = B_{fG_{\max}}/2\pi f_{G_{\max}}$$

In these equations, G_{max} is a maximum value of G, f_{Gmax} is the frequency at the maximum of G, f_{Bmin} and f_{Bmax} are the frequencies at a minimum value of B and a maximum value of B, respectively, and B_{fGmax} is a value of B at f_{Gmax}. Among those various components, we specifically address the analysis of R_1 (viscosity) in the circuit from the viewpoint of membrane fluidity [36–38, 76, 77].

The details of QCM and QCI are entrusted to many reviews, articles cited above, and another chapter on the QCO method. From these useful characteristics of QCM and QCI, it can be expected that QCM and QCI methods would give the key of the elucidation of anesthesia phenomenon.

3.3.2 Apparatuses and Procedure

In order to investigate the interaction between anesthetics and the biomimetic flexible lipid monolayer on the water surface using the dropping method, as mentioned in Section 3.2, we applied the procedure of attaching QCO horizontally on the lipid monolayer, which employs the flexible properties of lipid monolayer. It was Okahata group who first designed and introduced the QCM method [56], which is now applied to various investigations of intermolecular interactions such as monolayer-protein, Gangliosides-WGA and virus, molecular recognition such as the hydrogen bonding and van del Waals interaction [57–63, 78–84].

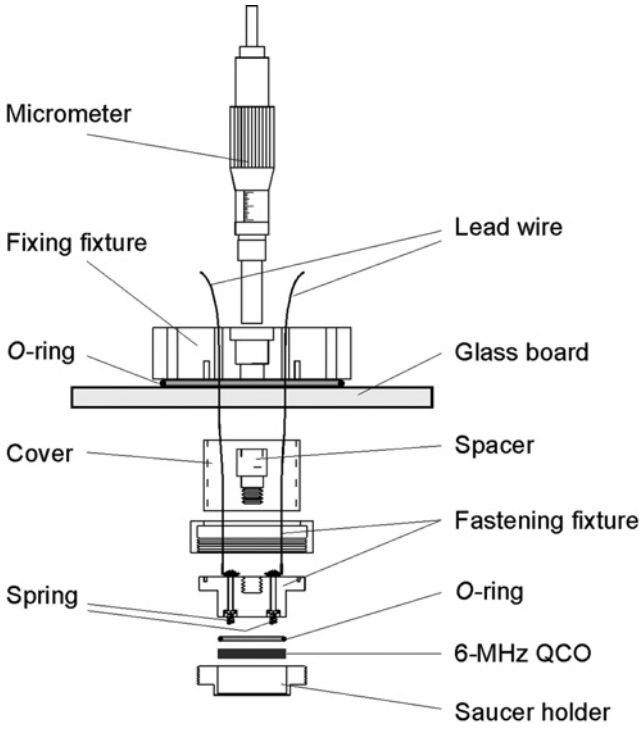

FIGURE 3.9 Central part of the QCO sensor. As the QCO attaches horizontally to the lipid monolayer, the saucer holder is specially processed. By installing a micrometer, it is possible to attach the QCO under the micrometer-order level and gentle condition.

For the detection of a very small physisorption behavior of anesthetic–lipid monolayer interaction, we also developed horizontally adhering type QCO apparatuses uniquely. Figure 3.9 shows a central part of the QCO sensor. An AT-cut QCO with a 6-MHz oscillator (manufactured by Hokuto Denko Corp.) is selected in the measurement. The area of QCO electrode and its thickness are 133 mm^2 and 0.25 mm, respectively. This QCO consists of two separate circuits one side for oscillating the QCO, and an opposite side for attachment to the lipid monolayer. The QCO is fixed with an O-ring in the poly(tetrafluoroethylene) saucer holder by pushing the fastening-type poly(tetrafluoroethylene) fixture. The saucer holder is specially processed so that only one side of QCO can attach horizontally to the lipid monolayer on the water surface. Two springs contacting with the QCO circuits are incorporated into the inside of the fastening-type fixture as two lead wires. A micrometer is also installed through the acrylic resin spacer in a center part of the fastening-type fixture. This micrometer makes it possible to attach the QCO horizontally and carefully on the lipid monolayer, at the micrometer-level and under slow-speed conditions (10 μm/s). The lipid monolayer attaches physically on the electrode surface of QCO by the hydrophobic interaction between the hydrophobic Au electrode surface and hydrophobic group (alkyl chain) of the

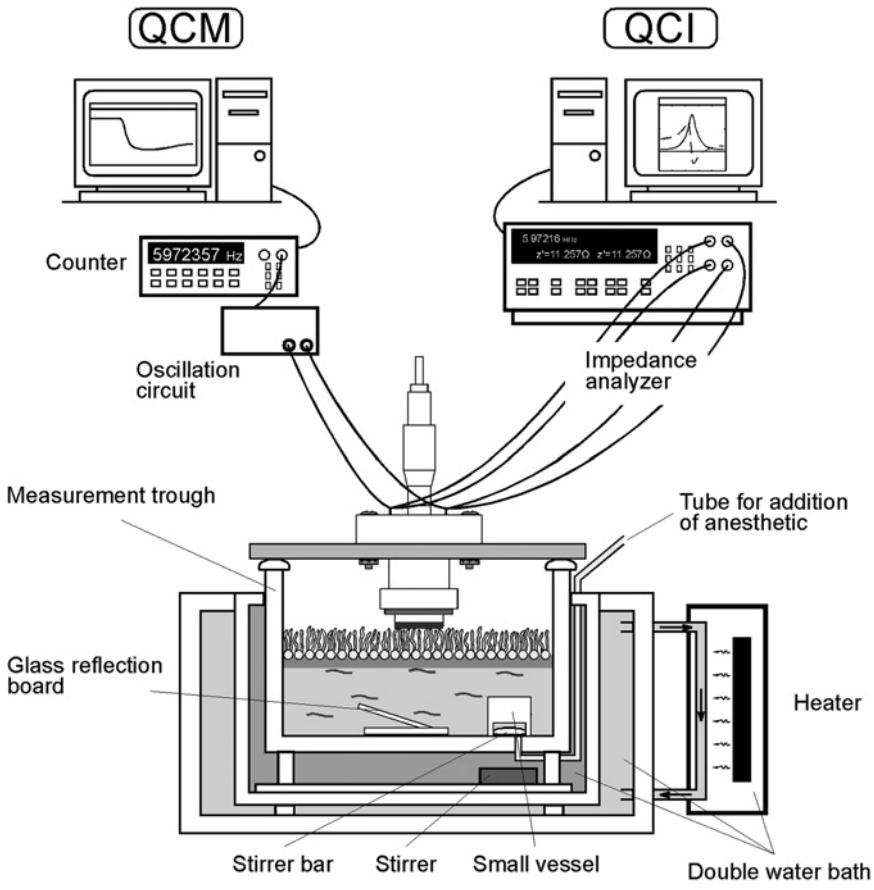

FIGURE 3.10 Schematic diagram of experimental apparatuses for both QCM and QCI measurements.

monolayer [78–84]. The whole QCO sensor is installed with a poly(tetrafluoroethylene) fixing fixture in a center of a glass board, which serves as a cover.

Figure 3.10 is a schematic representation of experimental apparatuses for both QCM and QCI measurements [47, 85, 86]. The measurement trough consists of polypropylene. A glass reflection board is mounted on the bottom of the trough to prevent wave reflection from the bottom [48,49]. A small poly(tetrafluoroethylene) vessel is mounted at the side of trough and a stirring bar is also placed in the vessel. The bar is stirred gently in the trough containing water at the rate of 1 rev/s by magnetic stirrer; the bar rotation is controlled by a slow-speed controller. Since the stirring is very slow, it does not affect the stability of lipid monolayer on the water surface. The vessel is also processed as the dissolved anesthetics by diffuse stirring into the water phase. The anesthetic (liquid) is injected into water phase through the poly(tetrafluoroethylene) tube and anesthetic droplet is stirred by the bar. The temperature of the measurement trough is maintained at 26 ± 0.01°C by use of a double water bath and also by controlling experimental environment at 27 ± 0.5°C. At the QCM, the resonance frequency is counted directly by the frequency counter through the oscillation circuit. At the QCI, the impedance measurement is performed continuously on the QCO, and the resistance is analyzed by the software for the impedance analyzer. QCM and QCI measurements are performed independently, respectively.

Figure 3.11 shows the typical time course of resonance frequency (F, Fig. 3.11a) and resistance (R, Fig. 3.11b) of QCO in contact with dipalmitoyl phosphatidyl choline (DPPC) monolayer on the water surface at 26°C. The horizontal axis (abscissa) represents time (hours), and the vertical axis (ordinate) represents the actual frequency and resistance. The horizontal axis zero corresponds to the time that QCO attached to the DPPC monolayer. When the QCO attached to the monolayer, F decreased by ∼1000 Hz and R increased by ∼200 Ω. Each amount of change was similar to the theoretical and empirical value [55–63, 65–68, 74, 75, 78–84, 87, 88]. After attaching the QCO, it is found that both F and R remain stable for several hours. This initial nonequilibrium state (time dependence) would be due to the equilibration of temperature of QCO and/or hydrophobic interaction between QCO and monolayer by attaching the QCO on the monolayer. Those stabilities were maintained within ± 0.5 Hz at QCM and ± 0.02 Ω at QCI for >8 h; therefore, the QCO

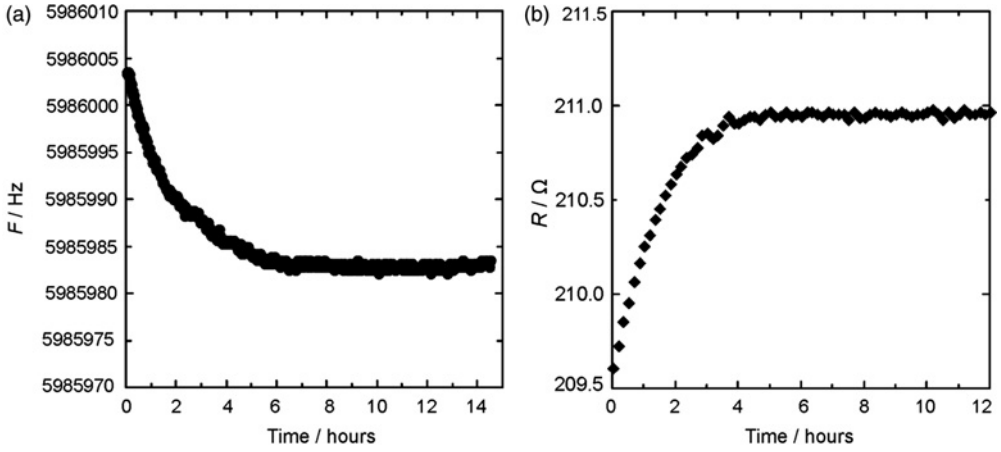

FIGURE 3.11 Typical timecourse of F and R of QCO in contact with DPPC monolayer on the water surface at 26°C. Both F and R are stable after passing for several times. These stabilities are maintained within ± 0.5 Hz at QCM and ± 0.02 Ω at QCI for longer than 8 h.

surface is maintained intact on the monolayer and is sensitive to each change under the monolayer [56–63]. There were some time-dependence patterns besides those shown in Fig. 3.10 until both F and R stabilized. However, when such stabilities were confirmed for ≥3 h, an experiment demonstrating the action of anesthetic on the lipid monolayer was subsequently conducted by the addition of anesthetic into the water phase (Fig. 3.9).

3.3.3 Time Course of Frequency (QCM) and Resistance (QCI)

It is known that the frequency and resistance of QCO are affected by the density and viscosity of the attached liquid phase (water phase in this study) [87, 88]. Since the concentration of anesthetic is on the mM level as mentioned above, the density and viscosity in the solution hardly change compared to those of water even if the anesthetic is dissolved in the water phase. Therefore, the change of frequency and resistance in this study is certainly due to the interaction between the lipid monolayer and anesthetic [56–64].

Here, we will explain how the time course is observed at both QCM and QCI by the addition of anesthetic, giving the interaction between DPPC monolayer and anesthetic enflurane as an example. Figure 3.12 shows the typical timecourse of frequency (QCM) and resistance (QCI) for QCO in contact with a DPPC monolayer after adding enflurane of 7 mM concentration (bulk phase) at 26°C. The lower half of the plot represents frequency and the upper half, resistance. The horizontal axis (abscissa) represents time (hours), and the vertical axis (ordinate) represents each frequency and resistance change [ΔF (Hz) and ΔR (Ω)] based on each stable frequency and resistance (Fig. 3.11) before the addition of enflurane. Enflurane was added in the water phase at the time of line A. After the addition of enflurane, ΔF decreased gradually (increase in adsorption) and ΔR also increased gradually (increase in viscosity) in response to the enflurane, and both ΔF and ΔR approached an equilibrium state. A typical hydrophobic enflurane possesses solubility, and the stirring bar is rotated gently in the water (1 rev/s); therefore, the delayed response (∼1 h) after the addition probably corresponds to the necessary time for the dissolution of enflurane into the water phase and the diffusion of enflurane from bulk solution (water phase) toward the DPPC monolayer/water interface [47, 85, 86, 89]. When both ΔF and ΔR begin to change, ΔF shifts steeply according to the

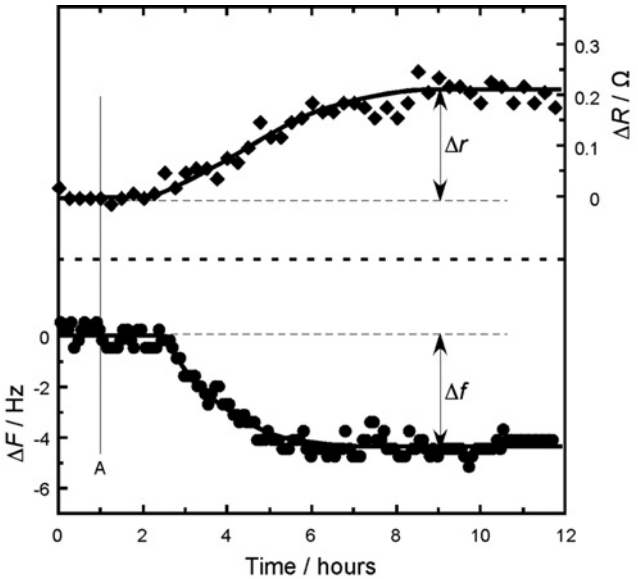

FIGURE 3.12 Typical timecourse of ΔF and ΔR of QCO in contact with DPPC monolayer after adding anesthetic enflurane of 7 mM concentration (bulk phase) at 26°C. Lower: ΔF; upper: ΔR. Enflurane was added in the water phase at the time of line A. Inserts Δf and Δr show each amount of change in frequency and resistance.

general adsorption phenomenon [78–84]; on the other hand, ΔR shifts gently. Because the viscosity change in the DPPC monolayer occurs by the adsorption of enflurane, the difference between ΔF and ΔR would appear in the process of change. The time interval between the beginning and end of the change is approximately several hours on both ΔF and ΔR. In the general observation of adsorption phenomenon by QCO using the monolayer [78–84], the addition reaction (chemical adsorption) to the specific part in the monolayer is often performed and the reaction time ends within several minutes in many cases. On the other hand, the present research consists in observing the physisorption phenomenon of the interaction between the lipid monolayer and anesthetics, as mentioned above. Actually, a specific part in which enflurane combines is not found in the DPPC monolayer, on comparison of the structure of DPPC molecule with enflurane molecule. Probably, it would take a long time for the dissolved enflurane to interact with and physisorb gently on the DPPC monolayer/water interface befoere it reaches an equilibrium state. It follows that this long time lapse (before reaching equilibrium state) would indicate that the reaction is not chemisorption but physisorption.

In the following section, the difference between the values before and after the addition of anesthetic [i.e., the difference between the standard value (zero position) before addition and the equilibrium value after addition] is defined as respective Δf for QCM and Δr for QCI (see Fig. 3.12 inset), and we will discuss the amount of these changes and their dependence on anesthetic concentration.

3.3.4 Concentration Dependence of Frequency (QCM) and Resistance (QCI)

3.3.4.1 DPPC versus Enflurane. Enflurane (CF_2H-O-CF_2-CClFH), a typical inhalation anesthetic, was synthesized in 1963, and this was the first research that was later applied clinically by another group in 1966 [41–43]. Enflurane is a halogenated ether-type anesthetic that is based on the structure and properties of previously administered anesthetics such as diethyl ether and chloroform. Compared to the first-synthesized halogenated anesthetic halothane (CF_3H-CBrClH), enflurane is superior with respect to its lower metabolic rate, smaller blood/gas partition coefficient, and higher analgesic action. Enflurane is a typical semihydrophobic molecule found in oxygen, fluorine, and chlorine atoms, and possesses a solubility of ~10 mM at 26°C [90]. In aqueous solution, water molecules surround the enflurane molecule and thereby form an enflurane-water hydrate in the solution (hydrophobic hydration).

Figure 3.13 shows enflurane concentration–dependent behavior in frequency [QCM (a)] and resistance [QCI (b)] for QCO in contact with a DPPC monolayer at 26°C [47]. The horizontal axis (abscissa) represents the enflurane concentration (bulk phase), and the vertical axis (ordinate) represents each frequency change (Δf) and resistance change (Δr), as defined in the previous section. In addition, the increase in Δf shows the decrease in actual value F. On the QCM (a), Δf gradually increased with an increase in enflurane concentration and asymptotically approached a saturation value of 3.4 Hz at around 6 mM. A further increase in concentration showed discontinuous increase and subsequent continuous increase: a second saturation value of 5.0 Hz. These processes are similar to the scenario of Langmuir's and/or BET's adsorption isotherm. On the QCI (b), there was no change in Δr at <2 mM. At >2 mM, Δr gradually increased with an increase in concentration and asymptotically approached a saturation value of 0.24 Ω at around 6 mM. A further increase in concentration showed discontinuous increase and subsequently a slight increase: a second saturation value of 0.29 Ω, similar to the case of the QCM (a). The amount of Δr change is somewhat small compared to the recent QCI measurement [65–73]. However, as the object that causes change is near

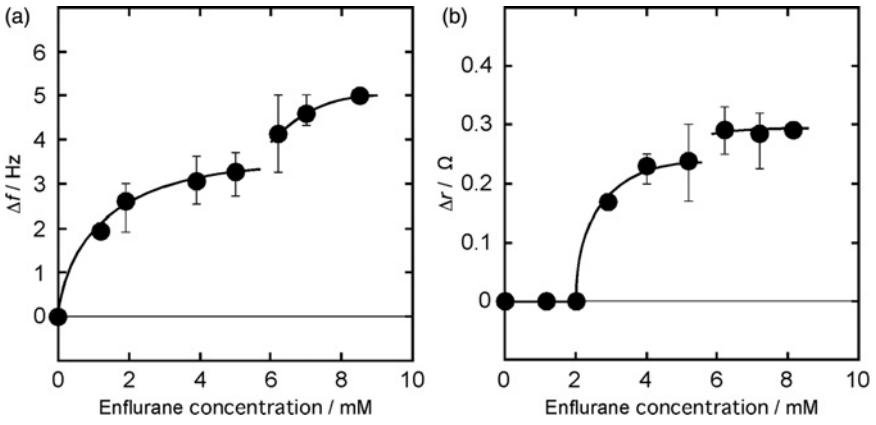

FIGURE 3.13 Enflurane concentration–dependent behavior of Δf (a) and Δr (b) for QCO in contact with DPPC monolayer at 26°C. Changes in Δf and Δr are defined in Fig. 3.12. Increase in Δf shows the decrease in actual value F.

the interface, including the lipid monolayer on the QCO, it is logical to assume that the amount of change will be small and certainly will be changing enough. It is quite interesting that the concentration at which Δf began to change ($\geq$ 1 mM) differed from that at which the Δr began to change ($\geq$ 3 mM), in other words, there is a specific concentration range where Δr does not change. These findings suggest that the action of enflurane to the DPPC monolayer is specific compared to the general adsorption process [78–84].

Another team [91] reported a study using ^{1}H-NMR spectroscopy, demonstrating that anesthetics (halothane, enflurane, methoxyflurane, and chloroform) show different actions on the isothermal phase transition between the lipid core and the hydrophilic interface in a DPPC vesicle. Therefore, the concentration of anesthetics that induced the transition of the lipid core is 2 times that required for the transition of a hydrophilic interface. Yet another group reported using ^{2}H-NMR spectroscopy to show that the interfacial structured water (restricted water) in the emulsion/water interface on the glycerol α-monooleate (GMO)/decane/^2H_2O reversed system (water-in-oil emulsion) changes into free water by enflurane–water hydrates [92]. Other investigators [93, 94] reported studies using ^{1}H- and ^{19}F-NMR spectroscopy and solubilization parameters to show that halothane and enflurane interact with the sodium dodecyl sulfate (SDS) micelle–water interface, at which the molecular axis of the halothane (C–C axis) is perpendicular to the interface (the hydrophobic F_3C– site penetrates the interface, and the hydrophilic –CHClBr site remains in a water phase); on the other hand, the molecular axis of enflurane (C–O–C–C axis) is parallel to the interface [93, 94]. Another team reported, using DSC and X-ray scattering, that enflurane preferentially interacts with DPPC lamellar-phase/water and DPPC liposomes/water interface, and causes the structural change of each lamellar phase and liposome [95]. These reports on anesthetic activity indicate that anesthetic hydrates interact with and release the interfacial structured water formed on the membrane/water interface without penetrating into the membrane lipid core; in other words, anesthetic hydrates physisorb on the interface.

As mentioned in the Section 3.2.1, the present DPPC monolayer obtained by the dropping method is of a semi-expanded state and also has a flexible and fluid structure, therefore elasticity-rich monolayer. Based on such the characteristic of the present DPPC monolayer and the reports cited above, the following model of the enflurane action of the DPPC monolayer would be possible in terms of *interfacial action* [47, 86]. In the first saturation range at ~6 mM, when the enflurane is added and dissolves into the water phase, enflurane hydrates physisorb on the interfacial structured water formed on the DPPC monolayer–water interface. Enflurane hydrates merely physisorb into the structured water and do not cause the interaction that disturbs the structured water at a small amount of enflurane hydrate ($\leq$ 2 mM). Therefore, Δf increases (adsorption mass of enflurane hydrate increases) and Δr does not change [i.e., the viscosity of the interfacial layer (DPPC monolayer/structured water) does not change]. An increase in the enflurane concentration corresponds to an increase in the amount of enflurane hydrates physisorbed on the DPPC monolayer/water interface, thereby further increasing Δf. On the local field such as the monolayer/water interface, an increase in the amount of physisorbed enflurane hydrates would generate the interaction and aggregation between physisorbed enflurane hydrates, and would also influence the structured water formed on the interface, thus leading to *distortion* and *release* of the structured water that is maintained by the week hydrogen bonding between hydrophilic groups of DPPC molecules and water molecules [96]. As a result, the interfacial structured water including enflurane molecules would be reconstructed at the interface. These processes promote the interaction between hydrophilic groups of DPPC molecules and also decrease the distance between those groups. Moreover, the interfacial structure may be strengthened by the existence of enflurane molecule because semi-hydrophobic enflurane interacts more strongly with hydrophilic groups of DPPC molecules than with structured (restricted) water molecules. These synergistic effects would show up as an increase in Δr (increase in viscosity) on the interface. This implies that the fluctuation of the fluid-structured DPPC monolayer is suppressed, leading to an increase in the density of the DPPC monolayer. Hydrophobic alkyl chains in DPPC molecules may also draw mutually (through attractive forces) by the suppression.

The experimental observation that both Δf and Δr eventually attain saturation values indicates that the physisorption of enflurane hydrates on the DPPC monolayer/water interface attained the initial equilibrium states at ~6 mM. From the amount of enflurane hydrates [3.4 Hz = 41.5 ng/cm^2 (Sauerbrey's equation)] by QCM, we roughly estimated the mean molecular area of enflurane hydrate. Here, we neglected the effect of the interfacial viscosity change. According to another report [92] the amount of hydrated water surrounding one enflurane molecule is approximately 30. By using this value, the molecular area of the enflurane hydrate is calculated as 2.9 nm^2 per each hydrate. It is assumed that enflurane hydrate has an *elliptical shape*, in which the molecular axis of the hydrate is the major axis, with the apparent molecular areas along the major and the minor axes measuring ~1.0 and ~0.63 nm^2 per each hydrate, respectively. The calculated value (2.9 nm^2 per each hydrate) is greater than that obtained for the major axis (1.0 nm^2 per hydrate). Considering the findings cited above, demonstrating that it is easy to orient the molecular axis of enflurane molecule in parallel to the micelle/water interface [94], the calculated molecular area indicates the formation of physisorption layer of enflurane hydrates where enflurane molecules are not in a dense state, and where those molecular axes orient parallel to the DPPC monolayer/water interface, in other words, the

formation of a complicated interface combining hydrophilic groups of DPPC molecules, enflurane molecules, and water molecules.

On the higher concentration at >6 mM, enflurane hydrates would physisorb still more on the interface, because the interface is already occupied at the semi-saturation level by the physisorbed enflurane hydrates at ∼6 mM and also loses its function as a barrier to the next physisorbed hydrates. Therefore, there exist the following two possibilities: (1) multi-physisorption of enflurane hydrates and (2) promotion of aggregation between hydrates. In the *multi-physosorption* model, enflurane hydrates physisorb easily and continuously (increase in Δf) because of the existence of the initial semi-saturated enflurane hydrate layer. That continuous physisorption process leads to the formation of an enflurane hydrate multilayer [47, 86, 97, 98]. Multilayering also further suppresses the interface, including the DPPC monolayer. This effect would cause a discontinuous increase and subsequent slight increase in Δr (increase in viscosity) on the interface. In the *promotion of aggregation* model, an increase in the physisorption of enflurane hydrates on the interface (increase in Δf), promotes the interaction between those physisorbed enflurane hydrates. That interaction process leads to the formation of a large enflurane hydrate cluster on the interface [41, 85, 86]. Clustering also strongly suppresses the interface, including the DPPC monolayer. This effect would cause a discontinuous increase and subsequent slight increase in Δr (increase in viscosity) on the interface. The increase in both Δf and Δr on the higher concentration range ($\geq$ 6 mM) may occur as a synergistic and/or simultaneous effect of both multi-physisorption and promotion of aggregation. Such easy physisorption of enflurane hydrates on the interface also causes a rapid second saturation state.

3.3.4.2 DPPC versus Isoflurane. Isoflurane (CF_2H–O–$CClH$–CF_3), a typical inhalation anesthetic, was synthesized by the Terrell group in 1965. Clinical use was permitted in the United States in 1980, and thereafter its use spread quickly [41–43]. Isoflurane is a structural isomer of enflurane. Compared to enflurane, isoflurane is superior with respect to the following points; low metabolic rate, small blood/gas partition coefficient, and almost no toxicity over the liver and kidneys. As well as enflurane, isoflurane is a typical semi-hydrophobic molecule and also possesses a solubility of ∼10 mM at 26°C [90, 99]. In aqueous solution, water molecules surround the isoflurane molecule and thereby form an isoflurane–water hydrate in the solution (hydrophobic hydration), as well as enflurane.

Figure 3.14 shows the isoflurane concentration–dependent behavior of frequency [QCM (a)] and resistance [QCI (b)] for QCO in contact with a DPPC monolayer at 26°C [24]. As in Fig. 3.13, the horizontal axis (abscissa) represents the isoflurane concentration (bulk phase), and the vertical axis (ordinate) represents each frequency change (Δf) and resistance change (Δr). In addition, the increase in Δf is accompanied by a decrease in the actual value of F. On the QCM (a), there was no change in Δf at <2 mM. At >2 mM, Δf gradually increased with an increase in isoflurane concentration and asymptotically approached a saturation value of 1.6 Hz at ∼6 mM. A further increase in concentration showed discontinuous increase and subsequent continuous increase: a second saturation value of 3.1 Hz. These processes are similar to the picture of Langmuir's and/or BET's adsorption isotherm. On the QCI (b), there was no change in Δr at <4 mM. At >4 mM, Δr gradually increased with an increase in concentration and asymptotically approached a saturation value of 0.14 Ω at ∼6 mM. A further increase in concentration showed discontinuous increase and subsequent slight increase or remained almost constant: a second saturation value of 0.18 Ω. As shown in Fig. 3.13, the concentration at which Δf began to change ($\geq$ 2 mM) differed from that at which Δr began to change ($\geq$ 4 mM). In the case of isoflurane, the action to the DPPC monolayer is specific.

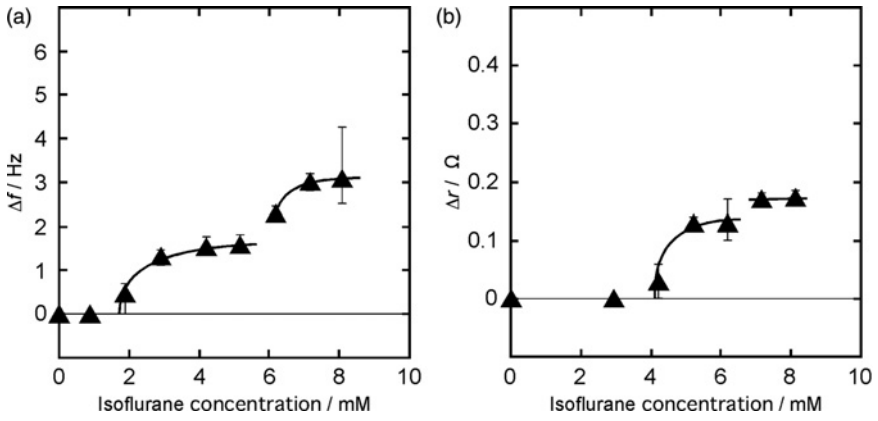

FIGURE 3.14 Isoflurane concentration–dependent behavior of Δf (a) and Δr (b) for QCO in contact with DPPC monolayer at 26°C. Changes in Δf and Δr are defined in Fig. 3.12. Increase in Δf shows the decrease in actual value F.

The general tendency, therefore, of the first and second saturation states with an increase in concentration, is similar to that for enflurane as seen in Fig. 3.13. However, there are two major differences between enflurane and isoflurane. One is the concentration at which both Δf and Δr began to change. With enflurane, Δf began to change at >1 mM; with isoflurane, change began at >2 mM. Therefore, it is more difficult to physisorb isoflurane than enflurane on the DPPC monolayer/water interface. In line with those phenomena, Δr began to change at >2 mM for enflurane and at >4 mM for isoflurane. Another difference is the amount of change for Δf and Δr. For example, first and second saturation values for Δf are 3.4 and 5.0 Hz for enflurane, respectively, while those of isoflurane are 1.6 and 3.1 Hz, respectively. Δr is also obtained at 0.24 and 0.29 Ω for enflurane, respectively, while those of isoflurane are obtained at 0.14 and 0.18 Ω, respectively. On the whole, the amount of change at isoflurane is about 50–60% smaller than that of enflurane. It is interesting that the mode of physisorption differs between enflurane and isoflurane, although these compounds have related isomeric forms.

Figure 3.15 shows the molecular structure of enflurane (left) and isoflurane (right) obtained by density functional theory (DFT) calculation with the B3LYP/6-31G(d) basis set (Gaussian 03 program) [100]. From the calculated optimized structure, enflurane molecule has a zigzag structure, with hydrophobic CF_2H– and –CF_2– separate from hydrophilic –O– and –CClFH, bordering on the molecular axis. Isoflurane also has a zigzag structure as well as enflurane. However, both the hydrophobic ends of CF_2H– and –CF_3 sandwich hydrophilic –O and –CClH–. Therefore, the hydrophobic and hydrophilic components of isoflurane do not differ significantly. The ellipticity of enflurane is less than that of isoflurane. Certainly, such clear structure of both enflurane and isoflurane would not necessarily be maintained in the water phase. However, the difference in arrangement of hydrophobic and hydrophilic components between enflurane and isoflurane (donor site) may appear as differences in hydration structure and also, more subtly, as differences in physisorption potency (easy for enflurane, difficult for isoflurane) in the specific reaction field such as the DPPC monolayer/water interface.

The curve shapes for both Δf and Δr in Fig. 3.14 are similar to those in Fig. 3.13 (enflurane). Therefore, it could possibly be explained by the physisorption model as well as enflurane. In the first saturation range, from 2 mM to approximately 6 mM, isoflurane hydrates physisorb on the interfacial structured water formed on the DPPC monolayer/water interface (increase in Δf). A small amount of isoflurane hydrate does not affect the structured water physically (no change in Δr). The increase in the amount of physisorbed isoflurane hydrate (further increase in Δf) does affect the structured water because of the interaction and aggregation between physisorbed isoflurane hydrates at the interface. As a result, *distortion* and *release* occur in the structured water, and the interfacial structured water, including isoflurane molecules, is reconstructed at the interface. This also implies a suppression of the interface, including the fluid-structured DPPC monolayer, and then subsequently an increase in Δr (increase in viscosity).

When the initial saturation values of both Δf (1.6 Hz) and Δr (0.14 Ω) were attained at around 6 mM, we roughly estimated the mean molecular area of isoflurane hydrate, as well as enflurane. Unfortunately, the amount of hydrated water surrounding one isoflurane molecule is not clear. When we assume 30 with molecules for isoflurane, the molecular area of the isoflurane hydrate is calculated as 6.2 nm^2 per each hydrate. Additionally, when we assume that the isoflurane hydrate is of elliptical shape, where the molecular axis of the hydrate is calculated as the major axis, the apparent

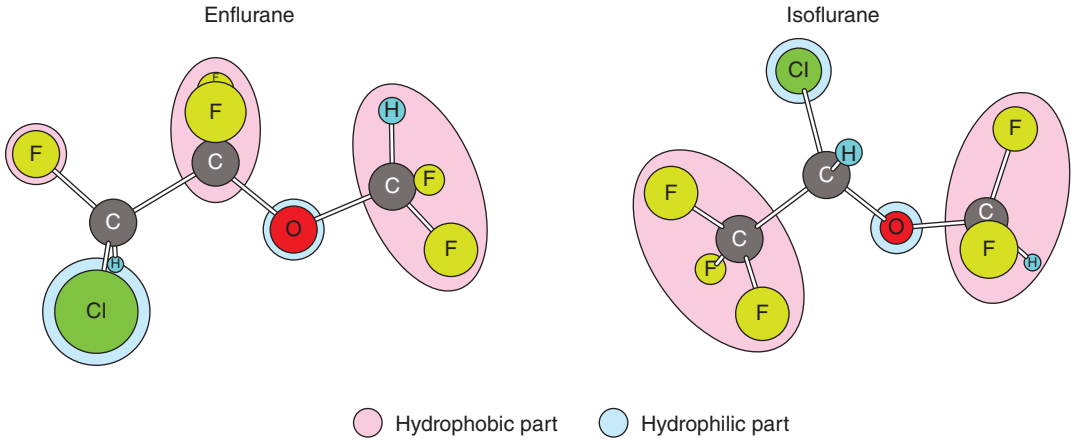

FIGURE 3.15 Molecular structure of enflurane (left) and isoflurane (right) by DFT calculation. Both enflurane and isoflurane have a zigzag structure. Gray indication (F–, –CF_2–, –CHF_2 in enflurane, and CF_3–, –CHF_2 in isoflurane) is the hydrophobic part, and light gray indication (Cl–, –O– in both enflurane and isoflurane) is the hydrophilic part.

molecular areas along the major and the minor axes are ~1.5 and ~1.3 nm^2 per each hydrate, respectively. Although the orientation of isoflurane hydrate on the interface is not clear, the experimental value (6.2 nm^2 per hydrate) is greater than that obtained by calculation (1.5 or 1.3 nm^2 per hydrate), regardless of the orientation of the hydrate. Therefore, physisorption layer of isoflurane hydrates is formed on the interface, where isoflurane molecules are not in a dense state and reach the saturation state by maintaining a certain amount of intermolecular distance, as found in enflurane as well.

At higher concentrations (>6 mM), *multi-physisorption* and/or *promotion of aggregation* of isoflurane hydrates would occur at the composite interface, which consists of hydrophilic groups of DPPC molecules, isoflurane molecules, and water molecules [40, 47, 85, 86, 97, 98], as well as enflurane. Continuous physisorption of isoflurane hydrates leads to multilayering of isoflurane and subsequently further suppression of the interface (multi-physisorption). Increase in physisorbed isoflurane hydrate also leads to aggregation of isoflurane and subsequently further suppression of the interface (promotion of aggregation). These effects cause the increase in Δf (increase in physisorbed isoflurane hydrates) and the increase in Δr (increase in the viscosity of interface). This physisorption mode experienced by the isoflurane hydrates also induces a rapid second saturation state.

3.3.4.3 DMPC versus Isoflurane. Figure 3.16 shows the isoflurane concentration–dependent behavior of frequency [QCM (a)] and resistance [QCI (b)] for QCO in contact with a dimyristoyl phosphatidyl choline (DMPC) monolayer at 26°C [24]. As shown also in Fig. 3.14, the horizontal axis (abscissa) represents the isoflurane concentration (bulk phase), and the vertical axis (ordinate) represents each frequency change (Δf) and resistance change (Δr). In addition, the increase in Δf shows the decrease in actual value F. On the QCM (a), Δf gradually increased with an increase in isoflurane concentration and asymptotically approached a saturation value of 2.2 Hz at around 5 mM. A further increase in concentration showed discontinuous increase and subsequent continuous increase: a second saturation value of 3.8 Hz. These processes are similar to the scenarios of Langmuir's and/or BET's adsorption isotherm, as well as in Figs. 3.13 and 3.14. On the QCI (b), there was no change in Δr at the measured concentration range.

Compared to the result in the action of isoflurane to the DPPC monolayer, two large differences exist. One is the concentration at which Δf began to change. For DPPC monolayer, Δf began to change >2 mM, while it was >1 mM for DMPC. Therefore, it may be easier to physisorb on the DMPC monolayer/water interface than on the DPPC monolayer/water interface. In line with these phenomena, the first and second saturation values (2.2 and 3.8 Hz) are larger than those at the DPPC monolayer/water interface (1.6 and 3.1 Hz). Another difference is the behavior of Δr. For the DPPC monolayer, Δr changed as a result of the action of isoflurane hydrate at the DPPC monolayer/water interface (Fig. 3.14). This tendency is shown in Fig. 3.13 for enflurane. On the other hand, Δr did not change at the DMPC monolayer/water interface. This suggests that the physisorption state of isoflurane differs between DPPC and DMPC monolayers.

As mentioned in the Section 3.2.2, the present DMPC monolayer state obtained by the dropping method is liquid-expanded (LE), in which two alkyl chains are disordered partially and the structure has *gauche*-type shape and disturbed state, indicating an expandability-rich monolayer. Such properties are quite different from those of DPPC monolayer that has an elasticity-rich state. In other words, the DMPC monolayer itself does not expand and/or shrink further, and maintains the expanding state. The interaction between the hydrophilic group of DMPC and water molecule is also weak (not structured), and the properties of water molecules in the

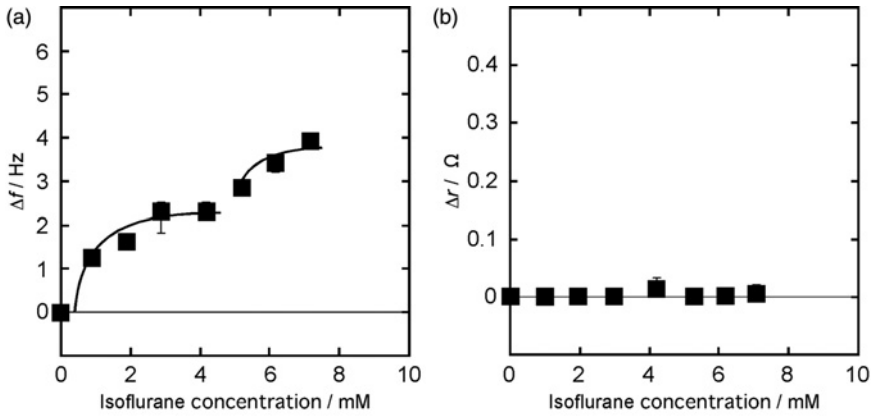

FIGURE 3.16 Isoflurane concentration–dependent behavior of Δf (a) and Δr (b) for QCO in contact with DMPC monolayer at 26°C. Changes in Δf and Δr are defined in Fig. 3.12. Increase in Δf shows the decrease in actual value F.

vicinity at the interface may be similar to those of bulk water phase. This state causes the action of isoflurane hydrate to differ from that of DPPC monolayer, namely, easy physisorption of hydrate on the DMPC monolayer/water interface and no change in the properties of the DMPC monolayer (no change in Δr) with the physisorption of hydrate. Therefore, it can be explained as a simple physisorption model of isoflurane hydrate to the DMPC monolayer. In the first saturation range, to ~5 mM, isoflurane hydrates physisorb on the DMPC monolayer/water interface (increase in Δf). An increase in isoflurane concentration leads to an increase in the amount of physisorbed isoflurane hydrate (further increase in Δf). On the other hand, isoflurane hydrates merely physisorb on the interface and would not give a physical influence to the interface [no change in Δr (viscosity)], even if those form aggregation on the interface.

After the first saturation value of Δf (2.2 Hz) was reached at ~5 mM, we roughly estimated the mean molecular area of isoflurane hydrate. As in Fig. 3.14, we assume the amount of hydrated water surrounding one isoflurane molecule to be 30. The molecular area of the isoflurane hydrate is calculated as 4.5 nm^2 per each hydrate. Considering the size of isoflurane hydrate as mentioned in Section 3.3.4.2, the physisorption layer of isoflurane hydrates is formed on the DMPC monolayer/water interface, where isoflurane molecules are not in a dense state and reach the saturation state by maintaining a certain amount of intermolecular distance, similar to the DPPC monolayer/water interface.

The calculated value (4.5 nm^2 per each hydrate) is smaller than that of the one on the DPPC monolayer/water interface; in other words, the amount of isoflurane hydrate is understandably more. As mentioned above, it would be difficult for the expandability-rich DMPC monolayer to cause the change of the interfacial properties by the physisorption of isoflurane hydrate. If such expandable state spread on the whole water surface, the DMPC monolayer/water interface may be more easily utilized to cause isoflurane hydrate to physisorb (many physisorption sites) compared to the elasticity-rich DPPC monolayer/water interface. As a result, isoflurane hydrates begin to physisorb at lower concentration and the amount of physisorption becomes large, compared to the DPPC monolayer/water interface. This also corresponds to the approach to the first saturation state at lower concentration. The difference in interfacial state (acceptor site) may be related to the difference in physisorption potency.

At higher concentrations (>5 mM), isoflurane hydrates would physisorb still more on the DMPC monolayer/water interface. On the other hand, the composite interface composed of hydrophilic components (hydrophilic groups of DMPC molecules, isoflurane molecules, water molecules), such as the DPPC monolayer/water interface, would not be formed at the first saturation state as discussed above. Therefore, it can also be explained as a simple *multiphysisorption* and/or *promotion of aggregation* model of isoflurane hydrate to the DMPC monolayer. This theory is supported by the observation that Δr does not change by >5 mM. Continuous physisorption of isoflurane hydrates leads to multilayering and/or aggregation of isoflurane themselves, and thereby a further increase in Δf (increase in physisorbed isoflurane hydrates). Compared to the composite DPPC monolayer/water interface (>6 mM), the existence of simple physisorbed isoflurane hydrates would facilitate the physisorption of further hydrates. Such a physisorption caused by the isoflurane hydrates also results in a rapid second saturation state.

3.3.4.4 DPPC-Cholesterol versus Enflurane. Figure 3.17 shows the enflurane concentration–dependent behavior of frequency [QCM (a)] and resistance [QCI (b)] for QCO in contact with a DPPC-cholesterol mixed monolayer at which a mole fraction of cholesterol (Chol) is 0.2 at 26°C. As in Fig. 3.13, the horizontal axis (abscissa) represents the enflurane concentration (bulk phase), and the vertical axis (ordinate) represents each frequency change (Δf) and resistance

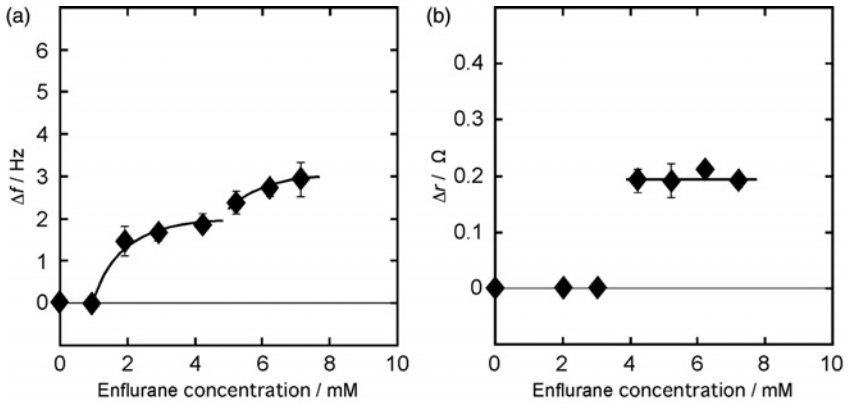

FIGURE 3.17 Enflurane concentration–dependent behavior of Δf (a) and Δr (b) for QCO in contact with a DPPC–cholesterol mixed monolayer at which a mole fraction of cholesterol is 0.2 at 26°C. Changes in Δf and Δr are defined in Fig. 3.12. Increase in Δf shows the decrease in actual value F.

change (Δr). In addition, the increase in Δf shows the decrease in actual value F. We decided to examine the action of enflurane to the mixed monolayer of 0.2 mole fraction of Chol, because the mixed monolayer shows unique monolayer morphology among various mole fractions of Chol, as mentioned in Section 3.2.4. On the QCM (a), there was no change in Δf at <1 mM. At >2 mM, Δf gradually increased with an increase in enflurane concentration and asymptotically approached a saturation value of 2.0 Hz at around 4 mM. A further increase in concentration showed discontinuous increase and subsequent continuous increase: a second saturation value of 3.0 Hz. These processes are similar to the scenario of Langmuir's and/or BET's adsorption isotherm, as well as those in Figs. 3.8, 3.14, and 3.16. On the QCI (b), there was no change in Δr at <3 mM. At ~4 mM, Δr showed sudden and discontinuous increase, and subsequently almost constant value of 0.20 Ω to 7 mM.

Compared to the result in the reaction of enflurane to the pure DPPC monolayer shown in Fig. 3.13, some important differences are found. On the change in Δf, the tendency is similar to the case of pure DPPC monolayer; however, the concentration at which Δf began to change is different. At the pure DPPC monolayer, Δf began to change from 1 mM; on the other hand, it is >2 mM at the DPPC-Chol mixed monolayer. Therefore, it is more difficult to physisorb on the mixed-monolayer/water interface than on the pure DPPC monolayer/water interface. The amount of change is also different. The first and second saturation values for Δf are each 3.4 and 5.0 Hz at the pure DPPC monolayer; on the other hand, those of mixed monolayer are each 2.0 and 3.0 Hz. The amount of change at the mixed monolayer is about 60% smaller than that at the pure DPPC monolayer. On the Δr change, a somewhat specific change was observed: discontinuous increase and subsequent constant value (0.20 Ω) at around 4 mM. This is quite different from that for the pure DPPC monolayer: first and second saturation states with increase in concentration (Fig. 3.13).

As mentioned in Section 3.2.4, the present DPPC-Chol mixed monolayer obtained by the dropping method is more highly condensed than the pure DPPC monolayer (elasticity-rich) on the water surface, as obtained by the Chol condensation effect. On such the mixed monolayer, the limiting molecular area A_0 was 0.48 nm^2 (Fig. 3.4) [31] and larger than that using the compression method (0.43 nm^2) [10]. Therefore, the difference between both values implies that the monolayer elasticity still remains in the mixed monolayer using the dropping method, even if it is subject to the influence of the Chol condensation effect. We have also found from QCM measurement that enflurane (4 mM) does not physisorb on the *n*-hexadecanol ($C_{16}H_{33}OH$: HA) monolayer/water interface [101]. HA forms a highly condensed (solid) monolayer using the dropping method (A_0 = 0.20 nm^2), as does that using the compression method. The HA monolayer/water interface would be stable and also have poor fluidity. These results indicate that enflurane cannot physisorb easily on the condensed monolayer/water interface.

On the basis of these mixed monolayer characteristics and our experimental results, we propose that the following model of the enflurane action to the DPPC-Chol mixed monolayer would be possible. At 1 mM, enflurane hydrates does not physisorb on the mixed-monolayer/water interface because of its more highly condensed state compared to the pure DPPC monolayer. On the first saturation range from 1 mM to approximately 4 mM that was observed at QCM measurement, hydrates physisorb on the interfacial structured water formed on the mixed-monolayer/water interface (increase in Δf). A small amount of enflurane hydrate does not physically influence the structured water (no change in Δr). At the point where interfacial properties (viscosity) do not change in the first saturation range, this process can be explained as a simple physisorption model of enflurane hydrate and is also similar to that of isoflurane physisorption to the DMPC monolayer (Fig. 3.16).

After the first saturation value of Δf (2.0 Hz) was reached at ~4 mM, we roughly estimated the mean molecular area of enflurane hydrate. Assuming the amount of hydrated water surrounding one enflurane molecule to be 30, as shown in Fig. 3.13, we calculated the molecular area of enflurane hydrate as 5.0 nm^2 per each hydrate. Considering the size of enflurane hydrate as mentioned in Section 3.3.4.1, the physisorption layer of enflurane hydrates is formed on the mixed-monolayer/water interface, where enflurane molecules are not in a dense state and reach saturation state by maintaining a certain of intermolecular distance, as is the case for the pure DPPC monolayer.

The calculated value (5.0 nm^2 per each hydrate) is larger than that on the pure DPPC monolayer/water interface; in other words, the amount of enflurane hydrate is understandably less. As mentioned above, the mixed monolayer is more highly condensed than the pure DPPC monolayer. If such a highly condensed state were to spread on the entire water surface, enflurane hydrates could not physisorb easily on the mixed-monolayer/water interface. As a result, the amount of hydrate is smaller than that of pure DPPC monolayer. The difference in interfacial state (acceptor site) may be related to the difference in physisorption potency. This may also be similar to the interpretation that the pattern of isoflurane physisorption differs between DPPC and DMPC monolayers.

At ~4 mM, Δr suddenly caused a discontinuous increase (0.20 Ω). Although the DPPC-Chol mixed monolayer is already condensing to some extent as a result of the Chol condensation effect, the mixed monolayer still has room to condense, as mentioned above. The amount of enflurane hydrate (physisorption-layer level of enflurane), to the extent that the mixed-monolayer/water interface is covered, would probably be required for further condensation. Such covering would cause distortion and release of structured water at the mixed-monolayer/water interface and the

reconstruction of the interface including enflurane molecules. This implies potential suppression of the interface and, therefore, an increase in Δr (increase in viscosity). Furthermore, the Δr did not cause a gradual or two-step change such as in the case of pure DPPC monolayer (Fig. 3.13), and showed discontinuous increase and subsequent constant value (0.20 Ω) to 7 mM. When the interface was reconstructed by covering the physisorption layer of enflurane, Chol condensation effect may function as a synergistic effect. Therefore, the reconstruction process of the interface may further strengthen the interaction between two hydrophobic alkyl chains in DPPC molecules with Chol (promotion of Chol condensation effect) and also cause them condense to a specific limit. This corresponds to Δr maintaining constant value (0.20 Ω) after discontinuous increase, despite an increase in concentration. In other words, above 4 mM, this phenomenon can be also explained as a simple physisorption model of enflurane hydrate to the mixed monolayer as described below.

At the higher concentration (>5 mM) that was observed at QCM measurement, enflurane hydrates would physisorb still more on the DPPC-Chol mixed-monolayer/water interface. Although the mixed monolayer is itself in a condensed state (not easily physisorbed), the interface would somewhat lose its function as a barrier to the next physisorbed hydrates because some enflurane hydrates would already be physisorbed on the interface. Therefore, this phenomenon can be explained as a simple *multi-physisorption* and/or *promotion of aggregation* model of enflurane hydrate on the mixed monolayer, as in the case of DMPC monolayer. This theory is also supported by the fact that Δr does not also change in this concentration range (5–7 mM), as mentioned above. Continuous physisorption of enflurane hydrates leads to multilayering and/or aggregation of enflurane, and thereby further increase in Δf (increase in physisorbed enflurane hydrates). Because there is no change in Δr (no influence on the interface), such a simple physisorption caused by the enflurane hydrates would also occur easily and lead to a rapid second saturation state. The amount of physisorbed hydrate is smaller than that of the pure DPPC monolayer (Fig. 3.13), and probably the change in interfacial properties (condensation) that occurred at ∼4 mM would reduce the physisorption potency of the acceptor site (interface) compared to the pure DPPC monolayer.

3.3.5 True Anesthesia Phenomenon

In the present study, the interaction between various lipid monolayers on the water surface and anesthetics has been investigated using a horizontally adhering type QCM and QCI measurement. It was found that anesthetics physisorb to the elasticity-rich DPPC monolayer and change its monolayer properties (viscosity), but that they physisorb only to the expandability-rich DMPC monolayer, and to the condensed DPPC-Chol monolayer, and that this results in specific changes in monolayer properties. In terms of physisorption (QCM measurement), the process described here showed a two-step change bordering on the concentration of 5–6 mM in all cases investigated, and it was suggested that anesthetic aggregation is probably formed on the monolayer/water interface [40]. It is interesting that anesthetics physisorb to the monolayer on the water surface, which is a comparatively simple system, and also change its monolayer properties depending on the type of monolayer.

More recent studies on the anesthesia phenomenon have regarded anesthetic action as the specific interaction between anesthetic and protein, and have focused on identifying the receptor of anesthetic. Many studies have also been conducted to identify the $GABA_A$ (γ-aminobutyric acidtype A) receptor, which is widely distributed, especially throughout the central nervous system, which is a major target, and many studies have also been performed on the interaction between anesthetics and $GABA_A$ [102, 103]. However, the characteristics of the anesthesia phenomenon, such as the anesthesia revelation at high concentration in body fluid and the reversibility of the phenomenon, cannot be explained only by a specific interaction corresponding to the simple relation between "key" and "keyhole" as in a generic drug. Actually, our measurement results suggest that the lipid parts and/or lipid/body-fluid interface in biomembranes also may be potential targets of anesthetic action.

It is clear from many studies spanning more than one century that only direct action on the lipid membrane (lipid theory) is not the origin of anesthesia revelation [2, 37–47, 85, 86, 90–94, 99–103]. However, it is also appropriate to assume that the results of these studies are not limited to the anesthetic–protein interaction, but that they include the wide-ranging effects of anesthetics on the molecular aggregate in the living body, which contains various lipid molecules and proteins. Although the action mechanism of anesthesia is very complicated and has not yet been elucidated, we believe that, with further investigation, clarification of the molecular action mechanism of anesthetics in response to the molecular aggregate that constitutes the biomembrane will not only deepen our understanding of the anesthesia phenomenon but will also contribute to future guidance in the proposed development of new anesthetics and improvement in the quality of medical treatment involving the use of clinical anesthesia.

4.1 INTRODUCTION

Currently, atomic force microscopy (AFM) occupies a very important position in a wide range of research areas in the sciences and engineering. Since its invention in 1984 by Binning et al. [1], AFM has been used as a powerful tool to explore surface structures down to the molecular scale, or even to the atomic scale depending on the samples and environment. In AFM, a nanostylus (probe tip) attached to the end of a microfabricated cantilever is scanned over a sample. A sensitive four-segment photodiode detects the vertical and lateral positions of the laser beam reflected off the back of the cantilever, which follows the surface undulations of the sample. Owing to this relatively simple optical lever method, AFM can be operated in various environmental conditions, including liquids and gases. This feature is particularly advantageous for biology-related research fields since it enables *in situ* imaging of biomolecules (e.g., proteins, DNA, peptides) and biological cells in aqueous solutions without requiring the complicated pretreatments of samples that are necessary for electron microscopy and fluorescence microscopy. In addition to surface imaging, AFM enables measurement of forces between the probe tip and the sample substrate; the tip and the substrate are scanned vertically (z-direction) and the tip−substrate interaction force is then estimated from the vertical deflection of the probe cantilever. Consequently, AFM enables measurement of the interaction forces of even a few piconewtons between the probe tip and the sample surface at subnanometer resolution in the z-direction. Such highly sensitive force measurements can be conducted in a local area ($<10 \times 10$ nm) along the x and y directions. Once a micrometer-sized particle is attached to the end of the cantilever, often called the colloid probe [2], one can measure the surface forces between the particle and the substrate.

Understanding the interaction forces between two opposing surfaces in liquids has been one of the central topics in colloid science for the past several decades because these forces directly influence the dispersion/aggregation state of colloidal systems, including suspensions and emulsions. The Derjaguin−Landau−Verway−Overbeek (DLVO) theory, developed in the 1940s, provided a way to estimate the dispersion stability of colloidal particles and is still widely used as a standard theory to quantitatively describe the surface forces in aqueous solutions. On the other hand, there was no experimental method to directly measure the interaction forces as a function of separation distance between two opposing interfaces before the 1970s; therefore, one had to rely on indirect methods such as the turbidity measurements of colloidal dispersions, observation of coalescence of two mercury drops, and measurements of soap film thickness [3,4]. In the 1970s, an innovative instrument called a surface force apparatus (SFA) was invented for directly measuring

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

interaction forces between two macroscopic surfaces in liquid and gaseous media [5]; since then, a number of SFA studies have helped to deepen the understanding of surface forces in various systems. Subsequently, since the early 1990s, AFM has been applied to the direct measurements of interaction forces in a variety of colloidal and biological systems. In force measurements with AFM, a probe tip or a colloid probe can be coated/functionalized with many kinds of molecules, including biological substances. This versatility has made AFM force measurement one of the most important methods in various research fields.

Biological systems comprise a number of the dynamic, physicochemical interactions between their components such as proteins, membranes, phospholipids, endocytic vesicles, and DNAs in biological fluids. Therefore, one of the best approaches to explore and explain the phenomena occurring in biological systems is to evaluate and quantify the dynamic interaction forces acting between these components. In addition, because of the recent rapid growth in the field of nanobiotechnology, engineered materials often come into contact with biointerfaces, including human bodies and environments, as exemplified by research focused on biocompatible materials, cell culture surfaces, and drug delivery systems. Thus, exploration and understanding of various interactions between a variety of materials and biointerfaces from the viewpoint of colloid science would enable the development of a conceptual framework for the predictive and effective design of engineered material surfaces with biological applications. AFM has been viewed as one of the most powerful instruments to achieve these goals.

In this chapter, we provide an overview of the rapid advances in AFM applications for force measurements in bioscience research. We describe developments and the keystone research results of force measurements, focusing mainly on the interactions of membranes, proteins, cells, and various material surfaces, together with descriptions of the methodologies employed for these measurements.

4.2 MEASUREMENT OF INTERACTION FORCES USING AFM

Before reviewing the measurements of interactions for various biointerfaces, we will provide a brief overview on the techniques for direct force measurement using AFM. As shown in Fig. 4.1, the sample is moved vertically (in z-direction) by expanding the piezo scanner to allow the probe to approach the sample surface and make contact with it, and contracting the piezo to retract the probe to the original position. The cantilever deflection (Δz) resulting from the probe−sample interaction is measured by the optical lever method. An attractive force, called the adhesion force, often appears after the probe and sample establish contact with each other. Most commercial AFMs have an operation mode so that these procedures can be conducted automatically. The probe−sample force (F) is calculated by Hooke's law, $F = k_c \Delta z$, where k_c is the spring constant of the cantilever. The surface of the probe tip can be modified with a variety of molecules by either physical adsorption or chemical reaction.

For the colloid probe, spherical particles typically in the diameter range of 1–30 μm are used. A particle is attached to the probe with epoxy glue or hot-melt epoxy resin using a micropositioning device such as a micromanipulator under observation with an optical microscope or a CCD camera.

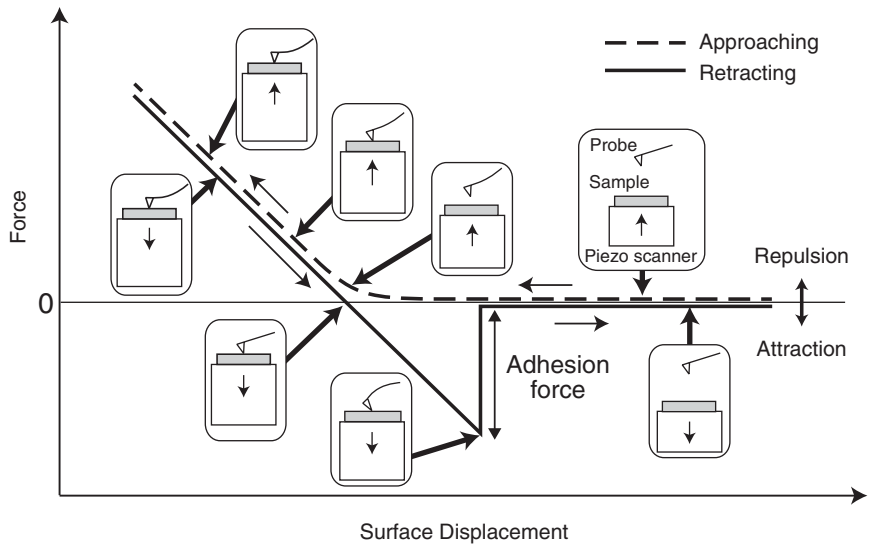

FIGURE 4.1 Schematic illustration of a force measurement between two surfaces using AFM shown along with a plot of force versus displacement.

The surface of the particles can be modified with various molecules before or after attaching to the probe tip.

Since the surface force is usually described as a function of the separation distance between two surfaces, it is of critical importance to determine this separation distance precisely. However, a standard AFM is not equipped to measure the separation distance directly and the following conversion procedure is consequently required to determine the separation distance [6]. Figure 4.2a illustrates a typical raw data trace for the force measurement between two hard, solid surfaces (such as metal oxides) obtained from a standard AFM. The raw output signals by AFM are the deflection of a probe cantilever bent upward/downward by the probe−sample interaction and the surface displacement of a sample stage (or a probe) driven by a piezoelectric transducer. One can easily calculate the probe−sample force from the deflection of the probe cantilever with Hooke's law, as mentioned above. When the probe comes closer to the sample surface (moving from right to left in Fig. 4.2a), the probe cantilever starts to deflect because of the probe−sample interaction. In the case of a sufficiently hard surface of samples, the force−displacement curve exhibits a linear profile after the closest contact between the probe and sample surfaces, where the deflection of the probe becomes equivalent to the displacement of the sample surface. The region of this linear profile can be assumed as that of the zero separation distance between the probe and sample surfaces and is often called the constant-compliance region. One can then transform the surface displacement into the separation distance, and a force−distance curve is obtained as shown in the inset of Fig. 4.2a.

When the surface of the samples is soft, it is more difficult to estimate the separation distance from the AFM force−displacement curve due to surface deformability. This is the case for the force measurements of biomolecules and cells, where they are usually attached to either or both the probe surface and substrate surface. As shown in Fig. 4.2b, the surface deformation changes significantly in the compliance region of the force−displacement curve. When the surface deformation is proportional to the applied force (e.g., a large bubble and a large droplet), a straight constant compliance region still appears with a more gradual slope compared with that of the rigid surfaces. In this linear deformation system, one can estimate the separation distance between two surfaces and their contact point on the assumption that the force from the deformed body or bodies is given by $k_d \Delta z$, where k_d represents a spring constant of the deformed body or bodies [7]. On the other hand, in the event of nonlinear deformation, the compliance region exhibits a curved profile instead of a straight line, and there are no distinct criteria for determining the contact region and the separation distance between the two surfaces. Apart from the separation distance, one can still measure the adhesion force (see Fig. 4.1) that would be influenced by several parameters such as the approaching/retracting velocity, the indentation depth, the applied load, and the contact time. Therefore, the main focus of AFM studies of biological materials and cells is often placed on these adhesion (or pull-off) forces.

4.3 INTERACTION OF MODEL MEMBRANES

Force measurement studies of biomembranes often employ artificial model membranes (i.e., lipid bilayers and giant unilamellar vesicles) as well as actual cell membranes, which are described in Section 4.5. In early-stage studies, SFA,

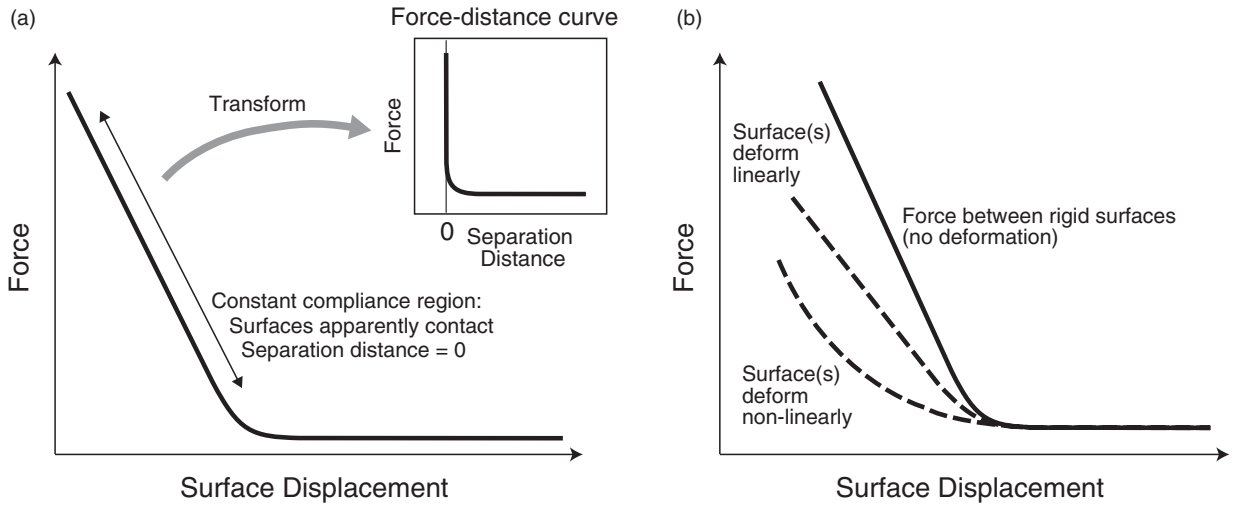

FIGURE 4.2 Schematic illustration of typical force−displacement curves between two surfaces obtained from AFM: (a) rigid surfaces and (b) deformable surfaces. The inset of panel (a) shows a force−distance curve transformed from the force−displacement curve.

which measures the forces between two macroscopic surfaces of area ∼1 cm^2, was used to investigate the interaction between lipid bilayers supported on mica surfaces [8]. These SFA measurements revealed that the short-range hydration/steric interactions between the supported lipid membranes are affected by the type and composition of the phospholipid molecules comprising the membranes. In contrast, application of AFM to the force measurements between lipid membranes was delayed by the difficulty in preparing the lipid bilayers on the AFM probe surface. Therefore, the early-stage AFM studies of lipid bilayers were largely limited to the imaging of lipid membranes supported on substrates [9], the measurement of mechanical strength of the supported lipid membranes [9], and the imaging of aggregation of polypeptides in supported lipid membranes [10].

Pera et al. [11] were the first to develop a method for forming a stable lipid bilayer on the surface of an AFM probe tip, which they used to measure the interaction force between two lipid bilayers supported on the surfaces of the tip and the planar mica in aqueous solution. They found that the salt concentration in the solutions drastically changes the interaction between the supported lipid bilayers, and that the addition of phosphate-binding proteins to the lipid bilayers increases the stability of the lipid bilayers. Following this study, the lipid bilayer was also successfully created on the surface of a colloid probe, which has a larger radius of curvature compared with a probe tip [12, 13]. This colloidal probe microscopy enabled the investigation of interactions between macroscopic bilayers that are more comparable in size to biological membranes.

The interactions of biomolecules with model membranes have also been studied. Carneiro et al. [14] measured the interactions of vesicular stomatitis virus attached to an AFM probe with membranes of different phospholipid compositions. They discovered that the adhesion forces differ drastically depending on the composition of the membrane phospholipids, revealing the high specificity of G protein binding to membranes containing phosphatidylserine. Wang et al. [15] measured the interactions of lysenin, a sphingomyelin-specific binding protein, attached to an AFM tip with the lipid membranes to successfully map the sphingomyelin-rich and -poor domains from the force curves. These types of measurements, however, have been reported by only a few researchers, mainly because of the difficulty in performing such precise measurements and in detecting false interactions such as membrane molecules being pulled out from a lipid membrane by a functionalized tip due to the strong tip−membrane interactions [16].

4.4 INTERACTION OF PROTEINS

One of the main applications of AFM to the force measurements of biomolecules has been single-molecule force spectroscopy (SMFS), where molecules of interest are attached on an AFM tip and allowed to interact with a solid surface with or without other molecules. The SMFS technique was first used by Florin et al. for proteins [17], and by Lee et al. for DNA [18]. The ligand−receptor binding force of individual biotin−avidin pairs was successfully quantified by measuring the adhesion forces between an avidin-immobilized tip and a biotin-functionalized agarose bead [17]. Following this study, much progress has been made to determine the static and dynamic interaction forces of a variety of biomolecule pairs. A number of papers have been published using the SMFS technique to investigate different types of interaction forces, including ligand−receptors [19–21], antigen−antibodies [22, 23], cell surface proteins [24, 25], and protein−DNA [26, 27]. In addition, SMFS has been applied not only to intermolecular force measurements, but also to the intramolecular force measurements of individual molecules such as the folding/unfolding of proteins, where a single molecule is held between the AFM tip and support and stretched thereby [28–30]. A detailed picture of the complex mechanical unfolding pathway of single proteins can be obtained through an energy landscape of the measured interactions [31].

The force curves obtained using SMFS look different from those between solid surfaces mentioned in Section 4.2. The molecules attached onto a cantilever and/or a substrate surface often interact with multiple binding sites when the two surfaces are brought into contact. By retracting the probe from the surface, the multiple bonds gradually rupture to cause "sawtooth" patterns with multiple attractive force maxima in the force curve. During the stretching of the molecule(s) bridging the probe and the substrate before the rupture, the force curve exhibits a specific curved profile, which is similarly observed for the polymer coils extended between two surfaces, as shown in Fig. 4.3. The force profiles obtained from SMFS are sometimes analyzed by fitting the physical models proposed originally for polymer stretching, such as the wormlike chain (WLC) model [32], so that an elastic property of the stretched molecule(s) can be characterized. This analysis is particularly useful to investigate the unfolding of proteins.

SMFS has also been applied to measure protein interactions with solid material surfaces such as glass [33], gold [34], and polystyrene [33,35]. In general, the protein−material interaction forces before their contact are dominated by electrostatic repulsion at large separation distances. Once the protein comes close to a material surface and contacts it, other forces such as hydrogen bonding, hydrophobic interactions, and hydration forces contribute to the adhesion force between the protein and the material. In addition to the simple material surfaces, one can explore the adsorption of protein onto model surfaces coated with various functional groups. Some examples include the self-assembled monolayers (SAMs) of alkanethiols on gold, where the alkanethiols have various

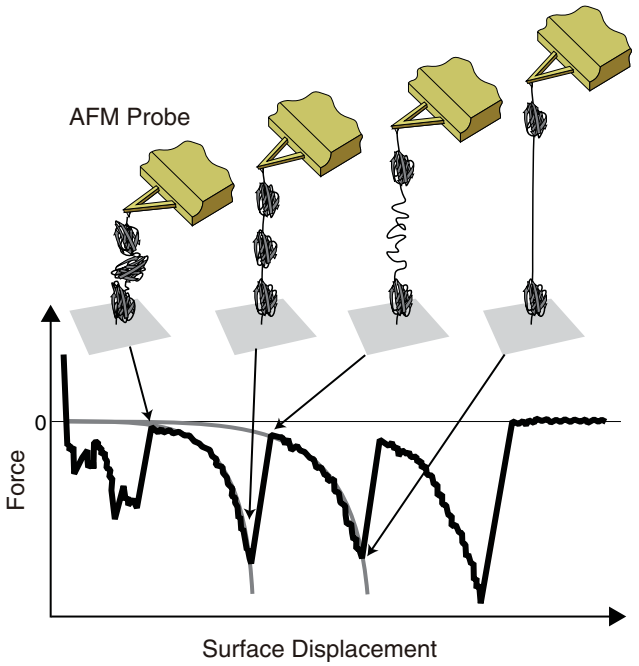

FIGURE 4.3 Schematic illustration of typical force curves for a protein stretching and the hypothesized structure of proteins. Gray lines show the fitted curves using the WLC model.

terminal groups. The investigations of protein interactions with model surfaces that have the terminal groups of $–CH_3$, $–NH_2$, –OH, and –COOH [34,36] revealed that among the four terminal groups, $–CH_3$ has the greatest effect and the strongest affinity for all the investigated proteins. The affinities of the $–NH_2$, –OH, and –COOH surfaces for proteins depend largely on the type of the protein, indicating that this interaction varies in a complicated fashion depending the type of model surface and protein applied.

For engineered surfaces, poly(ethylene oxide) (PEO) [also known as poly(oxyethylene) (POE) or poly(ethylene glycol) (PEG)] is most often used to create biologically inert, protective coatings. The graft polymerization of PEO layers onto material surfaces is used to protect against protein adsorption. The detailed mechanism of the interaction of the PEO layers with proteins, however, had been unclear despite numerous studies; the adsorption tests produced contradictory results showing that the net protein−PEO interactions were both attractive and repulsive. The direct force measurements using AFM with the protein-immobilized probe tip [37] or colloid probe [38] have revealed that the grafting density of the PEO layers has a significant influence: the PEO surfaces of low grafting density make attractive contact with human serum albumin (HSA) [37], whereas those of high grafting density have no affinity for HSA. The attractive forces observed for the PEO surfaces of low grafting density may originate from hydrogen bonds, van der Waals forces, and hydrophobic interactions between the proteins and the sparsely grafted PEO chains that have a sufficiently large degree of conformational freedom to interact with the proteins. Through experiments with bovine serum albumin (BSA) and three different hydrophilic polymer layers, Inoue et al. [39] found that the thickness of the polymer brush layer also has a relatively larger effect on the adhesion force than the chemical structure of the polymer brush layers.

By grafting polymers that can change their properties and structures in response to external stimuli, one can create environment-sensitive functional surfaces. A typical example of temperature-responsive polymers is poly(*N*-isopropylacrylamide) (PNIPAM), which undergoes a volume phase transition by swelling/shrinking in water at a temperature of ∼32°C. Because of this temperature-responsive behavior, PNIPAM has a wide range of practical applications such as in cell culture sheets, the attachment/detachment surfaces for biomolecules, and in medical diagnostic devices. From a fundamental perspective, the intermolecular forces between grafted PNIPAM chains and proteins have been studied by AFM [40, 41], indicating that the PNIPAM−protein interaction is almost repulsive at temperatures below the phase transition point, whereas it tends to be attractive at temperatures above the phase transition point. This temperature-sensitive behavior of the PNIPAM−protein interaction is caused by temperature-dependent hydration/dehydration of PNIPAM chains. Such an AFM method enables the evaluation of whether the surfaces grafted with a variety of stimuli-responsive polymers perform necessary environment-sensitive functions (for examples, see Ref. [42]). These studies demonstrate that the direct AFM measurement of adhesion force of proteins onto the engineered surfaces is a powerful tool for understanding the relationship between the physicochemical property and biocompatibility of the surfaces at the nanometer scale, whereby we can obtain useful information on the effective/efficient design of biomaterial surfaces with high functionalities.

4.5 INTERACTION OF CELLS

The AFM measurement of cells was first developed to investigate the nanomechanical properties of them, where the viscoelastic forces are monitored after an AFM probe makes contacts with and pushes downward the surfaces of cells attached to a substrate. Weisenhorn et al. [49] were the pioneers to quantify the elastic behavior of a living (lung carcinoma) cell from force curves and to obtain a Young's modulus for the cell. Radmacher et al. [44] successfully mapped the local Young's moduli of human platelets with a lateral resolution of ∼100 nm by analyzing the force curves obtained at different positions of the cell. In order to estimate the elastic modulus of the cell from force curves, the constant compliance region of the curves mentioned in Section 4.2 is

used. When an AFM probe is pushed against a cell surface, one obtains the constant compliance region, which is still straight for most cells due to their almost linear deformation against an applied load. The slope of the constant compliance region deviates from that for the force curve between hard surfaces. This deviation represents the degree of surface deformation, from which one can calculate the elastic moduli by fitting the physical models (e.g., the Hertz model) to the experimental data [45]. An example of the unique applications of AFM to such cell nanomechanics is cancer diagnosis [46], by taking advantage of an elastic property of cancerous cells exhibiting a lower Young's modulus value than normal cells.

On the other hand, in order to understand the process of microbial adsorption and adhesion to materials, cell–material interaction forces are measured and often analyzed in the context of DLVO theory assuming that cells act as spherical colloid particles. This approach inevitably includes a lot of approximation, because the DLVO theory is applicable only when surfaces are nondeformable and physicochemically homogeneous without any local structures, which is clearly not the case for biological cells. In addition, it is difficult to determine the separation distance for deformable cell surfaces, as mentioned in Section 4.2. To overcome these difficulties, several extended DLVO models have been proposed, which incorporate additional terms that are mainly steric interactions originating from polymeric structures [47, 48]. In general, the approaching forces measured between cells and AFM probes are strongly repulsive from long separation distances, much longer than the range of the electric double layer repulsion, regardless of the cell species used and their medium conditions (i.e., the ionic strength and pH). This indicates that the contribution of the steric force due to the compression of brush-like biopolymers on the cell surfaces is much larger than the classical DLVO force for such systems.

The adhesion forces between chemically modified AFM tips and cell surfaces are of great interest for evaluating the local properties of cell surfaces. Ahimou et al. [49] reported that the adhesion force between a yeast cell and a COOH-terminated probe varies with pH of the aqueous solution, indicating that the interaction between the cell and material surfaces is influenced by the electrostatic charges on their surfaces (i.e., the surface potentials). Similarly, Dorobantu et al. [50] showed that the force curves can be used to map the bacterial surface hydrophobicity using hydrophilic (OH) and hydrophobic (CH_3) tips. The force measurements between an AFM probe modified with proteins, such as receptors [51] and carbohydrate-binding protein [52], and cells have revealed strong adhesion forces due to specific binding, and their corresponding binding energies were also estimated quantitatively. These methods have been further developed to visualize the chemical heterogeneity of cell surfaces under native conditions by mapping the contour of adhesion forces over cell morphology.

An increasing number of reports have focused on the force measurements between a cell and a microsphere using a colloid probe (Fig. 4.4a), where the interaction forces have been measured at the single-cell, single-particle level. This is because in recent years many researchers have had a growing interest not only in cell surface recognition for drug delivery systems, but also in risk analysis of nanomaterials in the human body, where it is of fundamental importance to understand the adhesion/uptake of nanoparticles (NPs) onto/into cells and their resultant cytotoxicity. Pyo et al. [53] measured the adhesion forces of a silica microsphere toward three different types of cells, and concluded that the difference in adhesion force is reflected by the difference in van der Waals forces and/or hydrogen bonds at the cell–microsphere interface. Shinto et al. [54] measured the interaction forces of a melanoma cell with microspheres of different surface chemistries in a culture medium, and found that the presence/absence of interfacial serum proteins on the microsphere surfaces has a great impact on the measured adhesion forces. It is noted that serum contains extracellular matrix proteins and is usually added to the culture media to help the anchorage-dependent cells adhere to the surfaces of culture dishes. This suggests that some proteins are adsorbed from culture media onto the surfaces of materials and thus influence the cell–material interactions. Using smaller particles, Vasir and Labhasetwar [55] measured the force of NP–cell membrane interactions and related them to cellular uptake of the NPs. They covered an AFM tip with poly(D,L-lactide-*co*-glycolide) NPs with a diameter of approximately 300 nm, and demonstrated that the strength of the adhesive force of NPs with the cell membrane can be correlated with

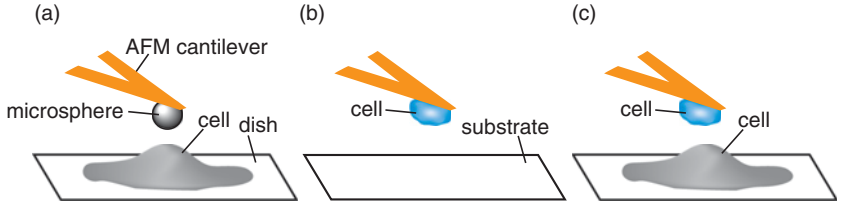

FIGURE 4.4 Illustrations of a colloid probe and a cell probe for the AFM force measurements of (a) microsphere–cell, (b) cell–substrate, and (c) cell–cell interactions.

the uptake amount of NPs by the cells, and hence the extent of the intracellular delivery of the encapsulated materials therein.

There have also been attempts to immobilize cells to the top of AFM tips to investigate cell adhesion. In order to immobilize relatively small cells such as *Escherichia coli*, Ong et al. [56] developed a procedure for coating the tip of an AFM cantilever with a confluent layer of cells, using polyethyleneimine to coat the tip for cell attachment and glutaraldehyde to form cross-linking bonds between the cells and the coated tip. Poly-L-lysine [57], concanavalin A [58], aminosilane [59], and polydopamine [60] are also used as adherent materials to immobilize cells onto tip ends. Alternatively, colloid probes coated with these adherent materials are also used to create a multiple-cell probe [61]. For relatively larger cells, Benoit et al. [62] succeeded in inventing a method to immobilize a single living cell on the top of an AFM cantilever (Fig. 4.4b). A cell in a culture medium was picked up by a tipless cantilever functionalized covalently with lectin under observation with an optical microscope. After this, the single-cell probe was positioned just above a target cell adhered on a dish surface and the cell–cell interaction forces were measured (Fig. 4.4c). The force measurements using such cell probes are often called single-cell force spectroscopy (SCFS).

The measurements of cell–cell interaction forces by SCFS have provided fresh insight into cellular adhesion and aggregation processes at the molecular level. Waar et al. [63] measured the adhesion forces between *Enterococcus faecalis* cells in a medium supplemented with specific antibodies, which act as inhibitors against the aggregation substance (Agg) that is a surface protein on the bacteria. They found that the Agg plays a key role in the strong adhesion forces between the cells. Panorchan et al. [64] investigated the role of vascular endothelial (VE) cadherin, the surface glycoprotein cadherin specific to the endothelium, in the adhesion between living endothelial cells, and revealed that VE-cadherin molecules expressed on the cell surfaces form bonds at a higher tensile strength than bonds formed by classical cadherin. Heterogeneous cell–cell interactions have also been studied using SCFS. Puech et al. [65] used SCFS to measure the binding forces of a melanoma cell line to human umbilical vein endothelial cells and demonstrated the capabilities of this technique. Alsteens et al. [66] quantified the forces between pathogenic *Candida albicans* yeast and hyphae cells, and found that hyphal formation induces strong cell–cell adhesions and that hyphal transition is important for strong biofilm formation.

In addition, the versatility of SCFS enables not only quantification of the single-molecule interactions occurring at the cell surface [58], where the interactions between a cell probe and target molecules immobilized on a substrate were measured, but also measurement of cell–material surface interactions [56,67] for exploring cell adhesion to the material surfaces. These results show that SCFS still has great potential in a variety of biological and medical applications.

4.6 CONCLUDING REMARKS

This chapter has presented an overview of how AFM has been employed for investigating the interaction forces involving biomolecules, cells, and engineered surfaces across various fields of bioscience. The studies introduced herein clearly show that AFM is arguably one of the best tools to help us gain direct understanding of how biomolecules and biosubstances behave down to the nanometer scale level in various environments.

Future applications of AFM will undoubtedly address even more important biological problems, and to achieve this goal, AFM force measurements should be further improved. For example, immediately required technological advances include increasing the sensitivity and the throughput of force measurements, as well as the improvement of protocols for attaching biomolecules and cells to probes and substrates. Further development of theoretical descriptions and treatments is also required to characterize in greater detail how the molecules behave and interact at the interfaces during force measurements. For SMFS, tracking the behavior of single molecules during force measurement by using additional techniques such as fluorescence resonance energy transfer (FRET) and total internal reflection fluorescence microscopy (TIRFM) will show fascinating potential. For SCFS, the combination of AFM with advanced light microscopy or other techniques for evaluating the changes in cell morphology and behavior will likely emerge in the foreseeable future. With these technological and methodological improvements, it is highly expected that the nanometer-scale analysis of interactions between biological substances using AFM will become a central subject to achieve a more comprehensive understanding of the complex behaviors of various biosystems.

5.1 INTRODUCTION

For a long time, bacteria were regarded as isolated cells that do not actively interact with each other. However, more recent findings have revealed that bacteria do interact with each other in several ways. For example, bacteria can communicate with each other by utilizing signaling molecules that coordinate their group behaviors. More recently, membrane vesicles (MVs) that derived from the cell membrane were shown to be involved in bacterial and bacteria-host interactions. These MVs are released from the bacteria and are packed with proteins, DNA, and even cell–cell signaling molecules. MVs are released into the environment and can be shuttled to the neighboring cells. Furthermore, bacteria can dynamically interact with each other by aggregating and forming multicellular biofilms. In the environment, it is assumed that the primary habitat for many bacteria is biofilms. The cell adhesions are usually mediated by extracellular polymers known collectively as an *extracellular polymeric substance* (EPS). EPS is also the key component in biofilm formation that holds the cells together.

Bacterial genetic experiments have greatly enhanced our knowledge of what is involved in these interactions and how such interactions are regulated. Still, biophysical knowledge is limited. Biophysical knowledge should be important to fill the gap of our understanding of what is exactly happening in the interface of these interactions. For instance, it is not clear how the signaling molecules enter and exit the cells or diffuse in different environments. It is not fully understood how MVs pinch off from the cell surface and furthermore how they fuse to the neighboring cells. In biofilm, many EPSs are identified but how they exactly hold tight of the cells is poorly understood. Answering these questions could enhance our knowledge and may also lead to new treatment of the bacteria.

Among many exciting bacterial interactions that have been reported, in this chapter we introduce the basic knowledge in cell–cell communication, MVs, and biofilm. We hope that this chapter would give a general introduction.

5.2 GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA

The bacteria average 0.5–10 μm in diameter, and certain shapes such as rods, bacilli, and cocci are common in many taxonomic groups. Bacteria can be divided into two major groups with respect to their cell envelope composition: Gram-positive and Gram-negative bacteria, and these bacteria will frequently be referred to as such in this chapter. *Gram-positive bacteria* have an inner membrane that is covered by a thick cell wall consisting of multiple layers of peptidoglycan. Teichoic acids reinforce the peptidoglycan. Gram-negative bacteria have a thinner peptidoglycan,which is covered by an outer membrane. The outer membrane contains lipopolysaccharides (LPSs) in its outer leaflet and phospholipids in its inner leaflet. Between the inner and outer membranes, including the peptidoglycan layer, is the periplasm. The periplasm contains specific enzymes that are not found in the cytoplasmic space. As we will see further, these two groups of bacteria have distinct systems in terms of bacterial interactions.

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

Generally, both Gram-positive and Gram-negative bacterial cells are negatively charged. Thus, the bacterial cells are often considered as a negatively charged colloidal particles in physical studies of surface interactions. Since the cell surfaces are usually decorated with fiberlike extracellular cell appendages such as flagella, pili, fimbriae, or EPS, the theory of soft particles in *Derjaguin–Landau–Verwey–Overbeek* (DLVO theory) [1] is applied to bacterial cells.

5.3 CELL–CELL COMMUNICATION IN BACTERIA

In cell–cell communication of bacteria, signaling molecules are produced in the environment and are detected by specific receptors that further modulate gene expressions. The main difference between secondary metabolites and signaling molecules is the presence of a receptor that specifically recognizes the molecule (Fig. 5.1). Many of the signaling molecules enhance their own production and are also called *autoinducers* (AIs). AIs accumulate in the environment as cell density increases. Cell–cell communication involving AIs is also called *quorum sensing* (QS), since gene expression is altered when the cell reaches a certain density [2]. Although several cell–cell signaling molecules are known, two main types of signaling molecules have been thoroughly investigated: (1) *N*-acyl homoserine lactones (AHLs) and small peptides [3] (Fig. 5.2). AHLs are produced in Gram-negative bacteria, while many Gram-positive bacteria use small peptides as their cell–cell signaling molecule. In addition to these molecules, a furanosyl borate diester (AI-2) has been shown to be produced by various Gram-negative and Gram-positive bacteria, suggesting that this molecule may represent a universal language used among bacteria. More recently, *diffusible signal factor* (DSF) was shown to be produced in a variety of Gram-negative bacteria. Cell–cell signaling is likely to be widely conserved among bacteria, and novel signaling molecules are yet to be identified.

5.3.1 Cell–Cell Communication in Gram-Negative Bacteria

5.3.1.1 AHL-Mediated QS. AHL is the typical signaling molecule produced by Gram-negative bacteria. It is not universal, but it is estimated that over 100 species of Proteobacteria use AHLs as signaling molecules [4]. The AHL QS systems generally consist of AHL synthetase, the LuxI family enzyme, and a LuxR family AHL receptor-transcriptional regulator [5]. The chemical structure of the AHL signal consists of a homoserine lactone that is usually coupled to fatty-acid chains. The fatty-acid chain varies in length, saturation, and substitution at the C3 position. The variations in the acyl sidechain confer signal specificity that is recognized by their cognate LuxR receptors. Once AHL binds to its cognate LuxR receptor, the LuxR induces or represses their target genes. Target genes include genes that are associated

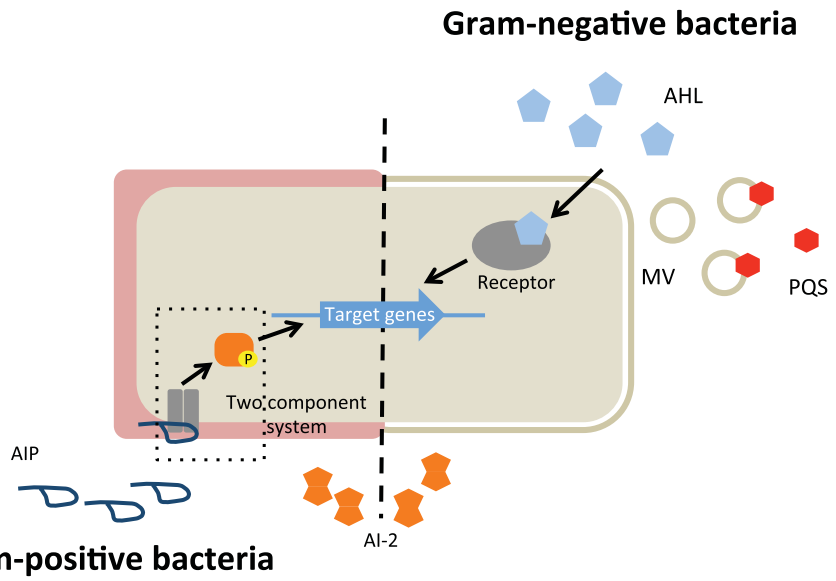

FIGURE 5.1 Cell–cell communication in bacteria. Serected signaling molecules are received by specific receptors. In Gram-negative bacteria, AHL signaling is one of the most widely characterized QS systems. PQS, produced in *P. aeruginosa,* is associated with MVs. Gram-positive bacteria use peptide signals (AIP) as signaling molecules. AIPs are sensed through two component systems. AI-2 is widely used among Gram-negative and Gram-positive bacteria.

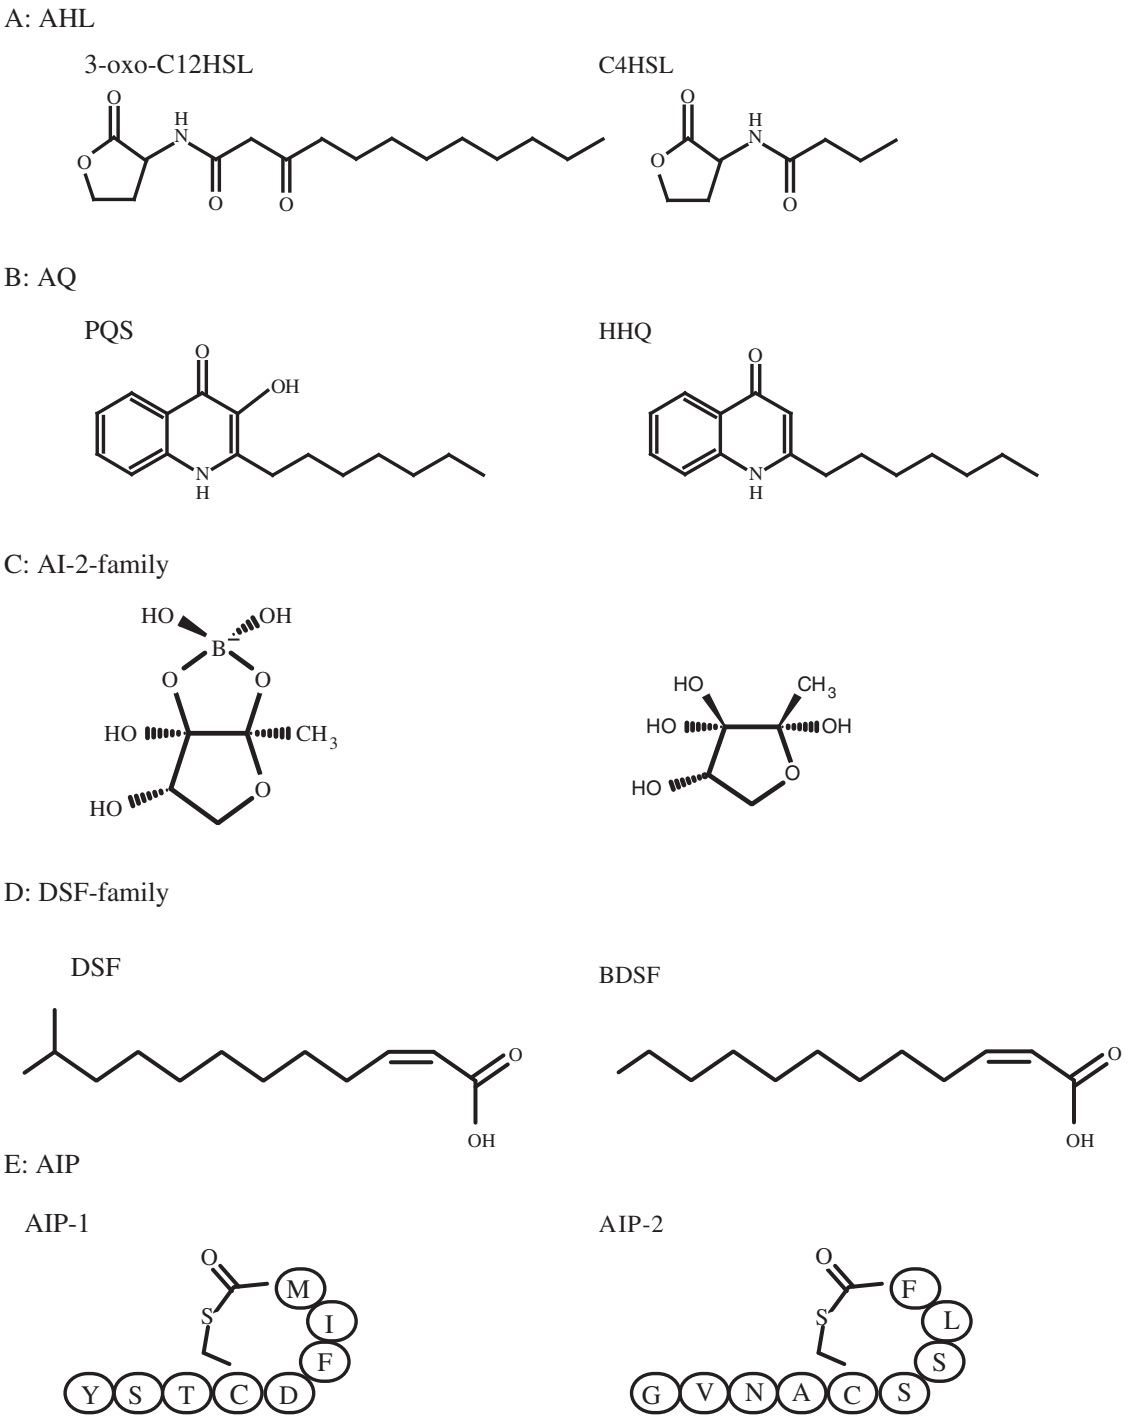

FIGURE 5.2 Chemical structures of selected bacterial cell–cell communication signals.

with biofilm formation, bioluminescence, plasmid transfer, motility, respiration, and virulence factors [6–10].

AHL signaling was first discovered in a marine bacterium *Vibrio fischeri,* which colonize the light organs of a specific squid species. *V. fischeri* produce the light in the light organs of the squid and in response to the bacterial cell density. This light production was found to be mediated by an AHL, 3-oxo-hexanoyl-homoserine lactone (3-oxo-C6HSL), which is produced by the *luxI* gene product [11, 12]. It has been reported that 3-oxo-C6HSL diffuse from the cell by passive diffusion [9]. Like the other AHLs, 3-oxo-C6HSL induces the expression of *luxI* by binding to LuxR. This positive

autoregulation enables the AHL concentration to increase rapidly once it is induced. This allows *V. fischeri* to switch from the low cell density free-living lifestyle from high cell density, host-associated lifestyle.

In some cases such as *Pseudomonas aeruginosa*, QS may regulate up to 300 genes, representing 5% of the genome [13], indicating the huge impact of QS on the cell physiology. *P. aeruginosa* is a ubiquitous environmental bacterium that is also known as an *opportunistic pathogen*. This bacterium is one of the model organisms in QS, which has been studied extensively. In *P. aeruginosa*, two complete QS systems, the *las* system and the *rhl* system, have been identified [5]. Each of these systems is composed of a LuxI and a LuxR family protein. The LuxI family proteins, LasI and RhlI produce *N*-(3-oxododecanoyl)-HSL (3-oxo-C12HSL) or *N*-butyryrl-HSL (C4HSL), respectively. 3-oxo-C12HSL is recognized by LasR and C4HSL is recognized by RhlR, LuxR family proteins. The two QS systems compose a hierarchial regulatory cascade where the *las* sytem positively regulate the *rhl* system. An additional QS system, which uses a chemically distinct type of signals known as the *Pseudomonas* quinolone signal (PQS) is also incorporated in the AHL QS systems. Many virulence factors are positively controlled by QS in *P. aeruginosa*. This has been investigated in various model systems, and the results show that mutants defective in QS are less virulentthan the parent strains [3]. Thus, QS blockers are expected as a strong candidate of therapeutic agents [14]. The QS systems are also affected by environmental conditions through several regulators that enable the bacteria to tune QS in response to the environment [15].

Although homoserine lactone signals typically possess fatty-acid sidechains, a new class of non-fatty-acid-based homoserine lactone signals was discovered in the phototrophic soil bacterium *Rhodopseudomonas palustris* [16]. *R. palustris* produce *p*-coumaroyl homoserine lactone by using *p*-coumaric acid rather than fatty acids. Similar to the fatty-acid sidechain AHLs, *p*-coumaroyl homoserine lactone is recognized by a LuxR family receptor, RpaR. Interstingly, *p*-coumaroyl homoserine lactone is produced from environmental *p*-coumaric acid, which is suggested to be obtained from the plant host. This is unique among all forms of AHL production because the fatty-acid sidechain AHLs are usually produced within the cell. Aryl-homoserine lactone is also produced in *Bradyrhizhobium* sp. BTAi1 and *Silicibacter pomeroyi* DSS-3[16, 17].

5.3.1.2 Quinolone Signal. In *P. aeruginosa,* a 2-heptyl-3-hydroxy-4(1H)-quinolone kwon as PQS has also been identified as a QS molecule [18] (Fig. 5.2). In addition, the precursor of PQS, 2-heptyl-4(1H)-quinolone (HHQ), acts as a signal, although PQS has a much higher affinity with their receptor PqsR [19]. PQS is involved in the regulation of virulence factors, and the molecule also chelates iron, which affects the iron metabolism of the cells [20]. Although the precise mechanism is unclear, PQS was shown to inhibit the anaerobic respiratory activity in *P. aeruginosa* [21]. Structurally related 2-alkyl-4-quinolones (AQs) are known to have antimicrobial activity, and PQS was also shown to repress the growth of Gram-negative and Gram-positive bacteria [22,23]. HHQ production is reported in *Burkholderia* species and in *P. putida*, and chemically related AQs are also produced in a number of *Burkholderia* species [24]. The main AQs produced in *Burkhlderia* species are 3-methyl derivatives of AQs and are implicated to regulate the AHL QS systems [25]. Although mutants deficient in AQ production presented altered colony morphology and increased elastase production in *B. pseduomallei*, the receptor remains to be identified [24].

5.3.2 Cell–Cell Communication in Gram-Positive Bacteria

QS in Gram-positive bacteria also relies on a signaling molecule and a receptor that specifically recognizes the signaling molecule. In many Gram-positive bacteria oligopeptides, called *autoinducing peptides* (AIPs), are used as a signaling molecule (Fig. 5.2) [26]. AIPs are encoded as precursors and become active signal peptides, once they are modulated. The final processed AIPs typically range in size from 5 to 17 amino acid residues and can be linear or cyclized. The signal peptides can also be posttranslationally modified. Because the peptide signals cannot pass the membrane, specialized transporters are required to secrete AIPs. Once secreted, AIPs are detected at the membrane through a two-component system, in which a sensor kinase is located at the membrane, and relay the signal to the intercellular response regulator by phosphorylation.

5.3.3 A Common Language for Gram-Negative and Gram-Positive Bacteria: AI-2

AI-2 is widely produced among Gram-negative and Gram-positive bacteria, indicating its role as a common language [27]. The presence of an interspecies signaling was first suggested by a work in which bioluminescent response of *V. harveyi* was induced by the addition of a supernatant from cultures of other bacteria [28]. The signal that induced this bioluminescent response was AHL-independent and was identified as AI-2 [29, 30]. AI-2 is produced by a spontaneous reaction of a very unstable molecule, 4,5-dihydroxy-2,3-pentanedione (DPD), which is synthesized by LuxS. DPD spontaneously cyclizes into different isomers in solution, and there is a possibility that the AI-2 molecule detected by the bacteria may differ [31, 32] (Fig. 5.2). LuxS homologs have been identified in more than 500 bacterial genomes that have been sequenced [27]. Still, it is not known whether AI-2 is used as a signal in these species, since LuxS has a crucial role in the central metabolic pathway, and AI-2 may be a

metabolic byproduct in some species. To distinguish whether AI-2 is used as a signal or it is a mere byproduct, the presence of a receptor that specifically detects AI-2 is important. So far, three types of receptors–LuxP, LsrB, and Rbs-like receptors–have been identified as being involved in the AI-2 response.

5.4 MEMBRANE VESICLES

Many microorganisms secrete intracellular substances to extracellular milieu to interact with other microbial cells for DNA transfer, small-molecule signaling, and predation. Encapsulation of microorganism-produced substances is an effective way to carry them to other organisms because they are highly concentrated and kept stable against numerous ambient stresses. MVs, which are spherical bilayered structures, ranged from approximately 50 to 250 nm in diameter, and naturally released from microbial cell surfaces of many microorganisms, are used for secretion of many kinds of substances produced in microbial cytoplasm to extracellular milieu (Fig. 5.3a). The observation of MVs in Gram-negative bacteria can be traced back to about the mid-1960s, along with the developments in the electron microscopic analysis [33–35]. MVs are found in every environment, from laboratory cultures, including planktonic and surface-attached biofilm, to natural environments [36, 37]. Conventionally, it has been assumed that MVs are liberated from only Gram-negative bacteria, but more recent studies have indicated that MV production is conserved among organisms spanning both prokaryotes and eukaryotes: Gram-negative and Gram-positive bacteria, archaea, and fungi [38]. MV had been considered as one secretion mechanism that is important for delivering certain toxic proteins, and studies of these vesicles have concentrated on pathogenic bacteria, but more recent studies indicate that nonpathogenic microbes also secrete MVs [39–41]. Because MV production is conserved among many microorganisms, it is likely to be crucial to microbial life.

5.4.1 Components of MVs

The components of MVs were studied mainly in Gram-negative bacteria. In Gram-negative bacteria, MVs consist mainly of phospholipids, LPS, outer-membrane proteins (OMPs), and periplasmic components.

5.4.1.1 Proteins Associated with MVs. The components of vesicular proteins have been developed by biochemical analyses. MVs derived from Gram-negative bacteria contain mainly OMPs and periplasmic proteins, but also contain proteins localized at inner membrane and cytoplasm [42, 43]. In Gram-negative pathogenic bacteria, many extracellular virulence factors are also packaged in MVs. In Gram-positive bacteria, extracellular proteins, membrane proteins, and cytoplasmic proteins are contained in purified vesicles. In many cases, the MV protein profile is quite different from that of cells, suggesting that a specific sorting mechanism may exist for vesicular proteins.

5.4.1.2 Phospholipids Associated with MVs. Phospholipid is also one of major components of MVs. The phospholipid consists of two fatty acids and a phosphate group attached to a glycerol backbone. Both components of the phosphate group and fatty acid in MVs are different from

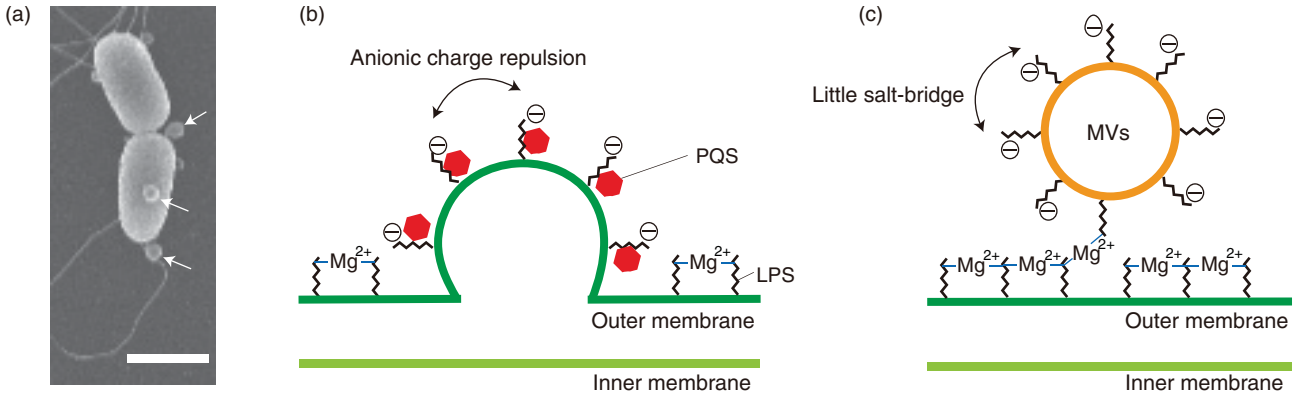

FIGURE 5.3 (a) Membrane vesicle production in *P. aeruginosa*. Bar indicates 1 μm. (b) One of the proposed models for MV formation in Gram-negative bacteria. Divalent cations usually stabilize outer membrane by forming salt bridges between negative charged phosphates of neighboring LPS. PQS strongly interacts with LPS, and anionic repulsion enhances membrane blebbing. (c) A proposed model of interaction of MVs with Gram-negative bacterial cells. Because of loose packing of anionic LPS, there is likely little salt bridge between neighbor LPSs in MVs. It is plausible that LPS of MVs is easily salt-bridged to the surface of cellular outer membrane.

those of the cells in *P. aeruginosa*. The major phosphate groups are phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and phosphatidylcholine (PC), and PE is usually most abundant in Gram-negative bacterial cells. On the other hand, MVs contain a high ratio of PG in *P. aeruginosa* [41,44]. The components of fatty acids are also different from cellular outer membrane and MVs in *P. aeruginosa* and other *Pseudomonas* strains; the percentage of stearic acids is highest in MVs in *P. aeruginosa* [41,44,45]. Abundant saturated and longer-chain fatty acids are known to decrease membrane fluidity [46], and MV membrane is considered to be more rigid than the cellular OM. Analyses using artificial lipid vesicles showed that lipid chain length is critical in achieving stability of vesicles [47]. These results suggest that abundant stearic acids contribute to the stability of MVs. Furthermore, fatty-acid profiles of extracellular MVs are different from cells in Gram-positive bacteria [48], MVs seems to be liberated from specific region on cellular membrane.

5.4.1.3 Other Components in MVs. The lumens of MVs can contain cytoplasmic components, containing DNA and RNA [49–52]. DNA is not only associated with the MV surface but is also localized inside of MVs [52], and DNA is protected from degradation by environmental stresses such as DNase. In *P. aeruginosa*, both chromosomal DNA and plasmids are packaged in MVs.

MVs also possess a cell–cell communication signal, PQS in *P. aeruginosa* [53] (Fig. 5.1). PQS is strongly associated with LPS on bacterial surfaces and stimulates MV liberation. Although hydrophobic substances seem to have difficulty in dissemination between bacterial cells, MVs serve as a mediator of the hydrophobic signal, PQS.

5.4.2 Biological Roles of MVs

It has been hitherto proposed that there exist multiple functions of MV liberation for microbes. MVs consistute a unique secretion system that transfers cellular substances to the environment, and some MVs fuse to other cells. Biological roles of MVs are roughly divided but not limited to the following three functions: delivery system, secretion of unnecessary substances, and maintenance of biofilm structure.

5.4.2.1 Delivery System. A primary biological role of MVs is trafficking vehicles of substances from donor cells to recipient cells that can be both prokaryotes and eukaryotes. Many pathogenic bacteria produce MVs, and several kinds of toxins are associated with MVs. MVs serve as vehicles for delivering these toxins to eukaryotic target cells. Because MVs are coated with LPS and phospholipids, which act as ligands against eukaryotic cells, MVs help to deliver toxic substances from bacterial cells to host cells effectively. In microbial communities, MVs also have a predatory role as they contain peptidoglycan hydrolase and induce cell lysis. It has been shown that MVs derived from various Gram-negative bacteria including *P. aeruginosa* possess antimicrobial activity against both Gram-negative and Gram-positive bacteria [54, 55].

On the other hand, MVs also play a role in bacterial communication. Although hydrophobic PQS rarely freely diffuses out of bacterial cells in *P. aeruginosa*, MVs serve as a shuttle for this compound [53]. Because PQS regulates motility, biofilm formation, and many virulence factor productions in *P. aeruginosa*, MVs help intraspecies communication.

DNA transfer from cell to cell via MVs has also been observed in Gram-negative bacteria and archaea [49, 56]. Packing DNA in MVs prevents DNA degradation from DNase in the environment and facilitates long-distance delivery of DNA from donor to recipients. As only intraspecies DNA transfers via MVs have been observed, it remains unknown whether interspecies DNA transfer actually occurs.

5.4.2.2 Secretion of Unnecessary Substances. MVs can also affect disposal of unnecessary substances accumulated in microbial cells. Accumulation of unnecessary compounds in the periplasm exerts a turgor pressure of the cell envelope in Gram-negative bacteria. For example, peptidoglycan fragments accumulated in the periplasmic spaces increase turgor pressure and MVs are discharged [57]. The production of MVs is also induced by internal damage such as the accumulation of misfolded envelope proteins or internal and external stress, which ultimately leads to cell death [58–63]. In addition, high concentrations of an antibiotic, such as gentamicin, and persistent organic pollutants, such as toluene, increase MV formation, and these compounds are highly concentrated in liberated MVs [64–66]. In this way, MVs can also function in defensive roles to survive by responding to stress and eliminating unnecessary substances from the cells.

5.4.2.3 Maintenance of Biofilm Structure. The third biological role of MVs is maintenance of biofilm structure formed by microbes. Biofilms are composed of cells and EPS that include exopolysaccharides, proteins, DNA, and lipids. The existence of MVs in biofilms has been confirmed in both mixed-environment and laboratory-generated single-species biofilms [37,67–70]. It is known that extracellular DNA is a critical matrix component of biofilm and maintains the stability of biofilm against environmental stresses [71]. MVs possess extracellular DNA on their surfaces, and MV surface-bound DNA in biofilms appears to be an electrostatic bridging component that is central to the interaction among MVs, bacterial cells, and other biofilm matrix components [72].

5.4.3 Surface Characteristics of MVs

The surface characteristics of MVs have been studied using Gram-negative bacteria. Similar to the cell surface, MV surface possess negative zeta potential [73]. On the cell

surface, LPS is negatively charged, and salt bridges consisting of divalent cations such as Mg^{2+} and Ca^{2+} are frequently formed between adjacent LPS molecules (Fig. 5.3b). PQS interacts strongly with LPS, and ionic interactions between PQS and LPS in the outer membrane enhance the anionic repulsion between neighboring LPS molecules [74]. Therefore, PQS enhances MV formation in Gram-negative bacteria [53, 75]. Particularly in *P. aeruginosa*, MVs secreted in the stationary phase possess more negative charges than that in the exponential phase [73], presumably due to the incorporation of PQS that is synthesized in the stationary phase.

Negatively charged MVs facilitates interaction with bacterial cells (Fig. 5.3c). Because MVs have higher surface curvature than the cells, the LPS terminal oligosaccharide sidechain, which is charged, is loosely packaged and the components are separated from each other. For loosely packed LPS, there is slight salt bridging by divalent cations such as Mg^{2+} and Ca^{2+} between adjacent LPSs. Because of cation depletion on MV surface, it is likely that the anionic MV surface would become salt bridged to cations around bacterial cells [54]. Indeed, negatively charged MVs rather than relatively neutral MVs interact easily with bacterial cells [73]. In this way, MV surface charge is a critical factor that affects the interaction with bacterial cells through physiochemical forces. Still, it remains largely unknown, how exterior MVs are incorporated to microbial cells in detail.

5.4.4 Future Perspectives in MV Research

Biochemical and biological studies have developed our understanding of the physiological roles of bacterial MVs, and growing evidence suggests that MVs are essential for microbial survival and pathogenesis. However, previous biological studies have been limited to obtaining comprehensive information for understanding their physicochemical behaviors and the mechanism of their formation. Surfaces of MVs are coated with several substances, including polysaccharides, pili, extracellular proteins, and extracellular DNA, and thus it is difficult to directly apply kinetic and equilibrium models, contrary to vesicles composed of pure phospholipids. Even though that is the case, physicochemical analyses are expected to stimulate the developments of comprehensive understanding in dynamics of bacterial MVs.

5.5 BIOFILM FORMATION

Biofilms are bacterial multicellular consortia covered with an EPS matrix that is often selfproduced. It is thought that the primary habitat for many of the bacteria is biofilms. Biofilms are not necessarily attached to the surface, but floating cell aggregates known as *flocs* or *activated sludge* share common characteristics with biofilms and can also be categorized as certain types of biofilms [76–78] (Fig. 5.4). Practical applications of biofilms include biological wastewater as activated sludge. On the other hand, they have negative effects on human activity and are associated with a wide range of problems in industry and infections. Until recently, most of our knowledge in bacteriology has been based on the studies of planktonic cells, but it is well known that biofilms differ from their planktonic counterpart. For instance, biofilms have increased antibiotic resistance, compared to planktonic

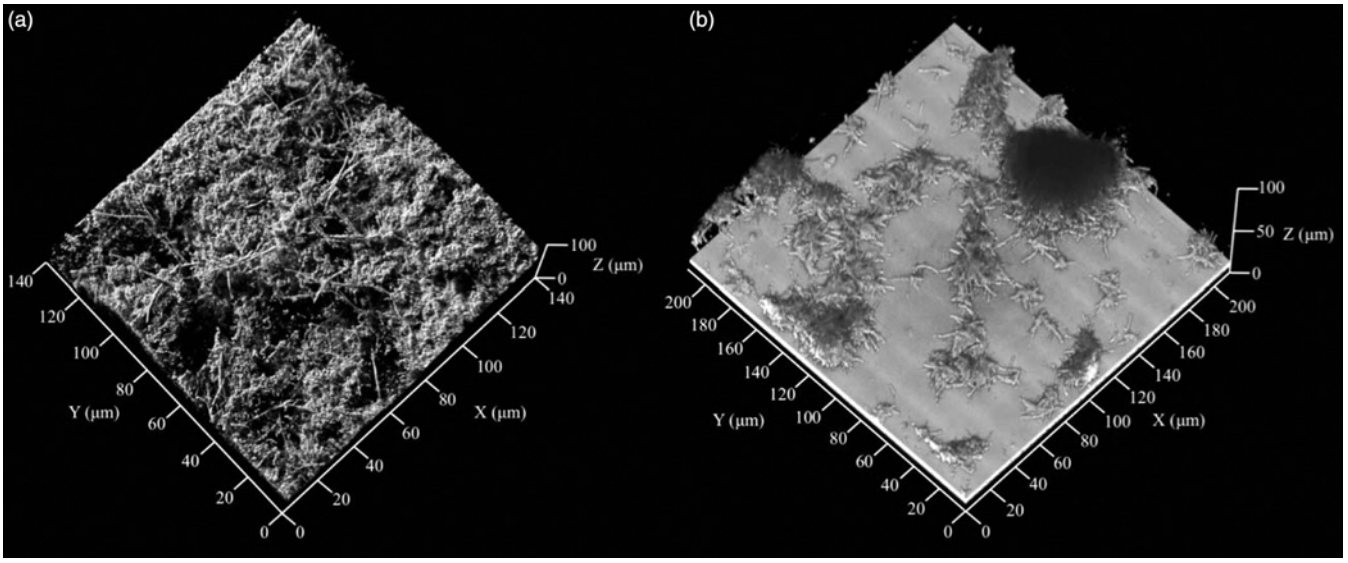

FIGURE 5.4 Microscopic image of surface-attached biofilms and bacterial aggregates visualized by confocal microscopy. (a) Surface-attached biofilms. Oral biofilm was formed on hydroxyapatite disk. The projection shows field of 140 × 140 μm (*x*–*y*) as indicated. (b) Bacterial aggregates of *Rhodococcus* sp. strain SD-74. The projection shows field of 220 × 220 (*x*–*y*). For related informations please see ref. 108.

cells, making it much more difficult to eradicate biofilms [79]. Hence there are wide demands for treating biofilms, and a better understanding of biofilms is necessary to tackle these problems.

5.5.1 Surface-Attached Biofilms

Surface-attached biofilms are relatively well studied compared to cell aggregates. Typically, surface attached biofilms undergo five stages [80]:

1. The cells attach to the surface reversibly (reversible attachment) at the pole of the cells. Fiber-like structures such as flagella, pili, and fimbriae are involved in this process.
2. Cells lie on the surface and attach to it irreversibly (irreversible attachment). EPS such as DNA, proteins, and LPS assist the adhesion between the cell and the surface.
3. Cells replicate and grow into microcolonies. At this stage, the cells are encapsulated in EPS that adhere the cells together.
4. Eventually, microcolonies grow into matured biofilms covered with EPS.
5. The biofilm mode of life terminates when some of the cells switch their lifestyle from biofilm to planktonic cells and disperse from the biofilms.

While physical properties of the surface determine whether the cells are able to attach to the surface, bacteria control the attachment by regulating motility and EPS production or cell appendages involved in surface attachment. With a combination of surface engineering technologies, the surface properties that effect cell attachment have been extensively studied. These studies not only should help us better understand the mechanism of cell–surface attachment but also may lead to design of materials that repel bacteria.

5.5.1.1 Surface Properties Affecting Bacterial Attachment.

Electrostatic and Hydrophobic Interactions. The interactions between the bacteria and the surface are primarily influenced by electrostatic and van der Waals forces [81]. Since most bacteria have a negative charged cell surface, bacteria are attracted to positively charged surfaces and electrostatic repulsion occurs with negatively charged surfaces. Electrostatic repulsion between the cell and the negatively charged surface can be overcome by extracellular appendages of the cells such as flagella, pili, fimbriae, and EPS that decorate the cell surface. In this case, the interaction of bacterial cells and the surface follow the theory of soft particles in DLVO theory proposed by Ohshima et al. [1]. After overcoming the electrostatic interactions, hydrophobic interactions influence the attachment of bacteria to the surface. Many bacteria prefer hydrophobic surfaces, while some bacteria prefer hydrophilic surfaces. It is important to note that bacteria may alter the surface property by secreting EPS or proteins.

Surface Roughness. In addition to the physicochemical properties of the surface, surface roughness has also been shown to affect cell attachment. Recent studies show that two surfaces with chemically identical properties may exhibit different cell attachment patterns, due to differences in surface topographies. In general, rougher surfaces in micrometric scale may support bacterial attachment by offering higher surface area for attachment and also protecting the cells from unfavorable conditions such as shear forces [82]. The effect of nanometer-scale roughness is more complex. Some bacteria attach better to nanoscale rough materials, while others attach better to nanometer-smooth material. A recent study shows that bacteria alter their cell appendage depending on the nanoscale surface topography, presumably to achieve a stronger and more stable attachment [83]. The study suggests that bacteria may sense the surface and topography and utilize different mechanisms to attach. How bacteria sense the surface topography is poorly understood and would be an interesting issue for future works.

5.5.1.2 Biological Regulation in Biofilm Formation.

c-di-GMP: The Central Biofilm Regulatory System. As physicochemical interactions determine the cell attachment to the surface, bacteria can decide whether to attach to or leave the surface by controlling the expression of cell appendages and motility. In a number of bacteria, including the biofilm model organisms, *P. aeruginosa*, a intracellular second messenger, bis-(3′-5′)-cyclic dimeric guanosine monophosphate (c-di-GMP), control EPS and motility in opposite directions [84]. In other words, when the c-di-GMP level is high, EPS production is stimulated and motility is inhibited, thus allowing the cells to irreversibly attach to surfaces and form biofilms. On the other hand, low c-di-GMP levels induce motility and inhibit EPS production. While c-di-GMP levels are elevated during formation of biofilms, they become low when cells disperse from biofilms. c-di-GMP levels are controlled by regulating the enzymes responsible for the production and degradation of c-di-GMP. There are several proteins involved in this process that are usually involved in sensing the changes in environmental conditions. These environmental conditions include nitric oxide, carbon and nitrogen limitation, and oxygen limitation [85]. Taken together, the c-di-GMP signaling network allows the bacteria to sense the environment and decide whether to settle down to form a biofilm. Hence bacteria have a sophisticated regulatory system that controls the bacterial adhesion to the surface.

Effect of Cell–Cell Communication on Biofilms. While c-di-GMP functions as part of the central regulatory system in biofilm formation, cell–cell communication has also been observed to affect biofilm formation in both Gram-negative and Gram-positive species.

In Gram-negative species, typically AHL-based QS has a positive effect on biofilm formation. For instance, in *P. aeruginosa,* a *lasI* mutant defective in 3-oxo-C12HSL productions, build a poorly structured biofilms compared to that of the wild type [6]. The *lasI* mutant biofilm was more sensitive to detergent removal. Because AHLs control diverse genes, the AHLs may affect biofilm formation through multiple pathways, such as the regulation of motility, respiration, and production of biosurfactants [86]. The studies in *P. aeruginosa* also indicate that the effects of AHLs on biofilm formation can be conditional, and may act differently due to the environmental condition [87].

In Gram-positive bacteria, the AIP signals affect biofilm in a species-dependent manner. *Staphylococcus aureus* is a leading cause of nosocomial infections, and many infections are related to biofilm formation. In *S. aureus*, AIP is encoded by *agrD*. The inactivation of the Agr QS system negatively regulated biofilm formation and is involved in biofilm dispersal [88]. In contrast, the Agr system positively control cell adherence biofilm formation in *Lactobacillus plantarum* and *Listeria monocytogenes* [89, 90].

Biofilms comes to an end when the cells inside biofilms disperse from the biofilms. Recent findings of intercellular signals that facilitate biofilm dispersal indicate that the cells can initiate this event in a coordinated fashion. *Diffusible signal factor* (DSF) is responsible for inducing cell dispersal in Gram-negative bacteria. DSF is a fatty-acid molecule. For example, *cis*-11-mehyl-2-dodecenoic acid is known as a DSF involved in dispersal in *Xanthomonas campestris* [91] (Fig. 5.2). Rpf sensors respond to the DSF signal and further control the gene expressions. Addition of DSF to *X. campestris* induces the dispersion of aggregates in the DSF deficient mutant, but not in the sensor-deficient mutant. A DSF-related signal, BDSF, has been characterized in *Burkholderia cenocepacia* [92] (Fig. 5.2). In *B. cenocepacia,* BDSF signaling has been linked with c-di-GMP [93]. The presence of BDSF results in the reduction of intercellular c-di-GMP levels, which, in turn, results in altered biofilm formation. To note, in *B. cenocepacia* H111, elevated c-di-GMP leads to reduction of surface associated biofilm production, which is an exception of the typical c-di-GMP regulation of biofilm. The presence of DSF family signal among phylogenetically distinct bacteria leads to the idea that this signal may serve as an interspecies signal.

5.5.2 Bacterial Aggregates

Biofilms that are not attached to the surface are usually referred to as *cell aggregates* or *flocs*. In addition, the biofilms formed in the liquid-air interface are called *pellicles*. In contrast to the surface-attached biofilms, where the initial step of biofilm formation is the attachment to the substratum, it is assumed that the bacterial aggregation is initiated by clustering of planktonic cells. Several factors that initiate cell clustering have been studied. As we will see, the underlining physical interactions are common in many aspects, between surface-attached biofilms and free-floating cell aggregates. However, some bacteria form surface-attached biofilms, while others form cell aggregates and what determines these lifestyles are not fully understood.

5.5.2.1 EPS Involved in Cell Aggregations. Since bacteria are negatively charged, cells must overcome the negative repulsion between the cells. As in the case of surface-associated biofilms, cell appendages are likely to help overcome the electrostatic repulsion. Degradation of the EPS usually results in the decomposition of the cell aggregates, suggesting that the EPS is also important in holding the cells together.

One of the main components of the EPS matrix is polysaccharides, which have been shown to play important roles in the formation of bacterial aggregation. For instance, in *Azospirillum brasilense*, extracellular polysaccharides and capsular polysaccharide, which is located at the outermost of the cell membrane, is important for cell aggregation [94]. In streptococci, highly organized hyaluronic acid in the capsule serves as extracellular polysaccharides that support cell aggregation [95].

Besides polysaccharides, nucleic acids such as deoxyribonucleotide (DNA) and ribonucleotide (RNA) are often found in the EPS. In many bacteria, extracellular DNA (eDNA) is produced by cell lysis that is induced by autolysis [96–98]. eDNA has been reported as one of the major components in surface-associated biofilms [99]. In line with these observations, it is reported that eDNA is involved in bacterial aggregation [100]. In *Micrococcus halodenitrificans* and *Vibrio costicolus* growing in nutritionally poor media, eDNA is secreted to the environment to maintain the cell aggregates [101]. The eDNA from different sources can stimulate bacterial aggregation, and the eDNA does not necessarily have to be self-produced [102]. Rather than the source of DNA, physicochemical factors such as the concentration and the length of eDNA is important for cell aggregation. Furthermore, thermodynamic analysis indicate that eDNA causes acid–base interaction between *S. epidermidis* cells that leads to cell aggregation [100].

5.5.2.2 Hydrophobic Interactions. A number of extracellular substances that are highly hydrophobic are reported to support cell aggregations. In *Lactobacillus acidophilus*, the S-layer protein is important for auto- or coaggregation with other bacteria [103]. The S layer is located at the outermost of the cell and consists of protein and glycoprotein. In

L. acidophilus, the S-layer protein increases the hydrophobicity of the cell surface, leading to the aggregation [104]. In *L. coryniformis,* it is known that a cell surface protein Cpf mediate coaggregation with other bacteria. Although the main biological function of Cpf is still unknown, Cpf exhibits a high content of hydrophobic amino acid, which is important for coaggregation with other bacteria. These findings suggest that the hydrophobicity of the cell surface is an important factor for bacterial aggregation.

5.5.2.3 Target-Specific Aggregation. Cell aggregations mediated by EPS or hydrophobic cells are unspecific events where, basically, any bacteria that may physically interact can coaggregate. In contrast, specific interactions that select their target cells for aggregation are reported. *Escherichia coli* require a specific protein to autoaggregate and adhere to host intestinal cells. The well-characterized aggregation-related protein referred to as an *autotransporter protein* is a membrane-associated protein that is transported by itself and displayed on cell membrane. The autotransporters antigen 43 and AIDA have a self-recognizing domain, and antigen 43–AIDA interactions mediate autoaggregation by binding specifically to each other [105, 106]. In *Neisseria meningitides,* a pilinlike protein PilX was shown to be essential for cell aggregation [107]. Cell aggregates were formed among the cells that possess PilX, whereas PilX-deficient mutants were not able to form aggregates with the wild-type strain. This result indicates PilX is required for each cells in the aggregates.

In the oral environment, tooth-associated biofilms are well known as dental plaques, which are formed by coaggregation of diverse oral bacteria [108, 109]. The polymicrobial aggregations is not a random event, but is well organized, and the constituent bacteria have specific partners with which to coaggregate. Lectins are one of the factors that are known to be involved in these specific aggregation events [110]. Lectins are carbohydrate-inding proteins, and each lectin has a specific target carbohydrate, thus allowing it to recognize the cell surfaces. Lectins are also involved in adhesion to host cell in many cases of infection as well as bacterial aggregations. In the case of *Streptococcus mutans,* a primary causative bacterium of the dental cavities, extracellular glucan, is required for cell aggregation. *S. mutans*, for instance, have a membrane-associated glucan-binding protein that specifically interacts with glucans present in the EPS [111]. This binding between glucans and cell associated glucan binding proteins causes aggregation.

5.6 CONCLUDING REMARKS

Bacteria interact with each other in many ways, such as through small molecules, MVs, and cell appendages that lead to the formation of biofilms. Much of our present understanding of these events is based on single-species pure culture. However, the real environment is a more complex polymicrobial world, where many bacterial species coexsit and interact with one another. Our understanding of such a polymicrobial world is just beginning. One of the ways to handle such a complex system may be physical approaches, where bacteria are often considered as particles. A successful application of the physical control of polymicrobial system is in wastewater treatment. Many bacteria are involved in this process to purify the water. In this process, physical control of the cell aggregates (also called *activated sludge*) is performed to regulate the aggregation of the cells. Aluminum salts, such as aluminum sulfate and poly(aluminum chloride), are added to the plant to neutralize the negative charge of the cells and therefore stimulate cell aggregation. Importantly, unlike stable colloidal particles, bacteria can alter their surface in response to the environment. Therefore, understanding both the biological and physical aspects of the bacteria would go hand-in-hand with our strides to obtain a deeper understanding of bacterial interactions and to develop further applications.

BIOFILM

Hisao Morisaki

Graduate School of Life Sciences, Ritsumeikan University, Kusatsu, Shiga, Japan

7.1 INTRODUCTION

Biofilms are aggregations of microorganisms attached to and growing on a surface [1]. Biofilms are not simple accumulations of attached microbial cells; rather, they contain extracellular polymeric substances (EPSs) as well as the microbial cells. The EPSs consist of several kinds of polymers such as polysaccharides, proteins, nucleic acids, and lipids [2]. These polymers are produced by the microbes attached to solid surfaces and play crucial roles in holding the biofilm itself and enclosing the microbial cells. The polymers form a network in which microbial cells and various materials are retained. The movement of materials inside the biofilm is limited by the network structure, which results in a gradient of materials such as nutrients and oxygen. These gradients and their combinations produce complex microscale environments inside biofilm and render the biofilm heterogeneous, containing various niches for microbes, resulting in a variety of microbes inhabiting therein [2].

Microbial cells in biofilm differ from the planktonic cells in three basic respects: (1) microbial cells are in an attached state, (2) their cell density is much greater, and (3) they live in a characteristic structure consisting primarily of microbial cells, EPS produced by the microbes, and the interstitial water occupying the regions among the EPS network. The gene expression of cells in biofilm is different from planktonic ones, and the high cell density in biofilm enable or force the cells in biofilm to interact with each other in various ways, such as cometabolism or competition over nutrient materials, cell communication via DNA fragment, or specific informative molecules such as *N*-acyl homoserine lactone and modified oligopeptide [3–10]. Thus, biofilm is not a simple mass of microbial cells but is functionally similar to a multicellular organism living in the characteristic structure [9, 10].

Biofilm is not isolated from its surrounding environment. It can trap various materials from outside and condense it inside as well as metabolize it into a variety of products that may alter the inside and/or outside environments. Thus, the surrounding environment and biofilm can affect each other. Studies concerning these effects are also important in biofilm research [11, 12].

Many articles examining various aspects of biofilms as described above have been published. A growing body of excellent reviews [2–15] have plotted the highlights of biofilm research carried out over the decades. For details on each topic or research field, the reader is referred to these articles and reviews.

Hereafter, in this chapter, the following aspects of the biofilm are overviewed and discussed: (1) biofilm formation process, (2) biofilm constituents, (3) biofilm and surrounding environment, and (4) review of biofilm research to date and future research prospects.

7.2 FORMATION PROCESS OF BIOFILM

Biofilm is ubiquitous in aquatic environments. We can find biofilms on the surfaces of various kinds of solids immersed in aquatic environments. The biofilm biomass increases along with time typically as a shape of sigmoid curve [16, 17]. Biofilm formation has been considered as the net result of the following physical, chemical, and biological processes

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

occurring in sequence [16, 18]: (1) adsorption of ions and/or macromolecules present in the bulk liquid resulting in the formation of conditioning film; (2) attachment, including both reversible and irreversible, of bacterial cells to the conditioning film; (3) bacterial growth and production of extracellular polymeric substances (EPSs) strengthening cell attachment and developing network structure formed by EPSs; (4) development of various kinds of microscale environments inside biofilm due to the concentration gradient of various kinds of materials (e.g., oxygen, nutrients), caused by differences in mass transfer and/or microbial utilization or production of the materials; (5) increase in the microbial cell number, including other kinds of bacterial species and microbes resulting from the establishment of various niches inside biofilm; (6) detachment of biofilm biomass, balancing with the biofilm biomass increment at later stages of biofilm formation, due to shearing by fluid shear stress, sloughing of random and sporadic event, which is observed more frequently in thicker biofilm, and abrasion caused by particle collisions to biofilm [19].

7.3 BIOFILM CONSTITUENTS

The formation and development of biofilm and the resultant biofilm properties are affected depending on (1) the substratum surface, (2) microbes, (3) EPS, and (4) interstitial water occupying the region between EPS network, as described below.

7.3.1 Substratum Surface

Biofilms can be formed on surfaces of various kinds of solid, either biotic or abiotic, such as stone, sand, concrete, bottom of a ship, inner face of a pipe, catheter, teeth, soil, food, and plants. These surfaces affect cell attachment, biofilm formation, activity, and community structure of microbes in biofilms. Additionally, biofilm can affect the surface and/or the solid on which it is formed.

7.3.1.1 Cell Attachment. Bacterial cell attachment is an essential step for biofilm formation. Under typical conditions (pH $\sim$ 7), both the bacterial cells and the substratum surfaces are usually negatively charged. Under these conditions, two kinds of opposite interactions exist between the cells and the surfaces: electrostatic repulsive and van der Waals attractive interactions. For cell attachment, the surface properties of bacterial cells relating to these interactions have important influence as well as substratum surface properties such as electric charge, hydrophobicity, and roughness [20–26]. Various studies on the cell attachment mechanism have also been conducted by applying colloidal theory [27] and considering the specific feature of microbial cells as "soft" colloidal particles [28–33].

7.3.1.2 Microbial Activity, Function, and Community Structure. The environment inside biofilm is different from that on the outside, affecting the activity, function, and microbial community structure of biofilm.

Even in the same stream, biofilms formed on sands and rocks are different in enzymatic activity and response to nutrient addition [34]. It has been reported that the bacterial isolates from biofilm formed on reeds (*Phragmites australis*) showed high hydrolysis activities for biopolymer [35] or biodegradable plastic [36].

Bacterial community structure of the biofilms formed on the submerged stem of reeds (*Phragmites australis*) varied with season not related with the lake water [37]. A characteristic community structure of the biofilms formed on reeds has also been observed [35]. Different microbial community structures were observed among biofilms formed on different kinds of materials [25, 38, 39].

7.3.1.3 Surface Deterioration. Biofilm can cause deterioration of the underlying substratum, including metal corrosion, dental caries, and food spoilage.

Metal or metal alloy corrosion by biofilms, referred to as *microbially influenced corrosion* (MIC), has been studied from various aspects, such as phenomenologically [40], thermodynamically [41], and theoretically [42]. Although there have been many studies on MIC mechanisms, the process is relatively poorly understood [43]. In situ monospecies biofilm is rare, so any study regarding the influence of multispecies biofilm as a whole and/or biofilm components on MIC [43] would seem to be useful to prevent and control MIC.

Dental plaque is a biofilm formed on teeth and is defined as the diverse microbial community found on tooth surface embedded in a matrix of polymers of bacterial and salivary origin. Since the 1960s, there has been an enormous expansion of knowledge of the biochemistry and bacteriology of the plaque microflora [44]. Biofilms on teeth also contain multibacterial species as other biofilms formed in natural environments. In the multispecies biofilms on teeth, cell–cell distance is fundamental for intermicrobial communication processes [10]. In further studies including the factors characterizing the oral ecosystem, the oral multispecies biofilms may serve as a paradigm for other biofilm system in general [10].

The surfaces of epithelial cells and medical devices also can be subjects of biofilm formation causing serious infectious problems [7, 45, 46]. Biofilm bacteria can be $\leq$1000 times less susceptible to antimicrobial stress than their freely suspended counterparts. Using compounds that kill or inhibit growth of microbe may lead to frequent development of resistance to antibiotics. Some *antibiofilm* strategies, such as iron metabolism interferences, negating quorum sensing and self-vaccinating biomaterials, which are assumed not to lead to the development of resistance, have been discussed [46].

Biofilms have caused problems in many branches of the food industry. The mechanisms involved in the biofilm formation and behavior, deleterious effects associated with their presence, and some of the current and emergent control strategies have been reviewed and discussed [12, 15, 47, 48].

The various activities of biofilms may be employed to aid the breakdown of a variety of pollutants and other unwanted compounds [49] such as polycyclic aromatic hydrocarbons [50, 51], PET [52], oil residue [53], and herbicide [54].

Biofilms contain multispecies bacteria in common and are formed under the effect of the surrounding environments that may also be influenced by biofilm. These features, containing multispecies microbes and mutual effects between biofilms and the surrounding environments, may provide the foundation for further studies.

7.3.1.4 Plant Surface. Biofilms can be formed on a variety of surfaces as described above. In the case of plants, surface-attached bacteria can be found on seeds, leaves, and roots [55, 56]. The surface of the older parts of roots often becomes encased within a tightly adhering amalgam of soil particles, plant- and microbial-derived mucilage, as well as microbial and plant cells. This so-called *rhizosheath* completely covers the root hairs [57]. These intimate associations between plant roots and microbes are considered as biofilms [58]. Biofilms grow on and around plant tissues, and an increasing number of studies have begun to reveal their importance in plant–microbe interactions [59, 60].

Plant-associated bacteria interact with host tissue surfaces during pathogenesis and symbiosis, and in commensal relationships. Biofilm-type structures that vary from small clusters of cells to extensive biofilms have been revealed through observations of bacteria associated with plants [61], such as at the root tip of *Arabidopsis thaliana* [62], in sweet corn leaf xylem vessels [63], and on bean leaves [64].

Studies concerning the interaction between biofilm-forming microbes and plants have begun at molecular level. Exudates of tomato roots strongly stimulating *Bacillus subtilis* to form biofilm ex planta, with an abundant small molecule in the exudates, L-malic acid, able to stimulate biofilm formation at high concentrations, have been reported [65]. They [65] proposed that small signaling molecules released by the roots of tomato plants are directly or indirectly recognized by the sensor histidine kinase KinD, triggering biofilm formation. Another team [66] showed that *B. subtilis* biofilm formation was triggered by certain plant polysaccharides. These polysaccharides served as a signal for biofilm formation as well as a source of sugars for the synthesis of the matrix exopolysaccharide.

7.3.2 Biofilm Microbes

Microbes living in a biofilm are different from the planktonic cells floating outside biofilm for the following reasons: (1) they are in an attached state; (2) they live in an environment inside biofilm, which is different from that outside biofilm, as will be discussed later (in Section 7.3.4); and (3) the cell density inside biofilm is far greater (>100–1000 times) than that outside biofilm, hence intermicrobe interactions are much more intensive. These differences influence the microbes inside biofilm as described below.

7.3.2.1 Phenotype and Gene Expression. As described by one group of investigators [67], the biofilm bacteria are phenotypically different from the planktonic state [68–70], and generally much more tolerant to antibiotics, biocides, and hydrodynamic shear forces compared with planktonic counterparts [7, 71]. These differences were attributed to significant changes in the patterns of gene expression between the two growth modes [72, 73]. In fact, different gene expression patterns, although the extent is varying, has been revealed between planktonic and biofilm cells in a variety of bacteria [67, 72, 74–76].

7.3.2.2 Multispecies Biofilm. Biofilms formed in nature contain multispecies of microbes. The species constituting a mixed biofilm and the interactions between these microorganisms critically influence the development and shape of the community [13]. Thus, extrapolation from the results using a model microbe, such as *Pseudomonas aeruginosa*, to biofilms in general is not suitable [8].

The bacterial cell density in biofilm is far greater than the outside environment, enabling gene transfer by transformation, transduction, and conjugation between biofilm organisms [77–79]. There are increased opportunities in biofilms for the transfer of mobile genetic elements (e.g., plasmids) that might encode the traits, such as resistance to antibiotics and/or heavy metals and the ability to degrade pollutants [78, 79]. Horizontal gene transfer in bacteria under both natural and engineered environments occurs through transposons and the transformation of naked DNA or plasmids, which leads to transfer of genetic traits [80].

Biofilm microbes frequently appear to differ metabolically from their free-living counterparts due to two possible reasons [81]: (1) physicochemical conditions of microscale environment inside biofilm differ from outside biofilm, and (2) the close proximity between microbes induces various interactions among biofilm members.

In general, interspecies interactions involve communication, typically via quorum sensing (see Section 7.3.2.3), and metabolic cooperation or competition. Interactions among species within a biofilm can be antagonistic, such as competition over nutrients and growth inhibition, or synergistic, such as the promotion of biofilm formation by coaggregation, metabolic cooperation where one species utilizes a metabolite produced by a neighboring species, and increased resistance to antibiotics or host immune responses compared to the monospecies biofilms [13].

Biofilm in nature contain various kinds of microbes such as algae, fungi, and protozoa as well as various species of bacteria. These microbes also interact antagonistically or synergistically. EPS polymers produced by diatoms have been implicated in promoting growth of specific bacterial taxa in estuarine biofilms [82]. Some bacterial strains can grow without organic nutrient when cocultured with diatom; *Cymbella microcephala*, in turn, in the presence of bacteria, enhance the growth and polysaccharide secretion of the diatom [83]. Other investigators [84] reported that in addition to desmids (a group of evolutionarily advanced green algae), diatoms, filamentous green algae, and transient nonmotile phases of flagellates represented the photosynthetic eukaryotes in a wetland biofilm. The corresponding information on protozoa in biofilms, such as their grazing rates, evidence of nutrient remineralization, and their susceptibility to mesoinvertebrate grazing, has been reviewed [85]. There are studies reporting the protozoan capacity to graze biofilm bacteria [86,87]. Contrary to this, in a natural bacterial biofilm, it was shown [88] that bacterial communities are much better buffered against influences of protozoan grazing than reported for their planktonic counterparts.

7.3.2.3 Cell–Cell Communication. Bacterial populations can communicate with one another using signal molecules such as *N*-acyl homoserine lactone in many Gram-negative bacteria such as *Vibrio fisheri* [89], and modified oligopeptide in a number of Gram-positive bacteria as *Staphylococcus aureus* [90]. By the accumulation of the signal molecules in the surrounding environment, a single cell can sense the number of bacteria (i.e., bacterial density), and therefore the population as a whole can make a coordinated response, such as swarming, toxin production, and biofilm formation [91].

The signal produced regulates its own production (autoinduction) leading to a positive-feedback response and greatly increased signal production. At critical densities, the binding of a regulator protein to the signal leads to the switching on of genes controlled [92, 93]. Cell communication involving the production and detection of diffusible signal molecules has become commonly known as *quorum sensing* (QS). Intra- and interspecies QS of bacteria have been reported in many articles. Interspecies QS between bacteria and fungi has also been reported [94].

It has been revealed that bacterial QS molecules are also recognized by eukaryotes that are colonized by QS-active bacteria. In this case, the cross-kingdom interaction can lead to specific adjustment and physiological adaptations in the colonized eukaryote [95].

The QS process can be disrupted by different mechanisms [96]. The degradation [97–101] or interference with [102–104] the signaling molecule is probably another important integral part in the complex QS circuit [95].

In addition to QS molecules, a diversity of other signals trigger biofilm formation. These include secondary metabolites such as antibiotics, pigments, and siderophores [105]. On the other hand, nonbiocidal molecules such as biosurfactants, enzymes, and metabolites produced by bacteria and other microorganisms can cause competitive interactions ranging from inhibition of initial adhesion to matrix degradation, jamming of cell–cell communications, and induction of biofilm dispersion [14].

7.3.3 Extracellular Polymeric Substances (EPSs)

Microbes in biofilm are enclosed in a complex structure composed of extracellular polymeric substances (EPSs). EPSs were initially termed *extracellular polysaccharides*; however, it has become clear that the biofilm matrix also contains proteins, nucleic acids, lipids, and other biopolymers such as humic substances [2]. The participation of multiple types of these molecules in the formation of extracellular matrix makes it impossible to present a single summary of biofilm matrix [105].

These EPS materials mechanically stabilize biofilm, mediate biofilm adhesion to surfaces, and form a cohesive, three-dimensional polymer network (biofilm matrix). In the biofilm matrix extracellular enzymes are immobilized as well as microbial cells, enabling metabolization of dissolved, colloidal, and solid biopolymers [2]. The EPS provides microbial habitats affected correspondingly by EPS characteristics, such as being structural, sorptive, surface-active, active, informative, redox-active, and nutritive as categorized in one report [8]. Each EPS component is discussed below.

Polysaccharides are a major fraction of the EPS matrix [106, 107], mostly long molecules, linear or branched, with a molecular mass of wide range: $0.5–2 \times 10^6$ Da (daltons) [2], wider than the range of $0.5–5 \times 10^6$ Da reported in another study [108]. Most exopolysaccharides are heteropolysaccharides consisting of a mixture of neutral and charged sugar residues. Owing to the presence of uronic acids (and, in some cases, ketal-linked pyruvate or, rarely, sulfate), many known exopolysaccharides are polyanionic [2]; sulfate is reported to be rich in marine biofilm [109]. In multispecies biofilms the presence of a species that produces exopolysaccharides may lead to the integration of other species that do not synthesize matrix polymers [110].

The biofilm matrix can contain considerable amounts of proteins that can far exceed the polysaccharide content on a mass basis [106, 111], functioning as enzymes or structural proteins. Various extracellular enzymes, such as protein-degrading enzymes, polysaccharide or oligosaccharide-degrading enzymes, phosphomonoesterases, and oxidoreductases [112], have been detected in biofilms, many of which are involved in the degradation of biopolymers. The low-molecular-mass resultings can be taken up and utilized as carbon and energy sources. The degradation of

structural EPS may also promote the detachment of bacteria from biofilms [2]. The nonenzymatic proteins in the matrix, such as the cell-surface-associated and extracellular carbohydrate-binding proteins (called *lectins*), and proteinaceous cell appendages (e.g., pili, fimbriae, flagella) can function to form and stabilize biofilm network structure through the interactions with EPS components [2].

Biofilms of various origins have been found to contain extracellular DNA (eDNA) varying in produced amount even between closely related species and in origin, such as generated through lysis of subpopulation of bacteria and active excretion from cells [2]. The eDNA is an integral part of the matrix [113, 114] and of the biofilm mode of life efficient in gene transfer [18]. Extracellular DNA can be used as C, N, and P sources by heterotrophic microorganisms and plays a significant role in bacterial biofilm formation in soil, and sediment environment [115].

Lipids are also found in the biofilm matrix [111]. Lipopolysaccharides are crucial for *Thiobacillus ferrooxidans* adherence to pyrite surfaces [116]. *Serratia marcescens* produces extracellular lipids with surface-active properties (known as *serrawettins* [117]) [2], capable of decreasing water surface tension by which the microbial cells can spread over a surface, although details of the mechanism remain to be clarified [118]. Other surface-active EPSs include surfactin, viscosin, and emulsan, which can disperse hydrophobic substances and render them bioavailable [2]. Biosurfactants can have antibacterial and antifungal properties and are important for bacterial attachment, detachment from oil droplets [119], or enhancement of oil degradation [120].

7.3.4 Interstitial Water among EPSs

Biofilm microbes live in the EPS matrix; thus the water occupying the interstitial region among EPSs is the immediate inhabiting environment for the microbes. The properties of interstitial water and the microbial behaviors inside biofilm will mutually affect each other. Some studies on interstitial water are described in this section.

7.3.4.1 Water Content and Mass Transfer. EPS biopolymers are highly hydrated and form a matrix, which keeps the biofilm cells together and retains water [8]. The water content of biofilm in a natural lake-water environment has been reported at >90% [17]. In general, the water content of biofilms reaches 90–99% of the total wet mass [121]. Although biofilm water content is high, mass transfer in biofilm is not the same as in water outside biofilm, due to the characteristic structure of biofilm matrix. Biofilm matrix is a kind of *bimodel pore structure* containing large macropores (water channels) between different cell–polymer aggregates and micropores inside these aggregates [121]. A significant amount of literature has been published on the relation between internal mass transfer and the physical characteristics of the biofilms [122–126]. The commonly accepted interpretation is that the effective diffusivity depends on the biofilm dry density (the mass of dry biofilm per unit wet volume); a decrease in diffusivity values has been empirically correlated with an increase in biofilm dry density [122]. However, one investigator [121] argued that the concept of tortuosity is more relevant for describing mass transfer inside biofilm matrices than is the more commonly accepted biofilm dry density. Tortuosity has a simple geometric meaning; it describes "the longer connecting path imposed by obstacles within porous solids relative to that for motion in unconstrained free space" [127].

EPSs affect the properties of interstitial water physically and chemically through functions such as selective material uptake with sieving by EPS network structure [2], thereby forming gradients of various materials by diffusion limitation in the matrix, resulting in formation of various niches for microbes.

Examples of experimentally measured gradients in biological activity within biofilms include adenylate charge [128], growth rate [129, 130], culturability [131], and the capacity for protein synthesis [132–134].

7.3.4.2 Ion Concentration in Biofilm. Nutrient ion concentration in biofilm has been reported to be far greater than that in the surrounding water. One team of investigators [135] examined the concentration of ammonium, nitrite, nitrate, and phosphate ions in biofilms formed on reed and stone surface in Lake Biwa (Japan), and found that the concentrations were 100s–1000s times higher compared with the lake water surrounding biofilm. They also found that the concentrations of the ions changed seasonally synchronizing with those of lake water. The higher ion concentrations in other biofilm samples compared with surrounding water were also confirmed in Lake Biwa [17].

Another group [136] measured the concentration of Ca, Sr, and Ti, as well as Fe, Mn, K, and Zn in biofilms and found the enrichment factor of 10^3–10^4 for these elements. An enrichment factor of 10^2–10^4 for Ca, K, Fe, Sr, Mn and Zn was reported in another study [137]. Another team [138] showed that a mineral fraction could reach between 2% and 40% of the EPS dry weight depending on the extraction method used, in which main minerals were Ca, Mg, Na, K, Al, Fe, Mn, P, Si, and S.

7.3.4.3 Condensation Mechanisms. Biofilm polymers contain both electrically positively and negatively charged sites. In other studies measuring the electrophoretic mobility (EPM) of biofilm fragments in buffer solution of various pHs [17, 139], biofilm fragments showed a negative EPM at neutral pH decreasing under acidic conditions, especially around pH 4, indicating the presence of functional group such as carboxylic acid. Those authors also observed positive EPM at

pH 2 indicating the presence of amino group. These observations are consistent with the reports that EPSs contain anionic groups (in uronic acids and proteins) and cationic groups (e.g., in amino sugars) [2, 140], and also indicate the excess existence of the functional groups carrying negative charge over the groups carrying positive charge resulting in a net negative charge of biofilm at neutral pH.

The existence of both negative and positive charges on EPS enables an electrostatic attractive interaction between biofilm and oppositely charged ions existing in surrounding water. The condensation mechanism of biofilm was analyzed by comparison with ion exchange resins [139]. A high ion uptake capacity of biofilm compared to that of ion exchange resins was reported, and the difference in the condensation mechanism between biofilm and ion exchange resin was suggested [139]. It was concluded the ions may be reserved in the interstitial region among EPS polymers as well as the charged sites on the polymers.

7.4 BIOFILM AND SURROUNDING ENVIRONMENT

Biofilm formation is a multistage dynamical process governed by various physicochemical principles and biological protocols [141], as has been described above in this chapter. Biofilms can be seen as catalysts (living ones). As opposed to chemical catalysts, they are able to grow and modify their internal structure in order to adapt to the operating conditions [121].

Data from a great number of authors have revealed how biofilm physical structure, formation, and development change with regulating conditions such as the hydrodynamics and composition of the external liquid, temperature, oxygen concentration, and pH [125, 142–148].

Contrary to the biofilms formed under controlled conditions, biofilms in nature are formed under the ever-fluctuating effects of the external environment. Biofilms are open and highly dynamic communities [149]. Biofilm-associated microbes, because of their ubiquity, diverse metabolic capabilities, and high enzymatic activity [150], have significant effects on external environments. This section focuses on these effects with respect to the formation of biofilms in nature.

7.4.1 Influence of Surrounding Environment on Biofilm

Light intensity has a significant effect on biofilm formation, development, and activity. Light-grown biofilms show significantly higher photosynthetic activity, bacterial density, ectoenzymatic activity (especially β-glucosidase) [151], and abiotic adsorption of organic matter [34] than do dark-grown biofilms. Algal photosynthesis can have a significant impact on bacterial productivity, biomass, biovolume, and enzyme production (α- and β-glucosidase and β-xylosidase) over longer time periods (24 h) at low photon flux densities ($\leq$100 μmol m^{-2} s^{-1}) [152]. A clear dependence of biofilm microbial community structure on light intensity is revealed; under high light conditions in one study, the initial colonizers of the substratum predominantly consisted of green algae, whereas at low light intensities, heterotrophic bacteria were the initial colonizers [153].

Higher-nutrient conditions combined with other factors, including light intensity, influence biofilms to a greater extent than do oligotrophic conditions [154–156].

Some studies report the significant effects of pH, temperature, and water flow on biofilm. One team [157] found significant differences in community structure among the streams varying in pH. An increase in river-water temperature (+4°C above an ambient temperature) induced the enhancement of degradation of recalcitrant [158]. High shear stresses decreased biofilm diversity and thus may slow down biofilm maturation, tending to maintain a younger biofilm [159].

Combination of several factors affects biofilms. It has been reported that bacterial biofilm community composition on the submerged macrophytes *Myriophyllum spicatum* and *Potamogeton perfoliatus* depends mainly on environmental factors (water level, conductivity, temperature, pH) and the plant chemical composition, especially the carbon and total phenolic content [160]. Another study [157] revealed that bacterial communities in streams located within rural catchments were significantly different from those within urban catchments.

Seasonal variation of biofilm microbial community structure in various sites such as lakes, rivers, and estuaries has been reported [37, 150, 161, 162].

7.4.2 Influence of Biofilm on Surrounding Environment

Positive relationships between the extracellular enzymatic activity of biofilm and DOC and biodegradable DOC content in flowing water have been found [34], with the suggestion that biofilm metabolism contributes to DOC dynamics in fluvial systems. The release of a significant amount of dissolved free amino acids into stream has also been reported [163]. Biofilm can condense various ions into EPS matrix through electrostatic interaction between electrically charged sites on polymers constituting the matrix and oppositely charged ions existing outside biofilm [17, 135, 139], as discussed in Section 7.3.4.3. Biofilms can condense various ions into the matrix, and also can release ions to the outside environment [139]. Biofilms are present in various sites and play a key role in the uptake or retention of inorganic and organic nutrients [11]. Biofilms may significantly influence on microbial ecology through the aquatic food web [11, 164].

7.5 PRESENT AND PROSPECTIVE BIOFILM RESEARCH

Biofilm is a consortium of microbes enclosed in the network structure formed by extracellular polymeric substances (EPSs). The biofilm microbes are in an attached state and they interact with each other in various ways physiologically and genetically to result in an assemblage of cells that are functionally similar to multicellular organisms.

Van Leeuwenhoek, using his simple microscopes, first observed microorganisms on tooth surfaces and can be credited with the discovery of microbial biofilms [5]. We now have a more comprehensive understanding of biofilm, specifically, that it is not a simple accumulation of microbial cells but is some sort of population of microbes tightly coordinating each other, inhabiting a characteristic structure composed of EPSs.

Microbial biofilms play a prominent role in the functions of many aquatic ecosystems, such as streams and rivers [4, 165] as well as in several industrial facilities, including sewage plants [166]. Researchers in the fields of clinical, food- and water-related, and environmental microbiology have begun to investigate microbiologic processes from a biofilm perspective [8]. Correspondingly, there is great interest in understanding the mechanisms that modulate the structure and function of microbial biofilms. Research on microbial biofilms is proceeding on many fronts. In this section, some of these will be discussed from a research perspective.

Biofilms have detrimental effects on a variety of solids such as metals, medical devices, industrial facilities, and foods. Biofilm also can contain pathogens causing serious infectious diseases. The demand for preventing or controlling biofilm formation and development has promoted various studies as described below.

The use of ultrasound coupled with pressure and/or heat may be promising to inactivate biofilm bacteria [167]. Carbon nanotube composites may be useful to prevent biofouling associated with biofilm formation [168].

Another study [14] reviewed how nonbiocidal molecules, involving nonbiocidal biosurfactants, enzymes, and metabolites produced by bacteria and other microorganisms, affect microbial interactions in multispecies biofilm, and discussed potential biological roles and perspectives of these compounds as alternative antibiofilm molecules of industrial and biomedical interest.

The use of enzyme-based detergents as biocleaners is expected as a viable option to overcome the biofilm problem in the food industry [12].

Bacillus subtilis was reported [169] to produce a factor (a mixture of D-leucine, D-methionine, D-tyrosine, and D-tryptophan) that prevented biofilm formation and could break down existing biofilms, acting at nanomolar concentrations. D-Amino acids have also been shown to prevent biofilm formation of *Staphylococcus aureus* and *Pseudomonas aeruginosa*, and the acids are produced by many bacteria. Thus it was deduced that D-amino acids might be a widespread signal for biofilm disassembly.

It is reported that the coating of substratum surface with an aqueous fish muscle extract, composed primarily of fish muscle α-tropomyosin, significantly reduced or delayed biofilm formation by all the isolates (urinary tract infectious isolates with various pathogenic and adhesive properties) under every condition examined [170]. A new type of drug delivery system using liposomes and various polymers may be useful in preventing biofilm formation on the surface of devices implanted into the human body [171].

Biocontrol strategies based on mechanisms regarding degradation of or interference with signaling molecule in quorum sensing seem to be sustainable methods because they have a more limited selective pressure for microbial survival than do biocide treatments [172].

There have also been studies on promoting biofilm formation and development, with the objective to apply the biofilm functions in various fields such as water treatment [173, 174], bioremediation [80, 175], and agriculture [176].

Biofilm function may be utilized electrochemically. Bacterial biofilms can generate electric power, and the underlying reasons for the exocellular electron transfer, including cellular respiration and possible cell–cell communication, have been discussed [177]. Another team [178] discussed the role of biofilm on the electric current production in microbial fuel cells (MFCs) and pointed out that the production of electric current is not the major advantage, but wastewater treatment or bioremediation using a cathode or anode may be much more promising than the electric current production of the MFC itself. Other researchers [179] showed that the EPS matrix produced by a *Sphingomonas* strain provides a favorable microenvironment for enzyme (horseradish peroxidase) while retaining its activity when immobilized on a biosensor electrode.

For further progress in biofilm microbiology, a variety of perspectives have been proposed. Another team [149] suggested a concept for biofilm research that is spatially explicit and solidly rooted in ecological theory, which might serve as a universal approach to the study of the numerous facets of biofilms. They stressed that in the wild, biofilms are open and highly dynamic communities and exist as part of a larger microbial network forming a metacommunity. Oral diseases are influenced by microbial communities, not by single pathogens. Thus, another report [10] suggested that substitution of "the community" for "the agent" would make Koch's first postulate applicable to oral polymicrobial diseases.

Biofilm microbes are submerged in the interstitial water occupying the EPS matrix. Thus, studies concerning the properties of the interstitial water seem to lead a new insight into biofilm formation and development. Inside, biofilm is nutrient-rich [180–182] and has been shown to depend on ion

exchange processes [183] and on ion reservation in the EPS network region [139]. It has been deduced that the EPSs, usually electrically charged, attract the charged materials such as nutrient ions from the surrounding water [17]. The nutrient enrichment will cause rapid growth of microbes, resulting in more EPS production, which accumulate nutrients further. This cycle may accelerate the nutrient accumulation and explain the very rapid formation and development of biofilm in natural environments where water quality is not so eutrophic. Other investigators [184] also reported a fast formation process of biofilm in a stream and found that younger biofilms ($\leq$8 days old) showed higher respiratory activity per cell, indicating a fast response of microorganisms to substrate availability. The gradient of nutrient concentration in biofilm may contribute to the spatial stratification and physiological differentiation in biofilms [185].

Regarding the biofilm formation process, another team [186], based on a new approach using 16S rRNA gene sequences for virtual metagenome reconstruction, reported that transporter- and biosynthesis-related modules enrichment extent changed along with biofilm maturation; initially both modules, then biosynthesis-related modules, and finally transporter-related modules were enriched.

Direct observation of biofilm formation process using micro-culture method as reported by Yamada et al. [187] may provide further insights in physiology of biofilms.

It has been reported that more colonies can be formed in a nutrient-poor agar medium than in a nutrient-rich medium for biofilm sample [17, 188]. Improvement of culture media may enhance our understanding about culturability of biofilm microbes.

Not only living cells but also regulated cell death and lysis may be important for biofilm development [189]. Biofilm formation by pathogens in the environment can play a role in the transmission of those pathogens. Another team [190] pointed out that occurrence of viable but nonculturable (VBNC) bacteria, including *Vibrio cholerae* in biofilms, has been reported and most likely such cells were overlooked previously because appropriate methods of detection were not employed. Various approaches to researching VBNC bacteria are now developed [191] and seem to be applicable for further studies.

BIOFOULING

Kazuho Nakamura
Faculty of Engineering, Yokohama National University, Japan

9.1 DEFINITION OF BIOFOULING

Fouling is the process of accumulation of unwanted material at an interface and impedes the function of the surface in a component or system [1–3]. For example, the performance of reverse-osmosis membrane in desalination plants can be decreased by scale formation or bacteria adhesion on the membrane surface [4, 5]. The material that accumulates on surface can consist of either living organisms or nonliving organic/inorganic substances. Biofouling is caused by the accumulation of microorganisms, bacteria, fungi, plants, algae, or animals on solid surface in contact with water. The features of these living organisms in biofouling processes are growth and multiplication, and they can form biofilm, which is complex, multispecies, multidimensional communities on the surface. In the natural environment there are some advantages for living organisms when they are attached to an interface between a solid surface and water because nutrients are brought to them and waste products are carried away.

The impact of biofouling is higher economical costs for preventing and controlling it. Biofouling can occur under circumstances where water is in contact with other materials. In our living environments or certain industrial systems, biofouling usually decreases the performance of systems or devices, necessitating the development and implementation of biofouling prevention an removal methods. In shipping industries biofouling on the ship's hull significantly increases drag for hydrodynamic performance and the cost of fuel, and antifouling paints with toxic molecules are usually applied to prevent the biofouling [2].

In this chapter the impact of biofouling in some industries, mechanisms of the biofouling process, and antibiofouling strategies are introduced.

9.2 FORMATION OF BIOFILMS

The development of biofilm depends on complex behaviors of microorganisms at the interface between solids and water. The mechanism of biofilm formation significantly impacts in various industries as biofouling and its controlling methods. Figure 9.1 shows a typical sequence of events that lead to the formation of biofilms [6, 7]; (1) formation of conditioning film, (2) initial adhesion of microorganisms, (3) production of extracellular polymer substance (EPS) and multiplication, and (4) maturation of biofilm. In the formation of conditioning film, various organic and inorganic matter adsorbs to the solid surface and the formed layer is called *conditioning film*. The adhesion of microorganisms bacteria to the surface occurs via various physicochemical interactions, which can be described by the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory, and bridging with EPS and cell appendages [6]. Biofilm is formed by growth and multiplication of the attached microorganisms and EPS produced by them. The matured biofilm has complex, multispecies, multidimensional communities.

9.3 BIOFOULING IN INDUSTRIES

When biofouling occurs in industrial operation, it interferes with efficiency of the operation. Effective control of biofouling is important to reduce operating costs, while some

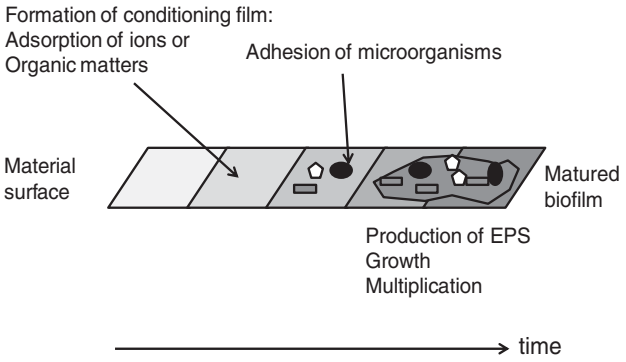

FIGURE 9.1 Adhesion of microbes and formation of biofilm.

biofilms are useful for the operation. In this section typical problems of the biofouling in some industries are introduced.

9.3.1 Biofouling in Heat Exchangers

Heat exchange systems are widely used in various industries, including power plants. Figure 9.2 shows the condenser in a power plant, which is core equipment and has heat exchange surfaces for condensing exhaust steam and for heat removal with the cooling fluid. Seawater is a typical cooling fluid employed in the condenser. The flow of the cooling fluid provided to adsorb the heat from condensing steam tends to create deposits on the heat exchange surface. The deposits are known as *fouling* and consist of biological deposits, sedimentation, precipitation, corrosion, and some inorganic substances [1].

The energy losses and economic cost associated with this fouling are significant. Fouling in heat exchangers is highly problematic for efficient operation and additional costs for design and maintenance. In coastal power plants using seawater as cooling fluid, the biological growth on the heat exchange surface is severe. The biological fouling layer causes higher heat transfer resistance and higher hydrodynamic resistance to flow of the cooling seawater in the heat exchangers. In addition to these difficulties in heat exchange operation, the design of excess heat transfer surface area and the maintenance needed for removing the fouling layer also increase the cost caused by the fouling.

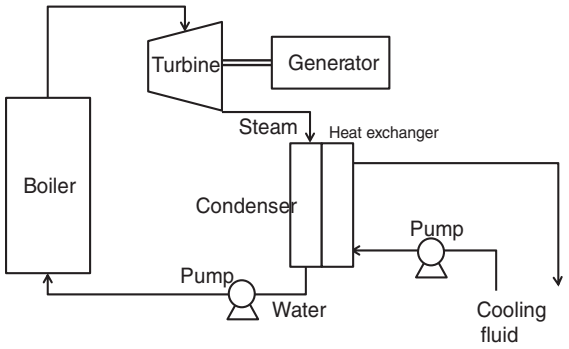

FIGURE 9.2 Heat exchanger in power plant.

Various methods have been used for preventing and removing fouling layer. The methods can be categorized into chemical and physical treatments. *Chemical* treatment consists in *oxidizing biocides*, which are chlorine, ozone, bromine, and peracetic acid; and *nonoxidising biocides*, which include glutaraldehyde and biodispersants. *Physical* treatment includes flushing, abrasive sponge balls, brushing, ultrasonic energy, and ultraviolet light. Chemical treatment with biocides are the most common approach to control biofouling, while these chemicals present toxic and carcinogenetic pollutants in the environment. Chlorine has been a measure biocide because of its effectiveness and relatively low cost. Chlorine can react with many organic substances found in water systems. Free chlorine reacts with water and the hypochlorous acid ionize:

$$Cl_2 + H_2O \rightarrow HOCl + HCl$$

$$HOCl \leftrightarrow H^+ + OCl^-$$

Hypochlorous acid shows effective biocidal activity.

9.3.2 Biofouling of Medical Devices

Biofouling in medical devices has been considered as a critical issue because it causes a wide range of health-related problems, including a risk of infectious diseases. Biofouling involves biofilm, which can develop on various surfaces such as living tissues, tooth surfaces, and medical devices. Bacteria within biofilms are much more resistant to antimicrobials than are those in planktonic condition. According to an estimate by the US National Institutes of Health (NIH), about 80% of all human bacterial infections are caused by biofilms and over 45% of all hospital-acquired infections in the US are caused by the medical device administered [1].

The development of biofilm by microbial involves the formation of conditioning film on the surface, irreversible attachment of bacteria; development of biofilm by attached bacteria, and detachment of single cell or large pieces from the biofilm. The bacteria in the biofilm produce EPSs. The EPS includes polysaccharides, proteins, and nucleic acids and determines physical properties of the biofilm. The features of the microorganism in biofilm in comparison with those in planktonic condition are high population density; presence of EPS matrix; a wide range of physical, metabolic, and chemical heterogeneities; and gene transcription profile. The negatively charged EPS is very effective in protecting bacteria from cationic antibiotics by restricting their permeation. The insensitivity of biofilm bacteria to antibiotics is also attributed to slow antimicrobial penetration, the stress response, substrate limitation, and the presence of persister cells [1].

For prevention and eradication of biofilm formation on medical devices, many studies have focused on developing novel materials, surface coatings, antimicrobial combinations, antifouling, antibiofilm agents, and physical treatments against biofilms [1,2]. In actual medical systems most devices used in medical environments are disposed of after a single use to reduce the risk of infection from contaminated products. The treatment of waste from medical industry, which is highly regulated, including these disposal devices, requires the most care and incurs high costs, and it is also an issue caused by biofouling.

9.3.3 Biofilms in Wastewater Treatment Processes

Biofilms in the natural environment are responsible for the removal of dissolved contaminants in environmental water and influence the quality of the water in which they exist. This characteristic is the basis for the employment of biofilms in wastewater treatment and the improvement of drinking water [3]. The wastewater discharged from various industries in addition to domestic sewage contains undesirable material that provides nutrients for microbial activity. The suitable biofilm systems convert the unwanted components to CO_2 and H_2O in aerobic reactions and to CO_2 and CH_4 in anaerobic conditions. The formation of biofilms and microbial aggregates is applied in biofilm reactors, such as trickle filter, rotating biological filter, aerobic fluidized-bed contactors, and anaerobic fluidized-bed contactors. These reactors are used for oxidation of organic matter, nitrification, denitrification, or anaerobic digestion of wastewater.

