where k_m and m_{re} are the mechanical stiffness and effective mass, respectively, of the beam resonator, L_r is the length of the beam, β_1 represents the frequency parameter of a fundamental mode of the beam, i represents the corresponding CMOS structural materials (e.g., metal and SiO_2), and E_i, ρ_i, A_i, and I_i are the Young's modulus, density, cross-sectional area, and moment of inertia of each structural layer, respectively. If the mere-metal resonator is designed, Eq. 1 can be greatly simplified by using only one uniform structural material. Precise resonance frequencies can be simulated by the finite-element analysis once more complicated or accurate structures of the CMOS-MEMS resonators are considered, as shown in Fig. 3.

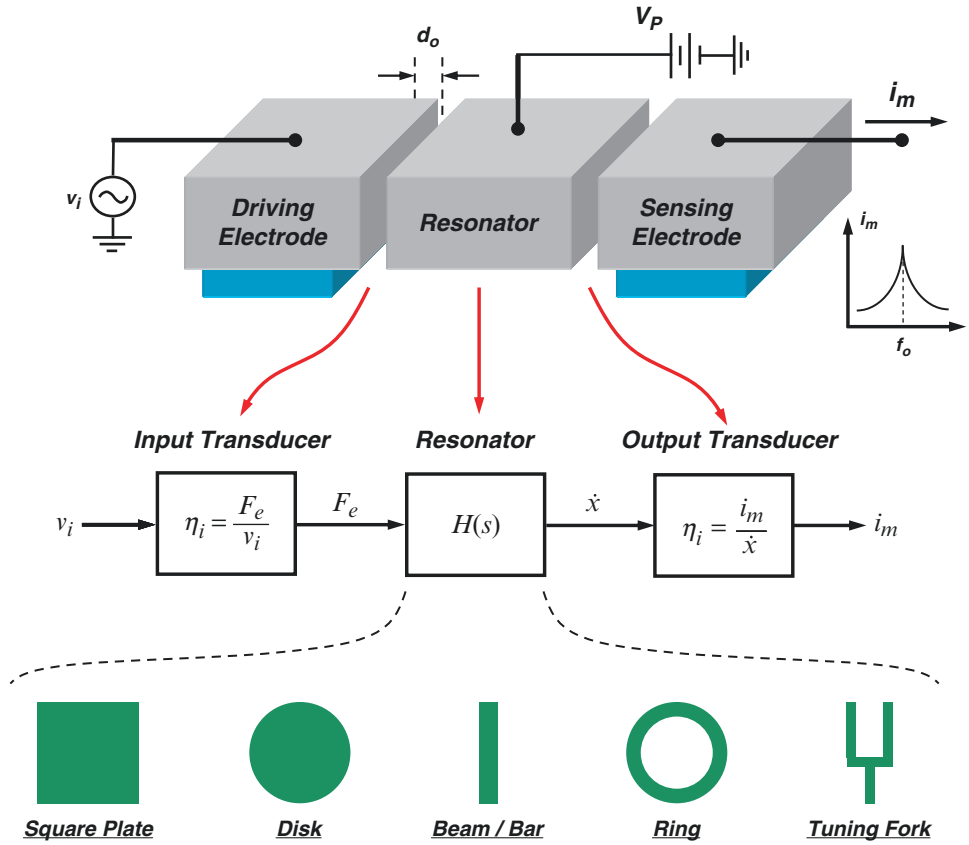
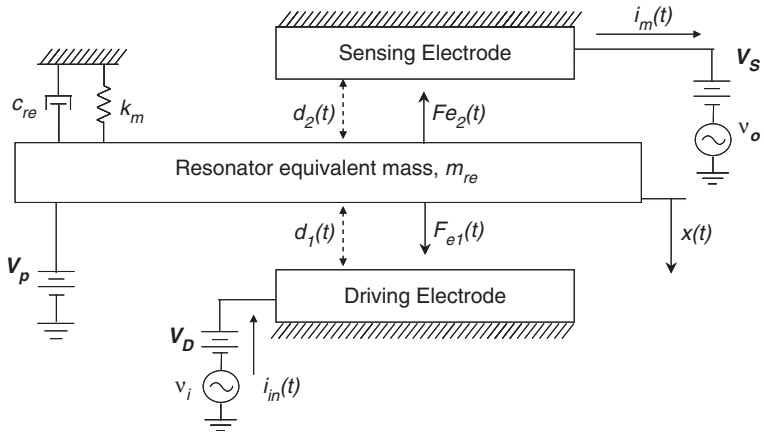
Transduction and Overall Transfer Function



After the resonance frequency is set through Eq. 1 based on the geometrical dimensions and material properties of a given resonator, one has to determine the capacitive transduction efficiency to obtain the most important parameter, the motional impedance R_m, and overall transmission of the CMOS-MEMS resonator. A block diagram shown in Fig. 4 can be used to facilitate the understanding of the CMOS-MEMS resonator which is modeled in an electrical domain by linking the mechanical transfer function $H(s)$ with the input/output electromechanical coupling coefficients, η_i and η_o. The overall admittance transfer function $Y = i_m/v_i$ of the CMOS-MEMS resonator can be expressed by

$$Y(s) = \frac{i_m(s)}{v_i(s)} = \left(\frac{F_e}{v_i}\right) \times \left(\frac{\dot{x}}{F_e}\right) \times \left(\frac{i_m}{\dot{x}}\right) = \eta_i \times H(s) \times \eta_o \quad (2)$$

where v_i and i_m represent the small-signal input driving voltage and output motional current of the resonator, F_e is the electrostatic force generated by v_i to drive the resonator into resonance, and $\dot{x}$



CMOS-MEMS Resonators, Fig. 3 Finite-element simulated modal frequencies and corresponding mode shapes of CMOS-MEMS resonators. (**a**) Tuning fork. (**b**) Free-free beam. (**c**) Flexural mode plate

CMOS-MEMS Resonators, Fig. 4 Conceptual schematic and block-diagram representation of a generalized capacitive MEMS resonator

represents the velocity of the resonator due to vibration. This is why η_i and η_o are treated as the electromechanical coupling coefficients where η_i converts the "electrical signal v_i" into the "mechanical force F_e" while η_i transforms the "mechanical velocity $\dot{x}$" into the "electrical current i_m". The mechanical transfer function $H(s)$ in Fig. 4 represents a general high-Q biquad response (cf. inset of Fig. 4) of the vibrating resonators, some of which are illustrated at the

CMOS-MEMS Resonators, Fig. 5 Equivalent lumped mechanical model for a capacitive MEMS resonator

bottom. Each type of resonators in Fig. 4 can be modeled by a simple mass-spring-damper system, as shown in Fig. 5, where the capacitive transducer gaps and voltage differences between the electrodes and the resonator are assumed to be different to preserve generality.

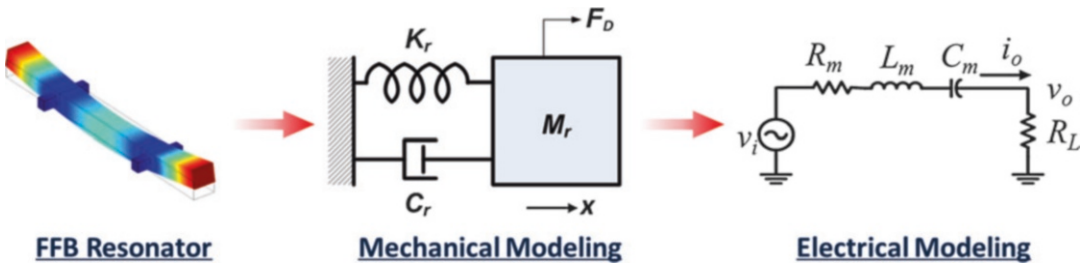
To derive the equivalent mechanical transfer function, $H(s)$, the equation of motion for the second-order mechanical system is used, given by

$$m_{re}\ddot{x} + c_{re}\dot{x} + k_m x = F_e \tag{3}$$

where x is the position of the mass away from its equilibrium position, m_{re} is the equivalent mass, c_{re} is the equivalent damping, k_m is the equivalent linear spring constant of the resonator, and F_e is the external driving force, respectively. Each element in Eq. 3 is assumed to be linear.

The force-to-velocity transfer function $H(s)$ can then be derived as

$$H(s) = \frac{\dot{x}}{F_e} = \frac{sX(s)}{F_e(s)} = \frac{1/m_{re}}{s^2 + \frac{c_{re}}{m_{re}}s + \frac{k_m}{m_{re}}}. \tag{4}$$



In Fig. 5, V_D, V_S, and V_P are the DC bias voltages applied into the input electrode, output electrode, and resonator structure, respectively. Based on the derivation of the capacitive transducers, the first-order electrostatic force and the output motional current of the resonator are given by

$$\begin{aligned} F_e &= -(V_P - V_D)\frac{\partial C_1}{\partial x}v_i \\ &= (V_P - V_D)\frac{\varepsilon_o A_1}{d_1^2}v_i \text{ and } \eta_i \equiv \frac{F_e}{v_i} \\ &= -(V_P - V_D)\frac{\partial C_1}{\partial x} \end{aligned} \tag{5}$$

$$\begin{aligned} i_m &= -(V_P - V_S)\frac{\partial C_2}{\partial x}\dot{x} \\ &= (V_P - V_S)\frac{\varepsilon_o A_2}{d_2^2}\dot{x} \text{ and } \eta_o \equiv \frac{i_m}{\dot{x}} \\ &= -(V_P - V_S)\frac{\partial C_2}{\partial x} \end{aligned} \tag{6}$$

where ε_o is the air permittivity; C_1 and C_2 are capacitors of the drive/sense ports, respectively; A_1 and A_2 are capacitive transducer areas of the drive/sense ports, respectively; and d_1 and d_2 are the capacitive transducer gaps of the drive/sense ports, respectively.

To simply describe the modeling procedure, Fig. 6 shows the CMOS-MEMS resonator, such as a free-free beam resonator, first modeled in mechanical domain as a mass-spring-damper (*MKC*) system. Then the *MKC* system is further transformed into a real *RLC* equivalent circuit in electrical domain through the electromechanical analogy. Based on Eqs. 2, 3, 4, 5, and 6, an equivalent series *RLC* model of an electromechanical resonator shown in Fig. 6 can be obtained with the motional elements expressed as

CMOS-MEMS Resonators, Fig. 6 Equivalent lumped electrical model for a capacitive MEMS resonator

$$L_m = \frac{m_{re}}{\eta_i \times \eta_o}, C_m = \frac{\eta_i \times \eta_o}{k_m}, R_m = \frac{c_{re}}{\eta_i \times \eta_o}. \tag{7}$$

For most capacitively transduced micromechanical resonators, their larger-than-conventional impedance (i.e., motional impedance R_m) is the main issue for system integration. Assuming the gap size d_o and overlap area A of the input and output transducers are symmetric, the motional impedance R_m in Eq. 7 can be further simplified as

$$R_m = \frac{c_{re}}{\eta_e^2} \cong \frac{\sqrt{k_m m_{re}} d_o^4}{Q \varepsilon_o^2 A^2 V_P^2} \tag{8}$$

where $\eta_e = \eta_i = \eta_o$, $d_o = d_1 = d_2$, $A = A_1 = A_2$, and Q is the quality factor of the resonator.

It is evident that to reduce R_m of a capacitive resonator, the stiffness, mass, gap size, and overlap area must be carefully designed under a V_P-constrained condition (high bias V_P is not desirable). Several design approaches can be adopted to reduce R_m, including (i) the gap size d_o should be as small as possible, (ii) the transducer overlap area A should be as large as possible, and (iii) the Q factor of the resonator should be as high as possible.

Thermal Stability

The nominal mechanical resonance frequency of the composite beam resonator (cf. Fig. 2b) composed of three structural materials, including metal (i.e., aluminum alloy), tungsten, and oxide, can be expressed as a combination of the resonance frequency of each portion for a given composite beam by an algebraic manipulation of Eq. 9 and given by [6]

$$f_{nom}{}^2 = \frac{m_{\text{metal}}}{m_r} f_{\text{metal}}{}^2 + \frac{m_{\text{tungsten}}}{m_r} f_{\text{tungsten}}{}^2 + \frac{m_{\text{oxide}}}{m_r} f_{\text{oxide}}{}^2 \tag{9}$$

where m_{metal}, m_{tungsten}, and m_{oxide} are the portion of mass of the composite beam for metal, tungsten, and oxide constituents, respectively, and f_{metal}, f_{tungsten}, and f_{oxide} are the mechanical resonance frequencies of beams for metal, tungsten, and oxide constituents, respectively. As a result, the linear temperature coefficient of frequency (TC_f) of the composite free-free beam resonator can be derived by taking the derivative of Eq. 9 with respect to temperature and then simplified as

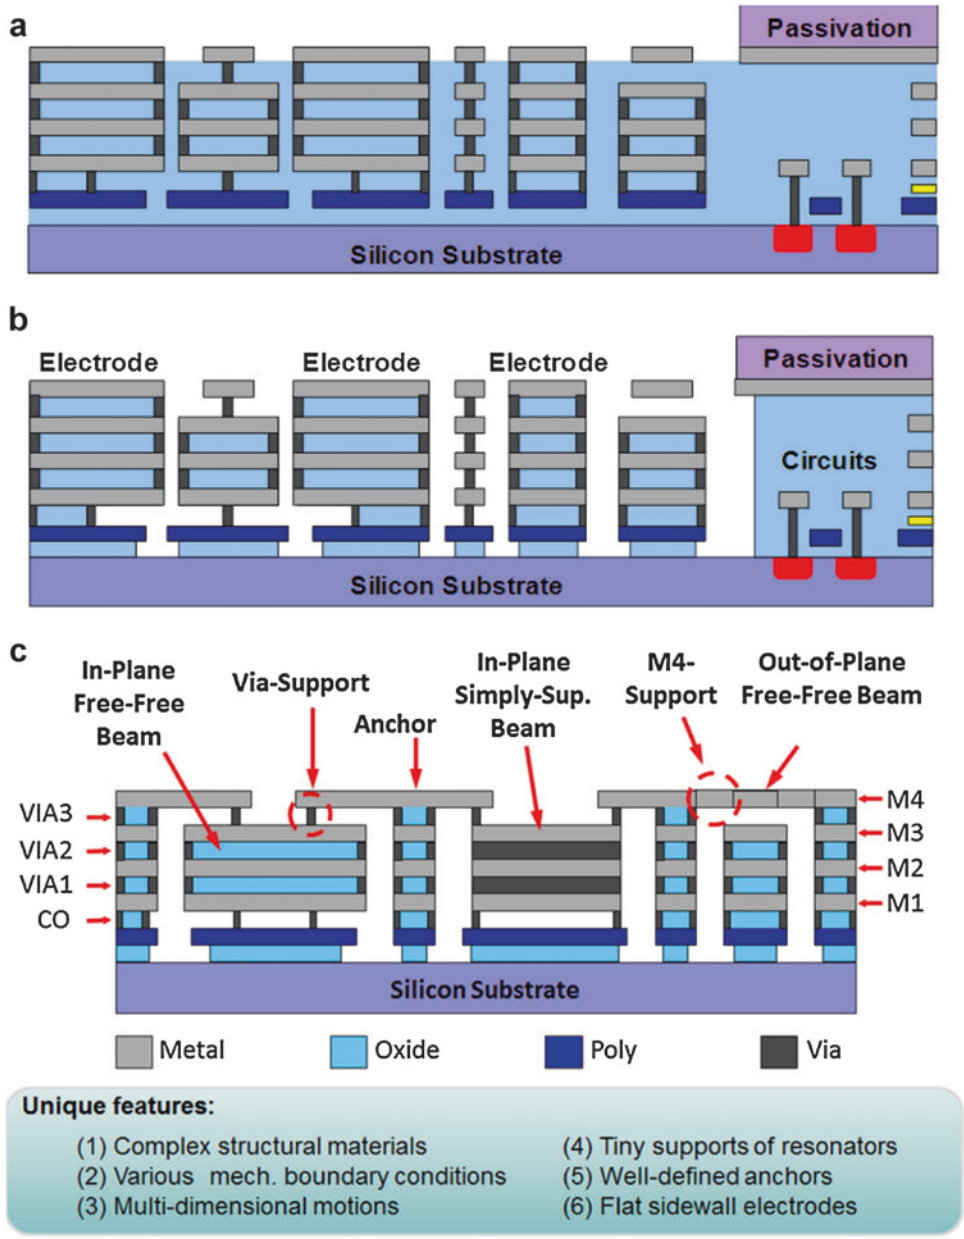
$$TC_{f1} = \frac{TC_{f1,\ \text{metal}} + A \cdot TC_{f1,\ \text{tungsten}} + B \cdot TC_{f1,\ \text{oxide}}}{1 + A + B} \tag{10}$$

where $A = \frac{m_{\text{tungsten}} \cdot f^2_{\text{tungsten}}}{m_{\text{metal}} \cdot f^2_{\text{metal}}} = \frac{E_{\text{tungsten}} \cdot I_{\text{tungsten}}}{E_{\text{metal}} \cdot I_{\text{metal}}}$ and $B = \frac{m_{\text{oxide}} \cdot f^2_{\text{oxide}}}{m_{\text{metal}} \cdot f^2_{\text{metal}}} = \frac{E_{\text{oxide}} \cdot I_{\text{oxide}}}{E_{\text{metal}} \cdot I_{\text{metal}}}$ and where $TC_{f1,\text{metal}}$, $TC_{f1,\text{tungsten}}$, and $TC_{f1,\text{oxide}}$ are the linear TC_fs of metal, tungsten, and oxide, respectively; E_{metal}, E_{tungsten}, and E_{oxide} are Young's moduli of metal, tungsten, and oxide, respectively; and I_{metal}, I_{tungsten}, and I_{oxide} are the moments of inertia of metal, tungsten, and oxide, respectively. In addition, the linear TC_f of each material in Eq. 10 can be expressed as [6]

$$TC_{f1,\ \text{mat}} = \frac{TC_{E1,\ \text{mat}} + \alpha_{1,\ \text{mat}}}{2} \tag{11}$$

where $TC_{E1,\,mat}$ and $\alpha_{1,\,mat}$ are the linear TC_E and the coefficient of thermal expansion (CTE), respectively, of each structural material. In Eq. 11, $TC_{E1,\,mat}$ is the major parameter to induce the resonance frequency drift as temperature changes (i.e., $TC_{f1,\,mat}$), indicating the structural oxide with positive TC_E is effective for passive temperature compensation of CMOS-MEMS resonators. To approach the ultimate goal of zero TC_f, thermal stability of the CMOS-MEMS composite resonators can be further improved by manipulating the ratio A and ratio B in Eq. 10, respectively. As an extreme case when both A and B are close to zero, it represents that TC_f of such a resonator is exactly the same with that of metal-type resonators, while structures with A of zero and infinite B belong to oxide-type resonators exhibiting positive TC_f.

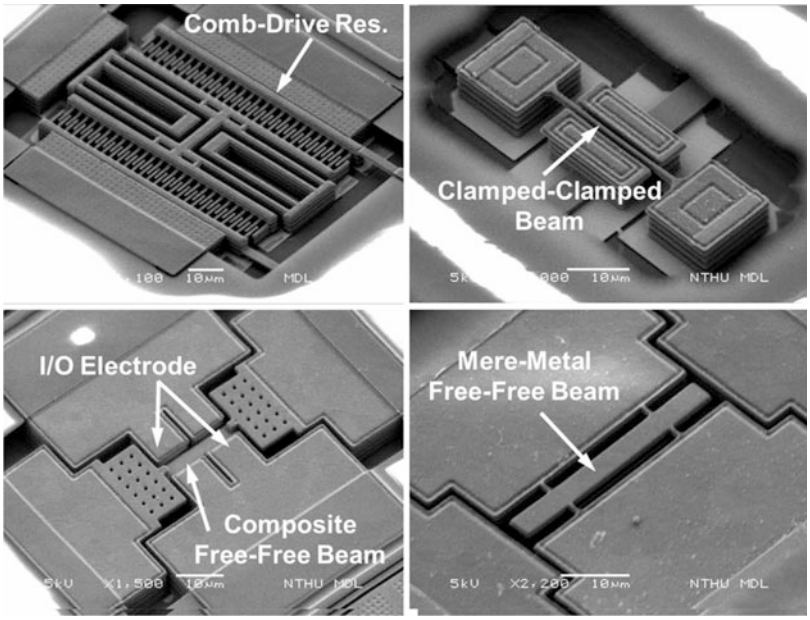
Methods of Fabrication



Several CMOS-MEMS resonator platforms [1–4] co-fabricating mechanical resonators and their amplifier circuits for MEMS/IC integration have been developed in the past decades. These platforms can be mainly categorized into two different release methods – oxide removal and metal removal maskless post-CMOS processes, implemented in both 0.35 μm 2-poly-4-metal (2P4M) and 0.18 μm 1-poly-6-metal (1P6M) CMOS technologies. In the following contents, their pros and cons will be discussed.

Oxide Removal Release Process in a 0.35 μm CMOS

To fabricate resonators using the platform illustrated in Fig. 7, chips are manufactured utilizing a standard 0.35 μm 2-poly-4-metal CMOS service from the Taiwan Semiconductor Manufacturing Company (TSMC) with a cross-sectional view shown in Fig. 7a, including two polysilicon layers underneath four metal layers [1]. CMOS circuit areas are masked by the passivation layer mostly comprised of silicon nitride while the MEMS regions (i.e., openings) expose sacrificial oxide to the release etchant. A commercial SiO_2 etchant, silox vapox III, with very high selectivity to metal layers, vias (i.e., tungsten), and contacts (i.e., tungsten) is utilized to release the resonator structures as depicted in Fig. 7b without the help of critical point dryers while the transistor circuits are still protected by the passivation layer. Figure 7c indicates that CMOS-MEMS resonators fabricated using this platform specifically possess several unique features including (i) complex structural materials which can be made of metal-oxide composite, metal composite, and mere-metal structures; (ii) various mechanical boundary conditions for resonators, such as fixed, pinned-pinned boundary, and free-free boundary designs; (iii) multidimensional displacements of resonators capable of in-plane and out-of-plane motions with respect to the substrate surface; (iv) standard CMOS vias (VIA) and contacts (CO) acting as tiny supports of resonators to effectively isolate the vibrating energy from resonators to their anchors; (v) well-defined anchors without undercut issue which is often seen in conventional CMOS-MEMS [7–11] or SOI process [12]; and (vi) better transducer efficiency attained by utilizing via-connected walls to form a flat sidewall electrodes, all of which offer a variety of flexible options suited for sensor and RF applications. Figure 8 presents the fabricated resonators, such as beam and comb-drive resonators. Note that the minimal electrode-to-resonator gap spacing is limited by the feature size of the 0.35 μm CMOS technology node such that the motional impedance of the fabricated resonators is in several MΩs due to their low electromechanical coupling coefficient.



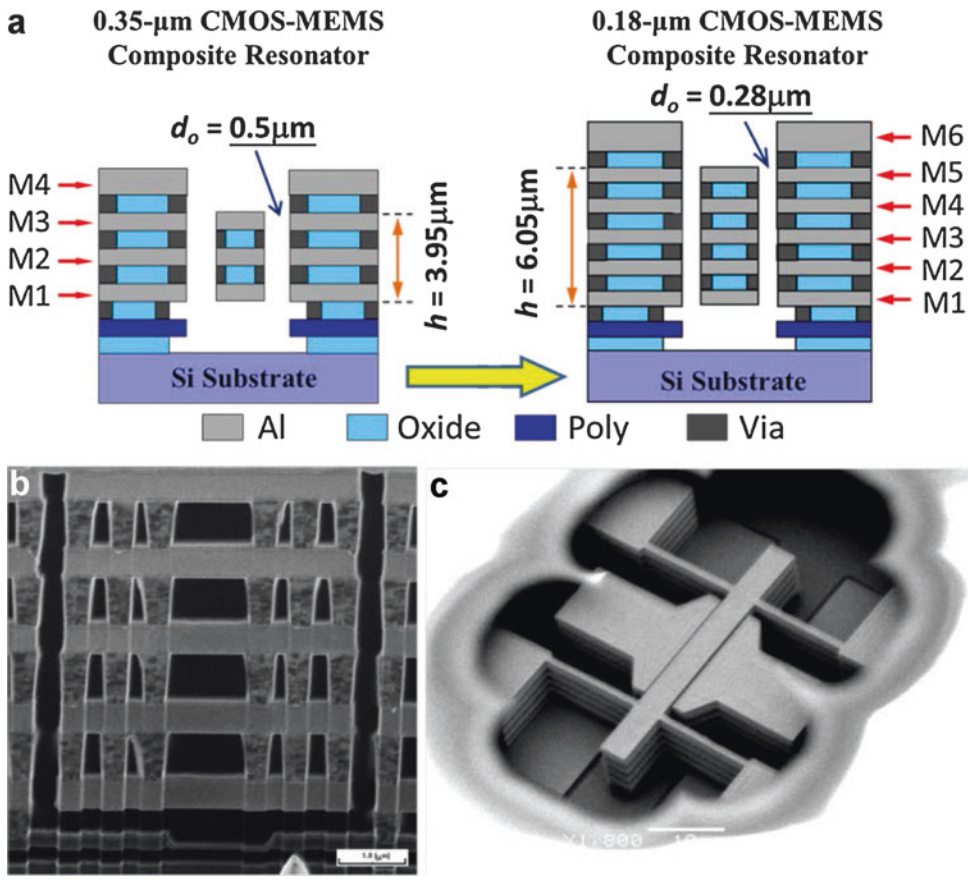
Oxide Removal Release Process in a 0.18 μm CMOS

To address the issue of high motional impedance in the previous platform, one can transfer this oxide removal process of section "Oxide Removal Release Process in a 0.35 μm CMOS" into a 0.18 μm CMOS as indicated in Fig. 9a [2]. The cross-sectional view of CMOS 0.18 μm BEOL and SEM of the fabricated resonator are shown in Fig. 9b, c, respectively. The electrode-to-resonator gap spacing is reduced

CMOS-MEMS Resonators, Fig. 7 Fabrication process flow for a CMOS-MEMS resonator in a 0.35 μm 2P4M technology under the oxide removal post process. (**a**) Chip prepared by the CMOS foundry. (**b**) Device is released by a buffer HF solution. (**c**) Various configurations of CMOS-MEMS resonators are realized in the platform

through the minimal feature size of the 0.18 μm CMOS (1.8X smaller than the 0.35 μm CMOS), while the transducer area can be increased by the six-metal stacking (four-metal stacking in the 0.35 μm CMOS). The combined merit of the gap and area leads to much lower motional impedance as compared to the 0.35 μm CMOS-MEMS resonators. The use of the 0.18 μm 1P6M platform implies the advanced technology nodes would lower the motional impedance, reduce the DC bias voltage, and attain higher resonance frequencies.

CMOS-MEMS Resonators, Fig. 8 SEM photos of the fabricated resonators using the oxide removal release process in a 0.35 μm CMOS technology



Metal Removal Release Process in a 0.35 μm CMOS

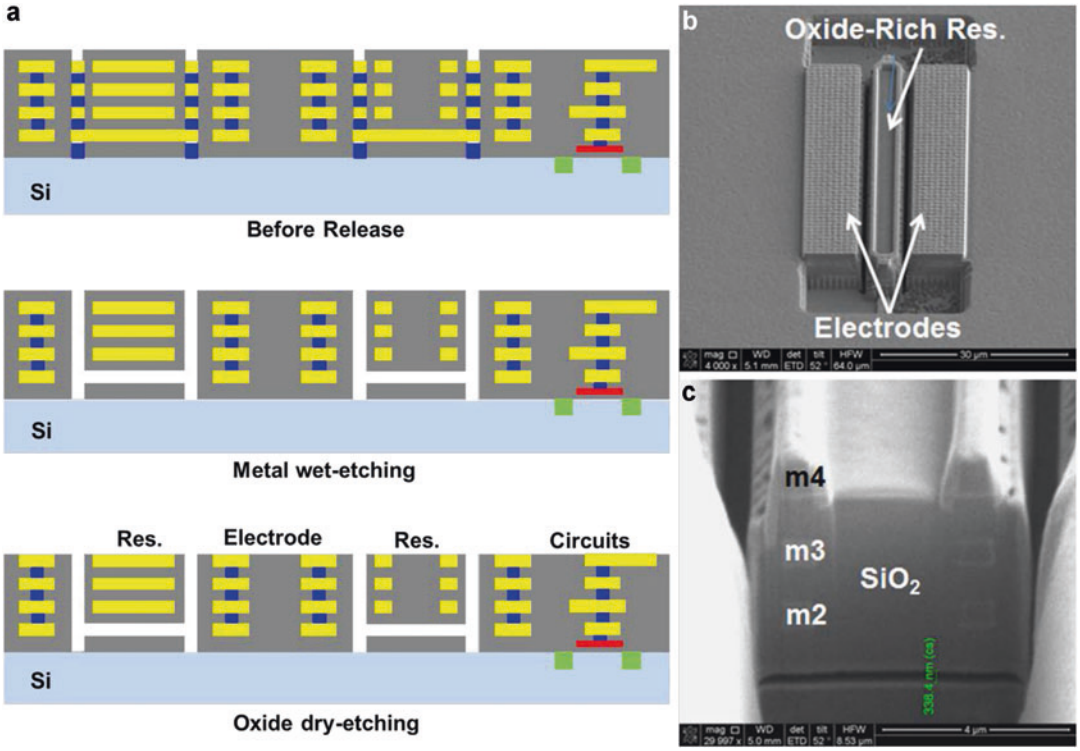
Although the oxide removal process only requires one maskless wet etching step, the metal-rich feature of the aforementioned resonators places a bottleneck on quality factor Q since the structural metal (AlCu) is often treated as a lossy acoustic material. Q of metal-rich resonators is often lower than 2,000, which is not sufficient for practical oscillator and filter implementations [3]. To address the low-Q issue in the oxide removal process, a metal removal post process has been developed as an alternative to form low-loss oxide-rich resonator structures to enable high Q.

As indicated in Fig. 10a, the device is first prepared by the CMOS foundry using a standard 0.35 μm 2P4M CMOS process. Then the etching solution containing H_2SO_4 and H_2O_2 is utilized to remove metal layers. This maskless etching technique provides excellent selectivity between the metal and dielectric layers; therefore, the issues from time-based etching in sections "Oxide Removal Release Process in a 0.35 μm CMOS" and "Oxide Removal Release Process in a 0.18 μm CMOS" can be greatly alleviated. Finally, reactive ion etching (RIE) is used to remove the passivation layer for the later wire bonding. Figure 10b presents a resonator SEM photo and its cross-sectional view, showing the metal layers are embedded inside the main SiO_2 structure. Q of the oxide-rich resonator is greater than 6,000, which is 6X higher than the metal-rich counterparts in sections "Oxide Removal Release Process in a 0.35 μm CMOS" and "Oxide Removal Release Process in a 0.18 μm CMOS."

Metal Removal Release Process in a 0.18 μm CMOS

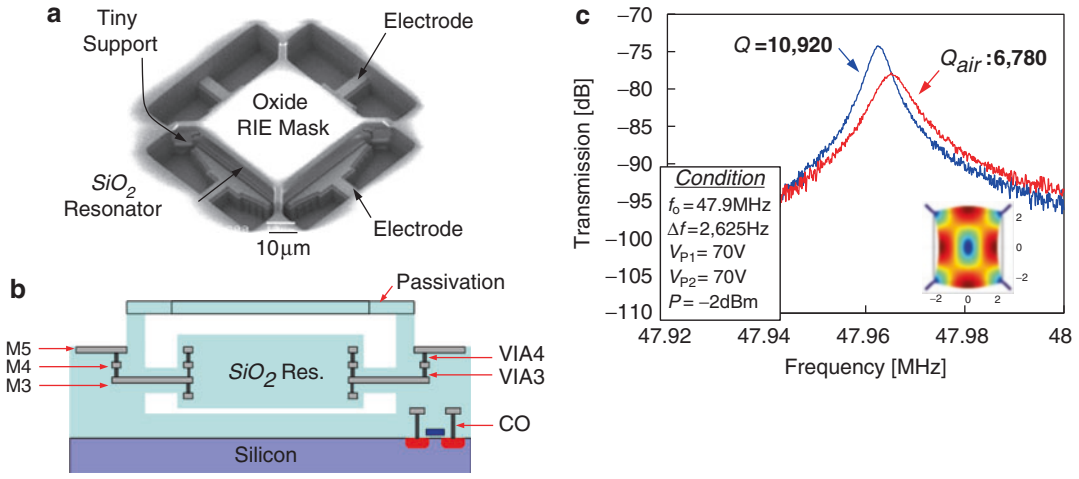
The release approach in section "Metal Removal Release Process in a 0.35 μm CMOS" has also been transferred into a 0.18 μm CMOS node as shown in Fig. 11 to gain the smaller feature size of the advanced CMOS for low motional impedance R_m [4]. To fabricate the resonators, the chips are manufactured using a standard TSMC 0.18 μm 1P6M CMOS foundry process. Then a metal wet etchant, comprising H_2SO_4 and H_2O_2, is utilized to remove the sacrificial metals, hence providing lateral air-gap spacing d_o of 0.38 μm. Finally, the RIE is utilized to open bond pads for later wire bonding. As can be seen in the cross-sectional view of the resonator in Fig. 11b, the resonator structure consists of more than 97 % SiO_2. As shown in Fig. 11c, such oxide-rich resonators

CMOS-MEMS Resonators, Fig. 9 CMOS-MEMS resonator in a 0.18 μm 1P6M CMOS-MEMS platform. (**a**) Technology transformation. (**b**) Cross-sectional view of 0.18 μm BEOL. (**c**) Free-free beam resonator realized in a 0.18 μm CMOS-MEMS platform



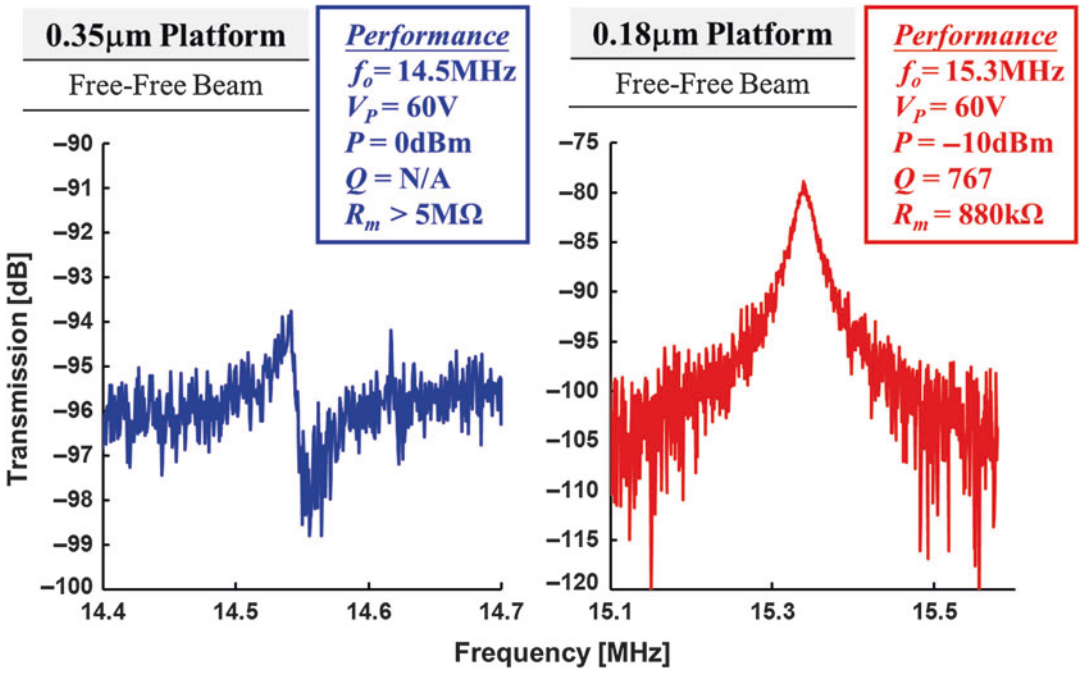
possess Q more than 10,000, which is comparable to commercial single-crystal silicon (SCS) or polysilicon-based resonators. Even tested in air, Q of the resonators is still greater than 6,000, an evidence of less squeeze film damping effect and suitable for resonant sensor applications.

Main Research Accomplishment



Motional Impedance R_m Reduction

The motional impedance governed by Eq. 8 is strongly dependent on the electrode-to-resonator gap spacing d_o. Figure 12 presents the performance comparison of similar free-free beam designs implemented in the 0.35 μm 2P4M and 0.18 μm 1P6M platforms, showing the advanced technology node (0.18 μm) would significantly lower the motional impedance R_m due to its smaller gap spacing (1.8X) and larger transduction area (1.6X) as compared to the 0.35 μm 2P4M technology.



In addition to the use of the advanced technology node, a mechanically coupled array design [13] offers an efficient approach to reduce the motional impedance R_m which is inversely proportional to the number of the constituent resonators in an array device. The more resonators mechanically coupled as an array, the smaller the motional impedance. Since the coupled array

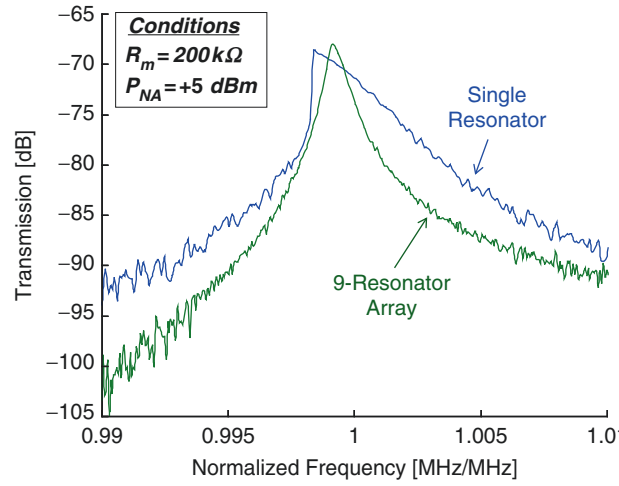
CMOS-MEMS Resonators, Fig. 13 Comparison of a single resonator and a nine-resonator array under the same DC bias and input power

becomes a multi-degree-of-freedom mechanical system, a high-velocity coupling scheme is used to accentuate the desired mode shape and reject the spurious modes. As shown in Fig. 13, the proposed nine-resonator and five-resonator arrays [13] have been experimentally characterized to have 10.1X and 3.7X smaller motional impedances, respectively, as compared to a single resonator. In addition, the resonator array benefits from the large transduction area to effectively reduce the required DC bias voltage while maintaining reasonable motional impedance.