The trickling filter is a common aerobic biofilm reactor. Figure 9.3 shows the trickling filter with a reactor consisting of a bed of filter media such as stones, ceramic material, or plastic media, providing a large surface area for microbial growth. The wastewater is distributed over the top surface of the filter medium bed with a bed depth of 1–2 m. The oxygen for the biological activity is available throughout the filter bed. The treated effluent from the bottom of the bed is collected in a settlement tank. The biofilm formed on the surface of the filter media in trickling filters is composed of bacteria, fungi, algae, protozoa, and other life forms, and the microorganisms in the biofilm degrade the organic matter in wastewater. The increase in biofilm thickness leads to limited oxygen diffusion to the deeper layers of the biofilm, which creates an anaerobic environment near the filter media surface. Figure 9.4 shows the structure of the biofilm on the surface of filter media and mass transfer around the biofilm. The efficiency of trickle filters depends on both reaction rate in biofilm and the operating conditions that affect the mass transfer condition among air, water and biofilm.

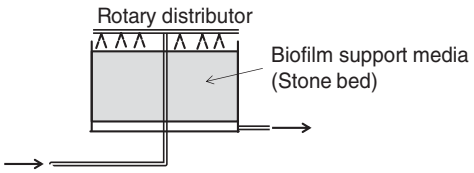

FIGURE 9.3 Trickling filter used for wastewater treatment.

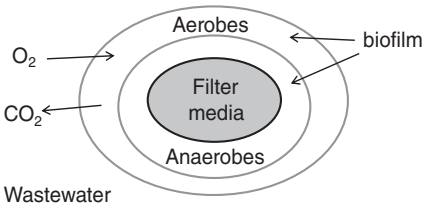

FIGURE 9.4 Biofilm on the surface of filter media.

Figure 9.5 is a schematic representation of a rotating biological filter. This filter has a series of disks mounted on a horizontal shaft. The disks consist of flat or corrugated plastic material. They are made to rotate so that biofilms accumulated on both sides of the disk are alternatively exposed to the wastewater and to the atmosphere. Rotation of the discs ensures effective mass transfer from the wastewater to biofilm, which improves the efficiency of the operation [3].

Figure 9.6 shows the fluidized-bed processes. Aerobic fluidized-bed processes use the media supporting active biofilms, including sand particles, glass, anthracite, polyester foam, or activated-carbon granules. The medium shows a higher surface area, which allows a large amount of biofilm to develop, compared to the media in static systems. The oxygen for the biofilm activity is provided by the injection of air from the bottom of the reactor. In this reactor highly efficient contact between wastewater and biofilm is achieved while the relatively higher energy consumption is required, due to the air injection and pumping. Anaerobic wastewater treatment processes are becoming popular because of their lower energy consumption compared to aerobic treatment processes with aeration. Biogas with a high concentration of methane produced as byproduct may be used as an energy source for the running power of the process. The *upflow anaerobic sludge blanket* (UASB) reactor is an anaerobic fluidized-bed reactor. Wastewater flows upward through the blanket of granular sludge. The granules are dense compact biofilms and are formed by aggregation of bacteria without any support matrix in the flow condition.

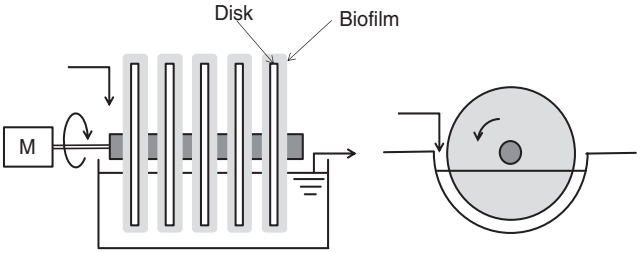

FIGURE 9.5 Rotating biological filter.

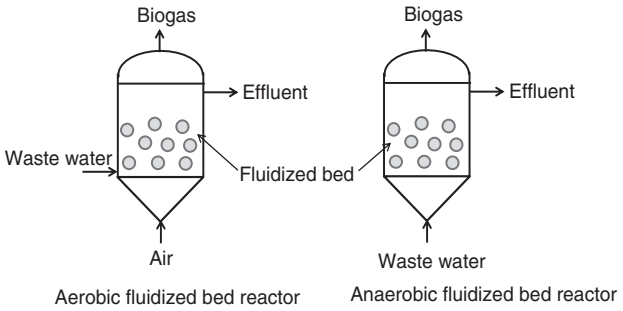

FIGURE 9.6 Fluidized-bed biofilm reactors.

9.3.4 Biofouling in Membrane Processes

The membrane filtration processes producing high-quality water are a key countermeasure against global shortage of water. Membranes are classified by the range of materials separated. *Microfiltration* (MF) membranes are capable of removing particulate matter, including pathogens such as *Cryptosporidium oocystsm*, while reverse-osmosis (RO) membranes retain solutes as water permeates through the membrane. The performance of membrane systems can be characterized as permeate flux, that is, a mass of water across a unit area of membrane per unit time. During membrane operation materials accumulate on and within the membrane structure and reduce the permeate flux by blocking or constricting pores and by forming a layer of additional resistance to flow across the membrane. Figure 9.7 shows the fouling layer formed on the membrane surface by the accumulated materials. This reduction in permeate flux is observed as a consequence of membrane fouling. The fouling is caused by matter presenting in feedwater such as particles, colloids, macromolecules, and ions. Microorganisms may also cause biofouling. They attach onto and within the membrane structure and grow and multiply and finally form biofilm, which compromises membrane performance [1, 2, 5].

Biofouling control strategies fall into two categories: (1) optimization of design and operation of membrane processes, including effective feedwater pretreatment methods, membrane cleaning methods, and operating pressure; and (2) development of antifouling membrane. As the water produced by membrane processes is intended for human consumption, the method of fouling removal is consists in backwashing or chemical cleansing using caustic solution or oxidants such as chlorine. However, the chemical cleansing can attack the membrane structure and reduce the life of the membrane. The design and fabrication of surface chemistries of membrane that are optimized with respect to not only flux and rejection properties but also chlorine resistance and retard adhesion and growth of biofilm, which are desired.

Membrane surface properties such as hydrophobicity, surface charge, and surface roughness will affect the membrane biofouling. The hydrophobic membranes would be easily fouled by bacteria compared with hydrophilic membranes because of the hydrophobic interaction between membrane surface and microorganisms. The membranes with negatively charged surfaces would show lower initial adhesion rate of bacteria on the membrane surface because of the electrostatic repulsive force between membrane surface and the surfaces of bacteria, which are negatively charged around neutral pH. The surface roughness is thought to promote bacterial adhesion. It can be considered that the membranes that have a hydrophilic, neutral or negatively charged, and smooth surface would be more effective in reducing the initial adhesion of microorganisms, which will cause the biofouling [5].

A strategy to control biofouling in the membrane processes is development of antibiofouling surface on the membranes. The membranes with neutral or negatively charged hydrophilic surface will deduce the electrostatic attraction force and hydrophobic interaction between the membrane and microorganisms. The membrane surface immobilized with antibacterial agents will kill the microorganism attached on the surface. The TiO_2 photocatalysis generates various active oxygen species, which decompose organic chemicals and kill bacteria, under light. The silver nanoparticle is also known as an antibacterial agent. Membranes that immobilized these antibacterial agents were reported to manifest antibiofouling activity [1, 2, 5].

11.1 INTRODUCTION

Biofouling, which is the deposition of particles such as proteins, cells, and bacteria at material surfaces, is a major concern in applications including biomedical implants, extracorporeal medical devices, drug delivery carriers, and biosensors. There are significant needs for the development of antifouling materials. The two strategies generally applied for antifouling are either (1) preventing the attachment of the biofoulants or (2) degrading them. Strategy 2 includes incorporating proteases or microbicidals into a coating to impart protein-degrading or bactericidal properties to the surfaces. This approach is less favorable because the degraded proteins and bactericides might cause biocompatibility problems in vivo, and there is a possibility for the emergence of antibiotic-resistant pathogenic strains. Instead of trying to "destroy" the attached particles, the first approach intends to develop "nonfouling" biomaterials that prevent protein adsorption to material surfaces from the beginning.

The development of a nonfouling surface is a major challenge in biomaterials. It is generally believed that nonspecific protein adsorption could activate thrombosis coagulation, elicit inflammatory responses, and cause adverse effects on the healing process for medical implants. A surface that is prone to nonspecific protein adsorption is usually also favorable for the adhesion of bacteria and thus increases the risk of infection. For ex vivo blood-circulating or surface-based diagnostic devices, nonspecific protein adsorption will degrade their performance.

In this chapter, a brief introduction of the major role of nonspecific protein adsorption on the performance of biomaterials will be given and the correlations between biofouling and material properties will be addressed from the perspectives of the adsorption mechanism and driving forces for protein adsorption. Key indices of material properties for protein adsorption will also be discussed. In Section 11.4, recent developments in the design of surfaces of low-fouling/nonfouling biomaterials will be reviewed in detail.

11.2 WHY NONFOULING IS RELEVANT IN BIOMATERIALS

11.2.1 Antithrombogenesis and Anti-inflammatory Response

Coagulation is the instant response of a normal tissue to an injury. It mainly involves a cellular (platelet) and a protein (fibrinogen) component in blood plasma. When the endothelium is damaged, exposure of the circulating blood to the underlying collagen substrate and tissue factor initiates the primary and secondary hemostasis processes. In primary hemostasis, platelets are activated and immediately form a plug at the site of injury. In the meantime, proteins of coagulation factors in the blood plasma respond in a complex cascade (secondary hemostasis) to cross-link fibrinogen to form fibrin strands and strengthen the platelet plug.

The coagulation cascade of secondary hemostasis includes two pathways: the intrinsic (contact activation) pathway and the extrinsic (tissue factor) pathway. Coagulation

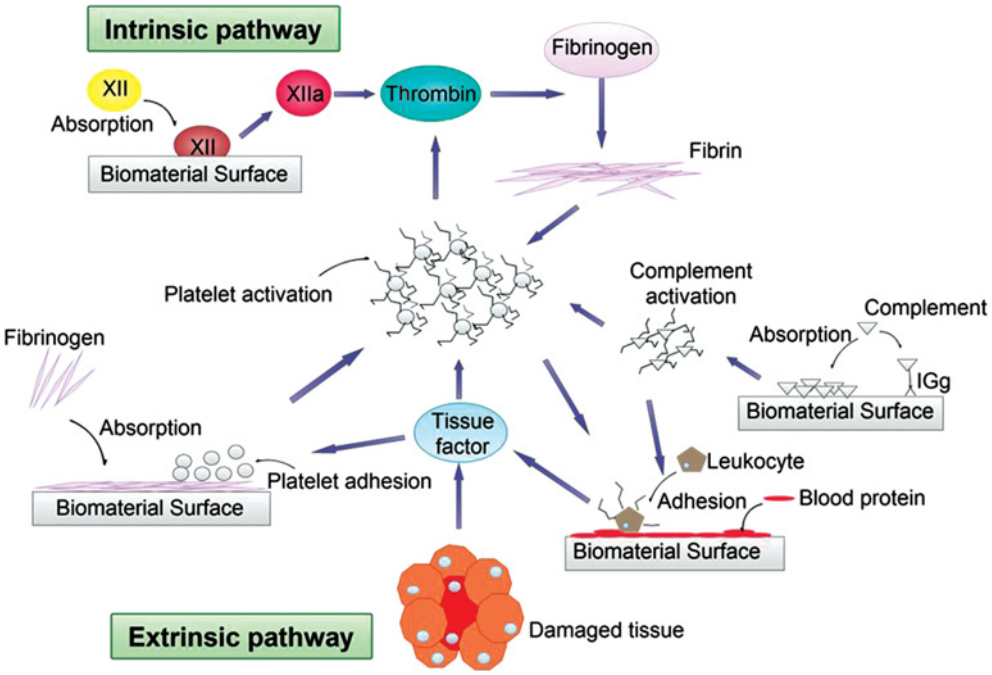

FIGURE 11.1 Relationship between the adsorption of blood proteins and the activation of the coagulation cascade, complement and platelets.

factor XII and tissue factor (TF) are the initiators of the intrinsic and extrinsic pathway, respectively. Both pathways lead to a common pathway for the generation of thrombin and the conversion of fibrinogen to fibrin.

Contact of blood and interstitial fluids with a biomaterial induces different responses. Immediately after the contact, proteins from the blood and interstitial fluids adsorb onto the material surfaces. Therefore, it is the adsorbed layer of protein, rather than the surface itself, that determines the activation of the platelets, coagulation cascade, complement system, and immune cells. Detailed descriptions of biomaterial-associated thrombosis and inflammatory response can be found in recent reviews [1, 2]. In brief, as illustrated in Fig. 11.1, the intrinsic pathway of coagulation can be induced by the contact activation of coagulation factor XII on material surfaces, which induces subsequent thrombin formation and further activates platelets and coagulation factors of the intrinsic and extrinsic systems and, thus, amplifies the coagulation cascade on biomaterial surfaces. Fibrinogen also tends to adsorb on biomaterial surfaces and initiates excess platelet adhesion. The attached platelets can be activated by TF released by damaged cells or activated leukocytes and complements resulting further thrombus formation on material surfaces.

Protein adsorption can also affect the inflammatory response of a biomaterial. For example, the exposure of integrin-binding domains of adsorbed fibrinogens could activate phagocytes and launch an inflammatory response [3]. Additionally, it is known that a high concentration of activated complements can contribute to the onset of inflammatory responses [4]. Because it is well established that complement is activated on contact with a biomaterial and the material surface is always coated with a layer of adsorbed protein, the inflammation due to complement activation is therefore associated with the protein adsorption of the biomaterial.

11.2.2 Host Response to Biomaterials

The normal healing response to a tissue injury is an intricate process and includes three sequential phases: (1) hemostasis and inflammation, (2) proliferation and granulation, and (3) remodeling. The immediate response to injury is the platelet aggregation and fibrin clot formation to reduce bleeding. Cytokines and growth factors are then released to attract white blood cells. Neutrophils are the major white blood cells appearing during the early stage of wound healing. This process is then followed by the migration of monocytes, which later differentiate into macrophages to clean up the wound site. In the proliferation phase, fibroblast and endothelial cells are recruited and grow to convert the fibrin clot into granulation tissue and form new blood vessels. Finally, in the remodeling phase, the granulation tissue is gradually replaced by extracellular matrix (ECM) deposited by fibroblasts. Usually, there is scar tissue formation, although it is possible to restore a completely normal tissue.

The biological response to an implant, termed the *foreign-body reaction*, is different from the response to an injury.

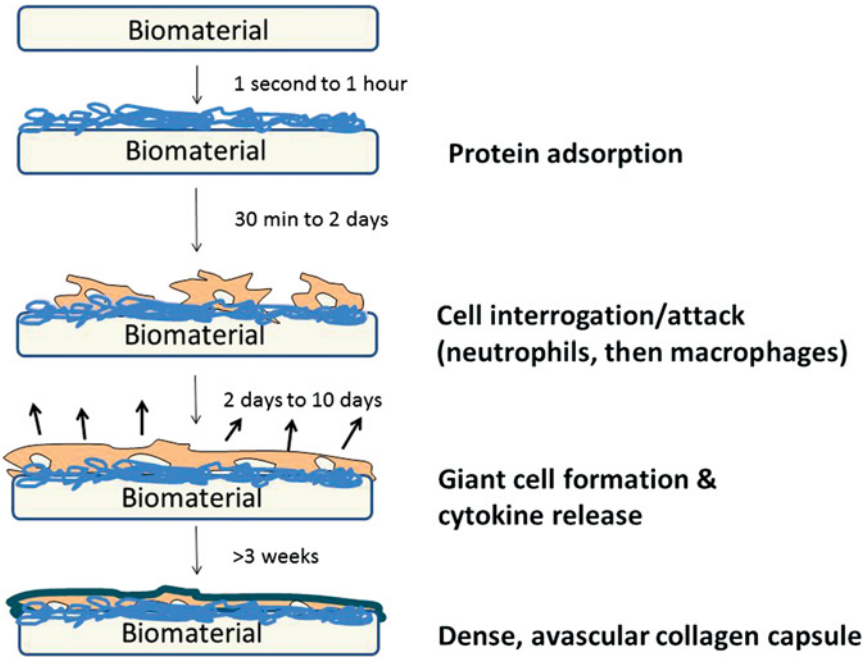

FIGURE 11.2 Sequential stages of a foreign-body reaction proposed by Ratner and Bryant [6].

Detailed reviews on this issue have been provided [1, 5]. Figure 11.2 is a simplified flowchart showing the key steps of the response suggested in one study [6]. The major difference in a foreign-body reaction is that the implantation of a biomaterial elicits immediate nonspecific protein adsorption, and the adsorbed proteins may undergo a different degree of conformational changes due to the effects of the interfacial energy between the material surfaces and the surrounding contacted body fluids. The adsorbed denatured protein can induce the adhesion of various cells, such as leukocytes, monocytes, and platelets, and consequently activate the release of cytokines and the subsequent inflammatory process. For small and degradable implants, the debris can eventually be cleaned up by the white blood cells. However, for implants much larger than the adhered macrophages, because the foreign body cannot be phagocytosed, the adhered macrophages therefore fuse together to form multinucleated foreign-body giant cells at the material surface, which may result in chronic inflammation and last for a lifetime. The final stage of the foreign-body reaction for this type of implant is the formation of an avascular, fibrous tissue to encapsulate the implant.

11.2.3 Antibacterial Property

Microbe-associated infection is one of the major causes for the failure of medical devices. For example, biofilm formations on medical devices such as dental/orthopedic/ cardiovascular prosthesis, catheters, and contact lenses lead to infections [7, 8]. Key strategies for designing implants that prevent microbial infections include the coating of biocidal agents on material surfaces. However, this practice cannot exclude the concern of developing an antibiotic-resistant pathogenic strain and the resulting contamination. Another strategy is to design surfaces that prevent the attachment of bacteria. The attachment of bacteria to a surface is usually followed by subsequent colonization and biofilm formation. Numerous studies indicate that the adhesion of bacteria increases the risk of infection. In vivo, the adhesion of bacteria often is mediated by the adsorbed protein film [9]. A surface that is less subjected to the nonspecific adsorption of proteins usually also has better resistance to bacteria adhesion [10, 11].

In general, the contact of blood or other body fluids to a normal tissue does not elicit nonspecific protein adsorption. However, a material that is identified by the biological system as a foreign body or as an abnormal tissue will trigger the defense system of the body and cause a substantial amount of protein adsorption. The amount, types, orientation, and conformational change of the adsorbed proteins on surfaces will all affect the subsequent biological response of the body to the material. Nonspecific protein adsorption, especially for those accompanied with conformational changes, often activates thrombogenesis and an inflammatory response and renders a surface prone to bacteria adhesion. However, because of the complexity of the determining factors on protein adsorption, the development of a truly nonfouling surface, also called a "stealth surface," remains a major challenge in the field.

11.3 PROTEIN ADSORPTION AND MATERIAL PROPERTIES

A *protein* is a macromolecule that consists of a polypeptide bond and is folded into a specific three-dimensional structure. The distribution of the primary sequence and the manner of protein folding provide the molecular surface with domains of various properties such as charge density and hydrophilicity. Because the properties of a protein surface are not uniform, the protein–surface interaction therefore depends not only on the "average" surface properties but also on the "nanoscale" variation in the surface topography and chemistry [11].

In addition to binding affinity, sometimes the behavior of protein adsorption is also affected by kinetic factors, such as the competitive adsorption of the three major plasma proteins of albumin, immune globulin, and fibrinogen immediately after the contact of the material with blood plasma. Dynamic effects also play a role in protein adsorption, due to the surface denaturation. Because the manner of protein folding might be perturbed by changing the microenvironment around the molecule, one expects to see conformational change induced by protein adsorption. A conformational change will alter protein surface properties, which, in turn, will affect the subsequent protein adsorption.

Under aqueous conditions, the protein adsorption behavior is affected not only by the properties of the protein molecule and material surface but also by the conditions of the water solutions. It is the cohesive and adhesive forces between these three substances that determine the protein–surface, surface–water, and protein–water interactions. Previous studies on protein adsorption tend to focus on the behavior of the surface–protein interaction. However, more recent studies indicate that in addition to the surface–protein interaction, the surface–water interaction (i.e., the hydration properties of the material) also plays a crucial role in determining the nonfouling property of the materials [12–14].

11.3.1 Adsorption Mechanism of Protein

As shown in Fig. 11.3, the dynamic protein adsorption mechanism includes two stages. In the first stage, protein molecules adsorb to the material surface rapidly and reach a pseudo–steady state. At this stage, the adsorbed protein retains its native conformation, and the adsorption is kept in the monolayer and reversible; thus, the protein can still be removed from the material surface. Later, in the second stage, the conformation of the adsorbed protein gradually deteriorates into a denatured form due to the effects of interfacial energy. The denatured protein exposes its hydrophobic core region and therefore tightly binds to the material surfaces. Thus, the adsorption becomes irreversible, and the adsorbed protein can hardly be removed from the surfaces [15–17]. A surface covered with denatured proteins can further induce multilayer protein adsorption. Judging from the abovementioned protein adsorption mechanism, a material can be made favorable for nonfouling by reducing the retention time of the protein molecules on the material surface or by preserving the adsorbed protein in its native form.

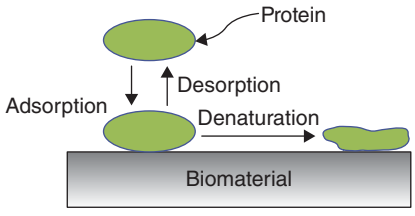

FIGURE 11.3 Two-stage protein adsorption mechanism: first stage, reversible adsorption; second stage, irreversible denaturation.

11.3.2 Protein–Surface Interactions

The major driving forces for protein adsorption include hydrophobic, electrostatic, van der Waals, and hydrogen bond interactions [18]. Adsorption induced by hydrophobic interaction is an entropy-driven process, which consists mainly in the release of "frozen waters" on the hydrophobic surfaces. A nonpolar hydrophobic surface usually exhibits significant protein adsorption because the interfacial energy between the surface and water is large, and its contact with an amphiphilic protein molecule often induces protein denaturation due to the effect of hydrophobic interaction.

Electrostatic interaction is a long-range force. Because most of the serum proteins are negatively charged in vivo, a negatively charged surface should be less favorable for protein adsorption, due to the electrostatic repulsive force. Nevertheless, it is unrealistic to design an antifouling surface based on the function of electrostatic repulsive force because the electrostatic force can be easily attenuated by the presence of abundant ions in the solution, and there are always proteins carrying either a "net" or "localized" positive charge, which is favorable for adsorption.

In contrast to the electrostatic force, the van der Waals interaction is a short-range force, which decays rapidly with the distance between the interacted surfaces. Therefore, introducing a surface-coated film that prevents close contact of the protein and surface can effectively reduce the protein adsorption of a surface. The superior protein resistance of PEG-functionalized surfaces is one of the most successful cases. It is believed that the grafted PEG layer on the material surface provides a repulsive elastic force, sometimes referred to as a *steric hindrance effect*, and substantially reduces the van der Waals interaction between proteins and the substrate materials.

In addition to the steric hindrance effect, many experimental and theoretical studies also suggest that the hydrogen bond interactions between the grafted PEG chains and water

molecules, or the hydration property of PEG, play an important role in its nonfouling property. For protein adsorption in an aqueous solution, both the surface–protein association and the surface–water dissociation processes are involved. Therefore, the affinities of not only the surface–protein but also the surface–water interactions need to be considered. A surface with a higher affinity to water than to protein molecules should exhibit a better nonfouling property. In other words, protein molecules are competing for the material surfaces with water molecules, and the hydration property of the material surfaces is thus crucial in determining the nonfouling property of the materials.

11.3.3 Surface Hydration

It has been demonstrated by many experimental and theoretical studies that various hydrated states of interfacial water exist. The water in a hydrated polymer system was categorized into nonfreezing, freezing bound, and freezing states in one study [19]. Water in the nonfreezing state is tightly associated with the polymer and does not exhibit a crystallization–melting transition. Freezing bound water exhibits a crystallization–melting transition but with considerably more supercooling than that of bulk water, suggesting that it is less closely associated with the polymer. Freezing water is water with a melting temperature and enthalpy close to those of bulk water. The same study [19] indicated that the bound water content (i.e., the nonfreezing and freezing bound water), depends on the chemical and high-order structure of each polymer. For a water content above a threshold, many water-soluble polyelectrolytes, such as hyaluronic acid and xanthan gum, form a gel. Water in such gels mostly exists as freezing bound water, which plays an important role in the junction formation of gelation. Similarly, the structure of water molecules adsorbed in different hydrophilic polymers was studied by differential scanning calorimetry (DSC) and Fourier transform infrared (FT-IR) spectrometry [20]. These researchers also observed that the adsorbed water first bound to the hydrophilic site to form nonfreezable water. Then, above a water content threshold, the adsorbed waters become freezable but at a temperature lower than 0°C. The melting peak of this freezable water merged together with the melting peak of a bulklike water frozen at 0°C at very high water contents.

On the basis of the DSC data for poly(2-methoxyethyl acrylate) (PMEA), a team of researchers classified hydrated waters into three types: nonfreezing water, freezing bound water, and free water [21]. These researchers attributed the excellent blood compatibility of the material to the existence of freezing bound water crystallized at approximately −40°C. Nevertheless, another team observed that poly-MPC hydrogel contained a larger amount of nonfreezable water than did the poly–Me$(EG)_n$MA hydrogel [22]. Because the equilibrium water contents for the two hydrogels were similar, these researchers suggested that instead of freezing bound water, the amount of nonfreezable water may play a crucial role in the nonfouling property of the materials. Other researchers proposed another viewpoint by suggesting that the nonfouling ability of a surface functional group can be evaluated with respect to its intrinsic hydration capacity, which represents the overall hydrating water and is estimated based on the partial molar volume of the functional group at infinite dilution [23]. From experimental measurements and simulation evaluations for a series of hydrophilic materials, including oligo(ethylene glycol), mannitol, sorbitol, and primary amine glycine, the authors suggested a critical threshold value of hydration capacity of approximately 0.15 for the initial screening of nonfouling materials. Additionally, instead of trying to establish a specific correlation between different hydrating states and protein resistance, some authors suggest that it is the existence of a nativelike hydrogen-bounded network of water near the surface that is essential for the antifouling property of a biomaterial [24–26].

11.3.4 Strategies for Nonfouling Design

One way to judge whether a system is prone to protein adsorption is to examine the interfacial energy difference of the system prior to and after protein adsorption. Consider the molecular association-dissociation behavior of a protein adsorption process in water as the simple diagram presented in Fig. 11.4. The free-energy change of the protein adsorption process ΔG_{ads} can thus be expressed as

$$\Delta G_{ads} = \gamma_{SP} + \gamma_{WW} - (\gamma_{SW} + \gamma_{PW}),$$

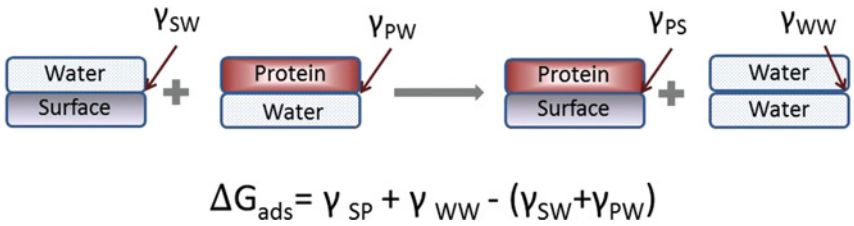

FIGURE 11.4 Illustration of the molecular association–dissociation behavior of a protein adsorption process.

where γ_{SP}, γ_{WW}, γ_{SW}, *and* γ_{PW} represent the surface–protein, water–water, surface–water, and protein–water interfacial energy, respectively, and $\gamma_{WW} = 0$. To minimize protein adsorption, the material surface should be designed to keep ΔG_{ads} as high as possible. There are two possible approaches for this goal: (1) to keep the interfacial energy between the material surface and the adsorbed protein γ_{SP} high and (2) to keep the interfacial energy between the surface and water γ_{SW} low. Proteins are amphiphilic molecules. The adsorption of a protein tends to reduce the surface-protein interfacial energy. Therefore, one expects to keep γ_{SP} high if the intermolecular forces between the surfaces and proteins are minimized. γ_{SW} is generally correlated to the hydrophilicity of the material surfaces. A hydrophilic antifouling biomaterial, such as PEG, usually exhibits a sufficiently low interfacial energy with water.

Previous research on protein–surface interactions has identified two main classes of surface coatings that can resist biofouling [11]. Among them, hydrophobic surfaces such as those of a copolymer with semifluorinated sidechains are known as *fouling release* materials, whereas hydrophilic surfaces of polymers such as PEG, are truly antifouling surfaces, often referred to as 'stealth surfaces." A hydrophobic surface exhibits a high interfacial energy with water and therefore exhibits significant protein adsorption on the surface to minimize the free energy. Nevertheless, because the interaction force between the nonpolar surfaces and proteins is low, the adsorbed proteins can be easily released by external forces such as a shear force due to fluid flow. However, because the prolonged retention of the protein molecules on a hydrophobic surface can induce protein denaturation, the antifouling characteristic of the 'fouling release' type surfaces usually is not stable and cannot last long.

Unlike the hydrophobic surfaces, a hydrophilic surface acquires its antifouling characteristic by reducing the surface–water interfacial energy and keeps the surface "undetected" by proteins in an aqueous environment [27, 28]. Water molecules, which are strong dipoles, exhibit a stronger interaction with a hydrophilic polar group than with a hydrophobic nonpolar group and therefore tend to bind on a polar/charged surface. Previous spectroscopic studies have demonstrated the existence of a nanometer-scale water layer with an increase in ordering on both hydrophobic and hydrophilic surfaces. The viscosity of the ordered water layer near a hydrophilic silica surface was demonstrated to be approximately 2–10^6 times greater than that of bulk water, which, however, is not observed for hydrophobic surfaces such as methylated silica or hydrogenated diamond [29]. The formation of a viscous interface provides evidence for the bonding between water molecules and the hydrophilic surfaces. Numerous studies have identified a strong correlation between surface hydration and nonspecific protein adsorption [12, 14, 23]. It is believed that the bound water layer forms a barrier to prevent protein adsorption on the surface. Nevertheless, the detailed correlation between the hydrated state and the nonfouling feature of the surfaces has yet to be clarified.

11.4 NONFOULING BIOMATERIALS

The nonfouling ability of a surface depends on its physicochemical properties. To obtain an antifouling surface, the use of materials with an intrinsic nonfouling chemical nature and with appropriate physical properties is necessary. There have been many attempts to identify the criteria for protein adsorption-resistant surfaces. In terms of material chemistry, several investigators tested the protein resistance of SAM surfaces terminated with various functional groups and proposed four common parameters that were likely to be important for protein resistance, including the presence of polar functional groups, the absence of any net charge, the presence of hydrogen bound acceptor groups, and the absence of hydrogen bond donor groups [30–32]. The first two criteria are generally accepted. Nevertheless, the criteria concerning the absence of hydrogen bond donor groups for protein adsorption-resistant surfaces remain controversial. Although one series of observations support the statement that the protein-resistant ability of a surface increases with the reduction of the number of hydrogen bond donor groups, this finding appears to contradict other findings [33]. For instance, SAMs of mannitol resist protein adsorption even though they contain a large number of hydrogen donors [34]. Additionally, there are nonfouling zwitterionic materials that form strong interactions with water molecules via charge–dipole interactions instead of hydrogen bonding [35].

In addition to chemical factors, the physical factors of surface packing and surface homogeneity of a material also play important roles in determining the antifouling performance of a surface. Therefore, finding an appropriate coating method to ensure optimized physical properties of a surface is also crucial in the development of an antifouling surface. Numerous studies have indicated that the protein resistance of a modified surface is dependent on the packing density, thickness, and molecular conformation of the surface film. In general, to assure protein resistance, it is necessary to have complete coverage of the surfaces by antifouling materials. For example, by making the grafting density of a PEGylated surface fall in the polymer brush regime, one can obtain a completely covered PEG-grafted surface [36]. Studies have indicated that as long as a surface is fully covered by PEG groups, the chain length does not have a strong effect on the protein resistance [37,38]. This statement was also supported by two studies [39,40] that revealed that SAMs of alkanethiolate with as few as two ethylene oxide terminal groups yielded superior protein resistance. This result occurred because the chain density of a short-chain SAM is much larger than the chain density of a grafted long-chain polymer. Nevertheless,

TABLE 11.1 Common Nonfouling Materials for Protein Adsorption

Category	Types	Materials
I	Nonionic hydrophilic materials	• OEG-/PEG-based materials • PEG-mimetic materials – Propylene suloxide – Polyglycerol dendrons and derivatives • Native/Natural-inspired materials – Peptide-based materials – peptoid-based materials – Polyoxazoline polymers – Saccharides-based materials – dextran, mannitol
II	Zwitterionic materials	• Polybetaines/ Zwitterionic SAMs – phosphobetaine (PB) – sulfobetaine (SB) – carboxybetaine (CB) • Polyampholytes/1:1 mixture of cationic and anionic SAMs
III	Amphiphilic materials	• Polymer with perfluoroalkyl tagged OEG as side chains • Hyperbranched amphiphilic fluoropolymers

an increase in surface chain density does not always increase protein resistance. Other workers reported that the packing density of OEG-SAM on silver is higher than that on gold, while the protein resistance of OEG-SAM on silver is worse [41–43]. The authors suggested that the OEG-SAMs on silver with a *trans* conformation are too dense to incorporate as much water as the OEG-SAMs on gold with a "helical" conformation. Studies on molecular dynamic simulations for protein adsorption on mixed SAMs of OEG-SAM and OH-SAM indicated that there is a correlation between the hydration and the protein resistance properties for surfaces with different OEG packing densities [44–46]. Mixed SAM surfaces with an OEG packing density that is either too high or too low exhibit higher protein adsorption. These results suggest that the appropriate packing density of an antifouling surface film should be dense enough to avoid the penetration of protein molecules and yet loose enough to allow for the incorporation of the hydrated waters.

Surface homogeneity is another important issue. As mentioned previously, a protein is a macromolecule with surface heterogeneity in charge and in hydrophobicity, and therefore, it is prone to bind to a defect site of a surface. A protein-resistant surface is thus expected to be homogeneous and defect-free. Nevertheless, certain data have indicated that some surfaces with mixtures of alternating positively/negatively charged groups or hydrophilic/hydrophobic groups also exhibit superior protein resistant ability [35, 47, 48]. These results do not contradict the abovementioned hypothesis, as it appears that a protein-resistant surface should be homogeneous. As long as the distance between the alternating groups is much smaller than the size of a protein molecule, the detailed structural distribution on the surface cannot be sensed by the protein molecule, and the surface can be considered homogeneous. For example, a polymer with zwitterionic sidechains, such as phosphatidylcholines, consists of both positive and negative charges in each pendent group, is homogeneous on a nanometer scale, and exhibits an excellent antifouling property. According to these arguments, a surface with nanometer-scale homogeneity can be considered as one of the criteria for protein-adsorption-resistant surfaces.

Various protein-resistant materials have been reported in the literature. As summarized in Table 11.1 herein, the nonfouling materials are classified into three categories: nonionic hydrophilic materials, zwitterionic materials, and amphiphilic materials. The listed materials all satisfy the criteria for protein-adsorption-resistant surfaces: the presence of polar functional groups, the absence of any net charge, and the exhibition of nanometer-scale homogeneity. In the following sections, the general methods for surface immobilization of these nonfouling materials will be first introduced. A detailed description of the antifouling mechanism, representative materials, and the design of network architecture of these three types of nonfouling materials will also be presented.

11.4.1 Surface Immobilization Techniques

There are two major methods to tether oligomers/polymers to surfaces: physisorption and covalent attachment [49]. In physisorption, nonfouling materials are typically tethered to a surface via conjugating of the nonfouling polymer chains to an anchoring group. For example, synthetic block copolymers of PEO-PPO-PEO (Fig. 11.5a) have been shown to reduce protein adsorption via the physisorption of the PPO anchoring group to the hydrophobic surfaces [50, 51]. Surface modification via physisorption usually has difficulty in reducing the protein adsorption below a certain limit because

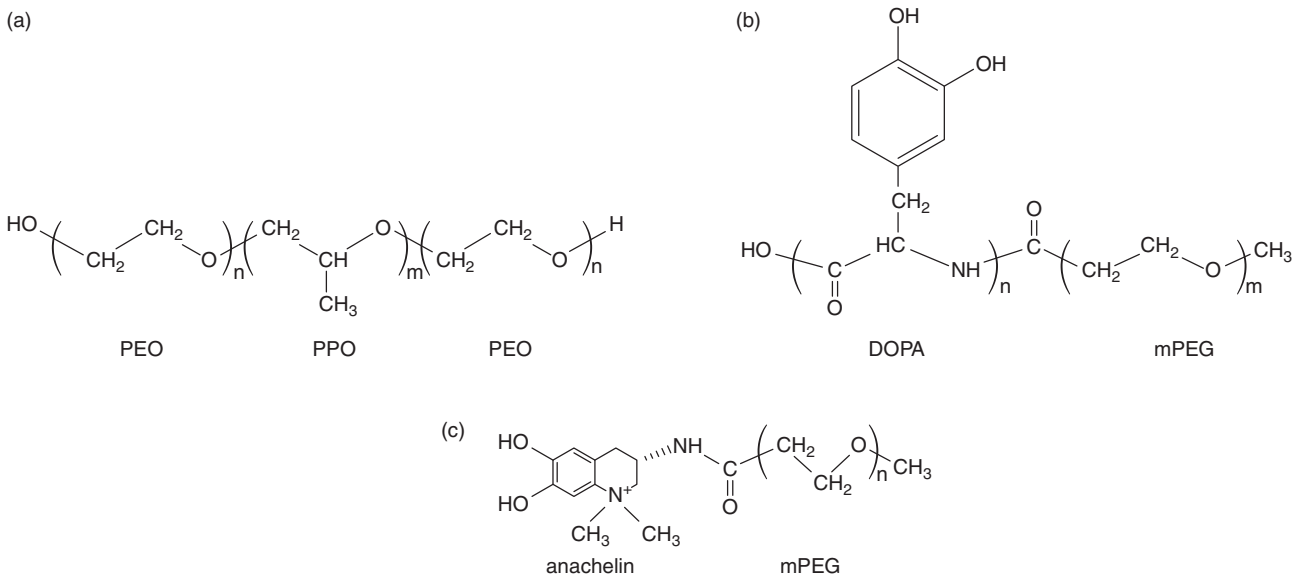

FIGURE 11.5 Structure of (a) PEO-PPO-PEO, (b) mPEG-DOPA, and (c) mPEG-anachelin derivative.

the adsorbed chain density is limited by the steric issue and the binding strength is not robust enough. Several anchoring groups, such as 3, 4-dihydroxyphenylalanine (DOPA) (Fig. 11.5b), a fragment of anachelin (Fig. 11.5c), and poly-L-lysine (PLL), have been developed on the basis of biomimetic strategies. DOPA is an unusual amino acid that is present in large amounts in mussel adhesive proteins. DOPA can form moisture-resistant bonds with various substrates including metals, metal oxides, glass, and plastics [52–54]. Anachelin is a compound used by cyanobacteria for biofilm formation [55], and PLL is a positively charged polypeptide [37]. The conjugation of various nonfouling groups with either one of these two compounds can promote adhesion to metal oxide substrates and provide surfaces with excellent protein-resistant ability.

In general, there are two main routes for the covalent attachment of nonfouling groups to a surface: (1) the *graft-to method*, where end-functionalized nonfouling polymer chains react with appropriate surface sites; and (2) the *graft-from method*, where nonfouling chains grow in situ from pregrafted initiator sites [56]. The graft-to method is simpler for preparation but tends to form a looser network with more defects [57–59]. The graft-from method is a better approach to grow polymer brushes with a high chain density and well-controlled film thickness because of the easy access of the reactive groups to the chain ends of the growing polymer. This method has been widely implemented with controlled free-radical polymerization to build high-density polymer brushes from planar surfaces. For instance, one group of investigators formed SAMs of initiator–mercaptoundecyl bromoisobutyrate on gold and then immersed the SAM-modified surfaces into a solution of oligo(ethylene glycol) methyl methacrylate (OEGMA) monomer for subsequent surface-initiated atom transfer radical polymerization (SI-ATRP). CuBr/bipyridine is added to the solution as a catalyst [60]. Figure 11.6 is a schematic representation of the structure of the OEGylated network prepared via this SI-ATRP method. The resulting surfaces successfully resisted the nonspecific adsorption of proteins when exposed to solutions of fibronectin and 10% fetal bovine serum. This SI-ATRP method is also applicable for the grafting of zwitterionic polymers such as p-SBMA and p-CBMA. Experiments indicated that polymer surfaces of p-OEGMA, p-SBMA, and p-CBMA formed using the SI-ATRP method all exhibited an increased resistance to nonspecific protein adsorption compared with SAMs with similar terminal groups. The authors attribute this improvement to an increase in the surface packing density of nonfouling groups on the surface as well as a steric repulsion from the flexible polymer brush surfaces [14, 61, 62].

11.4.2 Nonionic Hydrophilic Materials

Nonionic hydrophilic nonfouling materials contain polar groups but carry no electrostatic charges in the molecules. The primarily causes for the antifouling characteristic of this type of material is generally attributed to the formation of a hydration layer via hydrogen bonding. Because hydrogen bonding is relatively easy to break, the hydration state and nonfouling property of this type of material is closely correlated to the surface packing density [14]. For surfaces modified with polymer chains via direct attachment, the chain density is relatively low. It is essential to keep the distance between two adjacent chains smaller than the radius of gyration of the polymer chains in solution to ensure complete coverage and antifouling ability of the surfaces [36, 38]. In contrast, for surfaces modified with short-chained molecules, such as self-assembled monolayers (SAM), the chain density is usually high. Studies have indicated that sometimes reducing the packing density of a SAM-coated layer by changing the substrate [42, 63] or the solvent [44] and temperature [64] used in SAM preparation can increase the surface hydration and improve protein adsorption resistance. In addition to surface hydration, some authors have suggested that the steric repulsion [65–67] and chain flexibility [68] of the grafted polymer chains also contribute to the protein resistance of the surfaces.

11.4.2.1 OEG-/PEG-based Materials. Major nonionic hydrophilic nonfouling materials reported in the literatures are listed in the first category of Table 11.1. The oligo(ethylene glycol)/ poly(ethylene glycol) (OEG/PEG)-based materials are among the best and the most commonly used protein-resistant surfaces currently. PEGylated surfaces created using the linear/hyperbranched architectures of PEG grafts or comblike polymers with PEGylated sidechains in general exhibit good resistance to protein adsorption [14,36,69–71]. One study demonstrated that linear PEG (Fig. 11.7a) is more effective in preventing bacterial attachment than a surface with a PEG-like hyperbranched architecture (Fig. 11.7b) [64]. This effect was attributed to the differences in the strength of steric repulsion between the two molecular arrangements. However, whether the same effect works for protein resistance is yet to be confirmed. PEG is a long-chain ether consisting of many hydrogen bond acceptors. Many studies have shown that the methylation of its terminal hydroxyl group can reduce the number of hydrogen bond donors of the molecule and improve its resistance to protein adsorption [30, 32]. Similar effects of decreasing the number of hydrogen bond donors on the increasing of protein resistance ability were also observed for functional groups such as amino acids and saccharides. By replacing the hydrogen atom in the hydroxyl group with a methyl group, the protein resistance ability of these materials also increased.

The long-term stability problem of PEGylated polymers is a major limitation for their applications as antifouling coatings. PEGylated polymers tend to autoxidize and form aldehydes and ethers in a biological environment [72]. Nonfouling hydrophilic material alternatives have been continuously desired. Figure 11.7b–e shows the molecular structures of some promising nonfouling materials. Some of these

materials were designed based on the concept of preserving the main properties of PEG, such as dendritic polyglycerol (PG) and its derivatives and propylene sulfoxide. The others are either natural or bioinspired molecules. Peptide-based materials, peptoid-based materials, polyoxazoline, and saccharide-based materials all belong to this category. All of these materials displayed resistance to protein adsorption comparable to that of PEG SAMs.

11.4.2.2 PEG-Mimetic Materials. Dendritic polyglycerols (PGs) (Fig. 11.7b) and their derivatives are polyethers based on glycerol dendrimers and linear/hyperbranched polyglycidols [73–75]. These materials are highly biocompatible, and bulk PG exhibited higher thermal and oxidative stability than PEG. The protein resistance ability of this type of materials was attributed to their structural features, such as the presence of highly flexible aliphatic polyether or hydrophilic groups. Similar to hydroxyl-terminated OEG/PEGs, the methylation of all-terminal hydroxyl groups of PGs resulted in a significant improvement in protein resistance. Propylene sulfoxide (Fig. 11.7c) is derived from a parent functional group of dimethyl sulfide, which mimics the characteristics of the EG group and is more biocompatible than ethylene glycol [76].

11.4.2.3 NATURAL/Natural-Inspired Materials. Peptide-based materials were designed according to the rules of using amino acids that were hydrophilic, with uncharged sidechains, providing hydrogen bond acceptor groups and forming α-helical structures [77]. These design rules were consistent with the ones proposed by several coworkers [30–32]. The peptide bonding of this type of materials is expected to be more robust than the ether bonding of PEG-based materials. Peptoid-based materials (Fig. 11.7d) represent a promising class of bioinspired polymers that have a protein-like backbone with side chains on the nitrogen atom instead of the α-carbon [78–80]. Peptoids are highly designable because of the ease of introducing chemically diverse sidechains from simple building blocks. Poly(oxazoline) polymers (Fig. 11.7e) are generally obtained via the polymerization of 2-substituted oxazolines via a living cationic ring-opening mechanism (CROP), which yields polymers with narrow molecular weight distributions. Because of the versatility of this class of polymer, poly(oxazoline)s have the superior characteristic of the ease of preparation of polymers with various chemical functionalities and architectures [81]. For instance, one team prepared comb polymers with a polycationic poly(L-lysine) (PLL) backbone and poly(2-methyl-2-oxazoline) (PMOXA) sidechains. This PLL-*g*-PMOXA copolymer is able to spontaneously adsorb onto metal oxides surfaces and provides the adsorbed surfaces with excellent protein resistance [82]. Dextran and mannitol are saccharide-based natural materials. Surfaces grafted with saccharide-based materials mimic the antifouling glycocalyx present at endothelial cell surfaces. Polysaccharide is the major component of the glycocalyx, which prevents nonspecific protein adsorption with cell surfaces in serum. For example, polymers with hydrophilic dextrans or maltose dendrons grafted to a flexible polyvinylamine backbone as sidechains have been shown to effectively reduce protein adsorption [83–85]. Mannitol is a sugar alcohol derived from mannose by reduction. This material exhibits superior protein-resistant ability, although it contains a large number of hydrogen bond donors of hydroxyl groups, which is contradictory to the criteria of nonfouling materials proposed by several coworkers [30–32].

11.4.3 Zwitterionic Materials

Biomimetic zwitterionic materials, such as phosphorylcholine (PC), have attracted extensive attention recently because of their excellent antifouling performance. Similar to hydrophilic nonfouling materials, water hydration on the surfaces of zwitterionic materials is also believed to play a crucial role in their antifouling ability. Various studies have indicated that more bound water was observed around zwitterionic surfaces than other nonionic hydrophilic or hydrophobic surfaces [22, 86]. Another group of coworkers attributed the hydration of a zwitterionic material to the ionic solvation due to the strong charge–dipole interactions between the positive and negative charge units of the zwitterionic groups and water molecules [14, 87]. These authors suggested that the strength and nature of hydrations between ionic solvation for zwitterionic materials are different from those of hydrogen bonding for hydrophilic materials. However, based on Raman and infrared spectroscopy data, another team raised a different viewpoint, suggesting that the existence of an unperturbed native hydrogen bonded network near the surface is a necessary feature for antifouling properties [24–26, 88]. Another report suggested that the protein resistance ability of a surface is related to the accessibility of the protein surface to the surface molecules [35]. This hypothesis is based on the observation by Kane et al. that most of the protein-resistant surfaces contain kosmotropes. *Kosmotropes* are moieties known to be able to stabilize a protein structure by being excluded from protein surfaces [88]. A surface with zwitterionic moieties, such as betaine and taurine, exhibits a strong interaction with water molecules, which may cause the ordering of the water molecules near the surface and thus cause the surface molecules to be preferentially excluded from the protein surface.

Zwitterionic polyelectrolytes contain both cationic and anionic charges on the same macromolecular chain. There are two types of poly-zwitterionic materials: polybetaines and polyampholytes. Polybetaines possess the opposite charged groups on the same monomer units, while polyampholytes possess the anionic and cationic groups on different monomer units. Schematic diagrams similar to that

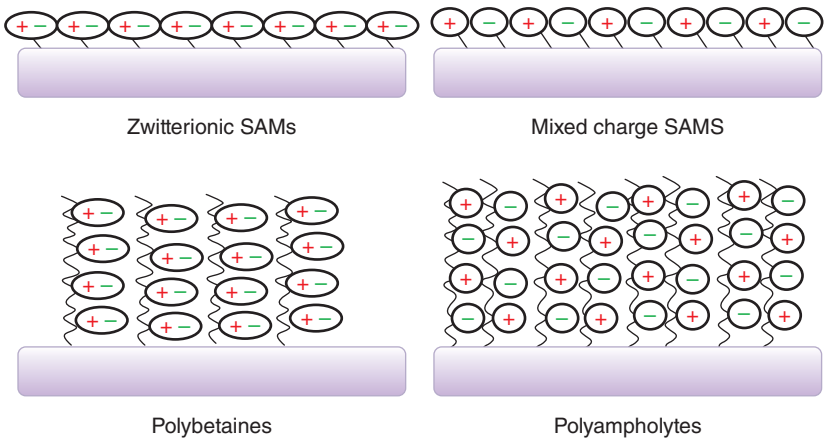

FIGURE 11.8 Schematic diagrams illustrating the ideal charge distributions of (a) zwitterionic SAM, (b) 1:1 mixture of cationic and anionic SAM, (c) polymer grafts of polybetaines, and (d) polymer grafts of polyampholytes.

proposed in one report [14] illustrate the ideal charge distributions of self-assembled monolayers containing zwitterionic terminal groups/a 1:1 mixture of cationic and anionic groups (Fig. 11.8a,b) and surfaces immobilized with polybetaines/polyampholytes (Fig. 11.8c, d). The extremely high dipole moment of zwitterionic groups in polymeric and SAM structures leads to strong inter- and intramolecular dipolar interactions and the association of the polymer chains, which provides the surface with a range of unique properties, such as ultralow protein resistance and stability over a wide range of pH values and ionic strengths [90]. Previous studies indicated that the charge balance, minimized dipole, uniformity of charge distribution, and packing density were key factors in determining the nonspecific protein resistance of the zwitterionic surfaces [14, 46, 91, 92]. A surface covered with a nanometer-scale homogeneous mixture of balanced charge groups can provide the surface with stable ultralow fouling properties. Experiments also indicated that due to the wetting transitions of the polyzwitterionic brushes driven by self-association, optimum chain lengths exist for the nonfouling polyzwitterionic grafts formed by the ATRP method [93,94].

11.4.3.1 Polybetaines. Betaine is a neutral compound with a positively charged functional group and a negatively charged anionic functional group, which may not be adjacent to the cationic site. In nature, various types of betaines can be synthesized by cells to serve as biological osmolytes for the protection of cells, proteins, and enzymes against environmental osmotic stress, high-salinity drought, or extreme temperature. The name of a betaine generally reflects its anionic moiety. Three major types of biomimetic polybetaines–phosphobetaine (PB), sulfobetaine (SB), and carboxybetaine (CB) (Fig. 11.9), all with the same cationic ammonium group–have been reported for their applications in nonspecific protein resistance. Among these polybetaines, a PB such as phosphorylcholine (PC) mimics the zwitterionic structure of the PC headgroups of membrane lipids. SB is an analoge of taurine betaine, which has been extensively studied due to the ease of synthesis [60, 94–98]. Polycarboxybetaine is the first synthetic polybetaine. CB groups are usually more hydrophilic than SB [99]. Because of the unique features of its dual functionality, polycarboxybetaine has the advantage of carrying abundant functional groups for ligand immobilization [100]. Nevertheless, by lowering the pH of the aqueous medium, a CB group can be protonated more easily than a SB group and consequently render the surface cationic [101]. Various immobilization methods, including physisorption via DOPA linkage [54], covalent fixation via SI-ATRP [98], and self-assembly [102], have been applied to demonstrate the non-fouling properties of the zwitterionic materials.

11.4.3.2 Polyampholytes. Polyampholytes, which carry both the positive and negative moieties along the polymer backbone or on the sidechains, have been synthesized by copolymerization of both anionic and cationic monomers.

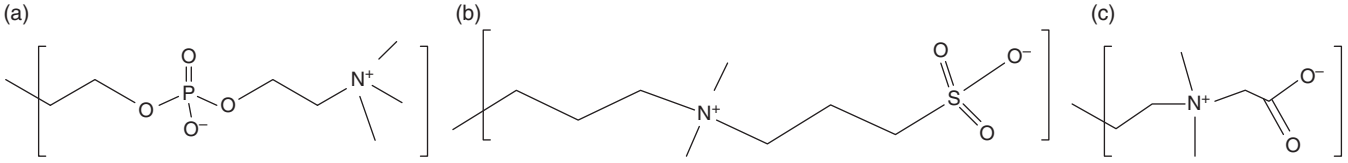

FIGURE 11.9 Chemical structures of (a) phosphobetaine (PB), (b) sulfobetaine (SB), and (c) carboxybetaine (CB).

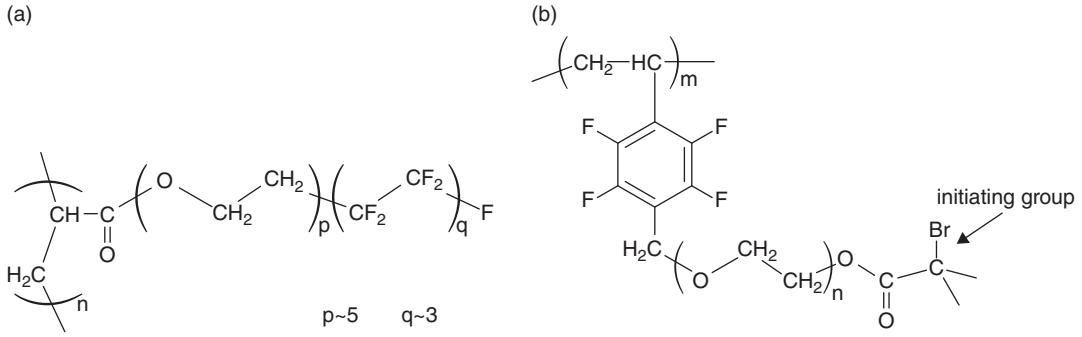

FIGURE 11.10 Molecular structures of amphiphilic polymers: (a) polymer with perfluoroalkyl tagged OEG as sidechains; (b) hyperbranched amphiphilic fluoropolymers.

Although these materials have received less attention in the literature than polybetaine systems, polyampholyte systems are promising for antifouling because the charge neutrality and the uniformity of the charge distribution of the polymers can be obtained by controlling the ratio of the two oppositely charged monomers of the reaction mixture before co-polymerization [103, 104]. It has been demonstrated that the ion pair comonomer polymers with negligible defects can be achieved, and the polymer surfaces displayed excellent resistance to protein adsorption for various polyampholytes such as negatively charged 2-carboxyethyl acrylate (CAA)-based or 3-sulfopropyl methacrylate(SA)-based mixtures with positively charged NH_2, dimethylaminoethyl methacrylate (DM), diethylaminoethyl methacrylate (DE), and [2-(acryloyloxy)ethyl] trimethyl ammonium chloride (TMA) [45,105,106]. Another promising polyampholyte system is polypeptides consisting of alternating positively charged residues such as arginine (Arg) or lysine (Lys) and negatively charged residues such as aspartic acid (Asp) or glutamic acid (Glu). Similar to natural proteins, this type of polyampholyte is biodegradable and the degradation products are nontoxic amino acids. Two reports demonstrated that peptides with alternating Glu/Lys or Asp/Lys have ultralow protein adsorption to various plasma proteins [107, 108]. SAMs with a 1:1 mixture of cationic and anionic charged groups also exhibit similar characteristics. It is believed that the possible rearrangement of charge groups due to the soft backbone of polyampholytes or the mobility of thiols on gold might reduce the defects in the charge distribution of polyampholytes and mixed SAM, respectively, and rendered both surfaces with nanometer-scaled homogeneity [14]. The polyampholytes/mixed SAMs system provides easy routes for the design of a wide range of new nonfouling zwitterionic surfaces.

11.4.4 Amphiphilic Materials

Amphiphilic nonfouling materials are polymers containing both of the hydrophobic fluorinated and hydrophilic PEGylated groups. These materials were designed to combine the *fouling release* characteristic of the low-energy fluorinated groups and the antifouling feature of the hydrophilic PEGylated groups. Amphiphilic nonfouling polymers with different molecular architectures have been reported, including a polymer with perfluoroalkyl tagged OEG as sidechains (Fig. 11.10a) and hyperbranched amphiphilic fluoropolymers synthesized by atom transfer radical polymerization from an amphiphilic monomer with an initiating group (Fig. 11.10b). The polymers with the amphiphilic sidechains tend to form a uniform lamellar structure parallel to the substrate [109]. The wettability of the surfaces of this type of polymer is environmentally responsive due to the rearrangement of the perfluoroalkyl and PEG groups in the lamellar structure. Surfaces coated with hyperbranched amphiphilic fluoropolymers exhibit a completely different surface molecular structure. The surfaces were designed based on the hypothesis that a surface composition with heterogeneity small enough in size will enhance resistance to protein adsorption [11]. Although this hypothesis lacks solid evidence, surfaces grafted with zwitterionic materials, which consist of nanometer-scaled heterogeneity in charge distribution, are consistent with this hypothesis. Hyperbranched amphiphilic fluoropolymers enhance the surface resistance to protein adsorption by introducing nanometer-scale variation in surface hydrophilicity/hydrophobicity. One study indicated that high protein resistance of this type of fluoropolymers can be achieved at an optimal hydrophilic-to-hydrophobic monomer ratio [47]. Another team also reported that surfaces coated with the hyperbranched fluoropolymers synthesized by atom transfer radical polymerization of an inimer shown in Fig. 11.10b exhibit surface heterogeneity small enough to resist protein adsorption [48]. It is believed that the effectiveness of the amphiphilic materials on protein resistance is closely related to the dedicate balance of the hydrophilicity between the polar and nonpolar groups. Further studies on the mechanism for protein resistance of this type of material are necessary.

11.5 CONCLUSIONS AND FUTURE PERSPECTIVES

The development of materials with ultralow protein adsorption has a wide range of industrial and biomedical applications. From the results of numerous studies on the mechanism of protein adsorption, it is generally accepted that the nonfouling properties of a material are closely related to the surface hydration behavior of the materials. General criteria for protein adsorption-resistant surfaces include the presence of polar functional groups, the absence of a net charge, the possession of nanometer-scale homogeneity, and being defect-free. PEG-based materials have long been the most commonly used antifouling materials. To overcome their limitation for long-term usage caused by the oxidation of the materials, various alternative materials have been developed. On the basis of the polarity of the materials, from high to low, these nonfouling materials are classified into three categories: zwitterionic materials, nonionic hydrophilic materials, and amphiphilic materials. Among these materials, the zwitterionic materials, which have the strongest interaction with water and tend to form a dense film on surfaces via interchain association, reveal especially promising outcomes for future development. It has been well documented that the protein resistance of a surface is determined not only by the chemical properties of the materials but also by the physical properties, such as the packing density and chain mobility, of the surfaces. Future studies on correlating the molecular-level details of a surface and the water hydration states for surfaces under various physicochemical conditions should provide useful information on understanding the antifouling mechanism and in developing adequate surface modification techniques for antifouling surfaces.

12.1 INTRODUCTION

The molecule-level interactions between materials and biological systems are not clear and completely understood. There is a need to decipher these interactions, as the surface modification of the biomaterial influences the response of proteins and cells, known as *biocompatibility* and *blood compatibility*, respectively. Thus, it is vital to comprehend the biomaterial surface to obtain insight on the nature of biological reaction [1]. It is well known that biomaterials have to satisfy many conditions for its successful use in biomedical applications [2, 3]. However, the nature of the surface of a biomaterial is the most important criterion, as biological reactions occur on the surface and at interfaces [1, 4, 5]. The surface properties such as hydrophilicity, chemical structure, and topography govern the adhesion and proliferation of cells, which play significant roles in biocompatibility as well as in tissue engineering applications [6–10].

The surface is a miniscule part and differs from the bulk of the biomaterial. This is due to the mode of preparation and the thermodynamics involved, which leads to structural reorganization, resulting in the change of the adsorption behavior and other related surface reactions in the biomaterial [11]. Therefore, it is essential to have a set of analytical techniques that can perform comprehensive characterization of both the bulk and surface properties of a biomaterial to evaluate and correlate the changes in the biological performance.

Collagen, the biopolymer, is found abundantly in the extracellular matrix and connective tissue of the mammals [12, 13]. The ease of preparation has enabled it to be widely used as a biomaterial [14]. This fibrous protein provides structural integrity and performs a vital role in the formation of tissues and organs [15]. The advantages of using a naturally derived material such as collagen as biomaterial are its high biocompatibility and intrinsic biological recognition [16–19]. Also, this biopolymer possesses features such as biodegradability and reduced antigenicity, which renders it as an excellent substrate for cell attachment and its growth [20–22], the criteria essential for its application as a biomaterial. Moreover, the structure of collagen and its interaction with host tissue allow it to act as an efficient matrix to produce diverse forms of biomaterials and therefore, it is used extensively in various biomedical fields such as scaffold in tissue engineering applications [23]. The structure and use of collagen scaffolds in various forms are depicted in Fig. 12.1. In addition to the above mentioned desired features, collagen is nontoxic and has a safe profile as a scaffold for biomedical purposes [14]. Thus, collagen-based biomaterials as scaffolds

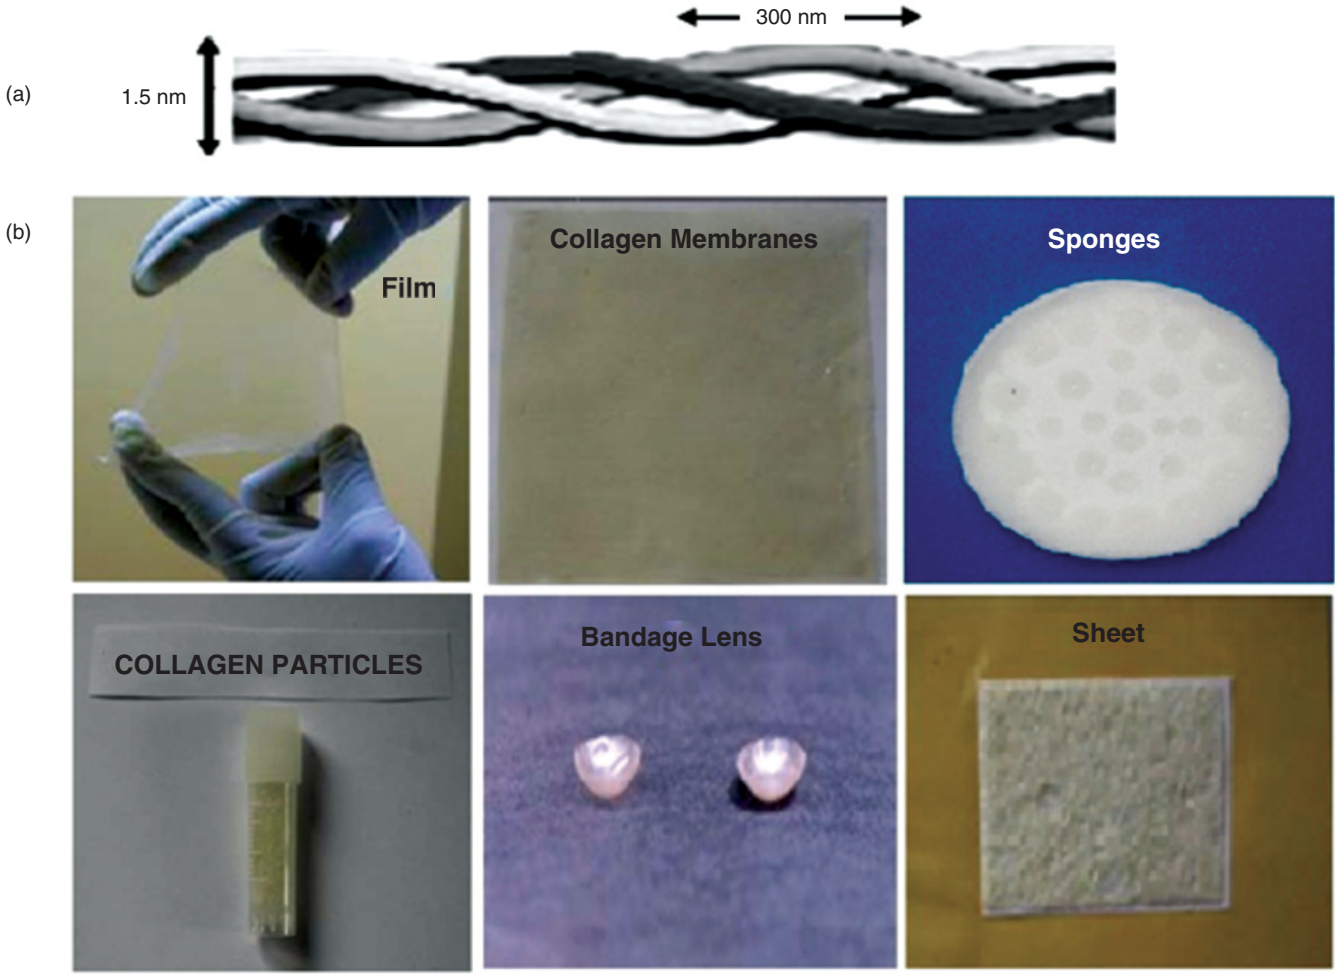

FIGURE 12.1 Schematic representation of collagen (a) triple helical structure and (b) its use as a scaffold in different forms for biomedical applications.

prepared in our CLRI laboratories have found application in tissue engineering and in regenerative medicine.

The use and application of nanoparticles for biomedical applications have gained significant importance. Among them, the role of silver nanoparticles as antimicrobial agent is well established and has been extensively utilized in the preparation of wound-dressing materials [24–26]. Moreover, it has found use as imaging agent [27, 28] and also in sustained-release drug delivery [29, 30]. Iron oxide (Fe_3O_4) nanoparticles have also found use in the biomedical field, where its magnetic properties have been used in the cell seeding into 3D scaffolds [31], cell labeling [32], contrast agent in MRI [33, 34], and as targeted delivery systems in the treatment of cancer-related diseases [35, 36]. Therefore, the incorporation of nanoparticles, particularly silver and Fe_3O_4, and their interactions with various biological molecules such as collagen have been the subject of investigation. This review presents an overview of the state of the art on the major tools applied to the characterization of collagen-based biomaterials as scaffolds for tissue engineering applications and in regenerative medicine. The characterization of nanoparticle-incorporated collagen scaffolds is divided into three main parts in this review: (1) *structural aspects*–focused mostly on determination of molecular mass, purity, and helical content confirmation in addition to other associated bulk thermal properties; (2) *chemical characteristics*–focused primarily on surface elemental analysis; and (3) *morphological characteristics*–observed at different length scales. It is expected that this type of evaluation can offer a reliable basis for comparison of collagen-based biomaterials as scaffolds and also assist in attaining new insights into the nature of reactions with these biomaterials. The techniques employed for the characterization of collagen-based biomaterials as scaffolds along with the format and obtained information are listed in Table 12.1. Although numerous methods can be used for the characterization of collagen scaffolds, the selected techniques mentioned in the table are the most preferred for the collagen-based scaffolds and thus, the

TABLE 12.1 Characterization Techniques for Collagen-Based Biomaterials Used as Scaffolds

Techniques	Collagen Format	Required Concentration	Obtained Information
SDS-PAGE [39]	Soln.	10–30 μg	*Structural* Size (Mol. wt)
CD [10]	Soln. or Film	Soln.: 0.125 μg/L Film: 100% dry wt.	*Structural* 2° and 3° structure
DSC [10]	Film	10 mg dry wt.	*Structural* Denaturation Temperature Heat capacity
XRD [10]	Film, sheets, sponges	<100 mg	*Structural* Crystalline phases
FTIR [11]	Film, sheet, sponges	<100 mg	*Chemical* Chemical Composition Molecular Orientation
XPS [5, 11]	Films, gels, sponges	Films: 20–650 μg/cm^2	*Chemical* Elemental Composition Chemical bonds Surface functional groups Film thicknesses
SEM [5,10]	Films, fibers, sponges	Films: 20–650 μg/cm^2	*Morphological* Topography Phases Defects (cracks, pits)
AFM [6]	Films and fibers	Films: 20–650 μg/cm^2	*Morphological* Topography Phases & defects Mechanical properties/Surface roughness

information acquired from these techniques enable to assess the suitability of the scaffolds for various biomedical applications.

12.2 STRUCTURAL INFORMATION

12.2.1 SDS-PAGE Analysis

Electrophoresis is the study of movement of charged molecules under the influence of an electric field. For low-molecular-weight molecules such as amino acid and carbohydrates, cellulose is used as support medium, while thin gels of agarose and polyacrylamide are widely used for larger molecules such as proteins (e.g., collagen). The mobility of a substance in the gel is governed by both its charge and its size. Thus, the general electrophoretic technique is not suitable and cannot be used to measure molecular weight of the biological molecules. For biological molecules such as collagen, the electrophoretic mobility will depend on size, provided it possesses uniform charge. The molecular weight of collagen is estimated when subjected to electrophoresis in presence of a detergent, sodium dodecyl sulfate (SDS) and a reducing agent β-mercaptoethanol. The SDS treatment disrupts the structure of the protein (2°, 3°, and 4°) such as in collagen to produce a linear polypeptide chain coated with negatively charged SDS molecules. The reducing agent β-mercaptoethanol cleaves the disulfide bonds in proteins and facilitates the denaturation process [10].

Assessment of collagen source is based on purity, and its breakdown into smaller fragments is performed via sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Visualization of protein fragments is done by loading of collagen sample in the wells of a thin gel when electric voltage is used to drive the protein fragments. The electrophoretic patterns of type I collagen obtained from Achilles tendon and fish scales are shown in Fig. 12.2.

The molecular weight for a chain of these collagens, using globular proteins as standards, was found to be approximately 100–150 kDa. In general, the molecular weight of collagen could be overestimated when globular proteins are used as molecular weight markers, due to high content of smaller amino acid residues, glycine, proline, and alanine, respectively [37]. Collagen isolated from fish scales and Achilles tendon is composed largely of α chain along with considerable amounts of inter- and intramolecular cross-linked components of α chains and β (dimer), as observed by other

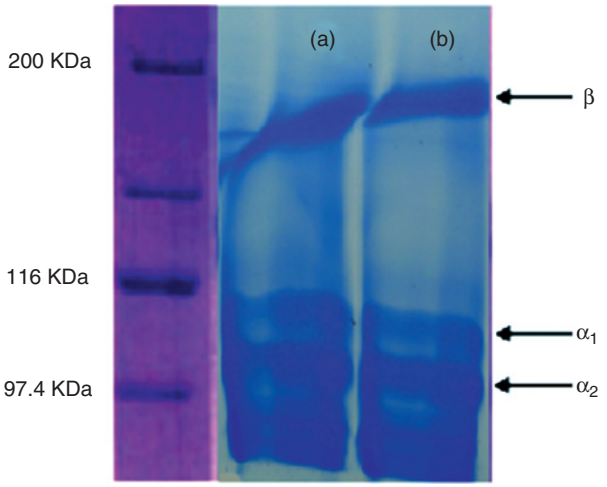

FIGURE 12.2 SDS-PAGE of collagen isolated from (a) Achilles tendon and (b) fish scales, respectively.

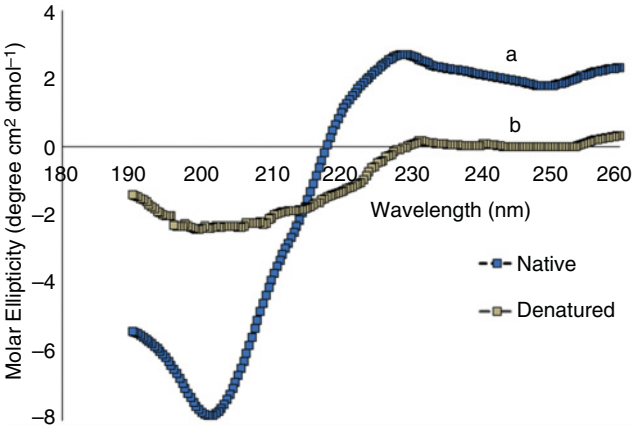

FIGURE 12.3 Circular dichroism spectra of collagen solution in its (a) native and (b) denatured states, respectively.

researchers [38, 39]. Thus, it is evident that lysine-derived cross-link was present in the soluble collagen fraction of tendons [40–42]. The extracted collagen from Achilles tendon comprised of at least two different α chains (αl and α2) with different mobilities, as evidenced in type I collagen from fish scales [43, 44]. Hence, SDS-PAGE can be used to determine purity and to elucidate the type of collagen.

12.2.2 Circular Dichroism (CD) Studies

The differential absorption of polarized light in asymmetric and circular manner forms the basis of circular dichroism and can be used to determine structure and conformation of proteins or the biological molecules [10, 45]. This technique has been extensively utilized to characterize the conformation and helical content of collagen extracted from different source materials. The structural, conformational changes of collagen extracted from different sources such as rat tail tendon, catfish and sepia cartilage, and fish scales in the presence of different surfactants have been studied in detail [46–48] using different techniques. The use of CD, for instance, enables us to determine the specific optical activity resulting from the orientation of amide bonds in highly ordered regions, which is used to elucidate and determine α helices and β sheets of the collagen structure [45, 49]. This is very essential as the triple-helical structure of the collagen imparts required structural properties to the cells and tissues that are utilized when used as scaffolds for tissue engineering applications [42, 50]. For example, CD as a technique has been employed for conformational analysis of collagen and structural effect even when incorporated in the polymer–collagen matrices, fabricated as scaffolds for tissue engineering purposes [9,51]. Also, for a comparative study to understand the behavior of MG63 osteoblast cells grown on the electrospun collagen and gelatin matrix, CD analysis indicated a massive loss of triple-helical structure in an electrospun collagen matrix and the random coils were similar to those found in gelatin [52].

Circular dichroism can be used to inspect helical content of collagen as a function of temperature and assists in understanding the changes in structure and its related chemistry [53]. The helical content of 3D-gelatin-based scaffolds prepared for biomedical applications was confirmed by CD studies [54]. In gelatin, the denatured form of collagen, a significant decrease in positive peak at 221 nm and also reduction in negative peak at 197 nm was recorded, respectively (see Fig. 12.3). This observation suggests that the thermal denaturation causes disruption of the collagen triple-helical structure, and this process is normally irreversible because the self-assembly of collagen chains in an appropriate manner is complex and complicated [55]. In collagen-based biomaterials, helicity of collagen plays an important role in the cellular remodelling responses [56, 57]. The in vitro remodelling rates and cell count of fibroblast improved drastically in gelatin compared to collagen matrix. This observation supports the fact that denatured collagen is responsible for the enhancement of remodelling rate needed for integration of implants [56]. However, it is also documented that mechanical properties of subchondral bone are greatly reduced with the increase in denatured collagen content [58]. Hence, the rate and extent of the helicity of collagen is vital in order to achieve better cell response both in vitro and in vivo as well as to maintain desired mechanical properties required for the efficient function of the tissue-engineered matrix.

The effect of incorporation of silver and iron nanoparticles in collagen has been documented in the literature. CD spectroscopy has also been widely used to characterize the interaction of collagen with that of other small molecules or with nanoparticles such as silver and iron oxide and also to

determine the effect on the stability of the collagen [59–62]. A study Xiufang *et al*. [63] using CD to determine the effect of metallic ions such as Fe^{3+}, Al^{3+}, and Ca^{3+} on the collagen molecules, found a large negative peak near 194 nm and a small positive peak near 222 nm in the CD spectra. The observed loss in ellipticity near 194 nm is attributed to the fact that the incorporation of metallic ions induces a change in secondary structure of collagen. The structural transition from random-helix coil in collagen occurs when the trivalent ions, especially Fe^{3+}, binds with negatively charged free carboxyl groups of collagen and results in cross-linking of the three strands of helices to induce a stretch force, which causes the helix to loosen and become random at the binding sites [63]. The effect of UV irradiation on the physicochemical properties of iron-cross-linked collagen examined via circular dichroic studies reveal changes in the collagen conformation only when subjected to prolonged UV irradiation [64]. This consequence is attributed to the additional stability provided by the crosslinking effect with iron nanoparticles. Recently, the interaction between the collagen-binding domain of Rhusiopathiae surface protein B ($rRspB_{31–348}$) and AgNPs by employing different methods such as CD spectroscopy has been investigated [65]. The CD spectroscopy was used to ascertain the cause for the loss of binding of $rRspB_{31–348}$ with collagen in presence of AgNPs. In order to evaluate this effect, three different ratios, 1:2, 1:6 and 1:10 of AgNPs were added to $rRspB_{31–348}$ and analyzed with far-UV CD spectroscopy. Since, nanoparticles that are not chiral don't affect the protein CD spectra [66], no shift in ellipticity was observed in the CD spectra for two different concentrations of 1:2 and 1:6 and similar secondary structure of $rRspB_{31–348}$ with well-defined antiparallel β-pleated sheets was noted. However, in case of 1:10 ratio, AgNPs did have some effect on $rRspB_{31–348}$, and the increase in ellipticity suggests loss of secondary structure of the protein. This analysis evidently indicates that AgNP-mediated inhibition to collagen binding is not due to a loss in the structural integrity of $rRspB_{31–348}$ but mainly due to the complex formation and its interaction with AgNPs [65].

The biocompatibility and antibacterial properties of photochemically synthesized silver nanoparticles stabilized by collagen were studied [67]. In the study, the UV-CD measurements for the changes in the secondary conformation of collagen in presence of AgNPs were carried out. The UV-CD spectra reveal that the presence of AgNPs in collagen neither alters its position (195 and 220 nm) nor the intensity and thus, the right-handed triple helical conformation of collagen is preserved. However, in another study, UV-CD as a scientific tool when employed to evaluate the secondary structure of proteins in solution showed silver nanoparticles capable of interacting with collagen in aqueous medium in presence of some commonly used cross-linkers [68]. More recently, collagen scaffolds containing AgNPs coated by different concentrations of mixed surfactant of PEG/TX-100 systems have been synthesized and characterized [69]. It would be interesting to study, if there is any difference in helicity as a function of temperature at these different concentrations. Also, no reports on the effect of conjugated silver and Fe_3O_4 NPs on collagen triple helicity as a function of temperature is available and can be conducted in near future. Furthermore, the conformational changes in the collagen cross-linked with AgNPs and also the effect of temperature on the protein conformation using CD technique are not well documented in the literature. However, it is important to note that the precision of the quantitative assessment of helicity is based on the accuracy to determine the solution concentration, molecular mass, and amino acid content. Also, the algorithms employed to convert the signals to obtain structural information are based on globular proteins and thus, the interpretation of CD data is usually difficult for fibrous proteins such as collagen [10].

12.2.3 Differential Scanning Calorimetry (DSC)

Differeential scanning calorimetry measures the temperature dependence of partial heat capacity and thus allows determination of the enthalpy. The heat capacity is calculated by the change in electrical energy needed to increase temperature of the sample compared to that of reference solvent regulated by heating rate. When the mass and temperature are known, heat capacity and melting temperature of the samples can be obtained [70].

DSC is employed to establish the bulk thermal properties of collagen-based biomaterials and also in the case of cross-linked collagen scaffolds [71,72]. Denaturation of collagen, an endothermic reaction, occurs at a very slow rate in equilibrium conditions and corresponds to the breakdown of triple collagen helix, yieling a random structure, gelatin. DSC studies of both collagen (native and anionic) and respective blends with chitosan confirmed the preservation of collagen triple helix because denaturated collagen do not have any thermal transition in the region of 47–51°C, which is the denaturation region [73]. The thermal denaturation of type I collagen vitrified gels using DSC has been conducted [74]. In thermal denaturation, the kinetic energy generated due to the heat interaction disrupts and denatures the secondary and tertiary structure of collagen. This denaturation process can be reversible or irreversible depending on the heating rate [75]. The activation energy of collagen vitrigels for the irreversible process ranges from 100 to 200 kJ/mol, while the reversible enthalpy was found to be 250–300 kJ/mol [74]. The temperature at which the protein like collagen unfolds is known as the *melting temperature* (T_m). The rate of sample heating can impact thermal transitions and so collagen like peptides are heated at rates no greater than 0.2°C/min for accurate determination [76]. The limitation here is that incomplete drying of sample can lead to errors in determination of the melting temperature.

Although DSC has been widely used to determine thermal transitions of collagen-based materials, only limited information on the interaction of nanoparticles, especially silver and Fe_3O_4, with collagen are available in the literature. An investigation of collagen scaffolds incorporated with silver nanoparticles capped by mixed surfactant PEG-TX-100 system was conducted [69]. The DSC results exhibited an increase in denaturation temperature (T_d) of collagen from 40°C to 45°C in presence of PEG+AgNPs system in collagen scaffold. However, it was observed that with the increase in concentration of PEG from 0.3 mM to 0.9 mM, the T_d value decreases. A similar trend was observed for collagen scaffolds having AgNPs+TX-100 systems. For mixed systems, namely, AgNPs coated with PEG+TX-100 into collagen scaffolds, the T_d values of collagen were noted to increase and reach maximum value of 47°C when the surfactant concentration was 0.6 mM. This suggests that mixed surfactants at optimum concentration stabilize the collagen structure [69]. However, no reports on the effect of cross-linking of silver nanoparticles with collagen scaffolds using DSC have been carried out. Similarly, limited information is available on the effect of Fe_3O_4 NPs incorporation on collagen using DSC technique. Collagen-based magnetic nanocomposites for oil removal applications have been performed [77]. The study used DSC to evaluate the changes in the hydrothermal stability of the collagen in presence of Fe_3O_4 NPs. The pristine collagen displayed an irreversible shrinkage known as *shrinkage temperature* or *hydrothermal stability* at 65°C. However, in presence of Fe_3O_4 NPs, the hydrothermal stability of collagen increased to 86.8°C. This observed increase in shrinkage temperature is attributed to the electrostatic interaction between citric acid coated on the Fe_3O_4 NPs and the side chain groups of collagen molecules present in the pentafibril assembly. Thus, DSC can serve as a tool to obtain valuable information on the structural changes along with thermal stability when nanoparticles such as silver and Fe_3O_4 are incorporated in collagen-based systems and thereby enabling to evaluate its applications in biomedical fields.

12.2.4 X-Ray Diffraction (XRD)

X-ray diffraction is a versatile and nondestructive technique used for the determination of the crystallographic identity of the synthesized biomaterial, structural composition, and phase purity and for calculating the mean particle size based on the broadening of the most prominent peak in the XRD profile [78]. Scherrer's equation: $D = K\lambda/\beta \cos\theta$ is used to calculate the average particle diameter D (in Å) [79]. Moreover, the intensity of the diffraction can be used to quantify the proportion of the synthesized nanoparticles (e.g., Ag/Fe_3O_4 NPs) formed in a mixture by comparing experimental peaks and reference peak intensities [80, 81].

In a report [82] on the synthesis and characterization of silver nanoparticles capped by PEG, the film XRD showed

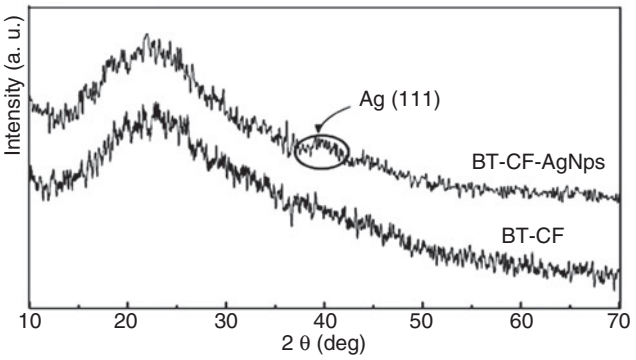

FIGURE 12.4 XRD pattern of BT-CF and BT-CF-AgNPs, respectively [85].

prominent peaks at 2θ values of about 38°, 44.2°, 64.4°, and 77.6°, which represent the (111), (200), (220), and (311) Bragg's reflections of silver having a face-centered cubic (fcc) structure, respectively. These are in accordance with the values reported for silver nanoparticles in the literature [83, 84]. Similarly, XRD showed these characteristic peaks for silver nanoparticles capped by the mixed surfactant (PEG+TX-100) systems. However, when these capped silver nanoparticles were incorporated in collagen scaffolds, an amorphous peak at 23° was noticed [68]. Also, XRD was employed to determine the structural information of the synthesized AgNPs stabilized by bayberry (BT) grafted collagen fiber (CF) [85]. The XRD pattern of BT–CF and BT–CF–AgNPs is shown in Fig. 12.4.

An amorphous peak at 23° attributed to the collagen fiber was observed in both while the XRD spectrum of BT–CF–AgNPs exhibited a weak peak at 39.3°, which is consistent with the Ag(111) plane diffraction peak of the Ag crystal [86]. Also, the broad and weak intensity of the Ag(111) face noticed was attributed to the small crystalline and good dispersion of AgNPs. In another study, XRD patterns of size-controlled silver nanoparticles on polyphenol-grafted collagen fiber ($Ag–EGCG_{0.3}–CF$) also exhibited a broad signal around 23° attributed to the amorphous polymer phase of the collagen fiber [87]. In addition, four diffraction peaks at 2θ = 38.3°, 44.4°, 64.6°, and 77.6° corresponding to the (111), (200), (220), and (311) crystal planes, respectively, which are characteristic of fcc crystalline silver, were observed. Similarly, XRD has been used to study the structural modifications and their effects on Fe_3O_4 NPs [88]. The XRD patterns of both bare and amine-functionalized Fe_3O_4 NPs synthesized their position and relative intensity of all diffraction peaks matched with the reference Fe_3O_4 diffraction data provided in the literature [79, 89]. A series of characteristic peaks at 2θ = 31°, 36°, 43°, 54°, 57°, and 63° corresponding to (200), (311), (400), (422), (511), and (440) Bragg reflections of cubic spinel structure of Fe_3O_4, respectively (see Fig. 12.5). Also, the particle size of bare and

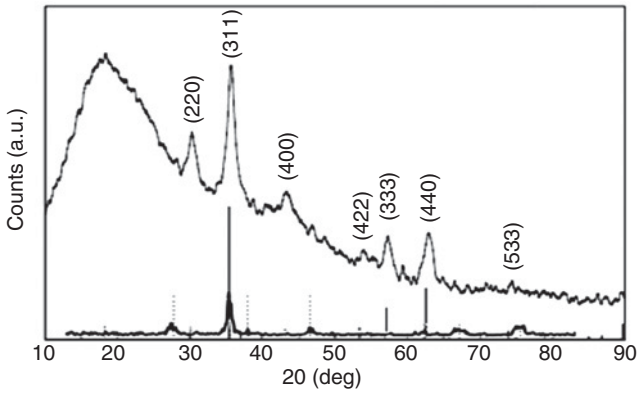

FIGURE 12.5 XRD pattern of bare and amino functionalized Fe_3O_4 nanoparticles [88].

amine- functionalized Fe_3O_4 nanoparticles were calculated by scans using Scherrer's equation. The diameters of bare and amino-functionalized Fe_3O_4 NPs were found to be 19 and 21 nm, respectively. Similarly, another team [90] compared the XRD spectra for Fe_3O_4 and surface- functionalized Fe_3O_4 NPs coated with 3-aminoprpyltriethyloxysilane (APTES) and mercaptopropyl triethyoxysilane (MPTES). The data (all curves) showed diffraction peaks at 2θ values of 18.6°, 30.4°, 35.7°, 37.3°, 43.2°, 53.7°, 57.3°, and 62.8°, indexed to the (111), (220), (311), (222), (400), (422), (511), and (440) planes, respectively. The structure was not changed in the functionalized Fe_3O_4 NPs as the samples patterns follow the standard Fe_3O_4 crystal pattern. However, the diffraction lines were narrowed to some degree, confirming that the XRD diffraction line becomes narrowed as the NPs size becomes larger after surface modification. Thus, XRD is a versatile, nondestructive technique that provides detailed information about the crystallographic structure of the material.

When Fe_3O_4 nanoparticles are introduced in collagen-based nanocomposites, most of the characteristic collagen peaks remain unchanged [77]. However, the XRD patterns of pristine collagen fibers and collagen-Fe_3O_4 nanobiocomposite revealed that the collagen-to-amorphous ratio decreased significantly in the case of nanobiocomposite. The decrease in peak is due to the reduction of intermolecular lateral packing of collagen and is attributed to the interaction of Fe_3O_4 NPs with collagen, which affects the packing order of collagen. It was concluded that the introduction of cross-links between collagen molecules and Fe_3O_4 NPs most probably lead to the decreased order in collagen organization.

The synthesis of collagen scaffolds cross-linked with functionalized (APTES and MPTES) Fe_3O_4 NPs can be attempted, which will have potential biomedical application in tissue engineering. Therefore, XRD can be employed to study and ascertain the crystallinity as well as to determine the particle size of these functionalized Fe_3O_4 NPs in the collagen matrix. Similarly, XRD can also be used to obtain valuable structural information for collagen scaffolds containing the conjugated Ag–Fe_3O_4 NPs as well as to estimate their particle sizes when incorporated in the collagen scaffolds.

12.3 CHEMICAL INFORMATION

12.3.1 Fourier Transform Infrared (FT-IR) Spectroscopy

Infrared (IR) spectroscopy, a vibrational spectroscopic technique capable of providing details of the chemical composition and molecular structures in cells and tissues by measuring the frequency of IR radiation needed to excite vibrations in molecular bonds, is applied to address various biomedical and pharmaceutical issues [91]. The simple IR instrumentation and also faster data collection leading to a superior signal-to-noise ratio (SNR) facilitates assessment of tissue specimens [92]. Biological macromolecules such as proteins and other nucleic acids have specific, fingerprint region (400–4000 cm^{-1}). Since changes in the molecular structure and cellular chemistry govern these spectral fingerprints; IR spectroscopy has to detect abnormal changes in cell and tissues. Also, the fingerprint region can be used to analyze the probe chemical composition and to determine the structural changes occurring in tissues and cells in real time at the molecular level without the help of markers [93, 94]. Therefore, FT-IR as an analytical technique has been employed in medical diagnostics [93].

Fourier transform infrared is a very sensitive probe of the H-bonded states within the triple helix and thus has been utilized to deduce the structure and also to characterize collagen [95]. The FT-IR spectrum of collagen shows characteristic bands sensitive to secondary and tertiary structural changes, which include the N–H stretching (3330 cm^{-1}), amide I, C=O stretching (1650 cm^{-1}); amide II, N–H bending and C–N stretching (1550 cm^{-1}); and amide III, C–N stretch, N–H bending vibrations (1250–1150 cm^{-1}). The 3330 cm^{-1} N–H stretching band shifts to 3300 cm^{-1} in gelatin, the denatured form of collagen. The absorbance ratio of the 1450 cm^{-1} band (C–H deformations) to the 1235 cm^{-1} band (amide III) has been used by many investigators to qualitatively determine the tertiary structure, although the exact ratio associated with the tertiary structure of collagen is not known. However, a band in the amide III region at 1235 cm^{-1} is not present in the spectrum of denatured collagen following a 60°C heat treatment. A team of investigators [96] reported absorbance ratio values ranging from 1.25 to 1.43 depending on the source of the collagen. The absorbance ratio for the collagen used in one study [97] was 1.1, indicating that the collagen was pure. Moreover, the IR absorption ratio A_{1234}/A_{1454} was found to be close to 1.0 in all collagen samples, which indicated that triple-helical structure of collagen

was preserved as compared to gelatin membranes showed a value of 0.59 in the same conditions [73].

Fourier transform infrared was also used to classify the interaction of template type I collagen with AgNPs [69, 98]. The prominent amide I (C=O stretching) band at 1650 cm^{-1}, amide II (N–H stretching) band at 1538 cm^{-1}, and the peaks in the range 1143-1301 cm^{-1} due to amide III (C–N stretching and N–H stretching) observed are due to pure collagen, owing to the rich amines in glycine and proline residues in this protein. However, the shift in bands results when AgNPs were added to collagen. This shift in the peaks is attributed to the association of the collagen molecules with AgNPs as the amines groups present in collagen moiety binds strongly with AgNPs via covalent–electrostatic interaction [69, 98]. In addition, the antisymmetric and symmetric vibrations of CH_2 alkyl chains observed at 2916 and 2849 cm^{-1} indicates that collagen forms a complex with AgNPs [98, 99]. A one-step in situ assembly of size-controlled AgNPs has been synthesized [87] on polyphenol-grafted collagen fiber with enhanced antibacterial properties. FT-IR studies confirmed the graft of epigallocatechin-3-gallate (EGCG) onto collagen fiber (CF) and the presence of phenolic hydroxyls of EGCG involved in the reduction of Ag^+. The FTIR spectrum displayed three characteristic adsorption bands at 1660, 1548, and 1238 cm^{-1} attributed to the amide I, II, and III bands of the collagen molecule, respectively. The adsorption band of EGCG–CF around 3385 cm^{-1} broadened mainly due to the strong hydrogen bond interaction between the phenolic hydroxyls of ECCG and the amino/amide groups of CF. New adsorption peak was observed at 1120 cm^{-1} due to C–O–H stretching vibration of phenolic hydroxyls in EGCG. However, the adsorption bands at 3385 cm^{-1} became narrow and shifted to longer wavelength most probably due to the partial destruction of hydrogen bonds between EGCG and CF, which implies the involvement of the OH groups in the reduction of silver. In addition, the damping of the peak at 1120 cm^{-1} further supported the reduction of silver ions coupled to the oxidation of phenolic hydroxyls of EGCG.

The characteristic absorption peak of Fe_3O_4 is at 582.85 cm^{-1}, which relates to strength of Fe−O bond [100]. Another group [101] reported the synthesis and characterization of biocompatible Fe_3O_4 NPs by the modified controlled chemical coprecipitation method from the solution of ferrous/ferric mixed-salt solution in alkaline medium. Fe_3O_4 NPs coated with sodium oleate were characterized using FT-IR. The peak at 3439.4 cm^{-1} was attributed to the stretching vibrations of –OH assigned to –OH absorbed by Fe_3O_4 NPs. Also, the peak at 583 cm^{-1} attributed to Fe–O bond was observed. For Fe_3O_4 NPs coated with sodium oleate, the peaks at 2924 cm^{-1} and 2854 cm^{-1} were observed, which are attributed to the stretching vibrations of $–CH_2$ and $–CH_3$ in sodium oleate. Also, addition peaks at 1702 and 1590 cm^{-1} due to C=O and C=C in sodium oleate was observed. All these indicated that sodium oleate was absorbed in the surface of Fe_3O_4 nanoparticles. Similarly, FTIR employed to characterize Fe_3O_4 NPs coated with oleic acid and oleyl amine revealed the nature of the bond formed between the surfactant and the surface atoms of Fe_3O_4 NPs [102].

Fourier transform infrared spectra of Fe_3O_4 NPs coated with silanes displayed S–H stretch vibration band at 2590 cm^{-1} due to presence of mercaptosilane in amino functionalized Fe_3O_4 NPs. Also, additional bands are observed in the spectra for silane modified Fe_3O_4 NPs compared to as synthesized uncoated Fe_3O_4 NPs. The main difference is the appearance of bands between 1000 and 1150 cm^{-1}, characteristic of silane layers and originates from Si–O–Si vibrations. i.e., the presence of bands at about 950, 1035 and 1128 cm^{-1} corresponds to the condensation of siloxane (Si-O) molecules onto the surface of the Fe_3O_4 NPs [103, 104]. However, no reports on cross-linking of these functionalized Fe_3O_4 and silver nanoparticles with collagen are available. Surface modification of both Ag and Fe_3O_4 NPs with oraganosilanes is an attractive approach in this context, as it can be biocompatible with collagen and find potential use in tissue engineering applications.

To the very best of our knowledge, only one report on Fe_3O_4 NPs cross-linked with collagen has been documented in the literature [105]. The investigation demonstrates that Fe_3O_4 modified via gum arabic (GA) and cross-linked with collagen can be used for the isolation of *Staphylococcus aureus* bacteria at ultralow concentrations. However, they have not used FT-IR as a tool to study the interaction of GA with Fe_3O_4 or with collagen. FT-IR is beneficial for identification of organic molecular groups and compounds due to the range of functional groups, side chains and cross-links involved. FT-IR studies can be conducted to gain more insight into the effect of these nanoparticles on the triple-helical structure of collagen. Hence, FT-IR can be employed to study coated Fe_3O_4 NPs and their interaction with cross-linked collagen, which find potential biomedical application in tissue engineering. Furthermore, no reports on the synthesis, characterization, and interaction of conjugated Ag–Fe_3O_4 NPs with collagen have been documented, and this aspect is yet to be studied. Hence, FT-IR as a characterization technique can be utilized for this purpose and might serve as an important tool for characterization of collagen-based biomaterials and scaffolds impregnated with Ag–Fe_3O_4 NPs.

12.3.2 X-Ray Photoelectron Spectroscopy (XPS)

X-ray photoelectron spectroscopy, also termed *electron spectroscopy for chemical analysis* (ESCA), is another nondestructive surface characterization method, which provides qualitatively or quantitatively elemental and chemical information from elements present on the solid surface (uppermost 10 nm) of the biomaterials [5,11].

The principle of XPS is based on the emission of electrons from matter in response to irradiation of the surface

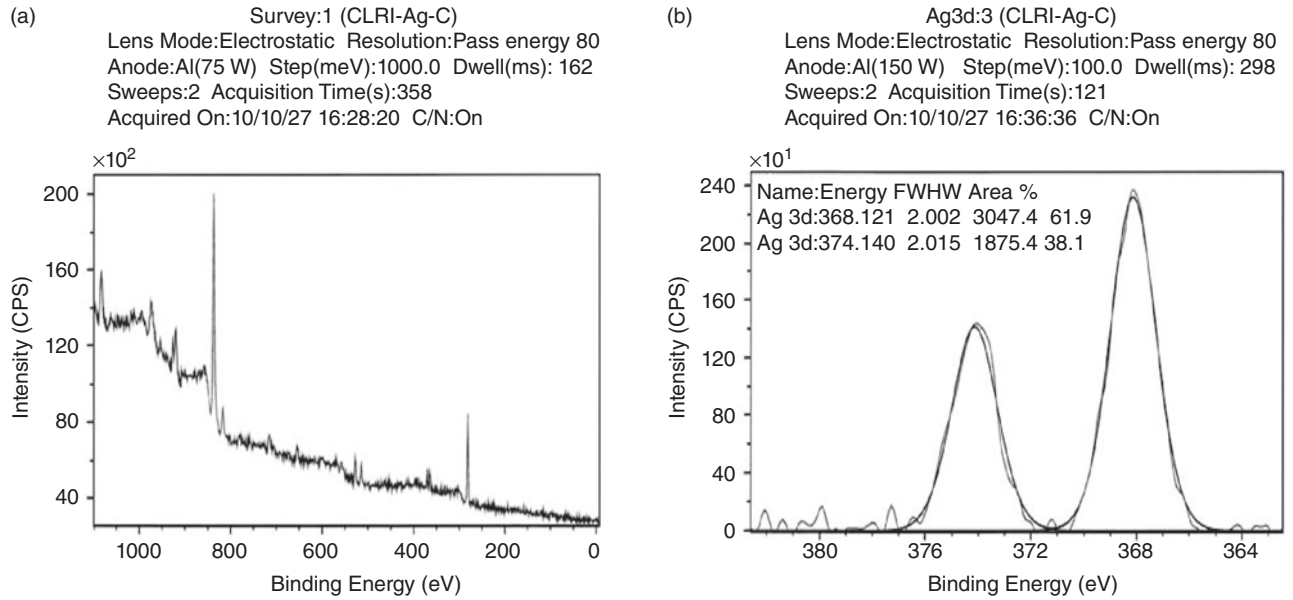

FIGURE 12.6 XPS spectra show (a) wide scan and (b) Ag 3*d* core level of AgNPs incorporated in collagen scaffold, respectively.

by a beam of monochromatic X rays. The kinetic energy (KE) of the ejected photoelectrons is unique for the different elements as well as sensitive to the chemical state of the atoms [106, 107]. The commonly used energies of X rays in experimental practice are 1253.6 eV (MgK_{α}) and 1486.6 eV (AlK_{α}). Since the emitted electrons have little ability to penetrate matter, only those electrons ejected near or from the outermost 100 Å of a polymeric sample can escape from the surface and thereby be quantified [106,108].

Isolation of collagen from animal tissues involves many crude preparation steps, and so it is important to characterize the chemical composition to assess contaminants, material homogeneity such as film formation in tissue culture wells and surface modification with adsorbed or chemically coupled growth or adhesion factors. The effect of fibroblast cell adhesion on the collagen-modified polystyrene plate was investigated [109]. The study used XPS as a characterization method to determine the effect of the structural changes of graft-polymerized polystyrene and the influence of surface amine group concentration on the extent of collagen (Col) immobilization. The peak with binding energy at 288.1 eV confirms the formation of CONH bonding and the covalent interaction between collagen and polystyrene. Also, the surface of the polystyrene grafted film showed the peak at 399.4 eV for C–N, whereas the collagen immobilized film exhibited amide components at the binding energies of 399.8 eV. The increase of CONH from 0% to 13% is probably due to covalent interaction, which results in the immobilization of collagen on the polystyrene film.

Poly(ethylene glycol) hydrogel surfaces modified to covalently attach cell adhesion protein such as collagen was performed to promote cell adhesion [110]. XPS demonstrated the immobilization of collagen on the PEG hydrogel surface. The XPS spectra show the formation of a new nitrogen peak, and it was found that immobilized collagen was dependent on the concentration of bifunctional linker NHS. The cell adhesion studies revealed that collagen immobilization resulted in a significant improvement of cell adhesion. Similarly, XPS has been employed to verify the biosynthesis of collagen by cells and for the confirmation of collagen coating to enhance the biocompatibility of titanium implants used for bone growth [111, 112]. The XPS scan spectra of collagen scaffold containing AgNPs is depicted in Fig. 12.6.

Similarly, spectra of Ag–$EGCG_{0.3}$–CF showed the presence of C 1*s*, N 1*s*, O 1*s*, Ag 3*p*, and Ag 3*d* core levels with no evidence of impurities [87]. The Ag 3*d* core level is fitted to two peaks, at 368.1 and 374.1 eV, assigned to $3d_{5/2}$ and $3d_{3/2}$, respectively. Splitting of the 3*d* doublet of Ag is 6.0 eV, which suggested the formation of silver nanoparticles. The core level O 1*s* at 523 eV can be attributed to presence of hydroxyl groups and surface adsorbed water on EGCG. The peak corresponding to lattice oxygen O^{2-} from Ag_2O was not observed; it can be concluded that the formed silver was predominantly metallic. The C 1*s* signal deconvoluted to three peaks by curve fitting using a mixed Gaussian and Lorentzian lineshape exhibited peaks at 284.5, 286.7, and 287.9 eV corresponding to C–C, C–O and C=O, respectively. Similarly, the N1s signal was deconvoluted as contributions arising from the presence of pyridinic, pyrrolic, and quaternary N parts [87].

X-ray photoelectron spectroscopy is useful for identifying oxidation states of metal/oxide ratio and also information on

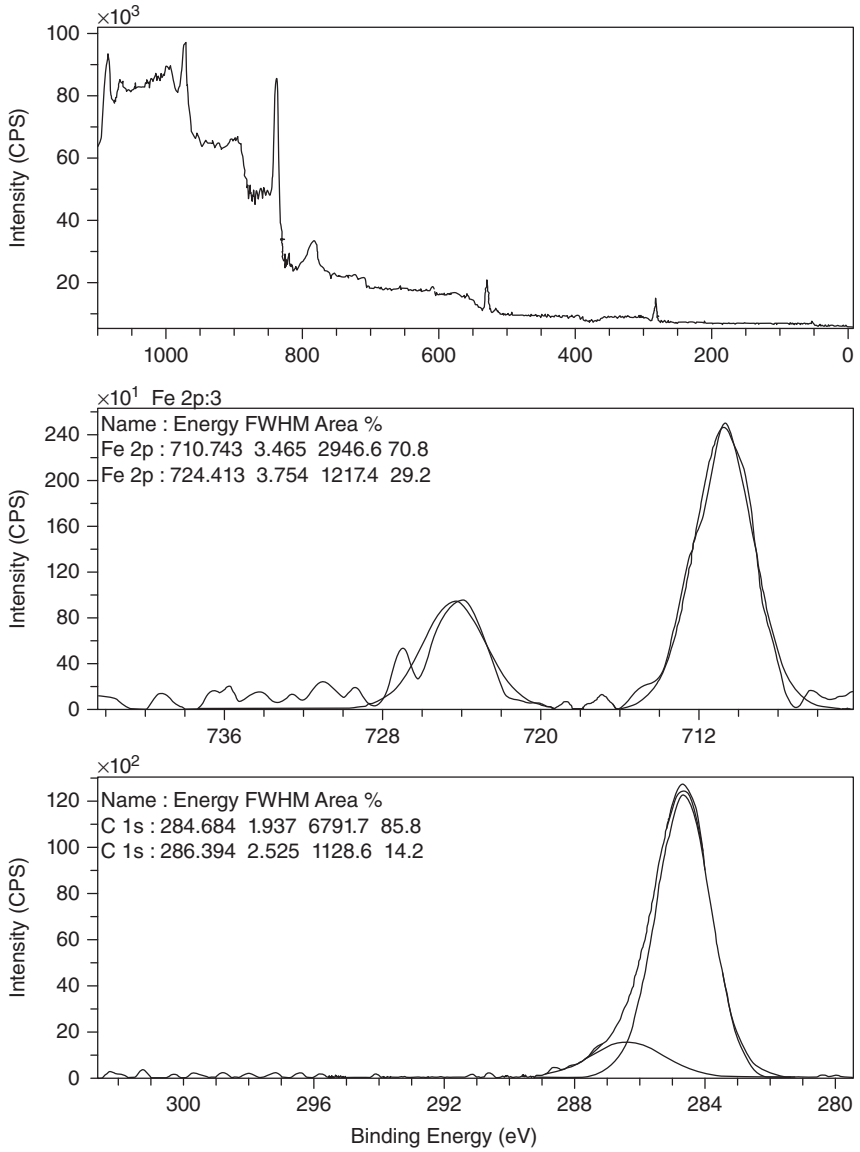

FIGURE 12.7 XPS of PEG capped Fe_3O_4 nanoparticles showing wide scan, Fe 2*p* and C 1*s* regions [114].

oxide thickness can be obtained. Zhang *et al*. [113] reported the synthesis of oleic acid coated monodisperse Fe_3O_4 NPs. The XPS spectrum shows peak at 284.6 eV ascribed to the carbon atoms in the aliphatic chain (C–C), and peaks at 287.4 and 288.3 eV to the carboxylate ($-COO^-$) moiety. The characteristic peak from Fe $2p_{3/2}$ core level electrons at 710.8 eV was noted. The Fe $2p_{1/2}$ peaks at 724.1 eV for 7 nm and 725.0 eV for 19 nm Fe_3O_4 NPs were attributed to the carboxylate–Fe bond. XPS can also provide information on the extent of coating on the nanoparticle or biomaterial surface. The XPS spectra of Fe 2*p* core level for Fe_3O_4 nanoparticles coated by PEG is a proof for the chemical structure of the Fe_3O_4 NPs illustrated in Fig. 12.7. The bonding energies at 710.8 and 724 eV, the characteristic peaks from Fe $2p_{3/2}$ and Fe $2p_{1/2}$ core-level electrons respectively were noticed. Two C 1*s* peaks positioned at 284.6 and 286.4 eV are ascribed to carbon atoms in the aliphatic chain (C–C) of the PEG molecules. XPS determines the elemental composition of the surface, typically to a depth of 3.5 nm at a takeoff angle of 45°, which was used in the experiment. The XPS spectra revealed almost complete coverage of the surface with the PEG stabilizer as the increased carbon and nitrogen signatures, compared to the precursor Fe_3O_4 NPs, was noted, which supported the hypothesis of polymer coverage. However, the detection of low levels of iron suggested that the polymer-layer depth may be lower than 3.5 nm [114].

In a study [115] of the surface organic modification of Fe_3O_4 NPs with KH570, XPS was used to analyze

unmodified and modified Fe_3O_4 with KH570. An Si 2*p* peak appeared at the binding energy of 101.3 eV along with prominent absorption peaks of C 1*s* and O 1*s* at 285.0 eV and 530.61 eV for KH570-modified Fe_3O_4 NPs. Surface composition (*w*) and binding energy (E_b) of Fe_3O_4 unmodified and modified obtained from XPS show that the content of Si was 1.36 wt% in modified Fe_3O_4 NPs, while the content of Fe decreased from 47.84 to 31.37 wt%. The electron binding energy of Fe $2p_{3/2}$ shifted from 711.0 to 711.46, eV due to surface modification. The reason is based on the fact that electronegativity of Si is stronger than that of H, which causes electron density around Fe and shielding effect to decrease, so the binding energy of Fe $2p_{3/2}$ increased. The binding energy shift of 0.46 eV was observed for Fe_3O_4 NPs after modification. This also proved the deduction that Fe–O–Si chemical bond between KH570 and Fe_3O_4 NPs were formed instead of the chemical bond Fe–OH. Similarly, another author [90] reported the silane bridged surface tailoring on Fe_3O_4 NPs using APTES and MPTES. The amino-coated and thiolated Fe_3O_4 showed a lower shift of binding energy of Fe $2p_{3/2}$ compared to bare Fe_3O_4 NPs. The peak of carbon at 284.9 eV is close to the data of the E_b of a long-chain alkyl, and the authors attributed it to the long-chain alkyl of APTES or MPTES. Also, the signal intensities increased as compared to bare Fe_3O_4. The E_b of Si 2*p* was 102.5 eV, close to the standard data for silane (101.9 eV). The E_b of N 1*s* was found to be 399.5 and 164.1 eV for S 2*p*, which is close to the standard data of N-C group (399.8 eV) and S–C group (163.8 eV). Hence, the above results reveal that silane coating of Fe_3O_4 NPs is successful. However, no report on the interaction of these coated Fe_3O_4 NPs with collagen is available in the open literature.

XPS is useful for identifying functional groups. For example, peak shapes of C 1*s* gives information about functional groups in organic materials. The limitation of XPS is the poor lateral resolution (10 μm), and the drawback of XPS, especially for the biological application, is the UHV condition that does not allow the analysis of the sample in liquid state. Hence, valuable information on the elemental composition, chemical state, quantification (imaging, depth profile) for collagen scaffolds cross-linked with aminosilane functionalized silver and Fe_3O_4 NPs can be obtained from XPS. Moreover, XPS can substantiate FT-IR data, indicating the formation of chemical bonds between the nanoparticles, and can serve as a valuable tool in determining the conjugation of Ag–Fe_3O_4 NPs and studying the interaction with collagen.

12.4 MORPHOLOGICAL INFORMATION

12.4.1 Scanning Electron Microscopy (SEM)

Scanning electron microscopy is generally used for studying the surface morphology and their cellular response to biomaterials [116, 117]. This technique uses a primary beam of electrons that interact with samples in vacuum causing emission of different types of electrons and electromagnetic waves. The ejected secondary electrons from the sample surface are gathered to demonstrate a high-resolution micrograph. Fixation is required for SEM sample preparation (if proteins, cells, or tissue are present). Also, drying and coating process are essential as they can modify surface morphology of surfaces that are subjected to changes in a hydrated environment [5]. For example, collagen films, if denatured, can collapse under the force of sputter coating and vacuum of the SEM imaging due to absence of sufficient structural integrity needed for analysis of collagen-based scaffolds.

Cell death and low proliferation rates are a common problem encountered on biomaterial matrices, and therefore, modifying the collagen matrix properties that lead to improved cell proliferation and their survival is necessary to develop novel and superior tissue-engineered constructs. The cell viability of poly anionic collagen (PAC) was assessed on rat cardiac fibroblasts, L6 myoblasts, and NIH 3T3 fibroblasts, respectively. When viewed under SEM, all these cell types were found to be grown uniformly with normal morphologies and the extra negative charges and RGD sites on the PAC support the enhanced cell proliferation [42]. Thus, SEM could be utilized to analyze the in vitro and in vivo biocompatibilities and the efficacy of different cell lines on PAC scaffolds incorporated with nanoparticles such as silver and iron oxide, which could be effective in the treatment of bone defects and regeneration of other soft tissues. The microstructures of collagen matrices with and without EDC/NHS-cross-linking (0, 2 mg/mL-EDC/NHS) were analyzed by SEM [118]. The EDC/NHS-collagen cross-linking led to parallel alignment of collagen with the size of interconnected pores ranging from 33 to 220 μm. MC3T3-E1 cells were found to attach and displayed improved cell proliferation on the surface of cross-linked collagen matrix. The crosslinking due to EDC/NHS facilitates the ability for self-assembly and self-organization of collagen into more ordered structure. The enhanced physicochemical properties of EDC/NHS-cross-linked collagen show promise as bioactive and bioresorbable scaffolds in bone tissue engineering applications. Silane, when cross-linked with collagen using EDC-NHS, has also shown proliferation of osteoblast cells [119]. Thus, silane- coated silver nanoparticles cross-linked with collagen via EDC-NHS has potential for treatment of cartilage defects and other hard-tissue repairs where SEM could be used to analyze the surface morphology and cell proliferations of the scaffolds.

Porous collagen scaffolds for the regeneration of soft tissues, SEM was used to analyze the morphology of the surface [50]. The collagen scaffold has shown better wound reduction and complete epithelialization on day 8 compared to day 16 required for the control. Thus, the scaffold could find use in the treatment of dermal wounds for effective within shorter time period and has potential in skin tissue engineering

applications. A comparison of gelatin and collagen scaffolds to ascertain the applicability of the scaffolds as a skin substitute, in vitro cell adhesion and cell proliferation tests for cultured fibroblast cells were conducted [120]. The morphology of scaffolds investigated by SEM displays a membrane like structure with interconnected pores for collagen scaffolds, while the gelatin scaffolds had some fibers among the continuous wall-like structure. The gelatin scaffolds possessed comparable properties particularly cell proliferation, with that of collagen scaffolds, although the increased degradation rate of gelatin significantly hinders its use in wound healing [120]. Therefore, it is essential to modify the gelatin scaffolds to decrease the degradation rate and be used as a substitute for collagen scaffold to lower the cost of materials for scaffold fabrication. Efficacy of collagen/gelatin sponge (CGS) with a gelatin concentration of 10 wt% as scaffold for sustained release of basic fibroblast growth factor (bFGF) for regeneration of skin tissues was studied using an in vivo animal model [121]. The study evaluated the wound area to determine the neoepithelial cells formation. The observed SEM images of the implanted collagen/gelatin sponges (CGS) impregnated with different concentrations of bFGF $\leq$50 $\mu g/cm^2$ after 1 and 2 weeks show that the CGSs impregnated with normal saline solution (NSS) became infected and degraded, whereas the CGSs impregnated with 7 or 14 $\mu g/cm^2$ bFGF displayed accelerated dermis like tissue formation. Furthermore, increase of bFGF to 50 $\mu g/cm^2$ did not enhance the wound healing process and faster tissue regeneration. This suggests that CGS can release positively charged growth factors bFGF (14 $\mu g/cm^2$) in a controlled manner and could solve the problem of the existing artificial dermis and has potential as a scaffold for the treatment of skin defects [121]. The surface morphology of a trilayer dermal equivalent (TDE) of chitosan-impregnated silver nanoparticles on chitosan–collagen scaffold displays the microstructure having pore size ranging from 80 to 200 μm, which facilitates the fibroblast to infiltrate and can be used to treat different types of skin defects [122]. Also, the SEM image of the cross-sectional morphology of TDE shows that the thickness of the trilayer equivalent as 1 mm, which has collagen–chitosan scaffold in addition to the silver nanoparticles incorporated chitosan films and silicone membrane.

The SEM images of the collagen-based scaffolds, along with the AFM, facilitate the assessment of collagen surfaces, and the information gathered can be used in the fabrication of better tissue-engineered scaffolds. The advantage of SEM technique is that acquisition of the micrographs of the inserted sample can usually be done fairly quickly, allowing for a large number of images to be obtained with varying magnifications. Apart from imaging the surface morphology of biomaterials, it can be combined with EDX for elemental distribution determination and IR or Raman spectroscopy to examine surface modification procedures [5]. Fabrication and characterization of assembled type I collagen–silver nanoparticle multilayered films showed that the intensity of the SERS spectra of assembled films in presence of 5 ng/μL collagen is twofold higher than that of 2 ng/μL collagen [98]. The AgNPs adsorbed on the 5-ng/μL collagen surface was higher as a result of the more positive charges available compared to the 2-ng/μL collagen surface (see Fig. 12.8). Hence, it was concluded that increase in collagen concentration provides a large surface area and porosity, along with a

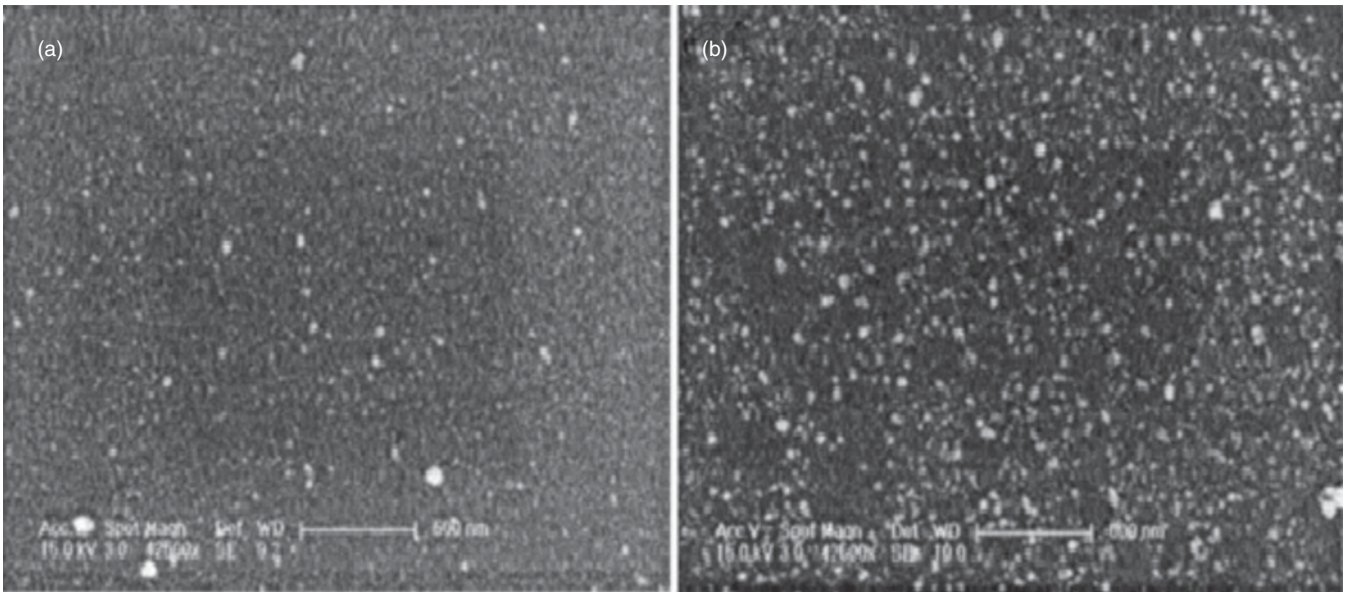

FIGURE 12.8 SEM images of substrate PDDA/AgNPs/collagen with different concentrations of collagen: (a) 2 ng/μL; (b) 5 ng/μL [98].

well-interconnected pore network to accommodate AgNPs. The SEM images showed that AgNPs anchored on a collagen scaffold increased with an increase in the collagen concentration, and the AgNPs tend to grow up simultaneously. Also, the effect of the number of layers of AgNPs was studied using SEM technique. The morphologies of multilayer quartz/PDDA/ AgNPs/(collagen/AgNPs)$_n$ films where n = 0,3,6 exhibit the uniform distribution of AgNPs on the surface. However, the increase of the number of AgNP layers results in the NP aggregations. This effect is due to the uniform distribution of positive charges of the collagen molecules on the surface and also the 3D collagen scaffolds facilitate the space required for the growth of the aggregates [98]. Likewise, the SEM images of a similar kind of study involving the collagen-templated assembly of silver nanoparticles indicate that the maximum formation of monodispersed AgNPs resulted when the Ag colloid:collagen ratio was 1:1(v/v) in comparison to 2:1 and 3:1 ratios, respectively [123]. Furthermore, at the incubation time of 2.5 h, uniform distribution with the least aggregation of AgNPs on the collagen surface was noted. At higher incubation time (>2.5 h), the AgNPs aggregation increased on the collagen surface [123].

The effect of AgNPs on collagen formation and deposition at the point of complete wound healing was carried out using an in vivo model [124]. SEM imaging showed regular and organized arrangement of collagen fibrils in the AgNP-treated group, whereas the untreated group display aggregated and random alignment of collagen fibrils. When observed under higher magnification (60,000×), the average diameters of the surface fibril were found to be 78.6 and 64.8 nm for AgNPs treated and untreated groups, respectively. Moreover, thorough examination at the region close to the fracture site reveals that the collagen fibers have a more regular and compact pattern in the case of AgNP-treated groups, while in the untreated groups the collagen fibers were found to be intermingled with a sparse arrangement. These findings are attributed to the uncontrolled deposition of collagen during the natural wound-healing process and thus, support the fact that collagen fibers directed with a particular orientation or arranged in an ordered manner demonstrates improved mechanical properties for healed skin treated by AgNPs compared to that of the untreated group. Therefore, it can be ascertained that AgNPs modulate collagen deposition in wound healing and demonstrate fetal wound healing rather than forming scars [125].

The nanohydroxyapatite synthesized using Fe_3O_4 NPs extracted from goat blood coated on collagen matrix was visualized with SEM [125]. The image displays the formation of flower shaped nHap with a particle size of 19 nm having a porous crystalline structure on the Fe_3O_4-collagen matrix. FESEM has been used to obtain information on the surface morphology of the collagen-based nanobiocomposite [126]. The image displays the banded structure having a characteristic *D*-periodicity of 64.61 nm indicative of quarter-staggered arrangement of collagen molecules into a pentafibril assembly. The attachment of Fe_3O_4 NPs on the collagen results in reduction of *D*-periodicity to 59.61 nm due to the dense packing of collagen molecules from the displacement of water molecules. Similarly, for the *in vitro* evaluation of the iron oxide nanoparticles coated with gelatin (GIOPs) derived from collagen, FESEM was carried out to investigate the morphological changes occurring on the GIOPs surface after soaking at different time intervals. Formation of needle-shaped type B carbonated apatite from the GIOPs in 12 days mimics the natural bone composition and signifies the bioactivity of the material [126].

One team of investigators [127] applied the Mag-TE technique to a cell-seeding process termed *Mag seeding* and studied the enhancement of cell-seeding efficiency into 3D porous scaffolds for tissue engineering. NIH 3T3 fibroblast cells (FBs) were used as model cells and MCLs (containing 10 nm Fe_3O_4 NPs) were added to FBs at a concentration of 100 pg/cell (lower than the cytotoxicity value) for magnetic labeling. Five collagen scaffolds with different pore sizes were chosen for the study. Histological observation using SEM revealed that cells were distributed in the scaffolds both by static and Mag seedings, with more cells being observed in the case of Mag seeding. The collagen scaffold (Col 1) with small pore size exhibited unique pattern of cell distribution as cells were distributed at the top of the scaffold instead of uniform distribution throughout observed in other cases. The histological observation also revealed that cells formed aggregates after Mag seeding particularly in Col 1 suggesting that the magnetic force in Mag seeding enhanced cell–cell interactions within the scaffold. In addition to cell–cell interactions, the authors speculated that *cell–scaffold* interactions within the scaffold could be enhanced by magnetic force. Moreover, cell-seeding efficiency by Mag seeding showed a good relationship with pore size. Hence, Mag-seeding efficiency may not depend on the composition of the scaffold. However, further study in this direction is needed to determine the cell-seeding efficiency of Mag seeding using scaffolds of various compositions. Since no reports are available on the conjugation of Ag–Fe_3O_4 NPs, their interaction with collagen, and their cell seeding with the Mag TE technique, an attempt can be made in this direction where SEM technique could prove vital for the histological study as well as cell compatibility studies of collagen scaffolds containing the conjugated Ag–Fe_3O_4 NPs.

12.4.2 Atomic Force Microscopy (AFM)

Topography, roughness, and mechanical properties of a biomaterial are essential factors that govern and influence the attachment of cells and their adherence on to the surface of the scaffolds [128–133]. AFM, a powerful tool, is used to determine surface morphology of the collagen-based

scaffolds along with the mapping of the mechanical and adhesive properties of the cells–scaffolds in high resolution [134, 135].

The surface topography of blends of collagen–elastin films for tissue regeneration was investigated via AFM [136]. The AFM images display collagen films having long folded pattern owing to the helical rod like structure of collagen. The morphology remained unaltered when the ratio of collagen/elastin blend was 19:1. However, with the increase in elastin concentration (>5%) results in the formation of buldges with the of diameters 1–2 mm due to rougher surfaces of the mixtures compared to elastin and collagen individually. Moreover, AFM images corroborate the predominant prevalence of collagen in the uppermost layers of the blends and also indicate that collagen when combined with elastin slows down the aggregation process of elastin and also the 3T3 cell adhesion and their proliferations. Also, the effect of UV radiation on the topography of these blends was monitored via AFM. It was observed that the size of the bulges of the blends became smaller and eventually disappeared with the increased level of exposure to UV radiation for longer duration. This observed effect was attributed to the effect of conformational changes caused by the modification of hydrophilic/hydrophobic properties and the loss of water in films due to photooxidation, which enhances the biocompatibility of the materials [136].

In an investigation of fabrication of assembled type I collagen-AgNPs multilayered films, AFM technique has been used to examine the morphology [98]. The images of collagen film immersed for 2 h in Ag colloids and assembled on different concentrations (10, 50, and 100 ng μL^{-1}) of the mica surface confirm the uniform coating of AgNPs for the highest concentration (100 ng μL^{-1}) with no significant aggregations on the collagen surface. This also suggests that the AgNP-coated collagen film has the largest surface for holding probe molecules such as 4-aminothiophenol (4-ATP) and methylene blue (MB) and can be utilized for SERS detection [98]. Similarly, the structural investigations of AgNPs doped on collagen and keratin based materials via AFM indicated a specific surface structure modification at micrometric scale in terms of roughness [137]. The elastic properties of the type I collagen fibrils formed by self-assembly were determined with the help of AFM [138]. The tip of the AFM was used as nanoindentor to determine the elastic properties from the force–displacement curves. The investigations show banding of the shell in the core of collagen fibril. The measurements display higher adhesion in the core of the collagen fibril compared to the shell, although the Young's modulus was found to be the same for both. Thus, AFM as a microdissection tool to probe local elasticity can be useful to gain insights into the collagen assembly and to determine mechanical properties [138].

The influence and effect of cross-linking and composition on the surface and mechanical properties, which affect the cell reactivity of collagen-based films, was determined using AFM [139]. AFM, along with SEM image analysis, reveals that the collagen bundles with diameter 0.82 ± 0.16 μm compared to 0.18 ± 0.28 μm observed for gelatin. The calculated height and roughness of the gelatin–collagen films were found to be 727 nm and 147 ± 30.5 nm, respectively, and these values were intermediate between the pure collagen and gelatin films. Moreover, the obtained average fibre diameter of 238 ± 29 nm for all collagen films and 64.4 ± 2.91 nm for the periodic banding of collagen for all films containing both non-cross-linked and cross-linked collagen indicate that altering the composition or cross-link status had no effect on the collagen fibril size or banding pattern. Cross-linking of collagen with NHS/EDC resulted in a significant increase in the stiffness of the collagen films and also tended to reduce the roughness of the films ($R_q = 0.417 \pm 0.035$ μm, $E = 31 \pm 4.4$ MPa). Gelatin films were generally smoother and more compliant than comparable collagen films ($R_q = 7.9 \pm 1.5$ nm, $E = 15 \pm 3.1$ MPa). As a result, the reactivity of myoblast C2–C12 and C2–C12-α2+ cell lines with all the films were reduced from the initial composition, stiffness, or roughness. Modification of physical properties of the films due to cross-linking results in decrease in the number of accessible cell binding sites and thereby reduces their capacity to support cell activity and curtails the efficiency of the collagen-based films and scaffolds [139]. Thus, it would be worthwhile to investigate the interaction of the surface-modified nanoparticles such as silver and Fe_3O_4 cross-linked with collagen and also their effects on the cellular responses. In this regard, AFM along with advanced optical microscopy can serve as a valuable asset and the obtained quantitative information can be used for the fabrication of better and novel tissue-engineered scaffolds with desired properties having potential applications in tissue engineering fields.

Cellular remodeling of collagen fibrils envisaged by time-lapse AFM exhibit that during alignment of cells, the matrix becomes deformed, due to the reorientation of individual collagen fibrils [140]. The cells caused the deformation of the matrix in an asymmetric manner, thereby leading to anisotropy in matrix rigidity. Thus, high tensile strength and flexibility of collagen fibrils add to the anisotropic rigidity of the matrix, which results in formation of directional cellular traction and cell polarization. This kind of complex entanglement of cellular protrusions with collagen fibrils maximizes the cellular traction, which further enhances the cell alignment process [140]. A more recent study shows that modulation of AgNPs foster the alignment of collagen and improves the mechanical properties required for tissue regeneration [124]. However, AFM was not employed to determine the tensile strength and surface roughness of the regenerated tissues. Also, experiments can be performed to determine the modulating effect of Fe_3O_4 NPs on the alignment of collagen fibrils where AFM can serve as a valuable tool to determine the morphology in addition to the surface roughness and

other mechanical properties that affect the tissue regeneration process.

12.5 CONCLUSIONS AND FUTURE PERSPECTIVES

The characterization of collagen-based biomaterial is necessary for the design of novel tissue- engineered matrices. Collagen, the versatile biomaterial, along with nanoparticles, especially silver and Fe_3O_4, finds application as tissue scaffolds and has been used in various fields of tissue engineering. With the development of new collagen-based biomaterial as scaffolds for tissue engineering applications, the need and search for special and improved analytical techniques for the characterization of these scaffolds has received attention. Several analytical tools have been employed to obtain details and insights on the effect of the collagen structure, its chemistry and the changes in the surface morphology when the silver and iron oxide nanoparticles interact with collagen molecule. Also, the cell morphologies in conjunction with the helicity and topography need to be evaluated as the response of cells to these collagen matrices is based on the characteristics of the biomaterial and thus, involve the changes in the secondary and tertiary structures of collagen in addition to the parameters such as chemical composition and surface roughness. Therefore, the choice of the techniques is crucial for the comprehensive characterization of collagen-based scaffolds and to investigate their influence and interaction with nanoparticles and cells.

The benefits and limitations along with the scope for future work for the methods of characterization that can be suitably applied to collagen biomaterials as scaffolds and to study their association or interaction with nanoparticles such as silver and Fe_3O_4 along with different cells needed for the development of novel biomaterials have been described. Hence, these types of characterizations are vital in the fabrication of collagen-based biomaterial as scaffolds for development of novel tissue-engineered matrices and to assess their cellular responses, which determines their potential in applications related to pharmacy and pharmaceutical sciences.

ACKNOWLEDGMENT

We would like to thank Professor Asit Baran Mandal, Director, CSIR-Central Leather Research Institute (CLRI), India, for the stimulating discussions and valuable suggestions, which are highly appreciated.

BIOMIMETIC POLYMER AGGREGATES: SELF-ASSEMBLY INDUCED BY CHEMICAL REACTIONS

Eri Yoshida

Department of Environmental and Life Sciences, Toyohashi University of Technology, Aichi, Japan

13.1 INTRODUCTION

Molecular self-assembly is the spontaneous association of molecules into thermodynamically and structurally stable aggregates joined through noncovalent bonds by van der Waals interaction, electrostatic attraction, and hydrogen bonding. Once the self-assembly occurs, the molecules construct three-dimensional structures on micro- and nanometer scales according to the respective rules. The self-assembly into the high-dimensional structures can be seen in many places in vivo, including protein folding [1], stacking of a base in the double helix of DNA [2], formation of biomembranes [3], and transport of lipophilic compounds by fatty-acid micelles [4]. The static self-assembly maintains the structure of the vital tissue, while the dynamic self-assembly provides the tissue with functions through dissociation and association. Such self-assembly is seen in the polymerization–depolymerization of tubulin proteins forming microtubules and in the formation of actin filaments [5]. This reversible self-assembly is controlled by the protein concentrations [6].

Based on the formation of the vital tissue through the self-assembly, proteins can perform individual functions, and the biomembranes can maintain fluidity to sustain life processes. The fluidity of the biomembranes also promotes the transport of substances including ions, electrons, and photons as mitochondria [7], erythrocytes [8], and chloroplasts [9]. Hence, many vital reactions involving electron transfer and photoreactions, such as the oxidation of a fatty acid in the citric acid circle [10] and oxidative phosphorylation [11], occur on the surface of or close to the biomembrane. These reactions often produce changes in the high-dimensional structure formed by the self-assembly [12, 13].

Artificially synthesized amphiphilic block copolymers form micelles and bilayer structures including vesicles in solution, as are the vital surfactants of lipids and fatty acids. The copolymers have often been used for the studies of the self-assembly into micelles [14] and already have many applications in industry such as separation technologies [15] and drug delivery [16]. The micellization of the block copolymers is promoted not only by the copolymer concentration but also by variation in the surroundings, such as temperature [17–21], pressure [22–26], pH [27–31], salt formation [30–35], and noncovalent bond cross-linking [36–38]. During the micellization caused by these environmental stimuli, the block copolymers molecularly dissolved in a solvent are converted in situ into amphiphilic copolymers.

This chapter describes the biomimetic self-assembly induced by electron transfer and irreversible photoreactions as new triggers using block copolymers.

13.2 SELF-ASSEMBLY INDUCED BY ELECTRON TRANSFER

Electron transport systems perform important functions concerning respiration and energy metabolism in eukaryotes [39, 40]. Electron transfer occurs at the mitochondria inner membrane consisting of the electron transport proteins [41] and the lipid bilayer built up by the self-assembly of

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

phospholipids [3, 11]. The electron transport proteins contain redox catalysts, such as nicotinamide, iron [42, 43], and quinones [44]. The electrons produced by these redox reactions transfer through the lipid bilayer. While the mechanisms of electron transport and the correlation to self-assembly have been clarified, self-assembly triggered by electron transfer has been applied to artificial polymeric surfactants.

The electron transfer-induced self-assembly has been found using some redox catalysts. The electrochemical self-assembly was established using the redox system of ferrocene for polyisoprene-*block*-poly(ferrocenyldimethylsilane) [45]. Other investigators also used the polyferrocenylsilanes composing block copolymers to obtain spherical micelles [46]. Other authors employed the redox of catechol for the self-assembly of 3,4-dihydroxyphenylalanine-containing poly(ethylene glycol) to prepare metal core–polymer shell nanoparticles [47], while other coworkers used the aniline oxidation for an oligoaniline-containing dendron–rod–dendron dumbbell-shaped block oligomer and succeeded in controlling the morphology through oxidation [48].

The redox system of 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) is useful as a trigger of the self-assembly of block copolymers. TEMPO is a stable nitroxyl radical [49] known as a *spin trapping reagent* [50], a *spin label reagent* [51], and a mediator for the controlled/living radical polymerization [52–55]. TEMPO forms a redox system in which the radical is converted into the oxoaminium cation by a one-electron oxidation and is converted into the aminoxy anion by a one-electron reduction (Fig. 13.1) [49,56]. The oxidation of TEMPO into the oxoaminium cation is caused by halogens, such as chlorine [49] and bromine [49, 57] and by metallic ions of copper(II) [58] and iron(III) [59], while the reduction into the aminoxy anion is brought about by phenylhydrazine [60], hydrazobenzene [61], quinones [62], ascorbic acid [63,64], and organometallic compounds [65]. Oxidation into the oxoaminium cation and reduction into the aminoxy anion is simultaneously caused by the disproportionation of TEMPO in ether by the strong acids of hydrochloric acid, nitric acid, tetrafluoroboric acid, fluoroantimonic acid, and perchloric acid [66, 67].

13.2.1 Oxidation-Induced Self-Assembly

Oxidation-induced self-assembly was determined using the oxidative redox system from TEMPO to the oxoaminium cation for a poly(4-vinylbenzyloxy-TEMPO)-*block*-polystyrene (PVTEMPO-*b*-PSt) diblock copolymer

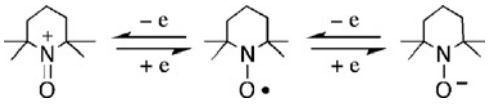

FIGURE 13.1 The redox system of TEMPO.

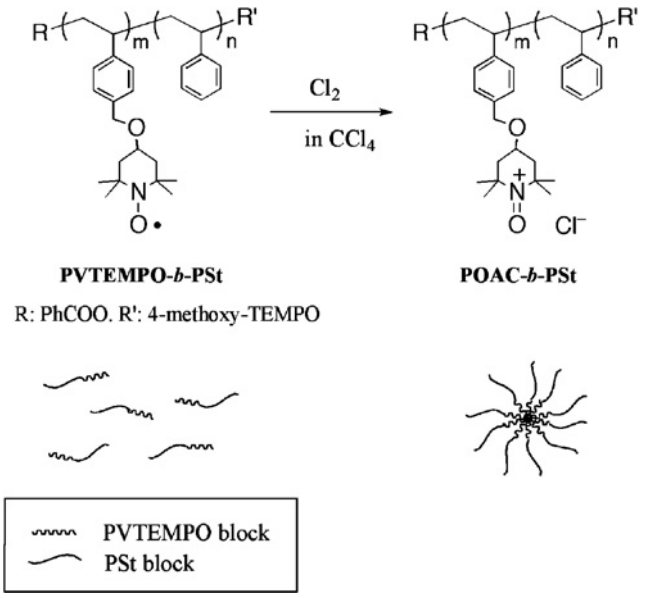

FIGURE 13.2 The oxidation-induced self-assembly of PVTEMPO-*b*-PSt. Mn(PVTEMPO-*b*-PSt) = 31,000-*b*-49,000.

supporting TEMPO on the sidechains (Fig. 13.2) [68]. PVTEMPO-*b*-PSt showed no self-assembly in carbon tetrachloride, a nonselective solvent. The isolated copolymer had a 15.6-nm hydrodynamic diameter. The copolymer self-assembled into micelles with a 49.5-nm diameter by the reaction with chlorine. ESR studies verified that the radical concentration of the TEMPO in the copolymer decreased due to the reaction with chlorine (Fig. 13.3a, b). The broad signal of the TEMPO based on the random orientation due to the restriction of its mobility by supported on the sidechains changed to a characteristic triplet attributed to the isotropy along with a decrease in the signal intensity by the reaction with chorine. The *g* values of the radicals before and after the reaction were 2.0066 and 2.0064, respectively. This negligible difference in *g* values indicates that they are identical radicals originating from the TEMPO. The conversion of the TEMPO was estimated to be 97% based on the integral curves of the radicals. UV analysis confirmed that the TEMPO was oxidized into the oxoaminium chloride (OAC) by chlorine based on the observed absorption at 360 nm originating from the OAC. It was found that PVTEMPO-*b*-PSt was converted into an amphiphilic poly(4-vinylbenzyloxy-OAC)-*b*-PSt (POAC-*b*-PSt) through the reaction with the chlorine to undergo micellization because OAC itself is insoluble in carbon tetrachloride. Figure 13.4 shows plots of the UV absorbance at 360 nm, the relative scattering intensity (I/I_0), and the hydrodynamic diameter (D_H) of the copolymer versus the molar ratio of chlorine to the TEMPO. The induction period of $\leq$0.2 of the chlorine ratio was observed for the plots of the hydrodynamic diameter. The scattering intensity also showed a slight increase up to 0.2, followed by a rapid

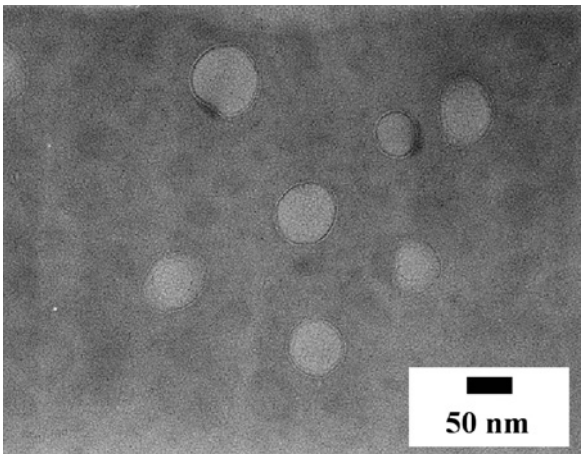

FIGURE 13.5 TEM image of the POAC-*b*-PSt micelles.

increase. It was found that the formation of only 16% of the OAC induced the micellization. TEM observations revealed that POAC-*b*-PSt formed spherical micelles (Fig. 13.5). The size of the micelles was almost equal to that estimated by the dynamic light scattering, suggesting that the micelles have difficulty in swelling in carbon tetrachloride due to the low affinity of OAC for the solvent.

The oxoaminium salts act as a two-electron oxidizing agent for converting alcohols into an aldehyde [69, 70] and ketone [69, 71], while the salts also serve as a one-electron oxidizing agent for water [49], amines [49, 56], sulfides [56, 72], and organometallic compounds [65, 73] to produce their radical cation salts or radical intermediates.

The POAC-*b*-PSt micelles quantitatively oxidized benzyl alcohol into benzaldehyde. Lack of change in the micellar size and the scattering intensity indicated that the copolymer maintained the micellar structure during the oxidation because the OAC was converted into the insoluble hydroxylamine hydrochloride salt, based on the two-electron oxidation for benzyl alcohol. Whereas signals of the pendant groups forming the micellar cores were not observed in the ^{1}H-NMR spectra due to the shielding by the PSt coronas, the signals of benzaldehyde were confirmed. The micelles oxidized benzyl alcohol in the cores and released benzaldehyde from them while maintaining the micellar structure.

The POAC-*b*-PSt micelles also oxidized *N,N,N′,N′*-tetramethyl-1,4-phenylenediamine (TMPD) to produce Wurster's blue chloride (Fig. 13.3c, d). Observation of the characteristic purple color and UV absorption of Wurster's blue indicated that the insoluble Wurster's blue chloride existed in the cores of the micelles. The ESR analysis revealed that the OAC reverted to the TEMPO by the one-electron oxidation of TMPD. The micelles were gradually dissociated into the isolated copolymers, due to the regeneration of the TEMPO.

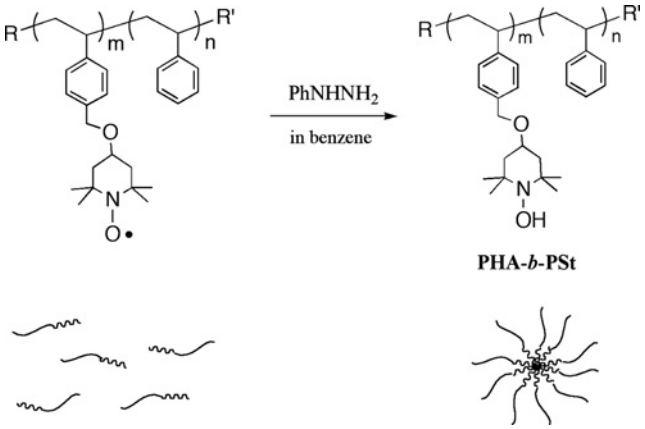

FIGURE 13.6 The reduction-induced self-assembly of PVTEMPO-*b*-PSt.

13.2.2 Reduction-Induced Self-Assembly

Reduction-induced self-assembly was attained using the reductive system from TEMPO to the aminoxy anion [74]. Red-colored PVTEMPO-*b*-PSt was converted into colorless micelles of poly(4-vinylbenzyloxy-hydroxylamine)-*b*-PSt (PHA-*b*-PSt) by the reduction with phenylhydrazine (PH) (Fig. 13.6). Formation of the hydroxylamine by this reduction was also confirmed by ^{1}H NMR. Variation in the scattering intensity distributions of the copolymers by the reduction is shown in Fig. 13.7. The size of the micelles was 55.6 nm, while that of the isolated copolymers was 19.2 nm. The plots of the UV absorption at 500 nm, relative scattering intensity, and hydrodynamic diameter of the copolymer versus the ratio of PH to the TEMPO (PH/TEMPO) are

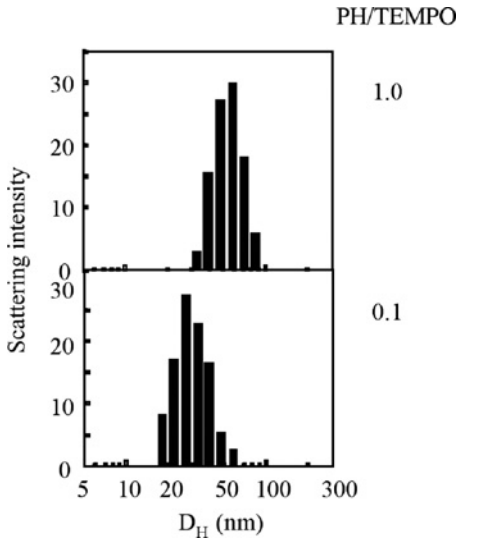

FIGURE 13.7 Scattering intensity distribution of the hydrodynamic diameter of the copolymer at 0.1 (a) and 1.0 (b) of PH/TEMPO.

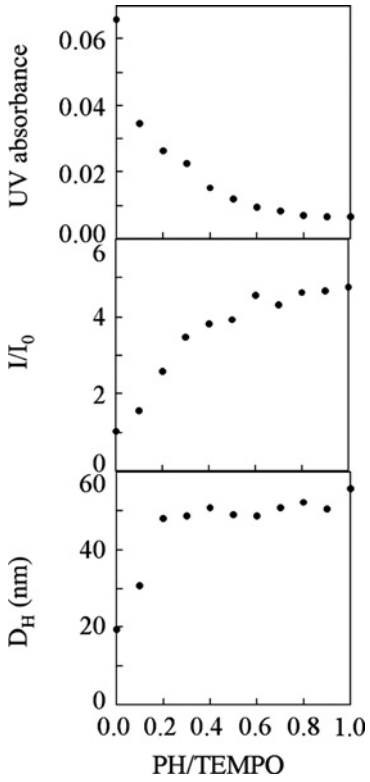

FIGURE 13.8 Plots of the UV absorbance at 500 nm, relative scattering intensity (I/I_0), and hydrodynamic diameter (D_H) versus the PH/TEMPO ratio.

shown in Fig. 13.8. As the PH ratio increased, the hydrodynamic diameter rapidly increased without an induction period and became steady over 0.2. No observation of an induction period indicated a strong aggregation force, based on the hydrogen-bonding attraction of the hydroxylamine in addition to the van der Waals interaction among the insoluble hydroxylamine hydrochloride.

The PHA-*b*-PSt micelles served as a reducing agent for oxygen [75], reverting to PVTEMPO-*b*-PSt.

13.2.3 Disproportionation-Induced Self-Assembly

Disproportionation-induced self-assembly of PVTEMPO-*b*-PSt was performed using hydrochloric acid in 1,4-dioxane (Fig. 13.9) [76, 77]. ESR demonstrated that the radical concentration of TEMPO decreased with an increase in HCl (Fig. 13.10), while UV analysis confirmed that the absorbance at 360 nm attributed to OAC increased as the disproportionation proceeded (Fig. 13.11). Figure 13.12 shows variation in the hydrodynamic diameter and scattering intensity of the copolymer by the disproportionation. The hydrodynamic diameter rapidly increased at a 0.8 molar ratio of HCl to the TEMPO, while the scattering intensity began to increase at 0.8. The micellization started at 0.8. The ratio at

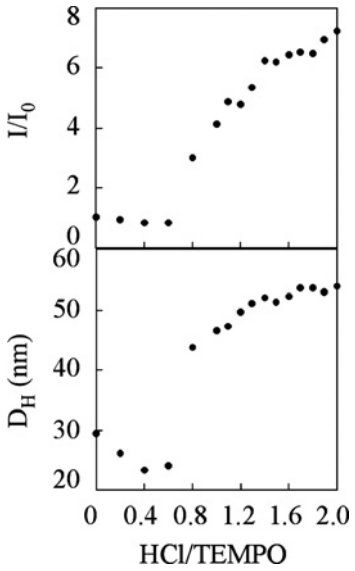

FIGURE 13.12 Variation in relative scattering intensity and hydrodynamic diameter of PVTEMPO-*b*-PSt versus HCl/TEMPO; [PVTEMPO-*b*-PSt] = 1.71 g/L.

which the micellization started was dependent on the acid strength. As the acid strength increased, the transition from unimers of the isolated copolymers to micelles occurred at a lower ratio of the acid (Fig. 13.13). The difference in micellization by the acid strength was accounted for by the difference in the solubility of the oxoaminium salts in 1,4-dioxane. The stronger acid provided a more soluble oxoaminium salt with a lower nucleophilic counteranion.

More recently, some applications of the TEMPO-containing micelles have been reported. A group of coworkers prepared the micelles supporting TEMPO on the core blocks by the self-assembly of an amphiphilic poly(4-amino-TEMPO acrylamide)-*block*-poly(ethylene glycol) diblock copolymer and poly(4-amino-TEMPO acrylamide)-*block*-poly(L-lactic acid)-*block*-poly(ethylene glycol) triblock copolymer and verified the utility of these micelles as EPR probes for bioimaging in vivo [78]. Another team demonstarted that the TEMPO-bearing micelles at the cores obtained by the self-assembly of PVTEMPO-*block*-poly(ethylene glycol) served as nanotherapeutic materials for diseases, such as cerebral and renal ischemia reperfusions and ulcerative colitis, due to their long blood circulation [79]. Another team of investigators prepared micelles

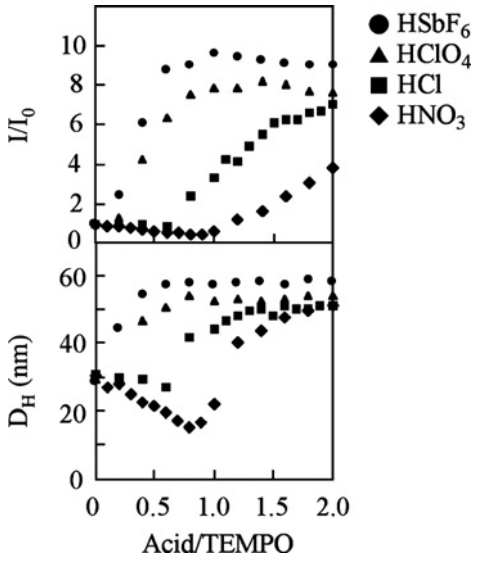

FIGURE 13.13 Variation in relative scattering intensity and hydrodynamic diameter of the copolymer during the micellization by four different acids; [PVTEMPO-*b*-PSt] = 1.71 g/L.

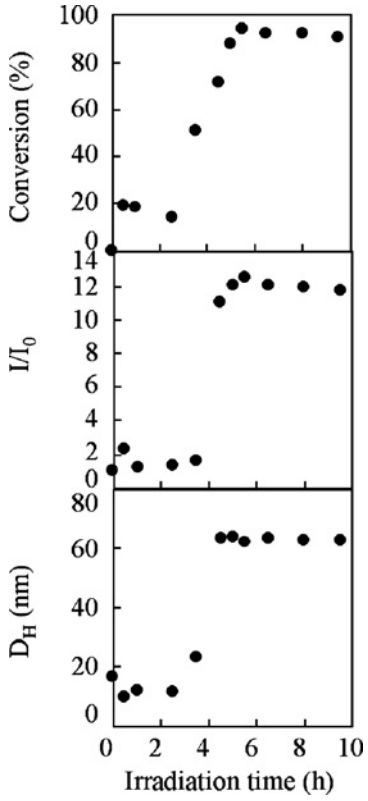
supporting TEMPO on the corona blocks by the self-assembly of poly(4-oxy-TEMPO methacrylate)-*block*-PSt and showed the potential as nanostructured organic radical batteries [80].

13.3 SELF-ASSEMBLY INDUCED BY IRREVERSIBLE PHOTOREACTIONS

Light reactions that occur during photosynthesis consist of irreversible photoreactions based on photooxidation. The irreversible reactions suppress the backward energy transfer and promote an efficient photon transfer. The fixation of the special structure formed by the irreversible photoreactions is also significant in holographic recordings for optical information–storage media because there is less volume shrinkage when recording holograms. Whereas there are a number of publications on the self-assembly induced by reversible photoreactions through the *cis–trans* isomerization and dimerization of azobenzene [81–83], spiropyran [84,85],



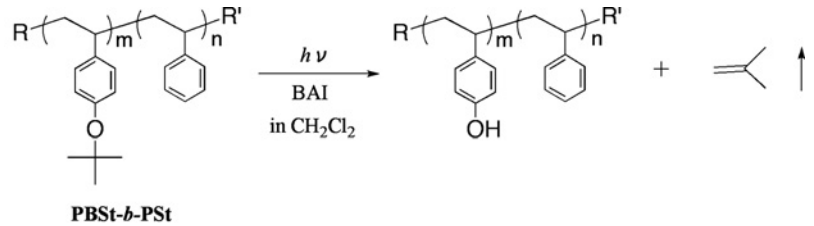


FIGURE 13.15 Variation in conversion, relative scattering intensity, and hydrodynamic diameter of the copolymer during irradiation using BAI; Mn(PBSt-*b*-PSt) = 15,000-*b*-97,000, $[\text{copolymer}]_0$ = 3.30 g/L.

stilbene [86–88], cinnamate [87], and triphenylmethane leukoresidues [89]. Because of the photoswitching function, only a few publications have reported the self-assembly by the irreversible photoreactions for small-molecule surfactants. Examples include the structure change by the photolysis of diazosulfonates [90–92], 1-iminopyridinium ylides [93], [4(4′-alkoxybenzoyl)phenylmethyl]phosphonic acids [94], and didecyl-2-methoxy-5-nitrophenyl phosphate [95]. The former three surfactants loose their surface-active ability by photolysis, resulting in the destruction of the micelles and vesicles. On the other hand, didecyl-2-methoxy-5-nitrophenyl phosphate formed vesicles by photolysis.

13.3.1 Photolysis-Induced Self-Assembly

Photolysis-induced self-assembly was established for a poly(4-*tert*-butoxystyrene)-*block*-polystyrene diblock copolymer (PBSt-*b*-PSt) that contained photodecomposable *tert*-butoxy groups [96, 97].

PBSt-*b*-PSt self-assembled into micelles in dichloromethane by irradiation in the presence of a photoacid generator of bis(alkylphenyl)iodonium hexafluorophosphate (BAI) (Fig. 13.14). Irradiation in the absence of BAI and the dark reaction in its presence produced no aggregates, indicating that the micellization was induced by the photolysis of *tert*-butoxy groups. The conversion of *tert*-butoxystyrene units into the vinyl phenol units [100] was confirmed by ^{1}H NMR. Figure 13.15 shows variation in the conversion of *tert*-butoxy groups to hydroxy groups, hydrodynamic diameter, and the

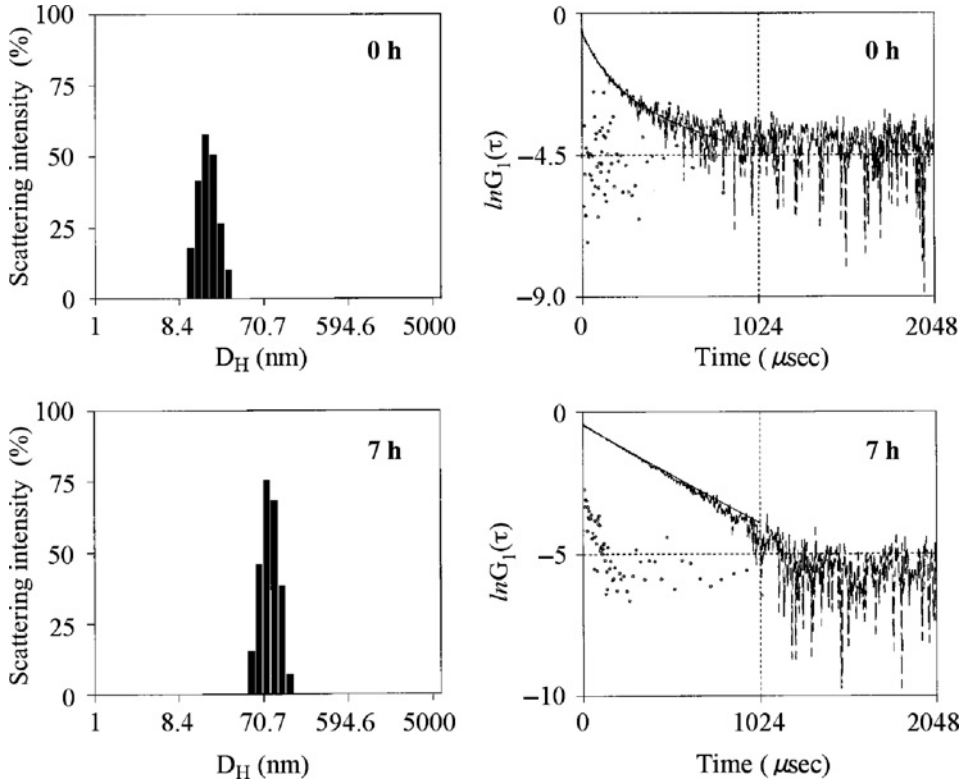

FIGURE 13.22 Scattering intensity distributions of the hydrodynamic diameter and plots of ln $G_1(\tau)$ versus τ for PPySt-*b*-PSt before (upper) and after irradiation for 7 h (lower); [PPySt-*b*-PSt] = 2.86 g/L

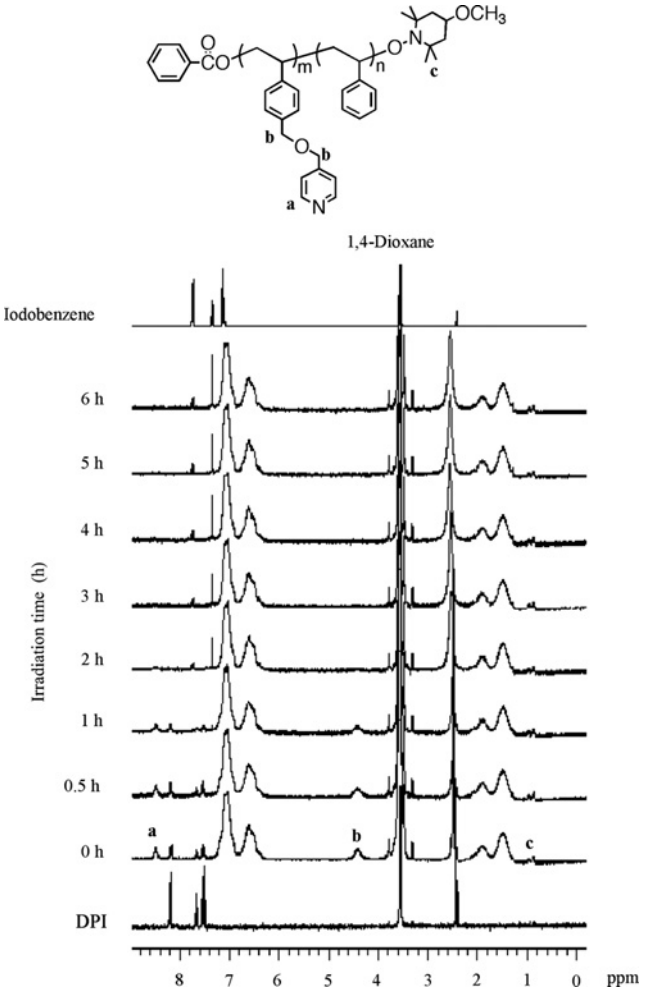

FIGURE 13.23 ^{1}H-NMR spectra of the copolymer during irradiation, DPI, and iodobenzene. Solvent: 1,4-dioxane-d_8; [PPySt-*b*-PSt] = 3.00 g/L.

relative scattering intensity of the copolymer during the irradiation in the presence of BAI. The good correlation of the plots of the hydrodynamic diameter and scattering intensity to the conversion indicated that the micellization occurred as photolysis of the *tert*-butoxy groups proceeded. The observation of the jump and the constant state within the short time period for the hydrodynamic diameter and scattering intensity suggests the rapid micellization due to the strong aggregation force of hydrogen bonding. The hydrodynamic diameter of the micelles averaged 63.0 nm, while that of the isolated copolymer was 16.6 nm. The TEM observations revealed that the photolysis-induced self-assembly provided spherical micelles (Fig. 13.16).

Micellization was also investigated using different kinds of photoacid generators, BAI, diphenyliodonium hexaflurophosphate (DPI), and triphenylsulfonium triflate (TPS) (Fig. 13.17). BAI and DPI produced a negligible difference in micellization, whereas TPS needed a longer irradiation time to promote micellization, in comparison. This difference among the photoacid generators in promoting micellization was based on their UV absorbance at 290 nm at which the photolysis proceeded; the photoacid generator that has a lower absorbance needed a longer irradiation time to initiate the micellization. It was found that the efficiency of the micellization was also dependent on the initial concentration of the photoacid generator. As shown in Fig. 13.18, the photoacid generator at a higher concentration provided a sharper and earlier transition during micellization, suggesting that the micellization was controlled by the concentration of the photoacid generator. The micellization was also controlled by the block length of the copolymer (Fig. 13.19). For the identical PBSt block length (Mn = 15,000), the copolymer with the shorter PSt block produced smaller micelles with a higher aggregation number.

More recently, the photolysis-induced self-assembly has also been determined using the photocleavage of *o*-nitrobenzyl esters contained in a poly(4,5-dimethoxy-2-nitrobenzyl acrylate)-*block*-PSt diblock copolymer [101]. They demonstarated that the micelles obtained by this self-assembly effectively encapsulated a fluorescent dye. Other coworkers found the self-assembly induced by photolysis involving the oxidation and reduction of an amphiphilic dendrimer consisting of oligo(*p*-phenylene vinylene) core branches and oligo(ethylene oxide) terminal chains [102]. This self-assembly was caused by the photooxidative cleavage of the double bond of the *p*-phenylene vinylene unit by oxygen, followed by the reduction of Au^{3+} ion into Au^0 by the hydroxy methyl radical generated by the photooxidation to produce the gold nanoparticles.

13.3.2 Photo-Claisen Rearrangement-Induced Self-Assembly

Photorearrangements have advantages in occurring without catalysts for a number of irreversible photochemical reactions. While a number of photorearrangements have been observed for *N*-aryl lactams [103, 104], the carboxylic acid derivatives of *N*-aryl amides [105,106], enol esters [107,108], enol lactones [109,110], and enamides [111,112] and the sulfonic acid derivative of *N*-aryl amides [113], the photo-Fries rearrangement [114–117], and photo-Claisen rearrangement [118, 119] have been investigated to determine the causes of the coloring of aromatic polyesters in sunlight and UV light [120].

Photo-Claisen rearrangement-induced self-assembly was performed using a poly(4-allyloxystyrene)-*block*-polystyrene (PASt-*b*-PSt) diblock copolymer. The allyloxystyrene units in PASt-*b*-PSt underwent photo-Claisen rearrangement in cyclohexane by irradiation at room temperature. However, it was revealed that the elimination of the allyl groups competitively occurred with the rearrangement (Fig. 13.20) [121]. No elimination occurred up to a ∼20%

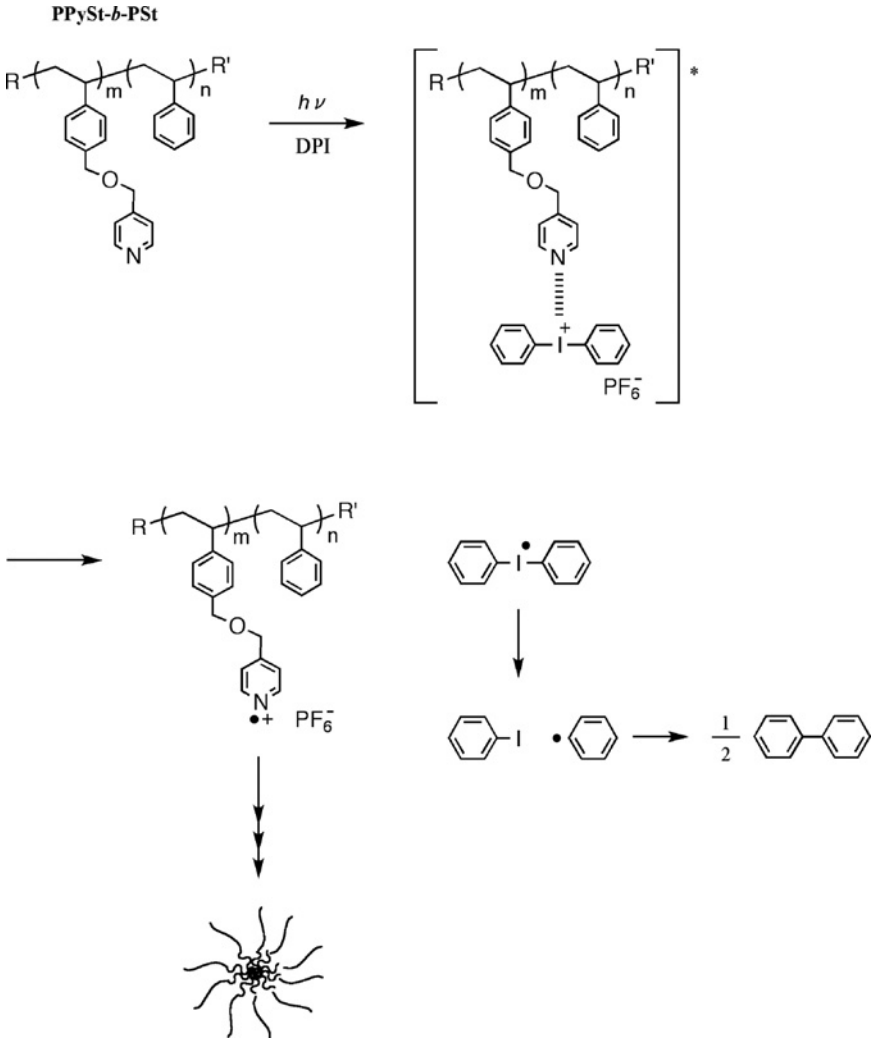

FIGURE 13.24 Photoreaction mechanism of PPySt-*b*-PSt and DPI.

conversion, and the quantitative rearrangement proceeded. However, over the 20% conversion, the elimination replaced the rearrangement and increased with the conversion. The rearrangement and elimination finally reached ∼50%. Light-scattering studies demonstrated that PASt-*b*-PSt formed micelles by this photoreaction. The scattering intensity distribution of the hydrodynamic diameter of the copolymer is shown in Fig. 13.21. Distribution of the hydrodynamic diameter of the isolated copolymers (35.3 nm) was shifted to that of the micelles (98.1 nm) by the reaction

13.3.3 Photoelectron Transfer–Induced Self-Assembly

The photoelectron transfer-induced self-assembly was attained through the photoreaction of the photoacid generator and electron donors. The diaryliodonium salt forms an exciplex with the electron donors and then undergoes photoelectron transfer from the electron donors to it to produce the cation radicals of the electron donors and the diaryliodine radical by the irreversible photodecomposition mechanism [122, 123].

A poly(4-pyridinemethoxymethylstyrene)-*block*-polystyrene (PPySt-*b*-PSt) diblock copolymer with the pyridine groups as the electron donors was irradiated at room temperature in 1,4-dioxane in the presence of DPI. The scattering intensity distributions and ln $G_1(\tau)$ versus τ for the copolymer solution before and after the reaction are shown in Fig. 13.22. $G_1(\tau)$ is the normalized time correlation function of the scattered field and is given by the following equation using $G_2(\tau)$, the time correlation function of the scattered intensity

$$G_2(\tau) = A(1 + \beta|G_1(\tau)|^2) \tag{13.1}$$

where A is a baseline that corresponds to the square of the average scattering intensity and β is an efficiency factor. The diameters of the micelles and isolated copolymers were estimated to be 68.9 nm and 27.2 nm, respectively. The copolymer was confirmed to form monodispersed spherical micelles based on the linear decay of the ln $G_1(\tau)$ value. For spherical particles with a monodispersity, $G_1(\tau)$ displays a single exponential decay curve and is represented by the following equations

$$G_1(\tau) = \exp(-\Gamma\tau) \tag{13.2}$$

$$\ln G_1(\tau) = (-\Gamma\tau) \tag{13.3}$$

where Γ is the decay constant and τ is the delay time [124]. ^{1}H-NMR analysis demonstrated that the micelles had cores formed by the PPySt blocks (Fig. 13.23). The signals originating from the pendant pyridinemethoxymethyl groups disappeared with the irradiation due to shielding of the PPySt core blocks by the PSt corona blocks. The signals of DPI also were replaced by signals of iodobenzene formed by the photodecomposition [122, 125, 126]. On the basis of the results that no micellization was induced by the irradiation of only DPI and by the dark reaction of the copolymer in the presence of DPI, the mechanism of the micellization was proposed (Fig. 13.24).

Variations in the signal intensity ratio of the methylene protons (b in Fig. 13.23) to the aromatic protons at 6.0–7.4 ppm in the ^{1}H NMR, hydrodynamic diameter, and scattering intensity during the micellization are shown in Fig. 13.25. The signal intensity reached zero at 4 h, while the hydrodynamic diameter and scattering intensity reached a steady state after 5 h, indicating that the micellization was completed within 5 h.

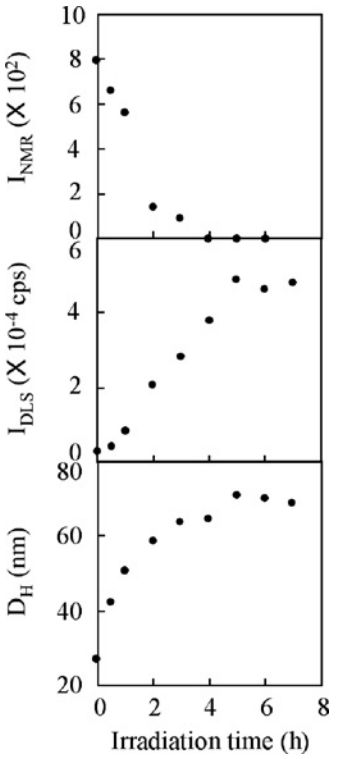

FIGURE 13.25 Variation in signal intensity ratio of methylene protons (**b** in Fig. 13.23) to the aromatic protons in ^{1}H NMR (I_{NMR}), scattering intensity (I_{DLS}), and hydrodynamic diameter of the copolymer during irradiation.