CMOS-MEMS Resonators, Fig. 14 Progress on quality factor of the CMOS-MEMS resonators developed in our group

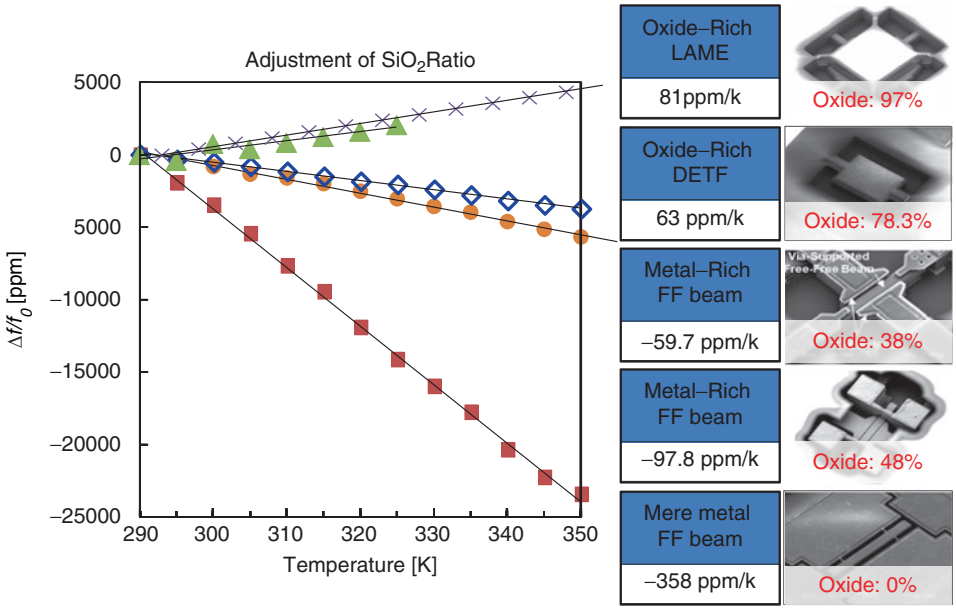
Quality Factor *Q* Improvement

As compared to the single-crystal or polysilicon-based MEMS resonators, Q of the CMOS-MEMS resonators becomes a main issue to be used in timing reference and spectral processing applications. Due to the lossy nature of the metal materials in the CMOS back-end-of-line (BEOL), CMOS-MEMS metal-rich composite resonators often suffer Q value limited to 1,000. Several approaches are proposed to resolve this bottleneck, including (i) adopting proper mechanical boundary condition and implement nodal support design (i.e., support at the motionless locations of the resonator to avoid acoustic loss), such as the use of a free-free beam resonator with nodal supports instead of a clamped-clamped beam version; (ii) utilizing high-Q structural material in BEOL, such as SiO_2-rich composite structure in Fig. 10, to attain high Q; and (iii) taking advantage of high-Q bulk mode instead of low-Q flexural mode, as illustrated in Fig. 11. Figure 14 finally presents the progress on quality factor of our developed CMOS-MEMS resonators in the past 5 years. As can be seen, Q greater than 10,000 has been realized by the combination of the nodal support design, oxide-rich structural material, and bulk-mode operation, thus greatly benefiting the future oscillator and filter performance.

Power Handling P_o Enhancement

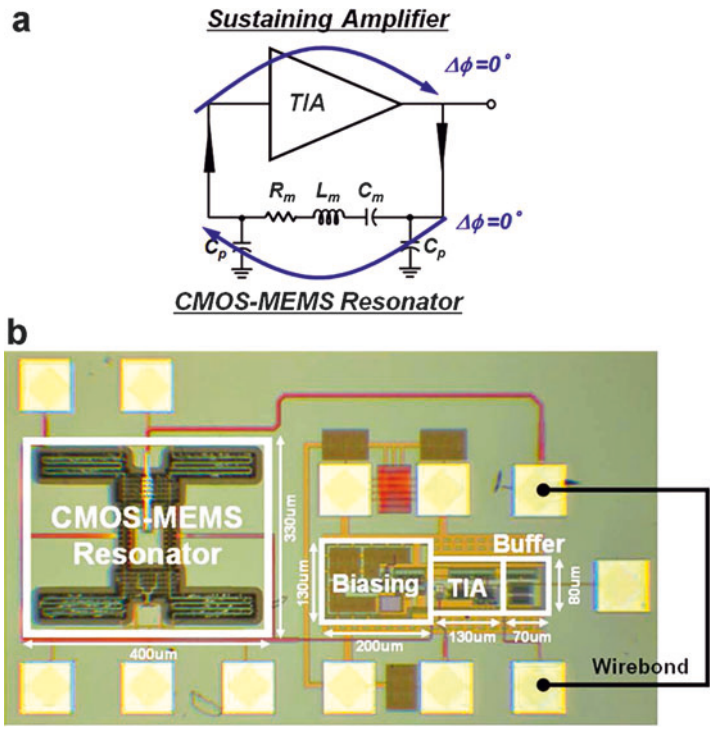
Upon high-input power levels, capacitive resonators often suffer the Duffing nonlinearity which resulted from both capacitive and mechanical nonlinearities, hence degrading output power and phase noise performance of oscillators implemented using those resonators. The mechanically coupled array design [13] described in section "Motional Impedance R_m Reduction" not only reduces their motional impedance R_m but greatly enhances the power handling capability P_o since the effective stiffness of the N-resonator array ideally is N times higher than that of a single resonator, thus contributing N times larger power handling ability. Figure 15 presents the frequency characteristics of single resonator and nine-resonator array designs under the same input power and motional impedance, where the former falls into the nonlinear regime, while the latter still preserves the linear vibration with a symmetrical frequency response and high Q.

CMOS-MEMS Resonators, Fig. 15 Comparison of the single resonator and nine-resonator array under the same motional impedance and input power



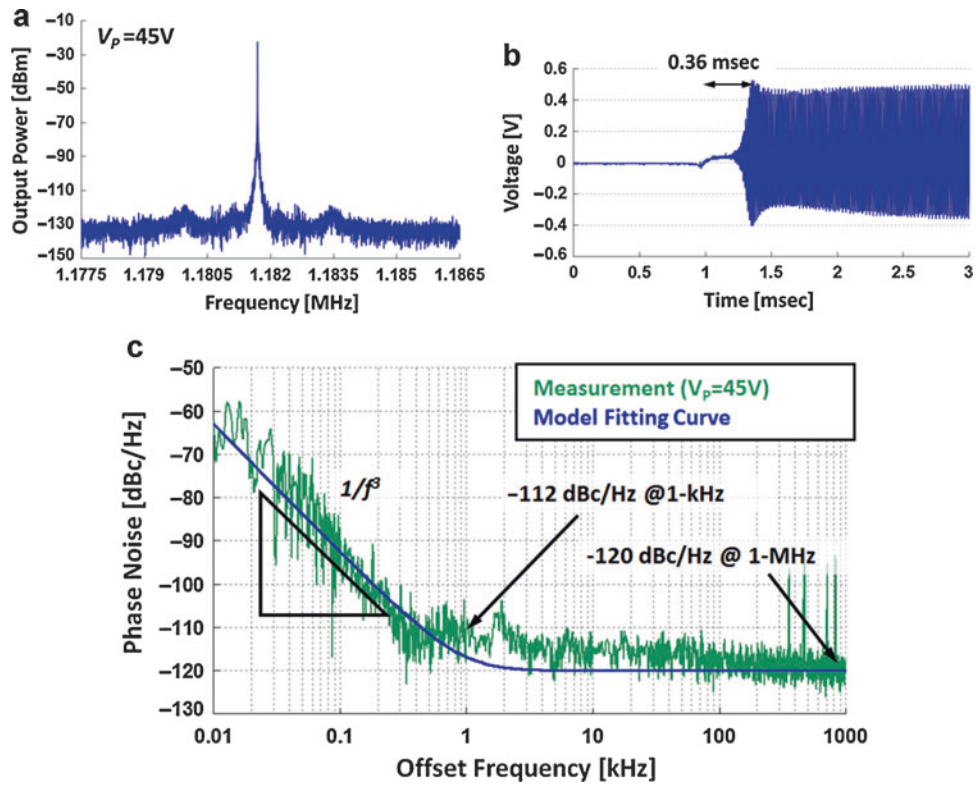
Temperature Compensation

The CMOS-MEMS resonators mostly composed of metals are sensitive to temperature variation due to the very negative temperature coefficients of Young's modulus (TC_Es) of their constituent metal materials. To improve the thermal stability of those CMOS-MEMS resonators, the silicon dioxide (SiO_2) of the CMOS BEOL possessing positive TC_E offers a simple and effective temperature compensation scheme where metal-oxide composite structures can be utilized to build resonators capable of improving their thermal stability [1]. For example, the oxide constituent ratio of the CMOS-MEMS resonators can be adjusted as indicated in Fig. 2 where the mere-metal, metal-rich, and oxide-rich structures would lead to very negative, slightly negative, and very positive temperature coefficients of frequency (TC_fs). Figure 16 presents the comparison of fractional frequency change versus temperature measurements for mere-metal, metal-rich composite, and oxide-rich composite beam resonators, indicating the near-zero TC_f is plausible once the ratio between SiO_2 and metal is optimized, such as manipulation of A and B in Eq. 10 to enable $TC_f \sim 0$. Thus, the use of SiO_2 as part of the composite structures in CMOS-MEMS resonators brings an easy and effective temperature compensation scheme [14].



Examples of Application

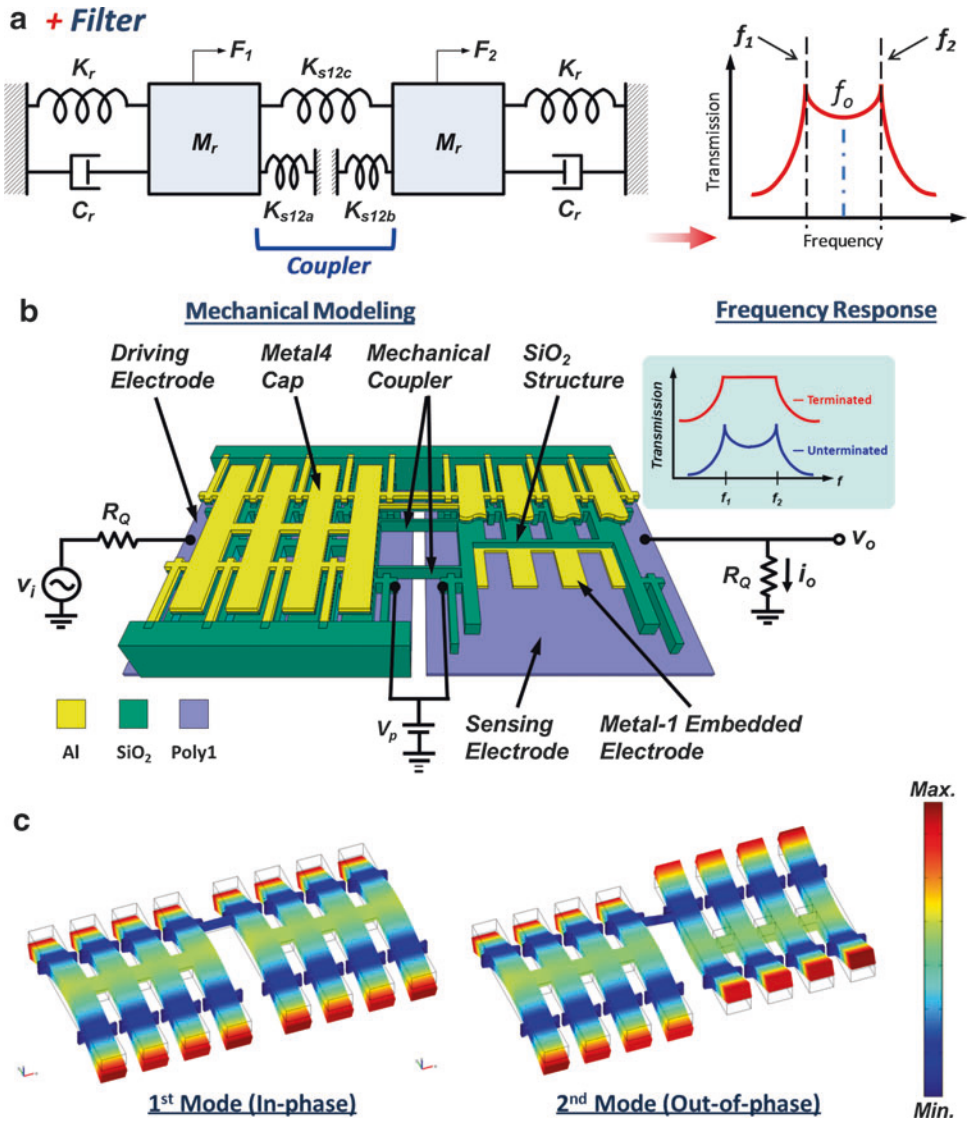
Oscillator Implementation



After addressing the major bottlenecks and their corresponding solutions to enhance the overall performance of the CMOS-MEMS resonators, the oscillator implementation is of great importance for timing, frequency synthesizing, and sensing applications. As depicted in Fig. 17a, a micromechanical resonator and its sustaining amplifier can form a closed loop to enable oscillation once the Barkhausen criteria (i.e., loop gain >1 and loop phase $= 0°$) are satisfied. Using a physical implementation shown in Fig. 17b as an example, a single-chip CMOS-MEMS oscillator has been successfully demonstrated in vacuum with the measured frequency-domain output spectrum and time-domain waveform shown in Fig. 18a, b, respectively. The measured phase noise performance in Fig. 18c is comparable to the silicon-based oscillators. Even in air (i.e., with

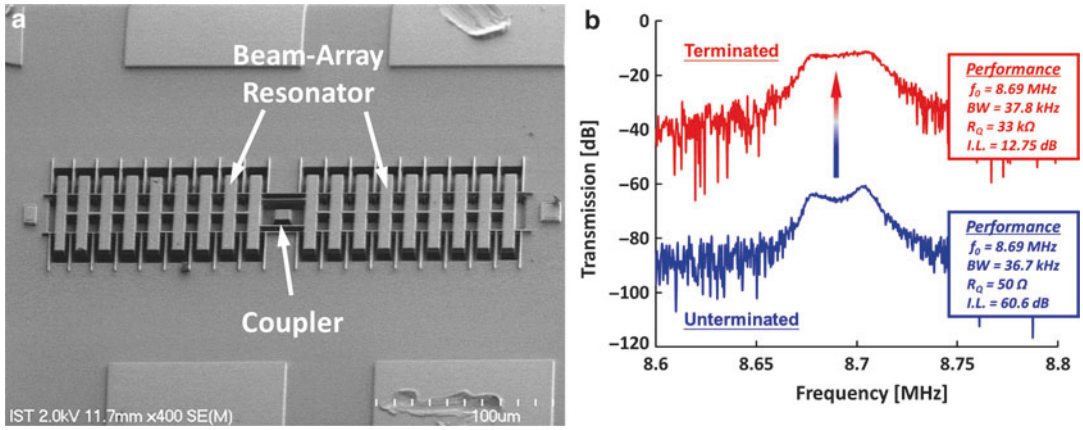
CMOS-MEMS Resonators, Fig. 16 Temperature coefficients of frequency can be adjusted by the constituent ratio of SiO_2 in CMOS-MEMS resonators

CMOS-MEMS Resonators, Fig. 17 (**a**) Top-level schematic and (**b**) optical view of the monolithic CMOS-MEMS oscillator



CMOS-MEMS Resonators, Fig. 18 (**a**) Frequency-domain response, (**b**) time-domain waveform, and (**c**) phase noise performance of the CMOS-MEMS oscillator

large squeeze film damping), the oscillator is still functional, indicating great potential to be used in gas, chemical, and mass sensing applications based on the frequency-shift mechanism. The abovementioned approaches to improve quality factor and power handling of the CMOS-MEMS resonators would eventually benefit the close-to-carrier and far-from-carrier phase noise performance, respectively, of the implemented oscillators. In addition, the reduction of the motional impedance described in the previous section would also lead to the overall phase noise reduction for the CMOS-MEMS integrated oscillators.



Filter Implementation

Another significant building block for frequency control and wireless communication is the frequency selection element. The developed CMOS-MEMS resonators can serve as the fundamental units for a band-pass filter. Since the resonance frequency of the CMOS-MEMS resonators is limited, it is best to be used in sensor front end with much lower operation frequencies. Figure 19a illustrates the concept of a fourth-order band-pass filter realized by two mechanical resonators, each of which is modeled by a mass-spring-damper system, coupled by a mechanical spring system to form a desired passband of the filter. The center frequency of the filter is determined by the resonance frequency of the constituent resonators, while the bandwidth is mainly set by the spring constant of the mechanical coupler. To simplify the filter design, the constituent resonators should be identical and the coupling element is designed in its quarter-wavelength configuration, allowing the center frequency of the filter to be set at the resonance frequency of

CMOS-MEMS Resonators, Fig. 19 (**a**) Equivalent mechanical circuit model, (**b**) perspective-view schematic, and (**c**) simulated filter modes of a mechanically coupled CMOS-MEMS band-pass filter

the resonators (f_o) while the frequencies (f_1 and f_2) of the two filter modes possess equal distance (i.e., separation) to the filter center frequency (f_o). Figure 19b presents the physical implementation of a CMOS-MEMS filter comprising two CMOS-MEMS resonator arrays mechanically coupled through a quarter-wavelength mechanical link to enable a narrow-bandwidth band-pass filter for channel selection [15]. The in-phase and out-of-phase filter modes shown in Fig. 19c form a passband of the filter. The fabrication process is similar to that of the CMOS-MEMS resonators in the previous section using the metal removal release process in a 0.35 μm CMOS technology [3], and the SEM view of the fabricated filter is shown in Fig. 20a. After filter termination, a flat passband and real insertion loss can be obtained as shown in Fig. 20b.

Definition

Manipulation matter at nanoscale is one of the main purposes of nanotechnology. In with the publication of the pioneering work, "Engines of Creation" in 1986, atom-by-atom assembly became less a dream and more a search for a practical technology to implement it. Researchers were getting more adept at using Atomic Force and Scanning Tunneling Microscopes (STMs), culminating with the now famous writing of the IBM logo in 1989 with 35 xenon atoms. The team, led by Andreas Heinrich of IBM Research-Almaden (California), has successfully stored one magnetic bit of data with just 12 atoms of iron and a full byte of data in 96 atoms. This represents a storage density that is at least 100 times denser than the largest hard drive platters or flash memory chips in 2012.

In the recent two decades, nanorobotic manipulation was developing rapidly. Nanorobotic manipulation was applied to atomic force microscope, scanning electron microscope, transmission electron microscope towards to nanomanufacture nanoassembly and nanofabrication.

The AFM consists of a cantilever with a sharp tip (probe) at its end that is used to scan the specimen surface. The cantilever is typically silicon or silicon nitride with a tip radius of curvature on the order of nanometers. When the tip is brought into proximity of a sample surface, forces between the tip and the sample lead to a deflection of the cantilever according to Hooke's law. Depending on the situation, forces that are measured in AFM include mechanical contact force, van der Waals forces, capillary forces, chemical bonding, electrostatic forces, magnetic forces (see magnetic force microscope, MFM), Casimir forces, solvation forces, etc. Along with the force, additional quantities may simultaneously be measured through the use of specialized types of probes (see scanning thermal microscopy, scanning Joule expansion microscopy, photothermal microspectroscopy, etc.). Typically, the deflection is measured using a laser spot reflected from the top surface of the cantilever into an array of photodiodes. Other methods that are used include optical interferometry, capacitive sensing, or piezoresistive AFM cantilevers. These cantilevers are fabricated with piezoresistive elements that act as a strain gauge. Using a Wheatstone bridge, strain in the AFM cantilever due to deflection can be measured, but this method is not as sensitive as laser deflection or interferometry. Prof. N. Xi's team developed a real-time, force feedback nanomanipulation system.

Scanning electron microscope is a real-time nanoscale observation equipment. With the benefit of big specimen chamber, a complex nanomanipulation system with multiple-DOFs could be constructed. Recently, the environmental scanning electron microscope (ESEM) with nanorobotic manipulation was employed to characterize the biological property of cells.

Prof. Fukuda's team is a leader of nanorobotic manipulation in FESEM from the beginning of

this century. The carbon nanotube was picked-up, assembled, measured, and fabricated by multiple DOFs nanomanipulator.

Dr. M. Rizuan and Dr. Y. Shen constructed a nanomanipulation system in order to characterize the biological property of cells with low pressure and different humidity. Two types of experiments have been conducted, i.e., mechanical properties of individual yeast cells and forces on cell-substrate area. Different kinds of spring constants (0.02 N/m, 0.09 N/m, and 0.7 N/m) and tip's shapes (sharp, flat, and needle-like) of the cantilevers have been used during the experiments. From the analysis, the compressed forces needed to penetrate the cell wall of the yeast cells using sharp and flat tips (0.02 N/m for both) which are in the range of 87–278 nN and 57–207 nN, respectively. Locality mechanical measurement has been performed using needle-like tip (0.09 N/m) on single-cell and mother-daughter cells where the elastic properties of the cells are in the range of 1.32–3.95 MPa.

Nanorobotic manipulation is a rapid developing technology on nanofabrication and nanoassembly. It is powerful with nanomaterial measurement and manipulation. With the control theory, the automation is employed to the nanorobotic manipulation system. A high efficacy nanorobotic manipulation center will be applied to nanomaterial, nanosensor, and biological samples.

Introduction

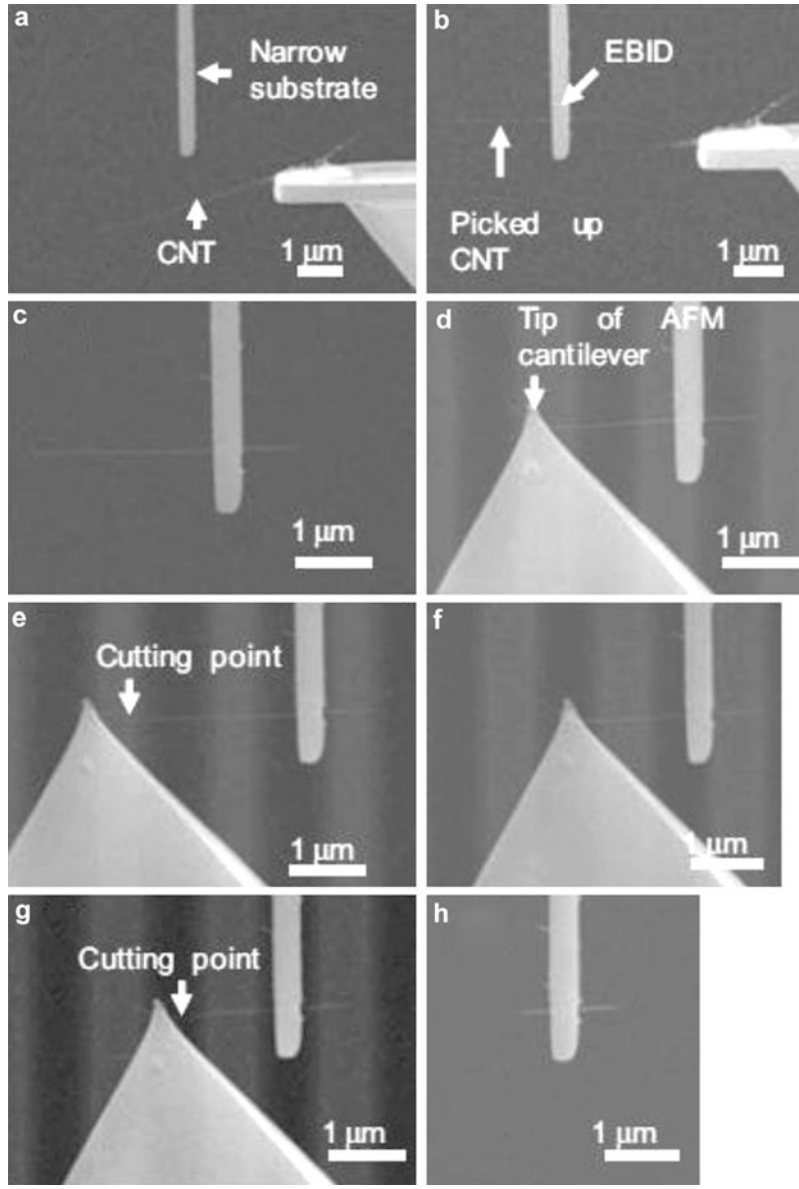
This entry is focused on the study of CNT interaction with environment and the application of CNT for pH and temperature sensing.

CNT Handling

Carbon nanotubes (CNTs) [1] have been widely used as nanobuilding blocks to assemble nanostructures and nanodevices. Therefore, the interaction between a CNT and an environment is important. In the present study, the interaction forces, which consisted mainly of van der Waals [2] forces, between a single multiwalled carbon nanotube tip and a gold surface were evaluated under a scanning electron microscope by means of nanorobotic manipulation. The influence of electron beam irradiation was also investigated. It was found that electron beam irradiation can increase the interaction forces by producing contamination at the contact area. The van der Waals forces were calculated theoretically, and the theoretical values were close to the experimental values. In the following, the measurement of van der Waals force between a CNT tip and a gold surface is introduced first, and then a method of manipulating CNTs in 3D is presented.

Measurement of van der Waals Force Between a CNT Tip and Gold Surface

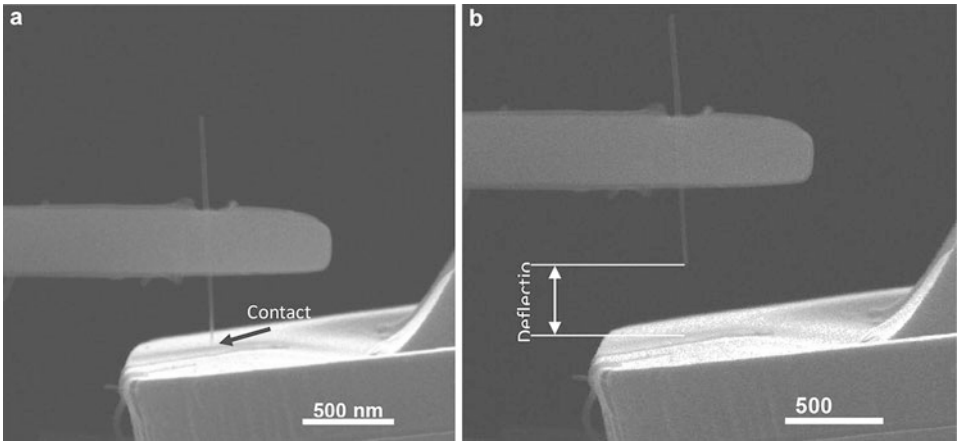
At the nanoscale, van der Waals force is one of the predominant surface forces that also include the electrostatic force, the Casimir force, etc. The measurement of nanoscale surface forces can help characterize the properties of nanomaterials and also be useful for the assembly of nanostructures and nanodevices. Carbon nanotubes (CNTs) as typical nanomaterials have been used for atomic force microscope (AFM) probes, nanotweezers, nanoposition sensors, and three-dimensional nanostructures. The interaction between a CNT and a substrate, including the van der Waals forces, is important for the assembly of these mechatronic applications. The deformation of a CNT placed on a substrate by surface van der Waals forces will significantly modify the idealized geometry of the free nanotube. The interaction has been investigated by AFM and molecular-mechanics simulations. The joint interaction forces with two CNT tips by chemical bonds were also investigated. Cumings and Zettl calculated the attractive van der Waals forces between the inner and outer layer. They demonstrated a lowfrictional nanoscale linear bearing realized from multiwalled carbon nanotubes (MWNTs). Zheng et al. showed through theoretical calculations that the extruded core of a MWNT oscillating on the outer shell caused the excess van der Waals interaction energy and



found that the oscillation frequency can be significantly higher than 1 GHz [3]. The effects of surface forces in a three-terminal nanorelay were investigated by Jonsson et al. [4]. They showed that van der Waals forces have a significant impact on the characteristics of the relay. For the calculation or analysis of van der Waals forces, a parameter called the Hamaker constant is an important value.

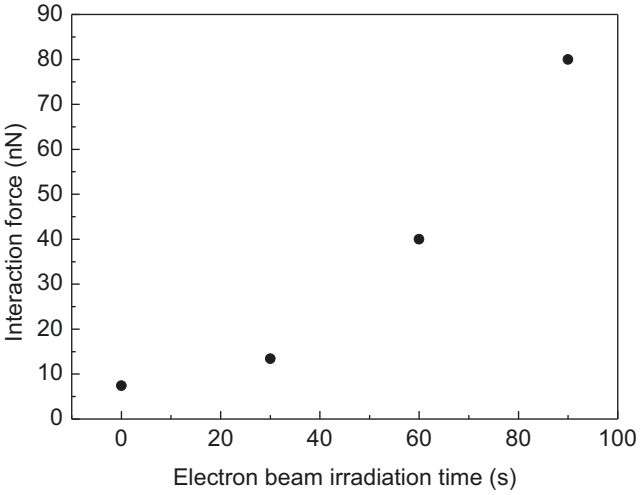
In previous studies, the Hamaker constant between a CNT and a surface was obtained by approximate calculation [5] or by original experiments [6]. Akita et al. obtained the Hamaker constant of 60×10^{-20} J for the sidewall of a CNT adhered on a silicon material surface [6]. For a CNT and a gold surface, Walkeajärvi et al. just used a typical value of 10×10^{-20} J for their calculation. For two CNTs, a previous report used the value of graphite to replace it. The van der Waals forces between a CNT tip and a gold surface are not clearly understood experimentally and need to be investigated. In particular, the interaction force is considered to be changed by irradiation of the electron beam during the observation in an electron microscope, because electron beam irradiation produces contamination on the observation area.

From an engineering viewpoint, it is important to control the interaction forces between CNT probes and metallic surfaces for nanodevice fabrication and assembly. This entry reports on the measurement of the van der Waals forces between a CNT tip and a gold surface under a scanning electron microscope (SEM) based on nanorobotic manipulation. The influence of electron beam irradiation was also investigated. The van der Waals forces were calculated theoretically and compared with the experimental values.



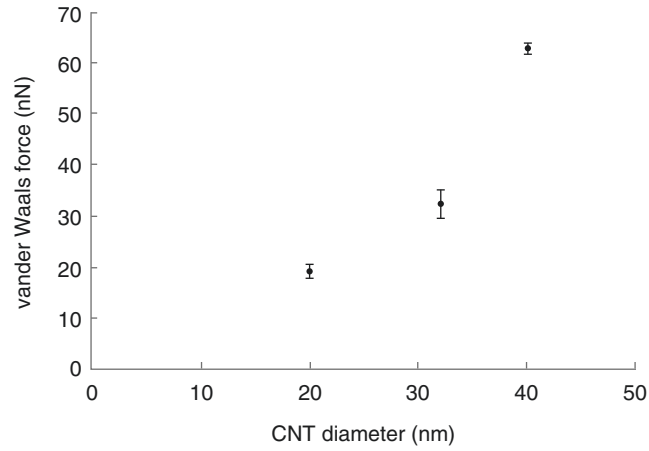
For the measurement of the interaction forces between the CNT tip and the surface of a gold substrate, a single MWNT probe was first prepared as shown in Fig. 1. The MWNT, typically 20–50 nm in diameter, was synthesized by the standard arc-discharge method. Figure 1a shows a single MWNT with diameter of 30 nm that was picked up from the CNT bundle by a nanorobotic manipulator under a SEM (JEOL, JSM-6500 F). The MWNT was fixed at the narrow substrate with electron beam–induced deposition (EBID) as shown in Fig. 1b. The deposition is caused by the dissociation of molecules adsorbed to a surface by high-energy electrons. In the present experiments, tungsten hexacarbonyl was used as precursor by filling into a glass tube and introducing it into the vicinity of the sample. The magnified image of the narrow substrate with MWNT is shown in Fig. 1c. It was etched to a width of 350 nm by a focused ion beam (FIB) process. The MWNT probe should be prepared with no impurities and straight with short length, because the bending phenomenon occurs easily and makes it difficult to measure the vertical interaction forces. Some methods such as electron beam–induced fabrication assisted with oxygen gas or current-induced fabrication can be used to adjust the CNT length. Here, the current-induced fabrication process was used. One end of the CNT was touched at the tip of the AFM cantilever as shown in Fig. 1d. The part of the CNT near the cantilever tip evaporated by joule heating when the electric current applied was 7–20 mA. The length of the MWNT probe was adjusted by using the same process as shown in Fig. 1d, e by the first process. Figure 1f, g show the second process. Finally, the MWNT probe is fabricated as shown in Fig. 1h.

In the present work, the interaction force measurement between the CNT probe and the gold surface of an AFM cantilever was performed experimentally. The AFM cantilever was coated by a gold layer with thickness of 40 nm. The interaction forces were measured from the deflection of the AFM cantilever. The CNT probe and AFM cantilever were connected to the ground to avoid the occurrence of electrostatic forces. The SEM was kept at low magnification (less than 10,000 times) during the operation to avoid contamination. Other type forces caused by chemical bonding can be negligible, because the CNT probe and the surface were kept clean under vacuum conditions. Therefore, the interaction force between the CNT tip and the surface of the AFM cantilever is considered to consist mainly of van der Waals forces. In the experiment, the AFM cantilever tip was moved to the



CNT Handling and Integration, Fig. 1 A multiwalled carbon nanotube was placed on an etched substrate. The length of the CNT was adjusted by the current-induced fabrication process

CNT tip by a nanorobotic manipulator, until they touched each other (Fig. 2a). Then the CNT probe was moved in the inverted direction until release of the adhesion by van der Waals forces. The position of the AFM cantilever was controlled in step motions, each step of moving was about 2 nm. When the CNT probe was released from the AFM cantilever surface, the AFM cantilever was stopped in a certain distance. The AFM cantilever was released where the attraction is less than the tension caused by the deformation of the cantilever. The deflection of the AFM cantilever was 370 nm in the present experiment (Fig. 2b). From this, the



CNT Handling and Integration, Fig. 2 The tip of a single CNT was adhered to an AFM cantilever surface. After that, the AFM cantilever was pulled back by a nanomanipulator. The interaction force between the carbon nanotube tip and the surface can be obtained from the deflection of cantilever

CNT Handling and Integration, Fig. 3 The relationship between the interaction force and electron beam irradiation time

interaction forces from the deflection of the AFM cantilever were calculated according to $F = \delta d$, where d is the deflection and is the elastic constant of the AFM cantilever, is 0.02 N/m (Olympus Corp., OMCL-TR400). Therefore, the interaction force between the CNT tip and the gold surface was calculated as 7.4 nN. The interaction force measurement was also performed under electron beam irradiation to affect the influence of interaction forces. The interaction forces were measured after irradiation for different times. After the above experiment to measure the van der Waals interaction forces, the contact area, where the CNT tip was adhered on the gold surface, was magnified to 30,000 times. The acceleration voltage of the SEM was 15 kV and the beam current was 30 pA. The irradiation periods were set at 30, 60, and 90 s. The interaction forces were obtained as 13.4, 40, and 80 nN, respectively, as shown in Fig. 3. The results show that electron beam

CNT Handling and Integration, Fig. 4 Three teams experiment results with error bar of van der Waals force

irradiation can increase the interaction forces between the CNT tip and the surface. The increment of interaction force is almost proportional to the electron beam irradiation time period.

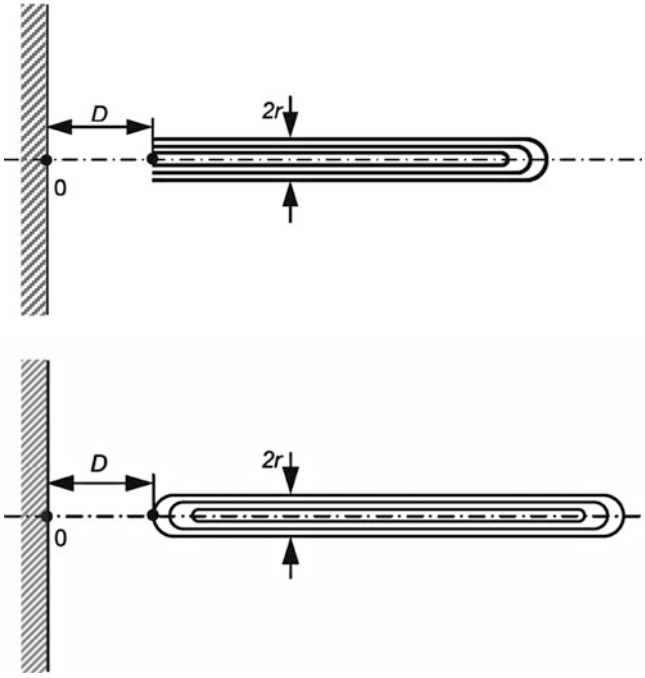
The increase of interaction force induced by electron beam irradiation is considered to result from the contamination produced at the contact area. In the experiment, the precursors come from the vacuum pump oils in the sample chamber; hence the contamination should be mainly amorphous carbon. This suggests that electron beam irradiation can be used to control the interaction forces in the nanonewton range for the assembly of CNT nanobuilding blocks.

We assume that the interaction between CNT tip and the surface is nonretarded and additive. The interaction energy can be described by Lennard-Jones's pair potential as the following equation

$$W = \frac{r^2\pi^2 C\rho_1\rho_2}{12D^2} = \frac{r^2 A}{12D^2} \tag{1}$$

where r is the radius of CNT, and C is the coefficient in the atom-atom pair potential. ρ_1 and ρ_2 are the numbers of atoms per unit volume in the two materials, and D the distance between the CNT tip and the surface, as shown in Fig. 5. A is the Hamaker constant.

Then the van der Waals forces are obtained by taking the derivative of the pair potential with respect to the distance,



$$F = W' = \frac{r^2 A}{6D^3} \tag{2}$$

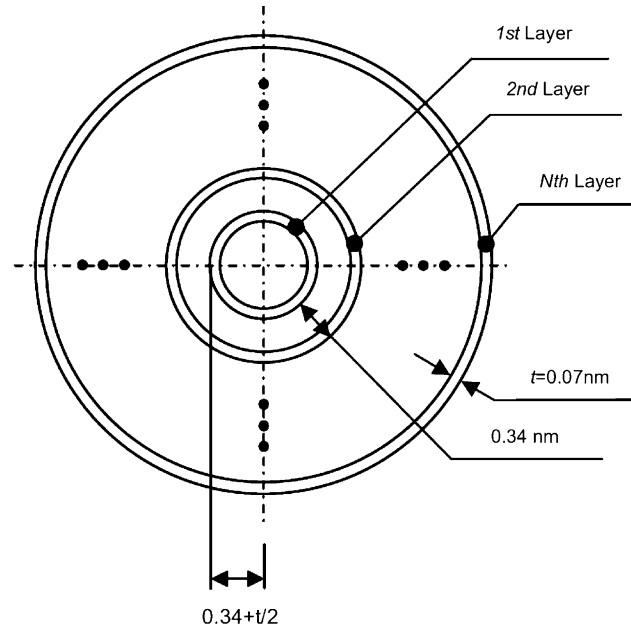
To calculate F, the Hamarker constant $A_{\mathrm{CNT}-Au}$ between the CNT and the gold surface interacting across vacuum is needed. The unknown $A_{\mathrm{CNT}-Au}$ can be obtained approximately by using the combining relation as the nonretarded Hamaker constant for carbon nanotube and gold surface [3], which is given by

$$A_{\mathrm{CNT}-Au} = \sqrt{A_{\mathrm{CNT}} A_{Au}}\,, \tag{3}$$

where A_{Au} and A_{CNT} are $5.47 \times 10^{-19} J$ [2] and $0.284 \times 10^{-19} J$ [5] from previous report, respectively. Thus, the $A_{\mathrm{CNT}-Au}$ is obtained as $1.246 \times 10^{-19} J$ from Eq. 3.

If the CNT is considered as a column, the van der Waals forces between the CNT tip and the gold surface are calculated as 77, 197, and 308 nN at the CNT diameters 20, 32, and 40 nm as shown in Fig. 4. It is simply assumed that the minimum distance D is about 0.3 nm, and the r is used as the radius of the CNT in Fig. 5 The calculated result is so much larger than the value of experimental result. Therefore, this mode which considers the CNT as a column cannot precisely get the van der Waals forces.