13.4 CONCLUSIONS

The biomimetic self-assembly induced by the chemical reactions occurring in vivo, such as electron transfer and irreversible photoreactions, was established using the block copolymers supporting the redox catalysts and photoreactive groups on the sidechains. These pendant groups were converted to solvophobic groups through these chemical reactions, resulting in the self-assembly of the copolymers. The reactions also involved the conversion of the pendant groups into other reactive groups to serve as an oxidant and reductant. The copolymers formed spherical micelles with some dozens of nanometers of hydrodynamic diameters by the self-assembly. Hence, the self-assembly induced by the chemical reactions provided nanoreactors of the spherical micelles with the functional groups supported on the core blocks. The chemical reactions employed as the trigger of the self-assembly in this study can be replaced by various reactions accompanied by the transfer of materials, electrons, photons, and energy. The significance and utility of the chemical reaction-induced self-assembly should increase as the applications of the functional nanoparticles formed by the self-assembly have expanded.

MOLECULAR INTERACTION IN BIOMIMETICS AND BIOSYSTEMS: CHIRALITY AND CONFINEMENT AT NANODIMENSION

Nilashis Nandi and Saheb Dutta
Department of Chemistry, University of Kalyani, West Bengal, India

14.1 INTRODUCTION

Biological systems have intrigued scientists since the beginning of scientific development. Natural bioystems fascinated the human intellect, and knowledge gleaned from the scientific studies of fundamental and applied aspects of various natural systems always remained tremendously beneficial for the development of civilization. Biological systems are inherently complex. Here, the term *complex* signifies that biosystems, in their natural state, possess the features described below. A complex biosystem is heterogeneous and multicomponent, with each component interacting with the others, and where the overall properties of the biosystem are significantly different from those of individual components. Common examples are proteins, nucleic acids, and membranes in their functional form such as present in a living cell. These molecules are present in an aqueous environment and often act together to complement or complete a particular life process. For example, membrane proteins are often part of the biological membrane, and the amphiphilic membrane structure is coupled with an aqueous environment. Similarly, protein and nucleic acids (RNA and DNA) are often fully active in aqueous media as present in cell. The structure and function of protein and nucleic acid deviate from their native state without the presence of surrounding aqueous environment. Moreover, often protein and nucleic acid interact to complete a bioprocess such as protein synthesis. Consequently, these systems are inherently complex. A complete understanding of such complex systems is impossible without the understanding of the interactions driving the structure and functions of these systems. Although the origin of the intermolecular interaction in all systems is invariably electromagnetic in nature, its manifestations in diverse physicochemical systems are of bewildering variety. Because of several factors such as variation in the charge distribution from one system to the other, diverse spatial geometry or topology of atoms, proximity and orientation of the neighboring nonbonded atoms, and interactions between groups or individual molecules, the resulting properties are often remarkable. Hence, studies of intermolecular interactions in complex biological systems and in relatively simple model mimetic systems as well, continue to attract attention. Such studies are not only of fundamental interest but are also important in developing bioinspired materials.

The structural aspects of biomolecules such as their chirality or dissymmetry often lead to unusual distance and orientation dependence of the interaction and resulting properties of the biomolecules are exotic. The proximity of the molecules in biosystems is another important factor in controlling their functionality. Confinement at nanolength scale augments the orientation dependence of intermolecular interaction in biomimetic and biological systems. The present review in this chapter starts with a discussion on the recent computational and experimental studies in biomimetic and biological systems where chirality and confinement lead to novel phenomena. The scientific knowledge gained from the related studies has biotechnological implication that such knowledge may be useful in developing new bioinspired materials.

Although chirality has ubiquitous presence in nature, its importance in intermolecular interaction is less frequently emphasized. It can be seen at the macroscopic length scale in plants and animal kingdoms, such as symmetry in patterns as well as shapes of leaves, respectively, and physiological features of various animals. It is a geometric property of various natural (as well as nonnatural) objects that renders them nonidentical and nonsuperimposable with their own mirror images. This broad definition of chirality includes diverse macroscopic objects such as hands (the word *chirality* originated from the Greek word *cheir*, meaning *hand*), animal organs, biological organisms, and macromolecules as well as microscopic objects such as various molecules as chiral entities [1–5]. If the object lacks an improper or alternating axis of symmetry, including both a center of symmetry and a plane of symmetry, then it is chiral [3, 4]. A necessary and sufficient condition for a molecule to be chiral is that it cannot be superimposed on its mirror image. A molecule possessing an asymmetrically substituted carbon atom is a common example of a chiral molecule. Thus objects of various length scales starting from macroscopic objects mentioned before, then mesoscopic objects (such as small to medium-sized aggregates of molecules) as well as small molecules could be chiral entities. Various molecules important for life such as protein, nucleic acid, lipids, and carbohydrates are chiral. Biochirality is thus all-pervasive in natural systems [6, 7]. A closer look at the structural hierarchy of biomolecules draws our attention to the fundamental and applied importance of chirality in life and qualitatively draws our attention to the structure function relationship in biology [8, 9].

The functionality of biomolecules is expected to depend on chirality. Naturally, biochirality is an intriguing aspect of life from various perspectives [1, 2, 6, 7, 10]. Since most of the functional biomolecules are chiral, the influence of chirality is observed at the molecular level in numerous biosynthetic pathways. However, the origin of biological homochirality has remained a fundamental unresolved problem [10]. Progress toward a quantitative understanding of the origin of the chiral preference or discrimination is challenging. Beyond the interest in developing a fundamental understanding of the origin and importance of overwhelming chiral discrimination observed in nature, knowledge about chirality-dependent interactions has practical significance as these interactions are important for catalysis, chiral polymer transition metal complexes, and asymmetric synthesis [11–14]. Understanding of chirality-dependent interactions in the reaction center of enzymes might play a tremendously important role in developing useful materials inspired by such biosystems. One well-known example of the importance of biochirality is noted in protein biosynthetic pathway. Although the relevance of chirality in this pathway seems obvious, considering the involvement of a number of chiral molecules in various steps, several questions remain unanswered concerning the role of biochirality in protein biosynthesis. It is to be noted that not only the proteinous active site but also the active site composed of nucleic acids (such as ribosomal transferase center) exhibit chirality dependent effects. Thus, chiral discrimination might be a general phenomenon exhibited by enzymes [1]. Active sites are cavities or clefts where the biological reaction takes place, and a number of active sites exhibit remarkable capacity of discrimination of noncognate substrates, including incorrect enantiomeric forms. Importantly, the confinement of substrates in the nanodimensional space of the active site plays an important role in the efficiency, accuracy, and speed of the biochemical reaction and the rejection of the non-cognate substrate.

Stringent chiral discrimination occurs within the enzymatic active site. Analyses of the molecular organization of the active-site structure and of the related interactions are useful in understanding the chiral specificity of enzymatic reactions. Crystallographic analysis provided clear insight into the microscopic organization of the enzymatic structures. Electronic-structure-based computations and molecular dynamics studies provided a unified perspective on the enzymatic reactions. The wealth of information provides a platform for analysis of the origin of the chiral preference exhibited by various enzymes. Enzymatic active sites are nanoflasks where vital biological reactions take place, and it is instructive to look into the molecular processes therein so that one can learn about the generic mechanisms used by these natural devices to utilize the cognate substrate and reject the others in a fast and accurate way. Although different enzymes and even enzymes in a given class can catalyze reactions of bewildering variety, studies so far offer great promise in identifying the role of chirality in the biological reactions and in following the fundamental correlation between chirality and life. Notably, the mechanism of discrimination between substrates is key to the ability of the enzymes to act as efficient biocatalysts. This mechanism is difficult to match by synthetic design, and this fact provides impetus for further study of the origin of enzymatic chiral discrimination. Interestingly, significant knowledge about chiral discrimination and interactions between molecules confined within a nanolength scale is gained from biomimetic systems, and hopefully this knowledge can be applied to understanding more complex systems.

Bilayers and monolayers are excellent models of biological membranes that exhibit fascinating chirality-dependent phenomena [15–20]. A number of biomimetic systems exhibit fascinating morphologies driven by the chiral structure of the constituent molecules. There has been significant progress toward understanding these systems through theoretical and computational studies. The constituents of the biological membranes such as lipids, cholesterols, and proteins are intrinsically chiral. It is no surprise that chirality plays an important role in the structure and function of biomembranes. The relationship between chirality and

morphology (as well as function) of biological membrane has fundamental importance. Mimics of biological membranes have technological implications, and detailed knowledge of the chirality-induced effects is essential for such future technological developments. The studies on simpler membrane-mimetic monolayer and bilayer membranes revealed that orientation-dependent interactions between molecules that are confined in a nanodimension exhibit interesting chiral discrimination effects. Diverse monolayer domain shapes formed from chiral amphiphiles draws our attention to the complicated interplay of intermolecular interactions and how these interactions lead to chiral discrimination. The origin of biological homochirality (predominance of only one enantiomeric form of amino acid and sugar rather than the corresponding racemic forms) is related to chiral discrimination and is a fundamental unresolved problem. This remained as a subject of intensive research [2,10]. Heteropairing of amino acid (L-enantiomer) and sugar (D-enantiomer) in today's living world is preferred by evolution. It is important to note that amino acids and sugars can racemize in aqueous medium, which could be a part of the prebiotic environment. This contradiction poses a problem in understanding the development of the enantiomeric excess of sugar and amino acids in either D or L form, respectively, as well as the retention of the same. One can define homochiral preference in biomimetic systems when interaction between same enantiomeric pairs (D–D or L–L) is favored over that between mirror-image pairs (D–L interaction). If homochiral interaction is strong, chiral phase separation may result from a racemic mixture, which is a chiral symmetry breaking or chiral segregation. On the other hand, heterochiral preference occurs where D–L interaction is preferred over D–D or L–L interaction. An understanding of the intermolecular interaction that controls the discrimination in biomimetic systems is expected to be useful in understanding the discrimination in biological systems.

The understanding gained from the recent computational studies described in the present review is that the restriction of free rotation of the amphiphile molecules at the air–water interface augments the orientation and distance dependence of intermolecular interaction. This ensures that the effect of chirality on the mesoscopic length scale organization of the amphiphilic aggregate is significant. These studies indicate that discrimination is manifested in confined spaces compared to that in the bulk phase and the restriction of dynamical motions (free rotation or translation) enhance the discrimination. Biological reactions occur in confined nanodimensional spaces. It involves L-amino acids and D-sugars (when natural chirality is relevant) and is significantly influenced by the chirality of the constituent molecules. Of the many examples of reactions, a few are relevant to protein biosynthesis, including transamination reaction, aminoacylation reaction, and peptide synthesis. Evidence of observable chiral discrimination in these reactions is available [2, 21–24]. These life processes (particularly the generation and retention of chiral structure of fundamental biological building blocks such as amino acids and peptides) is unlike the processes as observed in in vitro chemical reactions where the formation of racemic molecule is commonly favored over the enantiopure molecule.

As a specific example, we reiterate the progress of protein biosynthesis where influence of molecular chirality is significant. It is common wisdom that proteins are chiral at the primary level (length scale of the constituent amino acids), secondary (length scale of helix and β sheets) and higher (tertiary and quaternary) structural levels. In each case, both the basic building blocks and the architectures formed by such blocks are chiral. At the structural hierarchy of protein, only one enantiomer at the primary level renders the corresponding higher-level biological structure functional. Change in the enantiomeric form of the primary level is lethal for the functionality of the higher-level structure of protein. Protein biosynthesis is a multistep process and involves a number of small molecules such as amino acids, sugar, and adenosine triphosphate as well as large macromolecules such as synthetase, messenger mRNA, and transfer tRNA [8, 9]. Not only are protein molecules themselves chiral; most of the molecules involved in the process of protein synthesis are also chiral. It is tempting to conclude that chirality might have significance in the progress of the reaction. Molecular chirality influences the efficiency and accuracy of the process, rather than remaining as a structural feature developed randomly and without any specific purpose in nature. Rather, the chirality of the macromolecular protein structure and chirality of its constituent primary structural elements are assumed to influence its various functions such as molecular recognition and reactions performed by proteins. However, several lacunae of knowledge exist in understanding the recognition of other molecules, and reactions performed by them. The origin of the predominant homochirality in the protein structure and retention of enantiopurity (overwhelming L form of amino acid in the primary sequence) in protein structure and relationship of the chiral structure of protein with its functionality are less frequently explored.

With this end in view, we shall present a brief account of experimental works on chiral discrimination in biomimetic monolayers and protein biosynthesis systems. We present an overview of the recent computational studies that focus on influence of microscopic chirality on mesoscale structures in biomimetic systems such as monolayers and how the chirality of the reacting molecular segment influences the progress of protein biosynthesis. Studies have revealed that confinement at nanometer length scale enhances the chiral discrimination. Notably, these observations are related to the problem of understanding the correlation of chirality at various levels of structural hierarchy and the problem of understanding the retention of biological homochirality and the

heterochiral relationship between L-amino acid and D-sugar. In the following section we describe the scheme of the theoretical calculation applied to these systems.

14.2 METHODS OF THEORETICAL CALCULATION

We will discuss how the most notable feature of the domains formed from enantiomeric chiral amphiphiles is their curvature or handedness, and the absence of curvature is noted in the racemic state. Further, the domains are formed in the condensed phase where molecules are in close proximity. A focus of recent theoretical efforts in the case of biomimetic systems was to correlate the intermolecular interaction energy with the orientation and distance between neighboring chiral amphiphilic molecules [15–20]. The objective is to find the most favorable mutual orientation at various separations when a pair of molecules is in their minimal energy state and the individual molecules are in their most probable conformational state. For large molecules such as amphiphiles, the potential energy is a function of a large number of degrees of freedom. In principle, the intermolecular energy profile should be calculated as a function of all intra- as well as intermolecular degrees of freedom, which are relevant to the interface. However, the chirality induced effects are not significantly dependent on many of them. The theoretical calculations are performed at various degrees of consideration of molecular details, ranging from effective sphere, coarse-grained, to atomistic models [16]. Theory assumes that the intermolecular pair potential determines the mesoscopic chiral structure of the condensed-phase domain. This model has been successfully applied to monolayers and bilayers [15–20] and is described in this review.

The influence of the chirality on intermolecular interaction in biological reactions such as peptide synthesis and amino acylation reaction is studied based on the crystal structures of the active sites of the corresponding enzymes. The influence of chirality on the course of ribosomal peptide synthesis process is studied in a model of peptidyl transferase center in *Haloarcula marismortui* [25]. Similarly, the influence of chirality and electrostatic interaction in the first step of aminoacylation process is studied based on the crystal structure of the oligomeric complex of histidyl-tRNA synthetase from *Escherichia coli* complexed with ATP and histidinol and histidyl-adenylate [26]. The structural optimizations and the transition-state structure optimizations are performed using quadratic synchronous transient method 3 (QST3) [27–29], employing hybrid quantum-mechanical–semiempirical–molecular-mechanical theory (QM/MM). Transition states are identified using the frequency calculation and the presence of single imaginary frequency. The Gaussian suite [30] of programs is used in several calculations.

14.3 CHIRAL DISCRIMINATION IN BIOMIMETIC MONOLAYERS

In this section we present an overview of the recent results of the study of the chiral discrimination in amphiphilic monolayer using a combined hybrid quantum-mechanical–molecular-mechanical model. Earlier studies using classical theory–based computations using effective pair potential theory or coarse-grained models revealed that 1-*O*-hexadecyl glycerol (3-hexadecyl-oxy-propane-1,2-diol) monolayers exhibit an interesting crossover from heterochiral preference to homochiral preference and is consistent with the experimentally observed discrimination effects based on optical studies. It is interesting to note that both homochiral and heterochiral preferences can be observed in a particular monolayer system such as hexadecyl glycerol.

Significant orientation dependence of chiral discrimination is observed, which indicates that discrimination effects are dependent not only on intermolecular separation but also on their mutual orientation [31]. Monolayers of 1-stearoylamineglycerol [32] exhibit interesting chiral discrimination effects. The filigree-shaped domains of the *R*(+) enantiomers are curved clockwise, and those of the *S*(−)-enantiomers are curved anticlockwise (Fig. 14.1).

The appearance of curvatures in opposite directions indicates homochiral preference. On the other hand, the racemic mixtures form fractal-like domains without any specific curvature, suggesting heterochirality. The variation of the intermolecular interaction for the racemic pair as a function of the mutual tilt and azimuthal angles between the neighboring molecules shows a few deep minima at the shorter separation, and this feature remains unchanged at larger separations. Thus, the racemic domains are expected to have more favorable interactions at shorter separation. In contrast to the racemic pair potential, the corresponding plot of the enantiomeric pair shows that the minima occurring at the shorter separation are shallower than those at the larger separation of the same pair. The result indicates that the racemic pair will be energetically more favorable at shorter separation (compressed state in the condensed phase), which is suggestive of heterochiral preference. The corresponding state of the enantiomeric pair will be favorable at the larger separation, indicating that homochirality is favored in the enantiomeric system. It is revealed that the intermolecular energy profile of a pair of chiral molecules at nanoscale separation has specific orientation-dependent minima, differing for enantiomeric and racemic pairs. This difference is responsible for the chiral discrimination. When the molecules are widely separated, the dissymmetric nature of the orientation-dependent interaction is absent. No preferential mutual orientation is observed over the mesoscopic length scale, and the manifestation of chiral discrimination vanishes. This why the chirality-induced features are absent in liquid-expanded and gaseous phases of the monolayer [17]. The same trend is

noted in the case of a bilayer, where the helicity is observed at lower temperatures [19]. The reacting molecular segments in the active sites approach within nanoscale proximity in the course of a biological reaction. This proximity is important for chiral discrimination in biological reactions as discussed in the following section. Restriction of the orienational and translational degrees of freedom enhances the discrimination significantly when the molecule is restricted at the interface and surrounded by molecules in the condensed phase as noted in the present section for biomimetic monolayers. This is expected to be valid in biological nanosized cavities, which confine the reacting chiral segments. We are likely to conclude that similar principles can be operative in biological systems. Our computational studies support this view. In the following section, we present an overview of the recent studies on the influence of chirality of constituent molecules in the peptide synthesis and aminoacylation reaction, which are key reactions in the formation of peptides or proteins in cells.

14.4 EXPERIMENTAL STUDIES ON CHIRAL DISCRIMINATION IN PEPTIDE SYNTHESIS AND AMINOACYLATION REACTION

Protein biosynthesis occurs in successive stages in vivo. The major steps of protein synthesis are initiation, elongation, termination, release, folding, and posttranslational processing [8, 9]. The initiation step is the aminoacylation reaction, and this step is followed by the elongation step, which involves the peptide bond formation. The relationship between an amino acid (AA) and its cognate tRNA is established via the aminoacylation reaction. Once the aminoacyl tRNA is formed via the aminoacylation reaction, the polypeptide chain is lengthened by peptide bond formation between successive activated amino acid units. The aminoacylation reaction occurs in the active site of aminoacyl tRNA synthetase (Fig. 14.2). The elongation step takes place in the peptidyl transferase center, which is the active site (PTC). Subsequently, the termination codon of mRNA terminates the polypeptide chain synthesis and newly formed polypeptide is released. Finally, the newly formed polypeptide chain folds into its functional (biologically active) conformation [8, 9].

The aminoacylation reaction links the realm of the protein with the RNA world. Faithful translation of the genetic information is carried out in this step with surprising speed and accuracy [33–37]. The reaction occurs in two steps. The first step is the amino acid activation with the formation of aminoacyl adenylate and release of inorganic pyrophosphate. In the second step of the reaction, the 2′OH or 3′OH (hydroxyl group) (depending on the class to which the aaRS belongs) of the terminal adenosine of tRNA (A76) causes a nucleophilic attack at the carbonyl carbon atom of the aminoacyl-AMP. This result is the 2′- or 3′-esterification of the tRNA with the AA moiety and generation of AMP as the leaving group. Subsequently the product is released. Both activation and charging steps of 20 natural amino acids are catalyzed by 20 aaRSs. Subsequent step of protein synthesis after aminoacylation is the peptide bond formation occurring in the ribosome (a large and complex macromolecule). Pioneering studies revealed detailed organization at the molecular level of this functional molecular machine [38–47]. The active site of ribosome is termed the *peptidyl transferase center* (PTC). In this process, the α-amino group of the amino acid at A-site tRNA causes a nucleophilic attack at the carbonyl carbon of the ester bond connecting nascent peptide to P-site tRNA and forms an intermediate. The aminoacyl moiety attached to A76 of the tRNA in the A-site accepts the growing polypeptide from the tRNA in the P-site during peptidyl transfer. The new peptidyl-tRNA is subsequently translocated from the A-site to the P-site. The deacylated tRNA is translocated from the P-site to the exit (E)-site.

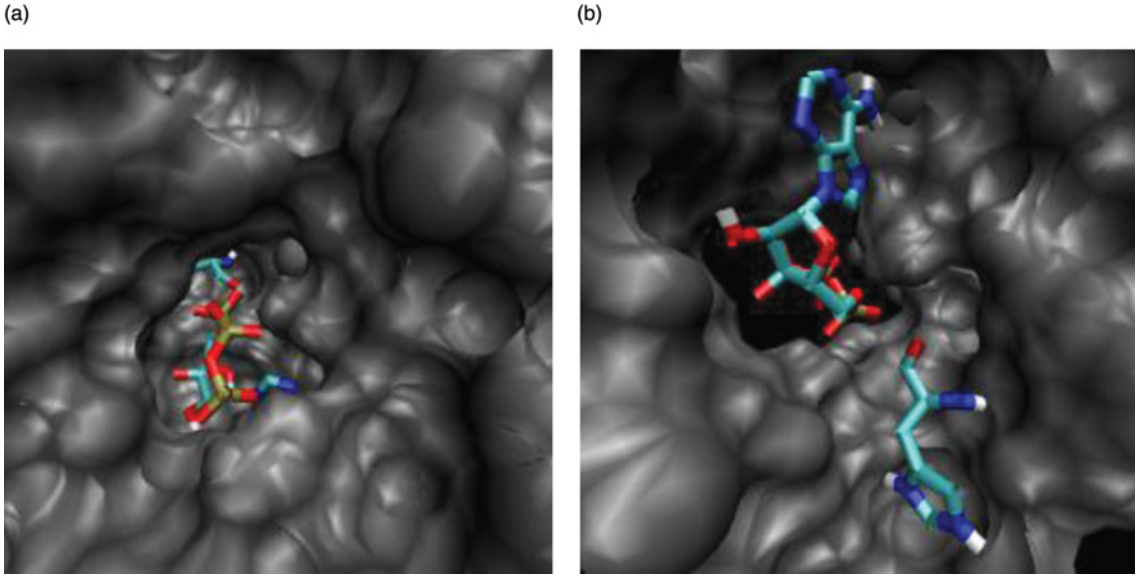

FIGURE 14.2 The active-site geometry of HisRS (1KMN.pdb) from *Escherichia coli* [26]. The ATP and histidinol are shown as bound substrate and substrate analog (analog of histidine), respectively. Two different views of the active site are shown: (a) from the perspective of the active site as viewed from the opening of the cavity; (b) as viewed from the amino acid binding site (few residues are omitted for clarity). The opening of the active site is ∼1.1 nm, and the tunnel length spanning the substrate and analogue is ∼1.7 nm. Images are prepared using VMD [108]. For a color version of this figure, see the color plate section.

Both concerted and stepwise mechanisms are proposed for the peptide synthesis. Two mechanisms are competitive and are studied in detail using experimental and computational methods. The stepwise mechanism takes place through a tetrahedral intermediate.

The residues composing the active-site wall within an enzyme not only enclose the reactants in a close separation but also confine them. This is a state of reduced degree of freedom for the reactants compared to the free state of the same moieties in the bulk, and this reduction in rotational and translational degrees of freedom enhances the stereoselectivity. Because of the reduction in rotational and translational degrees of freedom, reactant geometries with specific mutual orientations are more probable than their random mutual arrangements. The restriction of degrees of freedom is an important factor in steric recognition. However, the chiral discrimination is expected to be insignificant when the separation is rather large (several 10s of nanometers or larger separation). It has long been recognized that the enzymes, which are inherently chiral, are needed to orient both substrates and catalytic residues to preferentially stabilize one stereoisomeric transition state over another in the enzymatic reactions. The effectiveness of the catalytic activity of an enzyme in the rate enhancement significantly depends on the realization of tight binding, which is coupled with a high degree of steric recognition.

Both aminoacylation reaction and peptide bond formation exhibit strong chiral discrimination. The specificity of the aaRSs to incorporate a specific amino acid and its ability to discriminate between several competing substrates is well known. Synthetase ensures that only cognate substrates are selected from the large cellular pool of similar amino acids or tRNA to be incorporated within the active site. The ability to discriminate among amino acids is one of the major requirements for accurate translation of the genetic code because the structure of the cognate and noncognate amino acids may differ only in a subtle way in terms of charge distribution or spatial arrangements of groups attached to the chiral center. The frequency of misincorporation of noncognate amino acid is 1 in 10,000, which reflects a surprising accuracy of the mechanism. It was proposed that the acylation site rejects amino acids larger than the correct one because there is insufficient space for them. On the other hand, the smaller amino acids are cleaved by the hydrolytic editing site. However, this size- or volume-based mechanism is not capable of discriminatimg the enantiomeric species of the cognate amino acid as the D- and L-enantiomers that occupy identical total volumes.

Early studies indicated that when D-isomer is tested as substrates with particle-free supernatant of pancreas homogenate containing synthetase, no activity was observed [48]. Calendar and Berg observed that D-tyrosine could be esterified to $tRNA^{Tyr}$ and then could be incorporated into peptides [49, 50]. D-Tyrosine was incorporated into the peptide in an assay for a protein-synthesizing system. However, the L-tyrosine incorporation is much higher than the D-tyrosine incorporation. The reduced incorporation

of D-tyrosine indicates that the protein synthetic system is unfavorable toward the incorporation of D-amino acids into peptides. The overall rate of dipeptide formation is 30-fold higher for the L-enantiomer than the D-enantiomer. Yamane and coworkers studied stereoselectivity of peptide chain elongation [51]. Bergman and coworkers tested the specificity of L- and D-isomers of valine, isoleucine, and leucine for aminoacyl adenylate formation with valyl, isoleucyl, leucyl, and methionyl tRNA synthetases [52]. In all cases, formation of the D-aminoacyl adenylate is negligible or nil compared to the corresponding L-aminoacyl adenylate. Similar chiral specificity is noted for aspartyl tRNA synthetase of *Lactobacillus aerabinosus* [53]. Soutourina and coworkers concluded that in addition to D-tyrosine, D-enantiomers of other amino acids could be incorporated, based on an investigation of *E. coli* and *Saccharomyces cerevisiae* systems [54, 55]. Tamura and Schimmel studied the plausibility of chiral selectivity during the second step of aminoacylation using an RNA minihelix that recapitulates the amino acid attachment site within tRNA [56]. Formation of the [^{14}C]-L-Ala-minihelix is preferred over that of [^{14}C]-D-Ala-minihelix by a ratio of about 4:1. Stereoisomers of both Leu-*p*-dT_6dA_2 and Phe-*p*-dT_6dA_2 were also tested for chiral selectivity. A clear preference for L- over D-leucine (or phenylalanine) was observed. Chiral preference appears to occur during aminoacyl transfer from the 5′-phosphate to the minihelix. It might be noted that the mutual spatial orientation and distance between reacting molecular segments in the model system studied by the same two investigators [56] could differ from a corresponding biological system that might influence the observed ratio of selectivity. In a subsequent study, the same research group attempted to ascertain whether the free amino group attached to the asymmetric α-carbon of the amino acid played a role in the chiral selectivity of aminoacylation [22]. To address the question, the amino group of Ala was acetylated and *N*-acetyl-L- or D-Ala-aminoacyl oligonucleotide was used for the aminoacylation reaction. Nearly fourfold preference of L-Ala-minihelix^{Ala} over D-Ala-minihelix^{Ala} was observed. An energetic difference of <1 kcal/mol in the rate-determining step of the transition state is sufficient to give the observed fourfold preference for chiral specificity in the aminoacylation process. In a series of detailed studies Hecht and coworkers the extent of incorporation of D-amino acid into ribosome [57–60]. The result indicates that the D-isomer incorporation is severely inhibited compared to the natural isomer [58, 59]. The studies by Hecht and coworkers confirm that the incorporation of D-amino acids into a peptide is unfavorable relative to the incorporation of natural enantiomer. Several other examples of chiral discrimination in the protein biosynthetic pathway are available [61, 62].

It is important to remember that chirality is present also in the sugar ring of the nucleic acid structure. Significant influence of the chirality of the sugar ring involved in the CCA moiety is also noted [57]. This result is important in understanding the heterochiral relationship of D-sugar and L-amino acid in peptide synthesis, where the former is present as a part of the tRNA structure. While the *N*-acetyl-D-phenylalanyl–tRNA^{Phe} and *N*-acetyl-D-tyrosyl–tRNA^{Phe} produced only a small amount of dipeptide, the 2′- and 3′-deoxyadenosine analogs produced no detectable dipeptide formation. The result indicates that the effect of the sugar ring chirality is decisive over the peptide bond formation and alteration of the chirality of the same is unfavorable for the synthesis. Chiral discrimination is also studied in different model systems such as puromycine [9-{3′-deoxy-3′-[(4-methoxy-phenylalanyl)amino]-β-D-ribofuranosyl}-6(*N,N′*-dimethylamino) purine]. Note that the orientational degrees of freedom of A- and P-terminals in such analogs are in principle different from those within the ribosomal active site. Hence the mechanism and extent of discrimination might be different in these two cases. Another study employed a series of synthetic puromycin analogs to measure the activity of D-amino acid and β-amino acids in rabbit reticulocyte ribosome [21]. While the L-puromycin inhibits globin mRNA translation with an IC_{50} value of 1.8 μm, the corresponding D-puromycin or 9-{3′-deoxy-3′-[(4-methoxy-D-phenylalanyl)amino]-β-D-ribofuranosyl}-6(*N,N′*-dimethylamino) purine) inhibits globin translation, giving an IC_{50} value of 280 μm. The difference is 150-fold.

While the foregoing studies indicated that D-amino acid incorporation into proteins is practically impossible, Hecht and coworkers pointed out that alteration of the peptidyl transferase center might lead to enhanced D-amino acid incorporation [65]. Mutations in the 23SrRNA in the region of peptidyl transferase center (PTC) and helix 89 lead to conformational change in ribosome that alters its behavior in the protein synthesis. Modified ribosomes with mutations in regions 2447–2450 (belonging to the PTC region) and 2457–2462 (belonging to helix 89 region) of *E. coli* 23S rRNA and cell free protein synthesizing systems were prepared from mutant ribosomes. A high level of suppression in the presence of D-methionine and D-phenylalanine was observed. This indicates that the ribosome active-site structure is, at least partly, responsible for the discriminating mechanism and putative alterations may lead to enhanced incorporation of D-amino acid. The possibility of incorporation of D-isomer in a biosynthetic pathway or development of a racemic mixture cannot be ruled out, due to the presence of D-amino acid in several organisms [66]. The protein active site is complementary to substrate. With the proteins composed of L- and D-amino acids, it would be too cumbersome to maintain life. This could be a reason why evolution did not support the coexistence of protein composed of L- or D-amino acid. Equivalently, the development of protein structure composed of both L-and D-amino acids is unexpected. However, the foregoing view does not identify the mechanism of rejection of D-enantiomer when the

presence of the same are well known. The presence of D-amino acids in several biological organisms is known, for example, in the nonribosomal peptide synthesis and posttranslational modification therein [66–71]. A large number of biological molecules exhibit strong preference for either one of two enantiomeric forms (for each chiral center) of the nearly equal possible isomers. While the incorporation of D-amino acids is a hallmark of peptide-synthetase-based nonribosomal peptide synthesis [67, 68,71, 72] and post-translational modification [66, 69, 70], the RNA-dependent ribosomal synthesis of peptides and proteins exclusively incorporates only the 20 natural amino acids and selenocysteine with their natural chirality (L-form). Incorporation of D-amino acids into an organism can be toxic if it does not naturally occur in the same [71–81]. D-Amino acid occurs naturally in selected systems such as peptidoglycans of bacterial cell walls (D-Ala- and D-Glu-), in peptide antibiotics, and in the human brain (D-Asp and D-Ser are present at high concentrations). Several other examples of presence of D-amino acid in biological organism are noted. Dedkova and coworkers [65] pointed out that alteration of the peptidyltransferase center might lead to enhanced D-amino acid incorporation. The study indicates that the organization of PTC has a major influence on the process of synthesis and that alterations in PTC structure may lead to enhanced incorporation of D-amino acid.

The presence of D-enantiomers only in some specific organisms and its almost complete exclusion in the natural biosynthetic pathway of protein synthesis in today's world is now well established. This raises the question about the mechanism of chiral discrimination in biosynthetic pathways in different organisms [1]. Since the racemic compound in crystalline state is more stable than the corresponding enantiomeric form, it is unknown how the chances of racemization are avoided throughout the course of evolution in biological reactions. The answer to the question as to why the basic blocks of life are not being scrambled, and retain enantiomeric purity, is challenging as many biological systems incorporate D-amino acids as well as racemize in other cases as mentioned before. Computational analysis of the chiral discrimination in protein biosynthesis pathway is discussed in Section 14.5. These studies clarified the molecular aspects of the mechanism of chiral discrimination. In the following section, we discuss the mechanisms of retention of chirality and exclusion of noncognate enantiomer in protein biosynthesis reactions, particularly in aminoacylation and peptide bond formation steps as understood from computational analysis.

14.5 COMPUTATIONAL ANALYSIS OF CHIRAL DISCRIMINATION IN AMINOACYLATION REACTION

The aminoacyl tRNA synthetases (aaRSs) ensure that only cognate substrates as well as tRNA are selected from the large cellular pool of similar amino acids or other tRNAs. The frequency of misincorporation of noncognate amino acid is very low, which reflects a surprising accuracy of the mechanism. It is possible that a number of intricate contacts between aaRS and amino acid, which are favorable for cognate but unfavorable for noncognate amino acids, results in the successful recognition and concomitant discrimination. It might be assumed that the acylation site rejects amino acids larger than the correct one because there is insufficient space for them and the smaller amino acids are cleaved by the hydrolytic editing site. However, this size- or volume-based mechanism fails to discriminate the enantiomeric species of the cognate amino acid as the D- and L-enantiomers occupy identical total volumes.

In a series of studies, electronic-structure-based computations are carried out to understand the chiral discrimination in the first step of aminoacylation reaction (adenylation) [82–85]. A combined quantum-mechanical–semiempirical theory is applied to study the discrimination between L-His and D-His using a model of the corresponding active site of histidyl-tRNA synthetase (HisRS). The initial study showed that the substrate amino acid (His) is located within a network of interactions within the nanospace enclosed by the active-site residues [82]. The network of interaction is unfavorable when the D-amino acid is incorporated in the active-site geometry of the natural aaRS. The transition-state geometry corresponding to the activation by D-His is also unfavorable because of the lack of stabilizing interactions that are present in the transition-state structure corresponding to the activation by L-His [82]. Comparison of the reactant and the product geometry shows that the reacting moieties (amino acid and ATP) undergo a change in mutual separation and orientation during the course of the activation. The resulting variation in the energy is unfavorable for the D-His (as substrate) compared to L-His. All these results point out that the restriction of the degrees of freedom of the amino acid and confinement within a nanodimensional space enhances the chiral discrimination.

Chiral discrimination is described in further detail in a subsequent study [83]. The study shows that the variation of the interaction energies for the mutual approach of L-His and D-His toward ATP during nucleophilic attack are strikingly different. The result shows that the surrounding nanospace of synthetase confines the L-His and ATP in the global minima of the energy surface and proximally places the reactants in geometry suitable for the inline nucleophilic attack. The energy surface becomes highly unfavorable when the D-His is placed within the active site. The reorganization of the surrounding nanospace can somewhat improve the unfavorable nature of the intermolecular energy surface of D-His and surrounding residues. However, such a rearrangement requires large-scale structural reorganization of the synthetase structure and is unfavorable. In other words, the arrangement of the active site of synthetase to allow the incorporation of D-His is ruled out by the energy cost to be

paid for such misincorporation. The influence of active-site residues on the discrimination is also studied. Variation in the interaction energy as a function of relative separation between substrates (both L- and D-His) and important active-site residues are computed. The results emphasize the role of active-site residues in controlling the fidelity of the reaction. The interactions of both L-His and D-His with Glu83, Arg113, Arg259, and Tyr264 (all are active-site residues in proximity of the substrates) are studied using using *ab initio*/semiempirical theory. The result reveals the significant stability of the cognate amino acid (L-His) compared to D-His as a function of the separation between the active-site residues and His. The surrounding nanospace of synthetase confines the L-His and ATP to proximally place the reactants in geometry suitable for the inline nucleophilic attack. The confinement of reacting moieties placed within nanometer regime of an active site drives the corresponding reaction very precisely with remarkable discrimination capacity. The foregoing result shows that the set of active-site residues confine the amino acid and ATP in a potential well using an intricate interaction that is selective for the (natural) L-His for adenylation.

It is important to note that the significance of the surrounding active-site residues and the influence of confinement of substrates within the nanospace of active site on the chiral discrimination are not limited to the specific aaRS (HisRS) from a particular species (such as *E. coli*). Computational analyses have shown that the mechanism of chiral discrimination is common in other species studied [84, 85]. Crystallographic and biochemical studies revealed that a number of active-site residues are conserved in different species for a given aaRS. Comparison of the primary sequence and architecture of the active site of HisRS in three different species shows that the residues that are responsible for creating a network of important and favorable interactions with the substrate His and ATP are conserved in the active-site structures in different species studied such as *Escherichia coli, Thermus thermophilus*, and *Staphylococcus aureus* [84]. The relative arrangements of the conserved residues with respect to the substrates are conserved in these three organisms. The analysis suggests that the arrangement of residues in controlling the stringent chiral discrimination is developed through evolution and retained thereafter. In other words, the pattern of active-site organization and the concomitant network of interaction control the mechanism of the reaction. The accuracy of the reaction mechanism is developed through evolution to render the process of protein synthesis error-free. The active-site structure, so perfected, is possibly retained further. It is possible that the confinement of substrates within a nanodimensional space of active site and the resulting network of interaction are important guiding factors for the chiral discrimination exhibited by aaRSs in general [85]. The abovementioned electronic-structure-based computations indicate that the network of electrostatic interaction within the active site of aaRS has a decisive role in the chiral discrimination. The conclusions agree fairly well with the results from classical molecular dynamics simulations. Thompson and coworkers investigated the preference for acylation of L-Asp over D-Asp by aspartyl-tRNA synthetase (AspRS). Discrimination against D-Asp can be explained by the unfavorable binding with the D-Asp. Component analysis indicates that Coulomb interaction is the major favorable factor to the L-Asp binding [86].

A more recent computational study further shows that the network of substrate and active-site interaction has distinctive features for two classes of aaRSs and that few features are characteristic for each of the twenty aaRSs [87, 88]. For example, the molecular organization of the active-site nanospace of class I and class II aaRS are different. The difference is due principally to extended and bent states of ATP in the two classes. Computational studies show that the most feasible pathway for nucleophilic attack to αP is oppositely directed for classes I and II. It is also pointed out that the modes of nucleophilic attack by the oxygen atom of the carboxylic group of the substrate amino acid to the αP atom of adenosine triphosphate ATP are different. The *syn* oxygen atom of the carboxylic group attacks the αP atom of ATP in all class I aaRSs (except TrpRS) investigated, while the *anti* oxygen atom attacks in the case of class II aaRSs. The difference in mechanism is related to the fact that the relative arrangement of the ATP with respect to the AA is opposite in class I and class II aaRSs. Thus, the nucleophilic attack is energetically less favorable for class II aaRSs compared to the class I aaRSs (when the influence of the active site is excluded from consideration). However, this difference in the propensity of nucleophilic attack is counterbalanced by the bent state of ATP and the presence of Mg^{2+} ions and different sets of active site residues [87, 88]. The study shows that active site residues are not only involved in proper placement and orienting the substrates but also form a network of interaction with the substrates that is idiosyncratic for each aaRS. Thus, it is no surprise that the noncognate amino acids are excluded from entering the active site, leading to misincorporation. Obviously, the wrong enantiomer (such as D-amino acid) perturbs the network of interaction and is not favored. Another reason for the chiral specificity in aaRSs is noted [87]. The reduction of unfavorable electrostatic potential at the reaction center (between the attacking oxygen atom of the carboxylic acid group of substrate amino acid and αP atom of ATP) is an important prerequisite for the nucleophilic attack during the first step of aminoacylation reaction. The positively charged amino group of substrate amino acid (and the active-site residues close to the reaction center) plays a major role in reducing the aforesaid unfavorable electrostatic potential. Alteration of the chirality of substrate amino acid to the D-enantiomeric structure would change the spatial arrangement of the amino group. The resulting arrangement of groups is ineffective in reducing the potential. Thus, computational

analysis provides important insight into the factors responsible for chiral discrimination in the nanospace of the active site of aaRS.

14.6 COMPUTATIONAL STUDIES OF THE CHIRAL DISCRIMINATION IN PEPTIDE BOND FORMATION REACTION

Out of the several partial reactions of protein biosynthesis, peptidyl transferase reaction is one of the most intensively studied. Although ribosome is made up of RNA and proteins, the peptidyl transferase center is essentially composed of nucleic acid with no protein present within 1.5 nm distance of active site. The active site of the large subunit of the ribosome is composed of layers of conserved nucleotides. It is an important question as to how chiral discrimination is carried out by PTC and how the ribosomal pathway excludes amino acids other than the L-enantiomer. The mechanism of retention of enantiopurity is not straightforward to understand since D-amino acid is involved in nonribosomal peptide synthesis.

Few features of the reaction relevant to chiral discrimination are qualitatively understood from the experimental studies. First, the intermolecular energy profile of the reaction is expected to be orientation-dependent. Consequently, chiral discrimination may not be averaged out for all possible orientational degrees of freedom as in the case of same reaction in a solvent. Further, molecular segments involved in reaction (L-amino acid and D-sugar) being chiral, their chirality should influence the nature of the corresponding energy surface. Confinement within a nanospace must influence the discrimination exhibited by the reaction as also observed in biomimetic systems. It is pointed out in the literature that the preorganization of the active-site residues and their proximity is important for effective catalysis during the progress of the reaction [89]. All these factors are recently explored using computational methods to understand the molecular mechanism of the discrimination and are discussed as follows.

Peptide bond formation is studied using *ab initio* methods for L-alanine dipeptide formation considering both concerted and stepwise mechanisms [90]. In this study, the reacting amino acids are not covalently linked to any part of a larger structure, unlike those present in the CCA terminal in tRNA during peptide synthesis in PTC. The amino acid moieties are not surrounded by the active-site moieties. It is unlikely that chiral discrimination will be exhibited in such a system as the reacting moieties are free to assume various mutual arrangements without being constrained as they are not covalently linked to a larger structure (RNA) and neighboring residues (composing the PTC). As a result, discrimination is not expected to be observed, and the values obtained are averaged out over all possible mutual orientations. During the peptide bond formation, the $3'$ end of the A-site arrives at the P-site by a process of mutual rotation within active site [91,92]. The discrimination in the intermolecular energy surfaces of a pair of alanine molecules in the restricted orientational state (which is a simplified model of the A- and P-site terminals during their restricted rotation in PTC) is investigated [93]. The energy difference between the L–L pair and D-L-pair at given intermolecular orientation and separation for the same value of both variables for both pairs is defined as the chiral discrimination energy ($\Delta E_{\text{LL-DL}}$). When $\Delta E_{\text{LL-DL}}$ is negative, it is homochiral preference and when $\Delta E_{\text{LL-DL}}$ is positive, a heterochiral preference is dominant. It is ensured that the discrimination observed is not artificially generated by basis set superposition error (BSSE). The energy surface are calculated by MP2/6-311++G**, HF/6-311++G** and B3LYP/6-311++G** level of theories. The result shows that the interaction energy of the L–L pair and the corresponding interaction energy of the D–L pair are not identical with the variation in either the distance or the mutual orientation of two molecules. The plot of L–L pair is dissymmetric, revealing the underlying chirality of the molecules. In contrast, the plot for the D–L pair is symmetric around the 180° orientation, which reveals the racemic state of the neutral pair where the charge dissymmetry is also absent. Unlike the neutral case, the asymmetric charge distribution of the neighboring molecules (starting geometry) breaks the symmetry of the energy profile of the D–L zwitterionic pair, which can be observed in the corresponding dissymmetric nature of the energy profile.

It is pointed out that the very large difference between the energy surfaces of L–L and D–L pairs at specific orientations at same distances between the corresponding pairs is due to short-range repulsive interactions. In general, the short-range repulsive part of both van der Waals and electrostatic (Coulombic, dipolar or multipolar) interaction varies more sharply than does the corresponding long-range attractive part of the intermolecular interaction [94, 95]. The energy profile of L–L at a given short-range separation is less unfavorable than the corresponding energy profile of the D–L pair at the same intermolecular separation. However, the variations in intermolecular interaction energy are large at such short-range intermolecular distance, and this causes the large discrimination observed (which is the major source of the discrimination for neutral molecules). Favorable electrostatic interaction further contributes to the large homochirality of the $\Delta E_{\text{LL-DL}}$ for the zwitterionic pair in addition to the short-range steric repulsion. The basis set superposition error (BSSE)-corrected results show enhanced discrimination. Use of the higher-level Møller–Plesset perturbation theory (MP2) and further BSSE correction do not change the conclusions made at the Hartree–Fock (HF) level of theory. In other words, during the A-P rotatory movement, the L–L pair will pass through relatively low energy regions of the intermolecular energy surface compared to the D–L pair. The study suggests a possible method of D-amino acid exclusion.

The effect of confinement of substrates within the nanospace of PTC on the chiral discrimination is studied using hybrid quantum chemical studies [96]. The study shows that the interaction of the L–L pair can occur at significantly lower energy and without any steric constraint over the range of orientation. The interaction between the D–L pair is relatively unfavorable, and the corresponding energy profile has two minima only at limited range of orientations. The orientational space for the D–L pair is limited and experiences more steric clash with surrounding residues compared to the L–L pair. This is clear evidence of homochiral preference. In order to understand the origin of the observed discrimination, different surrounding residues are removed and the influence on the ease of the rotatory path is studied. Exclusion of the U2620 from the surrounding residues drastically diminishes the discrimination. This indicates that the U2620 has preferential nonbonded interaction with A- and P-terminals in the L–L form rather than the D–L form. However, homochiral preference remains significant. Entire preferred homochirality, as observed in experiment and calculated, is not due to U2620, and the residual discrimination is nonnegligible. All other residues are successively removed (A2485, A2486, C2487, A2488, A2637, G2540, U2451, and C2452) in order to identify the origin of residual discrimination, and this is noted to change little from that when U2620 was removed. It may be noted that the removal of backside residues such as A2485, A 2486, C2487, and A2488 gradually diminished the repulsive steric constraint but discrimination remained effectively unchanged. Finally, all residues are removed and two phenyl alanine groups are rotated without any surrounding residues in the same specified range of rotation. Interestingly, the discrimination is nonvanishing. Strong homochiral preference is still noted, which is entirely determined by the amino acid sidechains. Comparison of the relative energy gap of L–L and D–L pair plots including all surrounding residues except U2620 and the relative energy gap of L–L and D–L pairs with all surrounding residues removed clearly shows that the residual discrimination (as remained after removal of U2620) remained same in the specified range of orientation and is independent of other residues. This conclusion corroborates the results of previous study based on *ab initio* and DFT-based studies on interaction of alanine molecules where homochiral preference is noted as a function of mutual orientation [93]. The study quantitatively shows that the observed homochiral preference is due to U2620 residue as well as the amino acid sidechain at the A- and P-terminals. A major part of the discrimination comes from the variation of nonbonded interaction of rotating the A-terminal with U2620 during approach of the former toward the P-terminal. Significant discrimination is due to the difference in the sidechain interaction of A- and P-terminals themselves during the rotatory motion even when no surrounding residues are present.

It is important to address that how important is the chirality of the D-sugar in the context of the long-length-scale structural organization of the PTC. Explicitly, the question is whether the possible heteropairs and homopairs (other than the D-sugar and L-amino acid) can perform the peptide synthesis with similar efficiency in the natural biological surrounding (PTC). The influence of the D-sugar on the chiral discrimination in peptide synthesis has been investigated [97]. There could be several factors contributing to the discrimination: (1) the D-sugar ring might have favorable stereochemistry related to the structural organization of the tRNA itself, (2) the sugar ring might have the proper stereochemistry that can facilitate the rotatory path (through which the A-site tRNA $3'$-end flips into the P-site by rotating around the bond connecting the single strand $3'$-end) leading to the optimal orientation for peptide bond formation, and (3) the hydroxyl group attached to $2'$ can catalytically lower the transition-state barrier (related to the formation of the peptide bond) when positioned in a favorable stereochemical orientation.

Modeling studies show that the alterations in the chiral centers of the ribose sugar ring bring large scale structural changes in the tRNA structure. Such structural modifications are unfavorable for the peptide synthesis process [97]. It is observed that the presence of sugar ring in both terminals enhances the favorability of the rotatory path compared to the case when the sugar ring is removed. Since rotation of the A-terminal occurs around the $3'$ bond, the rotatory process is a mutual orientational motion of the amino terminal with respect to the A-site sugar ring. As a result, removal of the A-site sugar ring raises the energy due to the loss of favorable interaction. The ribose sugar ring and specifically that of the $2'$ chiral carbon of the A76 has also another influence on the peptide bond formation process. Experimental studies indicate that the hydroxyl group is responsible for the significantly high rate of the peptide synthesis in ribosome compared to that of an uncatalyzed one (in absence of ribosome). The role of $2'$ OH in the peptide synthesis was suggested [98–100]. The role of the $2'$ OH group into the rate enhancement produced by ribosome based on entropic contribution is proposed [101, 102]. The barrier heights of the transition states for the formation of peptide bond and the influence of the $2'$ OH group is studied for two different mechanisms (proton shuttle and anchoring mechanism), and the difference in the barrier heights is attributed to the absence of the $2'$ OH group, which results in removal of the chirality of the $2'$ carbon of the sugar ring [97]. It is noted that the reactant geometry contains a cycle of hydrogen bonds, and the hydrogen bond distances are further shortened in the transition state geometry. Several of these hydrogen bonds are absent when the $2'$ OH are removed. This result indicates that the change in the stereochemistry of the $2'$ center can alter the progress of the synthesis by several orders of magnitude. The observation corroborates the experimental data that the substitution of P-site tRNA $2'$ OH by $2'$ H and $2'$ F, results in 10^6 -fold reduction in the rate of peptide bond formation [24]. A

comparison of the transition states in the two cases indicates that the anchoring role of the 2′ OH group is responsible for lowering the barrier height compared to the case when the 2′ OH group is removed. The result strongly suggests that the chirality of the 2′ carbon is vital for the rate enhancement. Alteration of the stereochemistry at the 2′ center of sugar ring results in rise of the barrier height. Thus, the change in the stereochemistry of the 2′ OH makes the process as unfavorable. The computational study conclusively shows that the proper positioning of the group as well as the natural chirality (with respect to the 2′ center, at least) is vital for the reaction.

The residues present in the PTC surrounding the substrates (which are in proximity of nanometer length scale with the D-sugar) also influence the rotatory path and the discrimination. Although the bases are achiral, their interaction with the sugar ring can be orientation-dependent and can influence chiral discrimination. It was pointed out earlier that when achiral moieties have restricted orientational freedom, its interaction profile with a chiral moiety can have orientation dependence [104]. The orientation dependence can be different for L- and D-forms of the chiral moiety and might give rise to discrimination. The influence of various surrounding residues such as C2104, C2105, A2485, A2486, C2487, U2541, C2542, C2608, G2618, U2619, U2620, and A2637 on the rotatory path and their interaction with the sugar ring related to the A-site and P-site of the 50S ribosomal subunit of *Haloarcula marismortui* has been computationally investigated [97]. The removal of the surrounding residues affect the nonbonded interaction with the amino acid:sugar heteropair of natural chirality. It is concluded that while a set of surrounding residues have favorable influence on the peptide bond formation between A- and P-terminals within PTC, a number of other residues might have less influence on the same process.

The computational studies described earlier reveal that the molecular mechanism of the chiral discrimination involves the A- and P-amino acids, the D-sugar ring, and surrounding bases of the PTC. Several factors are noted to be responsible for discrimination and explain the high level of stereospecificity of the process. The factors can be summarized as follows. The chiralities of the amino acids at A- and P-terminals are most important. The rotatory path for the approach of D-amino acid toward the L-terminal is unfavorable because of steric hindrance between the amino acids themselves. Their nanoscale separation is important for discrimination, and at larger separation no discrimination is noted. The second factor is the restricted nature of the range of mutual orientation of the terminals during the rotatory path for the approach to form the peptide bond. This factor causes the resultant interaction profiles for L–L and D–L pairs to exhibit different forms of discrimination. The natural chirality (D-form) of the sugar ring has a favorable influence on the long-length-scale organization of the tRNA structure and is another factor for influencing discrimination. Alteration of the chirality of the sugar ring is unfavorable as it requires large structural rearrangements of tRNA. Favorable influence of the D-sugar ring is noted on the rotatory path for the process of approach to form the peptide bond. The removal of the sugar ring causes the rotatory path for approach to form the peptide bond as unfavorable, which indicates that the interaction of the D-sugar with the amino acids are more favorable than other homo- or heteropair combinations of the sugar amino acid pair. The stereochemistry of the 2′ center of the D-sugar has a vital influence as it catalyzes the peptide bond formation by making proper placement of the OH group that is involved in the catalysis. Analysis of the transition-state structure revealed that the alteration and removal of chirality of the 2′ center destabilize the transition state and renders the formation of peptide bond unfavorable. Finally, the nanoscale proximity of some of the surrounding bases present in PTC with the A- and P-terminals and their restricted orientation influence the discrimination. Thus, multiple factors control the discrimination in the peptide synthesis in PTC and allow accurate retention of the biological homochirality in the reaction.

14.7 CONCLUDING REMARKS

In the present review, we discussed recent experimental and computational analysis of the intermolecular interaction in the biomimetic and biological systems as influenced by chirality and confinement at nanodimension. Both the molecular chirality and confined geometries are found to be hallmarks of numerous biosystems and reactions therein. The confinement of neighboring amphiphiles in nanodimensional proximity in condensed state gives rise to interesting chiral discrimination and exotic morphology emerges as discussed in the present review. Similarly, chiral substrates confined in the active-site nanospace have significant influence on the course of vital biological reactions and exhibit stringent chiral discrimination, which plays a significant role in life processes. The microscopic understanding about the subject is beginning to emerge, and future research needed in order to understand the related principles of nature is identified. Recognition of the fact that the confinement of substrates in the active-site nanospace has significant influence on the course of vital biological reactions and chiral discrimination plays a significant role in the process of adding new dimensions to the *nanobiology* of respective biosystems. To recapitulate, *nanobiology* addresses biological and biophysical problems using tools, ideas, and materials of nanoscience and biology (biological systems are inherently nanodimensional) [105]. *Nanobiology* as a subject is outcome of an interplay between physics, chemistry, material science engineering, and biology and aims to devise ways to construct molecular machines by learning from nature. The ultimate goal is to be able to predictably manipulate and tailor them for targeted needs. If one needs to learn biological

systems at microscopic level, it is essential to know how to apply physical principles to the microscopic principles of the systems. Computational techniques play a great role in this direction. Several examples are available from the literature [1]. In one interesting study, Rothlisberger and coworkers used computational techniques to design eight enzymes that use two different catalytic motifs to catalyze the Kemp elimination reaction with measured rate enhancement of upto 10^5 and multiple turnovers [106]. The authors used quantum-mechanical transition-state calculation to create an idealized active site with protein functional groups positioned so as to maximize transition-state stabilization. Additional functional groups are included in the idealized active sites to further facilitate the catalytic activity. Density functional theory is applied to optimize the placement and orientation of the catalytic groups around the transition state for maximal stabilization. Using mutational analysis, authors confirmed that catalysis depends on computationally designed active site. X-Ray structures are used to determine the geometries. Increase in catalytic activity as well as in turnover was achieved. Other examples of utilization of computational methodology in designing biocatalyst are available in the literature [107]. The authors designed retroaldolases that use four different catalytic motifs to catalyze the breaking of a carbon–carbon bond in a nonnatural substrate. The study demonstrates a computation-based redesign of a novel retroaldolase activity in a scaffold that catalyzes an unrelated reaction. Many more examples are available [1] and indicate the promising future of the *nanobiology* as a subject that seems to be beneficial for humankind.

ACKNOWLEDGMENTS

Discussions with Dr. K. Thirumoorthy, Dr. S. Dutta Banik, Professor D. Vollhardt, and Professor B. Bagchi on various aspects of biomolecular system are gratefully acknowledged. Support by the Department of Science and Technology, India is also gratefully acknowledged. S.D. thanks the University of Kalyani for granting a research scholarship.

15.1 INTRODUCTION

In order to maintain active society, it is important to keep all citizens in good health. To protect people from serious disorders such as cancer and Alzheimer's disease, excessively sensitive and accurate diagnosis from very early stages of the target diseases are required. Usually, specific proteins related to particular disease are detected as biomarkers by certain techniques. However, target proteins are not always generated in significant amounts; in particular, the target protein level in early stages of the disease is quite low. In addition, huge amounts of coexisting proteins often disturb a specific protein sensing. Two researchers developed the biosensing system using a radioactive labeling technique, which is known as *radioimmunoassay* (RIA) [1]. In this method, radiolabeled antigens bound to ligand (antibody) on the surface prior to the sensing. When this surface is exposed to sample fluid, the labeled antigens are replaced with unlabeled target protein (antigen). The liberated RI-labeled antigen can be quantified with an extremely low detection limit by an RI detector. Development of the RIA method realized the detection of insulin in picomolar range, which is sufficient for sensitive diagnosis of diabetes. Thus, the high-sensitivity protein detection system has been recognized as a promising diagnostic method for detection of various diseases. However, RIA has restrictions on this use, because it requires radiolabeled reagents, specially trained technicians, special licenses (the case in Japan), and special arrangements for storage and disposal. To detect a trace amount of target proteins without RI labeling, new amplification techniques using several other methods have been developed, such as latex immunoassay [2–4], Western blotting [5], and enzyme-linked immunosorbent assay (ELISA) [6]. For example, ELISA has been developed by amplification of enzymatic reaction instead of RI labeling and attained the same detection level as that of RIA. In most cases, a labeling process of target antigen or antibody is required for amplification of the detection signal, which makes the system complicated and leads to high production cost. More recently, label-free immunosensing systems have been developed to recognize the target biomolecules. In these methods, specific surface events are monitored in seconds by physical quantity changes such as quartz frequency and refractive index. Thus, these systems can substantiate rapid biosensing more simply, without any labeling process. For example, quartz crystal microbalance (QCM) [7] detects adsorption of biomolecules by change in frequency of a quartz crystal resonator derived from mass and viscosity changes on the sensor surfaces, which can detect large biomolecules sensitively [8, 9]. The surface plasmon resonance (SPR) sensor is also a specialized instrument used to detect biomolecules in femtomolar range by refractive index changes on the surface [10]. These label-free immunosensing systems can output the association and dissociation of biomolecules on the surface as signal in second resolution. These instruments are now commercially available. Furthermore, new sensors are also developing such as a shear horizontal surface acoustic wave (SAW) sensor [11]. The sensitivity of the SAW

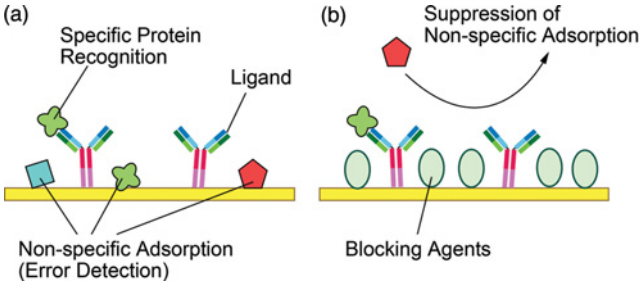

FIGURE 15.1 Protein adsorption behavior on hydrophobic and hydrophilic surfaces.

sensor is theoretically much higher than that of QCM, because that the frequency of the SAW (200−300 MHz) is much higher than that of conventional QCM (5−30 MHz). In addition, the SAW sensor surface is not limited to metal surfaces such as QCM and SPR sensors, which means that various types of surfaces such as carbon and titanium oxide are available for sensing.

Although the detection level can be improved by instrumental developments, an improvement of selective sensing is another important issue to be addressed. Because a nonlabeling sensing system cannot detect signals of a specific protein event but detects merely change in physical quantity of the surface by adsorbed whole molecules, nonspecific proteins disturb the specific protein recognition on the sensing surface. Thus, nonspecific protein adsorption should be minimized as much as possible in order to improve sensing performance (Fig. 15.1a). To suppress nonspecific adsorption on the sensor surface, blocking agents are generally employed after the immobilization of antibody. To fill up the nonspecific binding site, many kind of natural proteins such as bovine serum albumin (BSA), gelatin and casein have been employed as blocking agents (Fig. 15.1b). However, these blocking efficiencies are not sufficient, and there are two additional issues: (1) these kinds of natural polymer samples may contain dangerous bacteria, viruses, and prions, potentially inducing serious disease such as bovine spongiform encephalopathy (BSE); and (2) since performance varies somewhat between lots, it is difficult to maintain quality of the products.

For these reasons, synthetic products with high surface blocking performance are widely anticipated. Many synthetic polymers have been applied for surface modification of biosensors such as poly(vinyl alcohol), poly(ethylene glycol) (PEG), poly(2-hydroxyethyl methacrylate) (PHEMA) [12], poly(2-methacryloyloxyethyl phosphorylcholine) (PMPC) [13], and poly(2-methoxyethyl acrylate) (PMEA) [14]. For example, one team of investsigators reported that PEG immobilization in a tethered-chain configuration on the substrate surface effectively suppressed nonspecific protein adsorption [15]. We have also examined effective surface modification technology by our newly designed end-reactive PEG and applied them for high-performance biosensing surfaces. Here, we introduce PEGylation techniques to improve the specific molecular recognition efficacy on surfaces.

15.2 ADVANTAGES OF SUPPRESSING THE NONSPECIFIC ADSORPTION ON A SURFACE BY PEGylation

As stated above, nonspecific adsorption must be avoided for high-performance biosensing systems. Essential driving forces of protein adsorption on materials surface are derived from versatile interactions such as hydrophobic interaction, electrostatic interaction, the London dispersion force, and so on. In particular, hydrophobic hydration is one of the strongest interactions to promote the nonspecific protein adsorption on the surface. Thus, the surface modification techniques have focused on imparting hydrophilicity to the sensing surface for suppression of nonspecific protein adsorption. Poly(ethylene glycol) [PEG, also known as *poly(ethylene oxide)* (PEO) or *poly(oxyethylene)* (POE)] is one of the hydrophilic polymers most suitable for use as a modifier as it shows versatile functions in biotechnology and medicine. For instance, PEG is widely employed as a drug component such as a plasticizer, suppository base, and capsule [16–20]. PEG is an extremely low-toxicity polymer {e.g., PEG-750 (LD_{50} = 10 g/kg, intraperitoneally) [21], PEG-6000 (LD_{50} = 50 g/kg, orally) [22]}, which indicates that less interaction between PEG and biomolecules indicates relative lack of activity in a body. This unique character of PEG is derived from the hydrophilic chain with low interfacial free energy in water and high chain mobility. When PEG tethered layers are formed on a surface (PEGylation), steric stabilization by PEG prevents approach of protein on the surface (this is known as the *excluded-volume effect*). If we apply the PEGylation on the biosensing surfaces, the background noise by nonspecific adsorption of a large amount of coexisting proteins in the sample will be greatly suppressed. Hence, PEGylation techniques for biosensing surfaces have been investigated to improve the sensing performance.

15.3 PEG CHAIN BEHAVIOR ON SURFACES

In Section 15.2, we mentioned that PEGylation can impart a nonfouling characteristic on surfaces. To obtain maximum benefit from the PEGylation system, it is important to understand the PEG chain behavior on a surface. Modification techniques by terminally attaching polymer chains to surfaces have been widely used as biological applications; however, little was known about the kinetics of the tethered polymer chain on the surface at the molecular level in the early days. Hence, the physicochemical process of polymer chain attachment on the surface has been also investigated in recent

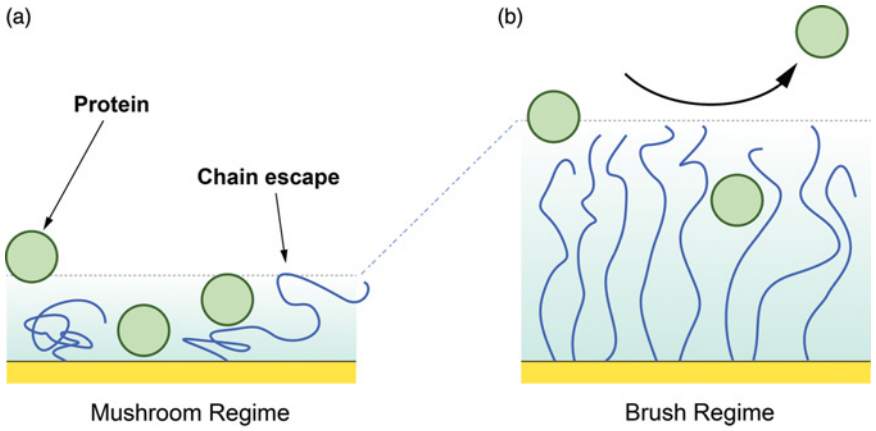

FIGURE 15.2 Behavior of PEG on surfaces: (a) mushroom regime (low density); (b) brush regime (high density).

decades. In a theoretical study, one researcher investigated the conformation of polymers attached on surface and suggested that there are different regimes for the grafted layer by density of grafted polymer on the surfaces [23]. The polymer chains forms a mushroomlike regime (well shrunken) on the surface when each chain is isolated and well separated; on the other hand, the polymer chains forms a brushlike regime (less shrunken) on the surface when the polymers are tethered densely on it [24]. It is also reported that the transition from the "mushroom regime" to the "brush regime" was monitored by measurement of the layer thickness on the grafted surface with gradient density [25,26]. The regime of the polymer as blocking agent on the surface is an important factor because the behavior of the polymer on the surface affects the blocking property derived from steric barrier of the surface. For example, the flexible polymer chains tethered on the surface transit from mushroom state to escape state when the polymer chains are compressed by proteins [27–29]; in other words, a steric barrier is not effective when the chain density is low (Fig. 15.2). Thus, the density of immobilized PEG on the surface is one of the most important factors for protein rejection property. A group of coworkers reported that the mass of absorbed protein decreased in a manner dependent on EG density [30]. This report showed that the density of the PEG chain affects the protein rejection on surfaces.

However, the nonfouling characteristic of PEG is derived from the spatial effect of PEG as well as the density of ethylene oxide units. It has been reported that PEG chain length affects the nonfouling characteristic [31] because steric sterilization by PEG random coils is strongly dependent on PEG layer thickness. Therefore, longer PEG chains with immobilized surfaces suppressed nonspecific protein adsorption more strongly. In contrast, this effect begins to decrease when PEG chain length exceeds 5 kDa. This means that reduction in PEG density on the surface allows space for nonspecific protein adsorption on that surface. Summarizing these observations, we concluded that 5 kDa of PEG is an appropriate length to ensure the highest level of nonfouling performance (Fig. 15.3).

The condition of the PEG immobilization process is also an important factor for construction of the PEGylated surface; specifically, concentration of PEG solution, ionic strength of the solution, flow time, and a number of immobilization cycles affect the density of the PEG on the surfaces [31, 32]. The combination of different lengths

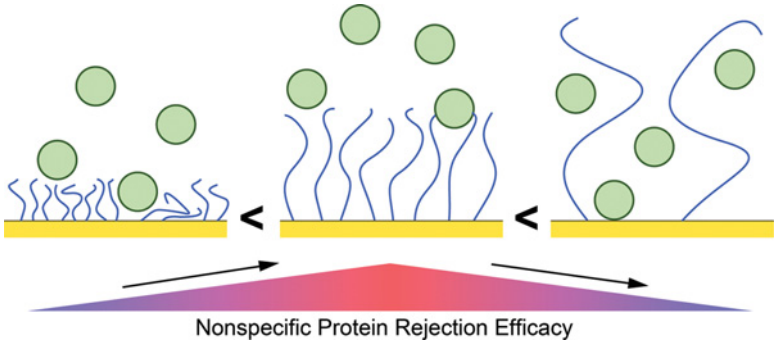

FIGURE 15.3 Correlation between PEG chain length and protein rejection efficacy.

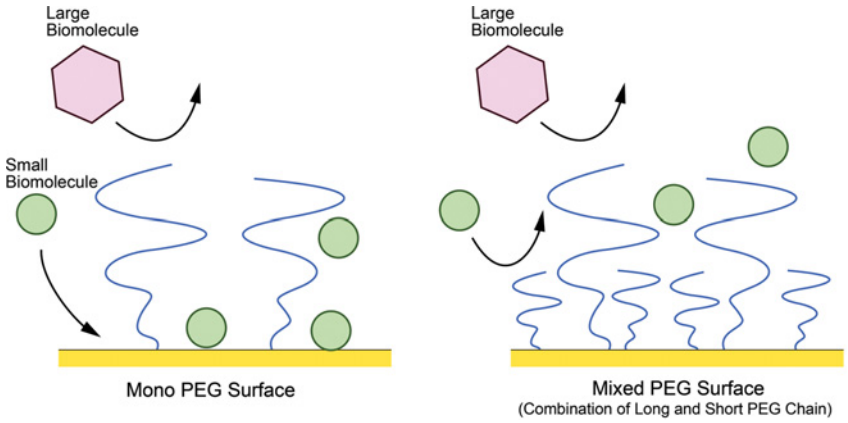

FIGURE 15.4 Difference in nonfouling character between mono-PEG surface and mixed-PEG surface.

of PEG immobilization on the surface is also an effective method for improving the nonfouling performance. We have reported that the combination of PEG (5k) and PEG (2k) tethered surface almost completely suppressed the nonspecific adsorption of low- as well as high-molecular-weight biomolecules [31–33], which indicated that two kinds of PEG chains suppress the nonspecific adsorption against different sizes of complementary biomolecules (Fig. 15.4). In this case, successive immobilization of longer PEG chain followed by shorter PEG chain is important point, because the density of the longer PEG chain is optimized first and shorter PEG chain fills the vacant spaces on the surface completely. This treatment improves the PEG chain density significantly.

15.4 FUNCTIONALIZATION OF PEG END FOR PEGylation ON SURFACE

In Section 15.3, we noted that the nonfouling characteristic of a steric barrier of PEG can be controlled by PEG density and thickness of the layer. To form the grafted PEG chains on a sensor surface, derivatization of one terminal of PEG should be required for tethering on a surface. At present, thiol-terminated PEG is widely used to immobilize the PEG chain on gold surfaces for biosensing systems such as SPR and QCM, because PEG chains were reported to be tethered on a gold surface strongly via S–Au bond (47 kcal/mol) [34]. We have been also employed this technique for the constructions of PEGylated surfaces [35–39]. Although immobilization by S–Au bond is quite a convenient technique for obtaining the densely packed PEG layer, this is not always a perfect method because of detachment of PEG chains from the surface. For example, S–Au bonds can be dissociated by oxidation of the thiol group [40–42]. Additionally, thiol-terminated compounds on gold surfaces can also be exchanged by other thiol-terminated compounds [43]. Thus, the structural stability of the S–Au bond depends on the surrounding environment. We have reported that the coordination method using a polyamine chain can be employed as an alternative technique for tethering. Although a coordination of amino group on a gold surface is not as strong (6 kcal/mol) as that in a S–Au bond [34], multipoint coordination by polyamine improves the immobilization stability. Actually, we have confirmed that the coordination of amino groups on gold surfaces was a primary factor when PEG-*b*-polyamine block copolymer was immobilized on a gold nanoparticle (GNP) surface [44]. Specifically, the size of GNPs prepared by poly(ethylene glycol)-*block*-poly((2-*N*,*N*-dimethylamino)ethyl methacrylate) (PEG-*b*-PAMA) under alkaline conditions was smaller (with high dispersion stability) compared with that prepared by neutral (or acidic) conditions. The results indicated that the polyamine is coordinated not by the electrostatic interaction between protonated amines and negatively charged gold surfaces but by chemisorption between lone pairs on nitrogen atoms and gold surfaces (Fig. 15.5). Actually, no detachment of PEG-*b*-polyamine was observed even under high-ionic-strength media [45]. We have also confirmed that three to six amino groups at the end of the PEG chain significantly improve the coordination stability compare with monoaminated PEG. On the contrary, the dispersion stability such as GNPs gradually decreases with further increase of the number of amino groups. The increase in amino repeating units at the end of PEG chain tends to decrease PEG brush density on the gold surface because of the exclusive area of polyamine segment on the surface.

From the information obtained, we have recently designed pentaethylenehexamine-terminated PEG (N6-PEG) for a surface modification agent. The performance of N6-PEG for immobilization on gold surface is very high because there is a multipoint gold–nitrogen bond of six amino groups. It is also confirmed that this PEG is useful for immobilization on carboxylated surfaces via covalent bond with active ester groups as well [33,46]. This technique can increase the PEGylation efficacy compared with monoaminated PEG

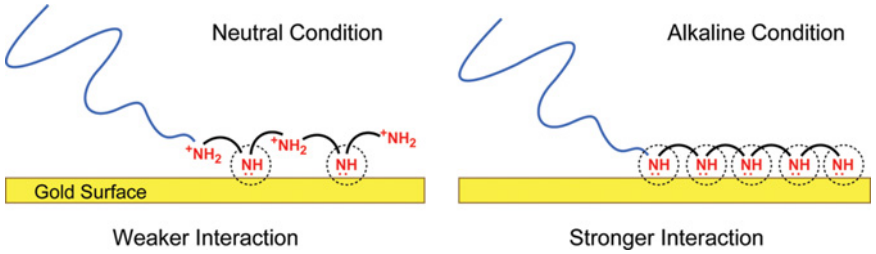

FIGURE 15.5 PEG-*b*-PAMA immobilization to gold surface in neutral condition and alkaline condition.

(N1-PEG), because part of the protonated amino groups can interact with anionic surfaces via electrostatic interaction to support esterification of the nonprotonated amino group (Fig. 15.6). N6-PEG is now commercially available from JSR Life Science, Japan as Blockmaster^{TM}.

For another example, PEG-*b*-polyanion such as poly(ethylene glycol)-*b*-poly(acrylic acid) (PEG-*b*-PAAc) is suitable for PEGylation of cationic surfaces, iron oxide surfaces, and so on [47–49]. However, PEG-*b*-PAAc is not always applicable, because the extremely hydrophilic PAAc segment decreases its interaction on positively charged substrate surface especially high ionic strength such as serum solution. We have reported that PEG-poly(4-vinylbenzylphosphonate) block copolymer (PEG-*b*-PVBP), which has a hydrophobic polystyrene chain in the polyanionic segment, showed strong affinity for the iron oxide surface. In this case, the interaction stability of multipoint anchoring of phosphate was enhanced via hydrophobic interaction between PVBP segment and iron oxide surface [50]. Recently, we have confirmed that the PEG-b-PVBP is also applicable to stainless surfaces to significantly improve their non-fouling characters.

Thus, PEGylation is a versatile system that imparts a nonfouling characteristic on various surfaces by suitably functionalized PEG. Design of the functionalization of PEG end plays an important role in PEGylation on various kinds of surfaces.

15.5 HYBRID IMMOBILIZATION OF PEG WITH LIGAND MOLECULES

The densely packed PEG tethered chain improves nonfouling performance on various kinds of surfaces. Multipoint anchoring is also an important factor in the stable immobilization of PEG chains on the surface under harsh environmental conditions. Coimmobilization of PEG tethered chain with ligand molecules is another important factor. In order to improve biosenesing performance, both specific protein recognition and suppression of nonspecific protein adsorption should be optimized at the same time. As stated above, the general blocking agents such as BSA are applied to the surface after immobilization of the ligand to fill any gaps on the surface for prevention of nonspecific protein adsorption. On the contrary, the PEGylation technique can be applied for not only blocking but also promoting ligand immobilization and specific recognition. We have reported that new construction of single-stranded DNA (ssDNA) and PEG coimmobilized surface using PEG-*b*-PAMA block copolymer showed high efficacy of hybridization. To form the coimmobilized surface, ssDNA chains were immobilized on the surface after

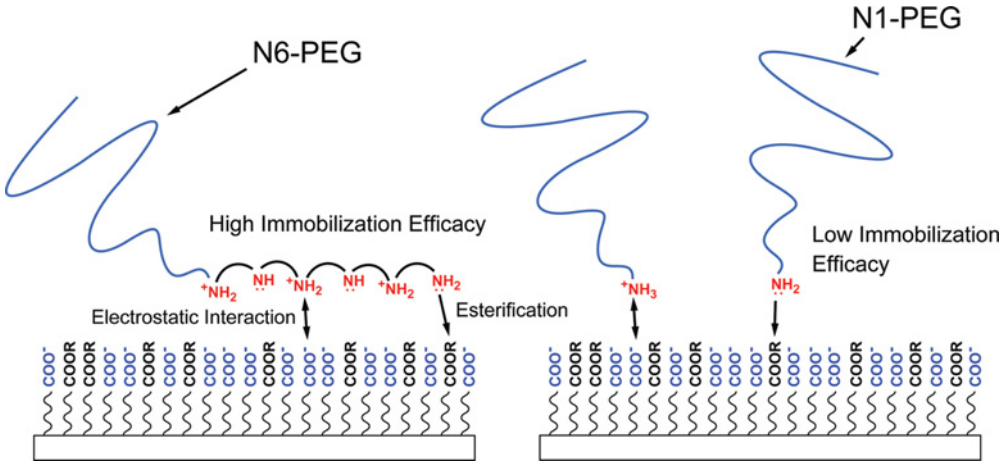

FIGURE 15.6 Immobilization of N6-PEG and N1-PEG on carboxylated surface. (Protonated N1-PEG interacts with negatively changed surface and hinders in accessing non-protonated N1-PEG to the surface.)

coating with PEG-*b*-PAMA. Under the suitable PAMA chain length, a high amount of ssDNA was immobilized under the standing fashion, which was supported by preimmobilized PEG-*b*-PAMA chain [51]. In this case, the amount of immobilized ssDNA was considerably improved by PEG-*b*-PAMA compared with bare gold surfaces, due to the electrostatic attractive force between a positively charged PAMA surface and negatively charged ssDNA. In addition, the recognition efficacy of a PEG-*b*-PAMA/ssDNA coimmobilized surface was also higher than that of the ssDNA surface, indicating that PEGylation improves the recognition efficacy of ssDNA on the surface. There is concern regarding the fact that coimmobilized PEG-*b*-PAMA controlled the ssDNA orientation on the coimmobilized surfaces in order to hybridize with complementary ssDNA effectively [51]. Thus, when we consider the design of a surface for the biosensing system, not only the nonfouling characteristic of the blocking agent but also the coimmobilization procedure should be addressed in forming highly sensitive immunosurfaces.

To understand this phenomenon in greater depth, we have also investigated the thrombin (TB) and thrombin binding aptamer (TBA) affinity on TBA/PEG-*b*-PAMA coimmobilized surface [52]. To control the coimmobilized surface condition, three kinds of PEG-*b*-PAMA with different chain lengths of PAMA were prepared to control the density of PEG (Fig. 15.7a). In addition, three kinds of TBAs with different numbers of thymine spacer units [TBA-T(*n*), where *n* = number of thymine) were also prepared to control the distance of TBA from the sensor surface (Fig. 15.7b). The result indicated that the amount of immobilized thiol-terminated TBA increased when the PAMA segment increased (20, 33, 50 AMA units), because exclusive area of PAMA segment tethered on the surface allowed further immobilization of TBA on the surface. However, TB binding efficacy on TBA/PEG-*b*-PAMA (20) coimmobilized surface is the highest among these surfaces even though the amount of immobilized TBA was the lowest (Fig. 15.7a). This result indicated that the molecular recognition efficacy could be controlled by coimmobilization of ligand and PEG in order to bind with the target more effectively. Furthermore, the distance of tethered TBA from the surface was also significantly affected to the TB binding efficacy. In the case of coimmobilization with PEG-*b*-PAMA (20), the TBA-T(40) showed the higher binding efficacy than TBA-T(20) and TBA-T(60) when the chain length of PEG was 5k. The result indicates that sufficient exposure of TBA from PEG layer is not obtained by using shorter spacers; in contrast, overexposure of the TBA from the dense PEG layer resulted from using longer spacers, which may induce folding or another unwanted orientation (Fig. 15.7b). Owing to these phenomena, we concluded that the surface for a biosensing system should be designed systematically to ensure high performance.

The PEG tethered chain on the biosensor surface also plays an important role in protection from denaturation of protein ligands such as antibody on surface. For example, we reported that the denaturation of the adsorbed protein on the surface was greatly suppressed by densely packed PEG tethered chains surrounding of the immobilized protein [39]. When the Fab′ of anti-CRP antibody (antibody fragment) was immobilized on the sensor chip surface, 90% of the CRP binding activity was lost on the constructed surface after 60 min, while the CRP binding activity did not decrease significantly when it was coimmobilized PEG chains at the

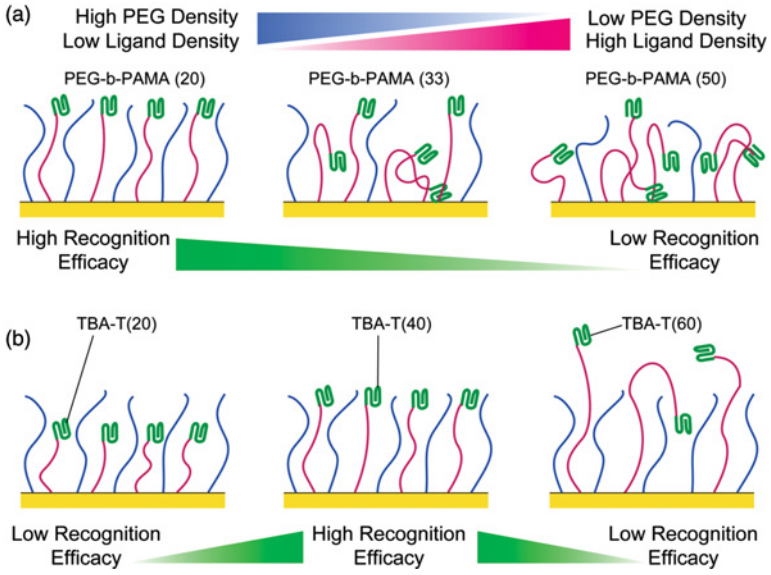

FIGURE 15.7 Schematic representations of various conditions of coimmobilization of PEG/ligand surfaces.

same time. Actually, more than 70% of the binding activity remained 60 min after construction of the CRP/PEG coimmobilized surface on gold sensor chip. This phenomenon indicated that densely packed PEGylation prevents denaturation immediately following protein immobilization.

To summarize, well-designed PEGylated surfaces greatly improve the specific recognition efficacy on the biosensor. The roles of PEG on the sensor chip surface were not only the suppression of nonspecific protein adsorption but also control of sensing performance of ligands. Investigation of PEG/ligand coimmobilized surface is one of the most important aspects in the design of the high-performance biosensing surface.

15.6 CONCLUSION

In this chapter, we introduced the basic interaction between biomolecules on the surface from the biosensor perspective. Suppression of nonspecific protein adsorption on the surface is one of the most important points in improving the property of the sensing surfaces. PEGylation techniques can improve nonfouling performance by the hydrophilic chain with low interfacial free energy in water and high chain mobility. The formation of hydrophilic and steric stabilized PEG layer can reject many complicated interactions such as hydrophobic interaction, electrostatic interaction, and intermolecular force. We introduced mainly the PEG immobilization techniques to improve the performance of nonspecific protein adsorption on surfaces as much as possible. The PEGylated surface shows not only suppression of nonspecific adsorption but also improvement of the immobilization efficacy of ssDNA, enhancement of the binding efficacy of specific protein binding, prevention of protein denaturation on the surface, and so on. Although an optimization of sensing performance depends on the targets, ligands, surfaces, and devices, PEGylation can be applied widely because suitable functionalization of the PEG end can accomplish the PEGylation on each kind of biosening surface. The tailor-made PEGylation technique is one promising ways to improve the biosening system.

BIOSEPARATION USING THERMORESPONSIVE POLYMERS

Kenichi Nagase and Teruo Okano

Institute of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University (TWIns), 8-1 Kawadacho, Shinjuku, Tokyo 162-8666, Japan

16.1 INTRODUCTION

In recent decades, stimuli-responsive polymers have attracted much attention in materials science. One such polymer most widely used in biomedical applications is the thermoresponsive polymer poly(*N*-isopropylacrylamide) (PIPAAm). This polymer exhibits phase transition behavior across its lower critical solution temperature (LCST), 32°C, which is near the normal human body temperature [1]. The polymer also exhibits hydrophilic/hydrophobic changes, attributed to hydration and dehydration, respectively. The intrinsic properties of PIPAAm are used in thermally modulated drug delivery systems [2], thermoresponsive enzymes [3], biosensors [4], and thermoresponsive cell culture substrates [5,6]. Some investigators have demonstrated that this thermoresponsive polymer could be used in bioseparations, such as chromatography matrices or cell separation tools. In this chapter, various bioseparations using PIPAAm and its derivatives are summarized.

16.2 THERMORESPONSIVE CHROMATOGRAPHY WITH HYDROPHOBIC INTERACTIONS

Chromatography is an effective tool in bioseparations. The separation of bioactive compounds using reversed-phase chromatography requires the addition of organic solvents as a mobile phase to modulate interaction between the stationary phase and analytes. However, the use of organic solvents in the mobile phase can potentially deactivate bioactive compound analytes. To avoid this issue, thermoresponsive chromatography without any organic solvents has been developed. Figure 16.1 illustrates the concept of thermoresponsive chromatography. Modified PIPAAm is used as the chromatographic stationary phase, and the prepared beads are packed into a column. The hydrophobicity of the modified PIPAAm stationary phase changes with changing temperature. At low temperatures, the PIPAAm stationary phase is hydrophilic as a result of hydration. Hydrophobic interactions between PIPAAm and analytes are therefore relatively weak. However, at elevated temperatures, the modified PIPAAm becomes hydrophobic as a result of dehydration, and hydrophobic interactions between the modified PIPAAm and analytes are enhanced. In this way, hydrophobic interactions between the stationary phase and analytes can be modulated by changing the column temperature. This chromatographic system requires no organic solvents to modulate hydrophobic interactions between the stationary phase and analytes, leading to preservation of the activities of bioactive analytes and a reduction in pollution associated with waste organic solvents.

Various PIPAAm-modifying methods and PIPAAm graft configurations have been investigated to develop effective stationary phases for thermoresponsive chromatography matrices.

PIPAAm terminally grafted silica beads were prepared through coupling reactions between amino groups on silica surfaces and PIPAAm with activated ester groups. (Fig. 16.2a) [7]. The prepared PIPAAm-modified beads were

packed in columns, and their performance was evaluated by observing the elution profiles of five hydrophobic steroids at various temperatures. At low temperatures (e.g., 5°C), hydrophobic steroids were eluted in short retention times, and were not separated (Fig. 16.3). However, with increasing

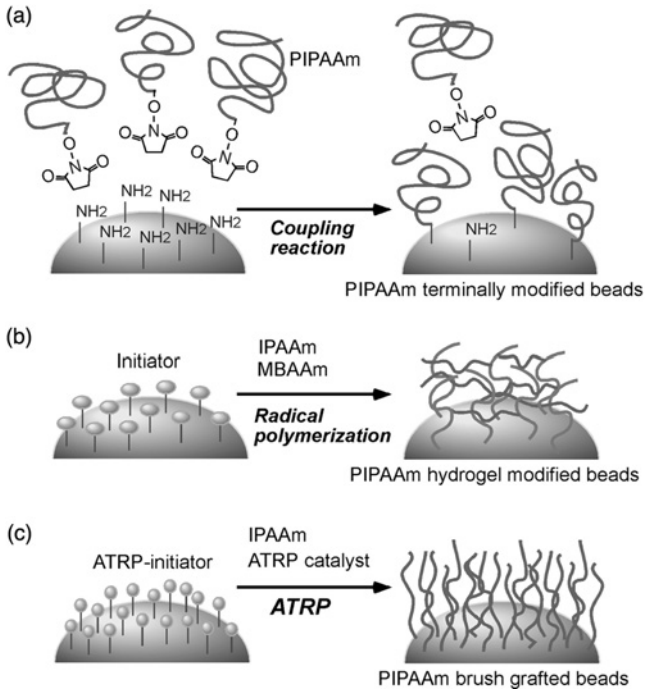

FIGURE 16.2 Various types of PIPAAm modification of bead surfaces for thermoresponsive chromatography matrices.

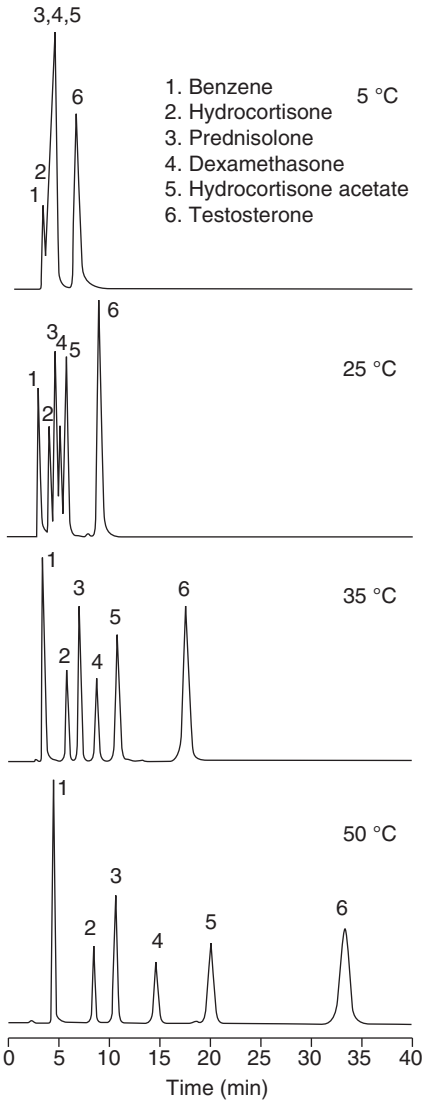

FIGURE 16.3 Chromatograms of hydrophobic steroids separated using column packed with PIPAAm-modified silica beads. (Adapted from Ref. 7. Copyright 1996, American Chemical Society.)

column temperature, the retention times of the hydrophobic steroids increased, because the hydrophobicity of the modified PIPAAm increases with increasing dehydration, leading to enhancement of hydrophobic interactions between the grafted PIPAAm and the steroids. At 50°C, baseline separation of the hydrophobic steroids was achieved.

PIPAAm-hydrogel-modified silica beads were prepared by radical polymerization using a premodified azo initiator on the surface and a cross-linker (Fig. 16.2b) [8]. The prepared beads were packed in a column, and the performance was evaluated by observing the elution behaviors of hydrophobic steroids. The retention times on the PIPAAm-hydrogel column were longer than those on PIPAAm terminally

modified beads, but the peaks in the chromatograms were wider for the PIPAAm-hydrogel-modified bead column than for the PIPAAm terminally grafted silica bead column. Steroid molecules tend to penetrate the PIPAAm-hydrogel layer and interact with PIPAAm, leading to wider peaks and longer retention times.

More recently, living radical polymerizations have been employed as useful and effective polymerization techniques. *Atom transfer radical polymerization* (ATRP), in particular, is a polymerization technique that enables accurate control of the polymerization and formation of densely packed polymer brushes on substrates [9, 10]. Modification of PIPAAm through surface-initiated ATRP has been used to prepare thermoresponsive chromatography matrices.

An ATRP initiator was immobilized on silica bead surfaces through a silane coupling reaction. ATRP was then performed using an ATRP catalyst, and densely packed PIPAAm brushes were grafted on the silica bead surfaces (Fig. 16.2c) [11]. Almost 10 times as much PIPAAm was grafted on the beads prepared by surface-initiated ATRP than on PIPAAm-hydrogel-modified beads or PIPAAm terminally grafted beads [12]. The prepared beads were evaluated as chromatographic matrices by observing the elution profiles of hydrophobic steroids at various temperatures. Significantly longer steroid retention times were observed compared with those obtained using PIPAAm terminally grafted beads or PIPAAm-hydrogel-modified beads, although the column length was only one-third that of the others. This is because there were more hydrophobic interactions between the steroids and the polymer as a result of the larger amount of PIPAAm on the beads. Also, in surface-initiated ATRP, the graft density can be modulated by changing the initiator density on the surface. The graft density of PIPAAm on the bead surfaces affected the thermally modulated dehydration properties and interactions between the PIPAAm graft interface and analytes [13, 14].

The hydrophobic interactions between grafted PIPAAm on beads and analytes were enhanced by incorporation of a hydrophobic monomer, *n*-butyl methacrylate (BMA), in PIPAAm, to improve the separation of relatively hydrophilic analytes.

A random copolymer of PIPAAm and BMA was prepared using a radical telomerization reaction, and the prepared P(IPAAm-*co*-BMA) was grafted on silica bead surfaces through a coupling reaction [15]. The prepared beads were evaluated by observing their hydrophobic steroid elution profiles at various temperatures. The retention times of the hydrophobic steroids increased with increasing BMA content of the copolymer, indicating that hydrophobic interactions between the steroids and copolymer increased with increasing BMA content. Also, the phase transition temperature decreased with increasing BMA content, and the temperature-dependent retention profiles of steroids are related to the phase transition temperature. On P(IPAAm-*co*-BMA)-modified beads, baseline separation of hydrophobic steroids was obtained at 30°C, whereas this steroid mixture was not separated on PIPAAm-homopolymer-modified beads. In addition, using a column packed with P(IPAAm-*co*-BMA)-modified beads, separation of a peptide mixture containing insulin chain A, β-endorphin fragment 1-27, and insulin chain B was performed [15], and phenylthiohydantoin amino acid analyses were performed using the same column [16].

BMA incorporation into PIPAAm brushes on silica beads was also performed to further enhance hydrophobic interactions between the polymer brushes and analytes. P(IPAAm-*co*-BMA)-brush-grafted beads were prepared by surface-initiated ATR copolymerization of BMA with IPAAm [17]. The separation efficiencies of benzoic acids and phenol, which are used as preservatives in fragrances, foods, and cosmetics, were evaluated using the prepared beads packed in a column. The retention time of the benzoic acids increased with increasing BMA content in the grafted copolymer brushes, because the copolymer brush hydrophobicity increased with increasing BMA content, leading to enhanced hydrophobic interactions between the copolymer brushes and analytes. High-resolution separation of benzoic acids was obtained using a column packed with copolymer-brush-grafted beads with a high BMA content. These results show that P(IPAAm-*co*-BMA)-brush-grafted beads can be used to separate relatively hydrophilic analytes [17].

16.3 THERMORESPONSIVE CHROMATOGRAPHY WITH ELECTROSTATIC INTERACTIONS

Ion exchange chromatography is an effective tool for separating ionic bioactive compounds such as peptides, and proteins, because almost all biological compounds have specific hydrophobic and ionic properties. However, ion exchange chromatography requires the addition of a large amount of salt to the mobile phase to modulate electrostatic interactions between the mobile phase and analytes. Excessive amounts of salts in the mobile phase can deactivate biologically active analytes. Desalting of the separated analytes is required in purification. To overcome these issues, thermoresponsive ion exchange chromatography matrices have been developed using thermoresponsive ionic copolymers.

Thermoresponsive cationic copolymers have been used as stationary-phase modifiers for separating acidic bioactive molecules. *N,N*-Dimethylaminopropylacrylamide (DMAPAAm) has been incorporated into thermoresponsive copolymers, and beads modified with a P(IPAAm-*co*-DMAPAAm-*co*-BMA) hydrogel have been used as thermoresponsive cationic chromatography matrices [18,19]. A column packed with the prepared beads was used to separate a mixture of adenosine nucleotides. The retention times decreased with

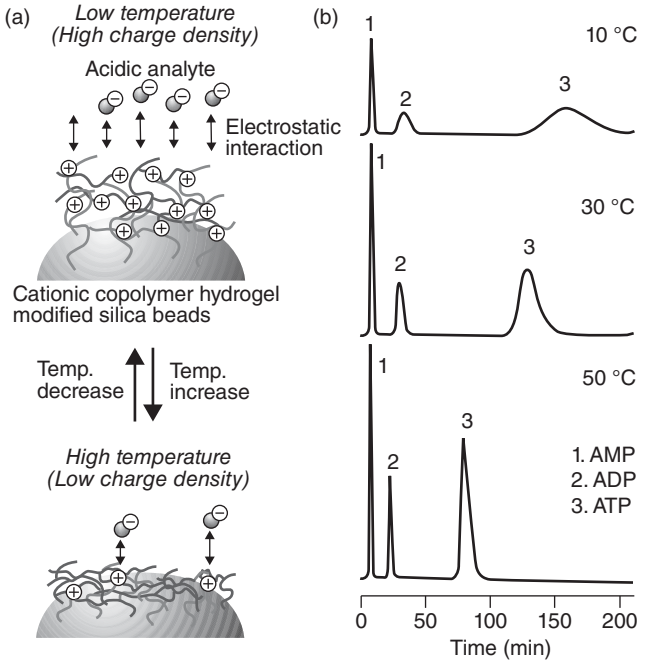

FIGURE 16.4 Thermoresponsive ion exchange chromatography: (a) temperature-modulated electrostatic interactions between thermoresponsive cationic copolymer and acidic biomolecules; (b) chromatogram of adenosine nucleotide mixture separated using column packed with beads modified with P(IPAAm-*co*-DMAPAAm-*co*-BMA) hydrogel. (Adapted from Ref. 19. Copyright 2004, Wiley.)

increasing temperature, because the basicity of the modified P(IPAAm-*co*-DMAPAAm-*co*-BMA) decreased with increasing temperature, as a result of the increased hydrophobicity of the dimethylamino group (Fig. 16.4). The results demonstrated that electrostatic interactions between a grafted cationic copolymer and analytes can be modulated by simply changing the temperature. Beads modified with the same copolymer hydrogel were used to analyze nonsteroidal anti-inflammatory drugs [20] and oligonucleotides [21].

For the separation of basic bioactive compounds, beads modified with a thermoresponsive anionic hydrogel were prepared by copolymerization of IPAAm and acrylic acid [22]. The elution behaviors of catecholamine derivatives on P(IPAAm-*co*-acrylic acid(AAc))-hydrogel-modified beads were observed at various temperatures. Four types of catecholamine derivatives were separated at high temperatures, whereas separation was not achieved using a column with PIPAAm-hydrogel-modified beads. The retention times of the catecholamine derivatives were in the same order as their hydrophobicities, indicating that hydrophobic interactions also contributed to the separation of catecholamine derivatives. The incorporation of a hydrophobic monomer into the thermoresponsive anionic copolymer P(IPAAm-*co*-AAc) therefore improved the separation efficiency.

A hydrophobic monomer, *tert*-butylacrylamide (tBAAm), was incorporated into a thermoresponsive anionic hydrogel to improve separation efficiency. A column packed with beads modified with a P(IPAAm-*co*-AAc-*co*-tBAAm) hydrogel was used to separate catecholamine derivatives; the retention times were higher and higher-resolution separation was achieved compared with those obtained using P(IPAAm-*co*-AAc)-hydrogel-modified beads [23]. In addition, angiotensin peptides were separated using a column packed with P(IPAAm-*co*-AAc-*co*-tBAAm)-hydrogel-modified beads; the separation time was shortened by changing the column temperature stepwise [24].

In thermoresponsive ion exchange chromatography, the graft configuration of the thermoresponsive polymer on the bead surface is important for the separation efficiency. Beads grafted with thermoresponsive ionic copolymer brushes were therefore prepared by surface-initiated ATRP.

A cationic monomer, 2-(dimethylamino)ethyl methacrylate (DMAEMA), was incorporated into PIPAAm brushes, and thermoresponsive beads with grafted cationic copolymer brushes were prepared as thermoresponsive anion exchange matrices [25]. A column packed with the prepared beads was used to investigate the elution behaviors of adenosine nucleotides at various temperatures. The adenosine nucleotide retention times were much higher than those observed using beads modified with thermoresponsive cationic hydrogels, in which large amounts of cationic copolymer were grafted on the bead surfaces, leading to strong electrostatic interactions between the stationary phase and the analytes. Also, when a step-temperature gradient was used, rapid changes in the retention times were observed compared with those for the column with thermoresponsive-hydrogel-modified beads. This is attributed to the graft configuration of the thermoresponsive cationic copolymer brush. On the thermoresponsive copolymer brush, each polymer chain moves freely, whereas the polymer chains are connected in the hydrogel, leading to a rapid temperature response [25].

For the effective separation of basic bioactive compounds, beads grafted with a thermoresponsive anionic copolymer, P(IPAAm-*co*-AAc-*co*-tBAAm), were prepared by surface-initiated ATRP [26]. A column packed with the beads was used for high-resolution separations of catecholamine derivatives and angiotensin peptides. The results were compared with those obtained using columns packed with copolymer-hydrogel-modified beads.

Beads modified with thermoresponsive ionic copolymer brushes adsorb proteins and can be used for protein purification. Silica beads grafted with thermoresponsive cationic copolymer, P(IPAAm-*co*-DMAPAAm-*co*-tBAAm), brushes were prepared by surface-initiated ATRP. The elution behaviors of an acidic protein [i.e., human serum albumin (HSA)] and a neutral protein (i.e., γ-globulin) were observed at various temperatures, using columns packed with the prepared

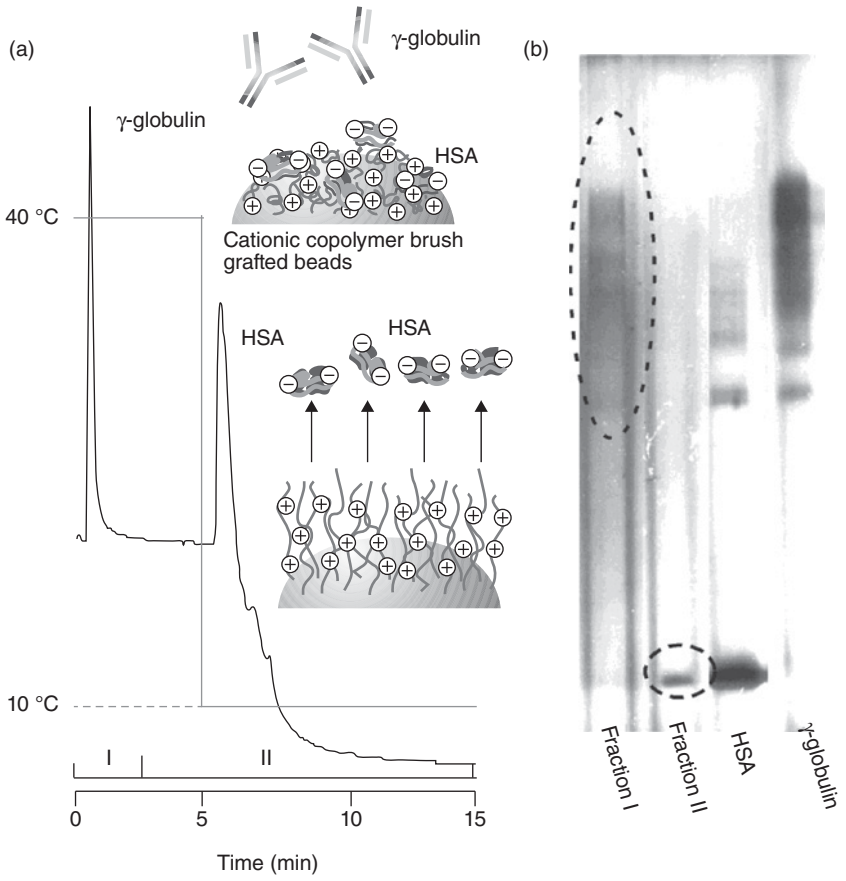

FIGURE 16.5 Separation of HSA and γ-globulin using thermoresponsive cationic copolymer brushes: (a) chromatograms with step-temperature gradients; (b) SDS-PAGE analysis of eluted proteins. (Adapted from Ref. 27. Copyright 2011, Elsevier.)

beads [27]. At high temperature, HSA was not eluted but γ-globulin was. This is because the acidic HSA was adsorbed on the cationic copolymer brushes through both electrostatic and hydrophobic interactions. The copolymer hydrophobicity increased with increasing temperature, as a result of dehydration of the grafted copolymer. However, a certain level of cationic charge remained even at high temperatures, although the charge density decreased with increasing temperature. The acidic HSA was therefore adsorbed on the copolymer brushes at elevated temperatures, but the neutral globulin was not. Because of this property, HSA and γ-globulin separation was performed using a step-temperature gradient (Fig. 16.5). A mixture of HSA and γ-globulin was loaded onto the column at 40°C; HSA was adsorbed on the copolymer brush surfaces and γ-globulin was eluted. The column temperature was then reduced to 10°C and the adsorbed HSA was recovered. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) analysis showed that the fractions at 40°C and 10°C contained purified γ-globulin and HSA, respectively.

Silica beads grafted with brushes of the thermoresponsive anionic copolymer P(IPAAm-*co*-AAc-*co*-tBAAm) were used as thermoresponsive protein adsorption materials for purification of basic proteins [28]. Lysozyme was absorbed on the thermoresponsive anionic copolymer brushes at high temperatures. This is also the result of hydrophobic and electrostatic interactions between the thermoresponsive anionic copolymer brushes and basic lysozyme. The protein adsorption properties of the copolymer-modified beads were used to purify egg-white lysozyme. At 30°C, whole egg-white proteins were loaded onto the bead-packed column; lysozyme was adsorbed on the copolymer brush surfaces, but the other proteins were eluted at this temperature. The temperature was then reduced to 10°C and the adsorbed lysozyme was recovered from the column. SDS-PAGE analysis showed that the fraction at 10°C contained only purified lysozyme [28].

16.4 THERMORESPONSIVE CHROMATOGRAPHY USING VOLUME EXCLUSION EFFECT OF PIPAAm

PIPAAm exhibits a temperature-dependent coil–globule transition. Below the LCST, PIPAAm chains swell and extend as a result of polymer hydration, but PIPAAm is dehydrated

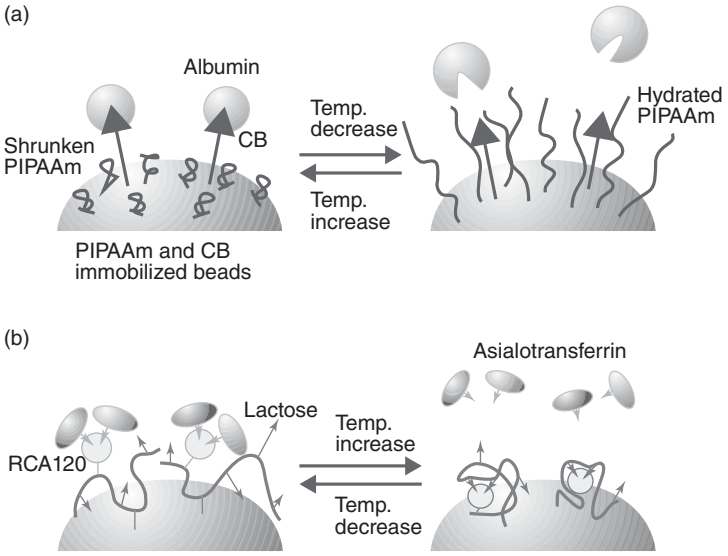

FIGURE 16.6 Affinity chromatography using thermoresponsive PIPAAm conformation changes: (a) selective adsorption and desorption of albumin; (b) selective adsorption and desorption of asialotransferrin. (Adapted from Refs. 30 and 31. Copyright 2002, 2003, American Chemical Society.)

and agglutinates above the LCST. On the basis of these properties, various types of thermoresponsive chromatography have been developed.

PIPAAm was grafted onto porous glass beads by a coupling reaction between the activated chain ends of PIPAAm and the amino groups on the glass bead surfaces [29]. A column was packed with the prepared PIPAAm-grafted glass beads as a gel permeation chromatography matrix. Below the LCST of PIPAAm (32°C), the elution times of dextrans of various molecular weights were shorter than those observed above the LCST. At lower temperatures, the grafted PIPAAm swells and extends, preventing dextran diffusion inside the glass bead pores. In contrast, above the LCST, the grafted PIPAAm on the glass beads dehydrates and shrinks, and dextran diffuses into the pores, leading to longer elution times. The elution times of dextran molecules can therefore be changed by changing the column temperature [29].

The PIPAAm modification site on porous beads is important for effective separation. Two types of PIPAAm-grafted polystyrene beads were prepared, using cyclohexanol and toluene as porogenic agents, in water [30]. When cyclohexanol was used, the PIPAAm was grafted on the outer surface and inside the pores, because radical polymerization occurred inside the pores. In contrast, when toluene was used, PIPAAm was grafted only on the external bead surfaces, because polymerization did not occur inside the pores. The elution profiles of dextran were observed using these prepared beads as gel permeation chromatography matrices. When the beads prepared with cyclohexanol were used, the dextran elution time was longer above the LCST than it was below the LCST. However, the opposite results were obtained using beads prepared with toluene. In other words, the elution time above the LCST was shorter than that below the LCST; the same results were observed using an unmodified column. These results show that temperature-dependent diffusion of analytes into the pores of porous beads can be achieved by grafting PIPAAm inside the pores [30].

Temperature-modulated PIPAAm extension and shrinkage have been used to develop new types of affinity chromatography. Cibacron blue F3G-A (CB), which is a specific ligand for HSA, and PIPAAm were immobilized on poly(glycidyl methacrylate-*co*-ethyleneglycol dimethacrylate) or poly(glycidyl methacrylate-*co*-triethyleneglycol dimethacrylate) beads (Fig. 16.6a) [31]. Albumin tended to adsorb on the beads, because the modified PIPAAm dehydrated and shrank, leading to exposure of albumin to coimmobilized CB. In contrast, at low temperatures, the adsorbed albumin was released, because the hydrated and expanded PIPAAm chains reduced the affinity between CB and albumin. These beads were used to purify albumin from human serum just by changing the temperature. Human serum was loaded onto the column at 37°C; albumin was adsorbed on the beads though the affinity between CB and albumin, whereas the other proteins were eluted. The temperature was then reduced to 20°C, and the adsorbed albumin was eluted, because the affinity between CB and albumin decreased as a result of PIPAAm chain extension [31].

Another type of thermoresponsive chromatography was used to purify asialotransferrin, using the affinity ligand *Ricinus communis* agglutinin (RCA120) and lactose, which competitively binds to RCA120 (Fig. 16.6b) [32]. PIPAAm chains, RCA120, and lactose were immobilized on sepharose beads. At low temperatures, the immobilized RCA120 was bound to asialotransferrin as a result of their affinity, but

lactose was unable to bind to RCA120, because of extension of the PIPAAm chains. However, at a higher temperature, the modified PIPAAm chains were hydrated, and they shrank, leading to an increase in the local concentration of lactose in the vicinity of RCA120. Lactose was bound to RCA120, and the bound asialotransferrin was released. The beads could therefore be used to purify asialotransferrin simply by changing the temperature.

16.5 THERMORESPONSIVE CHROMATOGRAPHY FOR HIGH-SPEED SEPARATION

In analytical chemistry, monolithic silica rod columns consisting of a single piece with a three-dimensionally interconnected structure have attracted attention as alternatives to bead-packed columns [33, 34]. Monolithic silica columns enable high-speed separation of analytes, because of the higher linear velocity of the mobile phase and reduced diffusion path lengths of analytes compared with those for bead-packed columns. The advantages of monolithic silica rod columns have been used in thermoresponsive chromatography matrices.

PIPAAm brushes were grafted on monolithic silica rod surfaces using surface-initiated ATRP, by flowing the reaction solution into a monolithic silica rod column (Fig. 16.7) [35]. The prepared PIPAAm-modified column was used to observe the elution behaviors of hydrophobic steroids. The steroid retention times were significantly shorter (<10 min) than those observed with a bead-packed column (>40 min). This is attributed to the reduced diffusion pathlengths of the analytes and higher linear velocity of the mobile phase in the monolithic silica rod. Additionally, introducing hydrophilic moiety on graft interface of PIPAAm brush on monolithic silica rod was performed for further

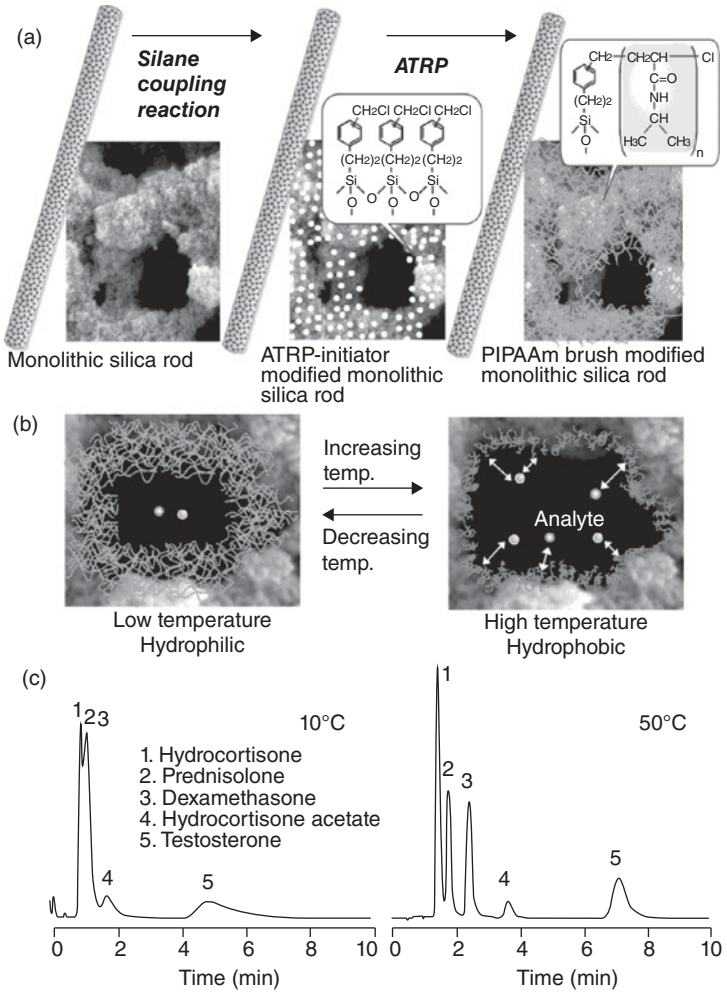

FIGURE 16.7 Thermoresponsive monolithic silica rod for high-speed separation: (a) scheme for preparation of monolithic silica rod; (b) thermally modulated interactions between PIPAAm brushes and analytes in monolithic silica rod; (c) chromatogram of hydrophobic steroids. (Adapted from Ref. 35. Copyright 2011, American Chemical Society.)

shortening of analysis time, because the polarity of PIPAAm graft interface affects elution behavior of analytes [14]. When the silica rod with grafted PIPAAm brushes was used, the separation of hydrophobic steroids was further shortened to within 5 min. These results indicate that thermoresponsive monolithic silica rods are alternatives to bead-packed columns for high-resolution separation of hydrophobic analytes with short retention times.

A thermoresponsive ion exchange monolithic silica rod column for high-speed separation of ionic biomolecules was prepared by modification of the silica rod with thermoresponsive cationic copolymer brushes. P(IPAAm-*co*-DMAEMA-*co*-tBAAm) brushes were grafted on the monolithic silica rod surface by surface-initiated ATRP [36]. The prepared monolithic silica rod column was used to investigate the temperature-dependent elution behaviors of adenosine nucleotides. The modified column separated an adenosine nucleotide mixture (AMP, ADP, and ATP) within 5 min, whereas a column packed with beads modified with the same copolymer brushes required approximately 100 min for separation. These results indicated that silica rods modified with thermoresponsive ionic copolymers are effective separation tools for ionic biomolecules.

16.6 THERMALLY MODULATED CELL SEPARATION USING PIPAAm

As progress has been made in biotechnology, the demand for cell separation technologies has increased. Fluorescence-activated cell sorting and magnetic cell sorting are widely used as precise cell separation methods. However, these cell separation methods require modification of cell surfaces using fluorinated antibodies or magnetic particles; this is undesirable when using original cells in their native state, such as in investigation of cell properties and in transplants in the human body. Also, these cell-sorting methods require expensive apparatus and incur high running costs. To overcome these issues, various cell separation systems using thermoresponsive polymers have been developed.

Cell separation using an aqueous two-phase system and PIPAAm-modified antibodies has been proposed as a concise cell separation procedure [37, 38]. Anti-CD34 antibodies for specific KG-1 cells were treated with itaconic anhydride and glucose to introduce vinyl groups into the antibodies. Then copolymerization of IPAAm and the antibodies with vinyl groups was performed, to produce PIPAAm-modified antibodies. The PIPAAm-modified antibodies were used for cell separation of KG-1 cells from Jurkat cells, using an aqueous two-phase system consisting of poly(ethylene glycol) (PEG) and dextran solutions. More than 80% of the KG-1 cells were obtained from the upper PEG solution phase, whereas few Jurkat cells were partitioned into the PEG phase, because the PIPAAm-modified antibodies tended to partition into the PEG solution phase. These results indicated that PIPAAm-modified antibodies enable partitioning of specific cells, using a simple method.

Cell separation using a PIPAAm cryogel, which was prepared by cross-linking polymerization under semifrozen conditions, has also been proposed [39, 40]. A Cu(II)–iminodiacetate ligand specific for *Escherichia coli* cells was bound to a PIPAAm cryogel, and *E. coli* cells were bound to the cryogel surface. At 25°C, 65% of the bound cells were eluted using 0.2 mol/L imidazole buffer solution. However, using the same buffer heated to 40°C, 85% of the bound cells were recovered, because the affinity between the cells and the ligand was reduced by disruption of the pore wall surfaces of the PIPAAm cryogel, induced by PIPAAm aggregation.

Other types of cell separation using a PIPAAm-grafted polypropylene (PP) membrane and adsorbed antibodies has been proposed [41]. A PIPAAm-grafted PP membrane was prepared by plasma-induced polymerization, and antimouse CD80 monoclonal antibodies (CD80mAb) or CD86 monoclonal antibodies (CD86 mAb) were adsorbed by incubation of the antibody solution. When the antibody CD80 mAb was adsorbed on the PP membrane, adsorption of CD80 cells was greater than that on a membrane with adsorbed CD86 mAb or an antibody-free PIPAAm-grafted PP membrane. When the temperature was reduced to 4°C, the adhered cells were recovered together with antibodies from the PIPAAm-grafted PP membrane, because the PIPAAm grafted on the PP membrane became hydrophilic and adhered cells were detached. CD80- or CD86-transfected cells were enriched to 72% or 66% from a 1:1 suspension using this method [41]. A similar method was used to adsorb anti-human CD34 monoclonal antibodies on a PIPAAm-grafted PP membrane to enrich CD34-positive KG-1a cells to 85% from a 1:1 cell suspension of KG-1a cells and Jurkat cells [42].

These methods enable simple separation of cells; however, they use antibodies, which are sometimes expensive and unstable, leading to high costs and low reproducibility. Additionally, the separated cells contain antibodies on the cell surfaces, which would lead to problems in research or in transplants in the human body. To avoid these issues, temperature-modulated cell separation methods without antibodies were investigated.

Lymphocyte subpopulations, B cells and T cells, were separated using a column packed with glass beads with grafted PIPAAm brushes [43]. PIPAAm brushes of various chain lengths were grafted on the glass bead surfaces by surface-initiated ATRP. The wettability of the PIPAAm brushes was determined using contact-angle measurements; the results showed that hydrophilicity increased with increasing PIPAAm brush length. Columns packed with glass beads with grafted PIPAAm brushes were used to investigate the retentions and recoveries of rat lymphocytes at 37°C and 5°C, respectively. Lymphocyte retention on the beads at 37°C decreased with increasing PIPAAm brush length,

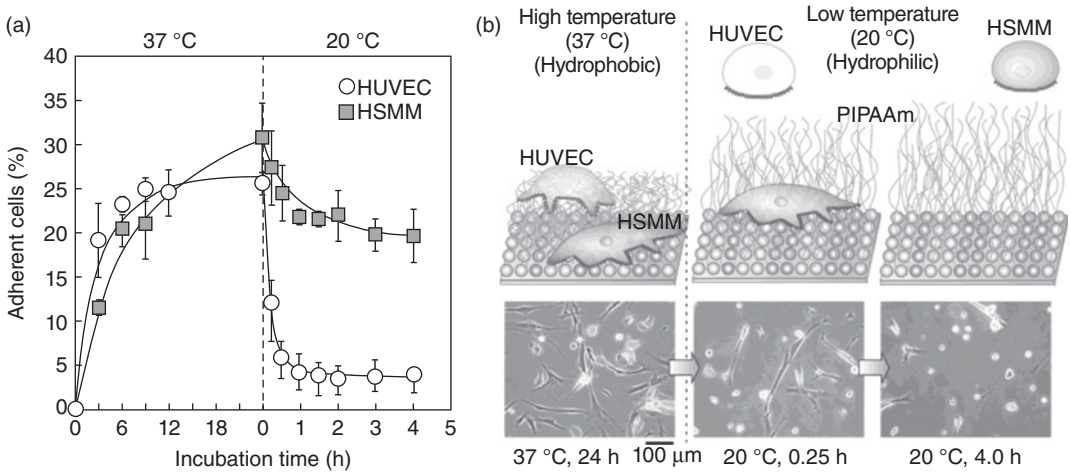

FIGURE 16.8 Temperature-modulated cell separation using PIPAAm brushes: (a) cell adhesion and detachment profiles; (b) cell morphologies on PIPAAm brushes. (Adapted from Ref. 44 with permission from The Royal Society of Chemistry.)

because the increased hydrophilic properties prevented lymphocyte retention on the PIPAAm brushes. However, at 5°C, the recovery rate increased with increasing PIPAAm brush length, because longer PIPAAm brushes tend to be hydrated and become hydrophilic, leading to lymphocyte desorption. Investigation of the subpopulation retention profiles showed that the B cells exhibited temperature-modulated retention and recovery, whereas low T-cell recovery rates were observed. This is probably because of the high adhesion properties of the T cells. These results indicated that a column packed with beads grafted with PIPAAm brushes could be used to modulate the ratio of B and T cells in lymphocytes simply by changing the temperature.

Human cells for cardiovascular tissue engineering can also be separated using PIPAAm brushes [44]. PIPAAm brushes were grafted onto a glass substrate by surface-initiated ATRP, and temperature-modulated adhesion and detachment of four types of human cells was observed. The cells all had similar adhesion rates to the PIPAAm brushes. However, different detachment rates from the PIPAAm brushes were observed. On the basis of these properties, human umbilical vein endothelial cells (HUVECs) and human skeletal muscle myoblast cells (HSMMs) were separated (Fig. 16.8). At 37°C, both types of cell adhered to the PIPAAm brushes. When the temperature was reduced to 20°C, the HUVECs were rapidly detached from the PIPAAm brushes, but the HSMMs were gradually detached from the PIPAAm brushes. In the initial incubation period at 20°C, concentrated HUVECs were obtained. In subsequent periods, a high ratio of HSMMs was recovered. These results indicated that adhesive cells can be separated using PIPAAm brushes, based on the different cell detachment rates.

Cell separation using the intrinsic detachment temperature of the cell has also been proposed [45]. Hydrophobized PIPAAm brushes were prepared on a glass substrate through surface-initiated ATRP by copolymerization with BMA as a hydrophobic comonomer. Cell adhesion at 37°C and detachment at 10°C and 20°C using the prepared P(IPAAm-*co*-BMA) brushes were observed. HUVECs were detached at 20°C, whereas normal human dermal fibroblast (NHDF) detachment was observed at 10°C; these results are attributed to the intrinsic metabolic activities of the cells [46]. On the basis of these properties, HUVECs and NHDFs were separated using multistep temperature changes. At 37°C, HUVECs and NHDFs both adhered to the copolymer brushes. The temperature was then reduced to 10°C, and the adhered NHDFs were recovered. The temperature was then elevated to 20°C, and the adhered HUVECs were recovered. These results suggested that each type of cell has an intrinsic temperature for detachment from thermoresponsive copolymer brushes, and the temperature difference could be used for cell separation.

These cell separation methods enable cell separation by simply changing the temperature, without modification of the cell surfaces. Such separated cells could be used in medical treatment.

16.7 CONCLUSIONS

In this chapter, various bioseparation techniques using thermoresponsive polymers were summarized. Thermoresponsive chromatography can be used to separate biomolecules simply by changing the temperature, without adding organic solvents or excessive amounts of salts to the mobile phase. Also, cell separation methods using thermoresponsive polymers are simple and do not require modification of the cell surfaces. These bioseparation techniques can be performed

by simply changing the external temperature, without using reagents that are harmful to biological compounds. These thermally modulated bioseparation methods are becoming increasingly important with progress in biomedical technology.

ACKNOWLEDGMENT

Part of the present research was financially supported by the "Funding Program for World-Leading Innovative R&D on Science and Technology (FIRST Program)," initiated by the Council for Science and Technology Policy from the Japan Society for the Promotion of Science (JSPS). This study was also facilitated and enhanced by the creation of innovation centers for advanced interdisciplinary research areas, through programs such as the Project for Developing Innovation Systems "Cell Sheet Tissue Engineering Center (CSTEC)" from the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan; the Development of New Environmental Technology Using Nanotechnology Project of the National Institute of Environmental Science (NIES), commissioned from the Ministry of Environment, Japan; and Grants-in-Aid for Young Scientists (B) Grant 24760580 from the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

BIOSURFACTANTS

Etsuo Kokufuta

Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan

17.1 INTRODUCTION

Surfactants (also known as *surface-active agents*) are amphiphilic molecules consisting of a polar headgroup and one or more hydrocarbon chains with hydrophobic character. Such molecules possess the ability to reduce the surface tension between liquid–liquid, liquid–solid, or liquid–gas phases. Biosurfactants (often called *microbial surfactants* or *bioemulsifiers*) are also amphiphilic molecules that are produced by a variety of microorganisms, such as bacteria, yeasts, and filamentous fungi. With respect to surfactant performance, such as emulsifying ability and solubilizing ability, many biosurfactants are comparable to synthetic surfactants. Rather, biosurfactants have several advantages over synthetic surfactants such as lower toxicity and higher biodegradability. Therefore, many studies have focused on the production, isolation, characterization, and application of biosurfactants. A computer-assisted literature search using Web of Science as a search engine provides research trends in this field over the past 38 years (see Fig. 17.1). Interestingly, the publications on glycolipids are greater in number than those in which the author(s) focused on the biosurfactants (compare red circles with blue squares in both "title" and "topics" in Fig. 17.1). This means that the glycolipids were studied beyond the scope of biosurfactants. Another remarkable feature is a jump in the number of publications, including the term *glycolipid*(*s*) in the keywords, which were observed between 1989 and 1991. This is due to a rapid increase in the publications in the research fields of biochemistry and molecular biology, chemistry, cell biology, microbiology, and biophysics, and, in particular, immunology. The field-dependent activities of biosurfactant research can be seen as the percentage against the total number (N_{tp}) of publications between 1975 and 2013. For example, for glycolipids (N_{tp} = 12,336 in topics), the order becomes chemistry (6.2%) > biophysics (7.5%) > materials science (1.5%) > physics (0.6%) > polymer science (0.4%); and for biosurfactants (N_{tp} = 3148 in topics), chemistry (20.8%) > materials science (5.4%) > biophysics (3.9%) > physics (0.9%) > polymer science (0.8%). It is likely that the activities in these research fields (other than in chemistry), which are closely related to *biocolloid and biointerface science*, are not as high as those in the biological and biochemical fields.

Taking the above observations into account, the author aims to provide the fundamentals of biosurfactants, in terms of (1) the classification based on chemical composition and structure, (2) the chemical and physical properties, and (3) the applications. The area of biocolloid and biointerface science is intended to become interdisciplinary, integrated with biosurfactant research, in the future. Although in a broad sense there are many surfactants produced by plants and animals, our focus is on microbial surfactants.

17.2 CLASSIFICATION

Biosurfactants are often classified by considering their chemical composition or their microbial origin. According to the chemical composition, microbial surfactants may be classified into five major groups: glycolipids, lipopeptides, phospholipids, fatty acids, and polymeric surfactants (see Fig. 17.1). They are further subdivided as shown in Table 17.1, which provides an overview of the variety of microbial surfactants.

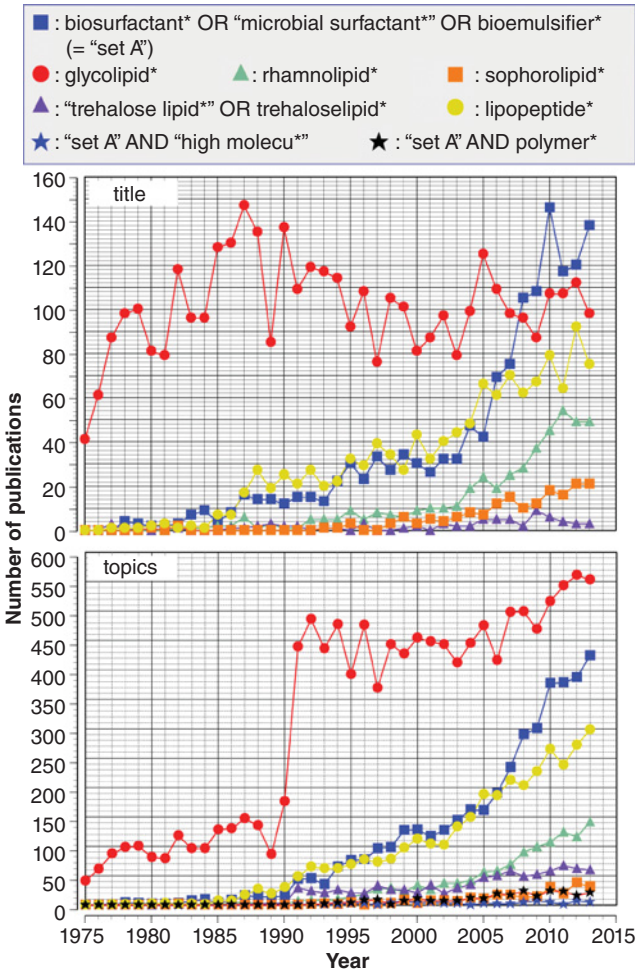

FIGURE 17.1 Annual change in the number of publications in the field of biosurfactants. The data were obtained by a year-by-year search for the terms (uppermost box) on the Thomson Reuters Web of Science (SCI-EXPANDED) research platform. The publications including the term(s) in the title are shown in "title," and those in which the term(s) appears in the keywords appear in "topics." An asterisk at the end of the term allows searches for all terms that begin with the word (e.g., "polymer*" retrieves the publications containing the terms such as polymer, polymeric, and polymerized). A phrase enclosed in double quotes was used to find exact matches; for example, "microbial surfactant*" for either microbial surfactant or microbial surfactants. Biosurfactants with high molar mass (i.e., polymeric biosurfactants) were searched from set A, which shows all the publications (red solid circles in "topics") dealing with biosurfactants.

Glycolipids, produced as extracellular or cell-wall-associated compounds by bacteria, yeasts, and fungi, are the most common and best studied. The major types of glycolipids are rhamnolipids, trehalolipids, and sophorolipids, among which a rhamnolipid (now commonly called *rhamnolipid 1*) was first discovered in metabolites of *Pseudomonas aeruginosa* strains [1]. Now it is well known that the rhamnolipids generally exist as one or two molecules of rhamnose, to which one or two molecules of β-hydroxydecanoic acid are bound, so that there are two major types: monorhamnolipids and dirhamnolipids (see Fig. 17.2). However, so many different rhamnolipids composed of one or two rhamnose and hydroxy fatty acids of different carbon numbers have been isolated and identified by such structural analysis methods as TLC, LC-MS, MS–MS, and NMR spectroscopy [2,3]. As a result, the nomenclature becomes longer and complex. Although the IUPAC names of two rhamnolipids are shown in Fig. 17.2, their synonyms are complicated from the beginning; for example, rhamnolipid 1 (or RHAMNOLIPID R-1) is Rhamnolipid R2, whereas rhamnolipid 2 is Rhamnolipid R1; see PubChem Depositor-Supplied Synonyms. To avoid such a complication, an expression as Rha-Ra-C10-C10 for Rhamnolipid 2 or Rha-C10 for R2 Ramnolipid 1 has been utilized (see Table 1 in Ref. 3).

Trehalolipids (or trehalose lipids) are a wide group of glycolipids, mainly constituted by the disaccharide trehalose linked at C6 and C6′ to mycolic acids, which are long α-chain branched-β-hydroxyl fatty acids. There is also another type in which a mycolic acid is bound to the trehalose molecule. Trehalose 6,6′-dimycolate (e.g., α,α'-trehalose 6,6′-bismycolate) and trehalose 6-monomycolate (e.g., α,α'-trehalose 6-mycolate) are typical of trehalose lipids (see Fig. 17.3). However, several microorganisms including the genera of *Rhodococcus*, *Mycobacterium*, *Arthrobacter*, *Nocardia*, and *Gordonia* produce different types of trehalolipids. The chemical structure of the main trehalose lipids along with the most commonly reported side chains has been summarized in a recent review [4], in which succinoyl trehalose lipids and trehalose tetraesters (see Fig. 17.4) are included together with trehalose mono- and dimycolates. However, note that the fatty acid carbon chains for each of the four main trehalose lipids described in Ref. 4 are not definite. To the best of the author's knowledge, most trehalose lipids, other than the two examples in Fig. 17.3, have neither PubChem Compound ID nor CAS number. For providing more insight into this puzzle, let us look at the case of trehalose tetraesters in Fig. 17.4. Although n = 5–9 [4] as well as $HOOCCH_2CH_2C(=O)$- at C2, $n = 6$ at C3, $n = 8$ at C4, and $n = 8$ at C2′ [5], another study [6] concluded that a trehalose tetraester produced by *Rhodococcus erythropoli*s 51T7 is a "mixture" containing 9–11 carbons (i.e., n = 8–10 in the structure in Fig. 17.4). Surprisingly, the lipid produced by the same microorganisms (*Rhodococcus erythropoli*s 51T7) appears in another report [7] as with a just "concrete" structure: heptanoate, instead of $HOOCCH_2CH2(=O)$- at C2; $n = 9$ at C3; $n = 7$ at C4; and $HOOCCH_2CH_2C(=O)$-, instead of fatty acid ester at C2′ [7, Fig. 1]. This is likely to be a rare case, but we must pay the greatest attention to the study at molecular level of the surfactant property and performance using succinoyl trehalose lipids or trehalose tetraesters.

Sophorolipids are a class of glycolipids constituted sophorose (2-*O*-ß-D-glucopyranosyl-D-glucose), to which a

TABLE 17.1 Classification of Biosurfactants Discussed in This Chapter

Biosurfactants	Subgroups	Examples shown in figures
Glycolipids	Rhamnolipids	Rhamnolipid 1, Rhamnolipid 2
	Trehalose lipids	Trehalose 6,6′-dimycolate
		Trehalose 6-monomycolate
		Succinoyl trehalose lipids
		Trehalose tetraesters
	Sophorolipids	Acidic sophorolipid and its lactonic form
	Others	Gingerglycolipids A, B, C
Lipopeptides	Surfactin	Surfactin A, B, C, D
Phospholipids	Phosphoglycolipids	General chemical structures are shown
	Glycophospholipids	for both lipids
Fatty acids	Microbial fatty acids	Corynomycolic acid

long-chain hydroxyl fatty acid is connected by a glycosidic bond. The first report [8] on sophorolipids produced by *Torulopsis magnolia* was published in 1961. The most common sophorolipids are composed of 9-octadecenoic acid ($CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH$) and 6′,6″-diacetylated sophorose moieties. This compound forms a macrocyclic lactone, in which the COOH group of the hydroxyl fatty acid chain is esterified with the OH group at C4″ of sophorose. Figure 17.5 shows the chemical structures of the acidic and lactonic forms. Note that the lactonic structure appeased in several reports contains an error in the description of the position of esterification of sophorose [9]. Sophorolipids can be produced by yeasts, such as *Candida bombicola*, *Yarrowia lipolytica*, *Candida apicola*, and *Candida bogoriensis*, using carbohydrates and lipophilic substrates. However, microbial sophorolipids occur as mixtures of lactonic and nonlactonic structures. For, example, it was found that more than 95% of the analogs are lactonic sophorolipids and all the sophorolipids produced were either mono- or diacetylated form, when *Candida bombicola* (yeast) was cultivated

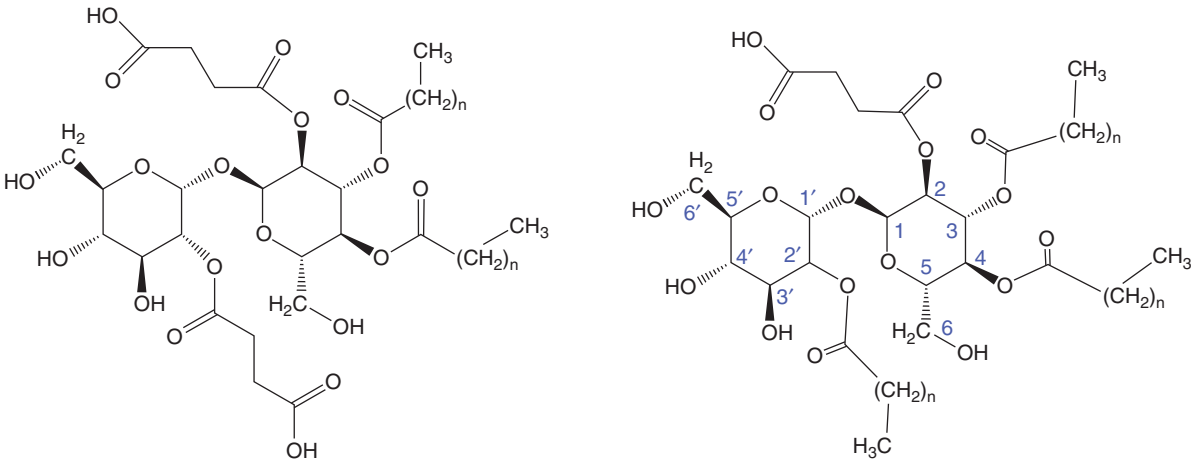
FIGURE 17.3 Two typical examples of trehalose lipids: α,α'-trehalose 6,6′-bismycolate {IUPAC name: [(2*R*,3*S*,4*S*,5*R*,6*R*)-3,4,5-trihydroxy-6-[(2*R*,3*R*,4*S*,5*S*,6*R*)-3,4,5-trihydroxy-6-[[(*E*)-3-hydroxy-2-tetradecyloctadec-11-enoyl]oxymethyl]oxan-2-yl]oxyoxan-2-yl]methyl (*E*)-3-hydroxy-2-tetradecyloctadec-11-enoate}; α,α'-trehalose 6-mycolate {IUPAC name: [(2*R*,3*S*,4*S*,5*R*,6*R*)-3,4,5-trihydroxy-6-[(2*R*,3*R*,4*S*,5*S*,6*R*)-3,4,5-trihydroxy-6-(hydroxymethyl)oxan-2-yl]oxyoxan-2-yl]methyl (*E*)-3-hydroxy-2-tetradecyloctadec-11-enoate}.



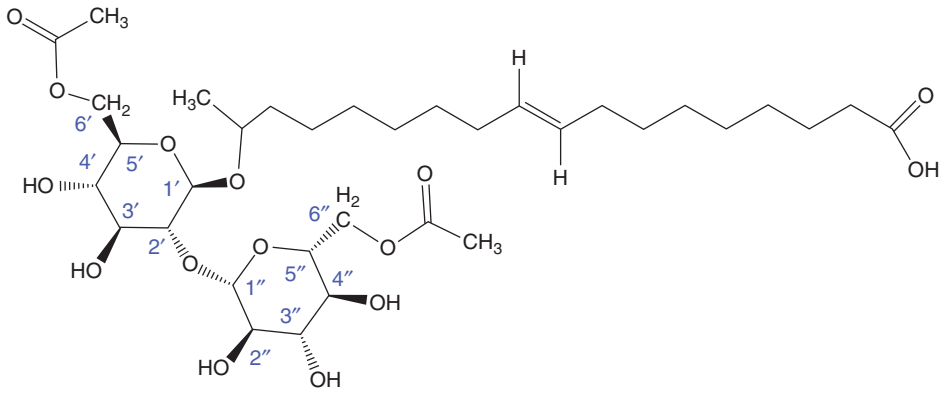


FIGURE 17.4 Structures of succinoyl trehalose lipids and trehalose tetraesters. For both lipids, $n = 5$–9 in Ref. 4 (for more details, see text). The structure of trehalose tetraesters was provided in Ref. 5, in which $n = 6$–8.

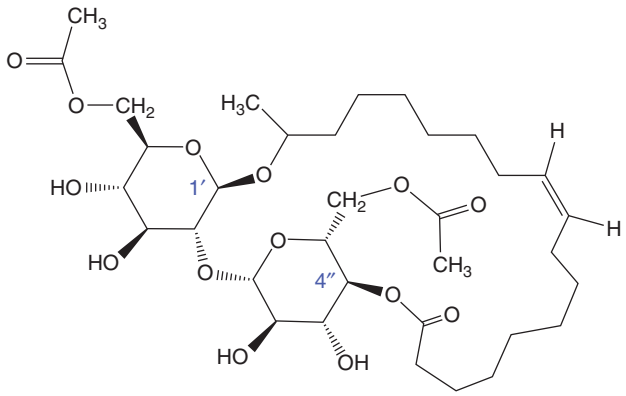

FIGURE 17.5 Acidic sophorolipid {IUPAC name: (*E*)-17-[(2*R*,3*R*,4*S*,5*S*,6*R*)-6-(acetyloxymethyl)-3-[(2*S*,3*R*,4*S*,5*S*,6*R*)-6-(acetyloxymethyl)-3,4,5-trihydroxyoxan-2-yl]oxy-4,5-dihydroxyoxan-2-yl]oxyoctadec-9-enoic acid} and its lactonic form. Note that the systematic name for acidic sophorolipid is (9*E*)-17-{[6-*O*-acetyl-2-*O*-(6-*O*-acetyl-*β*-D-glucopyranosyl)-*β*-D-glucopyranosyl]oxy}-9-octadecenoic acid, which is recorded in ChemSpider but not in PubChem. Also note that both acidic and lactonic forms have no CAS number.

in the presence of glucose and oleic acid under higher aeration [10]. In addition, a sophorolipid analog with a triunsaturated fatty acid was also obtained. Therefore, a method called *chemoenzymatic chemistry* has been developed to prepare a library of sophorolipid analogs from mixtures of natural sophorolipids [11].

At the end, a brief outlook of the plant glycolipids will be provided. In contrast to the microbial types, plant originated glycolipids attract interest in the pharmaceutical and medical areas. For example, three monoacyldigalactosylglycerols, gingerglycolipids A, B and C were isolated from *Zingiberis rhizoma*, and the structures were identified [12] (see Fig. 17.6). In addition, the structure dependence of three gingerglycolipids as an antiulcer agent was studied, so that these glycolipids have PubChem ID.

A number of bacterial species produce lipopeptides or peptide lipids, which consist of short linear chains or cyclic structures of amino acids, linked to a fatty acid via ester or amide bonds or both. Many of microbial lipopeptides are found to have surfactant properties, other than antibacterial or antifungal abilities, so that they are considered as a group of biosurfactants. The lipopeptide biosurfactants are further subdivided into iturin, fengycin, and surfactin, depending on their amino acid sequence and fatty-acid branching. Among these three, surfactin is one of the most effective biosurfactants. Surfactin was first discovered from the culture broth of *Bacillus subtilis* by Arima et al. [13]. Now it is well known that natural "surfactins" are a mixture of isoforms A, B, C, and D, the physiological properties of which are slightly different from each other [14]. An inherent structural aspect of these isoforms is a cyclic depsipeptide that contains one ester bond in addition to the amide bonds. As shown in Fig. 17.7, a peptide loop of seven amino acids (L-aspartic acid, L-leucine, glutamic acid, L-leucine, L-valine, and two D-leucines) is the same for each surfactin isoform, while the carbon number of a hydrophobic fatty acid is different from 13 to 16. Isoform C, with 15 carbons (3-hydroxy-13-methyl tetradecanoic acid), is commonly referred as to "Surfactin." In addition to the four surfactin isoforms, several linear surfactin analogs have been synthesized using solid phase peptide synthesis (SPPS) technique: for example, 3-hydroxy-13-methyltetradecanoyl-L-Glu-L-Leu-D-Leu-L-Val-L-Asp-D-Leu-L-Leu-OH [15]. Also, surfactinlike cyclic depsipeptides that have different molecular masses (1035, 1049, 1063, and 1077 g/mol), due to changes in the number of methylene groups in the lipid and/or peptide portions, were found to be produced by a marine bacterium (*Bacillus pumilus*) [16].

There are various analogs for the other lipopeptides, including iturin, and fengycin, and they are called "biosurfactant lipopeptides" in several articles [e.g., 17]. However, almost all reports focus on the biosynthesis of lipopeptides, without providing their surfactant properties and performance levels.

Most phospholipids are composed of a glycerol backbone, on which the C1 and C2 carbons are esterified with fatty acids and the C3 carbon is bound to a phosphate group via an ester bond. Although this is the most common explanation for phospholipids, a good classification involving compounds in which a sugar moiety is bound to the diacylglycerol and phosphate moieties would be desired when considering phospholipids as a class of biosurfactants. For this, William W. Christie, Technical Editor of AOCS Lipid Library [18], has made the following suggestions:

1. As the name suggests, "glycophospholipids" are lipid molecules that contain both phosphate and carbohydrate as integral structural components.
2. There are two main types of glycophospholipid based on a glycerol backbone, which are exclusively of microbial origin.
3. One type (phosphoglycolipids) is derived biosynthetically from *glycosyldiacylglycerols*, in which the sugar moiety is phosphorylated, that is, in which the carbohydrate moiety is linked to a diacylglycerol.
4. The second group (glycophospholipids) comprises more conventional phospholipids, with a phosphate moiety attached to a diacylglycerol and with the phosphate further glycosylated. According to his suggestions, it seems that phosphoglycolipids, such as 3-*O*-[6′-*O*-(1″, 2″-diacyl-3′-phospho-*sn*-glycerol)-α-D-glucopyranosyl]-1,2-diacyl-*sn*-glycerol types (see Fig. 17.8) isolated from *Mycoplasma laidlawii* falls into the broad class of biosurfactants. Also, this seems to be the case for such a glycophospholipid as 1′-(1,2-diacyl-*sn*-glycero-3-phosphoryl)-2′-*O*-(2′-amino-2-deoxy-D-glucopyranosyl)-*sn*-glycerol (see Fig. 17.9). However, a careful literature search using Web of Science showed that there are no publications dealing with both phosphoglycolipids and glycophospholipids. The main reason is probably that these phospholipid biosurfactants are isolated from the human pathogenic bacteria. Nevertheless, the reason why such phospholipids are included herein is to consider the future development of biotechnology, in particular of the gene engineering techniques.

Fatty acids consisting of long aliphatic chain(s) and carboxyl group(s) are typical compounds with surfactant properties. The classification of fatty acids is made according to how many carbons are in a chain, whether there is the double bond(s) in a chain, whether the chain is branched, and what functional group (e.g., OH) is attached to the chain. Fatty acids are usually derived from triglycerides or phospholipids in plants and animals. Also, several of microorganisms have been known to produce fatty acids of different sorts. As in a class of microbial biosurfactants, it has been claimed that the carbon number is the range of 12–14 for the saturated fatty acids [19]. However, corynomycolic acid ($C_{32}H_{64}O_3$; see Fig. 17.10) obtained as the extracellular product of

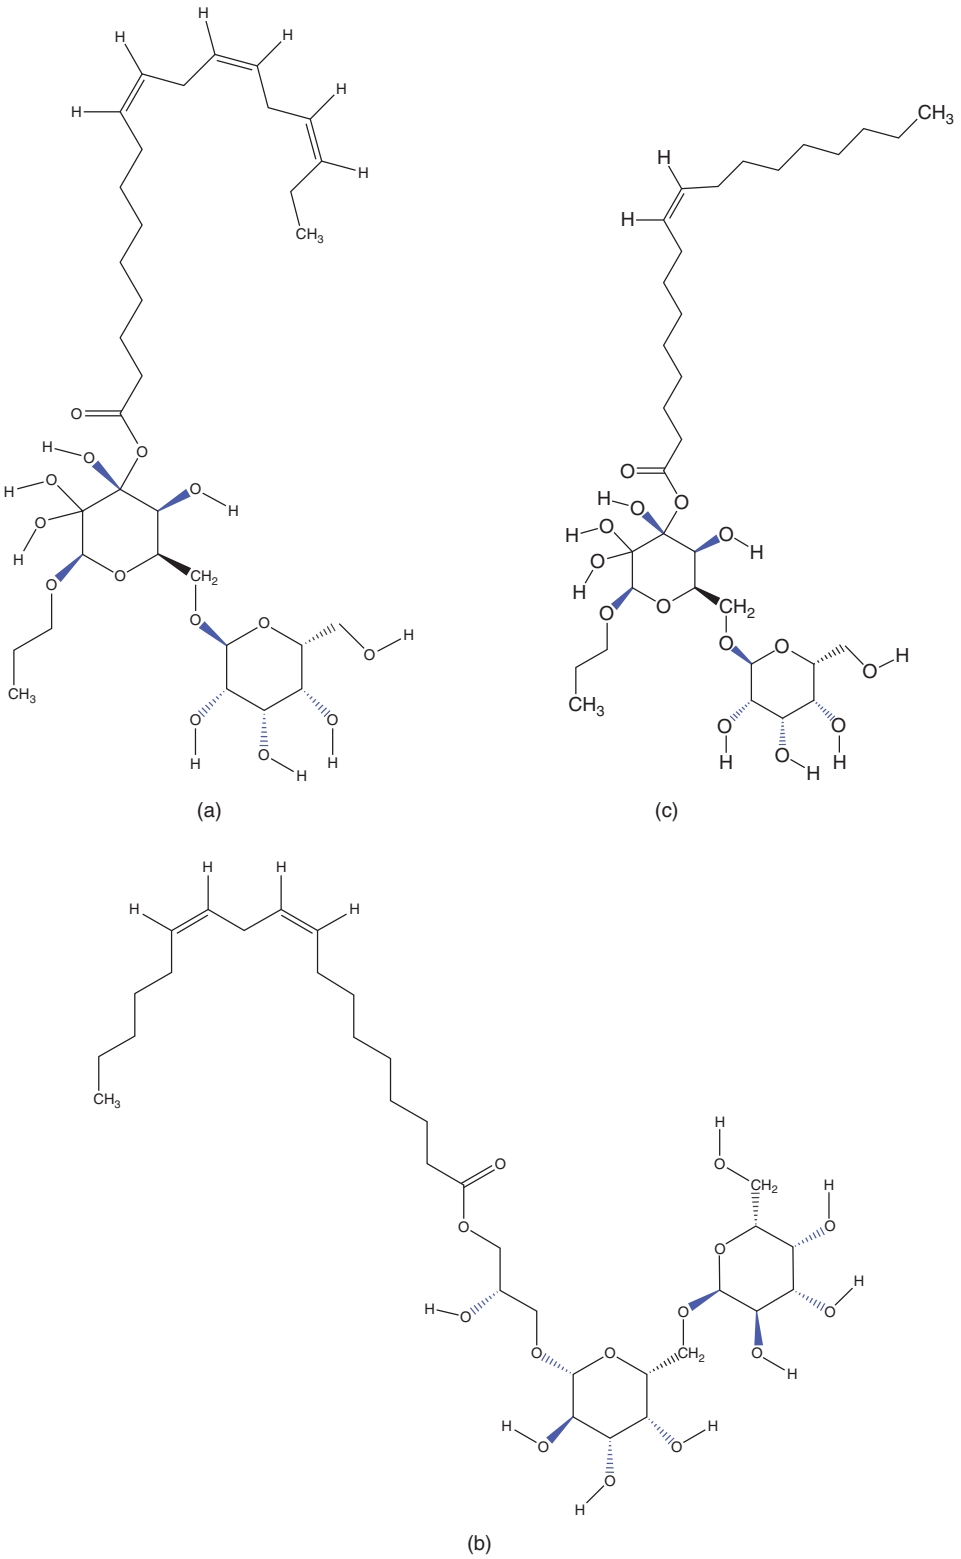

FIGURE 17.6 Gingerglycolipids A, B, and C as antiulcer agents. Gingerglycolipid A {IUPAC name: (2*R*,4*R*,5*S*,6*R*)-3,3,4,5-tetrahydroxy-2-propoxy-6-[[(2*S*,3*S*,4*S*,5*R*,6*R*)-3,4,5-trihydroxy-6-(hydroxymethyl)oxan-2-yl]oxymethyl]oxan-4-yl] (9*Z*,12*Z*,15*Z*)-octadeca-9,12,15-trienoate}; gingerglycolipid B {IUPAC name: [(2*S*)-2-hydroxy-3-[(2*R*,3*R*,4*S*,5*R*,6*R*)-3,4,5-trihydroxy-6-[[(2*S*,3*R*,4*S*,5*R*,6*R*)-3,4,5-trihydroxy-6-(hydroxymethyl)oxan-2-yl]oxymethyl]oxan-2-yl]oxypropyl] (9*Z*,12*Z*)-octadeca-9,12-dienoate}; gingerglycolipid C {IUPAC name: [(2*R*,4*R*,5*S*,6*R*)-3,3,4,5-tetrahydroxy-2-propoxy-6-[[(2*S*,3*S*,4*S*,5*R*,6*R*)-3,4,5-trihydroxy-6-(hydroxymethyl)oxan-2-yl]oxymethyl]oxan-4-yl] (*Z*)-octadec-9-enoate}.

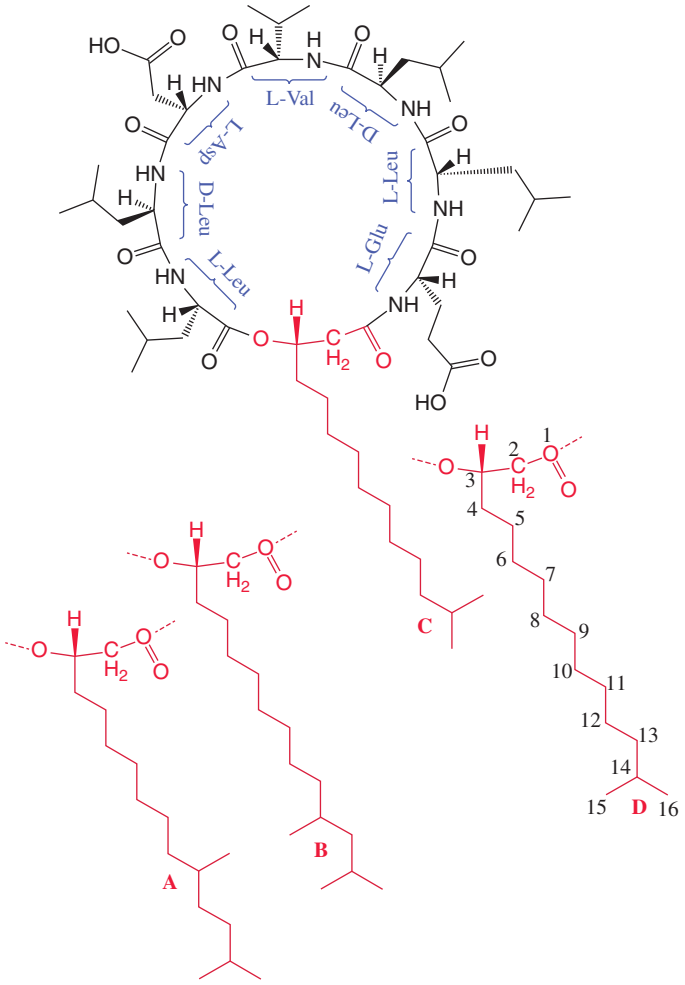

FIGURE 17.7 Four surfactin isoforms with different fatty-acid moieties highlighted in red: (a) 3-hydroxy-11-methyldodecanoic acid; (b) 3-hydroxy-12-methyltridecanoic acid; (c) see text; (d) 3-hydroxy-14-methylpentadecanoic acid.

Corynebacterium lepus grown on kerosene [20] has attracted much attention. Another interesting type is spiculisporic acid (see Fig. 17.11) from *Penicillium spiculosporum*, because the ring-opening form (secospiculisporic acid) of spiculisporic acid yields as a large amount of needle-like crystals in the culture broth [21]. For more detail classification of fatty acids, the AOCS Lipid Library [18] would be helpful, although almost all are products from animals and plants.

Although it is well known that biopolymers like xanthan gum (anionic polysaccharide) behave as an emulsifier or a surfactant, we focus here on microbially produced polymeric surfactants; in a stricter sense, polymeric surfactants are an extracellular product. The most typical example is *emulsan*, which is a potent extracellular polymeric bioemulsifier from *Acinetobacter calcoaceticus* RAG-1 [22]. However, this product was a complex consisting of the heteropolysaccharide and protein fractions, so that the chemical structure for the anionic polymer component, which was isolated from "native" emulsan, was reported very recently [23] (see Fig. 17.12). As the others, the following extracellular

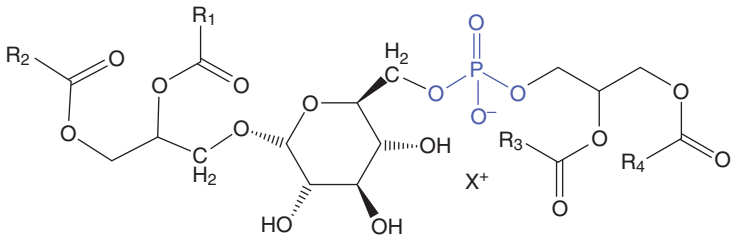

FIGURE 17.8 Typical example of phosphoglycolipids.

spiculisporic acid

secospiculisporic acid

FIGURE 17.11 Spiculisporic acid {IUPAC name: (2*S*)-2-[(1*S*)-1-carboxyundecyl]-5-oxooxolane-2-carboxylic acid} and secospiculisporic acid [IUPAC name: (3*S*,4*S*)-3-hydroxytetradecane-1,3,4-tricarboxylic acid]. The latter is the ring-opening form of spiculisporic acid in the lactone form.

polymeric bioemulsifiers have been known: (1) *biodispersan*, an extracellular dispersing substance from *A. calcoaceticus*, which is anionic heteropolysaccharide containing of four reducing sugars–glucosamine, 6-methylaminohexose, galactosamine, uronic acids, and an unidentified amino sugar [24]; (2) *alasan,* an alanine-containing anionic biosurfactant, which is produced by *A. radioresistens* KA-53 and composed of heteropolysaccharide and protein (called "AlnA") acting as the surface-active component [25, 26]; and (3) *liposan*, an extracellular water- soluble emulsifier from *C. lipolytica*, which is composed of protein and heteropolysaccharide (consisting of glucose, galactose, galactosamine, and galacturonic acid) [27]. In addition to the above, there are several studies for extracellular polymeric emulsifiers, whose chemical structures have remained unstudied for a long time, probably due to the complicated compositions; for example, emulsifying and surface active agents from *Corynebacterium hydrocarboclastus* [28].

17.3 CHEMICAL AND PHYSICAL PROPERTIES

Biosurfactants are synthetized by bacteria, yeasts, and fungi during cultivation with various carbon sources, and in special cases with hydrophobic substrates such as hydrocarbons. For the latter, the surfactant is produced as either an extracellular or cell-wall-associated matrix. The extracellular surfactant causes the emulsification of the hydrocarbon as the

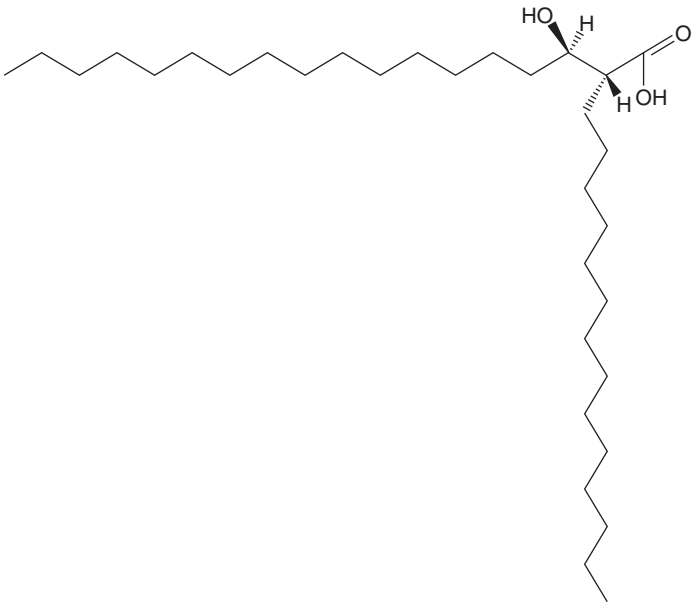

FIGURE 17.10 Structure of corynomycolic acid [IUPAC name: (2*R*,3*R*)-3-hydroxy-2-tetradecyloctadecanoic acid].

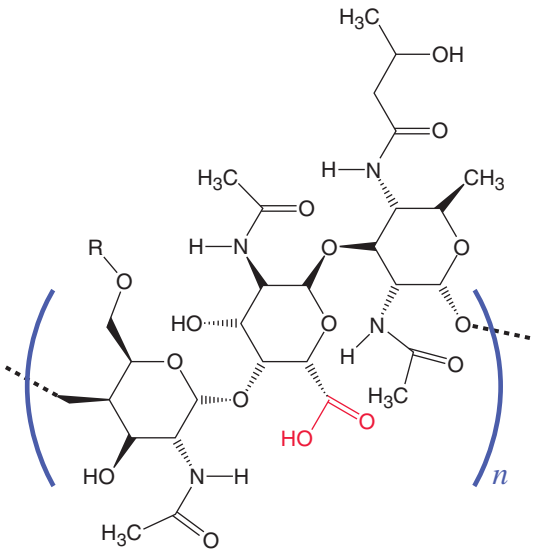

FIGURE 17.12 Structure of the anionic polysaccharide component isolated from the emulsan complex. R denotes acetyl or alcohol moiety.

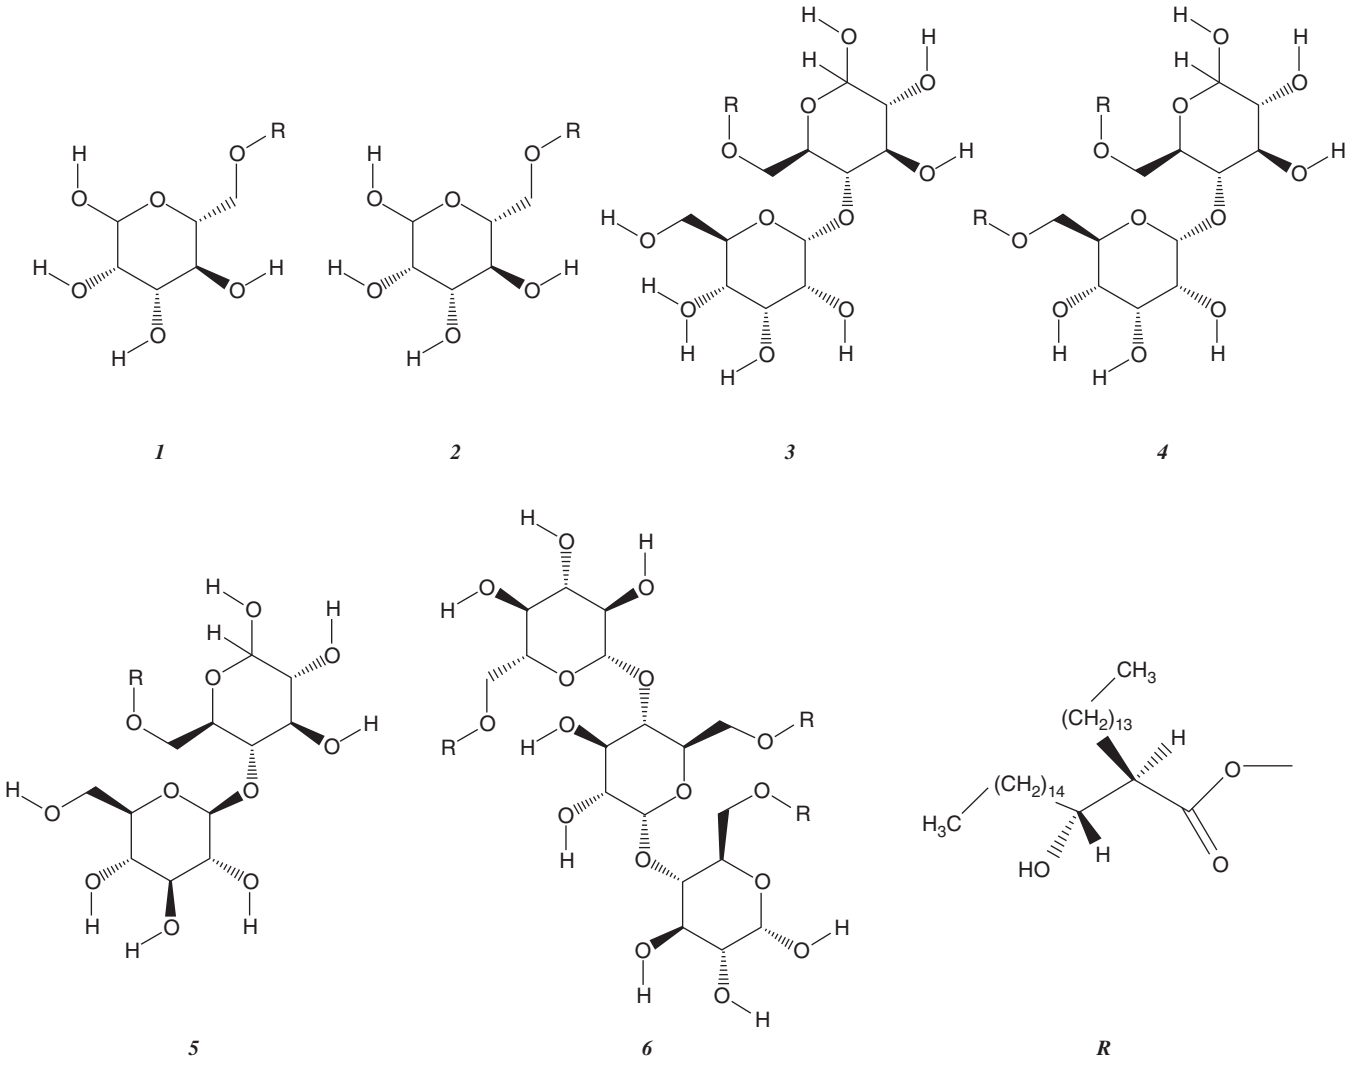
substrate during the cultivation, while the cell-wall-associated surfactant facilitates the penetration of the hydrocarbon to the periplasmic space. Although there is a big difference between microbial and usual surfactants in the synthetic process, both surfactants are composed of the lipophilic (or hydrophobic) and the hydrophilic moiety. The common lipophilic moiety of biosurfactants is the hydrocarbon chain of fatty acids, which are bound to the polar or hydrophilic group, such as the alcohol groups of glycolipids, the COOH groups of lipopeptides or fatty acids. Many of biosurfactants have been known to exhibit normal stability (or instability) to chemical compounds. For example, the ester linkages of glycolipids are broken by saponification with alkaline hydroxides, and this is the case for the *O*-glycosidic bonds. Other chemical reactions, like oxidation or esterification, could be carried out without difficulties.

For more details about the solubility of biosurfactants, the general features are as follows. Nonpolar glycolipids such as trehalose 6,6′-dimycolate and trehalose 6-monomycolate (Fig. 17.3) are soluble in hydrophobic solvents such as chloroform, whereas more polar glycolipids such as anionic trehalose tetraesters (Fig. 17.4) are soluble in $CHCl_3/CH_3OH$ mixtures. Rhamnolipids with two fatty acids (Fig. 17.2) are soluble in methanol, chloroform, ethyl acetate, ethyl ether, and aqueous $NaHCO_3$ solutions, but not soluble in *n*-hexane. Sugar lipids are usually soluble in ether, *n*-hexane, and chloroform at room temperature and in warm acetone and methanol. This is the case for the other sugar lipids as shown in Figs. 17.5 and 17.6. Surfactin (Fig. 17.7) is soluble in alkaline water solutions, methanol, ethanol, acetone, ethyl acetate, chloroform, dichloromethane, and acetic acid, but not in pure water, petroleum ether, and hexane. Phospholipids are generally soluble in aliphatic hydrocarbons, aromatic hydrocarbons and halogenated hydrocarbons solvents, such as ether, benzene, chloroform and petroleum ether and particularly soluble in aliphatic alcohols (e.g., ethanol). However, it is not clear whether glycophospholipids shown in Figs. 17.8 and 17.9 show solubility similar to the common phospholipids.



Spiculisporic acid (lactone form) and secospiculisporic acid (ring-opening form) (see Fig. 17.11) are complicated in their solubility behavior in water. Both acids are soluble in ether, but almost insoluble in water at room temperature. On heating, the solubility of the ring-opening form increases and reaches the level of 10 g/100 g solution at 60°C, at which the lactone form is almost insoluble. The solubility of the lactone form increases with increasing temperature > 70°C and reaches a similar level of the ring- opening form at 90°C. However, it should be noted that about 20% of the ring-opening form is still remaining in the water solution even at 90°C.

One of the most fundamental physical properties of biosurfactants is their surface tension (σ), interfacial tension (γ), and critical micelle concentration (CMC). Many studies dealing with different biosurfactants have reported these physical data. Most of the data were, however, obtained from "intact" products that mean "not complete" in the chemical structure. For example, it was reported that an unpurified polymer obtained from *C. hydrocarboclastu* reduces the surface tension of water (20°C) from 73 mN/m to 60 mN/m and the concentration dependence of σ shows two inflection points at 0.4 g/L and at 1.5 g/L, suggesting the acceptance of two CMC values [28]. Another example is a trehalose tetraester consisting of six components of fatty-acid chains [6] (see Fig. 17.4), whose water solution shows (against hexadecane) = 5 mN/m and CMC = 0.037 g/L at 25°C. Nevertheless, it is not the author's purpose to collect the data of this sort, so that a careful search has been performed to look for the physical data of biosurfactants with a definite structure. There have been only a very few studies in which a systematic comparison of biosurfactants was done. For example, six glycolipids with different structures from *Arthrobacter* sp. (strain DSM2567) have been compared with respect to their surface properties [29]. Table 17.2 shows the data from Ref. 29 with several modifications. Because the authors of that study [29] focused on the application of the biosurfactants into tertiary oil recovery, a high-concentration salt solution was used as the solvent, and the measurements were performed at 40°C. In addition, *n*-hexadecane ($C_{16}H_{34}$) as a model of diesel fuel was used for measuring the interfacial tension. Thus, we have to pay attention to these measuring conditions when comparing with the data of the usual surfactants. However, the following significant observations can be obtained:

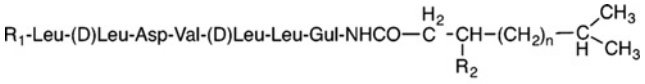
1. Glycolipid **1**, composed of mannose and corynomycolic acid (see Fig. 17.10), and glycolipid **2**, containing glucose instead of mannose, reduce the σ (72 mN/m)

TABLE 17.2 Surfactant Properties at 40°C of Glycolipids 1–6 from *Arthrobacter* sp.

Glycolipid	σ [a] (mN/m)	CMC[b] (mg/L)	γ[c] (mN/m)	CMC[d] (mg/L)
1	40	5	19	50
2	40	10	9	20
3	33	1	1	20
4	46	10	13	10
5	35	3	1	4
6	44	20	19	10

1 ***2*** ***3*** ***4*** ***5*** ***6*** ***R***

[a] Obtained with aqueous glycolipid solutions containing (gL^{-1}) NaCl (100), $CaCl_2$ (28), $MgCl_2$ (10).
[b] Determined from the lipid concentration dependence of δ.
[c] Against *n*-hexadecane.
[d] Determined from the lipid concentration dependence of γ.



of the salt solution to 40 mN/m and the γ (41 mN/m) against *n*-hexadecane to 19 mN/m (glycolipid ***1***) and 9 mN/m (glycolipid **2**).

2. With glycolipid **3** (maltose monoester), the corresponding values decrease to 33 mN/m and 1 mN/m, respectively, and with glycolipid **4** (maltose diester) only to 46 mN/m and 13 mN/m, respectively.
3. Thus, glycolipids **3** and **5**, consisting of two carbohydrate moieties and one fatty-acid moiety (***R***), show stronger reduction in σ and γ than do glycolipids **4** (two sugars and two fatty acids) or **1** and **2** (one sugar and one fatty acid).
4. The monoesters of maltose (glycolipid **3**) and cellobiose (glycolipid **5**) possess the best surfactant

behavior (minimum σ and γ values, 34 ± 1 mN/m and 1 mN/m, respectively) of the glycolipids studied.

5. Also the CMC values ranging from 1 to 50 mg/L confirmed that the combination of two sugars with one corynomycolic acid (i.e., glycolipids **3** and **5**) was superior to the other combinations including the trisaccharide triester (glycolipid **6**). Although the interpretation at the molecular level was not shown in that study [29], these results are likely to address structural aspect of glycolipid surfactants.

Another example is the data in another study [15] in which the hemolytic activity of chemically synthesized linear surfactin analogs was evaluated in relation to their physicochemical properties. Linear surfactin analogs (LSA) synthesized are as follows:

LSA(1): R_1 = COOH, R_2 = OH, n = 8; LSA(2): R_1 = COOH, R_2 = H, n = 8;
LSA(3): R_1 = $CONH_2$, R_2 = H, n = 8; LSA(4): R_1 = COOH, R_2 = H, n = 5;
LSA(5): R_1 = COOH, R_2 = H, n = 13

where LAS(2) is a chemically linearized analog of cyclic natural surfactin C (see Fig. 17.7) and LSA(3) has an amide group as R_1. The σ values of LSA(1) ~ LSA(5) and cyclic natural surfactin C were measured in a 5 mM Tris buffer (pH 8.5) at 25°C and compared with each other. The minimum value of σ decreases in order of LSA(5) (~39 mN/m) > LSA(1) ≈ LSA(2) ≈ LSA(3) (~37 mN/m) > LSA(4) (~ 35 mN/m) ≫ surfactin C (30 mN/m). In addition, the CMC value decreases in order of LSA(4) (1113 μM) ≫ LSA(3) (401 μM) > LSA(1) (374 μM) > LSA(2) (301 μM) ≫ surfactin C (62 μM) ≫ LSA(5) (8 μM). Obviously, a long acyl chain bound to the peptide is effective in decreasing CMC but not in reducing the surface tension. In the case of surfactin C, the cyclic peptide decreases CMC and reduces the surface tension effectively. To facilitate the understanding of these results at the molecular level, the structure of a micelle in an aqueous solution is of importance. The fundamental adsorption and self-assembly properties of two glycolipids, rhamnolipids and sophorolipids; a lipopeptide; surfactin; and a protein, hydrophobin, and their mixtures with other amphiphiles and surfactants have been studied using neutron reflectivity and small-angle neutron scattering [30].

17.4 APPLICATIONS

A large number of experimental studies have suggested the uses of biosurfactants in oil recovery and oil pollution remediation. The potential applications of biosurfactants in medicine and food industrial processes are also suggested. Almost 60 review articles published over the past 35 years refer to the potentialities of biosurfactants for these applications. It is likely that some of them become more realistic from a review [31] in which a scan and mapping were performed for 255 patents on bioemulsifiers and biosurfactants. The highest number of patents is issued for use in the petroleum industry (33%), followed by cosmetics (15%) as an antimicrobial agent and medicine (12%), and in bioremediation (11%). It is emphasized that bioemulsifiers and biosurfactants have advantages over chemically synthesized surface active compounds as follows: (1) less or no toxicity, (2) biodegradability, (3) a broad range of novel structural characteristics, (4) physical properties such as low interfacial tension and critical micelle concentration, and (5) high temperature stability and activity at extreme salinity and pH conditions. Also emphasized is that biosurfactants or bioemulsifiers may be tailored to meet specific requirements, because they can be produced by gene modified microorganisms, and then further modified by using biological or biochemical techniques.

There are many publications in which the applications of biosurfactants are qualitatively or semiquantitatively evaluated in terms of their physical data as mentioned previously. For example, a qualitative evaluation of nine biosurfactants (rhamnolipids, sophorolipids, and glucose lipids) with different chemical compositions and structures was made through comparison of their surface tension and CMC values without consideration of the specific application field(s) [32]. A semiquantitative evaluation of rhamnolipids (and also several commercial biosurfactants) was also made in terms of the environmental applications, in particular in the removal of heavy metals or organic contaminants in the soil (bioremediation) [33]. Thus, the size and morphology of rhamnolipid micelles [34] estimated by the small-angle neutron scattering technique, and the metal stabilization by biosurfactants were considered, although the colloidal properties of the soil were not taken into account in the discussion. There is a more practical evaluation [35] in which rhamnolipid and sophorolipid biosurfactants and their mixtures were examined in terms of the emulsification of oil, and their detergency and vegetable oil extraction ability for biodiesel application was discussed. With respect to the potential applications in medicine, a detailed review has been published [36].

It is of particular importance to note the productivity of biosurfactants in their applications other than the use as medicines. In large-scale production, low production yield and high cost for recovery and purification are general problems. Although the use of culture broth without the isolation and purification of biosurfactants would be possible in some cases, this does not provide an answer to the question of how to develop an effective method for increasing productivity, which is a basic issue in fermentation technology. The authors of one review [37] examined the biochemical and genetic mechanisms of rhamnolipid production by

P. aeruginosa and proposed the application of quorum-sensing signal molecules in enhancing the rhamnolipid production. Rather, as a simplified way to increase the productivity during cultivation of filamentous fungus (*Aspergillus niger*), a polyelectrolyte complex-based technique for microorganism immobilization [38] has been reported [39, 40]. These examples clearly suggest the need for interdisciplinary integration in future developments in this field.

18.1 INTRODUCTION

The central nervous system (CNS) is protected by the blood–brain barrier (BBB) and the blood–cerebrospinal fluid barrier (BCSFB). The BBB, a tissue site widely distributed in the cerebrum, is a specific biological barrier system, restraining and controlling the transports of endogenous and exogenous substances into the brain [1]. The primary roles of the BBB in physiology include maintenance of dynamic stability of the CNS, protection of extracellular microenvironment for brain cells, steady supply of nutrients into the brain via selective transport pathways, and the response of uncertain surrounding variations resulting from the activity of inflammatory cells [2]. The protein and ionic mediations in the BBB also sustain homeostasis for the CNS and regulate the drug delivery and efflux [3]. From the anatomic perspective, the components of the BBB contain brain microvascular endothelial cells (BMECs), astroglia, pericytes, and basement membrane [4]. Figure 18.1 is a schematic representation of the basic cellular structure in the BBB. In addition, interactions among the cerebral cells located between blood and the brain parenchyma lead to the particular configuration and biochemical characteristics of the BBB [5]. At the biomacromolecular level, BMECs display few pinocytotic vesicles, little fenestration, specific enzymes, factor VIII antigen, high transendothelial electrical resistance (TEER), low permeability, adenosine-5′-triphosphate (ATP)-binding cassette (ABC) transporters, and polarization of the membrane transporters, and can generate distinctive relations with the neighboring cells, rendering the unique trait of the BBB.

18.2 CELLULAR SYSTEM OF THE BBB

18.2.1 Tight Junctions

Tight junctions are the main infrastructure for separating molecules in the circulation system from the CNS and defending the external material invasion. This dense cell pattern is localized on the apical region between BMECs. With the function on compact closure for delivery, the tight junctions strictly confine the paracellular diffusion between apical and basolateral plasma membrane and restrict the mass transport between cells [7]. However, the tight junctions are not isolated and static fences in the BBB. Instead, the tight junctions are highly dynamic joints intimately regulated by ingredients in the CNS milieu [8]. One team of invesstigators found that the tight junctions can be regarded as a complex arrangement for transmitting signals between cells and are involved in the genetic expression, cell proliferation, and differentiation [9]. From the structural perspective, the tight junctions are parallel, interconnected, and transmembrane-protein-coupled seals. The transmembrane proteins can bind with cytoplasmic proteins in BMECs and interact with the basement membrane [2].

The extracellular proteins directly related to the tight junctions in the BBB are claudins and occludin [10]. The tight junction coproteins connecting with cytoskeletal actin comprise zonula occludens (ZOs), cingulin, 7H6, and AF-6. In addition, the cytoskeletal proteins can recruit signaling proteins and transcription factors. More than 40 proteins, including transmembrane proteins, cytoskeletal proteins, and

signaling proteins, are associated with the tight junctions and construct the protein complex for signal transmission and reception [11].

18.2.2 Neurovascular Unit

During cerebral development, aligned brain endothelia differentiate and evolve into microvessels with the BBB characteristics [12]. The brain microvessel walls dominate the feature of the BBB. It has been found that the effect of blood leakage enhances with an increasing diameter of the blood vessel, in general [13]. In addition, the biophysical and biochemical properties of BMECs determine the permeability of substances across the BBB [14]. However, the overall behavior of BMECs results from the cellular crosstalk among BMECs, neuroglia, pericytes, and the basement membrane [15]. Therefore, the brain astrocytes with their end feet touching BMECs, the microvessel-surrounding pericytes, and neurons can also affect the BBB permeability. The neurovascular unit (NVU) is composed of these brain cells and plays an essential role in the health and mediatory function of the CNS [16]. Moreover, the signal transmission among cells in the NUV strengthens the quality of the BBB and maintains the proper conditions for stabilizing the brain.

18.2.3 BMECs

Brain microvascular endothelial cells interact with cells in the NVU for regulating the selective transport between blood and the brain and metabolizing substances [17]. In addition, BMECs possess detoxifying functions by preventing poisons from infiltration into the brain [18]. The intrinsic difference between BMECs and other blood vessel endothelia is that the former possesses particular pathway molecules and conciliate the cells in the CNS [19]. The degree of impenetrability across the monolayer of BMECs is 50–100 times that of the microvessel endothelia in peripheral tissues [20]. This datum suggests severe limits to the transport of hydrophilic materials across BMECs. Moreover, the membrane thicknesses of BMECs are very much alike. The continuous basement membrane also contacts negatively charged BMECs, repelling molecules carrying negative charge into the brain. When compared with the endothelial cells in other organs, BMECs contain more and larger mitochondria. These mitochondria reinforce the energy system of BMECs, provide enzymes to destroy invading materials, activate various selective delivery systems, and assist the capture of required nutrients into the brain [21]. Furthermore, the complex proteins, such as the proteins at the tight junctions and the adherens junctions, fill up the interstices at the interface between BMECs and prohibit substances in the circulation system from entering the brain via the passive diffusion route. These mechanisms in BMECs can effectively shield the CNS to resist harmful hydrophobic substances. The BBB also includes the intercellular gap junctions [14]. However, the role of the gap junction proteins in the BBB permeability is not completely clear. In addition, the BBB is not merely a shelter for preventing the leakage of external blood molecules into the brain. Several membrane receptors and special transport systems in BMECs enable the brain to absorb essential hormones and to adjust ionic and metabolite concentration.

18.2.4 Astrocytes

Astrocytes are classified as neuroglial cells. The end feet of astrocytes form thin flat networks closely attached to the abluminal surface of BMECs and constitute one of the fundamental BBB morphologies (see Fig. 18.1) [22]. Astrocytes also possess several ionic channels and membrane receptors. The end feet of astrocytes contain a high surface density of the orthogonal arrays of particles (OAPs). The OAPs, such as water channel aquaporin 4 (AQP4) and K^+ channel Kir4.1, mediate the ionic level and volume of BMECs [23]. In addition, OAP/AQP4 is relevant to the expression of agrin in the basement membrane and intensifies the compactness of the BBB. Moreover, astrocytes play a significant role in the synthesis of proteoglycan, promote the charge selectivity and inductive ability of BMECs, and carry nutrients for neurons.

A certain part of microvessels in the CNS is deficient in astrocytes. However, these microvessels can still demonstrate the BBB traits. This is derived from the functions of soluble factors secreted by neighboring astrocytes. The astrocyte-secreted factors include transforming growth factor β (TGFβ), glia-derived neurotrophic factor (GDNF), basic fibroblast growth factor (bFGF), and angiopoietin 1 (Ang 1). Thus, the application of astrocyte-conditioning medium (ACM; the medium after cultivation of astrocytes) can improve the intensity of tight junctions between BMECs,

induce an appropriate expression of membrane protein transporters, and mimic the brain conditions in vivo for in vitro BBB models. Another team employed an ACM into the culture medium for growing human BMECs [24]. They found that the ACM can reduce 70% permeability across the BBB and enhance the expression of tight junction ZO-1.

18.2.5 Pericytes

When compared with peripheral blood vessels, the CNS vessels are surrounded by a relatively large quantity of pericytes [25]. Pericytes play a critical role in the formation of the BBB characteristics, particularly in the maintenance of the structural integrity at the cellular interface [26]. However, the importance of the brain microvascular pericytes is not limited to upholding of the BBB architecture. In fact, microvascular pericytes can assist angiogenesis in the brain and transmit signals to BMECs through several structural and molecular pathways such as the tight junctions, gap junctions, adhesion plaques, and soluble factors [27]. Therefore, the brain microvascular pericytes are significant in sustaining the brain homeostasis and holding the BBB unity.

The brain microvascular pericytes underlie the BMEC substratum, share the basement membrane with BMECs, and are necessary in the developmental process, biochemical signaling, and physical support of BMECs. For example, pericyte-secreted Ang 1 recognizes its receptor Tei-2 on BMECs for pertaining to the normal differentiation of BMECs [28]. A similar interaction is observed between BMEC-secreted platelet derived growth factor β (PDGFβ) and PDGF receptor β (PDGFRβ) on pericytes. It has been found that the mortality of newborn neonate, microvascular leakage, and hemorrhage probability increase in PDGFβ and PDGFRβ knockdown mice. Pericyte-secreted TGFβ is also a critical element for stabilizing and maturing blood microvessels. In mice without TGFβ and TGFβ type II receptor (TGFβR2), defective blood vessels are observed and can be attributed to the deficiency of TGFβ and TGFβR2, rendering the inhibition to endothelial proliferation and migration [29]. From the physiological perspective, the role of pericytes is comparable to that of astrocytes, in general. They secrete various factors to retain the dense paracellular junctions and the firm cellular wraps in the BBB. The intimate interaction between pericytes and astrocytes is also confirmed. Another group who investigated an *in vivo* BBB model of mice with/without pericytes [30] found that the presence of pericytes strongly affected the polarity of astrocyte end feet. The BBB model without pericytes leads to mislocalization of AQP4 and increases the BBB permeability. Therefore, the brain microvascular pericytes can directly stimulate BMECs, influence the function of astrocytes, and modify the BBB integrity.

The pathological situation can vary the percentage of pericytes covered on BMECs. Another team investigated the BBB structure of rats with traumatic brain injury [31]. They found that after the injury, the ratio of pericytes to BMECs decreases from 1:5 to 1:10 (or 1:12) within 2 h. In addition, the immovable pericytes on BMECs are degraded after the injury for 2 h. However, the relocation of astrocytes from the NVU is not observed. Another team investigated the BBB microstructure of cats under hypoxia [32]. They found that the hypoxemic condition induces the migration of 35% pericytes and thickens the basement membrane within 2 h. However, no obvious variation in BMECs is observed under hypoxia. Another team investigated the BBB structure of mice at sepsis via abdominal injection of lipopolysaccharide [33]. They found that the septicemia yields activated microglial cells, disrupted basement membrane, and detached pericytes from the basement membrane.

18.3 IN VITRO BBB MODEL

The in vitro BBB models belong to the category of cell models, which simplify the complicated circumstances in the brain in vivo and can standardize the related parameters, including the permeability. Therefore, the biomedical researchers have attempted to pursue an in vitro BBB model with a realistic feature of the BBB in vivo [34]. The replicated in vitro BBB models should be simple, reproducible, and reliable and imitate the brain to reflect the microvessels in vivo. The mimicking items of the in vitro BBB model include the anatomical similarity for normal and pathological conditions, the drug transfer route and the drug release mechanism into the CNS, the delivery pathways across the BMEC monolayer, and the proper expression of the membrane protein transporters.

Based on biological and philological observations, the primary objective of the *in vitro* BBB model is to reconstruct the BBB nature and simulate the transport mechanisms in vivo [35]. First, the in vitro BBB model should express sufficiently tight junctions to resist the penetration of substances across the BMEC monolayer via a paracellular pathway. A TEER value and/or permeability coefficient can be used as a typical evidence to judge the completeness and impenetrability of endothelial membrane in the in vitro BBB model. In addition, the appropriate expression of membrane protein transporters on BMECs in the in vitro BBB model indicates the homeostasis and the protection of the CNS [36, 37]. So far, the brain tissue from various mammalian species has been isolated for establishing the in vitro BBB model. These animals include rat, mouse, feline, canine, porcine, and bovine [38–46]. The discrepancy in the transport behavior among the in vitro BBB models from different animal species should be identified. In addition, the permeability obtained from the in vitro and in vivo (animal) BBB models should be assessed and distinguished.

18.3.1 Primary Culture

Joo and Kamushinain achieved the first *in vitro* BBB model by isolation of rat brain microvessels in 1973. Although human BMECs have been used in the in vitro BBB model and the related study, the human brains cannot be freely obtained [47]. In addition, the human brain tissue is often regarded as an improper source for research, although this aspect is under strong debate. Therefore, BMECs from porcine, bovine, and rodent sources are commonly used for the in vitro BBB model [48]. It has been confirmed that the primary culture of BMECs preserves the central feature of BMECs. However, several problems on the BBB characteristics arise in the primary culture using only BMECs. These include the cell purity such as the basement membrane containing an uncertain portion of pericytes. Moreover, BMECs may lose the function in vivo after isolation from tissue, due to the deficiency of mediation by the brain microenvironment. The cellular senescence after succeeding passage can also lead to the deprivation of the BBB traits and the feeble availability of the primary culture based merely on BMECs.

18.3.2 Coculture

The importance of the mechanisms in the cell-interacting NVU for the BBB characteristics, such as astrocyte-induced functions, is well recognized [10, 23, 44]. Therefore, it is inevitable to establish more complicated BBB models involving the other NVU elements except BMECs. The capability and diversity of the in vitro BBB models are thus promoted [49]. BMECs were cocultured with pericytes on porous membrane for studying the BBB permeability [50]. In addition, the cocultured BBB model can be applied to investigate the mass transport and the feedback behavior [51]. The cocultured BBB model can also be employed to evaluate the responsibility of various cells including astrocytes [52–55], pericytes [56], neurons [57], and microglia [58]. Moreover, a cocultured BBB model containing triple components of rat BMECs, astrocytes, and pericytes was recently established [59]. Rat BMECs, astrocytes, and neurons can also comprise a triple cocultured BBB model [60]. The fact that BMECs interconnect the NVU elements in vivo leads to accomplishment of the double and triple cocultured BBB models. These models benefit various BBB studies, including neuronal inflammation, disorder, and degeneration (Alzheimer's and Parkinson's diseases), disease evolution (infection of human immunodeficiency virus), drug abuse (alcohol and methamphetamine), and drug delivery into the CNS [61–65].

18.4 ABC TRANSPORTERS IN THE BBB

The ABC transporters belong to the transportation proteins on the membrane of BMECs. Through hydrolysis of ATP, the ABC transporters control the permeability of solutes across the BBB. In addition, the ABC transporters are regarded as the key mediators of drug distribution in and efflux from the CNS [66]. In fact, these efflux pumps in the BBB and the BCSFB obstruct the entrance of numerous chemicals into the CNS. The ABC transporters discovered include P-glycoprotein, multidrug resistance proteins (MRPs), and breast cancer resistance proteins (BCRPs). The multidrug resistance (MDR) is one of the major hindrances for delivering drug across BMECs. Therefore, the development of the non-ABC transporter substrates and the ABC transporter inhibitors can be an efficacious strategy to treat the brain-related diseases.

18.4.1 Mechanism of ABC Transporters

P-Glycoprotein, the phosphorylated glycoprotein, is a product of the MDR1 gene. P-glycoprotein is the first ABC transporter found from human BMECs. BMECs of monkeys, rats, mice, cats, dogs, cattle, and pigs can also express P-glycoprotein. This explains that P-glycoprotein is a common protective sentinel of the mammalian BBB [67]. P-Glycoprotein can also restrain harmful lipophilic chemicals from penetrating the BBB and protect the CNS. In clinical practice, it has been concluded that various therapeutic drugs with dissimilar molecular structure belong to the P-glycoprotein substrates [68]. For rodents, the genes to produce P-glycoprotein include mdr1a and mdr1b, which are analogous to MDR1 gene in human. In mdr1a knockout mice, the expression of P-glycoprotein in the BBB is inadequate and yields increases of 10–100 times in the permeability of drugs classified as the P-glycoprotein substrates [69]. Moreover, two other researchers investigated the effect of inhibitors on the blockage of P-glycoprotein efflux functions in the BBB [70]. They found an obvious enhancement in the concentration of various drugs in the brain. The rationale behind this observation is that P-glycoprotein plays an essential role in the transporter to expel drugs from penetrating through the BBB. Furthermore, it has been concluded that astrocytes can induce the expression of P-glycoprotein, MRP-3, MRP-4, and BCRP in rat BMECs [38]. In addition, the brain pericytes can stimulate the activity of P-glycoprotein on BMECs [71]. The brain pericytes also enhance the quantities of occludin, MRP-6, and mRNA on/in BMECs [72, 73].

18.5 SECRETED FACTORS FOR BBB REGULATION: MECHANISM AND INHIBITOR

Various components in the NVU regulate the BBB via the cellular secreted factors. The astrocyte-secreted factors include TGFβ, GDNF, bFGF, and Ang 1 [21]. These secreted factors from astrocytes mediate the compactness of the tight

junctions and the expression of the membrane proteins on BMECs [24]. In normal and pathological conditions, pericytes also generate secreted factors such as TGFβ1, matrix metalloproteinase (MMP), vascular endothelial growth factor (VEGF), bFGF, and Ang 1 [28]. These pericyte-secreted factors affect the activity of the ABC transporters, the brain physiology, and the integrity of the BBB [29].

18.5.1 TGFβ1

TGFβ belongs to a family of multifunctional peptide growth factors. TGFβ1, TGFβ2, TGFβ3, TGFβ4, and TGFβ5 are the subspecies of TGFβ. TGFβ type I and type II receptors are the two specific transmembrane receptors of TGFβ. Interactions between TGFβ and its receptors activate the intracellular signal transmission system, such as Smad protein and p38 mitogen-activated protein kinase, and the intercellular pathways of signal-regulating kinase [74]. In addition, TGFβ is an important endogenous molecule against the nerve diseases and disorders of the CNS [75]. Another group of investigators found that TGFβ1 secreted by brain pericytes can reduce the permeability across the BBB and stimulate the activity of P-glycoprotein on rat BMECs [71]. An application of SB431542, a competitive inhibitor of TGFβ1, decreases the efflux function of P-glycoprotein and increases the content of P-glycoprotein substrates, such as NaF and rhodamine 123, in rat BMECs. This demonstrates that TGFβ1 can upregulate the expression of P-glycoprotein in the BBB and may be closely related to the expression of the tight junction proteins. Others found that the pericyte-secreted TGF-β1 can induce the expression of VEGF receptor 1 under ischemic conditions to prevent the degeneration of blood vessels from oxygen suppression [76]. This explains the biochemical mechanism where pericytes regulate the vascular survival via TGFβ1.

18.5.2 VEGF

The VEGF family comprises six members: VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placenta growth factor. VEGF-A is the most important VEGF family member in the brain for vasculogenesis, angiogenesis, and regulation of the permeability across BMECs [77]. However, an overexpression of VEGF is related to various diseases and pathological situations such as the brain carcinoma, stroke, diabetic retinopathy, ischemia, brain injury, and BBB dysfunction [78–81]. VEGF is a water-soluble molecule residing in extracellular matrix (ECM) [82]. Before protease activation, VEGF is in an inactive state and can be regarded as one of the cellular inflammatory factors.

Another study revealed that BMECs under hypoxia secrete VEGF and phosphorylate vasodilator-stimulated phosphoprotein to suppress the expression of ZO-1 in the tight junctions, leading to an increase in the permeability across the BBB [83]. Another team investigated the effect of VEGF receptor flk-1 and Src inhibitors, SU5416 and PP2, on the function of P-glycoprotein [84]. They found that an increasing content of VEGF in the brain downregulates the activity of P-glycoprotein without altering the expressed quantity of P-glycoprotein. These findings confirm that an increase in the concentration of VEGF reduces the activity of P-glycoprotein in the BBB.

18.5.3 MMP-9

MMP is a kind of zinc- and calcium-dependent proteolytic enzyme, secreted by BMECs, astrocytes, and pericytes [85]. Zymogen and endogenous tissue inhibitors of metalloproteinases regulate the activation of MMP. In inflammatory states, MMP-2 and MMP-9 can disturb the physiology of the BBB. In addition, the various cellular components in the NVU can produce MMPs. BMECs secrete MMP-9, acreocytes MMP-2 and MT1-MMP, and pericytes MMP-3 and MMP-9. Moreover, MMPs can regulate the intercellular signaling mechanisms via remodeling of the relevant ECM molecules. Another study revealed that MMP-9 regulates the BBB by cleavage of occludin in the tight junctions [86]. In another study, the topical ischemia was found to increase the secretion of cerebral MMP-9 and yield a reduction in the quantity of ZO-1 in the tight junctions [87]. However, in the case of MMP-9 gene knockout, the mortality resulting from the rupture of the BBB decreases. Another team found that in rat stroke model, an application of BB1101, a general MMP inhibitor, can avoid the leakage of the BBB and reduce the BBB permeability [88].

18.6 NANOPARTICLES FOR DELIVERING PHARMACEUTICALS ACROSS THE BBB

There have been many investigations of applications of the colloidal drug delivery system, such as nanocarrier, to overcome the BBB and treat diseases and neurodegenerative disorders in the CNS. Figure 18.2 illustrates the typical structure of colloidal drug carrier with surface bioactive moieties. As indicated in this figure, the particle is coated with two antibodies for targeting. Another team of investigators modified sialic acid and similopioid peptide on poly(lactide-*co*-glycolide) (PLGA) nanoparticles (NPs) for improving the BBB permeability and the brain-targeting effect [89]. They found that sialic acid and similopioid peptide can prolong the central analgesic activity of loperamide for 24 h and extend the residence time for sustained release in the brain. Two other researchers concluded that after intravenous injection (IVI) of nanocarriers for 4 h, the order in the plasma concentration of coumarin 6 is polylactide (PLA)–tocopheryl polyethylene glycol succinate (TPGS) NPs > PLA–TPGS/transferrin NPs > PLGA NPs [90]. They also found that amphiphilic PLA–TPGS NPs can load a high

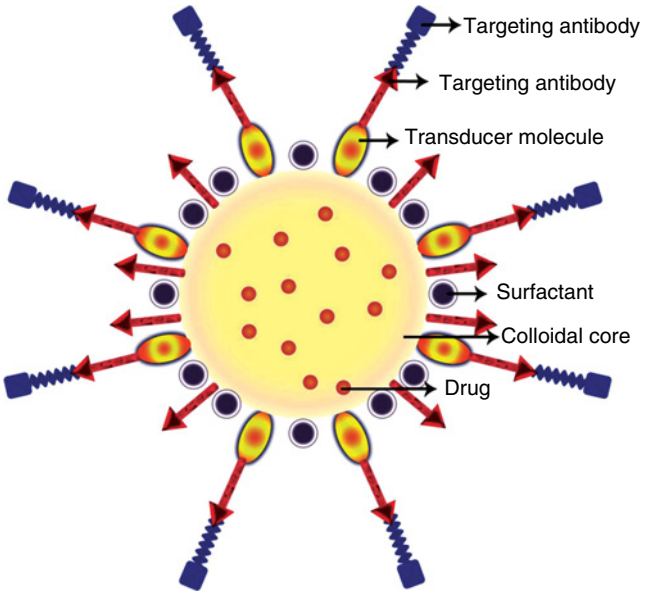

FIGURE 18.2 Schematic representation of colloidal drug delivery system with surface targeting antibodies.

content of coumarin 6 and maintain high particle stability. The main reason for the low plasma concentration of coumarin 6 by PLGA NPs is that hydrophobic PLGA NPs yields high affinity to monocytes, rendering a rapid elimination. In addition, the plasma concentration of coumarin 6 by PLA–TPGS NPs with surface transferrin is lower than that without surface transferrin. However, the former results in a higher concentration in the brain than the latter, demonstrating that surface transferrin can target the brain tissue. Another team found that a 12-amino-acid peptide (Pep TGN), displayed in bacteriophage Clone 12-2, generates a high brain-targeting effect [91]. They also concluded that the delivery efficiency of Pep TGN into the brain is higher than that of native M13 phage. In addition, a modification with Pep TGN on polyethylene glycol (PEG)-PLGA NPs improves the penetration across the BBB. Moreover, the uptake quantity of PEG-PLGA NPs with Pep TGN by bEnd.3 cells (immortalized mouse BMEC cell line) is higher than that without Pep TGN. Another group modified the transactivator of transcription (Tat) peptide and PEG on gelatin–siloxane (GS) NPs to escape the capture by reticuloendothelial system and transfer across the BBB [92]. They found that the modification with Tat peptide converts GS NPs from neutral surface charge into positive surface charge. In addition, Tat-PEG-GS NPs sustain a high brain concentration after IVI for 2 h. Another study revealed that a modification with trimethylated chitosan (TMC) on PLGA NPs promotes the BBB permeability [93]. From the analysis of brain tissue sections, large quantities of TMC-modified PLGA NPs accumulate in cortex, paracoele, the third ventricle, and choroid plexus epithelium. However, no brain uptake is observed in the case of PLGA NPs without TMC. In addition, the modification with TMC converts the particle surface charge from −20 mV to 20 mV and favors the adsorptive-mediated transcytosis (AMT) of TMC-PLGA NPs across the BBB. From the outcome of the Morris water maze behavioral test, coenzyme Q10-loaded TMC-PLGA NPs ameliorate the memory impairment of rats. Another study revealed that a modification with cationized bovine serum albumin (CBSA) reduces the negative charge on PEG–PLA NPs and benefits the particle uptake by negatively charged endothelia [94]. In addition, the tissue sections confirm that the surface charge is the main driving force for delivering PEG-PLA NPs with CBSA into the brain.Another group modified CBSA onto solid lipid nanoparticles (SLNs)–doxorubicin by replacing carboxyl groups with amines to obtain positively charged NPs [95]. They found that CBSA–SLN–doxorubicin can be endocytosed by endothelia and HNCG-1 tumor cells via the AMT. In addition, the uptake quantity of the particulate formulation by HNGC-1 tumor cells increases 6 times when compared with the doxorubicin solution dosage. Another group demonstrated that PEGylated polyamidoamine dendrimer conjugated fluorescein-doped magnetic silica NPs (PEGylated PFMSNs) can permeate the BBB via transcytosis [96]. They found that PEGylated PFMSNs can penetrate rat parenchyma and can be endocytosed by neurons after transport through endothelia and astrocytes. Intriguingly, PEGylation prevents PFMSNs from accumulation, reduces the adsorption of serum proteins, and enhances the probability of the BBB penetration. Another team applied human serum albumin NPs to adsorb HI 6 dimethanesulfonate and HI 6 dichloride monohydrate [97]. They found that from the adsorption isotherm, the Freundlich model is appropriate in these cases. In addition, from the BBB transport, the efficiencies of HI 6 dimethanesulfonate- and HI 6 dichloride monohydrate-coated human serum albumin NPs are, respectively, 1.5 and 2 times the efficiency of free oximes. Moreover, the inhibition efficacy of HI 6-loaded human serum albumin NPs to acetylcholinesterase is 2 times that of free oximes, suggesting a potential antidote for treating organophosphorus toxication. Another study revealed that β-hydroxybutyric acid–grafted docetaxel-loaded SLNs (HD-SLNs) assist the uptake by bEnd cells via monocarboxylic acid transporter [98]. In addition, the area under curve (AUC) of docetaxel in the brain by HD-SLNs is 12 times that by Taxotere. Another team found that penetratin-modified PEG-PLA NPs can infiltrate the BBB via lipid raft-mediated endocytosis or translocation processes via organelles such as Golgi apparatus, lysosome, and microtubule [99]. From pharmaceutical analysis, the penetratin modification is more effective in the uptake of PEG-PLA NPs in the brain than the low-molecular-weight protamine modification. In addition, penetratin can reduce the uptake quantity in non-targeting tissues. Another group of researchers investigated the influence of PEG chain length and particle size on the BBB penetration by PEGylated gold NPs [100]. They found that a

short PEG chain length yields small PEGylated gold NPs and the best BBB permeability occurs at the particle diameter of 4 nm. Another group prepared tacrine-loaded chitosan NPs by spontaneous emulsification [101]. They found that the release kinetics of tacrine follows the Fickian diffusion law. In addition, a modification with 1% polysorbate 80 advantages the BBB penetration and alters the tissue distribution in vivo. Another team investigated the effect of polysorbate 80-modified polybutylcyanoacrylate (PBCA) NPs on the integrity of porcine in vitro BBB model [102]. Based on the TEER value and the permeability of ^{14}C–sucrose and fluorescein isothiocyante–bovine serum albumin, a reversible disruption in the BBB is observed after incubation for 4 h. This suggests a temporal opening of the BBB by polysorbate 80-modified PBCA NPs.

NVU	neurovascular unit
PBCA	polybutylcyanoacrylate
PDGFβ	platelet derived growth factor β
PDGFRβ	platelet derived growth factor receptor β
PEG	poly(ethylene glycol)
pegylated PFMSN	pegylated polyamidoamine dendrimer-conjugated fluorescein-doped magnetic silica nanoparticle
Pep TGN	a 12-amino-acid peptide
PLA	polylactide
PLGA	poly(lactide-*co*-glycolide)
SLN	solid lipid nanoparticle
TAT	transactivator of transcription
TEER	transendothelial electrical resistance
TGFβ	transforming growth factor β
TMC	trimethylated chitosan
TPGS	tocopheryl poly(ethylene glycol)succinate
VEGF	vascular endothelial growth factor
ZO	zonula occluden

19.1 THE REAL CRISIS FOR TWENTY-FIRST-CENTURY MEDICINAL CHEMISTS IN PHARMACEUTICAL INDUSTRIES AND ACADEMIA

Most medicinal chemists in pharmaceutical companies and academia, such as universities and nonprofit institutes, continue to create new drug entities by using the conventional, traditional, and still reliable strategies and tactics of medicinal chemistry. Given that most diseases are currently usually diagnosed in well-developed symptomatic or terminal stages, that is, when multiple parts of a biological system are dysfunctional, it is little wonder that most of the molecularly targeted therapies have limited influence on the actual course of the disease. A recent article in *Nature Reviews Drug Discovery* [1] states: "Research and development (R&D) is the ultimate source of the economic value that the pharmaceutical industry creates. It is therefore not surprising that the evidence of a major decline in R&D productivity has led to a sense of crisis." The authors further comment that "Various solutions have been proposed, ranging from calls to re-engineer the R&D process to the radical suggestion that large pharmaceutical companies abandon internal R&D altogether. However, although decades of improvements to the R&D process and the introduction of new technologies, such as high-throughput screening, have substantially improved the efficiency of discrete steps in the R&D process, they have not been able to counteract the market and the institutional forces that underlie the decline in R&D productivity." We, as 'old-fashioned' medicinal chemists, think that the traditional medicinal chemistry dogma, that drugs should be designed to have specific chemical characteristics, contributes greatly to the real drug discovery crisis. Thus, a radically different way of thinking is needed, one that can lead to breakthroughs through chemical interaction-based drug discovery.

19.2 BORON TRACEDRUGS AS A CHALLENGE TO TRADITIONAL DRUG DESIGN METHODOLOGY

We recently proposed and pursued our concept of boron tracedrugs as "wonder drugs," based on our drug design of the ^{10}B carrier [2–5] for boron neutron capture therapy or BNCT [6, 7]. We proposed these not just as a new drug class with broad potential, but also as next-generation pharmaceutical drugs [8, 9]. We explain herein boron tracedrugs succinctly and clearly. We believe that frequently failed clinical trials over the last decade were due to intrinsic chemical characteristics rather than pharmacological characteristics of drugs designed by traditional drug design methodology. Since drugs, even molecularly targeted drugs, possess no intrinsic rational targeting mechanism associated with their chemical characteristics, they generally affect multiple molecular targets leading to multiple pharmacological effects. A further important point is that management of traceable data associated with the flow of goods, information, and other resources is integral to present logistics

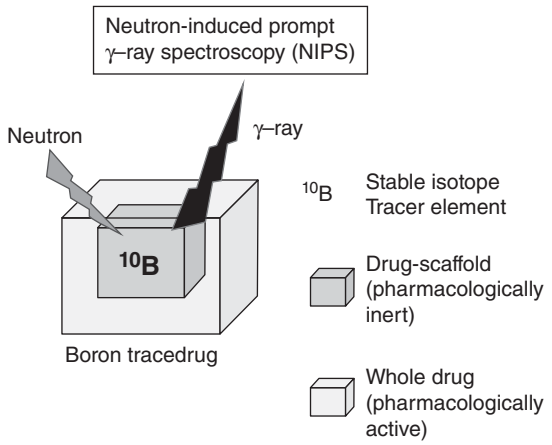

FIGURE 19.1 Conceptual design of boron tracedrugs.

information systems. However, many materials, such as drugs themselves, as yet have no general tags that enable their traceability. When these drugs need to be traced, the only option for tracking them is to analyze them by the appropriate analytical method or by using custom-made radioisotope-labeled synthetic compounds. For data management of tracking drugs, we propose our strategy and tactics for the use of boron tracedrugs.

The key design element of boron tracedrugs consists in their containing multiple (at least one) boron atoms firmly embedded in a molecular scaffold at a position that will have little or no influence on the functional group(s) and pharmacophore(s) of the drug to be traced. The traceability of boron tracedrugs is based on their neutron capture activity (followed by the generation of neutron-induced prompt γ rays) of the stable isotope boron-10 embedded in the drug. Thus, newly designed boron tracedrugs would be novel pharmaceuticals, the structures of which would always include natural boron (^{11}B, 80.4%; ^{10}B, 19.6%) as tracers, embedded in their scaffolds, as shown in Fig. 19.1.

There are many boron-containing compounds that have been used in drug development, including classes such as borinic esters and oxazaborolidines with antibacterial activity, as well as benzoxaborole for onychomycosis. Certain α-aminoboronic acids and related agents have anticancer, hypolipidemic, and antifungal activities; and diazaborines are antimalarial, whereas others, such as bortezomib, are protease and proteosome inhibitors [10, 11]. Thus, boron chemistry falls within the interest of synthetic organic chemists and medicinal chemists. Our concept of boron tracedrugs evolved from our previous drug design studies on the development of hypoxia-targeting ^{10}B carrier compounds described above. In particular, the pharmacokinetics of neutron-induced prompt γ-ray spectroscopy (NIPS) allows for the measurement of ^{10}B concentrations within a few minutes (see Fig. 19.1). We envisioned that if all pharmaceuticals contained ^{10}B embedded in their scaffold, research and developmental facilities would be simplified and "green chemistry" would be facilitated. Although boron is not an element commonly found in natural products or drugs, several bioactive boron-containing compounds are known. Although the creation of a boron tracedrug would seem to be a simple concept for researchers working on BNCT with NIPS, a search of the literature using PubMed and other tools revealed no previous reports of this application. Thus, such an application represents an unexplored area with much potential for next-generation neutron-related industrial development.

Here we should explain the difference between our boron tracedrugs and previously developed ^{10}B carrier drugs such as borocaptate sodium (BSH) and *p*-boronophenylalanine (BPA) used for BNCT. Boron tracedrugs seldom need to use ^{10}B-enriched boron reagents, which must be prepared custom-made and are very expensive. Thus boron tracedrugs can interact with a drug target both chemically (mainly by ^{11}B and partly by ^{10}B) and physically (only by ^{10}B with a natural abundance of $\sim$20%).

We suggest that boron tracedrugs will have a major impact on the developmental process of translational and clinical drugs for therapeutic and/or diagnostic use, and open a new era in medicinal chemistry without radioisotope technology. Research using such technology can be carried out in conventional laboratories without legal regulations (because of use of nonradioisotopes), except that related to the measurement of pharmacokinetics by prompt γ-ray analysis using neutrons in nuclear reactors and accelerators, including BNCT (^{18}F-BPA-positron emission tomography or ^{18}F-BPA-PET [12]), now under development. We also can use inductively coupled plasma atomic emission spectroscopy (ICPS) as a substitute for prompt γ-ray analysis when a neutron generator is not available in the laboratory. Boron tracedrugs can also be a good fit in the era of tailor-made or personalized medicine development, because of a less stringent requirement for the evaluation of absorption, distribution, metabolism, excretion, and toxicity (ADME/Tox) properties in early clinical drug development. Generally, at this stage of drug development, only a few drug candidates, selected on the basis of their preclinical investigation, should be applied to pharmacological assays. Boron tracedrugs have the added potential of being a new class of drugs, based on their physical destructive powers acquired by weak thermal neutrons used in BNCT. Possible applications include destruction of amyloid-β deposits (senile plaques) in the neocortex and τ inclusions as neurofibrillary tangles in neocortical neurons of patients with Alzheimer disease, of α-synuclein inclusions (Lewy bodies) in neocortical neurons of patients with Parkinson's disease/Lewy body dementia, and of other aberrant macromolecules in degenerative diseases frequently appearing in elderly patients [13].

Research on boron tracedrugs offers opportunities for research in engineering fields, in particular in nuclear engineering and neutron engineering, to develop human-friendly

atomic power reactors as neutron generators. In the chemical and chemical engineering fields, boron tracedrugs could help the pharmaceutical industry design diversity-oriented chemical libraries of boron-containing inorganic and organic compounds. The importance of traceability of synthetic materials, modified or natural products, biomolecules such as proteinaceous drugs/antibody drugs, interference RNAs for gene transfer systems, nanomaterials, and micromachines is apparent. However, there are no ethical discussions on the traceability of medicine(s) in patients except for a limited number of cases where drug accidents have occurred. Providing patients with drugs that guarantee high traceability is a priority for the entire field of pharmaceutical research and development in healthcare.

19.3 BORON TRACEDRUGS FOR NEUTRON DYNAMIC THERAPY (NDT), AS PHYSICIAN-FRIENDLY TOOLS

We now propose "new-fashioned" physics-based drugs, known as *boron tracedrugs*, for NDT, powered by neutron beams, as shown in Fig. 19.2. These tracedrugs are chemicals with characteristics different from those used as tracers.

After ^{10}B has captured a neutron, a nuclear reaction takes place to release two heavy particles, an α particle (^{4}He) and a lithium ion (^{7}Li). According to their high energies, these α particles and ^{7}Li nuclei can be regarded as short-range particles since they travel less than 10 μm in a microenvironment containing large numbers of macromolecules. When

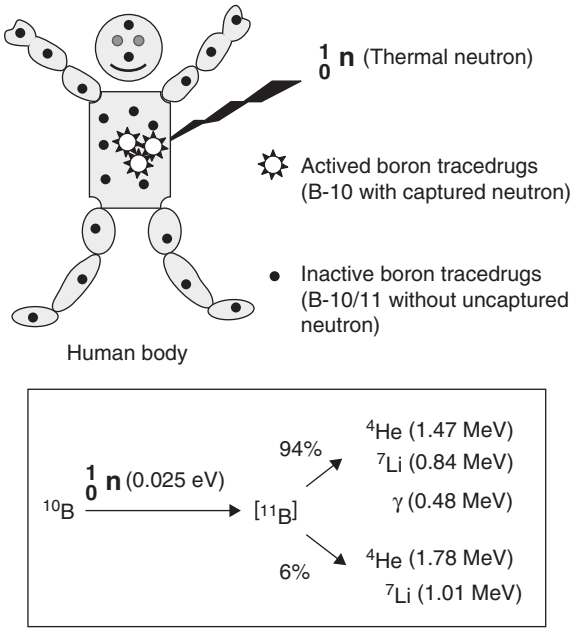

FIGURE 19.2 Conceptual design of a boron tracedrug for neutron dynamic therapy (NDT).

administered, these boron tracedrugs interact weakly with drug targets and endogenous molecules in the surrounding microenvironment, acting like prodrugs [14]. Only by capturing a neutron beam ("on-demand" or *honnête homme* signals) are they transformed to their active drug form to destroy drug targets by their great amount of energy (about 2.5 MeV generated from a thermal-neutron energy of 0.025 eV). Boron tracedrugs are designed to have on-demand traceability persistent during their lifetime. Such physics-based drugs are employed in radioimmunotherapy using radioisotopes for cancer treatment. Radioimmunotherapy involves the administration of radiolabeled monoclonal antibodies that are directed specifically against tumor-associated antigens. Clinical success has so far been achieved mostly with radiolabeled antibodies against CD20 (^{131}I-tositumomab and ^{90}Y-ibritumomab tiuxetan), for the treatment of lymphoma [15]. We are confident that NDT with the use of the stable isotope ^{10}B will have great advantage over radioimmunotherapy with radioisotopes especially with regard to convenience.

As the neutron source for BNCT, experimental nuclear reactors for clinical use have been commonly available. Installations of an accelerator-driven neutron source for BNCT are planned at some universities and institutes. In 2009, the Kyoto University Research Reactor Institute (Osaka, Japan) installed an accelerator-based intense neutron source for BNCT. Instead of nuclear reactors and in-room accelerators, we propose portable, mobile, desktop-type neutron generators as the neutron source for the clinical use of boron tracedrugs for NDT.

As mentioned earlier, the key structural feature of boron tracedrugs consists of their having multiple (at least one) boron atoms firmly embedded in a scaffold and located at a position that will have little or no influence on functional group moieties or pharmacophoric descriptors (i.e., be pharmacologically inert). Boron tracedrugs have unique characteristic physical effects due to their ^{10}B atoms; and their chemical and/or druglike effects are responsible for their pharmacodynamic characteristics. Marc Kirschner said the following in his vision for Initiative Systems Pharmacology at Harvard University: "In the past, the issues that caused drugs to fail were mainly off-target effects, but in many cases now, toxicity problems are on-target effects and the lack of efficacy in phase II and III trials is just unexplainable. So the question becomes: Could we develop a better way of predicting whether a drug will work or have an intolerable side-effect" [16]. Our answer is "yes," as we can supply boron tracedrugs for NDT as a better way to predict whether a drug will work or have intolerable side effects.

Shown schematically in Fig. 19.3, we present our recent results on boron tracedrugs for NDT [17]. In order to explore their destructive dynamic effect when bombarded by weak thermal neutrons, we performed thermal neutron irradiation of bovine serum albumin (BSA), a typical model biomacromolecule, treated with the boron tracedrugs.

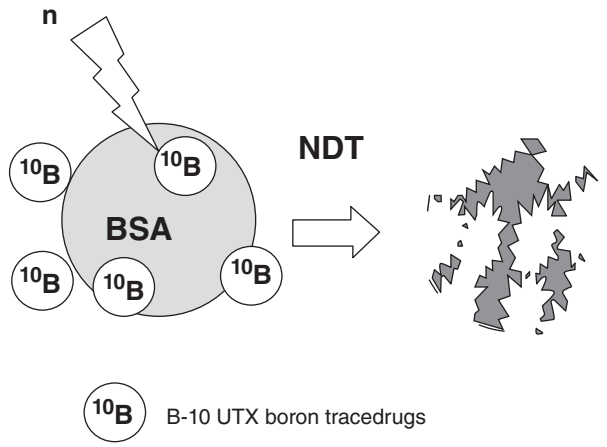

FIGURE 19.3 Schematic image of neutron dynamic therapy (NDT) using a boron tracedrug for bovine serum albumin (BSA) as a model macromolecule.

Boron tracedrugs, including the boron dipyrromethene (BODIPY)-containing compounds UTX-42, UTX-44, and UTX-47, and the curcuminoid compounds UTX-50 and UTX-51, were designed for NDT of BSA based on their molecular orbital calculations (Fig. 19.4).

Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) was performed to detect the decomposition of BSA by thermal neutron irradiation of this molecule treated with any of these boron tracedrugs. The combination of 1.0 μM BSA with a 100 μM concentration of any of these boron tracedrugs showed a decrease in the band density after irradiation. All tracedrugs tested caused destructive damage to BSA, the mechanism of which should be elucidated by further investigation. We speculate the mode of action of boron tracedrugs for NDT to be as follows. The nontoxic thermal neutron (0.025 eV), emitted by the neutron source in the nuclear reactor, reacts with the ^{10}B atom contained in the boron tracedrug (UTX-series drugs tested here), and is embedded in the environment of BSA. As was depicted in Fig. 19.2, after ^{10}B has captured a neutron, a nuclear reaction takes place, releasing high-energy α particles (^{4}He) and lithium ions (^{7}Li) that cause structural breakdown of the BSA macromolecule.

19.4 CONCLUSIONS

We describe here our concept of boron tracedrugs including their application for NDT. We consider such tracedrugs to be a potentially far-reaching new drug class that challenges the current predominance of conventional drugs that rely only on chemical interactions, particularly if this approach were to be extended to a wide range of drug types. Boron tracedrugs could be ideal medicines of the future, with applications as *diagnotherapeutics*, that is, drugs possessing properties of both diagnostics and therapeutics. Such application would derive from the information related to

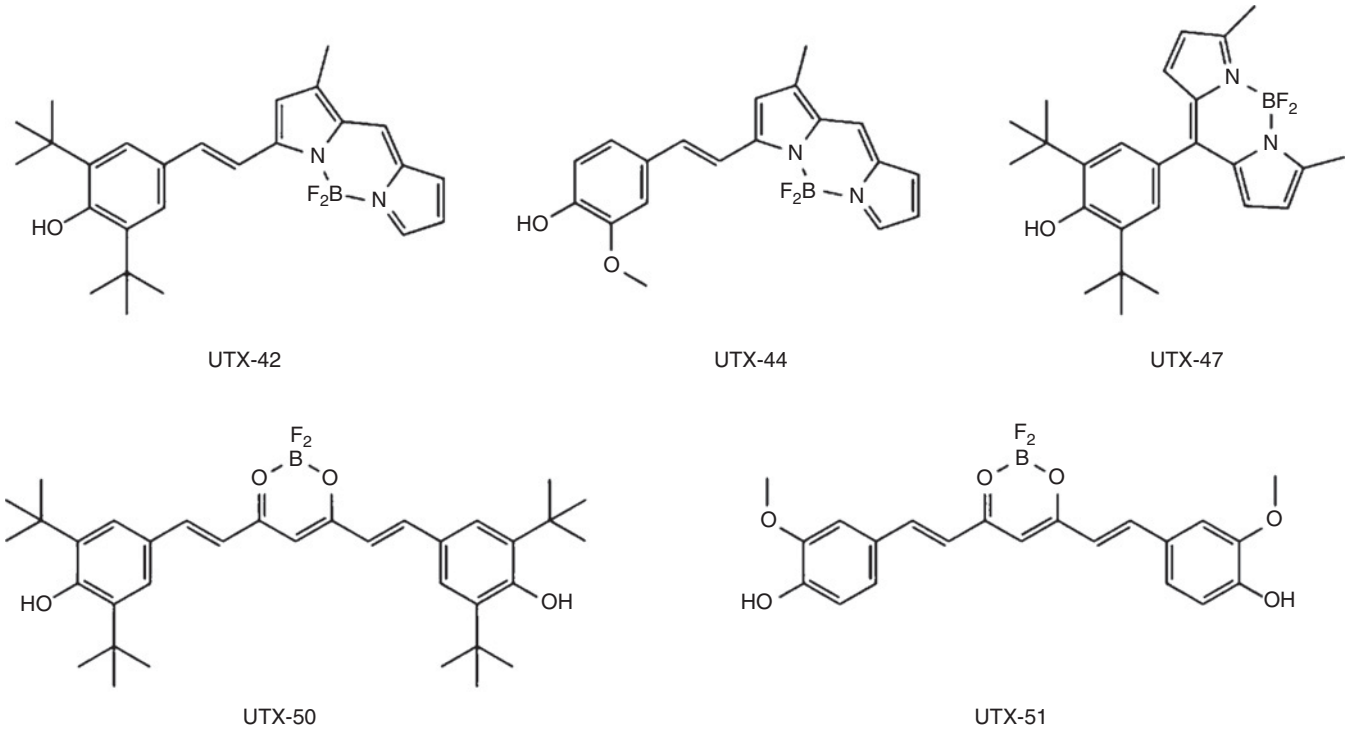

FIGURE 19.4 Designed boron tracedrugs for neutron dynamic therapy (NDT).

pharmacokinetics that would be available directly from the drugs themselves, without the need for additional treatments. These drugs could also be useful in the future when autopsy imaging and virtopsy (virtual biopsy) will become available for medical assessment of the cause of disease and death. In the near future, physics-based NDT using boron trace-drugs, as drugs possessing physical destructive power, could become applicable for all macromolecule-related diseases, against which conventionally pharmacodynamics-based or chemical interaction-based designed drugs have thus far been unsuccessful.

ACKNOWLEDGMENT

We thank Dr. Koji Ono and members of his group at the Research Reactor Institute, Kyoto University for their respective support, as well as all colleagues and coauthors of our previous reports. Finally, we gratefully acknowledge Dr. Kenneth L. Kirk (NIH) for his critical and valuable comments.

CARBOHYDRATES AS BIOCOLLOIDS IN NANOSCIENCE

20.1 INTRODUCTION

A *colloid* or *colloidal mixture* of plant or animal origin is a buoyant particle that is composed mostly of water bound together by extracellular polymeric substances and populated by some microorganisms. Colloids, entities of linear size ranging from 10^{-9} to 10^{-5} m, have shapes ranging from simple ones such as spherical, cylindrical, and cubical to complicated ones such as biconcave disk and rouleau. Biocolloids can have complex and interesting shapes; among these, toroid is common to bacterial DNA, plasmid DNA of eukaryotic cells, and most viral DNA, all of which can be isolated as a single intact chromosome. For instance, when DNA is isolated as a single intact chromosome, it is of toroid shape. This includes all bacterial DNA, all plasmid DNA of eukaryotic cells, and most viral DNA. DNA is highly condensed in toroidal arrays inside living cells, where gene transcription is inactive [1], and the in vitro condensation of DNA has attracted much attention in gene therapy [2]. It was proposed that the toroidal shaped DNA appearing in living organisms relates to the organized form of the helix in proteins and the double helix in DNA [3]. Biochemists used microorganisms to the biological synthesis of inorganic materials or with a variety of substances of animal origin [4]. Much of the recent research efforts have focused on developing new strategies to fabricate nanoconstructs with carbohydrates [5] as capping ligands because of their potential applications in the design and development of nanoscale devices and nanosensors for biomedical applications [6]. Carbohydrates contain many hydroxyl and carbonyl groups; these groups offer sugar-coated nanoparticle a unique hydrogen bonding capabilities in constructing supramolecular architecture. On surface coating with nanoparticles, they provide attractive nanoconstruction abilities for building smart nanomaterials. For example, nanowires of platinum or tellurium have been constructed from glucose stabilized platinum nanoparticles or starch-stabilized tellurium nanoparticles [7]. Despite a large number of applications, there are only very few reports on direct generation of platinum nanoparticles in a sucrose matrix. A "green" method has been developed to synthesize and stabilize platinum nanoparticles in starch matrix using glucose as the reducing agent [8]. Platinum oxide composites with homogeneous size distributions were synthesised and then these materials are stabilized with sucrose. This structure provides a robust, highly porous, and self-sustaining structure with large surface area, which is essential to facilitate incorporation of the platinum ions in the metallization process to give a high platinum loading content.

The use of supramolecules (carbohydrates, *block-co*-polymers, ionic liquids, fatty acids, lipids, phospholipids, polymers, proteins, and surfactants) in the shape-controlled synthesis of nanoparticles, nanocrystals, and other nanometer-sized objects is an important requirement for permanent applications in the field of nanobiotechnology [9–15]. Out of these, supramolecules (biopolymers, carbohydtates, phospholipids, proteins, etc.) have been directly used in biomineralization to produce biofunctional materials. Carbohydrates-capped nanomaterials have more relevance to biological applications than do other supramolecule-capped nanobiomaterials because the surface activity of monosaccharide, structural monomer units of carbohydrates, at the

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

liquid–solid biointerface plays a significant role. The main objective of this chapter is to summarise current knowledge of types, properties, and applications of biocolloids that influence nanoparticle–carbohydrate interactions and their implications on cellular uptake. In a biological medium, nanoparticles may interact with biomolecules such as carbohydrates, proteins, nucleic acids, lipids, and even biological metabolites, due to their nanoscale size and large surface-to-mass ratio. Controlling size and shape simultaneously remains an extremely difficult task, since the outcome of these syntheses is generally determined by a number of factors and is only partially characterized by the interplay of kinetics and thermodynamics. This difficulty increases when silver nanoparticles with a controlled size and shape are to be synthesized by green chemistry.

20.2 TYPES OF BIOCOLLOIDS

Many theoretical attempts have been made in the literature to electrophoresis analysis under various conditions. These include, for example, an isolated particle in an infinite medium [16], a particle near a boundary [17], and a particle near other particles [18]. However, available results are based mainly on uniformly structured, regular-shaped particles. A soft particle, or a particle having a porous structure, or comprising a rigid core and a porous layer, is often adopted to model biological cells [19] and particles such as humic substances [20], bacteria [21], and polyelectrolyte-coated particles [22] in their electrophoresis analysis. Under typical conditions, interestingly, the electrophoretic behavior of a soft particle can significantly differ from that of a rigid one. For a simpler mathematical treatment, previous electrophoresis analyses dealing with soft particles focused mainly on spherical particles of uniform structure [23] or nonuniform structure. Those for nonspherical soft particles are very limited. Two researchers [24] found that if the friction coefficient of its membrane layer is small, then the larger that coefficient, the larger its mobility, but this trend is reversed if that coefficient is sufficiently large.

Several types of biocolloids have been used as ultrasound contrast agents, including gas–liquid emulsions, liquid–liquid emulsions, liposomes, and other particles. The degree of acoustic backscatter depends on the intrinsic properties of the biocolloid. The compressibility of the biocolloid and the density difference between the biocolloid and surrounding tissue contribute to the acoustic backscatter. Nonlinear effects and resonance can also contribute considerably to the echo response. One advantage of the biocolloid is its payload capacity, making it amenable to multimodality imaging for the dual purposes of imaging and therapy. Another is the surface area for targeting. Biocolloids range in size between 10 nm to 10 μm in diameter and therefore can be engineered to present many ligands. Multiple ligand–receptor interactions can lead to firm adhesion, even in the face of hydrodynamic forces acting to dislodge the biocolloid.

Nanodrops are a type of liquid–liquid emulsion. The emulsion is formed by mechanical diminution of the fluorocarbon liquid into an aqueous phase. Droplet size can be controlled by sonication and extrusion techniques, as well as surfactant film curvature, to give diameters ranging between 10 and 1000 nm. The liquid fluorocarbon is dispersed in the form of small particles, nanodrops, within the aqueous phase. A surfactant layer on the fluorocarbon surface helps stabilize the tiny droplets from aggregating, coalescing, or coarsening. The surfactant layer also serves to passivate the surface from immunogenic and thrombogenic effects and provides a platform on which to attach targeting ligands and molecular contrast agents for other imaging modalities, such as magnetic resonance imaging. The fluorocarbon core can serve as a reservoir for hydrophobic drugs. Several different perfluorocarbon emulsions have been described as echo contrast agents. The liquid fluorocarbon phase is often highly hydrophobic, rendeering the particles stable against dissolution. Surface tension at the fluid–fluid interface drives the particle to adopt a spherical shape and limits its deformability. Thus, from a fluid mechanics perspective, the liquid droplets act very much like solid spheres. In general, liquid fluorocarbon nanoparticles scatter energy according to typical Rayleigh scattering theory [25]. For liquid or solid particles, the incompressibility of the interior phase prevents significant oscillation in the ultrasound field. While individual fluorocarbon nanoparticles in suspension are poorly reflecting, their aggregates can be echogenic [26]. Nanodrops therefore are suitable for applications involving high-frequency ultrasound and abundant target epitopes (to allow high accumulation by ligand receptor interactions), such as fibrin in thrombi [27]. Another fascinating imaging application of fluorocarbon nanoparticles has been the introduction of the *phase shift colloid*, where the liquid droplet vaporizes into a gas microbubble as a result of thermal activation [28]. The main benefit of such an agent is the combination of the high stability of the liquid–liquid emulsion with the high echogenicity of the gas–liquid emulsion. Problems, however, include lack of surfactant coverage after area expansion from the droplet to the bubble, leading to possible coalescence.

A *liposome* is a vesicle formed by a lipid bilayer membrane, enclosing an aqueous core. The interior and exterior compartments are separated by a semipermeable, hydrophobic membrane. Liposomes are fabricated by lipid self-assembly and postproduction processing. Typically, large multilamellar vesicles are formed by self-assembly during film hydration. High-power sonication with a cell disrupter at kHz frequencies creates localized shear stresses that break up these larger aggregates into smaller, unilamellar vesicles. Further size refinement can be achieved by forcing the liposomes through well-defined, microscale pores. Echogenic liposome formulations have been described [29]. Echogenic

particles have been found to produce detectable backscatter for ultrasound imaging. These include amorphous solid particles that contain gas pockets in their pores and fissures [30]. Similar to liposomes, gas pockets formed during rehydration may account for the detectable acoustic backscatter. The formation of these gas pockets depends strongly on the size and shape of surface features on the particle. Sizes of such particles can range within the submicrometer/nanometer order, and the gas pockets can be highly stable as a result of pinning of the interfacial contact lines within the solid crevices. Silica nanoparticles have also been tested as ultrasound contrast agents [31]. The *microbubble* is an ideal ultrasound contrast agent because it is extremely echogenic, as well as being biocompatible, multifunctional, and economical. Microbubbles are gas spheres ranging between 100 nm and 10 μm in diameter and are much smaller than the wavelength of diagnostic ultrasound, which is typically 100–1000 μm. The gas core has a low density and is highly compressible, allowing it to shrink and expand with the passage of an acoustic wave. The microbubble increases and decreases in diameter at a rapid velocity giving rise to a strong and unique echo. It is a fortuitous coincidence that the natural reaction time of a microbubble to a rapid pressure variation is on the order of microseconds. Thus, microbubbles resonate at frequencies typically used in ultrasound imaging, and resonance can be exploited to generate a very strong echo. Due to this high degree of backscatter in comparison to plasma and blood cells, a clinical ultrasound system is capable of detecting the signature from a single microbubble—a volume on the order of a femtoliter. Since microbubbles are too small to be resolved by current ultrasound instruments, microbubble imaging techniques are designed to differentiate their echoes from those arising from tissue based on changes in the echo spectrum and the response to changes in the amplitude or frequency of the wave. This provides an opportunity to detect a single microbubble adherent to a vascular target within the space of a single voxel and to distinguish the microbubble from the surrounding tissue. When a dilute microbubble suspension is driven by a harmonic pulse produced by a transducer element with a low peak negative ultrasound pressure, microbubble oscillation can be nearly sinusoidal with amplitude and shape that is a linear multiple of the transmitted wave. Increasing the pressure of the driving pulse or introducing a nearby boundary alters the oscillatory dynamics. The nonlinear dynamics and asymmetric profile result in echoes that contain harmonic multiples of the transmitted pulse. While tissue can also produce echoes that are rich in harmonic frequencies, substantial differences in the pressure and frequencies associated with harmonic spectra allow microbubble and tissue echoes to be differentiated. The advent of nonlinear imaging techniques has brought microbubbles to the forefront of ultrasound imaging agents. Pulsing schemes that exploit these nonlinear features involve trains of transmitted pulses with the amplitude scaled or the phase of the pulse changed between pulses.

20.3 PROPERTIES

A large number of infectious particles, including biocolloids, can be found in the subsurface suspended in the aqueous phase or adsorbed onto other colloid surfaces and/or the solid matrix [32]. The transport of biocolloids through saturated and unsaturated porous media is of significant interest, from the perspective of protection of groundwater supplies from contamination [33], assessment of risk from pathogens in groundwater [34], natural and enhanced bioremediation [35], and for the design of better water treatment systems to remove biocolloids from drinking-water supplies [36]. Microorganisms can also travel attached to abiotic particles [37]. Dispersion can be more important for colloids than for solutes, since it can lead to earlier breakthrough of the colloids. The biocolloids can attach to the soil–water interface, the air–water interface, or the triple contact of soil–water–air. Attachment/adsorption to these interfaces can be reversible or essentially irreversible under certain conditions, and is perhaps the most complex process, given the large number of colloid and grain surface characteristics that determine the probability of attachment, and the influence of the dissolved chemical species in the aqueous solution on attachment and detachment. There are processes that can result in the formation of clusters of biocolloids, either attached to an interface or mobile within the aqueous phase. Clusters can also be initiated via biological processes, to form biofilms [38]. Individual or clustered biocolloids can break off from the film, releasing them into the flowing aqueous medium [39]. To study the fate, transport of colloids and biocolloid at the pore scale, various investigators employed micromodels [40]. Resonance imaging has also been used [41, 42] to understand biocolloid transport at small scales. The main purpose of these microscale experiments has been to visualize biocolloid transport processes at the dimensions of a pore or collection of pores, validating or negating hypothesis that have been put forward with regard to processes that had not been actually observed; a secondary objective has been to quantify the importance of these processes.

20.4 CARBOHYDRATES IN NANOSCIENCE

To avoid the use of toxic organic solvents for the preparation of nanomaterials, researchers have explored the possibilities of preparing them in aqueous medium with the help of synthetic or commercial stabilizing or capping agents. With significant growth in the rather cross-disciplinary nanoscience research involving chemists, physicists, biologists, and engineers, researchers have become concerned about the need for developing more environmentally friendly and sustainable methods for the synthesis of nanomaterials. There is a current drive to integrate all the "green chemistry" approaches to design environmentally benign materials and processes.

Such an approach will also be of advantage for the integration of metal and alloy quantum dots into biologically relevant systems. Carbohydrates are by far the most abundant organic molecules found in nature, and nearly all organisms synthesize and metabolize carbohydrates [43]. The complex heterogeneity of carbohydrates in living systems is a direct result of several carbohydrate characteristics: the ability of different types and numbers of sugar residues to form glycosidic bonds with one another, the structural characteristics of these molecules, the type of anomeric linkage, the position, and the absence or presence of branching [44]. *Nanotechnology* is a field of science that is still under development and has a major influence on the industry from several years. Among variable nanomaterials and fields of their application, metal nanoparticles can be distinguished as the most popular in biology and medicine with gold and silver nanoparticles playing a prominent role. They were used as far as in fourth century for dyeing ceramics and stained glass [45]. Nowadays many methods of their syntheses have been elaborated in dependence on their shape and size to be obtained. Natural polymers like starch [46] and chitosan [47] have been used to stabilize silver nanoparticles by using different reducing agents. The concept of green nanoparticles preparation using β-D-glucose as the reducing agent was first reported by Raveendran et al. [46], and starch played the role of stabilizer. Soluble starch, the amylose component of starch, is a linear polymer formed by the-(1–4) linkages between D-glucose units and adopts a left-handed helical conformation in aqueous solution. Despite its slight branching, amylose behaves essentially like a linear polymer, forming films and complexes with ligands [48]. In the study reported in this chapter, the aldehyde terminal of soluble starch was used to reduce silver nitrate while the starch itself stabilized the silver nanoparticles. Heparin is a linear polysaccharide of glucose and a derivative of induronic acid. It is widely used in medicine as an anticoagulant. Studies show that nanocomposites synthesized with a use of heparin are more stable at physiological electrolyte concentrations than naked nanoparticles, because it binds to the particles, providing electrostatic repulsion from other particles [49]. The composites of nanosilver exhibit antibacterial activity against *Escherichia coli* and *Staphylococcus aureus*, and functionalized heparin exhibits anticoagulant properties [50]. Chitosan was described for the first time in 2004 as a stabilizing agent in nanoparticle synthesis. It was shown that the electrostatic attractive forces between amino groups in chitosan and $AuCl_4^-$ provide an effective driving force for the formation and stabilization of the gold and silver nanoparticles [51, 52]. Also, a method for the synthesis of nanoparticles of silver by incubation of its salts with the suspension of starch and *d*-glucose was described, in which glucose was used as the reducing agent and the starch as stabilizing agent. The starch can also act as a reducer of the silver salt. In this case the resulting silver nanoparticles are closed inside the helical structure of amylose [53]. Interestingly, honey was also used as reducing agent for the synthesis of silver nanoparticles having a size of 34 nm and showed stability in neutral or slightly alkaline solutions [54]. Carbohydrates perform numerous roles in living organisms, such as storage of energy; structural components; backbone of the genetic, immune system; fertilization; preventing pathogenesis; blood clotting, and development [55]. Carbohydrates contain many hydroxyl and carbonyl groups; these groups offer sugar-coated nanoparticle, unique H-bonding capabilities in constructing supramolecular architecture. On surface coating with nanoparticles, they provide attractive nanoconstruction abilities for building smart nanomaterials. One team of investigators [46] suggested an environmentally friendly method for the synthesis and stabilization of metal nanoparticles by suitable choice of materials and solvents. It was shown that by gently heating an aqueous solution of silver nitrate, soluble starch and glucose, one can synthesize "starched" silver nanoparticles in the 1–8-nm size range. While glucose serves as an environmentally benign reducing agent for the metal ions, starch provides stable surface passivation or protection to prevent the aggregation of these particles. These investigators also reported an environmentally benign method for the preparation of gold, silver, and gold–silver nanoparticles in water, using glucose as the reducing agent and starch as the protecting agent. The alloy nanoparticles are homogeneous, and their sizes are well within the quantum size domain (<10 nm) [56]. Stable silver nanoparticles were prepared by using soluble starch and iodometric titration confirmed the entrapment of silver nanoparticles inside the helical amylase chain [57]. Morphology and antibacterial activity of carbohydrate-stabilized silver nanoparticles were investigated [58], using carbohydrates (sucrose, soluble and waxy corn starch) as reducing as well as stabilizing agents. Chitosan is a transformed polysaccharide obtained by deacetylation of natural chitin, which is one of the most important natural polymers constituting the shells of crustaceans and the cell walls of many fungi. Chitosan is a potential polysaccharide and is used in the preparation of various films because of its excellent biocompatibility, biodegradability, nontoxicity, and adsorption properties [59–61]. Various chitosan nanocomposites of silver, gold, platinum, and palladium have been synthesized [62] in aqueous solutions. Metal nanoparticles were prepared by reduction with $NaBH_4$ in the presence of chitosan, which adsorbed onto the surface of metal nanoparticles and formed the metal–chitosan nanocomposites. Silver nanoparticles were synthesized in an alkaline aqueous solution of silver nitrate/hydroxypropyl starch using a chemical reduction method. *Hydroxypropyl starch* is a water-soluble/biocompatible starch derivative that plays a dual rule as reducing agent for silver ions and as stabilizing agent for the formed AgNPs. The effects of the reaction parameters, such as the concentrations of hydroxypropyl starch and $AgNO_3$, pH, temperature, and duration of the reaction

TABLE 20.1 Effects of Carbohydrates as Reducing and Stabilizing Agents on Morphology of Metal Nanoparticles

Carbohydrate/reagent	Stabilizer	λ_{max} (nm)	Morphology	Ref.
Glucose	HTAB	420	Nanocubes	86
Glucose	HTAB	378	Cubes, triangles, wires, and alignment of wires	87
Dendrimers				
Without NaOH		550		88
With NaOH		450		
Cotton	NaOH	425	Spherical	89
Glucose	NaOH	410	Cubic	90
Galactose	NaOH	420		
Maltose	NaOH	390		
Lactose NaOH		400		
β-D-Glucose		419	Monodisperse spherical	91
Chitosan		522	Red color	92
Heparin		401	Cluster to larger spherical	
Soluble starch		420	Spherical, pentagonal biprisms	93
D-Glucose	NaOH	410	Spherical	94
β-D-Glucose	$NaBH_4$	508	Ruby red	95
Dialdehyde–chitosan	HNO_3	416	Spherical	96
Guar gum (galactose, mannose)	NaOH	539	Spherical	97
D-Maltose without reagent		446	Spherical, monodispersed	98
NaCl, $NaNO_3$, CaC_{l2}			Aggregation	
Sucrose	Glucose	482	Spherical	99
Fructose		604	Cluster formation	
Sucrose		425		100
Sucrose	PVA	566	Nanoprisms or fibrils	81
Glucose		514	Spherical particles	101
Fructose and sucrose		404	Pink (Au), yellow (Ag)	
Sucrose	NaOH	415–425	Spherical	102
Glucose		410	Spherical	103
Fructose	SDS	425		
Sucrose		420		
Potato starch		375	Cubic	104
Cornstarch			Spherical	
Pueraria starch	NH_3	545	Spherical	105
Sago starch	NaOH, CTAB		Spherical, elongated fiber	106
Glucose		420	Fiberlike	107
Glucose	CTAB	400	Nanoplates, nanowires	108
Glucose	CTAB	400	Quantum dots	57

medium on the size and agglomeration of the formed silver nanoparticles were studied [63].

Another team [64] reported the synthesis of polysaccharide-stabilized gold and silver nanoparticles using naturally occurring polysaccharidesas as both the reducing and stabilizing agent. No other chemical reducing agent is needed. The gold nanoparticles prepared using chitosan as a protecting agent were of high monodispersity, and were comparable to citrate-stabilized gold nanoparticles. Among all of these agents, capping ligands play a vital role in transforming the spherical or triangular nanoparticles to nanodevices or nanosensors of any desired shape [65]. Much of the recent research has focused on developing new strategies to fabricate nanoconstructs with carbohydrates [66, 67] as capping ligands because of their potential applications in the design and development of nanoscale devices and nanosensors for biomedical applications [68]. Nanowires of platinum or tellurium have been constructed from glucose-stabilized platinum nanoparticles or starch-stabilized tellurium nanoparticles [69–72]. Current strategies for carbohydrate functionalization of Pt nanoparticles utilize thiol-tailored sugars as synthons [73–75]. Another group of coworkers have developed a "green" method to synthesize and stabilize carbohydrate-Pt nanocomposites in starch matrix using glucose as the reducing agent [76]. Another team [77] produced platinum oxide composites with homogeneous size distribution and then stabilized these materials with sucrose. The reduction was fastest in the case of sucrose followed by waxy corn and soluble starch, while stability of nanoparticles followed the order soluble

starch > waxy cornstarch > sucrose. The size and molecular weight were important for stabilization of the nanoparticles. This is required because the more hydrolyzed the carbohydrate, the better its ability to act as a reducing agent. The characteristic absorption peak due to the surface–plasmon resonance of platinum colloids was observed within the range of 415–425 nm. Glucose, fructose, or sucrose offers a weak reducer to produce Au^0 particles by $HAuCl_4$ in aqueous solution [78–80]. Another team reduced the $Au^{3+} \rightarrow Au^0$ reaction in the presence of sucrose in polyvinyl alcohol in hot water [81]. Chitosan has been employed to obtain different types of metal nanoparticle–polymer composites. Using chitosan as a polymeric matrix and $Na[BH_4]$ as reducing agent, relatively small silver nanoparticles have been reported [82]. Another group of coworkers used soluble starch and reported the synthesis of silver nanonanoparticles by using ascorbic acid as reducing agent [83]. Starch has also been used as a clean reducing agent of $AgNO_3$ [84]. Water-soluble starch containing the carbohydrate component amylose and other polymers have been employed as stabilizing agents [85]. Complete reduction of Ag^+ to Ag^0 occurred with change of color from colorless to golden yellow. Homogeneous spherical particles of 15 nm average size were obtained. Reduction in water-soluble starch by glucose and NaOH gave spherical particles [85]. Effects of carbohydrates and its monomers on the morphology of metal nanoparticles are summarized in Table 20.1.

21.1 INTRODUCTION

With the progress of a superaged society in Japan, the number of patients with osteoarthritis is increasing, and enormous pain and loss of motor skills can be caused by this disease [1]. As a result, the number of artificial joint replacements has been rapidly rising in recent years. In order to minimize both the physical and mental burden on patients, artificial joint replacement has come to provide several choices according to the severity of the disease, such as transposing a part of the joint rather than replacing the whole joint with an artificial joint. However, the application methods, effects, and risks of the respective techniques are still at the research-and-development (R&D) stage in terms of method selection. In this sense, it has been widely expected that alternative new materials for use as friction surfaces or partial cartilage replacement parts, which slides under high load in living tissue, would be made available. The use of *artificial hydrogel cartilage* with excellent lubricity is highly desired.

In the past few decades, most applications of total hip replacement have included ultra-high-molecular-weight polyethylene (UHMWPE), although metal-on-metal (MOM) or ceramic-on-ceramic (COC) articulations have also been used [2]. These joints have a UHMWPE cup against a metal or ceramic femoral head. To enhance the friction and wear properties of UHMWPE, there have been some attempts to modify the physicochemical structure of the surface. For example, the cross-linking of UHMWPE and the surface treatment with phospholipid polymeric brushlike layer could remarkably reduce wear [3–5]. These applications are basically applications of the materials harder than articular cartilage. On the other hand, there have been attempts to develop artificial cartilage made of soft materials with super lubricity based on a bionic design by elucidating the lubrication mechanisms of natural synovial joints [6–9]. Soft materials include elastomers, rubbers, and hydrogels. For example, poly(vinyl alcohol) (PVA) [10–13], one of the studied hydrogels most frequently for such applications, shows a very low friction coefficient under walking conditions lubricated with hyaluronate solution containing protein; however, the mechanical strength is not sufficient to be of practical use. To enhance the mechanical and tribological properties of PVA, the use of PVA powders with high molecular weight [11] and lubricant alterations [14, 15] have been reported. Some hydrogels show a low coefficient of friction under specific conditions and high water content comparable to natural articular cartilage. However, these hydrogels lack mechanical durability and wear resistance.

As candidates for practical use as artificial cartilage, new methods of preparing PVA hydrogels have been studied, such as combining different types of PVA gels with different structures, elastic moduli, and characteristics of permeability. This chapter presents a method for preparing biomimetic artificial PVA cartilage for use as artificial cartilage with superior lubricity based on bionic design [16, 17].

21.2 FUNDAMENTAL PROPERTIES OF PHYSICAL PVA GELS

For the preparation of PVA gels, various methods have been reported up to now [18]. Among them, an aqueous solution of PVA can form a hydrogel through a repeated freeze–thawing (FT) process [19–21], in which PVA solutions are repeatedly frozen and then allowed to thaw. This method results in the formation of microcrystallites that serve as physical cross-links to render the materials insoluble in water. Recently, a new PVA gelation technique was reported, which is called the *cast-drying* (CD) method [22]. This method attempts to provide a simple process at room temperature (∼25°C) starting from an aqueous PVA solution without using additional chemical reagents. Briefly, this new method produces a physically cross-linked transparent polymer network from water and PVA powders, resulting in a swollen PVA CD gel in water.

The PVA powder used in the current study, which has been frequently used for the preparation of physical gels by our group [22–27], was supplied by Kuraray Co., Ltd., Japan. There are several types of PVA powder with different degrees of polymerization and hydrolysis. Among them, a powder, catalog number: PVA117, was used here; the average degree of polymerization was higher as ∼1700, and the average degree of hydrolysis was also higher between 98 and 99 mol%.

21.2.1 Network Structure: Swelling Ratio and Crystallinity

To study the molecular and network structures (e.g., the formation of hydrogen bonds) of PVA physical gels, Fourier transform infrared (FT-IR) spectroscopy, X-ray diffraction (XRD), and differential scanning calorimetry (DSC) can be applied. In the present study, an attenuated total reflection (ATR) FT-IR method was carried out at room temperature. The ATR FT-IR spectra were recorded on an FT-IR spectrophotometer (Jasco FTIR610) equipped with an ATR attachment with a horizontal ZnSe crystal (Jasco PRO400S). The IR absorbance spectra were normalized on the basis of CH_2 bending vibrations that appear at approximately 1500–1400 cm^{-1}. The components of the absorption band were deduced from the second derivative of the spectra and were resolved by applying the curve-fitting method. Small-angle X-ray scattering (SAXS) measurements were performed at room temperature using a SAXS system with a wavelength of 0.1488 nm at BL10C in the Photon Factory, High Energy Accelerator Research Organization (KEK) [25,27]. A small and wide-angle X-ray scattering (SWAXS) system with a wavelength of 0.1542 nm operated at 40 kV and 50 mA (SAXSess, Anton Paar, PANalytical) was additionally used. The crystallinity was measured using a differential scanning calorimeter (DSC, DSC8000, PerkinElmer) and a thermogravimetric analyzer (TGA, TGA4000, PerkinElmer). Two samples were cut from each dried sample. Using one sample, the weight ratio of the crystalline portion of the polymers was calculated by DSC. Using the other sample, the true weight of the total polymer was calculated by TGA. From these measurements, the crystallinity was calculated using the literature data of the heat required to melt 100% crystalline PVA [28].

From the results of the FT-IR and XRD measurements, the network of CD and FT gels on nanometer scale was found to be composed of microcrystallites and amorphous zones, as shown schematically in Fig. 21.1a. On the other hand, the network structures of the CD and FT gels on micrometer scale differed from each other, as shown in the schematic models in Fig. 21.1b. This schematic model is similar to that proposed for the thermoresponsive poly(*N*-isopropylacrylamide) (NIPA) gel [29]. The network consists of dense and dilute regions of polymers, which can be introduced permanently by the gelation process. The degree of inhomogeneity can be controlled from transparent to opaque by changing the gelation temperature as well as the crosslink density [29,30]. The fluid flows out rapidly in the opaque hydrogel, whereas it flows extremely slowly in the transparent hydrogels. Similar models of both networks, NIPA and PVA, can be proposed since the opacity of both samples is attributed to the aggregation of crosslinks, in spite of the different mechanisms of network formation. Since the flow of water affects the surface friction [17], the average pore size and pore size distribution of the hydrogels are extremely important.

In the case of CD gels, the swelling ratio and the crystallinity depend strongly on the gelation temperature T_{gel}. The swelling ratio is defined here as W_t/W_d, where W_t is the weight of the swollen sample and W_d is the dehydrated weight after measuring W_t. The swelling ratio decreased and the crystallinity increased with increasing T_{gel} [27]. This is attributed to the decrement in the water content bound to the polymers by the increase in T_{gel}, which enhanced the growth of microcrystallites. Considering that a larger amount of water was evaporated from the polymer during sample preparation at higher T_{gel}, it is easy to understand that the size of the microcrystallites increased with increasing T_{gel}. In the case of FT gel, on the other hand, the swelling ratio and the crystallinity depended on the number of the freeze–thawing repetitions, and the formation of the microcrystallites was enhanced whenever the freeze–thawing cycle was repeated.

It should be noted that the experiments were conducted using the dried gels; therefore, it is necessary to confirm that the insights obtained for the dried gels are applicable to the swollen gels. Here, the experiments were conducted for the swollen gels with different swelling ratios, which were prepared using PVA117. The XRD measurements of the PVA-cast gel film showed that the average size of microcrystallites D and the average distance between microcrystallites L are

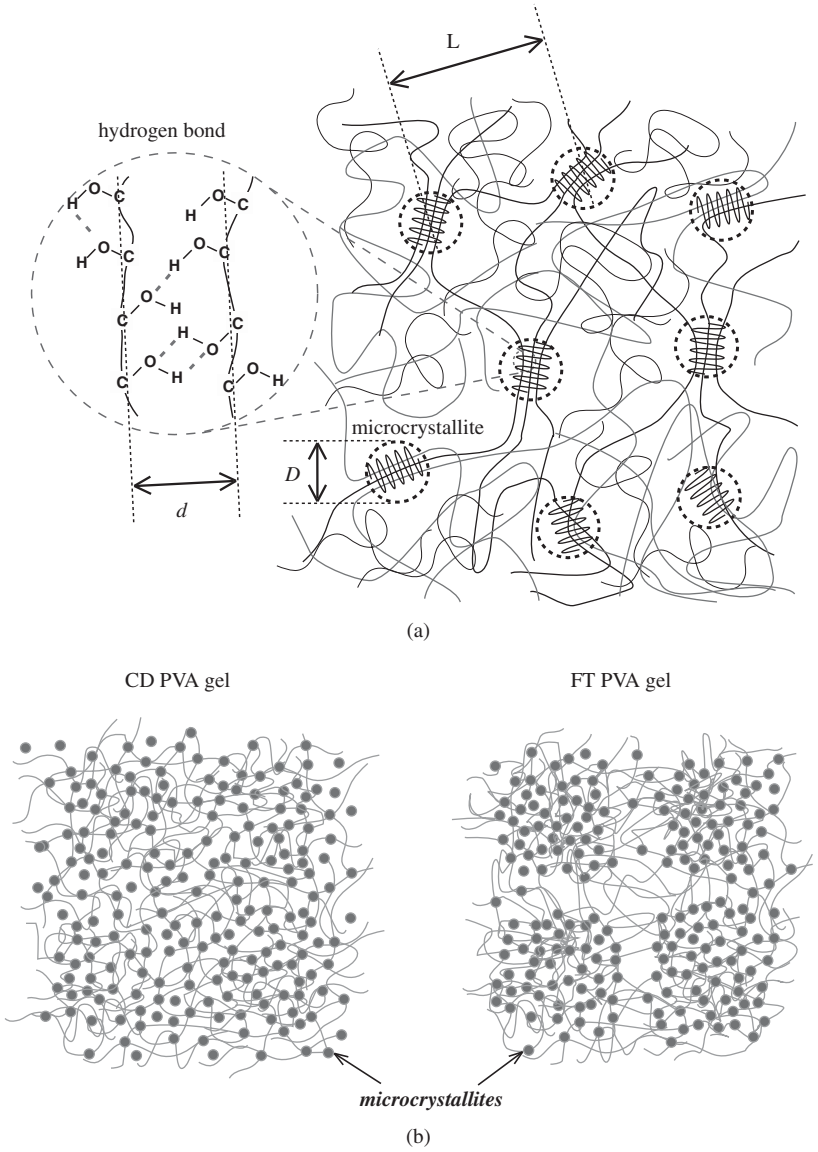

FIGURE 21.1 (a) Schematic illustration of network structure of physical PVA gels; (b) schematic models for two kinds of hydrogel structures.

not significantly different between the CD and FT gels. With an increase in W_t/W_d (from 1.05 to 3.33) in the swelling process, the peak position shifted to a lower wavelength and disappeared, which indicates that L increased, and became constant when W_t/W_d exceeded 1.8. Therefore, we can consider L of a gel with $W_t/W_d = 2$ to be L of the swollen gel [27]. Generally, the macroscopic size is not the same as the microscopic size because of defects of the polymer networks, such as the aggregation of network elements and distribution of the length between cross-links. However, the magnitude relationship of D and L between swollen and dried states is not affected, and therefore the network structures of the swollen gels can be qualitatively evaluated by the use of D and L of the dried states.

21.2.2 Conditions for Starting Raw Materials

To select the PVA powder used in the preparation of the CD gel, additional experiments were conducted using PVA powders as starting materials with different combinations of degrees of polymerization and hydrolysis [22,26,31]. The average degrees of polymerization and hydrolysis are high and high (sample A: PVA117), low and high (sample B), and high and low (sample C). Note that the low–low combination does not allow gelation. As shown in Fig. 21.2a, there was no difference in the FT-IR spectra of samples A and B, and the spectrum of sample C was quite different from both samples A and B. The absorption peaks could be assigned on the basis of literature reports [32–34]. The peak of O–H stretching is

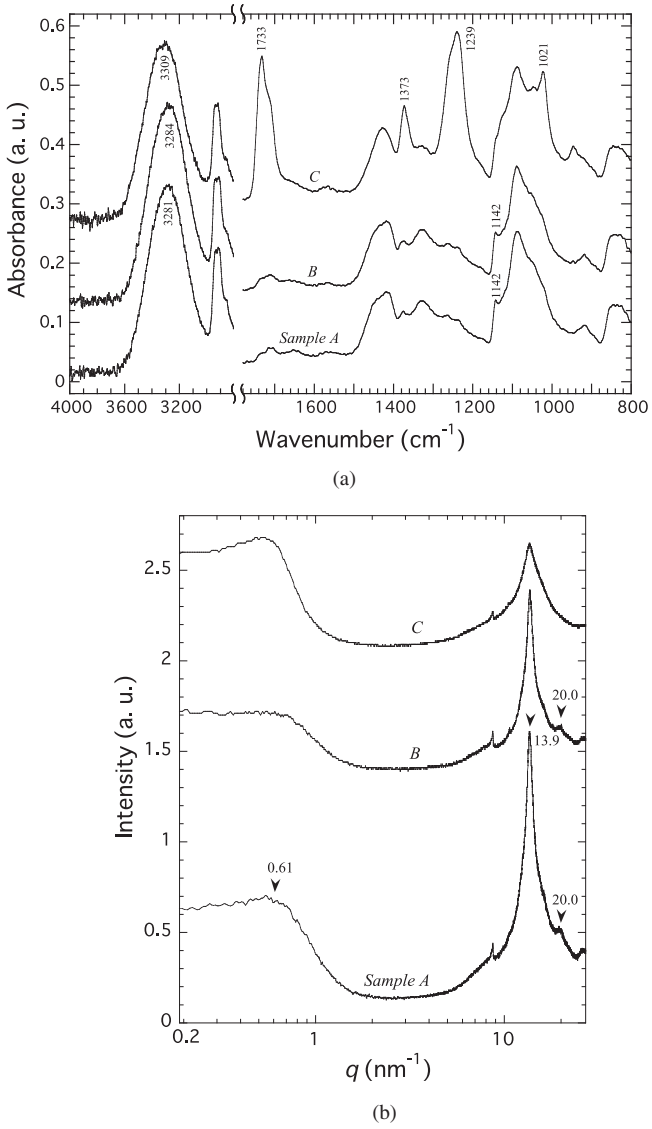

FIGURE 21.2 (a) ATR FT-IR; (b) SWAXS spectra of PVA cast films with different combinations of the degrees of polymerization and hydrolysis, the vertical axis (ordinate) of which is shifted for clarity.

observed at 3309 cm^{-1} for sample C, which is slightly larger than that of samples A and B at 3281 cm^{-1}. This evidence indicates that the acetic acid group in sample C prevented O–H groups from forming hydrogen bonds. As shown in Fig. 21.2b, the acetic acid group in sample C also increased C=O stretching at 1733 cm^{-1}, C–H stretching at 1373 cm^{-1}, and C–H deformation at 1239 cm^{-1}. Moreover, C–O stretching at 1142 cm^{-1} due to the formation of microcrystallites was not clearly observed in the spectrum of sample C. Although assignment of the peak at 1021 cm^{-1} is not clear, the appearance of this peak could have originated from the existence of acetic acid groups. As for the XRD spectra of as-prepared samples A, B, and C, on the other hand, a peak at $q = 13.9$ nm^{-1} ($d = 4.59$ Å) due to the hydrogen bonds between polymers was observed in all samples. However, the peak height of sample C was small, and D values of samples A, B, and C were, respectively, 2.6, 3.5, and 1.3 nm, which indicates that the acetic acid group in sample C prevented O–H groups from enhancing the crystal growth. Moreover, the peak intensity at approximately $q = 0.61$ nm^{-1} ($d = 10.3$ nm) of sample B was the broadest and the smallest of the three samples, which suggests that the microcrystallites were more randomly distributed without the specific structural modulation of L and that the network structure in the amorphous region was inhomogeneous. The slight shift of the peak position to a larger q indicates that L for sample B was slightly smaller than that for samples A and C. In addition, the small peak at $q = 20.0$ nm^{-1} ($d = 3.14$ Å) was not exclusively observed in sample C, which may be attributed to the high degree of hydrolysis in sample C. From these results, a high degree of polymerization is required to fortify an amorphous network by distributing the microcrystallite homogeneously, whereas a high degree of hydrolysis is required to make the large microcrystallites needed for crosslinking the amorphous region [22]. Therefore, it is important to use a starting material (PVA powder) with high degrees of polymerization and hydrolysis in order to obtain a swollen gel using the present cast-drying method.

21.3 TYPICAL EXAMPLES OF PHYSICAL PVA GELS: PREPARATIONS AND MECHANICAL PROPERTIES

From these measurements and analyses, it was confirmed that the CD gel obtained with high degrees of polymerization and hydrolysis was a three-dimensional network formed from an amorphous region cross-linked by microcrystallites (Fig. 21.1). It was also confirmed that the gel obtained had high water absorbence, good water retention, and excellent mechanical properties. Comparing the properties of CD gels to those of FT gels, it was confirmed that the swelling ratio (water content) and mechanical strength (stiffness, fracture toughness, and fatigue resistance) can be improved not only by increasing the crystallinity but also by adjusting the properties of microcrystallites, such as their size, number, and distribution. The properties are also determined by the macroscopic preparation conditions using simple treatments such as changes in temperature (freeze–thawing temperatures and drying temperatures) and humidity during the drying process, and postgelation treatment such as repeated water exchange with or without drying [23]. These factors could determine the network structures on multiple scales, and these factors in turn depend on the degrees of polymerization and hydrolysis of the PVA raw materials.

In the following text, we present the detailed preparation methods and mechanical properties for typical examples of

physical gels. Three different samples were prepared by the same PVA solution. The powder (PVA117) was mixed with pure water (deionized and distilled, Milli-Q water) at a concentration of 15 wt% and dissolved at a temperature above 90°C over a period of 2 h. The PVA pregel solution (15.0 g) was then decanted into a petri dish of polystyrene (with an inner diameter of 85 mm) at room temperature and dried at room temperature (or a specified temperature) to produce flat dense PVA films. Different types of physical crosslinked networks were obtained starting from this same PVA aqueous solution.

To fabricate FT gels, the solution in the petri dish was covered with a lid and sealed with Parafilm® to prevent evaporation for the water and left in a refrigerator at approximately −20°C for 7–24 h. It was then kept in a temperature-controlled container at 4°C. This freeze–thawing cycle was repeated 4 times. The gels were then immersed in a large amount of pure water until reaching their equilibrium states.

To fabricate FT-dry gels, the FT gels were sufficiently dried at room temperature and then immersed in pure water again.

To obtain CD gels, the solution in an uncovered petri dish was left to dry in air at room temperature until the weight became almost constant. This film was soaked in a large amount of pure water to obtain a PVA cast gel.

21.3.1 Swelling Ratio and Compression Stress

Figure 21.3 shows the swelling ratio and the 30% compression stress $\sigma_{30\%}$, which were measured at room temperature for the respective gels. The compression force was measured using a TA.XTPlus texture analyzer (Texture Technologies Co.) with a cylinder probe of 25 mm diameter [27]. The swollen samples were cut into 20-mm-diameter circles using a paper punch and then compressed by the cylindrical probe. The typical compression rate was 0.01 mm/s, and the sample was deformed by a 30% reduction. In this manner the compression stress $\sigma_{30\%}$, was obtained. The FT gel showed the largest W_t/W_d, and the FT-dry gel showed the largest $\sigma_{30\%}$. When $\sigma_{30\%}$ increased, W_t/W_d decreased correspondingly due to the decrease in the number of microcrystallites. The swelling ratio is correlated with the compression stress, i.e., $\sigma_{30\%}$ increases as W_t/W_d decreases.

According to the literature [9, 10], in the case of CD gels, the crystallinity increases and the swelling ratio decreases by repeated water exchange with drying. In the case of FT-dry gels, during a drying process, additional microcrystallites can be formed, resulting in a decrease in the swelling ratio and an increase in the compression stress as compared with FT gels. As shown in Fig. 21.3, the CD gel exhibited intermediate values of W_t/W_d and $\sigma_{30\%}$ between FT and FT-dry gels.

It has been reported that by water exchange with drying, the swelling ratio of CD gels decreases at first and becomes constant after several water exchanges (Fig. 21.4). The decrement of the swelling ratio resulted mainly from the formation of additional hydrogen bonds. The ATR FT-IR spectrum changed during the water exchange with drying due to the elution of noncross-linked polymers from the network and the formation of additional hydrogen bonds between the –OH groups of PVA. Among the characteristic properties of physically cross-linked gels, the elution behavior is particularly important mainly because elution is unavoidable in physical gels [23, 24]. As a result of elution, the number of free –OH groups increases, which are enhanced to form additional microcrystallites. Elution of polymers from PVA

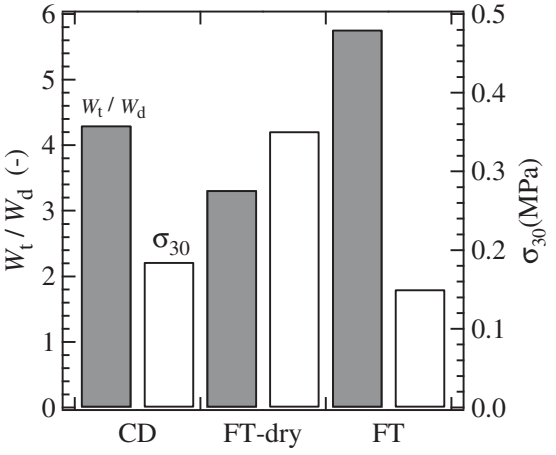

FIGURE 21.3 (a) Typical tearing curve of PVA cast gels prepared at room temperature (~25°C); (b) G_{av}, the average G in the flat region, was plotted against T_{gel}; (c) swelling ratio and compression stress for 30% reduction, σ_{30} of the respective gel.

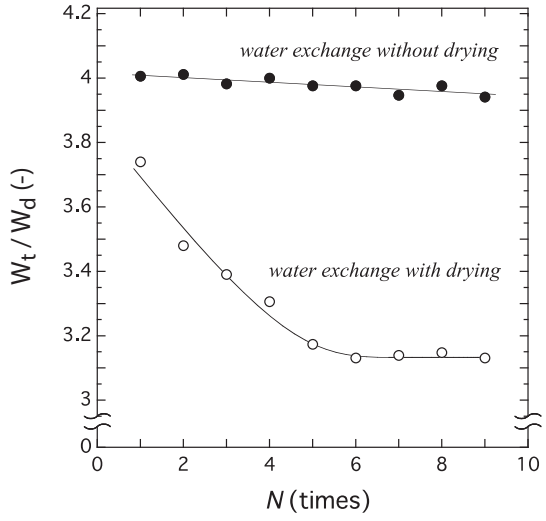

FIGURE 21.4 W_t/W_d of PVA cast gels during water exchange with or without drying. The solid lines are intended for visual guidance.

gels can be estimated by measuring quantitatively the total carbon in the outer water using a total organic carbon (TOC) analyzer, which will be described later. The non-crosslinked polymers elute during a simple swelling process, and the elution can be detected whenever the solvent water is exchanged. The amount of eluted polymers approaches zero after sufficient water exchange. The time revolution of the swelling ratio mentioned above corresponds to the change in elution amount.

It should be noted that the total change in W_t/W_d by water exchange with drying is ~15% (<5% by a single water exchange with drying) in the case of CD gel; W_t/W_d decreases more than 40% by a single water exchange with drying in the case of FT gel (Fig. 21.4).

21.3.2 Tearing Energy by a Trouser Tear Test

The tear energy G is defined as the fracture energy released per unit area of crack surface growth (J/m^2), which was obtained here by dividing the tear force by the gel thickness. The tear force was obtained by a trouser tear test in water [19]. The samples were cut into rectangle shape and an initial slit was made in one of the short sides, from which the tear was propagated. In this test, the rate of separation of the grips holding the gel was constant at 0.1 mm/s. As is seen in Fig. 21.5a, G of the CD gel exhibited a steady propagation after showing a peak at the initial stage. This large peak was attributed to the initial fracture energy needed to start the propagation in the vicinity of the end of the slit, where the polymer network was reinforced by the turbulence caused by cutting the slit. The average tearing energy G_{av} was obtained by averaging G in the flat region. When plotted against the cast-drying temperature T_{gel} shown in Fig. 21.5b, G_{av} increased with increasing T_{gel}. As shown in Fig. 21.6a, G of the CD gel is steady and time-homogeneous, whereas G of the FT gel shows stick–slip behavior due to the network inhomogeneity. G_{av} of the FT gel was much larger than that of the CD gel; G_{av} of the CD gel prepared at 60°C was still much lower than that of the FT gel.

Since G is not strongly dependent on the tearing speed, one can say that the CD gel is highly elastic. In the case of the CD gel, the crystallinity, which increases with increasing T_{gel}, is an essential factor for determining the tear resistance.

On the other hand, the crystallinity is of little relevance to G, suggesting that G is dependent not only on the size and number of the microcrystallites but also on their distribution [22]. The variation in G with time and the fracture surfaces of the CD and FT gels are shown in Fig. 21.6. The appearance of stick–slip behavior in the fracture pattern of the FT gel corresponds visually to the tearing curve, which resulted from the formation of fibrils of bundled polymers on micrometer scale. These results indicate that the microscopic network structure characterized by the presence of fibrils determines the tear energy for the FT gels.

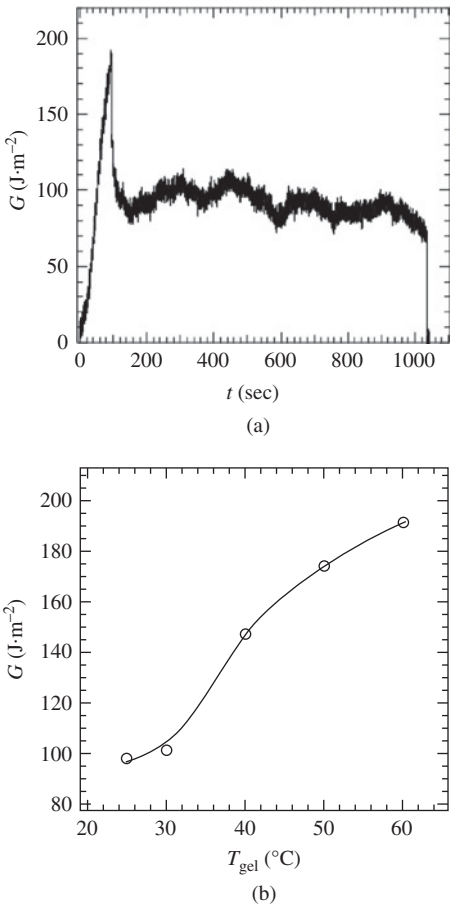

FIGURE 21.5 Fracture energy G of cast and FT gels during a tearing test with a pulling velocity of $v = 0.1$ mm/s: (a) fracture energy in tearing of T at a pulling velocity of $v = 0.1$ mm/s; (b) effects of tearing velocity and drying temperature on fracture energy of cast gels.

In order to further examine the differences of the fracture phenomena between CD and FT gels, the PVA solution was dried to some extent at room temperature before repeating the freeze–thawing process, which yielded gels mechanically intermediate between CD and FT gels [35]. The transparency of the gel increased with increased drying degree and G decreased rapidly. From these results, it was concluded that the large tear resistance was attributed to the macroscopic fibrils; therefore, much larger strength can be expected by controlling the structures of the fibrils.

21.3.3 Dynamic Friction Coefficient and Wear Ratio

To measure the mechanical properties of the physical PVA gels, reciprocating tests with ellipsoidal PVA specimens against a glass plate were conducted under conditions of continuous and constant loading [17]. The experimental conditions were as follows. The applied normal load was 2.94 N,

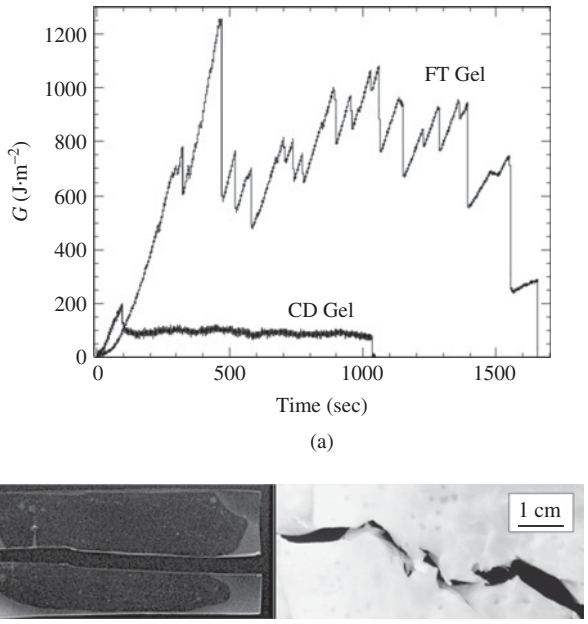

FIGURE 21.6 (a) Tear energy, G, of FT and CD gels during a tear test with a pulling velocity of $v = 0.1$ mm/s. (b) Fractured surfaces of CD (left) and FT (right) gels.

and the sliding speed and stroke length were 20 mm/s and 35 mm, respectively. The repetition number was 2000 cycles; therefore, the sliding distance for continuous testing was 140 m. The reciprocating tests were conducted in lubrication with saline at room temperature. As shown in Fig. 21.7, the FT gel showed larger initial friction with a gradual increase, a change that is similar to that of natural articular cartilage. In contrast, very low friction was maintained with the CD gel,

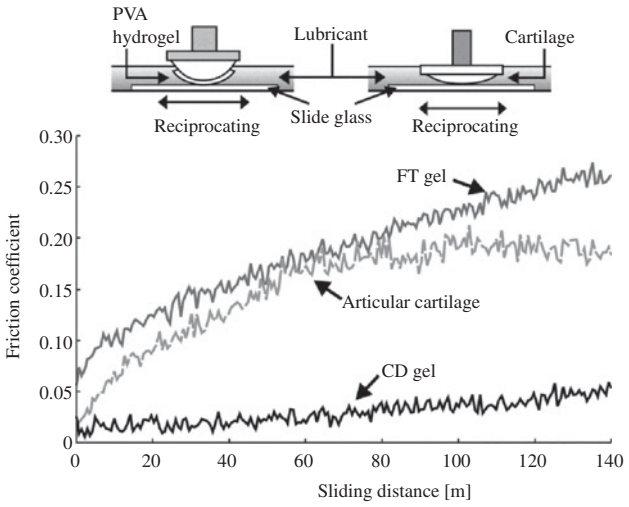

FIGURE 21.7 Time-dependent frictional behaviors of three types of PVA hydrogels in reciprocating tests in saline.

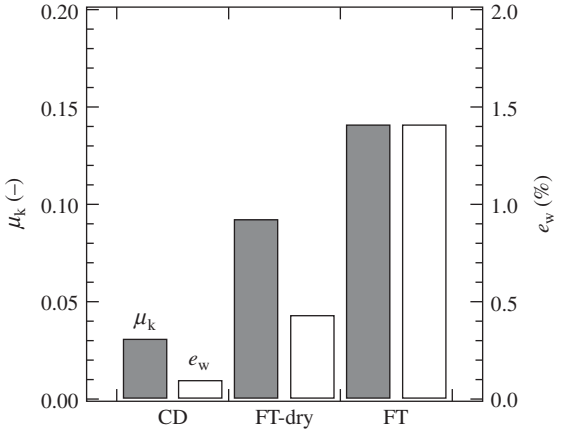

FIGURE 21.8 Coefficient of friction and wear ratio in reciprocating tests.

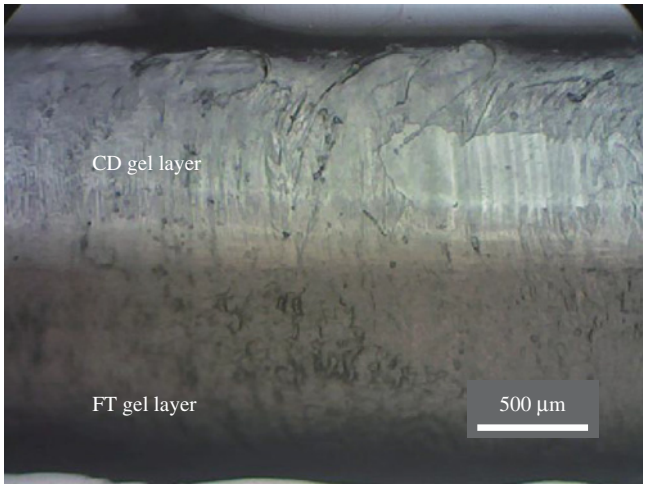
which exhibited a slight increase. The superior properties observed in the CD gel were evaluated using biphasic finite-element (FE) analysis. It was also shown that the friction and wear properties of the FT gel could be improved with the aid of boundary lubrication by adding simulated synovial fluid constituents.

The coefficient of kinetic friction μ_k was measured during linear reciprocating sliding (ball-on-plate mode) in water (no lubricant) using a ceramic femoral component ($\phi = 26$ mm, alumina ceramics) and plate gels. The test conditions were as follows: The normal load was 0.98–5.88 N, the sliding speed was 20 mm/s, the stroke was 25 mm, the cycle number was 2000, and the total sliding distance was 100 m.

Wearing of the polymers from the PVA gels was quantitatively estimated by measuring the total carbon (TC) in the solvents using a TOC analyzer (TOC-V_{CSN}, Shimadzu) that had a detection limit of 50 μg/L. The weight of the worn polymer W_e was then calculated from the TOC value, which was obtained by subtracting the total inorganic carbon (TIC) due to carbon dioxide from the TC. A reference sample of gel with water, the same sample set used for the wear measurements, was prepared. The weight ratio of sample to water was fixed at 1/50 (g/g). In order to obtain the real wear weight, both the TIC and the eluted TC were removed from the total TC after the wear measurement. The wear ratio e_W is defined as



$$e_W = \frac{W_e}{W_0} \times 100$$

where W_0 indicates the initial weight of the dried film.

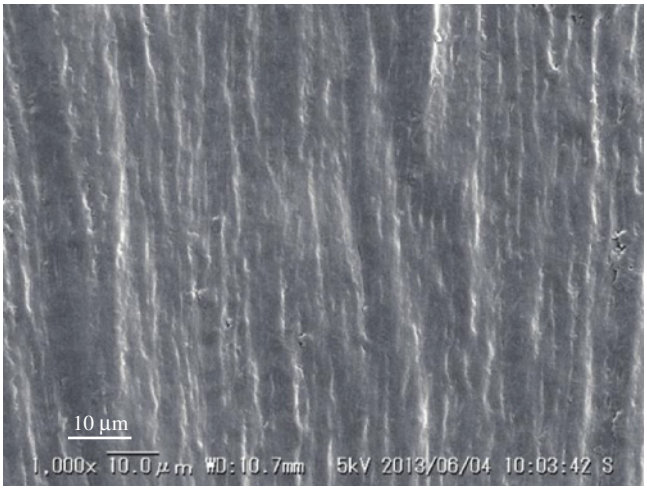


Figure 21.8 shows the friction and abrasion performance of the CD, FT, and FT-dry gels. The values of μ_k (averaged value between 1500 and 2000 cycle numbers) and e_W depended apparently on the gels. The CD gel showed the lowest μ_k and e_W. It was suggested that there is a correlation between e_W and μ_k and that low μ_k resulting in low e_W was possible.

21.4 MECHANICAL STRENGTHENING AND FUTURE VISIONS

For the application of hydrogels as artificial articular cartilage, several essential properties arerequired, such as biocompatibility, low friction, high wear resistance, suitable water content, and high mechanical strength (i.e., stiffness, fracture toughness, and fatigue resistance). PVA gels used for artificial cartilage are expected to combine superior mechanical strength and excellent lubricating properties comparable to natural synovial joints. Both CD and FT gels have high water absorbance and excellent mechanical properties as compared with other hydrogels. As shown in the present typical examples of physical gels, the CD gel showed the highest performance (high swelling ratio and low wear) among the three gels tested. However, CD gel alone cannot satisfy all required properties. Of the required properties, the mechanical strength and wear resistance of the FT and CD gels were poor as compared with natural synovial joints and further improvements are needed for practical uses.

(a)

(b)

FIGURE 21.9 (a) Cross section of a laminated gel of CD on FT gel in its swollen state; (b) SEM micrograph of an anisotropic dried FT gel. Fibrils are vertically oriented.

It may be difficult to significantly improve the mechanical properties using conventional fabrication methods. The conventional FT and CD fabrication methods are based on phase separation induced by the natural phenomenon of solidification and vaporization of water. In contrast to these simple and convenient methods, it is possible to improve the properties of gels by introducing artificial processes (Fig. 21.9). For example, there have been some attempts to control the polymer networks of FT and CD gels on multiple scales [17,35]. In the current study, a lamination method and hybrid techniques (Fig. 21.9a) using FT and CD gels were examined in order to improve the mechanical properties. The lamination allowed us to control the surface and bulk mechanical properties independently, which improved the mechanical and tribological properties. It was possible to realize higher mechanical performance by the synergistic interaction between the gels, which is partly attributed to the additional microcrystallites formed at the interface. Figure 21.10 shows the effects of the number of layers N on the mechanical properties while keeping the same total CD gel thickness. With increasing N, the breaking stress apparently increased, whereas the breaking strain did not evidently change. This is attributed to the different degrees of formation of the microcrystallites at the interface. Therefore, the swelling ratio, mechanical properties, and wear behavior can be controlled by laminating FT gel and CD gel.

A unidirectional freezing method is another example [35], by which a micrometer-scale fibril network structure can be formed in the network of FT gels (Fig. 21.9b). This

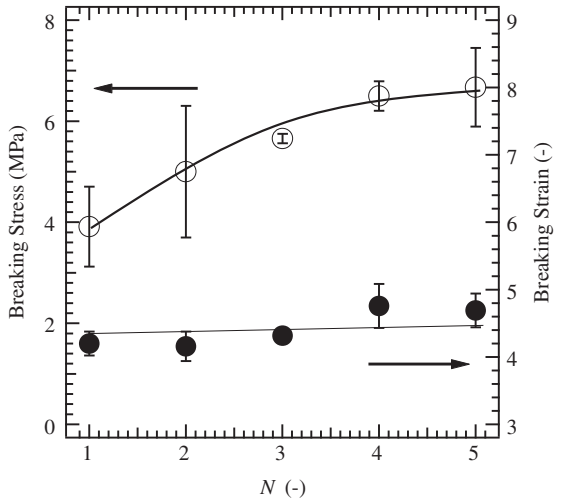

FIGURE 21.10 Breaking stress and strain of layered CD gels by a uniaxial loading test.

anisotropic network structure can lead to higher mechanical performance along the fibril direction. These techniques provide hierarchical network structures that could not be obtained by the conventional single process.

For the next step, the authors are currently developing hybrid hydrogels composed of cast-drying PVA on freeze–thawing PVA as another candidate material for artificial cartilage with superior lubricity. In fact, natural synovial joints have multiple layers, each layer of which has a respective function. Similarly, high performance is expected to emerge in hydrogels by hybridizing single layers with different properties. On the basis of the fundamental research, we are currently applying the hybrid techniques to the real system. The tribological properties were significantly improved within our preliminary experiments, which will be published elsewhere.

ACKNOWLEDGMENT

The authors express their thanks to Dr. S. Sasaki, Dr. S. Yarimitsu, Dr. K. Nakashima, and Dr. N. Sakai for their supports of experiments and many instructive comments. SUPERIOR TRIBOLOGICAL BEHAVIORS OF ARTICULAR CARTILAGE AND ARTIFICIAL HYDROGEL CARTILAGE

TERUO MURAKAMI[1] AND ATSUSHI SUZUKI[2]

22.1 INTRODUCTION

The various natural biological systems have rational and robust mechanisms and sustain their function with effective protective systems with restoration mechanism. In healthy natural synovial joints, the superior lubrication mechanism appears to maintain very low friction and minimum wear for a whole lifetime. However, the deterioration of articular cartilage and synovial fluid can break down lubrication mechanism in synovial joints and lead to osteoarthritis with damage of articular cartilage, which restrict the daily activities and produce serious pain in severe cases. For more than a half century since the successful clinical application of total hip prosthesis composed of ultra-high-molecular-weight polyethylene (UHMWPE) cup and stainless-steel head [1], the application of joint replacements to patients with osteoarthritis or rheumatoid arthritis brings the recovery of walking ability and the relief from serious pain. However, in certain cases of artificial joints, the revision operations have been conducted, due to the loosening of joint prostheses, which is usually derived from wear debris-induced osteolysis [2]. Therefore, the reduction of wear is strongly required for improvement in longevity of artificial joints.

In contrast, healthy natural synovial joints maintain very low friction and minimum wear for long life. To establish low friction and low wear in artificial joints, we should elucidate the synergistic lubrication mechanism in natural synovial joints and then apply the effective lubrication mechanisms to artificial joint systems. This chapter begins with a description of the adaptive multimode lubrication mechanism [3, 4] in natural synovial joints, followed by discussion of biphasic finite element (FE) analyses for reciprocating sliding of articular cartilage, conducted under both on/off (sporadic; intermittent) and continuous loading conditions. Next, the effective method to inhibit an increase in friction for sliding pair of articular cartilage and glass plate in reciprocating tests under continuous loading condition is discussed in terms of biphasic and boundary lubrication. Subsequently, improvements of lubrication performance in joint prostheses with compliant artificial hydrogel cartilage [5] are described. The lowering of elastic modulus at ∼1 MPa as rubbing compliant materials from ∼800 MPa of UHMWPE not only can reduce the contact stress level but also enhance the fluid film formation due to the significant elastic deformation effect. Furthermore, biphasic and boundary lubrication are important for artificial hydrogel cartilage. Therefore, FE analyses and experimental evaluation for two kinds of poly(vinyl alcohol) (PVA) hydrogels are described.

22.2 VARIOUS LUBRICATION MODES IN NATURAL SYNOVIAL JOINTS

Healthy synovial joints maintain excellent load-carrying capacity and lubricating properties with extremely low friction and minimum wear even under heavy-load conditions at

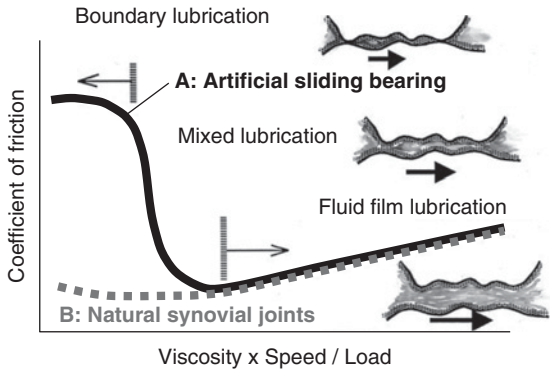

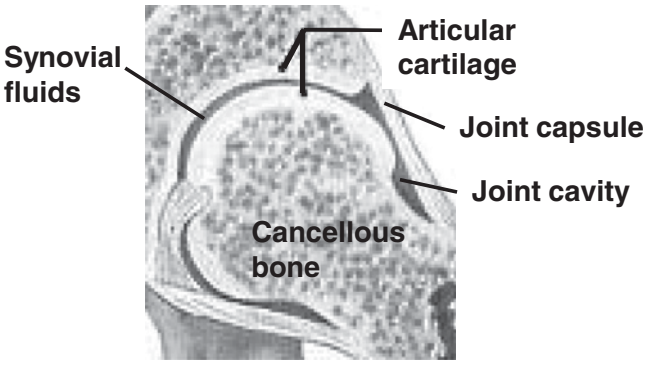

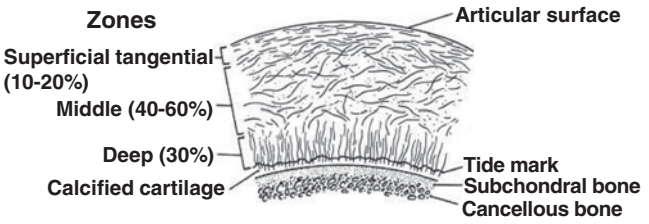

FIGURE 22.1 Stribeck curve and lubrication modes.

several times body weight in hip, knee, and ankle joints. The lubrication modes are usually differentiated on the basis of Stribeck curves as frictional behavior against the parameter for operating conditions as shown in Fig. 22.1. Most artificial rubbing systems such as sliding, bearing, and guiding are represented by nonlinear curves as indicated by curve *A* in Fig. 22.1. The friction varies with different lubrication modes, ranging from fluid film, mixed, and boundary lubrication, which vary according to the ratio of fluid film thickness to surface roughness. Usually, high friction and high wear are observed in boundary and mixed lubrication regimes as a result of direct contact between rubbing surfaces. On the contrary, the natural synovial joints appear to maintain low friction levels in a wider range of operating conditions (curve *B*).

In previous studies of fluid film lubrication versus boundary lubrication in major lubrication modes in natural synovial joints, other various lubrication mechanisms have been proposed. However, the variation in human daily activities is reflected in a wide range of operating conditions. Accordingly, it appears that the superior lubricating performance of natural joints is actualized not by a single lubrication mode but by a synergistic combination of various modes ranging from fluid film lubrication to boundary lubrication, corresponding to the severity of rubbing conditions [6]. The major lubrication mechanism would seem to be some form of elastohydrodynamic action determined by sliding or squeeze film action between porous surfaces, with boundary lubrication providing the surface protection in cases of severe loading and little movement [6]. Natural synovial joints have various geometric structures such as ball-and-socket, hinge, ellipsoidal, and other joint configurations, but in general are composed of epiphyseal parts covered with articular cartilage lubricated with synovial fluid (Fig. 22.2a [7]). The structure of articular cartilage is a depth-dependent complex fiber-reinforced structure (Fig. 22.2b [8]). Articular cartilage tissue consists of chondrocytes and an extracellular matrix (Fig. 22.3a [8]), which is composed mainly of proteoglycan and

FIGURE 22.3 Extracellular matrix (a) and surface structure (b) of articular cartilage.

collagen (type II). The collagen fibers are arranged in a configuration according to depth in three zones (Fig. 22.2b). Proteoglycan aggregate is composed of aggrecans noncovalently attached to hyaluronan (HA) with stabilizing link proteins. Aggrecan (Agg: aggregating proteoglycan) is composed of keratin sulfate and chondoroitin sulfate chains bound covalently to protein core molecules [8]. Thus, the proteoglycan is highly hydrophilic and therefore can store a large amount of water and support the compressive load with the aid of the confinement by collagen network. Thus, articular cartilage has high water content ranging from 70% to 80% and shows biphasic behavior in which both solid and fluid properties should be considered as indicated by the biphasic theory [9].

The compliant property of articular cartilage contributes to widening of the contact area as elastic deformation of the surface soft layer, with reduction of contact pressure and facilitation of fluid film formation by a soft elastohydrodynamic lubrication (soft EHL) mechanism. Therefore, such joints should be examined to evaluate the possibility of fluid film lubrication during walking. Various studies on minimum EHL film thickness for a smooth compliant surface predicted to be thinner than 1 μm during walking, and maximum height of the undeformed surface roughness of articular cartilage was estimated to be ≥1–2 μm. Thus problems with fluid film lubrication were evaluated, especially in cases where the film parameter in the ratio of minimum film thickness to composite roughness was <3. However, two investigators [10] evaluated the possibility of fluid film formation during normal walking by considering the elastic deformation of surface asperity in numerical EHL analysis. In their analysis, the flattening of surface asperity in the conjunction zone (load-carrying zone) was able to maintain fluid film thickness of ∼0.6 μm without interaction between rubbing surfaces during walking. This lubricating mechanism was called *micro-EHL*, which indicates the possibility of fluid film lubrication by effective hydrodynamic pressure as entraining and squeeze film action during normal walking.

Under slow movement conditions at which sliding speed is too low for hydrodynamic pressurization to sufficiently support a heavy load, the interstitial fluid pressurization in biphasic lubrication is expected to support most of the load and reduce friction [11–13]. The detailed biphasic lubrication mechanism in reciprocating motion is described in the following section.

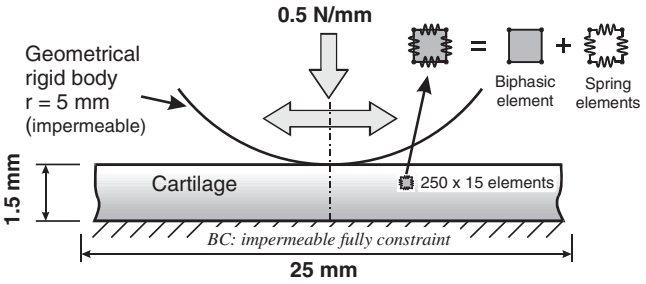
Under further slower conditions or severe thin-film conditions such as at startup after standing for a long time, some local direct contacts appear to occur between rubbing cartilage surfaces. Under these thin-film conditions, mixed lubrication and/or boundary lubrication modes are likely to prevail. In the boundary lubrication regime, the adsorbed films composed of glycoproteins [14], proteins [15], and/or phospholipids [16,17] are likely to play roles in friction reduction and protection of surfaces. When these adsorbed films on cartilage surfaces were removed, a nonfibrillar proteoglycan gel-like surface layer is expected to maintain low friction, due to its low shearing resistance, and protects the cartilage bulk tissue [18]. Articular cartilage surfaces are covered with adsorbed films on underlying proteoglycan gel-like layer as shown in Fig. 22.3b [17]. This surface structure gives superior tribological properties.

The hydration lubrication mechanism is considered to become effective for these surfaces in aqueous environment of synovial joints. One author [19] indicated the importance of enhanced viscosity around hydrated surfaces and called this mechanism "surface gel hydration lubrication." Another investigator [20] defined the hydration lubrication as "water lubrication of surface layer with hydrophilic polymers fixed to the surface," and indicated the remarkable friction reduction brought by recovery of hydration in surface zone during unloading in intermittent rubbing test. Other researchers [21,22] described hydration lubrication in terms of molecular level and boundary lubrication. They also discussed lubrication by hydrated ions trapped between charged surfaces in aqueous media and by other hydrated boundary species, including charged and zwitterionic polymer brushes, surfactant monolayers, liposomes, and biological macromolecules of synovial joints. In their experiment using a surface force balance for HA and HA/Agg complex films on mica surfaces at boundary lubrication condition, HA exhibited friction increase at low contact pressure, but surfaces bearing HA/Agg complex showed a low coefficient of friction of ∼0.01 at <1 MPa. Lubricin showed a little high coefficient of friction 0.02 at <0.5–1 MPa. However, friction increased for both surfaces coated with HA/Agg or lubricin at higher contact pressure. In contrast, the phosphocholine group, which is zwitterionic, is overall neutral but contains both negative (PO_4^-) and positive [$N^+(CH_3)$] charged groups and has a high level of hydration, showed extremely low friction. The zwitterionic phosphocholic groups appear to show higher hydration than does the HA/Agg complex. HA has only negatively charged groups ($-COO^-$), and Agg has only negatively charged groups ($-COO^-$ and $-SO_3^-$), which may influence the intense hydration. The detailed hydration lubrication mechanism should be clarified in further study.

Thus, the various lubrication modes appear to synergistically play important roles in reduction of friction and wear, depending on the severity of operating condition, in the adaptive multimode lubrication mechanism. In the following section, we describe the effectiveness of biphasic lubrication and boundary lubrication.

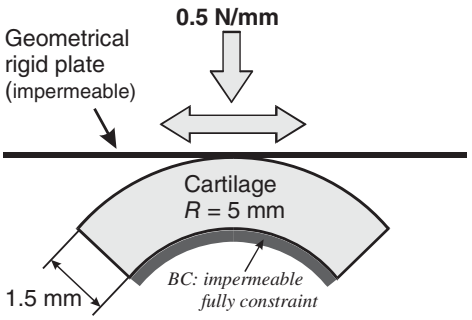
22.3 BIPHASIC LUBRICATION IN NATURAL SYNOVIAL JOINTS

Articular cartilage has high water content, ranging within 70–80% in tissue, and thus exhibits a time-dependent biphasic behavior due to the simultaneous coexistence of solid



and liquid phases under compressive loading or deformation [11]. Since an experimental finding of the importance of fluid-phase load support in maintaining low friction in mixed and boundary lubrication regimes [14] and a proposed boundary friction model based on biphasic lubrication [15], the effectiveness of biphasic lubrication with interstitial fluid pressurization has been demonstrated on the basis of the biphasic FE analyses and experimental observations [16,23]. When articular cartilage as biphasic material with low permeability is applied by compressive load, the fluid content in the tissue is trapped within the contact area and the collagen matrix network resists interstitial fluid pressure in aggregate solid matrix. Thus, the interstitial fluid pressure supports a significant proportion of the total load in the contact area. The time-dependent change in load support by interstitial fluid pressure in biphasic cartilage depends on the extent of exudation from cartilage tissue and rehydration of cartilage. If the fluid load support is maintained at a high level for a long time, the low friction is maintained because of low-level solid–solid interaction [16].

For reciprocating sliding under constant load, one team [24] introduced a sliding motion into their FE model and indicated the importance of migrating contact area for the sustainability of the biphasic lubrication in their biphasic FE analysis.



Another group [25] examined the compressive response of the articular cartilage using a high-precision testing machine with a feedback-controlled servomotor and estimated the material properties in physiological conditions for the biphasic FE model. For this model, the following three important features were adopted: (1) depth dependence of apparent Young's modulus of solid phase, (2) strain-dependent permeability as compaction effect, and (3) collagen reinforcement in tensile strain.

These properties were estimated by the curve fitting between the experimental time-dependent compressive behavior and simulation in indentation tests for cartilage specimens with cylindrical rigid indenter. Biphasic FE analysis was conducted using the commercial package ABAQUS (6.8-4). The biphasic tissue was modeled by CPE4RP (four-node bilinear displacement and pore pressure, reduced integration with hourglass control) elements, and a mesh was chosen as 0.1 mm thick with 0.1 mm breadth on surface. The bottom of the model was fixed and impermeable. The other surfaces were not fixed and were basically permeable except for the contact region.

To test the effects of joint contact, two simplified models were selected as on/off loading to cartilage (migrating contact) (model A; Fig. 22.4a) and continuous loading to cartilage (stationary contact) (model B; Fig. 22.4b) [26]. A load of 0.5 N/mm was applied at the center of the cylindrical indenter or against the center of cylindrical specimen in 1 s, and then the reciprocating motion was introduced at a speed of 4 mm/s over a stroke length of 8 mm.

(a) Model A: On-off loading to cartilage

(b) Model B: Continuous loading to cartilage

FIGURE 22.4 Cartilage models for biphasic FE analysis [26].

FE analyses for model A [25] showed that the tensile reinforcement by spring elements representing the collagen network and the depth-dependent elastic properties improved the proportion of the fluid load support, especially with sliding motion. The compaction effect on permeability in the solid phase was functional under conditions without migrating contact, whereas under sliding conditions the compaction effect was minimal.

In the simulation for two models [26], the reciprocation of a rigid cylinder or flat plate at 4 mm/s was started immediately after loading and continued for 508 s, for 127 cycles at a period of 4 s. Figure 22.5 shows the changes in interstitial fluid pressure. The initial fluid load support percentages are very high: 90% and 91% for models A and B, respectively. After 127 cycles, the high percentage of fluid load support (83%) was maintained even after 508 s in model A, but the percentage of fluid load support was remarkably decreased to 27% in model B under continuous loading.

The lowering in percentage of fluid load support indicates friction increase. On the basis of biphasic theory, time-dependent changes in friction coefficient μ_{eff} can be estimated for μ_{solid} as the coefficient of friction for solid–solid contact using the following formula.

$$\mu_{\text{eff}} = \mu_{\text{solid}} \left(1 - (1 - \Psi)\ W^{\text{p}}/W\right) \tag{22.1}$$

where W is the total load support, W^{p} is the load support by fluid pressure, and Ψ is the fraction of contact area of solid phase.

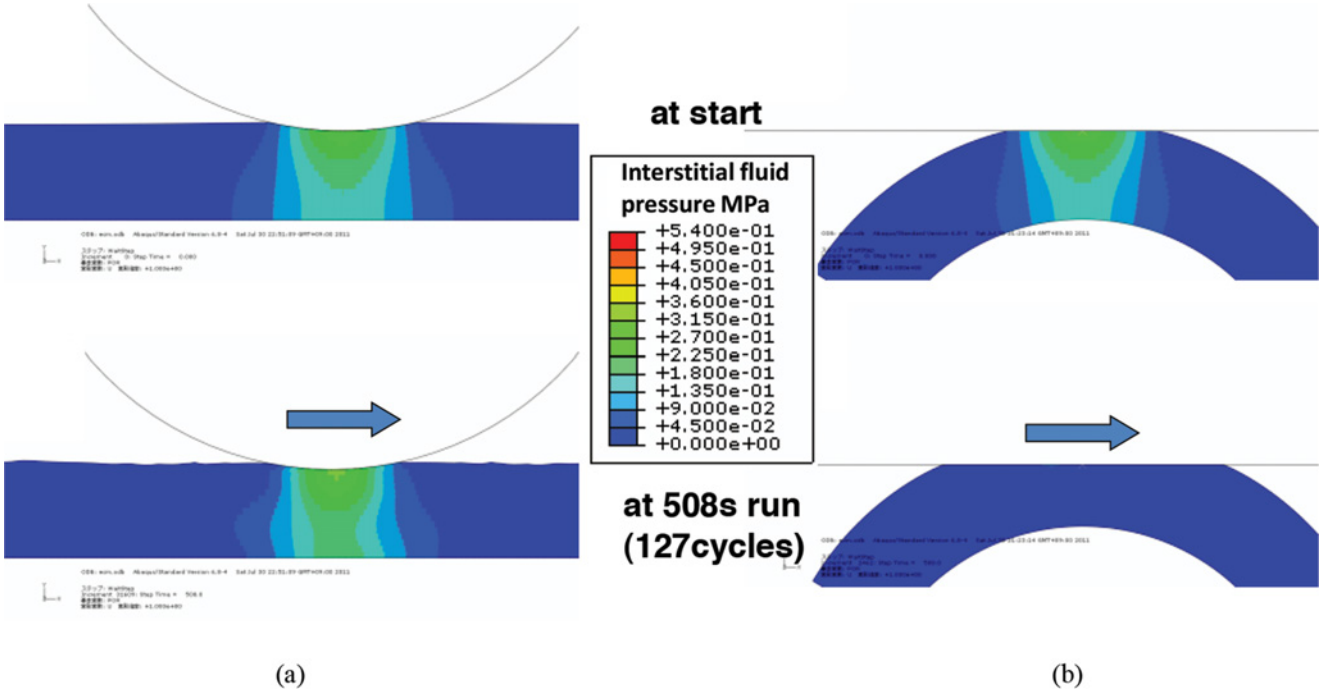


FIGURE 22.5 Changes in interstitial fluid pressure of articular cartilage: (a) on/off loading to cartilage; (b) continuous loading to cartilage (modified from Ref. 26). For a color version of this figure, see the color plate section.

In Fig. 22.6, the time-dependent changes in friction estimated from total traction force in biphasic FE analysis for assumption of $\mu_{solid} = 0$ or 0.01 and 0.2 are shown, where both adhesive and ploughing components are included as total traction force. It is worth noting for model A that the considerable low friction level is maintained as a result of the sustainability of interstitial fluid pressure depending on μ_{solid} in the reciprocating sliding. However, some ploughing resistance is included. In contrast, it is noteworthy that a significant gradual increase to a high friction level is observed in reciprocation for model B with $\mu_{solid} = 0.2$. Even under continuous loading conditions, low friction can be maintained if a low level of $\mu_{solid} = 0.01$ is sustained by effective boundary lubrication. For condition B, the ploughing action is negligible.

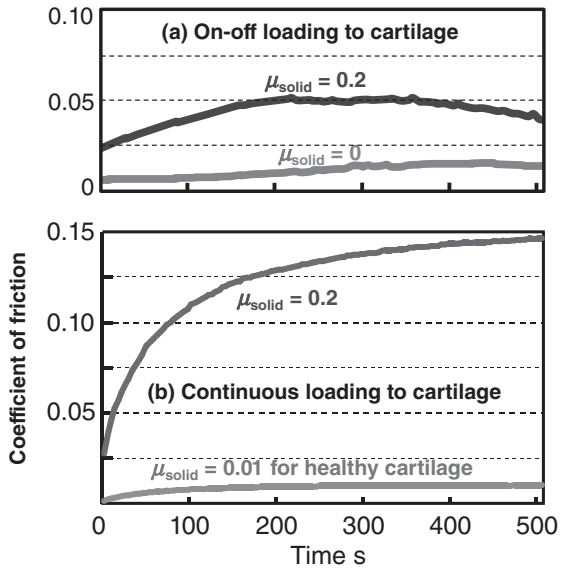

FIGURE 22.6 Changes in friction for reciprocating test of articular cartilage models.

Under operating conditions where the effectiveness of biphasic lubrication will be reduced, the roles of alternate lubrication mechanisms such as boundary lubrication and hydrated lubrication are examined in the following section.

22.4 BOUNDARY LUBRICATION IN NATURAL SYNOVIAL JOINTS

To maintain low friction and low wear in mixed or boundary lubrication regime where local direct contact occurs in natural synovial joints, adsorbed film formation on the articular cartilage surface appears to play an important role. Furthermore, the proteoglycan gel layer at the uppermost superficial zone in articular cartilage appears to play an important role in preserving low friction and low wear by the hydration lubrication mechanism even after removal of adsorbed film [18]. However, the interaction or synergistic action between adsorbed film and hydrated film/surface has not yet been

clarified. The importance of the role of charged polymer brushes, hydrated species, and lipidlike surfactant molecules in terms of molecular mechanisms of hydration lubrication in aqueous systems has been reported [21, 22].

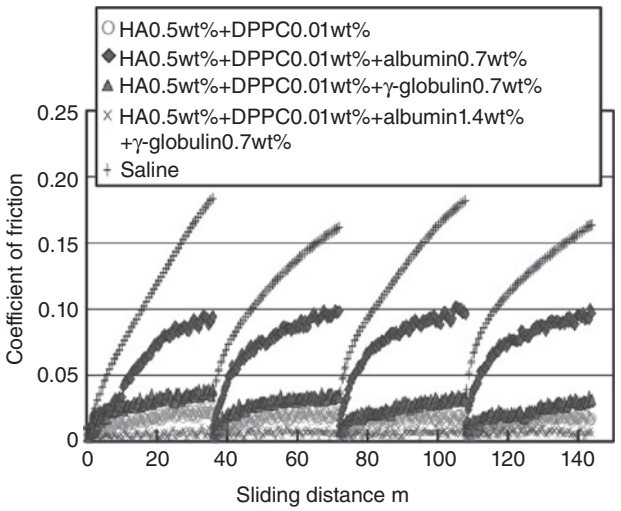
In order to examine the effect of boundary lubrication, the frictional behaviors in a sliding pair of ellipsoidal articular cartilage specimens and reciprocating glass plate were examined in the sliding condition for model B without migration of contact zone for cartilage as the most severe case [28–30]. An upper intact cartilage specimen with subchondral layer was prepared from a femoral condyle in a porcine knee joint (6–7 months old). The lubricants are saline solution containing 0.15 M NaCl (Otsuka Pharmaceutical Factory Inc., Japan), saline solution of 0.5 wt% sodium hyaluronate (HA, molecular weight: 9.2×10^5), HA solutions containing 0.7 wt% or 1.4 wt% bovine serum albumin (Wako Pure Chemical Industries Ltd., Japan), 0.7 wt% human serum γ-globulin (Wako Pure Chemical Industries Ltd., Japan), and/or 0.01 wt% L,α-dipalmitoyl phosphatidylcholine (L,α-DPPC) as an phospholipid liposome. In order to prevent bacterial growth in protein solutions as lubricant, 0.3 wt% sodium azide was added for protein solutions.

The reciprocating test was conducted at a sliding speed of 20 mm/s for rectangular reciprocating mode and at a stroke of 35 mm at a constant load of 9.8 N. At room temperature, reciprocating sliding movement began immediately after loading, and interrupted after 514 cycles at sliding distance of 36 m for running time of 30 min, and then the unloading state was maintained for 5 min. Subsequently, the reciprocating test resumed immediately after reloading and continued for a further sliding distance of 36 m. The restarting processes after unloading were repeated 3 times. The number of tests under the same conditions was 3.

Figure 22.7 shows frictional behavior for intact cartilage [30]. In saline, the initial low friction was observed, but friction gradually increased to a high level during the rubbing process. However, when movement resumed after unloading for 5 min a remarkable reduction in friction was observed, down to a level only a little higher than the initial friction. This phenomenon was attributed to the recovery in hydration and deformation. After restarting, friction again gradually increased.

It is noteworthy that even the addition of 0.01 wt% DPPC alone to HA solution exhibited a remarkable reduction in friction. Furthermore, the addition of 0.01 wt% DPPC accompanied by 1.4 wt% albumin, 0.7 wt% γ-globulin in HA solution (as a simulated synovial fluid) demonstrated the lowest friction levels at about 0.01 CF (coefficient of friction) without gradual increase prior to each 36 m sliding. On the other hand, the addition of DPPC with albumin alone or γ-globulin alone in HA solution shows higher friction than DPPC alone in HA solution but lower than saline solution.

To sustain superior tribological properties of articular cartilage, not only low friction but also minimum wear are



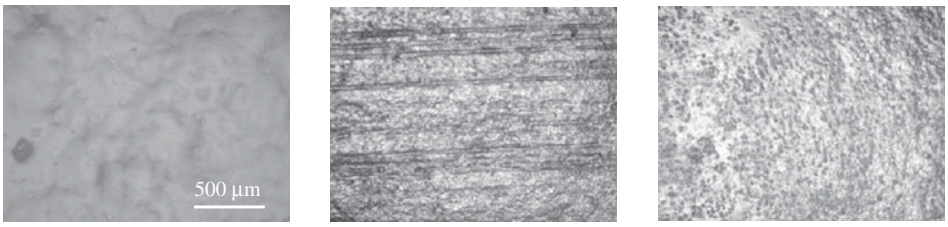


FIGURE 22.7 Changes in friction for reciprocating test of articular cartilage.

required in various daily activities. Therefore, the effect of wear on cartilage surfaces was evaluated. Representative photographs are shown in Fig. 22.8 [30]. Intact articular cartilage has a smooth surface with some irregularity. Tests with lubricants of HA solution containing 0.01 wt% DPPC exhibited low friction but mild wear with scratches on surfaces. However, minimum friction as low as 0.01 and little wear (Fig. 22.8c) were confirmed for simulated synovial fluid, where a superficial gel-like layer may have been slightly removed without scratching during rubbing.

We will now compare the effects of the addition of neutral phospholipid DPPC with and without protein. As shown in Fig. 7, the addition of DPPC alone in HA solution was highly effective in reducing friction for intact cartilage compared with the coexistence of DPPC and either albumin or γ-globulin in HA solution. This finding may suggest the formation of lubricating complex materials as membranelike and roller structures composed of DPPC and HA [31]. The detailed structure of the HA-DPPC complex has not yet been clarified, but the coexistence of DPPC and HA is likely to act synergistically as lamellar lubrication or related mechanism. Furthermore, for coexistence of DPPC and HA, an HA-DPPC composite boundary film was visually confirmed by in situ fluorescent observation [32] and friction was remarkably lowered, where the lubricating ability of the HA-DPPC complex as a gel-like film supposedly becomes effective because of the high water retention ability of HA. Thus, the HA solution containing DPPC showed an effective but limited protective property with local scratching as shown in Fig. 22.8. In contrast, the friction for HA solution with DPPC and albumin (steady-state CF $\sim$ 0.1) became higher than 0.07 for saline solution with DPPC and albumin [30] and about 0.02 for HA solution with DPPC. In this

(a) Before test

(b) After test with HA 0.5 wt% and DPPC 0.01 wt%

(c) After test with HA 0.5 wt%, DPPC 0.01 wt%, Albumin 1.4 wt% and γ-Globulin 0.7 wt%

FIGURE 22.8 Articular cartilage surfaces before and after reciprocating tests.

case, the albumin-DPPC composite was not found in composites containing DPPC, HA, and albumin [32], probably due to repulsive interaction between albumin and HA. In contrast, HA solution with DPPC and γ-globulin showed a lower CF ($\sim$0.03) than 0.07 for saline solution with DPPC and γ-globulin [30]. However, the supply of both albumin and γ-globulin at a defined ratio in HA solution containing DPPC could remarkably reduce the friction level (Fig. 22.7) and provide high wear resistance (Fig. 22.8).

One team of investigators attempted to determine why two kinds of proteins show different friction levels in HA solutions with DPPC [33]. In their study, HA solution with 1.4 wt% albumin and 0.7 wt% γ-globulin (albumin/globulin = A/G ratio of 2:1) or 0.7 wt% albumin and 1.4 wt% γ-globulin (A/G ratio of 1:2) showed very low wear during rubbing with PVA hydrogel. For low wear condition in the latter, the layered adsorbed film formation was observed by the fluorescent method. In such cases, it is suggested that the γ-globulin forms a protective adsorbed layer on the cartilage surface and that albumin is forms lower-shear layers. In contrast, in HA solution with 1.4 wt% albumin and 1.4 wt% γ-globulin (A/G ratio of 1:1) a heterogeneous adsorbed film was formed and higher wear occurred.

Fluorescent images showed that γ-globulin has stronger adsorption ability on cartilage than does albumin [28]. Furthermore, it was observed for binary protein solutions in the evanescent field within $\sim$200 nm from the surface, by total internal reflection fluorescence (TIRF) microscopy, that the bottom layer of stable protein-adsorbed film is composed mainly of γ-globulin and that the friction-induced enhancement of the formation of protein-adsorbed film occurs in lubricants with appropriate protein composition [34, 35].

The simulated synovial fluid of HA solution with 0.01 wt% DPPC, 0.14 wt% albumin, and 0.7 wt% γ-globulin is similar in composition to that in natural synovial fluid as HA solution containing lubricating constituents such as 1.25 wt% albumin and 0.75 wt% globulin (including $\alpha-$, $\beta-$ and γ-globulins) as medium values [36], 1.1 wt% albumin and 0.7 wt% globulin [37], or 1.9 wt% albumin, 1.1 wt% globulin and 0.01 wt% DPPC [17]. In this lubricant, the lubricating layered structure in adsorbed film is expected for low friction and minimal wear. In various daily activities, synovia constituents appear to play their appropriate roles depending on the severity of operating conditions. DPPC and albumin are likely to act as a low-shear layer, and γ-globulin functions as a protective film as strongly adsorbed on cartilage surface. HA can thicken the lubricating fluid film and form some lubricating gel-like layer. Regarding the role of lubricin as another lubricating constituent, another team [38] suggested that it anchors lipid layers on the cartilage. Elucidation of the synergistic mechanisms between lubricating constituents, on multiple scales, is expected with future studies.

22.5 LUBRICATION MODES IN ARTIFICIAL JOINTS

Most artificial joints are composed of UHMWPE and metallic or ceramic components. UHMWPE has a Young's modulus of $\sim$800 MPa, which is stiffer by two or three orders of magnitude than articular cartilage, and the minimum fluid film thickness is thinner than 0.1 μm for total hip and knee prostheses during stance phase of walking. The fluid film thickness is usually less than the surface roughness of rubbing materials. Therefore, mixed or boundary lubrication mode is the main lubrication mode and local direct contact occurs, resulting in medium friction and considerable wear. For hard-on-hard hip prostheses with high precision and high wear resistance, the possibility of fluid film formation is expected under normal walking conditions, but some problems such as stripe wear, streaking, and breakage of ceramic components may occur under severe operating conditions such as edge loading and/or malpositioning.

To improve the lubrication mode in artificial joints, the applications of compliant artificial cartilage materials have been proposed [5]. The application of compliant materials to the surface layer of the articular surface of total hip and knee replacements facilitates the formation of fluid film by a soft EHL mechanism accompanied by a wider contact area, but the film thickness during walking is not sufficiently thick. Previous studies showed that the values of minimum film

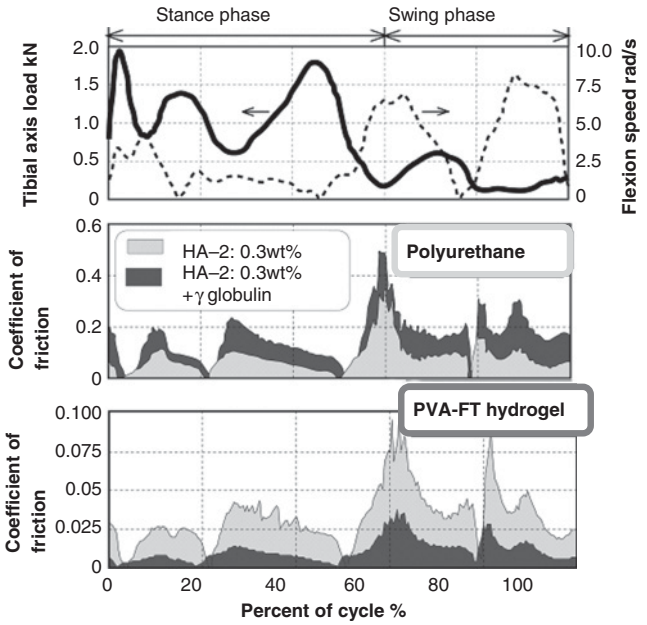

FIGURE 22.9 Frictional behavior of knee prostheses with soft layer in simulator [39].

thickness in simplified knee joint models with a 2-mm-thick soft layer of polyurethane (Young's modulus $E = 40$ MPa) and PVA hydrogel ($E = 1$ MPa) are 0.2 μm and 0.75 μm during stance phase of walking, respectively [39]. The surface roughness seemed to be greater than the minimum film thickness. To evaluate the lubrication modes, the frictional behaviors were examined for knee joint models composed of cylindrical femoral metallic components and flat tibial components with a soft layer of 2 mm thickness as artificial cartilage in a knee joint simulator [39]. The experimental results are shown in Fig. 22.9.

In Fig. 22.9, it should be noted that the knee prosthesis model with PVA hydrogel layer prepared by repeated freeze–thawing (FT) with high water content of 79 wt% and Young's modulus of 1.1 MPa exhibited lower friction in walking condition lubricated with HA solution containing serum protein than for the model with polyurethane layer with a *Young's* elastic modulus of 40 MPa. Maximum coefficient of friction for PVA hydrogel during stance phase was less than ∼0.01, but that for polyurethane increased to >0.2. The superiority of PVA hydrogel should be considered in terms of surface and biphasic properties in addition to differences in fluid film thickness.

In this simulator test, very low friction was confirmed for PVA hydrogel of high water content, but in reciprocating tests under thin-film conditions [33,41], even of high-water-content PVA hydrogel showed significant wear in HA solutions. Although various kinds of hydrogel as cartilage replacement have been developed, clinical application has not yet been completed. To extend the longevity of joint prostheses with artificial hydrogel cartilage, the improvement of tribological properties of artificial cartilage materials is required under various operating conditions in daily activities.

Therefore, in the following sections, the effectiveness of biphasic lubrication and boundary lubrication mechanisms in hydrogel in reciprocating motion are explored.

22.6 FRICTIONAL BEHAVIORS OF ARTIFICIAL HYDROGEL CARTILAGE

As stationary ellipsoidal specimens were placed on a reciprocating flat glass plate (a slide glass) in the reciprocating test, two kinds of artificial hydrogel cartilage specimens and the natural articular cartilage were prepared as described below [41].

22.6.1 Artificial Cartilage

The following two PVA hydrogel materials prepared by repeated freeze–thawing method and cast-drying method were used as specimens composed of a 2-mm-thick soft layer of PVA hydrogel adhered on acrylic ellipsoid (40 × 25 mm in diameter). Figure 22.10 [41] shows photographs, atomic force microscopy (AFM) surface images of their swollen states in water, and schema of microstructure for PVA hydrogels.

The PVA hydrogel preparations were as follows:

1. PVA hydrogel by repeated freeze–thawing (FT) method (Fig. 22.10a). The PVA (Kishida Chemical Co., Ltd., Japan) used in this method has a polymerization degree of 2000 and average degree of saponification of 98.4–99.8 mol%. PVA powder at 20 wt% was dissolved in pure water and heated at 120°C for 30 min in an autoclave and cast in a mold in air to control the specimen thickness, and then gelled by repeated freeze–thawing (FT) cycles (for periods ranging from 10 h at –20°C to 20 h at 4°C). The number of FT cycles was 5 times as optimum condition to establish maximum tensile strength and stiffness [42]. The elastic modulus of PVA hydrogel is 1.2 MPa, and the equivalent water content is 79%.
2. PVA hydrogel by cast-drying (CD) method (Fig. 22.10b) [43–45]. The PVA (Kuraray Co. Ltd., Japan) used in this method has a polymerization degree of 1700 and average degree of saponification of 98–99 mol%. An aqueous PVA solution was obtained by dissolving 15.0 wt% of the PVA powder into deionized and distilled water at 90°C for more than 2 h. The PVA solution was poured into a plastic dish of polyethylene and left in air at room temperature (∼25°C). The solution became very viscous within

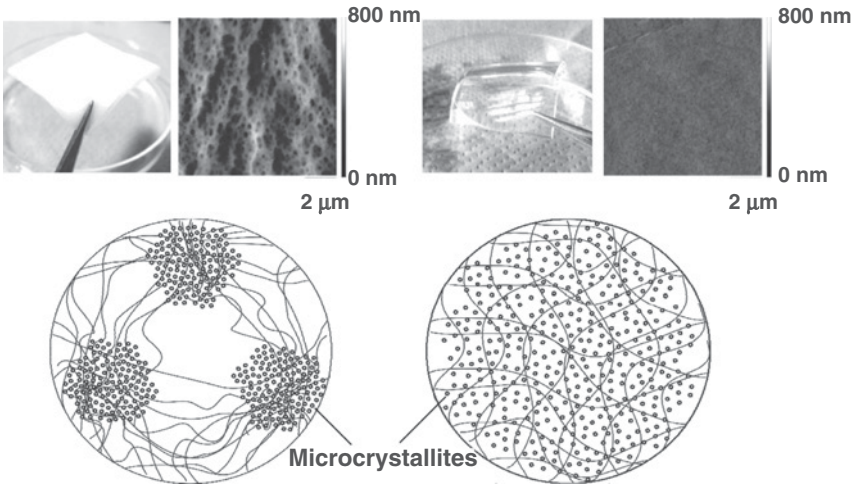

FIGURE 22.10 Photographs, AFM images, and schematic models for two PVA hydrogel structures (partly modified from Ref. 41).

several days and solidified within a week or more. The sample was usually prepared by the process of repeated water exchange with drying.

22.6.2 Articular Cartilage

The intact ellipsoidal articular cartilage specimens with subchondral layer were prepared from the femoral condyle of porcine knee joints as described above.

Reciprocating tests of stationary artificial hydrogel cartilage and articular cartilage specimens were conducted against reciprocating flat glass plate. In the reciprocating apparatus [28–30], the sliding speed and stroke length were 20 mm/s and 35 mm, respectively. Applied load was 2.94 or 9.8 N. The repeated test in interval of 36 m was conducted with the same conditions as mentioned above.

The friction levels of PVA hydrogel specimens and articular cartilage placed against a flat glass plate at continuous loading of 2.94 N in saline are shown in Fig. 22.11. The PVA-FT gel exhibited medium initial friction and time-dependent gradual increase similar to that for natural articular cartilage, where articular cartilage showed very low initial friction and gradual increase at a little lower level. In contrast, the PVA-CD gel exhibited very low friction with a more gradual increase. These differences are assumed to be related to the difference in biphasic lubrication as mentioned later.

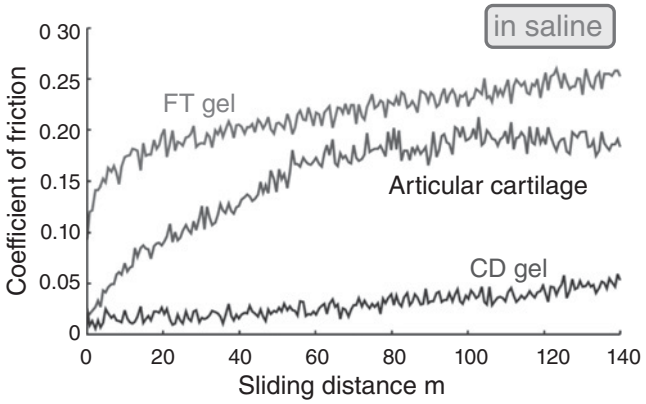

FIGURE 22.11 Frictional behaviors of PVA gels and cartilage in reciprocating tests [47].

22.7 BIPHASIC FINITE-ELEMENT ANALYSES FOR ARTIFICIAL HYDROGEL CARTILAGE

The biphasic FE analysis for two-dimensional models of PVA hydrogel cartilage similar to the cartilage model (model B) in Fig. 22.4 was conducted under continuous loading by an impermeable rigid plate in reciprocating motion. The biphasic element has uniform elastic modulus without spring and uniform permeability. A load of 0.2 N/mm was applied at the center of PVA hydrogel surface with a ramp time of 1 s, and then the load was held constant for a further 292 s during reciprocation motion at 4 mm/s and a period of 4 s.

The material properties of the PVA hydrogels were estimated from the stress–relaxation tests of cuboid ($10 \times 6 \times 4$ mm) under uniaxial compression at definite deformation after an average stress of 0.1 MPa had been attained [46]. The mechanical properties of two PVA hydrogel specimens are shown in Table 22.1 [41]. It is noteworthy that CD gel has a permeability that is two orders of magnitude lower than that of FT gel. The permeability of CD gel has a permeability level similar to that of natural articular cartilage.

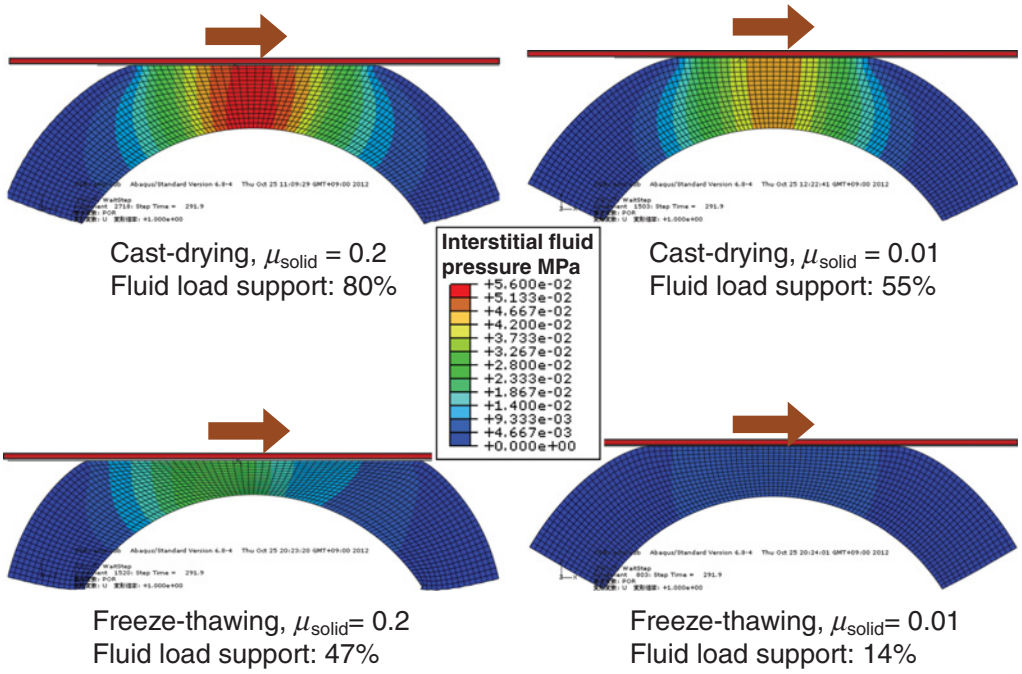

FIGURE 22.12 Changes in interstitial fluid pressure and fluid load support of PVA hydrogel [41]. For a color version of this figure, see the color plate section.

TABLE 22.1 Properties of PVA Hydrogels

Preparation method for PVA hydrogel	Permeability (m^4/Ns)	Young's modulus (kPa)	Poisson's ratio
Freeze–thawing (FT)	2.0×10^{-13}	110	0
Cast-drying (CD)	2.4×10^{-15}	190	0.41

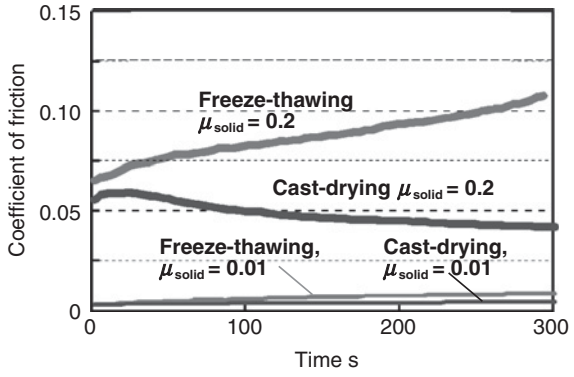

FIGURE 22.13 Frictional behaviors of two hydrogels estimated by biphasic FE analysis [41].

The interstitial fluid pressure with fluid load support after 292 s for two kinds of solid–solid friction conditions, as 0.01 and 0.2 in the reciprocating test, is shown in Fig. 22.12. The CD gel maintains significant pressure even after 292 s, but in FT gel the fluid pressure was remarkably reduced. For both PVA hydrogels, the high friction of solid–solid contact sustained fluid pressure levels that were higher than, and showed greater deformation than, those for low μ_{solid}. Therefore, caution is necessary because, contrary to expectation, the lower surface friction accelerates an increase in solid–solid contact.

The estimated frictional behaviors for PVA hydrogels in reciprocating tests are shown in Fig. 22.13. It is noticed that low friction property of surfaces (solid-to-solid) maintains a significantly low sliding friction level. Even for high μ_{solid}, use of a CD gel can result in a gradual decrease in friction, probably because of the rising fluid load support from the initial 74% to 80% levels in biphasic analysis (Fig. 22.12).

22.8 BOUNDARY LUBRICATION IN FREEZE-THAWING PVA HYDROGEL

The friction level for PVA-FT gel in saline is considered to be too high for clinical application. Therefore, to improve friction levels in FT gel, the effect of lubricant constituents was examined. We presented the detailed data in a previous paper [41]. As shown in Fig. 22.14, the combination of HA and DPPC with and without proteins could maintain a CF lower than ~0.01. Subsequently the wear resistance properties were examined. The simulated synovial fluid (0.5 wt% HA solution containing 0.01 wt% DPPC, 1.4 wt% albumin

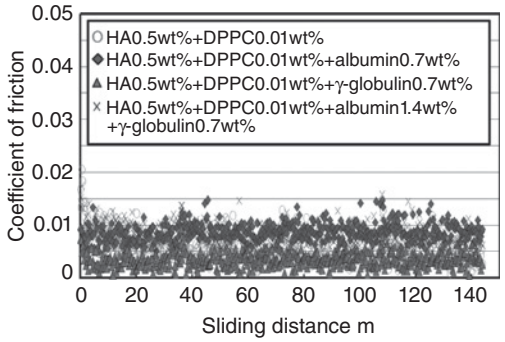

FIGURE 22.14 Influence of synovia constituents on changes in friction for PVA-FT hydrogel.

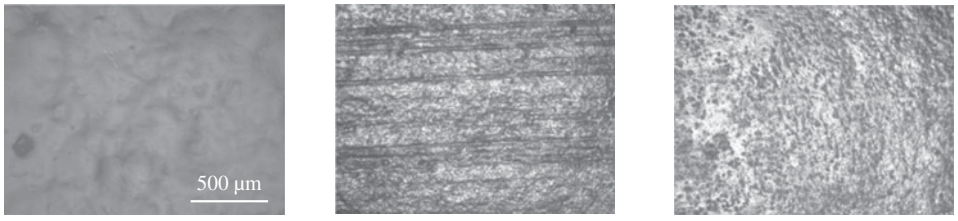
and 0.7 wt% γ-globulin) showed minimum wear (Fig. 22.15 [41]) similarly to articular cartilage. Thus, the reduction in both friction and wear for FT gel is possible with the aid of synovia in the human joint environment. However, biphasic lubrication has still important role in cases with changes in synovia constituents.



22.9 SUPERIOR TRIBOLOGICAL BEHAVIOR OF ARTIFICIAL HYDROGEL CARTILAGE

As artificial hydrogel cartilage containing high water content, two hydrogel showed quite different time-dependent frictional behaviors in reciprocating tests in saline (Fig. 22.11). In the measurement of time-dependent changes of the contact area in a static loading test [47], the FT gel showed an initial abrupt deformation and subsequent steady state. The CD gel showed a similarly initial abrupt deformation and maintained steady state, but its compressive deformation was lower than that of the FT gel. In contrast, natural articular cartilage showed gradual increase in deformation, as suggested by the usual biphasic model. These phenomena are likely to depend on the permeability, elastic (Young's) modulus, and structure of hydrogels. Detailed analysis for difference in deformation behaviors between PVA hydrogels and articular cartilage should be examined in further studies.

The high friction and constant compressive deformation of FT gel is considered to be due to biphasic properties with high permeability (Table 22.1). The interstitial fluid pressure in FT gel remarkably diminished after 292 s running as shown in Fig. 22.12, and therefore the fluid load support became small. The friction for FT gel in saline increased gradually as indicated by the curve for $\mu_{\text{solid}} = 0.2$ (Fig. 22.13). The frictional behavior for FT gel based on biphasic FE analysis with $\mu_{\text{solid}} = 0.01$ approximately corresponds to low friction in simulated synovial fluid.

In contrast, the low friction of CD gel with low permeability in saline is attractive because of the high interstitial fluid pressure sustained even after 292 s running. The measured coefficient of friction was lower than 0.05, and friction should be estimated by appropriate selection for $\mu_{\text{solid}} = 0.05$ or so to reflect the surface lubricity. Thus, the CD gel has considerably low friction property when pressed against a glass plate. In gel-on-gel combination, however, CD gels showed high friction and/or severe wear in saline and simulated synovial fluid [48]. Therefore, improvement of structure and properties of new hydrogels is necessary. We also [49,50] developed the hybridization of CD on FT gels, which showed better tribological performance in water lubrication. Related research on the hybrid gel indicated the superiority in tribological properties of promising hydrogels [51,52].

To summarize the important properties in optimum design of PVA hydrogels, it is pertinent to discuss the relation between the structures and properties of hydrogels. The material properties and structures in both PVA hydrogels appear to depend on the structure controlled by hydrogen bond. The schema for microstructure in PVA FT and CD hydrogels based on model proposed earlier [43,50] are shown in Fig. 22.10 [44]. The formation of hydrogen bonds and microcrystallites was identified using X-ray diffraction technique (XRD), Fourier transform infrared (FT-IR) spectroscopy, and measurements of the swelling ratio under repeated water exchanges [44]. Small-angle scattering indicates that the distance between microcrystallites in PVA-FT gel is shorter than in PVA-CD gel. As shown in Fig. 22.10, the milky white appearance of FT gel suggests the heterogeneous network

(a) Before test

(b) After test with HA 0.5 wt % and DPPC 0.01 wt%

(c) After test with HA 0.5 wt%, DPPC 0.01 wt%, Albumin 1.4 wt% and γ-Globulin 0.7 wt%

FIGURE 22.15 PVA-FT gel surfaces before and after reciprocating tests.

structure, and the transparency of CD gel indicates its uniform network structure. The network is generally composed of microcrystallites and amorphous zones. It is suggested that the fluid flows out rapidly from FT gel, which is composed of microcrystallites and considerable amorphous zones, as indicated by high permeability (Table 22.1), and porous texture in AFM image (Fig. 22.10). On the contrary, in the CD gel with low permeability, the fluid retained inside the gel flows out slowly, and thus the interstitial fluid pressure is maintained for a longer time under reciprocating tests. In reciprocating tests with an alumina ball placed against flat PVA hydrogel plates in pure water [49], the CD gel with low permeability showed lower wear and lower friction than did the FT gel with high permeability. The superiority of CD gel appears to be due to its better biphasic property in water.

Friction for biphasic materials under lubricated conditions is estimated from a combination of the friction for solid–solid contact and the negligibly low friction for fluid load support, as indicated in formula (22.1) for friction (above) [16,27], where high partitioning of load support by the fluid phase contributes to lowering of friction. Changes in load support in compliant hydrogels depend on not only permeability but also friction level for solid–solid contact. The lower friction for CD gel in saline (Fig. 22.11) appears to be caused by superior surface lubricity as $\mu_{\text{solid}} = 0.05$ or so as mentioned above. The smooth surface of CD gel may contribute to the reduction of friction in saline by suppressing interaction between rubbing surfaces. The rough and porous surface of FT gel may enhance interaction between rubbing surfaces in saline and increase friction, but improve the adsorbed film formation under lubricated conditions with a simulated synovial fluid resulting in low friction (Fig. 22.14) and minimum wear (Fig. 22.15 [41]). Elucidation of the exact lubrication mechanism for hydrogel should be continued in further studies.

Other improving methods for properties of PVA hydrogel are to additionally control the nanoscopic structure, to reinforce the structure with fibrous elements or other methods, and thus to enhance biphasic properties for efficient lubrication and load-carrying property. The PVA hydrogels based on the hydrogen-bonding network as physical bonding prepared without any additives or irradiative stimulus provides superior safety in the human body. The potential for restoration with hydrogen bonding in case of local fractures is an advantageous property.

For the clinical application of PVA hydrogel, durability, synergistic interaction with lubricants, ease of production, formability, appropriate fixation techniques, and other properties are required. In particular, the establishment of appropriate design in consideration of a multimode lubrication mechanisms not only for low friction but also for zero-wear and high fatigue resistance in the human body is required. To evaluate predictively the in vivo behaviors of two hydrogels, various studies such as those employing reciprocating tests and simulator tests should be conducted under biomechanically simulated environmental conditions. The desirable in vivo performance of PVA hydrogel implanted in rabbit knee joints in ongoing tests by a biomedical research group suggests the feasibility of clinical application. The optimization of tribological properties of hybrid gel will be actualized on the basis of the findings described above.

22.10 CONCLUSION

The superior lubricity of articular cartilage and artificial cartilage with high water content were described in reciprocating tests and biphasic FE analyses. The importance of adaptive multimode lubrication in both natural and artificial joints was discussed from the biotribological perspective under various operating conditions. In particular, friction and wear behaviors in reciprocating motion under continuous loading conditions were examined to clarify the effectiveness of biphasic lubrication and boundary lubrication. To mimic the performance of articular cartilage, two kinds of PVA hydrogels were prepared by repeated freeze–thawing and cast-drying methods. The application of biphasic finite-element analyses satisfactorily elucidated the time-dependent changes in load support ratio by fluid phase and friction. The roles of synovia constituents were discussed, accompanied by observation of adsorbed film formation in various experiments.