CNT Handling and Integration, Fig. 5 Schematic drawing of a CNT adhered to a surface with a tiny separation D. The CNT is $2r$ in diameter with open cap and closed cap



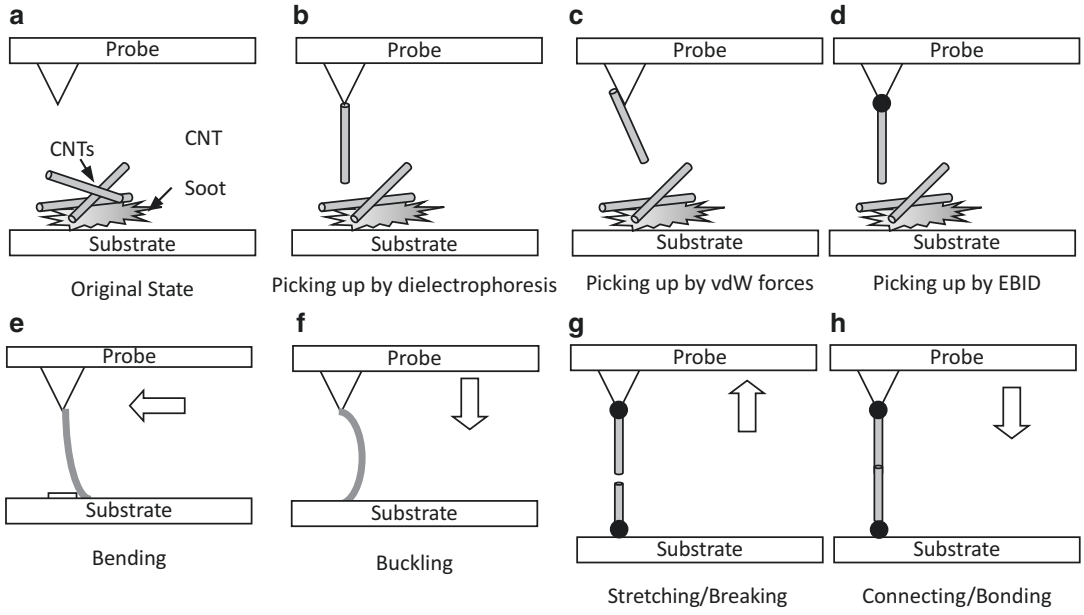
We suggest that the model of CNT can be considered as a multilayered cylinder as shown in Fig. 6. The cross-sectional area of the CNT is less than that calculated with the column model. Each layered cross-sectional area is described by following equations,

$$\begin{aligned} A_1 &= \pi(0.34 + t/2)^2 - \pi(0.34 - t/2)^2 \\ A_2 &= \pi(0.34 + t/2 + 0.34)^2 - \pi(0.34 - t/2 + 0.34)^2 \\ &\vdots \\ A_N &= \pi[0.34 + t/2 + 0.34(N-1)]^2 - \pi[0.34 - t/2 + 0.34(N-1)]^2 \end{aligned} \tag{4}$$

And the total cross-sectional area is,

$$A = \sum_{n=0}^{n=N-1} \left[\pi(0.34 + t/2 + 0.34n)^2 - \pi(0.34 - t/2 + 0.34n)^2\right] \tag{5}$$

Here, t is 0.07 nm, the diameter of carbon molecular. Then the total area is calculated as 148 nm^2. The distance between two layers is 0.34 nm that has clearly observed by a TEM [7]. N is the number of layers. The relationship between the number of layers and the radius of CNT can be approximated by $0.34N \approx r$ in our case. We obtained that the layer's number of the CNT is about 29, 47, and 59 at the CNT diameters at 20, 32, and 40 nm. Finally, the van der Waals forces were obtained theoretically as 15.9, 41.3, and 64.8 nN at the CNT diameters at 20, 32, and 40 nm from the Eq. 2. This result is very close to the experimental data. It demonstrates that the cylinder model is good or accurate enough for calculation of van der Waals force between CNTs and the surface. For more precise calculation, the CNT should be considered as a unit of carbon atoms. In that case, the sum of the forces between all individual atoms and the substrate needs to be calculated. Therefore, the shapes of CNT tip should be also taken into more careful consideration. Those are our future works.



CNT Handling and Integration, Fig. 6 Schematic drawing of a CNT described by multilayered cylinder model. The distance between layers of CNT is 0.34 nm. The t is the diameter of carbon molecule with 0.07 nm

In summary, a single MWNT was actually prepared with the nanorobotic manipulation, electron beam–induced deposition, and current-induced fabrication. The interaction forces between the MWNT tip and the gold surface were investigated and measured with an AFM cantilever, which were mainly consisted of van der Waals forces. The method proposed is easy to operate and have a large measurement range. It can be used for evaluation of connection strength during assembling of nanodevices. We also found that the electron beam irradiation can increase the interaction forces. The increase of interaction force induced by electron beam irradiation might be produced by the contamination. We suggest that the electron beam irradiation should be used to adjust the interaction forces in nanonewton scale during the assembly of CNT.

For calculating the van der Waals forces, the CNT was described by a multilayered cylinder model. The result of the experiment is very close to theoretical calculation. That model can be used to estimate the nanometer order van der Waals forces.

3D CNT Handling

Manipulations of CNTs in 3D space are very important techniques for assembling them into structures and devices. The basic step for this is to pick up a single tube from nanotube soot (Fig. 7a). This has been shown first by using dielectrophoresis through nanorobotic manipulations (Fig. 7b). The interaction between a tube and the atomic flat surface of AFM cantilever tip has been shown to be strong enough for picking up a tube onto the tip (Fig. 7c). By using electron beam–induced deposition (EBID), it is possible to pick up a nanotube onto a probe (Fig. 7d). For handling a tube, weak connection between the tube and the probe is desired. Bending and buckling a CNT as shown in Fig. 7e, f are important for the in-situ property characterizations of a nanotube, which is a simple way to get the Young's modulus of a nanotube without damaging the tube if performed in elastic range and hence can be used for the selection of a tube with desired properties. Plastic bending or buckling can generate intramolecular kink junctions of CNTs. Combined bending and buckling with shape fixing with EBID can be used for the shape modifications of a nanotube. Stretching a nanotube between two probes or a probe and a substrate has brought out several interesting results. The first demonstration of 3D nanomanipulations of nanotubes took this one as an example to show

CNT Handling and Integration, Fig. 7 3D manipulations of CNTs. Basic technique for such manipulations is to pick up an individual tube from CNT soot (**a**) or oriented array. (**b**) shows a free-standing nanotube is picked up by dielectrophoresis generated by nonuniform electric field between the probe and substrate, (**c**) and (**d**) show the same manipulation by contacting a tube with the probe surface or fixing (e.g., with EBID) a tube to the tip. Vertical manipulations of nanotubes also include bending (**e**), buckling (**f**), stretching/breaking (**g**), and connecting/bonding (**h**). This family is open for new strategies

the breaking mechanism of a MWNT and the tensile strength of CNTs. By breaking a MWNT in a controlled manner, some interesting nanodevices have been fabricated. This technique – destructive fabrication – has been presented to get sharpened and layered structures of nanotubes and to improve the length control of a nanotube. Bearing motion has also been observed in an incompletely broken MWNT. The reverse process, namely the connection of broken tubes, has been demonstrated recently, and the mechanism is revealed as rebonding of unclosed dangling bonds at the ends of a broken tube. Based on this interesting phenomenon, mechanochemical nanorobotic manipulations have been presented.

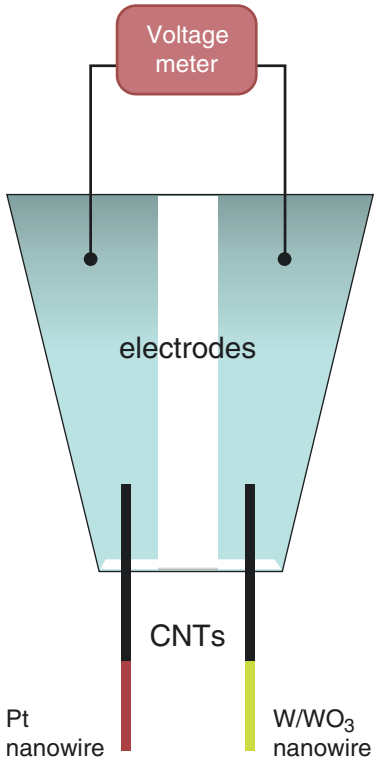
3D nanorobotic manipulations have opened a new route for the assembly of nanotubes into nanodevices.

In the following, we will focus on our recent advances in this field.

CNT Integration

A CNT integration method by mechanical engineering is nanorobotic manipulation [8–10] which has advantages such as real-time controllability, nanometer lever positioning resolution, and three-dimensional fabrications. The automation nanofabrication has a potential for auto nanostructure assembly fabrication and measurement. Nanomanipulation allows for the detection and manipulation of tiny entities such as single molecules, nanotubes, cells, viruses, proteins, and DNA molecules.

Fabrication of a pH Sensor Nanoprobe with Tungsten Oxide and Platinum Nanowires Based on Nanorobotic Manipulation



A novel solid-state pH sensor nanoprobe based on a tungsten oxide nanowire work electrode and a platinum nanowire counter electrode is reported. A cantilever is used for the electrodes

of the device and etched by a focused ion beam (FIB). Two multiple-walled carbon nanotubes (MWCNTs) are assembled to the separated electrodes of the cantilever. A tungsten probe is etched by an FIB to 300 nm in diameter and 25.4 μm in length. Then the probe is coated by parylene and the tip cut to expose the tungsten. A tungsten nanowire is used for the work electrode, and a platinum nanowire is used for the counter electrode. The nanowires are fabricated via the field emission method from carbon nanotube tips by introducing hexacarbonyltungsten ($W(CO)_6$) and trimethylcyclopentadienylplatinum ($CpPtMe_3$), respectively, inside a field emission electron microscope. The nanoprobe pH sensor is tested in acidic (pH 4.0, pH 6.1, and pH 6.a9) and alkaline (pH 8.0) buffer solutions and different responses are found. The sensitivity of the pH sensor nanoprobe was measured as −35.04 mv/pH.

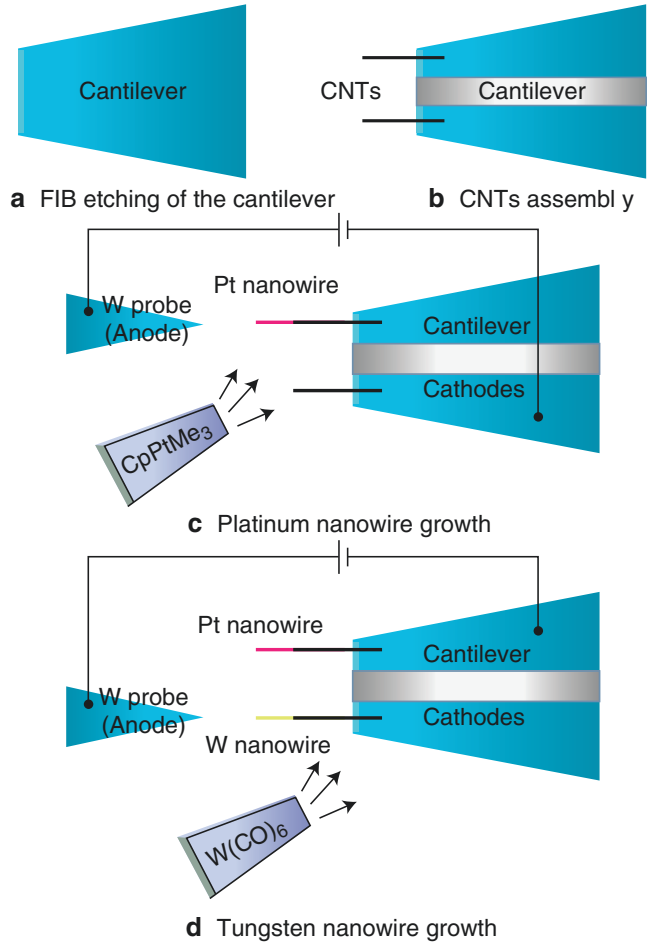
Chemical detection of single cells and their local environment has attracted much interest recently. The pH value is a promising parameter to describe the living condition of single cell. For examples in animal cells, pH controls the activity of key enzymes, protein synthesis, DNA and RNA synthesis, cell cycle, and ion conductance by membranes. The extracellular fluid pH is usually $7.35 \sim 7.45$, and in vascular smooth muscle cell (VSMC) the pH value is usually $7.0 \sim 7.2$. In some pathological conditions, such as hypoxia, acidosis, or alkalosis, pH can be fluctuated between 6.5 and 8.1, of VSMC pH corresponding generate phase when large fluctuations. And the oxygen changes primer pH to vascular effects of very complex, it may be by changes in intracellular Ca ion release and re-uptake, the activity of calcium channels on the plasma membrane or to adjust the sensitivity of the calcium ions in the contraction protein vasoconstriction state. The pH sensors towards biological cell require a resolution of 1 pH. The measurement of the pH value of a single cell is usually performed by visualizing the color change of indicators, chemical probes, H^+ sensitive microelectrodes, and nuclear magnetic resonance (NMR) spectrometry.

Traditionally, the measuring methods for pH values fall roughly into four categories: indicator reagents, pH test strips, metal electrode methods (hydrogen electrode, quinhydrone electrode, and antimony electrode method), and glass electrode methods. In recent decades, new techniques of pH detection have been developed such as optical-fiber-based pH sensors [11], mass-sensitive pH sensors [12], metal oxide pH sensors [13], conducting polymer pH sensors [14], nanoconstructed cantilever-based pH sensors [15], ISFET-based pH sensors [16], and pH-image sensors [17].

To detect the pH distribution for cytoplasm and understand the relation between pH and enzymes and protein in detail within a single cell, which has a scale of several to several tens of micrometers, many nanoscale pH sensors have been developed. Zhang et al. reported a solid-state pH sensor based on WO_3-modified vertically aligned MWCNTs, which use a WO_3-CNT array for the pH detection electrode. This sensor has sensitivity close to −40 mV/pH [18]. Fenster et al. reported a single tungsten nanowire pH- sensitive electrode, which has a sensitivity of −61.1 mV/pH [19]. The previous two pH sensors contain nanoscale tungsten pH sensitive electrodes and macroscale stranded hydrogen electrodes which are impossible to apply to a single cell. We have designed double nanometal electrodes which can avoid the size problem in cell pH detection (Fig. 8). We aimed to fabricate the pH sensor by using electrodes by which sensing of the proton concentration becomes possible if either the electrochemical equilibrium involves protons in the reaction or if a separation of the electrolyte is achieved by a proton-specific ionophore. The probe was fabricated by the platinum and tungsten oxide nanowire electrodes grown via field emission technique. Because of the scale of the nanowires, nanoscale resolution positioning and manipulation was required. To this end a nanorobotic manipulation system was employed. Figure 8 shows the concept of the proposed device. In this research, a platinum and tungsten dual nanowire electrode pH sensor has been fabricated. A nanoprobe pH sensor evaluation

CNT Handling and Integration, Fig. 8 Concept draws of nanowire probe pH sensor

system has been constructed, and the pH response of this sensor has been tested in acidic buffer solution (pH = 4, 6.1, 6.9) and alkaline buffer solution (pH = 8).



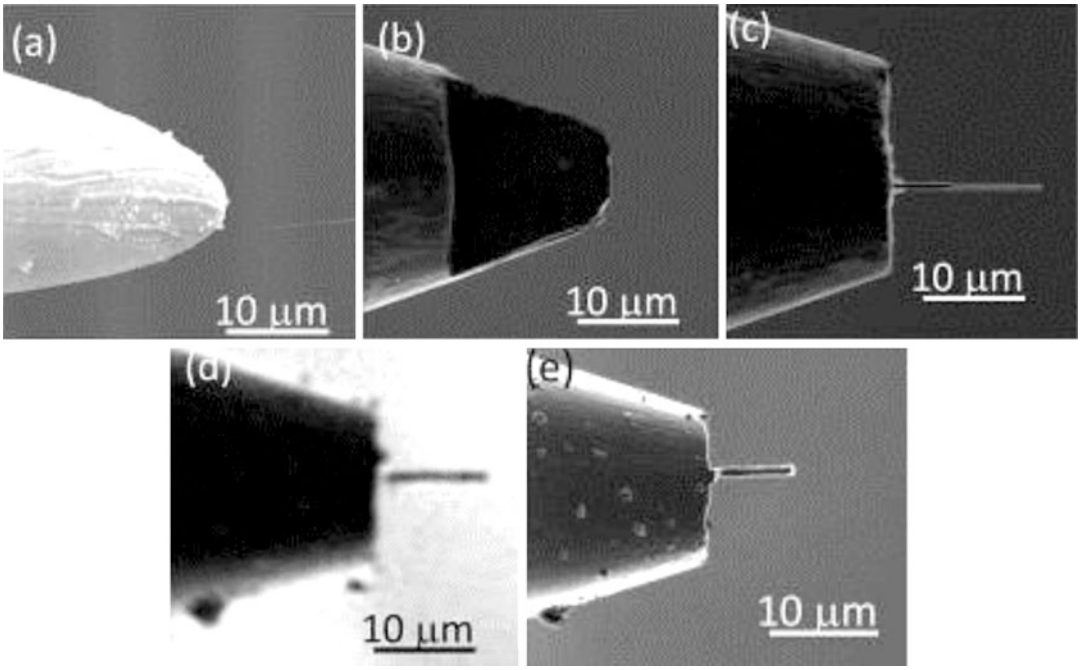
During the field emission nanowire growth, an MWCNT is employed for the cathode and a tungsten probe for the anode. Unit 1 and unit 4 were used to assemble the MWCNT emitters and set the tungsten probes as the anode.

The tungsten probe is etched by an FIB and then coated with parylene. Then the tip of the tungsten probe is opened using the FIB. The tungsten was set to manipulator 4 for anode. The carbon nanotubes were picked up by an AFM cantilever. An AFM cantilever (Olympus, OMCL-TR400PB-1) is set on the manipulator as the end-effector to pick up the MWCNT from the carbon bulk of MWCNTs which were synthesized by the arc-discharge method. The MWCNT is set up as the emitter (cathode) which has a low field emission voltage.

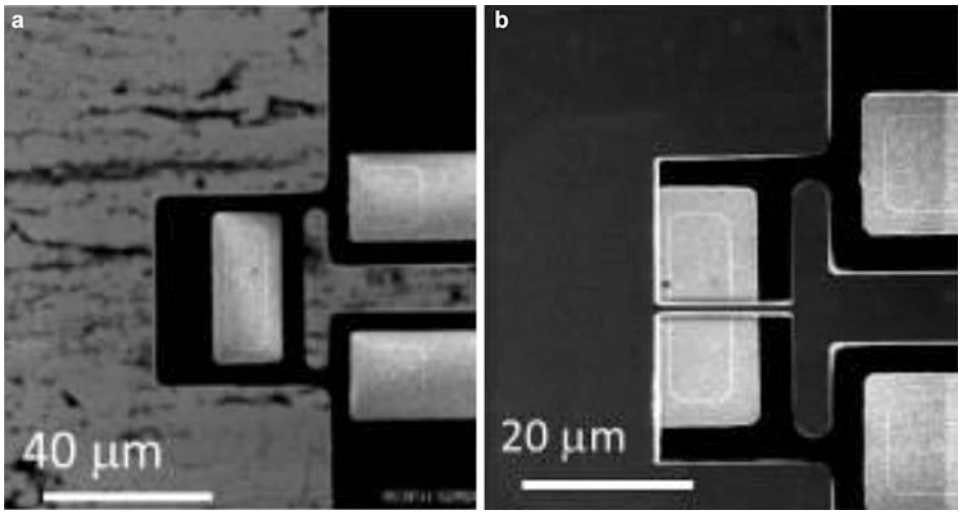
The fabrication procedure is shown in Fig. 9. A PZT cantilever was used as the substrate. The cantilever is etched by an FIB for separated electrodes (a). An FESEM was introduced for real-time observation and two units of manipulators inside the specimen chamber of FESEM were used to fabricate the device. An AFM cantilever was assembled to the manipulator to pick up CNTs from the carbon bulk. The CNTs were cut to 1.7 μm length by current, and fabricated to PZT cantilever (b). A tungsten probe was used for the anode in field emission. The probe was etched by an FIB and then coated with parylene. The FIB was then used to cut the tip of the probe to expose the conductive material to concentrate the electro field. The etched tungsten probe was positioned to the counter of the CNTs. For field emission of CNTs, the emission characteristics should be measured before growth. The trimethylcyclopentadienylplatinum precursor was inserted into the specimen chamber of the FESEM and a constant current applied to CNT 1 and etched tungsten probe to grow the platinum nanowire (c). Using the precursor hexacarbonyl tungsten and applying a constant current to the etched tungsten probe the CNT 2 resulted in the growth of the tungsten nanowire (d).

A tungsten nanoprobe (MicroManipulator Inc, MODEL 7B) was used as the anode for nanowire growth via field emission. To decrease the branching of the nanowire, the applied field needs to be concentrated. The cathode for the field emission is an MWCNT which is tens of micrometeres in diameter. The tip radius of the tungsten probe is nearly 1 μm as shown in Fig. 10a and needs to be reduced. The FIB technique is used to etch the tungsten tip to a 300 nm thick plane which is shown in Fig. 10b. The probe is then turned clockwise through 90°, and the plane etched to form a probe 300 × 300 nm in cross section (Fig. 10c). A parylene coating unit (Dix-coating, DACX-Lab) was employed to coat a 300–400 nm thickness of the polymer (Fig. 10d). The tip of the probe was etched by an FIB to remove the polymer as shown in Fig. 10e.

A dynamic force microscope (DFM) cantilever (KEYENCE OP-75041 DFM/SS) was used for the substrate CNTs. The cantilever comprises



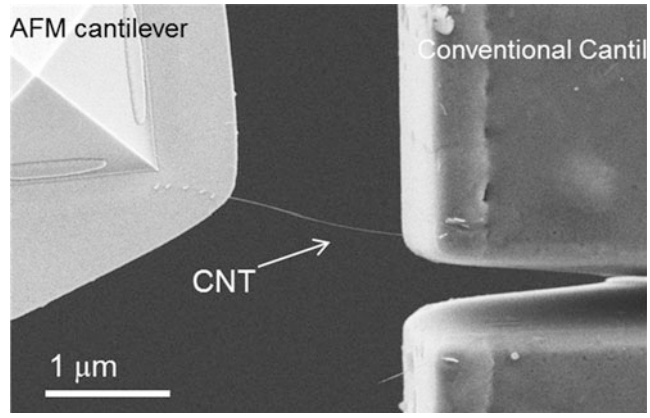
CNT Handling and Integration, Fig. 9 Concept draws of nanowire probe pH sensor



three layers. The bottom layer and the upper layer are insulators and the middle layer is alumina. We cut the edge of the cantilever and then separated the cantilever with FIB etching. The gap of the electrodes is 700 nm. Figure 11a, b, respectively, shows the cantilever before and after etching.

The CNTs were picked up from the carbon bulk by the AFM cantilever controlled by the nanorobotic manipulator. As shown in Fig. 12, the CNTs were assembled to electrodes of the PZT cantilever individually. The CNT 1 is 1.75 μm in length by 20 nm in diameter, and the CNT 2 is 1.78 μm in length by 31 nm in diameter as shown in Fig. 13a. Figure 13a, b shows the platinum nanowire growth on the tip of CNT 1. The platinum nanowire was grown from the MWCNT emitter by using the CpPtMe3 (STREM CHEMICALS purity 99 %) precursor. The pressure of the FESEM specimen chamber was about 5×10^{-3} Pa. A constant field emission current 1 μm was applied for 300 s with the gap at 0.62 μm. The gap of CNT 1 and the etched tungsten probe is set using the nanorobotic manipulator (a). The platinum nanowire is 209 nm in length (b). Figure 13c, d shows the tungsten nanowire growth on the tip of CNT 2. The tungsten nanowire grew from the MWCNT emitter by intruding $W(CO)_6$ (ALDRICH, 97 %) precursor. The pressure of the FESEM specimen chamber was again about 5×10^{-3} Pa. A constant field emission current of 500 nA was applied for 60 s at a gap of 0.70 μm. The gap of CNT 2 and etched tungsten probe is set by the nanorobotic manipulator (c). The platinum nanowire is 907 nm in length (d).

We constructed a pH sensor evaluation system as shown in Fig. 14. The buffer solutions were



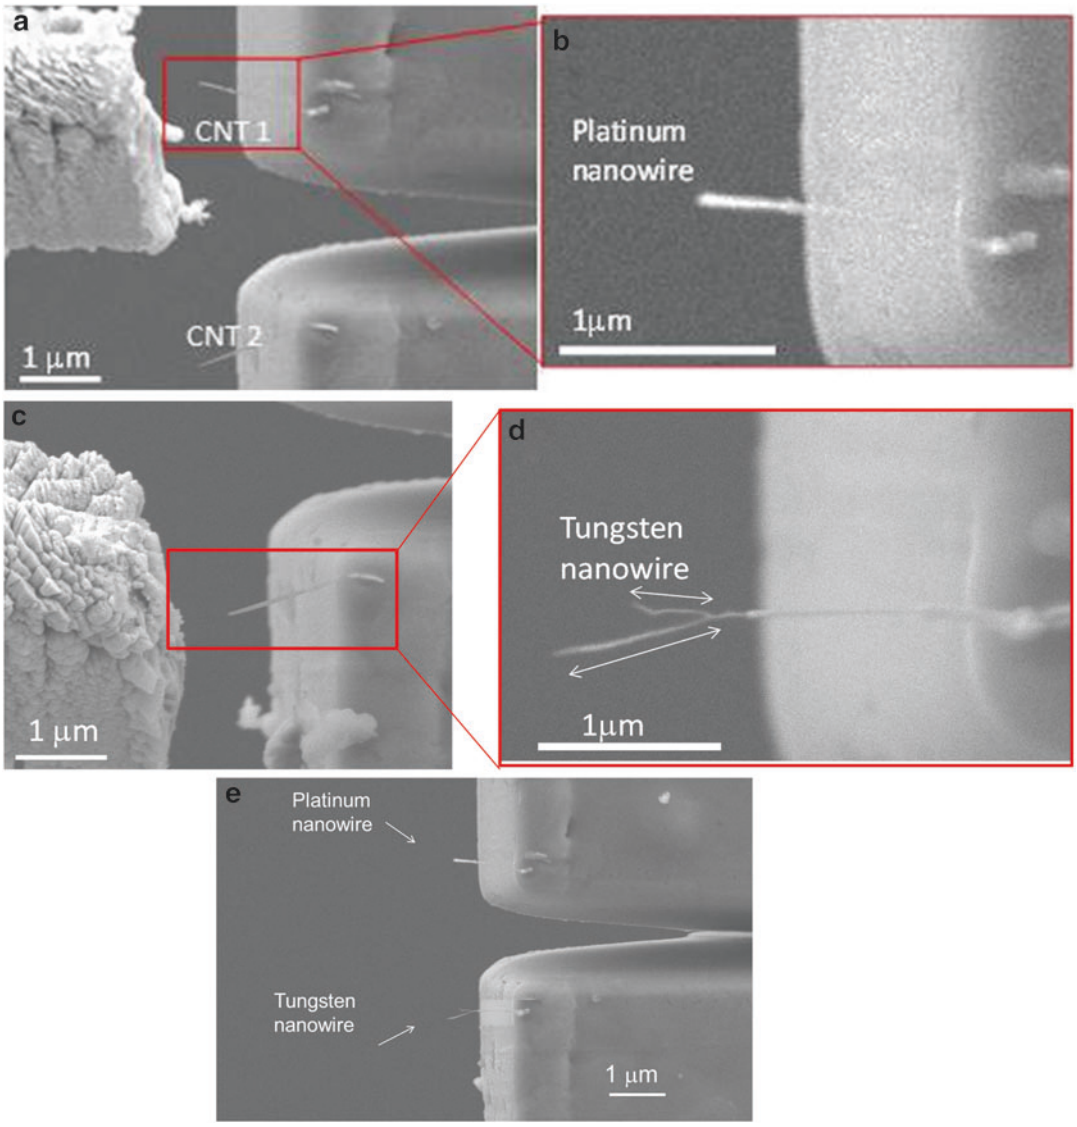
CNT Handling and Integration, Fig. 10 Fabrication of anode by FIB etching. (**a**) a tungsten probe tip (**b**) FIB etching to a plate (**c**) turned 90° and FIB etched to a needle. (**d**) etched tungsten needle coved with a parylene layer. (**e**) FIB etching the tip of the needle in order to cut the parylene layer at the tip area

CNT Handling and Integration, Fig. 11 Fabrication of the cantilever for output electrodes by FIB

introduced into the flow system. Next, a nanoprobe pH sensor was inserted to detect the electropotential together with a reference pH sensor for pH detection. A voltmeter which was constructed using a pA meter and a large resistance was employed to measure the electro potential. The characteristics were evaluated as the electro potential and pH values. Because of liquid

CNT Handling and Integration, Fig. 12 Fabrication of the cantilever for output electrodes by FIB

surface tension, the nanoprobe pH sensor has a risk of bending and being damaged. However, several buffer solutions are required for testing which increases the risk of damage to the nanoprobe pH sensor. It was necessary to provide a solution to this problem, and for this purpose we used continuous flow measurements. A container with an inlet and outlet was fabricated. Initially, buffer solutions of pH = 4 were flowed into the container and then the pH sensor nanoprobe was inserted into the solution. A reference pH sensor was placed close to the pH sensor nanoprobe in the container to monitor the real-time pH value. The electromotive force of the tungsten oxide and platinum nanowires was measured using a voltmeter. For the second step, a buffer solution of pH = 6.9 was flowed into the container, mixing with the previously introduced solution. The pH value changed to 6.1 as measured by the reference pH sensor. The electromotive force of the nanowires was measured. We continued to flow in the buffer solution of pH value 6.9 until the pH value of the container changed to 6.9. The electromotive force of nanowires was measure in this solution. A buffer solution of pH value of 9 was used to flow into the container, and when the pH value changed to 8, we again measured the electromotive force of the nanowires.

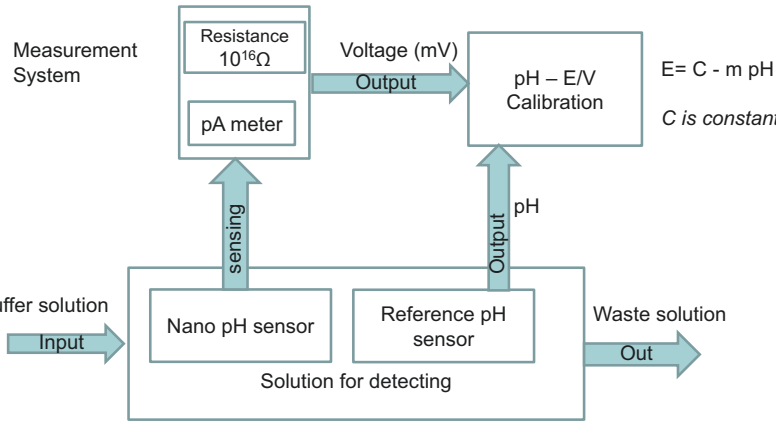


In order to prove that the nanoprobe pH sensor could be used to detect hydrogen ions based on the tungsten and tungsten oxide nanowire and the platinum nanowire and to discover the pH response of the CNTs, we fabricated double CNT electrodes and tested their pH response. Two CNTs were picked up from CNT bulks and assembled to FIB etched separated electrodes of a cantilever. The double CNTs device was tested with the buffer solution flow system using solutions with pH values of 4, 6.4, and 8. The electromotive force of the CNTs was a constant value of 0.018 mV.

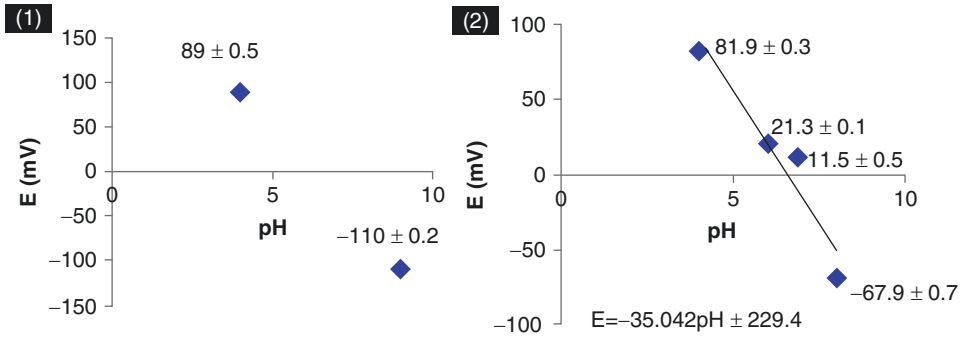
The term pH value was coined to describe the solution pressure $\mathrm{pH} = -\lg\left(\mathrm{cH/mol\ dm^{-3}}\right)$, in 1909 by Søren P. L. Sørensen pondus Hydrogenii or potentia Hydrogenii, of hydrogen ions in aqueous solutions. International Union of Pure and Applied Chemistry (IUPAC) defines the quantity pH in terms of the molality basis activity αH of hydrogen ions in solution:

$$pH = -\lg[a(H^+)] = -\lg\left[\frac{m(H^+)\gamma_m(H^+)}{m^0}\right] \quad (6)$$

Where $\alpha(H^+)$ is the activity of hydrogen ion H^+ (hydrogen 1+) in aqueous solution, $m(H^+)$, $\gamma_m(H^+)$ is the activity coefficient of H^+ (molality basis) at molality $m(H^+)$, and $m^0 = 1\ \mathrm{mol/kg}$ is the standard molality.



The nanoprobe pH sensor was evaluated using acidic and alkaline buffer solutions with pH 4 and 9 respectively, based on the solution flow system for a series of five times. The results reveal that the nanoprobe pH sensor can detect the pH for buffer solutions of acid (pH 4. 01, pH 6.1, and pH 6.9) and alkali (pH 8) (Fig. 15). Sensor 1 was used to test the buffer solutions at pH 4 and pH 9 to confirm that the sensor has a pH response in acidic and alkaline media. The open circuit potentials



CNT Handling and Integration, Fig. 13 (**a**, **b**) show typical growth of the platinum nanowire and (**c**, **d**) show the tungsten nanowire by field emission which was used for the work and the counter electrode. (**e**) shows the assembled pH probe sensor

(OCP) were 89.1 ± 0.5 and −110.0 ± 0.2 mV, respectively. The results of sensor 1 show that the pH sensor has different electromotive forces under acidic and alkaline conditions. Sensor 2 was used to test the pH sensitivity of the tungsten oxide and platinum nanowire pH sensor. The OCP values in buffer solutions of pH 4.0, 6.1, 6.9, and 8.0 were 81.9 ± 0.3, 21.3 ± 0.1, 11.5 ± 0.5, and −67.9 ± 0.7 mV, respectively. By calculation, the sensitivity of the nanowire pH sensor was −35.04 mV pH^{-1}. The error of the sensor is 0.1 mV level. The resolution of open circuit potentials are 0.01 mV and significant figure should be 0.1 mV. The experimental pH accuracy is 0.8 pH.

The performance of pH sensors is usually characterized by measuring the OCP of the electrodes in solutions with various pH values.

CNT Handling and Integration, Fig. 14 Block diagram for the nano pH sensor evaluation

CNT Handling and Integration, Fig. 15 pH sensors evaluation in the buffer solutions

A single-phase interaction electrode may similarly be envisaged, though no example of a pH electrode involving oxygen-deficit phases has been provided [18, 19]. By omitting hydration, the surface mechanism can be expressed as follows:

$$WO_3 + 2nH^+ + 2ne^- \Leftrightarrow WO_{3-n} + nH_2O \quad (7)$$

According to the Nernst equation for the equilibrium case, the electrode potential can be stated:

$$\begin{aligned} E &= E^0 - \frac{R \cdot T}{z \cdot F} \ln \frac{\alpha_{(WO_{3-n})}}{\alpha_{(WO_3)} \cdot \alpha_{(H^+)}^{2n}} \\ &= E^0 - \frac{R \cdot T}{z \cdot F} \ln \frac{\alpha_{(WO_{3-n})}}{\alpha_{(WO_3)}} - \frac{R \cdot T}{F} \ln \frac{1}{\alpha_{(H^+)}} \\ &= E^0 - \frac{2.303 \cdot R \cdot T}{F} pH \\ &= E^0 + mpH \end{aligned} \quad (8)$$

Where E is the measured potential, E^0 is the standard potential which is zero, R is the gas constant (8.314 J K^{-1} mol^{-1}), T is the absolute temperature (K), z is the signed ionic charge (mol), and F is the Faraday constant (96487.3415 C mol^{-1}). At room temperature $(T = 298\ K)$, during the reaction the $\frac{\alpha_{(WO_{3-n})}}{\alpha_{(WO_3)}}$ approximate to 1 [20], the slope m should be

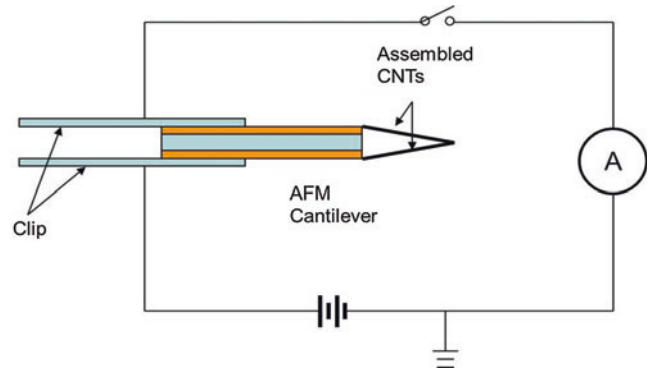
$$\begin{aligned} m &= -2.303 \cdot R \cdot T/F = -0.0591V/pH \\ &= -59.1mV/pH \end{aligned} \quad (9)$$

At the counter electrode, the platinum nanowire surface reaction can be described as follow [20]:

$$2H_2O \Leftrightarrow O_2 + 4H^+ + 4e^- \quad (10)$$

Here, platinum plays a role as catalyst, so the performance of this pH sensor is

−59.1 mV/pH. The sensitivity of the pH sensor nanoprobe which we fabricated was −35.04 mV/pH. The reason that this sensitivity had a bias with respect to that from the Nernst equation is due to the fact that the tungsten nanowire is not of a constant thickness. And the method of tungsten growth is field emission. The growth tungsten plays a role as field emission tip which is high temperature up to 1000 K. The high temperature leads to the decrease of sensitive of tungsten/tungsten trioxide nanowire hydrogen ion sensitive. The tungsten nanowire grown via field emission has a polycrystalline structure and the lattice direction was random. Various tungsten oxides covered the surface of the tungsten nanowire. The thickness of the tungsten trioxide is not constant, which leads to the observed bias in the value of the sensitivity.



We aim to detect the pH value and pH distribution inside a cell. Common cell has a size of 5–50 μm. We design an electrochemistry pH sensor with a potential to inject to the cell and measure the pH distribution. The issue is how to make an integrated probe type pH sensor. The previous research had designed the pH sensor with a sensitive nanowire work electrode, however the counter electrode is several centimeter in diameter. It is impossible to insert into a cell and measure the pH distribution inside the cell. This is the "size problem." Here, we integrated the nanowork electrode and counter electrode into a single device with a gap $1 \sim 2\mu m$ in between. The proposed pH sensor has to insert cell and detection the pH.

The advantages of the pH sensor are as follows. First, the design of this pH sensor is an integrated probe type sensor; to the author's knowledge this is the first design of a nanoscale integrated probe type pH sensor. Second, in the fabrication the nanowires were used for work electrode and counter electrode and fabricated on one probe. This sensor has a potential to detect pH value inside the cell. Second, the sensitivity of pH sensor is near to the theory calculation. And with the calibration and calculation the resolution of this pH sensor is 0.8 pH.

CNT Probe Thermal Sensor Based on Nanorobotic Manipulation

This part reports a thermal sensor assembled by two multiwalled carbon nanotubes (MWCNTs) inside a field emission scanning electron microscope (FESEM) which constructed a probe tip in order to detect the local environment of single cell. An atomic force microscope (AFM) cantilever was used for substrate which is composed by Si_3N_4 and double side was covered by gold layer. Two MWCNTs were assembled to both side of AFM cantilever individually by employing a nanorobotic manipulation. A second AFM cantilever was used as an end-effector to manipulate the MWCNTs to touch each other, and used electron beam induced deposition (EBID) to bonding the two MWCNTs. The MWCNTs probe thermal sensor was evaluated inside a thermostated container at 25–60 °C. The experimental results show the positive characteristics of the temperature coefficient of resistance (TCR).