It was shown that the synergistic combination of biphasic lubrication and boundary lubrication becomes effective to sustain superior lubricity in articular cartilage and PVA hydrogels even at slow movement under continuous loading.

ACKNOWLEDGMENT

The authors express their thanks to Dr. S. Yarimitsu, Dr. K. Nakashima, Dr. T. Yamaguchi, Professor Y. Sawae of Kyushu University, and Dr. N. Sakai of Kyushu Institute of Technology for their contributions to this work. Most of recent research was supported by KAKENHI 23000011.

SELF-ASSEMBLED CELL-MIMICKING VESICLES COMPOSED OF AMPHIPHILIC MOLECULES: STRUCTURE AND APPLICATIONS

Swati De and Ranju Prasad Mandal
Department of Chemistry, University of Kalyani, West Bengal, India

23.1 INTRODUCTION

The fundamental unit of life is the cell. For a long time, humans have been trying to mimic the cell and its functions by designing synthetic nanoreactors. Initial attempts to do so involved complicated synthesis. Self-assembled systems have been found to be easier to study than covalently linked systems. Among the most popular self-assembling substances are amphiphiles.

Amphiphile molecules have a hydrophobic part (tail) and a hydrophilic part (headgroup) (Fig. 23.1 and Table 23.1). Because of this dual nature, they self-assemble in aqueous solutions, assuming interesting structures [1–6]. The driving force for this self-aggregation is the *hydrophobic effect* [7], which arises mainly as a result of the entropic gain of the water structure as it is not in contact with the hydrophobic tails.

Phospholipids, such as DMPC and DPPC (Table 23.1), self-assemble in aqueous environments to form closed bilayer structures or vesicles. Usually lipids form lamellar bilayer structures but in dilute solutions they form vesicles (Latin *vesicula*, meaning "small bubbles"). The lipid building blocks of vesicles are often referred to as *tectons*. Vesicles are lamellar aggregates that curve to form a spherical structure that can enclose an inner aqueous compartment. This pioneering observation was first made by Bangham [8]. There is a close connection between vesicles and the constituting lipids, and so the terms *vesicle* and *liposome* (Greek *soma*, meaning "body"; i.e., body of lipids) are interchangeable. The importance of vesicles as potential membrane models was first noted by Gebicki and Hicks [9]. Later, Kunitake et al. [10] first showed that a completely synthetic amphiphile DDDAB (Table 23.1) can also form vesicles. In the present review, we will focus on vesicles formed by amphiphilic molecules and their varied applications.

23.2 PRINCIPLES OF VESICLE FORMATION

In this section, the factors guiding vesicle formation are discussed. The formation of vesicles can be viewed as a two-step process: (1) the amphiphile first forms a bilayer and then (2) the bilayer closes to form a vesicle.

23.2.1 Parameters

Broadly, the parameters described in the following sections guide vesicle formation.

23.2.1.1 Packing Parameter (p). The geometry assumed by an amphiphile-based self-assembly is described by the packing parameter (p) of the amphiphiles, which is defined as the ratio of hydrophobic volume (v_S) to the product of the headgroup area (a_S) and the chain length (l_S). This model of self-aggregation of phospholipids was developed by Israelachvili et al. [2].

$$p = \frac{v_S}{a_S \times l_S} \tag{23.1}$$

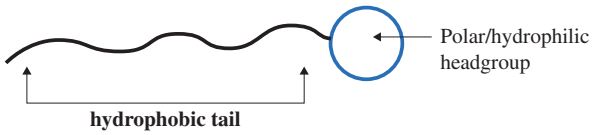

FIGURE 23.1 Amphiphile structure.

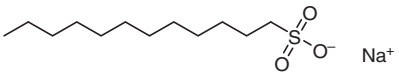
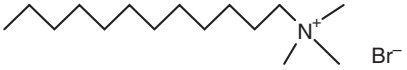
Table 23.2 shows the shapes of the predicted self-assembled structures, based on the value of p.

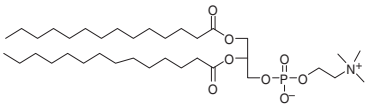
23.2.1.2 Interfacial Energy. The packing parameter (p) is based only on geometric considerations. However, there are free-energy factors that also drive self-assembly. The two main contributions to free energy are (1) interfacial energy of the hydrophobic–hydrophilic interface and (2) loss of entropy when the amphiphile tails are forced together to form a self-assembly.

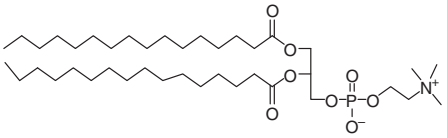
When interfacial energy is large and entropy loss small, then the minimization of the interfacial area drives the self-assembly. Thus the self-assembly will be such that minimizes the interfacial area per unit volume (A_V) [11]:

$$A_V = \frac{d \times \Phi}{l_S} \tag{23.2}$$





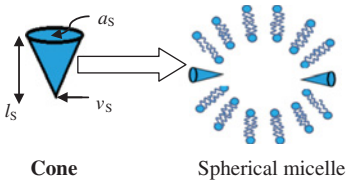


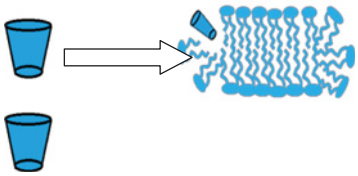


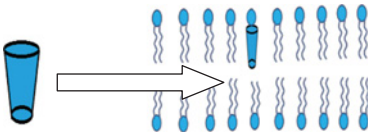
where

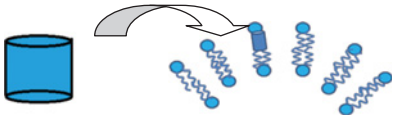
Φ = volume fraction of the hydrophobic domain
d = dimensionality
l_S = length of hydrophobic tail

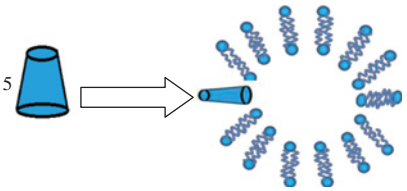
Since dimensionality assumes the lowest value ($d = 1$) for planar interfaces, such interfaces will be preferably formed compared to cylindrical ($d = 2$) or spherical ($d = 3$) domains [11].











23.2.1.3 Bending Elasticity of Bilayer. Another factor that effects vesicle formation is the bending elasticity of the bilayer [11, 12] i.e. the resistance it offers to a deformation

TABLE 23.1 Some Common Amphiphilic Molecules

Full name (IUPAC)	Structure	Abbreviation
Sodium dodecyl sulfate		SDS
Dodecyltrimethyl ammonium bromide		DTAB
Cetyltrimethylammonium bromide		CTAB
Cetyltrimethylammonium chloride		CTAC
Dimethyldioctadecyl ammonium bromide		DDDAB
Dihexadecyldimethyl ammonium bromide		DHDAB
Dioctadecyldimethyl ammonium chloride		DODAC
Dimyristoylphosphatidyl choline		DMPC
Dipalmitoylphosphatidyl choline		DPPC

TABLE 23.2 Effect of Packing Parameter (p) on Shape of Self-Assembled Amphiphilic Structures

Amphiphile	p	Shape	Structures formed
Single-chained amphiphiles with large headgroup area	$0 < p < \frac{1}{3}$		**Cone** Spherical micelle
Single-chained amphiphiles with small headgroup area	$\frac{1}{3} < p < \frac{1}{2}$		**Truncated cone** Cylindrical micelles
Double-chained lipids with large headgroup area	$\frac{1}{2} < p < 1$		**Truncated cone** bilayers
Double-chained lipids with small headgroup area	$p \sim 1$		**Cylinder** vesicles
Double-chained lipids with small headgroup areas, nonionic lipids	$p > 1$		**Inverted truncated cone** Inverted micelles

For $0 < p < \frac{1}{2}$, this model predicts the formation of micelles; for $\frac{1}{2} < p \leq 1$ vesicles are predicted and for $p > 1$, inverted micelles are predicted to form.

away from a spontaneous curvature of the bilayer. The circular rim of the bilayer disk gives rise to edge energy E_{disk}

$$E_{\text{disk}} = 2\pi R_{\text{V}}\gamma \tag{23.3}$$

where R_{V} = vesicle radius and γ = tension at the edge. This energy may be minimized by eliminating the edge if the bilayer closes to form a spherical vesicle [13] (Fig. 23.2).

However, there is an energy penalty, as bending of the bilayer to a closed vesicle requires a bending energy (E_{bend})

$$E_{\text{bend}} = 4\pi\chi \tag{23.4}$$

where χ = bending modulus. Thus the balance of edge tension and bending energy defines the *minimal vesicle size*; that is, when edge energy = bending energy, vesicle formation just begins

$$2\pi R_{\text{V}}\gamma = 4\pi\chi \tag{23.5}$$

so $R_{\text{V}} = 2\chi/\gamma$.

Thus vesicles easily form when the bilayer bending elasticity (χ) is low and the edge tension (γ) is high; in other words, hull closure to form a closed sphere provides adequate energy compensation (Fig. 23.2).

23.2.1.4 Rigidity of Bilayer and Transition Temperature (T_C). An important parameter in the formation of vesicular

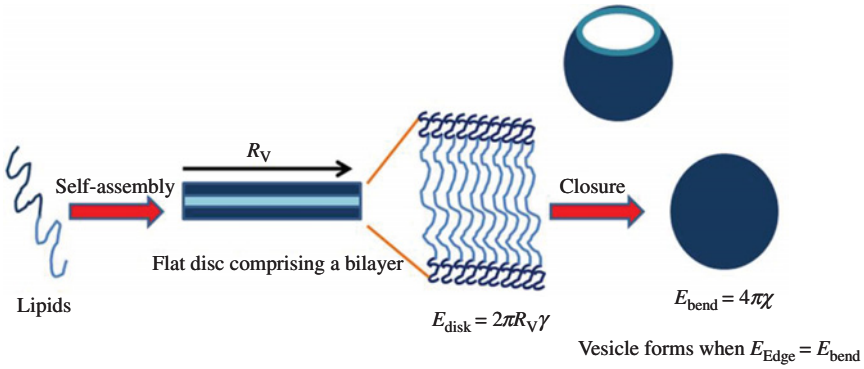

FIGURE 23.2 Energetics of curved vesicle formation from a planar bilayer. (From M. Antonietti et al., *Adv.Mater.* **15**, 1323–1333. Copyright © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim. Reprinted by permission of John Wiley & Sons.)

structures/liposomes is the rigidity of the bilayer. Phospholipid bilayers can exist in a liquid crystalline (*fluid*) state. or in a *gel* state. By increasing the temperature, the gel state bilayer "melts" at the transition temperature (T_C) and undergoes a transition from the gel into the liquid crystalline state. T_C depends on various factors, including lipid chain length, degree of saturation of lipid chain, and polar headgroup. Around T_C, bilayer permeability is very high. This is useful for triggered release of encapsulated matter.

Addition of a second component often changes bilayer characteristics. Addition of cholesterol to phosphatidylcholine bilayers alters the melting behavior of the bilayer since cholesterol prevents the phase transition. Usually, addition of cholesterol decreases bilayer permeability [14].

23.2.1.5 Formation of Nonequilibrium Vesicles. Often the shape and size of vesicles is guided by the preparation conditions (so-called nonequilibrium conditions). For such nonequilibrium vesicles, there is bilayer asymmetry [15], and many nonspherical shapes are possible [16].

These complex shapes arise only for nonequilibrium vesicles as equilibrium vesicles allow adjustment of V', that is, volume-to-area ratio by solvent permeation through the bilayer:

$$V' = \frac{6\pi^{1/2} \times V_S}{a_S^{3/2}} \tag{23.6}$$

Also the area differences (ΔA) are adjusted by rapid exchange of *tectons* between the inner and outer layers of the same vesicles or different vesicles:

$$\Delta A = A_{\text{inner leaflet}} - A_{\text{outer leaflet}} \tag{23.7}$$

23.3 CLASSICAL VESICLES

23.3.1 Classification

Vesicles can be classified according to their size and structure of the bilayer. Depending on the lipids used and the preparation conditions, the vesicles can vary widely in size and number of lamellae. Table 23.3 summarizes the classifications of vesicles based on size and bilayer structure. Figure 23.3 depicts the various types of vesicular structures.

Unilamellar vesicles comprise only one single bilayer (Fig. 23.3). Multilamellar vesicles (MLVs) consisting of many concentric shells of vesicles may also be formed [8,17]. These have an "onionlike" structure (Fig. 23.3) and are often termed "onion phases." Generally unilamellar vesicles are formed for dilute solutions of amphiphiles whereas MLVs are formed at high concentration.

23.3.2 Dynamic Processes Occurring in Vesicles

Vesicles are flexible and dynamic structures that exhibit Brownian motion in solution. Above T_C, vesicles can freely diffuse [18]. The diffusion rate of a vesicle is inversely proportional to size. The vesicles can also easily change shape (if the bilayer membrane is flexible). The amphiphiles making up the bilayer can diffuse laterally (Fig. 23.4). The

TABLE 23.3 Vesicle Classification Based on Size and Bilayer Structure

Type of vesicle	Abbreviation	Diameter (d)
Small unilamellar vesicles	SUV	20–100 nm
Large unilamellar vesicles	LUV	>100 nm
Giant unilamellar vesicles	GUV	>1 μm
Oligolamellar vesicles	OLV	0.1–1 μm
Multilamellar large vesicles	MLV	> 0.5 μm
Multivesicular vesicles	MVV	> 1 μm

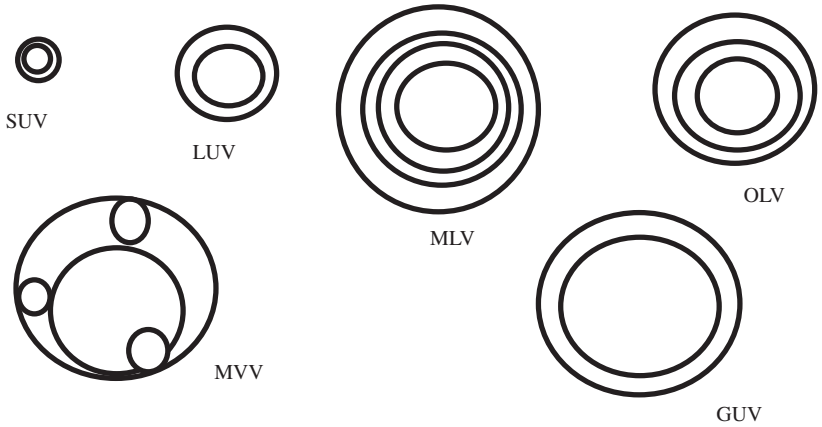

FIGURE 23.3 Morphology of different types of vesicles.

diffusion rate k_{diff} is high for shorter tails and higher temperatures. The amphiphiles can also undergo "flipflop" motion or transverse diffusion from the inner leaflet to the outer leaflet and vice versa (Fig. 23.4). This rate (k_{ff}) is high for short tails and at high temperatures. Amphiphiles can also temporarily leave the vesicle, diffuse in the surroundings and then finally come back to a vesicle. The rate of this exchange process is denoted by k_{ex} (Fig. 23.4).

Vesicles can also interact with one another to undergo aggregation, fusion and fission [18]. Aggregation is the formation of large clusters of vesicles while retaining the individual vesicular structure; that is, there is no mixing or leakage of the contents of the vesicles.

Fusion (Fig. 23.5) in the present context is the merging of smaller vesicles into larger ones. As a result, their membrane components and inner contents mix. *Fission* is the reverse of fusion; that is, smaller vesicles are formed from larger ones. These phenomena of aggregation, fusion and fission of vesicles bear strong resemblance to cellular processes such as endocytosis, exocytosis, and cell division [19].

23.3.3 Formation of Vesicles

Since the curvature energy of a bilayer in vesicles is higher than in the planar lamellar phase, energy is required to generate vesicles. Usually all the techniques employed for vesicle formation rely on some energy-providing mechanism. However, in some cases, spontaneous vesicle formation has also been observed.

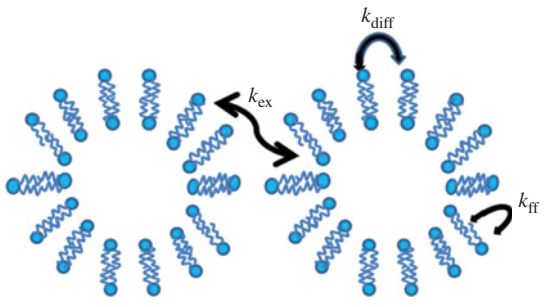

FIGURE 23.4 Dynamic processes occurring in vesicles.

23.3.3.1 Spontaneous Formation of Vesicles. In spontaneous formation process of vesicles, no external driving force is required. The classic example of spontaneous vesicle formation is for *catanionic* systems, where vesicles are obtained by mixing a cationic and an anionic surfactant [20, 21].

Spontaneous vesicle formation is also observed at low concentration in the binary phase diagrams of nonionic single-chain surfactants [22]. Such vesicles are stabilized by the addition of a rigid molecule such as cholesterol [23].

23.3.3.2 Energy-Driven Methods for Formation of Vesicles. There are several techniques for preparation of vesicles [13, 14,18,24–26]. All the different preparation procedures rely on two basic strategies: (1) hydration of lipid and (2) sizing of vesicles. In some methods, strategies 1 and 2 are combined together. Table 23.4 summarizes the common methods used for vesicle preparation.

1. *Lipid Film Hydration Method.* The phospholipid is dissolved in a suitable organic solvent in a round-bottomed flask. The solvent is then evaporated under reduced pressure using a rotary evaporator. The residual film consisting of the phospholipid bilayer is then hydrated with aqueous phase [25–27]. Although a large fraction of the vesicles obtained are MLVs, some GUVs may also be formed. The preferential formation of MLVs or GUVs is guided by the bilayer stacking during hydration stage (Fig. 23.6 summarizes this concept) [13].

   If the rate of bilayer separation is slow, MLVs are formed (Fig. 23.6a). If the rate of bilayer separation is high, GUVs are formed (Fig. 23.6b).

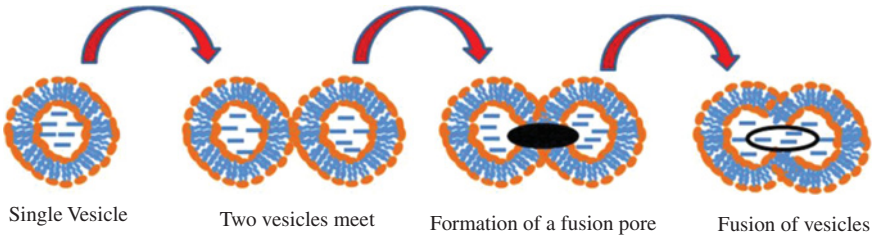

FIGURE 23.5 Vesicle fusion.

2. *Ether Injection Method*. This method was first reported by Bangham [17]. A lipid solution in diethyl ether is slowly injected into an aqueous solution at 50–60°C and under reduced pressure. Subsequently, ether vaporizes leading to the formation of unilamellar vesicles. Depending upon the condition employed, SUVs or LUVs are obtained. Two other investigators [28] developed a similar method but using ethanol instead of ether.
3. *Sonication Method.* The aqueous phase can be added to the surfactant/cholesterol mixture in organic solvent and the mixture then sonicated using a probe sonicator for a brief time period (3 min). This produces MLVs [29]. Sometimes, vigorous shaking or vortexing is required for homogenization.
4. *Reverse-Phase Evaporation*. Here a lipid-containing organic solvent (chloroform or ether) is emulsified with an aqueous phase by sonication [30]. This results in a water-in-oil (w/o) emulsion. Controlled removal of the organic phase using rotary evaporator results in LUVs as well as MLVs. Lower phospholipid concentrations yield a higher percentage of LUVs compared to MLVs. A critical step in this procedure is when most of the organic solvent has evaporated. A gel is then formed; this needs vigorous vortexing to be converted into a fluid state. One group of researchers have proposed many variations to this method [31].
5. *Solvent Spherule Method*. Rapid mixing of an organic phospholipid phase and an aqueous phase produces an oil-in-water (o/w) emulsion containing small spherules of lipid-containing solvents. This is followed by removal of organic phase thus resulting in the conversion of the spherules into MLVs [32].
6. *Hydration of Proliposomes*. Proliposomes are stable and dry powders containing a phospholipid and encapsulated material, such as a drug. These are formed by drying an organic solution of a phospholipid and drug resulting in particles consisting of a drug at the core encapsulated by a phospholipid shell. The organic phase can be removed in a rotary evaporator [33]. These proliposomes form MLVs when hydrated (Fig. 23.7).
7. *Detergent Dialysis*. This method is commonly used to produce LUVs. Here, phospholipids are solubilized in aqueous phase using surfactant micelles. Dialysis

TABLE 23.4 Methods of Vesicle Preparation and Type of Vesicle Formed

Method	Type of vesicle formed
Lipid film hydration	MLVs and GUVs
Ether injection method	SUVs, LUVs
Sonication	MLVs
Reverse-phase evaporation	LUVs, MLVs
Solvent spherule method	MLVs
Hydration of proliposome	MLVs
Detergent dialysis	LUVs
Reducing size and lamellarity of MLVs	LUVs, SUVs
Microfluidization	SUVs, LUVs
Electroformation	GUVs
Membrane contactor method	LUVs
Freeze drying of double emulsions	SUVs
Vesicle preparation by curvature tuning	SUVs
Hydration of phospholipids deposited on nanomaterials	SUVs, LUVs
Using supercritical fluids	LUVs

results in coalescence of the phospholipid rich micelles to form LUVs [34].

8. *Reducing Size and Lamellarity of MLVs*. MLVs can be easily formed. SUVs and LUVs ($d\sim$ 30–50 nm) can then be formed from MLVs by using French press [35, 36], sonication [29], homogenization [37], and membrane extrusion [38, 39]. The French press technique involves the extrusion of MLV suspensions at high pressure through a small orifice resulting in SUVs [35, 36]. Homogenization involves pumping of the vesicular suspension through an orifice and subsequent collision with a stainless steel wall at very high pressure to break down the MLVs. However, membrane extrusion is the most common method for converting MLVs to SUVs and LUVs [38, 39]. In this method, an MLV containing suspension is extruded several times through the pores of an etched polycarbonate membrane resulting in smaller vesicles. The minimum vesicle size attainable is governed by membrane pore size [40].
9. *Microfluidization*. This is one of the latest and most effective techniques for vesicle preparation. It involves fluid flow in narrow channels of cross section <500 μm. There is a detailed review on vesicle preparation using microfluidization [41]. The microhydrodynamic focussing (MHF) technique was first proposed by Jahn et al. [42] for preparing monodisperse SUVs and LUVs. This involves the counter diffusive flow of an aqueous buffer and solution of a phospholipid in isopropyl alcohol (Fig. 23.8).

This leads to some zones of low alcohol content where the phospholipids are forced to self-assemble into bilayers which finally close to form vesicles. In a variation of this technique, GUVs of diameter 4–20 μm form when two immiscible oil and water phases are made to flow in a single microchannel [43] using sorbitan monooleate and sterylamine as emulsifiers. Subsequently, the water droplets are frozen and removed from the oil phase by precipitation. The ice particles are then introduced into a hexane solution of a phospholipid. Evaporation of hexane followed by hydration results in the formation of GUVs. Water-in-oil-in-water (w/o/w) double emulsions containing a phospholipid in toluene–chloroform mixture, when subjected to a microfluidic process as above also results in GUVs [44] (Fig. 23.9).

10. *Electroformation*. Here, the phospholipid film deposited on electrodes is hydrated in presence of an electric field. This results in monodisperse GUVs. More GUVs can be formed, when thin films of phospholipids are obtained by spin coating the corresponding solutions on ITO slides [45] or on silicon wafers [46].
11. *Membrane Contactor Method*. Here a phospholipid solution in ethanol is extruded into an aqueous phase using a membrane contactor (Fig. 23.10) [47]. A tubular porous glass membrane with mean pore size 900 nm was initially used as the membrane contactor. Later polypropylene hollow fibers were used [48]. The main advantage of this method is the

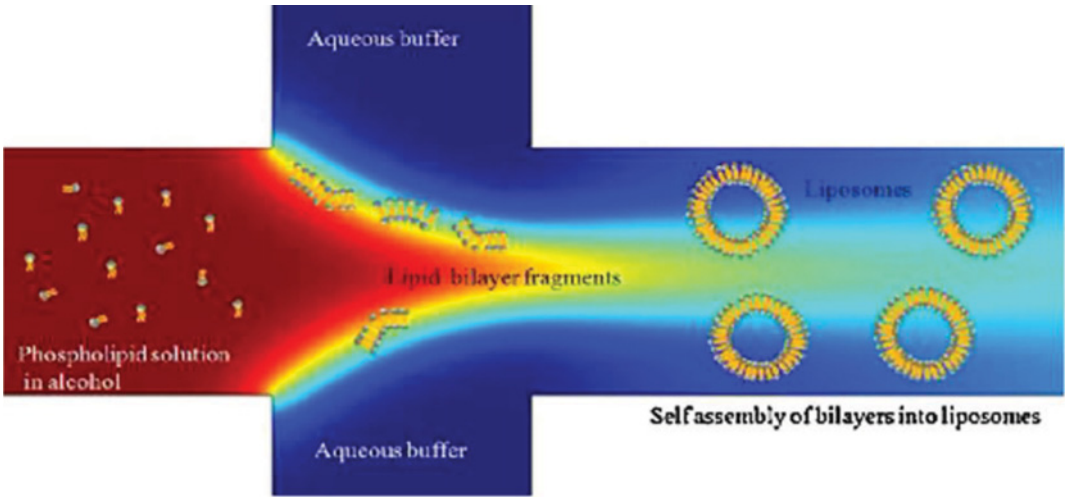

FIGURE 23.8 Formation of vesicles/liposomes by the MHF technique. (From Y.P. Patil et al., *Chem. Phys. Lipids* **177**, 8–18. Copyright © 2014 by Elsevier. Reprinted by permission of Elsevier.)

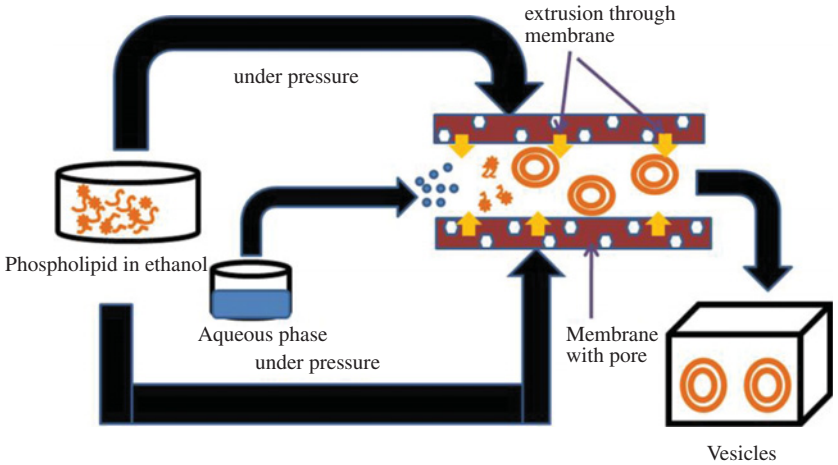

FIGURE 23.10 Formation of vesicles using a membrane contactor.

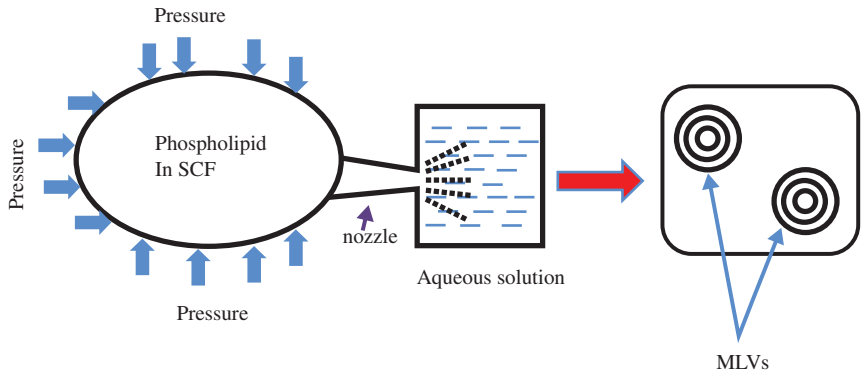

FIGURE 23.11 Preparation of MLVs using supercritical fluids.

possibility for continuous operation and large-scale applications.

12. *Freeze Drying of Double Emulsion*. Freeze drying of lipids dissolved in *t*-butyl alcohol/water system results in lipid cakes. Hydration of these cakes leads to MLVs that can be converted to LUVs/SUVs by extrusion [49].
13. *Vesicle Preparation by Curvature Tuning*. The contributions of various factors such as bilayer spontaneous curvature and curvature-induced stress to vesicle formation have been reviewed [50]. Spontaneous vesicle formation can be achieved using a rapid change of pH whereby MLVs can be converted to SUVs [51]. One team of investigators [52] introduced a novel modification to this using a *solventless* method. Charged lipids were mixed with lysopalmitoyl phosphatidylcholine and then subjected to rapid pH change to generate SUVs [52]. This obviates the need to prepare MLVs in the first step.
14. *Hydration of Phospholipids Deposited on Nanomaterials*. Vesicles can also be formed by hydration of phospholipids that have been previously deposited on electrospun amphiphilic nanofibers, composed of polymers [53]. Spontaneous vesiculation was observed on adding the nanofibers to water. The nanofibers acted as templates for self-assembly of lipids. The vesicular size is determined by the phospholipid: polymer ratio in the nanofiber, that is, by its hydrophilicity.
15. *Vesicle Preparation Using Supercritical Fluids*. Supercritical fluids (SCFs), such as carbon dioxide, are being increasingly used instead of organic solvents because of some of their useful properties. The use of SCFs for preparing vesicles has been reviewed [54]. MLVs can be prepared by taking a compressed mixture of the phospholipid, SCF, and an organic cosolvent and injecting this mixture through a nozzle into aqueous phase (Fig. 23.11).

A supercritical antisolvent (SAS) method was used to prepare small vesicles [55]. In this method, the organic cosolvent containing the phospholipid is sprayed into the supercritical fluid, which acts as the antisolvent leading to precipitation of the lipid particles. These particles on hydration in aqueous buffer form vesicles.

23.4 NOVEL VESICULAR SYSTEMS–GOING BEYOND LIPIDS

In the previous section, the classical vesicular systems solely based on phospholipids were discussed. The phospholipid based vesicles, although being very efficient drug delivery agents, suffer from two important drawbacks: (1) high formulation cost and (2) limited stability [56,57]. Because of the presence of ester bonds, phospholipids are easily hydrolyzed [56]. They are also prone to peroxidation processes [57]. These inherent disadvantages of the phospholipid vesicles were key factors that led to the development of other vesicular systems that can overcome these drawbacks. A number of such novel vesicular systems (discussed below) have been developed over the years (Table 23.5).

TABLE 23.5 Novel Vesicular Systems

Vesicular system	Principal components
Niosomes	Nonionic surfactant, cholesterol, and water
Ethosomes	Phospholipids, alcohol (high amount), and water
Transferosomes	Phospholipids, surfactants, alcohol, and aqueous buffer
Sphingosomes	Sphingolipids, cholesterol, and acidified water
Pharmacosomes	Colloidal dispersions of drugs covalently bound to lipids
e-Liposomes	A liposome encapsulating an emulsion nanodroplet
Polymerosomes	Polymer-based vesicles
Catansomes	Pair of oppositely charged surfactants forming a vesicle

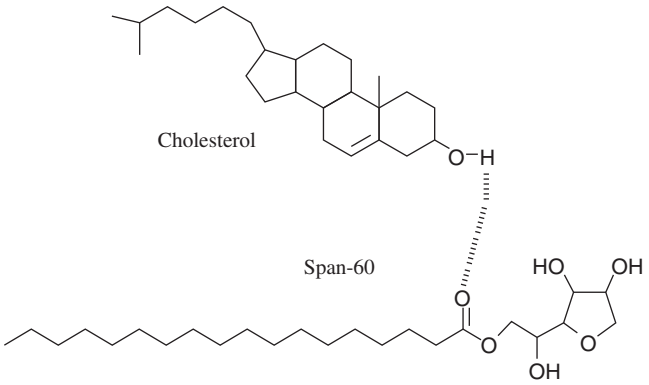

FIGURE 23.12 Noncovalent interactions between cholesterol and Span 60.

23.4.1 Niosomes

Niosomes are vesicles consisting mainly of nonionic surfactant and cholesterol. They were introduced by Handjani-Vila et al. in 1979 [58]. Niosomes have longer shelf life and stability than do conventional lipid vesicles, and they also possess the ability for targeted drug delivery in a controlled and sustained manner [59–64]. Niosomes were first introduced commercially for cosmetic applications by L'Oreal.

Vesicle formation is known to depend on *hydrophile–lipophile balance* (HLB). Thus HLB is a valuable guideline for choice of nonionic surfactants for niosome formulations. With the sorbitan esters of fatty acids (i.e., Spans), niosome formation occurs for HLB = 4–8 [60]. On the other hand, hydrophilic surfactants with HLB = 14–17 cannot form vesicles because of their high aqueous solubility [64]. Alkyl ether and ester surfactants can also be used for niosome formulation [59–62,65,66].

Cholesterol is added in niosomal formulations as it can interact with nonionic surfactants [67] (Fig. 23.12). Cholesterol modulates bilayer permeability, niosome fluidity, and vesicle rigidity [58,59,68]. Increasing the cholesterol content leads to a more homogeneous size distribution of niosomes and also smaller niosomes [69].

Often diacetyl phosphate is added as it is known to increase vesicle size, lead to vesicle charging, and also increase entrapment efficiency [66]. The niosomal bilayers (e.g., for phospholipid bilayers) are in either the gel or liquid state, depending on the temperature. The phase transition temperature (T_C) of the nonionic surfactant affects its entrapment efficiency. Span 60, which has a higher T_C (Table 23.6), forms "less leaky" niosomes at ambient temperature (~25°C) as it is in the ordered gel state. So Span 60 niosomes show higher entrapment efficiency than Span 20 or 80 niosomes [66]. Our work on gold nanoparticle synthesis is in concurrence with these findings [69].

Unlike phospholipid vesicles, niosomes are easier to prepare as nonionic surfactants are resistant to aerial oxidation.

TABLE 23.6 HLB Values and T_C of Some Sorbitan Esters

Surfactant	HLB	T_C (°C)	Chain length (number of carbons)
Span 20	8.6	16	C12 (monolaurate)
Span 40	6.7	42	C14 (monopalmitate)
Span 60	4.7	50	C18 (monostearate)
Span 80	4.3	~12	C18 (monooleate)

The same method as used for conventional vesicles can be used here. Often, in pharmaceuticals, the proniosome method is employed as a "ready to use" application [70]. The proniosome powders may be processed to form beads, tablets, or capsules. By this method aggregation, fusion and leaking can be prevented.

23.4.2 Ethosomes

Ethosomes are novel vesicular systems used for dermal and transdermal delivery of drugs to the skin [71–74]. Ethosomes are soft lipid vesicles that contain phospholipids, high concentration of alcohol (ethanol or isopropyl alcohol), and water. In comparison to phospholipid vesicles without ethanol, ethosomes have a more loosely packed bilayer. Differential scanning calorimetry indicates that ethosomal bilayers have a lower T_C compared to other bilayers [71]. The bilayers in ethosomes are thus highly fluid, facilitating deeper skin penetration. Ethosomes are generally unilamellar vesicles.

23.4.3 Transferosomes

Transferosomes overcome the shortcomings of the liposomal and niosomal systems for transdermal drug delivery, namely, poor skin permeability, leakage, and aggregation [75]. The transferosome consists of a lipid bilayer with specially tailored properties, due to the incorporation of *edge activators* into the bilayer [75]. Suitable edge activators are the bile salts, such as sodium cholate, sodium deoxycholate, and the nonionic surfactants Span 80 and Tween 80. A 3–10% alcohol (ethanol) solution is also added along with aqueous phase. Transferosomes can disrupt the organized structure of lipids in the stratum corneum of skin [77,78]. Transferosomes may be MLVs or LUVs.

23.4.4 Sphingosomes

Sphingosomes are clinically employed delivery systems for chemotherapy [79]. To overcome the instability of ester-based lipids, ether- or amide-linkage-containing lipids (sphingolipids) are used [80,81]. A *sphingosome* is a bilayered vesicle where the inner aqueous compartment is entirely enclosed by a natural or synthetic sphingolipid/cholesterol

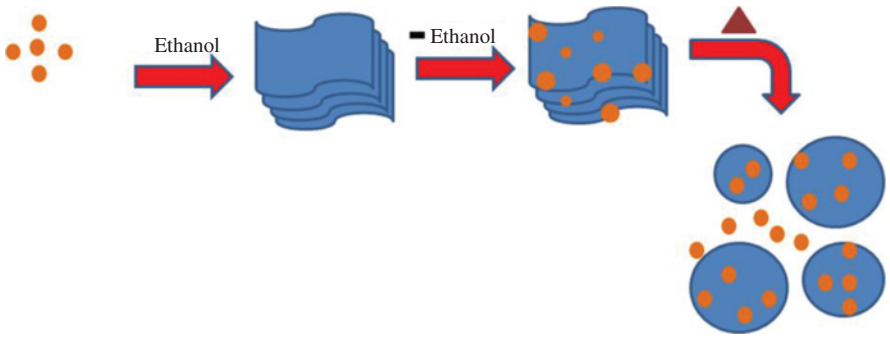

FIGURE 23.13 Mechanism for the formation of e-liposomes.

bilayer. The sphingolipids have longer circulation times and slower release rates compared to other lipids. Sphingosomes are usually prepared by the Bangham film method [17] forming MLVs. These MLVs can be reduced in size via extrusion through a polycarbonate membrane, through sonication, or using French press. Small unilamellar sphingosomes can interact with target cells via adsorption, endocytosis, and fusion (merging) of the sphingolipid bilayer with the plasma membrane of the cell to release the drug in the cytoplasm.

23.4.5 Pharmacosomes

When drugs linked to lipids form vesicles, they are called *pharmacosomes*. These can easily pass through biomembranes. Drugs having active functionalities such as –COOH, –OH, and $–NH_2$ can be linked to the lipid molecule producing an amphiphilic prodrug [82]. Pharmacosomes are site-specific, thus reducing drug toxicity. Pharmacosomes are prepared from the prodrug by ether injection or by hand-shaking.

23.4.6 e-Liposomes

An *echogenic liposome* or an *e-liposome* is a vesicle/liposome encapsulating an emulsion nanodroplet [83,84]. e-Liposomes are useful in drug delivery applications. Drugs are encapsulated inside the e-liposomes and on application of ultrasound, the emulsion changes from liquid to gas, thus increasing the volume inside the vesicle and causing vesicle rupture with subsequent drug release.

First small (< 100-nm) vesicles are formed and then ethyl alcohol is added. The alcohol interacts with polar region of the membrane and causes the spherical vesicles to unfold into sheets. Then alcohol is removed by centrifugal separation but the sheet remains stable at temperatures below the T_C of the lipids. Next, a nanoemulsion of a high-vapor-pressure liquid, such as perfluorohexane or perfluoroheptane, is added to the sheets and heated to $\leq$50°C (above T_C of the lipids). Now the e-liposome forms spontaneously, entrapping the emulsion (Fig. 23.13).

Dynamic light scattering indicates the e-liposomes to be 400–1200 nm in diameter (Fig. 23.14a). Cryo-TEM images of e-liposomes are shown in Fig. 23.14b.

The cryo-TEM images indicate an outer lipid membrane encapsulating the emulsion droplet.

23.4.7 Polymerosomes

To overcome the problems of using liposomes for drug delivery (mentioned earlier), various strategies have explored the use of polymers to reinforce the bilayer and prevent vesicle fusion. The polymerosome is formed from a block copolymer that is organized in a bilayer enclosing an aqueous internal cavity [85–87]. Polymerosomes are prepared by the film hydration method discussed earlier.

Because of the larger thickness of polymer bilayers (5–20 nm) compared to lipid bilayers (3–5 nm), the release rates from polymerosomes are slower. Also the stability of polymer vesicles are higher. Polymerosomes have been used for delivery of anticancer drugs such as paclitaxel (hydrophobic) and doxorubicin (hydrophilic) [88]. The latter is encapsulated in the internal cavity, whereas the former is incorporated into the bilayer during polymerosome formation to form a *polymer–drug cocktail* [88], which shows higher apoptosis in tumors than do the two drugs administrated separately.

To stabilize liposomes and achieve long circulation, poly(ethylene glycol) (PEG) can be been added to liposomes to produce "stealth liposomes" [89]. PEG provides steric hindrance and prevents fusion of the liposomes. This brings about an enhancement in the *in vivo* circulation times.

23.4.8 Catansomes

The spontaneous formation of vesicles from a mixture of single-chain cationic and anionic surfactants was first reported first by Kaler [21]. Since then a lot of work has been done [22].

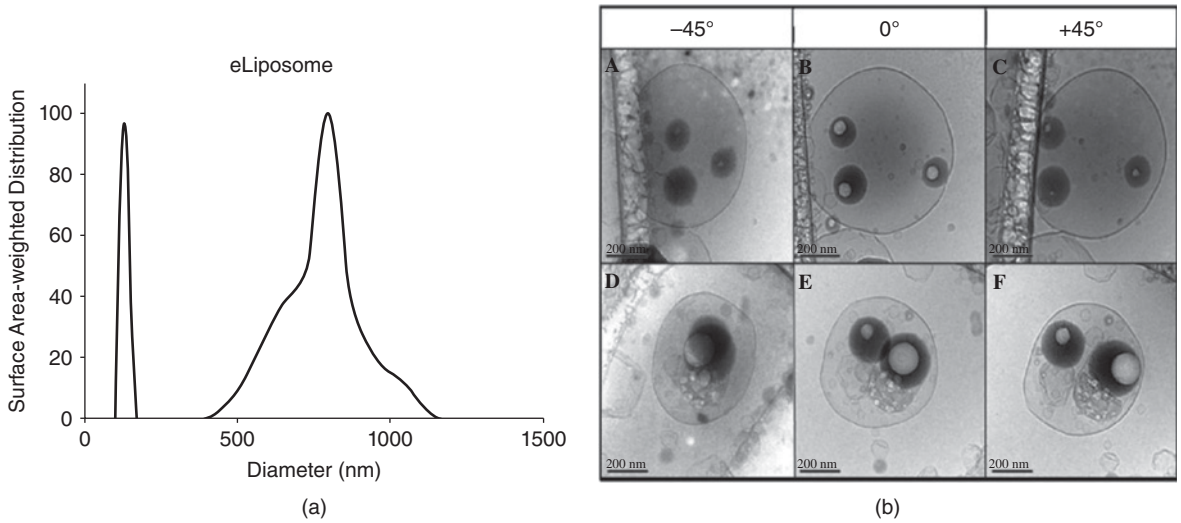

FIGURE 23.14 (a) Dynamic light scattering results for e-liposomes; (b) cryo-TEM images of e-liposomes. (Both images from J.R. Lattin et al., *Colloids Surf. B: Biointerfaces* **89**, 93–100. Copyright © 2012 by Elsevier. Reprinted by permission of Elsevier.)

23.5 VESICLE CHARACTERIZATION TECHNIQUES

Since the functioning of vesicles is strongly dependent on their properties such as size, shape, lamellarity, and surface charge, accurate characterization of vesicles is necessary. Table 23.7 lists the various characterization techniques for vesicles.

23.5.1 Morphology

Several electron microscopy techniques can be employed to study the size and morphology of vesicles. These include scanning electron microscopy (SEM), transmission electron microscopy (TEM), cryo-TEM, freeze–fracture transmission electron microscopy (FF-TEM), atomic force microscopy (AFM) [90], and scanning tunneling microscopy (STM). Optical microscopy is used to visualize the vesicles and also provide a rough estimate of their size.

TABLE 23.7 Some Popular Vesicle Characterization Techniques

Niosome parameter	Technique used
Morphology	SEM, TEM, freeze fracture electron microscopy, optical microscopy
Size distribution	Dynamic light scattering (DLS), SEC, AFFF, Coulter counter
Membrane thickness	SAXS
ξ- potential	Electrophoretic mobility
Stability	DLS, release studies
Entrapment efficiency	Centrifugation, dialysis, gel chromatography, HPLC, fluorescence, UV–visible spectroscopy
In vitro release	Dialysis using membranes
pH sensitivity assessment	Fluorescence spectroscopy

Abbreviations: AFFF–asymmetric field flow fractionation; HPLC—high-pressure liquid chromatography; SAXS—small-angle X-ray scattering; SEC–size exclusion chromatography; SEM–scanning electron microscopy; TEM–transmission electron microscopy.

23.5.2 Size Distribution

Size (diameter) of vesicles can be determined using dynamic light scattering (DLS) or photon correlation spectroscopy (PCS). DLS provides accurate information on the particle size and size distribution. One limitation of DLS is that it does not provide information on the shape of the system.

Size exclusion chromatography (SEC) may be used to fractionate vesicular population on the basis of their hydrodynamic size [91]. Another recent technique is *asymmetric field flow fractionation* (AFFF) [92]. This technique depends on the application of an external field (electric/magnetic/centrifugal force) in a direction perpendicular to the flow of a colloidal suspension. It can be used to measure size distribution of highly polydisperse samples.

23.5.3 Membrane Thickness, Lamellarity, and Fluidity

Vesicles can be morphologically classified according to the number of membrane bilayers (lamellae) into uni- and multilamellar vesicles. The number of lamellae can be determined by AFM, NMR, small-angle X-ray scattering (SAXS) [93], and electron microscopy [94]. The fluidity of the membrane can be assessed by fluorescence studies [95].

TABLE 23.8 Some Popular Liposomal Drug Formulations

Product	Drug	Company	Disease
Ambisome	Amphotericin B	Gilead	Fungal infection [101]
Doxil	Doxorubicin	Johnson & Johnson	Ovarian cancer [102],breast cancer
Daunoxome	Daunorubicin	Galen	Kaposi's sarcoma [103]
Marqibo	Vincristine	Talon	Acute lymphoblastic leukemia [104]

Source: From T.M. Allen et al., *Adv. Drug Deliv. Rev*. **65**, 36–48. Copyright © 2013 by Elsevier. Reprinted by permission of Elsevier.

The microviscosity of the membranes can be determined by fluorescence polarization studies [96].

23.5.4 Zeta-Potential and Surface Properties

The stability of vesicles is highly dependent on surface charge or ξ-potential. ξ-potential can be measured using a DLS instrument or by measuring electrophoretic mobility using laser Doppler velocimetry [97].

23.5.5 Stability

There is no direct method for estimating the stability of vesicles. However, DLS studies on a time-dependent basis can provide an idea about vesicular stability.

23.5.6 Entrapment Efficiency

The entrapment efficiency (EE) of vesicles is defined as the amount of active substances loaded within the vesicular structure and can be expressed as

$$\text{EE} = \frac{\text{amount entrapped}}{\text{total amount}} \times 100 \qquad (23.8)$$

where total amount = amount of the drug used in the preparation. The EE can be determined by various methods. One is by separating the unentrapped drug by dialysis or gel filtration. EE can also be determined fluorimetrically using a marker.

23.5.7 In Vitro Release Study

The *in vitro* drug release can be studied by using a dialysis tubing [98]. The vesicles containing encapsulated drugs are placed in prewashed dialysis tubing, which can be sealed. The dialysis sac is then dialyzed against a suitable dissolution medium. Samples are taken out at regular time intervals and centrifuged, and the supernatant is analyzed for drug content using UV spectroscopy, HPLC, and other techniques.

23.5.8 pH Sensitivity Assessment

Often vesicular drug delivery systems are targeted for internal delivery via endocytosis. They experience a gradual decrease in pH, and thus many vesicular formulations have been developed to exploit this factor. pH sensitivity assessment of vesicular drug delivery systems has also been used to evaluate bilayer thickness [99].

23.6 APPLICATIONS OF VESICLES

23.6.1 Drug Delivery

The concept of drug delivery using carrier molecules was first proposed by Paul Ehrlich in 1909, when he proposed the idea of "magic bullets." Later, it was established that liposomes can indeed entrap drugs and can be used as drug delivery systems (DDSs) [100]. Then followed extensive studies employing liposomal amphotericin [101] and liposomal doxorubicin [102], and these studies ultimately led to the first clinical trials for drugs based on liposomes. Since then, liposomal systems have served as the most clinically established DDSs to deliver drugs, genes, and vaccines [85]. (Table 23.8 summarizes a few of the popular clinically approved liposomal products.)

The recent past has witnessed the development of a new generation of liposomal DDS, specifically, those that respond to stimuli (i.e., temperature, pH, ultrasound, light, enzymes). More recently, other groups [105, 106] have published extensive reviews on triggered-release liposomal DDS. The first of these were the temperature sensitive liposomal DDS; for example, delivery of liposomal methotrexate was fourfold higher in heat-treated tumors than in nonheated ones [107]. This was followed by the formulations using pH-sensitive liposomes that are stable at physiological pH (i.e., pH $\sim$ 7.4). They destabilize under acidic conditions (e.g., in tumors), leading to pH-triggered release [108]. Phospholipid liposomes containing disulfur bridges are sensitive to the redox potential of the medium. On reduction of the S–S bond, the liposomes rupture, releasing their contents [109]. Ultrasound can trigger drug release from echogenic or e-liposomes [110]. Light can act as a trigger for photosensitive liposomes [111]. Enzyme-triggered liposomes have also been studied e.g. liposomes triggered by phospholipase C [112], alkaline phosphatase [113], and others. Virosomes are surface-functionalized toward specific targets (i.e., virus mimics). These have been widely used for vaccination by the delivery of antigens [114].

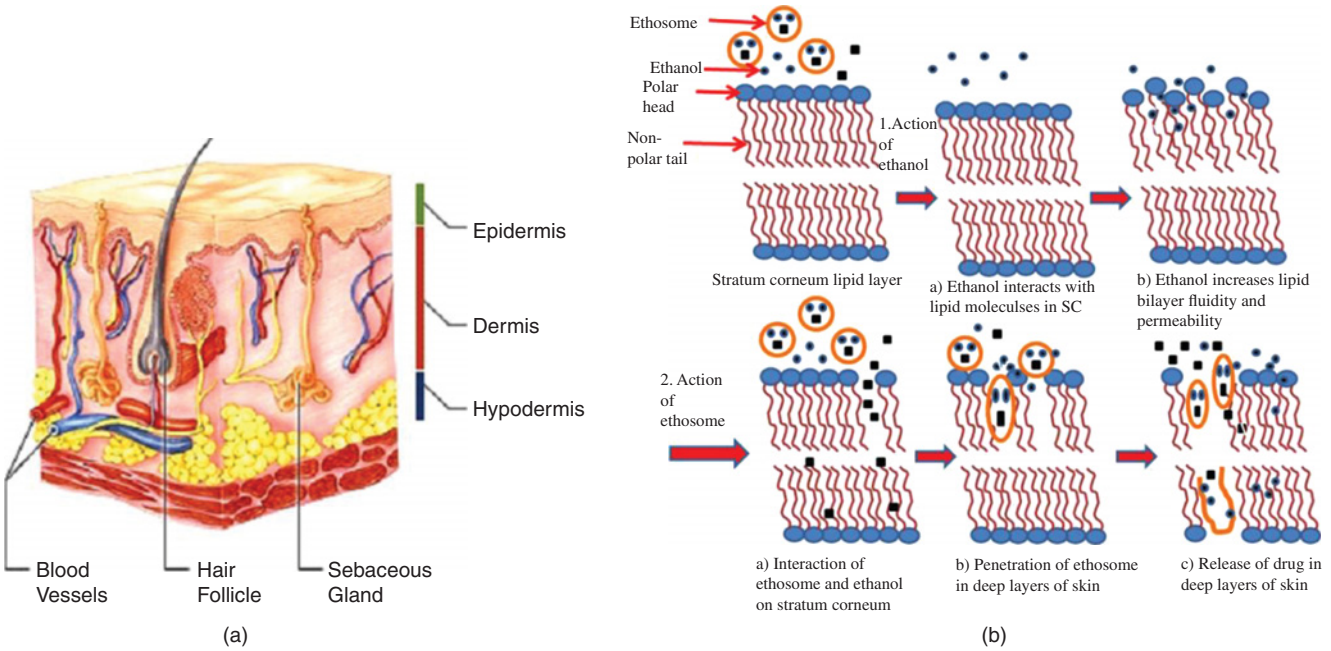

FIGURE 23.15 (a) Diagram of skin; (b) mechanism of action of ethosomes on human skin. (Both illustrations taken from open-access resource, *J. Adv. Pharm. Technol. Res*. **1**, 274–282.)

The polymer-based liposomes (i.e., polymerosomes) discussed earlier have been used for delivery of anticancer drugs such as paclitaxel (hydrophobic drug) and doxorubicin (hydrophilic drug) [88]. Liposomes have also been used as effective delivery systems for DNA [115] and siRNA [116]. Niosomes have also been used extensively as DDS for many applications [117, 118]. Niosome-based airjet nebulizers using the drug beclomethasone dipropionate (BDP) have also been prepared [119].

Theranostics is the development of specific therapies for various diseases combined with diagnostic capabilities, all combined into a single formulation [120]. Liposomes loaded with iron oxide nanoparticles were thus used [121]. Prolonged circulation time was noted and monitoring was done by studying the fluorescence of QDs.

23.6.2 Cosmetic Applications

Vesicular systems find widespread applications in the cosmetic industry. The stratum corneum (SC) of human skin is composed of insoluble keratins surrounded by the cell envelope (Fig. 23.15a).

The skin presents a formidable barrier for delivery of drugs and other materials. Cosmetic and drug formulations for the skin have focussed on efforts to overcome the skin barrier [122]. Deformable liposomes and transferomes were the first generation of elastic vesicles introduced that could penetrate skin and deliver material [123]. More recently, ethosomes (discussed earlier) [73,124] have been found to have improved skin penetration ability. The mechanism of action of ethosomes is as proposed as follows (Fig. 23.15b).

First, ethanol in ethosomes interacts with the lipid molecules via the polar headgroup region of the SC, hence increasing the bilayer fluidity. Subsequently, the ethosomes penetrate the lipid layer and fuse with lipids, resulting in release of the encapsulated material.

Another team of researchers formulated antioxidant ethosomes for topical delivery [125]. A US-based company, Osmotics Inc., recently reported a new type of cellulite cream called *lipoduction*, which uses ethosome technology to deliver ingredients directly into skin fat cells thus improving the appearance of cellulite.

Apart from ethosomes, niosomes have also been used for cosmetic formulations. Niosomes made from a Brij 52/cholesterol mixture using black tea extract were formulated as an active sunscreen agent [126]. US Patent 4,830,857, entitled *Cosmetic and Pharmaceutical Composition Containing Niosomes and a Water-Soluble Polyamide and a Process for Preparing This Composition*, was obtained C 1989 [127]. Another group obtained US patent 6,319,508 in 2001 [128], entitled *Anhydrous Cosmetic Composition Containing a Fatty Phase and Pro-liposomes*, where they prepared an anhydrous cosmetic makeup formulation containing a vesicular lipid phase and other used additives.

23.6.3 As Self-Assembled Nanoreactors

For a long time, vesicular systems have been explored as potential nanoreactors [129, 130]. The requirements for a

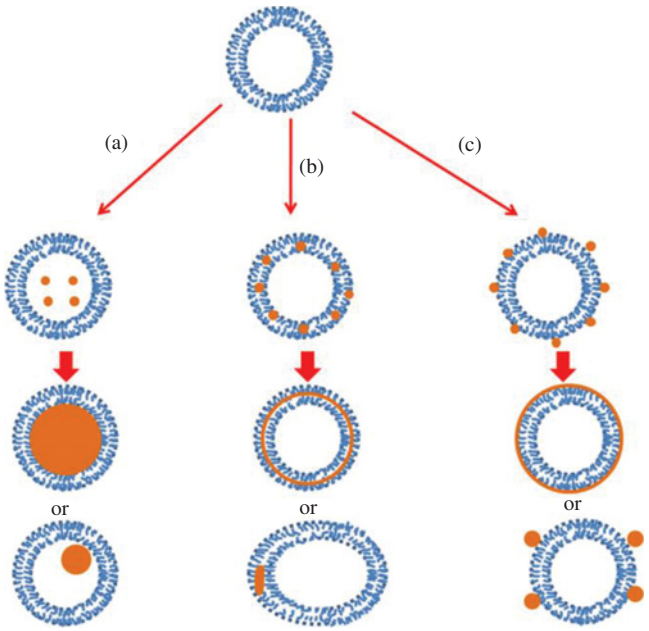

FIGURE 23.16 Synthetic strategies employed for the synthesis of materials using soft vesicles. (From R. Dong et al., *Accounts Chem. Res*. **45**, 504–513. Copyright © 2012 by American Chemical Society. Reprinted by permission of American Chemical Society.)

vesicle to act as nanoreactor have been listed in a review [130]. Briefly, they are (1) stable reactor membrane; (2) resistance offered by the vesicle to external destabilizing factors (e.g., pH, temperature, ionic strength), and (3) entrapment of reactants in the inner vesicular compartment. Others have studied a number of enzymatic reactions inside liposomes [131,132]. Green fluorescent protein (GFP) has been synthesized within liposomes [133].

Another group have provided an extensive review on the use of soft vesicles in the synthesis of hard materials [134]. They discussed such synthesis using three main strategies as depicted in Fig. 23.16: (a) reaction compartmentalization within the hydrophilic core; (b) membrane-restricted reaction within the bilayers, and (c) surface-reactive templating and synthesis at the outer surfaces of the vesicles.

Pioneering work on the synthesis of nanoparticles in the inner aqueous compartment of vesicles as per the logic depicted in Fig. 23.16a was done by Tricot and Fendler in the mid-1980s [135]. Rhodium-coated CdNPs were synthesized in situ in dihexadecyl phosphate vesicles. Subsequently core–shell metal sulfide nanocrystals were also synthesized employing this strategy [136]. Our group synthesized gold nanoparticles (GNPs) using span/cholesterol-based niosomes [69]. The surfactant HLB value, "leakiness" of the niosomes, and rigidity of the bilayer are important parameters that dictate the size and shape of the GNPs (Fig. 23.17).

The second strategy depicted in Fig. 23.16b utilizes the inner portion of the vesicle bilayer as a microreactor. By this strategy, hydrophobic nanoparticles (NPs) can be prepared in an aqueous environment. GNPs have been prepared in bilayers employing this strategy whereby $AuCl_4^-$ was incorporated in the bilayer as a counterion [137]. Hydrophobic quantum dots have also been prepared using this strategy [138].

According to the third strategy, the outer surface of the vesicles is the specific site for material synthesis. Initially, the precursors adsorb and react at the vesicle surface. Then the products nucleate, grow, and gradually cover the vesicle. Removal of the vesicle material leaves hollow micro- or nanocapsules. Hollow silica particles were synthesized by such vesicle-templating methods [139, 140]. Other workers have also used reactive catanionic vesicles as reactive precursors, not as templates to prepare ZnNPs [141, 142].

23.6.4 As Organized Assemblies for Fluorescence-Based Studies

For a long time, fluorescence probing was considered as a simple, convenient, and noninvasive tool to study vesicular systems. One team of investigators have carried out exhaustive fluorescence studies probing various aspects of lipid vesicles [143–145]. They have also probed the interaction of bile salts with vesicles using various fluorescence probes. Another group [146] have reviewed the main trends in the development of fluorescent probes for monitoring the structure, dynamics, and interactions in membrane-mimicking lipid bilayers.

Solvation dynamics studies in vesicles were carried out by several groups. These studies provide valuable insight into the polar solvent dynamics in vesicular systems. One group in particular have contributed significantly to solvation dynamics in phospholipid vesicles [147, 148]. Their study reveals two solvation components: the slow (>1-ns) response has been attributed to water bound at the vesicle interface, while the faster (∼600-ps) component is assigned to water in the inner aqueous core of the vesicles. Another group used time-resolved fluorescence and NMR to study solvent relaxation in lipids [149].

Niosomes have also been studied by fluorescence methods. Our group has performed fluorescence resonance energy transfer (FRET) studies in span/cholesterol niosomes and span-only micelles [150]. It was shown that FRET efficiency is more in niosomes compared to micelles. This is evidenced by a larger decrease in fluorescence of the donor in presence of the acceptor.

In recent times, *fluorescence correlation spectroscopy* (FCS) has emerged as a powerful technique to study biological systems at the single molecule level with high spatial resolution [151]. One team [152] studied the interactions of Nile red molecules with lipid vesicles using the on/off fluctuations in the fluorescence signal. FCS has been used [153] to determine the diffusion coefficient (D_t) of an organic molecule in

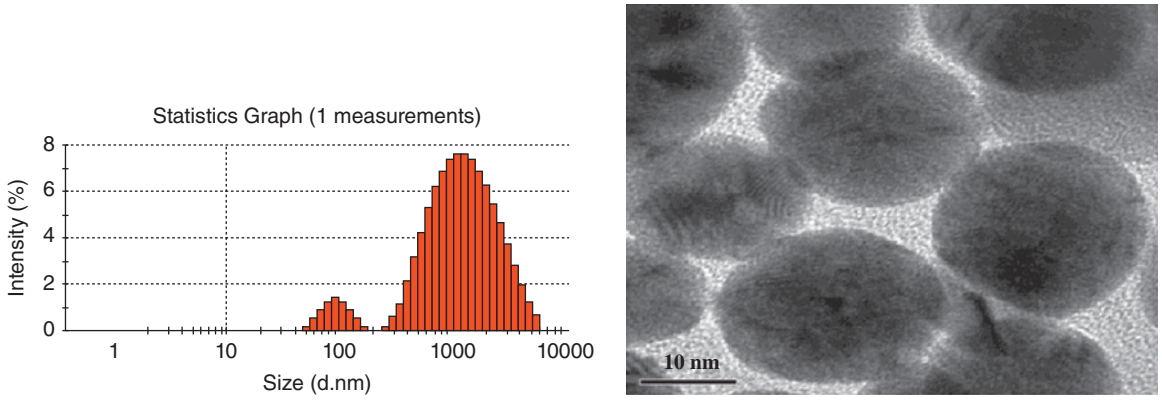

FIGURE 23.17 (a) Dynamic light-scattering data for GNPs synthesized in Span-based niosomes; (b) TEM image of GNPs synthesized in Span-based niosomes. (Both images from S. De, et al., *J. Colloid Inerface Sci*. **396**, 9–15. Copyright © 2012 by Elsevier. Reprinted by permission of Elsevier.)

giant unilamellar vesicles (> 25 μm). Others [154] have used FCS to study diffusion in GUVs and supported bilayers.

Another team of investigators used FCS to study dye diffusion in gel and fluid phases of a singl-lipid vesicle [155]. The D_t values determined were 5 $\mu m^2/s$ in the gel phase (for DPPC vesicle at 20°C) and 40 $\mu m^2/s$ in the fluid phase. The same group has studied dye diffusion in giant multilamellar niosomes of Triton X-100/ cholesterol [156] and catanionic vesicles of SDS/DTAB [157]. They found that the D_t values exhibit a much narrower distribution in niosomes compared to catanionic vesicles, indicating that the niosomes are quite homogeneous with small viscosity variation. This group has also performed time-resolved picosecond studies under a confocal microscope to study the solvation dynamics of Coumarin 153 (C-153) inside a single giant vesicle, the solvation time varying from 750 to 1000 ps [157]. Another team [159] used FCS to analyze binding of fluorescently labeled peptides to lipid vesicles. The peptides were labeled using Alexa 488, and the vesicles used were LUVs of phosphatidyl choline and phosphatidyl serine.

23.7 FUTURE PERSPECTIVES AND DIRECTIONS OF RESEARCH ON VESICLES

In the biological system, chemical reactions are often coupled in time and space. Nature, realizing this coupling, has designed well-defined reaction environments, the most sophisticated of which is the cell. Thus the cell is the primary source of inspiration for research in general. One step toward mimicking cells *in vitro* is the development and study of self-assembling nanoreactors. In the second half of the twentieth century, the use of lipid-based vesicles as potential biomimicking systems has received considerable attention.

In this chapter, we have focused on the principles of vesicle formation, the present *state-of-the-art* synthetic strategies, and the various types of vesicles and their characterization and applications. The most popular application of vesicular systems is as drug delivery vehicles. In medical science, vesicles constitute one of the most successfully translated drug delivery systems that are currently in clinical use for a variety of diseases such as cancer and inflammatory and dermatological diseases and also as vaccines. With the advent of novel vesicles (e.g., ethosomes and e-liposomes), drug delivery and cosmetic formulations have undergone a paradigm shift from the existing formulations. Such clinical profiles are important for the future development of vesicular systems with combined therapeutic–diagnostic (i.e., *theranostic*) capabilities. Vesicle–nanoparticle hybrids are a stepping stone in this direction. Liposomal vesicles have been used for synthesis of nanoparticles (QDs, magnetic NPs, GNPs, etc.). Vesicle templating is an important route for preparation of hollow nanospheres, which have manifold uses.

However, all success in vesicle-based applications depends on the stability of the vesicles. In this chapter, we have discussed how the stability of vesicles can be improved, for example, by using polymers (polymerosomes) and catanionic amphiphile pairs, that is, catansomes.

The future advancement of vesicular technology demands that smart and multifunctional vesicle hybrids be developed for biological, chemical, and catalytic applications. These hybrids must be stable and biocompatible. In this perspective, the evolution of vesicles is still ongoing. The future of vesicle research will witness the "survival of the fittest vesicle" for the manifold applications of vesicles.

ACKNOWLEDGMENTS

S.D. thanks the Department of Science and Technology, India; Council for Scientific and Industrial Research, India;

and Swedish Research Council, Stockholm for funding. The University of Kalyani is acknowledged for providing infrastructural facilities. R.P.M. acknowledges the University of Kalyani for a university research fellowship. We are both grateful to Professors S.P. Moulik and N. Nandi for helpful discussions and suggestions. Finally, we thank Professor Ohshima for his inspiration and encouragement throughout the process.

24.1 INTRODUCTION

Most cells in the human body are commonly exposed to an extracellular environment. For cell survival and proliferation, cells require not only a signal from growth factor receptor but also an additional signal from adhesion receptor family molecules, integrins. Once normal cells detach from the extracellular matrix (ECM), they undergo programmed death termed *anoikis* [1, 2]. This process plays a fundamental role in preventing the dissemination of the cells to inappropriate site. In contrast, malignant cell types are often known to be independent of anchorage, which causes deregulated survival and growth [1, 2]. Cell-adhesion-mediated regulation of cell survival/death is not restricted in normal cells. It has also been demonstrated previously that leukemic cell adhesion to bone marrow fibronectin confers a multidrug resistance, commonly referred to *cell-adhesion-mediated drug resistance* (CAM-DR) [3], which could be a major cause of recurrence in acute leukemia [4–6]. These facts suggest that signals generated by aberrant interactions between adhesion molecules on cellular membrane and surrounding ECM environment are involved in cancer progression.

The ECM proteins often have concealed functional sites within their own structure. These cryptic active sites (matricryptic sites) are disclosed by proteolytic cleavage with ECM-degrading proteinases, which are secreted in pathological state such as inflammation and cancer. Exposure of matricryptic sites has been implicated in various diseases. We previously found that fibronectin harbors an antiadhesive site (YTIYVIAL) within the 14th FNIII repeat. A 22-mer peptide containing this active site, labeled FNIII14, has an ability to suppress cell adhesion to fibronectin substrate (Fig. 24.1a,b). The antiadhesive effect of FNIII14 is due to inactivation of β1-integrin [7, 8].

This matricryptic antiadhesive site could be exposed by degradation of fibronectin with inflammatory proteinases, including matrix metalloproteinases, MMP-2/9 [9]. Amino acid sequences similar to the YTIYVIAL of FNIII14 are presented in the other ECM proteins, such as collagens and tenascin (TN)-C. One of them, a sequence YTITIRGV, which is located in the FNIII repeat A2 domain of the alternative splicing region of TN-C, was found as another matricryptic site. A 22-mer peptide containing YTITIRGV, labeled TNIIIA2 (Fig. 24.2), enhances cell adhesion by inducing conformational and functional activation of β1-integrin [10]. The proadhesive effect of TNIIIA2 is also exposed by proteolytic degradation of TN-C. Moreover, it has been defined that TNIIIA2 specifically binds to cell surface heparan sulfate proteoglycans (HSPG), syndecan-4 (Fig. 24.3a–c), and the TNIIIA2/syndecan-4 complex laterally interacts with

β1-integrin to keep the conformation of integrin active (Fig. 24.4) [10]. Thus, we have obtained effective tools, FNIII14 and TNIIIA2, that enable us to control activation status of β1-integrins, either positively or negatively.

24.2 INACTIVATION OF β1-INTEGRIN BY FNIII14 INCREASES CHEMOSENSITIVITY OF ACUTE MYELOGENOUS LEUKEMIA (AML) CELLS

Although hematopoietic cells are usually nonadhered in blood vessels, integrin-mediated cell adhesion to fibronectin is fundamentally implicated in proliferation of hematopoietic stem and progenitor cells [11]. In contrast, hematopoietic tumor cells could proliferate without integrin ligation. Loss of *anchorage dependence* in cell proliferation is one characteristic of leukemic cells.

The majority of hematopoietic tumor cells are chemosensitive. For example, around 80% of patients with acute myelogenous leukemia (AML) might experience complete remission by anticancer drug prescription. Nevertheless, the percentage of long-term disease-free survival in AML patients is relatively low (30–50%). High relapse rate is a serious problem remaining in AML treatment. A number

(b,c) Effect of syndecan-4 knockdown on expression of TNIIIA2 activity: (b) WI38VA cells transfected with syndecan-4 siRNA were treated with TNIIIA2 and then examined for β1 integrin activation (c) or cell adhesion to fibronectin (d). (Scale bars, 100 μm.)

of studies demonstrated that the primary cause of this relapse is believed to be the minimal residual disease (MRD) in bone marrow [4,12,13]. As a mechanism of the MRD after chemotherapy, several groups have demonstrated that the AML cells acquire multidrug resistance when these cells adhere to fibronectin through $\alpha 4\beta 1$- or $\alpha 5\beta 1$-integrin, commonly referred to as *cell-adhesion-mediated drug resistance* (CAM-DR) [14]. These reports led us to presume that inactivation of β1-integrin might contribute to overwhelming the persistence of MRD in AML. As described above, we

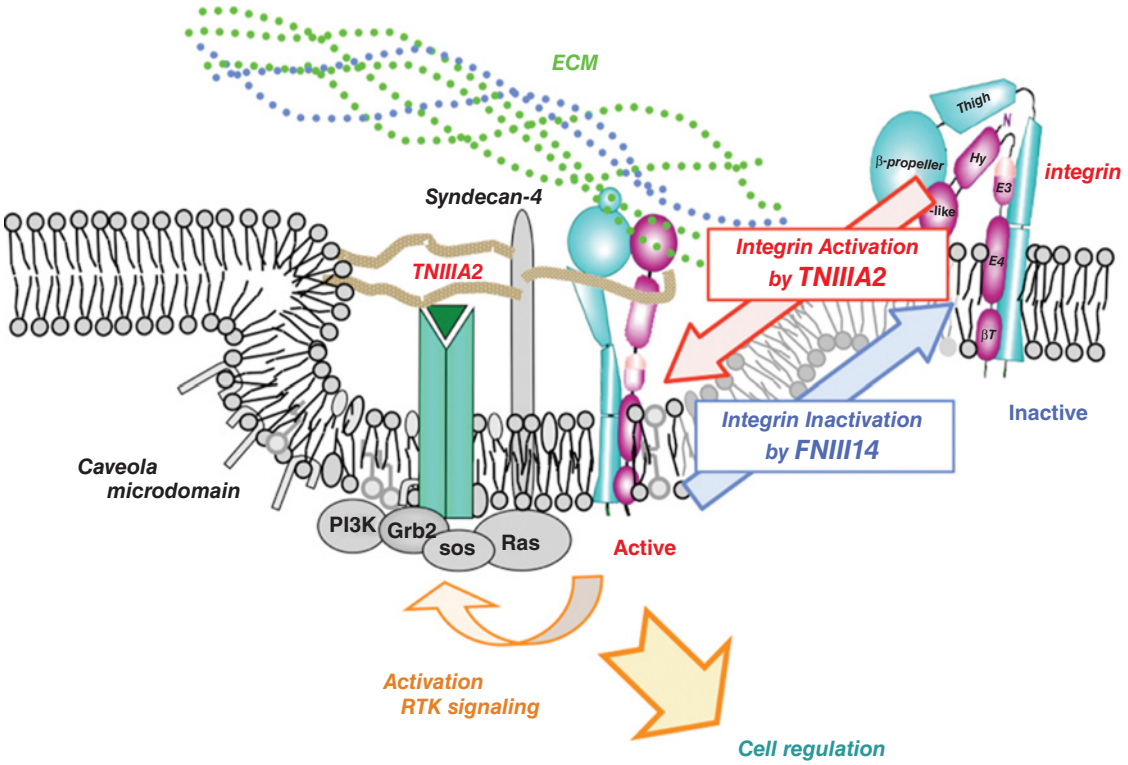

FIGURE 24.4 The intrinsic mechanism of cell regulation mediated through integrin activation and inactivation, induced by TNIIIA2 and FNIII14.

previously found antiadhesive peptide FNIIIA4 from fibronectin and reported that its antiadhesive effect is due to $\beta 1$-integrin inactivation. Therefore, it is expected that combined administration of antiadhesive peptide FNIII14 with anticancer drug administration might give a complete eradication of AML.

On the basis of this concept, we first examined the in vitro effect of FNIII14 on CAM-DR of hematopoietic tumor cells. When human AML cell line U937 cells were seeded on a fibronectin-coated plate and treated with the anticancer drug cytosine arabinoside (Ara-C), their viability was significantly higher than that of cells seeded on BSA-coated plate (Fig. 24.5). This suggests that U937 cells seeded to fibronectin-coated plate acquired CAM-DR through adhesion to fibronectin. The increased viability of cells on the fibronectin substrate was completely abrogated by addition of antiadhesive peptide FNIII14 (Fig. 24.5). Similar observations were obtained using other hematopoietic tumor cell line HL60 and fresh leukemic cells from six patients (data not shown). This in vitro experiment shows that the antiadhesive peptide FNIII14 might be effective in inhibition of CAM-DR.

We then examined the effect of this peptide in AML chemotherapy in an in vivo experimental system. An AML mouse model has been constructed by intravenous injection of human AML cell line U937 into the X-ray-irradiated SCID

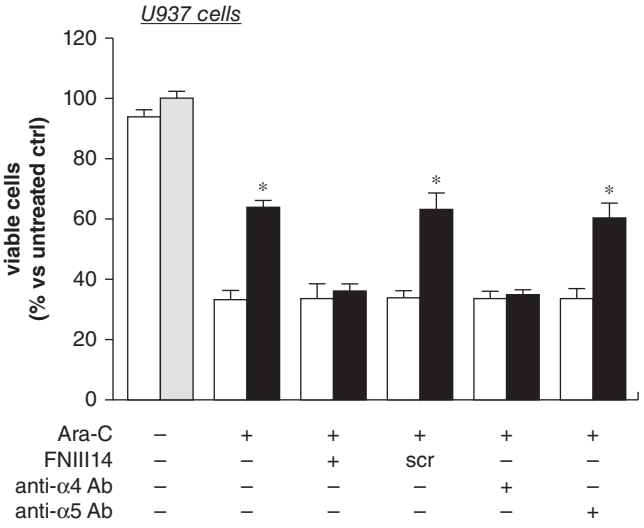

FIGURE 24.5 Effect of FNIII14 on the chemoresistance of leukemic cell lines induced by the interaction between integrin $\alpha 4\beta 1$ and fibronectin. U937 cells were seeded on 96-well plates coated with BSA (□) or fibronectin (■) and then incubated in the absence or presence of Ara C, FNIII14, FNIII14scr, anti-$\alpha 4$-integrin monoclonal antibody, and anti-$\alpha 5$-integrin monoclonal antibody. After 24 h, the viable cell number was evaluated by MTT assay. ($^*P < 0.05$.)

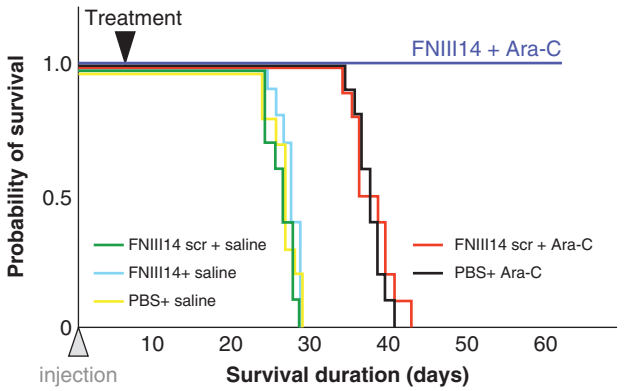

FIGURE 24.6 Combination therapy using FNIII14 and Ara C. Kaplan–Meier survival curves of mice treated with PBS and saline (yellow line), PBS and Ara-C (black line), FNIII14scr and saline (green line), FNIII14scr and Ara-C (red line), FNIII14 and saline (light blue), and FNIII14 and Ara-C (blue line) are shown. U937 cells were injected from tail vein, and Ara-C and peptide was administrated 7 days after U937 cell transplantation. (n = 6 for each group.)

mouse [15]. In this model mice, AML cells were detected only in bone marrow at days 7 after transplantation of AML cells, and all the mice consequently died by systemic dissemination of AML cells around day 25 (data not shown). As shown in figure 6, the mean survival of the mice administrated with vehicle, FNIII14, or FNIII14scr without Ara-C treatment, was around day 25. When the AML model mice were treated with anticancer drug Ara-C, their survival durations were prolonged, but all mice died around 35 days after U937 cell transplantation. In contrast, all of the mice treated with FNIII14+Ara-C survived even at the end of the observation period, day 62 (Fig. 24.6). In the FNIII14+Ara-C treated group, AML cells residing in bone marrow, which were detected at day 7 after transplantation, disappeared completely at day 62. Meanwhile, there were no differences in the number of white blood cells, neutrophils, lymphocyte, and platelets when the complete blood count was monitored for 11 days in the mice administrated with Ara-C alone or FNIII14+Ara-C (data not shown). Taken together, the combined administration of anticancer drug with β1-integrin inactivator "peptide FNIII14" might be a promising treatment to improve the prognosis of AML patients.

24.3 FORCED ADHESION TO FIBRONECTIN THROUGH SUSTAINED ACTIVATION OF β1-INTEGRIN BY TNIIIA2 CAUSED APOPTOSIS IN HEMATOPOIETIC TUMOR CELLS

One of extracellular matrix proteins, TN-C, is constitutively expressed in adult lymphoid tissues [16, 17]. Moreover, upregulation of TN-C expression in pathological states including tumorigenesis has been reported [18, 19]. These observations imply that the bone marrow of patients with hematopoietic malignancy probably show highly increased expression of TN-C. As described in Section 24.1, peptide TNIIIA2 derived from TN-C has the ability to enforce cell adhesion by activating β1-integrin. Therefore, we are interested in the effect of TNIIIA2 on hematopoietic tumor cells.

To elucidate this effect, we used Burkitt's lymphorma cell line Ramos cells, in which integrin $\alpha 4\beta 1$ is highly expressed as the major fibronectin receptor, but is incapable of contributing to cell adhesion because these receptors are ordinarily in the inactive state. When Ramos cells were enforced to adhere to the fibronectin by activating integrin $\alpha 4\beta 1$ with TNIIIA2, the number of viable cells was unexpectedly decreased without any antitumor drug administration (Fig. 24.7). This decrease in Ramos cell survival, induced by TNIIIA2, was almost completely blocked by concomitant administration of peptide CS1, an integrin-$\alpha 4\beta 1$ antagonist (Fig. 24.7). Addition of TS2/16, an anti-β1 integrin monoclonal antibody that has the ability to activate β1-integrin, also decreased Ramos cell survival (data not shown). Since this decrease in Ramos cell viability was accompanied by cell surface expression of phosphatidylserin (data not shown) [20], and since Z-VAD, a general caspase inhibitor, could completely cancel the effect of TNIIIA2 on Ramos cell viability (data not shown) [20], TNIIIA2 induced apoptosis in Ramos cells.

We next attempted to determine whether the induction of apoptotic cell death by enforced cell adhesion was specific in Ramos cells. When TNIIIA2 was added to U937 cell culture, these cells were forced to adhere to fibronectin substrates via activation of integrin $\alpha 4\beta 1$ (Fig. 24.8a,b). Under these experimental conditions, induction of adhesion and resulting decrease in viable cell number were observed in TNIIIA2-treated U937 cells. Moreover, we also employed several hematopoietic tumor cells with various expression levels of $\alpha 4\beta 1$ [20] and showed that TNIIIA2-mediated enforced cell adhesion through vigorous and sustained activation of β1-integrin leads apoptotic cell death in non-adherent hematopoietic tumor cells.

These observations seem to be inconsistent with the concept of CAM-DR as shown in Section 24.3. This discrepancy might be explained by the extent of cell adhesion to fibronectin substrate. In other words, "moderate adhesion" of tumor cells to fibronectin seems to confer their continuous survival. Actually, in a series of previous reports that mentioned CAM-DR, chemoresistance in tumor cells was induced by spontaneous cell adhesion to fibronectin, in which no artificial integrin activators were added in their experimental conditions [14,21–23]. In contrast, the peptide TNIIIA2 has the potent ability to induce β1-integrin activation and keep it for a long period [10], although cytokine-stimulated cell adhesion to fibronectin is rapid (reaching a maximum

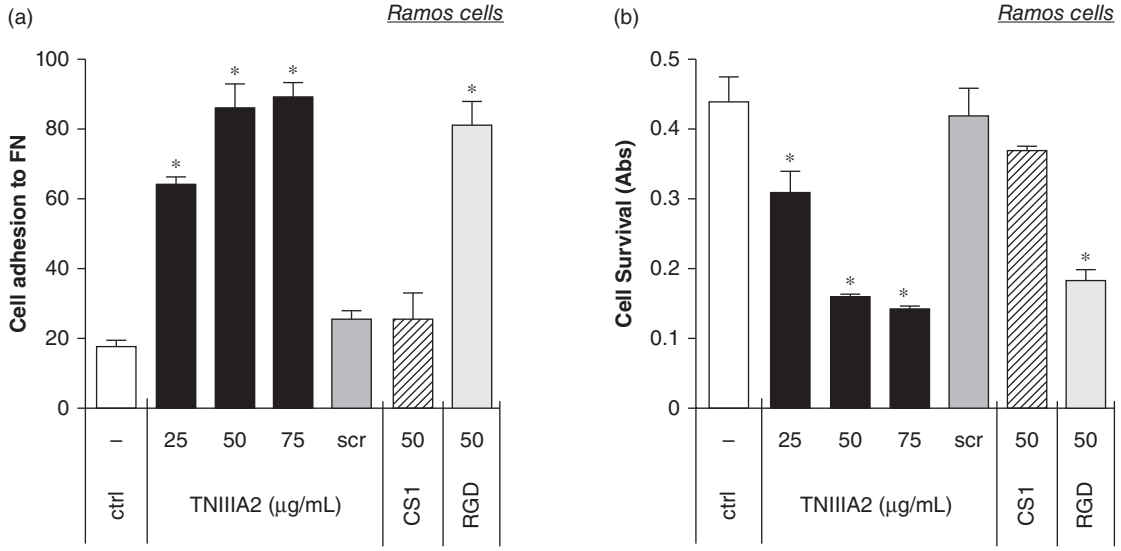

FIGURE 24.7 Effect on cell growth of forced adhesion of Ramos cells to FN. (a) Results of cell adhesion assay. The percentage of adherent cells is shown relative to the total number of cells seeded into the well. (b) Effect of induced adhesion to FN on Ramos cell survival is shown. (CS1 = connecting segment 1 peptide.)

within 30 min) but transient (returning to basal levels after several hours) [24]. From these facts, we presumed that this difference in the state of β1-integrin activation caused the difference in adhesion-induced cellular responses. It appears likely that CAM-DR may be induced through weak or moderate adhesion to fibronectin, and that tight and prolonged adhesion may turn on the proapoptotic signaling pathways, although it could not be ruled out the possibility that physiological amount of TNIIIA2 released in vivo may contribute to the induction of CAM-DR.

24.4 TNIIIA2-INDUCED ACTIVATION OF β1-INTEGRIN ENHANCES INTRACELLULAR DRUG ACCUMULATION IN HEMATOPOIETIC TUMOR CELLS

During cancer chemotherapy, development of multidrug resistance in tumor cells is a major complicating factor in tumor eradication. Acquisition of multidrug resistance might be induced by high-dose and long-term exposure to antitumor drugs. As mentioned above, TNIIIA2 could confer sensitivity

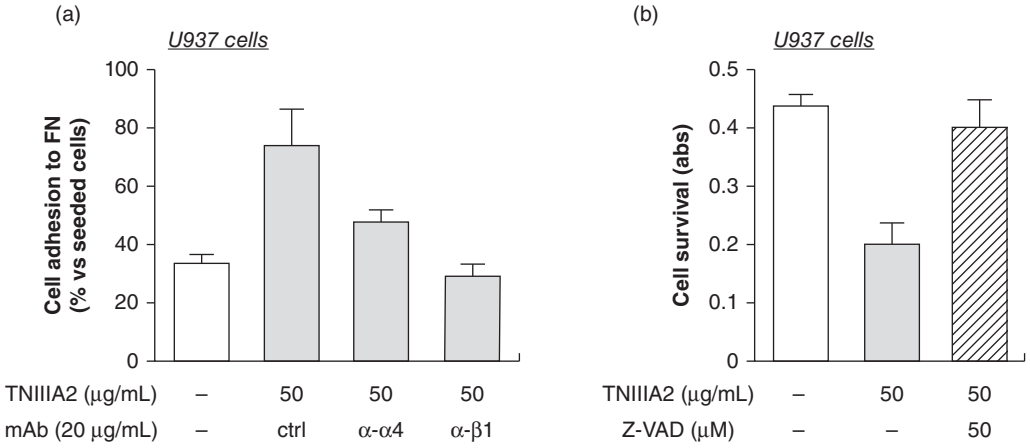

FIGURE 24.8 Peptide TNIIIA2-induced suppression in cell survival of U937 hematopoietic tumor cell. (a) U937 cells suspended in serum-free medium were seeded on fibronectin-coated plate in the presence or absence of TNIIIA2 and anti-integrin antibodies. Cell adhesion activity at 30 min after seeding was evaluated. (b) U937 cells were seeded as described above in the presence or absence of TNIIIA2 and Z-VAD. Viable cell number at 48 h after seeding was evaluated by WST assay.

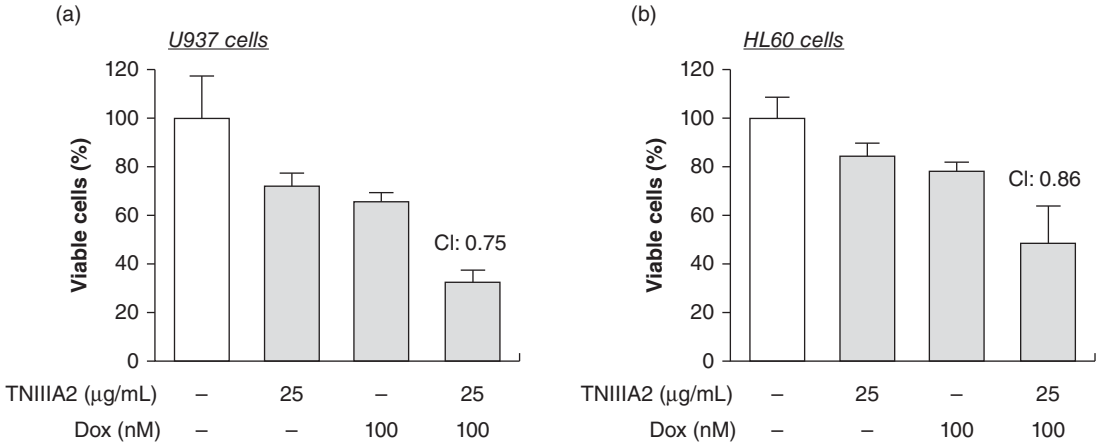

FIGURE 24.9 TNIIIA2-induced increase in chemosensitivity to Dox in hematopoietic tumor cells. U937 cells (a) and HL60 cells (b) were seeded in the presence or absence of TNIIIA2. Then Dox was added to culture medium. Viable cell number was evaluated by WST assay and then combination index (CI) was calculated (CI = [viability at Dox^+/$TNIIIA2^+$]/([viability at Dox^+] × [viability at $TNIIIA2^+$])). (According to C1, notations 1, >1, and <1 reveal additive, antagonistic, and synergistic, respectively.)

for apoptotic cell death to hematopoietic tumor cells through induction of tight and prolonged cell adhesion. Therefore, it is possible that the combined administration of TNIIIA2 with anticancer drug increases the efficacy of chemotherapy.

To test a possible clinical usefulness of TNIIIA2, U937 hematopoietic tumor cells were treated with the anticancer drug doxorubicin (Dox) in the presence or absence of TNIIIA2. When U937 cells were treated with Dox alone, around 30% decrease in their survival was observed (Fig. 24.9a). Approximately 70% decrease in the viable cells was observed by treatment with Dox in combination with TNIIIA2 (Fig. 24.9a). Almost the same results were obtained using another AML cell line HL60 (Fig. 24.9b). When synergism between TNIIIA2 and Dox was evaluated by calculation of "combination-index (CI)" [25], the effect of TNIIIA2 on the enhancement of anti-tumor activity of Dox was not additive, but synergistic. These observations indicate the possibility that TNIIIA2 could enhance the effect of an anticancer drug.

In order to clarify the mechanism underlying enhanced chemo-sensitivity in TNIIIA2-treated hematopoietic tumor cells, we next examined the level of intracellular drug accumulation in these cells. Flow cytometric analysis showed that the level of intracellular Dox was elevated when β1-integrins of U937 and HL60 cells were activated by TNIIIA2 (Fig. 24.10a,b). Increase in the Dox accumulation was dependent on the duration and dosage of TNIIIA2 administration (unpublished observation). Furthermore, elevation in the level of intracellular Dox was also elevated

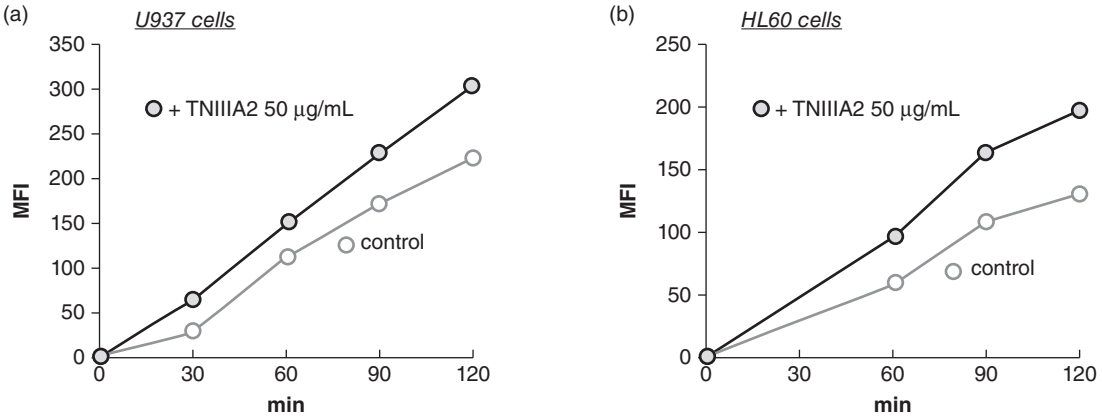

FIGURE 24.10 TNIIIA2-induced intracellular Dox accumulation in hematopoietic tumor cells. U937 cells (a) and HL60 cells (b) were seeded in the presence or absence of TNIIIA2. Then Dox was added to culture medium. Intracellular Dox level was analyzed by FACS.

by the β1-integrin-activating monoclonal antibody (unpublished observation). These results suggest that TNIIIA2-induced β1-integrin activation renders hematopoietic tumor cells chemosensitive through an intracellular accumulation of anticancer drug level. Although the mechanisms underlying TNIIIA2-mediated intracellular drug accumulation are still unclear, TNIIIA2 might be useful for tumor chemotherapy.

24.5 TNIIIA2-MEDIATED β1-INTEGRIN ACTIVATION ACCELERATES ERYTHROID DIFFERENTIATION OF HEMATOPOETIC TUMOR CELLS

Tumor cells are characterized not only by elevated proliferation and immortality. Poor differentiation is also accepted as one of intrinsic character of tumor cells. Therefore, differentiation-inducing therapy has attracted attention as a possible clinical approach of anticancer treatment.

Differentiation of hematopoietic stem and progenitor cells occurs ordinarily in bone marrow and fetal liver. Adhesive interactions between hematopoietic stem or progenitor cells and the surrounding microenvironment play a pivotal role in the regulation of appropriate proliferation and differentiation [11,26–30]. In the case of erythropoiesis, cell adhesion of erythroid progenitor cells via the fibronectin receptors integrin $\alpha4\beta1$ and $\alpha5\beta1$ has been reported as a key event for their differentiation [31–39]. However, the substantial function of these fibronectin receptors in erythroid differentiation was not fully understood.

As shown in Fig. 24.10a,c, we demonstrated that TNIIIA2 is able to accelerate hemin-induced erythroid differentiation in K562 leukemic cells, by the enhancement of cell adhesion. TNIIIA2-induced acceleration of erythroid differentiation was significantly revoked by antagonists such as anti-α5-integrin antibody and RGD peptide. Moreover, peptide FNIII14, which has an ability to reverse β1-integrin activation, abrogated an enhanced differentiation of K562 cells induced by concomitant administration of hemin with TNIIIA2 (Fig. 24.11a,c). These results suggest that the TNIIIA2 is able to work as an accelerator for hemin-induced erythroid differentiation, and this effect of TNIIIA2 is mediated through enhanced adhesion of K562 cells to fibronectin via β1-integrin activation.

K562 cells express only integrin-$\alpha5\beta1$ as fibronectin receptors [40]. In fact, TNIIIA2-mediated forced cell adhesion of K562 cells was suppressed only by the antagonist for integrin $\alpha5\beta1$ (Fig. 24.11b). No effect of the antagonists for integrin $\alpha4\beta1$ was observed in TNIIIA2-induced K562 cell adhesion (Fig. 24.11b). However, the TNIIIA2-mediated acceleration of hemin-induced erythroid differentiation was significantly blocked not only by an antagonist for integrin-$\alpha5\beta1$ (RGD peptide) but also by an antagonist for integrin-$\alpha4\beta1$ (CS1 peptide) (Fig. 24.11d). In order to resolve this contradiction, changes in the expression of α4-integrin during hemin-induced erythroid differentiation were evaluated. As a result, expression of α4-integrin became detectable 1 day after initiation of K562 differentiation, when these cells were concomitantly administrated with TNIIIA2 (data not shown) [41]. TNIIIA2-induced upregulation of α4-integrin was attenuated by α5-integrin agonist RGD. There was no difference in the level of α4-integrin expression when K562 cells were stimulated with hemin alone (data not shown) [41]. From these results, forced adhesion to fibronectin substrate through integrin-$\alpha5\beta1$ induces expression of integrin-$\alpha4\beta1$ in K562 erythroid progenitor cells, and this seems to be a prerequisite for acceleration of hemin-stimulated erythroid differentiation. Thus, modulation of the integrin activation status was implicated in regulation of erythroid differentiation. Further investigation would be necessary to ascertain if the proadhesive effect of TNIIIA2 could commonly play a role in hematopoiesis in vivo.

24.6 TNIIIA2-MEDIATED β1-INTEGRIN ACTIVATION LEADS DEREGULATED HYPERPROLIFERATION TO NONTRANSFORMED FIBROBLASTIC CELLS

Disruption of adhesive interaction between β1-integrin and fibronectin induces apoptosis, termed *anoikis*, in adherent nontransformed cells such as fibroblastic cells and epithelial cells [1, 2]. When NIH/3T3 cells were cultured in the serum-deprived conditions, their viability became decreased (Fig. 24.12a, gray line). Since this decrease in the number of viable cells was significantly abrogated by general caspase inhibitor Z-VAD (Fig. 24.12b, black line) and the β1-integrin-activating mAb, it was due to induction of anoikis elicited by the serum deprivation. Proadhesive peptide TNIIIA2 completely rescued NIH/3T3 cells from anoikis (Fig. 24.12a,b). This "cell-protective effect" of TNIIIA2 was abolished by antagonists for integrin-$\alpha5\beta1$, such as anti-α5-integrin antibody and RGD peptide (Fig. 24.12b). These results suggested that TNIIIA2 has a potential to render normal fibroblastic cells resistant to anoikis by its effect on β1-integrin activation.

On the other hand, platelet-derived growth factor (PDGF) acts as a potent mitogen stimulating cell survival and proliferation for both untransformed and transformed mesenchymal cells. PDGF ligation to its receptor PDGFR induces the activation of its intrinsic tyrosin kinase, which, in turn, activates the Ras/MAP kinase pathway [42]. It has been established that cell adhesion to ECM through integrins is also indispensable for cell proliferation [43]. We recently found that TNIIIA2 significantly accelerates PDGF-induced proliferation of NIH/3T3 cells adhered to fibronectin substrate (Fig. 24.13). PDGF could enhance cell proliferation in a dose-dependent manner, whereas excessive concentration of

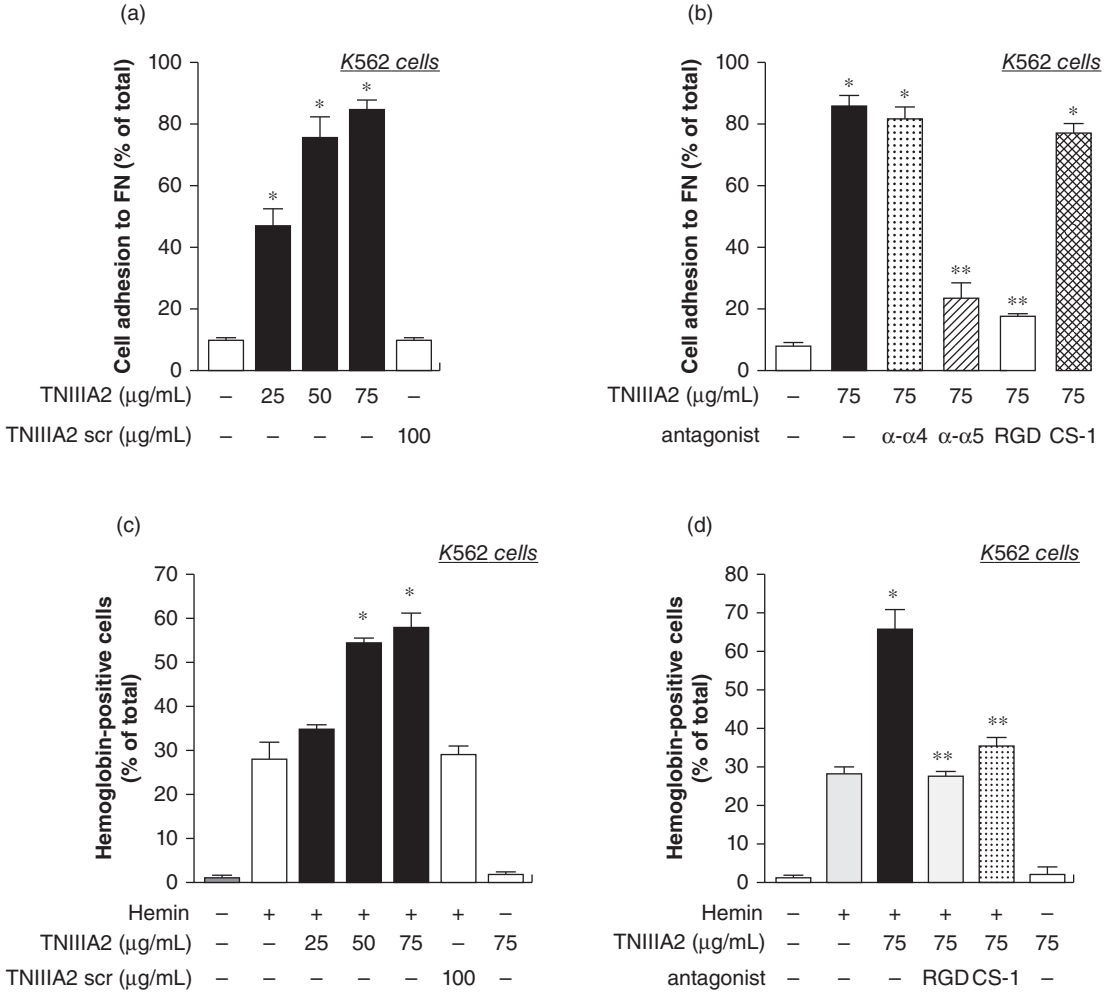

FIGURE 24.11 Adhesion-dependent acceleration of hemin-induced erythroid differentiation of K562 cells. (a) Dose dependence of TNIIIA2-induced adhesion of K562 cells. (b) Effects of antagonist for $\alpha 5\beta 1$-integrin (α-$\alpha 5$ Ab and RGD) and $\alpha 4\beta 1$-integrin (α-$\alpha 4$ Ab and CS1) on TNIIIA2-induced adhesion to FN in K562 cells. (c) Effect of TNIIIA2 on erythroid differentiation of K562 cells, induced by hemin. (d) Effects of antagonist for $\alpha 5\beta 1$-integrin (RGD) and $\alpha 4\beta 1$-integrin (CS1) on TNIIIA2-induced acceleration of erythroid differentiation.

PDGF (>10 ng/mL) showed no further enhancing effect on cell proliferation. However, once the cells face TNIIIA2, in the presence of PDGF, proliferation of PDGF-stimulated cells became more aggressive (Fig. 24.13). Almost the same results were also obtained even when TNIIIA2 was replaced by 9EG7, an anti-$\beta 1$-integrin monoclonal antibody that has the ability to activate $\beta 1$-integrin (Fig. 24.13). Combined administration of PDGF with Mg^{2+} that also has ability to activate $\beta 1$-integrin shows enhanced cell proliferation if compared with that of NIH/3T3 stimulated with PDGF solely (Fig. 24.13). In the series of experiments, both collocalization of PDGFR with $\beta 1$-integrin and enhancement of PDGFR autophosphorylation were also observed in NIH/3T3 cells stimulated with PDGF in combination with TNIIIA2 (data not shown). These results suggested that hyperproliferation of NIH/3T3 cells was caused by TNIIIA2-mediated potentiated and sustained activation of $\beta 1$-integrin. Since TNIIIA2 originates from tenascin-C that is highly expressed in tumor and tumor stromas, TNIIIA2-induced deregulated cell proliferation might be associated with tumorigenesis and/or tumor progression. Therefore, the active site of TNIIIA2 in the tenascin-C protein molecule might be a promising target for reducing cancer promotion.

24.7 CONCLUDING REMARKS

Adhesive interactions of cells with surrounding ECM through integrins are important to a variety of cellular events, although hormonal factors are known to function as a ligand

for cell surface receptors regulating cellular events. However, no reports referring to the "activation status" of β1-integrin in regulation of cellular responses have appeared in the literature. In this chapter, we mentioned the possibility that the changes in the state of β1-integrin activation contribute to the modulation of various cellular functions. Further investigations of the role of integrin activation status in disease outbreak and its progression might be attractive. Peptides FNIII14 and TNIIIA2, which enable us to control activation status of β1-integrins, either positively or negatively, might become beneficial tools.

It has generally been considered that the activation of integrins is regulated by *inside–out* signals from the cell interior. This signaling switch is triggered by an extracellular soluble agonist such as certain chemokines or growth factors. On the other hand, several artificial factors are known to activate β1-integrin. These include divalent cations such as Mn^{2+} and Mg^{2+} and anti-β1-integrin mAbs, which bind directly to the extracellular domain of β1-integrin. Cell surface molecules tetraspan/TM4SF, CD87/uPAR, and CD47/IAP are also known to modulate integrin activity via interaction with extracellular domains of β1-integrin. For example, CD151 constitutively associates with integrin-α3, and serves as a constitutive potentiator for $\alpha 3\beta$1-integrin activity through a direct association [44, 45]. We previously demonstrated that TNIIIA2 binds to cell surface syndecan-4 and that the formed TNIIIA2/syndecan-4 complex could activate β1-integrin by their lateral interaction to the ectodomain

of β1-integrin. This *outside–out* signaling might contribute to keep β1-integrin conformation active [10]. This relationship among TNIIIA2, syndecan-4, and β1-integrin may provide another example of the regulatory roles of extracellular domains in cell adhesion signaling [46–48].

In this chapter, we referred to the effect of two peptides containing matricryptic sites of fibronectin and tenascin-C, respectively. These bioactive regions might have been reexposed when parental ECM was degraded by inflammatory proteinases, which were reportedly secreted in pathological conditions including cancer. Therefore, at the site of cancer promotion and progression, these matricryptic sites possibly play important roles for inducing pathological cellular responses. Important implication of the "activation status of β1-integrin" in the modulation of cellular responses has been shown in this chapter. Thus, these matricryptic active sites in FNIII14 and TNIIIA2 might be a promising target for developing novel anticancer approaches.

DEPTH PROFILE OF Kr^+-IRRADIATED CHITOSAN

Kazunaka Endo

Division of Colloid and Interface Science, Research Institute for Science and Technology, Tokyo University of Science, Japan

25.1 INTRODUCTION

Chitosan is especially known to be a most powerful adsorbent of natural origin and is widely used for the prevention of water pollution by highly toxic chlorinated aromatic compounds and metal ions [1]. Chitosan is inexpensive, environmentally benign, harmless to humans, and a hugely obtainable biomass, which makes it very promising and attractive for use in many applications. It is also found in many biomedical applications, including tissue engineering, owing to its biocompatibility, low toxicity, and degradation in the body by enzymes such as chitosanase and lysozyme, which has opened up avenues for modulating drug release in vivo in the treatment of various diseases. These chitosan-based delivery systems range from microparticles to nanoparticles to gels and films. Ion beam irradiation is also a useful method for modification of surface properties, such as wear resistance, corrosion resistance, and biopolymer compatibility. A composite film of the chitosan/carbon nanotube complex has been proposed as a material of blood biocompatibility, due to the advantage of ion beam irradiation [2].

On the other hand, the use of C13 NMR and X-ray photoelectron spectral analysis for chitosan has been studied in an attempt to clarify the electronic structure in the formation of properties of biological molecules from the DFT calculations [3], and to understand the changes in adsorption behavior of chemically modified biopolymer chitosan (cross-linked biopolymer) [4].

In the present study, we aim to analyze Raman and valence X-ray photoelectron spectra of chitosan film with Kr^+ ion beam irradiation. In order to simulate the experimental Raman and valence X-ray photoelectron spectra (VXPS) of the Kr^+ ion-irradiated film, we performed quantum-chemical calculations at B3LYP/6−31G** level using the GAUSSIAN 09 program [5].

25.2 COMPUTATIONAL METHOD

The first-geometry of model molecules {chitosan monomer [H-($C_6H_{11}NO_4$)-O-H] or dimer [H-($C_6H_{11}NO_4)_2$-O-H], adamantine derivative [$C_{10}H_{12}(CH_3)_4$] for diamondlike carbons, adamantine ($C_{10}H_{16}$) for amorphous carbons, pyrene ($C_{16}H_{10}$) for graphite} was optimized at AM1 method in MOPAC software. We optimized these molecules using a second-geometry method within hybrid density functional theory, which was Becke's three-parameter hybrid functional model [6], with the correlation functional model due to Lee et al. [7] (B3LYP), using 6-31G** bases. In the optimization, we adopted eigenvalues and eigenvectors of these molecules in order to simulate the valence X-ray photoelectron spectra, as considered by Koopmans' theoremlike method. The intensity of valence XPS was estimated from the relative photo-ionization cross section for Mg Kα radiation using the Gelius intensity model [8,9]. In the case of the relative atomic photoionization cross section, we used the theoretical values from Yeh [10].

To simulate the valence XPS, we started with a superposition of peaks centered on each vertical ionization potential (VIP). As described previously, each peak is represented by a Gaussian curve. In the case of the linewidth [i.e., $WH(k)$], we used $WH(k) = 0.10I_k$ (proportional to the ionization energy) for valence XPS.

In order to account for and somewhat quantify solid-state effects in chitosan, diamondlike carbon, amorphous carbon, and graphite in our investigations, we defined a quantity *WD* in our earlier work [11–14]. The quantity *WD* denotes the sum of the workfunction of the sample (*W*) and other energy effects (with *D* as delta), such as the polarization energy and so on. The *WD* can be estimated from the difference between experimental or theoretical electron binding energy (I_c or I_k) of model molecules, and the experimental core and valence electron-binding energy of the solid chitosan, diamondlike carbon, amorphous carbon, and graphite. In order to compare the calculated binding energy for the model molecules and the experimental binding energy of the solid substances, one has to shift each computed value (I_c or I_k) by a quantity *WD* as $I'_c(= I_c - WD)$ [or $I'_k(= I_k - WD)$], to convert to I'_c (or I'_k) on a common binding energy axis (relative to the Fermi level).

After the geometry optimization, in order to take into account the anharmonicity effects in the calculation of vibrational frequencies, one uses the scaling factor for the calculated frequencies. As Scott and Random [15] showed the scaling factor as 0.9614 in the calculations of vibrational frequencies at B3LYP/6-31G** level for some small molecules under the room temperature, we also estimated the scaling factor as 0.9614.

To simulate Raman spectra of the carbonized chitosan film, we started with a superposition of peaks centered on each Raman shift for the four model components of chitosan, diamondlike C, amorphous C, and graphite. Each peak was represented by a Gaussian curve. In the case of the linewidth [*WH*(*k*)], we used $WH(k) = 50\ cm^{-1}$ for Raman shift, in order to simulate the Raman spectrum of carbonized chitosan film.

All calculations were performed by ab initio hybrid calculations in the GAUSSIAN 09 program on a Panasonic CF-N9 notebook personal computer.

25.3 EXPERIMENTAL METHOD

We used commercially available chitosan (Wako Chemical co., Inc). Krypton ion bombardment was carried out at an energy of 150 keV with fluences ranging from 1.0×10^{13} to 1.0×10^{15} ions cm^{-2} in the base pressure of $<4.0 \times 10^{-4}$ Pa at room temperature using a RIKEN 200-kV low-current implanter. The beam current density used was about 0.2 μA cm^{-2} to prevent the specimen from heating.

Experimental photoelectron spectra of the samples were obtained on a JEOL JPS-9010 MC spectrometer using Mg-Kα (1253.6 eV) radiation. The applied power was operated at 15 kV, and 20 mA. The base pressure of the analysis chamber was $<8.0 \times 10^{-7}$ Pa. Energy-scale calibration was achieved using the Au $4f_{7/2}$(83.8 eV) transition. Dispersion compensation yielded an instrumental resolution of 0.5 eV from full width at half-maximum for the Ag3*d* line of silver. Multiscan averaging on a multichannel analyzer was used for

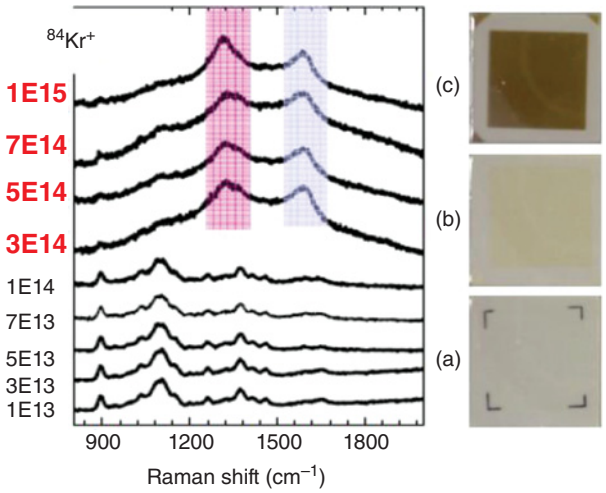

FIGURE 25.1 Raman shift of chitosan film modified by Kr^+ ion beam bombardments in the wavenumber range of 800–2000 cm^{-1} with surface color changes of a), b), and c) of chitosan films modified by Kr^+ ion beam bombardments at $1 \times 10^{13} - 1.0 \times 10^{14}$ (a), $3 \times 10^{14} - 5.0 \times 10^{14}$ (b), and $7 \times 10^{14} - 1.0 \times 10^{15}$ (c) ions cm^{-2}, respectively.

the valence band region, although a very low photoelectron emission cross section was observed in this range.

Raman shift measurements were performed on the samples in the wavenumber range from 800 to 2000 cm^{-1} using a Raman spectrometer (LabRAM, Jobin-Yvon, France) equipped with a HeNe ion laser (632.8 nm).

25.4 RESULTS AND DISCUSSION

We have studied the electronic state of chitosan from C13 NMR and X-ray photoelectron spectral analysis from the

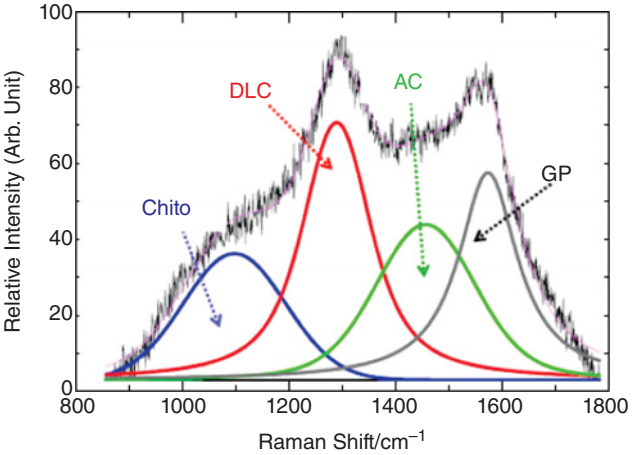

FIGURE 25.2 Experimental Raman spectra of carbonized chitosan film irradiated by Kr^+ ion beam at 1.0×10^{15} ions cm^{-2} (resolved spectra identified by four model components of chitosan, diamondlike C, amorphous C, and graphite).

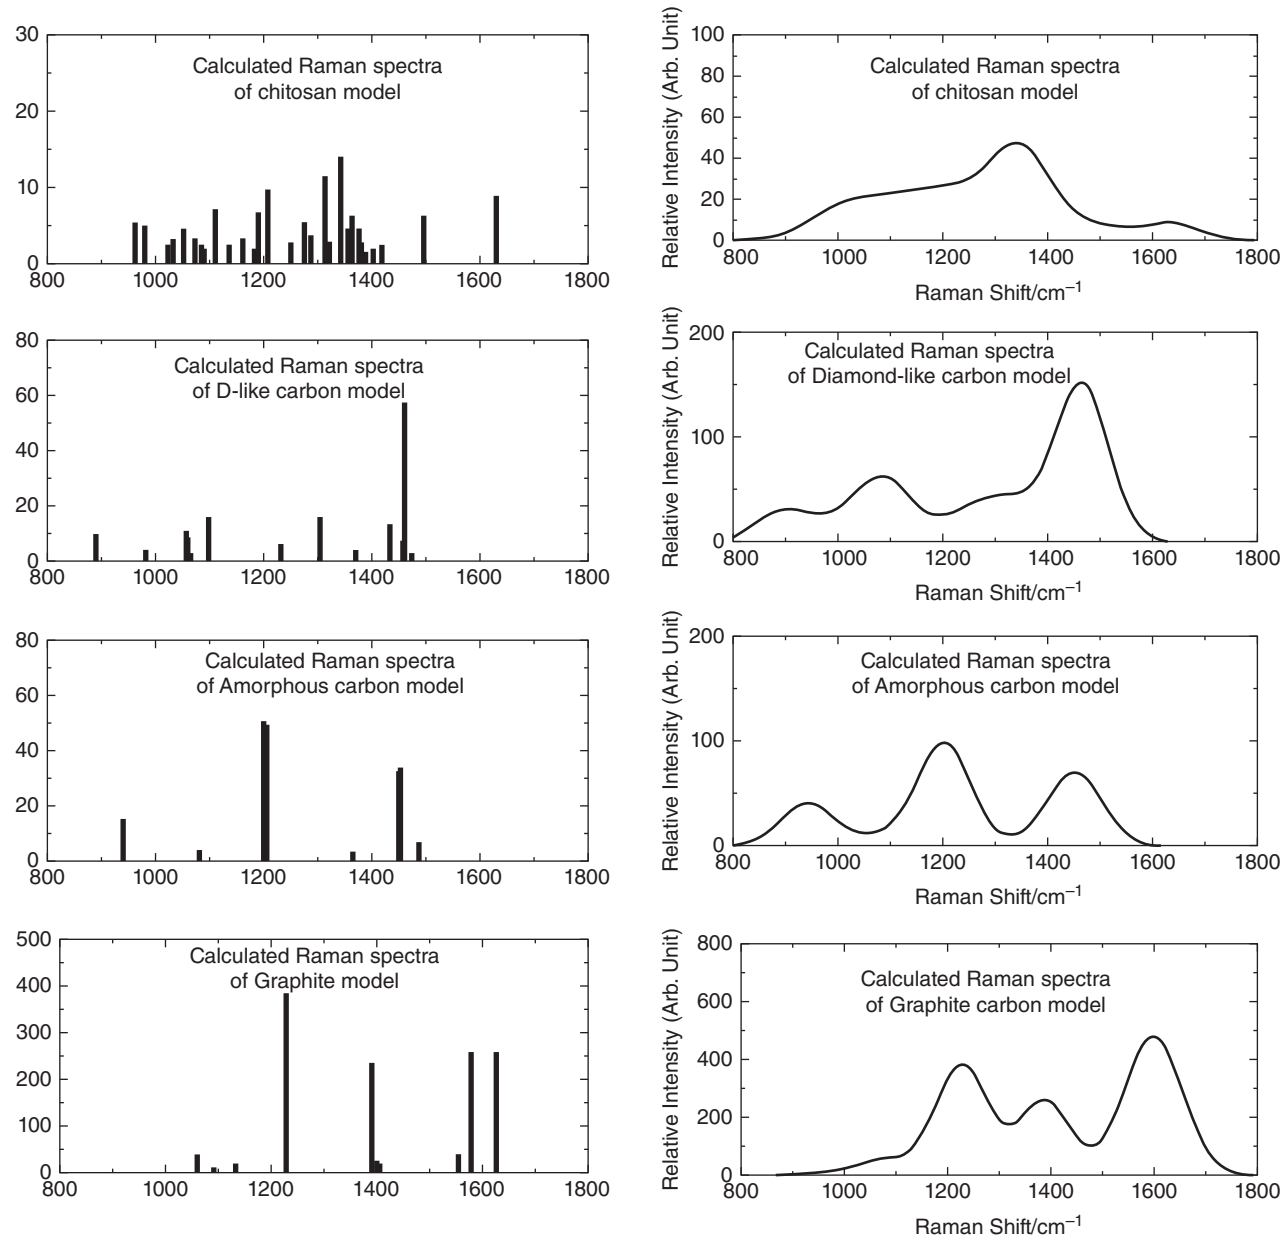

FIGURE 25.3 Simulated Raman spectra of chitosan ($C_6H_{13}NO_5$), diamondlike C [$C_{10}H_{12}(CH_3)_4$], amorphous C ($C_{10}H_{16}$), and graphite ($C_{16}H_{10}$) models for carbonized film.

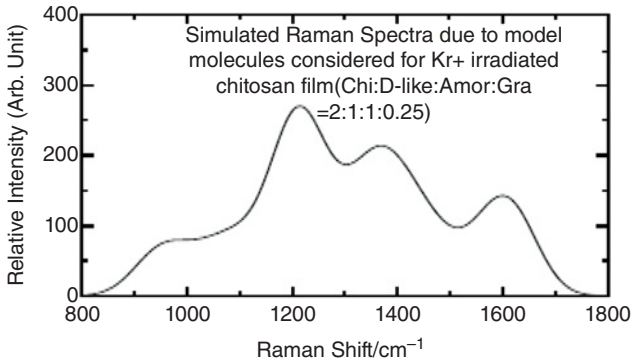

DFT calculations [3]. In this study, we focus on analysis of Raman and valence X-ray photoelectron spectra for carbonized chitosan film with Kr^+ ion irradiation to clarify the constitutional structure for the depth profile assignments of nm and μm orders.

25.4.1 Raman Shift Spectral Analysis

Figure 25.1 shows the Raman shift of chitosan films with Kr ion 150-keV energy bombardment at fluences ranging from 1.0×10^{13} to 1.0×10^{15} ions cm^{-2} in the base pressure of $<4.0 \times 10^{-4}$ Pa at room temperature. In the figure, the peak intensities of pure chitosan film appeared in the Raman shift range of 850–1700 cm^{-1} at 150 keV energy irradiation at fluences of 1.0×10^{13} –1.0×10^{14} ions cm^{-2}, while the strong double broader peaks at around 1300 and 1600 cm^{-1} are due to carbonized change [as seen in surface color changes of parts (b) and (c) of chitosan films on the right side in Fig. 25.1) with the 150 keV energy irradiation at fluences of 3.0×10^{14} ~1.0×10^{15} ions cm^{-2}.

In Fig. 25.2, we show the experimental Raman spectrum of carbonized film with Kr^+ ion bombardment at fluences of

(a) Simulated Raman Spectra of carbonized chitosan film

(b) Experimental Raman Spectra of carbonized chitosan film

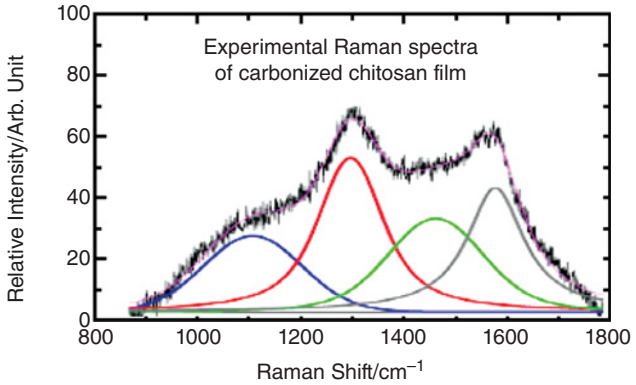

FIGURE 25.4 Simulated Raman spectrum of carbonized film on the upper side (a) with the experimental result on the lower side (b).

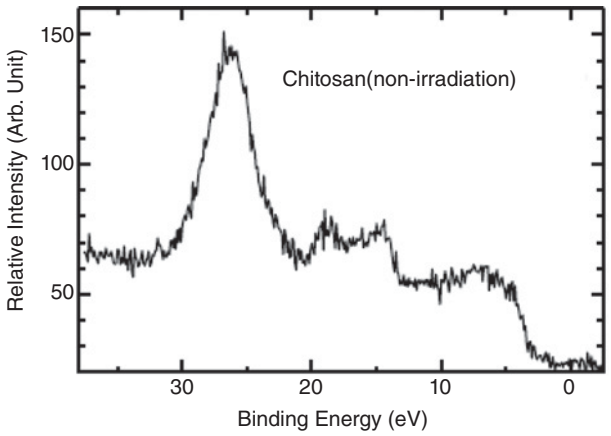

1.0×10^{15} ions cm^{-2}. We assumed the strong double broader peaks at around 1300 and 1600 cm^{-1} to be due to diamondlike carbon and graphite carbon, respectively, although the strong peak at around 1300 cm^{-1} was already analyzed as disordered carbons involved nanometer-scale cluster diamond crystalas [16]. In the figure, the Raman experimental spectrum of the carbonized film was shown to be due to four component contributions of chitosan (Chito), diamondlike carbon (DLC), graphite (GP), and amorphous carbon (AC). We thus performed the depth profile assignment at micrometer scale for the carbonized film from MO-DFT hybrid calculations at the B3LYP/6-31G** level using the model molecules {chitosan monomer [H-($C_6H_{11}NO_4$)-O-H] for chitosan, adamantane-derivative [$C_{10}H_{12}(CH_3)_4$] for diamondlike C, adamantane ($C_{10}H_{16}$) for amorphous C, pyrene ($C_{16}H_{10}$) for graphite} of the four components.

In order to analyze the experimental Raman spectrum of carbonized film in Fig. 25.2, we simulated four kinds of line spectra for Chito, DLC, AC, and GP models, respectively, on the left side in Fig. 25.3, while four kinds of broader simulated spectra enveloped with the Gaussian-line-shaped functions were given on the right side in the figure. Each Raman spectral intensity in Fig. 25.3 was obtained from Raman activity using the B3LYP/6-31G** method of four model molecules. This enabled us to obtain relative ratios of 2:1:0.5:0.375 for Chito:DLC:AC:GP of carbonization film from simulation Raman spectrum. In Fig. 25.4, we showed the simulated Raman spectrum of carbonized film on the upper side with the experimental result on the lower side. In the figure, the theoretical peak at around 1600 cm^{-1} due to graphite contribution corresponds well to the experimental one.

25.4.2 Valence Band X-Ray Photoelectron Spectral Analysis

It is well known that the XPS measurements are useful for examining the depth profile of materials at the nanometer level. In Fig. 25.5, we show experimental valence X-ray

(a) VXPS of chitosan film with nonirradiation.

(b) VXPS of chitosan film with 150 keV energy irradiation.

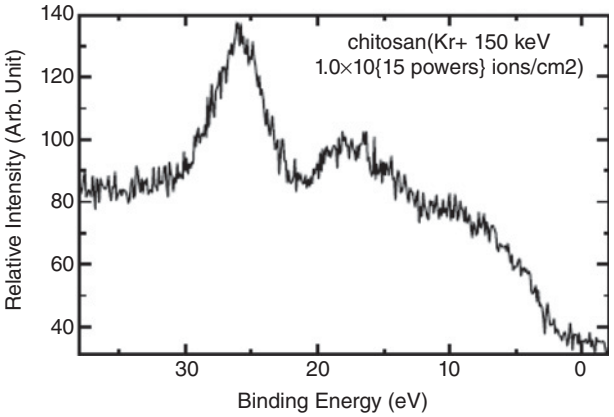

FIGURE 25.5 Experimental valence X-ray photoelectron spectra of chitosan films with non- and Kr^+ ion irradiation (1.0×10^{15} ions/cm^2) on the upper (a) and lower (b) sides, respectively.

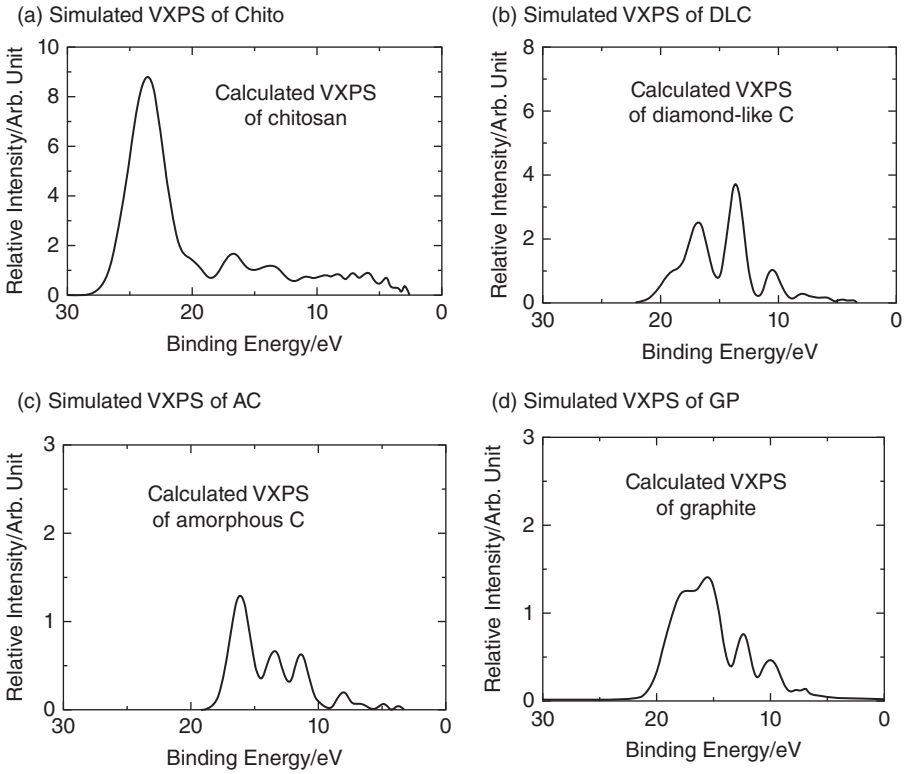

FIGURE 25.6 Simulated valence X-ray photoelectron spectra of chitosan ($C_{12}H_{242}N_2O_9$), diamondlike C ($C_{10}H_{12}(CH_3)_4$), amorphous C ($C_{10}H_{16}$), and graphite ($C_{16}H_{10}$) models for carbonized film.

photoelectron spectra of chitosan films with nonirradiation and Kr^+ ion irradiation (1.0×10^{15} ions/cm^2) on the upper (a) and lower (b) sides, respectively. The spectrum of the film with Kr^+ ion irradiation is seen to be lower broadening peak (at around 25 eV), due to presence of oxygen, than the spectrum with nonirradiation, so that carbonization of the Kr^+ ion-irradiated film can be predicted to have advanced by using the result of Raman spectral analysis for the irradiation film. Then, for the observed valence photoelectron spectrum of the carbonized film with the irradiation, we also determined that the spectrum is due to four component contributions of chitosan (Chito), diamondlike carbon (DLC), amorphous carbon (AC), and graphite (GP).

Figure 25.6 shows the simulated valence X-ray photoelectron spectra of chitosan ($C_{12}H_{242}N_2O_9$), diamondlike carbon [$C_{10}H_{12}(CH_3)_4$], amorphous carbon ($C_{10}H_{16}$), and graphite ($C_{16}H_{10}$) models as the four constitutional contributions for the carbonized film from B3LYP/6-31G**-level calculations. By considering the four component contributions, we obtained relative ratios of 1:0.5:0.5:1 at nanometer order for Chito:DLC:AC:GP of carbonization film, as shown in a simulated spectrum with the experimental one in Fig. 25.7.

We were thus able to analyze the carbonization of the chitosan film with Kr^+ ion bombardments as constitutional ratios of the depth profile from valence X-ray photoelectron and Raman spectral analysis at both nanometer and micrometer orders. Each constitutional ratio at micrometer order is chitosan:DLC:amorphous carbon: graphite carbon = 2:1:0.5:0.375, while the ratios at nanometer order are chitosan:DLC: amorphous carbon:graphite carbon = 2:1:1:2). The graphite constitution of the carbonized film is a small ratio of 0.375 in three kinds of carbon allotropes at micrometer order. On the other hand, the graphite ratio is around 2 times that of other carbon allotropes at nanometer order.

25.5 CONCLUSION

We analyzed valence X-ray photoelectron and Raman spectra of chitosan film modified by Kr^+ ion beam bombardments from B3LYP/6-31G**-level calculations. Experimental Raman spectra of the carbonized film with Kr^+ ion bombardment were found to be due to four component contributions of chitosan (Chito), diamondlike carbon (DLC), graphite (GP), and amorphous carbon (AC). By considering the four constitutional contributions, we performed depth profile assignments at nanometer and micrometer scales for the carbonized chitosan film in valence X-ray photoelectron spectroscopy and Raman shift experiments, respectively,

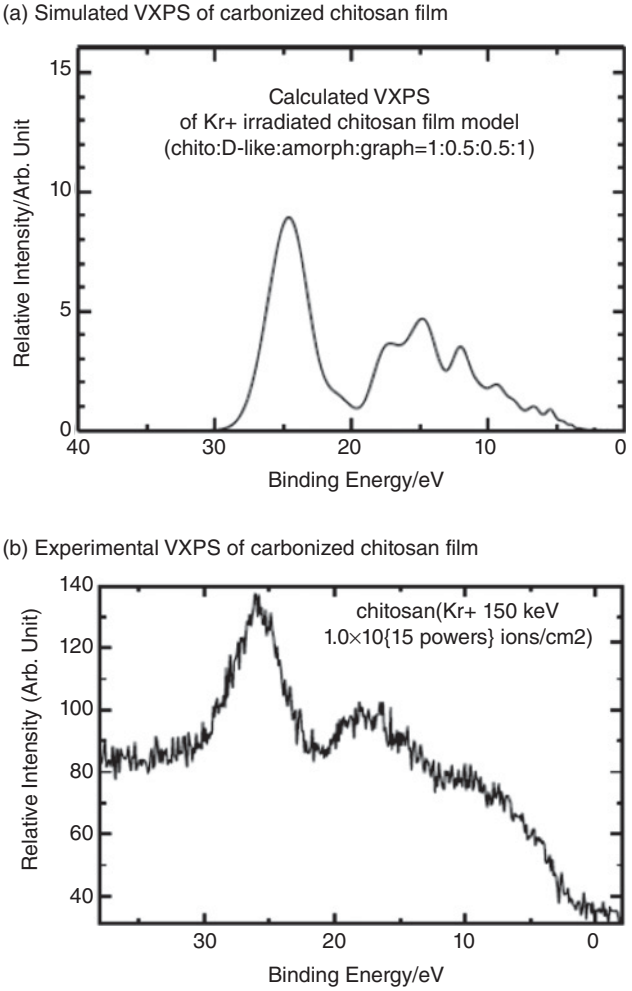

FIGURE 25.7 Simulated VXPS of carbonized film on the upper side (a) with the experimental result on the lower side (b).

from MO-DFT hybrid calculations in GAUSSIAN 09 using the model molecules. Carbonizations of the film by Kr^+ irradiation were obtained as Chito:DLC:AC :GP = 2:1:0.5:0.375 at micrometer order from Raman spectral analysis, while they were determined as Chito:DLC:AC:GP = 2:1:1:2 at nanometer order from valence X-ray photoelectron spectral analysis.

ELECTRONIC STRUCTURE OF CHITOSAN

Kazunaka Endo

Division of Colloid and Interface Science, Research Institute for Science and Technology, Tokyo University of Science, Japan

26.1 INTRODUCTION

Chitosan is especially known as a most powerful adsorbent of natural origin and is widely used for the prevention of water pollution by highly toxic chlorinated aromatic compounds and metal ions [1]. It is inexpensive, environmentally benign, harmless to humans, and a hugely obtainable biomass, which makes it very promising and attractive for use in many applications. Chitosan is easily prepared from chitin by deacetylating its acetoamide groups with a strong alkaline solution. Chitin is a highly chemically stable natural biopolymer isolated from crustaceans (lobster, shrimp, crab, etc.), some invertebrates, and fungi [2]. It is produced in vast amounts ($\leq 10^{11}$ tons per year), second only to cellulose on a worldwide basis [3]. On the other hand, cellulose is an essential consistent in the assembly of plant cell walls. It has the significant biological functions of providing cells with mechanical strength and framework. As one of the most abundant natural polymers, it has found many important applications in areas such as food, drug delivery systems, and textile and pulp–paper industries. Elucidation of the structural and dynamic properties of cellulose is, therefore, fundamental to understanding its role in plant cell walls and its functionality in applications.

We have selected chitosan and cellulose for study of C13 NMR and X-ray photoelectron spectra (XPS) for the following reasons. Both compounds play a well-known and important role in the electronic structure involved in the formation of biological molecules. To understand the changes in adsorption behavior of chemically modified biopolymers, cellulose and chitosan (cross-linked biopolymers), it is necessary to first study the chemical bonding of unmodified cellulose and chitosan. On the other hand, cellulose and chitosan have a compact geometric structure that is convenient for molecular orbital (MO) calculations, and possess four different oxygen atom–based functional groups that make cellulose and chitosan suitable models for X-ray photoelectron spectroscopy (XPS) study.

26.2 EXPERIMENTAL METHOD

We used commercially available cellulose (Sigma Chemical Co., Inc.), and chitosan (Wako Chemical Co., Inc., respectively. They were pressed into the pellets before XPS measurements.

The XPS of the pellets for cellulose and chitosan were obtained on a PHI 5400MC ESCA spectrometer, using monochromatized Al Kα radiation. The spectrometer was operated at 600 W, 15 kV, and 40 mA. Photon energy was 1486.6 eV. A pass energy of 37.75 eV was used for high-resolution scans in a valence band analysis (range 50 eV). The angle between the X-ray source and analyzer was fixed at 45°. Spot size was 3 × 1 mm. Dispersion compensation yielded an instrumental resolution of 0.5 eV from full width at half-maximum for the Ag3*d* line of silver. Multiscan averaging on a multichannel analyzer was used for the valence band region, although a very low photoelectron emission cross section was observed in this range. Gold of 2.0 nm thick was deposited on the pellets of the samples using an ion sputter unit (Hitachi E 1030) for the scanning electron microscope. A low-energy electron floodgun was used in order to avoid any charging effect on the surface of the sample. We used the Au4*f* core level of the gold decoration on

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

the samples as a calibration reference. The C1*s* line positions of $-CH_2OH$ groups in the samples could be fixed at 286.7 eV for cellulose and chitosan, respectively.

For the ^{13}C-NMR spectra, we referred to experimental results of (α-D-glucose, β-D-glucose, and β-D-glucosamine) [4–6], cellobiose [7], cellulose [7], and chitosan [8].

26.3 THEORETICAL BACKGROUND

26.3.1 NMR Chemical Shielding Tensor

We used the shielding tensor equation by the sum-over-states DFT perturbation theory. The shielding tensors [9] are given as follows:

$$\sigma_{uv} = \sigma_{uv}^{d} + \sigma_{uv}^{po} + \sigma_{uv}^{p1} \tag{26.1}$$

$$\sigma_{uv}^{d} = \alpha^2 \sum_{k} \left\langle k \left| h_{uv}^{11} \right| k \right\rangle \tag{26.2}$$

$$\sigma_{uv}^{po} = \alpha^2 \sum_{k} \sum_{j} \left\langle k \left| h_{u}^{01} \right| j \right\rangle \left\langle j \left| \left(\Lambda_j - \Lambda_k\right)_v \right| k \right\rangle \tag{26.3}$$

$$\sigma_{uv}^{p1} = 2\alpha^2 \sum_{k} \sum_{j} \left\langle k \left| h_{u}^{01} \right| a \right\rangle \beta_{ak}(v) \tag{26.4}$$

The Hamiltonians for the model molecule under a magnetic field are

$$h_u^{11} = \frac{\left(\vec{r} - \vec{R}_k\right)\left(\vec{r} - \vec{R}_N\right)\delta_{uv} - \left(\vec{r} - \vec{R}_N\right)_u \left(\vec{r} - \vec{R}_k\right)_u}{\left|\vec{r} - \vec{R}_N\right|^3} \tag{26.5}$$

$$h_u^{01} = \frac{cl_{Nu}}{\left|\vec{r} - \vec{R}_N\right|^3} \tag{26.6}$$

In this approach, an individual gauge for localized orbitals (IGLO) is implemented by the following transformation

$$B_{ak}(v) = \sum_{m} \left\{ \frac{\sum_{n} \left(-\frac{1}{2c}\langle a|l_{nv}|n\rangle + \sum_{i} \langle a|(\Lambda_n - \Lambda_j)_v|j\rangle\langle j|F^0|n\rangle \right) U_{nm}}{e_m - e_a - \Delta E_{m\to a}^{xc}} \right\} \times U_{km} \tag{26.7}$$

$$\left(\Lambda_j\right)_u = -\frac{1}{2c}\left(\vec{R}_j \times \vec{r}\right)_u \tag{26.8}$$

where F^{o} is the unperturbed DFT Hamiltonian operator, U_{km} is the unitary matrix of a transformation from the canonical to localized MOs, m corresponds to canonical MOs, and indices k, l, and n correspond to localized MOs.

26.3.2 XPS

For comparison between calculations for a single molecule of the model and experiments on a solid, we must shift each computed vertical ionization potential (VIP), I'_k by a quantity WD as $I_k = I'_k - WD$. To convert to ionization energy I_k relative to other energy effects, as stated in our previous studies [10, 11].

In order to obtain the accurate CEBEs, we used the generalized transition-state (GTS) method. In the GTS method, a team of coworkers [12] proposed the extension of Slater's transition-state method [13] and approximated the endothermicity ΔE=E(1)–E(0) by

$$\Delta E = [F(0) + 3F(2/3)]/4, \tag{26.9}$$

where $F(\lambda) = \partial E(\lambda)/\partial\lambda$, and λ ($0 < \lambda \leq 1$) is assumed to be a continuous variable, with $E(0)$ and $E(1)$ denoting the energies of the initial and final states, respectively. For example, for the ionization of an electron from molecular orbital (MO)ϕ_k of interest, λ represents the fraction of electron removed, and according to the Janak theorem [14], $F(\lambda)$ is the negative orbital energy $\varepsilon_k(\lambda)$. This procedure is applied in the following way. In the unrestricted generalized transition-state (uGTS) method, we removed $^2/_3\alpha$ electron from MO ϕ_k of interest.

For the VIPs of the valence regions, we used the so-called restricted diffuse ionizations (rDI) model, which was proposed for use with the HAM/3 method [15]. In the rDI model, half of the electron is removed evenly from the valence MOs and the negative charge of the resulting orbital energies correspond to calculated VIPs. This allows us to obtain all valence VIPs in a single calculation.

The intensity of valence XPS was estimated from the relative photoionization cross section for Al K radiation using the Gelius intensity model [16, 17]. For the relative atomic photoionization cross section, we used the theoretical values from Yeh [18].

26.4 CALCULATIONS

26.4.1 NMR Chemical Shielding Tensor

In the case of solving the nonlinear equations involving a Hartree–Fock-like DFT equation, we think it is the best way to select a better initial condition. We considered molecular models from X-ray diffraction data for α-D-glucose, β-D-glucose, β-D-glucosamine, and cellobiose, respectively.

First- and second-geometry optimizations for saccharide and monoaminosugar molecules were performed by the semiempirical AM1 method, and at HF/6-31G(*d*,*p*) level with the program GAUSSIAN 09 [19], respectively. In the case of the optimizations for the model molecules from the X-ray diffraction data, we fixed the positions of the atoms except for H atoms and optimized the positions of H atoms. For cellulose and chitosan, we adopted the model tetramer from X-ray diffraction data. We also performed the geometry optimization for the tetramer model of the biopolymers by using the AM1 method, and at the HF/6-31G(*d*,*p*) level. In the optimization of the molecules, we fixed the positions of the atoms except for H atoms in a glucose unit, and all proton positions were optimized. We performed the ^{13}C shielding calculations of the dimer model due to a deMon NMR program, after we removed the dimer model, cutting both glucose edges off from the tetramer. Reference standard tetramethyl silane (TMS) was optimized also under a similar calculation level. Figure 26.1 shows the model molecules of saccharide, monoaminosugar, cellulose, and chitosan, respectively.

Chemical shift calculations were carried out with the program deMon NMR [9]. We used the Perdew-Wang-91 (PW91) [20–22] exchange correlation potential, the approximation Loc.1 SOS-DFTP, and polarized valence double-ζ(DZVP) basis [23] of (621/41/1*) for C and N, and (41) for H with auxiliary fitting functions labeled (5,2;5,2) for C, N and O, and (5,1;5,1) for H, respectively.

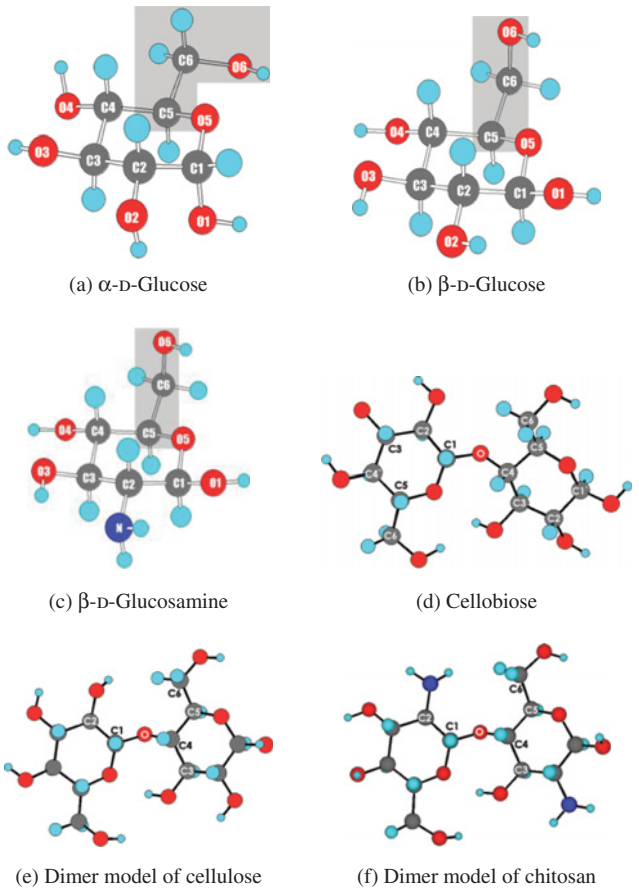

FIGURE 26.1 Model molecules of saccharide, monoaminosugar, cellulose, and chitosan.

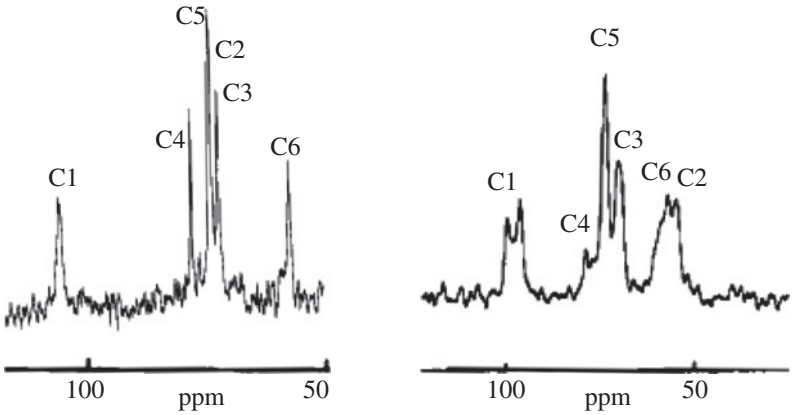
26.4.2 XPS



The model dimer molecules of cellulose and chitosan obtained in NMR calculations were calculated by deMon DFT programs [24, 25]. DeMon calculations were also performed with the Perdew-Wang-91 (PW91) [20–22] exchange correlation potential. In running the deMon program, we used a nonrandom grid and polarized valence double-ζ(DZVP) basis [20] of (6121/41/1*) for C and N, and (41) for H with auxiliary fitting functions labeled (5,2;5,2) for C, N and O, and (5,1;5,1) for H.

26.5 RESULTS AND DISCUSSION

As shown in the monomer models (α-D-glucose, β-D-glucosamine) for cellulose and chitosan, respectively, in Fig. 26.1, the structure of both biopolymers is similar except for the substitution of one OH group in cellulose by the NH_2 group in chitosan. In both compounds one can select six nonequivalent carbon atoms (C1–C6) and four nonequivalent oxygen atoms from different functional groups: –O– (O5), which belongs to the glucose ring; –O– (O1, O4), which links the adjacent glucose rings; OH (O3); and CH_2OH (O6). According to the experimental results, ^{13}C-NMR signals [11, 12] show six nonequivalent carbons of C1–C6 for both cellulose and chitosan polymers in Fig. 26.2. For the XPS of the cellulose, experimental CEBEs of O1s consist of two different –O– and –OH peaks centered at 532.9 and 533.5 eV, respectively, and the C1s is also due to two kinds of –O–CH–O– and –CH(OH) peaks at 288.1 and 286.7 eV. Therefore we will analyze the spectra for the biopolymers by deMon DFT [9,24,25] calculations using the model dimers.

26.5.1 ^{13}C-NMR Chemical Shielding Tensor

26.5.1.1 Saccharides and Aminosugar. In Table 26.1, we show the calculated carbon shielding constants (σ^d, σ^{p0}, σ^{p1}, σ^{total}), and chemical shift (δ_{calc}) for α-D-glucose, β-D-glucose, and β-D-glucosamine, respectively, with the experimental chemical shift (δ_{exp}) referring to the shielding constant of TMS. These compounds were selected to reflect the monomer units in cellulose and chitosan. It can be seen in Table 26.1 that the calculated chemical shifts (δ_{calc}) of C1–C6 carbons for α-D-glucose, β-D-glucose, and β-D-glucosamine are in considerably good accordance in the experimental ^{13}C values (δ_{exp}) in solution in the average absolute deviation (AAD) of $\pm$ 3.1 ppm. We can see from the calculation result

that the chemical shielding of C1–C6 carbons depends on the total paramagnetic shielding constants (σ^{p0} and σ^{p1}), since the diamagnetic term (σ^d = 252−254 ppm) of six carbons is almost constant. The shielding orders of carbon nuclei for saccharides and aminosugar in Table 26.1 follow C1 [–O–$\underline{C}$H(OH)–] > C2–C5 [–$\underline{C}$H(OH)– or –O–$\underline{C}$H–C] > C6 [–$\underline{C}H_2$(OH)], and C1 [–O–$\underline{C}$H(OH)–] > C5 (–O–$\underline{C}$H–C) > C3, C4 [–$\underline{C}$H(OH)–] > C6[–$\underline{C}H_2$(OH)] > C2 [–$\underline{C}$H(NH_2)], respectively. In order to compare the calculated carbon chemical shifts of the typical disaccharide molecule for cellulose with the experimental values in solid, we used the cellobiose compound shown in Fig. 26.1d. Table 26.2 also shows the calculated 12 carbon shielding constants and chemical shifts with the experimental ^{13}C chemical shift values referring to the shielding constant of TMS. The 12 carbon chemical shifts are classified into five species, due to the differences among the neighbor oxygen functional groups: C1 carbon, which bonded to two ether (–O–) groups is at the lowest field (δ_{exp} = 104.6 ppm); C1′ carbon, which has –O– and –OH groups and exists at the next lower field (δ_{exp} = 97.5 ppm); and C4, which, bonded to one –O– group, is observed at the second next lowest field (δ_{exp} = 85.5 ppm). Carbons in the –CH(OH) group are in the range of δ_{exp} = 72.4−79.7 ppm, and carbons in the –CH_2(OH) group are at the highest field (δ_{exp} = 63.8 ppm). The calculated results correspond well to the order of the experimental values in solids in AAD of ±1.9 ppm. For cellobiose results, the chemical shielding of 12 carbons is also seen to be determined dominantly with the total paramagnetic shielding constants.

26.5.1.2 Cellulose and Chitosan. In Table 26.3, we showed the calculated 12 carbon shielding constants and chemical shifts of the dimer models for cellulose and chitosan with the six experimental ^{13}C shift values referring to the shielding constant of TMS. In the table, we adopted experimental ^{13}C values of C4′ and C4 for cellobiose and β-D-glucosamine, respectively, for comparison of the calculated C4′ values of the model molecules, because the C4′ carbon of the model molecules bonds to the –OH group. Then, the calculated values exist in the AAD range of ± 3.1 ppm for both cellulose and chitosan, and are also in good accordance with experimental ones. Carbon NMR chemical shielding is also dominated by the total paramagnetic shielding constants, since the diamagnetic shielding constants are very similar.

In Table 26.3, the shifts of C1 and C1′ carbons bonded to two oxygen atoms are much lower-field than all other carbons in cellulose and chitosan. For C4 and C6 carbons of both models, the former carbon shift bonded to an ether group is at the lower field, while the latter carbon in the –$\underline{C}H_2$(OH) group exists in the higher field. These results correspond to a tendency of C1, C1′, C4, and C6 for cellobiose.

In the case of C2 and C2′ carbons for both polymers, the carbon nuclei in the –$\underline{C}$H(NH_2) group of chitosan are at the highest field of all carbons. This is so because the total paramagnetic terms of C2, C2′ carbons in the chitosan model have much higher values than those terms in the cellulose model, since the diamagnetic term has an almost constant value (σ^d = 251−255 ppm).

26.5.2 XPS

26.5.2.1 Valence XPS. It is interesting to discuss the experimental spectrum in detail from a theoretical viewpoint. We showed the theoretical valence spectra of cellulose and chitosan by deMon DFT calculations using the dimer models with experimental ones in Fig. 26.3 panels (a) and (b), respectively. The simulated results for cellulose and chitosan are in considerably good accordance with the experimental ones in the figure. Tables 26.4 and 26.5 summarize the experimental peaks, calculated VIPs, main atomic orbital (AO) photoionization cross sections (PICSs), orbital nature, and functional group. In Figure 26.3a,b, the intense peaks at around 26 eV are due mainly to $s\sigma$(O2s–C2s) bonding of the –O–C group for the biopolymers. From the simulation spectra in Fig. 26.3 we can discern an energy range of 21–23 eV in the difference between cellulose and chitosan. In the case of chitosan,

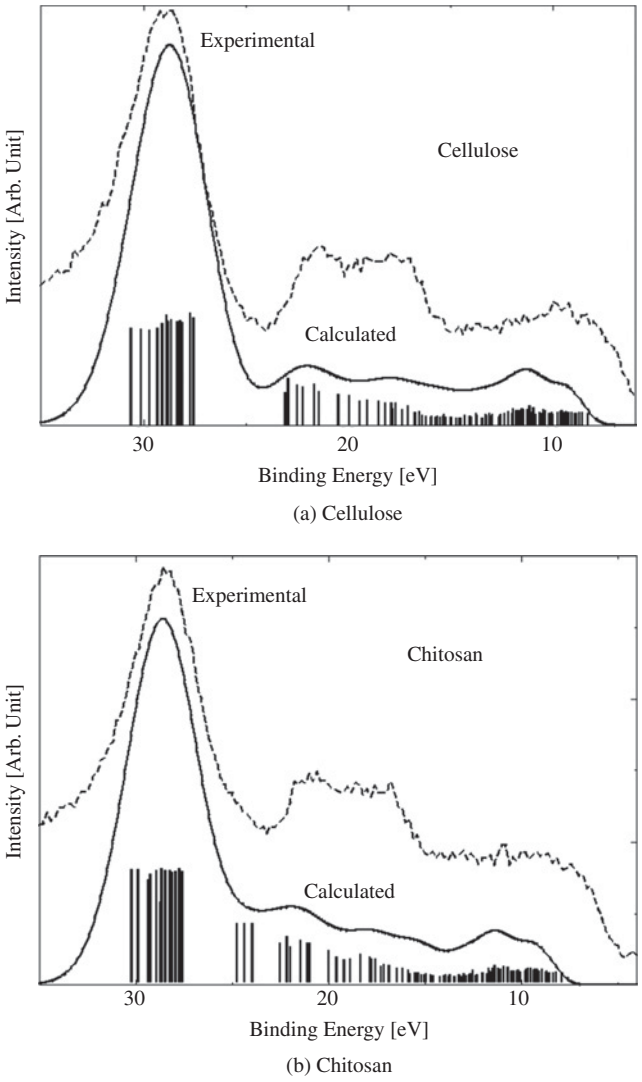

FIGURE 26.3 Valence XPS of (a) cellulose and (b) chitosan.

the shoulder peak at ∼22 eV results from the $s\sigma$(N2s–C2s) bonding of the H_2N–C group. Broader and shoulder peaks in the range of 13–20 and 3–13 eV result dominantly from $p\sigma$ bonding and $p\pi$ (lone-pair) nonbonding, respectively, for both polymers. Furthermore, we examined contribution of each atom for the simulated spectra in Fig. 26.4a,b, where we can see that the intense peak at ∼26 eV is due to the O and O + N atoms for cellulose and chitosan, respectively. For both polymers, the carbon contribution is a little larger than the oxygen one for a broader peak in the range of 13−20 eV. In the case of a broader peak between 3.0 (or 5.0) and 13 eV, the oxygen contribution also seems to dominate.

26.5.2.2 CEBEs of the Biopolymers. Table 26.6 shows the CEBEs of the model monomers for the biopolymers using the uGTS method with scaled-pVDZ basis. In the table, we showed the *WD* values of the polymers from the differences between calculated CEBE values for the model molecules and experimental ones for the solid polymers. We thus estimated an energy range of 5.9 and 5.7 eV for averaged *WD* values of cellulose and chitosan, respectively. The *WD* values from the CEBEs are the most reliable, as described in our previous work [10, 11].

26.6 CONCLUSION

We have analyzed ^{13}C-NMR chemical shielding and valence XPS of cellulose and chitosan by deMon DFT calculations using the model dimers. For ^{13}C-NMR chemical shielding, the calculated chemical shifts of (α-D-glucose, β-D-glucose, and β-D-glucosamine) and cellobiose with DZVP basis are in considerably good accordance with the experimental values in the average absolute deviations (AAD) of ± 3.1 and 2.0 ppm, respectively. The calculated ^{13}C shifts of the dimer models correspond well to the experimental ones of both solid polymers in the AAD of ± 3.1 ppm. The carbon NMR

27.1 INTRODUCTION

Collagen represents the most abundant protein in mammals, accounting for up to 35% of the protein content in the body [1]. At present 28 different types of collagens [2] are known to be involved in shaping and maintaining the extracellular matrix (ECM) by forming fibrillar or other large-scale assemblies [3]. Collagen builds up tissue-specific geometries of stable architecture that impart mechanical strength and stability to the ECM and mediate cell attachment, morphology, proliferation, and migration [4–7].

Collagen type I is the main collagen of skin and bone and the major constituent of most ECM variants. Three left-handed supercoiled polypeptide chains [two α1(I) and one α2(I)] of a polyproline-II-like conformation form a right-handed triple helix with a diameter of 1.5 nm and a length of 300 nm [3,8,9]. The collagen molecules form fibrils with diameters in the range of 20–70 nm in a multistep, entropy-driven self-assembly process termed *fibrillogenesis* [3,10,11]. Turbidimetric analysis of the fibril formation in vitro showed an initial lag phase followed by a growth phase with sigmoidal increase of the fibril formation rate [12,13]. It has been suggested that the formation of dimers and trimers takes place during the lag phase while rapid lateral aggregation involving five trimers (*microfibril*) occurs in the following growth phase. Further growth occurs by linear and lateral addition of the trimeric units, which results in the formation of collagen fibrils [14, 15]. When inspected by electron microscopy [16] or AFM [17], collagen fibrils present a repeating pattern of ∼67 nm (D-band periodicity) perpendicular to their axes.

In vivo, collagen fibrils are arranged in complex three-dimensional (3D) arrays, very often in an aligned manner to fulfill biomechanical functions such as resisting high-tensile forces in tendons. Collagens can be found as parallel fiber bundles in tendons and ligaments [18], as concentric waves in bone [19], or as orthogonal lattices in corneas [20]. The spatial organization of collagen fibers in vivo is believed to play an important role in directing cell behavior and fate decisions. For example, it has been reported that fibroblasts align along oriented collagen fibril matrices via contact guidance [21–24]. The direction of cell repopulation and the distribution of newly synthesized collagen was determined by the alignment of collagen fibrils [22]. Thus, in order to mimic the ECM structure of tissues and, in particular, to investigate the influence of the shape of ECM structures on cell behavior, it is of great interest to create aligned collagen fibril matrices for cell culture studies. However, the reconstitution of collagen matrices in vitro results in isotropic structural networks with arbitrarily oriented collagen fibrils [25].

Several methods have been developed to reconstitute aligned collagen matrices in vitro. Elsdale and Bard introduced a technique that involved draining of a supporting coverslip in one direction during gelation of a collagen solution [21]. Torbet and Ronzière exposed a gelling collagen solution to a strong magnetic field [26]. Under this condition the fibrils were aligned as a result of the diamagnetic properties of collagen molecules [24,26–28]. Two other researchers

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

[29] made use of magnetic beads to align the collagen fibers by moving the beads in the gelling solution toward the poles of an external magnet. The effect of collagen fibril alignment was also observed in microfluidic channels (<100 μm width) as result of a short initial pressure-driven flow and subsequent static gelation of a collagen solution [30].

However, the previously reported methods require rather complex technical equipment and do not provide broad application in cell biology because of the limited size of the area covered by the artificial matrices. Importantly, none of the abovementioned techniques enables the variation of the collagen fibril alignment, density, and morphology.

We therefore introduced new techniques based on a microfluidic system (Section 27.2) and on collagen self-assembly on mica surfaces (Section 27.3) to create well-aligned and "native" collagen fibril matrices covering large areas. These methods also allow control of the density and orientation of the collagen fibrils by different means.

27.2 SHEAR FLOW DEPOSITION OF COLLAGEN MATRICES

27.2.1 Fibers in Shear Flow

In a simple shear flow, ellipsoidal particles usually align in the flow direction but change their orientation by 180° in a tumbling motion. This effect was first described by Jefferey [31], who calculated the motion of a single ellipsoid in a shear flow independent of inertia of fluid and particle. According to Ref. 31, the motion of an ellipsoid in an unbounded simple shear flow is given by the following equations

$$\tan\theta = \frac{Cr_e}{\left(r_e^2\cos^2\phi + \sin^2\phi\right)^{\frac{1}{2}}} \tag{27.1}$$

$$\tan\phi = r_e \tan\left(\frac{2\pi t}{T} + k\right) \tag{27.2}$$

where the angles φ and θ describe the orientation of the fiber with respect to the flow direction (in spherical coordinates), r_e is the effective aspect ratio of the particle (length/diameter), C is the orbit constant, and k is the initial value of φ. The spheroid will rotate with a period

$$T = \frac{2\pi}{\gamma}\left(r_e + r_e^{-1}\right) \tag{27.3}$$

under the actions of the shear rate γ. The particle is aligned with the vorticity axis for $C = 0$ and located in the plane of flow for C approaching infinity [31].

The motion of a fiber near a wall was reported to result in smaller angular velocities of the particles and larger periods between fiber rotations [32–35], whereas another team [36] claimed shorter periods of rotation. In regions closer to the wall than a half-fiber length, fibers were observed to follow a "pole vaulting" motion or a "springy rotation" during which the mass center of the fiber moved away from the wall [34,37]. With increasing flexibility of the fibers, the rotation changed toward snake-and-helix rotation and coil formation [37]. Additionally, fibers performing a "rolling–sliding motion" perpendicular to the flow direction were described [38]. With increasing aspect ratio and distance to the wall, the number of perpendicularly oriented fibers decreased. In the near-wall regions fibers with particle aspect ratio (length/diameter of particle) $r_p = 40$ stayed aligned with the flow direction whereas those with $r_p = 10$ moved toward an orientation perpendicular to the flow direction [39].

27.2.2 Experimental Approach

In Figure 27.1 we illustrate the experimental approach for the shear flow deposition of collagen matrices with adjustable orientation, density, and morphology by variation of the collagen solution, shear rate and substrate properties. The key element of the corresponding experimental setup is a microfluidic system with two parallel channels (length 8 mm, width 1 mm, height 73.6 μm) as well as inlet and outlet ports. The channels were fabricated by mirocasting of polydimethylsiloxane (PDMS) and the ports were integrated into a polycarbonate manifold. For detailed information concerning the technology, we refer the reader to Ref. 40. The open side of the channels can be placed on coverslips of different surface modifications, thus allowing for studies on the impact of surface hydrophilicity/hydrophobicity on the properties of the collagen matricies obtained. To improve the contact between the microfluidic system and the coverslips,

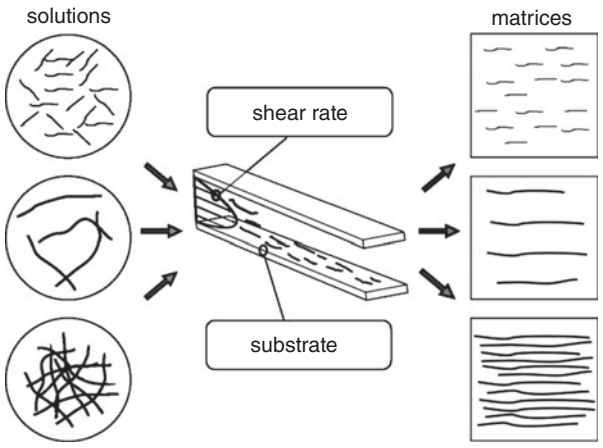

FIGURE 27.1 Scheme of the experimental approach for preparation of collagen fibril matrices that are adjustable in orientation, density, and morphology by variation of collagen solution, shear rate, and substrate.

additional channels for the application of vacuum were integrated into the PDMS.

The hydrodynamic flow (flow rate) of the collagen solutions in the microchannels can be controlled by a syringe pump that is connected via poly(ether–ether–ketone) (PEEK) tubing to external valves and to the microfluidic system [41]. Deposition of the collagen fibrils is performed under conditions of laminar flow. In all experiments reported, the Reynolds number (as a criterion for laminar flow) was <1.

The collagen matrices obtained can be analyzed by applying optical or atomic force microscopy in combination with image analysis for quantification of fibril alignment and coverage. For details on the analysis performed to obtain the results presented in this section, we refer the reader to Ref. 41. Two fibril deposition methods are described below.

27.2.2.1 Method A: Deposition of Collagen Fibrils during Fibril Formation. The method described here allows the deposition of aligned collagen matrices consisting of in situ formed fibrils onto planar surfaces. The microfluidic system is placed in an incubator at 37°C whereas the syringe pump for flow generation is kept below 4°C. To avoid early fibrillogenesis, the collagen solution is prepared at a temperature of 4°C and is drawn into chilled syringes, which then are directly installed into the syringe pump. Afterward the streaming process begins with pumping the chilled collagen solution from the syringe through the heated tubing. The length of the tubing towards the microfluidic channel can be varied, thereby influencing the conditioning time the collagen solution remains within the heated tubing before entering the channel.

Figure 27.2a shows confocal reflection microscopy (CRM) and atomic force microscopy (AFM) images of the collagen matrices prepared at three different concentrations on poly(octadecene-*alt*-maleic acid) (POMA) surfaces [42]. The flow rate was set to 11 μL/min and corresponds to a conditioning time of 5 min. The increase of the collagen solution concentration resulted in a significant increase of collagen fibril coverage (6.9% for 0.2 mg/mL, 29% for 0.4 mg/mL, and 83% for 0.8 mg/mL, at the middle position). Furthermore, visual inspection reveals an increase of the fibril length for the higher collagen concentrations. Collagen matrices deposited at a solution concentration of 0.2 mg/mL consist of single, short, and bent collagen fibrils that increase in length at a solution concentration of 0.4 mg/mL and further at 0.8 mg/mL. Furthermore, the increase of the collagen solution concentration also caused an increase in the fibril orientation (FWHM 41.4° for 0.2 mg/mL, 31.1° for 0.4 mg/mL, and 30° for 0.8 mg/mL; see Figure 27.2b and Table 27.1).

As described above, collagen fibrillogenesis is a multistep process whose dynamics depends on the starting solution concentration [25,43]. With increasing starting concentration the process of fibril formation is accelerated and higher numbers of fibrils are formed [25], which could explain why there are shorter and fewer fibrils for lower concentrations in contrast to longer fibrils and more dense matrices for higher starting concentrations. Turbiditiy measurements showed lag times for solution concentrations around 0.2 mg/mL exceeding the conditioning time of 10 min [25]. Thus, it could be assumed that fibril formation does not take place under these conditions. However, it was reported that the lag time disappeared when the neutralized collagen solution was kept at 4°C for a period of >5 min. Since the collagen solution in the experiments reported above was stored at 4°C for ≤1 h before streaming [41], it can be expected that a lag time as described above is not relevant anymore. Thus, fibrils might begin to form as early as in the chilled storage reservoir or while streaming through the tempered tubing.

In order to reveal correlations between the conditioning time of the collagen solution in the tempered tubing before entering the channel and the morphology of the resultant collagen fibril matrices, streaming experiments were performed at varied lengths of tubing between the syringe and the microfluidic channel. The length of the tubing was varied for a constant flow rate of 11 μL/min according to calculated conditioning times of 5, 10, and 30 min of the collagen solution in the tempered tubing. After 5 min of conditioning, dense and aligned fibrillar matrices consisting of long and short collagen fibrils are formed, whereas after 30 min mainly long, aligned, and more individual collagen fibrils appear (see Figure 27.3). The reproducibility of the experiments decreased with increasing conditioning time, due to the formation and adsorption of rather large fibril aggregates. Image analysis was not possible on matrices from solutions with 30 min conditioning time. However, differences between the matrices referring to morphology and structure are directly obvious from the CRM images (Figure 27.3).

27.2.2.2 Method B: Deposition of Fully Developed Collagen Fibrils. The method described here was developed to create highly aligned matrices consisting of long and "mature" collagen fibrils. Solutions containing appropriate low concentrations of this type of fibril can be obtained by homogenization and centrifugation of collagen gels [41]. Subsequently, the readily processed supernatant is pumped through the microfluidic channel. The orientation and density of the resulting collagen matrices can be varied with the flow rate, concentration of the collagen solution, and the type of surface coating [41]. In the following subsections we discuss the influence of these parameters on the collagen matrices obtained.