Nanomechanical and nanoelectromechanical devices have been widely investigated in recent years. The precise and controllable nanofabrication methods are important to develop the novel type of nanodevices. One-dimensional nanostructure such as nanowires and nanotubes are basic building blocks for NEMS. Since carbon nanotubes (CNT) have been discovered many applications have been developed such as mass sensor, nanoradio, and nanomotor. Nanowire is a solid one-dimensional nanostructure which includes metallic nanowires, semi conductive nanowires, and nonmetal nanowires which have applications as nanoneedles, nanohotwire transistor, and nanogenerator. One challenge is to assemble and apply a nanosensor to detect the local environment of single cell. The single cell is the basic element of life and it is the converging point of meter, energy and information. Because of the size of the cell, nanodevice is needed for measurement and manipulation. A thermometer is a device that measures temperature or temperature gradient using a variety of different principles of mechanical, thermojunctive, thermoresistive, and radiative (infrared and optical pyrometers). To use as a sensor, the extremely small size of the CNT can

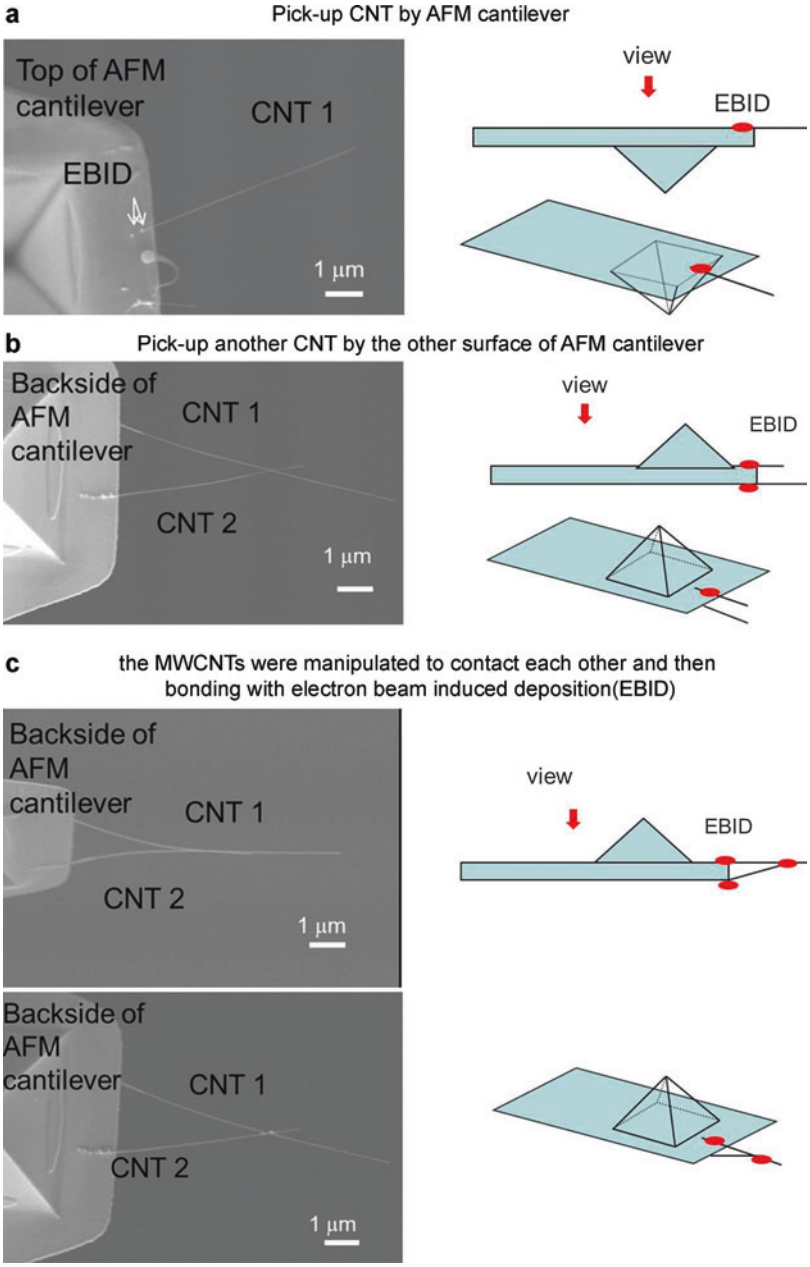
CNT Handling and Integration, Fig. 16 Concept drawing of the MWCNTs probe thermal sensor

provide accurate measurement at nanoscale size and reduces the possibility of disturbing the local environment. In addition, the small size sensor implies very low power consumption. To use as a temperature sensor, CNT can have the smallest time constant and provides the extremely rapid time response with the measured object's temperature.

C. K. M. Fung. et al. reported a CNT-based thermal sensor. With two Au electrodes, the bundled CNTs were assembled in between on the substrate. C. Y. Kuo et.al. fabricated lateral growth of CNTs between two electrodes thermal sensor. The CNTs grow on the substrate between electrodes. F. Arai, et al. reported a single CNT thermal sensor with a CNT assembled on four electrodes. The former sensors have advantages of smaller size, lower energy cost, and suitable to measure the specimens within 2D surface. Due to the restriction of the architecture design, these sensors can only measure the specimens with the size larger than 1 mm scale.

We proposed a thermal sensor assembled by two multiwalled carbon nanotubes (MWCNTs) inside a field emission scanning electron microscope (FESEM). The advantage of the MWCNTs probe sensor is to detect the local environment of single cell with high accuracy as shown in Fig. 16. The basic idea is to detect temperatures by the thermal coefficient of resistance. The biological cells are commonly alive and cultured at temperature for 35–37 °C. When the temperature goes up to 43 °C most cells will be exterminated. We aim to evaluate the thermal sensor in the range of 30–60 °C.

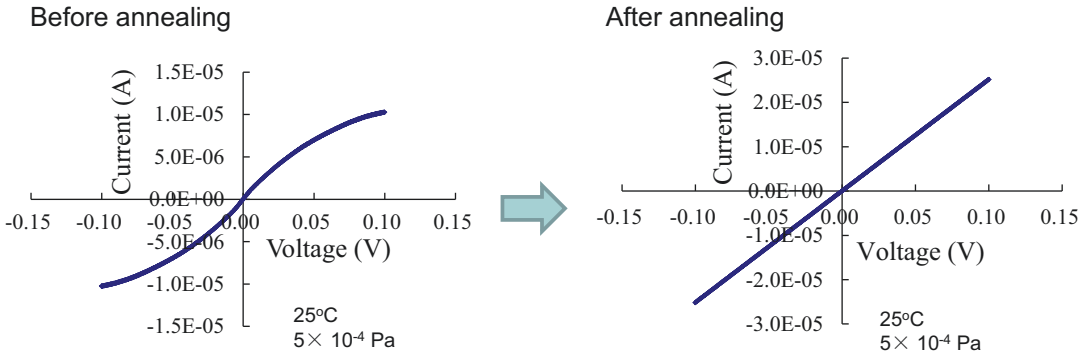
A nanowire probe is designed by temperature coefficient of resistance (TCR) method. The electrical resistance of a conductor is dependent upon collisional processes within the wire; the resistance could be expected to increase with temperature since there will be more collisions. An intuitive approach to temperature dependence leads one to expect a fractional change in resistance which is proportional to the temperature change:



$$\frac{\Delta R}{R_0} = \alpha \Delta T \tag{11}$$

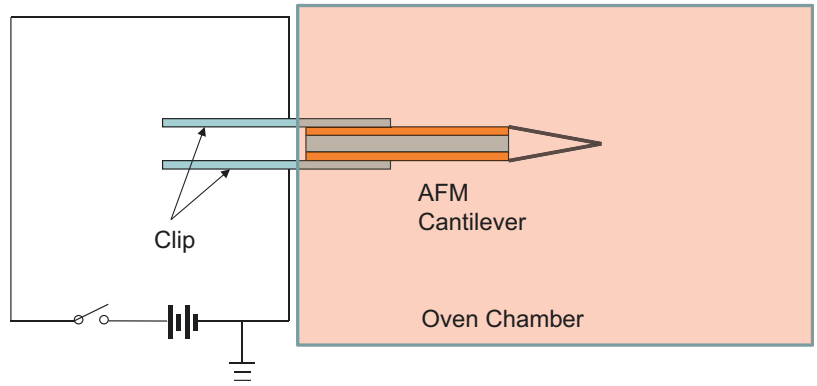
Here ΔR is the resistance change. R_0 is the initial resistance at 0 K. α is the temperature coefficient of resistance. ΔT is the temperature change.

Based on temperature coefficient of resistance, we designed a probe type thermal sensor by CNT. The basic design is the resistance of CNT change since temperature change. An AFM cantilever was used for substrate which is constructed by Si_3N_4 and coated by Au layer both sides. CNTs were assembled to the surface of AFM cantilever. Then use another cantilever to force the CNTs to touch each other.



An AFM cantilever (Olympus, OMCL-TR400PB-1) is used as an end-effector to pick up the MWCNT. An AFM cantilever is constructed by Si_3N_4 and coated by Au layer on two sides. We use AFM cantilever as robot hand for MWCNT pick up and assembly. The MWCNT probe is fabricated from its bulks which are synthesized by arc-discharge method.

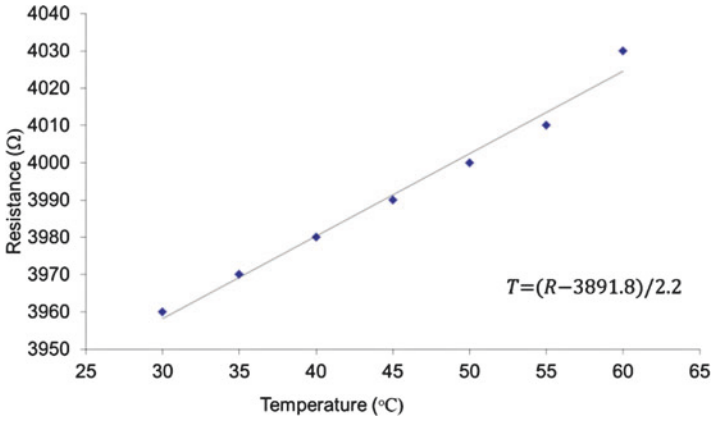
First, the AFM cantilever was manipulated to pick up a CNT from CNT bulk, which was



CNT Handling and Integration, Fig. 17 Assembly of MWCNTs probe thermal sensor. (**a**). Pick up CNT by AFM cantilever. (**b**) Pick up another CNT by the other surface of AFM cantilever. (**c**). The MWCNTs were manipulated to contact each other and then bonding with electron beam induced deposition (*EBID*)

synthesized by arc-charge method. The top surface of cantilever was used to pick up CNT 1. The cantilever was moved to below the CNT and went up in order to use Au surface to touch and bonding the CNT with van der Waals force. Electron beam induced deposition points were used to reinforce the bonding of CNT 1 and Au substrate as shown in Fig. 17a. Second step, we turned the cantilever over. And we assembled CNT 2 to the back surface of the Au surface as shown in Fig. 17b. Third step, we used another cantilever to manipulate CNT 1 in order to touch CNT 2. Then, an EBID was deposited on the CNT's contact point to improve the bonding as shown in Fig. 17c. In total four MWCNTs probe thermal sensors were fabricated. The MWCNTs were synthesized by

CNT Handling and Integration, Fig. 18 Annealing of CNT



CNT Handling and Integration, Fig. 19 Schematic of evaluation of thermal sensor

arc-charge method. Defects of MWCNTs are issues of mechanical and electrical applications. Annealing is a method to solve this problem. We applied sweep voltage −1–1 V to anneal the CNT. The Fig. 18 shows the anneal I-V curve. Figure 19 shows the schematic of thermal sensor evaluation. A probe thermal sensor was placed to the holder which is colored yellow. The two sides of AFM cantilever were connected to positive and negative electrodes individually. The probe sensor was set into an oven and tested for I-V curve from 30 °C to 60 °C for every five degrees.

The oven was set to 30 °C and maintained at this temperature for 2 h. Then we tested the I-V response of the MWCNT probe thermal sensor. The resistance was 3960 Ω with the standard error of 1.5 Ω. For next step, the oven temperature was increased from 5°C to 35 °C in 1 h and maintained 2 h. The resistance was 3970 Ω with the standard error of 7.4 Ω. The test points at 40 °C, 45 °C, 50 °C, 55 °C and 60 °C was set-up. The tested resistance was 3980 Ω, 3990 Ω, 4000 Ω, 4010 Ω, and 4030 Ω with standard error 1.0 Ω, 1.9 Ω, 1.3 Ω 11.1 Ω, and 1.0 Ω.

The result of CNT annealing was shown in the Fig. 20. The I-V curve had been returned to linear. The defects of CNTs were repaired. The mechanism can be described like this, the CNT were cover some of amorphous carbon. When sweep current is applied to the CNT the remote joule heating [21] investigated to the amorphous carbons and rebuilt the defects of bonding at CNTs. When the charge carriers flow pass the CNT, the vibration of lattices of CNT will absorb the charge carrier energy and create a phonon.

The experimental results show that temperature coefficient of resistance of CNT was linear in Fig. 20. The relationship is temper = resistance −3891.8/2.2. And the standard error was at 10 Ω level. The metallic MWCNT usually has a

CNT Handling and Integration, Fig. 20 Evaluation result

resistance of several k Ω. Here the increase in temperature was set to 5 °C because of the oven's limitations. According to the Eqs. 5 and 6, the temperature coefficient of resistance is calculated as 0.05 %.

The total resistance thermal sensor

$$R_{\text{total}} = R_{\text{CNT}} + R_{c1} + R_{c2} + R_{c3} \tag{12}$$

Where, R_{total} is the total resistance of nanothermal sensor. R_{c1} is contact resistance of CNT 1 and Au substrate. R_{c2} is the contact resistance of CNT 2 and Au substrate. R_{c3} is the contact resistance of two CNTs. And the resistance of CNT can be calculated by the following equation.

$$R_{\text{CNT}} = \rho_{NT} \times \frac{L}{\pi\left(\frac{d}{2}\right)^2} \tag{13}$$

Where, R_{CNT} is the resistance of CNT. ρ_{NT} is the resistivity of the CNT. L is the length of the CNT. d is the diameter of the CNT. In this experiment, CNT 1 is approximately 3 μm in length and 37 nm in diameter. The CNT 2 is approximately 3 μm in length and 42 nm in diameter. The ρ_{NT} is $3.8 \times 10^{-5}\Omega\text{cm}$ [22]. By the calculation the $R_{\text{CNT}} = 1.8\,\text{k}\Omega$.

Chun Lan et al. discussed the metal carbon contact resistance and resistance of CNT. The MWCNT resistivity is 0.33 $k\Omega/\mu m$ and specific contact résistance of CNT and Au surface is 4.4 $k\Omega\mu m$.

$$R_{\text{CNT}} = 33\frac{k\Omega}{\mu m} \times 6\mu m \approx 1.98k\Omega \tag{14}$$

$$R_{c1} + R_{c2} = \frac{4.4k\Omega\mu m}{2.5\mu m} = 1.76\ k\Omega \tag{15}$$

So

$$R_{c3} \approx 210\ \Omega\ \sim 390\Omega \tag{16}$$

The calculation results of CNT resistance meet the reference data and the theoretical calculation. The MWCNT can be considered as a graphene cylinder. The single crystal graphite shows the linear thermal response when the temperature is higher than 200 K. The evaluation result of nanothermal sensor is linear.

In summary, this section presented the CNT integration and applications and fabrication of a functional pH sensor with a double metallic nanowire. A cantilever was used for the electrodes of the device and etched by an FIB. Two CNTs were assembled to the separated electrodes of the cantilever. A tungsten probe was etched by an FIB to 300 nm in diameter and 25.4 μm in length. Then the probe was coated by parylene and the tip cut to expose the tungsten. A tungsten nanowire with 907 nm length and a platinum nanowire with 209 nm length grew from the tip of the CNTs via field emission by introducing hexacarbonyltungsten and trimethylcyclopentadienylplatinum, respectively, inside a field

emission electron microscope. The acid and alkali response of the pH sensor was tested; the sensor was able to detect the pH value, and the performance of the pH sensor was −35.04 mv/pH. We hope that these findings will be rapidly adopted in the field of biochemical detection.

Coarse-Grained and Hybrid Simulations of Nanostructures

Richard Gowers and Paola Carbone
School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester, UK

Synonyms

Mesoscopic simulations; Multiscale simulations

Definition

In computational chemistry coarse-grained (CG) models are defined as molecular models where some details (i.e., degrees of freedom) of the original chemical structure have been removed. The resulting models are a coarser description of the chemical systems compared with the original ones and can then be used to perform either molecular dynamics or Monte Carlo simulations [1]. The reduction of the models' degrees of freedom enables the simulation of systems whose size is comparable with that of the experimental ones and the timescale spanned by these simulations can reach microseconds.

Overview

Computer modeling is a powerful technique to gain molecular level details of chemical systems under different physical conditions and enables to relate macroscopic observations with changes in the chemical and physical state of the system. However, all modeling techniques rely on computer hardware, and therefore their use is limited by the available computer power. State-of-art simulations can nowadays reach the size of few millions of atoms, but if standard high-performance computers are used, the system size usually does not exceed few hundred thousand particles. Indeed, during a molecular simulation, the number of interatomic interactions that must be computed every iteration is proportional to N^2, where N is the total number of system particles [1]. This heavy use of the CPUs limits not only the size of molecular models but also the timescale the system can be simulated for.

One way to circumvent this problem is to reduce the number of interacting particles (N) in the systems, simplifying the models and modifying the original interacting parameters to include in an implicit way the neglecting details. The simplest example of such coarse graining is the development of united-atom (UA) force fields [2] where the hydrogen atoms and the aliphatic carbon to which they are covalently bonded are modeled as a single entity. The assumption underlying the development of such force fields is that the physics of the model is not affected by neglecting the explicit interactions involving the aliphatic hydrogen atoms. A similar decision on how many and which atomistic details can be neglected in a molecular model (procedure known as mapping scheme) is the key decision that must be carefully made every time a new coarse-grained model is developed if some of the system chemical and physical features have to be maintained. It has been indeed shown that mapping schemes which retain different features of the original molecule perform differently depending on the property analyzed [3].

The model simplification done in the UA force fields can therefore be carried on at much larger scale: large group of atoms can be lumped up in single super-atoms (or beads) and even entire colloidal particles can be modeled as single rigid bodies.

A very broad distinction can be made between those CG models aiming at preserving some chemical details of the original system and those which instead preserve only the shape of large

molecular aggregates. The former can reproduce with a certain degree of accuracy the system enthalpy, while the latter reproduce the only entropic effects, and it is typically employed in modeling colloidal systems [3–6].

Procedures

Since different features of the atomistic model can be used as target properties, several procedures to develop the effective interactions between the beads have been proposed. Some of the most popular methods used in materials science are briefly introduced below.

Structural Based Model

The target property to reproduce is the structure of the atomistic model. The CG non-bonded part of the force field is therefore refined until it reproduces structural correlation functions such as the radial distribution function (RDF) of the atomistic system. The quality of the agreement is quantified using a merit function of the form

$$\chi^2 = \sum \left(y_{\text{target}} - y_{CG} \right)^2 \qquad (1)$$

where y_{target} and y_{CG} are the correlation functions calculated from the atomistic and CG model, respectively. The sum is over all coordinates and simulations. The minimization of χ is a nonlinear inverse problem for which no analytical expression is available and where linearization is unsuccessful. An iterative procedure is therefore run and the CG force field parameters are consequently adjusted. Two iterative procedures are usually employed: one uses Monte Carlo simulations [7] and the other one molecular dynamics [8]. In both cases, the new CG model is built upon the atomistic one and the existence of a one-to-one correspondence between the two models enables an easy interchange between the two model resolutions [3].

Thermodynamic Models

The aim of these types of models is to reproduce some thermodynamic properties of the atomistic system. The CG potential is usually modeled using a Mie (generalized Lennard-Jones) function

$$V(r) = C_\varepsilon \left\{ \left(\frac{\sigma}{r} \right)^n - \left(\frac{\sigma}{r} \right)^m \right\} \qquad (2)$$

where n and m are the exponents controlling the softness of the potential, σ is the particle diameter, ε is the potential well depth, and C is chosen in such a way that the minimum of the potential corresponds to $-\varepsilon$.

The key parameters to control and iteratively optimize are ε and σ. In some procedure the exponents n and m can also be varied. The target properties for the CG model include partition coefficients [9], density, and interfacial tension [10]. Another more systematic approach to obtain the sought force field parameters involves the solution of a molecular-based equation of state (EoS) which takes advantage of the fact that for some molecular fluids the SAFT EoS can be solved [11].

Force Matching

In this type of method [12, 13] the CG interactions are again parameterized using the underlying atomistic interactions, but in this case the difference to be minimized is that between the atomistic and CG forces and the minimization is solved using a variational approach

$$\chi^2 = \frac{1}{3N} \left\langle \sum_{I=1}^{N} \left(F_{\text{target}} - F_{CG} \right)^2 \right\rangle \qquad (3)$$

where the angular brackets denote average over the trajectory, F_{target} is the net force on the atomistic site I, F_{CG} is the force on the same CG site, and N is the number of sites (beads) in the CG model. Within this type of CG model a one-to-one correspondence between the atomistic and CG resolution is again established, and reintroduction of atoms in the mesoscopic model is possible.

Excess Entropy Model

In this case the function which needs to be minimized is the relative entropy (S_{rel}) which is defined as the difference between the distributions of configurations generated by the atomistic (P_{at})

and CG (P_{CG}) models. Using the Kullback–Leibler divergence formalist, one can define S_{rel} as

$$S_{\text{rel}}(U) = \int P_{\text{at}} \frac{P_{\text{at}}}{P_{CG}(U)} dR \tag{4}$$

where U is the CG potential and the average is evaluated over the CG configurational space, but weighted according to the atomistic probability distribution, P_{at}. S_{rel} provides a variational framework for determining the approximate CG potential (U) that reproduces target atomistic distributions [14, 15].

Dissipative Particle Dynamics

The techniques presented above despite simplifying the molecular model still retain a quite high degree of chemical specificity. If however much larger systems must be simulated, a mesoscopic approach such as dissipative particle dynamics (DPD) can be employed. Such method can sample large conformational space in relatively short time, and therefore systems of the order of hundreds of nanometers can be simulated [16, 17]. In this method, each bead represents a much larger amount of material than the previously discussed methods, such as an entire molecule or a few molecules of solvent. Because each DPD particle represents such large portion of the chemical system, the standard analytical functions used to model the particle-particle non-bonded interactions (Eq. 2) cannot be used. Therefore, in DPD the forces are expressed as the sum of three contributions

$$F_{ij} = F_{ij}^{C}(r_{ij}) + F_{ij}^{D}(v_{ij}) + F_{ij}^{R}(\theta) \tag{5}$$

where F_{ij}^{C} represents a conservative repulsive force between particles and it is notably weaker than the standard short distance forces (Eq. 2) allowing particles to pass through each other (the so-called soft potential). Such weak short-range interaction is a necessary consequence of the much larger mapping scheme used in this modeling technique. F_{ij}^{D} is a dispersive force between particles which is a function of their relative velocity and represents the effect of fluid viscosity. Finally, F_{ij}^{R} is a random force, a function of a Gaussian random number θ, which replicates the thermal and vibrational energy of the system.

Because all of these forces, including the random force, are applied between pairs of particles, momentum is conserved throughout the system. DPD simulations are tuned to replicate hydrodynamic properties by adjusting the strength of each of these three forces. DPD has been used to model problems which are otherwise out of reach using particle-based methods, including modeling self-assembly and phase diagram of complex fluids.

Mean Field Theory

A radically different approach to coarse graining is that which simplifies the molecular systems at such level that its discrete nature (the fact that is made by individual atoms) is replaced by a continuum mean field. In this context the molecular system is modeled using a grid of points on which an effective field, representing the averaged interaction caused by the presence of all the system particles within a cutoff distance, which is identified with the mesh of the grid, acts. In its basic form, to obtain the field (H_{eff}), the free energy of the system is minimized with respect to the distribution of all possible configurations of the system, P. Since both P and H_{eff} are not known, an iterative process is used until self- consistency is reached [18]:

$$P = \frac{\exp\left(\frac{-W}{k_B T}\right)}{\sum_N \exp\left(\frac{-W}{k_B T}\right)} \tag{6}$$

$$W = \frac{\partial H_{\text{eff}}}{\partial P} \tag{7}$$

where k_B and T are the Boltzmann constant and the temperature, respectively, W is the intermolecular potential, and the summation is run over all the N possible states of the system.

Applications in Materials Science

The procedure briefly presented above can be used in a variety of contexts in both materials science and biology. All have been indeed used

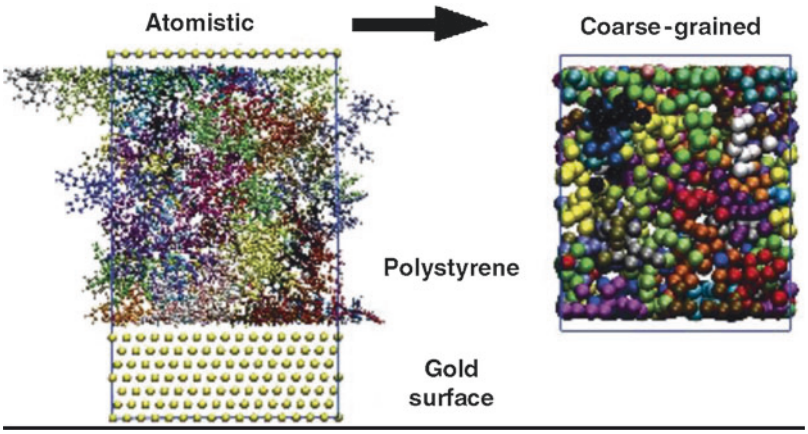
to model synthetic and biopolymers, complex and simple liquids, surfactants, and mixtures of them [3–6]. Below, three examples of such applications in materials science are presented.

Predicting Self-Assembly Properties for Amphiphilic Copolymers

Amphiphilic copolymers are polymer chain formed by more than one type of monomer each with a different polarity. When dissolved in solvents, they self-assemble in a variety of morphologies which are function of the relative chemical affinity of the solvent and monomers and the chain microstructure (the monomer sequence within the chain). Such self-assembled nanometric structure can then be used in a variety of applications from drug and gene delivery agents to emulsion stabilizers [19]. The a priori prediction of their phase diagram is very difficult to achieve, and modeling can help in avoiding the synthesis of many different materials. Using an atomistic model for such simulations is however not possible; therefore CG models have become a popular choice. Mainly using DPD [20] and thermodynamics model [21], it has been recently possible to follow at the self-assembly process and build entire phase diagrams for such systems [20].

Predicting the Long-Time Dynamics of Ionic Liquids

Ionic liquids (ILs) are high molecular weight ion pairs formed by organic cations and bulky counterions. They are liquid at room temperature and below so that they can be exploited in a considerable number of extraction and other chemical processes. Knowing the dynamics of ILs at low temperature can therefore improve the design of the ideal solvent for a specific extraction process; however such experiments are very difficult to carry out since the IL's viscosity increases very rapidly lowering the temperature [22]. CG modeling can help in gaining such data as the dynamics of the model is sped up compared with the experimental one by a factor which depends on the CG scheme used. Using CG models it has been possible to show that certain type of ILs with long aliphatic chains can self-assemble [23] and that at low temperatures they present an increased dynamic heterogeneity which is due to an increasing number of slow ions, while the amount of fast ions stays almost constant with temperature [24].



Calculating Interphase Thickness of Polymer Films on Solid Surfaces

When in contact with a solid surface, polymers exhibit complex behavior and understanding and characterizing this behavior is important in the design and development of nanostructures. Such systems are difficult to model as interactions at both small and long length scales need to be included.

A common approach to studying these systems therefore is to propagate information from the smaller length scales into the larger-scale models, and such an approach has been used for modeling polystyrene in contact with a gold surface [25]. Using data from atomistic-scale simulations of small amounts of the nanostructure, a coarser model was constructed (see Fig. 1). This model had reduced the number of particles in the polymer by means of coarse graining and also modeled the gold surface implicitly. This meant that each particle in the polymer interacted with the surface through a single function of normal distance instead of being a sum of interactions with many particles in the surface. This mesoscale model enabled the simulations of much larger volumes and led to the identification of an interphase thickness in which the polymer presents structural properties different than those in bulk.

Future Directions

Coarse-graining techniques have become powerful and well-established tools to access large length and timescales. The use of such techniques however is not without any drawbacks. In certain cases the degrees of freedom coarse-grained away in the mesoscale models represent crucial details without which the behavior of the models no longer faithfully recreate the phenomena that are to be studied. This is, for example, the case in molecular systems where short-range directional non-bonded interactions such as hydrogen bonds are present [3].

Coarse-Grained and Hybrid Simulations of Nanostructures, Fig. 1 An example of the reduction in detail possible when using coarse graining.

To circumvent this limitation typical of traditional coarse-graining techniques, the possibility of mixing both coarser and finer levels of detail in a single simulation in so-called hybrid-scale simulations has been recently explored. These two levels of detail are present simultaneously in the model allowing specific parts of the system to be modeled at a higher level of detail while allowing other parts to use a computationally cheaper model [26].

Two main approaches can be identified for such hybrid-scale simulations. Indeed one can mix either CG and atomistic force fields or particle-based (CG or atomistic) and field models. Both approaches are briefly explained below.

Hybrid Atomistic/Coarse-Grained Models

In models where atoms and CG beads are simultaneously present, in order to calculate the interactions between pairs of atoms or beads, preexisting standard force fields can be used [27]. However, interactions between atoms and beads, the so-called cross terms, must also be evaluated. These cross term interactions could be parameterized using one of the previously described coarse-graining methods; however this is an undesirable option because it would greatly aggravate the work required to derive the model and increase the number of parameters within the model. Instead, a commonly used solution is the use of virtual sites which are geometrical points identified in the finer (atomistic) resolved regions of the model which collect the interactions coming from the model coarser parts. If the CG model is derived from the atomistic one, as it is in the case of structural based or force matching models, the CG mapping scheme is built on the chain atomic structure and each bead center of mass corresponds either to a specific atom or to the center of mass of all the atoms lumped up in it. Thus, it is easy to identify in the atomistic resolved part of the model the positions of the virtual beads and use them as pinning position to collect any mixed interactions. The VS can therefore be seen as coarse-grained representation of a group of atoms, placed at their center of mass, which facilitate their interaction with coarse-grained beads. When a coarse-grained particle interacts with the atoms of a certain group, it is with the virtual site representation of that group. To ensure that all particles can interact with each other, all atoms must be mapped to such a virtual site.

Once all such pairwise interactions have been evaluated, the net force on each virtual site is transferred onto the constituent atoms. This is done on a mass-weighted basis, so that heavier atoms get a larger share of the force from the virtual site. This process ensures that Newton's third law is obeyed and, when used in molecular dynamics simulations, that linear momentum is conserved:

$$F_{\text{atom}} = F_{vs} \cdot \frac{m_{\text{atom}}}{m_{vs}} \tag{8}$$

where $\boldsymbol{F}$ refers to the net force and m the mass of the particle. Using this method, non-bonded

interactions no longer cross between the different resolutions and the coarse-grained force field can be used to describe and parameterize these interactions. This means that once an atomistic and coarse-grained force field is chosen, it is also possible to start creating hybrid-scale models.

Using virtual sites, models which mix both atoms and coarse-grained beads can be constructed. In these models selected chemical motifs are kept at a fine level of detail, while all other sections are coarse-grained. The choice of where to leave fine levels of detail is left to intuition, typically dipoles, including hydrogen bonding sites, or areas where steric factors are of great importance are kept at fine resolution. This approach allows a detailed description of some parts of the model to be combined with a less computationally intensive description of other parts of the model [27, 28]. The Hamiltonian for the simulation system can be defined as

$$H = K_{\text{atoms}} + K_{CG} + V_{\text{bonds}} + V_{nb(cg-cg)} + V_{nb(aa-aa)} + V_{nb(vs-cg)} \quad (9)$$

where K refers to the contribution from kinetic energy and V refers to potential energy between particles.

Adaptive Resolution Models

If what needs to be modeled at high resolution is a particular recurring chemical motif in the molecular system, then the model resolution can be static, which means that during the construction of the model, one decides which chemical moieties are modeled with the different resolutions and this model choice is kept for the entire simulation. However, in some cases it is more suited to define a geometrical region within the simulation box which is modeled with a different resolution. In this case, the total number of degrees of freedom of the model will change over the time depending on how many chemical species enter or leave that region (or regions) [29]. Usually systems are constructed to have a region of interest containing molecules modeled at atomic details, surrounded by a region of coarse-grained molecules. As simulations of such systems progress, the molecules are free to move between these two regions of different resolution, and a method to allow the transition between the two model resolutions is therefore required. To handle such transition, a buffer region (known as healing region) between the two levels of detail is used which allows the molecules to gradually change from one level of detail to another. In this healing region, the models switch from using one force field to the other as a function of their position within the healing region

$$V = \lambda V_{AA} + (1 - \lambda) V_{CG} \quad (10)$$

where λ refers to a switching function between the two force fields. Great care must be taken to ensure that there is no discontinuity in the force acting on the particles, as this would create mass transfer between different regions of the simulation box. Transitioning from the coarse region into the fine detail region is particularly difficult as it involves reintroducing the degrees of freedom that have previously been discarded.

Hybrid Particle Field Models

As the computational cost of both molecular dynamics and Monte Carlo simulation methods scales as $O(N^2)$, increasingly larger simulations become too demanding to produce results in a timely manner. An alternative to this particle-based approach is hybrid models where the particles surrounding a specific atoms or CG bead is replaced by a continuum field and the interparticle non-bonded interactions are calculated with respect to that external field. This method scales as $O(N)$, making the simulation of extremely large systems possible.

This approach is becoming popular in modeling polymer blends or solutions where the polymer chains self-assemble creating specific morphologies. A commonly used field method for simulating such polymer nanostructures is the single-chain mean field theory (SCMF) [30]. In this, single polymer chains or large molecules are separated and each determines its non-bonded interaction with respect to an external

field rather than having to interact with every other particle in every other molecule. To construct the mean field, self-consistent field (SCF) theory is used, where the particle density of a given chemical species (ϕ_A) is measured at all points on a discrete grid. The force caused by the mean field for a particle of species A at a given position is then given as

$$F_A(r) = -k_B T \sum_{A'} \chi_{AA'} \frac{\partial \phi_{A'}(r)}{\partial r} - \frac{1}{\kappa}\left(\sum_A \frac{\partial \phi_A(r)}{\partial r} - 1\right) \quad (11)$$

where k_B and T are the Boltzmann constant and temperature. The term $\chi_{AA'}$ is a Flory-Huggins mixing parameter between two species and must be defined between all combinations of species and κ represents the compressibility of the system. The first term defines how favorably different species can mix, while the second term tries to balance the particle density. This field varies both spatially and temporally and must be updated as the simulation progresses. However the variation of the field is slow with respect to the intramolecular forces, meaning that several particle moves can be done before the field must be updated. Within this approach while the intermolecular interactions are calculated via the SCMF theory, the intramolecular interactions (i.e., bonds, angles, and torsions) are handled at the same level of precision as conventional particle-based simulations. Initial work on this method used Monte Carlo to perform the particle moves [31] as the use of Monte Carlo allows the possible conformational space of the molecules to be sampled effectively. More recently molecular dynamics has also been used [32]. Since the calculation of the interactions with a discrete grid is computationally quick to perform, with each particle only interacting with eight different points rather than all their neighbors, this method is also particularly well suited to the increasing parallel nature of the hardware available, with some software able to achieve hyper-parallelism (achieving a speedup greater than n using n processors) [32].

Definition

Compliant mechanisms gain their motion from the deflection of elastic members.

Main Text

Compliant mechanisms offer an opportunity to achieve complex motions within the limitations of micro- and nano-fabrication. Because compliant mechanisms gain their motion from the constrained bending of flexible parts, they can achieve complex motion from simple topologies. Traditional mechanisms use rigid parts connected at articulating joints (such as hinges, axles, or bearings), which usually requires assembly of components and results in friction at the connecting surfaces [1–3]. Because traditional bearings are not practical and lubrication is problematic, friction and wear present major difficulties.

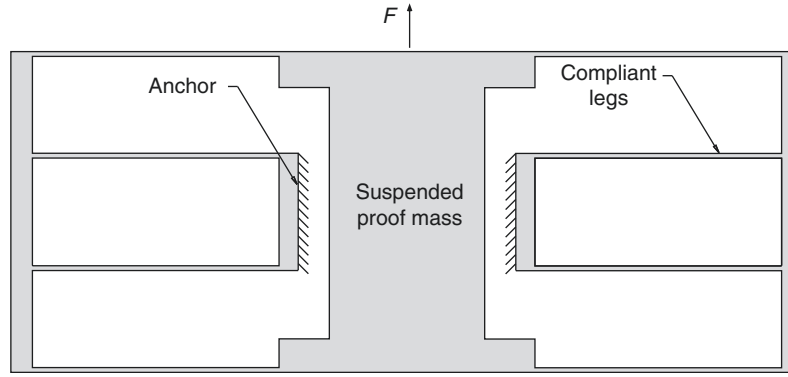
Nature provides an example of how to effectively address problems with motion at small scales. Most moving components in nature are flexible instead of stiff, and the motion comes from bending the flexible parts instead of rigid parts connected with hinges (for example, consider hearts, elephant trunks, and bee wings). The smaller the specimen, the more likely it is to use the deflection of flexible components to obtain its motion. And so it is with man-made systems as well, the smaller the device, the greater the advantages for using compliance [1].

Advantages of Compliant Mechanisms

Some of the advantages of compliant mechanisms at the micro- and nanoscales include the following:

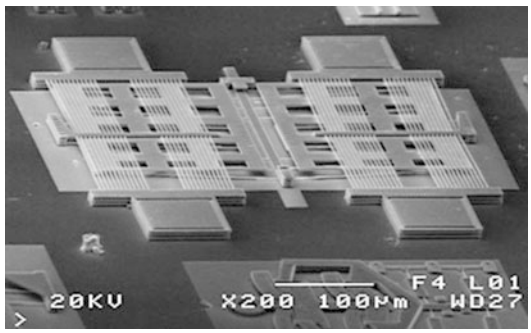
Can be made from one layer of material. Compliant mechanisms can be fabricated from a single layer. This makes them compatible with many common microelectromechanical system (MEMS) fabrication methods, such as surface micromachining, bulk micromachining, and LIGA. For example, consider the folded beam suspension shown in Fig. 1. This device is often used as a suspension element in MEMS systems. It offers a simple approach for constrained linear motion, and also integrates a return spring function. The device can achieve large deflections with reasonable off-axis stiffness. The compliant mechanism makes it possible to do these functions with a single layer of material.

No assembly required. Compliant mechanisms that gain all of their motion from the deflection of flexible components are "fully compliant mechanisms," where devices that combine both traditional and compliant elements are called "partially compliant mechanisms." Fully compliant mechanism can usually be fabricated without assembly of different components.



Small footprint. Some compliant mechanisms can also be designed to have a small footprint on the substrate on which they are built. Various strategies can be used to decrease the size of a mechanism. Figure 2 shows a thermal actuator that uses multiple layers to achieve a small footprint.

Friction-free motion. Because compliant mechanisms gain their motion from deflection of flexible members rather than from traditional articulating joints, it is possible to reduce or eliminate the friction associated with rubbing surfaces. This results in reduced wear and eliminates the need for lubrication, as described next.

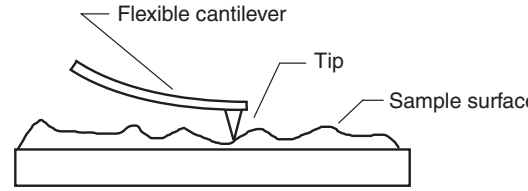


Wear-free motion. Wear can be particularly problematic at small scales, and the elimination of friction can result in the elimination of wear at the connecting surfaces of joints. For devices that are intended to undergo many cycles of motion, eliminating friction can dramatically increase the life of the system.

No need for lubrication. Another consequence of eliminating friction is that lubricants are not needed for the motion. This is particularly important at small scales where lubrication can be problematic.