Influence of Flow Rate. In Figure 27.4a we show CRM and AFM images of collagen matrices prepared on POMA surfaces at different positions along the microfluidic channel. The collagen solution concentration was adjusted to 3 μg/mL, and the flow rate was set to 11 μL/min. The resultant matrices

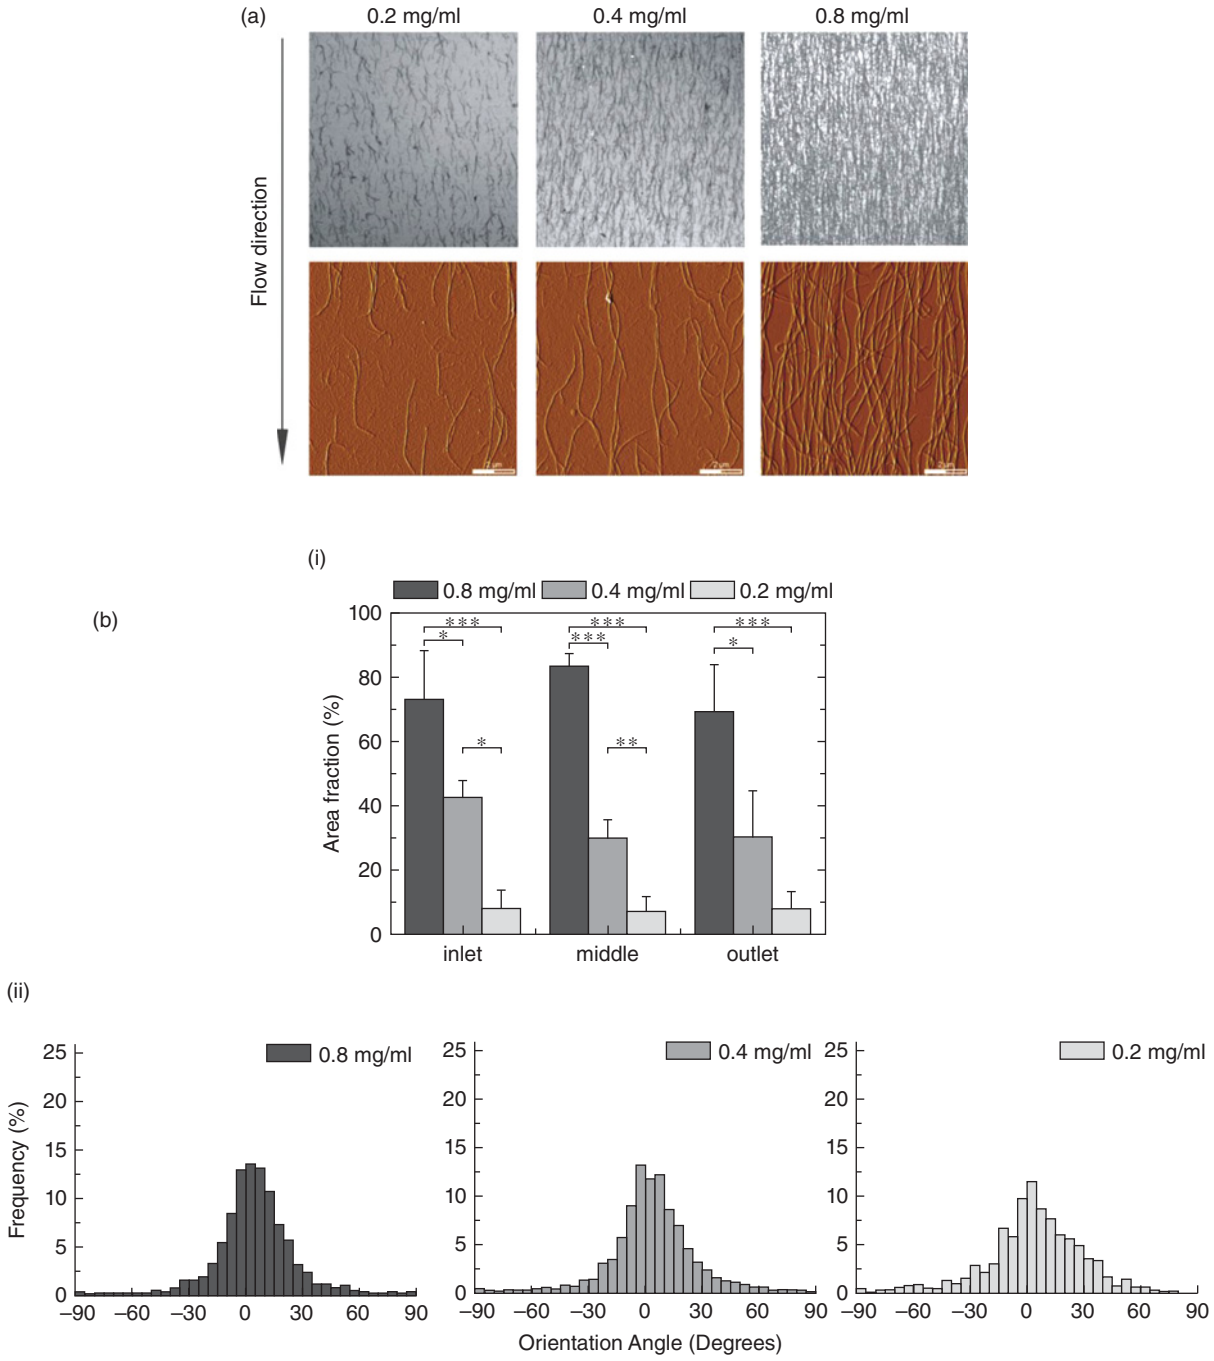

FIGURE 27.2 CRM (first row) and AFM (second row) images of aligned collagen fibril matrices prepared according to method A at collagen solution concentrations of 0.2, 0.4, and 0.8 mg/mL on POMA-coated substrates with a flow rate of 11 mL/min and a conditioning time of 5 min (a) and quantitative influence of the collagen solution concentration on the density and orientation of the obtained collagen fibril matrices (b): (i) relative area fraction (y axis) of collagen fibril coverage at three different positions (x axis) is plotted ($n \pm 3$, ±SD, $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$); (ii) distribution of collagen fiber angles for different concentrations at middle position of the channel. consisted of long, highly aligned, and individual collagen fibrils. The density of the collagen matrices decreased along the channel axis. A possible reason for this observation might be a depletion of collagen across the channel length [44] since very low-concentration solutions were employed.

Figure 27.4b shows how the applied flow rate influences the alignment and coverage of fully developed collagen fibrils on POMA surfaces. The best alignment could be achieved for 11 μL/min (FWHM 14.4°; see Figure 27.4b and Table 27.1). Parallel alignment of the fibrils was consistent across the whole length and width of the microfluidic channel, whereas the decrease of the collagen fibril coverage along the channel from inlet to outlet was observed for all matrices prepared according to method B. With decreasing flow rate, the amount of adsorbed collagen fibrils increased independently of the channel position (17% for 11 μL/min, 38% for 4 μL/min, and 65% for 0.45 μl/min, at inlet position; see Figure 27.4b). For higher flow rates, less fibril coverage across width and length of the channel was observed. The fibril alignment remained almost constant (FWHM: 14.4° for 11 μL/min and 16.3° for 4 μL/min; see Figure 27.4b and Table 27.1). For the lowest flow rate (0.45 μL/min), an increasing amount of nonaligned aggregates at the inlet and outlet of the channel was observed. Consequently the orientation of the fibrils significantly decreased under these conditions (FWHM = 30.1°). The appropriate adjustment of the flow rate thus enables the generation of highly aligned matrices, which are at the same time adjustable in density.

Influence of Collagen Concentration. Results obtained for matrices prepared at collagen concentrations of 3 ± 0.1 μg/mL and 14 ± 2.5 μg/mL are compared in Figure 27.5a and Table 27.1. The increase of the solution concentration to 14 ± 2.5 μg/mL resulted in an increase of fibril coverage from 18% at 3 ± 0.1 μg/mL to 35% at 14 ± 2.5 μg/mL at (at the inlet position), whereas the fibril orientation slightly decreased (FWHM 14.4°–17°) at higher collagen solution concentration. The decrease of alignment cannot be attributed to the relative lack of orientation of the collagen fibrils as such but to an increase of aggregates of nonaligned collagen fibrils. Nevertheless, the results demonstrate that the density of matrices prepared according to method B is also adjustable by choosing appropriate solution concentrations.

Influence of Substrate. In order to investigate the fibril–surface interactions and to possibly increase the density and alignment of the collagen fibrils, the authors of Ref. 41 employed substrates that differed in the degree of hydrophobicity/hydrophilicity. Beyond POMA, also poly(ethylene-*alt*-maleic-acid) (PEMA)-coated glass as well as freshly cleaned glass coverslips were used [41]. The experiments were performed at a flow rate of 11 μL/min. For POMA-modified surfaces, higher coverage (14%) of collagen fibrils could be achieved as compared to PEMA-modified (7%) and bare glass slides (6%) (see Figure 27.5b). The alignment

of collagen fibrils on POMA-coated and glass substrates was higher than on PEMA-modified substrates (FWHM 14.4° for POMA; 18.1° for PEMA, 13.9° for glass; see Figure 27.5b and Table 27.1).

The copolymers POMA and PEMA consist of alternating units of maleic acids and alkyl chains [42]. However, the comonomer octadecene in POMA is rather big compared to the small ethylene residue in PEMA [42]. Consequently, thin films of these copolymers show differences in hydrophobicity and structural characteristics ranging from a nearly nonswollen, hydrophobic film for POMA to highly swollen copolymer brushes for PEMA [42]. Covalent attachment of the collagen to the copolymers could be excluded, since the other comonomer of both copolymers (POMA and PEMA) was in the nonreactive diacid form. Instead, the higher coverage on POMA-coated substrates was attributed to hydrophobic interactions between the collagen and the alkyl chains of the POMA-coated substrate surface. The hydrophilic gel-like structure of PEMA and the smooth and nonswollen glass surface apparently do not favor adsorption of the hydrophobic collagen. Moreover, the soft nature of the swollen PEMA film possibly impedes the alignment of the collagen fibrils, due to the hindrance of the hydrodynamic flow by the polymer chains in the interfacial region [45].

27.2.3 Possible Mechanism of Fibril Alignment

Because *prealignment* effects [46] appear to play a minor role in this system and as the viscosity only slightly influences the fibril alignment–as matrices produced according to method B showed the highest degree of alignment despite the low viscosity of the utilized solutions–the formation of longer fibrils (besides the flow rate) seems to critically determine the alignment (Table 27.1) pointing at the underlying mechanism of a mechanical alignment. Fibers in a simple shear flow usually align in the direction of flow; however, their orientation can change by 180° in a tumbling motion [31]. This motion was observed in a low-Reynolds-number regime for pulp fibers that reveal rigidities in the same range as collagen fibrils (pulp fibers, 5.4 GPa [47]; collagen fibers, 5.5 GPa [48]). Thus it is likely that the collagen fibrils interact with the wall during the tumbling motion. If one end of the fibril attaches to the surface, the remaining part can be aligned by the streaming fluid in a position of low hydrodynamic resistance, that is, parallel to the flow direction. However, due to additional interaction of the fibril with the surface, not all fibrils align parallel to the flow. Near the wall, the number of fibers aligning in the flow direction was reported to be higher for higher aspect ratios ($r_p > 40$) [39,49]. Since aspect ratios of the long fibrils in our system are comparable to those of reported in Ref. 49, inertia effects may contribute to the increase of fibril alignment with increasing length. Thus, it can be concluded that fibril alignment is dependent on (1) the flow rate (which influences the shear stress/force in the system (tubing and channel)) and (2) the length of the fibrils, and to a lesser degree (3) the viscosity of the solution (which also influences shear force, but in a much lower order than the flow rate).

27.2.4 Comparison with Other Methods

Compared to microfluidic approaches [30] with narrow flow channels (channel width <30 μm), the methods described above allow the preparation of homogeneously aligned collagen matrices covering an area of several square millimeters. Therefore, these matrices are more suitable for cell culture studies since the average cell diameter is much smaller than the lateral dimensions of the covered area. Furthermore, in comparison to other current techniques, the degree of fibril alignment is very high and can be varied with the flow rate in the channel. Highest alignment was achieved with 47% and 68% of the collagen fibrils within 5° of the channel axis for method A and method B, respectively. In comparison, Lee et al. reported 40% of the collagen fibrils to be within 5° of the channel axis, whereas for increasing channel width this percentage decreased. The examples presented thus indicate that the method introduced in Ref. 41 produces highly aligned matrices that are of comparable or better quality than those obtained by other current techniques and that are at the same time tunable in morphology.

27.3 COLLAGEN SELF-ALIGNMENT ON MICA

27.3.1 Directing Collagen Self-Assembly into Ultrathin Matrices

Recently, a method was developed to create structurally well-defined and nanoscopically reproducible two-dimensional (2D) matrices of highly aligned type I collagen molecules [17,50,51]. In a first step, a layered crystal of muscovite mica is cleaved, exposing an atomically flat surface. Subsequently, a drop of buffer solution is placed onto the freshly cleaved mica [52]. A buffer solution containing the collagen molecules is then injected into the buffer solution covering the mica surface. This initiates the adsorption and self-assembly of highly aligned fibrillar collagen structures on the supporting mica surface. The direction of collagen alignment is determined by the crystallographic orientation of the mica substrate [53]. The pH value, electrolyte content, and electrolyte concentration of the buffer solution play a crucial role in guiding the self-assembly process of the collagen molecules into higher-ordered structures [50] (Figure 27.6). The assembly time of the collagen matrix ranges from minutes to a few hours and depends on the collagen concentration, the pH value, the electrolyte content, and the temperature of the buffer solution [17,50]. Depending on the self-assembly conditions, this collagen matrix could establish

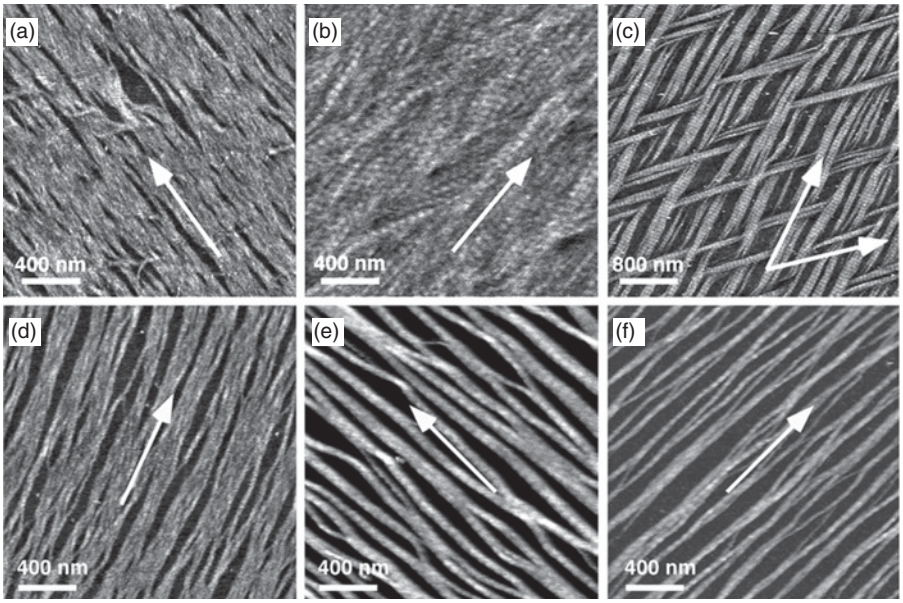

FIGURE 27.6 Directed self-assembly of ultrathin nanoscopic collagen matrices in physiological buffers. (a–c) Demonstration of influence of electrolytes on collagen self-assembly. (a) Collagen matrix self-assembled from collagen molecules in 200 mM NaCl at pH 7.5 buffered with 50 mM Tris-HCl. The aligned fibrils did not show any periodical structure along their axes. (b) Collagen matrix self-assembled in 200 mM KCl at pH 7.5 buffered with 50 mM Tris-HCl. (c) Collagen matrix self-assembled in 200 mM KCl at pH 8.5 buffered with 50 mM Tris-HCl. Along their axes the fibrils (arrows) showed a D-band periodicity of ≈66 nm, typical for collagen assembled in vivo. (d–f) Self-assembly of collagen matrices in physiological buffers. (d) Collagen matrix self-assembled in PBS; the collagen molecules assembled into fibrils that aligned (arrows) into similar patterns such as observed for fibrils assembled with NaCl (a). (e) Collagen matrix self-assembled from collagen molecules in a buffer mimicking the eukaryotic cytoplasmic environment (130 mM monopotassium glutamate, 8.5 mM monosodium glutamate, 10 mM Hepes, 2 mM $MgCl_2$, 1 mM Na_2ATP, 1 mM EGTA, 0.5 mM NaH_2PO_4, 0.5 mM Na_2HPO_4, 0.5 mM $CaCl_2$, pH 7.2 adjusted with KOH). (f) Collagen matrix self-assembled in a buffer mimicking the eukaryotic extracellular environment (109.2 mM NaCl, 4.1 mM KCl, 1.7 mM $CaCl_2$, 0.65 mM $MgCl_2$, 7.9 mM monosodium glutamate, 0.4 mM NaH_2PO_4, 0.3 mM Na_2HPO_4, 27 mM $NaHCO_3$, 20 mM Hepes, pH 7.4 adjusted with NaOH). Both the extracellular and intracellular buffers promoted collagen fibrils to establish the D-band periodic structure. Topographs exhibit a color scale corresponding to a vertical range of 5 nm. [Reprinted from *Small* 3 (2007), D.A. Cisneros, J. Friedrichs, A. Taubenberger, C.M. Franz, D.J. Muller, Creating ultrathin nanoscopic collagen matrices for biological and biotechnological applications, 956–963. Copyright 2007, with permission from John Wiley & Sons.]

characteristic structural features observed for native collagen fibrils [17]. The self-assembled collagen matrix consists of highly ordered collagen fibrils and exhibits a thickness of ≈3 nm, which corresponds to the average diameter of one collagen microfibril.

27.3.2 Adjusting the Collagen Matrix Density by pH Change

Assembling the collagen matrix in buffer solutions having identical electrolyte compositions but different pH values guided the assembly of the collagen molecules into different 2D matrices [50]. At low pH values of 2.5 and 3.5, the collagen molecules adsorbed as globular structures onto the mica surface. This observation correlates well with the low tendency of collagen fibrils to self-assemble at low pH values [3]. Most probably, the globular structures observed represent monomeric collagen or aggregates of a few collagen molecules. Between pH 4.5 and 8.9, the collagen molecules assembled into fibrillar structures that formed structurally well-defined matrices, indicating that the assembly of collagen molecules into the matrices readily occurred at pH values as low as 4.5. However, increasing the pH value of the buffer solution toward the pI of collagen (≈9.3 [54]) decreased the density of collagen fibrils forming the 2D matrix. At pH 9.3 the density of collagen fibrils adsorbed onto the mica was about half that obtained within the pH range 4.5–8.9. Increasing the pH above 9.3 further decreased the density of fibrils

forming the collagen matrices. These results demonstrate that the density of collagen fibrils forming the final 2D matrix can be precisely controlled by the pH value of buffer solution.

27.3.3 Role of Electrolytes in Determining Final Collagen Matrices

In addition to pH changes, it was observed that the electrolyte type and the electrolyte concentration of the buffer solution could influence the assembly of collagen molecules into nanoscopic matrices [50]. When assembled in the absence of K^+, the collagen fibrils exhibited a high degree of parallel alignment (Figure 27.6a). The collagen fibrils mainly associated laterally, thereby forming flat (≈3-nm) elongated structures called *microribbons* [50]. Remarkably, the fibrillar structures assembled under these conditions did not display the characteristic D band (Figure 27.6a), such as observed for collagen fibrils assembled in vivo [16]. This situation changed when K^+ was present during the self-assembly process. In this case the collagen molecules assembled into fibrillar structures that exposed their native 67-nm periodic structure (Figure 27.6b). When assembled in the presence of K^+ at a higher pH value, collagen fibrils displayed a crossed pattern (Figure 27.6c) such as observed for the self-assembly of α-synuclein fibrils [55].

The supramolecular assembly of collagen molecules was also studied in buffers mimicking physiologically relevant conditions. Assembled in phosphate-buffered solution (Figure 27.6d), the collagen matrices were structurally similar to matrices assembled at high NaCl concentrations but in absence of K^+ (Figure 27.6a). This indicated that the K^+ concentration of ≈ 4.1 mM within the PBS buffer was not sufficiently high to promote the D-band formation of the self-assembled collagen fibrils. However, when assembled in a buffer mimicking the intracellular environment of eukaryotic cells [56], the collagen matrices showed a well-pronounced formation of the D band (Figure 27.6e). The formation of the D-band periodicity may be assigned to the much higher K^+ concentration of the buffer solution in which the self-assembly of the collagen fibrils took place. Although they contained a K^+ concentration of only 4.1 mM, buffer solutions mimicking the extracellular environment of eukaryotes [56] also promoted D-band formation (Figure 27.6f). This suggests that other electrolytes may assist K^+ in promoting D-band formation of collagen. It may be assumed that certain electrolyte compositions may promote the formation of D-band periodicity, even in the absence of K^+. However, further experimental work is needed to prove this.

27.3.4 Structural Features of Self-Assembled Collagen Fibrils Resembling In Vivo Fibrils

At increased spatial resolution, substructural details within the D band of the fibrils self-assembled into the 2D matrix could be resolved. The multi banded sub-structures of D-banded collagen fibrils resembled those observed by transmission electron microscopy of positively stained collagen fibers extracted from rat tail tendon [16]. From this structural correlation it could be concluded that the collagen structures self-assembled in vitro established similar structural details as collagen fibrils assembled in vivo [17].

27.3.5 Reshaping Collagen Matrices on Nanoscale

After assembly of the collagen matrix, single fibrils could be realigned in a controlled manner using the AFM stylus as nanotweezers [50,57]. After initiation of the self-assembly of collagen molecules (Figure 27.7a), the final matrix structure was imaged by AFM in the tapping mode, where the maximum force applied by the stylus was sufficiently small

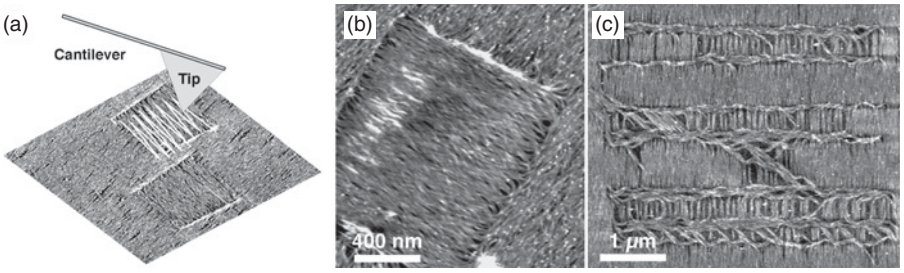

FIGURE 27.7 Designing nanoscopic collagen matrices using an AFM cantilever as a nanotool. (a) After preparation of the collagen matrix, the stylus of the AFM cantilever is pushed onto the matrix to design new patterns and structures (white lines). This induces the collagen molecules to reassemble into the fast-scanning direction of the stylus. (b,c) AFM topographs of patterns created with the method described. Note how collagen molecules are sometimes knotted into complex nanostructures. Experiments were performed on native collagen molecules in buffer solution at pH 7.5 (200 mM NaCl, 50 mM TrisHCl). Full gray levels of topographs correspond to a vertical scale of 4 nm. [Reprinted from *Small* **3** (2007), D.A. Cisneros, J. Friedrichs, A. Taubenberger, C.M. Franz, D.J. Muller, Creating ultrathin nanoscopic collagen matrices for biological and biotechnological applications, 956–963. Copyright 2007, with permission from John Wiley & Sons.]

to prevent reversible or irreversible structural distortions [58]. Predefined regions of the matrix were scanned using contact-mode AFM in order to manipulate the collagen fibrils. Reimaging of the manipulated region in tapping mode showed that the collagen fibrils realigned in the fast-scanning direction of the AFM stylus (Figure 27.7a). In this way, it was possible to create highly organized patterns on the nanometer scale (Figure 27.7b,c).

27.3.6 Collagen Matrices Showing Enhanced Stability after Maturation

The collagen fibrils of the matrix could be realigned only within the first 5 h after the self-assembly of the collagen matrix took place. After this time, the individual fibrils could not be reoriented. Thus, it was concluded that the collagen fibrils strengthened their bonds or enhanced the number of these bonds within the matrix. It could be further suggested that these bonds, increasing the mechanical stability of the matrix, formed relatively slowly. The maturation time of ≈5 h observed here for the collagen matrix stabilization is very similar to the time of 6–8 h during which collagen gels begin to lose their ability to be reorganized by fibroblasts in cell culture [59]. This suggests that the maturation process that takes place in the 2D matrices of self-assembled collagen fibrils is similar to that in 3D networks of collagen fibrils, and that a similar process may take place in tissues. After this setting period, the structured collagen matrices were mechanically stable. When the matrices were reinvestigated after a few months of storage at room temperature in a buffer solution, it was found that both the orientation and mechanical stability of the collagen matrices had not changed [57].

27.3.7 Insight into Collagen Self-Assembly through Time-Lapse AFM

As described in the previous sections, the D-band periodicity of self-assembled collagen fibrils forming 2D matrices matches that of collagen fibrils and fibers found in vivo. These findings were, however, obtained from static AFM topographs. To gain insight into the dynamic process of collagen self-assembly, time-lapse high-resolution AFM imaging was applied. Figure 27.8 shows time-lapse AFM topographs of collagen fibrils adsorbed and aligned onto the supporting mica surface (Figure 27.8a,b). The longitudinal and lateral growth of these fibrils could be followed over the timecourse of the time-lapse AFM (Figure 27.8c–e). As the recording of AFM topographs continued, several other fibrils adsorbed onto the mica and aligned in the same direction as the previously adsorbed fibrils (Figure 27.8d–f). Independent of the time of their adsorption, all fibrils continuously grew laterally and longitudinally until they covered the entire support with a ≈3-nm-thick matrix. On approaching, it was possible for adjacent fibrils to fuse laterally (Figure 27.8h,i). Sometimes, this lateral fusion of two fibrils left local defects, such as gaps or slight mismatches of the D-band periodicity. About 50% of these defects, which occurred at the initial stages of the self-assembly process, disappeared over time. This self-healing process may be promoted by collagen molecules from the buffer solution and represents a self-organization process that significantly contributes to the toughness and strength of collagen fibrils from tendons. During wound healing, fibroblasts increase the synthesis of the ECM and decrease its degradation [5, 6]. Such self-organizing capabilities of collagen to heal out defects could contribute to faster and more efficient tissue repair.

27.3.7.1 Early Fibrils and Fibril Flexibility. The self-assembly kinetics of collagen molecules into fibrils forming the 2D matrix depended on the collagen concentration of the solution [17]. The smallest isolated fibrillar structures observed exhibited dimensions of $\approx 800 \times 20$ nm. Considering that only the width of the isolated fibrils imaged appears wider due to nonlinear AFM stylus–sample convolution effects [60], the widths taken from the thinnest collagen fibrils of ≈5 nm embedded in the collagen matrix are not broadened through convolution effects [61]. The dimensions of 800×5 nm corresponded well to those of early fibrils [62] observed to occur during the development of chicken tendon. It has been proposed that early fibrils could represent the building blocks of collagen fibril assembly [63]. Time-lapse AFM could also monitor the fusion of the tips of two collagen fibrils growing toward each other [64]. The fusion of fibrillar tips requires intrinsic flexibilities, which allows both fibril ends to match each other. After tip fusion, the fibril continuously grew in longitudinal and lateral directions. This ability of fibrils to match each other for fusion enabled the formation of a uniform collagen matrix coating the entire supporting mica surface.

27.3.7.2 Collagen Fibrils Grow in Steps. Increasing the temporal resolution of time-lapse AFM provided further insights into the molecular mechanisms of fibril growth. To initiate collagen self-assembly, single collagen molecules were injected into the buffer solution at a low concentration. Recording the width of a growing collagen fibril over time revealed discrete jumps (Figure 27.8l, vertical arrows between horizontal lines). This indicates that single fibrils changed their widths in average step sizes of 3.7 ± 1.3 nm. This step size corresponds well to the average diameter ≈ 3.3 nm of a single microfibril [65, 66]. From this observation it followed that collagen fibrils assemble in two steps: In the first step, presumably five collagen molecules fused laterally and collapsed. This collapse initiated the formation of a microfibril, which assembled with the larger collagen fibrils, as indicated by the growing steps of fibril.

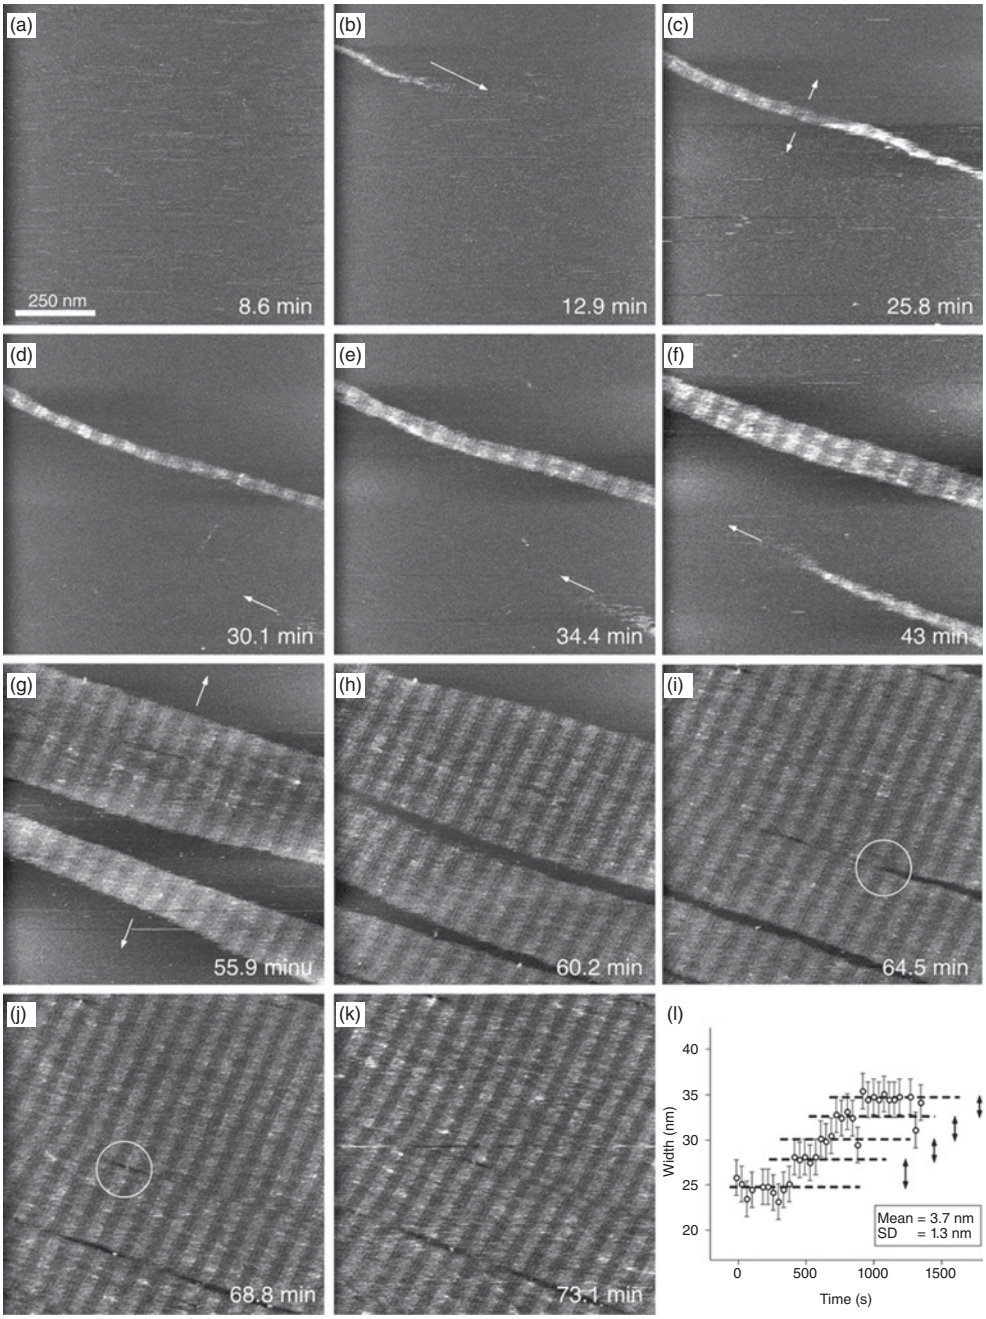

FIGURE 27.8 Self-assembly of collagen matrices observed by time-lapse AFM: (a–e) Collagen molecules of the buffer solution assemble into fibrils that grow laterally and longitudinally (arrows) onto a mica support. The typical D-band periodicity known from collagen fibrils grown in vivo can be clearly resolved in the self-assembled fibrils. (f–k) AFM topographs of a fibril growing longitudinally toward the center of the topograph while another fibril grows laterally. The growing collagen fibrils assemble into a 2D matrix covering the entire mica support. The height of the matrix corresponds to ≈3 nm. Most defects formed by growing fibrils that collide [see circle in panel (i)] disappear after the fibrils have fused (i–k). Tapping-mode AFM topographs were recorded in buffer solution (pH 9.2, 50 mM glycine, 200 mM KCl, 27°C, at a collagen concentration of 12 mg/mL) and exhibit a full gray level corresponding to a vertical scale of 5 nm. (l) Width of a single collagen fibril plotted over a certain growth time followed with time-lapse AFM. Note how the width changes by discrete steps (horizontal lines and vertical arrows), which have an average width of 3.7 ± 1.3 nm. [Reprinted from *Small* **3** (2007), D.A. Cisneros, J. Friedrichs, A. Taubenberger, C.M. Franz, D.J. Muller, Creating ultrathin nanoscopic collagen matrices for biological and biotechnological applications, 956–963. 27.4 SUMMARY

Recent developments in the preparation of aligned collagen fibril matrices by shear flow and by using the collagen self-assembly on mica have been reviewed. We demonstrated and discussed in detail the options of both methods and compared them with other techniques.

The shear flow deposition method introduced by the authors of Ref. 41 allows one to create collagen matrices differing in alignment, density, and morphology. These matrix properties can be varied by choosing appropriate process parameters. The versatility of this method allows for the easy and quick preparation of fine-tuned biofunctionalized matrices to enable advanced strategies in cell biology and tissue engineering. In particular, the well-defined matrices provide the opportunity to characterize and control the adhesion, orientation, and migration of cells. Using the resulting options, the surface-engineered collagen substrates were used to guide neurite outgrowth and elongation in vitro [67]. Since the collagen fibril architecture in vivo is tissue-specific and cellular fate decisions critically depend on the surrounding ECM [68, 69], cell biology experiments to investigate the effect of collagen fibril length and density on stem cell differentiation are of great interest. For that purpose, the formation of aligned collagen fibrils will be further elaborated to incorporate glycosaminoglycans such as heparin and heparan sulfate [70], which mediate growth factor and protein binding [71]. This method is also applicable for building up 3D matrices through layer-by-layer deposition and for the coating hollow tubular structures to be used as conduit in nerve repair.

In the second part of the chapter we demonstrated that collagen molecules can be processed into an ultrathin (≈3-nm) collagen matrix. Collagen fibrils of this 2D matrix can be precisely aligned at the nanometer scale. Adjusting the buffer conditions controls the spacing and structural orientation of collagen fibrils to highly reproducible matrices. These buffer conditions also determine whether the fibrils establish their native D-band periodic structure. Currently, the self-assembly of collagen matrices is conducted using muscovite mica as the supporting surface. In the future, self-assembly of the matrices should be carried out on other surfaces. Alternative approaches may involve floating theses layers from the supporting surface and using them for coating nonbiological and biological materials. Experiments extending these matrices to other materials and applications are in progress. Collagen matrices may be further mechanically and physically stabilized by the introduction of crosslinks between the fibrils using the enzyme lysyl oxidase [72]. This would allow biotechnologically promising applications to functionalize the matrices by almost any given type of protein fused to collagen-binding domains. These matrices would provide a native environment for proteins, eliminating nonspecific protein interactions with the supporting surface [73, 74]. Most importantly, such an approach would provide a matrix to cover biosensors. In future, functionalization of this ultrathin matrix with other proteins may allow the development of a toolbox for biosensors or biomaterials. In nature, cells adapt and modify the surrounding ECM by mechanical or chemical means [75]. It is of tremendous cell biological and medical interest to be able to create biomaterials that regulate cellular functions. Artificial environments may be developed for cells that include essential natural substrates that lead cells to desired states of differentiation or activation. Existing applications of collagen as a biomaterial include their use as drug delivery systems, for skin replacements, and as matrices for cell culture [76]. The collagen matrices described provide nanostructured patterns, which may in the future be functionalized with ECM proteins or biochemical signals to regulate cell functions [77].

ACKNOWLEDGMENT

We gratefully thank Elsevier and Wiley for permitting the reuse of material from Refs. 41 and 51 for the preparation of this chapter.

COLLOIDAL CRYSTALLIZATION

TSUNEO OKUBO

Institute for Colloidal Organization, Hatoyama 3-1-112, Uji, Kyoto 611-0012, Japan

28.1 INTRODUCTION

More recent research has focused on colloidal crystals, that is, the crystal-like distribution of colloidal particles in suspensions of aqueous and organic solvents [1–13]. Many researchers have studied structural colors, interparticle reactions, crystal structure, morphology of single crystals, phase transition, crystallization kinetics of nucleation and crystal growth, physicochemical properties (rigidity, viscosity, etc.), structural changes induced by external fields (e.g., gravity, centrifugal and electric fields, shearing forces), and technical applications (photonic crystals, colloidal lithograpy, etc.).

As is well known, all kinds of substances or materials are composed of a huge number (on the order of Avogadro's number, ideally) of elementary particles (atoms, molecules, colloidal particles, etc.). There exist three states of substances–gas, liquid (normal and ordered liquids), and solid (crystals and amorphous solids), depending on the distribution of the elementary particles as a function of time. In *gas* state, all the elementary particles move freely by the thermal energy $k_{\mathrm{B}}T$ given to each elementary particle in the modes of translation and rotation. Here, k_B is the Boltzmann constant and T is the absolute temperature. When an elementary particle collides with other particles or with a container wall, it is simply reflected. In *liquid* state, all the elementary particles also move freely but maintain short nearest-neighbor interparticle distances. The elementary particles in *solid* state also move in the vibrational and rotational modes with thermal energy but keep their equilibrium points. It is easy to distinguish between a crystal and an amorphous solid; the former distributes *in order* and the latter, *in disorder*. Irrespective of the kind of elementary particles, all the substances have three states depending on the abovementioned conditions. Thus, *colloidal gases*, *colloidal liquids*, and *colloidal crystals* are sound scientific terms that refer to substances whose elementary particles are colloidal particles themselves. It should be noted here that many researchers have used the term *colloidal glasses* for highly concentrated suspensions of polydisperse colloidal particles. This author, however, proposes the *amorphous solid* instead, which is much better than the *glass*, following the simplified definition of states of substances.

Two groups of colloidal crystals have been studied intensively hitherto: those in (1) diluted and deionized aqueous suspensions (*soft* systems) [14–33] and (2) concentrated suspensions mainly in the refractive index (RI)-matched organic solvents (*hard* systems) [34–39]. Soft crystals are very convenient models for studying both *soft*- and *hard*-sphere systems, depending on the ionic concentrations of suspension; examples are *soft* crystals in the exhaustively deionized state and *hard* crystals in the presence of a rather large amount of salt, such as sodium chloride. The hard crystal is best for study of crystallization only by the interparticle repulsive interaction due to the thermal movement of particles, excluding volume effects (or steric stability effects). On the other hand, soft crystals also result from *repulsive interaction* between particles; these phenomena are termed *electrostatic repulsion* and *excluded-volume effects*. We should note here that in the usual crystals, such as metals, proteins, and ice, *attractive interactions* between elementary particles play an important role in the crystallization process, as will be described below.

We should note that most colloidal particles in water acquire *negative charges* on their interfaces with water in order to lower the enlarged Gibbs free-energy interface by

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

two mechanisms: by the (1) *dissociation of ionizable groups* and (2) *preferential adsorption of ions* from suspension. These ionic groups leave their counterions, and these excess charges accumulate near the interface, forming an electrical double layer. The counterions in the diffuse region are distributed according to a balance between the thermal diffusive forces and the forces of electrical attraction with colloidal particles. The importance of the electrical double layers for the colloidal crystallization of soft system has been clarified by many researchers [1–33]. The giant size of single crystals is the result of the exhaustively deionized and diluted suspension of colloidal spheres, where the number of nuclei available for crystallization is drastically reduced [23–33]. Colloidal crystals are very visually appealing, with their strong structural colors, because the interparticle distance is often just in the order of the light wavelength, with each single crystal reflecting light in different colors, due to *Bragg diffraction*.

In this chapter, general features of colloidal particles and their crystallization in terms of their structural, kinetic, and dynamic properties such as morphology, crystallization kinetics, physicochemical properties, and electrooptical phenomena, especially in aqueous media, are reviewed and discussed.

28.2 PREPARATION AND CHARACTERIZATION OF BIOLOGICAL AND SYNTHETIC COLLOIDAL PARTICLES

28.2.1 Biological Colloidal Particles

There exist several biological colloidal particles. Tobacco mosaic virus (TMV) (cylinderlike, 18 nm in diameter and 300 nm in length) is typical as rodlike colloidal particles [40–443]. Further large assembling of TMV was also studied [44]. Cowpea mosaic virus (CPMV) is also rod-shaped [45]. Purified samples of bacterial cellulose (*nata de coco*) is rod-shaped, 1–2 μm in length and 10 × 50 nm in cross section, and their suspension shows heavy iridescent birefringence [46]. Various kinds of 2D assemblies of H-shaped streptavidin mutants form, depending on the pH values [47]. Filamentous bacteriophage *fd* virus is also interesting as one of the rodlike biological polymers [48]. Microcrystalline cellulose is rodlike but rather polydisperse ellipsoidal [49, 50]. Microcrystalline cellulose was stabilized in aqueous media by grafting the cellulose with poly(ethylene glycol) or carboxylation [51]. Typical collagen is a rodlike polymer with a 280 nm length and 1.2 nm diameter and is composed of three amino acid chains wound into coaxial helices [52–54]. The temperature-induced gel–sol transition of the small chains of collagens is a very interesting phenomenon. The shape of *Lypocodium* spore is determined by the combination of hemisphere and tetrahedron, but close to sphere totally (30 μm in size) [55]. Pollen particles (10–50 μm in size) from many kinds of flowers are typical examples of biological colloidal particles. However, many of them are not so stable and not dispersed homogeneously in water. Diatoms are typical examples of inorganic and naturally occurring colloidal particles [56]. Their shape and surface structure are beautiful–spherical, ellipsoidal, linear, triangle, crescentlike, violinlike, and so on. Fossil colloidal spheres of radiolarian are rather monodisperse in size [57]. Diatoms and radiolarians originate from algae and plankton, respectively. However, their main chemical components are the same: *silica*. Oceanic colloidal particles such as Palau white clay will be also grouped into a biological colloidal particle.

28.2.2 Polymer Colloidal Particles

Monodispersity in size of spherical particles plays an important and basic role for in colloidal organization. Highly monodisperse polystyrene and poly(methyl methacrylate) spheres (PMMA, size ranging from ∼20 nm to several mm in diameter) are now available commercially. In particular, polystyrene spheres such as Dow polystyrene and Duke Scientific sulfonated polystyrene spheres have been used so often among researchers as the standard samples [58–65]. Anionic and cationic polystyrene spheres are synthesized by using anionic and cationic initiators, respectively. However, we should note that the cationic ones are generally unstable, as described below in detail. Various kinds of core–shell spheres, where the hard core is coated with a soft shell and vice versa, have been prepared by the copolymerization method, for example [1,60,63]. PMMA stabilized by thin layers (∼10 nm) of poly-12-hydroxystearic acid spheres were used in a mixture of decalin and tetralin (or carbon disulfide) to match the refractive index of the spheres in the field of the hard colloidal crystallization [66–71]. Monodisperse poly(1*H*,1*H*-heptafluorobutyl methacrylate) spheres (138 nm in diameter) were synthesized [72]. Several kinds of fluorine-containing polymer spheres, poly(tetrafluoro ethylene), PTFE, copolymer of tetrafluoroethylene and perfluorovinylether, and copolymer of perfluoroethylene and perfluoropropylene, were also used to study colloidal organization [73, 74]. Colloidal spheres having cores rich in polystyrene and shells rich in hydrated poly(2-hydroxyethyl methacrylate) were synthesized [75–77]. Heterocoagulation of large cationic spheres with small anionic polyacrylate beads followed by heat annealing produced core–shell particles [78]. Hollow polyelectrolyte capsules were prepared by means of stepwise adsorption of polyelectrolytes followed by dissolution of the templating core [79]. Furthermore, vesicle-templated polymer hollow spheres were synthesized [80]. Polyelectrolyte multilayer coatings on the colloidal particles have been studied extensively [81–84].

Anisotropically shaped colloidal particles are most interesting for study of the organization including crystallization. Anisotropy-shaped polymer particles, such as symmetric doublets [85], asymmetric doublets [85], and egg-shaped [86], ellipsoidal [85], beadlike [87], snow dole-like, dumbbell-like, raspberrylike [88, 89], clenchlike, comfitlike (*framboidal*) [90], golfball-like [91], red-blood corpuscle-like [92, 93], disklike, and polyhedral [94, 95] particles are now available at laboratory scale. Monodisperse ellipsoidal polystyrene particles have been prepared by the unique method of stretching the polystyrene spheres dispersed in the film of poly(vinyl alcohol) [96, 97]. Bowl-shaped particles were used for study of the orientation and inclusion phenomena [98–100]. Monodispersed colloidal gel spheres have been synthesized. Gel spheres of poly(*N*-isopropylacrylamide) are famous as typical samples of thermosensitive hydrogels [101].

28.2.3 Inorganic Colloidal Particles

Monodispersed colloidal particles of metals [102], metal oxide [103], and metal sulfides [104] have been synthesized intensively. Colloidal silica spheres have been used often for study of colloidal organization phenomena such as colloidal crystallization and drying patterns for >20 years [105, 106]. Highly monodisperse colloidal silica spheres ranging from 5 nm to 10 mm in diameter are now available commercially. Colloidal silica spheres coated with other functional groups, dyes, fluorescent probes, and so on using the reactive silanol groups have been studied [107–110]. Colloidal silica spheres modified with linear-type polymers and their colloidal crystallization have been studied intensively [111–116]. The dispersion property of colloidal silica spheres coated with a layer of end-grafted poly(dimethylsiloxane) was studied in heptanes [117]. Titania (TiO_2) colloidal spheres are synthesized in a diffusion flame reactor and by others [118–122]. Spherical (polyhedral in the strictly sense) gold particles ranging from 2 nm to several μm in diameter are famous as the hydrophobic colloidal spheres and their aggregates by the addition of salts following the Shultz–Hardy rule [123, 124]. Similar-sized aggregates (∼1 μm) from gold preparticles are obtained [125]. Gold spheres have been also synthesized [126, 127]. Studies using silver spheres were also reported [128, 129]. Small silver spheres capped with dodecanethiol were prepared and formed ordered arrays after drying [130]. Syntheses and their organization of the similar-sized agglomerates (1.5 μm in diameter) from the diamond preparticles (4–6 nm in diameter) have been reported [131, 132]. Spherical particles of unique morphology of boehmite, α-AlOOH, were obtained by aging acidic solutions of alminum perchlorate [133–135]. Colloidal spheres of CdS and ZnS have been prepared [136–138]. Charge reversals of CdS colloidal spheres under the Langmuir–Blodgett membrane were reported [139]. Molybdenum sulfide particles were synthesized in microemulsion [140]. Colloidal copper dispersion was studied [141]. Copper oxide(I) spheres (∼200 nm in diameter) were synthesized [142]. Colloidal spheres of PbI_2 were prepared [143]. Core–shell-type (CdSe)ZnS particles (2.3–5.5 nm) have been studied [144]. Core–shell microspheres consisting of single-walled carbon nanotubes and $CaCO_3$ were synthesized [145].

Symmetric polyhedron-shaped particles are prepared mainly from metals. Cubic colloidal particles (20–50 nm in size) composed of MgO, CdO, PbSe, PbTe, and αFe_2O_3 have been synthesized [146, 147]. Cube-shaped platinum particles have been prepared [148]. Hexahedron-shaped particles of WO_3, InS_3, and SnO_2 were also obtained [130]. Octahedrons of In_2O_3 were prepared [121]. Octahedron-shaped alnite $Fe_3(SO_4)_2(OH)_5.2H_2O$ was crystallized on heating acidic solutions of ferric sulfate [134, 135]. Flowerlike particles formed from $FeCl_2$ and bipyridine are beautiful. Whisker-shaped particles (5 μm in wing length) were synthesized by Matsushita Sangyo Co. (Osaka). Hexahedral copper oxide (CuO) particles were obtained [103]. Furthermore, Au, Ag, Ni, and Al are known to produce octahedron-shaped particles [130].

Spindle-shaped colloidal silica particles have been prepared [149]. Rod-shaped [150–153] and platelike particles of gold [154, 155] are available at laboratory scale. Stacking aggregates of platelike gold particles are also interesting [154]. Platelike particles of nickel(II) hydroxide coated with polyacrylate were stable in aqueous suspension [156]. Platinum colloidal particles of different shapes were synthesized [157]. Rod-shaped (or ellipsoidal) particles of β-FeOOH are obtained from $FeCl_3$ after 6–10 months at room temperature as a red suspension at the bottom of the container [158]. Rodlike boehmite (γ-AlOOH) particles have been used for study of phase transition [159]. α-Alumina, α-Al_2O_3 particles (average size ∼200 nm) with an irregular shape are available commercially. Silica- coated boehmite rods (e.g., 230 nm in length, 9 nm in diameter) [160] were synthesized according to the method of Buining [161]. Sterically stabilized gibbsite, $Al(OH)_3$ platelets are also used for the crystallization phenomena [162]. Ellipsoidal TiO_2 [163] and rodlike rutite-type particles [164]were prepared. Bentonite (or montmorilonite) particles are platelike in shape, but their monodispersity is not extensive [49]. However, rather monodispersed bentonite particles were obtained by the fractional repeated centrifugation technique [165–168]. Ellipsoidal plate-shaped particles of tungstic acid, $H_2WO_4{\cdot}H_2O$, are highly monodispersed [169–172]. Howevere, these particles disappear after several weeks in the deionized state with coexistence of ion exchange resins, since the tungstic acid particle is one of the sparingly water-soluble electrolytes in water (like silver chloride) and is ion-exchanged for a long period. Rod-shaped or spindle-shaped V_2O_5 particles have been prepared [173]. Disklike manganese oxide particles were synthesized and their ordered arrays were studied [174].

Monodisperse cylindrical (or rod-shaped) particles of nickel dimethylglyoxime were obtained, and an ordered array of the particles was observed [175]. Disklike pseudocubic [52], ellipsoidal [176], peanut-shaped [177], and hexagonal plate-shaped hematite (αFe_2O_3) particles [177] were prepared by the sol–gel method. Spindle-shaped hematite particles coated with polymer brush were synthesized and their crystallization was studied [178]. A disk-like particle (3 nm in diameter and 0.1 nm thick) of a synthetic trioctahedric hectorite has been studied [179–181]. Laponite, synthetic hectorite clay, is a disklike particle [182, 183].

28.2.4 Basic Characteristics of Colloidal Particles

Characterization of the surface charges is very important for study of colloidal crystallization, especially in aqueous media. The stoichiometric charge density of colloidal particles can be determined conveniently by conductometric titration [184]. The titration curves have been shown in several papers, for example [49,185–187]. Potentiometric (pH) determination of charge density has been reported [188].

For colloidal particles, irrespective of shape, the *counterion* association, that is, the strong associative interaction between the charges on the particles and their counterions, which deprives some of the counterions of freedom of thermal motion, has been a subject of extensive theoretical and experimental study. The effective charge number as a fraction of the stoichiometric one (β), which is determined from conductance [1,149,189], electrophoretic mobility [190], dielectric [191], and osmotic pressure measurements [192], decreases as the analytical (stoichiometric) charge number of a particle (Z) increases. The relationship between β and Z is shown in Eq. (28.1) [185].

$$\log \beta = 2.61 - 0.87 \log Z, \quad \text{for } Z > 3000 \qquad (28.1)$$

Note that the β values for colloidal spheres with very large Z values become extremely small. For example, 99.9 % of total counterions are associated with the charges on the sphere surface when Z is 10^6. The charge renormalization effect has been discussed in the literature [193–195]. Counterion binding of colloidal spheres has also been discussed [196]. We should note here that 1-β corresponds to the counterion binding at the surface of the Helmholtz layer in electrical double layers.

28.3 WHY CRYSTAL STRUCTURES FORM

Many researchers have clarified that the colloidal crystals form by Brownian movement of colloid-sized particles and by interparticle *repulsion* according to the principle of deadspace minimization [11,20,25–31]. In other words, particles form crystal-like distribution *spontaneously* with the help of Brownian thermal movement of particles by maximizing packing density [197]. Kepler's proposal that the volume density of the most densely packed 3D sphere, with face-centered cubic (fcc) lattices, is $\pi/18^{1/2}$ ($= 0.90689\ldots$) has been approved by Hales [198, 199]. The volume density of the most dense 2D packing (hexagonal structure) was found to be $\pi/12^{1/2}$ ($=0.906899\ldots$.) [200, 201]. For 2D ellipses, it proves to be very difficult to calculate the volume density of the most dense packing. Densities of the seven kinds of packing have been calculated hitherto [202]. For 3D ellipsoids, density is rarely discussed theoretically. It should be noted here that some of protein molecules opt to form close-packed 2D ordering. For example, spherical molecular chaperone and rectangular catalase molecules form hexagonal and rectangular 2D sheet structures in solid state [203].

A team of investigators [3,64] clarified that colloidal crystallization takes place by Kirkwood–Alder transition. When extrarepulsive interaction (such as electrostatic repulsion) is in effect among colloidal particles in addition to the repulsion forces from their *Brownian movement*, colloidal crystallization takes place easily even at the very low particle concentrations. The thickness of the *electrical double layers* is estimated approximately with the Debye screening length l_D as given by Eq. (28.2). Debye length corresponds to the distance from the colloidal surface, where the electrostatic potential decreases to be 1/2.7 compared to that at the slipping zone:

$$l_D = \left(4\pi e^2 n / \epsilon k_B T\right)^{-1/2} \qquad (28.2)$$

Here, e is the electronic charge, ϵ is the dielectric constant of the solvent, and n is the concentration of *diffusible* or *free-state* cations and anions in suspension. Thus, n is the sum of the concentrations of diffusible counterions and "foreign salt," and of both H^+ and OH^- from the dissociation of water. Maximum value of l_D in water is $\sim$1 μm, which is estimated from Eq. (28.2) by taking $n = 2 \times 10^{-7}$ (M) $\times N_A \times 10^{-3}$ cm^{-3}, where N_A is the Avogadro number. It should be noted that the electrical double layers form always, without exception, in the colloidal dispersions of a solid in a polar liquid.

In the deionized state, the electrical double layer is very thick, and the interparticle repulsive forces prevail over long distances, as long as *micrometers*, although the forces become very weak. Formation of the crystal-like ordering is explained nicely with the *effective soft-sphere model*. The effective diameter d_{eff} of spheres includes the Debye screening length l_D and is given by the diameter plus twice the Debye length. When d_{eff} is shorter than the observed intersphere distance l, a gaslike distribution is observed. When d_{eff} is comparable to or a bit shorter than the intersphere distance, the distribution of spheres is usually liquidlike. When the effective diameter is close to or greater than the

observed intersphere distance, crystal-like ordering forms. The effective soft-sphere model has been supported by many researchers from the systematic comparison of d_{eff} with l values [11,20,25,28–31]. We should note again that the *colloidal* crystals, liquids, and gases are analogous to and models of the structures of actual molecules and atoms in the state of crystals, liquids, and gases [3,66].

The lattice spacing of colloidal crystals changes according to the particle concentration *exclusively*, which definitely supports the importance of the interparticle *repulsion* induced by Brownian movement of particles themselves and also the electrostatic interparticle *repulsive* forces. The formation of Coulomb crystals for the trapped spherical plasma with a single sign (plus) of charge has been reported [204]. This observation also strongly supports the important role of *electrostatic repulsion forces* for the crystallization in addition to the *Brownian movement* of the respective plasmas. Quite a few researchers have proposed the occurrence of intersphere *attraction* forces instead of *repulsion* for colloidal crystallization. However, this idea has been proved to be absolutely erroneous [11,205]. Colloidal crystallization takes place by interparticle repulsion *exclusively* irrespective of particle concentration ranging from very diluted to concentrated suspensions. We should note here that typical crystals in nature such as ice, metals, and proteins form by the *attraction*, not *repulsion*, of like colloidal crystals.

The critical concentration of melting of colloidal crystals in the deionized aqueous suspension ϕ_c in volume fraction is very sensitive to the degree of deionization of the suspensions. According to the author's experience, stock suspension must be deionized with the coexistence of the mixed beads of cation and anion exchange resins for more than *one month*, ideally, for 1–10 years. Furthermore, the sample suspensions prepared by dilution of the stock suspension with pure water must be deionized further >3 weeks before measurement. Most reliable ϕ_c values have been obtained for exhaustively deionized suspensions of monodisperse polystyrene spheres and colloidal silica spheres having diameters of 80–200 nm located around 0.0003 in volume fraction irrespective of sphere diameter [20]. The sharp increase in ϕ_c was observed, however, for spheres of <60 nm diameter [20]. Colloidal spheres that are not large enough compared with the sizes of solvent water, hydronium ions and other simple ions, can not contribute to the formation of electrical double layers.

28.4 MORPHOLOGY AND PHASE DIAGRAM OF COLLOIDAL SINGLE CRYSTALS

The close-up color images in Fig. 28.1 show typical examples of the single crystals of monodispersed silica spheres appearing in aqueous dispersions. The stock suspensions were deionized exhaustively by the coexistence of cation and anion exchange resins for >10 years. Cells were placed

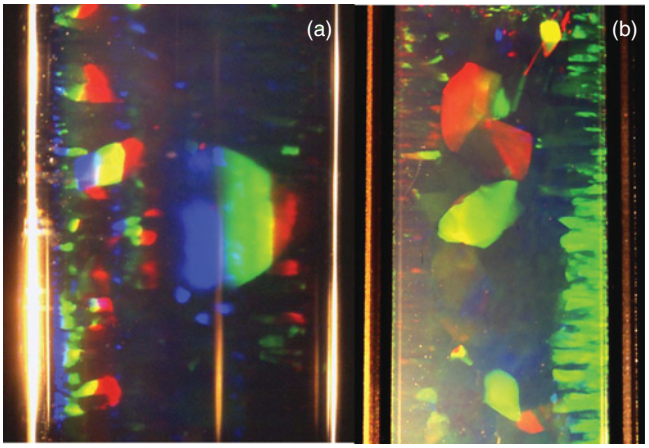

FIGURE 28.1 Close-up images of colloidal crystals in test tube (a) and in a plain cell (b) at 25°C. (a) CS91, ϕ; = 0.00083, 18 days after preparation and 1 h after mixing; (b) CS81, $\phi = 0.00095$, 7 days after preparation and 40 min after mixing. For a color version of this figure, see the color plate section.

in a test tube (Fig. 28.1a) and a quartz glass optical container for fluorescence measurements, 10 mm in width, 10 mm in depth, and 40 mm in height (Fig. 28.1b). The resins coexisted in the bottom of the cell (the parts of the bottom are cut here). The pictures were taken 18 days and 7 days after suspension preparation, and 1 h and 40 min after upturn mixing, respectively. Sphere concentrations were 0.00083 and 0.00095, respectively, in volume fraction. In these experimental conditions, very few nuclei form and the single crystals become very large. These colloidal single crystals can be observed with the naked eye, and they are quite large and beautiful. Influence of the polydispersity of colloidal spheres on the critical concentration of *crystal–liquid* phase transition has been discussed [206–211]. It should be noted here that the effective polydispersity of colloidal spheres decreases sharply in the deionized aqueous suspension, since the effective diameter $d_0 + 2 \times l_D$ comes to be very large compared with the real diameter. Here l_D is given by Eq. (28.2). The critical concentration of melting or crystallization (ϕ_c) in deionized suspensions increased sharply with increasing polydispersity of the spheres. It should be noted that morphology of colloidal crystal is essentially the same as that of other typical crystals. Most metal crystals are composed of single crystals surrounded by grain boundaries. Lattice spacings of colloidal crystals, studied by reflection spectroscopy in detail [28–31,33], are very long, several thousand times greater compared with that of metals, and just in the range of light wavelengths. There are two basic kinds of single crystals (observable in Fig. 28.1): (1) red, blue, yellow, and blocklike crystals, are formed by the *homogeneous nucleation mechanism* in the bulk phase far from the cell wall; and (2) green and pillarlike crystals grow by the *heterogeneous nucleation mechanism* along the cell wall. It should be noted

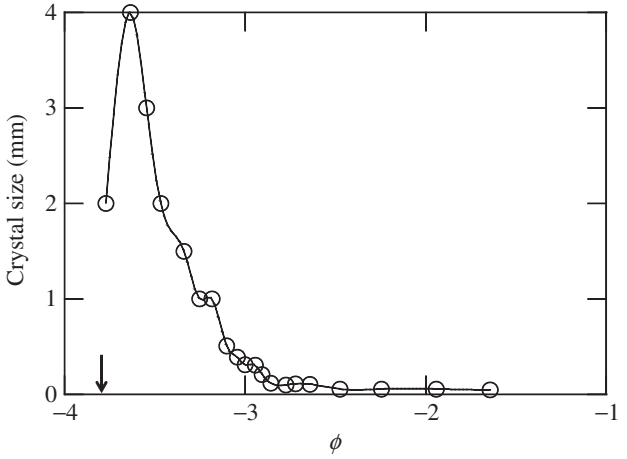

FIGURE 28.2 Mean single-crystal sizes as a function of sphere concentration. Polystyrene spheres (D1B76), 109 nm in diameter, critical concentration of melting: 0.00016 (ϕ).

that each single crystal is surrounded by grain boundaries and that the crystals are densely packed [212,213]. When the incident light angle is changed slowly, the packing state of the single crystals is observable.

The single crystals suddenly became much larger when the sphere concentration decreased in the exhaustively deionized suspensions [11,20,23]. A typical example of the mean size of the single crystals relative to sphere concentration is shown in Fig. 28.2. This observation is quite understandable, because crystal size should increase with decreasing nucleation rate, and also with decreasing number of nuclei. Nucleation rate, of course, decreases as sphere concentration decreases. When the sphere concentration is comparatively high, size of colloidal crystals is very small, and single crystals are not observed with the naked eye. Colloidal single crystals have been observed by polarizing microscopy [214].

Another group of investigators have measured the melting temperature of colloidal crystals, for the first time, as a function of sphere concentration [4]. Heat of melting and entropy change were 16–21 kJ/mol and 42–67 J/K, respectively. This author [18,105,215, 216] measured melting temperatures of exhaustively deionized colloidal crystals. The crystalline sediments of monodisperse stearylated silica spheres formed by gravity [217]. Phase diagrams and dynamics of colloidal crystals and colloidal liquids were discussed experimentally and theoretically in detail [10,16,218–225].

28.5 LATTICE STRUCTURE OF COLLOIDAL CRYSTALS

Generally speaking, structures of colloidal crystals are face-centered cubic (*fcc*) or body-centered cubic (*bcc*) lattices. Square-ordered structures, however, were observed when two plates of a cell were oriented in a wedge geometry [7]. Abundant data on the colloidal lattice structures indicate that *fcc* lattices are most stable and transform into *bcc* lattices when (1) particle concentration is very low, (2) a small amount of salt is added, (3) the suspension temperature is raised, (4) the particle charge density is high, or (5) high pressure is applied [11,20]. The coexistence of *fcc* and *bcc* crystal lattices is closely related to the increased free space for particles forming lattice structures; in other words, the *fcc* form is more dense than the *bcc* one. The *fcc* and *bcc* structures are observable visually by a metallurgical microscope, especially in sedimentation equilibrium, and the interparticle distances can be determined from microscopic observation. However, it is usually difficult to observe the 3D lattice structures microscopically, even by scanning microscopy. Amorphous solid (or glass) structures are observed for highly polydispersed colloids, especially in rather concentrated suspensions. The lattice spacing of colloidal crystals can be studied conveniently by reflection and transmission optical spectroscopy. The shape of a spectrum pattern is a single peak, a double peak, or a single peak with a shoulder. The peak wavelengths originating from *fcc* and *bcc* are always close together, with a difference of only 1.03 in the ratios of their peak wavelengths. The author's group clarified that the cationic charged colloidal crystals formed, although the spheres were not as chemically stable as in the deionized condition [226]. Furthermore, core–shell-type spheres formed colloidal crystals in deionized aqueous media [227, 228].

Several types of asymmetric colloidal crystals have been studied, especially in sedimentation equilibrium in deionized suspensions of anisotropic particles. Cylindrical colloids of nickel dimethylglyoxime (9.6 μm in length, 0.12 μm in diameter) were ordered in a hexagonal array [175]. It is now clear that the particles are oriented to reduce the deadspace as effectively as possible. Bowl-shaped polystyrene particles were also oriented in deionized suspension (see Fig. 28.3a) [98, 99,229]. Interestingly, these particles included spheres of various sizes in their cavities (see Fig. 28.3b). Both the host and guest particles were not in direct contact, but remained separated by the electrical double layers formed around the particles. The particle distribution of ellipsoidal poly(tetrafluoroethylene) on transformation from unsymmetric to symmetric crystals has been observed, with dilution accompanied by thickening of the electrical double layers [99]. Asymmetrically ordered structures, similar to paved bricks, have been formed in rectangular tungstic acid colloids. Ordered phases of platelike particles were observed in rather concentrated dispersions [98, 99].

It is well known that the rodlike and/or disklike colloidal particles form nematic, smectic (or lamellar), and columnar ordering. One researcher [230] studied the nematic ordering of tobacco mosaic virus (TMV) and found that this ordering

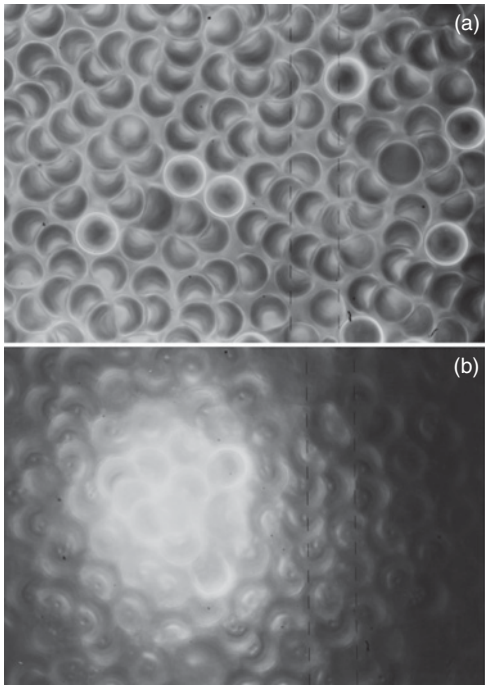

FIGURE 28.3 Microscopy of arrangement of bowl-shaped colloidal particles (DR728) (a) and their inclusion with colloidal spheres (N1000) (b). (a) $\phi^* = 0.000199$; (B) $d_0 = 1.02$ mm, $\phi^* = 0.00241$, length of the full scale: 10 μm.

takes place because the loss in orientational entropy is compensated by the gain in packing entropy. The nematic suspensions of rodlike boehmite (AlOOH) [159,231], Li_2Mo_6 wires [232], V_2O_5 ribbons [233], and imogolite nanotubes [234, 235] have been studied intensively. A magnetically oriented microcrystal array was obtained for $LiCoPO_4$ microrods, mesocrystals of L-alanine and lysozyme [236–240].

28.6 ALLOY CRYSTALS OF COLLOIDAL MIXTURES

Opal is one of the typical examples of colloidal alloys fixed in solid state, which may form during the course of sedimentation of the mixtures in suspension having different but rather monodisperse-sized colloidal spheres [241, 242]. Colloidal alloy structures are very interesting because most of the structures of metal alloys also appear in colloidal suspensions of binary mixtures of spheres. The superlattice structures observed hitherto in colloidal systems are of the AlB_2, $NaZn_{13}$, $CaCu_5$, $MgCu_2$, NaCl, and AB_4 types [243–251]. Note that these alloy structures are explained by changes in the effective size ratio, that is, the effective size of small spheres, including the electrical double layers versus that of large spheres [241,245], and the segregation effect [252].

28.7 COLLOIDAL CRYSTALLIZATION KINETICS

Most kinetic measurements on colloidal crystallization showed an induction period, after which the crystal growth starts, especially in diluted suspensions (see Fig. 28.4a). This observation supports the theory that the kinetics of colloidal crystallization is explainable by the classical diffusive crystallization theory, including nucleation and crystal growth processes [253–256].

The number of nuclei that germinate per unit of time, the nucleation rate v_n, is given by

$$v_n = \phi l^3 \Big/ \left[\left(4\sqrt{2}/3 \right) \pi (d_0/2)^3 L^3 t_i \right] \qquad (28.3)$$

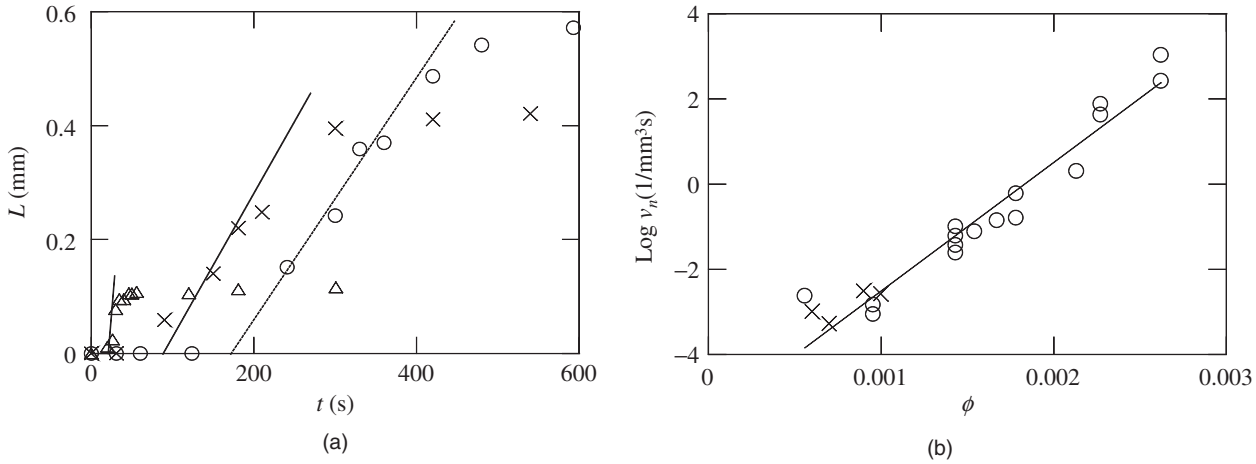

FIGURE 28.4 (a) Crystal size estimated from the half-width during course of crystallization of CS91 spheres at 23°C. Circles, $\phi = 0.00143$; crosses, 0.00179; triangles, 0.00262; (b) nucleation rates of CS91 spheres at 25°C. Circles, taken from Ref. 254; crosses, Ref. 253.

where ϕ is the volume fraction of sphere particles and L and l are the mean size of single crystals formed and the nearest-neighbor intersphere distance, respectively; d_o is the diameter of sphere particles. t_i is the induction period and corresponds to the time of nucleation process.

Colloidal crystallization processes consist in rapid growth of a metastable crystal (step 1) and slow reorientation toward the stable crystal (step 2). The first crystal growth rate of a metastable crystal v_1 is given by [256]

$$v_1 = v_{1\infty}\left[1 - \exp(-\sigma)\right] \tag{28.4}$$

Here, σ is the relative supersaturation given by $(\phi - \phi_c)/\phi_c$, ϕ_c is the critical concentration of melting, and $v_{1\infty}$ is the maximum crystal growth rate. Equation (28.4) is further simplified as follows:

$$v_1 = v_{1\infty} - v_{1\infty}\phi_c/\phi \tag{28.5}$$

Equation (28.5) shows that the growth rate decreases linearly as the reciprocal sphere concentration increases; this observation has been supported experimentally, but only in a very low sphere concentration range [256].

The peak profile in reflection spectroscopy became sharp with time during the course of crystallization, which corresponds to an increase in crystal size. The background intensity decreased in the course of crystallization, which is ascribed to the diminution in the multiple scattering of the suspension. The nearest-neighbor intersphere distance l is determined from the peak wavelength [257]. The calculated value of the nearest-neighbor intersphere distance is obtained from the sphere size and concentration [257].

As was described earlier, an excellent agreement between l and l_0 has been obtained, which demonstrates that the lattice spacing of the colloidal crystal changes according to the sphere concentration exclusively, and furthermore, that the crystals form by intersphere repulsion due to Brownian movement of the spheres themselves and also by the electrostatic intersphere repulsive forces.

The nucleation rate v_n increased substantially as sphere concentration increased, as is shown in Fig. 28.4b. This rate increased by 10^{10}-fold when ϕ increased by 10^2-fold. An increase in sphere concentration is followed by an increase in v_n, and number of nuclei, and resulted in a decrease in the size of single crystals formed, as discussed in one report [36]. It should be mentioned here that the size of single crystals, observed with by the naked eye, is polydisperse, as has often observed (see Fig. 28.1 for examples) [23]. Therefore, any clear separation of the nucleation step from the crystallization process will be difficult, and the nucleation reaction may remain operative even in the crystal growth period.

The fast and slow crystal growth rates, v_1 and v_2, were evaluated for colloidal crystallization. The v_1 values in the diluted suspensions decrease linearly as the reciprocal concentration of spheres increases [254]. It should be noted that the importance of the dynamic phase transition has been reported for colloidal crystals and for other crystals such as metals and polymers. v_2-value decreases as sphere concentration increases. The slow crystallization step is ascribed to the *reorientation* of the metastable crystals formed in the first step toward the stable ones matched with the other crystals mediated by the grain boundaries and the cell wall. When sphere concentration is high, the number of the metastable crystals formed is huge and their size becomes quite small. Then, a very long time will be required for matching of the crystals with other crystals and with the cell wall. The occurrence of *Ostwald ripening* is also highly plausible in the slow process, though direct observation was not successful until one team [258] observed the ripening for colloidal crystallization processes.

The kinetics of colloidal crystallization in alcoholic organic solvents and their aqueous mixtures have been studied by reflection spectroscopy [259]. Kinetic study of colloidal crystallization in acetonitrile has been performed for silica spheres modified with polymers on their surfaces [260, 261]. Kinetic analysis of the crystallization of ellipsoidal particles under an alternating electric field was also undertaken [262]. The authors studied the kinetics of crystallization in shear flow [263]. Kinetic analyses conducted by one team of investigators [264, 265] to elucidate the mechanisms of colloidal crystallization must be cited here. Dynamics of crystallization in hard-sphere suspensions has been studied intensively by several research groups [266–271]. Crystallization kinetics has been studied and reviewed for both soft- and hard-sphere systems [272, 273].

28.8 STATIC AND DYNAMIC LIGHT SCATTERING AND SMALL-ANGLE NEUTRON SCATTERING

Figure 28.5 shows the static light-scattering intensity $I(q)$ and the effective diffusion coefficients, estimated from the dynamic light scattering D_{eff}, as a function of scattering vector q for the colloidal silica spheres (diameter 103 nm) at $\phi = 0.0049$ [274]. Circles and crosses (tickmarks) indicate the data for the suspensions with and without coexisting ion exchange resins. The suspensions are "crystal" and "liquid," respectively. Surprisingly, very sharp peaks appeared for the crystals. The measurements have been taken at very short intervals of half a degree (0.5°). However, this interval was not always narrow enough for the determination of the reliable values of the peak scattering vector q_m. Static and dynamic light-scattering measurements have been performed mainly for various sizes of colloidal silica spheres [275, 276] and polystyrene spheres [277–279]. Backscattering of light

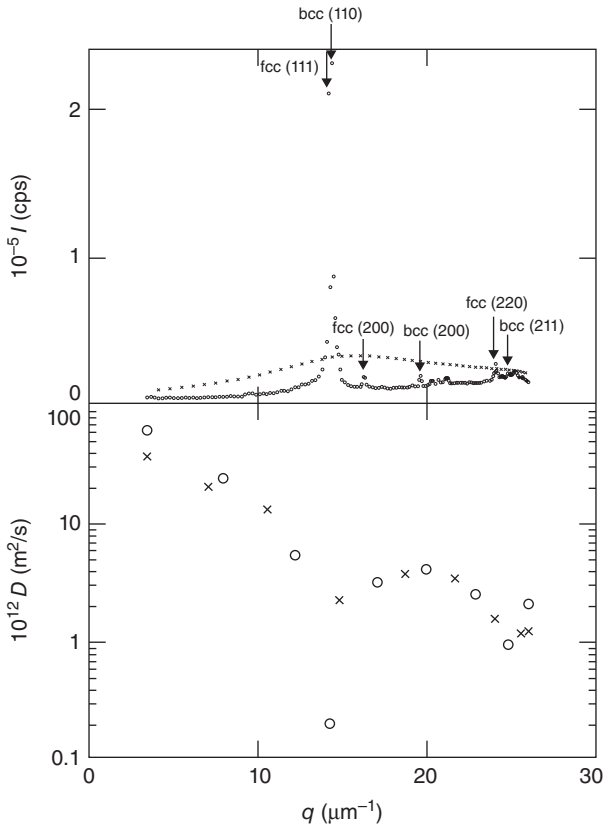

FIGURE 28.5 Static and dynamic light-scattering measurements of CS81 spheres at 24°C, $\phi = 0.0049$.

measurements on the several colloidal crystal systems was also reported [280].

The diffusion coefficients D evaluated from the cumulative analysis are also shown in Fig. 28.5. The D values decreased as the scattering vector increased, whereas the background intensity of scattered light for the crystals increased as q increased. Furthermore, the diffusion coefficients from the suspensions showing peaks in the light-scattering curve were substantially low. According to two authors [281], the *effective diffusion coefficient* D_{eff} is given by

$$D_{\text{eff}} = D_0 / S(q) \tag{28.6}$$

where D_0 is the diffusion coefficient of spheres in "gas" suspension and $S(q)$ is the structure factor. The constancy of $D_{\text{eff}} \times S(q)$ has been satisfactory for colloidal liquids, within experimental error. The interparticle structure factor $S(Q)$, which is important to know for insight into the dynamic particle distribution and the particle interaction, has been observed from light-, X-ray-, and neutron-scattering measurements for deionized and salt-containing colloidal suspensions [67,282–291]. The effect of polydispersity of colloidal spheres on the structural factor was discussed in detail [292].

28.9 STRUCTURAL RELAXATION TIMES OF COLLOIDAL CRYSTALS

Fluctuation of colloidal spheres in the crystal structure is discussed with respect to the structural relaxation time (τ). Two kinds of τ values, in fast (τ_{f}) and slow steps (τ_{s}), are observed by the stopped-flow technique. The former is expressed as follows:

$$\tau_{\text{f}} = D_0^2 / 6D_{\text{tr}} \tag{28.7}$$

Here, D_0 is the mean intersphere distance and D_{tr} is the cooperative translational diffusion constant in strongly interacting structures. The D_{tr} value of spheres is given by the Einstein–Stokes equation for self-diffusion:

$$D_{\text{tr}} = k_{\text{B}} T / (3\eta\pi d_{\text{eff}}) \tag{28.8}$$

Here, η is the viscosity of the solvent. The essential point in the fluctuation of spheres is that the D_{tr} and τ_{f} values observed in the colloidal crystals agree with the calculated values from Eqs. (28.7) and (28.8) when d_{eff} is used instead of d [true diameter of colloidal sphere in Eq. (28.8)] [293, 294]. Agreement between the calculation and observation in the deionized suspensions of monodisperse polystyrene spheres was excellent. It should be noted here that the Debye screening length does not correspond to the hydrodynamic length quantitatively. The hydrodynamic length will be shorter than the Debye length because many of the solvent molecules flow freely through the simple ion clouds of the electrical double layers. One investigative team observed particle motion directly by a microscopy and concluded that the observed translational diffusion constants agreed with the value calculated from Eq. (28.8) using the real value of the sphere diameter [295]. However, the tendency of $D_{\text{obs}} < D_{\text{calc}}$ is not denied in their paper, especially for small spheres, specifically, $D_{\text{obs}} = 3.6 \times 10^{-9}$ cm^2 s^{-1} and $D_{\text{calc}} = 4.0 \times 10^{-9}$ cm^2 s^{-1} for $d = 0.458$ μm.

The τ_{f} value is given by the simple relation [61,296]

$$\tau_{\text{f}} \sim \eta / G \tag{28.9}$$

where G denotes the rigidity or dynamic (local shear) elastic modulus of the suspension. G ranges from 0.01 to 10 Pa for colloidal crystals, and these values are not far from those of previous reports by the dynamic method [6,297–300].

The effect of the electrical double layers on the translational diffusion constant of colloidal spheres has been discussed using photon correlation spectroscopy [301, 302] and also theoretically [303]. The diffusion constant showed a minimum value when the double-layer thickness was comparable to the radius of the particle [10]. Dynamic light-scattering measurements have been carried out in detail for colloidal crystals [304–311]. Particle motion was studied

by the tracer diffusion method for concentrated colloidal suspensions [312].

28.10 RIGIDITY OF COLLOIDAL CRYSTALS

The elastic modulus is one of the most fundamental properties of colloidal crystals and has been measured by various techniques. The static elastic moduli of crystals of monodisperse polystyrene spheres were evaluated from reflection spectrum measurements at sedimentation equilibrium [313]. This author has measured *static* moduli of colloidal crystals by several methods: microscopic observation [49,99,125,175,186,283,314–317] and reflection spectrum methods in sedimentation equilibrium [187,248,318], reflection spectroscopy under centrifugal compression [319], and a direct-current (DC) electric field method [320].

On the other hand, the *dynamic* (shear) elastic modulus has been measured [321] by shear wave propagation experiments. Those researchers measured elastic moduli of flocculated suspensions of colloids in the presence of foreign salt [322–324]. The dynamic moduli of colloidal crystals, especially in the deionized suspensions, have been studied by several teams of investigators [5, 6,296–298,325–330]. This author has measured the dynamic elastic moduli by the structural relaxation method [293, 294] and rotator viscometry [331–333].

The experimental results on the rigidity of colloidal crystals are summarized as follows [11]. *First*, the dynamic elastic modulus is always smaller than the static one. The metastable colloidal crystals are formed rapidly, with structural relaxation times ranging from 10 ms to 1 s. However, formation of the stable crystals in an equilibrium state requires a long time. The elasticity of the metastable crystals is low. Thus the dynamic moduli are smaller than the static rigidity in most cases. Figure 28.6 shows the plots of log G (rigidity) against log N (sphere number per unit volume) reported so far for some colloidal crystals of monodispersed polystyrene spheres with diameters ranging from 91 to 109 nm. G values are denoted by open circles; crosses (tickmarks) and open triangles represent the static ones, which we evaluated at sedimentation equilibrium. The filled circles, filled squares, and filled triangles denote dynamic rigidities.

Second, log G of colloidal crystals, including amorphous solids, increases linearly with a slope of unity as log N increases. The order of magnitude of the modulus may be expressed in terms of the magnitude of the thermal fluctuation δ of a sphere as [3]

$$G \sim f/l \sim \left(k_{\mathrm{B}}T\big/< \delta^2 >\right)\big/l \qquad (28.10)$$

where f is the force constant, l is the intersphere distance, δ is the thermal fluctuation of a sphere in the effective potential valley, $k_{\mathrm{B}}T$ denotes the product of the Boltzmann constant

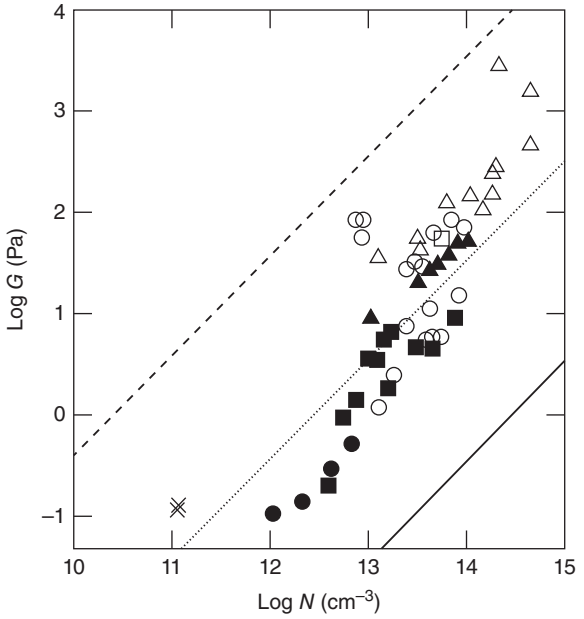

FIGURE 28.6 Rigidities of colloidal crystals as a function of number density of colloidal spheres. Open circles, reflection spectroscopy [187]; crosses (tickmarks), microscopy [315]; open triangles, rotator viscometry [331]; open squares, DC electric fields [320]; solid circles, see Ref. 313; solid triangles, see Refs. 5, 325; solid squares, see Ref. 6. (Redrawn using data from Ref. 182.)

and the temperature. Introducing a nondimensional parameter g for $<\delta^2>^{1/2}/l$, the modulus is obtained as a linear function of N, as follows:

$$G \sim Nk_{\mathrm{B}}T\big/g^2 \qquad (28.11)$$

For $g = 1$, Eq. (28.11) gives the rigidity of an ideal gas having the same sphere concentration. Lindemann's law of crystal melting tells us that $g < 0.1$ holds for a stable crystal.

Third, rigidity of the colloidal crystals, including an amorphous solid, is larger than that of colloidal liquid when comparisons are made at the same sphere concentration. *Fourth*, the rigidity of colloidal crystals increases substantially as the deionization of the suspension proceeds. *Fifth*, the rigidity of the amorphous solid increases as the polydispersity of spheres increases, and the G value of the crystal is smaller than that of amorphous solids at the same particle concentration. *Sixth*, the rigidity of the structured suspensions increases as the particle charge density decreases, which is due to the extended electrical double layers formed with the counterions of the particles. *Seventh*, rigidity at a certain concentration of particles initially increases further. A maximum value of G was observed around 85 nm in diameter. It is interesting to note here that Eq. (28.11) holds for all kinds of substances, including metals, proteins, ice, and colloidal crystals. Rough values of the substances are estimated using Eq. (28.11).

Rigidities of colloidal alloys [334] and the colloidal crystals in alcoholic organic solvents [235, 236] have been studied.

28.11 VISCOSITY AND VISCOELASTICITY OF COLLOIDAL CRYSTALS

This author has measured viscosities of colloidal liquids and colloidal crystals in exhaustively deionized aqueous suspensions, for the first time, with the use of Ostwald-type and rotational viscometers [331,337–341]. The viscosity of the deionized suspension was very sensitive to the degree of deionization of the suspension and decreased substantially when the suspension was contaminated with ionic species. The reduced viscosity η_{sp}/c (specific viscosity η_{sp} divided by particle concentration c) of colloidal liquids was much higher than that predicted by Einstein's equation and decreased sharply with increasing ion concentration. The specific viscosity of colloidal spheres can be expressed as follows:

$$\eta_{sp} = \eta/\eta_0 - 1 = k_1\phi + k_2\phi_2 + \cdots \qquad (28.12)$$

Here, η and η_0 are the viscosities of the colloidal suspension and the solvent; ϕ is the concentration of the colloids (volume fraction); k_1 is the Einstein coefficient, 2.5; and k_2 denotes the electrostatic interaction parameter, which is very large for the deionized suspensions. The deviation of the observed η_{sp} values from Einstein's equation was very significant in the deionized liquids. However, the $\eta_{sp} - \phi$ relationship agreed very well with the Einstein equation in the presence of an excess amount of sodium chloride. Qualitatively speaking, the large k_2 observed implies that the electrostatic repulsion interaction is significant and the shells of the electrical double layers around the spheres are very thick. Furthermore, η_{sp}/c increased as the charge density decreased and/or the polydispersity index increased.

Viscometric properties of colloidal crystals are very peculiar. A peak in the relative viscosity against concentration curves showing the phase transition between colloidal crystals and liquids was observed for the deionized spheres (see Fig. 28.7). A sharp increase in shear stress with increasing shear rate was observed for the colloidal crystals, from which the rigidity was evaluated as described in the preceding section. Furthermore, log η of colloidal crystals decreased linearly with a slope close to -1 as log(*shear rate*) increased. This strongly supports the solidlike nature of the suspensions. The log η – log(*shear rate*) plots for the colloidal liquids showed non-Newtonian flow with constant viscosity irrespective of shear rate. Viscosities of colloidal crystals were studied by other groups [296,330,342].

Viscoelastic properties of colloidal liquids and crystals in the deionized aqueous suspension have been studied in detail [333,343–348]. The slopes of the log(*shear stress*) versus log(*shear rate*) and/or log(*storage modulus*) versus log(*angular frequency*) plots for the colloidal crystals were zero, and increased to unity as the structure transformed to liquids.

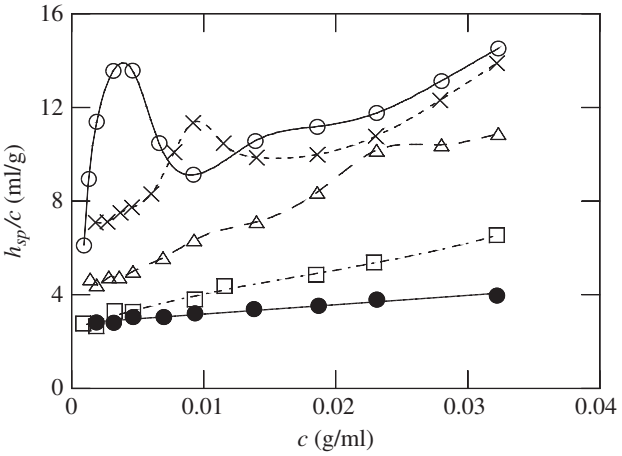

FIGURE 28.7 Plots of η_{sp}/c against c for polystyrene spheres at 25°C. Open circles, [NaCl] = 0 M; crosses, 6.67×10^{-6} M; triangles, 2×10^{-5} M; squares, 6.67×10^{-5} M; solid circles, 2×10^{-4} M.

28.12 EXTERNAL FIELD EFFECTS ON COLLOIDAL CRYSTALS

The rigidity of colloidal crystals is very small, ranging from 10^{-2} to 10^3 Pa. On the other hand, rigidity values of metals range from 10^{10} to 10^{12} Pa. Thus, colloidal crystal is distorted very easily by the weak external fields, such as the gravitational field, shearing forces, elevated pressure, presence of an electric field, or centrifugal compression. The gravitational compression of colloidal crystals occurs easily. From the height dependence of the lattice spacing determined from reflection spectroscopy, the rigidity of the colloidal crystals has been determined. Furthermore, from the concentration dependence of the intersphere distance, at the bottom layer in the observation cell, the static elastic modulus can be determined in the sedimentation equilibrium as was described in Section 5.1.

Colloidal crystals in a rotating disk are also compressed in the centrifugal field (see Fig. 28.8) [310]. Beautiful color bands appeared under the centrifugal field. The elastic moduli at various sphere concentrations can be obtained from variation in the reflection peak wavelengths as a function of the distance from the center in the centrifugal equilibrium. These color bands clearly show that the intersphere reactions are repulsive, and that the repulsive forces are counterbalanced by the centrifugal fields.

Electric-force-induced change in the lattice structure of colloidal crystals has been studied by several researchers

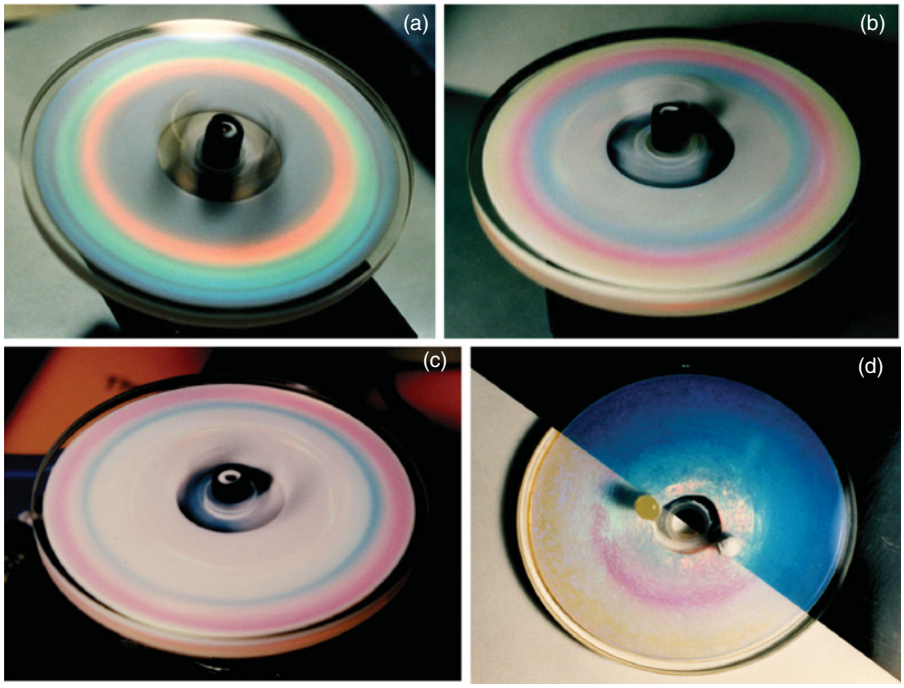

FIGURE 28.8 Close-up color images of colloidal single crystals of D1K88 (a,b) and D1B72 spheres (c,d) in a rotating cell. $\phi_{D1K88} = 0.0617$, $\phi_{D1B72} = 0.0820$. Images captured with (a) obtuse-angle illumination and (b,c) acute-angle illumination, and (d) photograph showing the observation cell on black and white papers. For a color version of this figure, see the color plate section.

[11,20,349] and by the author's group [350–363]. The beautiful effect of waveform transformation from square to triangle has been observed [350–363]. This effect is explained by the fact that the translational motion of the charged spheres is too slow to allow us to follow up changes of the electric field. Our research group observed second-order harmonics in the electrooptic effects of colloidal crystals (see Fig. 28.9). The frequency of the output was just twice that of the input field. In order to study the causes of the generation of the second-order

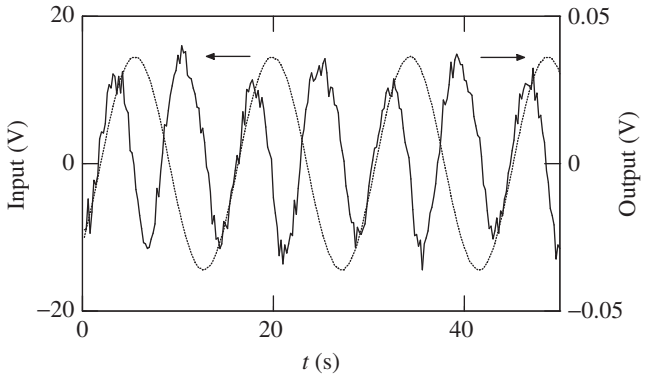

FIGURE 28.9 Waveform of the applied field (dotted-line curve) and reflection (solid-line curve) signals of colloidal crystals of CS82 spheres at 25°C. $\phi = 0.048$, $E = 3.7$ V/cm, $f = 0.07$ Hz, T-type cell. (Redrawn using data from Ref. 353.)

harmonics, time-resolved reflection spectra were measured in a sine-wave electric field. The peaks shifted shorter and then longer wavelengths periodically. Changes in the peak profiles, including the peak intensities and half-widths, were also observed clearly under a sine-wave electric field. The peak wavelengths were plotted against time. The frequency observed was the same as that applied. However, the integrated intensities of the reflection peak profile for the whole gamut of wavelength changes were modulated drastically, and the frequency was just twice the one applied. In other words, second-order harmonics were obtained for the integrated intensity. The calculation of the integrated intensities is quite consistent with observation using the photomultiplier. The observed harmonics were caused by the nature of colloidal crystals themselves.

The amplitudes, alternating-current (AC) components of the electrically induced shear waves as a function of the frequency applied, showed several peaks in the curves. The peak shifted to higher frequencies as sphere concentration increased. The appearance of the peaks demonstrates the existence of some characteristic frequencies for the viscoelastic colloidal crystals. We observed the harmonic oscillation on the shear waves of colloidal crystals from electrooptical effects using electric light-scattering measurements. At 90° scattered light is detected from incident white light. One research team studied the electrooptics of colloidal crystals in organic solvents and gels [360]. Another group clarified

the nonlinear effect for the modulation signal from the optical measurements in the AC electric field [327,364]. *Synchronous oscillation* remained even after the sine-wave electric current was turned off. This is due to the sheared waves of the crystals. The photonic trapping effect of colloidal crystals has been studied [362, 363]. Two-dimensional ordering induced by the electric field has been reported by several research groups [365–367]. The magnetic field effects on the orientation of anisotropic colloidal particles are now well known [237–240,368]. Crystal–liquid phase transition induced by ultraviolet light irradiation was reported for colloidal suspension containing malachite green [369].

Colloidal crystal structures have been studied at high pressure ($\leq$200 MPa) [370]. Formation of *bcc* lattices from liquid and/or transformation from *fcc* to *bcc* lattices was observed under elevated pressure. These observations were explained by the increase in effective charge number on the colloidal surface and the decrease in the Debye screening length as pressure increases.

Shearing deformation of colloidal crystals has been studied by several researchers. One pair of investigators reported that the Bragg diffraction spots diffused as the shear rate increased, and turned into diffraction rings characteristic of liquid structures at high shear rates [14,61,371]. Two other researchers observed a shear melting at high shear rates [6,14]. On the other hand, another pair of linvestigators reported that their suspension did not exhibit disappearance of order at any shear rate, but showed changes in the lattice structure at moderate volume fraction (0.05–0.50) [372]. Another team proposed that the shear-induced melting was due to screw dislocation [342]. Yet another group conducted small-angle neutron scattering measurements of colloidal crystals undergoing shear [373]. Small G values have been obtained under shear [14,61,374–377]. This author found that fcc and bcc lattices coexisted under flow, although the lattices were more or less deformed and melted at high shear rates [378]. Deformation of the electrical double layer from a spherical shape was deduced at low sphere concentrations under shear, and the sliding-layer model proposed by two other investigators [372] was supported especially at high sphere concentrations. Structural changes under shearing flow have been further studied by several researchers [379–383].

The intersphere distances in the crystal of monodisperse polystyrene spheres in the deionized suspension are sensitive to the coexisting water-soluble polymers in the following order [384]:

$$\text{PEG} > \text{PVA} > \text{none} > \text{PVP} \cong \text{HPC} > \text{PAA}_\text{m} \quad (28.13)$$

Here, PEG, PVA, PVP, HPC, and PAA_m indicate poly(ethylene glycol), poly(vinyl alcohol), poly(vinyl pyrrolidone), hydroxypropyl cellulose, and poly(acrylamide), respectively. On the other hand, the order is observed microscopically in the sedimentation equilibrium [384]:

$$\text{PVA} > \text{PEG} > \text{PVP} > \text{HPC} > \text{PAA}_\text{m} \quad (28.14)$$

These orders are explained by the strength of the intersphere repulsion forces through the electrical double layers, which is sensitive to the polymer adsorption on the colloidal surfaces by the hydrophobic and/or dipole–dipole interactions. The scheme of the adsorption mechanism has been proposed by another team [12]. Furthermore, crystal structures in organic solvents and water–organic solvent mixtures have been studied by several groups [2,64,314,315,317,318,385].

Thermosensitive colloidal crystals have been made using the hydrogels of *N*-isopropylacrylamide [101,386–396]. Details on the gel sphere crystals are described in Chapter 41.

28.13 COLLOIDAL CRYSTALLIZATION IN MICROGRAVITY

Another team [397] reported morphological properties of the colloidal crystals of hard-sphere systems in microgravity using Space Shuttle *Columbia*. Colloidal crystallization has been studied kinetically in microgravity, produced by parabolic flights of an aircraft [398–401]. Crystal growth rates decreased in microgravity by about 25% compared with those in normal gravity. One of the main causes for the retardation in microgravity was suggested to be elimination of the downward diffusion of spheres, which may enhance intersphere collisions. The absence of convection of the suspensions in microgravity was also much more important than the elimination effect of downward diffusion. Crystal growth rates of the colloidal alloys of binary mixtures of monodispersed polystyrene and/or silica spheres have been studied in microgravity [402]. The rates increased substantially up to $\sim$1.7-fold in microgravity compared with those in normal gravity. We should note that the *segregation* effect is familiar for binary mixtures of colloid and powder science; large spheres are segregated upward and small ones downward in normal gravity. In microgravity such segregation disappears and the homogeneous mixing takes place favorably, which leads to rapid alloy crystallization. Gravitational effects on the alloy crystallization from bimodal colloidal dispersions were discussed by two other investigators [403].

28.14 TWO-DIMENSIONAL COLLOIDAL CRYSTALS

Two-dimensional distributions of polystyrene spheres at the air/water interface have been studied by measurement of surface pressure–surface area isotherms [404, 405]. Two-dimensional ordering of polystyrene spheres has also been

studied [406–409]. Another author noted that electrostatic repulsion between charged particles is enhanced at an interface between an aqueous phase and air, especially at large particle separation [7]. At the interface a particle has an asymmetric counterion distribution, which results in a dipole moment normal to the water interface. It has also been shown that the interaction near a water–air interface became repulsive and long-ranged [410,411]. The interaction energy decayed in inverse proportion to the salt concentration. Another team [409] observed a transition from the original hexagonal shape to a rhombohedral configuration when the monolayers at the air–water surfaces were compressed on a Langmuir trough. Furthermore, they observed that the particle structure at air–water interfaces was very sensitive to the salt concentration in the aqueous phase. At low salt concentration ordered structure formed as a result of interparticle repulsion, while at high salt concentration the spheres formed 2D clusters [409]. 2D colloidal crystals also form by cooperative intercolloidal electrostatic repulsion such as with 3D colloidal crystals. Melting of 2D crystals and solids have been studied in detail [62,412–417]. 2D colloidal crystals were studied at the electrode interface. ABC-type triblock terpolymer films formed highly oriented and ordered double-helical rodlike structures by solvent evaporation [418]. 2D phase transition of colloidal crystals has been discussed theoretically [419].

28.15 BIOLOGICAL COLLOIDAL CRYSTALS

In general, the result of crystal-like ordering of colloidal particles *in suspension state* is called as *colloidal crystal formation* as described in Section 28.1. Colloidal crystal ordering in solid state is often observed in biological systems such as insects, birds, and fishes. Sea mice is the polychaete *Aphroditae* and one of the marine worms, found along oceanic continental shelves. They have a brightly iridescent furry appearance. The fur consists of hairs, which are packed with arranged little tubules as found in a hexagonal honeycomb. The TEM image of the ordered structure within the spines closely resembles the hexagonal 2D colloidal crystal [420,421].

The peacock (*Pavo* spp.) is famous for its brightly colored tail feathers. The structure of these feathers has been studied and measured by SEM and TEM microscopy [422]. Structural colors of the wings of the *Morpho* butterflies were also studied in detail by [423,424]. The synergism between regularity and irregularity in the structures was the main cause of the characteristic blue color of *Morpho* wings. It was also found that the pigments close to the iridescent structure enhance the blue coloring by reducing background light. The Japanese jewel beetle, *Chysochroa fulguidissima*, emits beautiful iridescent colors. Detailed optical analyses of the colors of dorsal surface were performed [425]. The color change in the fish *Motile iridophores*, that inhabits tropical areas is due to the reflection of light from multilayered thin-film interference [426,427].

28.16 NEW COLLOIDAL CRYSTAL SYSTEMS

Typical colloidal spheres are hard solid spheres. Recently new types of colloidal crystals have been developed. Gel spheres will locate in between linear-type polymers and hard colloidal spheres from the perspective of colloidal chemistry. Most gel spheres are whitish turbid in aqueous media, implying the existence of interfaces with refractive indices different from those of solvent molecules. Thus, fundamental structures and properties of most gel crystals are quite similar to those of colloidal crystals. Gel crystals are reviewed and discussed in Chapter 41.

The author's group (Fujii S., Nakamura, Y., Okubo, T., unpublished results) observed strong iridescent colors during drying of an aqueous suspension of poly(*n*-butyl acrylate) particles. Glass transition temperature of this polymer is $-54°C$, and the rubber liquid state at room temperature. The colors are due to formation of emulsion crystals. When the suspension was dried, however, the iridescent colors disappear, since the suspension becomes unstable as water content decreases. The final state of the particles is rubberlike liquids.

Strongly colorful and angle-independent liquidlike structures formed in ionic liquids [428–431]. Poly(methyl methacrylate)-grafted colloidal silica spheres were dispersed in 1-ethyl-3-methyl imidazolium bis(trifluoro methane sulfonyl)amide at room temperature. The iridescent colors changed with particle concentration.

Another team reported a new type of diamondlike colloidal crystal formed from oppositely charged and equally sized gold and silver particles [432]. Furthermore, core–shell-type clusters, where the shell is formed by the particles in excess, were prepared from oppositely charged silver and gold particles [433,434]. These regulated aggregates are a highly interesting finding, since most researchers assumed that only polydisperse aggregates should form from cationic and anionic colloidal spheres by electrostatic interparticle attraction. The important role of electrical double layers was also proposed for crystallization.

Oil-in-water-type emulsions containing 10% surfactant showed the iridescent colors ascribed to the lyotropic liquid crystal structures [435]. One team [436] prepared brightly colored emulsion crystals composed of mixtures of aqueous $Na_2S_2O_3$ solution and THF solution of hydroxylpropyl cellulose. The color changed from deep purple to pink as the concentration of $Na_2S_2O_3$ changed from 45 to 50 wt%. The color change was explained by Mie's scattering theory in combination with the Christiansen effect.

As was described in Section 28.3, spherical plasma with positive charges formed crystal structures [204]. This

"plasma crystal" supports the important role of interparticle electrostatic repulsion. Recently, keen interest has focused on the gas-, liquid-, and crystal-like distributions of dusty plasmas in space, that is, low-temperature plasmas containing charged macroparticles [437]. The main cause for the plasma crystallization interparticle electrostatic repulsions, which are quite similar to colloidal crystallization.

Another group of coworkers [438, 439] found stable micrometer-sized water droplets in polar oils without any additives. Under appropriate conditions the oil-dispersed water droplets formed a body-centered cubic (*bcc*) lattice with a lattice spacing of the order of 10 μm, and some of the crystals remained stable for ∼2 years without droplet coalescence. This crystallization has been explained by the electrostatic repulsion between charged water droplets [438–443].

28.17 MISCELLANEOUS

A colloidal particle in suspension state is assumed to be a type of polyelectrolyte existing on colloidal surfaces, since a large number of charges always distribute on the colloidal surfaces. This assumption prompted physicochemical studies of colloidal suspensions such as mean activity coefficient, osmotic coefficient, heat of dilution, and partial molal volume. One team [444] measured the mean activity coefficients, osmotic coefficients, and single- ion activities of monodisperse polystyrene spheres in the colloidal crystal state, although the proposal of intersphere *attraction* in the study was denied strongly and intersphere *repulsion* was clarified to be essential for colloidal crystallization exclusively by the author himself [11]. There is no experimental evidence to support the idea of *attraction*. One investigator [192] measured the osmotic pressure and then the osmotic coefficient of gaslike and liquidlike colloidal dispersions of carboxyl-group-containing spheres, a copolymer of butyl acrylate and styrene, by a membrane osmometer against pure water. Very small osmotic coefficients ranging from 0.02 to 0.04 have been observed, which supported the theory of significant counterion binding in a colloidal sphere. Note here that a simple method to measure osmotic pressure was proposed [445, 446]. Two other researchers [447] derived an equation of state for colloidal crystal and liquid by direct osmotic pressure measurements of colloidal dispersions. A theoretical approach to an equation of state has been formulated mainly by computer simulation, and the results supported the effective soft-sphere model [7,448–451].

Dielectric dispersion may afford important information on the dynamic properties of colloidal crystals. However, most of work has been done in the presence of sodium chloride salt, for example [12,452–454]. Thus, the systems were always gaslike or liquidlike. The author measured conductivity dispersion of colloidal crystals, for example [20]. The characteristic frequency increased sharply as the sphere size decreased, sphere concentration increased, and/or salt concentration increased.

Refractive indices of colloidal dispersions and films, which are important for study of physicochemical properties such as light-scattering analyses, were measured [455–461]. The author measured refractive indices of colloidal crystals [462]. The reduced RI increments of colloidal liquid were higher than those of corresponding colloidal gas in the presence of sodium chloride. A sharp peak was observed in the reduced RI increments in the colloidal crystal–sphere concentration curve. The peak corresponds to the phase transition between colloidal crystals and liquids.

28.18 APPLICATION OF COLLOIDAL CRYSTALS

Fixation of colloidal crystal structures in solid state has been the first step in most of colloidal crystal application studies. Poly(methyl acrylate) films containing crystal arrays of colloidal silica spheres were prepared successfully by two different teams [463,464]. In general, the lithography process is divided into two steps: (1) providing a master or composite pattern for pattern replication and (2) the actual replication, where the pattern transferred is made quickly and precisely. In the standard techniques of lithography, replication shorter than several the 10s of nm scale is difficult [465]. For the fabrication of nanometer-scale structures, electron and ion beam lithography techniques are appropriate. However, these methods require a long processing time and incur higher costs [466]. To overcome these difficulties, colloidal lithography has been developed [465]. Two investigators [467] evaporated colloidal suspension (spheres 300 nm in diameter) on a glass plate and obtained the regions of hexagonally packed spheres. After platinum deposition they obtained ordered arrays of triangular areas. Later, deposition over the entire surface of a macroscopic substrate was achieved [468]. Furthermore, the coating techniques such as spin coating and the Langmuir–Blodgett method were developed [469, 470]. Recent development on the colloidal lithography is amazing [471, 472].

Preparation of photonic crystals includes the addition of structured solid materials composed of two components having different refractive indices and having periodically ordered structures in the scale of light wavelengths. Using these materials, a photonic bandgap (PBG) filter is formed. This technique is quite interesting for the design and construction of new types of devices. Production of the first photonic bandgap was reported in 1991 [473]. Structures exhibiting full PBG in the microwave, millimeter, and submillimeter regimes were initially fabricated in 2004 or earlier. Now, submicrometer-length-scale photonic crystal has been developed rapidly using colloidal crystals as the starting material [474–486]. Another team [487] synthesized monodisperse

hollow polymer spheres and studied the photonic crystal function including magnetic field effects. Theoretical predictions were also shown, based on energy considerations. A 2D crystal of monodisperse magnetic particles was formed as a liquid surface [488]. Another team [489] observed 2D and 3D self-assembly of magnetic particles by interparticle magnetic repulsion forces on liquid surfaces using the layer-by-layer technique. The possibility of using spheres in photonic bandgap applications was also reported. Furthermore, tunable paramagnetic colloidal photonic crystals were developed [490]. Another team [491] prepared photonic rubber sheets with tunable color by elastic deformation, and also studied the tunable structural color in colloidal photonic crystals [492]. In order to obtain large single crystals, another team studied template-directed colloidal crystallization [493]. Frankly speaking, there are still many difficulties to be solved before practical use of colloidal crystals is possible.

Semiconductor crystals with radii smaller than the bulk exciton Bohr radius show the highly effective bandgap of the material. ZnS growth on CdSe crystals was prepared to provide very high fluorescent quantum yield of 50% [489, 490,493, 494].

28.19 CONCLUDING REMARKS

Colloidal crystals are the suspensions in which colloidal particles distribute regularly as atoms and molecules do in metals and protein crystals. Giant colloidal crystals were found to emit brilliant iridescent colors by the Bragg diffraction method and are visually spectacular. In this chapter, recent research on the structural colors, morphology, crystallization kinetics, structural and dynamic properties, electrooptic effects, and other aspects of colloidal crystals have been discussed. Formation of giant colloidal crystals is due to the electrostatic intersphere *repulsion* and to the highly expanded *electrical double layers* surrounding colloidal spheres. Morphology, lattice structure, and physicochemical properties have been described as being quite similar to those of typical crystals found in nature, such as those in metals, protein, and ice, when different lineal scales are correctly taken into account.

Several concerns are recommended for experimental study of colloidal crystallization. First, ionic contamination of the sample suspension must be avoided as carefully as possible, especially in aqueous suspension. Most of the author's experiments were made for exhaustively deionized aqueous suspensions. Colloidal crystallization is substantially influenced by the ionic concentration of the suspension because of the significant contribution of the electrical double layers formed around colloidal particles in aqueous suspension. Accurate determination of the ionic concentration of the aqueous colloidal suspensions is extremely difficult, since ionic contamination of the suspensions takes place always and easily from the suspension container and air. In the author's laboratory, most sample suspensions coexisted for a long time with an excess amount of mixtures of cation and anion exchange resins. In this case, the salt concentration should be on the order of 10^{-7} mol/L. Very careful experiments must be made to avoid the ionic contamination in order to obtain the reliable data. We should note that exhaustive deionization is achieved only by ion exchange resins that have coexisted for a long time, typically more than one year.

We should focus on why *repulsive*—rather than *attractive*–interparticle interaction is important in colloidal crystallization. The latter is quite common for most crystals in nature, including metals, proteins, and ice. For typical crystals in nature, the elementary particles described in Section 28.1 are very small, and the contribution of both the transitional and rotational diffusion constants given in Eqs. (28.15) and (28.16) are so large that the ordering including crystallization will be quite difficult without very strong interparticle attractive forces:

$$D_{\mathrm{tr}} = k_{\mathrm{B}}T/3\pi\eta d \tag{28.15}$$

$$D_{\mathrm{r}} = k_{\mathrm{B}}T/\pi\eta d^3 \tag{28.16}$$

Here, D_{tr} and D_{r} are the translational and rotational diffusion constants of a sphere (where d = diameter), $k_{\mathrm{B}}T$ is thermal energy, and η is the viscosity of solvent. On the other hand, the diffusive forces of very large colloidal particles are too weak to form ordering without the presence certain other interparticle repulsion forces. Without additive repulsion interactions the colloidal particles will associate easily with each other. Maintaining balance or equilibrium between attractive and repulsive interparticle reactions is very important for effective ordering.

DIELECTRIC PROPERTIES OF BIOLOGICAL MACROMOLECULES AND BIOMOLECULE–WATER INTERFACES

Brandon Campbell, Lin Li, and Emil Alexov

Computational Biophysics and Bioinformatics, Physics Department, Clemson University, Clemson, SC 29634, USA

29.1 BACKGROUND

In order to understand the electrostatic and dielectric properties of biological systems, one should take into account that at normal conditions all biological macromolecules exist in water and are surrounded by other macromolecules, ions, and ligands [1] (Fig. 29.1a) [2, 3]. Such a complex system is characterized by the constant motion of the entities within it as they interact with each other and undergo collisions in the crowded environment of the cell. Some of these entities, such as ions, are objects that have a spherically symmetric shape and do not change during a considered reaction. Others, such as water molecules, do not greatly change their shape, but are quite mobile and change both their position and orientation. Finally, macromolecules and ligands are complex objects made of many atoms, which, despite being chemically connected, are not rigid but constantly undergo conformational changes. Taking all of these together, the system made of macromolecules and water, if considered at the atomic level of detail, exhibits an enormous degree of freedom. Typically explicit modeling of such systems is done via molecular dynamics simulations [4, 5]. However, the explicit sampling of all essential states, those required for a given process, may not be an easy task or may not even be possible for systems consisting of millions and more atoms.

To reduce the complexity of explicit modeling, one can adopt an implicit approach and model the biological macromolecules and water molecules via continuum electrostatics [6] (Fig. 29.1b) [2, 3]. However, this should be done without losing much of the detail of the explicit approaches, which, in turn, requires description of dielectric properties via a function that mimics the effects of explicit atom considerations. The difficulties stem from several sources. Macromolecules and ligands are very inhomogeneous. While they are typically very polar, they may not be very polarizable because of constraints posed by the chemical bonds and compactness of the 3D structure. In addition, they constantly sample different conformation states, and thus affect the interior and the molecular surface of the system. The water phase is equally complex because water molecules possess the ability to propagate inside macromolecules [7] or bind tightly to the molecular surface [8, 9]. The ability of water molecules to form hydrogen bonds with the atoms of macromolecules [10], especially in cavities and macromolecular interiors, greatly restricts their ability to reorient and respond to the local electrostatic field, thus affecting their dielectric properties. Ions can bind to molecular surfaces or even inside the macromolecule and drastically change the local electrostatic field [11]. In this chapter, we describe these specific effects reflecting the complex nature of macromolecule–water systems and provide conceptual approaches to capture these atomic details via continuous electrostatics and structure-based dielectric functions.

29.2 MACROMOLECULAR DYNAMICS AND ITS EFFECT ON THE MACROMOLECULAR INTERIOR AND MOLECULAR SURFACE

Biological macromolecules are flexible inhomogeneous objects. The intrinsic motions can be grouped into several distinctive categories: (1) thermal fluctuations of atoms, amino or nucleic acids, or entire domains; (b) conformational changes induced by a function (such as binding a ligand or undergoing catalytic reaction); (3) intrinsically disordered macromolecules; and (4) conformational changes caused by a change of the environment such as pH or salt concentration. Below we briefly outline these effects in separate sections.

29.2.1 Thermal Fluctuations of Atoms, Amino or Nucleic Acids, or Entire Domains

At nonzero temperature all atoms fluctuate around their equilibrium positions. Most biological macromolecules function at room temperature (293.15 K), and at this temperature thermal fluctuations can be on various scales ranging from negligibly small changes [12] to relatively large-scale [13] structural changes [14, 15]. Small structural fluctuations of individual atoms in a highly packed macromolecular interior, perhaps, have very little effect on the electrostatics and the corresponding dielectric constant. This statement is reinforced by the fact that most of the atoms in the macromolecular core are apolar, carrying no or little partial charge, and thus have no direct effect to the local electrostatic field. In contrast, if these atoms are located at the molecular surface, they are typically polar, carrying significant partial charge. Therefore, their fluctuations affect both the local electrostatic field at and nearby the molecular surface and at the same time change the geometry of the macromolecule–water boundary, altering the interactions with individual water molecules [16].

Atoms within a macromolecule are connected with their neighbors via chemical bonds and other nonbonded interactions. Thus any structural fluctuation of a given atom, in principle, should affect the other atoms within the macromolecule. This connectivity results in collective motions involving groups of atoms (amino or nucleic acids) or entire structural domains [17–20]. Obviously these structural fluctuations will have a greater effect on the macromolecular interior and macromolecular surface than will the fluctuation of a single atom. The structural changes can be as large as almost doubling the original dimension of the macromolecule [21]. However, the density of the macromolecular interior is typically affected much less than the molecular surface (i.e., the density remains almost unchanged), but large structural domains change their mutual positions greatly affecting the shape of the molecular surface. If such an ensemble of structures is about to be modeled, one should consider that the molecular surface (and to a less extent the molecular interior) cannot be described by a simple geometric function.

29.2.2 Conformational Changes Induced by Macromolecular Function

Any macromolecule interacts with something else, may it be a small substrate, a ligand, a membrane, or another macromolecule [22]. Such interactions are expected to affect the local and global conformation of the interacting partners as indicated by numerous experiments [23–26]. A particular example are enzymes that bind their ligand in a typically well-defined active-site pocket, which, in turn, closes after recognition to provide a supporting environment for the

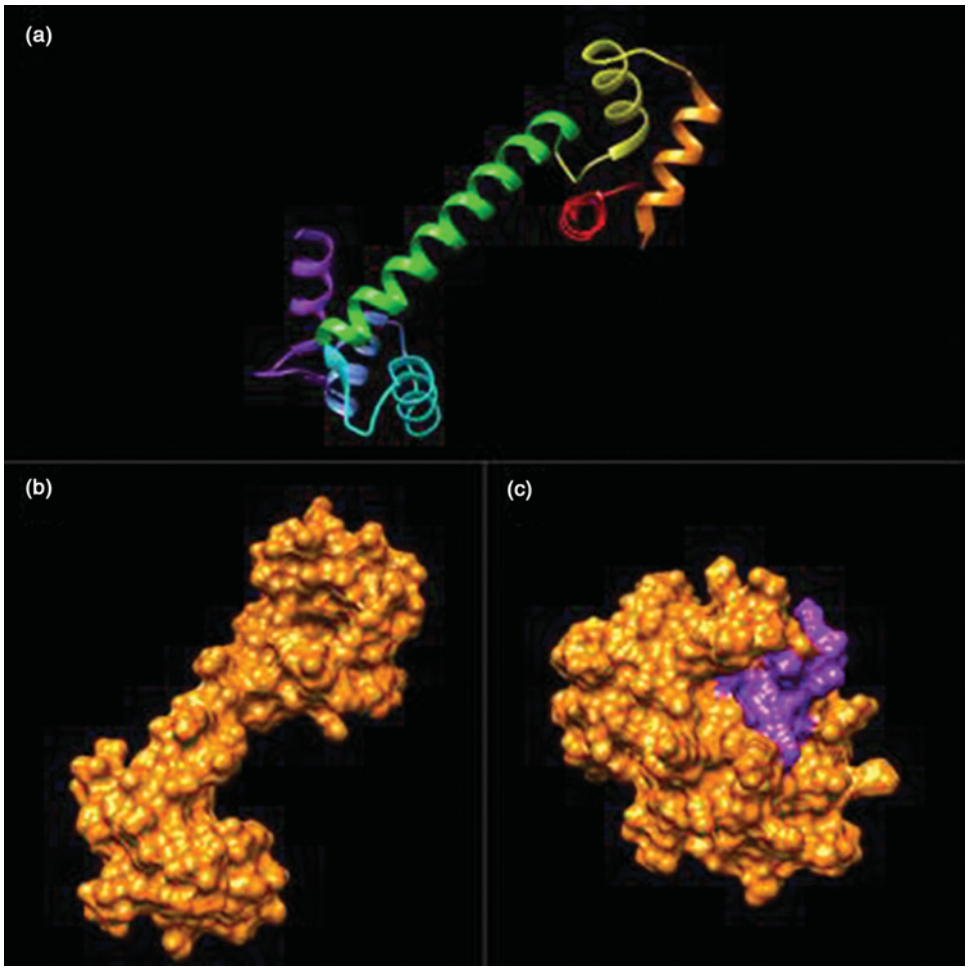

FIGURE 29.2 (a) Ribbon structure of apo calmodulin (PDB ID 4BW7), colored to illustrate the various tertiary structural components of the protein; (b) molecular surface of apo state of calmodulin; (c) structural changes of calmodulin (PDB ID 2LGF) after it has complexed with the peptide L-selectin, a glycoprotein receptor. [Molecular graphics and analyses were performed with the UCSF Chimera package. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (supported by NIGMS P41-GM103311).]

corresponding reaction [27–29]. Such cases represent the class of reactions that affect the local macromolecular interior and macromolecular surface, but have little or no effect on the rest of the macromolecular–water system.

On the opposite end of the spectrum are so-termed allosteric reactions, reactions that are promoted by the binding of a ligand at a distance from the active-site region [30, 31]. There are two basic explanations for the uniqueness of such reactions: (1) the reaction involves changes of a significant part of the molecular surface, not just the region around the active site; and (2) the reaction causes the signal to propagate from the allosteric site to the active site, and this involves a chain of conformational changes throughout the entire macromolecule.

Perhaps the most extreme effects are observed in reactions involving the rearrangement of structural domains. A typical example is calmodulin (Fig. 29.2a) [3, 32], which in the apo form (before the reaction) adopts an extended conformation (Fig. 29.2) [3, 32], but after binding the cognate peptide, undergoes a large conformational change to adopt a compact form (Fig. 29.2c) [3, 33]. In terms of ensemble modeling of electrostatic and dielectric properties of such a diverse conformational space, one should develop a specific approach to account for the population of different conformational states [34].

29.2.3 Intrinsically Disordered Macromolecules

In parallel with conformational changes occurring as a function of time (during the corresponding biological reaction or experimental duration), many macromolecules exist as a multitude of conformations. Typically such macromolecules

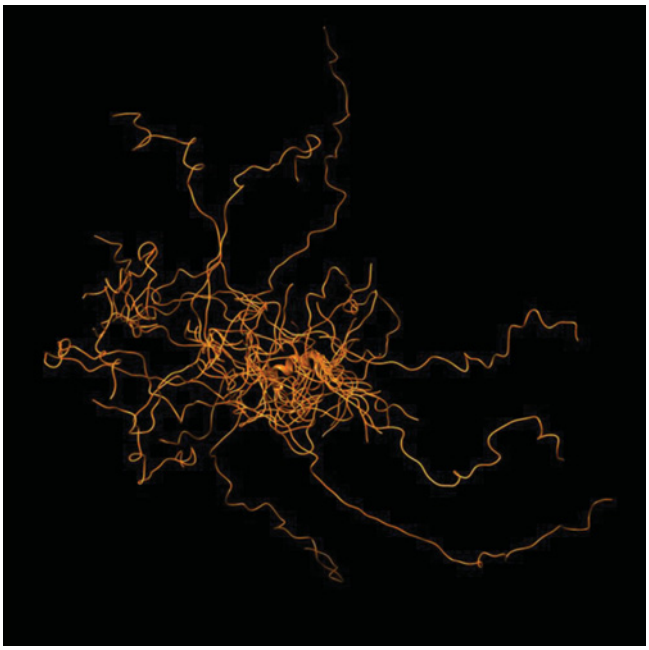

FIGURE 29.3 Image of the intrinsically disordered phosphoprotein TSP9. [Molecular graphics and analyses were performed with the UCSF Chimera package. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (supported by NIGMS P41-GM103311).]

are referred to as *intrinsically disordered molecules* [35–37]. The disorder may be local, involving a loop or small structural segment, or the entire macromolecule may exist in numerous alternative conformations (Fig. 29.3) [3, 38]. Such phenomena affect both the molecular surface definition and the properties of the molecular interior. Typically the macromolecule or parts of the macromolecule are disordered before the reaction, which is thought of as the macromolecule possessing the ability to respond to different ligands and adopt appropriate configurations for each particular partner [39–42]. However, opposite cases do exist where parts of the macromolecular structure become unstructured after the reaction or binding [43].

29.2.4 Conformational Changes Caused by a Change in Environment Due to pH or Salt Concentration

Biological macromolecules are located in different subcellular compartments and different organs/tissues, with each of them having characteristic pH and salt concentrations [44–46]. Their pH optimum of stability is correlated with the pH optimum of the corresponding reaction [47]. Thus the macromolecules sense different pH and salt concentrations when being transferred from one compartment to another or simply because the reaction involves changes of the environment. The effect of pH can be relatively small, inducing local conformational changes caused by protonation or deprotonation of a particular titratable group. Such conformational changes typically do not affect the macromolecular interior and have a small effect on the molecular surface as well. However, exceptions do occur as indicated in a recent study on coupling between local conformational fluctuations, ligand binding, and structural transitions in staphylococcal nuclease [48]. Protein–protein interactions can be greatly affected by the local pH [49–51] as well as protein stability [52, 53]. At the same time, pH- induced changes can be very large, changing the equilibrium between monomeric and dimeric states of macromolecules [54–56]. Perhaps the most drastic change is expected to occur when the entire structure of a macromolecule changes shape from one suitable for the water phase to a shape suitable for insertion into a biological membrane as in the case of the CLIC protein family [57, 58]. Obviously the effect on the electrostatics of such large-scale conformational changes cannot be mimicked with any dielectric function.

29.3 WATER MOLECULE DYNAMICS AND ITS EFFECT ON PROTEIN INTERIOR AND MOLECULAR SURFACE

The water phase, which consists of indistinguishable water molecules, is sometimes considered the simplest phase to model electrostatically, but may also be the most complicated. Water molecules in the liquid phase are quite free to diffuse and to change their orientation [59]. These changes in bulk water are reduced because of the water molecule's tendency to form hydrogen bonds with its neighbors, resulting in water clusters. However, these clusters are not static, since water molecules frequently exchange their hydrogen bonds and change their affiliation and orientation. The situation is completely different at the macromolecule–water interface. Depending on the physical nature of the macromolecular surface, mostly hydrophilic or partially hydrophobic, the ability of water molecules to diffuse and to reorient will be minimally or drastically affected. In addition, frequently the water molecules at the molecular surface can be involved in specific interactions, mostly via hydrogen bonds, with atoms of the macromolecule, thus further affecting their flexibility [60]. The most significant change of bulk water properties happens when water molecules are buried inside the macromolecular interior [61]. Such waters, if their residential time is long enough, are referred to as *structured waters* [62–64]. There are also many experimentally documented cases of structured waters being crucial for various reactions. The examples include *proton wires*, where chains of structured waters serve as a conduit for proton transport [65–68], water-mediated reactions [69, 70], structure waters acting as a *placeholders* for ligands in apo conformations [71–73], and cases where structured waters are an inherent part of the protein structure and aid in the stability [74–76] or flexibility [77, 78] of the proteins.

29.4 MODELING MACROMOLECULAR INTERIOR AND MACROMOLECULE–WATER INTERFACES

Typically the electrostatics, the potential distribution or polar solvation energy, in a system consisting of biological macromolecules and water is calculated via the Poisson–Boltzmann equation [79–81] or generalized Born approaches [82, 83]. Many methods and tools exist for modeling electrostatics in biological systems [84–90]. At the first level of approximation, the space of the system must be divided into two (or three) regions with distinctive dielectric properties. These regions are divided into the space occupied by the macromolecule by the rest of the space occupied by the water phase. While this is quite a straightforward approach, it faces a major challenge in determining the molecular surface of the macromolecule. Various methods exist for building the boundary between a macromolecule and water. The simplest and perhaps most illustrative approach is the van der Waals (vdW) molecular surface method. In this approach the molecular boundary is delivered as a surface made from vdW spheres, representing atoms within the macromolecule [91]. The radius of these spheres is force field-dependent and the aggregate of these spheres represents the molecular boundary, or vdW surface (vdWS). While this approach is simple, it suffers from the presence of many small cavities at the surface created by neighboring spheres. These cavities cannot be accessed by water molecules.

A second approach that attempts to alleviate these artificial cavities is the *solvent accessible surface* (SAS) approach, which utilizes a rolling spherical probe that travels across the vdWS. The radius of the probe corresponds to the average radius of a water molecule and the center of the probe traces out the molecular surface. Another similar approach to SAS is the *solvent excluded surface* (SES) method, which uses probes that roll across a molecular boundary [92]. In this approach the molecular boundary is determined from the volume difference calculated between a probe accessible to the molecular boundary and one that is inaccessible. While these approaches are considered simple, there are many other approaches that require more complicated mathematical procedures for determining the molecular surface, such as the *blobby* surface, *skin* surface, and methods that map the molecular surface onto a virtual three-dimensional grid for calculations [93]. Each of the various methods has its benefits and deficiencies, and often the best choice may lie in the intended use, either visualization or calculation.

29.5 ROLE OF IONS

Typically ions are considered to be part of the water phase, which provides screening of electrostatic interactions via redistribution of their local density [94]. However, ions can bind to the macromolecular surface or macromolecular interior and thus drastically affect the local electrostatic potential [95, 96]. If the ion position can be detected experimentally [97, 98], then the ion can be treated as a part of the macromolecular structure and no further considerations are needed. However, especially for surface-bound ions, the positions frequently cannot be experimentally resolved and have to be predicted [99, 100].

29.6 DIELECTRIC PROPERTIES OF BIOLOGICAL MACROMOLECULES AND BIOMOLECULE–WATER INTERFACES

In this section we describe approaches to account for all or some of these effects occurring at the atomic level of detail into the modeling of electrostatic potential using a single structure. Three important and distinctively different regions of space should be considered: (1) the water molecules within the immediate water shell surrounding the protein, (2) the cavities inside the protein, and (3) the inhomogeneous protein matrix [16].

As mentioned previously, the water molecules in the immediate vicinity of the protein interface may not be as mobile and flexible [101, 102] as the water molecules in the bulk phase [103], and the molecular surface may undergo constant changes. Obviously the dielectric properties of these water molecules cannot be modeled with the bulk dielectric constant of 80. Perhaps a lower dielectric constant should be used. In addition, the dielectric constant should depend on the topology of the protein surface; for instance, the immediate water shell around a convex surface should be assigned a lower dielectric constant (water reorganization is more restricted) than for cases over concave protein surfaces [104, 105]. The extra complexity comes from the structural changes occurring at the molecular surface, which from an ensemble-averaged perspective, should result in a smooth transition from macromolecular to water phases. Such a smooth transition can be captured via a smooth dielectric function [16], rather than by a sharp dielectric boundary. The larger the structural fluctuations are, the smoother the macromolecule–water transition should be. In this regard, unstructured macromolecules or macromolecules undergoing extremely large conformational changes, such as calmodulin, should be approximated with a custom-designed dielectric function that depends on the overall shape of the transition.

Additional complexity arises when describing dielectric properties of a macromolecule–water interface due to the treatment of ions, especially surface- bound ions. While various approaches of the modified Poisson–Boltzmann equation do exist in order to account for the finite size of ions and other physical effects, the best treatment is to include ions explicitly when modeling by making ions part of the macromolecular structure [100]. Such an approach does not require modification of the dielectric function.

The second region requiring special attention involves the cavities inside macromolecules. The water molecules in small cavities are likewise small in number, in some cases just a single water molecule, and typically their mobility is highly restricted. In contrast, in large cavities the water molecules may form clusters and may act collectively [106]. In addition, the residence time of water molecules can vary significantly [107], as some water molecules are almost permanent in the macromolecular interior while others spend just a fraction of their time there. Thus, for a correct description of these effects on the dielectric properties of the internal cavities, one needs to assess the size, shape, and accessibility of the cavity and to assign an appropriate dielectric constant. Having in mind that the size and shape of the cavities is subject to structural fluctuations as well, the dielectric function should also provide a smooth transition from the macromolecular matrix to the macromolecular cavity [16].

The third region, and the most difficult to address, is the space occupied by the macromolecule. As discussed above, macromolecules are quite inhomogeneous entities, and atoms in biomolecules have different charges and flexibilities depending on their packing and their mutual interactions. The dielectric function describing such complex environments should reflect the physical nature of the macromolecule. The most straightforward approach is delivered from atomic densities of the corresponding atoms [16]. It is expected that the space occupied by loosely packed and charged atoms will have a significant tendency to reorganize and to respond of the local electrostatic field. This should be modeled as a region of high dielectric constant. Such regions are the protein surfaces, which are loosely packed and rich in charged and polar residues. In contrast, regions of tightly packed uncharged atoms, as in the hydrophobic core, have little ability to respond to the local electrostatic field and should be modeled with a low dielectric constant. All of these features can be captured with the so-termed Gaussian method of representing atomic densities by using it to deliver a smooth dielectric function as described in Ref. 16. Essentially, one uses atomic coordinates and forcefield parameters to convert the atomic densities into a local dielectric constant as originally described by Nicholls and Pickup [108] and further developed by Li et al. [16]. Given a macromolecule with N atoms, the density of an atom i is represented by a Gaussian distribution

$$\rho_i(r) = e^{\frac{r_i^2}{\sigma_i^2 R_i^2}} \tag{29.1}$$

where $\rho_i(r)$ is the density at position r, r_i is the distance between the center of the atom i and position r, R_i is the van der Waals (vdW) radius of atom i, and σ_i is the relative variance. After the density of each atom within the macromolecule is generated, the density in the overlapping areas occupied by multiple atoms is calculated by

$$\rho_{\text{mol}}(r) = 1 - \Pi_i[1 - p_i(r)] \tag{29.2}$$

where the $\rho_{\text{mol}}(r)$ denotes the density at position r by multiple atoms, and $\rho_i(r)$ is the density of a single atom i, which can be obtained from Eq. (29.1). This product function guarantees that the density at the overlapping region is higher than the density generated by any involved single atom, but the density $\rho_{\text{mol}}(r)$ should not be greater than 1. Finally, the smooth dielectric function is delivered from the density distribution using the linear function

$$\varepsilon = \rho \cdot \varepsilon_{\text{in}} + (1 - \rho) \cdot \varepsilon_{\text{out}} \tag{29.3}$$

where ε on the left denotes the dielectric distribution, ε_{in} denotes the reference dielectric values in the molecule when the density is 1, ε_{out} denotes the dielectric value for the water phase, and ρ is the density, which can be obtained from Eq. (29.3).

The resulting dielectric constant distribution is illustrated in Fig. 29.4 [3, 109], where the Gaussian-based smooth

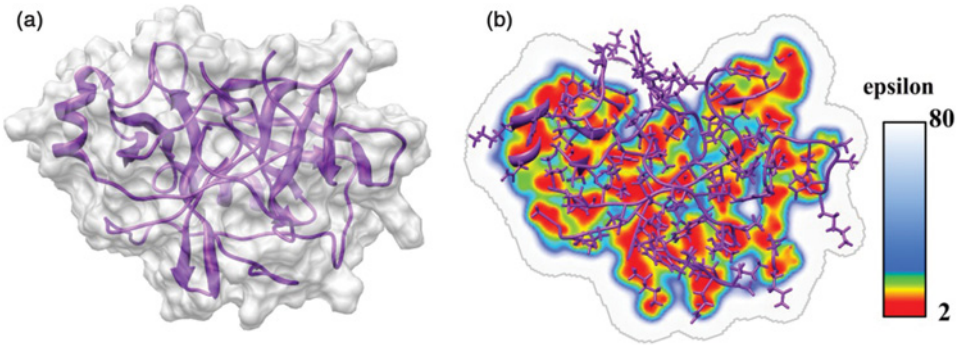

FIGURE 29.4 (a) Structure of the Bovine Eglin protein (PDB ID 1ACB); (b) dielectric distribution of the Gaussian smooth method for this protein. [Molecular graphics and analyses were performed with the UCSF Chimera package. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (supported by NIGMS P41-GM103311).] For a color version of this figure, see the color plate section.

dielectric constant is delivered for a particular macromolecule, the bovine α-chymotrypsin-eglin protein. One can appreciate that the dielectric constant is indeed a smooth function and there are no sharp dielectric jumps across the space. It can also be seen that the macromolecular interior, the internal cavities, and the macromolecule–water interface are modeled differently from the bulk water phase.

29.7 CONCLUDING REMARKS

It should be clarified that this chapter does not deal with the "optimal" value of the macromolecular homogenous dielectric constant, which is an ongoing debate in current scientific literature [110–118]. Instead, we emphasize that the dielectric constant of macromolecules is not constant at all [16]. This is the reason why various studies use numerous "optimal" dielectric constant values [119–123]. This is also the reason why, if one uses a homogeneous dielectric constant, the optimal value depends on the reaction modeled [124, 125]. The smooth Gaussian-based dielectric function [16] addresses many of these issues by providing a structure-based approach of mimicking the ability of different regions to react to the local electrostatic field.

NMR OF DRUG DELIVERY COUPLED WITH LIPID MEMBRANE DYNAMICS

EMIKO OKAMURA

Faculty of Pharmaceutical Sciences, Himeji Dokkyo University, 7-2-1, Kamiohno, Himeji 670-8524, Japan

30.1 INTRODUCTION

Molecular mechanisms of drug–biomembrane interactions are of great significance as a primary stage of bioactivity in the cell. The lipid bilayer membrane, as a platform of vital functions, is a dynamic structure where molecules are always fluctuating under physiological conditions [1]. The mechanism of drug delivery is related to the molecular dynamics in this soft, fluid membrane interface. In situ observation to capture dynamic aspects of membranes and drugs is important because it can provide the molecular picture of drug delivery to the membrane without undesirable perturbation.

Nuclear magnetic resonance (NMR) spectroscopy is a versatile method for studying drug delivery from water to membranes [2]. It is noninvasive and tells us about the structures and dynamics of both drugs and membranes at the molecular level. High-resolution solution NMR is informative, and also suitable for drug delivery studies, to shed light on molecules of drugs and membrane lipids always moving and fluctuating in abundant water. Multinuclear NMR often provides site-selective information about drugs and membranes simultaneously and independently. Now the development of instrumentation and computational techniques enables us to determine static and dynamic properties of both drugs and membranes in situ.

In this chapter, the NMR research of drug deliveries is reviewed mainly on the basis of our recent studies. A small-sized anticancer 5-fluorouracil (5FU), an anesthetics sevoflurane (SF), an endocrine disruptor, bisphenol A (BPA) and its fluorinated derivative (FBPA), and a neuropeptide, leucine-enkephalin (L-Enk) are addressed as a model drug; for the structures, see Fig. 30.1. Special focus is on the dynamic feature of deliveries of these molecules related to the lipid membrane dynamics. Prior to the survey of delivery study, the dynamic aspects of lipid bilayer membranes, as a platform of delivery processes, are briefly summarized. It is emphasized how the dynamic feature of drug deliveries is coupled with such membrane dynamics.

30.2 DYNAMICS OF MEMBRANES AS A PLATFORM OF VITAL FUNCTIONS

The lipid bilayer membrane is a fluid, soft interface that separates the inside from the outside of a living cell. The boundaries of membranes are not smooth but rough at the molecular level [3]; molecules are always fluctuating in a membrane environment. Because molecular movements in membranes are closely related to vital functions, it has been an issue of great attention how molecular dynamics is modified in such confined but fluid geometries.

Lipid molecules that form biomembrane matrices are mostly in a liquid-crystalline state. Under physiological conditions, the lipids exhibit two-dimensional liquidlike properties in the lateral direction to the membrane surface. The idea was introduced as the fluid mosaic model by Singer and Nicolson more than four decades ago [4]. Since then, the dynamic aspects of lipid membrane matrices have been

The characters i–v represent (i) lateral diffusion of lipids in plane of the bilayer, (ii) protrusion along the bilayer normal, (iii) rotational diffusion and wobbling of lipids, (iv) undulation, and (v) flipflop of lipid molecules between the two monolayers (see text for details).

unveiled at a molecular level, by the use of many physicochemical techniques involving spectroscopies and computer calculations.

At present, the lipid motions in fluid membranes are categorized by a variety of dynamical modes with wide range of timescale [3, 5, 6]. As illustrated in Fig. 30.2, the motions include (1) lateral diffusion of lipids in the plane of the bilayer; (2) protrusion, the movement of individual lipids or lipid segments along the bilayer normal; (3) rotational diffusion and wobbling of lipids; (4) undulations, the collective movements of membrane patches; and (5) flipflop of lipid molecules between the two monolayers of bilayer, as well as bond oscillations and *gauche–trans* isomerization of lipid alkyl chains. The approximate correlation times of the respective modes are in the wide range from picoseconds to hours [5]. It is expected that drug deliveries are concerted with such dynamic behaviors of membrane lipid molecules (Fig. 30.2).

In real cell membranes, the dynamical features are more complex because of the heterogeneous distribution of lipid microdomains called the "raft" [7, 8], and the presence of membrane proteins and a system of filaments called the *cytoskeletons* [1]. Generally, the presence of macromolecular proteins and the raft-forming cholesterol makes the membrane less fluid [9, 10].

30.2.1 Diffusion

Lateral *diffusion* of lipids in the parallel direction to the membrane surface is the typical index of molecular dynamics in membranes. Pulsed-field-gradient (PFG) NMR spectroscopy [11] is a noninvasive technique to directly measure the molecular diffusion not only in the three-dimensional (3D) isotropic solution but also in a two-dimensional (2D) anisotropic membrane. It tells us about how the movement of every membrane component is modified in a two-dimensional confined but soft space without perturbing the system. Although its application to the membrane system has been limited because of the low signal resolution and slow diffusion of molecules, more recent PFG studies have obtained well-resolved NMR signals in highly viscous membrane environments, using labeling or magic-angle spinning technique [12, 13].

One team of investigators have observed and compared the self-diffusion of lipid molecules in size-controlled micelles and vesicles as freestanding model of fluid membranes without labeling or using the spinning technique [14]. The success is due to the application of high-resolution solution-state NMR in combination with the PFG technique. The extent of boundary restriction has been controlled by employing the micelles and vesicles with average diameters of 3 nm (micelle), 30 nm [small unilamellar vesicle (SUV)], and 100

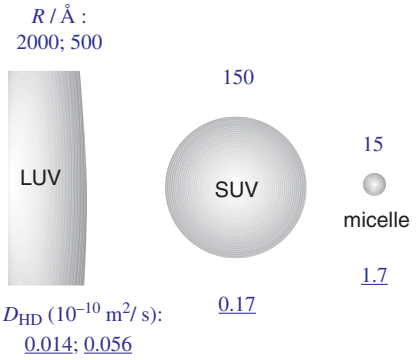

FIGURE 30.3 Schematic illustration of size-controlled vesicles and micelles as model of confined fluid membrane. The radii of the respective particles are given by R in Å units. Underlined values represent D_{HD}, the self-diffusion coefficient of each particle estimated from the hydrodynamic (HD) diffusion in H_2O at 303 K.

and 400 nm [large unilamellar vesicle (LUV)]. It is noted that LUV is characterized by almost negligible surface curvature effect [15], in contrast to the highly curved micellar surface (Fig. 30.3).

In recent decades, a specially designed high-field-gradient probe has been developed for a high-resolution solution NMR apparatus [14], to obtain a reliable signal of molecular motion in a highly viscous membrane environment. The probe can exert a field gradient of ≤13.5 T/m. Generally, the self-diffusion coefficient D is determined as the slope of the Stejskal–Tanner plot [16], by using the echo signal attenuation as a function of the field gradient strength G. The Stejskal–Tanner equation is given by

$$\ln \frac{I(G)}{I(0)} = -D(\gamma\delta)^2 \left(\Delta_{\text{diff}} - \frac{\delta}{3}\right) G^2 \qquad (30.1)$$

where $I(G)$ and $I(0)$ are the echo signal intensities where the field gradient is present and absent, respectively; γ, the gyromagnetic ratio; δ, the gradient pulsewidth; and Δ_{diff}, the diffusion time interval, respectively. As listed in Table 30.1, the high-field-gradient NMR shows that the lipid diffusion in membrane is enhanced in the order of micelle > SUV > 100-nm LUV ≈ 400-nm LUV [14], in accordance with the surface curvature dependence of the dynamical structure in such lipid aggregates [15].

It is interesting that the slowdown of lipid motions in membranes is leveled off in 100- and 400-nm LUVs, although the hydrodynamic (HD) continuum model [17] shows that the lipid aggregate diffusion is slowed down in inverse proportion to the aggregate size. In fact, it is also found that the lateral diffusion coefficient of the fluid lipid in 800-nm LUV is as large as $\sim 1 \times 10^{-11}$ m^2 s^{-1} [18], more than one order of magnitude as fast as the rotational and the translational diffusion of LUV by the HD continuum model (both of the order of 10^{-13} m^2 s^{-1}). Even in a cell-sized giant vesicle (of 10–20 μm diameter), the lateral diffusion coefficient is reported to be 0.8×10^{-11} m^2 s^{-1} at relevant temperature [19, 20]; not so much decreased as compared to the 800-nm LUV, although the vesicle size is more than one order of magnitude

TABLE 30.1 Self-Diffusion Coefficient of Lipids in Lysophosphatidylcholine Micelle, EPC SUV and LUV Determined by High-Field-Gradient NMR Method

		Self-diffusion coefficient (10^{-10} m^2 s^{-1})		
	Method	Headgroup	Chain core	Ref.
In micelle (3 nm)[a]	PFG NMR	0.65 ± 0.02	0.63 ± 0.02	14
		0.5–1.3[b]		55
In SUV (30 nm)	PFG NMR	0.24 ± 0.01	0.28 ± 0.01	14
	PFG NMR	0.23–0.24[c]		56
In LUV (100 nm)	PFG NMR	0.12 ± 0.01	0.14 ± 0.01	14
In LUV (400 nm)	PFG NMR	0.13 ± 0.01	0.15 ± 0.01	14
	FRAP	0.124–0.134[d]		57
		0.12[e]		58

[a] Average diameters of the particles determined from quasielastic light scattering are given in parentheses.
[b] Summarized values for ionic surfactants at 303 K.
[c] For dioleoyl-PC (DOPC) SUV at 298 K.
[d] For planar DOPC bilayer at 296 K.
[e] For dipalmitoyl-PC (DPPC) bilayer at 333 K.
General notes: The lipid concentrations are fixed to 30 mM. Diffusion coefficients are independently determined from the choline methyl signal and the chain methylene or methyl signal, respectively. Diffusion coefficients of lipids, estimated from the fluorescence recovery after photobleaching (FRAP) and molecular dynamics (MD) simulation, are also listed.

larger in the giant vesicle. Therefore, we can say that the lipid lateral diffusion in the giant vesicle is considerably large, as compared with the rotational and translational diffusion by the HD estimate, $\sim 10^{-14}$ m^2 s^{-1}.

30.2.2 Protrusion

Protrusion, the movement of individual lipids or lipid segments in the vertical direction to the membrane surface, is expected to relate closely to the mechanism of drug transport processes through the cell membrane. The vertical fluctuation or the out-of-plane vibration of the lipid molecules in membranes has been a subject of interest for more than two decades, and studied by using physicochemical techniques involving 2D NMR [21–24] and incoherent quasielastic neutron scattering [3, 25].

Most recently, the solution NMR has been applied to the cell-sized giant vesicle (CSV) of $\sim$10 μm diameter, to shed light on how lipid motions and fluctuations are modified in giant cell-sized membranes [26]. 2D nuclear Overhauser enhancement spectroscopy (NOESY) and the one-dimensional (1D) transient NOE spectra of CSVs have been systematically compared to the results of LUVs from 100 to 800 nm in diameter. Although no alteration is found in the chemical shifts and the longitudinal relaxation times (T_1) of phospholipid segments in CSV and LUV, the broad bandwidth of the ^{1}H-NMR signal and the large ^{31}P-NMR chemical shift anisotropy of CSV show a remarkable slowdown of the lipid tumbling motion in CSV with the rotational correlation time (τ_c) from subsecond to second order. In addition, the ^{1}H-^{1}H NOE enhancement (η) of the CSV lipid signal demonstrates the proximity between the hydrophilic headgroup and alkyl chains of the lipid [26]. The proximity is the result of the large protrusion in the vertical direction of the CSV surface, despite the slight curvature of the membrane. It is possible, however, that the protrusion motion is limited by the incorporation of hydrophobic molecules in CSV, although almost little effect is found in the presence of cations around the membrane surface [27].

30.3 DRUG DELIVERY RELATED TO MEMBRANE DYNAMICS

A large number of drugs, especially those containing small molecules, are transferred to the inside of living cells by passing through the plasma membrane based on the passive transport without the help of membrane transport proteins [28]. In these cases, drug binding from water to lipid bilayer membranes is of great importance as a preliminary stage of the biological action in the cell. As described in the previous section, lipid bilayer membranes are dynamic structures where the molecules are always moving and fluctuating in a confined geometry. Drug delivery mechanisms are expected to follow such dynamics in the fluid membrane. In particular, the drug permeation is expected to be closely related to the drug motion in the vertical direction to the membrane surface.

In this section, the dynamic aspects of drug deliveries are described. Our attention focuses on (1) the diffusivity of drugs in the membrane, (2) the kinetics of membrane binding and dissociation, and (3) the *dynamic* binding probability to quantify the efficiency of drug delivery from water to the membrane. The dynamic scheme of the delivery process is illustrated in Fig. 30.4. The solution NMR enables us to quantify (1) how much, how fast, and how efficiently the drug is bound to membrane; and (2) how rapidly the drug is moving within the membrane.

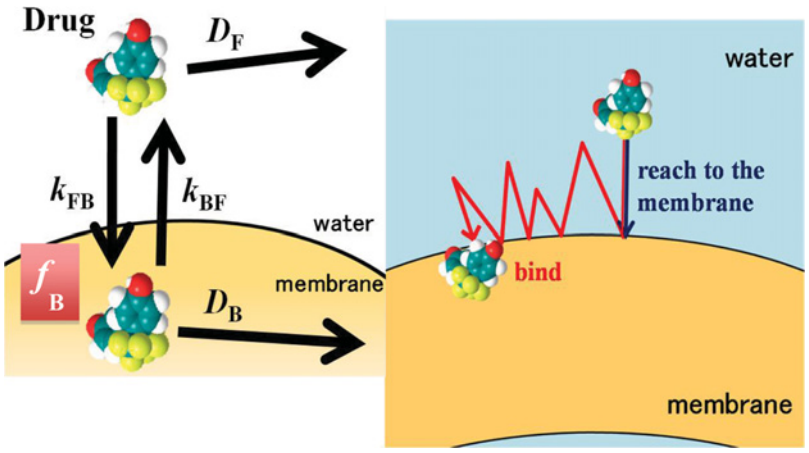

FIGURE 30.4 Dynamic model of drug delivery from water to the membrane. Left panel illustrates the diffusivity of the drug in water (D_F) and the membrane (D_B), the bound fraction (f_B), and the rate constants of membrane binding (k_{FB}) and dissociation (k_{BF}). Right panel shows "the *dynamic* binding probability" to quantify how efficiently the drug is bound to the membrane (see text).

30.3.1 Diffusion of Drugs in the Membrane

PFG NMR spectroscopy is powerful in terms of its ability to directly capture the molecular diffusion of drugs as well as lipids in a confined, anisotropic membrane. In the early 2000s, the diffusion of lipids and trapped drugs has been simultaneously observed in the freestanding membrane system, by using high-field-gradient high-resolution solution NMR at 600 MHz [14]. The self-diffusion of an endocrine disruptor, bisphenol A (BPA; 4,4′-isopropylidenediphenol; Fig. 30.1) is directly monitored, and was compared to the result for lipid molecules in size-controlled micelles and vesicles as described in Section 30.2.1.

As listed in Table 30.2, the BPA diffusion slows down in large-sized LUVs as compared to that in SUVs and micelles. It is also emphasized that the slowdown of lipid motions in membranes is leveled off in 100- and 400-nm LUVs, although the hydrodynamic (HD) continuum model gives the slowdown in diffusion in inverse proportion to lipid particle size. Recall that the surface curvature effect in LUV can be neglected at the molecular level. The situation is quite analogous to the membrane lipid motion in micelles and vesicles described in Section 30.2.1.

The above result implies that BPA mobility is related to membrane lipid dynamics. In fact, the simultaneous observation of the lipid diffusion in membranes shows that the BPA mobility is comparable to the respective lipid movement (Table 30.2); it is synchronized or concerted with the lipid matrix motion [14]. Thus it is rational to consider that the BPA diffusion in membrane is dominated by the dynamic property of the membrane matrices. It is clearly shown in Table 30.2 that the *intra*aggregate motion plays a significant role when the confined system is fluid and soft [14]. Because BPA has a high affinity for the membrane interface [29], the motion is decelerated by the site-specific, strong binding to the membrane lipid. The situation is in clear contrast to the movements of benzene and toluene [14], these movements are relatively independent of the membrane lipid motions as a result of the weak interaction with the membrane lipids.

The diffusion motion of a fluorinated BPA derivative, FBPA [$(CF_3)_2C(C_6H_4OH)_2$] (Fig. 30.1) has also been analyzed by ^{19}F NMR in combination with the PFG technique [30]. It is found that the diffusion coefficient of FPBA bound to 100-nm LUV is almost analogous to the value of nonfluorinated BPA; the mobility of FBPA in LUV is two orders of magnitude smaller than the mobility in water, and corresponds well to the movement of the membrane lipid, egg phosphatidylcholine (EPC) in LUV. Another team of investigators have reported that the mobility of cholesterol and the mobility of dimyristoylphosphatidylcholine (DMPC) in the membrane are shown to be equal, by using solid-state PFG NMR at 303–333 K [31]. The translational motions of cholesterol seem to be governed by the *intra*membrane fluidity. In contrast, the magic-angle spinning (MAS) solid-state PFG NMR [32, 33] shows that indole and an anti-inflammatory drug, ibuprofen, are moving faster than the membrane lipid, which is similar to the mobility of benzene and toluene [14]. A recent molecular dynamics (MD) simulation has also pointed out that an anesthetic, halothane, can move more than one order of magnitude faster than the membrane lipid [34].

With regard to an anticancer drug, 5-fluorouracil (5FU, Fig. 30.1), it is also found that the mobility of 5FU in EPC LUV is concerted with the EPC movement, although the molecular size of 5FU is much smaller than the EPC molecule [35]. This finding comes from the success in the simultaneous observation of membrane-bound and unbound (free) components as well as the membrane lipid, by the use of multinuclear ^{19}F and ^{1}H NMR in situ. In ^{19}F NMR, the self-diffusion coefficients of membrane-bound and free 5FU can be independently determined by combining the PFG technique. The method relies on the mobility difference between

TABLE 30.2 Self-Diffusion Coefficients of BPA in Water and in Model Confined Fluid Membrane

[a] The hydrodynamic (HD) estimate of the overall translational diffusion D_T is inversely proportional to the HD radius d as $D_T = k_BT/6\pi\eta d$, where k_B represents the Boltzmann constant; T, the absolute temperature; and η, the solvent viscosity. The HD estimate to the overall rotational diffusion D_R is $D_R = k_BT/8\pi\eta d^3$. This corresponds to an additional translational diffusion of $\sim k_BT/8\pi\eta d$ and does not change the magnitude order of the HD estimate listed.
General notes: The diffusivity of the membrane lipid molecule is also shown. For the experimental conditions, see Table 30.1. The hydrodynamic (HD) diffusion coefficients [17] of the whole particle itself are listed in the right column.

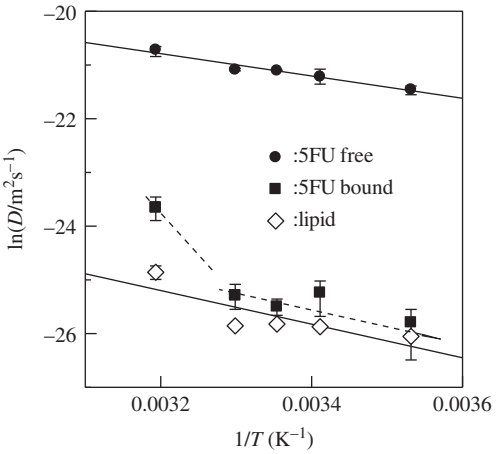

FIGURE 30.6 Temperature dependence of the self-diffusion rates of membrane-bound and free 5FU together with the mobility of the membrane lipid. For free 5FU and the lipid, the temperature dependences of the diffusion are of the Arrhenius type with activation energies of 21 kJ/mol (free 5FU) and 26 kJ/mol (lipid), respectively. Note that the dependence of the bound 5FU diffusion deviates from the Arrhenius type at 313 K (see text). (Reprinted with permission from Ref. 35. Copyright 2008 AIP Publishing LLC.)

the bound and the free components, where the signal decays can be treated as a biexponential function of the field gradient strength, G (Fig. 30.5) [35]. In Fig. 30.6, the diffusion coefficients of free and bound 5FU molecules are plotted as a function of the reciprocal temperature, together with the mobility of the membrane lipid. As compared to the free 5FU, the mobility of the membrane-bound 5FU is found to slow down by almost two orders of magnitude. At 283–303 K, the 5FU mobility in the membrane is almost comparable to that of the membrane lipid molecules. This means that the molecular motion in the fluid membrane environment is closely related to the *intra*membrane fluidity. The temperature dependence of the 5FU diffusion in the membrane is found to be of Arrhenius type, with the activation energy of diffusion motion, 26 kJ/mol [35]. In addition, the activation energy of 5FU is very close to the value of the membrane lipid [35, 36].

Although 5FU is moving as rapidly as the lipid matrix motion, the mobility is enhanced at high temperature. This is shown in Fig. 30.6 at 313 K. The enhancement of the 5FU mobility in the membrane is probably due to the fact that the lateral diffusion of 5FU is accelerated within the lipid membrane, or the fact that the membrane-bound 5FU rapidly exchanges with the free 5FU molecule as a result of the loose binding in the lipid matrices at high temperature [35].

30.3.2 Kinetics of Membrane Binding and Dissociation

As demonstrated in Fig. 30.4, the translational motion of drugs in the vertical direction to the membrane surface is closely related to the drug entry into the cell across the lipid membrane. The authors have focused on the drug motion in the *normal* direction to the lipid membrane, from the viewpoint of the exchange kinetics of free and bound drug molecules between bulk water and lipid membranes. The rate constants of membrane binding k_{FB} and dissociation k_{BF} of 5FU, a pentapeptide L-Enk (Fig. 30.1), and FPBA have been quantified by high-resolution solution NMR in combination with the PFG technique [30, 37, 38]. To evaluate the rate constants k_{FB} and k_{BF}, both ^{19}F- and ^{1}H-NMR signals have been analyzed by using the analytical formula of the Bloch equation with exchange terms. In this section, the focus is on how to quantify the exchange rate constants k_{FB} and k_{BF} of the drug by analyzing the NMR signal, and how the drug exchange motions differ from each other and how the diffusivities of the respective motions are differs from the diffusivity described in Section 30.3.1.

30.3.2.1 Hydrophilic Drugs. As mentioned in Section 30.3.1, the application of PFG NMR to the membrane system enables us to separate the signals of free and membrane-bound drugs in situ. In such cases, the exchange rate constants

of drug molecules can be obtained by (1) completely decomposing the drug signal into free and bound components, (2) evaluating the diffusion coefficients of the respective components by using the Stejskal–Tanner plot [16], and (3) fitting the analytical formula of the Bloch equation to the experimental signal intensities of each component.

A typical example is the case of 5FU [37]. When the 5FU exchange motion between the bulk water and lipid membrane is under equilibrium as

$$\text{Free (F)} \underset{k_{BF}}{\overset{k_{FB}}{\rightleftharpoons}} \text{bound (B)}, \tag{30.2}$$

the analytical signal intensity formulas are derived by using the Bloch equation in combination with the diffusion and exchange terms as [39]

$$I_F(G) = \left\{ \frac{I_{F0}}{2} + \frac{\lambda I_{F0} + k_{BF} I_{B0}}{2\Delta} \right\} \exp\{(-\sigma + \Delta)\tau\} + \left\{ \frac{I_{F0}}{2} - \frac{\lambda I_{F0} + k_{BF} I_{B0}}{2\Delta} \right\} \exp\{(-\sigma - \Delta)\tau\} \tag{30.3}$$

and

$$I_B(G) = \left\{ \frac{I_{B0}}{2} - \frac{\lambda I_{B0} - k_{FB} I_{F0}}{2\Delta} \right\} \exp\{(-\sigma + \Delta)\tau\} + \left\{ \frac{I_{B0}}{2} + \frac{\lambda I_{B0} + k_{FB} I_{F0}}{2\Delta} \right\} \exp\{(-\sigma - \Delta)\tau\} \tag{30.4}$$

where $I_F(G)$ and $I_B(G)$ are the PFG NMR signal intensities of free (F) and bound (B) components. λ, σ, and Δ are

$$\lambda = \frac{1}{2}\left\{k_{BF} - k_{FB} + D_B(\gamma\delta G)^2 - D_F(\gamma\delta G)^2\right\}, \tag{30.5}$$

$$\sigma = \frac{1}{2}\left\{k_{BF} + k_{FB} + D_B(\gamma\delta G)^2 + D_F(\gamma\delta G)^2\right\}, \tag{30.6}$$

and

$$\Delta = \sqrt{\lambda^2 + k_{BF}k_{FB}}, \tag{30.7}$$

where D_F and D_B are the diffusion coefficients of free and bound 5FU. The exchange rate constants, k_{FB} and k_{BF}, can be determined by fitting Eqs. (30.3) and (30.4) to the signal intensities, $I_F(G)$ and $I_B(G)$ [37].

It is found that k_{FB} and k_{BF} of 5FU are 0.2 ± 0.1 and $4.1 \pm 1.5\ s^{-1}$ at 303 K where the membrane lipids are in the fluid liquid-crystalline state [37]. This corresponds to the half-value periods of binding and dissociation, t_{FB} and t_{BF}, of 3.5 and 0.17 s, respectively. The timespan of the membrane binding and dissociation of 5FU are found to be on second and a subsecond timescales, respectively. The temperature dependence shows that the exchange rate constants, k_{FB} and k_{BF}, are of Arrhenius type with the activation energy of the exchange motion, ~57 kJ/mol [37]. The activation energy is more than twice as high as that of the translational diffusion in the lipid membrane (26 kJ/mol) mentioned in Section 30.3.1. This indicates that the 5FU motion in the vertical direction to the membrane surface is restricted as compared with the translational diffusion in the membrane.

Molecular dynamics of peptide binding to the membrane is crucial for a better understanding of the primary stage of the bioactivities in the cell. In situ NMR is expected to be powerful to gain insight into the mechanistic view of peptide functions in a natural manner. The proton NMR is effective because ^{1}H is abundant in the natural system. Recently, the PFG ^{1}H NMR method has been also applied to explore the dynamics of peptide binding to fluid lipid membranes [38]. The kinetics of binding of a neuropeptide, leucine-enkephalin (L-Enk, Fig. 30.1) to lipid bilayer membranes has been quantified by PFG ^{1}H NMR in situ. The peptide signal has been analyzed by solution of the Bloch equation with exchange terms in the presence of EPC LUV of 100 nm diameter as confined, but fluid model cell membranes [38]. Even when membrane-bound and free states of L-Enk cannot be distinguished in the one-dimensional (1D) ^{1}H-NMR spectrum, the PFG technique unveils the bound component of L-Enk after the preferential decay of the free component at the high field gradient. The rate constants of the peptide binding and dissociation are 0.040 and 0.40 s^{-1} at 303 K [38]. The values correspond to the lifetime of the peptide binding of the order from 1 to 10 s.

30.3.2.2 Hydrophobic Drugs. As described in Section 30.3.2.1, PFG ^{19}F and ^{1}H NMR allow us to quantify how fast 5FU and L-Enk are bound to the membrane and dissociate from the membrane. The method is based on the simultaneous detection of bound and free (unbound) states of the drug in situ. The bound and free states are distinguishable in case of rather hydrophilic drug such as 5FU and L-Enk because of the relatively slow exchange of the drug molecules between these two states [37, 38]. In contrast, the permeation of a hydrophobic drug across the membrane is generally too rapid [1] to permit easy distinction between bound and free states. In fact, the ^{19}F-NMR signal of the hydrophobic FBPA is still observed as a singlet even in the presence of EPC LUV, as illustrated in Fig. 30.7. This means that the bound component of FBPA is exchanging so rapidly with the free component that we cannot distinguish these two states on the NMR timescale. When molecules are in rapid exchange between the bound and free states, the NMR spectra consist of a single set of peaks whose chemical shifts are averaged between these the two states [2]. Although the

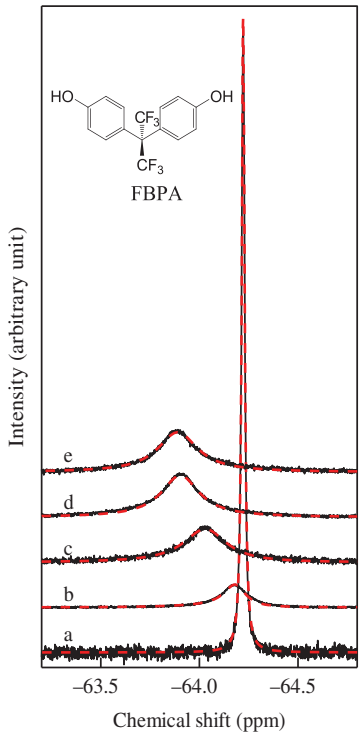

FIGURE 30.7 One-dimensional ^{19}F-NMR spectra of FBPA in the absence (a) and presence of (b) 0.4, (c) 1, (d) 4, and (e) 40 mM EPC LUV at 303 K. The solid lines show the observed spectra and the dashed lines show the fitting results of Eq. (30.15) to the respective NMR signals. (Reprinted with permission from Ref. 30. Copyright 2011 American Chemical Society.)

bound and free components are averaged in the NMR spectra, the exchange rate constants are nonetheless obtainable from an analysis of the spectra that relies on the expression of 1D NMR signal intensity by a set of Bloch equations with exchange terms [30].

When a hydrophobic FBPA molecule is exchanging between the bound (B) and the free (F) states, a set of Bloch equations with exchange terms can be written as

$$\frac{dM_{\mathrm{B}}}{dt} = -\left(\frac{1}{T_{2\mathrm{B}}^{0}} + \frac{i\omega_{B}^{0}}{2\pi} + k_{\mathrm{BF}}\right) M_{\mathrm{B}} + k_{\mathrm{FB}} M_{\mathrm{F}} \qquad (30.8)$$

and

$$\frac{dM_{\mathrm{F}}}{dt} = -\left(\frac{1}{T_{2\mathrm{F}}^{0}} + \frac{i\omega_{\mathrm{F}}^{0}}{2\pi} + k_{\mathrm{FB}}\right) M_{\mathrm{F}} + k_{\mathrm{BF}} M_{\mathrm{B}}, \qquad (30.9)$$

where M_{B} and M_{F} are the signal intensities of B and F components, and T_{2i}^{0} and ω_{i}^{0} (i = B or F) are respectively the transverse relaxation time and the resonance frequency of the pure B or F states of FBPA. The analytical solution of Eqs. (30.8) and (30.9) is, therefore, expressed as a function of the frequency ω

$$M_{\mathrm{B}}(\omega) = \frac{M_0}{\pi} \frac{\beta_{\mathrm{F}} f_{\mathrm{B}} + k_{\mathrm{FB}} f_{\mathrm{F}}}{\beta_{\mathrm{B}}\beta_{\mathrm{F}} - k_{\mathrm{BF}} k_{\mathrm{FB}}} \qquad (30.10)$$

and

$$M_{\mathrm{F}}(\omega) = \frac{M_0}{\pi} \frac{\beta_{\mathrm{B}} f_{\mathrm{F}} + k_{\mathrm{BF}} f_{\mathrm{B}}}{\beta_{\mathrm{B}}\beta_{\mathrm{F}} - k_{\mathrm{BF}} k_{\mathrm{FB}}} \qquad (30.11)$$

where

$$\beta_{\mathrm{B}} = \frac{1}{T_{2\mathrm{B}}^{0}} + \frac{i\omega_{\mathrm{B}}^{0}}{2\pi} + k_{\mathrm{BF}} - \frac{i\omega}{2\pi} \qquad (30.12)$$

and

$$\beta_{\mathrm{F}} = \frac{1}{T_{2\mathrm{F}}^{0}} + \frac{i\omega_{\mathrm{F}}^{0}}{2\pi} + k_{\mathrm{FB}} - \frac{i\omega}{2\pi} \qquad (30.13)$$

and f_j is the fraction of the j (= B or F) state. Under the equilibrium condition

$$k_{\mathrm{BF}} f_{\mathrm{B}} = k_{\mathrm{FB}} f_{\mathrm{F}}, \qquad (30.14)$$

the observed 1D NMR signal intensity is finally given as

$$M(\omega) = M_{\mathrm{B}}(\omega) + M_{\mathrm{F}}(\omega) = \frac{M_0}{\pi} \frac{\beta_{\mathrm{F}} f_{\mathrm{B}} + k_{\mathrm{FB}} f_{\mathrm{F}} + \beta_{\mathrm{B}} f_{\mathrm{F}} + k_{\mathrm{BF}} f_{\mathrm{B}}}{\beta_{\mathrm{B}}\beta_{\mathrm{F}} - k_{\mathrm{BF}} k_{\mathrm{FB}}} \qquad (30.15)$$

As the transverse relaxation times $T_{2\mathrm{B}}^{0}$ and $T_{2\mathrm{F}}^{0}$ and the frequencies ω_{B}^{0} and ω_{F}^{0} are evaluated from the 1D ^{19}F NMR spectra in both presence and absence of LUV [30], the parameters k_{BF}, k_{BF}, f_{B}, and f_{F} can be finally determined by fitting Eq. (30.15) to the observed signal intensity and reduced by using the relations $f_{\mathrm{B}} + f_{\mathrm{F}} = 1$ and Eq. (30.14).

It is found that the rate constant of FBPA-binding k_{FB} is enhanced from 22 to 280 s^{-1} by increasing the lipid concentration in LUV [30]. The k_{FB} is much larger than that of hydrophilic 5FU (0.2 s^{-1}) described in Section 30.3.2.1 [37]. The dissociation rate constant k_{BF} of FBPA is in the range from 68 to 107 s^{-1}. The rate constants obtained correspond to the half-value periods of the FPBA binding and dissociation, t_{FB} and t_{BF}, of 3–32 and 5–10 ms, respectively [30]. The timespan of the membrane binding and dissociation of FBPA is found to be a 10^{-3}–10^{-2} -s timescale, which is two to three orders of magnitude as fast as the 5FU binding of a 10^{-1}–10^{0} -s timescale.

30.3.3 Thermodynamic Stability

30.3.3.1 5FU and L-Enk. The success in distinguishing the bound and free 5FU signals enables us to quantify in what amount of the drug is bound to the membrane in situ. This is accomplished by integrating the respective components of the 5FU signal. The quantification is achieved after the signal decomposition of the 1D NMR spectrum or the PFG NMR application. In the 1D ^{19}F-NMR spectrum of 5FU at 303 K, the membrane-bound fraction is found to be ∼0.1 relative to the total signal intensity of 5FU in water [35]. This is consistent with the bound fraction obtained by the PFG ^{1}H-NMR measurement; note that the PFG analysis is effective because the decomposition of the 1D ^{1}H-NMR spectrum is not successful because of the overlap of the bound and free components [35, Fig. 4B]. Both ^{19}F and ^{1}H NMR results of the 5FU bound fraction about 0.1 at 283–313 K give the binding free energy, ranging from −4 to −2 kJ/mol; the magnitude is very close to the thermal fluctuation, 2.4–2.6 kJ/mol.