High precision. Flexures have long been used in high precision instruments because of the repeatability of their motion. Some reasons for compliant mechanisms' precision are the

Compliant Mechanisms, Fig. 1 A folded-beam suspension is an example of a widely used compliant mechanism in microelectromechanical systems (MEMS) applications



Compliant Mechanisms, Fig. 2 This scanning electron micrograph shows a thermal actuator that uses multiple layers of compliant elements to achieve large amplification with a small footprint

backlash-free motion inherent in compliant mechanisms and the wear-free and friction-free motion described above. The cantilever associated with an atomic force microscope (Fig. 3) is an example application.

Integrated functions. Like similar systems in nature, compliant mechanisms have the ability to integrate multiple functions into few components. For example, compliant mechanisms often provide both the motion function and a return-spring function. Thermal actuators are another example of integration of functions, as described later.

High reliability. The combination of highly constrained motion of compliant mechanisms, the relative purity of materials used in micro/nanofabrication, and wear-free motion result in high reliability of compliant mechanisms at the micro/nanoscale.

Compliant Mechanisms, Fig. 3 The cantilever of an atomic force microscope (AFM) is an example of compliance employed in high-precision instruments

Challenges of Compliant Mechanisms

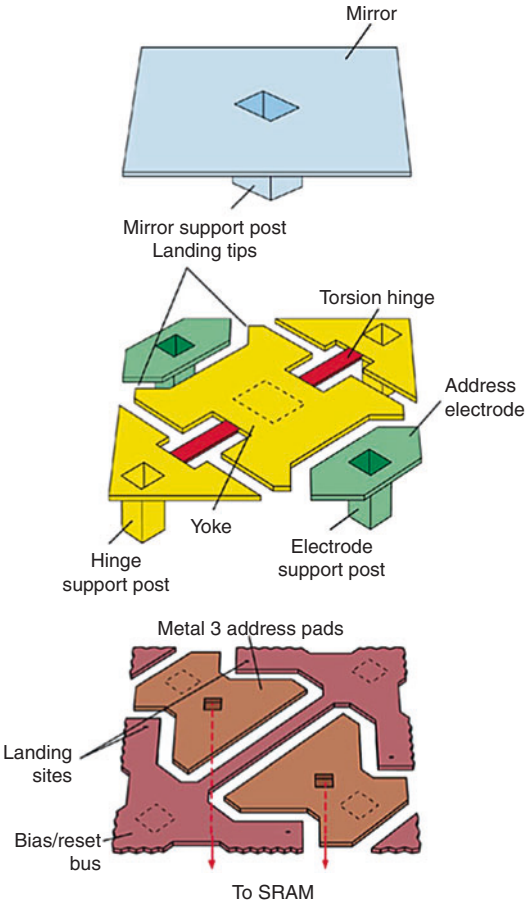
Compliant mechanisms have many advantages, but they also have some significant challenges. A few of these are discussed below [1].

Limited rotation. One clear drawback of compliant mechanisms is the general inability to undergo continuous rotation. Also, if a fully compliant mechanism is constructed from a single layer of material, then special care has to be taken to ensure that moving segments of the compliant mechanism do not collide with other segments of the same mechanism.

Dependence on material properties. The performance of compliant mechanisms is highly dependent on the material properties, which are not always well known.

Nonlinear motions. The deflections experienced by compliant mechanisms often extend beyond the range of linearized beam equations. This can make their analysis and design more complicated.

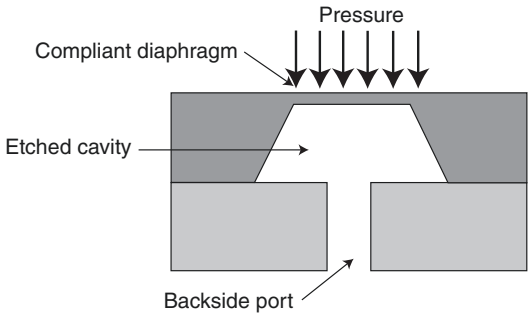
Fatigue analysis. Because most compliant mechanisms undergo repeated loading, it is



important to consider the fatigue life of the device. Interestingly, because of the types of materials used and their purity, many MEMS compliant mechanisms will either fail on their first loading cycle or will have infinite fatigue life. Because of the low inertia of MEMS devices, it is often easy to quickly test a MEMS device to many millions of cycles. Factors such as stress concentrations, the operating temperature, and other environment conditions can affect the fatigue life.

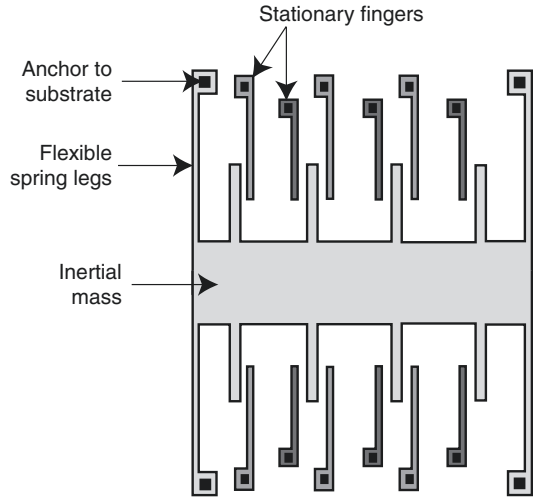
Difficult design. Integration of functions into fewer components, nonlinear displacements, dependence on material properties, the need to avoid self-collisions during motion, and designing for appropriate fatigue life, all combine to make the design of compliant mechanisms nontrivial and often difficult.

Example Applications of Compliant Mechanisms



Examples of MEMS compliant mechanisms are shown here to further illustrate their properties and to demonstrate a few applications.

Digital Micromirrors. One of the most visible commercially available microelectromechanical systems is Texas Instruments' Digital Micromirror Device (DMD™), which is used in applications such as portable projectors. The DMD is a rectangular array of moving micromirrors that is combined with a light source, optics, and electronics to project high-quality color images. Figure 4 shows the architecture of a single DMD pixel. A 16-μm-square aluminum mirror is rigidly attached to a platform (the "yoke"). Flexible torsion hinges are used to connect the yoke to rigid posts. An applied voltage creates an electrostatic force that causes the mirror to rotate about the torsion hinges. When tilted in the on position, the mirror directs light from the light source to the projection optics and the pixel appears bright. When the mirror is tilted in the off position, the light is directed away from the projection optics and the pixel appears dark. The micromirrors can be combined in an array on a chip, and each micromirror is associated with the pixel of a projected image. The torsion hinges use compliance to obtain motion while avoiding rubbing parts that cause friction and wear. The hinges can be deflected thousands of times per second and infinite fatigue life is essential.



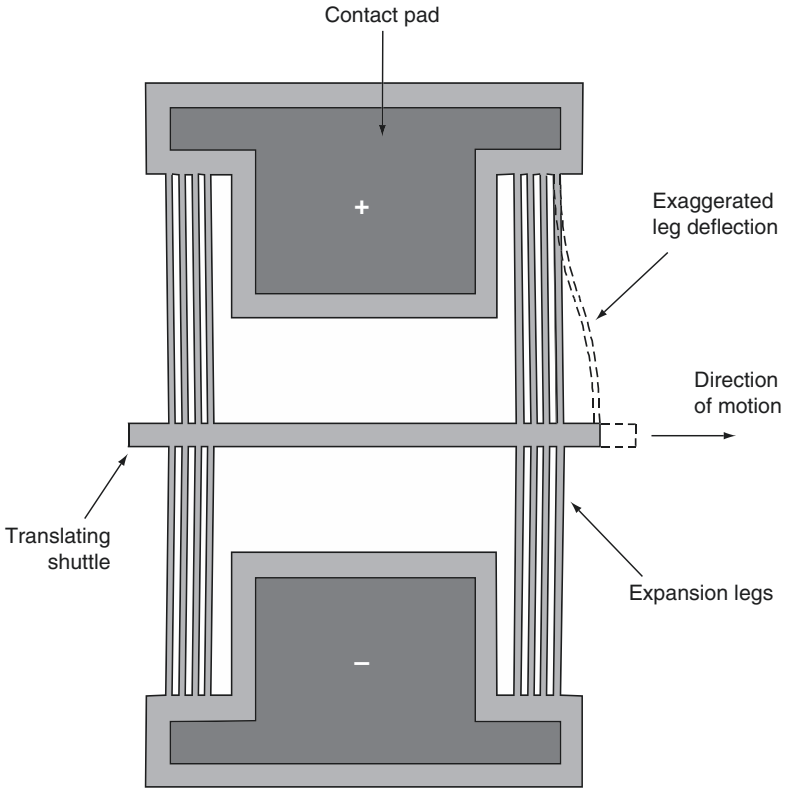
Compliant Mechanisms, Fig. 4 Texas Instrument's Digital Micromirror Device (DMD™) uses compliant torsion hinges to facilitate mirror motion (Illustration courtesy of Texas Instruments)

Piezoresistive pressure sensors. A sensor is a device that responds to a physical input (such as motion, radiation, heat, pressure, magnetic field), and transmits a resulting signal that is usually used for detection, measurement, or control. Advantages of MEMS sensors are their size and their ability to be more closely integrated with their associated electronics. Piezoresistive sensing methods are among the most commonly employed sensing methods in MEMS. Piezoresistance is the change in resistivity caused

Compliant Mechanisms, Fig. 5 The strain on a compliant diaphragm of a piezoresistive pressure sensors results in a detectable change in resistance, which is correlated with the pressure

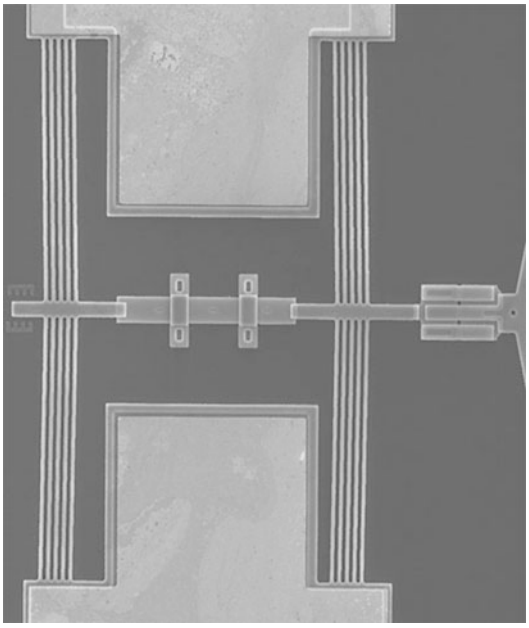
Compliant Mechanisms, Fig. 6 This accelerometer makes use of compliant legs that deflect under inertial loads. The deflection results in a detectable change in capacitance and is correlated with the corresponding acceleration

by mechanical stresses applied to a material. Bulk micromachined pressure sensors have been commercially available since the 1970s. A typical design is illustrated in Fig. 5. A cavity is etched to create a compliant diaphragm that deflects under pressure. Piezoresistive elements on the diaphragm change resistance as the pressure increases; this change in resistance is measured and is correlated with the corresponding pressure.



Capacitive acceleration sensors. Accelerometers are another example of commercially successful MEMS sensors. Applications include automotive airbag safety systems, mobile electronics, hard drive protection, gaming, and others. Figure 6 illustrates an example of a surface micromachined capacitive accelerometer. Acceleration causes a displacement of the inertial mass connected to the compliant suspension, and the capacitance change between the comb fingers is detected.

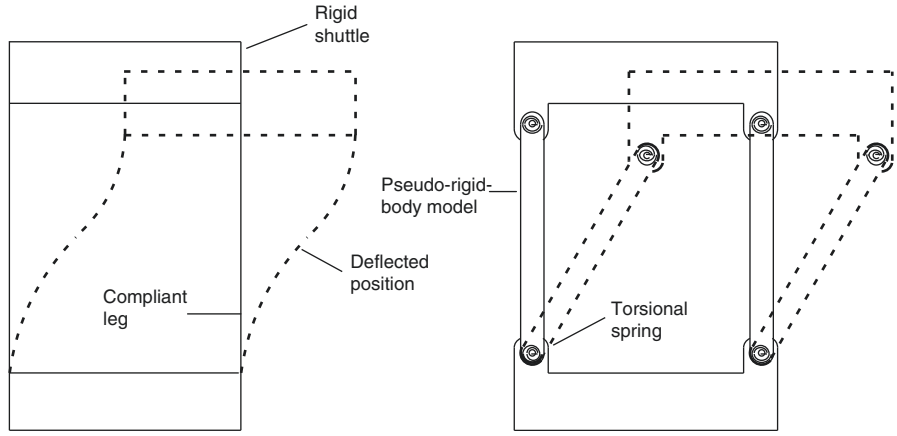
Thermal actuators. A change in temperature causes an object to undergo a change in length, where the change is proportional to the material's coefficient of thermal expansion [4]. This length change is usually too small to be useful in most actuation purposes. Therefore, compliant mechanisms can be used to amplify the displacement of thermal actuators. Figure 7 illustrates an example of using compliant mechanisms to amplify thermal expansion in microactuators. Figure 8 shows a scanning electron micrograph of a thermomechanical in-plane microactuator (TIM) illustrated in Fig. 7. It consists of thin legs connecting both sides of a center shuttle. The leg ends not connected to the shuttle are anchored to bond pads on the substrate and are fabricated at a slight angle to bias motion in the desired direction. As voltage is applied across the bond pads, electric current flows through the thin legs. The legs have a small cross-sectional area and thus have a high electrical resistance, which causes the legs to heat up as the current passes through them. The shuttle moves forward to accommodate the resulting thermal expansion. Advantages of this device include its ability to obtain high deflections and large forces, as well as its ability to provide a wide range of output forces by changing the number of legs in the design.



Analysis and Design of Compliant Mechanisms

Multiple approaches are available for the analysis and design of compliant mechanisms. Three of the most developed approaches are described below.

Finite element analysis. Finite element methods are the most powerful and general methods available to analyze compliant mechanisms.



Compliant Mechanisms, Fig. 7 A schematic of a thermomechanical in-plane microactuor (TIM) that uses compliant expansion legs to amplify the motion caused by thermal expansion

Compliant Mechanisms, Fig. 8 A scanning electron micrograph of a thermal actuator illustrated in Fig. 7

Commercial software is currently available that has the capability of analyzing the large, nonlinear deflections often associated with compliant mechanisms. The general nature of the method makes it applicable for a wide range of geometries, materials, and applications. Increasingly powerful computational hardware has made it possible to analyze even very complex compliant mechanisms. It is also possible to use finite element methods in the design of compliant mechanisms, particularly once a preliminary design has been determined. But in the early phases of design, other methods (or hybrid methods) are often preferred so that many design iterations can be quickly analyzed.

Pseudo-rigid-body model. The pseudo-rigid-body model is used to model compliant mechanisms as traditional rigid-body mechanisms, which opens up the possibility of using the design and analysis methods developed for rigid-body mechanisms in the design of compliant mechanisms [1]. With the

Compliant Mechanisms, Fig. 9 The pseudo-rigid-body model of the compliant parallel-guiding mechanism consists of appropriately located pin joints and torsional springs (this device is a building block of other devices, such as the folded-beam suspension)

pseudo-rigid-body model approach, flexible parts are modeled as rigid links connected at appropriately placed pins, with springs to represent the compliant mechanism's resistance to motion. Extensive work has been done to develop pseudo-rigid-body models for a wide range of geometries and loading conditions. Consider a simple example. The micromechanism shown in Fig. 9 has a rigid shuttle that is guided by two flexible legs. (Note that the folded-beam suspension in Fig. 1 has four of these devices connected in series and parallel.) The pseudo-rigid-body model of the mechanism models the flexible legs as rigid links connected at pin joints with torsional springs. Using appropriately located joints and appropriately sized springs, this model is very accurate well into the nonlinear range. For example, if the flexible legs are single-walled carbon nanotubes, comparisons to molecular simulations have shown the pseudo-rigid-body model to provide accurate results [5]. The advantages of the pseudo-rigid-body model are realized during the early phases of design where many design iterations can be quickly evaluated, traditional mechanism design approaches can be employed, and motions can be easily visualized.

Topology optimization. Suppose that all that is known about a design is the desired performance and design domain. Topology optimization shows promise for designing compliant mechanisms under such conditions. The advantage is that very little prior knowledge about the resulting compliant mechanism is needed, and any biases of the designer are eliminated [6]. Topology optimization is often integrated with finite element methods to consider many possible ways of distributing material with the design domain. This has the potential to find designs that would not otherwise be discovered by other methods. Infinite possible topologies are possible and finite element methods can be employed to evaluate the different possibilities. The resolution of the design domain mesh can be a limiting factor, but once a desirable topology is identified, it can be further refined using other approaches.

Conclusion

Compliant mechanisms provide significant benefits for micro- and nano-motion applications. They can be compatible with many fabrication methods, do not require assembly, have friction-free and wear-free motion, provide high precision and high reliability, and they can integrate multiple functions into fewer components. The major challenges associated with compliant mechanisms come from the difficulty associated with their design, limited rotation, and the need to ensure adequate fatigue life. It is likely that compliant mechanisms will see increasing use in micro- and

nano-mechanical systems as more people understand their advantages and have tools available for their development.

Definition

Computational chemistry uses physics-based algorithms and computers to simulate chemical events and calculate chemical properties of atoms and molecules. In drug design and discovery, diverse computational chemistry approaches are used to calculate and predict events, such as the drug binding to its target and the chemical properties for designing potential new drugs.

Overview

Computational methods are nowadays routinely used to accelerate the long and costly drug discovery process. Typically, once the drug discovery target is selected, drug discovery activities are divided into those for (1) the *hit identification* phase, in which the aim is the identification of chemical compounds with a promising activity toward the target; (2) the *lead generation* phase, in which hit compounds are improved in potency against the target; and, finally, (3) the *lead optimization* phase, in which lead compounds are optimized, generating drug-like molecules ultimately able to exert their beneficial pharmacological effect in patients (Fig. 1). Computations can help in all these drug discovery activities, from drug target identification, commonly a receptor

Computational Chemistry for Drug Discovery, Fig. 1 Drug discovery pipeline, typically formed by three phases, namely, "hit identification," "hit to lead," and "lead optimization." Different computational approaches can be applied to each phase of the drug discovery pipeline

or an enzyme, to the design and optimization of a new drug-like compound. While computational methods for target identification rely mainly on computational sciences such as bioinformatics and computational genomics, different computational approaches are used once the target has been identified and the search for small molecule inhibitors has commenced, starting from the hit identification phase, moving toward the lead generation and optimization phases (Fig. 1). At that point, routinely applied computational chemistry approaches include methods for structure-based drug design (SBDD), when structural data of the target protein are available, and ligand-based drug design (LBDD), when structural information of the target is missing or not fully reliable. Overall, these methods facilitate the identification of promising chemical scaffolds that interfere favorably with the target's function, producing a positive pharmacological effect. Experimental biochemical and pharmacological data on the new compounds, such as their in vitro inhibitory potency and in vivo efficacy, can be used to check the computational predictions while also forming the basis upon which better models can be constructed, leading to the design of superior compounds [1].

The impact of computational chemistry on drug discovery has been intensified in the last few decades by the rapid development of faster architectures and better algorithms for time-affordable high-level computations. Several theoretical methods that were once prohibitive for effective drug discovery are now increasingly used for hit identification and lead generation. Recently, for example, CPU-intensive and GPU-based free energy perturbation (FEP) calculations have been applied to accurately estimate the binding free energy of closely related chemical analogs, generating very promising results for lead generation and optimization [2]. Also, classical molecular dynamics (MD) is currently proposed as a practical computational tool for studying the energetics and kinetics of a ligand binding to a target protein. This is relevant for lead optimization, representing a new frontier in computationally driven drug discovery. Recently, in fact, compounds have been evaluated not only for their ability to bind tightly to the target but also for their capacity to remain bound to the target for a long time (i.e., considering k_{on} and k_{off} of binding), increasing the chances of efficacy in vivo. Finally, in the last decade, quantum mechanics (QM) has become ever more accessible for performing SBDD for lead generation and optimization. For example, QM and hybrid QM/MM methods are increasingly used to study the interaction of covalent inhibitors with a drug discovery target.

It is challenging to tailor a perfect fit between a new compound and its target in order to generate potent inhibitory effects (i.e., high affinity), which is the goal during the lead generation phase.

However, there are several other challenges during the lead optimization phase. A potent inhibitor is not a drug. There are other physicochemical variables that dictate the pharmacokinetics (PK) of each compound, affecting their drug-likeness and, ultimately, their efficacy and safety in vivo. Absorption, distribution, metabolism, excretion, and toxicity (ADMET) are key parameters that need to be optimized to generate a drug candidate with good chances of success in clinical trials. ADMET prediction at early stages of the drug discovery process is key to preventing, or at least limiting, later failures in costly clinical trials. In this respect, computational methods for chemometrics and quantitative structure–activity relationship (QSAR) approaches play a prominent role in creating predictive models for selecting and prioritizing compounds, typically during the lead optimization phase.

Thus, each computational chemistry method can impact and accelerate a given phase of the drug discovery process, from docking and MD for hit identification and lead generation to QSAR for ADMET optimization (see Fig. 1). Detailed methodological descriptions of each method can be found in many excellent review articles and books that focus on the theoretical background of computational chemistry [3–5]. This essay aims instead to comprehensively outline the applicability of the computational chemistry methods and approaches used nowadays to accelerate drug design and discovery, with particular emphasis on SBDD. The point is to show how each computational approach suits better a certain phase of the drug discovery pipeline, from SBDD for the hit identification and lead generation phases to QSAR methods for lead optimization, where drug-like properties are tuned to generate a promising drug candidate. The everyday use of once-prohibitive computational methods, such as MD- and QM-based methods for SBDD, will also be highlighted.

Computational Methods for SBDD

Computational approaches to structure-based drug design (SBDD) rely on knowledge of the target protein structure, which is usually provided by high-resolution X-ray crystallography or NMR data. Through a detailed analysis of the interaction between the target structure and the (new) ligands, SBDD approaches allow informed decisions to be made in designing more potent (i.e., with high affinity for the target) and selective compounds. Therefore, these methods are mostly used for hit identification and during the hit-to-lead phase (Fig. 1). A wide range of computational chemistry approaches can be applied to SBDD, including force field-based methods such as molecular docking calculations, classical MD- or Monte Carlo (MC)-based simulations, and more sophisticated QM-based methods [1, 6]. Ultimately, the new rationally designed compounds must be experimentally evaluated to verify whether they are potent inhibitors. The experimental test of each compound demonstrates the interdisciplinary nature of effective drug discovery. It is also essential for establishing and evaluating the predictive power of computational approaches in identifying and generating promising drug candidates.

Force Field-Based Approaches for SBDD

Computational approaches based on molecular mechanics (MM) allow the energy and several properties of molecular systems to be computed [3]. The basic functional form of a force field describes the potential energy of the system, which is determined as the sum of different contributions that are parameterized to reproduce experimental or ab initio data. The interactions are divided into bonded interactions and nonbonded interactions. The typical force field equation (Chart 1) contains the terms for the bonded (highlighted in red) and nonbonded (highlighted in blue) interactions. In detail, the bonded terms describe the chemical bonds between two neighboring atoms, bond angles between three atoms, and dihedral angles between four atoms. Improper dihedral–angle terms can be additionally applied to maintain planar or tetrahedral conformations. The functional form of the bond and angle terms is

Computational Chemistry for Drug Discovery, Chart 1 Typical force field equation

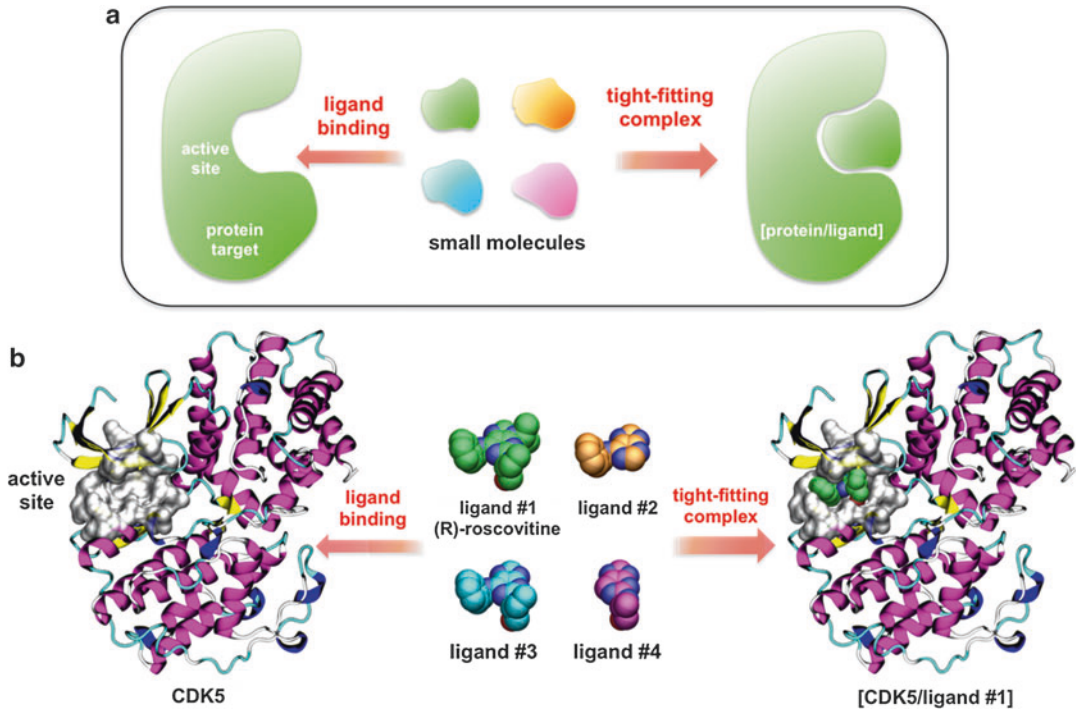
$$V = \sum_{\text{bonds}} K_R(\mathrm{R} - \mathrm{R}_{eq})^2 + \sum_{\text{angles}} K_\theta(\theta - \theta_{eq})^2 + \sum_{\text{dihedrals}} \frac{V_n}{2}[1 + \cos(n\phi - \gamma)] + \sum_{i<j}\left[\frac{A_{ij}}{\mathrm{R}_{ij}^{12}} - \frac{B_{ij}}{\mathrm{R}_{ij}^{6}} + \frac{q_i q_j}{\varepsilon \mathrm{R}_{ij}}\right]$$

bonded interactions

non-bonded interactions

Lennard-Jones term (van der Waals interactions)

Coulomb term (electrostatic interactions)

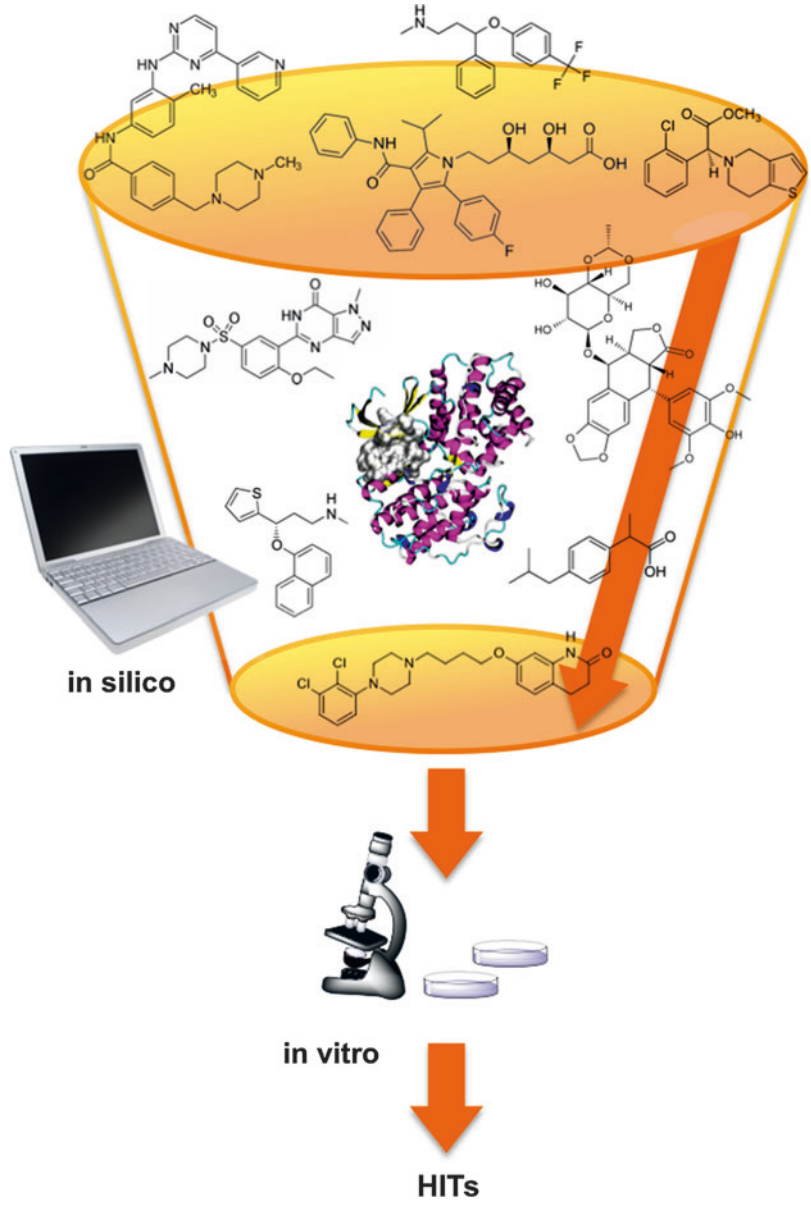


$$V_{vdW} = \sum_{i<j}\left[\frac{A_{ij}}{\mathrm{R}_{ij}^{12}} - \frac{B_{ij}}{\mathrm{R}_{ij}^{6}}\right] \quad + \quad V_{el} = \sum_{i<j}\left[\frac{q_i q_j}{\varepsilon \mathrm{R}_{ij}}\right]$$

quadratic, while the dihedral term uses a trigonometric function. In the typical force field equation, **R** is the distance between two atoms i and j that are bound together via a covalent bond, θ is the bond angle, $\mathbf{R}_{\text{eq}}$ and θ_{eq} refer to equilibrium bond lengths and angles, and K_R and K_θ are the vibrational constants. V_n is the torsional barrier corresponding to the nth barrier of a given torsional angle with phase γ. The last term of the typical force field equation refers to the nonbonded interactions, which are composed of a Lennard-Jones term for the van der Waals interactions and a Coulomb term for the electrostatic interactions between atoms i and j.

Force fields like AMBER, OPLS, GROMOS, and CHARMM are extensively used to study standard biomolecular systems such as protein, DNA, and RNA. Corrections and extensions are recurrently developed and reported for treatment of carbohydrates, lipids, ions, and other molecules of relevant biological interest, including drugs. Particularly relevant for drug design are the generalized AMBER force field (GAFF) and CHARMM general force field (CgFF), which provide suitable parameters for computations of drug-like organic molecules. The main advantage of using force field-based approaches is their relatively low computational cost compared to QM-based methods. For this reason, force field-based methods are by far the most applied in computational drug discovery. These include molecular docking and virtual screening of millions of novel compounds to identify new inhibitors, as well as de novo design and classical molecular dynamics simulations (see below).

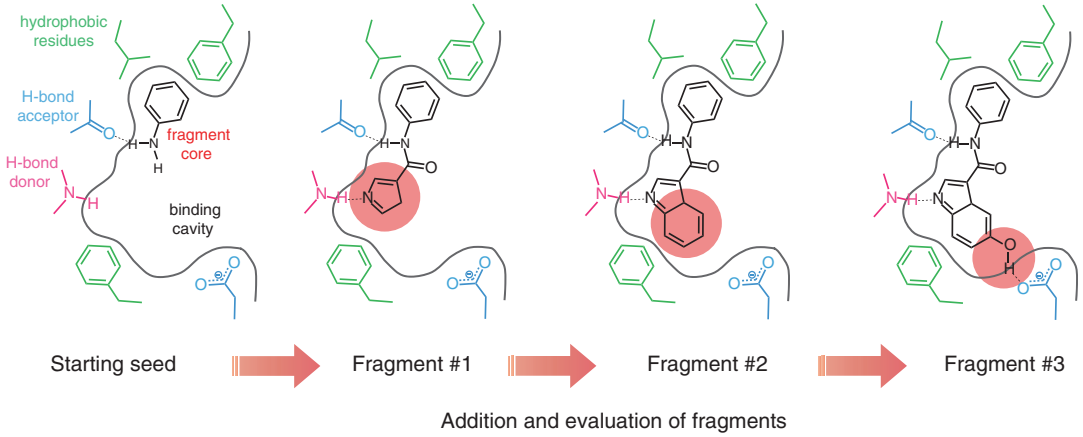
Virtual Screening and Molecular Docking for Drug Discovery



Virtual screening (VS) and molecular docking are broadly applied approaches in computational SBDD [1]. The ultimate goal of these methods is to identify compounds that dock well inside a targeted pocket (Fig. 2). These computational approaches are thus mostly used to identify promising hits and generate new leads. A compound able to fit into a target pocket would likely interfere with the target function, representing a promising chemical scaffold for the design of a new drug. GLIDE, GOLD, AUTODOCK, DOCK, and ICM-Dock are some of the more popular docking software. They are all used to increase the chances of identifying novel bioactive molecules from among the many small molecules that can be (virtually) screened. Starting from large compound collections, which can contain millions of different small molecules, VS protocols filter those collections and reduce them into smaller sets of active compounds with promising predicted activity against the target (Fig. 3). Usually, a library of hundreds of thousands or millions of virtual compounds is screened against a selected target. Then, a more sophisticated docking protocol, for example, a protocol that includes some receptor flexibility, can be used to rescore the best few thousand scored compounds. It is usually advisable to visually inspect the highly scored compounds, looking at each pose. This step reduces the risk of false-positive results, often induced by highly scored compounds that bind by adopting unlikely conformations or bind far from the pocket region of interest. After visual inspection, a few compounds are selected for

Computational Chemistry for Drug Discovery, Fig. 2 (**a**) Scheme of the ligand binding of a small molecule to the target proteins. (**b**) Binding of the tight-fitting ligand #1 [(R)-roscovitine] to the cyclin-dependent kinase-5 (CDK5) [23]. Other ligands (#2 to #4) are also shown. CDK5 is an attractive pharmacological target for drug discovery. CDK5 deregulation is implicated in many neurodegenerative processes such as Alzheimer's and Parkinson's diseases and amyotrophic lateral sclerosis. CDK5 is depicted with ribbons. The protein active site is represented in molecular surface, while a series of small ligand analogs with different chemical features – ligands #1–4 – are shown in space-filling representation. Different colors highlight the different characteristics of the four ligands

in vitro testing. VS is thus typically used for hit identification during drug discovery, where the goal is to identify new chemical scaffolds with promising, i.e., weak, inhibitory activity against the target. Hits are then used as a starting point to develop leads, i.e., more potent inhibitors (Fig. 1). Usually, hit compounds are experimentally identified as inhibitors characterized by IC_{50} (i.e., the concentration of inhibitor required to block 50 % of the target activity) around ~10–100 or higher microM activity, while lead compounds have IC_{50} in the low nanoM range.



To predict and evaluate ligand–target interactions, molecular docking must correctly pose the ligand into the catalytic site and associate an energy score with each pose. There are two main steps during each docking calculation: the posing of the ligand into the pocket and the scoring of the final pose. To identify the possible binding poses, a conformational sampling of the ligand in the target active site is performed for each docking run. Each ligand pose is generated by exhaustive conformational searches performed by systematic or deterministic searches of rotatable bonds or by mapping the target/ligand geometric complementarities. More sophisticated search methods employ stochastic searches such as MC sampling procedures or evolutionary algorithms. Then, each final pose is scored, according to the chosen scoring function, and in VS, compounds are ranked according to their relative final energy score. Thus, a good docking pose is characterized by a favorable score, which should reflect and match experimental data, if available. The scoring step is thus as crucial as the posing step, where the ligand is accommodated into the binding site.

Computational Chemistry for Drug Discovery, Fig. 3 A typical virtual screening protocol starts with a large compound collection, which is virtually screened against a given target. Then, the most promising ligands are tested in vitro, leading to the identification of hit compounds (characterized by a concentration for 50 % target inhibition (IC_{50}) of ~100–10 μM). Ultimately, hit compounds will be transformed into lead molecules, which are more potent inhibitors that will be also tested in vivo for efficacy and safety

Although posing and scoring are often considered as independent problems, they are actually interconnected. This becomes clear when we consider that the primary criterion for the conformational selection of the bound ligand is its energy score, which is used to rank and select ligand poses among all the possible binding modes. Nowadays, there are several functions for scoring ligands, from force field-based scoring functions to knowledge-based potentials. Each scoring function has its own peculiarities and drawbacks. Care is therefore required in their selection and initial benchmarking, before embarking in a VS campaign. At times, multiple scoring functions are used to generate a consensus score, as the average or linear combination of single scoring function.

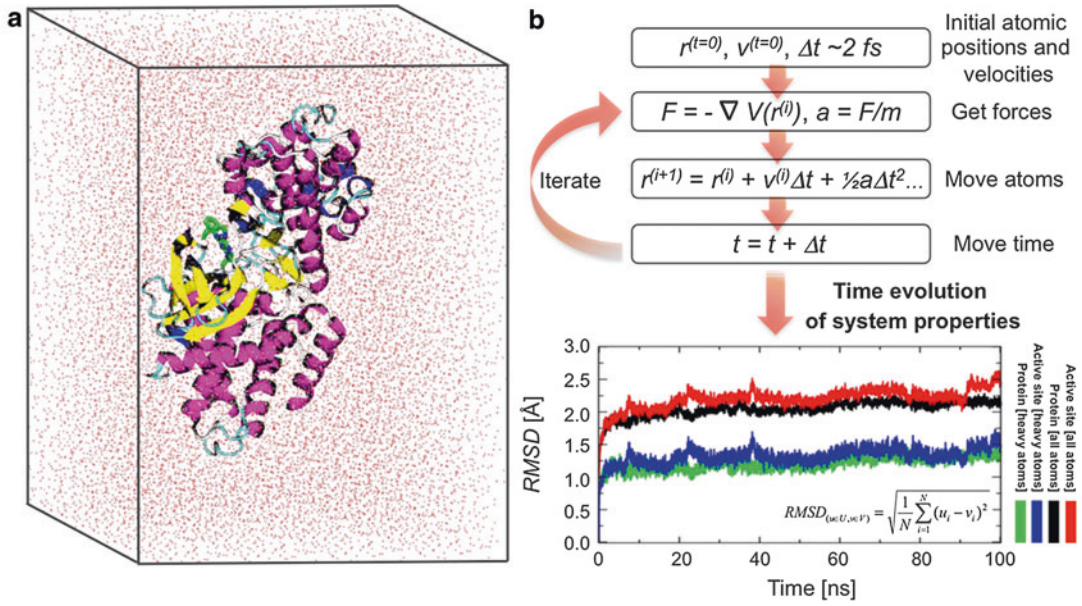
The challenges in achieving a correct score in VS and docking calculations include a proper treatment of electrostatics, as well as an exact

Computational Chemistry for Drug Discovery, Fig. 4 The de novo design of ligands is performed by building each compound within the active site. On the basis of an X-ray structure of the target protein, compounds are built within the binding cavity, using a number of fragments that can be joined together to create a new drug-like compound. Selected interaction centers are shown in green (hydrophobic residues), blue (H-bond acceptors), and magenta (H-bond donors). A starting fragment core (seed) is then grown into a bigger compound that can favorably interact with the target

evaluation of the desolvation energy of the ligand and binding pockets, and the explicit inclusion of entropic effects upon ligand binding. Recently, there has been intense investigation of the role of buried waters in the protein's pockets, which could act as a bridge for better ligand binding. A further challenge is that these methods consider a quasi-static complementarity between the ligand and its target. The restriction of target flexibility allows a limited induced fit upon binding but can potentially cause the miss of an important fraction of good hits/inhibitors during VS. To overcome this, recent docking algorithms and protocols allow multiple conformations of a few active-site residues that can be affected upon ligand binding, while other approaches try to solve the same issue via MD simulations or MC search [7]. Although rigid docking calculations are still preferred for VS of large compound libraries, flexible docking protocols are increasingly used nowadays, showing better predictivity than more static approaches.

Computational De Novo Design of Drug-Like Molecules

Computational de novo drug design means designing novel compounds from scratch, building them directly inside the binding site of the target macromolecule, piece by piece. As with docking and VS, the final goal is to explore chemical diversity and identify hit compounds that can fit well into the cavity of interest and likely interfere with the target function. De novo design programs include BOMB, BUILDER, GenStar, CONCERT, and several others, each with slightly different features and specifications [8]. The design process builds the new ligand directly within the binding pocket from an initial seed that can be as small as a hydrogen atom (Fig. 4). Then, ligand-growing and ligand-linking approaches are mainly used to transform one, or more, small fragments into a single drug-like compound with good predicted affinity for the target. With the ligand-growing method, functional groups are added to chemical handles of the core fragment, which is placed into the active site. Functional groups are usually available from an exhaustive list containing all sorts of aromatic and nonaromatic rings, aliphatic chains of varying length, etc. The user can therefore cherry pick the most interesting functional groups from the list and add those to the chemical handles of the core, generating new compounds. In contrast, ligand-linking methods use functional groups to

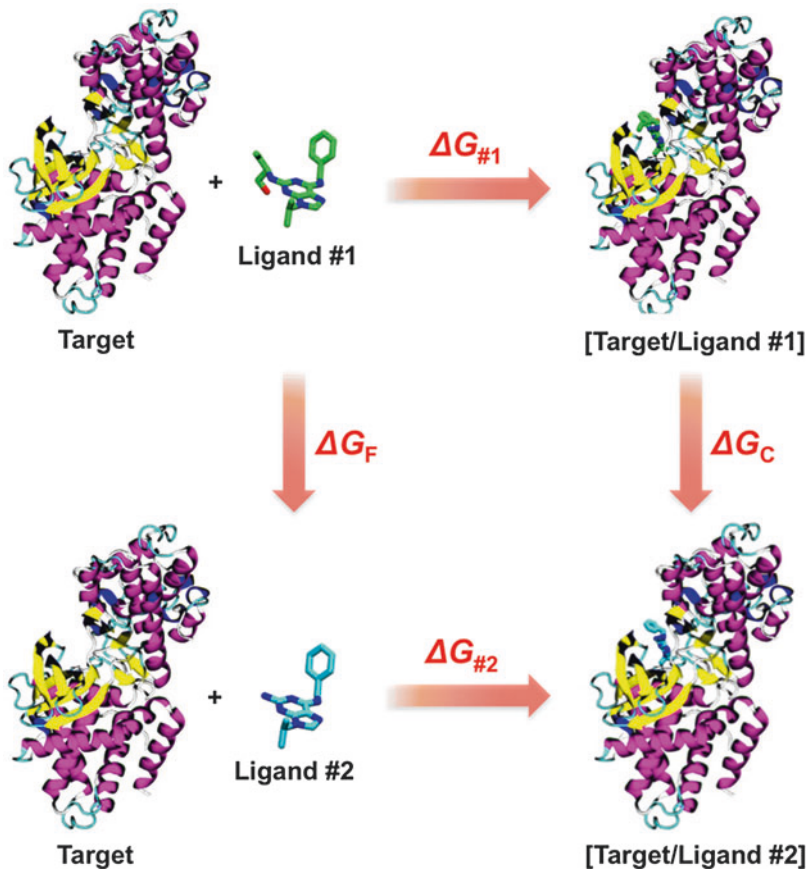


connect two or more fragments found or placed in the pocket, forming a single drug-like compound. In both procedures, the ligand construction is carried out by adding typical drug fragments that, once linked to the starting chemical core, are evaluated by considering several favorable conformers, usually followed by a geometry optimization of the newly formed compound within the target structure. Then, the obtained target/ligand complexes are scored in the same way and with the same limitations as scoring functions for VS and molecular docking.

The main advantage of de novo approaches, compared to docking and VS, is the possibility of exploring a virtually infinite search space and expanding chemical diversity. Drug-like molecules have been estimated to be in the order of 10^{60}–10^{100}. In this extremely large chemical space, the de novo design method allows the user to focus on chemical structures of interest, expanding on what is found in commercial libraries and converging on promising scaffolds that can be optimized ad hoc. The main risk is combinatorial explosion, due to the many combinations of functional groups and new compounds that could be constructed. In addition, the chemical space is limited by the synthesizability of the newly designed compounds, which might easily become too complex to be made in the lab. To overcome this, synthesizability constraints are often included in protocols for de novo computational design. Close collaboration between computational and synthetic chemists is also recommended. Ultimately, de novo molecular design methods help the hit identification phase by widening the chemical horizon for novel chemical scaffolds [2].

Molecular Dynamics for SBDD

Classical molecular dynamics (MD) simulations compute the time evolution of a system by applying Newtonian mechanics [3]. The method relies on force fields, which have been appropriately parameterized to describe biomolecular systems, such as the AMBER, OPLS-AA, and GROMOS force fields (see section above). These classical force fields provide a good description of the energetics of macromolecules such as proteins and nucleic acids. Also, in classical MD simulations of biological systems, there can be an explicit description of the water environment, with realistic molecular systems that can easily be constituted by a few hundred thousand atoms or more. In this respect, widely applied force fields for water molecules in biomolecular systems are the TIPnP models (Fig. 5).



In drug design, classical MD simulations are mainly used to accurately calculate the binding free energy of the ligand to its target, explicitly taking into account the flexibility of the system, temperature, and entropic effects. MD is, however, much more computationally expensive than VS and docking. Therefore, MD is mostly recommended for, and so far applied to, lead optimization, where a promising compound is improved through small chemical modifications. MD simulations can suggest favorable chemical modifications through a detailed, although computationally demanding, understanding of the ligand–target interactions. MD simulations of realistic models of pharmaceutically relevant targets include the fatty acid amide hydrolase (FAAH) embedded into an explicit membrane environment [9, 10], the muscarinic acetylcholine receptors (mAChRs) and other GPCRs model systems bound to drugs, voltage-gated ion channels, and protein kinases, among others [11]. These types of studies elucidate the dynamical behavior of the ligand/target complex, highlighting key interactions that are likely responsible for drug binding and, ultimately, drug efficacy. In addition, the ability to simulate drug binding and unbinding events permits researchers to evaluate the residence time of the ligand into the binding pocket, which directly relates to the k_{on} and k_{off} of binding. The correct balance of these parameters is quite important in assuring a stable binding, which is at the basis of drug efficacy. Finally, the use of short MD runs as a post-processing and rescoring tool for docking results has been shown to improve the original docking score [7]. In this case, the docking binding pose relaxes, after introducing full flexibility into the system through MD, generating an optimized ligand/target complex that

Computational Chemistry for Drug Discovery, Fig. 5 (**a**) Typical MD model system, which shows a protein in explicit solvent. In this example, CDK5 is in complex with (R)-roscovitine, embedded in explicit water molecules [23]. (**b**) Scheme of MD simulation steps, which can provide information on the time evolution of certain selected system properties – e.g., the root mean square deviation (RMSD) expressed in Å of the overall protein and its active site, compared to the initial X-ray structure

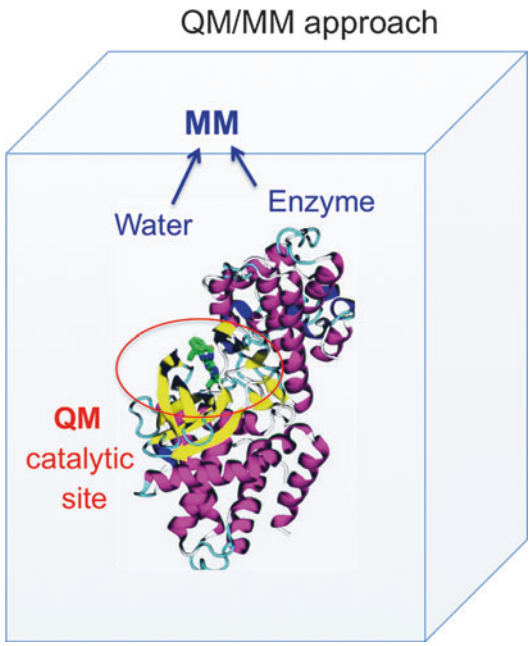
leads to more accurate energy scores. Indeed, MD has lately been proposed, and preliminarily used, as a tool for screening medium-sized compound libraries (a few hundred or so compounds), with a protocol for dynamic docking that is expected to replace static VS in the near future [11].

Many biochemical events, such as diffusion events in the cell, can happen at long timescales spanning from micro- or milliseconds to seconds or even much longer. Those events are usually termed "rare" events. Often, these rare events require the overcoming of energetics barriers, which (in the case of ligand binding) are related to large protein conformational changes or ligand diffusion. That is, the biological phenomenon of ligand binding often consists of simulating a rare event. These simulations, and the accurate calculation of the associated free energy, require enhanced sampling methods, which can efficiently explore the free energy landscape of the rare biochemical event under investigation. These methods include umbrella sampling, steered MD, accelerated MD, thermodynamic integration, metadynamics, and others. They are often used in computational biophysics to study a ligand's binding/unbinding mechanism and other rare events [3]. A conventional method for the characterization of chemical events in computational biophysics is thermodynamics integration used to sample rare events by defining a path between the initial and final state. Then, thermodynamic parameters characterizing the system are changed gradually so that, at each stage, the system is in "constrained equilibrium." More simply, in the case of ligand binding, a suitable reaction coordinate can be chosen to discriminate between the bound and unbound states. Then, forces acting on this coordinate are monitored. The integration of the averaged forces along the binding path provides a good estimate of the free energy of the binding process. This method has been widely applied to numerous issues in biochemistry and biophysics,

Computational Chemistry for Drug Discovery, Fig. 6 Schematic representation of a thermodynamic cycle for the evaluation of the relative free binding energies of ligand #1 and ligand #2 to CDK5 [23]

including enzymatic chemical reactions [12–15], because it offers a rigorous evaluation of the free energy of the investigated process. With thermodynamic integration, one is essentially limited to compute the free energy landscape of one or two collective variables. In a more complex case, a more advanced method, e.g., metadynamics, is needed. Metadynamics allows the free energy landscape to be mapped by adding an external potential to the simulation, overcoming energetics barriers, and returning a thorough description of the explored free energy space. To restrict the virtually immense searchable configuration space, which is dictated by the degrees of freedom of the model systems, one must specify a restricted number of collective variables (i.e., the coordinates of interest) that properly describe the chemical event under study. In this way, for example, the path of the ligand, from the solvent to the target active site, can be simulated and examined, providing useful information on the dynamics and energetics of binding [16].

The free energy perturbation (FEP) method is a final example of free energy calculation methods that have successfully impacted SBDD. FEP calculations have demonstrated predictive power in calculating relative free binding energies of close analogs of active chemical scaffolds [2]. In this case, perturbations of each compound, which involve force field parameters, convert the initial ligand #1 into ligand #2, through a thermodynamic cycle (Fig. 6). The binding free energy difference between the ligands *#1* and *#2* is calculated as $\Delta\Delta G_{\text{bind}} = \Delta G_{\#1} - \Delta G_{\#2} = \Delta G_F - \Delta G_C$, where ΔG_F and ΔG_C are the energies associated with the unbound ligands in solution and with the target/ligand complexes, respectively. This allows the energetics of binding



for the ligand *#1* and *#2* to be calculated, taking into full account the cost of the ligand's hydration. FEP theory has been broadly used for computational drug design purposes in combination with a Monte Carlo (MC) conformational search [17]. In this approach, a stochastic algorithm is used to randomly change the ligand within the target's active site. These random changes can also involve translational or rotational degrees of freedom of the ligand and of the residue side chains of the target. Whether a step is accepted or rejected is decided based on the Metropolis criterion, which generally accepts steps that lower the overall energy and occasionally accepts steps that increase energy. This prevents the system from getting stuck in local energy minima, allowing hopping over the energy barriers. As a drawback, an MC search lacks information about the timescale of the binding process.

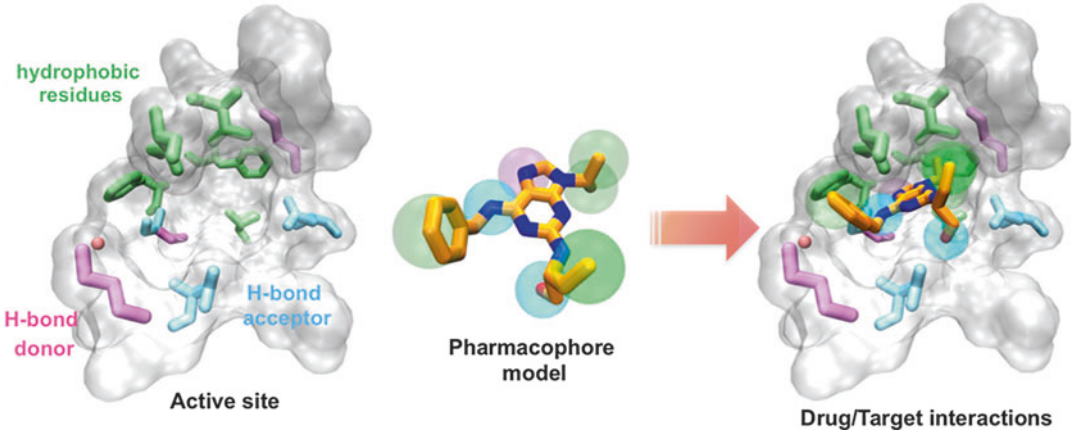
All these methods and approaches can provide detailed mechanistic insights for discriminating between a few selected compounds that have successfully passed previous screening tests. Importantly, the continual development of more powerful processors and algorithms is allowing systems of increasing size and complexity to be studied. Protein folding, drug binding, membrane transport, and large conformational changes of proteins can nowadays be observed by performing long-timescale simulations, up to tens of microseconds, and more. For example, access to longer timescales has encouraged the study of binding kinetics. Calculations of the association and dissociation constants for the target/ligand complex – i.e., K_{on} and K_{off}, respectively – provide important information on the (ir)reversibility of the drug binding process, helping in the lead optimization phase. Overall, *state-of-the-art* MD simulations are nowadays a powerful SBDD tool.

Quantum Mechanics for SBDD

Quantum mechanics (QM) methods are the most advanced and computationally demanding methodologies, which are used to characterize the structure, dynamics, reactivity, and energetics of molecules. QM methods can be mainly classified as ab initio and density functional theory (DFT) methods. Ab initio QM methods aim to solve the Schrödinger equation, dealing with the wave function of the system. A variety of ab initio schemes have been proposed, from the simplest Hartree–Fock (HF) theory to the more sophisticated Møller–Plesset (MP) perturbation theory that includes correlation effects and applies a perturbation to the HF solution. In DFT, the central idea, proposed by the theorem of Hohenberg and Kohn in 1964, is that the ground-state energy of a system of interacting electrons is a unique functional of its electron density. Nowadays, calculations at the DFT level of theory are the method of choice for studying the electronic structure of realistic biochemical model systems, due to a rather balanced equilibrium between accuracy and computational affordability. DFT-based approaches in drug design are used to look at system properties that strongly depend on electronic structure, such as electrostatic potential maps used to characterize the binding site of the target or QM calculations to define the most probable protonation state of key residues located in the binding site. QM-derived scoring functions for better affinity evaluations in docking calculations is another field of application of QM for drug design. QM is also crucial for developing MM force fields to describe nonstandard residues, such as drug-like molecules [18].

The most common SBDD use of QM is the study of the catalytic and inhibitory mechanisms of pharmaceutically relevant enzymes. An atomic-level understanding of the inhibitory mechanism and its energetics can provide important information for improving existing drugs and designing new and more potent inhibitors. Indeed, QM-based investigation of enzymatic reaction mechanisms are linked to drug discovery through the design of inhibitors that resemble the structure and physicochemical properties of the enzymatic transition state (TS). This is because QM methods allow the study of bond-forming/breaking reactions, which characterize enzymatic catalysis and covalent inhibition. During new bond-forming events, polarization and charge transfer effects

Computational Chemistry for Drug Discovery, Fig. 7 QM/MM approach. A small part of the enzyme is treated at the QM level, while the remaining part of the system, i.e., water and protein, is treated at the MM level of theory



between the ligand and the active-site residues can be captured fully only via an explicit description of the electronic structure. Thus, QM-based methodologies allow the catalytic and inhibitory mechanisms to be deciphered in great detail. This information can ultimately facilitate and guide the design of better inhibitors, such as potent TS analogs [18].

Nevertheless, the applicability of most QM methods is limited to studying relatively small molecular systems in the gas phase, while biological systems in a realistic solution environment usually comprise thousands of atoms (~20,000 to ~100,000 atoms c.a.). This picture becomes even more complicated when dealing with membrane proteins, where the lipid bilayer can exert a role for drug binding. In this case, the model system can consist of ~250,000 atoms or more, making the use of QM prohibitive [15, 19]. To overcome this, QM methods are usually paired with classical MM approaches in the hybrid QM/MM scheme (Fig. 7). This allows the crucial part of the system in which the reaction takes place (the protein active site and the ligand) to be treated at the QM level, while the rest of the system is described with a classical MM force field. Since its first appearance in 1976, the QM/MM approach has become increasingly popular in studying enzymatic reaction mechanisms [20]. It has been of paramount importance in modern computational chemistry for allowing the multiscale modeling of complex chemical systems. The scientific impact of the QM/MM approach was acknowledged with the 2013 Nobel Prize in Chemistry.

For studying biological systems, the QM/MM scheme has been successfully coupled to ab initio MD methods, such as Car–Parrinello and Born–Oppenheimer MD. In this way, model systems of a few hundred atoms (i.e., the protein active site and the ligand) are simulated at their actual temperature, thus including entropic effects, during picosecond timescale trajectories. Of several different schemes for first-principles-based dynamics, the Car–Parrinello method has been widely used to study numerous pharmaceutically relevant targets, including phosphatases, hydrolases, and lactamases [6, 10]. Ab initio MD permits an atomic-level understanding of catalytic and inhibitory mechanisms in biological systems, providing results that can be directly compared with experiments. The practical impact of these high-level computations seems more applicable to the lead optimization phase, while a much broader applicability of QM-based methods is foreseen in SBDD over the next decade [18, 20].

Ligand-Based Drug Design Approaches

Ligand-based drug design (LBDD) approaches are applied when the three-dimensional structure of the target is unknown or when it is not fully reliable (i.e., homology models of the target are based on poor sequence identity) [1]. In this case, the experimental activity data of active compounds are generally used to construct pharmacophore models. These models include an ensemble of steric and electronic features

Computational Chemistry for Drug Discovery, Fig. 8 An example of a pharmacophore model of (R)-roscovitine, which tightly binds CDK5 [23]. Crucial interacting residues of CDK5 are shown in *green* (hydrophobic residues), *blue* (H-bond acceptors), and *magenta* (H-bond donors). The regions of the ligand that match those types of interaction are indicated with the same color

(usually indicated as descriptors) that are likely to be those mainly responsible for activity (Fig. 8). Typical descriptors are physicochemical features such as molecular weight, geometry, surface accessible area, aromaticity index, electronegativity, polarizability, and solvation properties. In general, a proper set of descriptors should cover a broad chemical diversity space. In this way, the more relevant descriptors for building predictive pharmacophores are likely to be recognized. These are then used to help identify new active compounds, for example, in a virtual library of drug-like molecules. The same principles are valid for molecular similarity methods, where similitudes in geometrical or physicochemical properties among active compounds are used to identify new active compounds from among the many that can be virtually screened. A similarity coefficient, such as the Tanimoto or Euclidean coefficients, is then used to identify whether a set of new compounds is likely to interact with a given target [5].

Geometrical and electronic descriptors are used to build a quantitative structure–activity relationship (QSAR), which results in a mathematical model able to predict the biological activity of new compounds [5]. For example, activity data of active molecules can be used to extract mathematical models for early prediction of activity or, more often, metabolic properties that could generate toxicity problems. Conventional 3D QSAR models consider the ensemble of conformations, orientations, tautomers, stereoisomers, and protonation states of the initial ligand set. More exotic multidimensional 4D or 5D QSAR models have also been developed, which take into account all energy contributions of ligand binding, including solvation energy and conformational entropy. Usually, linear regression and principal component analysis can be combined for a partial least square analysis that directly relates the reduced set of descriptors to the biological activity. However, a nonlinear relation is often present between the biological activity and the descriptors used. Therefore, nonlinear regression models using machine-learning algorithms have recently been introduced in QSAR. Of these, artificial neural networks algorithms are used to discover the relationship between descriptors and biological activity via an iterative process [21].

Absorption, distribution, metabolism, excretion, and toxicity (ADMET) are the key parameters that can be optimized with QSAR approaches to get a drug candidate with a proper drug-like pharmacokinetic (PK) profile. ADMET and PK

properties are critical to the success of any drug discovery program. A poor drug-like PK profile can result in the rapid metabolism and elimination of the compound from the body. A drug-like compound should be characterized by certain physicochemical properties, which are loosely recapitulated in Lipinski's rule of five. This says that an optimal orally bioavailable drug should have a molecular weight less than 500, less than 5 H-bond donor sites, and less than 10 H-bond acceptor sites, while the log of the octanol/water partition coefficient (logP), a measure of hydrophobicity, should be below 5. Despite its practical utility for quickly evaluating drug-likeness, it is nowadays clear that this rule can only estimate the compound's probable success by highlighting potentially problematic aspects of its physicochemical and structural profile [22]. In fact, many approved drugs, such as large macrolide antibiotics (MW $\sim$ 1000), differ in one or more descriptors from Lipinski's rule. Other important features can heavily affect the PK profile. For ideal absorption and distribution, an aqueous solubility above 10^{-6} M is advised (logS > -6). Transport properties, such as membrane permeability and brain/blood partitioning (log BB), for allowing blood–brain barrier penetration must also be taken into account in certain drug discovery projects. Additionally, interactions with influx/efflux transporter proteins or metabolic enzymes can greatly affect the final therapeutic effect and should be considered in the early phases of a drug discovery program. That is, for a given molecular structure, properties such as solubility, membrane permeability, partition coefficients, blood–brain barrier penetration, plasma protein binding, and metabolite formation are computed and compared against a database of known drugs. Computational tools and methods for predicting ADMET properties and producing predictive statistical models are thus valuable. These statistical models are trained on experimental ADMET data obtained from several tested compounds. These computational tools are therefore crucial for selecting, prioritizing, and optimizing promising lead compounds.

Conclusions and Perspective

This essay describes some key aspects of the most effective computational chemistry methods for accelerating drug discovery, showing how different challenges can be tackled with these methods. Each computational method is suited to a particular drug discovery phase (see Fig. 1). Indeed, over the last two decades, it has become increasingly evident that computational methods can accelerate the identification, design, and optimization of small molecules as promising drug candidates. SBDD approaches suit better the hit identification and lead generation phase, where new active small molecules are designed, identified, and transformed into potent inhibitors. QSAR methods are usually better for lead optimization, where drug-like properties are tuned to increase efficacy and lower attrition in drug development. In addition to conventional methods (such as virtual screening and QSAR), methods that were once prohibitive for effective drug design, such as molecular dynamics simulations and quantum-mechanics-based methods, are nowadays frequently used in all phases of the drug discovery pipeline, broadening drug discovery's computational arsenal. In fact, the advent of faster algorithms and better computer hardware will allow more extensive use of molecular dynamics and first-principles-based simulations. We therefore envisage that computational chemistry methods will have an even greater impact on drug discovery in the future years.

Computational Micro-/Nanofluidics: Unifier of Physical and Natural Sciences and Engineering

A. T. Conlisk
Department of Mechanical Engineering, The Ohio State University, Columbus, OH, USA

Synonyms

Microscale fluid mechanics; Nanoscale fluid mechanics

Definition

Because of the small scale of the fluid conduits, electric fields must often be used to transport fluids especially at the nanoscale. This means that the fluids must be electrically conducting, and so microfluidics and nanofluidics require the user to be knowledgeable in fluid mechanics, heat and mass transfer, electrostatics, electrokinetics, electrochemistry, and, if biomolecules are involved, molecular biology.

Introduction

The term microfluidics refers generally to internal flow in a tube or channel whose smallest dimension is under 100 μm. Nanofluidics refers to the

same phenomenon in a conduit whose smallest dimension is less than 100 nm.

Microchannels and nanochannels have large surface-to-volume ratio, so that surface properties become enormously important. In fully developed channel flow, the pressure drop $\Delta p \sim \frac{1}{h^3}$, where h is the small dimension, and so the pressure drop is prohibitively large for a nanoscale channel. Thus a solvent fluid such as water, proteins and other biomolecules, and other colloidal particles are most often transported electrokinetically. This means that the art of designing micro- and nanodevices requires a significant amount of knowledge of fluid flow and mass transfer (biofluids are usually multicomponent mixtures) and often heat transfer, electrostatics, electrokinetics, electrochemistry, and molecular biology. Details of the character of these fields of study can be found in the book by the author [1].

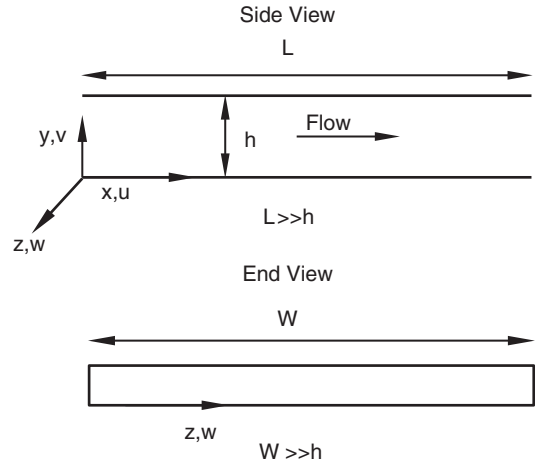
The study of micro-/nanofluidics requires knowledge of all of the abovementioned fields and so has a unifying effect. Moreover, nanofluidics opens the door to the discovery of the structure and conformation of biomaterials such as proteins and polysaccharides through molecular simulation.

In dealing with devices with small-scale features, microscale and below, there are three activities that normally comprise the design process; these are the following:

- Modeling: computational and theoretical
- Fabrication
- Experimental methods

Modeling is often done prior to the fabrication process as a guide as to what can be done. Experimental methods are usually used to assess the performance of a device, among other purposes.

Surface-to-Volume Ratio



Consider a channel of rectangular cross section having dimensions in the (x, y, z) coordinate system of (L, h, W) with the primary direction of fluid motion being in the x direction. Then the surface-to-volume ratio is given

$$\frac{S}{V} = 2\left(\frac{1}{L} + \frac{1}{h} + \frac{1}{W}\right) = 6m^{-1} \tag{1}$$

for a channel having all three dimensions $L = h = W = 1m$. On the other hand, for a channel having dimensions (10 μm, 10^{-2} μm, 10 μm),

$$\frac{S}{V} \sim 2 \times 10^{8} m^{-1} \tag{2}$$

This means that surface properties become very important at the microscale and nanoscale and surfaces are routinely engineered to achieve a desired objective. In most devices the nanoscale features interface directly with microscale features. A typical channel geometry is depicted in Fig. 1.

Computational Micro-/Nanofluidics: Unifier of Physical and Natural Sciences and Engineering, Fig. 1 Geometry of a typical channel. In applications $h \ll W, L$, where W is the width of the channel and L is the length in the primary flow direction. u, v, and w are the fluid velocities in the x, y, and z directions

Fluid Mechanics

Micro- and nanofluidics generally involve the flow of electrically conducting fluids, *electrolyte solutions*, that are assumed to be incompressible, having a constant density. Generally, the flows are internal, bounded on each side by walls, and are assumed to be fully developed. In this case, referring to Fig. 1, the governing equation for the velocity u in a channel is given by

$$\mu \frac{\partial^2 u}{\partial y^2} = \frac{\partial p}{\partial x} - B_x \tag{3}$$

where p is the pressure and B_x is a body force. The no-slip condition is applied at each wall: $u = 0$ at $y = 0, h$.

Mass Transfer

The molar flux of species A for a dilute electrically conducting mixture is

$$\vec{N}_A = -D_{AB}\nabla_{CA} + m_A z_A c_A \vec{E} + c_A \vec{V} \tag{4}$$

Here D_{AB} is the diffusion coefficient, R is the universal gas constant, T is the temperature, $z_A m_A$ is called the ionic mobility with $m_A = \frac{FD_{AB}}{RT}$, z_A is the valence, $F = 96500 \frac{Coul}{mole}$ is Faraday's constant, and $\vec{E}$ is the electric field. Equation 4 is called the Nernst-Planck equation, and the electric field term in the flux equation is called *electrical migration*. The boundary condition of interest here is that the solid walls in Fig. 1 are impermeable to species A, or $N_{A_y} = 0$ at $y = 0, h$.

In the absence of a velocity field $\vec{V}$ and in one dimension, Eq. 4 can be integrated to give

$$c_A = c_{A0} e^{-zA\phi} \tag{5}$$

and this is termed the *Boltzmann distribution* for the concentration of species A.

The Electric Field

An electric field is set up around any charged body and is defined as the force per charge on a surface. Electrical charges are either positive or negative, and like charges repel and opposite charges attract. For two bodies of charge q and q', the *electric field* is defined by

$$E = \frac{F}{q'} = \frac{q}{4\pi\epsilon_e r^2} \quad \frac{N}{C} \tag{6}$$

and is directed outward from the body of charge q and toward the body having a charge q' if $q > 0$, and the electric field is in the opposite direction if $q < 0$. In general, the electric field is a vector. This formula is called *Coulomb's Law*, and ϵ_e is called the *electrical permittivity.* The electrical permittivity is a transport property like the viscosity and thermal conductivity of a fluid.

The electric field due to a flat wall having a surface charge density σ in $\frac{Coulomb}{m^2}$ on one side is directed normal to the surface and has magnitude

$$E = \frac{\sigma}{2\epsilon_e} \tag{7}$$

A wire is characterized as having a line charge density, and if charges are distributed over a volume, a volume charge density is defined and called ρ_e in $\frac{Coulomb}{m^3}$.

The *electrical potential* is defined as the work done in moving a unit of charge, and mathematically

$$\phi = -\int_a^b \vec{E} \bullet d\vec{s} \tag{8}$$

The units of the electric potential are $\frac{Nm}{C} = 1\,Volt = 1\,V$. This formula is similar to the formula for mechanical work given by

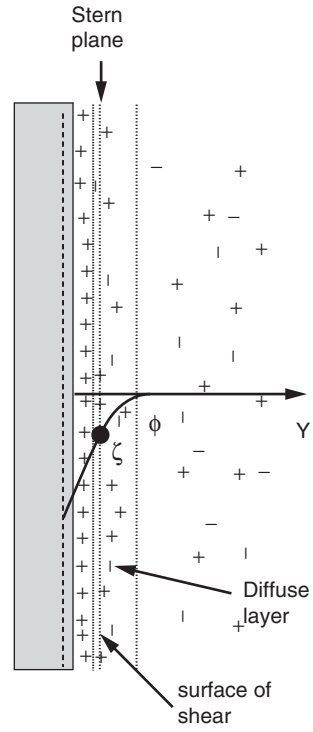
$$W = -\int_a^b \vec{F} \bullet \vec{ds} \tag{9}$$

In differential form the electrical potential is given by

$$\vec{E} = -\nabla\phi \tag{10}$$

For a single charge *Gauss's Law* is given by

$$\int\int_S \epsilon_e \vec{E} \bullet d\vec{A} = q \tag{11}$$



For a volume that contains a continuous distribution of charge, ρ_e, summing over all the charges using the definition of the integral, Gauss's Law becomes

$$\int\int_S \epsilon_e \vec{E} \bullet d\vec{A} = \int\int\int_{\mathcal{V}} \rho_e d\mathcal{V} \tag{12}$$

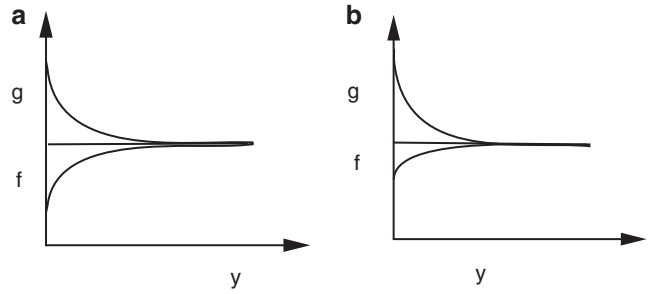
Using Eq. 12 and the differential form of the definition of the electrical potential, it follows that

$$\nabla^2\phi = -\frac{\rho_e}{\epsilon_e} \tag{13}$$

This is a *Poisson equation* for the potential given the volume charge density. The combination of Eqs. 4 and 13 is called the *Poisson-Nernst-Planck* system of equations.

Computational Micro-/Nanofluidics: Unifier of Physical and Natural Sciences and Engineering, Fig. 2 The electric double layer (EDL) consists of a layer of counterions pinned to the wall, the Stern layer, and a diffuse layer of mobile ions outside that layer. The wall is shown as being negatively charged and the ζ potential is defined as the electrical potential at the Stern plane

Electrochemistry



Electrochemistry may be broadly defined as the study of the electrical properties of chemical and biological material [2]. In particular much of electrochemistry pertinent to micro- and nanofluidics involves the study of the behavior of *ionic solutions* and the *electrical double layer* (*EDL*). Electrochemistry of electrodes is important to understand the operation of a *battery.*

An ionic or electrolyte solution is a mixture of ions, or charged species immersed in a solvent, often water. It is the charged nature of ionic solutions that allows the fluid to move under the action of an electric field, provided by electrodes placed upstream and downstream of a channel in a *nanopore membrane*. The term *membrane* is used to mean a thin sheet of porous material that allows fluid to flow in channels that make up the porous part of the membrane. Those channels are often like those channels depicted in Fig. 1.

Because the surface-to-volume ratio is so large in a nanoscale channel, the properties of the surface are extremely important. Fluid can be moved by an electric field if the surfaces of a channel are charged. If the surface is negatively charged, a surplus of positive ions will arrange themselves near the wall. This is shown in Fig. 2. It is because of this excess charge that allows fluid to be transported by an externally applied electric field.

The nominal length scale associated with the EDL is the *Debye length* defined by

$$\lambda = \frac{\sqrt{\epsilon_e RT}}{FI^{1/2}} \tag{14}$$

Computational Micro-/Nanofluidics: Unifier of Physical and Natural Sciences and Engineering, Fig. 3 (**a**) Debye-Hückel [5] picture of the electric double layer. Here *g* denotes the cation mole fraction and *f* denotes the anion mole fraction. The Debye-Hückel model assumes the cation and anion wall mole fractions are symmetric about a mean value which occurs for low surface charge densities. (**b**) Gouy-Chapman model [3, 4] of the EDL allows many more counterions than coions to collect near the charged surface and is valid at higher surface charge densities. From [1]

where F is Faraday's constant, ϵ_e is the electrical permittivity of the medium, I is the *ionic strength*, $I = \sum_i z_i^2 c_i$, c_i is the concentrations of the electrolyte constituents at some reference location, R is the universal gas constant, z_i is the valence of species i, and T is the temperature.

The ion distribution within the EDL can be described by using the number density, concentration, or mole fraction. Engineers usually prefer the dimensionless mole fraction, whereas chemists usually use concentration or number density.

There are two views of the ion distribution within the electrical double layer that are generally thought to be valid and have been verified by numerical solutions of the governing equations (see the section on electrokinetic phenomena below). The Gouy-Chapman [3, 4] model of the electric double layer allows counterions to collect near the surface in much greater numbers than coions. This model as numerical solutions suggest [1] occurs at higher surface charge densities. The Debye-Hückel picture assumes that coions and counterions collect near the surface in roughly equal amounts, above and below a mean value. These pictures are depicted in Fig. 3.

Molecular Biology

The nanoscale is the scale of biology since many proteins and other biomolecules have nanoscale dimensions. Many of the applications of nanofluidics such as rapid molecular analysis, drug delivery, and biochemical sensing have a biological entity as an integral part of their operation. Moreover, using nanofluidic tools, DNA sequencing is now possible. The book by Alberts [6] is a useful tool for learning molecular biology.

Nucleic acids are polymers consisting of nucleotides. Those based on a sugar called *ribose* are called ribonucleic acids (RNA), and those based on *deoxyribose* are called deoxyribonucleic acids (DNA). RNA is single stranded, while DNA is usually double stranded although single-stranded DNA (ss-DNA) does exist. Nucleotides contain five-carbon sugars attached to one or more phosphate groups (a phosphorus central atom surrounded by four oxygens) and a base which can be either adenine (A), cytosine (C), guanine (G), or thymine (T). Two nucleotides connected by a hydrogen bond are called a base pair (bp). *Protein synthesis* begins at a gene on a particular strand of a DNA molecule in a cell [6].

There are seven basic types of proteins classified according to their function, although different authors use different terms to describe each class; see, for example, Alberts [6], panel 5-1. *Enzymes* are catalysts in biological reactions within the cell. For example, the immune system responds to foreign bacteria and viruses by producing *antibodies* that destroy or bind to the antigen, the foreign agent. The antigen is the catalyst, or

Computational Micro-/Nanofluidics: Unifier of Physical and Natural Sciences and Engineering,

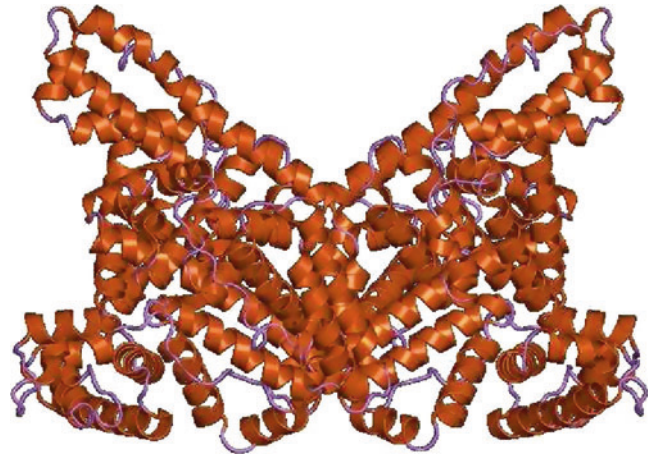


Fig. 4 Ribbon view of the protein albumin depicting its folding pattern, the *secondary structure* of a protein. From the European Bioinformatics Institute, public domain www.ebi.ac.uk

reaction enhancer, for inducing the immune response: the production of the antibodies. Proteins are responsible for many of the essential functions of the body, including moving material into and out of cells, regulating metabolism, managing temperature and *pH*, and muscle operation, among other functions.

Proteins are large and complex molecules, polymers made up of a total of 20 amino acids and held together by peptide bonds. The 20 amino acids have *side chains* that can be *basic*, *acidic*, *polar*, or *nonpolar*. Because they are so large, they cannot be described easily in a single chemical formula or picture. Thus molecular biologists depict proteins and other macromolecules in distinct levels of structure. The *primary structure* is the amino acid sequence, the order in which the 20 amino acids appear. The *secondary structure* depicts the folding properties of a protein as depicted in Fig. 4. Proteins are further described by more complex folding of the secondary structure (*tertiary structure*) and a *quaternary structure* if the protein has more than one backbone.

Proteins are usually negatively charged, and thus nanopore membranes for rapid molecular analysis can be used to separate different types of proteins and other biomolecules based on different values of size and charge. Biomolecules are what is termed soft material in that they are porous and deform under stress. Indeed, recent measurements of the conformation of albumin show that it may take the shape of a wedge, looking like a piece of pie. With the explosive growth of computer capability, conformations of biomolecules are actually being computed using molecular simulation tools like molecular dynamics and Monte Carlo schemes.

Ion channels are natural conical nanopores whose walls are made of proteins that play a crucial role in the transport of biofluids to and from cells. The basic units of all living organisms are cells. In order to keep the cells functioning properly, there needs to be a continuous flux of ions in and out of the cell and the cell components. The cell and many of its components are surrounded by a plasma membrane which provides selective transfer of ions. The membrane is made up of a double layer of lipid molecules (lipid bilayer) in which proteins are embedded. Ion channels are of two categories: carrier and pore. The *carrier* protein channel is based on the binding of the transport ion to a larger macromolecule, which brings it through the channel. A *pore* ion channel is a narrow, water-filled tunnel, permeable to the few ions and molecules small enough to fit through the tunnel (approximately 10 A in diameter).