The binding amount of L-Enk is not so large; it ranges, for example, from 0.09 for 5 mM L-Enk to 40 mM lipid LUV from the PFG ^{1}H-NMR analysis [38]. This indicates that 0.45 mM of L-Enk is bound to the LUV that corresponds to the peptide/lipid molar ratio of 0.011. The binding free energy ΔG of L-Enk is estimated as −2.9 kJ/mol at 303 K, the magnitude close to the thermal fluctuation, 2.5 kJ/mol. The value is analogous to the result of 5FU mentioned above, and it is reasonable in terms of the rather hydrophilic nature of L-Enk and 5FU.

30.3.3.2 FBPA. The thermodynamic stability of hydrophobic FBPA molecules in membranes can also be quantified in situ, by fitting Eq. (30.15) to the observed 1D ^{19}F-NMR spectra. It is found that the bound fraction f_B gradually increases with increase of the lipid concentration in LUV, and it finally comes to almost unity at high lipid/FBPA molar ratio [30]. It is noted that the result is consistent with the chemical shift, the transverse relaxation time, and the diffusivity variations as a function of the lipid concentration [30]. The f_B values are also comparable with the fraction ${f_B}^{\omega}$, which is estimated from the observed chemical shift ω_{obs} at the FBPA peak maximum, in accordance with the two-site model where ω_{obs} is equal to the weighted average of the chemical shifts of pure free and bound components ω_F^0 and ω_B^0:

$$\omega_{obs} = \left(1 - f_B^{\omega}\right)\omega_F^0 + f_B^{\omega}\omega_B^0 \qquad (30.16)$$

For FBPA, the difference in the free energy ΔG between the bound and the free states is calculated to be −20 ± 2 kJ/mol at 303 K, the value independent of the molar ratio of lipid/FBPA. The ΔG of −20 kJ/mol indicates that the hydrophobic FBPA prefers the membrane interior to the bulk water. This is consistent with the previous NMR result of non-fluorinated BPA that it is located between the lipid headgroup and hydrocarbon chain region most adjacent to the interface, with the two methyl groups oriented toward the inside of the bilayer [29]. The situation is in contrast to rather hydrophilic 5FU and L-Enk described in Section 30.3.3.1, where the magnitude of the binding free energy is very close to the thermal fluctuation [35, 38].

The temperature dependence of ΔG informs us of the differences in the entropy ΔS and in the enthalpy ΔH between the free and the bound states of FBPA. The ΔS of FBPA binding is (157 ± 10) J/(mol K), about 2.5 times as large as that of 5FU, (63 ± 29) J/(mol K) [30]. The large ΔS value of FBPA indicates that FBPA avoids the hydrophobic hydration in bulk water and is remarkably stabilized in the membrane. ΔH of FBPA [(28 ± 3) kJ/mol] and 5FU [(15 ± 9) kJ/mol] are both positive [30], indicating the endothermic binding of both drugs to the membrane. For FBPA, $T\Delta S$ is much larger than ΔH ($\Delta H < T\Delta S$), whereas $\Delta H \simeq T\Delta S$ for 5FU [30]. The binding of the FBPA is found to be entropy-driven.

30.3.4 Dynamic Binding Probability

The efficiency of drug transfer from water to membranes (right panel in Fig. 30.4) is of significance to consider the drug delivery mechanism. One group of investigators have introduced a *dynamic* binding probability P to quantify the efficiency, which is defined by a ratio t_R/t_B, where t_R is the mean time interval for a drug to reach at first to the membrane surface, and t_B is the interval for the drug to bind to the membrane, as illustrated in Fig. 30.8 [30]. t_R is evaluated by the analytical formula of the reaction time of diffusion-controlled reaction [40], and t_B is calculated from the observed k_{FB} as $t_B = {k_{FB}}^{-1}$. Regarding the spherical system of radius r_s where the spherical vesicle of radius r_v is

placed on the center (Fig. 30.8), the mean time interval t_R is given as

$$t_R = \frac{r_s^2}{D} \frac{(1-x^2)(5+6x+3x^2+x^3)}{15x(1+x+x^2)} \qquad (30.17)$$

where $x = r_v/r_s$ [30]. D, the diffusion coefficient of FBPA in the bulk, is evaluated by using the movement of the drug molecule relative to the center of the vesicle. The calculated results of t_R, t_B, and P ($= k_{FB}\, t_R$) are listed in Table 30.3. For FBPA, it is found that the dynamic binding probability P is in the range of 0.030 ± 0.022. This means that the ratio (N_{FBPA} to reach memebrane)/(N_{FBPA} to bind to membrane) (where N_{FBPA} = number of FBPA molecules) is ~40. The binding probability P of the hydrophilic 5FU is, in contrast, almost five orders of magnitude smaller than FBPA. The difference in hydrophobicity between FBPA and 5FU is found to affect the efficiency of drug transfer to the membrane.

30.3.5 Effect of Cholesterol

Cholesterol plays a significant role in regulating structure, dynamics, and functions of biological membranes [7–10,41–44]. Under physiological conditions where molecules are fluctuating at soft membrane interfaces [2, 5], cholesterol stiffens the membrane lipids; the lipid molecules reduce the freedom of motion in the membrane [9, 10]. The delivery process is likely to be limited in such rigid membrane environments. In fact, it has been reported that the permeability of small molecules is inhibited by the presence of cholesterol [45–47]. Cholesterol also suppresses the permeability of water via the auaporin-4 channel in the membrane [48] and permeability of Ca^{2+} mediated by the ionophore A23187 [49]. It is reported that the presence of cholesterol decreases the drug binding affinity to the membrane [50, 51].

Most recently, the high-resolution solution NMR has been applied in a study of the delivery of a fluorinated anesthetic, sevoflurane (SF, fluoromethyl 2,2,2-trifluoro-1-[trifluoromethyl]ethyl ether; Fig. 30.1), to cholesterol-containing LUV from water at a clinically relevant concentration [52]. SF is a hydrophobic molecule with its solubility in water, several hundred μM at ambient temperature. The low solubility in water results in SF preference for the hydrophobic membrane interior. Utilizing that SF contains fluorine nuclei, both ^{19}F and ^{1}H NMR are used to monitor SF molecules in the membrane. The NMR chemical shift, the longitudinal relaxation time (T_1), and the diffusion coefficient are analyzed to quantify how the SF uptake is modified by the presence of cholesterol in the membrane.

It is found that the uptake of SF is limited in the cholesterol-rich membrane. The limited uptake of SF is related to the rigidity of the membrane where the molecular movements are restricted by the presence of cholesterol. This is demonstrated by the slowdown of the lipid diffusion at high cholesterol fraction in the membrane [52].

30.4 CONCLUDING REMARKS AND FUTURE PERSPECTIVES

High-resolution solution-state NMR spectroscopy is a powerful method to gain insight into the molecular picture of membrane fluctuation and drug transport processes in membranes. In this chapter, two kinds of in situ NMR methods used to observe the molecular dynamics in model cell membranes are described. One is to apply multinuclear NMR spectroscopy in combination with the pulsed-field-gradient (PFG) spin-echo technique. The criterion is that the signals assigned to membrane-bound molecules are insensitive to the PFG application because of the motional slowdown in the membrane environment, whereas the signal assigned to free (unbound) species is attenuated preferentially with increasing the field-gradient (FG) strength. The simultaneous observation of the membrane-bound and free signals enables one to quantify the amount of drug that is bound to the membrane and how rapidly the drug is moving within the membrane in relation to the thermal fluctuation of the soft, fluid environment. The other method is to analyze 1D NMR spectra by using the solution of the Bloch equation with exchange terms. The method is particularly useful where the bound and the free components of the drug are indistinguishable because of the rapid exchange on the NMR timescale. The

diffusivity, the kinetics of membrane binding and dissociation, the dynamic binding probability, and the thermodynamic stability of hydrophilic and hydrophobic drugs are quantified by NMR in situ without any perturbation of the system. The results are summarized in Table 30.4.

It is reasonable to consider application of the in situ NMR method to the living system. Permeation of the drug to the internal part of the cell via the cell membrane is an issue of great significance not only as the primary stage of bioactivities but also for the purpose of rational drug design. Although endocytosis is thought to be a typical mechanism for drug entry into the cell, it is still unknown, in some cases, how the passive transport of the drug proceeds through the biological membrane. Fluorescence labeling is a commonly used technique. Although it is sensitive, it sometimes modulates the intracellular delivery of the drug [53]. In this sense, the label-free, in-cell NMR method is advantageous. The in situ technique is effective for observing real-time processes of cellular uptake of drugs without perturbing the system. Actually, the transport of a hydrophobic ion across the *Escherichia coli* membrane has been most recently analyzed with time resolution, by using nonlinear optical second-harmonic generation (SHG) [54]. Real-time in-cell NMR is to be realized to quantify the kinetics of drug delivery to natural human cells, in relation to the cell membrane dynamics.

STIMULUS-RESPONSIVE INTELLIGENT DRUG DELIVERY SYSTEM BASED ON HYDROXYAPATITE-RELATED MATERIALS

MAKOTO OTSUKA

Research Institute of Pharmaceutical Sciences, Faculty of Pharmacy, Musashino University, Nishi-Tokyo 202-8585, Japan

31.1 INTRODUCTION

For the treatment of intractable diseases, slow-release drug delivery systems could provide the required dose at the required time to the targeted site. Such systems reduce undesirable side effects and achieve a long-term therapeutic concentration at a specific site [1]. Slow-release systems are often coupled with biodegradable solid devices, which gradually degrade in the body and continue to release the drug for a long period [2]. Solid-type slow-release systems are mainly implanted surgically, which is often invasive and difficult depending on the site [3]. Microspheres composed of a biodegradable microgel have been explored as an injectable device [4], which allow the drug to be released over a period of several weeks. Injectable materials that self-assemble into a solid in the body would be another solution to avoid surgical implantation. The slow-release drug delivery systems are useful for practical therapeutics without concern about a patient's compliance. However, the biggest drawback of this dosage form is that, once applied, stopping the application of the drug is difficult. When the disease condition changes, it is not possible to change the dose.

On the other hand, intelligent drug delivery systems are capable of adjusting drug release rates in response to the physiological need of the patient [5,6]. Intelligent drug delivery systems are based mostly on stimulus-responsive polymers that sense a change in a specific variable and activate the delivery, as this phenomenon is reversible [7]. It is important to develop intelligent drug delivery systems to understand physiological systems and mechanisms of the human body and related diseases.

In order to develop a stimulus-responsive intelligent drug release system for skeleton hard tissues, it is vital that the characteristics of bone graft remodeling by osteoclasts and osteoblasts be fully understood. Since bone resorption and formation occur repeatedly in the functional units called *bone multicellular units*, which maintain the dynamic equilibrium of mineral density in normal bone [8], uncoupling between bone resorption by osteoclasts and bone formation by osteoblasts causes an absolute decrease in the amount of bone in osteoporosis. We have, therefore, developed a stimulus-responsive intelligent drug release system to improve bioaffinity and drug delivery ability to skeleton hard tissues by enhancing the interaction between the composites and bone cells for applications as cell scaffold devices [7].

This review focuses on the process of developing an intelligent drug release system for biological stimulus-responsive drug release for skeletal hard tissues. It consists of hydroxyapatite-related compounds that mimic natural bone, and the system shows stimulus-responsive drug release for a long period of time to hard tissues or the whole body.

31.2 SLOW DRUG RELEASE FROM SELF-SETTING APATITE CEMENTS

The conventional bioactive ceramics on the market, such as hydroxyapatite (HAp), β-tricalcium phosphate, and bioglass

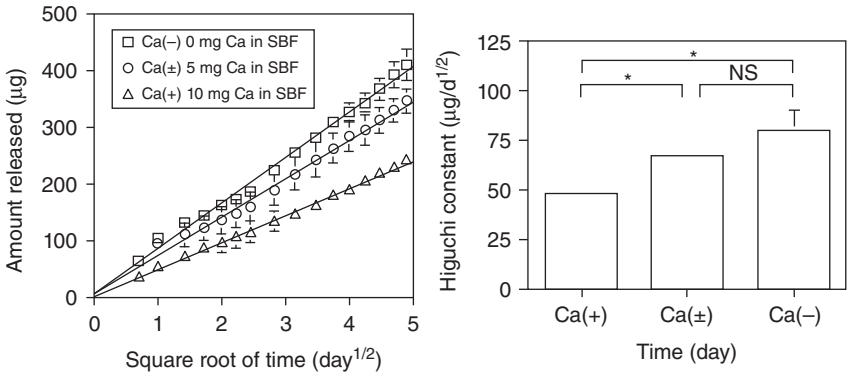

FIGURE 31.1 Calcium-level-responsive in vitro drug release from AP cement containing estradiol.

ceramics, have good bioaffinity, and can directly connect with bone [9]. However, these materials could remain in bone for an extended period and alter its mechanical strength because their chemical composition and geometric structure are very different from those of natural bone and they exhibit lower bioaffinity [9]. Two investigators [10] developed an injectable apatite cement formulation (AP) consisting of an equimolar mixture of tetracalcium phosphate [TECP; $Ca_4(PO_4)_2O$] and dicalcium phosphate dihydrate (DCPD; $CaHPO_4.2H_2O$], which had the capacity of self-setting in vivo, within the bone cavity. The development of the cement established good prospects for minimally invasive surgical techniques developed in recent years, which are less aggressive than the classical surgical methods [11]. Drug delivery systems for several drugs [12,13] have been developed on the basis of biocompatible self-setting AP cement [10, 14] that is transformed into hydroxyapatite with lower crystallinity in the body. After implantation of the AP cement, initial drug release from the cement was found to be greater than that at a later stage [13]. The rate-limiting step of drug release from the matrix system was basically the drug diffusion process in the micropores of the matrix. The drug release from drug-loaded cement matrix systems follows the Higuchi equation [15]

$$M_t = A\sqrt{C_s \frac{D_i \varepsilon}{\tau}(2C_d - \varepsilon C_s)t} \qquad (31.1)$$

where M_t is the amount of drug released after time t, A is the surface area of the device, D_i is the diffusion coefficient of the drug, C_s is the solubility, C_d is the concentration of drug in the matrix, τ is the tortuosity, and ε is the porosity.

31.3 EFFECT OF CALCIUM LEVEL ON IN VITRO DRUG RELEASE FROM APATITE CEMENT [16]

It is well known that fine calcium phosphate fine crystals are precipitated after soaking in simulated body fluid (SBF), since SBF has a high degree of supersaturated concentration with respect to the solubility of hydroxyapatite [17]. In order to clarify the calcium concentration dependences of the in vitro drug release from apatite cement containing estradiol, their drug release rates were measured in different dissolution media with high or low calcium concentrations. The in vitro estradiol levels released from the AP cement systems in 0, 5, and 10 mg of calcium/100 mL SBF were 410, 346, and 241 μg after 24 days, respectively, indicating that the estradiol release rate from the apatite cement decreased with increasing calcium concentration in dissolution media (Fig. 31.1). The result of in vitro estradiol release in SBF suggested that change in the geometric structure of the device surface depends on the degree of calcium concentration in SBF. The cement surface was covered with precipitated fine hydroxyapatite crystals during the drug release test as a result of the high degree of supersaturation of SBF with respect to the solubility of hydroxyapatite, and inhibited drug release. Conversely, in SBF at unsaturated calcium levels, the hydroxyapatite in the cement matrix dissolved and/or eroded, accelerating drug release. Therefore, in vitro estradiol release from the cement matrix was reflected decreasing or increasing effective diffusivity of estradiol in the pores, indicating that the release rates depended on calcium levels in SBF, which explains the calcium-level-responsive drug release from the matrix.

31.4 CALCIUM-LEVEL-RESPONSIVE DRUG RELEASE OF APATITE CEMENTS CONTAINING ANTIOSTEOPOROSIS DRUG IN HEALTHY AND DISEASED RATS AND THERAPEUTIC EFFECTS [16]

After subcutaneous implantation of AP cements containing estradiol into osteoporotic rats, the plasma calcium levels and the drug release from the cements [18, 19] were measured [16]. Healthy model rats have a constant plasma calcium concentration of around 10 mg/100 mL (Fig. 31.2, left).

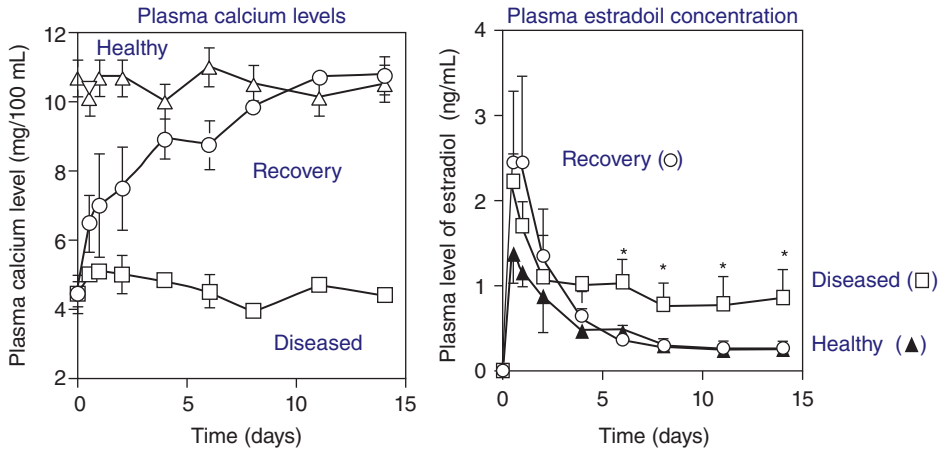

FIGURE 31.2 Calcium-level-responsive drug release from AP cement containing estradiol in ostseoporotic rats.

However, the diseased model rats maintained a low calcium level of ~5 mg/100 mL during drug release. In contrast, the plasma calcium level of the recovery model rats was increased by feeding them calcium, and reached healthy level of around 10 mg/100 mL after 7 days.

The plasma estradiol concentrations in the diseased model rats increased rapidly (Fig. 31.2, right), attaining a maximum level (C_{max}) of 2.23 ng/mL, and then decreased gradually, yet after 5 days were still significantly higher than those in the healthy group. In the recovery model rats, the plasma estradiol concentrations increased rapidly, attaining C_{max} of 2.55 ng/mL. These levels, however, decreased gradually, and after 5 days were almost the same as those of healthy rats. In contrast, C_{max} of the healthy rats (1.43 ng/mL) was much lower than that of the diseased and recovery model rats. The in vivo estradiol release of the recovery model rats supported the hypothesis that the drug release behavior of the apatitic cement drug delivery system was responsive to plasma calcium levels.

The bone mineral density (BMD) of the diseased and the recovery model rats was measured by bone mineral densitometry (Fig. 31.3). The BMD of the recovery model (IR) and control diseased (CR) groups was significantly increased compared with that before the experiment in the control group (CD) and implanted group (ID) without calcium feeding, indicating that calcium feeding was an important factor and estradiol-loaded cement implantation was effective for the therapeutic improvement in diseased model rats. In terms of the BMD, the diseased rats ranked as follows: IR > CR > ID > CD, indicating that the increase of BMD was a combination effect of the estradiol release from the cement and plasma calcium concentration. These results suggest that plasma estradiol levels are regulated by the characteristics of apatite cements, and the degree of osteoporosis is improved

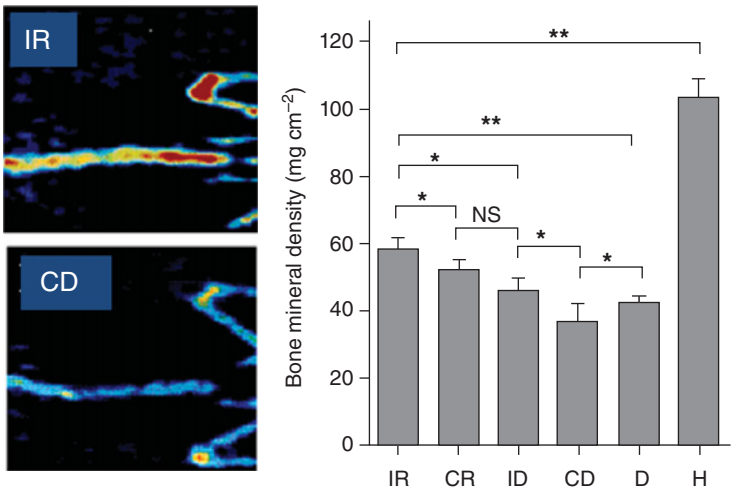

FIGURE 31.3 BMD of implanted apatite cement containing estradiol in osteoporotic rats. For a color version of this figure, see the color plate section.

by implantation of estradiol-loaded apatite cement with sufficient calcium supplementation.

31.5 DRUG DELIVERY SYSTEM CONTAINING VK2 BASED ON SELF-SETTING APATITE/COLLAGEN COMPOSITE CEMENTS (AC) [20]

Several researchers [21, 22] reported an HAp/collagen composite with a nanostructure that is similar to natural bone. They also reported that the molecular interaction between apatite and collagen induced the formation of nanostructure particles, which have characteristics and biocompatibility similar to those of natural bone. The results indicated that the biomimic materials had significantly high bioaffinity with natural bone after implantation, and the molecule-level structure of inorganic and organic composites is a very important factor for the biocompatibility of artificial bone in vivo. To develop artificial self-setting bone cement with almost the same chemical formulation as natural bone, the AC bulk powder was obtained by grinding the AP cement powder (TECP and DCPD) with 20% type I bovine collagen in a vibration mixer mill. The X-ray powder diffraction (XRD) profiles of the sample cements (Fig. 31.4, left) were measured to evaluate the test material characteristics as an index of bioaffinity. The fresh fixed physicalmixed AC (PAC) cements showed typical diffraction peaks of HAp at $2\theta = 31.8$ and 32.8° with additional peaks at $2\theta = 28.9$ and 29.5° due to TECP and at $2\theta = 26.5°$ due to DCPD. The XRD results indicated that the majority of metastable calcium phosphates, DCPD and TECP, transformed into low-crystallinity HAp, but some parts of DCPD and TECP did not transform, and remained in the cements. In contrast, the XRD profiles of AC had broad peaks at 31–33° due to bonelike HAp and no peaks due to TECP and DCPD (Fig. 31.4, left). These results also suggested that crystalline transformation of AP is accelerated by the addition of collagen and mechanical treatment. The transformed apatite structure in the AC was similar to natural bone apatite with low crystallinity reported by another team [21, 22] because the bonelike nanoapatite crystals precipitated out on collagen matrices during the setting time after mixing of the solution.

Scanning electron microscopy (SEM) and electron probe microanalysis (EPMA) (Fig. 31.4, right) were performed to characterize the element dispernsability in the AC [20]. The SEM of PAC without grinding showed a rough surface and large particles (>20-μm-diameter), indicating that the cement was a heterogeneous system. In contrast, AC with grinding showed a smooth surface consisting of particles of <1–2 μm in diameter.

In order to develop bone regenerative artificial bone systems based on the AC cement, it is necessary that bone growth factors be loaded in bioactive artificial bone matrices and slowly released over time. One team of investigators [23] reported that metacarpal bone mineral density was increased in osteoporosis through the administration of menatetrenone, [vitamin K_2 (VK2), an antiosteoporosis drug]. Therefore, VK2 was selected as a model drug and loaded in the bone cement matrices to develop a drug delivery system. Three types of the AC and AP cement (500 mg) containing 10 mg of VK2 were developed as follows: APK: VK2 loaded in the AP; PACK: VK2 loaded in the PAC without grinding; and ACK: VK2 loaded in the AC with grinding. The AC cements containing VK2 were implanted into the backs of rats and the density was measured using bone mineral densitometry. Microradiograms of AP and AC were obtained by dual-energy X-ray absorptiometry after implantation in the rats, and the cement mineral content (BMC) was evaluated based on these microradiograms.

The effects of VK2 on the BMC of AC cements implanted in osteoporotic rats were investigated (Fig. 31.5, left). The BMC profile of ACK was significantly higher than those of

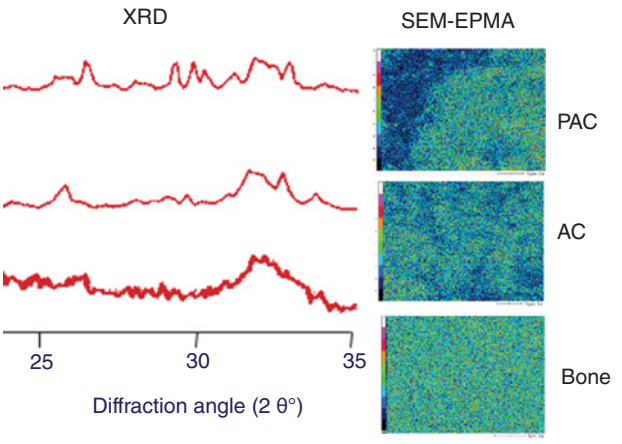

FIGURE 31.4 Effects of grinding of element dispersibility of AC and PAC by electron probe microanalyzer. For a color version of this figure, see the color plate section.

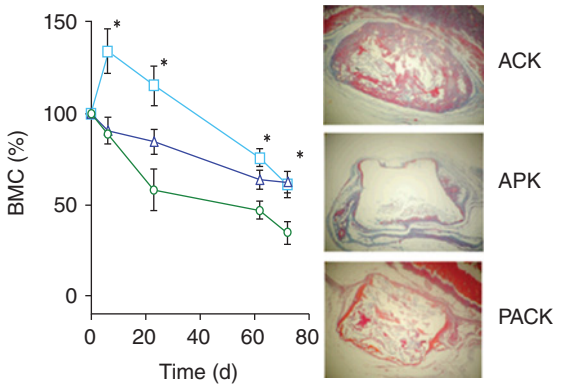

FIGURE 31.5 BMC profiles of implanted apatite/collagen composite cement containing VK2 in osteoporotic rats and their cross-sectional micrographs after 72 days.

PACK and APK. In contrast, the microstructure of ACK was significantly different from that of APK, and that difference was drastically affected by the duration of the experiment. For ACK, BMC reached its peak at day 7. PACK and APK recorded the highest and lowest degradation rates of BMC, respectively. At day 21, the amount of BMC present was ranked as follws: ACK > APK > PACK.

Micrographs of the cross sections of the apatite/collagen cements containing VK2 were taken after 72 days of implantation (Fig. 31.5, right). After implantation, it was discovered that the APK cement had undergone deformation, but there was no evidence to suggest penetration of organic components into the cement material. Like for the PACK cement with a reduction in diameter but an increase in thickness, the shape of the ACK cement had been completely distorted after 72 days. The BMC result of the cements loaded with VK2 suggests that their formulation has a significant effect on the rate of biodegradation. After 72 days, the ACK cement exhibited an increase in BMC, which was also higher than that of the PACK cement. The organic components had penetrated deeply into the center of the ACK. These results suggested that the changes in BMC were more dynamic for the ACK than for the PACK cement. As shown in the XRD results (Fig. 31.4, left), grinding the apatite/collagen composite cement can lead to a crystalline structure that is more or less the same as natural bone, which could have an influence on the release of bone growth factors such as VK2 and the regeneration and absorption of bone during the experimental period.

31.6 BIODEGRADATION OF THE AC BLOCK WITH INTERCONNECTING PORES AS A SKELETAL BONE CELL SCAFFOLD [24]

Since interconnective pores in bonelike materials are therapeutically effective for bone regeneration in the body through the introduction of bone cells and blood vessels [26], interconnective porous biomaterials are useful as a scaffold for bone cell cultures for implant. One team of researchers [26] discovered that the various types of interconnective void and pore in artificial bone enhanced the transition from artificial material to natural bone. These voids played a key role in stimulating tissue invasion and biocompatibility. On the basis of the test results, it can be suggested that continuous voids supported the formation of new bone by allowing the bone cells and/or tissues to penetrate into the voids more readily and the growth of new blood vessels to commence. Since artificial bone is fabricated with favorable properties using AC with connective voids, these devices could be utilized as a bone cell scaffold to culture bone marrow extracted from patients for bone regenerative medicine. Artificial bone materials with interconnecting pores (ACC) as a cell scaffold device were therefore prepared, and their biocompatibility was investigated after implantation into rats. The ACC blocks [25] were prepared on the assumption that the AC cement in a mold ($10 \times 10 \times 7.5$ mm) contained 60 organized stainless-steel needle-like male dies 600 μm in diameter (Fig. 31.6, left). The XRD result indicated that the calcium phosphates of ACC transformed into biological HAp with no peak due to the presence of raw materials, as previously reported [21]. The total porosity of the ACC cement was 64% by combining the micro- and macropores, which were 40% and 23%, respectively.

After the artificial bone blocks were implanted subcutaneously into female SD rats, their BMC profiles were determined by dual-energy X-ray absorptiometry (Fig. 31.6, right). The analysis revealed that the BMC of ACC increased rapidly to around 120% after 28 days but dropped to 105% after 56 days. A similar trend was also observed for the AC block (ACN) cement as its BMC rose to approximately 110% after weeks 1–3, and at day 56 the BMC was around 98%. In contrast, the BMC of the AP block (APN) decreased steadily throughout the entire experiment and at day 56 it was recorded to be approximately 90%. On the basis of these results, it is clear that the cement system will ultimately

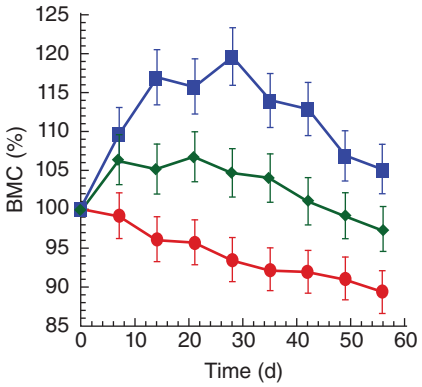

FIGURE 31.6 Plot of time versus changes in BMC of cement blocks implanted in rats (■, ACC; ♦, ACN; ●, APN) and photograph of ACP block.

determine the changes in the BMC profile. A decrease in the BMC from all implanted blocks was observed during the latter stages of the experiment, at 40–56 days, owing to the abdomen and phagocytosis on the surface of macropores by osteoclastlike cells, bearing a resemblance to bone remodeling. Photographs of removed implants also indicated that the deformation of the cement blocks can be considered as an indication of biological activity; the order of this activity was ACC > CAN > APN.

31.7 DRUG RELEASE FROM BIODEGRADABLE APATITE/COLLAGEN COMPOSITE CEMENTS WITH INTERCONNECTIVE MACROPORES [27]

To improve biocompatibility during cell culture in bone regenerative medicine, three-dimensional (3D) perforated porous apatite/collagen composite cement, ACC with drug delivery capability was developed. The ACC drug delivery device was prepared to pour the AC cement paste containing 3% indomethacin (IMC) into a mold ($10.0 \times 10.0 \times 7.5$ mm) containing 0, 20, 40 or 60 stainless needles to generate interconnective macropores [27].

The in vitro drug release tests of the ACC devices were carried out in SBF at pH 7.25. Since the rate-limiting step of drug release from the drug-loaded matrix systems was basically the drug diffusion process in the micropores in the matrix, the drug release from the matrix systems follows the Higuchi equation [Eq. (31.1)]. The in vitro IMC release from ACC with various numbers of macropores showed straight lines at the initial drug release stage (Fig. 31.7, left) on the Higuchi plot. The Higuchi release constant (HC) was evaluated using the initial slope of the Higuchi plot as the drug release rate. The relationship between HC and A of ACC (Fig. 31.7, right) had a straight line, suggesting the adequacy of the Higuchi equation. The result therefore suggested that the rate of drug release can be controlled by the number of macro-pores for culturing bone cells.

31.8 IN VITRO BONE CELL ACTIVITY–RESPONSIVE DRUG RELEASE FROM BIODEGRADABLE APATITE/COLLAGEN BONE CELL SCAFFOLD WITH INTERCONNECTIVE MACROPORES [28]

Since the crystalline structure of AC was almost the same as that of natural bone [18], the material was phagocytized at the surface of macropores by bonelike cells, similar to the remodeling of bone. Therefore, the rapid bioabsorption of AC may be considered to be similar to the biological action of active bone cells [29]. In order to clarify the role of osteoclasts during drug release from the apatite/collagen nanocomposite, the influence of the dissolution medium on the drug release capabilities of the device based on a physicochemical model for the nanoscale biointeface between bone matrices and bone cells was investigated. AP, AC, and ACC blocks containing 2.5% VK2 were obtained in the mold ($10.0 \times 10.0 \times 7.5$ mm) to form interconnective macropores (0–60 stainless-steel needles).

To clarify the role of bone remodeling in the drug delivery system based on AC matrices, a physical in vitro dissolution model was established. The drug release profile was investigated in an SBF solution with a pH of 7.25 to simulate osteoblastlike conditions (SOB) and in an acetate buffer with a pH of 4.5 to simulate osteoclastlike conditions (SOC) [28].

The effect of the dissolution medium on the in vitro release of VK2 from AP, AC, and ACC60 indicated (Fig. 31.8) that virtually no drugs were being released from the AC block

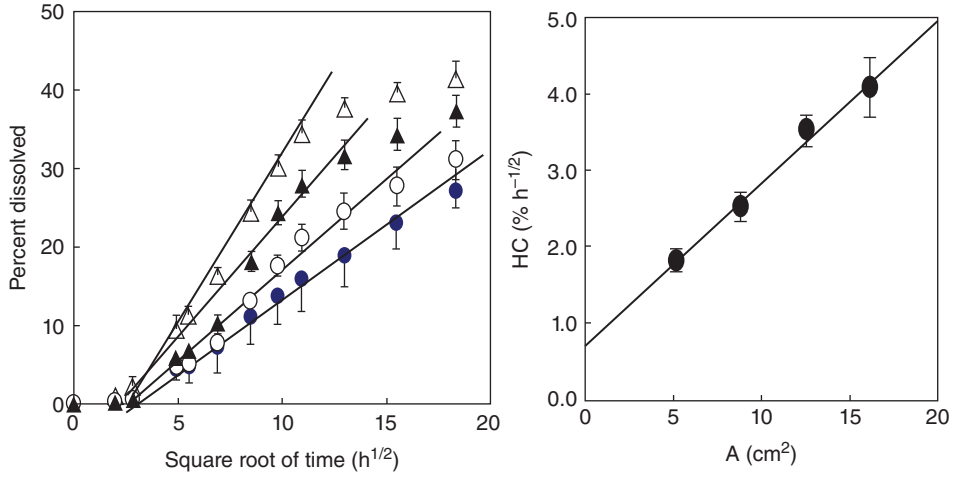

FIGURE 31.7 Effect of macropore number on IMC release of ACC block (●, $n = 0$; ○, $n = 20$; ▲, $n = 40$; △, $n = 60$; A, block surface area; HC, Higuchi content).

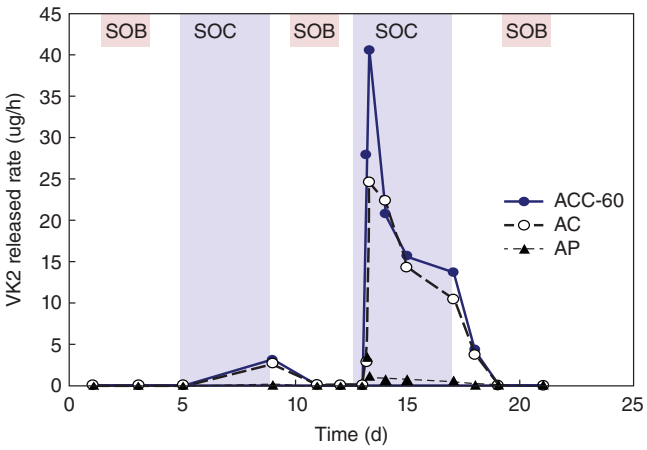

FIGURE 31.8 Effect of dissolution medium on in vitro release of VK2 from AP, AC, and ACC.

and ACC60 in SOB, but the situation was quite the opposite in SOC, with significant improvements in the drug release rates. The drug release and calcium phosphate dissolution results suggested that the HAp matrices in the device were dissolved in SOC, and the drug release was accelerated with increasing porosity. In SOB, however, the device was covered with precipitated HAp particles, inhibiting the release of drugs from the micropores. The drug release from AC and ACC blocks was dependent on the dissolution medium. However, this was not the case for the AP block.

31.9 IN VIVO BONE CELL ACTIVITY–RESPONSIVE DEOXYRIBONUCLEIC ACID (DNA) RELEASE FROM INJECTABLE SELF-SETTING APATITE CEMENT AND APPLICATION TO GENE THERAPY [30]

The therapeutic effect of plasmid DNA complexes in current gene therapy is not satisfactory because of the short duration of their gene expression. Gene delivery systems that release the plasmid complex for long periods are thus required. However, an efficient DNA slow-release system has not been established owing to the low dispersion stability of the DNA/polycation complexes. Since hyaluronan (HA) could be deposited onto the DNA/polycation complexes, stabilize their dispersion, and be used to prepare very small particles, DNA/polycation/HA complex particle-releasing systems could be developed using injectable materials that self-set in the body in a biodegradable solid device. This section describes the development of DNA/polyethyleneimine (PEI)/HA ternary complex-releasing systems based on biocompatible, biodegradable apatite cement with inorganic components similar to bone and teeth. Injectable self-setting apatite cement containing pDNA-*GM-CSF*/PEI/HA [encoding granulocyte macrophage colony-stimulating factor (GM-CSF)] was prepared, and the efficacy of the durable DNA complex release system was examined [31]. An injectable apatite cement slurry was prepared as follows. The apatite/atelo-collagen composite cement bulk powder was ground with 20% atelocollagen in a vibration mixer mill. The AC cement bulk powder was mixed with 25 mM phosphoric acid, and a condensed suspension of DNA/PEI/HA complex small particles was then mixed with the apatite cement slurry. When the apatite cement is implanted into the body, it is expected to be degraded by osteoclasts to release the DNA complex, since it is known that osteoclasts dissolve and resorb bone by secreting an acidic liquid [32].

In order to simulate this, DNA-releasing ability was evaluated with MLC6 cells, an osteoclast-like cell line with the same function as osteoclasts [32]. B16 melanoma cells were used as nondegrading control cells.

Release of the DNA complexes from the apatite cement was faster with MLC6 cells than with B16 cells (Fig. 31.9). The DNA complexes were continuously released from the apatite cement including collagen, which showed an XRD pattern similar to that of natural bone. Higher affinity of the collagen-containing cement with MLC6 cells than that with other polymers was also confirmed microscopically (Fig. 31.9).

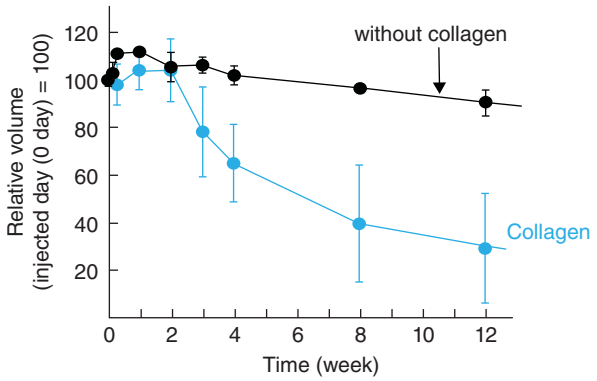

FIGURE 31.10 Effect of collagen content on biodegradation rate of apatite/collagen composite contents containing DNA complexes.

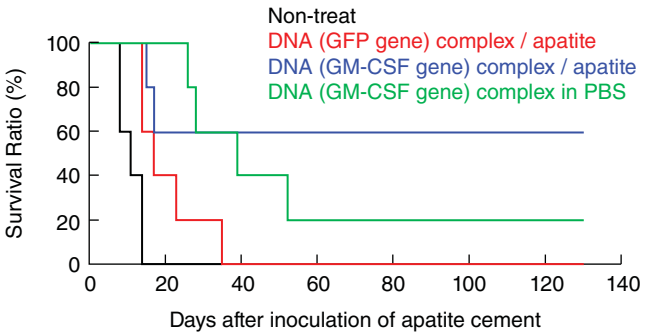

FIGURE 31.12 Therapeutic effects of slow-release apatite system on solid tumor of rats.

Osteoclasts also resorb excessive apatite, such as an ectopic bone, in the body [33]. Thus, the apatite cement inoculated into tumor-bearing mice was expected to be degraded by the cells. Apatite cement slurry including DNA/PEI/HA ternary complex particles was inoculated into the femurs of mice using an injection syringe, and the volume of the inoculated apatite cement was evaluated by X-ray computed tomography (CT). The solidified cement gradually degraded, and the degradation rate was dependent on the quality of the cement. Apatite cements with collagen again showed much faster degradation (Fig. 31.10) than did those without collagen. The crystal structure of the cement similar to that of natural bone was readily recognized by osteoclasts.

The therapeutic effect of the bone cell activity–responsive slow-releasing apatite system was then examined in tumor model mice. DNA/PEI/HA complex particles were prepared with the pDNA encoding mouse granulocyte macrophage-colony-stimulating factor (GM-CSF) or green fluorescent protein (GFP) (Fig. 31.11). The DNA complex particles were mixed with apatite cement slurry including 5% collagen. B16 cells were subcutaneously inoculated under the abdominal skin of mice. When the tumor size increased to 4 mm, apatite cement slurry including DNA complex was injected once around the tumor. The volume of apatite cement solidified in the body was also evaluated.

The tumors grew rapidly in the control mice. In contrast, in one of five mice that received a single dose of pDNA (GM-CSF)/PEI/HA complex particles without apatite cement, complete disappearance of the tumors was observed (Fig. 31.11). An apparent therapeutic effect was also seen in the other four mice, in which tumor growth remained suppressed for 10 days after the injection, but tumor growth then restarted. A significant effect was seen in mice injected with pDNA (GM-CSF)/PEI/HA complex particles in the apatite cement, and a complete response was seen in three of the five mice, without any tumor regrowth for ≤100 days (Fig. 31.11). X-Ray CT was performed to evaluate the reduction rate of apatite cement volume in the mice. The volume reuction rate in the three mice in which the tumor disappeared was higher than that in the other two mice that showed tumor regrowth. The therapeutic result (Fig. 31.12) suggested that

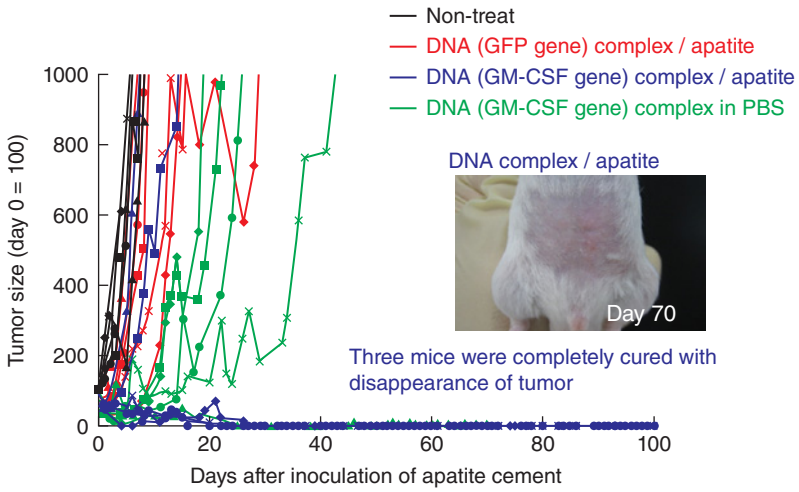

FIGURE 31.11 Therapeutic effects of slow-release apatite system on solid tumor of rats.

the rat group with pDNA (GM-CSF)/PEI/HA complex particles in the apatite cement had the best survival score. This indicates the importance of successive release and the potential of the injectable apatite cement as a durable gene transfection device.

ACKNOWLEDGMENTS

The author is deeply grateful to Professor William I. Higuchi, University of Utah, for his leadership in our international collaboration research. The author also thanks Dr. Tomoko Ito, Shin-Yamanote Hospital and Dr. Atsuo Ito, NIAIST, for their scientific advice. Finally, the author thanks to Mr. Kazuki Yoneoka, Mr. Ryuhei Hirano, Mr. Hidenori Nakagawa and Mr. Tomoaki Kuninaga for their experimental work.

DRYING STRUCTURE

TSUNEO OKUBO

Institute for Colloidal Organization, Hatoyama 3-1-112, Uji, Kyoto 611-0012, Japan

32.1 INTRODUCTION

Most structural patterns in nature form via *self-organization* accompanied by the *dissipation* of free energy and in the nonequilibrium state. In order to understand the very complex mechanisms of the dissipative self-organization of the simple model systems, instead of the complex nature itself, study of the *evaporating*, *convectional*, *sedimentary,* and *drying* dissipative patterns during dryness of suspensions and solutions is important, although these four kinds of structures are correlated cooperatively and overlap each other [1–3]. Studies of the drying patterns of colloidal suspensions and solutions also provide important knowledge in both biological and industrial fields.

Evaporation of the solution and suspension takes place first at the air–liquid interface during the course of liquid drying [4, 5].

Lowering of temperature of liquid close to the interface takes place heterogeneously depending on the location, which will induce the convectional flow of solvent by the effects of Marangoni and gravitational convection. Degree of lowering of water temperature at the surface area comes to be more than 1 degree even at room temperature, and evaporation of water from the liquid surface is not inhibited completely without thorough shielding of the liquid from atmosphere.

Typical *convectional* patterns are *Benard cells* [6, 7], the hexagonal circulating pattern, and *Terada cell* [8–10], the spokelines spreading throughout the entire the liquid surface accompanied by a high number of cell convections in the normal direction of the spokelines. More recently, whole processes of the convectional patterns have been identified experimentally [11–15]. Theoretical studies of the convectional patterns have been reported mainly using Navier–Stokes equations [16–20]. However, these are not always successful, even when the theories are compared with the actual observation, since the actual drying processes are not so simple.

Sedimentary dissipative patterns during the course of drying suspensions have been studied in detail on a coverglass, a watchglass, a glass dish, and other surfaces, for the first time, in the author's laboratory [13, 21–28]. Broad ringlike patterns were formed in suspension state. It was clarified that the sedimentary particles were suspended in suspension by the electrical double layers around the particles and always moved by the balancing of the force fields between the convectional flow and the gravitational sedimentation. Dynamic cluster and bundle-like sedimentary patterns form synergistically from the spokelike convectional structures of coffee [14] and black tea [15].

Drying dissipative patterns have been studied for many kinds of colloidal particles, linear-type synthetic and biopolyelectrolytes, water-soluble neutral polymers, ionic and nonionic surfactants, gels, colloidal polymer complexes, and dyes by many researchers hitherto [1–3, 29–35]. The macroscopic *broad ring* patterns of the hill accumulated with the solutes formed. Macroscopic *spokeline* patterns, specifically, spokelike cracks or fine hills including flickering spokelike ones, were also observed for many solutes. Beautiful *fractal* patterns such as branchlike, arclike, blocklike, starlike,

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

crosslike, and stringlike confiigurations were often observed at the microscopic scale, especially in the thin and central areas of the dried film.

We should note several important findings in the drying processes: (1) primitive, vague sedimentary patterns are formed in concentrated suspensions or solutions before dryness and grow toward fine structures during the processes of solidification [27]; (2) *information* on the suspensions and solutions, shape, and size of solute and atmospheric humidity and temperature, for example, is *transferred* into the drying patterns (some of this information is transferred to the drying patterns accompanied by the selection and amplifying effects by the static and dynamic interaction of solutes with other solutes and/or substrate surfaces; nowadays, detailed molecular and colloidal information is available in part from the drying patterns themselves . . . as is well known, the three major groups of biopolymers are *polypeptides*, *polysaccharides*, and *polynucleotides*; the chemical structures of these mainchains are quite different from each other; it is very interesting to discuss how these structures influence the drying patterns; and (3) *dissipative crystallization* of synthetic and biological polyelectroytes has been clarified [36–42]. Accumulation, uneven distribution, symmetric distribution, ordering of polymer single crystals, coupling of single crystals with dissipative broad ring patterns, and other distribution patterns have been clarified.

We should note that all theoretical studies of the drying patterns made thus far have been quite unsatisfactory because any theoretical studies have derived from the final drying patterns only a part of so many integrated processes. Deegan et al. [43, 44] have reported traces of spokelike patterns in the suspensions of polystyrene spheres under a microscope. They introduced the *capillary flow theory* accompanied by the *pinning effect* of the contact line of the drying drop. This theory states that the broad ring size should remain at the outside edge of the initial liquid. The pinning effect seems to have been researched quite heavily. From our series of the drying experiments of suspensions and solutions, however, this effect is not always supported experimentally, because the broad ring size decreases sharply as solute concentration decreases, especially in the low concentration range [1–3]. The broad ring size changes mainly because of the excluded volume of each solute and/or structural formation among the solutes [1–3]. Theoretical discussion of the *cooperativity* itself, including the information transfer among the cooperative and consecutive drying processes, namely, evaporation, convection, sedimentation, and solidification is desired in near future.

32.2 CONVECTIONAL PATTERNS

The most famous *convectional* pattern is the *hexagonal circulating* one. The *Bernard cell* has been observed when liquids contain platelike colloidal particles as monitors and are heated homogeneously in a plain pan [6, 7]. Another typical convectional dissipative pattern consists in spokelines, which were observed in the whole area at the liquid surface and also appeared in various substrates sometimes accompanied by a vast number of small *cell convections*. The spoke patterns with cell convections were observed formerly for the membranes of Chinese black ink on water [8–11, 45]. The author likes to call the spoke pattern the *Terada cell*. Convectional patterns, especially Terada cells, were observed directly in the initial drying process of Chinese black ink in a glass dish [11], the 100% ethanol suspensions of colloidal silica spheres [12], a cup of Miso soup [13], coffee [14], black tea [15], and colloidal crystals of poly(methyl methacrylate) (PMMA) spheres on a coverglass and a watchglass [46, 47]. Distorted Bernard cells were often observed for Miso soup, coffee, and black tea. For the 100% ethanol suspensions of colloidal silica spheres, Terada cell–type convectional flow was observed clearly with the naked eyes, and the convectional patterns changed dynamically with time. Deegan et al. [43, 44] reported the traces of spokelike patterns in the suspensions of polystyrene spheres (1 μm in diameter) under a microscope.

Coffee with cream shows very clear convectional patterns, especially at the initial stage during the course of dryness [14]. Mean sizes of coffee and coffee plus cream colloidal particles were 460 and 210 nm, respectively, and the former was twice as large as the latter. This strongly supports the theory that coffee particles tend to aggregate in suspension state. On the other hand, each coffee particle is coated with cream layers (composed mainly of oils and fats) and forms small and stable dispersions. Zeta-potentials of coffee both without and with cream were negative, at −24 and −52 mV, respectively. These values in the zeta-potential also support the theory that cream-coated coffee particles are more stable than bare coffee particles in suspension state, since the colloidal particles having large absolute values of zeta-potential are more stably dispersed in general. Actually, significant sedimentation of coffee without and with cream in a test tube did not take place for about 1 day and 3 days at 8°C, respectively.

Figure 32.1 shows the change in patterns of iced coffee during the drying processs in the presence of cream on a coverglass. The stock suspension of coffee plus cream was diluted with the same amount of pure water before the observation was made. The formation of *clusters* from the spokelines and then further growth of *bundles* from the clusters from the outside edge toward the central area at the liquid surface is observed, although the distinction between clusters and bundles is difficult. Twenty-five minutes after setting, the vague blocklike or broad ringlike patterns appeared from the central area to the outside region of the air–liquid interface. Furthermore, a large number of short spokelines were observed at the outer edge of the liquid. The integrated

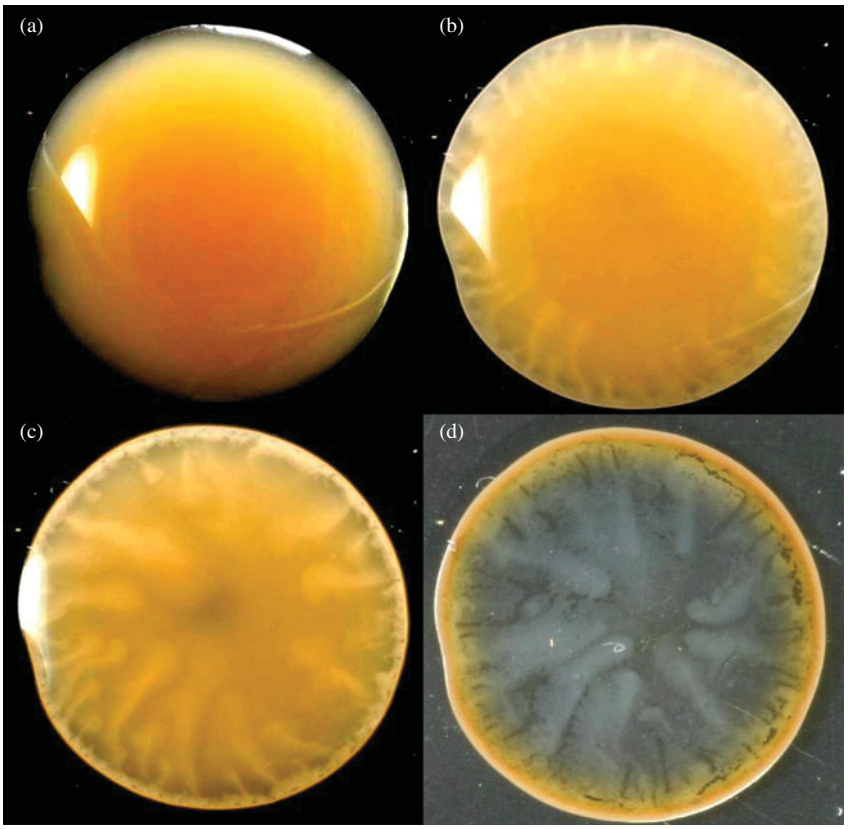

FIGURE 32.1 Convectional, sedimentary, and drying patterns of coffee (for iced coffee) with cream on a coverglass at 27°C, 1.26 wt%, 0.1 mL: (a) 10 min; (b) 50 min; (c) 1 h 40 min; (d) 3 h 25 min after setting. For a color version of this figure, see the color plate section.

convectional patterns of the spokelines form. In one study, after 50 min, integrated clustering of several spokelines began and although their number decreased, they became thick and clear. Furthermore, bundles of the cluster were recognized in the inner area of the liquid surface. The number of clusters and/or bundles decreased, from 35, 20, 16, and 12 to 12 after 50 min, 1 h 40 min, 2 h 40 min, 3 h 15 min, and 3 h 25 min, respectively. Quite similar convectional patterns have been observed for colloidal crystal suspension of PMMA spheres in a watchglass [47]. Furthermore, vigorous changes in convectional flow of colloidal silica spheres in ethanol also support the formation of the clusters and bundles [12]. Figure 32.1d illustrates a scenario in which the drying proccess was almost completed at the broad ring area, with the inner area still in liquid state, athough the drying cycle was completed very soon. In other words, the bundle-like patterns already represent a typical sedimentation pattern in the final stage of convection. It should be noted that the clusters and then bundles originated in the spokelines and always change their forms *dynamically* and *cooperatively*.

When a large amount of coffee-plus-cream suspension was set in a watchglass, then (1) the circulating line patterns were observed within 30 min, (2) between 4 and 30 min total flow of suspension at the liquid surface was in the direction from center to outside edge, (3) the total flow was reversed from the outside edge toward the center after 30 min, (4) growth of the spokelines toward the central area and formation of the clusters and bundles were observed, and (5) after about 7 h, the large bundles further grew into approximately three blocks of bundles. At the initial stage within 4 min, appearance and disappearance of the circulating lines took place in random directions. However, several regularly oriented circulating lines and circles appeared soon. Interestingly, two circles on the right side moved together toward the right outer edge while maintaining their relative positions. This observation supports the theory that the direction of the total flow of the suspension at the liquid surface is induced toward outer edge from the center by the integration of all convectional circulating lines from ~13 to 26 min.

Growth processes of the spokelines are further observed in detail using the extended illustrations as is shown in Fig. 32.2. Around 20 minutes after setting, few and short spokelines appeared at the outside edge. Then the number of the spokelines increased. These spokelines further grew toward the central area accompanied by the dynamical fusion and separation between the neighboring spokelines and clusters (see

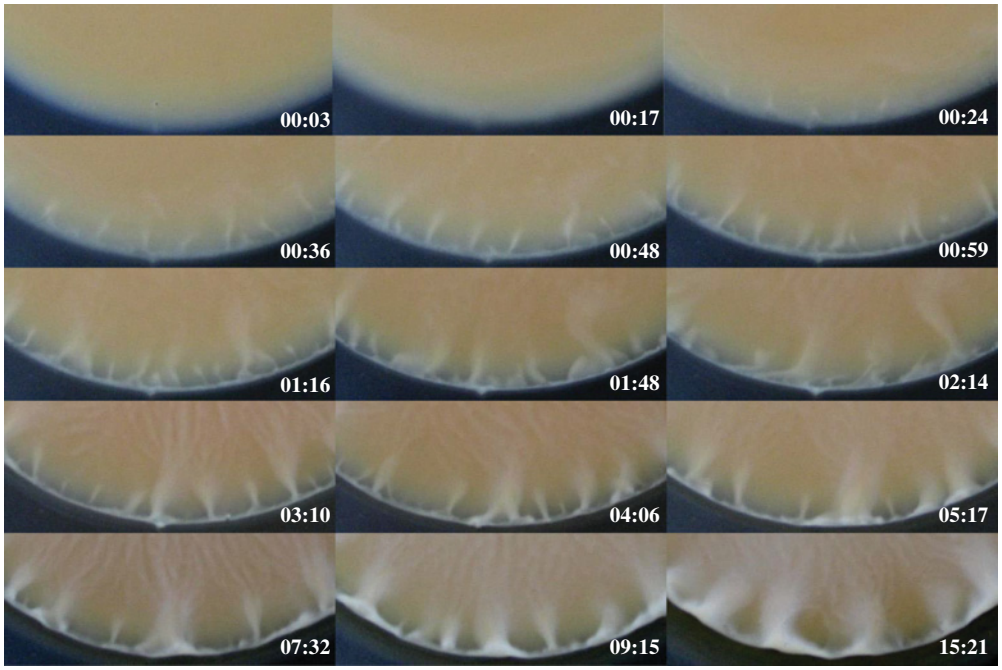

FIGURE 32.2 Time dependence of convectional patterns of coffee with cream in a large watchglass; extended areas of lower outside region. Liquid temperature changes from ~70°C to 20°C.

images ranging from 48 min to 15 h 21 min). Both of long and short spokelines increased sharply with time between 20 and 40 min. However, this number began to decrease after one hour. It should be noted that the decrease in number is accompanied by the formation of clusters and bundles. Quite similar changes in number were observed also for the convectional patterns of suspensions of poly(methyl methacrylate) (PMMA) on a coverglass [46] and a watchglass [47].

Summarizing our observations of convectional patterns of coffee with cream in a large watchglass, (1) at the initial stage within 4 min, the appearance and disappearance of the circulating lines took place at random directions; (2) between 4 and 20 min, total flow of convection at the surface layers was from the center toward the outside edge; (3) around 20–30 min after setting, few and short spokelines appeared at the outer edge, and then the number of spokelines began to increase; (4) at the same time as spokeline formation, total flow of convection was reversed from the outer edge to the central area and the outward flow remained until solidification started; (5) growth of the spokelines and formation of the clusters and bundle took place between 48 min and 15 h.

Here, the vigorous convectional flow of alcohol suspension of monodisperse colloidal silica spheres should be mentioned [12]. A series of the convectional, sedimentary and drying patterns of ethanol suspension of colloidal silica spheres (110 nm in diameter) were studied on a watchglass. Vigorous convectional flow was reflected in a beautiful dynamic change in convectional patterns. In the initial state within 50 min after the suspension was set for an initial volume fraction of 0.006, the spokelike patterns formed in the outer area of the monomer suspension. The suspensions of the spokeline area drop in the outer region of the central liquid pool, sometimes bridged by the mother suspension pool and disappearing when most of the drop suspensions flow down to the mother suspension. Again the suspension flow took place from the mother suspension pool toward the outside edge, resulting in the appearance of the spokelike suspension drops. Surprisingly, these dynamic changes in patterns took place simultaneously and in integrated fashion. Between 60 and 75 min, the mother suspension area decreased with time and the initial convectional patterns changed drastically in response to the different patterns, similar in configuration to a lotus-root section. After 90 min the suspension remained in the central area only, and broad rings formed in the final course of dryness, which is quite similar to the sedimentary patterns observed for aqueous suspensions. Interestingly, colloidal particles disappeared just at the central deepest point of the drying pattern.

Typical convectional patterns observed hitherto are spokelines (Terada cells) [11, 14, 15, 46–51], hexagonal circulating cells (Benard cells) [7, 13, 14], circulating cells [11, 14] in a smokelike configuration [11], with integrative circulation [12] and microscopic cell convection (Terada cells) [11]. It should be noted that the convectional patterns have been observed only for colloidal suspensions and not for typical solutions. Anisotropic colloidal particles did work as an optically good indicator of the convectional flow, according to the flow birefringence effect. However, we should note that

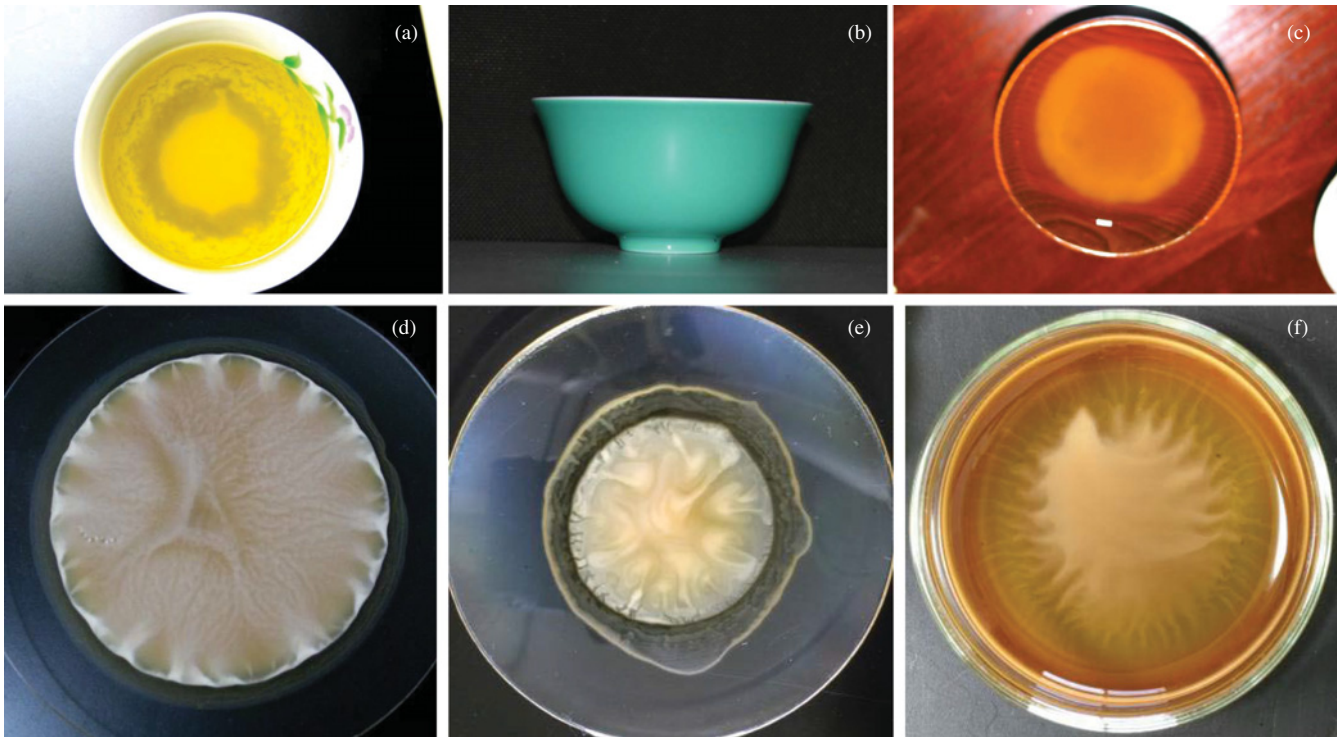

FIGURE 32.3 Typical examples of broad ringlike (a–c), cluster (d), bundle (e), and flamelike (f) sedimentation patterns of (a,b) green tea, (c) miso soup, and (d–f) coffee. (a) In a teacup at 24°C; (b) side view of a teacup; (c) in a bowl at 24°C; (d) in a watchglass (150 mm), 10 mL, 2.3 wt%, with cream, from 70°C to 20°C, after 12 h 25 min; (e) in a watchglass (50 mm), 1 mL, 0.7 wt%, with cream, after 9 h 20 min; (f) in a glass dish (42 mm), 3 mL, 2.3 wt%, with cream, after 20 h 5 min. For a color version of this figure, see the color plate section.

the convections, which are quite similar to those observed for the colloidal suspensions, should exist even in solution systems such as polymers and simple solute solutions.

The convectional flow of solvent and solutes is most important among the evaporation, convection, sedimentation, and solidification processes during the drying process. It should be noted further that information on the size, shape, conformation, and/or flexibility of particles and polymers is transformed from the initial convectional process toward the succeeding sedimentation and then solidification proceeds integratively and is accompanied by the amplification and selection processes. The important role of Marangoni convection in the metal colloidal crystallization process was proposed [52]. Experimental and theoretical studies on the convectional flow of colloidal particles have been reported, although these studies have not yet proved satisfactory [20, 52–62].

32.3 SEDIMENTATION PATTERNS

In most Japanese hotels, a guest will find in his or her room a set of green tea, which is composed of green tea granules in a paper filtering bag, a teacup, and hot water. The green tea is prepared conveniently by shaking the teabag dipped into hot water in a cup. The author was pleased to find that the broad ring always formed within <10 min in green tea in a cup left unattended on a disk. Figure 32.3a shows typical examples of the broad-ring patterns of green tea [28]. The broad ring, which is the hill accumulated with green tea colloidal particles, was formed in the inclined inner wall of the cup, and not in the deepest central area. In order to clarify the reasons for this broad-ring pattern in standing green tea, the authors have reviewed the literature on the sedimentation patterns and also the drying dissipative patterns of the monodisperse colloidal silica spheres and other particle systems on a coverglass, in a glass dish, polystyrene dish, and several sizes of watchglasses during the course of drying aqueous and ethanol suspensions [12–15,21–28,35,46–48,63,64]. The broad-ring patterns always formed unexpectedly rapidly in the suspension state irrespective of the cells used. The broad-ring structures were confirmed to be formed by the delicate balancing of the upward (and/or outerward) convectional flow of the colloidal particles in an inner wall and downward gravitational sedimentation (and/or innerward convectional flow). The important role of the microscopic cell convection in the liquid phase was supported for the broad-ring formation of suspensions and solutions.

The broad rings of the sedimentation patterns became sharp with time in many cases. Sharpness of the broad rings was sensitive to changes in room temperature and/or humidity [23]. Interesting sedimentation and then drying patterns were also formed during the course of dryness of binary and ternary colloidal crystal mixtures among the colloidal silica spheres of 183 nm, 305 nm, and 1.21 μm diameter in aqueous suspensions on a watchglass, a glass dish, and a coverglass [25, 26]. Colorful macroscopic broad-ring-like drying patterns appeared on the basis of the sedimentation structures. In a watchglass, for example, macroscopic sedimentation and then drying patterns were composed of the outer and inner layers of small and large spheres, respectively, for the binary mixtures by the segregation effects [25].

Most of the sedimentation patterns observed thus far have broad rings. However, vague but wrinkled microscopic sedimentation patterns were observed even in the suspension phase for bentonites [27]. These patterns became clearer and finer close to the solidification process. It has since been clarified that the drying patterns form integratively on the basis of the sedimentation patterns, which, of course, also originated from the convectional patterns in suspension state. The typical sedimentation patterns observed are broad-ring [14, 15, 46, 47, 50, 51], flamelike (clusters and bundles) [12, 14, 15], and vague wrinkled patterns [27], and some of them are shown in Fig. 32.3.

32.4 DRYING PATTERNS OF COLLOIDAL DISPERSIONS AND COLLOIDAL CRYSTALS

Drying patterns observed by a close-up camera and an optical microscope are called *macroscopic* and *microscopic patterns* in the present context. In the drying patterns65, stratified *s*tructures of solutes formed from micro- to macroscales. Most extended microscale patterns of colloidal crystals of polystyrene spheres were fractal patterns [65]. The *stratified* pattern formation is observed in general for many kinds of colloidal particles in suspension state.

Figure 32.4 shows the typical patterns formed in the drying of a series of the colloidal crystal suspensions of silica spheres, with their diameters ranging from 56 nm (a) to 1090 nm (d) at 0.0333 of the sphere concentration [63]. The spokelike cracks formed from the outside edge toward the center. Interestingly, the cracks were introduced in the final stage of dryness along the outer edges first, where the dryness proceeded in advance. New cracks developed successively and cooperatively keeping the same angle with the adjacent older cracks [66]. Dried film is transparent, and many cracks are observed for small spheres. When sphere size increases, film becomes whitey and the crack number decreases sharply. Increase in size will result in increase in the elastic modulus of the film, followed by decrease in crack number. The cracks originated from the convectional patterns formed typically for spherical colloidal particles as described above. It should be noted here that many potential cracks formed in the suspension state by the cell convections and the convectional flow of spheres and solvents. Broad rings are also observed at the outer edges, especially for small spheres. A main cause of broad rings is the convection flow of solvent and colloidal spheres. In particular, the flow of colloidal spheres from the center toward the outer edges in the lower layer of the liquid drop is important, which was observed directly from the movement of the temporally aggregates formed in the aqueous suspensions of Chinese black ink particles [11] and PMMA spheres [47, 48], for example. Interestingly, broad rings tend to shift toward the central area as sphere size increases, with the appearance of a hill of the spheres in the center region for the largest spheres as shown in Fig. 32.4. Furthermore, it is impressive to observe a hole in the central area where quite a few spheres are distributed. The spokelike cracks and broad ring patterns are quite familiar for so many kinds of colloidal spheres. Shape of colloidal particles is also reflected in the drying patterns. The spokelike cracks disappear for the nonspherical (anisotropically shaped) particles [27, 67] in addition to the very large spheres [68]. Figure 32.4 demonstrates that information such as the size and shape of colloidal particles is transferred via sedimentation processes to the drying patterns of spokelike cracks and broad rings. In other words, size and shape of the colloidal particles is estimated qualitatively from the drying patterns.

One of the typical examples of the transfer processes from the sedimentation to the solidification is shown in Fig. 32.5. The drying frontier of the fractionated bentonite suspensions moves from right to left with time in the pictures.[27] Border between the liquid and solid regions is the frontier zone of dryness. After setting the bentonite suspensions, vague wrinkled sedimentation patterns appeared. As time elapsed, the drying frontier moved to the left side, and the vague sedimentation patterns formed in the liquid phase became clearer and finer during the course of solidification. These observations strongly support the notion that the primitive and vague sedimentation patterns previously formed in liquid phase become sharper based on the sedimentation patterns toward solid phase.

Figure 32.6 shows typical examples of the cooperative drying pattern formation between colloidal silica spheres (1.2 μm in diameter) and sodium chloride [22]. Colorful crosslike patterns of NaCl, which are surrounded with the dendritic silica spheres of 183 nm [48], 305 nm [23], and 560 nm in diameter were observed [24].

Binary [25] and ternary mixtures [26] of colloidal silica spheres having different sizes showed an interesting *segregation effect* in their drying patterns. The semiquantitative estimation of sphere size and the mixing ratio in the original suspensions was made successfully from the drying patterns. From the peak profiles in the reflection spectroscopy, AFM

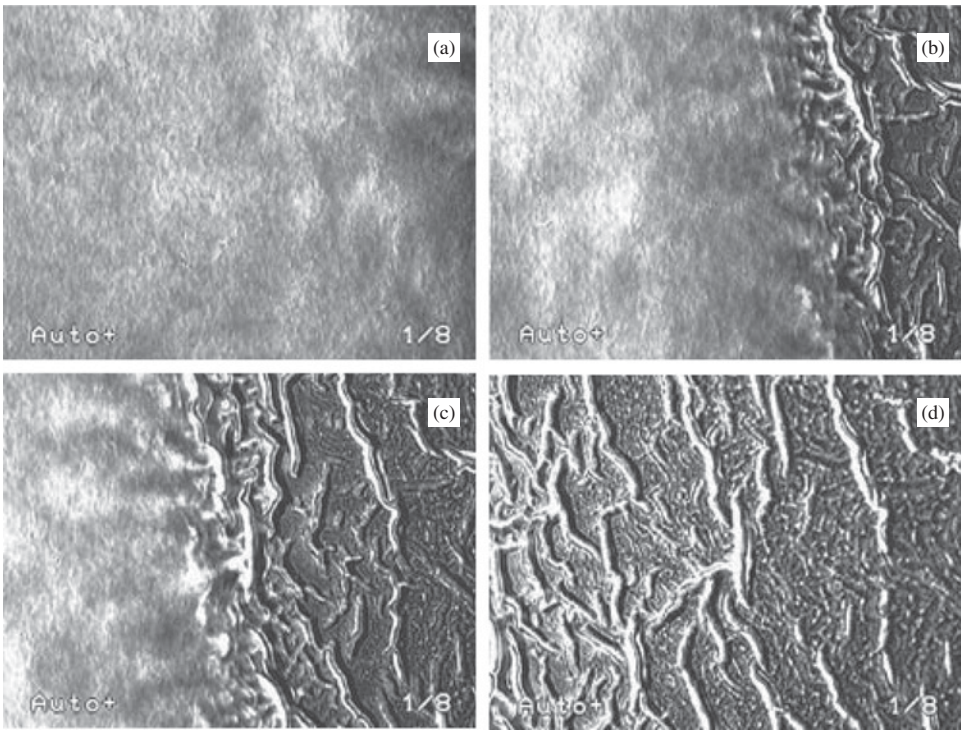

FIGURE 32.5 Change in patterns of bentonite suspension at the boundary regions of sedimentation and solidification processes with time on a coverglass at 25°C (4.6 mg/mL, 0.05 mL): (a) 46 min 30 s, (b) 48 min, (c) 48 min 45 s, (d) 49 min 50 s after setting (length of bar = 10 μm).

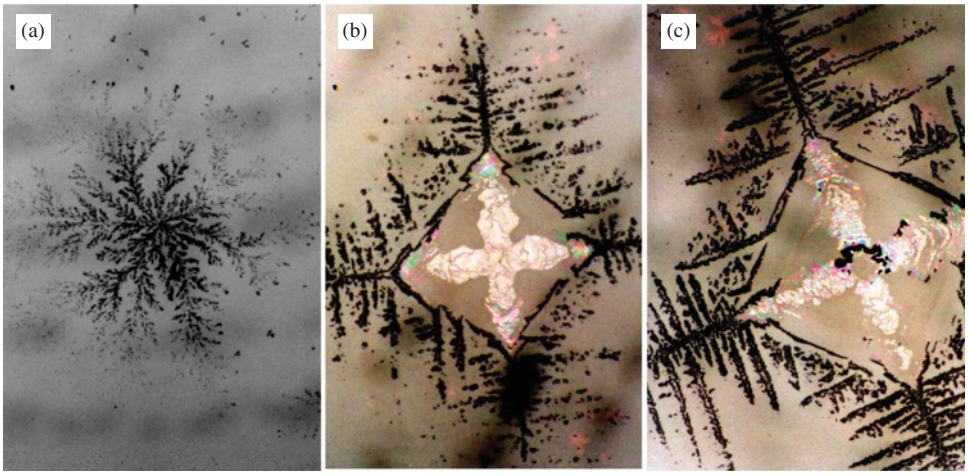

FIGURE 32.6 Microscopic drying patterns of silica spheres (1.2 μm in diameter) in the presence of sodium chloride in a glass dish at 24°C ($\phi = 0.00129$, 10 ml): (a) [NaCl] = 0.0003 M; (b) 0.001 M; (c) 0.003 M.

measurements, and the thickness profiles of the dried film, the segregation took place during the course of dryness; that is smaller spheres distribute outward and orient broad rings separately and independently to each other. Blue, pink, and white color bands corresponding to the accumulation areas of small (183-nm-diameter), medium (300-nm-diameter), and large colloidal silica spheres appeared in close-up color pictures of macroscopic patterns of the binary and ternary mixtures. Widths of the color bands changed quantitatively with the mixing ratio. Linearity between the widths of the pink bands and the mixing ratio was excellent. Semiquantitative analyses of mixing ratio and sphere size are clarified to provide information on drying patterns.

The drying patterns of biological colloids, lycoposium spore particles (31 μm in average diameter) were also studied [68].The vague broad-ring structure was observed, and the size of the particles on a coverglass decreased with a corresponding decrease in particle concentration. Microscopic drying patterns almost disappeared except for the short chain-like patterns. These observations support the theory that the convectional contribution to drying patterns is still effective in the lycoposium suspension, although the convectional forces are very weak compared to the sedimentary forces.

The mechanism of a multibranched and honeycomb network drying pattern formation of gold suspension on substrates has been discussed in the literature [69, 70]. Dissipative patterns during dryness of colloidal suspension ejected by inkjet printing have been studied [71].

32.5 DRYING PATTERNS OF POLYMER GEL SPHERES

In general, polymer solution, which is composed of linear-type polymers and their solvents, is *transparent*. The main cause of the transparency is the fact that the unit's size in the dynamic thermal motion of the polymers, which is close to the size of their monomer units, is very small compared with light wavelengths and rather close to size of solvents. Furthermore, there are *no interfaces* between the polymer solutes and solvent phases, since polymers and solvents are able to change their location rather freely because of their own thermal motion. On the other hand, size of the typical colloidal spheres is close to or larger than light wavelengths, and 100–1000-fold greater than that of the medium (solvent) molecules. Thus colloidal dispersion is *turbid* except for those in the refractive-index (RI)- matched condition between spheres and medium. In other words, turbid dispersion supports the existence of the *interfaces* in a sense of colloid chemistry. We should note here that most of gel dispersions are also turbid, and their nature seems to be just in between polymer solution and colloidal dispersion. Study of the macroscopic and microscopic drying patterns of gel spheres is, therefore, highly attractive.

Several years ago, the authors studied the drying patterns of small size poly (*N*-isopropylacrylamide), pNIPAm(70-5) gels (72 nm in hydrodynamic diameter at 20°C and 28 nm at 50°C, and 5% in the degree of cross-linking) on a coverglass [72]. The principal macroscopic patterns at 25°C were the small size of single or multiple broad rings of the hill accumulated with the gels. As the temperature rose to 50°C, the drying pattern area extended to the beautiful *flickering spoke-like patterns* transitionally. These observations supported the theory that the extended gels at low temperatures tend to associate weakly with each other, whereas gels at high temperatures shrink and move rather freely by the convectional flow of water medium molecules, although a weak intergel attraction on a substrate still remains.

Drying dissipative patterns of monodisperse thermosensitive gel spheres of poly(*N*-isopropylacrylamide),

*at 20°C

pNIPAm(200-10) [73], pNIPAm(200-5) [74], pNIPAm(200-2) [68], pNIPAm(200-0.5) [75], pNIPAm(400-5) [76], pNIPAm(600-5) [77], and pNIPAm(1500-5) [76] were studied systematically. Table 32.1 shows the fundamental properties of pNIPAm gel spheres. Zeta-potential (ζ-pot.) values derived from the electrophoretic mobility measurements are always *negative*. The absolute values are small compared with those of the typical hard spheres, −30 to −60 mV, but far from zero. These ζ-values of pNIPAm gels are consistent with the formation of the electrical double layers around the gel–water interfaces [77–80]. The ρ-values in the table show the *effective density* of the gel spheres' inner hydrodynamic diameter, given by the ratio of gel concentrations in weight percent (wt%) against volume percent (vol%) (100ϕ). Evaluation of vol% was made uniquely from the reflection spectroscopy of gel crystals in the deionized aqueous suspension [77–80]. The ρ-values at low temperatures were quite small, whereas those at high temperatures were large (see Table 32.1). The ρ-values increased sharply as the degree of cross-linking increased, especially at low temperatures. The ρ-values increased slightly as the sphere size increased at any temperatures, when comparison was made among the gels having the same degree of cross-linking as is seen in Table 32.1.

Formation of the monodispersed agglomerated particles of pNIPAm spheres and their ordered arrays were observed, for the first time, in the drying patterns. Figure 32.7 demonstrates the typical drying patterns showing the oriented arrays of the agglomerates of pNIPAm gel spheres on each substrate. Microscopic ordered-structures on the substrates were (a) flickering ordered spokelines, (b) ordered rings, (c) net structures, and (d) latticelike structures of the agglomerated particles. The net and lattice structures formed more favorably at high degree of cross-linking, at high gel concentrations, and/or at high temperatures. It was found that the ordered spokelines (a) and rings (b) formed first during the course of dryness, and then the net (c) and lattice ordering (d) formed integratively from (a) and (b). We should note here that the suspensions of pNIPAm gel spheres emit the Bragg diffraction light at any temperatures examined between 20°C and 50°C and form the *colloidal crystal* structure especially in the deionized suspension state with coexistence of the

PEGMA-P2VP(1)	385	0.93	+23	52,92

cation and anion exchange resins [77–83]. The ordering was clarified to form by the extended *electrical double layers* in addition of the *excluded volume effect* of the gels themselves, although most researchers have believed thus far that pNIPAm gels crystallize by the *excluded volume effect* exclusively [84–90].

Several investigators prepared cationic hydrogel spheres, AIBA-P2VP [91] and PEGMA-P2VP [92], and studied their crystallization [91, 92] and drying patterns in detail [51, 52]. The characteristic properties of these spheres are compiled in Table 32.2. The high ρ-values and ζ-potentials support the theory that cationic gels are rather dense with polymers but contain small amounts of water in gel domain. Microscopic drying patterns quite similar to those of pNIPAm gels were observed for these cationic gel spheres. Thus, the net and lattice structures of agglomerates form always for gel systems and not for typical colloidal hard-sphere systems.

The drying patterns form by the successive and cooperated processes of the *evaporation*, *convection*, *sedimentation*, and *solidification*, although these four processes are correlated strongly and overlap each other. *Agglomeration* of the single gel spheres is similar to *aggregation* of the gel spheres. However, in the authors' opinion, agglomeration and aggregation are different. *Agglomeration* takes place by *weak* and *integrative* affinitive interactions among the monomer gel components, resulting in monodisperse associates, whereas *aggregation* forms by the *strong* intersphere attraction forces resulting in the presence of polydisperse associates. We should pay attention to the impact of the ordered convectional flow of the single agglomerated particles and also weak interaction between the single spheres and the substrate on the formation of the monodispersed agglomerates. Several agglomeration phenomena have been reported thus far. As is well known, monodispersed colloidal silica spheres produced by the Stoeber method form via the agglomeration of the monodispersed prespheres of several nanometers in their size [93]. The processes of the formation of monodispersed colloidal silica spheres and their orientation on the substrates are similar to those of the agglomeration of the thermosensitive gel spheres and their orientation in this study.

Polymer complexation will be another example of a phenomenon similar to the present agglomeration of gels. As is well known, most of the polyion complexation between macrocations and macroanions proceeds by the strong electrostatic attraction and resulting in the polydispersed aggregates [78]. However, the polymer complexes formed from the weak hydrogen-bonding attraction represented by the complexation between poly(acrylic acid) and poly(ethylene glycol) led to formation of the monodisperse colloidal spheres and further their colloidal crystallization in both suspension- and dried film states [49].

32.6 DRYING PATTERNS OF SYNTHETIC AND BIOLOGICAL POLYMERS

Figure 32.8 shows the microscopic drying patterns of polyethylene glycol (PEG500K and PEG200K) observed by

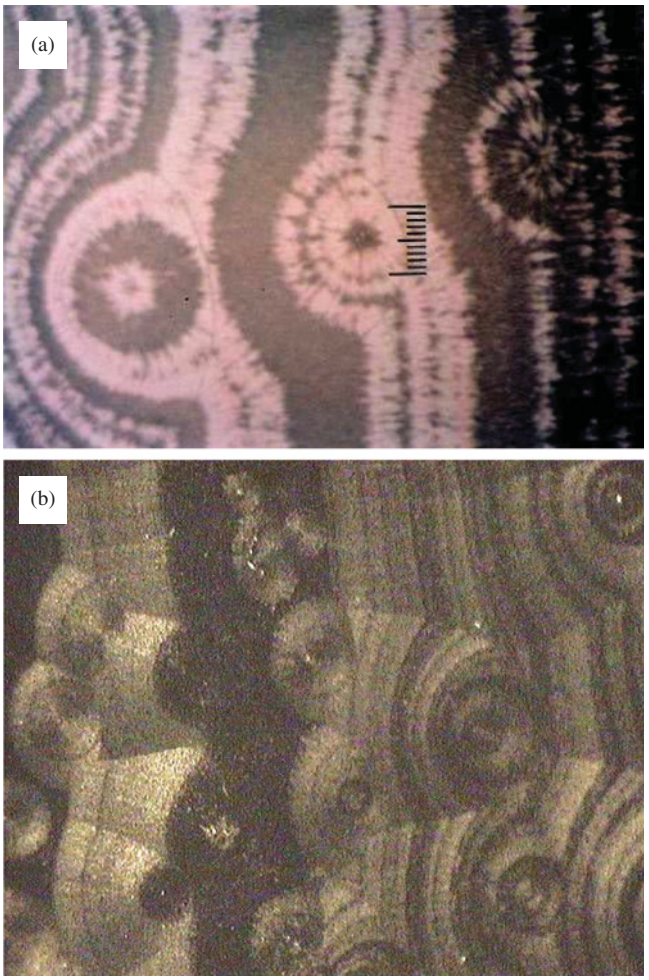

FIGURE 32.8 Microscopic (a) and polarizing microscopic drying dissipative patterns (b) of PEG500K (a) and PEG2000K solution (b) on a watchglass at 24°C: (a) 0.01 monoM, 4 mL, 45 h 25 min after setting, full scale at 100 μm; (b) 0.1 monoM, frame size 2.6 × 3.4 mm.

the optical microscopy and polarizing microscopy, respectively [37]. Clearly, of the coupled structures of *spherulites* and *lamellae*, with the latter originating from the ring-drying pattern, are observed. Morphology of PEG crystals was influenced greatly during the drying, process, although the lattice structure should not be changed at all during the dissipative processes. The *coupling effect* is a typical example of dissipative crystallization of polymers. One investigator studied drying patterns of PEG polymer with salt on Teflon plate [38].

Characteristic coupling dissipative effects of spherulites (or hedrites) were also observed for one of the anionic polyelectrolytes, sodium polymethacrylate [39]. The ringlike arrays of the large spherulites along the broad ring area, a very large single spherulite, and the bundle of the spherulites at the central area formed on a coverglass, a watchglass, and a glass dish, respectively. The fine structure of a single spherulite crystal at the central area (a) and the outer edge (b) formed, respectively, on a watchglass.

Drying patterns of poly(allylamine hydrochloride), one of the cationic polyelectrolytes, were studied on a coverglass [36]. The fractal patterns of 1.2–1.6 in dimension were observed as is shown in Fig. 32.9. Surprisingly, shape of the polymer crystals changed from crosslike to curved patterns as initial polymer concentration increased. Furthermore, crystal size increased with increasing concentration, which is reverse in tendency with the change in crystal size in solution state. It should be recalled that conformation of polyelectrolytes changes from *rod* to *coil* as polymer concentration increases. Thus, it is highly plausible that the shape information of the polymer at the initial solution state was transferred to the drying patterns. Drying patterns of a series of poly(*N*-alkylpyridinium halide) were observed [95]. The patterns were influenced substantially by the hydrophobicities of the polyelectrolytes. Several researchers discussed the drying fractal patterns with the use of fractal theory [96–99]. Drying processes of highly concentrated polymer solution have been studied, where buckling of the surface membrane during dryness takes place [84–86].

Drying patterns of several biological polyelectrolytes, grouped into polypeptides [40, 103, 104], polysaccharides [41, 105–108], and polynucleotides [42, 109, 110] were studied in the author's laboratory. Typical microscopic patterns are shown in Fig. 32.10 for polypeptides (a–c), polysaccharides (d–f), and polynucleotides (g–i). For polypeptites, rodlike, spherulite (or hedrite), and street roadlike crystals formed. Rodlike, dendritic rods, swordlike and hedrite crystals were observed for polysaccharides. For polynucleotides, dendritic, rodlike, dendritic long rods, swordlike, and spherulite crystals were observed. Microscopic patterns are similar in part and unique with respect to each other among intra- and inter-segmental groups. The conformations of these polymers are differentiated by the kind of polymer, for example, helical, stretched rod, β-sheet, or twisted ribbon; also, by the chemical structures of the mainchains are also quite different to each other among the groups. However, it is interesting and suggestive to observe the rather common type of drying patterns among the biological polyelectrolytes. Furthermore, we should note that these microscopic patterns appeared at the specified places, at the central areas, and/or close to the outside edges, for example. The macroscopic patterns of the biological polyelectrolytes showed clearly the dissipative crystallization effects such as accumulation, segregation and orientation. For the diluted NaDNA solution [42], for example, the orientation of the long dendritic rods formed along the spokelines, which supports the important role of the convectional flow processes of the polymer molecules during the course of dryness.

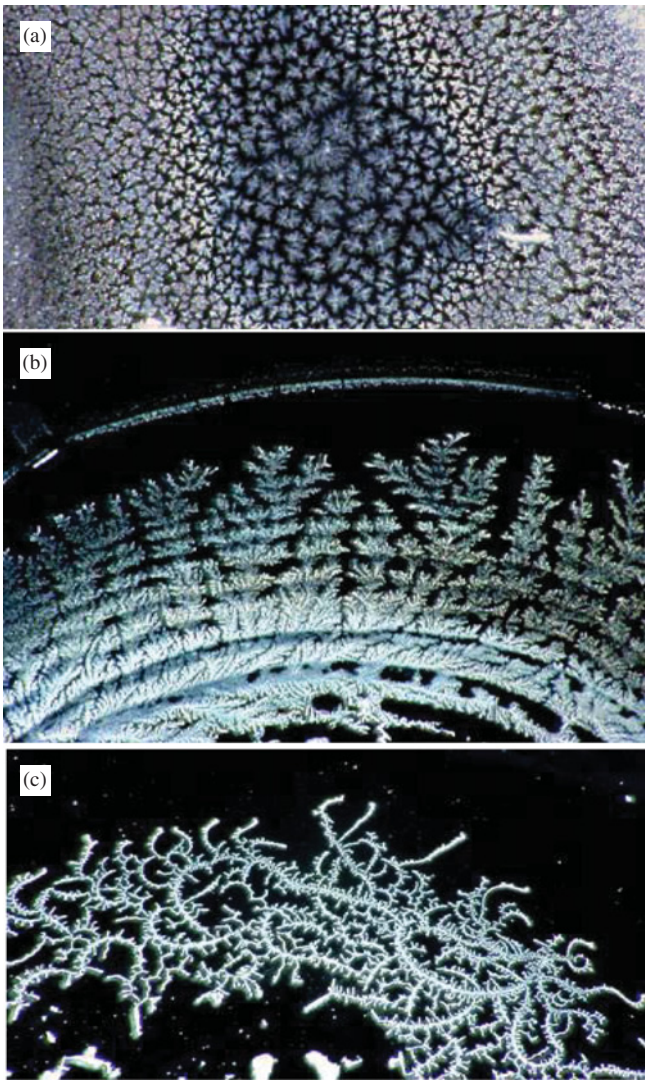

FIGURE 32.9 Microscopic patterns of PAL on a coverglass at 25°C. In water, 0.1 mL (a) 1×10^{-5} monoM, (b) 1×10^{-4} momoM, and (c) 1×10^{-3} monoM (length of bar = 200 μm).

Full scale is at 100 μm (a–g) and 50 μm (h,i). For a color version of this figure, see the color plate section.

Influence of double-stranded and/or triple-stranded complex formation of KPolyA and KPolyU on the drying patterns has been studied [110]. Macroscopic broad ring size decreased by complexation. It was difficult to determine whether microscopic patterns of dendritic long rods originated from single-stranded or double-stranded helices. The inclusional association constants were determined from the bent points in the curves of the broad ring size versus surfactant concentration when a finite amount of cyclodextrin was presents [111]. The short and thick rodlike microscopic drying patterns were observed for the inclusional complexes. Recently, drying crack and ring patterns in spherulites of poly(*L*-lactic acid) were studied in detail [112]. One researcher studied the crystal structure of collagen solution [113,114]. Drying patterns of β-cyclodextrin (βCD) and their inclusional complexes with sodium *n*-alkylsulfates have also been studied [107, 115, 116]. Association constants of the inclusion associates were estimated from the macroscopic drying patterns.

32.7 DRYING PATTERNS OF IONIC AND NEUTRAL SURFACTANTS

The microscopic patterns of cationic surfactant, *n*-dodecyltrimethylammonium chloride, were observed [117]. Basic structures were crosslike. However, crystal size and shape changed as a function of the distance from the film center. Drying patterns of a series of *n*-alkyltrimetylammonium bromides (alkyl: *n*-decyl, *n*-dodecyl, *n*-tetradecyl, and

n-hexadecyl) were studied [118]. Microscopic drying patterns such as rodlike, dendritic, and granule-like patterns were observed, and they changed as a function of the carbon number of the alkyl group, surfactant concentration, and the distance from thecenter of the pattern. Drying patterns of aqueous solution of sodium *n*-alkylsulfates (alkyl: *n*-hexyl, *n*-octyl, *n*-decyl, *n*-dodecyl, and *n*-hexadecyl) on a coverglass were observed [119]. Branched stringlike microscopic patterns appeared to increase irrespective of number.

Film surfaces of polyoxyethylene alkyl ethers changed from the *rough* to *smooth* as the HLB (hydrophile–liophile balance) values of the surfactants increased [120]. Furthermore, film thickness profiles as a function of the distance from the center of the film shifted from the center-accumulated hill shape to the broad ringlike structure as is shown in Fig. 32.11. Macroscopic and microscopic drying patterns of surfactant molecules were found to give important information on the association and dissociation phenomena.

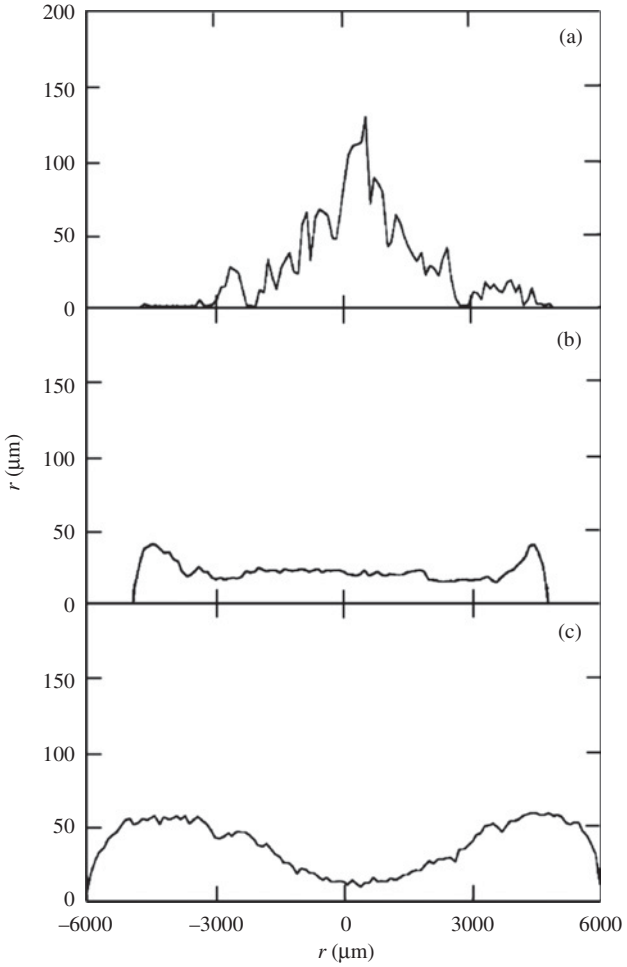

FIGURE 32.11 Thickness profiles of dried films of polyoxyethylene(5) stearyl ether (a), polyoxyethylene(10) stearyl ether (b), and polyoxyethylene(20) stearyl ether (c) at 25°C. In water, 0.06 M, 0.05 mL.

32.8 DRYING PATTERNS OF SIMPLE ELECTROLYTES

Drying patterns of simple electrolytes such as KCl, NaCl, $CaCl_2$, and $LaCl_3$ were studied [121]. Macroscopic broad rings formed at the outside edge of the drying film area, which shrank from the initial solution area, especially at low salt concentrations. The microscopic blocklike and dendritic crosslike patterns were observed for all the salt examined. Size of single crystals dried on a coverglass increased as salt concentration increased. The drying patterns of the binary mixtures of the salts were also observed. Size of the broad ring increased sharply by mixing, whereas the microscopic patterns were insensitive to the mixing.

32.9 DRYING PATTERNS OF OTHER SOLUTES

Droplets of the aqueous caffeine solutions were dried on various substartes (glass, polystyrene, and polyester) [122]. Coexistence of α- and β-caffeine was observed and the alpha and beta forms were locally separated. Drying patterns of porphyrin derivatives were observed on silica [123].

Professor D. Jishiashvil of Georgian Tech University performed interesting drying experiments (D. Jishiash, J. Okamoto, A. Tsuchida, and T. Okubo, unpublished results). A drop of water was placed on the Ge:GeO_2 film, where Ge and GeO_2 are crystal state and amorphous matrix. Then, water-soluble GeO_2 was solved, and the drying patterns appeared at the dried spot, when the liquid-drop was dried. Two examples of the microscopic pictures are shown from the central to the outside edge in Fig. 32.12. Macroscopic broad rings also formed. Furthermore, colorful microscopic patterns appeared. Interestingly, aqueous GeO_2 solution did not show similar microscopic patterns on any substrates including Si wafer.

Drying patterns of fluorescence dyes, rhodamine 6G, uranine, 7-hydroxy coumarin, and 7-amino-4-(trifluoromethyl) coumarin, for example [124]. The macroscopic broad ring patterns formed for all the ethanol solutions examined. Size of the ring increased with increasing dye concentration, but sharply above the certain critical dye concentration. Microscopic fine patterns including the streetlike, needle-like, and flowerlike crystals formed.

32.10 TRANSFERRING INFORMATION ON SOLUTIONS AND SUSPENSIONS TOWARD THE DRYING PATTERNS

As described in the Introduction section one of the main purposes of the author's drying experiments is to obtain *information* on solutes, solvent, and atmosphere from the drying patterns. It has now been clarified that information on solutions and suspensions, shape and size of solutes and

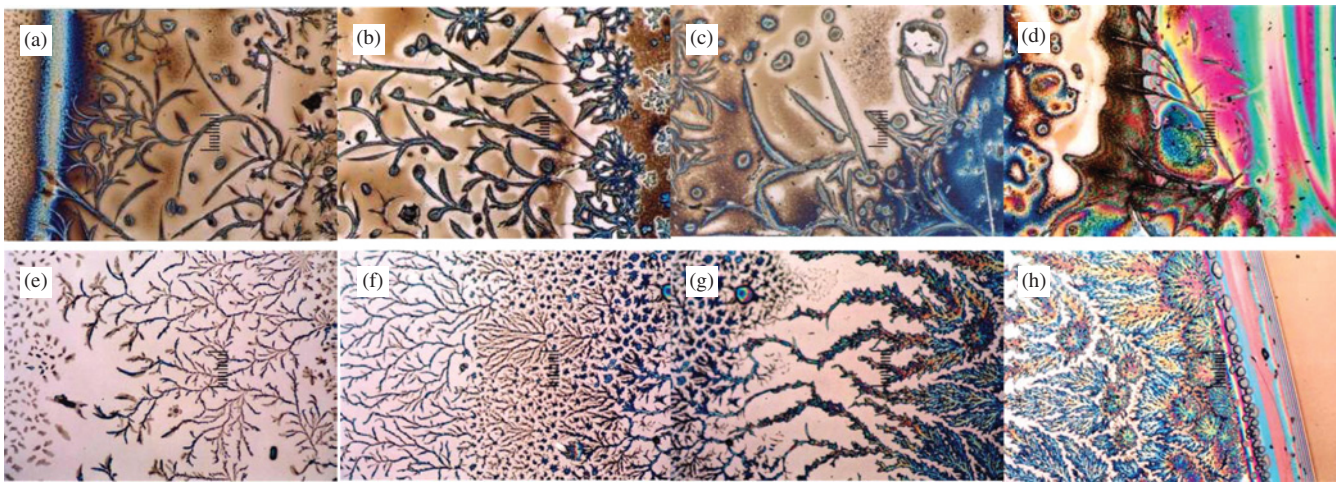

FIGURE 32.12 Microscopic drying patterns of Ge:GeO_2 film. (a–d) code 23b, on Si, 5×, full scale at 200 μm; (e–h) code 24b, on Si, 40×, full scale at 25 μm, from the central area to the right edge. For a color version of this figure, see the color plate section.

temperature and humidity, for example, is transferred to the drying patterns by the cooperative and successive processes of evaporation, convection, sedimentation, and solidification. Therefore, it is highly plausible that a part of the information is available from the macroscopic and microscopic drying patterns. The relationships between the *information* and *drying patterns* are summarized in Table 32.3 mainly by applying the data of the drying patterns found in the author's group.

For example, increase in the solute concentration of the initial solutions and suspensions has resulted in increase of the size and height of the broad ring and decrease of number of spokelines. Interestingly, single crystal size in the broad ring area increase with increasing solute concentration, which is opposite in tendency to crystallization of the solution and suspension in the bulk phase. We should note here that the macroscopic and microscopic drying patterns originated from the integrated *information* of solutes and atmosphere. The assignment of the solutes and atmosphere from the drying patterns will be made correctly, when the specific drying patterns appeared. For example, when the *ordering of the agglomerates* was observed, the solutes are highly plausible to be *gel spheres*.

32.11 MISCELLANEOUS

Film formation mechanisms from polymer colloidal dispersions have been studied extensively for more than 50 years, and are correlated closely with the drying patterns [125–141]. Three processes are proposed here: (1) close-packing processes of polymer colloids by evaporation of solvent; (2) deformation of the particles followed by disappearing voids, although the original particles are still distinguishable; and (3) continuous film formation by the diffusion of polymer across particle boundaries. Cracking patterns of the films induced by the shrinkage during dryness were also investigated for the paste layers of clay, sand, and water deposited on rigid substrates [142–144]. Characteristic pattern formation in the dried thin film on a substrate has been reported. Wormlike and hexagonally packed domains were obtained from asymmetric organic–organometallic diblock copolymers [145]. Honeycomb patterns of polymers were studied intensively by one group of investigators [146]. Self-organization of a chromophore-labeled double chain amphiphile was reported [147]. Superhelix-to-tubule transformation of J-aggregates was studied by TEM [148]. Adsorbed and dried patterns of ionic surfactants were studied by several researchers [149–152].

32.12 CONCLUDING REMARKS

Most of the self-organization phenomena in nature are known to take place accompanied by dissipation of free energy and in the nonequilibrium state. Among a huge number of the dissipative self-organization events, study on the drying processes will be one of the most convenient and simple. This author studied the drying processes of (1) evaporation, (2) convection, (3) sedimentation, and (4) solidification as systematically as possible. Several important factors that determine the drying patterns will be discussed here. *First*, we will discuss the importance of *integrativity* among processes 1–4 during the course of dryness. We should note that the primitive patterns having information on solutions and suspensions will have formed already in the evaporation and convection processes. Furthermore, the primitive patterns are further transferred to the sedimentation and then solidification structures with *selection* and *amplification* of the initial information of solution and suspension. *Second*, the important role of the *interaction between solutes and substrates* must be

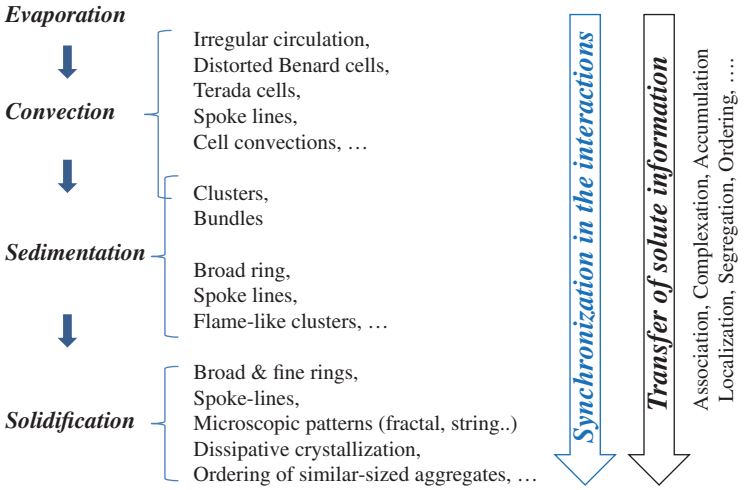

FIGURE 32.13 Synchronized pattern formation processes during the course of dryness of suspensions and solutions.

discussed. For example, extended conformation of macroions will be retained during the drying process through the interaction of the solutes and substrate. The stretched conformation of the macroions will change rather easily in the bulk solution state during the course of concentration toward coil conformation. However, when the stretched polymer chains interact with the substrate, change of their conformation will be delayed throughout the drying process. Thus, the initial conformation will be transferred to the drying pattern. *Third*, the important role of the *concentration* of solutes by the evaporation of solvent during dryness must be discussed for the organization of solutes. Solute concentration will correspond to enhancement the intersolute repulsion forces, which are inevitable for the organization of colloidal systems as understood easily from colloidal crystallization. *Fourth*, the important role of the *gravitational effect* for convectional flow of solvents and solutes has been clarified. Marangoni convection is also important. *Fifth*, the most important factor in self-organization during dryness will be the *translational thermal movements* of all the relating elementary substances, including solutes, solvents, and components of the substrate surfaces. Each component has its own thermal energy $k_B T$. Analyses of *information* included in the initial solutions and suspensions from the drying dissipative patterns are still quite unsatisfactory at present. Further experimental and theoretical detailed studies are desired for understanding of the dissipative structural formation mechanisms in nature.

The total drying processes of solutions and suspensions are compiled in Fig. 32.13. It should be noted that synchronization of each processes will be one of the most important factors determining the actual drying patterns.

ELECTROPHORETIC MOBILITY OF COLLOIDAL PARTICLES

HIROYUKI OHSHIMA

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki Noda, Chiba 278-8510, Japan

33.1 INTRODUCTION

Electrophoresis is a phenomenon in which charged colloidal particles move in an electrolyte solution under an external electric field. The particles in the stationary state move with a constant velocity as a result of the balance between the applied electric field and a viscous resistance exerted by the liquid on the particles. We treat the case where the magnitude of the applied electric field $\boldsymbol{E}$ is not very large. In such cases the particle velocity $\boldsymbol{U}$, which is called the *electrophoretic velocity*, is proportional to $\boldsymbol{E}$ in magnitude. The ratio of the magnitude of the velocity $\boldsymbol{U}$ to that of the applied field $\boldsymbol{E}$ is called the electrophoretic mobility μ, which is defined by $\mu = U/E$ (where $U = |\boldsymbol{U}|$ and $E = |\boldsymbol{E}|$).

In the case of hard particles without surface structures the electrophoretic mobility μ depends on the zeta-potential ζ of the particle. The *ζ-potential* is defined as the potential at the slipping plane, at which the liquid velocity relative to the particle is zero. If the slipping plane is located at the particle surface, ζ becomes equal to the surface potential ψ_0. In the following, we treat the case where $\zeta = \psi_0$ and where particles are of spherical or cylindrical shape.

On the other hand, in the case of soft particles, that is, hard particles covered with an ion-penetrable surface layer of polyelectrolytes, the zeta-potential concept loses its meaning and the *Donnan potential* in the surface layer plays an essential role in electrophoresis of soft particles.

In this chapter we derive equations for the electrophoretic mobility of hard and soft colloidal particles.

33.2 SMOLUCHOWSKI'S, HÜCKEL'S, AND HENRY'S EQUATIONS

Theories of the electrophoretic mobility of hard colloidal particles were developed by Smoluchowski [1], Hückel [2], and Henry [3]. Overbeek [4] , Booth [5], and Dukhin et al [6, 7]. Wiersema et al. [8] solved numerically the full kinetic equations, describing the electrophoresis of spherical hard particles. The computer calculation of the electrophoretic mobility of a spherical particle was considerably improved by O'Brien and White [9]. Approximate analytic mobility expressions, on the other hand, have been proposed by various authors [1–5, 7, 8, 10, 12, 17, 20–29]. In this section we deal with early electrophoresis theories of Smoluchowski [1], Hückel [2], and Henry [3].

We consider a spherical particle of zeta potential ζ in an electrolyte solution. If the particle radius a is much greater than the Debye length κ^{-1}, that is, $\kappa a \gg 1$, then the electrophoretic mobility μ is given by Smoluchowski's equation [1]

$$\mu = \frac{\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}}{\eta}\zeta \tag{33.1}$$

where ε_{r} and η are, respectively, the relative permittivity and the viscosity of the electrolyte solution and ε_0 is the permittivity of a vacuum. Equation (33.1) can be derived from the balance of two forces acting on the particle surface per unit area carrying a charge density σ, that is, the electric force σE and the frictional force. Since the liquid velocity

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

decays from $\boldsymbol{U}$ at the particle surface to zero over distances of the order of the Debye length κ^{-1}, the frictional force is given by $\eta U/\kappa^{-1}$. Thus the force balance condition gives $\sigma E = \eta U/\kappa^{-1}$. We replace the surface charge density σ with the particle surface potential $\psi_0 = \sigma/\varepsilon_r\varepsilon_0\kappa$, which expresses the fact that at the particle surface the potential slope ψ_0/κ^{-1} is equal to the electric field strength $\sigma/\varepsilon_r\varepsilon_0$. Further, by equating ψ_0 and ζ, we obtain E [Eq. (33.1)].

In the opposite limit case where the particle radius a is much smaller than the Debye length κ^{-1}, that is, $\kappa a \ll 1$, μ is given by Hückel's equation [2].

$$\mu = \frac{2\varepsilon_r\varepsilon_o}{3\eta}\zeta \tag{33.2}$$

Equation (33.2) can be derived from the balance between the Stokes resistance $6\pi\eta aU$ and the electric force QE acting on the particle carrying the total surface charge $Q = 4\pi a^2\sigma$ and the zeta-potential ζ, which may be replaced by the Coulomb potential $\psi_o = Q/4\pi\varepsilon_r\varepsilon_0 a$.

For the case of arbitrary values of κa and low ζ, the mobility μ is given by the following Henry's equation [3], which bridges Smoluchowski's equation (33.1) and Huckel's equation (33.2)

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\zeta f(\kappa a) \tag{33.3}$$

with

$$f(\kappa a) = 1 - e^{\kappa a}\{5E_7(\kappa a) - 2E_5(\kappa a)\} \tag{33.4}$$

where $E_n(\kappa a)$ is the exponential integral of order n and is defined by

$$E_n(\kappa a) = (\kappa a)^{n-1}\int_{\kappa a}^{\infty}\frac{e^{-t}}{t^n}dt = a^{n-1}\int_a^{\infty}\frac{e^{-\kappa r}}{r^n}dr \tag{33.5}$$

where $f(\kappa a)$ is Henry's function. An accurate approximate expression for Eq. (33.5) has been derived [24]:

$$f(\kappa a) = \frac{2}{3}\left[1 + \frac{1}{2\left(1 + \dfrac{2.5}{\kappa a\{1 + 2\exp(-\kappa a)\}}\right)^3}\right] \tag{33.6}$$

As $\kappa a \to \infty$, $f(\kappa a) \to 1$ and Eq. (33.6) gives Smoluchowski's equation (33.1), while if $\kappa a \to 0$, then $f(\kappa a) \to {}^2/_3$ [Hückel's Eq. (33.2)].

For the case of a cylindrical particle of radius a and zeta-potential ζ, the electrophoretic mobility depends on the orientation of the particle with respect to the applied electric field. When the cylinder is oriented parallel to the applied electric field, its electrophoretic mobility $\mu_{//}$ is given by Smoluchowski's equation [1]:

$$\mu_{//} = \frac{\varepsilon_r\varepsilon_o}{\eta}\zeta \tag{33.7}$$

If, on the other hand, the cylinder is oriented perpendicularly to the applied field, then the mobility $\mu_{//}$ depends not only on ζ but also on the value of κa and is given by

$$\mu_{\perp} = \frac{\varepsilon_r\varepsilon_o}{\eta}\zeta f(\kappa a) \tag{33.8}$$

with

$$f(\kappa a) = 1 - \frac{4(\kappa a)^4}{K_0(\kappa a)}\int_{\kappa a}^{\infty}\frac{K_0(t)}{t^5}dt + \frac{(\kappa a)^2}{K_0(\kappa a)}\int_{\kappa a}^{\infty}\frac{K_0(t)}{t^3}dt \tag{33.9}$$

where $K_0(x)$ is the zero-order modified Bessel function of the second kind. Equation (33.9), which is Henry's function for cylindrical particles, was first derived by Henry [3]. The following approximate expression for Eq. (33.9) has been derived [23]:

$$f(\kappa a) = \frac{1}{2}\left[1 + \frac{1}{\left(1 + \dfrac{2.55}{\kappa a\{1 + \exp(-\kappa a)\}}\right)^2}\right] \tag{33.10}$$

As $\kappa a \to \infty$, $f(\kappa a) \to 1$ and Eq. (33.10) gives Smoluchowski's equation (33.7), while if $\kappa a \to 0$, then $f(\kappa a) \to {}^1/_2$ (Hückel's limit).

For a cylindrical particle oriented at an arbitrary angle between its axis and the applied electric field, its electrophoretic mobility averaged over a random distribution of orientation is given by [26, 27]

$$\mu_{av} = \frac{1}{3}\mu_{//} + \frac{2}{3}\mu_{\perp} \tag{33.11}$$

Figure 33.1 summarizes Henry's functions for spheres and cylinders.

33.3 GENERAL THEORY OF THE ELECTROPHORETIC MOBILITY OF SPHERICAL HARD PARTICLES

Consider a spherical hard particle of radius a moving with a velocity $\boldsymbol{U}$ in a liquid containing a general electrolyte composed of N ionic species with valence z_i and bulk concentration (number density) n_i^{∞}, and drag coefficient λ_i ($i = 1, 2, \ldots, N$). The origin of the spherical polar coordinate system (r, θ, ϕ) is held fixed at the center of the particle, and the polar axis ($\theta = 0$) is set parallel to $\boldsymbol{E}$ (Fig. 33.2). For

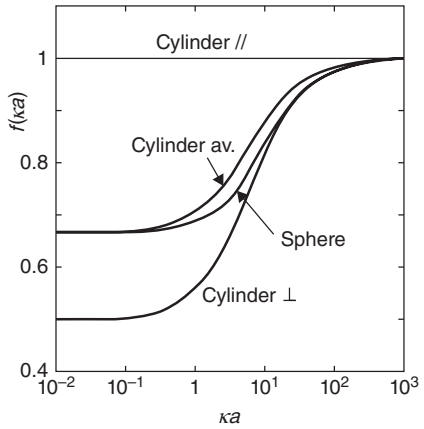

FIGURE 33.1 Henry's function $f(\kappa a)$ for a sphere and a cylinder of radius a as a function of scaled radius κa. The cylinder is oriented parallel ($\mu_{//}$) or perpendicularly ($\mu_{//}$) to the applied electric field. For a cylindrical particle oriented at an arbitrary angle between its axis and the applied electric field, its electrophoretic mobility averaged over a random distribution of orientation is given by $\mu_{av} = (\mu_{//} + 2\mu_{//})/3$. (From Ref. 19.)

a spherical particle, $\boldsymbol{U}$ takes the same direction as $\boldsymbol{E}$. The main assumptions are as follows: (1) the Reynolds number of the liquid flow is small enough to ignore inertial terms in the Navier–Stokes equation and the liquid can be regarded as incompressible, (2) the applied field $\boldsymbol{E}$ is weak so that the particle velocity $\boldsymbol{U}$ is proportional to $\boldsymbol{E}$ and terms of higher order in $\boldsymbol{E}$ may be neglected, (3) the slipping plane (at which the liquid velocity relative to the particle becomes zero) is located on the particle surface (at $r = a$), (4) no electrolyte ions can penetrate the particle surface.

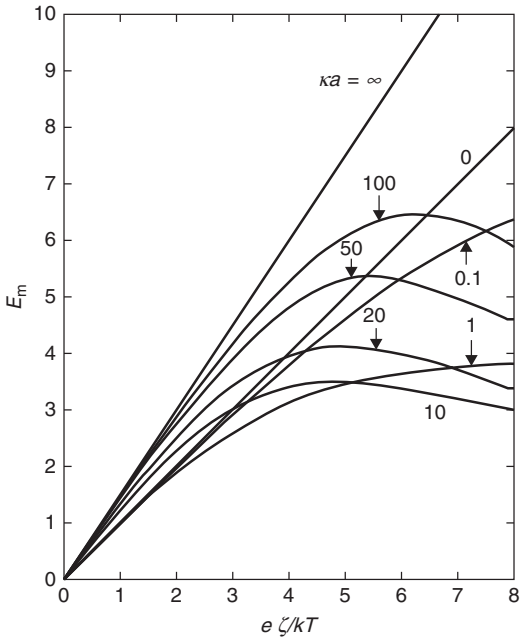

FIGURE 33.2 The scaled electrophoretic mobility E_m of a positively charged spherical colloidal particle of radius a in an aqueous KCl solution at 25°C as a function of scaled zeta-potential $e\zeta/kT$ for various values of κa. Calculated by the method of O'Brien and White [9]. E_m is defined by Eq. (33.24). (From Ref. 19.)

The motion of charged colloidal particles in a liquid containing an electrolyte caused by an externally applied electric field can be described by the Navier–Stokes equation for the liquid flow around the particle, continuity equations for the liquid flow and the flow of the ionic species, and the Poisson equation connecting the electric potential and the concentrations of the ionic species. The Navier–Stokes equation for the liquid flow $\boldsymbol{u}(\boldsymbol{r})$ around the particle is given by

$$\eta \nabla \times \nabla \times \boldsymbol{u}(\boldsymbol{r}) + \nabla p(\boldsymbol{r}) + \rho_{el}(\boldsymbol{r}) \nabla \psi(\boldsymbol{r}) = \boldsymbol{0}, \; r > a \qquad (33.12)$$

where η is the viscosity of the electrolyte solution, $p(\boldsymbol{r})$ is the pressure at position $\boldsymbol{r}$, $\rho_{el}(\boldsymbol{r})$ is the charge density resulting from the mobile charged ionic species, $\psi(\boldsymbol{r})$ is the electric potential, and $r = |\boldsymbol{r}|$.

Ohshima et al. [12] derived the general expression for the electrophoretic mobility of a sphere.

$$\mu = \frac{a^2}{9} \int_a^\infty \left(1 - \frac{3r^2}{a^2} + \frac{2r^3}{a^3}\right) G(r) dr \qquad (33.13)$$

with

$$y = \frac{e\psi^{(0)}}{kT}$$

$$G(r) = -\frac{e}{\eta r} \frac{dy}{dr} \sum_{i=1}^{N} z_i^2 n_i^\infty e^{-z_i y} \phi_i \qquad (33.14)$$

where $\psi^{(0)}$ is the equilibrium potential, y is the corresponding scaled quantity, and ϕ_i is related to the deviation $\delta\mu_i$ of the electrochemical potential of ith ionic species by

$$\delta\mu_i(\boldsymbol{r}) = -z_i e \phi_i(r) E \cos\theta \qquad (33.15)$$

With

$$\varphi_i(r) = r + \frac{a^3}{2r^2} + f_i(r) \qquad (33.16)$$

where the first term r on the right-hand side corresponds to the potential of the applied external field $\boldsymbol{E} \cdot \boldsymbol{r}$; the second term $a^3/2r^2$, to deviation of the external field due to the presence of the particle core; and the third term $f_i(r)$, to the contribution of the relaxation effect of electrolyte ions.

It can be shown that Smoluchowski's equation (33.1) can be derived for the case where Eq. (33.16) is approximated by

$$\phi_i(r) = \frac{3a}{2} \qquad (33.17)$$

If Eq. (33.16) is approximated by

$$\phi_i(r) = r \tag{33.18}$$

then Hückel's equation (33.2) is derived. Finally, Henry's equation (33.3) can be derived when

$$\phi_i(r) = r + \frac{a^3}{2r^2} \tag{33.19}$$

For a cylinder oriented perpendicularly to the applied field, the general expression for $\mu_{//}$ is given by [23]

$$\mu_\perp = \frac{a^2}{8}\int_a^\infty \left[1 - \frac{r^2}{a^2}\left\{1 - 2\ln\left(\frac{r}{a}\right)\right\}\right] G(r)dr \tag{33.20}$$

with

$$\varphi_i(r) = r + \frac{a^2}{r} + f_i(r) \tag{33.21}$$

where r is the distance from the cylinder axis. Henry's equation (9) for $\mu_{//}$ can be derived when Eq. (33.21) is approximated by

$$\varphi_i(r) = r + \frac{a^2}{r} \tag{33.22}$$

33.4 RELAXATION EFFECT

Henry's mobility Eq. (33.3) assumes that the double-layer potential distribution around a spherical particle remains unchanged during electrophoresis, assuming $\phi_i(r) = 0$. For high zeta-potentials, however, the double layer is no longer spherically symmetric. This effect is called the *relaxation effect* (the double-layer polarization or the surface conduction). Henry's Eq. (33.3) does not take into account the relaxation effect, and thus, this equation is correct to the first order of zeta-potential ζ. If the relaxation effect is taken into account, then the electrophoretic mobility μ becomes dependent on the ionic drag coefficient λ_i. We introduce the scaled ionic drag coefficient m_i defined by

$$m_i = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta z_i^2 e}\lambda_i \tag{33.23}$$

For an aqueous KCl solution at 25°C, $m = 0.176$ for K^+ ions and $m = 0.169$ for Cl^- ions. In Fig. 33.2 we plot the electrophoretic mobility μ of a positively charged sphere in an aqueous KCl solution at 25°C ($\varepsilon_r = 78.5$ and $\eta = 0.891$ mPa • s) as a function of scaled zeta-potential $e\zeta/kT$ for several values of κa calculated by the method of O'Brien and White [9]. Here E_m is the scaled electrophoretic mobility defined by

$$E_m = \frac{3\eta e}{2\varepsilon_r\varepsilon_o kT}\mu \tag{33.24}$$

The cases of $\kappa a = \infty$ and $\kappa a = 0$, which are both straight lines, correspond to Smoluchowski's Eq. (33.1) and Hückel's Eq. (33.2), respectively. It is seen that there exists a mobility maximum due to the relaxation effect.

The following approximate mobility expression for a sphere of radius a and zeta-potential ζ, which is correct to order $1/\kappa a$, is applicable for $\kappa a \geq 10$ and arbitrary ζ [12]:

$$\begin{aligned}\mu = {} & \mathrm{sgn}(\zeta)\frac{\varepsilon_r\varepsilon_o}{\eta}\left\{|\zeta| - \frac{2F}{1+F}\left(\frac{kT}{ze}\right)H\right\} \\ & + \mathrm{sgn}(\zeta)\frac{2\varepsilon_r\varepsilon_o kT}{3\eta e}\left[\frac{1}{\kappa a}\left\{-18\left(t + \frac{t^3}{9}\right)K\right.\right. \\ & + \frac{15F}{1+F}\left(t + \frac{7t^2}{20} + \frac{t^3}{9}\right) - 6(1+3\overline{m})(1-e^{-\overline{\zeta}/2})G \\ & + \frac{12F}{(1+F)^2}H + \frac{9\overline{\zeta}}{1+F}(\overline{m}G + mH) \\ & \left.\left. - \frac{36F}{1+F}\left(\overline{m}G^2 + \frac{m}{1+F}H^2\right)\right\}\right]\end{aligned} \tag{33.25}$$

with

$$\begin{aligned}&\overline{\zeta} = \frac{ze|\zeta|}{kT},\ F = \frac{2}{\kappa a}(1+3m)(e^{\overline{\zeta}/2}-1),\ G = \ln\left(\frac{1+e^{\overline{\zeta}/2}}{2}\right) \\ &H = \ln\left(\frac{1+e^{\overline{\zeta}/2}}{2}\right),\ m = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta z^2e^2}\lambda,\ \overline{m} = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta z^2e^2}\overline{\lambda} \\ &K = 1 - \frac{25}{3(\kappa a+10)}\exp\left[-\frac{\kappa a}{6(\kappa a-6)}\overline{\zeta}\right],\ t = \tanh(\overline{\zeta}/4)\end{aligned} \tag{33.26}$$

A mobility expression for a sphere correct to order ζ^3 and applicable for $ze\zeta/kT \leq 3$ and arbitrary κa is given below [24]:

$$\begin{aligned}\mu = {} & \frac{2\varepsilon_r\varepsilon_o\zeta}{3\eta}\left(1 + \frac{1}{2[1+2.5/\{\kappa a(1+2e^{-\kappa a})\}]^3}\right) \\ & - \frac{2\varepsilon_r\varepsilon_o\zeta}{3\eta}\left(\frac{ze\zeta}{kT}\right)^2\left[\frac{\kappa a\{\kappa a + 1.3\exp(-0.18\kappa a) + 2.5\}}{2\{\kappa a + 1.2\exp(-7.4\kappa a) + 4.8\}^3}\right. \\ & \left. + \left(\frac{m+\overline{m}}{2}\right)\frac{9\kappa a\{\kappa a + 5.2\exp(-3.9\kappa a) + 5.6\}}{8\{\kappa a - 1.55\exp(-0.32\kappa a) + 6.02\}^3}\right]\end{aligned} \tag{33.27}$$

Simple approximate mobility expressions for a sphere of radius a correct to order 1 applicable for with $\kappa a \geq 30$ have been derived for various cases [25]:

1. Charged particles in a symmetric electrolyte solution of valence z

$$\mu = \mathrm{sgn}(\zeta)\frac{\varepsilon_r\varepsilon_o}{\eta}\left\{|\zeta| - \frac{2F}{1+F}\left(\frac{kT}{ze}\right) \times \ln\left[\frac{1+\exp(ze|\zeta|/2kT)}{2}\right]\right\} \quad (33.28)$$

with

$$F = \frac{2}{\kappa a}(1+3m)\left\{\exp\left(\frac{ze\,|\zeta|}{2kT}\right) - 1\right\} \quad (33.29)$$

$$m = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta z^2 e^2}\lambda \quad (33.30)$$

2. Positively charged particles ($\zeta > 0$) in a 2–1 electrolyte

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\left\{\zeta - \frac{2F}{1+F}\left(\frac{kT}{e}\right)\ln\left[\frac{1}{2} + \frac{1}{2}\sqrt{\frac{2}{3}\exp\left(\frac{e\zeta}{kT}\right) + \frac{1}{3}}\right]\right\} \quad (33.31)$$

$$F = \frac{\sqrt{6}}{\kappa a}(1+3m_-)\left\{\exp\left(\frac{e\zeta}{2kT}\right) - 1\right\} \quad (33.32)$$

$$m_- = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta e^2}\lambda_- \quad (33.33)$$

3. Negatively charged particles ($\zeta < 0$) in a 2–1 electrolyte

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\left\{\zeta + \frac{2F}{1+F}\left(\frac{kT}{e}\right) \times \ln\left[\frac{1}{2}\exp\left(-\frac{e\zeta}{2kT}\right) + \frac{1}{2}\sqrt{\frac{1}{3}\exp\left(-\frac{e\zeta}{kT}\right) + \frac{2}{3}}\right]\right\} \quad (33.34)$$

$$F = \frac{\sqrt{3}}{\kappa a}(1+3m_+)\left\{\exp\left(\frac{e\,|\zeta|}{kT}\right) - 1\right\} \quad (33.35)$$

$$m_+ = \frac{\varepsilon_r\varepsilon_o kT}{6\eta e^2}\lambda_+ \quad (33.36)$$

4. Positively charged particles ($\zeta > 0$) in a 1–2 electrolyte

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\left\{\zeta - \frac{2F}{1+F}\left(\frac{kT}{e}\right) \times \ln\left[\frac{1}{2}\exp\left(\frac{e\zeta}{2kT}\right) + \frac{1}{2}\sqrt{\frac{1}{3}\exp\left(\frac{e\zeta}{kT}\right) + \frac{2}{3}}\right]\right\} \quad (33.37)$$

with

$$F = \frac{\sqrt{3}}{\kappa a}(1+3m_-)\left\{\exp\left(\frac{e\zeta}{kT}\right) - 1\right\} \quad (33.38)$$

$$m_- = \frac{\varepsilon_r\varepsilon_o kT}{6\eta e^2}\lambda_- \quad (33.39)$$

5. Negatively charged particles ($\zeta < 0$) in a 1–2 electrolyte

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\left\{\zeta + \frac{2F}{1+F}\left(\frac{kT}{e}\right)\ln\left[\frac{1}{2} + \frac{1}{2}\sqrt{\frac{2}{3}\exp\left(\frac{e\,|\zeta|}{kT}\right) + \frac{1}{3}}\right]\right\} \quad (33.40)$$

with

$$F = \frac{\sqrt{6}}{\kappa a}(1+3m_+)\left\{\exp\left(\frac{e\,|\zeta|}{2kT}\right) - 1\right\} \quad (33.41)$$

$$m_+ = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta e^2}\lambda_+ \quad (33.42)$$

In these equations F corresponds to Dukhin's number, expressing the relaxation effect. It can also be shown that mobility expressions $\mu_\perp$ for cylinders of radius a oriented perpendicular to the applied field correct to order 1 coincides with the mobility expressions for a sphere of radius a [see Eqs. (33.28)–(33.42)] [28].

Similarly, approximate mobility expressions for a sphere of radius a and zeta- potential ζ in a mixed electrolyte solution can be derived. For a sphere moving in a mixed solution of 1:1 electrolyte of concentration n_1 and 2:1 electrolyte of concentration n_2, we obtain for a positively charged sphere ($\zeta > 0$)

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\left\{\zeta - \frac{2F_{-1}}{1+F_{-1}}\left(\frac{kT}{e}\right)\ln\left(\frac{1+\beta}{2}\right)\right\} \quad (33.43)$$

with

$$F_{-1} = \frac{2(1+3m_{-1})}{\kappa a\sqrt{1-\alpha/3}}\left\{\exp\left(\frac{e\zeta}{2kT}\right)-1\right\},$$
$$m_{-1} = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta e^2}\lambda_{-1} = \frac{2N_A\varepsilon_r\varepsilon_o kT}{3\eta\Lambda^o_{-1}}$$

$$\alpha = \frac{3n_2}{n_1+3n_2}, \beta = \sqrt{\frac{\alpha}{3}+\left(1-\frac{\alpha}{3}\right)\exp\left(\frac{e\zeta}{kT}\right)} \qquad (33.44)$$

where λ_{-1} and Λ^o_{-1} are, respectively, the drag coefficient and the limiting conductance of the counterions (anions) of valence -1 and m_{-1} is the corresponding scaled drag coefficient. The electrophoretic mobility μ is thus given by the following equation. For a negatively charged sphere, we obtain

$$\mu = \frac{\varepsilon_r\varepsilon_o}{\eta}\left[\zeta+\left(\frac{1}{1+F_{+1}}+\frac{1}{1+F_{+2}}-2\right)\left\{\frac{\zeta}{2}-\left(\frac{kT}{e}\right)\ln\right.\right.$$
$$\left.\left.\times\left(\frac{1+\beta}{2}\right)\right\}+\left(\frac{1}{1+F_{+1}}-\frac{1}{1+F_{+2}}\right)H(\zeta,\alpha)\right] \qquad (33.45)$$

with

$$H(\zeta,\alpha) = \frac{(1-\alpha)}{2}\sqrt{\frac{3}{\alpha}}\left\{\left(\frac{e\zeta}{kT}\right)\ln\left[\left(\frac{1+\sqrt{\alpha/3}}{1-\sqrt{\alpha/3}}\right)\left(\frac{1-\beta}{1+\beta}\right)\right]\right.$$
$$-2\ln\left(\frac{\beta+\sqrt{\alpha/3}}{1+\sqrt{\alpha/3}}\right)\cdot\ln\left(\frac{1-\beta}{1+\beta}\right)$$
$$-\mathrm{Li}_2\left(\frac{\beta+\sqrt{\alpha/3}}{1+\sqrt{\alpha/3}}\right)+\mathrm{Li}_2\left(\frac{\beta-\sqrt{\alpha/3}}{1-\sqrt{\alpha/3}}\right)$$
$$-\mathrm{Li}_2\left(-\frac{\beta-\sqrt{\alpha/3}}{1+\sqrt{\alpha/3}}\right)+\mathrm{Li}_2\left(-\frac{\beta+\sqrt{\alpha/3}}{1-\sqrt{\alpha/3}}\right)$$
$$\left.-\mathrm{Li}_2\left(-\frac{1+\sqrt{\alpha/3}}{1-\sqrt{\alpha/3}}\right)+\mathrm{Li}_2\left(-\frac{1-\sqrt{\alpha/3}}{1+\sqrt{\alpha/3}}\right)\right\}$$
$$-\frac{e\zeta}{2kT}+\ln\left(\frac{1+\beta}{2}\right)$$

$$F_{+1} = \frac{2}{\kappa a}(1+3m_{+1})\left\{\exp\left(\frac{e|\zeta|}{2kT}\right)-1\right\},$$
$$F_{+2} = \frac{\sqrt{3}}{\kappa a}(1+3m_{+2})\left\{\exp\left(\frac{e|\zeta|}{kT}\right)-1\right\},$$
$$m_{+1} = \frac{2\varepsilon_r\varepsilon_o kT}{3\eta e^2}\lambda_{+1} = \frac{2N_A\varepsilon_r\varepsilon_o kT}{3\eta\Lambda^o_{+1}}, \quad m_{+2} = \frac{\varepsilon_r\varepsilon_o kT}{6\eta e^2}\lambda_{+2}$$
$$= \frac{N_A\varepsilon_r\varepsilon_o kT}{3\eta\Lambda^o_{+2}} \qquad (33.46)$$

where $\mathrm{Li}_2(z)$ is a dilogarithm function [defined by $Li_2(z) = \sum_{k=1}^{\infty}(z^k/k^2)$], which can easily be evaluated via Mathematica,

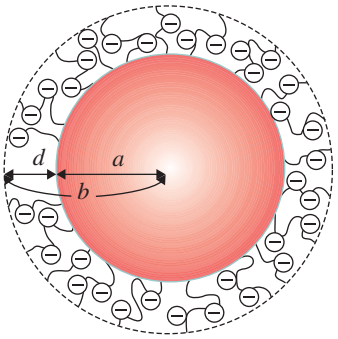

FIGURE 33.3 A spherical soft particle in an external applied electric field $\boldsymbol{E}$; a = radius of the particle core and d = thickness of the polyelectrolyte layer coating the particle core. $b = a+d$.

for example, and where λ_{+1} and Λ^o_{+1} are, respectively, the drag coefficient and limiting conductance of counterions (cations) of valence $+1$, λ_{+2} and Λ^o_{+2} are those of counterions (cations) of valence $+2$, and m_{+1} and m_{+2} are the corresponding scaled drag coefficients.

33.5 ELECTROPHORETIC MOBILITY OF SOFT PARTICLES

The electrophoretic mobility of soft particles, that is, a hard particle covered with an ion-penetrable surface layer of polyelectrolytes (Fig. 33.3) is quite different from that of hard particles without surface structures in that the mobility of hard particles is determined by the particle zeta-potential, but the concept of zeta-potential loses its meaning for soft particles and the mobility of soft particles depends on the Donnan potential in the surface layer.

Consider now a spherical soft particle moving with a velocity $\boldsymbol{U}$ in a symmetric electrolyte solution of valence z and bulk concentration (number density) n in an applied electric field $\boldsymbol{E}$ [30–48]. We suppose that the uncharged particle core of radius a is coated with an ion-penetrable layer of polyelectrolytes of thickness d and that ionized groups of valence Z are distributed within the polyelectrolyte layer at a uniform density N so that the polyelectrolyte later is uniformly charged at a constant density $\rho_{\mathrm{fix}} = ZeN$. The polymer-coated particle thus has an inner radius a and an outer radius $b = a + d$ (Fig. 33.3). Let the drag coefficient of coions be λ_+ and that of counterions be λ_-. We adopt the model of Debye–Bueche [49] that the polymer segments are regarded as resistance centers distributed uniformly in the polyelectrolyte layer, exerting frictional forces on the liquid flowing in the polyelectrolyte layer.

The fundamental electrokinetic equations for the liquid velocity $\boldsymbol{u}(\boldsymbol{r})$ at position $\boldsymbol{r}$ are [19, 20, 30, 34]

$$\eta\nabla\times\nabla\times\boldsymbol{u}+\nabla p+\rho_{e1}\nabla\psi=\boldsymbol{0}, \quad r>b \qquad (33.47)$$
$$\eta\nabla\times\nabla\times\boldsymbol{u}+\gamma\boldsymbol{u}+\nabla p+\rho_{e1}\nabla\psi=\boldsymbol{0}, \; a<r<b \qquad (33.48)$$

Equation (33.47) is the usual Navier–Stokes equation. The term $\gamma \boldsymbol{u}$ on the left-hand side of Eq. (33.48) represents the frictional forces exerted on the liquid flow by the polymer segments in the polyelectrolyte layer, and γ is the frictional coefficient. If it is assumed that each resistance center corresponds to a polymer segment, which, in turn, is regarded as a sphere of radius a_p and the polymer segments are distributed at a uniform volume density of N_p in the polyelectrolyte layer, then each polymer segment exerts the Stokes resistance $6\pi\eta a_\mathrm{p}\boldsymbol{u}$ on the liquid flow in the polyelectrolyte layer so that

$$\gamma = 6\pi\eta a_\mathrm{p} N_\mathrm{p} \tag{33.49}$$

The general mobility expression for a soft sphere is given by [34]

$$\begin{aligned}\mu = {} & \frac{b^2}{9}\int_b^\infty \left[3\left(1-\frac{r^2}{b^2}\right) - \frac{2L_2}{L_1}\left(1-\frac{r^3}{b^3}\right)\right] G(r)dr \\ & + \frac{2L_3}{3\lambda^2 L_1}\int_a^\infty \left(1+\frac{r^3}{2b^3}\right) G(r)dr \\ & - \frac{2}{3\lambda^2}\int_a^b \left[1 - \frac{3a}{2\lambda^2 b^3 L_1}\left\{(L_3+L_4\lambda r)\cosh\left[\lambda(r-a)\right]\right\}\right. \\ & \left. - \left\{-(L_4+L_3\lambda r)\sinh\left[\lambda(r-a)\right]\right\}\right] G(r)dr \end{aligned} \tag{33.50}$$

where $G(r)$ is given by Eq. (33.14) and

$$\lambda = (\gamma/\eta)^{1/2} \tag{33.51}$$

$$\begin{aligned} L_1 = {} & \left(1 + \frac{a^3}{2b^3} + \frac{3a}{2\lambda^2 b^3} - \frac{3a^2}{2\lambda^2 b^4}\right)\cosh\left[\lambda(b-a)\right] \\ & - \left(1 - \frac{3a^2}{2b^2} + \frac{a^3}{2b^3} + \frac{3a}{2\lambda^2 b^3}\right)\frac{\sinh\left[\lambda(b-a)\right]}{\lambda b} \end{aligned} \tag{33.52}$$

$$\begin{aligned} L_2 = {} & \left(1 + \frac{a^3}{2b^3} + \frac{3a}{2\lambda^2 b^3}\right)\cosh\left[\lambda(b-a)\right] \\ & + \frac{3a^2}{2b^2}\frac{\sinh\left[\lambda(b-a)\right]}{\lambda b} - \frac{3a}{2\lambda^2 b^3} \end{aligned} \tag{33.53}$$

$$L_3 = \cosh\left[\lambda(b-a)\right] - \frac{\sinh\left[\lambda(b-a)\right]}{\lambda b} - \frac{a}{b} \tag{33.54}$$

$$L_4 = \sinh\left[\lambda(b-a)\right] - \frac{\cosh\left[\lambda(b-a)\right]}{\lambda b} + \frac{\lambda a^2}{3b} + \frac{2\lambda b^2}{3a} + \frac{1}{\lambda b} \tag{33.55}$$

If we neglect the relaxation effect, we approximate $\phi_\pm(r)$, where $\phi_+(r)$ and $\phi_-(r)$ are, respectively, the ϕ_i function for coions and counterions in Eq. (33.14), by

$$\phi_\pm(r) = \phi_\pm(b) = b + \frac{a^3}{2b^3} \tag{33.56}$$

We thus obtain the following approximate expression for the electrophoretic mobility of a soft particle:

$$\mu = \frac{2\varepsilon_\mathrm{r}\varepsilon_\mathrm{o}}{3\eta}\left(1+\frac{a^3}{2b^3}\right)\frac{\psi_\mathrm{o}/\kappa_\mathrm{m} + \psi_\mathrm{DON}/\lambda}{1/\kappa_\mathrm{m} + 1/\lambda} + \frac{ZeN}{\eta\lambda^2} \tag{33.57}$$

with

$$\psi_\mathrm{DON} = \left(\frac{kT}{ze}\right)\ln\left[\frac{ZN}{2zn} + \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right] \tag{33.58}$$

$$\begin{aligned} \psi_o = {} & \frac{kT}{ze}\left(\ln\left[\frac{ZN}{2zn} + \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right]\right. \\ & \left. + \frac{2zn}{ZN}\left[1 - \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right]\right) \end{aligned} \tag{33.59}$$

$$\kappa_m = \kappa\left[1 + \left(\frac{ZN}{2zn}\right)^2\right]^{1/4} \tag{33.60}$$

where ψ_DON and ψ_o=$\psi(b)$ are, respectively, the Donnan potential and the surface potential of the surface layer, and κ_m is the Debye–Hückel parameter in the surface layer that involves the contribution of the fixed charges *ZeN*. Equation (33.57) consists of two terms: the first term is a weighted average of the Donnan potential ψ_DON and the surface potential ψ_o. It should be stressed that only the first term is subject to the shielding effects of electrolytes, tending toward zero as the electrolyte concentration n increases, while the second term does not depend on the electrolyte concentration. In the limit of high electrolyte concentration, all the potentials vanish and only the second term of the mobility expression remains:

$$\mu \to \mu^\infty = \frac{ZeN}{\eta\lambda^2} \tag{33.61}$$

Equation (33.61) shows that as $\kappa \to \infty$, μ tends to a nonzero limiting value μ^∞. This is a characteristic of the electrokinetic behavior of soft particles, in contrast to the case of the electrophoretic mobility of hard particles, which should reduce to zero as a result of the shielding effects, since the mobility expressions for rigid particles do not have μ^∞, as schematically shown in Fig. 33.4.

Also we note that Eq. (33.57) does not depend on the potential $\psi^{(0)}(a)$ at the slipping plane at $r = a$. This means that the mobility of soft particles is insensitive to the precise position of the slipping plane. In other words, for such cases, the zeta-potential loses its meaning.

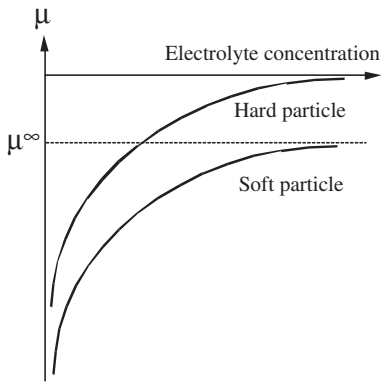

FIGURE 33.4 Schematic representation of the electrophoretic mobilites of soft and hard particles plotted as functions of electrolyte concentration.

In order to take into account the relaxation effect outside the surface charge layer, we approximate $\phi_{\pm}(r)$ by [46]

$$\phi_{+}(r) = \phi_{+}(b) = b + \frac{a^3}{2b^2} \tag{33.62}$$

$$\phi_{-}(r) = \phi_{-}(b) = \left(b + \frac{a^3}{2b^2}\right) \cdot \frac{1}{1+F} \tag{33.63}$$

with

$$F = \frac{2}{\kappa b}(1 + 3m_{-})\left(e^{y_o/2} - 1\right) \tag{33.64}$$

Here F corresponds to Dukhin's number. By using Eqs. (33.62) and (33.63), we finally obtain

$$\begin{aligned}\mu = {} & \frac{2\varepsilon_r\varepsilon_o}{3\eta}\left(1 + \frac{a^3}{2b^3}\right)\frac{\psi_o/\kappa_m + \psi_{DON}/\lambda}{1/\kappa_m + 1/\lambda} + \frac{ZeN}{\eta\lambda^2} \\ & \times \left(1 - \frac{F}{1+F}\cdot\frac{1}{1+e^{-y_{DON}}}\right) \\ & - \frac{F}{1+F}\cdot\frac{2\varepsilon_r\varepsilon_o}{3\eta}\left(1 + \frac{a^3}{2b^3}\right)\left(\frac{kT}{ze}\right)\left[2\ln\left(\frac{1+e^{y_o/2}}{2}\right)\right. \\ & \left. + \frac{\kappa}{\lambda}\left(e^{y_o/2} - 1\right) - \frac{\kappa^2}{2\lambda(\lambda+\kappa_m)}\cdot\frac{e^{y_{DON}} - 1}{1+e^{-y_{DON}}}\right] \end{aligned} \tag{33.65}$$

where y with subscripts o and Don are the scaled surface and Donnan potentials, respectively. For other electrokinetics of hard and soft particles, the reader should refer to the literature [19–21].

ELECTROSTATIC INTERACTION BETWEEN COLLOIDAL PARTICLES

HIROYUKI OHSHIMA

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki Noda, Chiba 278-8510, Japan

34.1 INTRODUCTION

When two charged particles approach each other in an electrolyte solution, the electrical double layers around the particles overlap each other, resulting in electrostatic interaction between them [1–10]. In this chapter we derive expressions for the potential energy of the electrostatic interaction between charged particles for various cases. We treat not only hard particles without surface structures but also soft particles, that is, hard particles covered with an ion-penetrable surface layer of polyelectrolytes. In the latter case we consider before and after contact of the surface layers of interacting particles.

34.2 INTERACTION BETWEEN HARD PARTICLES

34.2.1 Interaction between Two Parallel Plates: Low-Potential Case

Consider first two parallel dissimilar plates 1 and 2, separated by a distance h immersed in a liquid containing N ionic species with valence z_i and bulk concentration (number density) n_i^∞ ($i = 1,2, \ldots, N$). We take an x axis perpendicular to the plates with its origin at the right surface of plate 1, as in Fig. 34.1.

We assume that the electric potential $\psi(x)$ outside the plates ($0 < x < h$) obeys the following one-dimensional planar Poisson–Boltzmann equation (see Chapter 78):

$$\frac{d^2\psi(x)}{dx^2} = -\frac{1}{\varepsilon_r\varepsilon_0}\sum_{i=1}^{N} z_i e n_i^\infty \exp\left(-\frac{z_i e\psi(x)}{kT}\right) \quad \text{for } 0 < \times < h \tag{34.1}$$

The boundary conditions at the plate surface depend on the type of the double-layer interaction between plates 1 and 2. If the surface potentials of plates 1 and 2 remain constant at their unperturbed surface potentials ψ_{01} and ψ_{02} during interaction, respectively (interaction at constant surface potential), then

$$\psi(0) = \psi_{01},\ \psi(h) = \psi_{02}, \tag{34.2}$$

On the other hand, if the surface charge densities of plates 1 and 2 remain constant at σ_1 and σ_2 (electrostatic interaction at constant surface charge density), respectively, then

$$\left.\frac{d\psi}{dx}\right|_{x=0^+} = -\frac{\sigma_1}{\varepsilon_r\varepsilon_0},\quad \left.\frac{d\psi}{dx}\right|_{x=h^-} = \frac{\sigma_2}{\varepsilon_r\varepsilon_0}, \tag{34.3}$$

where we have assumed that the influence of the external fields within the plates can be neglected.

The interaction force P can be calculated by integrating the excess osmotic pressure and the Maxwell stress over an arbitrary closed surface Σ enclosing either one of the two interacting plates. As Σ, we choose two planes located at $x = -\infty$ (in the bulk solution far from the plates) and $x = x'$

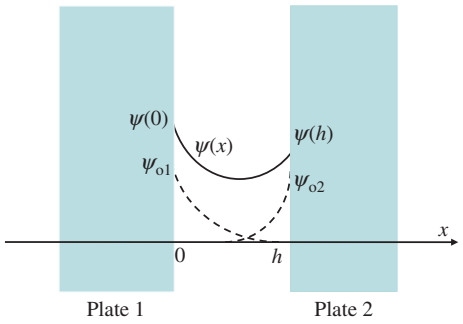

FIGURE 34.1 Potential distribution $\psi(x)$ across two interacting parallel dissimilar plates 1 and 2 carrying unperturbed surface potentials ψ_{01} and ψ_{02}, respectively, at separation h.

$(0 < x' < h)$ enclosing plate 1. Here x' is an arbitrary point in the region $0 < x < h$ between plates 1 and 2. Thus the force $P(h)$ of the double layer interaction per unit area is given by

$$P_{\text{pl}}(h) = \sum_{i=1}^{N} n_i^{\infty} kT \left[\exp\left(-\frac{z_i e\psi(x')}{kT}\right) - 1\right] - \frac{1}{2}\varepsilon_r\varepsilon_0 \left(\left.\frac{d\psi}{dx}\right|_{x=x'}\right)^2 \tag{34.4}$$

which, for the low-potential case, can be linearized to

$$P_{\text{pl}}(h) = \frac{1}{2}\varepsilon_r\varepsilon_0 \left\{\kappa^2\psi^2(x') - \left(\left.\frac{d\psi}{dx}\right|_{x=x'}\right)^2\right\} \tag{34.5}$$

Here $P(h) > 0$ corresponds to repulsion and $P(h) < 0$ to attraction. The corresponding interaction energy $V_{\text{pl}}(h)$ between two parallel plates per unit area can be obtained by integrating $P_{\text{pl}}(h)$ with the result that

$$V_{\text{pl}}(h) = \int_h^{\infty} P_{pl}(h)dh \tag{34.6}$$

34.2.2 Derjaguin's Approximation for Calculation of Interactions between Two Spheres or Cylinders

Once the interaction energy $V_{\text{pl}}(h)$ between two parallel plates at separation h is obtained, one can derive the following expressions (Fig. 34.2).

We give below Derjaguin's approximation to calculate the sphere–sphere interaction energy [11] and the cylinder–cylinder interaction energy [12, 13]:

$$V_{\text{sp}}(H) = \frac{2\pi a_1 a_2}{a_1 + a_2}\int_H^{\infty} V_{\text{pl}}(h)dh \quad \text{for two spheres} \tag{34.7}$$

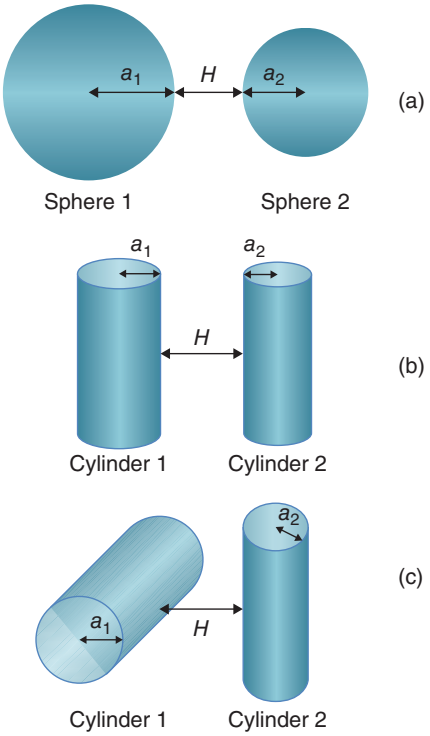

FIGURE 34.2 Interaction between two spheres or cylinders 1 and 2 of radii a_1 and a_2, respectively, at separation H: (a) two spheres; (b) two parallel cylinders; (c) Two crossed cylinders.

$$V_{\text{cy}//}(H) = \sqrt{\frac{2a_1a_2}{a_1 + a_2}}\int_H^{\infty} V_{\text{pl}}(h)\frac{dh}{\sqrt{h - H}}$$

for two parallel cylinders (34.8)

$$V_{\text{cy}\perp}(H) = 2\pi\sqrt{a_1a_2}\int_H^{\infty} V_{\text{pl}}(h)dh$$

for two crossed cylinders (34.9)

34.2.3 Low-Potential Case

For the low-potential case, expressions for the interaction energy between two parallel plates, two spheres, and two parallel or crossed cylinders are easily derived. The results are given below. In the following expressions, superscript ψ stands for the interaction at constant surface potential, σ for the interaction at constant surface charge density, and ψ–σ for the interaction for the case where the surface potential and the surface charge density of pates 1 and 2 are, respectively, kept constant during interaction.

1. Interaction energy $V_{\text{pl}}(h)$ per unit area between two parallel plates 1 and 2 carrying unperturbed surface

potentials ψ_{01} and ψ_{02}, respectively, at separation h between their surfaces [14–16]:

$$V_{\rm pl}^{\psi}(h) = \varepsilon_{\rm r}\varepsilon_0\kappa\left[\left(\frac{\psi_{01}+\psi_{02}}{2}\right)^2\left\{1-\tanh\left(\frac{\kappa h}{2}\right)\right\} - \left(\frac{\psi_{01}-\psi_{02}}{2}\right)^2\left\{\coth\left(\frac{\kappa h}{2}\right)-1\right\}\right] \quad (34.10)$$

$$V_{\rm pl}^{\sigma}(h) = \varepsilon_{\rm r}\varepsilon_0\kappa\left[\left(\frac{\psi_{01}+\psi_{02}}{2}\right)^2\left\{\coth\left(\frac{\kappa h}{2}\right)-1\right\} - \left(\frac{\psi_{01}-\psi_{02}}{2}\right)^2\left\{1-\tanh\left(\frac{\kappa h}{2}\right)\right\}\right] \quad (34.11)$$

$$V_{\rm pl}^{\psi-\sigma}(h) = \varepsilon_{\rm r}\varepsilon_0\kappa\left[\frac{\psi_{01}\psi_{02}}{\cosh(\kappa h)} + \frac{1}{2}\left(\psi_{01}^2-\psi_{02}^2\right)\{1-\tanh(\kappa h)\}\right] \quad (34.12)$$

2. Interaction energy between two spheres 1 and 2 of radii a_1 and a_2 carrying unperturbed surface potentials ψ_{01} and ψ_{02}, respectively, at separation H between their surfaces

$$V_{\rm sp}^{\psi}(H) = \pi\varepsilon_{\rm r}\varepsilon_0\frac{a_1a_2}{a_1+a_2}\left\{(\psi_{01}+\psi_{02})^2\ln(1+e^{-\kappa H}) + (\psi_{01}-\psi_{02})^2\ln(1-e^{-\kappa H})\right\} \quad (34.13)$$

$$V_{\rm sp}^{\sigma}(H) = \pi\varepsilon_{\rm r}\varepsilon_0\frac{a_1a_2}{a_1+a_2}\left\{-(\psi_{01}+\psi_{02})^2\ln(1-e^{-\kappa H}) - (\psi_{01}-\psi_{02})^2\ln(1+e^{-\kappa H})\right\} \quad (34.14)$$

$$V_{\rm sp}^{\psi-\sigma}(H) = 4\pi\varepsilon_{\rm r}\varepsilon_0\frac{a_1a_2}{a_1+a_2}\left\{\psi_{01}\psi_{02}\arctan(e^{-\kappa H}) + \frac{1}{4}\left(\psi_{01}^2-\psi_{02}^2\right)\ln(1+e^{-2\kappa H})\right\} \quad (34.15)$$

3. Interaction energy per unit length between two parallel infinitely long cylinders 1 and 2 of radii a_1 and a_2 carrying unperturbed surface potentials ψ_{01} and ψ_{02}, respectively, at separation H between their surfaces:

$$V_{\rm cy//}^{\psi}(H) = -2\varepsilon_{\rm r}\varepsilon_0\sqrt{\kappa}\sqrt{\frac{2\pi a_1a_2}{a_1+a_2}}\left[\left(\frac{\psi_{01}+\psi_{02}}{2}\right)^2 \mathrm{Li}_{1/2}(-e^{-\kappa H}) + \left(\frac{\psi_{01}-\psi_{02}}{2}\right)^2\mathrm{Li}_{1/2}(e^{-\kappa H})\right] \quad (34.16)$$

$$V_{\rm cy//}^{\sigma}(H) = 2\varepsilon_{\rm r}\varepsilon_0\sqrt{\kappa}\sqrt{\frac{2\pi a_1a_2}{a_1+a_2}}\left[\left(\frac{\psi_{01}+\psi_{02}}{2}\right)^2 \mathrm{Li}_{1/2}(e^{-\kappa H}) - \left(\frac{\psi_{01}-\psi_{02}}{2}\right)^2\mathrm{Li}_{1/2}(-e^{-\kappa H})\right] \quad (34.17)$$

$$V_{\rm cy//}^{\psi-\sigma}(H) = \sqrt{2}\varepsilon_{\rm r}\varepsilon_0\sqrt{\kappa}\sqrt{\frac{2\pi a_1a_2}{a_1+a_2}}\left[\psi_{01}\psi_{02}e^{-\kappa H}\times\Phi\left(-e^{-\kappa H},\frac{1}{2},\frac{1}{2}\right) - \frac{1}{2}\left(\psi_{01}^2-\psi_{02}^2\right)\mathrm{Li}_{1/2}(-e^{-2\kappa H})\right] \quad (34.18)$$

where $\mathrm{Li}_s(z) = \sum_{k=1}^{\infty} z^k/k^s$ and $\Phi(z,s,a) = \sum_{k=0}^{\infty} z^k/(k+a)^s$ are, respectively, a polylogarithm function and a Lerch transcendent.

4. Interaction energy between two crossed infinitely long cylinders 1 and 2 of radii a_1 and a_2 carrying unperturbed surface potentials ψ_{01} and ψ_{02}, respectively, at the closest separation H between their surfaces:

$$V_{\rm cy\perp}^{\psi}(H) = 4\pi\varepsilon_{\rm r}\varepsilon_0\sqrt{a_1a_2}\left[\left(\frac{\psi_{01}+\psi_{02}}{2}\right)^2\ln(1+e^{-\kappa H}) + \left(\frac{\psi_{01}-\psi_{02}}{2}\right)^2\ln\left(\frac{1}{1-e^{-\kappa H}}\right)\right] \quad (34.19)$$

$$V_{\rm cy\perp}^{\sigma}(H) = 4\pi\varepsilon_{\rm r}\varepsilon_0\sqrt{a_1a_2}\left[\left(\frac{\psi_{01}+\psi_{02}}{2}\right)^2\ln\left(\frac{1}{1-e^{-\kappa H}}\right) - \left(\frac{\psi_{01}-\psi_{02}}{2}\right)^2\ln(1+e^{-\kappa H})\right] \quad (34.20)$$

$$V_{\rm cy\perp}^{\psi-\sigma}(H) = 4\pi\varepsilon_{\rm r}\varepsilon_0\sqrt{a_1a_2}\left[\psi_{01}\psi_{02}\arctan(e^{-\kappa H}) + \frac{1}{4}\left(\psi_{01}^2-\psi_{02}^2\right)\ln(1+e^{-2\kappa H})\right] \quad (34.21)$$

It can be shown that the unperturbed surface potentials ψ_{01} and ψ_{02} of particles 1 and 2 are, respectively, related to the surface charge densities σ_1 and σ_2 by

$$\psi_{0i} = \frac{\sigma_i}{\varepsilon_{\rm r}\varepsilon_0\kappa} \quad (i=1,2) \quad (34.22)$$

34.2.4 Linear Superposition Approximation: Arbitrary Potential Case

Although it is generally difficult to derive the interaction energy between two particles with arbitrary surface potential, a simple approximation method [the linear superposition approximation (LSA)] is available to derive the interaction energy between particles at large particle separations $\kappa h \gg 1$ or

$\kappa H \gg 1$. Expressions for the interaction energy obtained with the help of the linear superposition approximation, which do not depend on the type of the double-layer interaction, can be applied both to the constant surface potential and constant surface charge density cases as well as their mixed case. In addition, the results obtained on the basis of the linear superposition approximation can be applied not only to hard particles. The interaction energy based on LSA involves the effective surface potentials $\psi_{\text{eff }1}$ and $\psi_{\text{eff }2}$ of two interacting particles, which are derived as follows.

Consider the interaction energy between two parallel plates 1 and 2 at separation h with arbitrary (unperturbed) surface potentials ψ_{01} and ψ_{02}, respectively, in a symmetric electrolyte solution of valence z and bulk concentration n. We take an x axis perpendicular to the plates with its origin at the surface of plate 1. The unperturbed potential distributions $\psi_1(x)$ and $\psi_2(x)$ for plates 1 and 2 in the absence of interaction, respectively, can be derived from by solving Eq. (34.1) for the present case with the result that

$$\psi_1(x) = \frac{2kT}{ze} \ln\left(\frac{1+\gamma_1 e^{-\kappa x}}{1-\gamma_1 e^{-\kappa x}}\right) \tag{34.23}$$

$$\psi_2(x) = \frac{2kT}{ze} \ln\left(\frac{1+\gamma_2 e^{-\kappa(h-x)}}{1-\gamma_2 e^{-\kappa(h-x)}}\right) \tag{34.24}$$

with

$$\gamma_1 = \tanh\left(\frac{ze\psi_{01}}{4kT}\right), \gamma_2 = \tanh\left(\frac{ze\psi_{02}}{4kT}\right) \tag{34.25}$$

The asymptotic forms of the unperturbed potentials $\psi_1(x)$ and $\psi_2(x)$ produced at large distances by plates 1 and 2, respectively, in the absence of interaction can be derived from Eqs. (34.23) and (34.24)

$$\psi_1(x) = \psi_{\text{eff1}} e^{-\kappa x} \tag{34.26}$$

$$\psi_2(x) = \psi_{\text{eff2}} e^{-\kappa(h-x)} \tag{34.27}$$

where ψ_{eff1} and ψ_{eff2} are, respectively, the effective surface potentials of plates 1 and 2

$$\psi_{\text{eff1}} = 4\gamma_1 = 4\tanh\left(\frac{ze\psi_{01}}{4kT}\right), \psi_{\text{eff2}} = 4\gamma_2 = 4\tanh\left(\frac{ze\psi_{02}}{4kT}\right) \tag{34.28}$$

The potential distribution $\psi(x)$ around the midpoint between plates 1 and 2 can thus be approximated by

$$\psi(x) = \psi_1(x) + \psi_2(x) = \psi_{\text{eff1}} e^{-\kappa x} + \psi_{\text{eff2}} e^{-\kappa(h-x)} \tag{34.29}$$

By noting that for large separation h, $\psi(x)$ is small so that Eq. (6) can be employed, we substitute Eq. (34.29) into Eq. (34.5) to obtain

$$P(h) = 2\varepsilon_r \varepsilon_0 \kappa^2 \psi_{\text{eff1}} \psi_{\text{eff2}} e^{-\kappa h} \tag{34.30}$$

The interaction energy $V(h)$ per unit area of plates 1 and 2 is thus

$$V_{\text{pl}}(h) = \int_h^\infty P_{\text{pl}}(h)dh = 2\varepsilon_{\text{r}} \varepsilon_0 \kappa \psi_{\text{eff1}} \psi_{\text{eff2}} e^{-\kappa h} \tag{34.31}$$

From Eq. (34.31) as combined with Derjaguin's approximation, the interaction energy between two spheres or cylinders of radii a_1 and a_2 at large separations can be derived. The results are given below.

1. Interaction energy per unit area between two parallel plates at separation h:

$$V_{\text{pl}}(h) = 2\varepsilon_{\text{r}} \varepsilon_0 \kappa \psi_{\text{eff1}} \psi_{\text{eff2}} e^{-\kappa h} \tag{34.32}$$

2. Interaction energy between two spheres of radii a_1 and a_2 at separation H:

$$V_{\text{sp}}(H) = \frac{4\pi a_1 a_2}{a_1 + a_2} \varepsilon_{\text{r}} \varepsilon_0 \psi_{\text{eff1}} \psi_{\text{eff2}} e^{-\kappa H} \tag{34.33}$$

3. Interaction energy per unit length between two parallel cylinders of radii a_1 and a_2 at separation H:

$$V_{\text{cy}//}(H) = 2\sqrt{\frac{2\pi a_1 a_2}{a_1 + a_2}} \sqrt{\kappa} \varepsilon_r \varepsilon_0 \psi_{\text{eff1}} \psi_{\text{eff2}} e^{-\kappa h} \tag{34.34}$$

4. Interaction energy between two crossed cylinders of radii a_1 and a_2 at separation H:

$$V_{\text{cy}\perp}(H) = 4\pi\sqrt{a_1 a_2} \varepsilon_{\text{r}} \varepsilon_0 \psi_{\text{eff1}} \psi_{\text{eff2}} e^{-\kappa H} \tag{34.35}$$

In the arbitrary potential case, tt can be shown that the unperturbed surface potentials ψ_{01} and ψ_{02} of particles 1 and 2 are, respectively, related to the surface charge densities σ_1 and σ_2 by

$$\psi_{0i} = \frac{\sigma_i}{\varepsilon_{\text{r}} \varepsilon_0 \kappa} \ (i = 1, 2) \tag{34.36}$$

which reduces to Eq. (23) for the low-potential limit.

34.3 INTERACTION BETWEEN SOFT PARTICLES

For the case of interaction between soft particles, one must solve the Poisson–Boltzmann equations for both regions inside and outside the surface layer [17–26]. Consider two parallel dissimilar soft plates 1 and 2 of thicknesses d_1 and d_2, respectively, separated by a distance h immersed in a liquid containing N ionic species with valence z_i and bulk concentration (number density) n_i^∞ ($i = 1, 2, \ldots, N$). We treat the case where fixed charges are distributed in the surface layers of plates 1 and 2 at uniform densities of ρ_{fix1} and ρ_{fix2}, respectively. We take an x axis perpendicular to the plates with its origin at the right surface of plate 1, as in Fig. 34.3

We assume that the electric potential $\psi(x)$ outside the plates ($0 < x < h$) obeys the following one-dimensional planar Poisson–Boltzmann equation:

$$\frac{d^2\psi(x)}{dx^2} = -\frac{1}{\varepsilon_r\varepsilon_0}\sum_{i=1}^{N} z_i e n_i^\infty \exp\left(-\frac{z_i e\psi(x)}{kT}\right) - \frac{\rho_{\text{fix1}}}{\varepsilon_r\varepsilon_0} \quad \text{for } -d_1 < x < 0 \tag{34.37}$$

$$\frac{d^2\psi(x)}{dx^2} = -\frac{1}{\varepsilon_r\varepsilon_0}\sum_{i=1}^{N} z_i e n_i^\infty \exp\left(-\frac{z_i e\psi(x)}{kT}\right) \quad \text{for } 0 < x < h \tag{34.38}$$

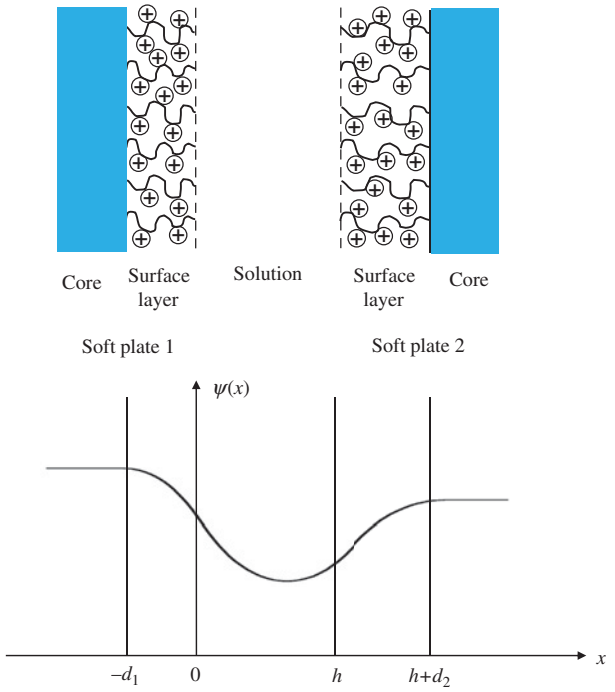

FIGURE 34.3 Interaction between two parallel dissimilar soft plates 1 and 2 covered with surface layers of thicknesses d_1 and d_2, respectively, at separation h and potential distribution $\psi(x)$ across them.

$$\frac{d^2\psi(x)}{dx^2} = -\frac{1}{\varepsilon_r\varepsilon_0}\sum_{i=1}^{N} z_i e n_i^\infty \exp\left(-\frac{z_i e\psi(x)}{kT}\right) - \frac{\rho_{\text{fix2}}}{\varepsilon_r\varepsilon_0} \quad \text{for } h < x < h + d_2 \tag{34.39}$$

By solving these equations subject to the appropriate boundary conditions, we can obtain the interaction energy between soft particles. The results for the low-potential case are given below.