Electrokinetic Phenomena

As the scale of the channels in a nanopore membrane becomes smaller, pressure, the normal

means for driving fluids through pipes and channels at macroscale (Fig. 1), becomes very difficult [1] since the pressure drop required scales as h^{-3} where h is the (nanoscale) channel height. Since in many applications the fluids used are electrically conducting, electric fields can be used to effectively pump fluid. Moreover electrically charged particles can move relative to the bulk fluid motion, and thus species of particles can be separated.

These *electrokinetic phenomena* are generally grouped into four classes [1]:

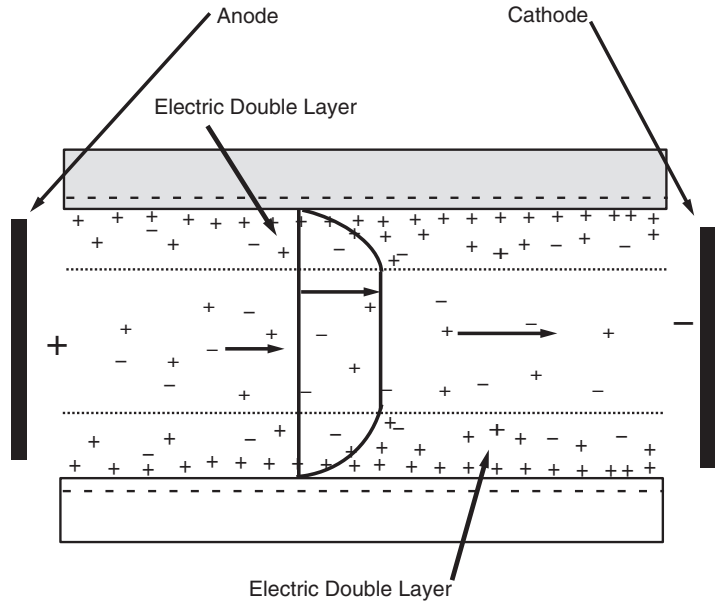
1. Electroosmosis (electroosmotic flow): the bulk motion of a fluid caused by an electric field
2. Electrophoresis: the motion of a charged particle in an otherwise motionless fluid or the motion of a charged particle relative to a bulk motion
3. Streaming potential or streaming current: the potential induced by a pressure gradient at zero current flow of an electrolyte mixture
4. Sedimentation potential: the electric field induced when charged particles move relative to a liquid under a gravitational or centrifugal or other force field

By far the two most important of these phenomena are electroosmosis and electrophoresis, and for the purposes of the theme of this entry, electroosmosis is discussed exclusively.

The dimensionless form of the streamwise momentum equation in the fully developed flow region in the absence of a pressure gradient is

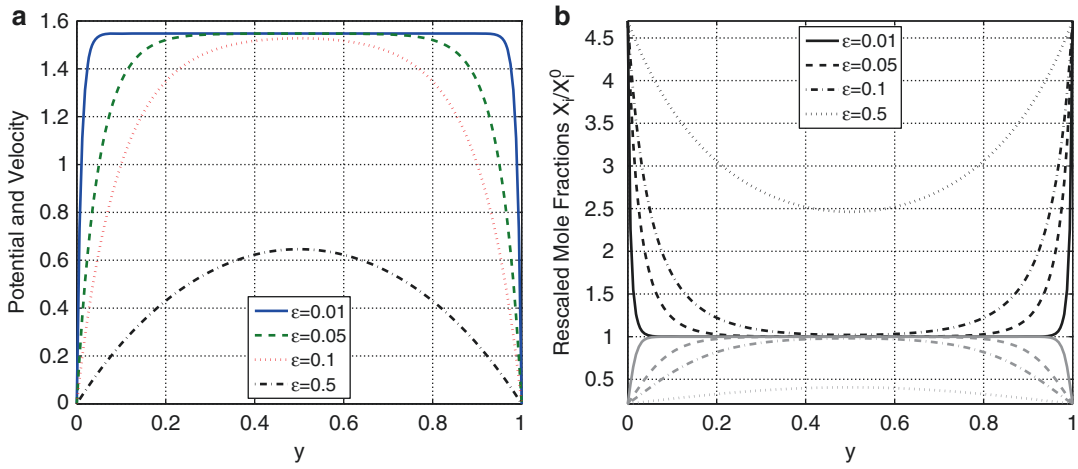
$$\epsilon^2 \frac{\partial^2 u}{\partial y^2} = -\beta \sum_i z_i X_i \tag{15}$$

and the Poisson equation for the potential in dimensionless form is



$$\epsilon^2 \frac{\partial^2 \phi}{\partial y^2} = -\beta \sum_i z_i X_i \tag{16}$$

where the partial derivatives in this one-dimensional fully developed analysis are really total derivatives, $\epsilon = \frac{\lambda}{h}$ and $\beta = \frac{c}{I}$ where c is the total concentration including the solvent and I is the ionic strength. Here X_i is the mole fraction, but if the electrolyte concentrations are scaled on the ionic strength, $I = \sum_i z_i c_i$, $\beta = 1$. It is seen from Eq. 15 that the combination of the electrodes that create an electric field and the excess charge in the electrical double layers produces the electrical force that balances the viscous force causing the electrolyte to move, and this is depicted in Fig. 5.



The fluid velocity satisfies the no-slip condition at the wall, and the electric potential satisfies $\phi(0) = \phi(1) = 0$. Then both the equations and the boundary conditions are identical and on a dimensionless basis $u(y) = \phi(y)$. In reality, the potential does not vanish at the wall, but if a Dirichlet boundary condition holds and the potential satisfies $\phi = \zeta$ at $y = 0{,}1$ and thus $u = \phi - \zeta$, where ζ is the *dimensionless* ζ-potential at the wall. Results for the potential and velocity and the concentrations scaled on the ionic strength are presented in Fig. 6 [1]. Note that for $\epsilon << 1$, the fluid velocity is constant away from the walls of the channel, unlike the Poiseuille flow of pressure-driven flow.

Dimensional Analysis

The equivalence of the dimensionless velocity and the dimensionless potential is important because the measurements of the velocity are equivalent to the measurements of the electric potential. Moreover, it is noted that a Debye length of $\lambda = 1$ nm in a $h = 100$ nm channel gives the same value of $\epsilon = 0.01$ as a $\lambda = 100$ nm Debye length in a $h = 10$ μm channel so that microscale measurements can be validated by nanoscale computations and, conversely, nanoscale computations can be validated by miscoscale experiments. Note that this similarity analysis does not apply for unsteady flow since there is no time derivative in the potential equation.

Closure

Physics of fluids at the nanoscale is dominated by the large surface-to-volume ratio inherent at this length scale, and thus the surfaces of a channel or membrane become extremely important. Indeed, the pressure drop across a rectangular channel in a nanopore membrane, $\Delta p \sim \frac{1}{h^3}$, is prohibitively large for the efficient operation of a nanofluidic device if $h = O(nm)$. Thus fluid, charged biomaterials such as proteins, and colloidal particles are most often

transported electrokinetically at the nanoscale. The art of designing micro- and nanofluidic devices therefore requires a significant amount of knowledge of fluid flow, mass transfer and sometimes heat transfer, electrostatics, electrokinetics, electrochemistry, and molecular biology.

The common thread is micro-/nanofluidics, which plays the role of unifying and integrating these fields. In particular, nanofluidics opens the door to reveal the structure and behavior of flows around nanoparticles and the conformation of proteins and other biomolecules using molecular simulations.

Definitions

Nanomaterials (or nanostructured materials, nanocomposites) are materials with characteristic size of structural elements on the order or less than several hundreds of nanometers at least in one dimension. Examples of nanomaterials include nanocrystalline materials, nanofiber, nanotube, and nanoparticle-reinforced nanocomposites, as well as multilayered systems with submicron thickness of the layers.

Atomistic modeling is based on atoms as elementary units in the models, thus providing the atomic-level resolution in the computational studies of material structure and properties. The main classical atomistic methods in materials research are (1) molecular dynamics technique that yields "atomic movies" of the dynamic material behavior through the integration of the equations of motion of atoms and molecules, (2) Metropolis Monte Carlo method that enables evaluation of

the equilibrium properties through the ensemble averaging over a sequence of random atomic configurations generated according to the desired statistical-mechanics distribution, and (3) kinetic Monte Carlo method that provides a computationally efficient way to study systems where the structural evolution is defined by a finite number of thermally activated elementary processes.

Mesoscopic modeling is a relatively new area of computational materials science that considers material behavior at time and length scales intermediate between the atomistic and continuum levels. Mesoscopic models are system/phenomenon specific and adopt coarse-grained representations of the material structure, with elementary units in the models designed to provide a computationally efficient representation of individual crystal defects or other elements of micro/nanostructure. Examples of the mesoscopic models are coarse-grained models for molecular systems, discrete dislocation dynamics model for crystal plasticity, mesoscopic models for nanofibrous materials, cellular automata, and kinetic Monte Carlo Potts models for simulation of microstructural evolution in polycrystalline materials.

Computer Modeling of Nanomaterials

Rapid advances in synthesis of nanostructured materials combined with reports of their enhanced or unique properties have created, over the last decades, a new active area of materials research. Due to the nanoscopic size of the structural elements in nanomaterials, the interfacial regions, which represent an insignificant volume fraction in traditional materials with coarse microstructures, start to play the dominant role in defining the physical and mechanical properties of nanostructured materials. This implies that the behavior of nanomaterials cannot be understood and predicted by simply applying scaling arguments from the structure–property relationships developed for conventional polycrystalline, multiphase, and composite materials. New models and constitutive relations, therefore, are needed for an adequate description of the behavior and properties of nanomaterials.

Computer modeling is playing a prominent role in the development of the theoretical understanding of the connections between the atomic-level structure and the effective (macroscopic) properties of nanomaterials. Atomistic modeling has been at the forefront of computational investigation of nanomaterials and has revealed a wealth of information on structure and properties of individual structural elements (various nanolayers, nanoparticles, nanofibers, nanowires, and nanotubes) as well as the characteristics of the interfacial regions and modification of the material properties at the nanoscale. Due to the limitations on the time and length scales, inherent to atomistic models, it is often difficult to perform simulations for systems that include a number of structural elements that is sufficiently large to provide a reliable description of the macroscopic properties of the nanostructured materials. An emerging key component of the computer modeling of nanomaterials is, therefore, the development of novel mesoscopic simulation techniques capable of describing the collective behavior of large groups of the elements of the nanostructures and providing the missing link between the atomistic and continuum (macroscopic) descriptions. The capabilities and limitations of the atomistic and mesoscopic computational models used in investigations of the behavior and properties of nanomaterials are briefly discussed and illustrated by examples of recent applications below.

Atomistic Modeling

In atomistic models [1, 2], the individual atoms are considered as elementary units, thus providing the atomic-level resolution in the description of the material behavior and properties. In classical atomistic models, the electrons are not present explicitly but are introduced through the interatomic potential, $U\left(\vec{r}_1, \vec{r}_2, \ldots, \vec{r}_N\right)$, that describes the dependence of the potential energy of a system of N atoms on the positions $\vec{r}_i$ of the atoms. It is assumed that the electrons adjust to changes in atomic positions much faster than the atomic nuclei move (Born-Oppenheimer approximation) and the potential energy of a system of

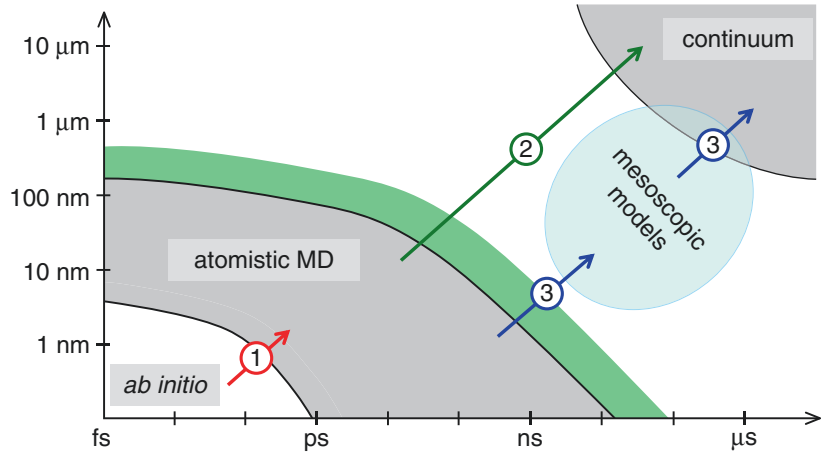
interacting atoms is uniquely defined by the atomic positions.

The interatomic potentials are commonly described by analytic functions designed and parameterized by fitting to available experimental data (e.g., equilibrium geometry of stable phases, density, cohesive energy, elastic moduli, vibrational frequencies, characteristics of the phase transitions, etc.). The interatomic potentials can also be evaluated through direct quantum mechanics–based electronic structure calculations in so-called first-principle (*ab initio*) simulation techniques. The *ab initio* simulations, however, are computationally expensive and are largely limited to relatively small systems consisting of tens to thousands of atoms. The availability of reliable and easy-to-compute interatomic potential functions is one of the main conditions for the expansion of the area of applicability of atomistic techniques to realistic quantitative analysis of the behavior and properties of nanostructured materials.

The three atomistic computational techniques commonly used in materials research are

1. Metropolis Monte Carlo method – the equilibrium properties of a system are obtained via ensemble averaging over a sequence of random atomic configurations, sampled with probability distribution characteristic for a given statistical mechanics ensemble. This is accomplished by setting up a random walk through the configurational space with specially designed choice of probabilities of going from one state to another. In the area of nanomaterials, the application of the method is largely limited to investigations of the equilibrium shapes of individual elements of nanostructure (e.g., nanoparticles) and surface structure/composition (e.g., surface reconstruction and compositional segregation [3]).
2. Kinetic Monte Carlo method – the evolution of a nanostructure can be obtained by performing atomic rearrangements governed by predefined transition rates between the states, with time increments formulated so that they relate to the microscopic kinetics of the system. Kinetic Monte Carlo is effective when the structural and/or compositional changes in a nanostructure are defined by a relatively small number of thermally activated elementary processes, e.g., when surface diffusion is responsible for the evolution of shapes of small crystallites [4] or growth of two-dimensional fractal-dendritic islands [5].
3. Molecular dynamics method – provides the complete information on the time evolution of a system of interacting atoms through the numerical integration of the equations of motion for all atoms in the system. This method is widely used in computational investigations of nanomaterials and is discussed in more detail below.

Molecular Dynamics Technique



Molecular dynamics (MD) is a computer simulation technique that allows one to follow the evolution of a system of N particles (atoms in the case of atomistic modeling) in time by solving classical equations of motion for all particles in the system,

$$m_i \frac{d^2 \vec{r}_i}{dt^2} = \vec{F}_i, \quad i = 1, 2, \ldots, N \qquad (1)$$

where m_i and $\vec{r}_i$ are the mass and position of a particle i and $\vec{F}_i$ is the force acting on this particle due to the interaction with other particles in the system. The force acting on the ith particle at a given time is defined by the gradient of the interparticle interaction potential $U\left(\vec{r}_1, \vec{r}_2, \ldots, \vec{r}_N\right)$ that, in general, is a function of the positions of all the particles:

$$\vec{F}_i = -\vec{\nabla}_i U\left(\vec{r}_1, \vec{r}_2, \ldots, \vec{r}_N\right) \qquad (2)$$

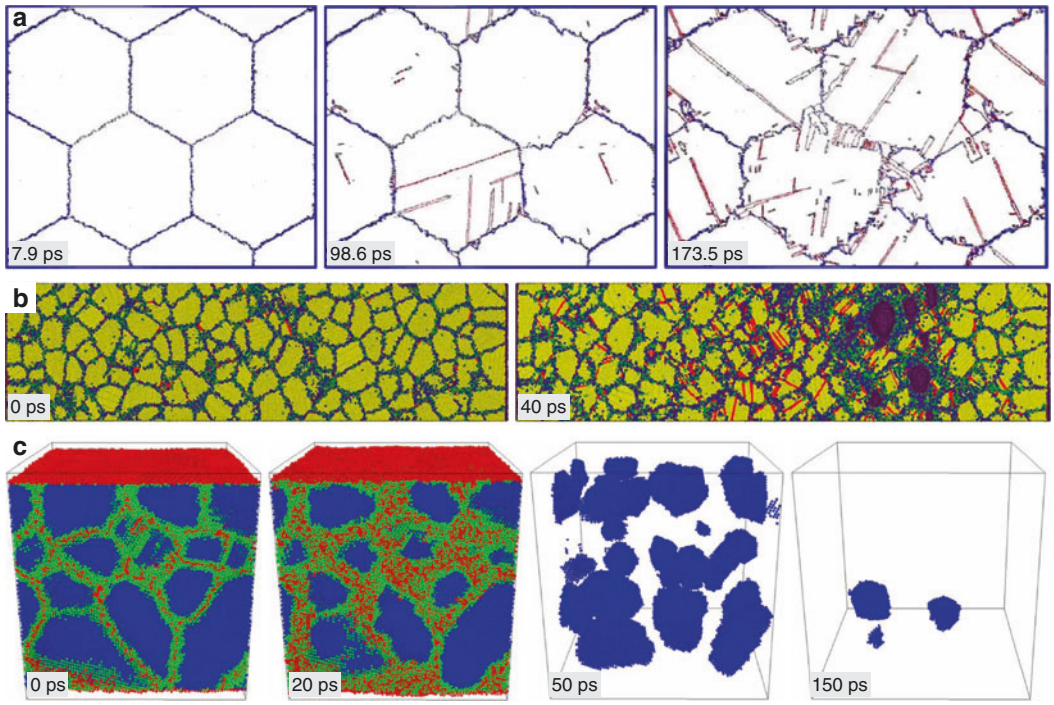
Once the initial conditions (initial positions and velocities of all particles in the system) and the interaction potential are defined, the equations of motion, Eq. 1, can be solved numerically. The result of the solution is the trajectories (positions and velocities) of all the particles as a function of time, $\vec{r}_i(t)$, $\vec{v}_i(t)$, which is the only direct output of a MD simulation. From the trajectories of all

Computational Study of Nanomaterials: From Large-Scale Atomistic Simulations to Mesoscopic Modeling, Fig. 1 Schematic representation of the time- and length-scale domains of fist-principle (*ab initio*) electronic structure calculations, classical atomistic MD, and continuum modeling of materials. The domain of continuum modeling can be different for different materials and corresponds to the time and length scales at which the effect of the micro/nanostructure can be averaged over to yield the effective material properties. The *arrows* show the connections between the computational methods used in multiscale modeling of materials: The *red arrow* #1 corresponds to the use of quantum mechanics–based electronic structure calculations to design interatomic potentials for classical MD simulations or to verify/correct the predictions of the classical atomistic simulations; the *green arrow* #2 corresponds to the direct use of the predictions of large-scale atomistic simulations of nanostructured materials for the design of continuum-level constitutive relations describing the material behavior and properties; and the two *blue arrows* #3 show a two-step path from atomistic to continuum material description through an intermediate mesoscopic modeling

particles in the system, however, one can easily calculate (sometimes by sampling the ensemble of initial conditions) the spatial and time evolution of structural and thermodynamic parameters of the system. For example, a detailed atomic-level analysis of the development of the defect structures or phase transformations can be performed and related to changes in temperature and pressure in the system (see examples below).

The main strength of the MD method is that only details of the interatomic interactions need to be specified and no assumptions are made about the character of the processes under study. This is an important advantage that makes MD to be capable of discovering new physical phenomena or processes in the course of "computer experiments." Moreover, unlike in real experiments, the analysis of fast nonequilibrium processes in MD simulations can be performed with unlimited atomic-level resolution, providing complete information on the phenomena of interest.

The predictive power of the MD method, however, comes at a price of a high computational cost of the simulations, leading to severe limitations on time and length scales accessible for MD simulations, as shown schematically in Fig. 1. Although the record length-scale MD simulations have been demonstrated for systems containing more than 10^{12} atoms (corresponds to cubic samples on the order of 10 µm in size) with the use of hundreds of thousands of processors on one of the world's largest supercomputers [6], most of the systems studied in large-scale MD simulations do not exceed hundreds of nanometers even in simulations performed with computationally efficient parallel algorithms (shown by a green area extending the scales accessible for MD simulations in Fig. 1). Similarly, although the record long time scales of up to hundreds of microseconds have been reported for simulations of protein folding performed through distributed computing [7], the duration of most of the simulations in the area of materials research does not exceed tens of nanoseconds.



Molecular Dynamics Simulations of Nanomaterials

Both the advantages and limitations of the MD method, briefly discussed above, have important implications for simulations of nanomaterials. The transition to the nanoscale size of the structural features can drastically change the material response to the external thermal, mechanical, or electromagnetic stimuli, making it necessary to develop new structure-property relationships based on new mechanisms operating at the nanoscale. The MD method is in a unique position to provide a complete microscopic description of the atomic dynamics under various conditions without making any *a priori* assumptions on the mechanisms and processes defining the material behavior and properties.

On the other hand, the limitations on the time and length scales accessible to MD simulations make it difficult to directly predict the macroscopic material properties that are essentially the result of a homogenization of the processes occurring at the scale of the elements of the nanostructure. Most of the MD simulations have been aimed at investigation of the behavior of individual structural elements (nanofibers, nanoparticles, interfacial regions in multiphase systems, grain boundaries, etc.). The results of these simulations, while important for the mechanistic understanding of the elementary processes at the nanoscale, are often insufficient for making a direct connection to the macroscopic behavior and properties of nanomaterials.

With the fast growth of the available computing resources, however, there have been an increasing number of reports on MD simulations of systems that include multiple elements of nanostructures. A notable class of nanomaterials actively investigated in MD simulations is nanocrystalline materials – a new generation of advanced polycrystalline materials with sub-micron size of the grains. With a number of atoms on the order of several hundred thousands and more, it is possible to simulate a system consisting of tens of nanograins and to investigate the effective properties of the material (i.e., to make a direct link between the atomistic and continuum descriptions, as shown schematically by the green arrow #2 in Fig. 1). MD simulations of nanocrystalline materials addressing the mechanical [8, 9] and thermal transport [10] properties as well as the kinetics and mechanisms of phase transformations [11, 12] have been reported, with several examples illustrated in Fig. 2. In the first example, Fig. 2a, atomic-level analysis of the dislocation activity and grain-boundary processes occurring during mechanical deformation of an aluminum nanocrystalline system consisting of columnar grains is performed and the important role of mechanical twinning in the deformation behavior of the nanocrystalline material revealed [8]. In the second example, Fig. 2b, the processes of void nucleation, growth, and coalescence in the ductile failure of nanocrystalline copper subjected to an impact loading are investigated, providing important pieces of information necessary for the development of a predictive analytical model of the dynamic failure of nanocrystalline materials [9]. The third example, Fig. 2c, illustrates the effect of nanocrystalline structure on the mechanisms and kinetics of short-pulse laser melting of thin gold films. It is shown that the initiation of melting at grain boundaries can steer the melting process along the path where the melting continues below the equilibrium melting temperature and the crystalline regions shrink and disappear under conditions of substantial undercooling [12].

The brute-force approach to the atomistic modeling of nanocrystalline materials (increase in the number of atoms in the system) has its limits in addressing the complex collective processes that involve many grains and may occur at a micrometer length scale and above. Further progress in this area may come through the development of concurrent multiscale approaches based on the use of different resolutions in the description of the intragranular and grain boundary regions in a well-integrated computational model. An example of a multiscale approach is provided in Ref. [13], where scale-dependent constitutive equations are designed for a generalized finite element method (FEM) so that the atomistic MD equations of motion are reproduced in the regions where the FEM mesh is refined down to atomic level. This and other multiscale approaches can help to focus computational efforts on the important regions of the system

Computational Study of Nanomaterials: From Large-Scale Atomistic Simulations to Mesoscopic Modeling, Fig. 2 Snapshots from atomistic MD simulations of nanocrystalline materials: (**a**) mechanical deformation of nanocrystalline Al (only atoms in the twin boundaries left behind by partial dislocations and atoms in disordered regions are shown by *red* and *blue* colors, respectively) [8]; (**b**) spallation of nanocrystalline Cu due to the reflection of a shock wave from a surface of the sample (atoms that have local fcc, hcp, and disordered structure are shown by *yellow*, *red*, and *green/blue* colors, respectively) [9]; and (**c**) laser melting of a nanocrystalline Au film irradiated with a 200 fs laser pulse at a fluence close to the melting threshold (atoms that have local fcc surroundings are colored *blue*, atoms in the liquid regions are *red* and *green*, in the snapshots for 50 and 150 ps the liquid regions are blanked to expose the remaining crystalline regions) [12]

where the critical atomic-scale processes take place. The practical applications of the multiscale methodology so far, however, have been largely limited to investigations of individual elements of material microstructure (crack tips, interfaces, and dislocation reactions), with the regions represented with coarse-grained resolution serving the purpose of adaptive boundary conditions. The perspective of the concurrent multiscale modeling of nanocrystalline materials remains unclear due to the close coupling between the intragranular and grain boundary processes. To enable the multiscale modeling of dynamic processes in nanocrystalline materials, the design of advanced computational descriptions of the coarse-grained parts of the model is needed so that the plastic deformation and thermal dissipation could be adequately described without switching to fully atomistic modeling.

Mesoscopic Modeling

A principal challenge in computer modeling of nanomaterials is presented by the gap between the atomistic description of individual structural elements and the macroscopic properties defined by the collective behavior of large groups of the structural elements. Apart from a small number of exceptions (e.g., simulations of nanocrystalline materials briefly discussed above), the direct analysis of the effective properties of nanostructured

materials is still out of reach for atomistic simulations. Moreover, it is often difficult to translate the large amounts of data typically generated in atomistic simulations into key physical parameters that define the macroscopic material behavior. This difficulty can be approached through the development of mesoscopic computational models capable of representing the material behavior at time and length scales intermediate between the atomistic and continuum levels (prefix *meso* comes from the Greek word μέσος, which means middle or intermediate).

The mesoscopic models provide a "stepping stone" for bridging the gap between the atomistic and continuum descriptions of the material structure, as schematically shown by the blue arrows #3 in Fig. 1. Mesoscopic models are typically designed and parameterized based on the results of atomistic simulations or experimental measurements that provide information on the internal properties and interactions between the characteristic structural elements in the material of interest. The mesoscopic simulations can be performed for systems that include multiple elements of micro/nanostructure, thus enabling a reliable homogenization of the structural features to yield the effective macroscopic material properties. The general strategy in the development of a coarse-grained mesoscopic description of the material dynamics and properties includes the following steps.

1. Identifying the collective degrees of freedom *relevant for the phenomenon under study* (the focus on different properties of the same material may affect the choice of the structural elements of the model);
2. Designing, based on the results of atomic-level simulations and/or experimental data, a set of rules (or a mesoscopic force field) that governs the dynamics of the collective degrees of freedom;
3. Adding a set of rules describing the changes in the properties of the dynamic elements in response to the local mechanical stresses and thermodynamic conditions.

While the atomistic and continuum simulation techniques are well established and extensively used, the mesoscopic modeling is still in the early development stage. The central problem of the mesoscopic modeling is the design of the mesoscopic force field or, in general, the "equations of motion" that describe the dynamics of the collective degrees of freedom in the mesoscopic system. In principle, the equations for the collective degrees of freedom can be derived from the equations of motion of atoms and formulated as the so-called generalized Langevin equation by applying the Mori-Zwanzig projection operators [14, 15]. While formally exact, this equation is difficult to apply to real systems, since a number of parameters of this equation should be evaluated by considering the so-called projection dynamics that is different from the real microscopic dynamics of the corresponding atomistic system [16]. Moreover, the generalized Langevin equation is a stochastic integrodifferential equation with memory effects, which is difficult to apply to large-scale mesoscopic simulations. Therefore, apart from polymer systems, where the Mori-Zwanzig formalism is shown to be a practical tool for constructing mesoscopic computational models [16–18], the mesoscopic force fields for various nanomaterials are usually designed based on semiempirical approaches. There is no universal mesoscopic technique or methodology in the development of such semiempirical force fields, and the current state of the art in mesoscopic simulations is characterized by the development of system-/phenomenon-specific mesoscopic models.

The mesoscopic models used in materials modeling can be roughly divided into two general categories: (1) the models based on lumping together groups of atoms into larger dynamic units or particles and (2) the models that represent the material microstructure and its evolution due to thermodynamic driving forces or mechanical loading at the level of individual crystal defects. The basic ideas underlying these two general classes of mesoscopic models are briefly discussed below.

The models where groups of atoms are combined into coarse-grained computational particles are practical for materials with well-defined structural hierarchy (that allows for a natural choice of

the coarse-grained particles) and a relatively weak coupling between the *internal* atomic motions inside the coarse-grained particles and the *collective* motions of the particles. In contrast to atomic-level models, the atomic structure of the structural elements represented by the coarse-grained particles is not explicitly represented in this type of mesoscopic models. On the other hand, in contrast to continuum models, the coarse-grained particles allow one to explicitly reproduce the nanostructure of the material. Notable examples of mesoscopic models of this type are coarse-grained models for molecular systems including polymers [19–21] and mesoscopic models for carbon nanotubes and nanofibrous materials [22–26]. The individual molecules (or mers in polymer molecules) and nanotube/nanofiber segments are chosen as the dynamic units in these models. The collective dynamic degrees of freedom that correspond to the motion of the "mesoparticles" are explicitly accounted for in mesoscopic models, while the internal degrees of freedom are either neglected or described by a small number of internal state variables. The description of the internal states of the mesoparticles and the energy exchange between the dynamic degrees of freedom and the internal state variables becomes important for simulations of nonequilibrium phenomena that involve fast energy deposition from an external source, heat transfer, or dissipation of mechanical energy.

Another group of mesoscopic models is aimed at a computationally efficient description of the evolution of the defect structures in crystalline materials. The mesoscopic models from this group include the discrete dislocation dynamics model for simulation of crystal plasticity [27–29] and a broad class of methods designed for simulation of grain growth, recrystallization, and associated microstructural evolution (e.g., phase field models, cellular automata, and kinetic Monte Carlo Potts models) [27, 28, 30]. Despite the apparent diversity of the physical principles and computational algorithms adopted in different models listed above, the common characteristic of these models is the focus on a realistic description of the behavior and properties of individual crystal defects (grain boundaries and dislocations), their interactions with each other, and the collective evolution of the totality of crystal defects responsible for the changes in the microstructure.

Two examples of mesoscopic models (one for each of the two types of the models discussed above) and their relevance to the investigation of nanomaterials are considered in more detail next.

Discrete Dislocation Dynamics

The purpose of the discrete dislocation dynamics (DD) is to describe the plastic deformation in crystalline materials, which is largely defined by the motions, interactions, and multiplication of dislocations. Dislocations are linear crystal defects that generate long-range elastic strain fields in the surrounding elastic solid. The elastic strain field is accounting for ~90 % of the dislocation energy and is responsible for the interactions of dislocations among themselves and with other crystal defects. The collective behavior of dislocations in the course of plastic deformation is defined by these long-range interactions as well as by a large number of local reactions (annihilation, formation of glissile junctions or sessile dislocation segments such as Lomer or Hirth locks) occurring when the anelastic core regions of the dislocation lines come into contact with each other. The basic idea of the DD model is to solve the dynamics of the dislocation lines in elastic continuum and to include information about the local reactions. The elementary unit in the discrete dislocation dynamics method is, therefore, a segment of a dislocation.

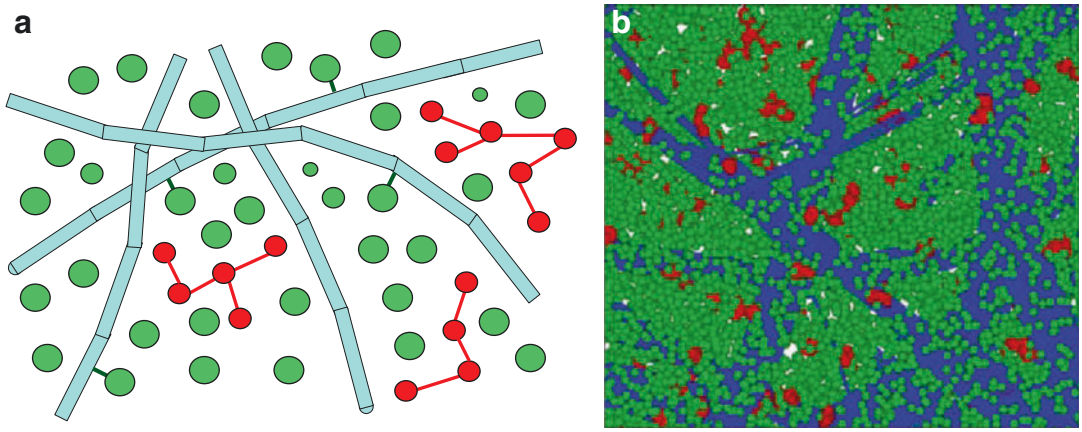
The continuous dislocation lines are discretized into segments, and the total force acting on each segment in the dislocation slip plane is calculated. The total force includes the contributions from the external force, the internal force due to the interaction with other dislocations and crystal defects that generate elastic fields, the "self force" that can be represented by a "line tension" force for small curvature of the dislocation, the Peierls force that acts like a friction resisting the

dislocation motion, and the "image" force related to the stress relaxation in the vicinity of external or internal surfaces. Once the total forces and the associated resolved shear stresses, τ^*, acting on the dislocation segments are calculated, the segments can be displaced in a finite difference time integration algorithm applied to the equations connecting the dislocation velocity, v, and the resolved shear stress, e.g., [28]

$$v = A\left(\frac{\tau^*}{\tau_0}\right)^m \exp\left(-\frac{\Delta U}{kT}\right), \tag{3}$$

when the displacement of a dislocation segment is controlled by thermally activated events (ΔU is the activation energy for dislocation motion, m is the stress exponent, and τ_0 is the stress normalization constant) or

$$v = \tau^* b/B, \tag{4}$$



that corresponds to the Newtonian motion equation accounting for the atomic and electron drag force during the dislocation "free flight" between the obstacles (B is the effective drag coefficient and b is the magnitude of the Burgers vector of the dislocation).

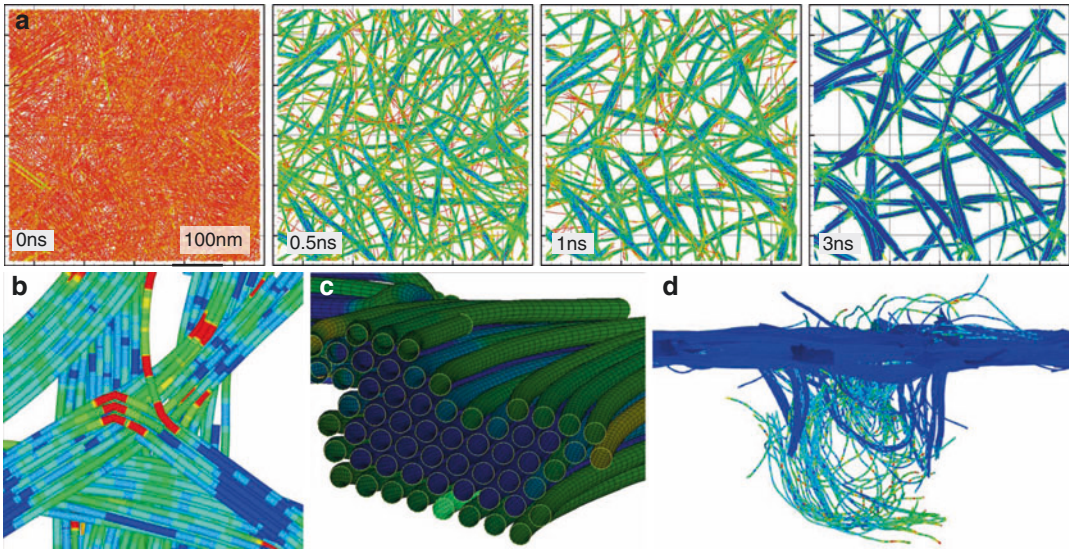
Most of the applications of the DD model have been aimed at the investigation of the plastic deformation and hardening of single crystals (increase in dislocation density as a result of multiplication of dislocations present in the initial system). The extension of the DD modeling to nanomaterials is a challenging task as it requires an enhancement of the technique with a realistic description of the interactions between the dislocations and grain boundaries and/or interfaces as well as an incorporation of other mechanisms of plasticity (e.g., grain boundary sliding and twinning in nanocrystalline materials). There have only been several initial studies reporting the results of DD simulations of nanoscale metallic multilayered composites, e.g., [31]. Due to the complexity of the plastic deformation mechanisms and the importance of anelastic short-range interactions among the crystal defects in nanomaterials, the development of novel hybrid computational methods combining the DD technique with other mesoscopic methods is likely to be required for realistic modeling of plastic deformation in this class of materials.

Mesoscopic Model for Nanofibrous Materials

The design of new nanofibrous materials and composites is an area of materials research that is currently experiencing a rapid growth. The interest in this class of materials is fueled by a broad range of potential applications, ranging from fabrication of flexible/stretchable electronic and acoustic devices to the design of advanced nanocomposite materials with improved mechanical properties and thermal stability. The behavior and properties of nanofibrous materials are defined by the collective dynamics of the nanofibers and, in the case of nanocomposites, their interactions with the matrix. Depending on the structure of the material and the phenomenon of interest, the number of nanofibers that has to be included in the simulation in order to ensure a reliable prediction of the effective macroscopic properties can range from several hundreds to millions. The direct atomic-level simulation of systems consisting of large groups of nanofibers (the path shown by the green arrow #2 in Fig. 1) is beyond the capabilities of modern computing facilities. Thus, an alternative two-step path from atomistic investigation of individual structural elements and interfacial properties to the continuum material description through an intermediate mesoscopic modeling (blue arrows #3 in Fig. 1) appears to be the most viable approach to modeling of nanofibrous materials. An example of a mesoscopic computational model recently designed and parameterized for carbon nanotube (CNT)-based materials is briefly discussed below.

The mesoscopic model for fibrous materials and organic matrix nanocomposites adopts a coarse-grained description of the nanocomposite constituents (nanofibers and matrix molecules), as schematically illustrated in Fig. 3. The individual CNTs are represented as chains of stretchable cylindrical segments [22], and the organic matrix is modeled by a combination of the

Computational Study of Nanomaterials: From Large-Scale Atomistic Simulations to Mesoscopic Modeling, Fig. 3 Schematic representation of the basic components of the dynamic mesoscopic model of a CNT-based nanocomposite material (**a**) and a corresponding molecular-level view of a part of the system where a network of CNT bundles (*blue* color) is embedded into an organic matrix (*green* and *red* color) (**b**)



conventional "bead-and-spring" model commonly used in polymer modeling [19, 20] and the "breathing sphere" model developed for simulation of simple molecular solids [21] and polymer solutions [32].

The degrees of freedom, for which equations of motion are solved in dynamic simulations or Metropolis Monte Carlo moves are performed in simulations aimed at finding the equilibrium structures, are the positions of nodes defining the segments, the positions of the molecular units, and the radii of the spherical particles in the breathing sphere molecules. The potential energy of the system can be written as

$$U = U_{T(\text{int})} + U_{T-T} + U_{M-M} + U_{M(\text{int})} + U_{M-T} \quad (5)$$

where $U_{T(\text{int})}$ is the potential that describes the internal strain energy associated with stretching and bending of individual CNTs, U_{T-T} is the energy of intertube interactions, U_{M-M} is the energy of chemical and nonbonding interactions in the molecular matrix, $U_{M(\text{int})}$ is the internal breathing potential for the matrix units, and U_{M-T} is the energy of matrix–CNT interaction that can include both nonbonding van der Waals interactions and chemical bonding. The internal CNT potential $U_{T(\text{int})}$ is parameterized based on the results of atomistic simulations [22] and accounts for the transition to the anharmonic regime of stretching (nonlinear stress–strain dependence), fracture of nanotubes under tension, and bending buckling [33]. The intertube interaction term U_{T-T} is calculated based on the tubular potential method that allows for a computationally efficient and accurate representation of van der Waals interactions between CNT segments of arbitrary lengths and orientation [23]. The general procedure used in the formulation of the tubular potential is not limited to CNTs or graphitic structures. The tubular potential (and the mesoscopic model in general) can be parameterized for a diverse range of systems consisting of various types of nano- and microtubular elements, such as nanotubes, nanorodes, and microfibers.