1. Interaction energy per unit area between two parallel soft plates 1 and 2 carrying fixed charge densities ρ_{fix1} and ρ_{fix2}, respectively (Fig. 34.3):

$$V_{\text{pl}}(h) = \frac{1}{4\varepsilon_r\varepsilon_0\kappa^3}\left[\{\rho_{\text{fix1}}\sinh(\kappa d_1) + \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \left\{\coth\left(\frac{\kappa(h+d_1+d_2)}{2}\right) - 1\right\} - \{\rho_{\text{fix1}}\sinh(\kappa d_1) - \rho_{\text{fix2}}(\kappa d_2)\}^2 \left\{1 - \tanh\left(\frac{\kappa(h+d_1+d_2)}{2}\right)\right\}\right] \tag{34.40}$$

2. Interaction energy between two soft spheres of inner radii a_1 and a_2 and outer radii $b_1 = a_1 + d_1$ and $b_2 = a_2 + d_2$ carrying fixed charge densities $\rho_{\text{fix 1}}$ and $\rho_{\text{fix 2}}$, respectively (i.e., the thicknesses of the surface layers of soft spheres 1 and 2 are d_1 and d_2, respectively) (Fig. 34.4a):

$$V_{\text{sp}}(H) = \frac{1}{\varepsilon_r\varepsilon_0\kappa^4}\left(\frac{\pi b_1 b_2}{b_1 + b_2}\right)\left[\{\rho_{\text{fix1}}\sinh(\kappa d_1) + \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \ln\left(\frac{1}{1 - e^{-\kappa(H+d_1+d_2)}}\right) - \{\rho_{\text{fix1}}\sinh(\kappa d_1) - \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \ln(1 + e^{-\kappa(H+d_1+d_2)})\right] \tag{34.41}$$

3. Interaction energy per unit length between two parallel soft cylinders of inner radii a_1 and a_2 and outer radii $b_1 = a_1 + d_1$ and $b_2 = a_2 + d_2$ carrying fixed charge densities $\rho_{\text{fix 1}}$ and $\rho_{\text{fix 2}}$, respectively (i.e., the thicknesses of the surface layers of soft spheres 1 and 2 are d_1 and d_2, respectively) (Fig. 34.4b):

$$V_{\text{cy//}}(H) = \frac{1}{2\varepsilon_r\varepsilon_0\kappa^{7/2}}\sqrt{\frac{2\pi b_1 b_2}{b_1 + b_2}}\left[\{\rho_{\text{fix1}}\sinh(\kappa d_1) + \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \text{Li}_{1/2}(e^{-\kappa(H+d_1+d_2)}) + \{\rho_{\text{fix1}}\sinh(\kappa d_1) - \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \text{Li}_{1/2}(-e^{-\kappa(H+d_1+d_2)})\right] \tag{34.42}$$

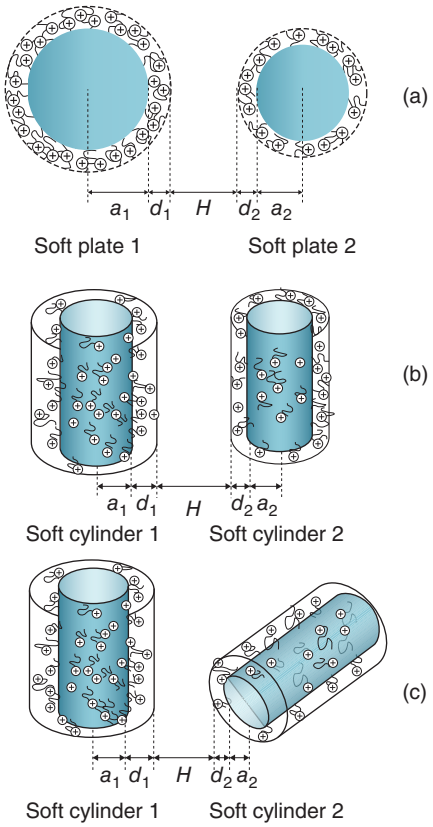

FIGURE 34.4 Interaction between two soft spheres or cylinders 1 and 2 of radii a_1 and a_2 covered with surface layers of thicknesses d_1 and d_2, respectively, at separation H: (a) two soft spheres; (b) two parallel soft cylinders; (c) two crossed soft cylinders.

4. Interaction energy between two crossed soft cylinders of inner radii a_1 and a_2 and outer radii $b_1 = a_1 + d_1$ and $b_2 = a_2 + d_2$ carrying fixed charge densities $\rho_{\text{fix }1}$ and $\rho_{\text{fix }2}$, respectively (i.e., the thicknesses of the surface layers of soft spheres 1 and 2 are d_1 and d_2, respectively) (Fig. 34.4c):

$$V_{\text{cy}\perp}(H) = \frac{\pi\sqrt{b_1 b_2}}{\varepsilon_r\varepsilon_0\kappa^4}\left[\{\rho_{\text{fix1}}\sinh(\kappa d_1) + \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \ln\left(\frac{1}{1-e^{-\kappa(H+d_1+d_2)}}\right) - \{\rho_{\text{fix1}}\sinh(\kappa d_1) - \rho_{\text{fix2}}\sinh(\kappa d_2)\}^2 \ln(1+e^{-\kappa(H+d_1+d_2)})\right] \tag{34.43}$$

For the arbitrary potential case, it can be shown that the interaction energy takes the same form as Eqs. (34.32)–(34.35) for hard particles, but the effective potential takes the different form from that for hard particles. It can be shown that the unperturbed surface potentials ψ_{01} and ψ_{02} of soft particles 1 and 2 are, respectively, related to the fixed charge densities ρ_{fix1} and ρ_{fix2} by

$$\psi_{0i} = \left(\frac{kT}{ze}\right)\left(\ln\left[\frac{\rho_{\text{fixi}}}{2zen} + \left\{\left(\frac{\rho_{\text{fixi}}}{2zen}\right)^2 + 1\right\}^{1/2}\right] + \frac{2zen}{\rho_{\text{fixi}}}\left[1 - \left\{\left(\frac{\rho_{\text{fixi}}}{2zen}\right)^2 + 1\right\}^{1/2}\right]\right) \quad (i = 1, 2) \tag{34.44}$$

which, for the low-potential limit, reduces to

$$\psi_{0i} = \frac{\rho_{\text{fixi}}}{2\varepsilon_r\varepsilon_0\kappa^2} \quad (i = 1, 2) \tag{34.45}$$

Note that if the ionized group of valence Z and number density N_i are distributed within the surface layer of particle i (i =1, 2), then we have $\rho_{\text{fix }i} = ZeN_i$. It is also to be noted that the unperturbed surface potential $\psi_{0\,i}$ of soft particle i (i = 1,2) with a thick surface layer ($d_i \gg 1/\kappa$) is related to the Donnan potential $\psi_{\text{DON }i}$ in the surface layer of particle i by

$$\psi_{0i} = \psi_{\text{DON}i} - \left(\frac{kT}{ze}\right)\tanh\left(\frac{ze\psi_{\text{DON}i}}{2kT}\right) \quad (i = 1, 2) \tag{34.46}$$

where the Donnan potential $\psi_{\text{DON }i}$ is given by

$$\psi_{\text{DON}i} = \left(\frac{kT}{ze}\right)\text{arcsin h}\left(\frac{\rho_{\text{fix}i}}{2zen}\right) = \left(\frac{kT}{ze}\right)\ln\left[\frac{\rho_{\text{fix}i}}{2zen} + \sqrt{\left(\frac{\rho_{\text{fix}i}}{2zen}\right)^2 + 1}\right] \tag{34.47}$$

Equation (34.47) reduces to $\psi_{0\text{i}} = \psi_{\text{DON}i}/2$ (i = 1, 2) in the low-potential limit.

34.4 INTERACTION BETWEEN TWO SOFT PARTICLES AFTER CONTACT

In this section we consider two theoretical models for the interaction between two parallel soft plates, that is, a two-stage model and a three-stage model

34.4.1 Two-Stage Model

de Gennes [27] proposed a theory of the interaction between two colloidal particles covered with graft polymers (i.e., polymer brush layers), assuming that when the two brushes come into contact, they are squeezed against each other but they do not interdigitate. If brushes are charged, then electrostatic repulsion between brushes must also be taken into

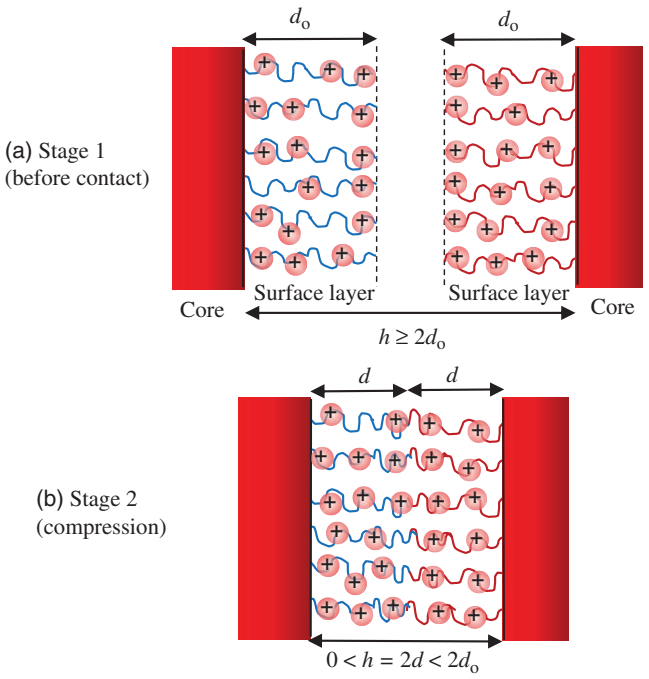

FIGURE 34.5 A two-stage model [28] for the interaction between two parallel plates covered with polyelectrolyte brush layers at separation h, where d_0 is the thickness of the intact brush layer. (a) *Stage 1*–interaction at $h \geq 2d_0$ before the two brushes come into contact. (b) *Stage* 2–after the two brush layers come into contact, compression of the interacting brush layers occurs with decreasing h for $0 < h = 2d < 2d_0$. The thickness d of the interacting brush layers, which is always equal to $h/2$, decreases as compression proceeds with decreasing h.

account in addition to the steric repulsion. Ohshima [28] extended the model of de Gennes [27] to the case of charged polymer brushes (polyelectrolyte brushes) and obtained an expression for the electrostatic repulsion between brushes after they come into contact. In this theory we restricted ourselves to the case where the brushes are squeezed against each other but they do not interdigitate. This model consists of two stages: (1) interaction before contact and (2) interaction between two compressed brush layers (Fig. 34.5).

34.4.1.1 Stage 1: Interaction before Contact. First we consider the electrostatic interaction between two parallel similar plates covered with a layer of polyelectrolyte brushes of intact thickness d_0 at separation h immersed in a solution of infinitely large volume containing an electrolyte of valence z and bulk concentration (number density) n. We first treat the case where the brush layers on the interacting plates at separation h are not in contact ($h \geq 2d_0$). We assume that dissociated groups of valence Z are uniformly distributed in the intact brush layer at a number density of N_0. It can be shown that the repulsion per unit area between two parallel soft plates before contact is approximately given by

$$P(h) = 64nkT \tanh^2(y_0/4) \exp[-\kappa(h - 2d_0)] \quad h \geq 2d_0, \tag{34.48}$$

where y_0 is the scaled unperturbed potential at the front edge of the intact brush layer (i.e., the potential at the boundary between the brush layer and the surrounding electrolyte solution before the two brushes come into contact) and is given by

$$\begin{aligned} y_0 &= y_{\text{DON}} - \tanh(y_{\text{DON}}/2) \\ &= \ln\left[\frac{ZN_0}{2zn} + \sqrt{\left(\frac{ZN_0}{2zn}\right)^2 + 1}\right] \\ &\quad + \frac{2zn}{ZN_0}\left[1 - \sqrt{\left(\frac{ZN_0}{2zn}\right)^2 + 1}\right] \end{aligned} \tag{34.49}$$

34.4.1.2 Stage 2: Repulsion between Compressed Brush Layers. Next we consider the situation after the two brushes come into contact. In this case the thickness of each compressed brush layer, which we denote by d ($\leq d_0$), is always half the separation h:

$$h = 2d \leq 2d_0 \tag{34.50}$$

Since the density of dissociated groups increases as h decreases, it is now a function of h. We denote by $N(h)$ the density of dissociated groups after contact. Following de Gennes [27], we assume that when the two brushes come into contact, they are squeezed against each other but they do not interdigitate. We also assume that the brushes are contracted in such a way that the density of dissociated groups is always uniform over the compressed brush layers. In other words, the product of $N(h)$ and d is constant and always equal to $N_0 d_0$:

$$N(h)d = N(h) \cdot \frac{h}{2} = N_0 d_0 \tag{34.51}$$

The interaction force $P_e(h)$ per unit area between the two brush layers after contact is thus given by

$$P(h) = 2nkT\left[\sqrt{1 + \left(\frac{ZN_0 d_0}{znh}\right)^2} - 1\right], 0 < h \leq 2d_0 \tag{34.52}$$

Equation (34.52) is the required expression for the interaction force $P(h)$ per unit area between two charged brush layers after they come into contact.

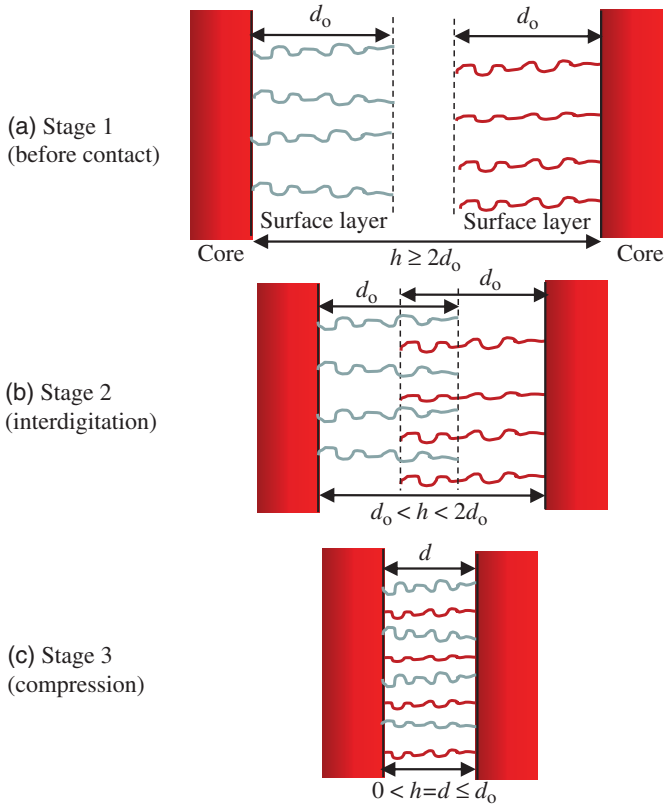

FIGURE 34.6 A three-stage model [29] for the interaction between two parallel plates covered with polyelectrolyte brush layers at separation h, where d_0 is the thickness of the intact brush layer. (a) *Stage 1*–interaction at $h \geq 2d_0$ before the two brush layers come into contact. (b) *Stage 2*–after the two brush layers come into contact, interdigitation of the two interacting brush layers proceeds with decreasing h for $d_0 \leq h < 2d_0$ until full interdigitation occurs at $h = d_0$ (stage 2). The thickness of the interacting brush layer remains constant at d_0. (c) *Stage 3*–compression of the interacting brush layers occurs with further decreasing h for $0 < h = d < d_0$. The thickness d of the interacting brush layers, which is always equal to h, decreases as compression proceeds with decreasing h.

34.4.2 Three-Stage Model

This model assumes that the interaction process consists of three stages: 1–3 [29] (Fig. 34.6).

Stage 1 corresponds to interaction before contact of the brushes of the interacting plates. In stage 2 interdigitation proceeds until the front edge of the polymer brush on either one of the interacting plates reaches the surface of the opposing plate core, that is, until full interdigitation occurs. In stage 3, after full interdigitation, compression of the polyelectrolyte brushes starts.

34.4.2.1 Stage 1: Interaction before Contact. The interaction force per unit area between two parallel soft plates before contact is approximately given by Eq. (34.49).

34.4.2.2 Stage 2: Repulsion between Interdigitated Brushes. Consider the interaction between two parallel interdigitated brushes as shown in Fig. 34.6 (stage 2). In this figure, the regions $0 < x < h–d_0$ and $d_0 < x < h$ correspond to intact brushes and the region $h–d_0 < x < d_0$ to interdigitated brushes. Note that the density of ionized groups is N_0 for the regions $0 < x < h–d_0$ and $d_0 < x < h$ and $2N_0$ for the region $h–d_0 < x < d_0$ due to interdigitation. Thus the scaled Donnan potential y_{DON1} in the regions $0 < x < h–d_0$ and $d_0 < x < h$ is given by

$$y_{DON1} = \text{arcsin h}\left(\frac{ZN_0}{2zn}\right) = \ln\left[\frac{ZN_0}{2zn} + \sqrt{\left(\frac{ZN_0}{2zn}\right)^2 + 1}\right] \tag{34.53}$$

and the scaled Donnan potential y_{DON2} in the region $h–d_0 < x < d_0$ is given by

$$y_{DON2} = \text{arcsin h}\left(\frac{ZN_0}{zn}\right) = \ln\left[\frac{ZN_0}{zn} + \sqrt{\left(\frac{ZN_0}{zn}\right)^2 + 1}\right] \tag{34.54}$$

Further we introduce

$$\kappa_1 = \kappa\sqrt{\cosh(y_{DON1})}, \kappa_2 = \kappa\sqrt{\cosh(y_{DON2})} \tag{34.55}$$

where κ_1 and κ_2 can be interpreted as the Debye-Hückel parameters in the regions $0 < x < h- d_0$ and $d_0 < x < h$ and in the region $h-d_0 < x < d_0$, respectively. It can be shown that the electrostatic force $P(h)$ per unit area between two parallel interdigitated brushes at separation h is given by

$$\begin{aligned} P(h) = 4nkT \Bigg\{ & \sinh^2\left[\frac{y_{DON2}}{2} - \frac{(y_{DON2} - y_{DON1})}{2G(h)}\right. \\ & \left.\sinh(\kappa_1(h-d_0)) \cdot \cosh\left(\kappa_2\left(\frac{h}{2} - d_0\right)\right)\right] \\ & -\frac{1}{4}\left(\frac{\kappa_2}{\kappa}\right)^2\left(\frac{y_{DON2} - y_{DON1}}{G(h)}\right)^2 \\ & \sinh^2[\kappa_1(h-d_0)] \cdot \sinh^2\left[\kappa_2\left(\frac{h}{2} - d_0\right)\right]\Bigg\} \\ & \text{for } d_0 < h < 2d_0 \end{aligned} \tag{34.56}$$

where $G(h)$ is defined by

$$\begin{aligned} G(h) = & \sinh[\kappa_1(h-d_0)]\cosh\left[\kappa_2\left(\frac{h}{2} - d_0\right)\right] \\ & -\left(\frac{\kappa_2}{\kappa_1}\right)\cosh[\kappa_1(h-d_0)]\sinh\left[\kappa_2\left(\frac{h}{2} - d_0\right)\right] \end{aligned} \tag{34.57}$$

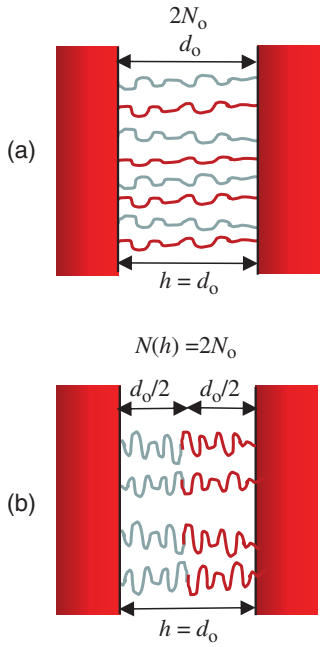

FIGURE 34.7 Interaction at $h = d_0$ for a three-stage model (a) and a two-stage model (b). The densities of ionized groups have the same value of $2N_0$ for two cases (a) fully interdigitated brushes of thickness d_0 at separation $h = d_0$ (at transition from stage 2 to stage 3 in a three-stage model) and (b) half-compressed brush layers of thickness $d/2$ at separation $h = d_0$ (at stage 2 in a two-stage model).

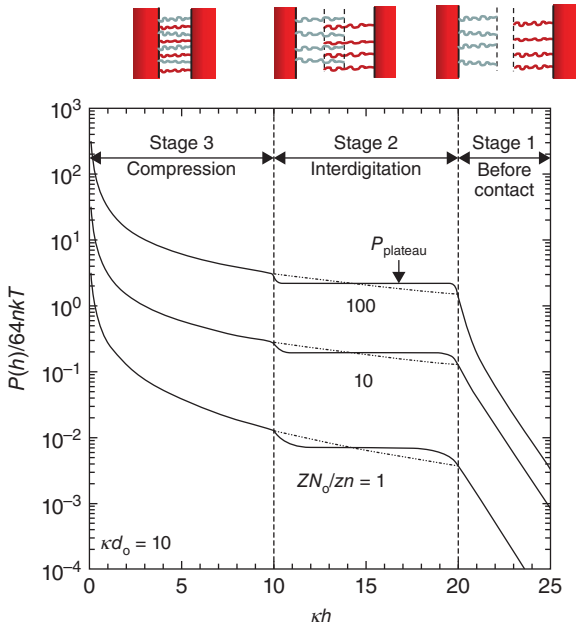

FIGURE 34.8 Scaled repulsion $P/64nkT$ per unit area between two parallel plates covered with a polymer brush layer as a function of scaled separation κh for $ZN_0/zn = 1$, 10, and 100 (i.e., $y_{DON1} = 0.4812, 2.312, 4.605$; $y_{DON2} = 0.8814, 2.998, 5.298$, respectively) at $\kappa d_0 = 10$. Solid lines represent stage 1 (interaction before contact) ($h \geq 2d_0$), stage 2 (interdigitation proceeds for $d_0 \leq h < 2\,d_0$), and stage 3 (compression proceeds for $0 \leq h < d_0$) [29]. Dotted lines correspond to the two stage-model [28].

34.4.2.3 Stage 3: Repulsion between Compressed Brushes. Consider the interaction between two brushes at separation $h = d_0$, where the front edge of each of the brush layer just reaches the surface of the opposing core. As is illustrated in Fig. 34.7a, the density of ionized groups becomes twice ($2N_0$) as large as that of the intact brush layer (N_0). This situation is the same as the situation when the same brush layers (carrying the intact thickness d_0 and the density N_0 of ionized groups) are half compressed so that the density of ionized groups becomes twice ($2N_0$) as large as that of the intact brush layer (N_0) (Fig. 34.7b).

With further decreasing h, compression of the brush layers in the present model (*with* stage 2) and that in the previous model (*without* stage 2) both proceed in the same way. Thus as long as stage 3 ($0 < h < d_0$) is concerned, the three-stage model and the two-stage model become equivalent, both giving the same force expression $P(h)$. The interaction force $P(h)$ per unit area between the two brush layers is thus given by Eq. (34.52):

$$P(h) = 2nkT\left[\sqrt{1 + \left(\frac{ZN_0 d_0}{znh}\right)^2} - 1\right] \quad \text{for } 0 < h \leq d_0 \tag{34.58}$$

It is seen that Eq. (34.58) is the same as the result for the previous model without stage 2.

In Fig. 34.8 we give some results of the calculation of the interaction force $P(h)$ acting between two parallel polyelectrolyte brush layers as a function of reduced separation κh for several values of ZN_0/zn at scaled brush thickness $\kappa d_0 = 10$ (Fig. 34.8).

In Fig. 34.8 we also plot the result of the two-stage model (dotted lines). We see that the interaction force is always repulsive before and after the two brushes come into contact. We see that for large ZN_0/zn and thus high y_{DON1} and y_{DON2}, in stage 2 the interaction force $P(h)$ becomes almost constant independent of plate separation h. This plateau value $P_{plateau}$ is obtained from Eq. (34.56)

$$P_{plateau} = 4nkT\left\{\sinh^2\left[\frac{y_{DON1} + \sqrt{2}y_{DON2}}{2(1+\sqrt{2})}\right] - \left(\frac{y_{DON1} - y_{DON2}}{2(1+\sqrt{2})}\right)^2 \cosh(y_{DON2})\right\} \tag{34.59}$$

which is independent of h and d_0.

34.5 ELECTROSTATIC INTERACTION BETWEEN TWO INTERPENETRATING SOFT PARTICLES

In this section we give a three-stage model of the electrostatic interaction between two interpenetrating charged spherical soft particles with no particle core (space-charged porous spheres) in an electrolyte solution [30] (Fig. 34.9).

In other words, there are three stages: (1) interaction before contact between the two spheres, (2) partial interpenetration, and (3) full interpenetration, that is, engulfing of one sphere by the other. This is an extension of the work of Dähnert and Rödenbeck [31], who considered the interaction between two interpenetrating vesicle-like surface-charged particles, to the case of the interaction of space charge porous spheres. Analytic expressions for the interaction energy and force between two interpenetrating weakly charged porous spheres as a function of particle separation are derived for the respective stages on the basis of the linearized Poisson–Boltzmann equations for the electric potential distribution.

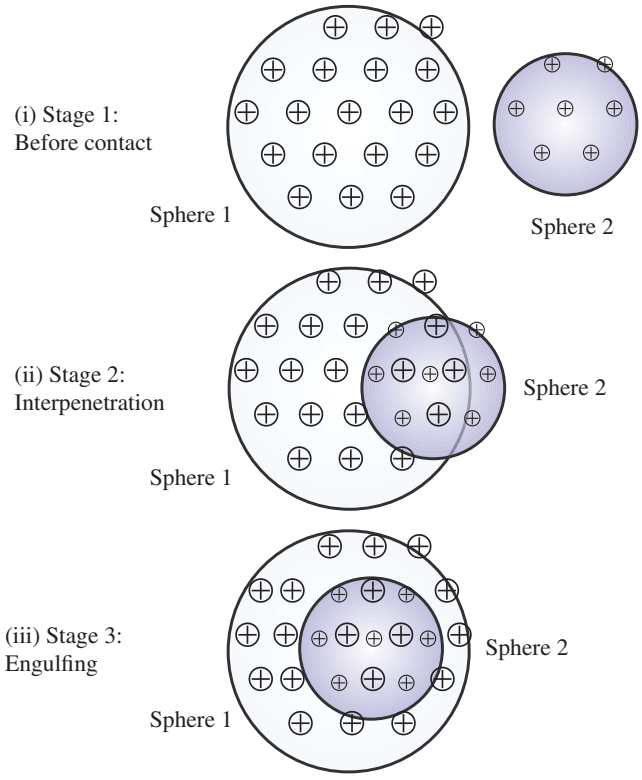

FIGURE 34.9 Three-stage model for the electrostatic interaction between two charged soft spheres 1 and 2: (a) before contact, (b) interpenetration, (c) engulfing.

34.5.1 Linearized Poisson–Boltzmann Equations for Two Interacting Charged Porous Spheres

Consider two charged porous spheres of radii a_1 and a_2 carrying fixed charges of constant volume densities ρ_1 and ρ_2, respectively, at separation R between their centers O_1 and O_2 in an electrolyte solution containing N ionic species with valence z_i and bulk concentration (number density) n_i ($i = 1,2, \ldots, N$) (in units of m^{-3}) in three stages: (1) interaction before contact, (2) interpenetration, and (3) engulfing [30]. Without loss of generality, we may treat the case in which the radius a_1 of sphere 1 is larger than or equal to the radius a_2 of sphere 2:

$$a_1 \geq a_2 \tag{34.60}$$

We assume that the relative permittivity in spheres 1 and 2 take the same value ε_r as that of the electrolyte solution and that the electrical potential ψ is low enough to allow the linearization of the Poisson–Boltzmann equations for ψ.

The linearized Poisson–Boltzmann equation in the respective regions can generally be given by

$$\Delta\psi = \kappa^2\psi - \frac{\rho}{\varepsilon_r\varepsilon_0} \tag{34.61}$$

where ρ is the fixed charge density in the respective regions in three stages. For example, in stage 2 (Fig. 34.10),

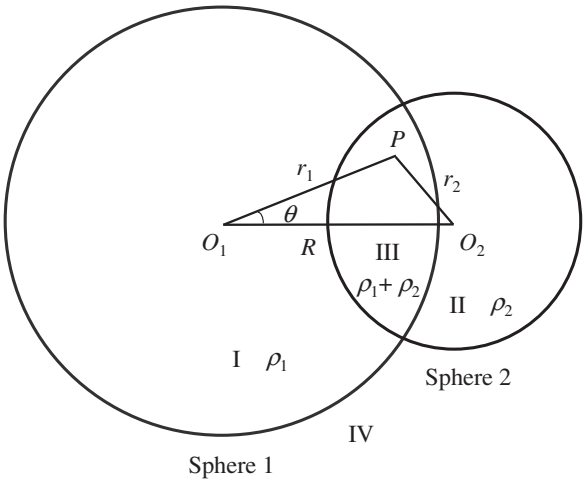

FIGURE 34.10 Interaction between two interpenetrating spheres 1 and 2 at separation R between their centers. $a_1 - a_2 < R < a_1 + a_2$. Region I: inside sphere 1 and outside sphere 2. Region II: inside sphere 2 and outside sphere 1. Region III: inside both spheres 1 and 2. Region IV: outside both spheres 1 and 2. A reference point P lies in region III.

we have

$$\rho = \begin{cases} \rho_1 & \text{for region I} \\ \rho_2 & \text{for region II} \\ \rho_1 + \rho_1 & \text{for region III} \\ 0 & \text{for region IV} \end{cases} \tag{34.62}$$

The solution to Eq. (34.61) can be expressed as the sum

$$\psi = \psi_1 + \psi_2 \tag{34.63}$$

where ψ_1 and ψ_2 are, respectively, the unperturbed potentials for spheres 1 and 2 in the absence of the interaction between the two spheres. It can be shown that the interaction energy $V(R)$ between two charged porous spheres 1 and 2 at separation R is given as follows.

34.5.1.1 Stage 1: Interaction between Two Porous Spheres before Contact.

$$V(R) = \frac{4\pi a_1 a_2 \rho_1 \rho_2}{\varepsilon_r \varepsilon_0 \kappa^4} \left\{ \cosh(\kappa a_1) - \frac{\sinh(\kappa a_1)}{\kappa a_1} \right\} \left\{ \cosh(\kappa a_2) - \frac{\sinh(\kappa a_2)}{\kappa a_2} \right\} \frac{e^{-\kappa R}}{R} \quad \text{for } R \geq a_1 + a_2 \tag{34.64}$$

34.5.1.2 Stage 2: Interaction between Two Partially Interpenetrating Charged Porous Spheres.

$$\begin{aligned} V(R) = \frac{2\pi a_1 a_2 \rho_1 \rho_2}{\varepsilon_r \varepsilon_0 \kappa^4 R} \Bigg[& \frac{1}{\kappa^2 a_1 a_2} \left\{ 1 + \frac{\kappa^2}{2} \left(R^2 - a_1^2 - a_2^2 \right) \right\} \\ & + \frac{\kappa^2}{24 a_1 a_2} (R - a_1 - a_2)^2 \{ R^2 + 2(a_1 + a_2) R - 3(a_1 - a_2)^2 \} \\ & + \left(1 - \frac{1}{\kappa^2 a_1 a_2} \right) e^{-\kappa R} \cosh(\kappa(a_1 - a_2)) \\ & - \left(\frac{1}{\kappa a_1} - \frac{1}{\kappa a_2} \right) e^{-\kappa R} \sinh(\kappa(a_1 - a_2)) \\ & - \left(1 + \frac{1}{\kappa a_1} \right) \left(1 + \frac{1}{\kappa a_2} \right) e^{-\kappa(a_1 + a_2)} \sinh(\kappa R) \Bigg] \\ & \text{for } a_1 - a_2 \leq R \leq a_1 + a_2 \end{aligned} \tag{34.65}$$

34.5.1.3 Stage 3: Interaction for Case Where Sphere 2 Is Engulfed by Sphere 1.

$$V(R) = \frac{4\pi a_1 a_2 \rho_1 \rho_2}{\varepsilon_r \varepsilon_0 \kappa^4 R} \left[\frac{(\kappa a_2)^2 R}{3 a_1} - \left(1 + \frac{1}{\kappa a_1} \right) e^{-\kappa a_1} \left\{ \cosh(\kappa a_2) - \frac{\sinh(\kappa a_2)}{\kappa a_2} \right\} \sinh(\kappa R) \right] \quad \text{for } 0 \leq R \leq a_1 - a_2 \tag{34.66}$$

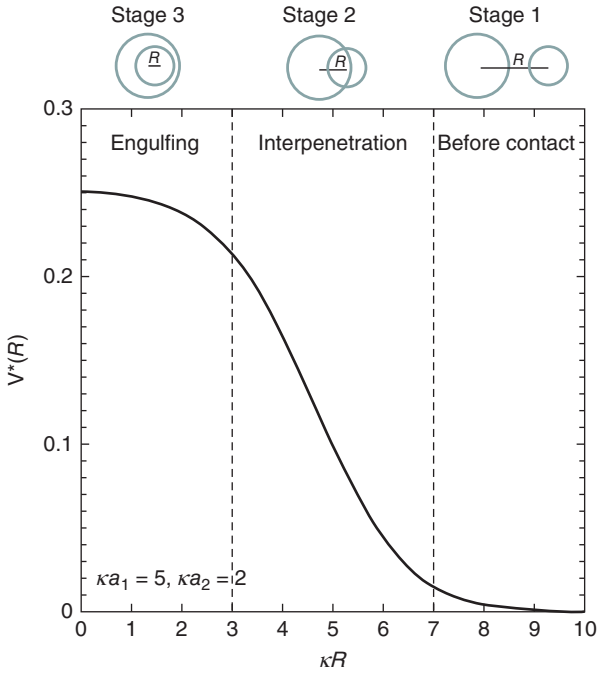

FIGURE 34.11 Scaled potential energy $V^*(R) = V(R)/(4\pi a_1 a_2 \rho_1 \rho_2/\varepsilon_r \varepsilon_0 \kappa^3)$ between two dissimilar charged soft particles with no particle core (porous spheres) 1 and 2 at separation R between their centers for three stages of interaction, that is, interaction before contact, interpenetration, and engulfing. Calculated with $\kappa a_1 = 5$ and $\kappa a_2 = 2$ [30].

Some results of the calculation of the interaction energy between two charged porous spheres are given in Fig. 34.11, which shows the results for the interaction between two dissimilar spheres with $\kappa a_1 = 5$ and $\kappa a_2 = 2$.

We see that the electrostatic interaction between two interpenetrating spheres is repulsive if the fixed volume charges ρ_1 and ρ_2 of the two spheres are of the same sign and attractive if they are of the opposite sign in all stages 1, 2, and 3 and that the interaction force $P(R)$ exhibits a maximum in magnitude in stage 2 and becomes zero at $R = 0$. At $R = 0$, at which the centers of spheres 1 and 2 coincide with each other, the potential energy $V(R)$ of the electrostatic interaction between two spheres 1 and 2 reaches a maximum in magnitude so that the interaction force $P(R)$ between the two spheres becomes zero. Note that the zero separation $R = 0$ corresponds to an unstable equilibrium for two likely charged spheres.

PHYSICOCHEMICAL PROPERTIES AND CLINICAL APPLICATIONS OF SURFACTANT-FREE EMULSIONS PREPARED WITH ELECTROLYTIC REDUCTION ION WATER (ERI)

KEN-ICHI SHIMOKAWA AND FUMIYOSHI ISHII

Department of Pharmaceutical Sciences, Meiji Pharmaceutical University, Tokyo, Japan

To facilitate the application of ERI lotion (surfactant-free emulsions containing ERI) as a component of medical drugs, we evaluated the healing effects of this water on burn wounds. A 15-month-old boy had a burn injury caused by boiling water that extended from the left forearm to the hand. An extensive skin defect was observed from the left forearm to the dorsum of the hand, and a II_b/III-degree burn was diagnosed. The burn was treated by applying ERI lotion, antibiotic/steroid combination ointment, and vitamin A/E ointment with wrap therapy. Skin color was almost normal after 74 days, and no functional impairment was observed, showing a favorable course. The burn wound completely healed without the formation of a hypertrophic or keloid scar or pigmentation. These results suggested that extensive II/III burns may be treated adequately with this topical therapy.

Since surfactant agents markedly damage skin tissue sensitized by, for example, burn wounds and atopic dermatitis, surfactant-free emulsions are expected to be the new bases of drugs for external use.

35.1 INTRODUCTION

The electrolysis of water containing a small amount of salt produces a form of water that is useful and generally known as *functional electrolyzed water*. Various types of functional water can be produced depending on the electrolysis conditions used, and these types of water have been classified into two major categories. One is functional electrolyzed acidic water, which is generated at the anode and is used mainly for sterilization. The other is functional electrolyzed alkaline water, which is generated at the cathode and is used primarily for drinking and washing [1,2]. Many studies have examined electrolyzed acid water, and revealed that it has strong bactericidal activity and is safe and environmentally friendly. Therefore, this water has been used in various fields [3–5] such as washing food [6, 7] and medicine [8–11].

Functional electrolyzed alkaline water is used as drinking water, as a supplement to sustain and promote health, and as a treatment. However, few studies have examined functional electrolyzed alkaline water, and its usefulness has not been adequately confirmed.

We previously conducted several studies on ERI [12–21]. The resulting ERI produced using the general method of producing functional electrolyzed water was physically electron-rich water that was obtained after the application of electric current–voltage to water containing a small amount of salt using a special diaphragm system. This water was found to have cleansing, deodorizing, antimicrobial, and antidust actions because its potent alkalinity and negatively charged ions detached and removed dirt and bacteria that cause odor [12]. Since ERI prevents oxidation, it also has rust-preventing and antiseptic actions. Furthermore, stable emulsions of various types of oils have been prepared using ERI with no emulsifiers, thereby demonstrating its emulsifying action [13, 14]. Capitalizing on these properties, ERI

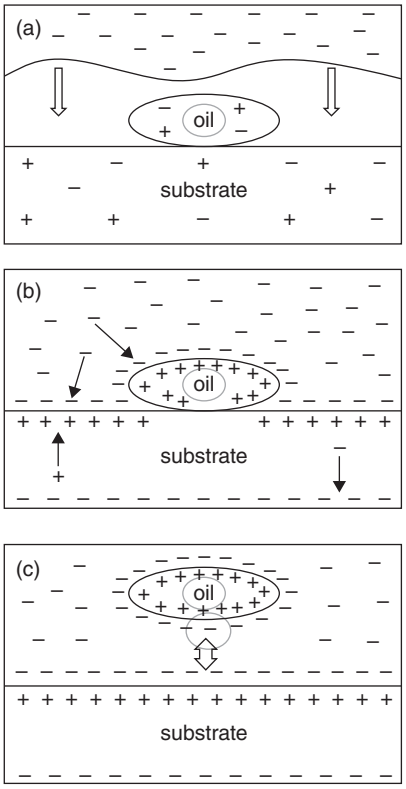

FIGURE 35.1 The mechanism of cleansing by ERI. (a) When ERI comes into contact with oil, the surface of oil becomes positively charged because of the large amount of negatively charged ions. (b) The oil surface with cations attracts anions, and these anions envelop the oil surface and simultaneously cover the oil surface. (c) The anions as a group on the oil surface and those on the oil surface electrostatically repel each other, and their separation promotes the detachment phenomenon.

is widely used as a cleansing agent in various industrial products [12].

The mechanism of cleansing with ERI is as follows. ERI is anionic water that contains a large amount of negatively charged electrons obtained from ion exchange membranes and electrodes by electrolysis. Therefore, when ERI comes into contact with oil, the surface of the oil becomes positively charged, due to the large amount of negatively charged ions (Fig. 35.1a). The oil surface with cations attracts anions, and these anions envelop the oil surface and simultaneously cover the substrate surface (Fig. 35.1b). The anions as a group on the oil surface and those on the substrate surface electrostatically repel each other, and their separation promotes the detachment phenomenon (Fig. 35.1c) [12].

Surfactant-free stable emulsions have been prepared using these properties, and their function has been reported in detail [12]. Emulsions prepared using emulsifier-free electrolytic reduction ion water coagulate less, are more stable, and have a shorter particle diameter than do emulsions prepared using an emulsifier (egg lecithin). Therefore, utilizing the emulsification effect of electrolytic reduction ion water, surfactant-free stable emulsions can be prepared to reduce skin reactions to surfactant stimulation or allergic reactions. This electrolytic reduction ion water is expected to be particularly applicable to medical drugs, cosmetics [13, 14], and foods that are used for a prolonged period.

Magnesium aluminum silicate is a sheet-type clay mineral and a saponite in the smectite group. Magnesium aluminum silicate markedly increases viscosity and is thixotropic when dispersed in various types of solvents; therefore, they can be used as agents to improve the textures of cosmetics, prevent pigment sedimentation in paints, catalyze specific reactions, add adsorptive properties to functional films, and prevent the dripping of adhesives [22]. Smectites have a basic three-layered structure (tetrahedral–octahedral–tetrahedral layers) in which an octahedral layer with an Mg atom in the center and six apical oxygen atoms is present between regular tetrahedral layers with an Si atom in the center and four apical oxygen atoms. The surface layer of saponite is negatively charged because of the isomorphous substitution of parts of Si and Mg in the smectite structure with Al. Therefore, saponite increases its volume more than 10-fold when dispersed in water due to ion adsorption and water entry into the interlayer areas, thereby forming a highly viscous gel.

We previously prepared magnesium aluminum silicate solutions using various solvents including ERI, and reported their rheology characteristics by measuring oscillation with a stress control-type rheometer [15]. Using ERI as a dispersion medium, the gel–sol conversion occurred at a low frequency (external factor). In addition, gel was prepared using ERI containing magnesium aluminum silicate, and gel characteristics for various types of salt were evaluated in detail [16]. The findings obtained revealed that the presence of Ca^{2+} rendered the system unstable, whereas uni- and multivalent cations excluding Ca^{2+} markedly improved gel stability.

Emulsions for medicine such as creams are generally prepared with lecithin as an amphoteric surfactant or polysorbate as a nonionic surfactant. Some surfactants excluding lecithin are known to induce stimulant dermatitis, and may sometimes cause allergic symptoms [5]. Surfactant-free emulsions are optimal for biological safety. However, emulsification itself is difficult in the absence of surfactants, and temporal stability is poor. Therefore, surfactant-free stable emulsions were prepared using the cleansing effects of ERI, and their functionalities were reported [13]. Surfactant-free emulsions prepared with ERI were more stable and had a smaller mean diameter than did those containing egg yolk lecithin as a surfactant. These findings suggested that skin-irritating reactions and allergic symptoms due to surfactants could be reduced by preparing surfactant-free stable emulsions using the emulsification effect of ERI. Therefore, we prepared magnesium aluminum silicate gel using ERI as a dispersion medium, and reported its physiochemical characteristics [15, 16].

In addition, to evaluate its application to medical drugs, we evaluated the healing-promoting effects of ERI on burns and atopic dermatitis, and demonstrated its effectiveness in alleviating these symptoms [17–20].

Taken together, the above findings indicate that ERI can be used to prepare drugs with a drug delivery system (DDS) that can better maintain the gel state than those prepared with purified water. ERI with emulsification characteristics and a gel drug-maintaining function are useful for preparing controlled release transdermal therapeutic drugs.

In this review, we described surfactant-free emulsions prepared by the addition of various types of oils to ERI containing magnesium aluminum silicate, and evaluated their physiochemical characteristics [21]. Surfactant-free emulsions may be used as the new bases for drugs for external use because surfactant agents have been shown to markedly damage skin tissue sensitized by, for example, burn wounds and atopic dermatitis. Therefore, we discussed the possibility of the clinical application of surfactant-free emulsions with a case report [18–20].

35.2 PREPARATION AND PHYSICOCHEMICAL PROPERTIES OF SURFACTANT-FREE EMULSIONS PREPARED WITH ERI CONTAINING MAGNESIUM ALUMINUM SILICATE

The surfaces of smectites are negatively charged by the isomorphous substitution of some silicate and magnesium ions by aluminum ions in the smectite structure, and this results in the formation of cardhouse structures. These cardhouse structures produce viscosity. The dispersion forms a gel with progression of cardhouse structures but forms a sol after the application of a shear force, thereby showing thixotropic properties. Smectites are widely used as rheology modifiers and texture enhancers, and particularly as a cosmetic material because they markedly increase viscosity and are highly thixotropic, spread well over the skin, and are non-greasy [23].

Therefore, various types of oils were added to ERI containing 3% magnesium aluminum silicate (GE100), and the physiochemical characteristics of the emulsions were evaluated [21]. Changes in the thixotropy of GE100 are shown in Fig. 35.2 and Table 35.1. In Fig. 35.2, the dotted and solid lines indicate thixotropy before and after ultrasonication, respectively. Shearing stress clearly increased after ultrasonication, and may have been because the honeycomb structure of magnesium aluminum silicate was more finely dispersed, resulting in denser binding.

In addition, as shown in Table 35.1, a comparison of thixotropy before and after ultrasonication showed a 60% increase in the hysteresis loop area rate after ultrasonication.

Oil concentrations of 0.1, 1 and 10% (jojoba oil, squalane, olive oil, or MCT) were subsequently added to GE100, and the mixtures were ultrasonicated. Changes in thixotropy are shown in Fig 35.3 and Table 35.2. Figure 35.3 shows that the shearing stress decreased as the concentration of each type of oil increased, and this was attributed to the suppressed formation of the card-house structures of magnesium aluminum silicate with an increase in the percentage of oil.

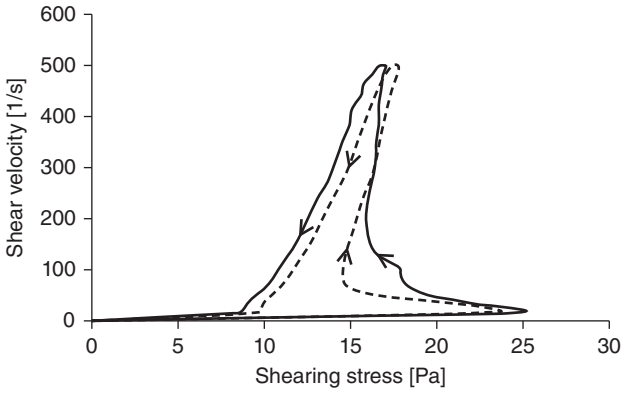

FIGURE 35.2 Thixotropic changes in magnesium aluminum silicate gels prepared using ERI (GE100) sonicated by ultrasonication. Dotted line, before ultrasonication; solid line, after ultrasonication. Each linear arrow shows the direction of the hysteresis loop.

The hysteresis loop area also decreased with an increase in the oil concentration, as shown in Table 35.2 and Fig. 35.3. The rate (%) of the hysteresis loop area of GE100 containing each type of oil to that of GE100 alone (2042 Pa/s) was the highest for MCT (143%) at a concentration of 0.1%, and the lowest also for MCT (58%) at a concentration of 10% (Fig. 35.4). On the other hand, GE100 containing olive oil showed high rates (134% and 103% at concentrations of 0.1% and 10%, respectively). In Table 35.2, thixotropy was compared among GE100 emulsions containing various types of oils at a concentration of 0.1% or 1% in terms of the rate (%) of the hysteresis loop area of GE100 containing each type of oil expressed as a percentage of that of GE100 alone (2042 Pa/s). The results obtained showed that the hysteresis loop area rate was more than 100% at a low oil concentration, which indicated that thixotropy was increased. An increase

TABLE 35.1 Effects of Ultrasonic Treatment on Hysteresis Loop Areas of Magnesium Aluminum Silicate Gels Prepared Using GE100

	Hysteresis loop area (Pa·1/s)	Area ratio (%)
GE100 before ultrasonication	1278 ± 33	100
GE100 after ultrasonication	2042 ± 67	160

Notes: GE100 = electrolytic reduction ion water (ERI) containing 3% magnesium aluminum silicate. Mean ± SD, $n = 3$.

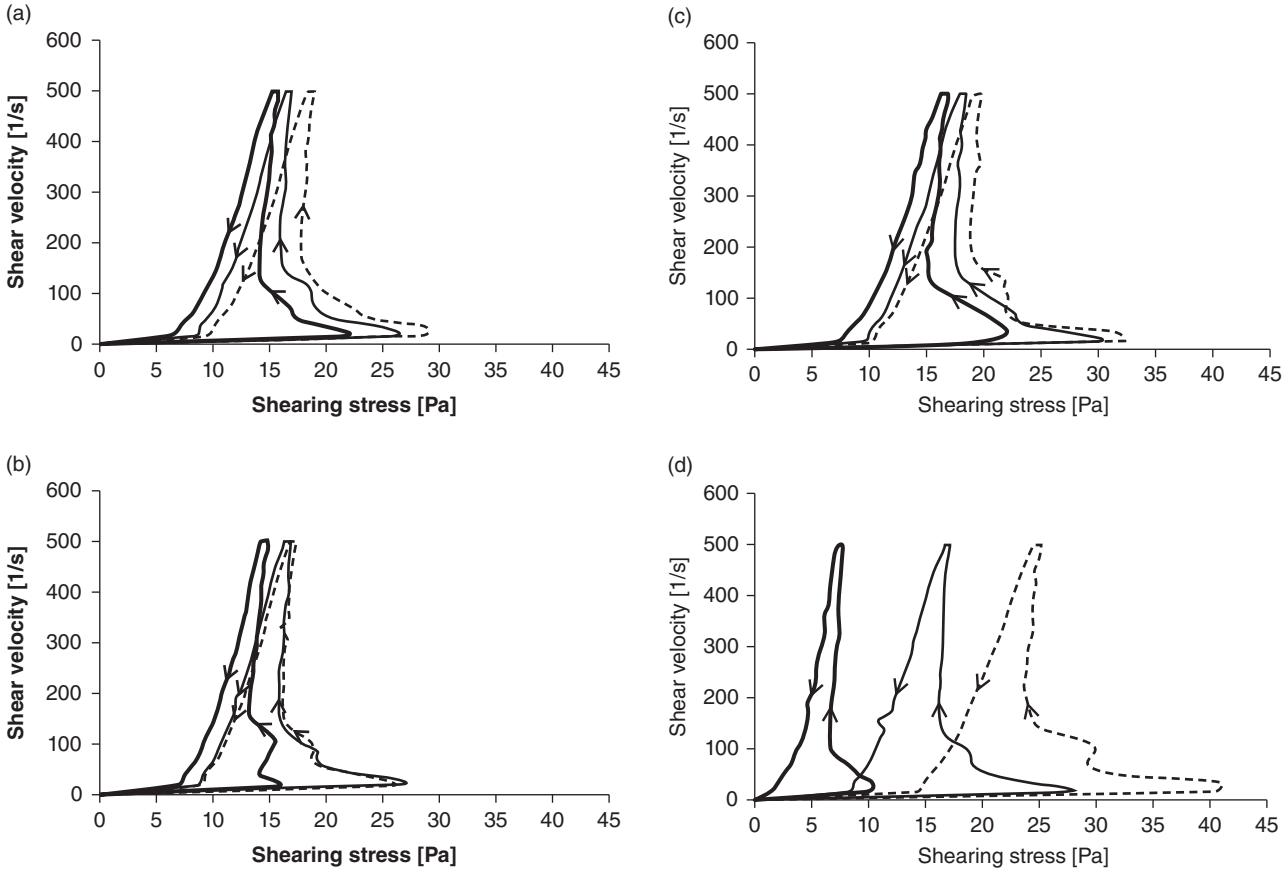

FIGURE 35.3 Thixotropic changes in different gels containing various oils. Dotted line, GE100 + 0.1% oil; thin solid line, GE100 + 1% oil; thick solid line, GE100 + 10% oil. (a) Jojoba oil; (b) squalene; (c) olive oil; (d) MCT. Each linear arrow shows the direction of the hysteresis loop.

in thixotropy reflected high viscosity in the static state and low viscosity after the application of a shear force. When an emulsion is topically applied to the skin, oil added to GE100 may allow a highly viscous state to be maintained, thereby providing moisturizing effects, and also improve viscosity and malleability. However, the hysteresis loop area rate was less than 100% in GE100 containing each type of oil at a concentration of 10%. This suggested that the formation of the cardhouse structures of magnesium aluminum silicate may have been prevented when the oil concentration in GE100 was increased. The hysteresis loop area rate was the lowest for MCT (58%), which may have been because MCT is a medium chain fatty-acid triglyceride of caprylic acid (8-carbon straight-chain fatty acid) and its viscosity is lower than that of the other long chain fatty acids. The hysteresis loop area rate of 10% olive oil was higher (103%) than that of the other types of oils at a concentration of 10%. This may have been because olive oil is a longchain fatty acid that

TABLE 35.2 Thixotropic Values of Emulsions Containing Various Oils

	Hysteresis loop area (Pa/s)		
GE100 + oil (%)	0.1%	1%	10%
GE100 only	–	–	2042 ± 67 (100)
GE100 + jojoba oil	2419 ± 138 (118)	2219 ± 152 (109)	1842 ± 62 (90)
GE100 + squalane	2039 ± 142 (100)	2178 ± 129 (107)	1485 ± 170 (73)
GE100 + olive oil	2741 ± 319 (134)	2496 ± 64 (122)	2101 ± 257 (103)
GE100 + MCT	2916 ± 377 (143)	2301 ± 76 (113)	1184 ± 124 (58)

Notes: Mean ± SD, $n = 3$.

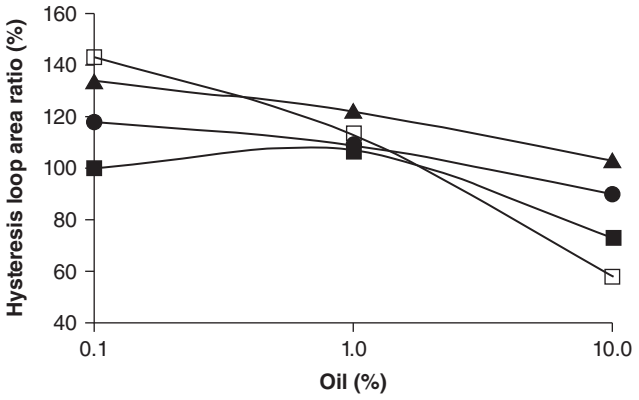

FIGURE 35.4 Relationship between content rate (%) of various oils and hysteresis loop area (• GE100 + jojoba oil; ■ GE100 + squalene; ▲ GE100 + olive oil; □ GE100 + MCT).

consists mainly of oleic acid (monounsaturated 18-carbon fatty acid), and the higher viscosity of this oil than MCT affects thixotropy. The dynamic viscosity of olive oil is known to be approximately 85 mPa · s at 20°C, whereas that of MCT is approximately 23 mPa · s [24].

The rate (%) of the hysteresis loop area of GE-100 containing each type of oil to that of GE-100 alone (2042 Pa/s) was the highest for MCT (143%) at a concentration of 0.1%, and the lowest also for MCT (58%) at a concentration of 10% (Fig. 35.3). On the other hand, GE-100 containing olive oil showed high rates (134 and 103% at concentrations of 0.1% and 10 %, respectively).

Table 35.3 shows the zeta-potential of the oil droplets in each emulsion. The zeta-potential of GE100 containing jojoba oil at concentrations of 0.1 and 1% was low (−38.3 and −37.3 mV, respectively). However, no significant differences were observed in the zeta potential among the other types of emulsions (range: −23.4 - −26.8 mV). A comparison of zeta potentials revealed that samples of GE-100 containing 0.1 or 1% jojoba oil had low values (Table 35.3).

Based on the Derjaguin–Landau–Verwey–Overbeek theory (DLVO theory) [25, 26], these results suggested that the emulsion containing jojoba oil at a low concentration may be more stable than the other emulsions.

The mean particle diameters of the oil droplets in each emulsion are shown in Table 35.4. The mean particle diameters were small for olive oil and MCT. According to the Stokes equation [I], the smaller the particle diameter, the lower the particle rise velocity. Therefore, emulsions of olive oil and MCT with small particle diameters may be more stable.

TABLE 35.3 Zeta-Potentials of Oil Droplets in Various Emulsions (mV)

GE100 + oil (%)	0.1	1	10
GE100 + jojoba oil	−38.3	−37.3	−22.3
GE100 + squalane	−26.9	−31.0	−26.4
GE100 + olive oil	−26.1	−26.5	−25.2
GE100 + MCT	−23.4	−30.5	−26.8

TABLE 35.4 Mean Diameters of Oil Droplets in Various Emulsions (nm)

GE100 + oil (%)	0.1%	1%	10%
GE100 + jojoba oil	363 ± 329	573 ± 278	452 ± 244
GE100 + squalane	355 ± 610	376 ± 832	471 ± 401
GE100 + olive oil	250 ± 204	271 ± 267	327 ± 475
GE100 + MCT	238 ± 182	266 ± 179	295 ± 299

Notes: Mean ± SD, $n = 220$.

$$v = \frac{d^2|\rho_0 - \rho|g}{18\eta} \tag{35.1}$$

where v = particle fall or rise velocity; d = particle diameter in the dispersed phase; ρ,ρ_0 = densities of the dispersed phase and dispersion medium, respectively; g = acceleration due to gravity; η = viscosity of dispersion medium.

These results on thixotropy and particle diameter indicate that when oil is added at a low concentration (0.1%), the MCT emulsions produced may have a better texture and be more stable, and when oil is added at a low (0.1%)–high (10%) concentration, the olive oil emulsions produced may have a better texture and be more stable (Tables 35.2 and 35.4).

Oil is added to GE100 because it moisturizes the skin when emulsions are applied [27]. In addition, fat-soluble drugs can be added to the oil layer and used as bases for drugs for external use. Potent steroids are initially used as a general treatment method for atopic dermatitis, and are changed to weaker steroids with the alleviation of symptoms [28]. However, synthetic surfactants such as sorbitan sesquioleate and glyceryl monostearate are used as emulsifiers, and have been shown to markedly damage sensitive skin tissue. In addition, drugs and cosmetics contain antiseptics such as paraoxybenzoic acid, which can cause allergic contact dermatitis and contact urticarial; therefore, concerns have been expressed regarding the influences of their long-term use on the skin [29].

The GE100 used in this study was ERI containing magnesium aluminum silicate, which is frequently used in cosmetics and improves the texture of the emulsion for topical application to the skin. Oil was added to this GE100 for moisturizing effects, and emulsions were prepared. The various types of oils evaluated in this study are currently used in drugs, cosmetics, and foods. The emulsions obtained by the addition of each oil can prevent the adverse effects associated with long-term use on the skin because of the absence

of surfactants, antiseptics due to the bactericidal effects of ERI (S100) as the main solvent of GE100, and antioxidative agents, such as dibutylhydroxytoluene, tocopherol [12], or ascorbic acid, due to the reductive effects of ERI itself. Oil-in-GE100 emulsions are expected to be used as new bases for external drugs.

35.3 EFFECTS OF ELECTROLYTIC REDUCTION ION WATER (ERI) LOTION PREPARED WITH SURFACTANT-FREE EMULSIONS ON BURN WOUND HEALING (CASE REPORT)

The main surgical primary emergency disorders observed in children include injuries, burns, inflammatory diseases, and the accidental ingestion of foreign bodies [30, 31]. Of these, the number of burn cases is high, and burns are often severe in infants. Local therapy with disinfectants and ointments containing steroids or antibiotics has conventionally been performed to inhibit infection of the wound surface when treating degree II/III burns. However, this conventional therapy has gradually changed to occlusive dressing therapy with wound dressings (such as polyurethane films, hydrocolloids, polyether foam, and hydrogels), which maintains the moist environment in the burn area and optimizes the repair function of the body [32–34]. Previous studies reported that plastic films for food wrapping (wrap films) can be inexpensive materials that are appropriate for dressings, and therapy using wrap films (wrap therapy) is an effective burn treatment method [35, 36].

In this case report, wrap therapy was performed as a conservative treatment with an ERI lotion, antibiotic/steroid combination ointment, and vitamin A/E ointment, and favorable results were obtained [19].

Case Report A 15-month-old male sustained a burn injury to the dorsum of the hand and was treated on an outpatient basis in another hospital. He was referred to our hospital 4 days after the injury. An extensive skin defect was observed over the entire dorsum of the hand. He was diagnosed with a II_b/III burn. The treatment course from the first consultation day to 130 days after the initiation of treatment is shown in Fig. 35.5.

Figure 35.5a shows the state of the damaged area on the first consultation day. Marked redness and swelling of the fingers and dorsum of the left hand and left wrist were observed. The central area of the dorsum of the hand was whitish in color. The skin was detached from the lower half of the fingers to the entire dorsum of the hand. Therefore, an ERI lotion (ERI containing 10% squalane, 5% jojoba oil, 4% glycerin, 3% algisium C, and 0.1%hyaluronic acid, A.I. System Products Corp., Aichi, Japan), antibiotic/steroid combination ointment (Hysetin-P® ointment containing chloramphenicol, fradiomycin sulfate, and prednisolone, Fuji Pharma Co., Ltd., Tokyo), and vitamin A/E ointment (Juvela® ointment containing tocopherol and vitamin A oil, Eisai Co., Ltd., Tokyo) were applied to the burn area, and wrap therapy was

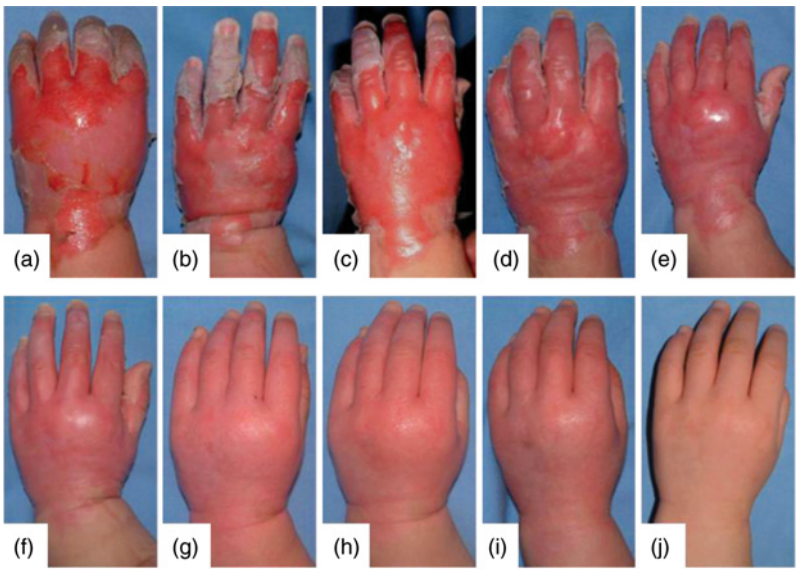

FIGURE 35.5 A case involving treatment of the dorsum of the left hand with ERI lotion, antibiotic/steroid combination ointment, and vitamin A/E ointment employing wrap therapy. (a) Before treatment; (b) day 2 after treatment; (c) day 3 after treatment; (d) day 5 after the treatment; (e) day 7 after treatment; (f) day 10 after treatment; (g) day 21 after treatment; (h) day 32 after treatment; (i) day 74 after treatment; (j) day 130 after treatment.

initiated. Figure 35.5b shows the state of the damaged area 2 days after the initiation of therapy. Redness and swelling were still observed, but swelling was slightly reduced. Redness and swelling were still present after 3–5 days (Fig. 35.5c,d). After 7 days, Hysetin-P ointment as the antibiotic/steroid ointment was changed to Dexan-G® ointment containing betamethasone valerate and gentamicin sulfate (Fuji Pharma Co., Ltd., Tokyo), and burn treatment was continued employing a similar method (Fig. 35.5e). Figure 35.5f shows the state of the damaged area after 10 days. Redness and swelling persisted despite a slight reduction in redness. Figure 35.5g shows the state of damaged area after 21 days. Skin redness further decreased, and there was no functional impairment. After 32 days, epithelialization of the dorsum of the hand was completed (Fig. 35.5h). Figure 35.5i shows the state of the hand after 74 days. Despite slight skin redness, no functional impairment was observed, showing a favorable course. Redness was negligible 130 days after the initiation of therapy (Fig. 35.5j). There was neither scar formation nor pigmentation, and skin color was normal in appearance. Therefore, the burn wound was considered to have completely healed.

Burn injuries often require surgical skin grafting depending on their depth in addition to conventional topical therapy. Our patients had II/III burns. However, since their parents hoped for treatment on an outpatient basis, wrap therapy was performed as a conservative treatment with an ERI lotion, antibiotic/steroid combination ointment, and vitamin A/E ointment. Hysetin-P ointment was changed to Dexan-G ointment 7 days after the initiation of therapy in this patient because ointments exhibiting the stronger anti-inflammatory activity of topical steroids are considered to be more effective.

In this case report, the tissue repair course for burn healing advanced smoothly, resulting in complete healing without the formation of a hypertrophic or keloid scar or pigmentation. These results suggest that extensive II/III burns can be adequately treated by topical therapy with an ERI lotion, antibiotic/steroid combination ointment, and vitamin A/E ointment.

STEADY-STATE COUPLING IN ENZYME MEMBRANE

KAZUO NOMURA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka, Japan

36.1 INTRODUCTION

The enzymatic reaction across an enzyme membrane is a coupled membrane phenomenon. Immobilization of an enzyme on the membrane enables its activity to be retained for a long time period; therefore, many types of membrane reactors using an enzyme as a catalyst have been designed to remove different kinds of residual organic compounds from water in the environment. Across the enzyme membrane, the artificially synthesized compounds can be decomposed by virtue of the enzyme from natural sources, where the reaction product is separated, concentrated and collected.

It has been pointed out that in the membrane system under a stationary-state condition, coupling phenomena between the material flows and the chemical reactions can be observed [1–3]. Steady-state coupling between the diffusion of the reaction participants and the velocity of the chemical reaction in an artificial enzyme membrane has been described in this chapter.

In the membrane systems consisting of a membrane with a bound enzyme and aqueous solutions, the enzymatic reaction and the diffusion of the reaction participants occur simultaneously [4,5], in which recovery of the reaction product concentrated into the aqueous phase on one side can be performed. Based on the distinct difference in membrane permeability to 4-nitrophenol and that to 4-nitrophenylphosphate, a membrane reactor system of an acid phosphatase–immobilized enzyme membrane, which is capable of separating and concentrating the product of the enzymatic hydrolysis without any other externally applied forces, has been designed, as described in a previous paper [6]. The observed steady-state recovery flux of the product has been found to obey the Michaelis-Menten equation.

On the other hand, based on the nonequilibrium thermodynamics, a general expression for the distribution depth of the reaction affinity within a membrane can be derived as the relaxation length of the reaction affinity, starting with the phenomenological equations for the reaction rate and diffusional fluxes of the reactants and products [2].

In this chapter, we describe how this theoretical approach has been applied to the membrane system with immobilized acid phosphatase to evaluate the degree of the steady-state coupling between the enzymatic reaction rate and the diffusional fluxes, determining the relaxation length, which is a function of the maximum reaction rate, the Michaelis constant, and the diffusion constants of the solutes [7].

36.2 THEORETICAL BACKGROUND

Based on linear nonequilibrium thermodynamics, a general expression for the distribution of the affinity of the chemical reaction within a membrane can be derived from the phenomenological equations given for the reaction rate and diffusional flows of the reactants and products under steady-state conditions [2,3]. In this study, this theoretical approach has been applied to a membrane with an immobilized enzyme to evaluate the degree of the steady-state coupling between the enzymatic reaction rate and the diffusional fluxes across the membrane in the linear region, determining the relaxation length, which is a function of the maximum reaction rate and

the Michaelis constant for the enzymatic reaction and the diffusion coefficients of the reaction participants.

We consider the membrane system in which a chemical reaction catalyzed by an enzyme, acid phosphatase, is taking place. For our system, the following reaction is included

$$\mathrm{S} \rightarrow \mathrm{P} + \mathrm{p} \tag{36.1}$$

where S, P, and p denote the substrate (4-nitrophenyl phosphate), the main product of the hydrolysis (4-nitrophenol), and phosphoric acid, respectively. In the enzyme membrane, the transports of the reactant and the products and the chemical reaction occur simultaneously.

According to nonequilibrium thermodynamics [1,8,9], the dissipation function Φ for the enzyme membrane system can be written in terms of a set of flows that includes the chemical reaction rate and the conjugate forces as

$$\Phi = T\sigma = \sum_i J_i \nabla(-\mu_i) + vA \ (i = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.2}$$

where σ denotes the internal entropy production (rate); T, J_i, and μ_i are the absolute temperature, the flux of solute i, and the chemical potential (total chemical potential) of solute i, respectively; and v and A are the chemical reaction rate and the chemical affinity for the chemical reaction, respectively. For the chemical reaction [Eq. (36.1)], the chemical affinity is expressed as

$$A = -\sum_i \nu_i \mu_i \ (i = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.3}$$

where ν_i denotes the stoichiometric coefficient of species i, that is, $\nu_{\mathrm{S}} = -1$, $\nu_{\mathrm{P}} = 1$, $\nu_{\mathrm{p}} = 1$. In terms of the dissipation function given by Eq. (36.2), flows can be described as a linear function of forces by a set of phenomenological equations

$$J_i = \sum_j l_{ij} \nabla(-\mu_j), \ v = l_{chem} A \ (i,j = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.4}$$

where the l_{ij} values and l_{chem} are the phenomenological coefficients. According to the Curie–Prigogine principle [1,2,8,9], a vector flow and a scalar flow cannot be coupled in the isotropic medium, so all the crossterms for the reaction rate and the diffusional fluxes of the solutes disappear in Eq. (36.4). An alternative set of phenomenological equations can be expressed in terms of the resistance coefficients, r_{ij} values, and r_{chem}, as

$$\nabla(-\mu_i) = \sum_j r_{ij} J_j, \ A = r_{chem} v \ (i,j = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.5}$$

The balance equation (continuity equation) for solute i can be expressed in terms of the molar concentration c_i as

$$\frac{\partial c_i}{\partial t} = -\nabla J_i + \nu_i v \ (i = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.6}$$

where ν_i denotes the stoichiometric coefficient of chemical species i in the chemical reaction. Accordingly, under the condition of the steady state ($\partial c_i / \partial t = 0$), the following relation holds:

$$\nabla J_j = \nu_j v \ (i = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.7}$$

Differentiating Eq. (36.5) and applying the condition of steady state [i.e., Eq. (36.7)], we obtain

$$\nabla^2(-\mu_i) = \left(\sum_j \nu_j r_{ij} \right) v \ (i,j = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.8}$$

or

$$\nabla^2(-\mu_i) = \left(\sum_j \nu_j r_{ij} \right) l_{chem} A \ (i,j = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.9}$$

We have assumed that summation of the resistance coefficients is independent of the position within the membrane. Consider that the diffusional flux is only in the direction perpendicular to the membrane surface (direction along the x axis). Multiplying both sides of the equation by ν_i and carrying out the summation over i, we obtain a differential equation by virtue of Eq. (36.3) as

$$\frac{d^2 A}{dx^2} = (\lambda^{-2}) A \tag{36.10}$$

where the coefficient λ^{-2} (λ is the relaxation length [2]) is a function of l_{chem} and r_{ij} values as

$$\lambda^{-2} = l_{chem} \sum_{i,j} \nu_i \nu_j r_{ij} \ (i,j = \mathrm{S}, \mathrm{P}, \mathrm{p}) \tag{36.11}$$

The solution of Eq. (36.10) gives the distribution of the chemical affinity of the reaction within the enzyme membrane, $A(x)$, in general, as

$$A(x) = \frac{A(a)\sinh(x/\lambda) + A(0)\sinh[(a-x)/\lambda]}{\sinh(a/\lambda)} \tag{36.12}$$

where the membrane is assumed to be bound by two planes normal to the x axis at $x = 0$ and $x = a$.

Next, the phenomenological coefficients included in the expression of the relaxation length [Eq. (36.11)] will be considered for the case of the enzymatic reaction in the membrane system.

Based on the Michaelis-Menten reaction mechanism, in general, the enzymatic reaction scheme for the hydrolysis of the phosphoric acid monoester is expressed as

$$\mathrm{E} + \mathrm{S} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{X} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \mathrm{E} + \mathrm{P} + \mathrm{p} \tag{36.13}$$

where E, S, X, P, and p denote the enzyme (acid phosphatase), the substrate (4-nitrophenyl phosphate), the enzyme–substrate complex, the main product (4-nitrophenol), and phosphoric acid, respectively; $k_1, k_2, k_3,$ and k_4 are rate constants. Because the enzyme catalyzes the hydrolysis of the substrate, the total reaction can be regarded as a first order reaction

$$\mathrm{S} \underset{k_-}{\overset{k_+}{\rightleftharpoons}} \mathrm{P} + \mathrm{p} \tag{36.14}$$

where k_+ and k_- are the rate constants.

First, we consider the phenomenological coefficient l_{chem} according to the rate law of the first-order reaction with respect to the substrate [Eq. (36.14)], as

$$v = k_+ c_\mathrm{S} - k_- c_\mathrm{P} c_\mathrm{p} \tag{36.15}$$

where c denotes the concentration for each species. The rate equation can be expressed in terms of the chemical affinity for the reaction [Eq. (36.14)], as

$$v = k_+ c_\mathrm{S} \left[1 - \exp\left(-\frac{A}{RT}\right)\right] \tag{36.16}$$

where A can be given as a function of the concentrations and the standard chemical potentials, μ^0, as

$$A = -(\mu_\mathrm{P} + \mu_\mathrm{p} - \mu_\mathrm{S}) = -\Delta\mu^0 + RT \ln \frac{c_\mathrm{S}}{c_\mathrm{P} c_\mathrm{p}} \tag{36.17}$$

$$\Delta\mu^0 = \mu_\mathrm{P}^0 + \mu_\mathrm{p}^0 - \mu_\mathrm{S}^0 \tag{36.18}$$

where the activity coefficients for the solutes (reactants and products) are assumed to be unity. In the range of the steady state, it can be assumed that $A/RT \ll 1$ holds for the chemical affinity of the reaction. In this linear region, provided that $\exp(-\Delta\mu^0/RT) \equiv K = k_+/k_-$, the following expression for the reaction rate can be obtained from Eq. (36.16) [K is the equilibrium constant for the reaction, Eq. (36.14)]:

$$v = k_+ c_\mathrm{S} \left(\frac{A}{RT}\right) \tag{36.19}$$

Comparing Eq. (36.19) with the last equation in the phenomenological equation, Eq. (36.4), we obtain

$$l_{chem} = \frac{k_+ c_\mathrm{S}}{RT} \tag{36.20}$$

Taking into account the Michaelis-Menten mechanism as represented by Eq. (36.13), the rate equation can be obtained under a steady-state condition, $dc_\mathrm{X}/dt = 0$:

$$v = \frac{dc_\mathrm{P}}{dt} = \frac{k_1 k_3 c_\mathrm{S} c_\mathrm{E}^0 - k_2 k_4 c_\mathrm{P} c_\mathrm{p} c_\mathrm{E}^0}{k_2 + k_3 + k_1 c_\mathrm{S} + k_4 c_\mathrm{P} c_\mathrm{p}} \tag{36.21}$$

$$= \frac{\dfrac{k_3 c_\mathrm{S} c_\mathrm{E}^0}{K_\mathrm{M}} - \dfrac{k_2 c_\mathrm{P} c_\mathrm{p} c_\mathrm{E}^0}{K_\mathrm{P}}}{1 + \dfrac{c_\mathrm{S}}{K_\mathrm{M}} + \dfrac{c_\mathrm{P} c_\mathrm{p}}{K_\mathrm{P}}} \tag{36.22}$$

where c_E^0 is the initial concentration of the enzyme:

$$K_\mathrm{M} = \frac{k_2 + k_3}{k_1} \quad K_\mathrm{P} = \frac{k_2 + k_3}{k_4} \tag{36.23}$$

By making the right side of Eq. (36.21) equal to zero, the ratio of the rate constants for the total reaction of the enzymatic reaction [Eq. (36.14)], k_+/k_-, can be confirmed to be a function of only the rate constants in the Michaelis-Menten mechanism as [10]

$$\frac{k_+}{k_-} = \frac{k_1 k_3}{k_2 k_4} \tag{36.24}$$

Since the most important case for our enzyme–membrane system as a membrane reactor device for the residual organic compounds in water is the low concentration range of the reactant in external water, we consider the limited region of the substrate concentration, $c_\mathrm{S} \ll K_\mathrm{M}$. This substrate concentration condition leads the following equation [Eq. (36.25)] provided that $c_\mathrm{P} c_\mathrm{p} \ll K_\mathrm{P}$. The latter condition generally holds for the Michaelis-Menten mechanism; in other words, the rate of the backward reaction for the products is negligible:

$$v = \frac{k_3 c_\mathrm{S} c_\mathrm{E}^0}{K_\mathrm{M}} - \frac{k_2 c_\mathrm{P} c_\mathrm{p} c_\mathrm{E}^0}{K_\mathrm{P}} \tag{36.25}$$

On the basis of this equation, it turns out that the phenomenological coefficient l_{chem} can be expressed in terms of the kinetic parameters for the enzymatic reaction as

$$l_{chem} = \frac{k_3 c_\mathrm{E}^0 c_\mathrm{S}}{K_\mathrm{M} RT} = \frac{V_\mathrm{max} c_\mathrm{S}}{K_\mathrm{M} RT} \tag{36.26}$$

where V_max and K_M are the maximum value of the enzymatic reaction rate and the Michaelis constant for the enzyme membrane, respectively, which can be obtained from analysis of the substrate concentration dependence of the reaction rate.

The other factor that determines the relaxation length λ is the resistance for the transport of reaction participants, as represented by Eq. (36.11). The resistance for the transport is related to the friction for transport through the membrane.

We assume that two participants, substrate S and the reaction product P, diffuse within the membrane. According to Spiegler's treatment [11], the diffusion coefficient of species i, namely, D_i, is expressed in terms of the friction coefficients provided that the friction between two solutes is negligible as

$$D_i = RT/(f_{iw} + f_{im}) \ (i = \mathrm{S}, \mathrm{P}) \tag{36.27}$$

where f_{iw} and f_{im} denote the friction coefficients between i and the solvent, and i and the membrane matrix, respectively. The linear relation between the diffusional flux $J_i = c_i v_i$ and its conjugate driving force $\nabla(-\mu_i)$ is given as follows:

$$\nabla(-\mu_i) = (f_{iw} + f_{im})\frac{J_i}{c_i} \ (i = \mathrm{S}, \mathrm{P}) \tag{36.28}$$

Therefore, in this membrane system, it is evident from the first equation of Eq. (36.5) that the resistance coefficients are expressed as

$$v_i v_S r_{iS} + v_i v_P r_{iP} = RT/D_i c_i \quad (i = \mathrm{S}, \mathrm{P}) \tag{36.29}$$

We have assumed that the effect of the small ion, that is, phosphate anion (p), can be neglected. Finally, summation of the resistance coefficients in Eq. (36.11) leads to the following equation:

$$\sum_{i,j} v_i v_j r_{ij} = RT\left(\frac{1}{D_\mathrm{S} c_\mathrm{S}} + \frac{1}{D_\mathrm{P} c_\mathrm{P}}\right) \tag{36.30}$$

Substituting Eqs. (36.26) and (36.30) into Eq. (36.11), we obtain the expression for the relaxation length that has the dimension of length:

$$\lambda = \left[\frac{K_\mathrm{M}}{V_{\max} c_\mathrm{S}}\left(\frac{1}{D_\mathrm{S} c_\mathrm{S}} + \frac{1}{D_\mathrm{P} c_\mathrm{P}}\right)^{-1}\right]^{1/2} \tag{36.31}$$

36.3 RESULTS AND DISCUSSION

36.3.1 Membrane Permeation across the Ionomer Membrane

Under the same conditions concerning solution pH values, the stirring speeds in the internal and external solutions and temperature for the measurements for the immobilized enzyme membrane, the flux measurements were carried out separately [6] for the product, 4-nitrophenol (PNP), and the reactant, 4-nitrophenyl phosphate (PNPP), across the perfluorocarboxylate ionomer membrane of the sodium form that was used as the supporting membrane for the enzyme immobilization. A perfluorocarboxylate polymer membrane

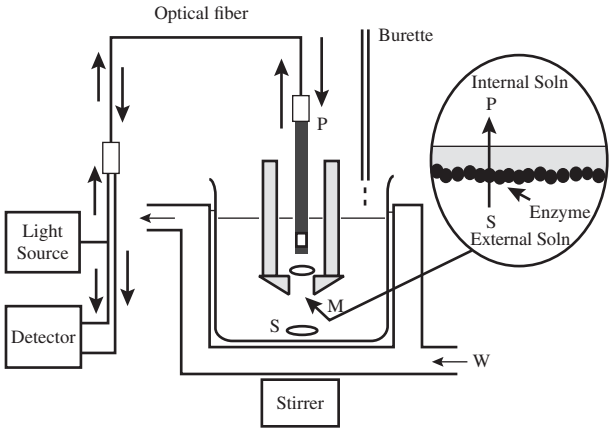

FIGURE 36.1 Schematic diagram of assembled system for measurements of flux across the perfluorocarboxylate ionomer membrane with or without the immobilized enzyme. Time dependence of the absorption spectrum was followed using an immersed probe (P) connected to a fiberoptic UV spectrophotometer. Arrows (→) show the path of the ultraviolet radiation. The membrane, magnetic spin bar, and thermostatically controlled water are designated by M, S, and W, respectively. (Adapted from Ref. 6.)

(Flemion 230, kindly supplied by the Asahi Glass Co., Tokyo, with an ion exchange capacity of 1.4 mmol univalent ion/dry [12]) was used as the supporting material for the enzyme. Initially, both the external and internal solutions contained only 0.1 moldm^{-3} NaCl. The pH values of both compartments were adjusted with a 0.1 moldm^{-3} sodium acetate buffer (pH = 4.8). The flux measurement was started by injecting a small volume of the 4-nitrophenyl phophate solution or 4-nitrophenol solution into the external solution. The timecourse of the concentration was followed by the fiberoptic spectrometer setup shown in Fig. 36.1 at 25.0°C. Each compartment was stirred at a speed of 650 rpm.

A higher permeability has been observed for 4-nitrophenol in contrast to 4-nitrophenyl phosphate, to which this membrane exhibits no significant permeability under the conditions of the experiments. An example of the time course for the amount of each compound transported across the membrane without the enzyme is shown in Fig. 36.2. The steady-state flux of 4-nitrophenol J_P has been obtained from the slope of the linear portion after a transient region in the timecourse curve.

According to the time lag method, the diffusion coefficient was obtained from the timecourse curve of the amount transported across the ionomer membrane. The time lag was obtained from the point where the straight line in a range of steady state and the baseline intersect, as demonstrated in Fig. 36.2. The time lag θ is expressed in terms of the diffusion coefficient D and the membrane thickness, a, as [13]

$$\theta = \frac{a^2}{6D} \tag{36.32}$$

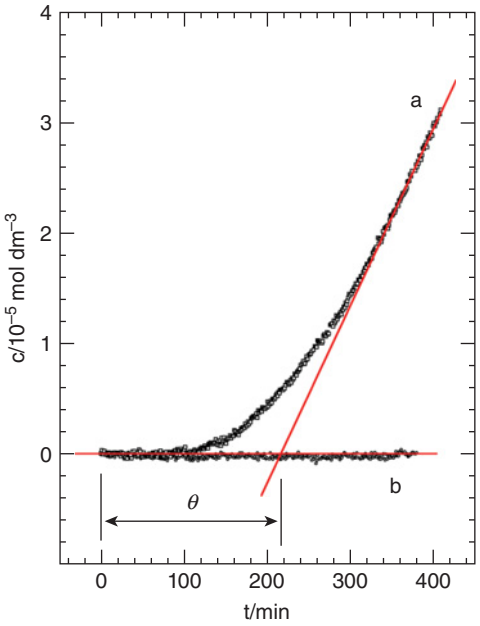

FIGURE 36.2 Typical time dependence of concentration of 4-nitrophenol in internal solution obtained from change in optical absorbance at 317 nm (a) and that of 4-nitrophenyl phosphate in the internal solution obtained from change at 310 nm (b). Initially, both the external and internal solutions contained a 0.1 mol dm^{-3} acetate buffer solution (pH 4.8) and 0.1 mol dm^{-3} NaCl. A small amount of the aqueous solution of 4-nitrophenol (or 4-nitrophenyl phosphate) was injected into the external solution at time zero. The initial concentration of 4-nitrophenol (or 4-nitrophenyl phosphate) just after the injection in the external solution was 1×10^{-2} mol dm^{-3}. Time lag θ is shown by the point where the straight line in the steady state and the base line intersect. (Adapted from Ref. 7.)

According to this equation, the diffusion coefficient D for the ionomer membrane was obtained as 8.0×10^{-9}cm^{2}s^{-1}.

36.3.2 Immobilization of Enzyme

As described in a previous paper [6], 30 μL of a mixture of 25 μL of the enzyme solution (10 mg/mL acid phosphatase, EC 3.1.3.2, from potato, CalBiochem) and 25 μL of the aqueous buffer solution (0.1 mol dm^{-3} sodium acetate buffer pH 4.8 with 0.1 mol dm^{-3} NaCl) was placed on the surface of the one side of the perfluorinated carboxylate ionomer membrane (Flemion 230, Asahi Glass Co.). After leaving it at 25°C for one hour, the membrane with the enzyme was stored at 5°C overnight. After the membrane covered with the enzyme suspension was restored at room temperature, 50 μL of the mixed solution of the cross-linking reagent (2.5 wt% glutaraldehyde solution) [14–16] with an equivalent volume of the phosphate buffer solution (pH 7.4) was placed into the enzyme suspension on the membrane surface. After one hour, one side of the membrane, over which the enzyme was immobilized in the micropores, was washed with 0.1 mol dm^{-3} NaCl solution. The immobilized enzyme membrane mounted in the cell assembly was stored at 5°C before the flux measurement.

36.3.3 Hydrolysis of 4-Nitrophenylphosphate across Immobilized Enzyme Membrane

The assembled measuring system for the flux of the hydrolysis product is schematically illustrated in Fig. 36.1. The area of the membrane surface adjacent to the solution (diffusion area) was 0.20 cm^2. Initially, both the external and internal solutions contained only 0.1 mol dm^{-3} NaCl. The measurement was started by injecting the substrate solution into the external solution. On the basis of the distinct difference between the membrane permeability to the reaction product and that to the reactant (substrate), a membrane reactor system has been designed. Acid phosphatase (EC 3.1.3.2) from potato was immobilized on the perfluorocarboxylate ionomer membrane by placing the enzyme solution on the supporting membrane without suction. Disodium 4-nitrophenyl phosphate was used as the substrate for the enzyme-catalyzed reaction. The pH of either solution in the membrane system for the measurements was adjusted to 4.8 using a 0.1 mol dm^{-3} sodium acetate buffer.

Because the ionomer membrane exhibits a high permeability only to the reaction product (4-nitrophenol), the liberation of 4-nitrophenol in the enzyme membrane produces the diffusional flux of the product to the internal solution. After the flux measurement, the pH of the internal solution was adjusted to pH 8.5, then the UV absorption spectrum of the solution was measured to confirm that the absorbance of the 4-nitrophenyl phosphate near its absorption maximum, 310 nm, was not entirely detected, while the absorption due to 4-nitrophenol at 400 nm was observed. The flux of the reaction product J_P at the steady state was obtained from the slope of the linear portion of the timecourse curve for the amount of the reaction product in the internal solution. All the measurements were carried out at 25.0°C. The internal and external compartments were stirred at a speed of 650 rpm.

From the dependence of J_P on the initial substrate concentration c_S of the external solution, the Michaelis constant for the immobilized acid phosphatase K_M^* and the maximum flux of the reaction product J_P^{max} were determined [6,17,18]. The dependence of J_P on the substrate concentration has been found to follow the relation of the Michaelis-Menten type (Fig. 36.3a):

$$J_P = \frac{J_P^{max} c_S}{K_M^* + c_S} \tag{36.33}$$

From the double reciprocal plot of $1/J_P$ vs. $1/c_S$, the Lineweaver–Burk plot, (correlation coefficient; $R = 0.999$) as shown in Fig. 36.3b, we have obtained K_M^* and J_P^{max}. These

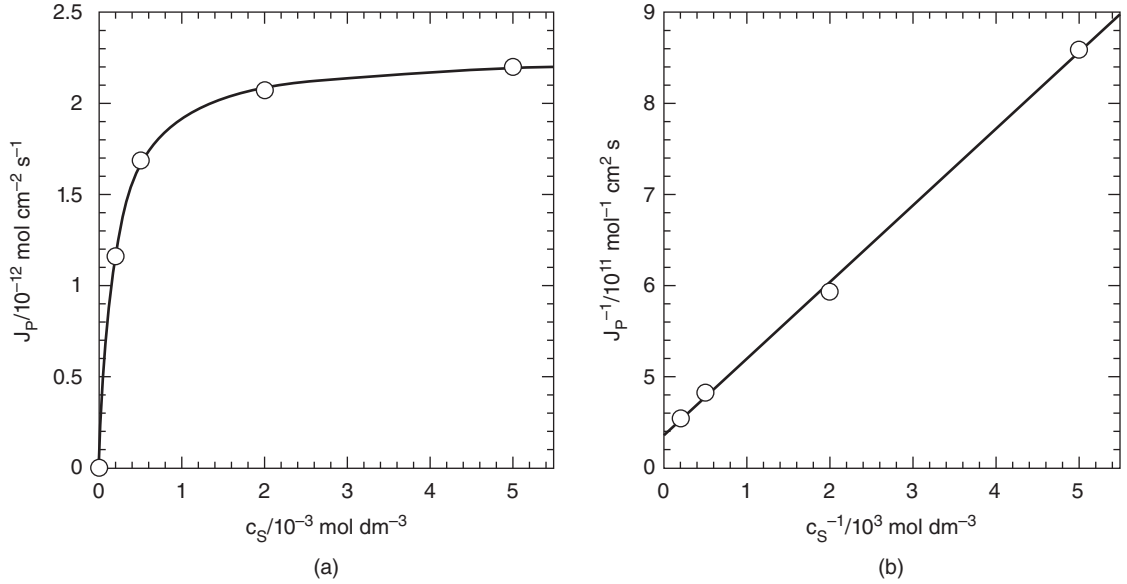

FIGURE 36.3 (a) Substrate concentration dependence of flux of hydrolysis product across enzyme membrane at pH 4.8. The steady-state flux of 4-nitrophenol produced during the hydrolysis of 4-nitrophenyl phosphate in the enzyme membrane system J_P was determined by following the absorption spectra of the internal solution. (Adapted from Ref. 6.) (b) Plot of $1/J_P$ versus $1/c_S$ for the enzyme membrane system [panel (a)].

values of K_M^* and J_P^{max} are listed in Table 36.1 together with the maximum velocity and the Michaelis constant K_M for the free enzyme reaction in an aqueous solution. For the acid phosphatase from potato, K_M values reported in the literature are 4.9×10^{-4} mol dm^{-3} in maleate buffer, pH 6.0, at 37°C [19], 4.3×10^{-4} mol dm^{-3} in acetate buffer, pH 4.9, at 38°C [20], and 6.2×10^{-4} mol dm^{-3} in acetate buffer, pH5.5, at 38°C [21].

The relation between the diffusional flux and the reaction rate of the enzymatic reaction for the enzyme membrane under the steady state condition will be given in the next section.

36.3.4 Degree of Coupling between Reaction Rate and Diffusional Flux in the Enzyme Membrane System

According to the theoretical consideration in the preceding section, the relaxation length λ for the enzyme membrane can be evaluated as a parameter for the region (depth in the x-axis direction from the membrane surface) where the enzymatic reaction proceeds accompanied by diffusion of the reaction participants.

TABLE 36.1 Michaelis-Menten Parameters for Fluxes across Enzyme Membrane (Immobilized Acid Phosphatase from Potato) and for Free Enzyme (Acid Phosphatase from Potato)

	K_M (mol dm^{-3})	J_P^{max} (mol cm^{-2}s^{-1})	V_{max} (mol dm^{-3}s^{-1})
Enzyme membrane	1.92×10^{-4}	2.29×10^{-12}	
Free enzyme	8.1×10^{-5}		3.7×10^{-8}

We first consider a limiting case in which the resistance coefficients for the product (PNP) and those for the substrate (PNPP) are equal (i.e., $r_{SS} - r_{SP} = -r_{SP} + r_{PP}$), then $1/D_S c_S = 1/D_P c_P$. The effects of the ratio of the two terms, $1/D_S c_S$ and $1/D_P c_P$, on the value of λ will be investigated later. For this limiting case, the following equation for the relaxation length can be obtained from Eq. (36.31):

$$\lambda = \left(\frac{2K_M}{V_{max}} D_P\right)^{1/2} \tag{36.34}$$

Under the steady-state condition, we obtain the following relation from Eq. (36.7)

$$\left(\frac{\partial J_S}{\partial x}\right) = -\left(\frac{\partial J_P}{\partial x}\right) = -v \tag{36.35}$$

where subscripts S and P refer to the substrate (PNPP) and the reaction product (PNP), respectively. The enzymatic reaction rate, v, denotes the local velocity of the reaction. Integrating Eq. (36.35) from the membrane surface on the external substrate solution side, $x = 0$, to the other membrane surface on the internal solution side, $x = a$, we obtain

$$J_S(a) - J_S(0) = -\{J_P(a) - J_P(0)\} = -J_R \tag{36.36}$$

where

$$J_R \equiv \int_0^a v dx \tag{36.37}$$

Since we consider the situation where the substrate concentration at the membrane surface on the opposite side ($x = a$) is equal to zero, $J_S(a) = 0$. On the other hand, we consider the case when the external buffered solution contains only the substrate molecules so that $J_P(0) = 0$. Therefore, from Eq. (36.36), we obtain

$$J_S(0) = J_P(a) = J_R \tag{36.38}$$

The flux $J_P(a)$ is equivalent to the experimentally observed flux of P under the steady-state condition. It should be noted that Eq. (36.38) expresses the relation between the flux of the substrate from the external solution outside the membrane and the rate of the reaction through which the substrate molecules are consumed within the enzyme membrane, and that between the reaction rate and the flux of the product toward opposite-side solution, which is observed. This supports the experimentally observed fact that the flux of P is expressed in terms of a Michaelis-Menten-type equation [Eq. (36.33)]. By using the averaged reaction rate of the enzymatic reaction within the membrane, $\bar{v}$ ($= \{\int v dx\}/a$), we can rewrite Eq. (36.38) as

$$\bar{v} = \frac{J_P}{a} \tag{36.39}$$

Accordingly, the maximum velocity of the enzymatic reaction, V^*_{max}, and the maximum flux, J_P^{max}, which has been obtained from the reciprocal plot for the product flux across the enzyme membrane (listed in Table 36.1) can be related as

$$V^*_{max} = \frac{J_P^{max}}{a} \tag{36.40}$$

The maximum velocity for the enzyme membrane has been obtained according to Eq. (36.40). As a result, for this case, the relaxation length λ was obtained using Eq. (36.34) to be 29.0 μm.

The distribution of the affinity of the reaction in the enzyme membrane can be obtained from Eq. (36.12). Since we consider the case where the concentration of the substrate at the surface, $x = a$, is zero, then

$$A(a) = 0 \tag{36.41}$$

so that we obtain

$$\frac{A(x)}{A(0)} = \frac{\sinh[(a-x)/\lambda]}{\sinh(a/\lambda)} \tag{36.42}$$

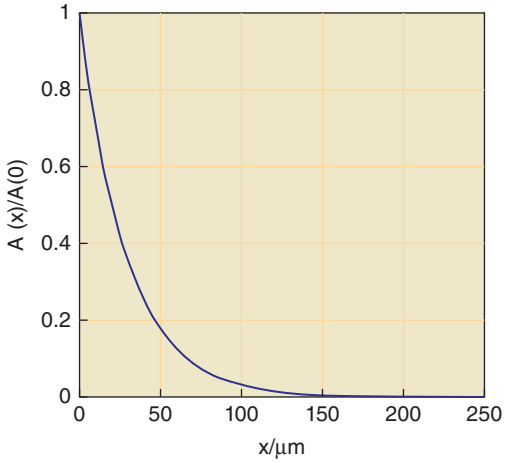

FIGURE 36.4 Affinity distribution $A(x)$ within acid phosphatase–immobilized membrane for case 1: $\lambda = 29$ μm. (Ref. 7)

Figure 36.4 shows the affinity distribution calculated using Eq. (36.42) (case 1). The value of a was 250 μm (membrane thickness [6]).

When the bound enzyme is not uniformly distributed throughout the membrane, it is likely that the inert layer in which the enzyme is not immobilized exists with a certain thickness. For preparation of the enzyme membrane, immobilization of the enzyme was carried out spontaneously by placing the enzyme solution on the external solution-side surface of the supporting membrane without suction. Therefore, the enzyme immobilized onto the surface region is not likely to be fully distributed into the core region of the membrane far from the membrane surface [22]. As the next example, consider the case where the enzyme is immobilized only in the active layer within which the enzyme's distribution is uniform (case 2).

The distribution of the affinity was calculated according to Eq. (36.42). The thickness of the inert layer is denoted by δ ($a + \delta = 250$ μm). As seen from the balanced equation [Eq. (36.6) for P], Eq. (36.43) holds in the inert layer under the steady-state condition:

$$\frac{dJ_P}{dx} = 0 \tag{36.43}$$

Therefore, the flux of the product is independent of the position within the inert layer and at the interface on the internal solution side. The calculated results for case 2 are plotted for each value of the active layer thickness a in Fig. 36.5.

So far, it has been assumed that the contributions of the frictional term for the product and that for the substrate are comparable in the expression of λ. The influence of the frictional terms on the affinity distribution is being investigated. The results of the calculations are shown in Fig. 36.6. It is

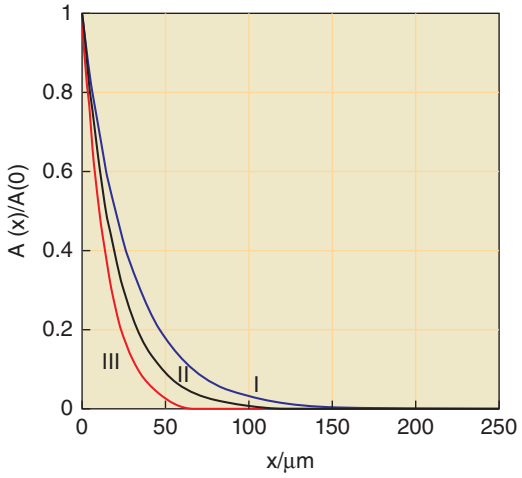

FIGURE 36.5 Affinity distribution $A(x)$ for acid phosphatase–immobilized membrane for case 2. Curve I: inert layer's thickness, $\delta = 0$ μm. Curve II: $\delta = 125$ μm. Curve III: $\delta = 182.5$ μm. (Ref. 7)

seen from the comparison in this figure that the influence of the relative value of the frictional terms, $1/D_S c_S$ and $1/D_P c_P$, is not very significant.

In boundary regions including membranes as a barrier for mass transports, an invariant concentration distribution for each chemical species is formed under the stationary-state condition. In the case where chemical reactions occur within the boundary region, the concentration distribution is changed depending on the reaction rate. The reaction layer thickness due to the acetaldehyde oxidation catalyzed by alcoholdehydrogenase has been evaluated from the steady-state pH distribution in the unstirred layer near the bilayer lipid membrane, which was measured by the microelectrode method, by one group of

investigators [23]. In their membrane system, the enzyme exists in the aqueous phase in the membrane vicinity. On the other hand, the concentration distribution of the reacting species or the product in the enzyme layer of the biosensor in operation was investigated for the glucose oxidation catalyzed by glucose oxidase, where a platinum microtip was used for the scanning electrochemical microscopic measurements [24].

36.3.5 Quantity of Immobilized Acid Phosphatase

Two enzyme membranes with different amounts of the immobilized enzyne were prepared separately [25]. Acid phosphatase (EC 3.1.3.2) from sweet potato with a protein concentration of 57 mg/mL was obtained as a suspension with 1.8 mol dm^{-3} aqueous $(NH_4)_2SO_4$ (Sigma, St. Luis). The perfluorocarboxylate ion-exchange membrane (Flemion 230, kindly supplied by the Asahi Glass Co., Tokyo, with an ion exchange capacity of 1.4 mmol univalent ion/g dry) was mounted in the cell for the flux measurements. The mixed suspension of the enzyme and aqueous acetate buffer solution was placed on the surface of the external solution side of the ion exchange membrane. After leaving it at 25°C for one hour, the enzyme suspension on the membrane was removed and diluted with 0.1 mol dm^{-3} acetate buffer to analyze the enzyme activity. Two enzyme membranes of different enzyme amounts were prepared. For these enzyme membranes, the immobilization process mentioned above was carried out 2 or 3 times. The cell for the measurement with approximately 2 mL of an internal solution of acetate buffer was stored at 5°C, while the flux measurements were not carried out. The amount of the enzyme placed on the membrane for the immobilization E and that of the immobilized enzyme on the membrane E_n, are shown in Table 36.2. Thus, this immobilization procedure for acid phosphatase from sweet potato involves only a process of incorporating the enzyme into the micropores of the perfluorinated ionomer membrane without any cross-linking reagent.

For free enzyme in aqueous solution of a 0.1 mol dm^{-3} acetate buffer (pH 4.8), the enzymatic reaction rate of hydrolysis of PNPP was investigated. From the Hanes–Woolf plot

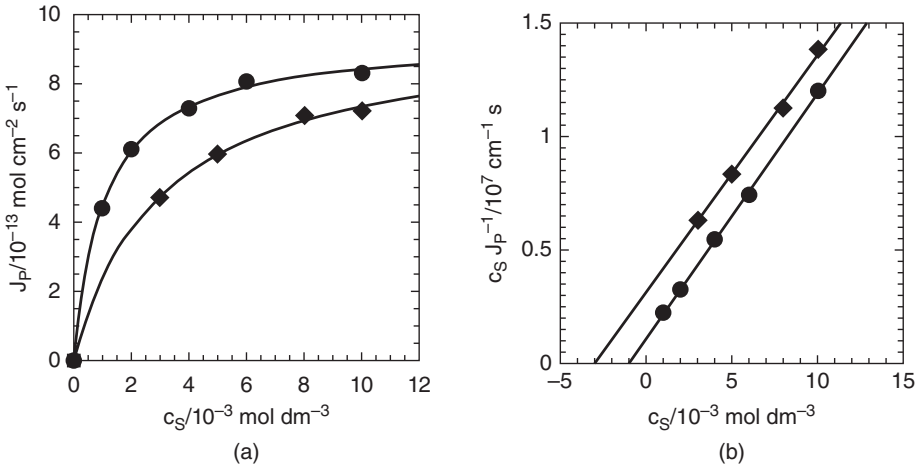

FIGURE 36.7 (a) Substrate concentration dependence of flux of reaction product across immobilized enzyme membranes at pH 4.8. Quantity of immobilized acid phosphatase from sweet potato for each membrane was determined: ♦ 0.88 enzyme U (M-a), ● ; 2.66 enzyme U (M-b). (Adapted from Ref. 25.) (b) Plot of Hanes–Woolf type for immobilized enzyme membranes [panel (a)], ♦ M-a, ● ; M-b. (Adapted from Ref. 25.)

for the initial reaction rate, the Michaelis constant K_M was determined to be 6.14×10^{-5} mol dm^{-3}. The values of K_M reported in the literature are 6.8×10^{-5} mol dm^{-3} (in 0.2 mol dm^{-3} acetate buffer, pH 5.8, at 35°C) [26] and 1.4×10^{-4} mol dm^{-3} (in 0.1 mol dm^{-3} acetate buffer, pH 5.6, at 40°C) [27]. The dependence of the enzyme activity on the enzyme unit in bulk solution was investigated at a fixed high concentration of PNPP in the saturated region of the initial rate versus the substrate concentration curve. The initial concentration of PNPP was 5×10^{-4} mol dm^{-3}. A linear relationship exists between the reaction rate and the enzyme unit. Using this calibration curve, the change in the amount of the enzyme placed on the membrane after each immobilization step was determined.

Flux measurements were carried out using the same apparatus as illustrated in Fig. 36.1. The layer of immobilized acid phosphatase was on the external solution side of the membrane. Initially, external and internal solutions contained only 50 mL and 2 mL of 0.1 mol dm^{-3} acetate buffer (pH = 4.8), respectively. The reaction was started by injecting a small volume of 0.1 mol dm^{-3} PNPP into the external solution. The amount of PNP transported into the internal solution was followed by measuring the timecourse of the optical absorbance at 317 nm. In Fig. 36.7a, the dependence of the PNP flux in a stationary state on the initial substrate concentration is shown for the two enzyme membranes.

In Fig. 36.7b, the flux divided by the initial substrate concentration is plotted against the initial substrate concentration (Hanes–Woolf-type plot). In this plot, the x intercept and the slope give K_M, and $1/J_{max}$, reespectively. The determined value of K_M and J_{max} are shown in Table 36.3.

In both enzyme membranes, the enzyme–substrate affinity was apparently lower than that in the solution. The amount of the immobilized enzyme is thought to have an effect on the enzyme–substrate affinity. The value of the maximum flux J_{max}, divided by the amount of the immobilized enzyme on the membrane E_{total}, can be regarded as the enzyme activity per unit. Compared to the free state of the enzyme, the immobilized enzyme on the membrane would be in a dense state. In the enzymatic reaction, the enzyme forms a complex with the substrate. Thus, the reaction proceeds through a intermediate state formed by the interaction of the substrate with the active site of the enzyme. This suggests a possible effect of the dense state of the enzyme on the formation of the enzyme–substrate complex.

EVALUATION OF ZETA-POTENTIAL OF INDIVIDUAL EXOSOMES SECRETED FROM BIOLOGICAL CELLS USING A MICROCAPILLARY ELECTROPHORESIS CHIP

Takanori Akagi and Takanori Ichiki
Department of Bioengineering, Graduate School of Engineering, University of Tokyo

37.1 INTRODUCTION

Biological cells are known to secrete membrane vesicles, which are called *exosomes* and *microvesicles*, with specific characteristics including size and composition [1]. Exosomes are small vesicles (30–100 nm) released by exocytosis from multivesicular bodies (MVBs) of the endosomes of cells and contain an array of proteins, lipids, and nucleic acids derived from the parent cells. More recent studies have revealed that regardless of the distance between cells, exosomes participate in intercellular communication in the immune system, cancer development, and cancer metastasis, for example, by stabilizing the circulating microRNA (miRNAs) and mRNAs in the ribonuclease (RNase)-rich environment of body fluids [2]. Furthermore, exosomes have the potential for use in therapeutic and diagnostic applications including tumor-derived exosome-based cancer vaccines [3] and exosomal RNA-based diagnostic and prognostic markers [4]. However, there is little knowledge concerning their physical properties, such as the surface charge.

Electrostatic interaction is a strong interaction between an exosome and a cell; hence, evaluating zeta-potential, measures of surface electric charge, of exosomes is necessary for understanding the mechanisms of intercellular communications. Zeta-potential, which can be estimated from the electrophoretic mobility (EPM), is one of the electrical properties of exosomal surfaces. For evaluating zeta-potential of particles or cells, several automated zeta-potential analyzers can be used to measure the electrophoretic velocity of a number of particles or cells moving in a stationary plane within a short timeframe have been developed and are now commercially available [5]. However, they are not suitable for obtaining the precise distribution of the zeta-potential profile, especially when the samples are mixtures of heterogeneous particles because they cannot perform particle-by-particle measurement [6]. Hence, particle-by-particle measurement is also required for the electrrokinetic evaluation of exosomes.

On the basis of the abovementioned background, we have investigated the electrokinetic evaluation of exosomes using an on-chip microcapillary electrophoresis (μCE) system equipped with a laser darkfield microscope to realize the sensitive tracking of individual exosomes [7, 8].

37.2 EXOSOME PREPARATION

Exosome samples secreted from six types of cell, normal prostate epithelial PNT2 cells, prostate cancer PC3 and PC-3Mluc-C6 (PC-3ML) cells (Xenogen), normal breast epithelial MCF10A cells, and breast cancer MDA-MB-231 (MM231) and MDA-MB-231-luc-D3H2LN cells (MM231LN) (Xenogen) cells cultivated in vitro were collected and used in this study. The cells were grown to confluence in medium supplemented with 10% fetal bovine serum (FBS), 100 μg/mL kanamycin, 100 units/ml penicillin, and 100 μg/mL streptomycin in a humidified atmosphere of 95% air and 5% CO_2 at 37°C. Exosomes were prepared from the culture medium as described previously [9]. The culture

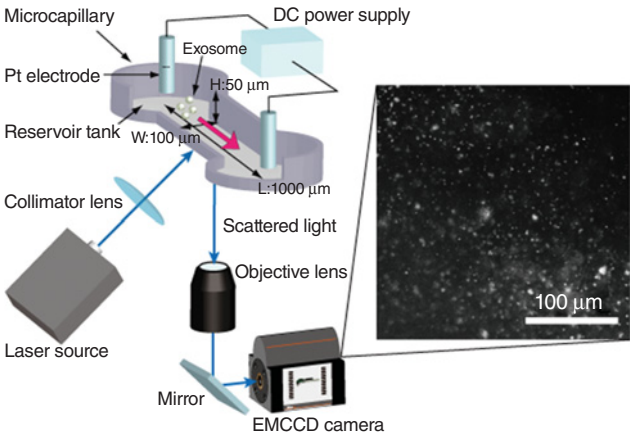

FIGURE 37.1 Schematic diagram (a) and photograph (b) of the on-chip microcapillary electrophoresis (μCE) system equipped with a laser darkfield microscope. This system enables the sensitive imaging of individual exosomes in a darkfield by detecting laser light scattered by exosomes using an EM-CCD camera.

medium was replaced with serum-free RPMI medium and the cells were incubated for 24 h. Exosomes were extracted from the supernatant of the serum-free cell culture medium by differential ultracentrifugation performed as follows. The cell culture was centrifuged twice at 2000 × *g* for 15 min using a centrifuge (Tomy LC-220) and the resulting supernatant was recentrifuged at 12,000 ×*g* for 35 min using an ultracentrifuge (Beckman Coulter Optima L-90K). Then, the clarified supernatant was subsequently ultracentrifuged at 110,000 × *g* for 70 min. The resulting pellets were washed in a large volume of phosphate buffered saline (PBS) and finally centrifuged at 110,000 × *g* for 70 min. The washed pellets containing exosomes were then suspended in PBS.

37.3 ELECTROPHORESIS SYSTEM FOR EXOSOMES

Figure 37.1 is a schematic diagram of the on-chip μCE system equipped with a laser darkfield microscope. The system comprises a μCE chip, a pair of platinum electrodes, a high-voltage DC power supply [Matsusada Precision HVL-1.1P(A)], a 488-nm laser source (50 mW, Melles Griot 85-BCD-030-053), an inverted microscope (Nikon Ti-U), and an electron multiplying charge-coupled device (EM-CCD) camera (Andor iXon3 897). The poly(dimethylsiloxane) (PDMS) μCE chip was fabricated using a method described previously [10].

Samples suspended in PBS (1.06 mM KH2PO4, 155.17 mM NaCl, 2.97 mM Na_2HPO_4•$7H_2$, pH = 7.4, ionic strength 0.16) were introduced into the flow channel of the μCE chip, and electrodes were placed in the reservoir tanks. After the μCE chip was mounted on the microscope, electrophoretic migration was recorded under an electric field of 50 V/cm. This on-chip μCE system enables the sensitive imaging of individual exosomes in a darkfield by detecting laser light scattered by exosomes using an EM-CCD camera. The electroosmosis velocity induced inside the microchannel was measured by suspending charge-free beads of 500 nm diameter (Otsuka Electronics) in the electrophoresis buffer in a control experiment conducted before and after each electrophoresis experiment. Since the measured velocity of the migrating samples includes the electroosmosis velocity weakly observed in the microchannel, the true EPM, μ_{ep} was calculated as follows

$$\mu_{ep} = (U_{em} - U_{eo})/E \tag{37.1}$$

where U_{em} is the apparent electrophoretic velocity, U_{eo} is the electroosmotic flow velocity, and E is the electric field strength (V/cm). Furthermore, the zeta-potentials ζ of exosomes were calculated from the measured EPM using the Smoluchowski equation

$$\mu_{ep} = \frac{\varepsilon_r \varepsilon_0}{\eta}\zeta \tag{37.2}$$

where η is the viscosity coefficient of the buffer solution, and ε_r and ε_0 are the relative permittivity of the solution and the permittivity of vacuum, respectively. Note that, strictly speaking, factors with some degree of uncertainty are unfortunately included in the Smoluchowski equation used to analyze the electrophoresis of biological particles such as exosomes. Hence, in this chapter, we use both zeta-potential and EPM as parameters to provide information about the surface charge of exosomes.

37.4 RELATION BETWEEN ZETA-POTENTIALS OF EXOSOMES AND THEIR ORIGINATING CELLS

The EPM distributions of both cells and exosomes derived from the parent cells are shown in Figs. 37.2 and 37.3 [7]. Figure 37.2a shows the zeta-potential distributions of exosomes derived from MCF10A, MM231, and MM231LN cells. The averages ± standard deviations of the zeta-potential distributions of exosomes were −8.8 ± 2.5 mV (MCF10A), −10.2 ± 2.4 mV (MM231), and −10.9 ± 2.3 mV (MM231LN). The zeta-potential distributions of exosomes derived from MM231and MM231LN cells showed negative shifts compared with those of exosomes derived from MCF10A. Figure 37.2b shows the zeta-potential distributions of MCF10A, MM231, and MM231LN cells. The averages ± standard deviations of these zeta-potential distributions were −9.2 ± 2.1 mV (MCF10A), −10.9 ± 1.9 mV (MM231), and −11.6 ± 2.1 mV (MM231LN). Interestingly, the zeta-potentials of exosomes from tumor cells tend to show a negative shift compared with those of exosomes from normal cells (p <0.05,

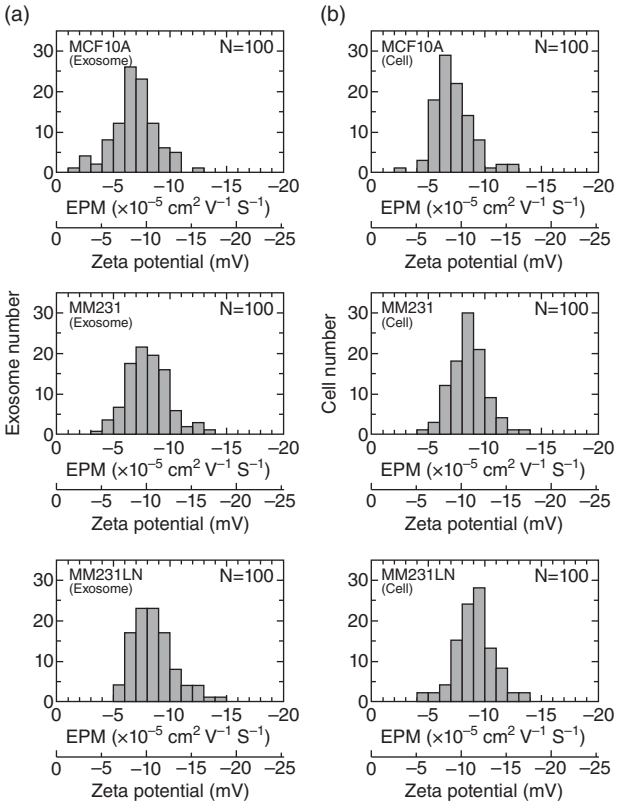

FIGURE 37.2 (a) Zeta-potential distributions of exosomes derived from normal breast epithelial cells (MCF10A), and breast cancer cells (MM231 and MM231LN). (b) Zeta-potential distributions of MCF10A, MM231, and MM231LN cells.

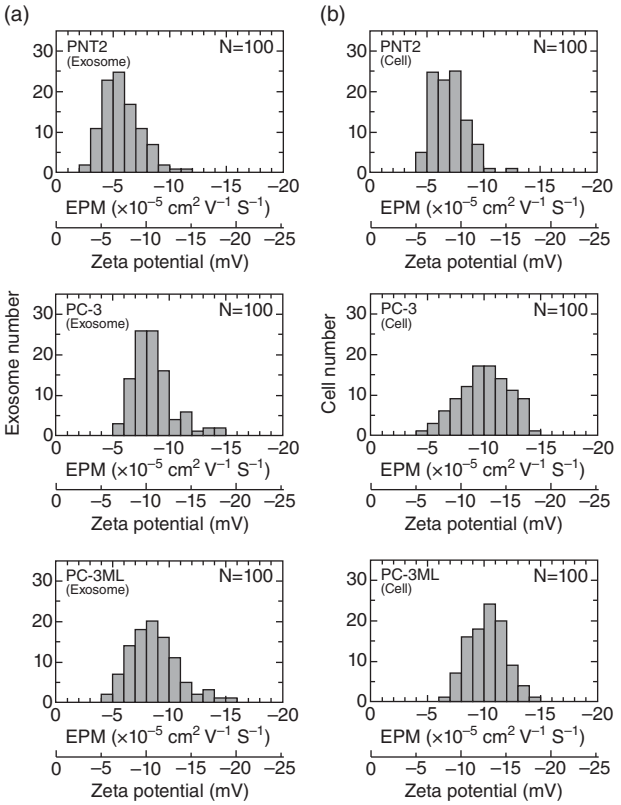

FIGURE 37.3 (a) Zeta-potential distributions of exosomes derived from normal prostate epithelial cells (PNT2) and prostate cancer cells (PC3 and PC3ML). (b) Zeta-potential distributions of PNT2, PC3, and PC3ML cells.

Dunnett's test). In contrast, there was no large difference between the relative standard deviation of the zeta-potential of exosomes and that of their cells of origin, which was approximately 10% at the most.

Moreover, a similar tendency was observed for human prostate cells. Figure 37.3a shows the zeta-potential distributions of exosomes derived from PNT2, PC3, and PC3ML cells. The average ± standard deviations of zeta-potential of exosomes were −7.4 ± 2.2 mV (PNT2), −11.0 ± 2.3 mV (PC3), and −11.1 ± 2.7 mV (PC3ML). Figure 37.3b shows the zeta-potential distributions of PNT2, PC3, and PC3ML cells. The average ± standard deviations of zeta-potentials of the corresponding cells were −8.9 ± 1.9 mV (PNT2), −12.8 ± 2.8 mV (PC3), and −13.1 ± 2.1 mV (PC3ML). The zeta potential of exosomes secreted from tumor cells shows a negative shift compared with that of exosomes from normal cells ($p < 0.05$, Dunnett's test).

To further examine the correlation between the zeta-potentials of exosomes and their cells of origin, the average zeta-potential of six types of exosome and their cells of origin are plotted in Fig. 37.4. There is a strong correlation between the average zeta-potential of exosomes and that of their cells

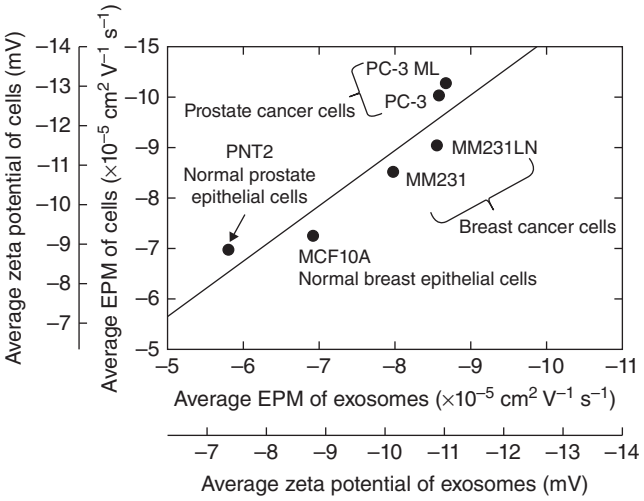

FIGURE 37.4 Comparison of average zeta-potentials of six types of exosome and their cells of origin measured using on-chip microcapillary system. The correlation coefficient between the average EPMs of cells and exosomes is 0.92.

of origin (correlation coefficient: 0.92). This fact means that the zeta-potential of exosomes strongly reflects that of their parent cells.

The zeta-potential of cancer cells changes owing to abnormal expression of sugar chains with malignant transformation [11]. Therefore, exosomes may well reflect changes in the sugar chains in their parent cells due to malignant transformation. Indeed, it has recently been reported that exosomes also bear saccharide groups such as mannose, polylactosamine, α-2,6 sialic acid, and complex *N*-linked glycans.

37.5 EFFECT OF SIALIDASE ON THE ZETA-POTENTIAL OF EXOSOMES

To investigate the relationship between the level of sialic acids and the electrical properties of the exosomal surface of normal prostate PNT2 and prostate cancer PC3 cells, the zeta-potential of desialylated exosomes was measured using the on-chip μCE system equipped with a laser dark-field microscope [8]. Figure 37.5 shows the zeta-potential distributions of exosomes derived from PNT2 and PC3 cells before and after treatment with sialidase. The means and standard deviations of the zeta-potential distributions of the exosomes derived from PNT2 and PC3 cells were -7.4 ± 2.2 and -11.0 ± 2.3 mV, respectively. The zeta-potential of exosomes secreted from PC3 cells was significantly more negative than that from PNT2 cells ($p < 0.05$, Tukey's test). In contrast, the means and standard deviations of the zetapotential distributions of exosomes derived from PNT2 and PC3 cells after treatment with sialidase were -4.1 ± 2.6 and -4.6 ± 3.3 mV, respectively. There was no significant difference between the zeta-potentials of the exosomes (p=0.668, Tukey's test). The variations of the mean zeta potential of exosomes of PNT2 and PC3 cells were +3.3 and +6.4 mV, respectively. The shift in the zeta-potential of exosomes of PC3 cells after sialidase treatment was about twice as large as that of the exosomes of PNT2 cells.

On the basis of these results, schematic images of the surface of exosomes secreted from cancer and normal cells are shown in Fig. 37.6. According to Ohshima's model [12], the EPM of a particle covered with a polymer, such as a cell or an exosome, can be determined using the electrical and mechanical properties of the polymer and the physical properties of the buffer solution. Therefore, sialic acids on the exosome surface can be considered as one of the factors contributing to the net negative charge of exosomes.

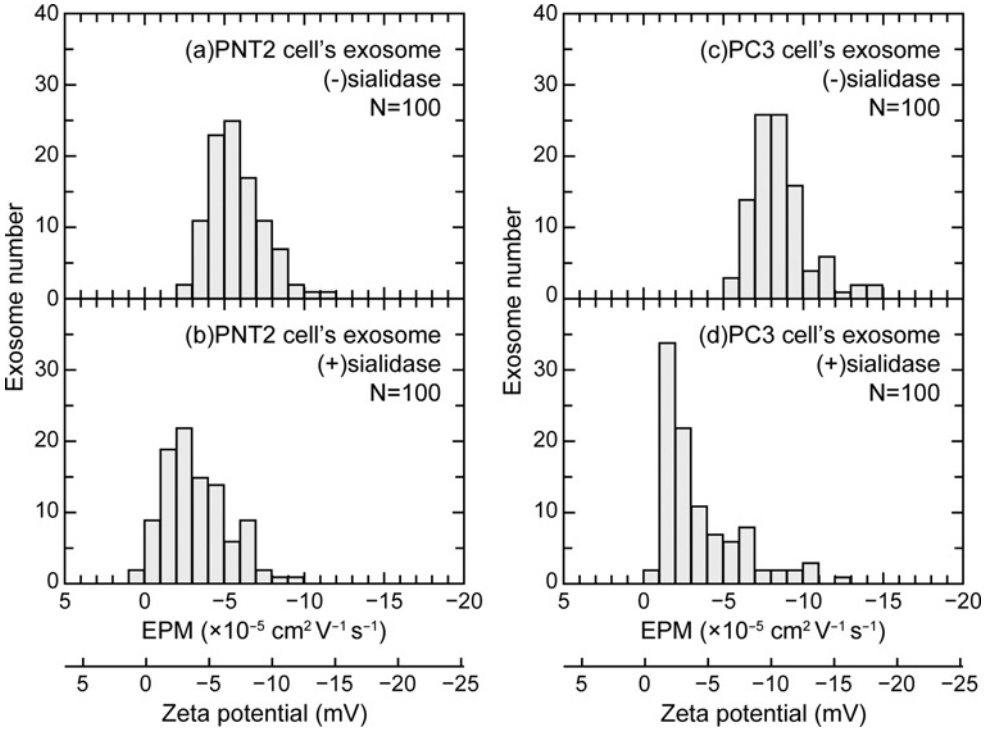

FIGURE 37.5 Effect of sialidase treatment on zeta-potential distributions of exosomes secreted from human normal prostate epithelial PNT2 cells (left) and human prostate cancer PC3 cells (right) evaluated using the on-chip μCE measurement system.

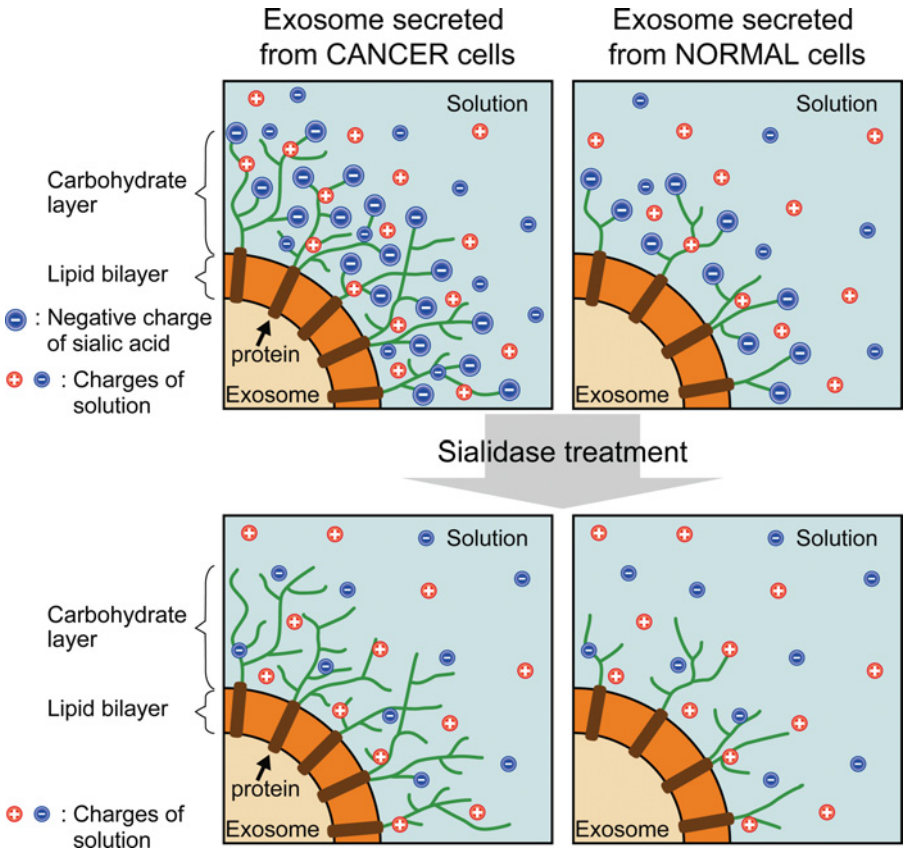

FIGURE 37.6 Schematic illustrations of charge distribution on the surface of exosomes secreted from cancer (left) and normal (right) cells before and after treatment with sialidase.

37.6 CONCLUSION

The EPM measurement system using a μCE chip was demonstrated to be suitable for analyzing events on the surface of individual exosomes. The difference in EPMs between exosomes secreted from normal and cancer cells and one of the mechanisms were revealed. Unfortunately, EPM cannot provide the disease-specific information. Hence, this methodology is expected to be useful for the prescreening of exosomes derived from prostate cancer without the need for labeling.

FLOCCULATION DYNAMICS ON THE BASIS OF COLLISION-LIMITED ANALYSIS

YASUHISA ADACHI

Faculty of Life and Environmental Science, University of Tsukuba, Ibaraki, Japan Tsukuba, Ibaraki, Japan

38.1 INTRODUCTION

Colloidal suspensions are unstable in nature, as a result of the effect of attractive interactions due to the universal van der Waals forces and specific electrostatic or chemical attraction exerted between heterogeneous surfaces of colloidal particles [1]. Therefore, in principle, when a colloidal suspension is placed for a long period of time, all particles will stick to each other to form an aggregate as a result of collisions. Collisions are induced by the influence of Brownian motion, the velocity difference in the flow field of shear and extension flow, turbulence, or field force such as gravity [2–5]. However, collisions usually will be hindered by the repulsive force induced by the presence of electric double layer or the steric interference of adsorbed molecules such as surfactants or macromolecules on the colloidal surface [6, 7]. If these repulsive interactions are reduced or removed, flocculation will begin to take place upon collision between two particles. Sequence of collision will result in the growth of flocs. The important factors involved in this process are as follows:

1. The rate of flocculation [8]
2. The geometric structure of resulting flocs [9]
3. The relation between the structure of flocs and other properties; such as the rate of sedimentation and the rheology of suspension [10, 11].

These factors are controlled by the chemical and hydrodynamic condition of the suspension schematically illustrated in Fig. 38.1. Therefore, the rate is controlled by the condition of hydrodynamic transportation and chemical reaction. Additiionally, the geometric structure of flocs reflects their formation process controlled by the rate of flocculation. For a description of sedimentation and the rheological process, information on geometric structure is essential. Scheme of analysis is given mainly by hydrodynamic conditions, and the difference in substances is related to chemical conditions. Here, our main interest is in using a model system. An application of the model suspension initially formed of uniform monodispersed spheres is useful for analysis of these factors and their relations. Thus, analysis of flocculation rate based on the colloidal interaction and transport phenomena can be based on spherical geometry of particles. Many numerical simulations for the reproduction of fractal geometry are reported for flocs formed of monodisperse spheres [29]. Experimental efforts to confirm these predictions are also reported using monodispersed suspension. It should be noted, however, that the formed structure also influences the rate of flocculation [12, 13]. In this chapter, the rate theory of flocculation is summarized followed by the result on the structure of flocs. An emphasis on the enhancement of collision process by the application of polymer flocculants will be treated in the last part of this chapter [14].

38.2 POPULATION BALANCE EQUATION

In an unstable suspension, the size distribution of flocs will change in accordance with the progress of flocculation

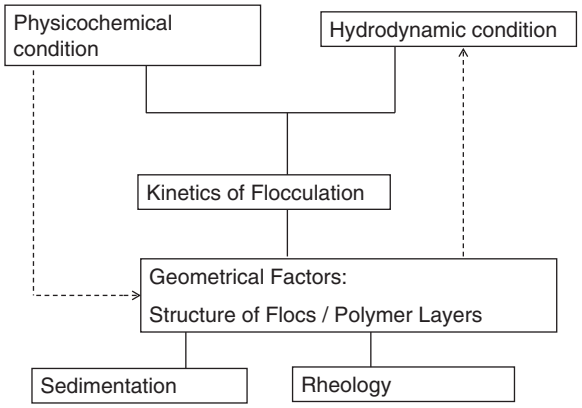

FIGURE 38.1 A correlation diagram of physical properties of a floc. The broken line represents influence at geometric factors on the collision process.

as illustrated in Fig. 38.2. Smoluchowski expressed the temporal evolution of size distribution of flocs, assuming that the flocculation process is a sequence of binary collision Cwithout any breakups of flocs. He proposed the following equation for the population balance of floc size distribution:

$$\frac{dn_k}{dt} = \frac{1}{2}\sum_{\substack{i=1\\ i+j=k}}^{i=k-1} \beta(a_{i,}a_j)n_i n_j - n_k \sum_{j=1}^{\infty} \beta(a_k, a_j)n_j. \qquad (38.1)$$

In other words, the rate of change in the concentration of the k-fold cluster (a floc composed of k primary particles) n_k is equal to the sum of the rate of formation of the k-fold cluster by the collision pair between i-fold and j-fold clusters satisfying $k = i + j$ and the rate of distinction of k-fold clusters by the collision with other clusters. The flocculation kernel, called a *collision frequency function* in case the flocculation process is controlled by collision, $\beta(a_i, a_j)$, is determined as a function of radius of the pair of two colliding particles reflecting the mechanism of collision process. In case the rate of collision is equal to that of coagulation, that is, the coagulation process is limited by the rate of collision, the process is termed *rapid*.

38.3 BROWNIAN COAGULATION

38.3.1 Collision Process under Brownian Motion

When interacting forces acting between colloid particles are removed, the rate of flocculation is determined by the rate of collision between colloid particles. Colloid suspension in such condition will flocculate spontaneously even when placed in a static condition by the effect of Brownian motion. The rate of collision between colloid particles immersed in a stagnant fluid can be derived by analyzing the diffusion process between colloidal particles (Fig. 38.3). If we take J_B as the value of rate of collision of i-fold clusters to the j-fold cluster, the value can be expressed by the application of Fick's first law as follows:

$$J_B = 4\pi r^2 D_{ij}\frac{\partial n_i}{\partial r}, \qquad (38.2)$$

where D_{ij} denotes the relative diffusion constant between the i-fold cluster and the j-fold cluster. If we assume that

$$n_i(r) = 0 \quad \text{at } r = R_{ij} = a_i + a_j \qquad (38.3)$$

and

$$n_i(r) \to n_{ib} \quad when\ r \to \infty \qquad (38.4)$$

we obtain J_B as

$$J_B = 4\pi R_{ij} D_{ij} n_{ib} \qquad (38.5)$$

where subscript b denotes the value at bulk solution. If we remember that there are n_j j-fold clusters in unit volume, the following equation for the total number of collisions in unit volume is derived:

$$\beta_B(a_{i,}a_j)n_i n_j = 4\pi R_{ij} D_{ij} n_i n_j. \qquad (38.6)$$

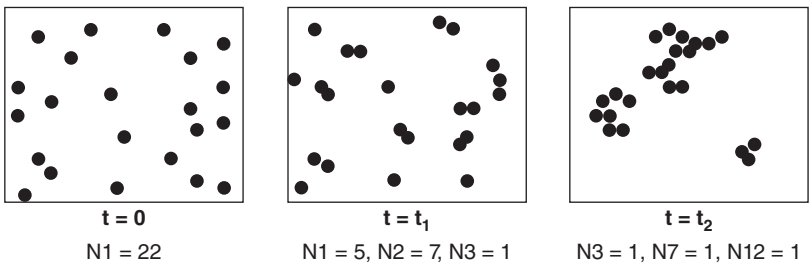

FIGURE 38.2 Temporal evolution of floc size distribution.

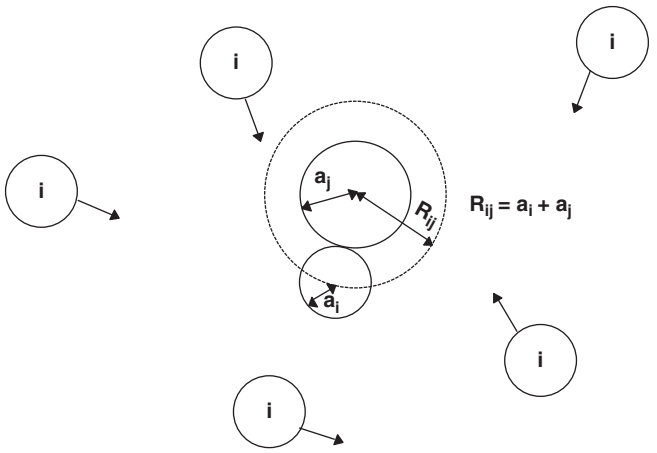

FIGURE 38.3 Diffusion of i-fold clusters relative to j-fold cluster.

In this expression, subscript b indicating the bulk is omitted. An expression of Einstein relation on the relative displacement between the i-fold and j-fold clusters can be written

$$\begin{aligned} 2D_{ij}t &= \overline{(\Delta X_i - \Delta X_j)^2} \\ &= \overline{\Delta X_i^2} - 2\overline{\Delta X_i \Delta X_j} + \overline{\Delta X_j^2} \\ &= \overline{\Delta X_i^2} + \overline{\Delta X_j^2} \\ (\therefore \overline{\Delta X_i \Delta X_j} &= 0 \quad (\textit{independence of Brownian motion of two clusters})) \\ &= 2D_i t + 2D_j t = 2(D_i + D_j)t. \end{aligned} \tag{38.7}$$

Thus, the relative diffusion constant of two clusters is the sum of diffusion constant if the independency of the Brownian motion of the two clusters is maintained.

Furthermore, substituting an expression of the Stokes–Einstein relation will yield,

$$\begin{aligned} \beta_B(a_i, a_j) &= 4\pi(a_i + a_j)\left(\frac{k_B T}{6\pi a_i \mu} + \frac{k_B T}{6\pi a_j \mu}\right) \\ &= \frac{2k_B T}{3\mu}(a_i + a_j)\left(\frac{1}{a_i} + \frac{1}{a_j}\right) \\ &= \frac{2k_B T}{3\mu}\left(2 + \frac{a_j}{a_i} + \frac{a_i}{a_j}\right). \end{aligned} \tag{38.8}$$

In other words, the collision frequency function of the Brownian coagulation is determined by the ratio of the size of colliding particles.

38.3.2 Smoluchowski Solution

In this case, coagulation begins in the early stage with monodispersed suspension of spherical particles, where we can assume that

$$a_i \approx a_j \tag{38.9}$$

the following approximation

$$(a_i + a_j)\left(\frac{1}{a_i} + \frac{1}{a_j}\right) \cong 4 \quad \text{(Smoluchowski approximation)} \tag{38.10}$$

will lead to the constant value of collision frequency function as follows:

$$\beta_B(a_i, a_j) = \frac{8k_B T}{3\mu}. \tag{38.11}$$

On the basis of this assumption, Smoluchowski derived the following solution for the temporal evolution of the total number concentration of clusters and their size distributions. Thus, substitution of Eq. (38.11) into Eq. (38.1) will yield

$$\frac{dN(t)}{dt} = -\frac{4k_B T}{3\mu}N(t)^2 \tag{38.12}$$

where

$$N(t) = \sum_{k=1}^{\infty} n_k. \tag{38.13}$$

The integrated expression with initial concentration of $N(t) = N(0)$ at $t = 0$ is derived as

$$\frac{1}{N(t)} - \frac{1}{N(0)} = \frac{4k_B T}{3\mu}t. \tag{38.14}$$

Substitution of this result into Eq. (38.1) will yield

$$\frac{n_k(t)}{N(t)} = P^{k-1}(1 - P) \tag{38.15}$$

where

$$P = \frac{\left(\frac{t}{\tau}\right)}{\left(1 + \frac{t}{\tau}\right)}, \tau = \frac{3\mu}{4k_B T N(0)}. \tag{38.16}$$

Equation (38.15) demonatrates that the size distribution on the basis of Smoluchowski approximation is a geometric progression with a common ratio of P and the first term of (1-P); τ is the coagulation time, denoting the time required for the number of particles reduce to half of $N(0)$.

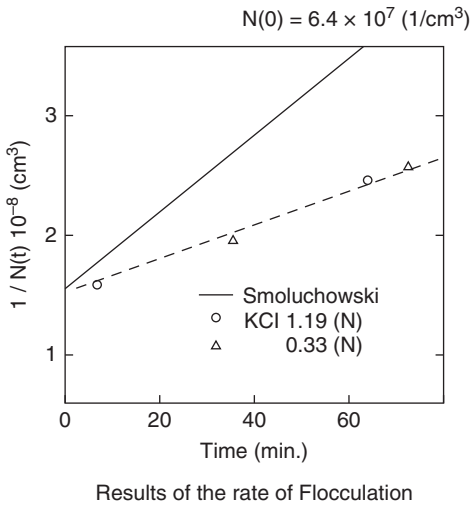

FIGURE 38.4 Exprimental result of kinetics of Brownian coagulation. Solid lines represent the prediction on the basis Smoluchowski theory [8].

Experimental data on the kinetics of rapid coagulation were obtained by numerous researchers using the dispersion of polymer latices (PSL) [16–21]. All the results supported the linear relation between $1/N(t)$ versus t. However, the measured rates are 40–70% smaller than the theoretical prediction (Fig. 38.4). This effect is usually described by the collection factor α_B, termed the *coagulation coefficient*. One investigator [22] analyzed this factor by ascribing it to the effect of hydrodynamic interaction between colliding particles. Since the Hamaker constant calculated in accordance with Spielman's theory gives a reasonable value, this result has been accepted by many researchers. However, there still remains the mysterious result of experiment. More specifically, the experimental data obtained for the dependence of the reduction in the initial particle concentration in the region of very dilute suspension cannot be explained by the theory of Spielman. More recently, another team [23] verified that the effect of volume fraction on the hydrodynamic interaction in the case of rapid Brownian coagulation is effective for only two or three orders of magnitude higher-concentration regions. It may be worthwhile to examine the original assumption of the mean field approximation adopted by Smoluchowski.

38.3.3 Self-Similar Solution

Since the derivation of Smolukowski approximation is based on the assumption limited to the early stage of coagulation, it seems difficult to apply the relation in the analysis of flocculation at a later stage. However, support for the theory of Brownian coagulation was originally obtained from experiment with polydisperse aerosols [24]. It has been reported that the functional forms of size distributions of aerosol observed in different places are the same, implying the presence of a universal function for the size distribution function [25]. This observation leads to the insight of Smoluchowski population equation at a later stage. In the case of Brownian coagulation, two other investigators [26] demonstrated the consistent presence of a self-preserving size distribution function of coagulated flocs with Smoluchowski population equation. Thus, if a sufficiently long time has elapsed after the onset of coagulation, the size distribution will converge to a certain functional form [27]. In this case, floc size distribution can be expressed by a product of the size of sample and a self-preserving function. Variability of the function is reduced by a representative value of the sample. Therefore, the number concentration of floc with volume of v is expressed as:

$$n(v,t) = \frac{N(t)^2}{\phi}\Psi(\eta), \tag{38.17}$$

where η is the dimensionless volume, defined as,

$$\eta = \frac{v}{\bar{v}} = \frac{N(t)v}{\phi}, \tag{38.18}$$

$$N(t) = \int_0^\infty n dv \tag{38.19}$$

and

$$\phi = \int_0^\infty n v dv. \tag{38.20}$$

Two investigators [28] calculated the asymptotic form of $\Psi(\eta)$ for the case of Brownian coagulation in Eq. (38.8). Using their results, temporal variation of the total number concentration of clusters, is obtained as,

$$\frac{dN(t)}{dt} = -\frac{4.26\, k_B T}{3\mu} N(t)^2. \tag{38.21}$$

This result is noteworthy, since the obtained factor 4.26 is close to 4.0, which is the theoretical value predicted on the basis of Smolukowski approximation Eq. (38.10). Thus, it was concluded that in the case of Brownian coagulation the predicted rate of coagulation taking into account the size distribution increases by only ~5% from the rate constant obtained for uniform spheres. The rate of Brownian coagulation is nearly constant from the beginning to later stages, where we expect self-preserving size distribution of flocs.

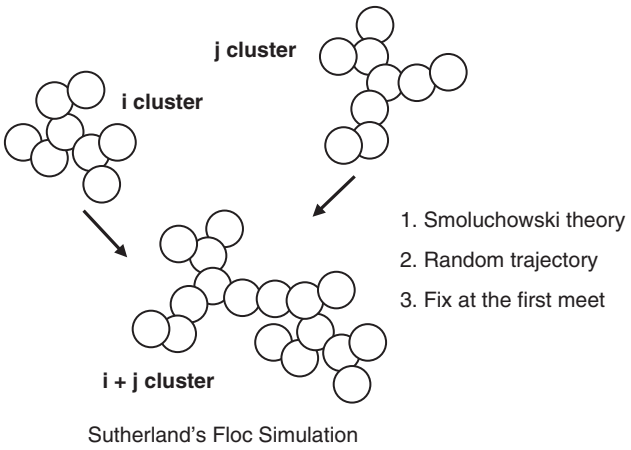

FIGURE 38.5 Sutherland's floc simulation of cluster–cluster collision model.

38.3.4 Effect of Fractal Structure of Flocs on Flocculation Rate

The conclusion in the previous section is questioned in terms of the effect of the formation of fractal structure of flocs. Thus, in the later stage, the concept of cluster–cluster aggregation in accordance with the collision sequence of Smoluchowski theory with an assumption of rigid adhesion of colliding cluster pairs will result in the formation of extremely bulky structure of flocs. The density decreases with an increase of size of floc. This relation is usually expressed as

$$a_f = a_0 i^{1/D} \tag{38.22}$$

where a_0 is the diameter of primary particle, a_f is the radius of floc, and D is the fractal dimension. This relation is numerically predicted by the cluster–cluster addition model proposed in the literature [29,30] (Fig. 38.5) and expanded [31]. The result was confirmed by floc structure composed of PSL particles [32]. The shapes of resulted flocs are obviously far from sphere remaining the ambiguity of collision radius and Stokes diameter. Analysis of the effect of this factor on the population equation was reported [32]. However, in this case, because the effect of structure development in collision radius and Stokes radius counterbalance each other, the influence of the development of floc structure on the rate of coagulation was not detectably large.

One of the most important characteristics of fractal aggregate is, however, that the development of fractal structure is followed by the increase of occupied volume by floc structure. In other words, the free space that can be used for diffusion will be substantially decreased in accordance with the progress of coagulation [13]. Through this effect, the number concentration will be increased, reflecting the decrease of free volume as illustrated in Fig. 38.6. With this picture,

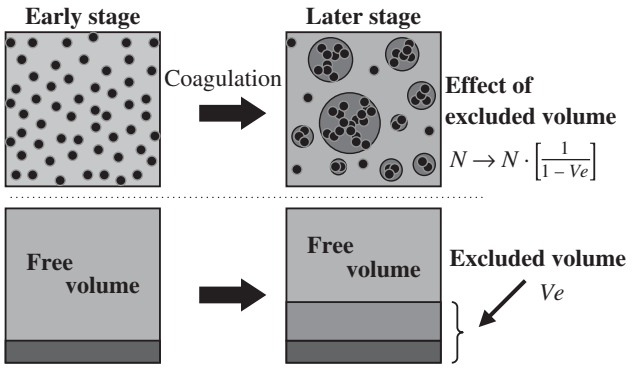

FIGURE 38.6 Increase of excluded volume and decrease of free volume with development of floc structure in Brownian flocculation [13].

the rate of coagulation is modified as

$$\frac{dN(t)}{dt} = -\alpha_B \frac{4k_B T}{3\mu} N(t)^2 \left(\frac{1}{1-V_e}\right)^2 \tag{38.23}$$

where V_e denotes the effective excluded volume of floc structure defined as

$$V_e = \sum_{i=1}^{N} \frac{\pi}{6} d_{f_i}^3 \tag{38.24}$$

This scenario was verified by a careful measurement on the rate of Brownian flocculation under optical microscope (Fig. 38.7). As for the definition of d_f, the lengths of the major axes of the best-fit ellipses for corresponding flocs were adopted. As shown in Fig. 38.8, the rate of coagulation gradually

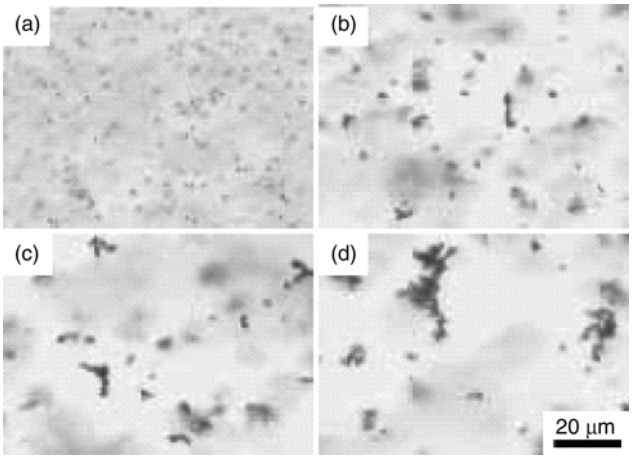

FIGURE 38.7 Typical snapshot of the state of coagulation for rapid Brownian coagulation. Date represents (a) 0 min., (b) 10 min., (c) 20 min. and (d) 30 min. After the onset of coagulation, $N_0 = 1.5 \times 10^9$ (1/cm^3); 1040 nm. PSL dispersion was coagulated in a 1.24 M KCl [13].

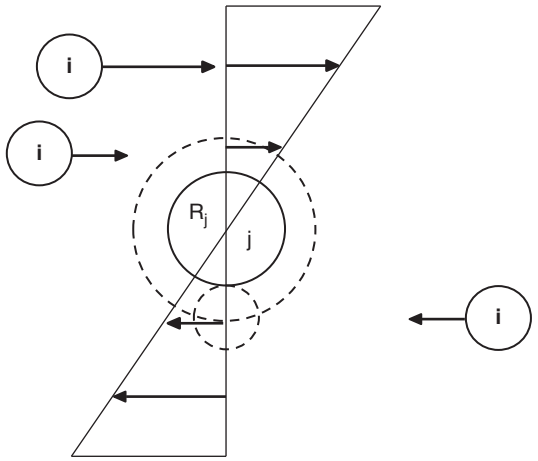

FIGURE 38.9 Coagulation in shear flow.

increases in the later stage. The prediction on the basis of Eq. (38.23) agrees well with these results.

38.4 COAGULATION IN SHEAR FLOW

38.4.1 Collision Frequency in Shear Field

In many situations of practical application, the operation of flocculation is carried out in a mixing flow. Therefore, analysis of flocculation in a flow field can be regarded as an issue of engineering subject in addition to its scientific appeal. The most simple problem is that the rate of flocculation in a simple shear flow, which was initially formulated by Smoluchowski [15], is the starting basis of this regime; however, the treatment and solution obtained for the simple situation is also important when flocculation in turbulent flow is considered.

Imagine that a viscous Newtonian fluid is placed in a gap between two parallel plates moving oppositely at the same velocity to the direction parallel to the surface of the plates. A simple shear flow field with velocity distribution of

$$u(y) = Gy \tag{38.25}$$

will be generated as shown in Fig. 38.8. Here G denotes the shear rate or velocity gradient. When colloidal particles are immersed in this field, they will cause collisions subject to the motion of fluid. Smoluchowski [15] derived the theory of rate of coagulation by assuming the number of collisions per unit time to be in a unit volume. Let us place a sphere with radius a_i (which represents an i-fold cluster) at the origin and assume that the number of collisions with another spheres of radius a_j (which represents a j-fold cluster) distributed with number concentration of n_j (Fig. 38.9). The number of collisions experienced by the first sphere, J_s, can be obtained by calculating the fluid volume crossing the collision sphere with radius $R_{ij} = a_i + a_j$ as follows:

$$\begin{aligned} J_s &= 2\int_0^{R_{ij}} Gy \cdot 2\sqrt{R_{ij} - y^2}\,dy \cdot n_j \\ &= \frac{4}{3}R_{ij}^3 G n_j. \end{aligned} \tag{38.26}$$

Therefore, the collision frequency function can be derived as,

$$\beta_s(a_i, a_j) = \frac{4}{3}R_{ij}^3 G. \tag{38.27}$$

In the early stage of coagulation starting from monodispersed spheres with radius a_0, the rate of coagulation can be derived as,

$$\frac{dN(t)}{dt} = -\frac{16}{3}a_0^3 G N(t)^2. \tag{38.28}$$

If we can assume that

$$\phi = \frac{4\pi}{3}a_0^3 N(0) = \text{Const.} \tag{38.29}$$

Equation (38.28) is reduced to,

$$\frac{dN(t)}{dt} = -\frac{4}{\pi}\phi G N(t). \tag{38.30}$$

The solution of Eq. (38.30) can be easily obtained as

$$\ln\left(\frac{N(t)}{N(0)}\right) = -\frac{4\phi G}{\pi}t \tag{38.31}$$

Equation (38.31) indicates that the value of ϕGt is an essential factor in controlling and evaluating the degree of flocculation in shear flow. In accordance with Eq. (38.27), we

should also note that the collision frequency in a shear flow is proportional to the third power of the particle diameter. Later, we will see that this conclusion can be extended to the case where coagulation takes place in a turbulent flow.

38.4.2 Interaction between Colloid Particles in Laminar Shear Flow

The treatment in the previous section does not factor in the effect of interaction between two approaching particles. In reality, in addition to colloidal interaction (electrostatic repulsion and Van der Waals attraction), the relative motion between colloidal particles immersed in a viscous liquid is hydrodynamically influenced by the presence of other particles. This factor is essentially important when the rate of coagulation in the flow field is considered. In the absence of attractive forces, approaching particles will never encounter each other because of this effect. The relative trajectory of two spheres in a shear field was first obtained by Lin et al. [33]. More general expressions for the flow field of two sphere interaction in the linear flow field were derived by other investigators [34]. Their results were combined with colloidal interaction to calculate the relative trajectory of two approaching spheres in a flow field [36, 37]. When the discussion is limited to the binary collisions between two equal-sized spheres in the absence of electrostatic repulsion, the following approximate form using a collection factor for collision frequency function [21]

$$\beta_s = \alpha_s \frac{16}{3} a_0^3 G \tag{38.32}$$

$$\alpha_s = C_A^{0.18}, C_A = \frac{A}{36\pi\mu a_0^3 G} \tag{38.33}$$

can be used to predict the rate of coagulation.

38.4.3 Effect of Formation of Floc Structure on Shear Coagulation Rate

The treatment of coagulation in flow field described so far is limited to the initial stage of coagulation where binary collision between singlets is dominant. However, it is obvious that, in the later period, the formation and developments of fractal structure of floc can be a considerable factor in the rate of coagulation [12]. If we replace the assumption of uniform primary spheres by flocs of the same size, the temporal evolution of floc number concentration $N(t)$ can be expressed as follows:

$$\frac{dN(t)}{dt} = -\alpha_s \frac{16}{3} a_f^3 G N(t)^2 \tag{38.34}$$

Remember that the value of a_f is a function of the number of primary particles described in Eq. (38.22);

$$a_f = a_0 i^{1/D} \tag{38.22}$$

and i can be expressed as,

$$i = \frac{N(0)}{N(t)}. \tag{38.35}$$

Substituting Eqs. (38.22) and (38.35) into Eq. (38.34) yields,

$$\frac{dN_f}{dt} = -\alpha_s \frac{16}{3} a_0^3 G \left(\frac{N(0)}{N(t)}\right)^{3/D} N(t), \tag{38.36}$$

where α_s is the capture efficiency between flocs, which is obtained by hydrodynamic trajectory analysis of approaching flocs in a shear field, assuming that (1) shapes and size of flocs are equal-sized spheres, (2) effects of permeability on the collision trajectory is ignored, and (3) the attractive force is estimated as the van der Waals force of two primary particles (Fig. 38.10). The resulting value of α_s can be approximated as follows:

$$\alpha_s = C_A^{0.18}, C_A = \frac{Aa_0}{36\pi\mu a_f^4 G} = \frac{A}{36\pi\mu(\frac{N(0)}{N(t)})^{4/D} G}. \tag{38.37}$$

Substituting Eq. (38.37) into Eq. (38.36) yields

$$\frac{N(t)}{N(0)} = (1 - \frac{3 - 4\times 0.18 - D}{D} \cdot \frac{16}{3} \cdot \alpha_s a_0^3 N(0) G t)^{\frac{D}{3-4\times 0.18-D}} \tag{38.38}$$

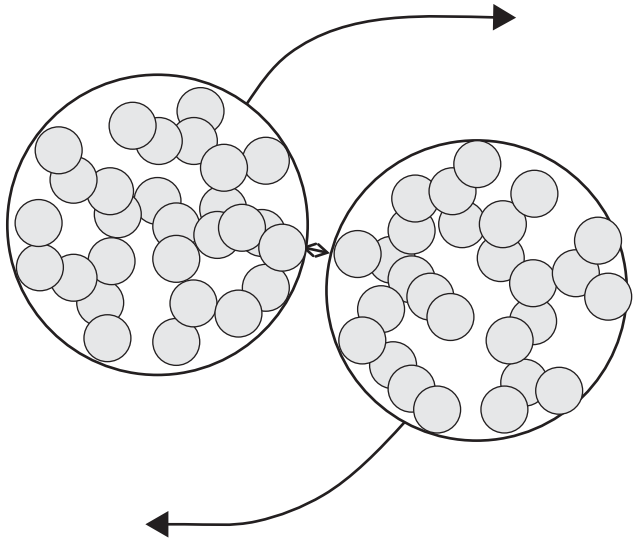

FIGURE 38.10 Collision process of two flocs in shear flow. Hydrodynamic interaction is calculated for two impermeable spheres enclosing floc, while Van der Waals attraction is that of two primary particles.

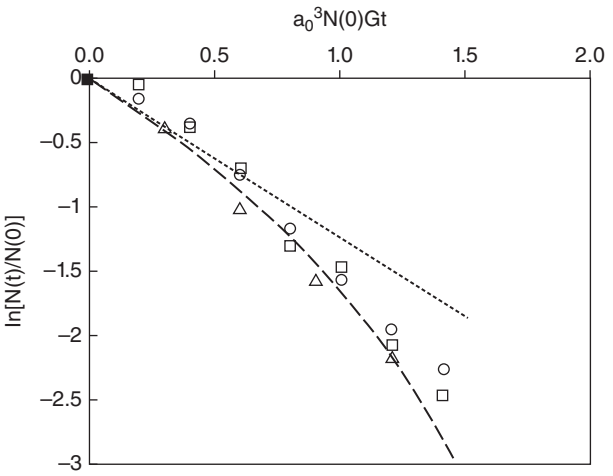

FIGURE 38.11 Temporal variation of the number concentration of flocs including later stage of coagulation where fractal structure of flocs are developed in shear flow [12].

The validity of Eq. (38.38) was confirmed by a careful measurement of the temporal variation of the total number concentration of flocs coagulated in a laminar shear flow generated in a gap between two concentric cylinders. The data thus obtained were plotted in Fig. 38.11. As demonstrated in this figure, the prediction on the basis of Eq. (38.38) yields a good agreement with the experimental data of the progress of flocculation in the later stage. It should be noted that one investigator [38] pointed out the importance of the effect of permeability in reducing the contribution due to the hydrodynamic infection. However, our experimental result did not confirm this prediction.

38.5 INITIAL STAGE OF BRIDGING FLOCCULATION IN A TURBULENT MIXING

38.5.1 Schematic Picture of Flocculation with Polymer Flocculants in a Practical System

In most practical applications, flocculation operation is carried out in turbulent flow. However, as can be easily imagined, the process of flocculation in the usual application is very complicated. If we assume the normal operation of water treatment where flocculation of coll veroidal dispersion is initiated on the addition of polymer flocculants, we will recognize that the process of flocculation consists of several elementary processes taking places simultaneously as illustrated in Fig. 38.12:

1. Dilution of flocculants into homogeneous solution
2. Collision between colloidal particles
3. Stretching of polymer chain
4. Collision of polymer chain and colloidal particles
5. Reconformation of adsorbed polymer chain on the surface of colloidal particles
6. Formation of polymer bridge between colloidal particles
7. Rearrangement and breakup of floc structure

All these processes take place simultaneously in the flow field of turbulent mixing. Therefore, analysis of turbulence from the perspective of the flocculation process can be regarded as an important issue for better control of colloidal flocculation. In the last section of this chapter, an analysis of collision process between colloidal particles in a turbulent flow is introduced to normalize the mixing flow condition, which will be ultimately useful for the evaluation of the effect of polymer flocculants applied in the same mixing condition.

38.5.2 Collision Process in Turbulent Flow

Turbulent flow can be regarded as a superposition of eddies with different sizes. The kinetic energy of turbulent fluctuations generated by unstable hydrodynamic condition of the main flow is transmitted from larger eddies, which will produce a number of intermediate-sized eddies, sequentially resulting in the generation of enormous numbers of small energy-dissipating eddies, and eventually dissipating into heat. This is the so-called cascade process of energy transfer of turbulence. Kolmogoroff [39] proposed a hypothesis of local isotropy of turbulence for small-scale eddies. In other words, in fully developed turbulence, the anisotropic character of the main flow will be lost through the cascade process, and consequently the statistical properties of small- scale eddies can be determined independently of the directional information of the main flow. On the basis of this argument, Kolmogoroff introduced an important length scale λ, which characterizes the size of an energy-dissipating eddy and termed it the *microscale of turbulence*

$$\lambda = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \tag{38.39}$$

where ν and ε denote the kinematic viscosity of fluid and the rate of energy dissipation per unit mass, respectively. If the length scale of the region of interest is smaller than λ, the fluctuating field of turbulence can be treated as homogeneously isotropic. The magnitude of λ is roughly 30–100 μ m, which is sufficiently larger than the collision radius of the colloidal particle, and because of their higher shear rates, which essentially dominate the collision rates between colloidal particles, the assumption of local isotropy is applicable to estimation of the rate of coagulation, and the turbulent coagulation can

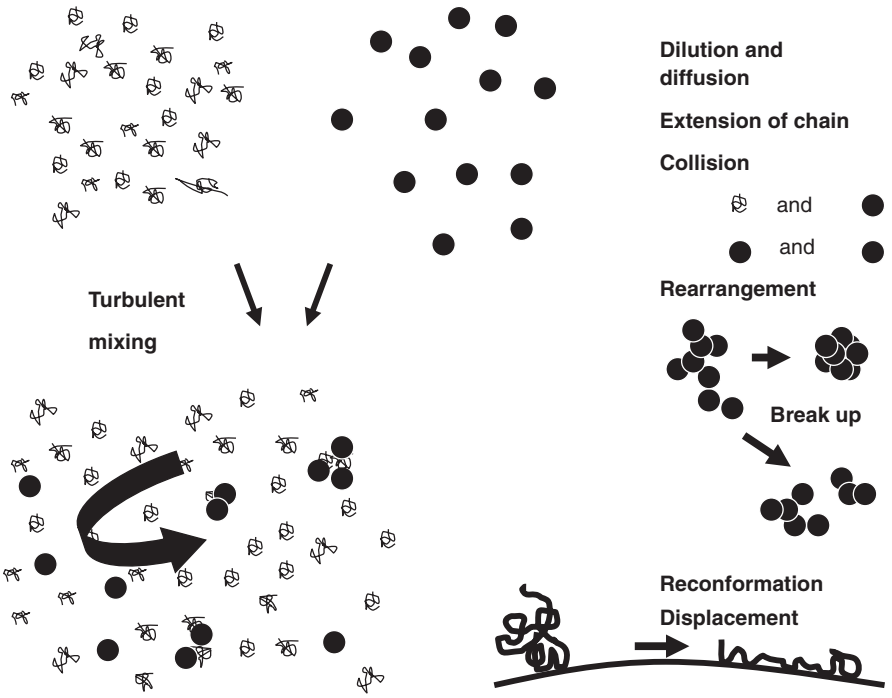

FIGURE 38.12 Schematic drawing of bridging flocculation in turbulent mixing.

be treated as a sort of shear coagulation. A treatment of turbulent coagulation was first carried out by Camp and Stein [40] in a practical manner assuming that the collision mechanism of colloidal particles in a turbulent flow is analogous to that in laminar shear flow. In order to estimate the rate of coagulation in a turbulent flow, they simply used the effective velocity gradient $\sqrt{\varepsilon/\nu}$, in place of the shear rate G, in the collision frequency function in a shear flow [Eq. (38.27)]. This simple idea constitutes a starting point for the study of turbulent coagulation. A more rigorous derivation of the rate of turbulent coagulation was formulated later by investigators [4] who obtained the collision frequency of j-fold clusters experienced by an i-fold cluster by calculating the inward flux of mean flow crossing the surface of collision sphere with collision radius of R_{ij} as

$$J_T = 2\pi R_{ij}^2 \cdot \overline{\left|\frac{\partial u_r}{\partial r}\right|} R_{ij} n_j \tag{38.40}$$

where u_r denotes the radial component of velocity fluctuation. Using the results of the statistical analysis of isotropic turbulence by another author [41] and assuming a normal distribution of $\partial u_r/\partial r$ that was experimentally supported [40], other investigators determined the collision frequency function as

$$\beta_T(a_i, a_j) = \sqrt{\frac{8\pi\varepsilon}{15\nu}} R_{ij}^3 \tag{38.41}$$

If we compare this result with that obtained for a laminar shear flow expressed by Eq. (38.27), the collision process of a colloidal particle in a turbulent flow can be treated essentially the same as that in a laminar shear field.

In the case of colloidal particles immersed in a viscous liquid, however, collision frequency function is modified by a factor of α_T, which takes into account the hydrodynamic interaction. The effect hydrodynamic interaction is emphasized by the coagulation experiment of latex particles by several workers [43–45]. For rapid coagulation in the initial stage starting from monodispersed spheres, the temporal variation of the total number concentration of clusters can be expressed by

$$\frac{dN(t)}{dt} = -\frac{1}{2}\alpha_T \sqrt{\frac{8\pi\varepsilon}{15\nu}} (2a_0)^3 N(t)^2 \tag{38.42}$$

In the case of rapid coagulation, α_T can be approximated by

$$\alpha_T = \left(\frac{A}{36\pi\mu a_0^3 \sqrt{\frac{4\varepsilon}{15\pi\nu}}} \right)^{0.18} \tag{38.43}$$

If we apply the initial-stage approximation, then

$$\phi = \frac{4\pi}{3} a_o^3 N(0) = \frac{4\pi}{3} R^3 N(t) = \text{Const.} \tag{38.44}$$

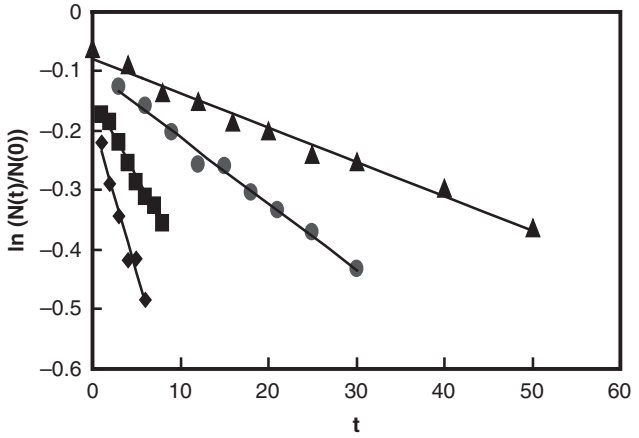

FIGURE 38.13 Temporal variation of total number of clusters per unit volume in the case of salt-induced coagulation as a function of the number of mixing steps (t), where [KCl] = 1.12 M. The total number concentration of PSL particle: (♦) 4.83×10^8 1/cm^3; (■) 2.52×10^8 1/cm^3; (●) 1.07×10^8 1/cm^3 ; (▲) 5.11×10^7 1/cm^3 [59].

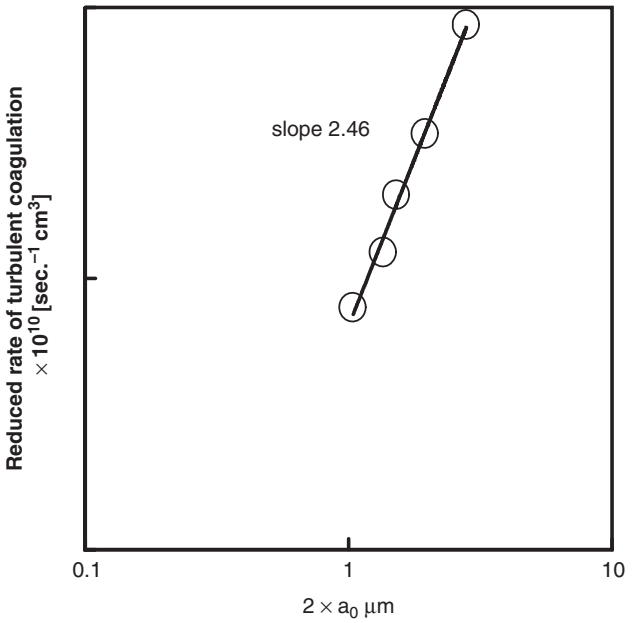

FIGURE 38.14 Reduced rate of turbulent coagulation as a function of the diameter of primary particles [59].

We can solve Eq. (38.42) approximately as

$$\ln \frac{N(t)}{N(0)} = -\alpha_T \sqrt{\left(\frac{24\varepsilon}{5\pi\nu}\right)}\phi t \tag{38.45}$$

In a fixed condition of the mixing, the value of ε can be regarded constant. Therefore, it should be noted that the rate of coagulation is proportional to the 2.46th power of the size of primary particles under certain mixing conditions.

In Fig. 38,13, the temporal variation of $N(t)$ for the case of coagulation of latex particles induced under the condition of rapid coagulation is plotted against t. This experiment was carried out using a homemade mixing device of end-over-end rotation of two small bottles. As indicated by the plotted data, the linear relation between $\ln(N(t))$ and t is confirmed. The slope, denoting the rate of coagulation, is proportional to $N(0)$. Coagulation rates of latex particles obtained for different particle diameters are divided by each N(0) and compared as a function of diameter of primary particles in Fig. 38.14 [59]. Although control of the mixing operation is rather crude, as demonstrated in this figure, the progress of coagulation are found to obey the prediction of Eqs. (38.43)–(38.45) well. Another previous trial in comparison of different mixing procedures confirmed the same tendency [21,44]. This finding forms a basis for establishment of the evaluation of turbulent mixing on the basis of collision process of colloidal particles.

38.5.3 Historical Review of Concept of Nonequilibrium Flocculation

Currently, various types of polymer flocculants have been developed for application to many industrial process, mining operations, papermaking, and water treatment procedures to enhance solid–liquid separation and to control the rheological state of colloidal dispersion. Although such applications have long developmental histories [46,47], the dynamic process explaining exactly how polymer flocculants will induce flocculation is still unclear. Previous studies demonstrate the concept of optimum dosage in inducing colloid flocculation and indicate that colloids will stabilized by the excess or overdosage rather permanently. The experimental results of optimum dosage have generated speculation regarding the concept of polymer bridging. A pioneering study [48] pointed out the varying degree of colloidal stability that can be obtained simply by changing the mixing method. Two investigators [49] showed that higher-molecular-weight polymers will act as more effective flocculants as well as stabilizers. The stabilizing mechanism is recognized as a steric effect of the adsorbed polymer layer to avoid the approach of colloidal particles on collision. In case of either flocculation or stabilization, the adsorption of polymer is critically important in understanding the mechanism of change of colloidal dispersion. Another major effort was made to study the conformation of polymer at interfaces [50,51]. One author demonstrated the importance of the role of charge [52] and also demonstrated the dynamic concept of nonequilibrium flocculation [53]. Specifically, in practical situations, polyelctrolytes, that is, polymer chains with charged groups, are more effectively utilized as flocculants. Two authors [54] demonstrated that in concentrated suspension, pellet floc, that is, large, high-density flocs with excellent dewaterability, can be formed under the condition that the charge of colloidal

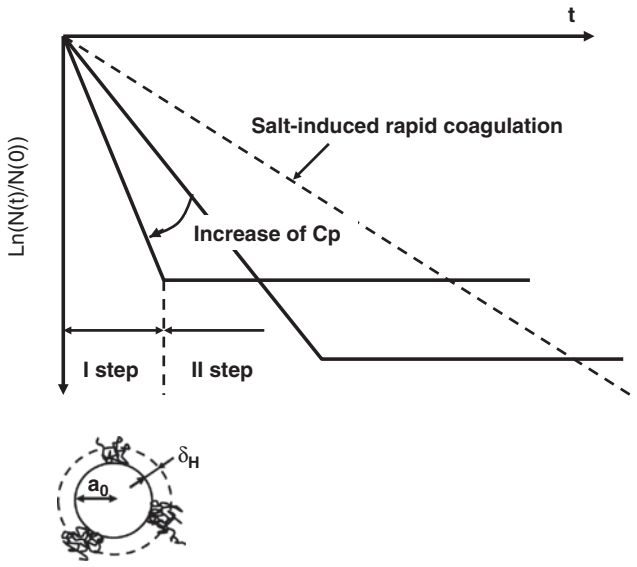

FIGURE 38.15 Illustration of concept of the progress of flocculation induced by polymer flocculant at overdosage [58].

particles will be neutralized by the adsorption of oppositely charged polyelectrolyte. It should be noted that the picture of pelletization is consistent with the concept of nonequilibrium flocculation [55]. Those authors [55] attempted systematic analysis of the role of polyelectrolytes in the relation between adsorption of polyelectrolytes and their effect on colloidal stability, however, they have not stressed the dynamic aspect, which is critically important. Probably one of the most important events of flocculation takes places immediately after the onset of mixing operation where the system is placed far from equilibrium.

38.5.4 Initial-Stage Dynamics of Bridging Flocculation of PSL Particles Induced by Polyelectrolytes under High Ionic Strength

In the last part of the previous section, the principle of the normalizing method of turbulent mixing in terms of collision rate of colloidal particles was explained. The established procedure has been used to evaluate the protruding length of polymers attached to the surface of colloidal particles. Thus, if we apply the polymer flocculants to the colloidal dispersion, the collision radius will be effectively increased to enhance the rate of flocculation.

Clear results can be obtained, if sufficient amount of polymer flocculants is supplied to the colloidal surface. In Fig. 38.15, we illustrate a concept of the progress of flocculation at the overdosage of polymer flocculants. Important information can be obtained on comparison of the progress of flocculation with excess addition of flocculants and that of salt-induced rapid coagulation (without polymer). From the