Simulations performed with the mesoscopic model demonstrate that the model is capable of simulating the dynamic behavior of systems consisting of thousands of CNTs on a timescale extending up to tens of nanoseconds. In particular, simulations performed for systems composed of randomly distributed and oriented CNTs predict spontaneous self-assembly of CNTs into continuous networks of bundles with partial hexagonal ordering of CNTs in the bundles, Fig. 4a–c [23, 33]. The bending buckling of CNTs (e.g., see

Computational Study of Nanomaterials: From Large-Scale Atomistic Simulations to Mesoscopic Modeling, Fig. 4 Snapshots from mesoscopic simulations of systems consisting of (10,10) single-walled carbon nanotubes: (**a**) spontaneous self-organization of CNTs into a continuous network of CNT bundles (CNT segments are colored according to the local intertube interaction energy) [23]; (**b**) an enlarged view of a structural element of the CNT network (CNT segments colored according to the local radii of curvature and the *red* color marks the segments adjacent to buckling kinks) [33]; (**c**) a cross section of a typical bundle showing a hexagonal arrangement of CNTs in the bundle [23]; (d) snapshot from a simulation of a high-velocity impact of a spherical projectile on a free-standing thin CNT film [34]

Fig. 4b) is found to be an important factor responsible for the stability of the network structures formed by defect-free CNTs [33]. The structures produced in the simulations are similar to the structures of CNT films and buckypaper observed in experiments. Note that an atomic-level simulation of a system similar to the one shown in the left panel of Fig. 4 would require $\sim 2.5 \times 10^9$ atoms, making such simulation unfeasible.

Beyond the structural analysis of CNT materials, the development of the mesoscopic model opens up opportunities for investigation of a broad range of important phenomena. In particular, the dynamic nature of the model makes it possible to perform simulations of the processes occurring under conditions of fast mechanical loading (blast/impact resistance, response to the shock loading, etc.), as illustrated by a snapshot from a simulation of a high-velocity impact of a spherical projectile on a free-standing thin CNT film shown in Fig. 4d [34]. With a proper parameterization, the mesoscopic model can also be adopted for calculation of electrical and thermal transport properties of complex nanofibrous materials [35, 36].

Future Research Directions

The examples of application of the atomistic and mesoscopic computational techniques, briefly discussed above, demonstrate the ability of computer modeling to provide insights into the complex processes that define the behavior and properties of nanostructured materials. The fast advancement of experimental methods capable of probing nanostructured materials with high spatial and temporal resolution is an important factor that allows for verification of computational predictions and stimulates the improvement of the computational models. With further innovative development of computational methodology and the steady growth of the available computing resources, one can expect that both atomistic and

mesoscopic modeling will continue to play an increasingly important role in nanomaterials research.

In the area of atomistic simulations, the development of new improved interatomic potentials (often with the help of *ab initio* electronic structure calculations, red arrow #1 in Fig. 1) makes material-specific computational predictions more accurate and enables simulations of complex multicomponent and multiphase systems. Further progress can be expected in two directions that are already actively pursued: (1) large-scale MD simulations of the fast dynamic phenomena in nanocrystalline materials (high strain rate mechanical deformation, shock loading, impact resistance, response to fast heating, etc.) and (2) detailed investigation of the atomic structure and properties of individual structural elements in various nanomaterials (grain boundaries and interfaces, nanotubes, nanowires, and nanoparticles of various shapes). The information obtained in large-scale atomistic simulations of nanocrystalline materials can be used to formulate theoretical models translating the atomic-level picture of material behavior to the constitutive relations describing the dependence of the mechanical and thermal properties of these materials on the grain size distribution and characteristics of nanotexture (green arrow #2 in Fig. 1).

The results of the detailed analysis of the structural elements of the nanocomposite materials can be used in the design and parameterization of mesoscopic models, where the elementary units treated in the models correspond to building blocks of the nanostructure (elements of grain boundaries, segments of dislocations, etc.) or groups of atoms that have some distinct properties (belong to a molecule, a mer unit of a polymer chain, a nanotube, a nanoparticle in nanocomposite material, etc.). The design of novel system-specific mesoscopic models capable of bridging the gap between the atomistic modeling of structural elements of nanostructured materials and the continuum models (blue arrows #3 in Fig. 1) is likely to become an important trend in the computational investigation of nanomaterials. To achieve a realistic description of complex processes occurring in nanomaterials, the description of the elementary units of the mesoscopic models should become more flexible and sophisticated. In particular, an adequate description of the energy dissipation in nanomaterials can only be achieved if the energy exchange between the atomic degrees of freedom, excluded in the mesoscopic models, and the coarse-grained dynamic degrees of freedom is accounted for [34]. A realistic representation of the dependence of the properties of the mesoscopic units of the models on local thermodynamic conditions can also be critical in modeling of a broad range of phenomena.

In general, the optimum strategy in investigation of nanomaterials is to use a well-integrated multiscale computational approach combining the *ab initio* and atomistic analysis of the constituents of nanostructure with mesoscopic modeling of the collective dynamics and kinetics of the structural evolution of the material and leading to the improved theoretical understanding of the factors controlling the effective material properties. It is the improved understanding of the connections between the processes occurring at different time and length scales that is likely to be the key factor defining the pace of progress in the area of computational design of new nanocomposite materials.

Automatic data analysis workflow for RNAi; Systems level data mining for RNAi

Definition

Computational systems bioinformatics for RNAi screening and therapeutics is defined as complete computational workflow applicable to the hypothesis generation from large-scale data from image-based RNAi screenings as well as the improvement of RNAi-based therapeutics; the workflow includes automatic image analysis compatible to large-scale cell image data, together with unbiased statistical analysis and gene function annotation.

Introduction

RNA interference (RNAi) defines the phenomenon of small RNA molecules binding to its complementary sequence in certain messenger RNA, recruiting a specific protein complex to dissect the whole mRNA and thus silencing the expression of the corresponding gene. It is a highly conserved system within living cells to quantitatively control the activity of genes. In 1998, Fire et al. first clarified the causality of this phenomenon and named it as RNAi [1], and the following decade saw RNAi evolving into a powerful tool for gene function study. In 2006, Fire and Mello were awarded Nobel Prize in Physiology or Medicine; and by 2007, scientific papers using high-throughput screening based on RNAi kept piling up while clinical trials of RNAi-based therapeutics on various diseases raised the expectation on a trend of soon-to-come "super drugs." Unfortunately, by late 2009 nearly all the first trend clinical trials have been terminated, meanwhile, researchers are struggling to effectively quantify the high-content information obtained from RNAi-based screening experiments.

Although facing obstacles, it is still believed that the combination of nanotechnology and systems biology would restore and amplify the glory of RNAi on both research and therapeutic areas. This entry will summarize the challenges facing RNAi-based therapeutics – especially the difficulty of delivery and some possible solution through chemoinformatics in nanometer scale; also difficulties facing RNAi-based high-content screening will be reviewed with suggestions on possible solutions.

RNAi-Based Therapeutics: How-to and What-to Deliver

Currently, various RNAi-based therapeutics are being tested in clinical trials but before the application becomes clinical, several problems have first to be solved. One of the critical challenges is how to specifically and effectively deliver the objects into the targeted cells. Serious side-effects in patients could be caused by off-target effects or immune response as reported in literatures [2, 3].

Apparently, the therapeutic goal is to achieve RNAi therapy, that is, systemically administered nucleic acids must survive in circulation long enough to reach their target tissue, enter the desired cells, "escape" their endosome or delivery packaging, and finally become incorporated into the RNA-induced silencing complex (RISC) – a towering task, and surprisingly, researchers have advanced a number of plausible solutions in recent years, including the use of specialized nanoparticle filled with an RNAi-based cancer therapy to target human cancer cells and silence the target gene. However, what making the task even more difficult for therapeutics is: everything now happens in vivo.

Chemoinformatics Solutions

Libraries have been built based on natural products and combinatorial chemistry with millions of compounds to date. The compound library is used to screen and locate small molecules to bind a particular protein, RNA or DNA. Virtual screening utilizing molecule fragments even can design unknown compounds with reasonable binding affinity to desired targets. However, these large-scale screening compounds tend to bind multiple targets (off-target effects) even after optimizations [4]. Also, it is virtually impossible to derive a solid algorithm or theory to screen and locate all bindings and inhibitions and their combinations every protein currently know. The lack of genome-scale coverage is a clear disadvantage of a compound based assay. Along with the lack of specificity comes the challenge of on-target potency. Even after a target has been identified the drug-like compounds have to be further engineered to increase efficiency and decrease off-target activities.

To a large extent, chemoinformatic approaches, where the target of a compound can be predicted by in silico alignment, modeling algorithms, and virtual screening, provide a more efficient way to screen compounds to the desired targets. A successful application has been reported for the inhibition of SARS protease [5]. The chemoinformatics approach excels at optimization around a small number of well defined targets, while RNAi approaches can more readily identify unknown pathways and phenotypes with no prior knowledge of the target.

Data Analysis for RNAi HCS: Challenge from Millions of Cells

Large volumes of datasets generated from RNAi HCS of RNAi prohibits manual or even semi-manual analysis; thus, automated data analysis is desperately needed [6, 7]. In the context of genome-wide RNAi HCS using cultured cells from Drosophila, a series of automated methods on cell image processing [8], online phenotype discovery [9, 10], cell classification, and gene function annotation [11] have been developed. All these methods are integrated into an automated data analysis pipeline, G-CellIQ (Genomic Cellular Image Quantitator), to support genome-wide RNAi HCS.

A lot of decisions need to be made en route to a genome-scale RNAi screens, including the selections of appropriate animal models, reagents for igniting RNAi, screening formats, and type of readouts (see [12] for a review). The focus here is arrayed high-content RNAi screening, a systematic screen with reagents spotted in 384- or 96-well plates and where each gene or gene group is knocked down individually. The readout of HCS is obtained through microscopy, which captures multiple phenotypic features simultaneously [13]. Compared with other screening approaches, RNAi HCS can offer broader insight into cellular physiology and provide informative and continuous phenotypic data generated by RNAi. However, the automated processing and analysis of the magnitude of image data presents great challenges to applying such findings at the genome level.

Image Processing: Cell Segmentation and Quantification

The scale of datasets has always been a huge obstacle. For example, in [6], approximately 17000 overlapping cells were segmented semi-manually across 10 months from an HCS targeting around 200 genes or gene combinations. However, such low-dimensional screens are not genome-wide, as they can only cover 1–2 % of the genome. For automatic data analysis, the following work needs to be accomplished.

1. Preprocessing: where empty images, incomplete cells, and other artifacts are identified and discarded
2. Cell segmentation: where dense or overlapping cells are segmented accurately
3. Feature extraction: where informative features are extracted to quantify cell morphology

Cell segmentation is the cornerstone for the whole data analysis workflow. While existing image analysis methods can handle the processing of standard images, they are limited in their scope

and capability to handle genome-wide RNAi HCS analysis. Thresholding methods basically set a cutoff on the intensity of pixels and classify them into background and foreground (cell), and they may fail due to uneven background and illumination levels. Rule-based correction on over- and under-segmentation starts from relatively simple segmentation methods (like watershed), and use a series of heuristic rules, like distance between neighborhood nuclei and properties of putative cell boundaries, such methods suffer from difficulties in devising rules to merge the cell cytoplasm.

Phenotype Identification, Validation, and Classification

Given the quantified features describing cell morphology, the following work is essential to address the biological function of morphological profiles.

1. Define biologically meaningful phenotypes to compose cell populations based on single cell morphology.
2. Model existing phenotypes and identify novel phenotypes online to continuously generate new data.
3. Assign cellular phenotypes into different sub-phenotypes to address morphological changes caused by RNAi treatment.

Statistical tests, artificial neural networks [6], Support Vector Machine-Recursive Feature Elimination (SVM-RFE) [14], genetic algorithms, and various other methods have been used to select or extract informative subsets of features and model certain phenotypes. However, phenotypes are usually defined a priori from pilot datasets. Human intervention is currently necessary for image-based datasets of genetic or chemical perturbations where the dynamic range of cellular phenotypes cannot be predicted before data collection. Failing to accurately measure phenotypic variations will cause concomitant classification errors and mislead functional analysis; and it is impossible to perform manual analysis during the screening process where millions of images are acquired. Thus, the ability of these screens to identify new phenotypes is greatly limited [9].

Statistical Analysis and Gene Function Annotation

RNAi HCS inherits various statistical questions from traditional high-throughput screening, and the properties of image readouts raise specific challenges.

1. Summarizing gene function scores from quantified morphological change
2. Data triage and normalization based on readout from positive and negative control wells
3. Repeatability test and consolidation of scores from biological replicates
4. Cluster analysis, visualization, and biological interpretation of results

A comprehensive review [15] summarizes different dataset generated by RNAi screens and traditional small molecule screens. It also reviews statistical analysis methods applicable to most of problems outlined above. Quantitative morphological signatures (QMS) [6] represent the efforts on interpreting RNAi HCS datasets: use the similarity score to a panel of existing phenotypes to explore the broad phenotypic space. However, problems remain open when the discriminative ability of such scores is confounded by multiple phenotypes following a single RNAi treatment, so repeatability tests can become more complicated [6]. The use of publicly available databases on drugs and disease-related biological processes to interpret RNAi HCS datasets also remains unresolved.

G-CellIQ: An Integrated Automated Data Analysis Tool for RNAi High-Content Screening

Computational Architecture of G-CellIQ

G-CellIQ (**G**enomic **CELL**ular **I**maging **Q**uantitator) is developed to process large volumes of digital images generated from large-scale HCS studies. The workflow for G-CellIQ can be simplified as "three modules handling three databases." Images generated from HCS are stored in a Raw image database; the Image processing/cell morphology quantification

module segments each image into single cells and creates a quantified cell database; the Phenotype modeling and cell classification module compares each cell's morphology to a panel of "reference" phenotypes (which can be defined both manually and automatically) and generates a morphology score; the annotation of gene function module then summarize single cell scores into scores for cell populations, images and wells, and the consolidated scores for involved genes form a single gene function profile database.

Image Processing and Cell Morphology Quantification

A segmentation method consisting of nuclear segmentation, cell body segmentation, and over-segmentation correction [8] is used in G-CELLIQ. Each cell body is described by 211 morphological features; automatic image quality control is applied to filter images where the signal from certain channels is extremely dark or bright or cells are located at the edge of an image.

Nuclear segmentation cell nuclei are first separated from background using a binarization method which implements an adaptive thresholding [8]. To segment clustered nuclei, the nuclei shape and intensity information are integrated into a combined image and processed with Gaussian filter and the nuclei centers are detected as local maxima in the gradient vector field (GVF); after that, nuclei are segmented using the marker-controlled seeded-watershed method.

Cell body segmentation Preliminary cell body segmentation is done using an adaptive thresholding algorithm. Due to the large size of HCS dataset, seeded-watershed method is used to segment the touching cell bodies. Results from nuclei segmentation are used as the seed information [16].

Over-segmentation correction is necessary when there are multiple nuclei existing within cells. For cell segments smaller than a given size threshold, its neighboring cell segments sharing the longest common boundary are determined and the intensity variation in a rectangular region across the common boundary of touching cell segments are calculated. If the intensity variation was smaller than a given threshold, the corresponding cell segments are merged.

Feature extraction The detailed shape and boundary information of nuclei and cell bodies is obtained through the proposed segmentation method. To capture the geometric and appearance properties, 211 morphology features belonging to five categories were extracted following [11].

Online Phenotype Discovery, Phenotype Modeling, and Cell Classification

Expert opinion is implemented to identify a panel of reference phenotypes while candidate groups of informative features are selected to describe typical phenotypes. SVM-RFE and GA-SVM method are used to select the feature sets with the best performance for cross validation. A series of SVM classifiers are trained to differentiate the reference phenotypes from all others, and a continuous value rather than binary class label is used as the output of SVM to indicate each cell's morphological similarity to typical phenotypes.

A novel method is designed to do online phenotype discovery [9, 10]; it is based on online phenotype modeling and iterative phenotype merging. For the modeling part, each existing phenotype is modeled through a Gaussian Mixture Model (GMM), and each model is continuously updated according to information of newly incorporated cells with a minimum classification error (MCE) method. For the merging part, the newly generated cell population is iteratively combined with each existing phenotype, one at a time. Then an improved gap statistics method is used to identify the number of possible phenotypes in the combination. Through cluster analysis, some of the cells in the new populations are assigned into the same cluster as samples from existing phenotypes, and those cells are merged by existing phenotypes to help update the phenotype models. On the other hand, some cells are never merged and remain as candidate novel phenotype for validation by statistical tests [9, 10].

Annotation of Gene Function

After assigning each cell a score vector corresponding to its similarity to reference

phenotypes, all cells in control condition are pooled to model a baseline for cell morphology. All morphology scores are normalized to the Z-score relative to this control baseline. The scores for the qualified cells are then averaged to form scores for each well. In order to select repeatable wells from those undergoing the same dsRNA treatment, a series of repeatability tests are applied to scores for different well. The weighted average of the scores is then calculated for the repeatable wells and generated scores for each treatment condition (TC). Similar procedure consolidates the score from biological replicate TCs to form a score vector for each gene. Hierarchical clustering is implemented group genes with similar function scores into the same phenocluster.

RNAi HCS Applying G-CellIQ

Since more than 75 % of human disease genes have *Drosophila* orthologs, the pursuit of genes involved in normal fly morphogenesis and migration is expected to reveal mechanisms conserved in humans [17]. An example of using G-CellIQ in the context of RNAi HCS using cultured *Drosophila* cell lines is presented next.

Regulatory of cell shape change. A genome-scale RNAi screening is carried out for regulators of *Drosophila* cell shape. Drosophila Kc187 cell lines are utilized in the screen and wild-type cells have hemocyte-like properties. Using dsRNA to target and inhibit the activity of specific genes/proteins, the role of individual genes in regulating morphology can be systematically determined.

Work in [9, 10] relies on part of the genome dataset to target the group of kinase-phosphatases in order to develop and validate online phenotype discovery methods. A panel of five existing phenotypes is set by expert labeling and online phenotype discovery. In order to address the level of penetrance in this dataset, the phenotypic scores for single cells are sorted according to similarity to wild-type cells, and if a certain well has significantly less (at least one standard-deviation) wild-type cells than control wells, wild-type cells from this well are removed to reveal the phenotypic change relating to RNAi treatment.

Roles of Rho family small GTPases in development and cancer. Three automated and *quantitative* genome-wide screens for dsRNAs that induce the loss of the Rho-induced cytoskeletal structures (lamellipodia, filopodia, and stress fibers) are performed to identify putative Rho protein effectors. Candidate effectors identified in such image-based screens are readily validated in the context of the whole organism using the large number of mutant fly lines coupled with the vast arrays of in vivo techniques available to fly biologists [18].

Following image segmentation, feature extraction, classification of single cells, and scoring of individual wells, an image descriptor is assigned to each gene. Hierarchical clustering can then be used to cluster the image descriptor and identify groups of genes when targeted by RNAi result in quantitatively similar morphologies. Previous studies reported in [6] demonstrated that clustering results identifies groups of functionally related genes that operate in similar signaling pathways. These groups of genes are termed as "Phenoclusters" [19]. To validate the hypothesis generation ability of G-CELLIQ, 32 dsRNAs/wells are randomly selected from a dataset where individual kinases and phosphatases were inhibited by RNAi. Each dsRNA/well was assigned an image descriptor, and hierarchical clustering was used to group genes/wells. dsRNAs in this analysis clustered into two broad groups. One group of 19 conditions included 10/10 control conditions, as well as dsRNAs targeting the Insulin receptor (InR). Strikingly, the other large cluster of 13 conditions included 3/3 dsRNAs previously identified in a genome-wide screen for regulators of MAPK/ERK activation downstream of the EGF/EGFR activity [20]. These results demonstrate that automated high-throughput imaging can discriminate distinct morphologies and be used to model functional relationships between signaling molecules.

Definition

Concentration polarization (CP) is a complex phenomenon observed at the interfaces of micro/nanofluidic devices due to the formation of significant concentration gradients in the electrolyte solution resulting in accumulation and depletion of ions near the interfaces.

This chapter provides an overview of the underlying theory and physics that is predominantly observed on the integration of microfluidic channels with nanofluidic devices. Nonlinear electrokinetic transport and concentration polarization phenomenon are discussed in detail along with recent advancements in utilizing this phenomenon for designing novel devices.

Electrical Double Layer (EDL) and Electroosmotic Flow

A solid in contact with an aqueous solution acquires a surface charge (σ_s) due to the dissociation of ionizable groups on the solid walls. The fixed surface charge on the solid surface in contact with the liquid develops a region of counterions (ions with charges opposite to the solid surface) in the liquid to maintain the electroneutrality at the solid–liquid interface. This screening region is denoted as the electrical double layer (EDL) or Debye length (DL). For instance, in the case of silica channel with *KCl* electrolyte solution, the dissociation of silanol groups would make the channel negatively charged and affect the distribution of K^+ counterions in the solution. The layer where the ions get strongly attracted toward the channel surface due to the electrostatic force is called the inner layer with a typical thickness of one ion diameter. The outer Helmholtz plane separating the liquid and the diffusive layer constitute the liquid side part of the EDL. The ionic species in the diffusive layer are influenced by the local electrostatic potential, and the species distribution at equilibrium can be described by the Boltzmann equation. The thickness of the diffusive layer spans between 1 and 100 nm. The EDL thickness (λ_D) is given by [1]:

$$\lambda_D = \left(\frac{\varepsilon_0 \varepsilon_r RT}{F^2 \sum_{i=1}^{m} z_i^2 c_0} \right) 1/2 \qquad (1)$$

where F is Faraday's constant, z_i is the valence of ionic species i, c_0 is the bulk concentration of the electrolyte solution, ε_0 is the permittivity of free space, ε_r is the relative permittivity of the medium, m is the total number of ionic species, R is the universal gas constant, and T is the absolute temperature.

The thickness of the EDL plays a significant role in the transport of miniaturized devices. In microfluidic channels, the fluid transport is often controlled by electric fields, as it eliminates the use of external mechanical devices [1]. The electric field aids better control when compared to using pressure-driven techniques. Furthermore, the electric fields overcome the high pressures needed to transport the fluid at such length scales as the pressure follows a power–law relation with respect to the height (h) of the channel. The electric field acts on the charged counterions present at the interface of solution and stationary charged wall (i.e., at the EDL regions), resulting in the motion of the fluid which is referred as electroosmotic flow (EOF) [1]. As the EDL thickness in these channels is much smaller compared to their height $\left(\frac{h}{\lambda_D} \gg 1\right)$, the fluid flow has a plug-like flow characteristic. However, recent advancements in the fabrication technology [2] have motivated researchers around the globe to investigate the transport phenomenon in channel sizes of the order of few hundreds of nanometers. Transport in these devices is referred to as "nanofluidics." The electrical double layer in these devices spans much of the diameter or channel height leading to many interesting transport phenomena compared to its microscopic counterpart. The electroosmotic velocity no longer follows a plug-like flow characteristic but follows a Poiseuille-like (parabolic) characteristic as the electrokinetic body force is not just confined to a thin layer adjacent to the channel surface. Along with the aforementioned difference, the micro and nanofluidic systems also exhibit a different ion transport characteristic which is discussed below. In nanofluidic systems, as the EDL thickness

becomes comparable to the channel height $\left(\frac{h}{\lambda_D} \approx 1\right)$, there is a predominant transport of the counterions inside the channel, thus enabling the channel to be ion-selective [1]. These features are not observed in the microfluidic channels, as the counter-ionic space charge is confined to a very thin layer adjacent to the surface and the region away from the surface is essentially quasi-electroneutral (i.e., both co-ions and counterions are present away from the surface). Along with the EDL, the surface charge also plays a prominent role in controlling the transport inside the nanofluidic systems [2]. Similar ion-selective phenomenon was also observed in the intraparticle and intraskeleton mesopores of particulate and in membrane science [3].

Owing to the differences in the electrokinetic transport phenomena between the micro- and nanofluidic devices, the integration of these two devices paves way to complex physics. The models and the underlying theory developed to understand the electrokinetic transport in such systems are elaborated in section "Electrokinetic Theory for Micro/Nanochannels." A detailed discussion on the concentration polarization phenomenon and its applications are presented in section "Concentration Polarization." Finally, a brief summary is presented in section "Summary."

Electrokinetic Theory for Micro/Nanochannels

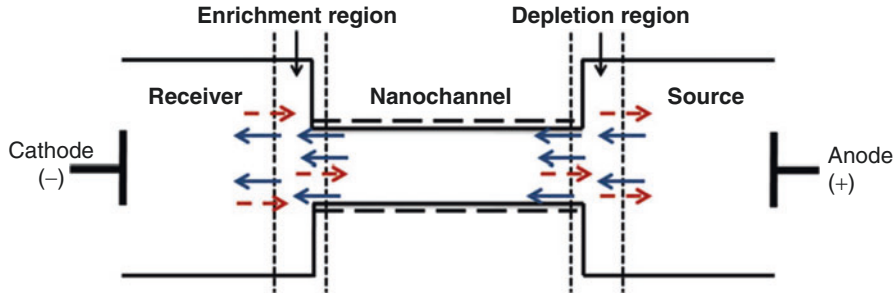
A complete set of equations for modeling the electrokinetic transport and to account for the EDL effects in micro/nanofluidic channels are presented. To understand the electrokinetic transport, space charge model developed by Gross et al. [4] is used extensively in the literature. The model solves the classical Poisson–Nernst–Planck (PNP) equations, which describe the electrochemical transport and the incompressible Navier–Stokes along with the continuity equations are solved to describe the movement of the fluid flow. These coupled systems of equations are more intensive, mathematically complicated, and computationally expensive. Though many linearized approximations were proposed to this model to study the electrokinetic transport [2], the governing equations of the complete nonlinear space charge model is discussed in this chapter.

In electrokinetic flows, the total flux is contributed by three terms: a diffusive component resulting from the concentration gradient, an electrophoretic component arising due to the potential gradient, and a convective component originating from the fluid flow. The total flux of each species in the solution is given by

$$\boldsymbol{\Gamma}_i = -D_i \nabla c_i - \Omega_i z_i F c_i \nabla \phi + c_i \boldsymbol{u} \tag{2}$$

where $\boldsymbol{\Gamma}_i$ is the flux vector, D_i is the diffusion coefficient, Ω_i is the ionic mobility, c_i is the concentration of the i^{th} species, $\boldsymbol{u}$ is the velocity vector of the fluid flow, and ϕ is the electrical potential. Note that the ionic mobility is related to the diffusion coefficient by Einstein's relation, $\Omega_i = \frac{D_i}{RT}$ [5]. The electrical potential distribution is calculated by solving the Poisson equation,

$$\nabla \cdot (\in_r \nabla \phi) = -\frac{\rho_e}{\in_0} \tag{3}$$



where ρ_e is the net space charge density of the ions defined as

$$\rho_e = F\left(\sum_{i=1}^{m} z_i c_i\right) \tag{4}$$

The mass transfer of each buffer species is given by the Nernst–Planck equation,

$$\frac{\partial c_i}{\partial t} = -\nabla \cdot \Gamma_{\mathrm{i}} \tag{5}$$

Equations 3, 5, and 2 are the classical Poisson–Nernst–Planck (PNP) equations, which describe the electrochemical transport. The incompressible Navier–Stokes and the continuity equations are considered to describe the movement of the fluid flow through the channel, i.e.,

Concentration Polarization at Micro-/Nanofluidic Interfaces, Fig. 1 Schematic illustration of ion-enrichment and ion-depletion effect in cation-selective micro/nanofluidic channel. The *solid arrows* indicate the flux of cations and the *dotted arrows* indicate the flux of anions. At the nanochannel–anodic junction, both the anions and cations are depleted, while there is an enhancement of both the ions at the cathode–nanochannel junction

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t}+\boldsymbol{u}\cdot\nabla\boldsymbol{u}\right)=-\nabla p+\mu\nabla^2\boldsymbol{u}+\rho_e\boldsymbol{E} \quad (6)$$

$$\nabla\cdot\boldsymbol{u}=0 \quad (7)$$

where $\boldsymbol{u}$ is the velocity vector, p is the pressure, ρ and μ are the density and the viscosity of the fluid, respectively, and $\boldsymbol{E}=-\nabla\phi$ is the electric field. $\rho_e\boldsymbol{E}$ is the electrostatic body force acting on the fluid due to the space charge density and the applied electric field. Elaborate details on other simplified models are discussed in the review article of Schoch et al. [2].

Concentration Polarization

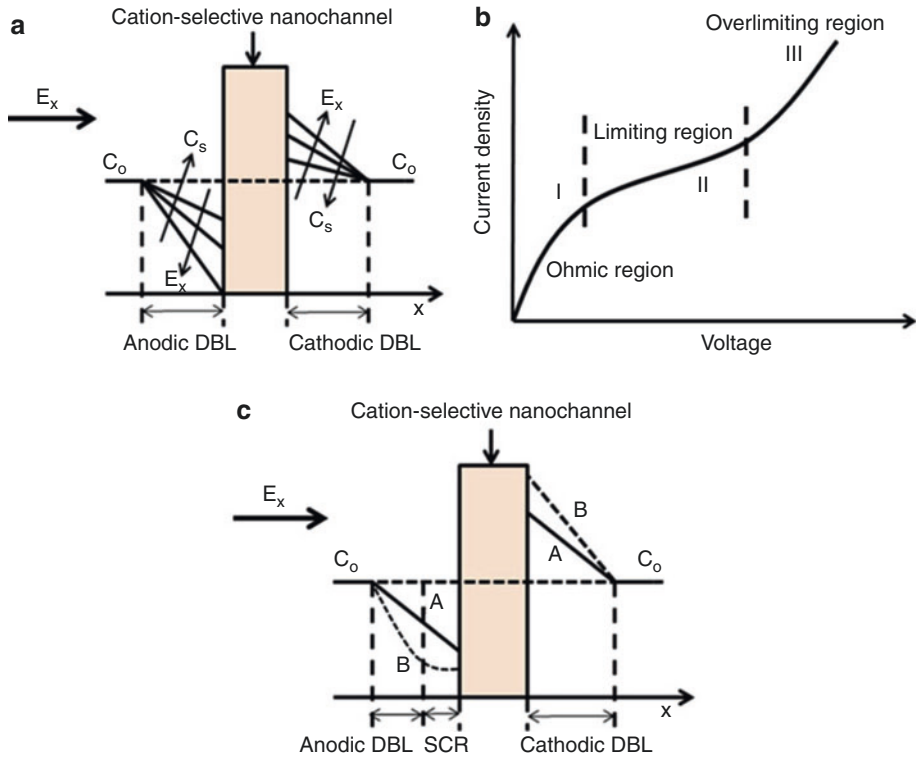
Concentration polarization (CP) is a complex phenomenon observed at the interface regions of micro/nanofluidic devices due to the formation of significant concentration gradients in the electrolyte solution near the interfaces causing accumulation of ions on the cathodic side and depletion of ions on the anodic side for a negatively charged nanochannel surface. This phenomenon was also observed in the field of colloid science and in membrane science which was extensively studied for over 40 years, and the early works of CP phenomenon is comprehensively reviewed by Rubinstein et al. [6]. The pioneering works from Rubinstein and his coworkers had revealed electrokinetic instabilities [7] in the concentration polarization regions leading to the breakdown of limiting current and resulting in the overlimiting conductance regimes in the ion exchange membranes. Such complex phenomenon could not be postulated using the classical equilibrium model of EDL [6]. All the underlying CP physics observed near the interfaces of micro/nanochannels are summarized in the following subsections.

Enrichment/Depletion Effects

In micro/nanofluidic devices, Pu et al. [8] first experimentally observed the CP effects near the interfaces and provided a simple model to explain the accumulation and depletion physics which is summarized below. For a negatively charged nanochannel, the EDL would be positively charged. For an overlapped EDL, as discussed in section "Electrical Double Layer (EDL) and Electroosmotic Flow," the nanochannel becomes ion-selective, resulting in higher cation concentration than anions. Thus, the flux of cations is higher compared to the anions in the nanochannel. With the application of positive potential at the source microchannel or reservoir (see Fig. 1), the cations move from the source (anode) reservoir to the receiving (cathode) reservoir end, while the anions move in the opposite direction through the nanochannel. At the cathodic side, the anion flux from the ends of reservoir to the nanochannel junction is higher compared to the anion flux from the junctions to the nanochannel as the anions are repelled by the negatively charged nanochannel. This difference in fluxes causes an accumulation

of anions at the cathode–nanochannel junction. The cation flux from the nanochannel to the cathode junction is greater than from the cathode junction to the reservoir as the cations have to balance the anions present at this junction. This results in an accumulation of cations as well at the nanochannel–cathode junction. At the anodic side, the anion flux from the nanochannel to the anode junction cannot balance the anion flux from the anode–nanochannel junction to the reservoirs due to the limited anions passing through the nanochannel. This results in a depletion of anions at this junction. The cation flux from the reservoir to the anode–nanochannel junction is less than the cation flux entering the nanochannel as the cations are attracted by the positively charged nanochannel. This in turn leads to the depletion of cations at this junction. To summarize, for a negatively charged nanochannel, both the cations and anions accumulate at the cathodic interface and are depleted at the anodic interface. The phenomenon is reversed for a positively charged nanochannel surface. A schematic diagram highlighting the accumulation and the depletion physics for a negatively charged nanochannel is displayed in Fig. 1.

Nonlinear Electroosmosis



As discussed in the previous section, the integration of micro/nanofluidic devices leads to the accumulation and depletion of ions near the interfaces. Several numerical and experimental studies were carried out to gain a better understanding of the physics at these interfaces. The studies revealed complex and interesting physics at the depletion interface compared to the enrichment side. Rubinstein et al. [6] theoretically predicted the presence of space charges at the depletion region under large electric fields. The presence of the induced space charges near the depletion interface results in a nonequilibrium electrical double layer outside the nanochannel. The induced space charges under the action of the external electric field lead to nonlinear electroosmosis or otherwise known as electroosmosis of the second kind. The electroosmotic flow of the second kind was found to be directly proportional to the square of the applied electric field. Furthermore, the induced space charges also result in the generation of vortices at the depletion interface along with inducing large pressure and voltage gradients at this junction. Jin et al. [9] also reported similar physics from their extensive numerical study. In the case of a flat ion exchange membrane, Rubinstein et al. [7] derived a 2D nonequilibrium electroosmotic slip (u_s) for an applied voltage (V) using the linear stability analysis to impose strong vortex field near the membrane:

$$u_s = -\frac{1}{8}V^2 \frac{\overline{\frac{\partial^2 c}{\partial x \partial y}}}{\overline{\frac{\partial c}{\partial y}}} \tag{8}$$

where x and y are the axes parallel and perpendicular to the ion-exchange membrane, respectively. Experiments performed by Kim et al. [10] also reveal the nonequilibrium EOF near the micro/nanofluidic junctions. The application of electric field on the surface of particles also results in such induced space charges which spread over a larger region than the primary EDL resulting in highly chaotic flow patterns. A recent review by Höltzel and Tallarek [3] provide a detailed discussion on the polarization effects around membranes, packed beds, and glass monoliths. Recent advancements by Rubinstein and Zaltzman [11], however, revealed that the extended space charge region was not a part of the EDL, but develop from the counterion concentration minimum zone with the co-ions expelled under the action of the electric field. They further claim that the space charges would be present in the system even without equilibrium EDL. Their analysis included the study of the space charge dynamics in concentration polarization regions using 1D and three-layer models of EDL. From the understanding of these extended space charge layers, another important phenomenon, namely, the nonlinear current characteristics in micro/nanochannels is addressed below.

Nonlinear Current–Voltage Characteristics

There has been growing interest in the development of micro/nanofluidic devices as ionic filters

Concentration Polarization at Micro-/Nanofluidic Interfaces, Fig. 2 (**a**) Schematic distribution of ionic concentration in equilibrium concentration polarization under axial electric field (E_x). The local electroneutrality is maintained at both enrichment (cathodic interface) and depletion (anodic interface) diffusion boundary layers (DBL). The concentration gradients become steeper with the decrease in the ionic strengths (c_s) and at higher electric fields, (**b**) displays the nonlinear current–voltage characteristics for an ion-selective micro/nanochannel, and (**c**) shows the nonequilibrium concentration distribution due to the induced space charge region (SCR) (shown as *dotted lines* (*B*)) in the depleted region under very large electric fields

and nanofluidic batteries to control both ionic and molecular transport in aqueous solutions [2]. As discussed before, when the diameter/height of a charged channel scales comparable to the EDL, there is a predominant transport of the counterions inside the channel. Thus, the transport of electrical current inside the nanochannel is primarily due to the counterions. This feature enables the micro/nanochannel to be used as an ion exchange membrane. However, understanding the passage of ionic currents through such ion-selective solids is the most fundamental physical problem that has stimulated extensive research in this field for over a decade. Furthermore, the concentration polarization physics near the interfaces play a pivotal role in understanding the current–voltage characteristics. Figure 2a shows that the concentration gradients (CP regions) near the interfaces become steeper with the decrease in the ionic strength (c_s) and at higher electric fields ($\boldsymbol{E}_x$). At low electric fields, the current increases linearly with the applied voltage following the Ohm's law (region I in Fig. 2b).

However, at higher electric fields, the ion concentration in the depleted CP zone (i.e., near the anodic interface region) reaches toward zero and the classical Levich analysis [5] predicts a diffusion-limited current saturation according to which a saturation of current density occurs at a constant level described as the "limiting-current density" (region II in Fig. 2b).

The ionic current can be calculated considering the Fick's first law:

$$I = nFAD\frac{dc}{dx} \tag{9}$$

where n is the number of electrons transferred per molecule, D is the diffusion coefficient, and A is the electrode surface area. The concentration gradient is generally approximated by a linear variation (5),

$$I = nFAD\frac{c_0 - c(x=0)}{\delta} \tag{10}$$

where c_0 is the bulk electrolyte solution and δ is the diffusion boundary layer (DBL) thickness at the solid–liquid interface and $c(x=0)$ represents the concentration at the anodic (depletion) solid–liquid interface. δ typically ranges between 10 and 400 μm in ion exchange membranes [6], while it depends on the microchannel length in the case of micro/nanochannels [10].

From Eq. 10 it is clear that the current I reaches a maximum value when the concentration at $c(x=0)=0$, resulting in a limiting/saturation current as predicted by the classical Levich theory.

$$I_{lim} = \frac{nFADc_0}{\delta} \tag{11}$$

However, experimental studies in micro/nanofluidic devices (also in membrane science) revealed ionic currents larger than the limiting value and this regime was termed as the overlimiting current regime (region III in Fig. 2b). Further, the limiting current region is termed as the limiting resistance region (in micro/nanofluidic devices) due to the large but finite limiting differential resistance as the current does not saturate to a limiting value but has a slope which is smaller than the ohmic region. The nonlinear current characteristics in micro/nanochannels are a subject of intensive discussions in the literature [3]. Earlier studies indicated that water dissociation effects leading to the generation of H^+ and OH^- ions were responsible for such overlimiting currents. Later, Rubinstein et al. [7] postulated that some mechanism of mixing should be present that destroys the DBL as lower δ leads to higher currents (from Eq. 11). Maletzk et al. [12] coated the surface of cation-exchange membranes with a gel which does not allow mixing. From these experiments, they observed a saturation of current with no enhancements in the current, thereby confirming the earlier postulation of Rubinstein. Further, the fluid flow in the overlimiting regime revealed strong fluctuations indicating convection close to the surface. This convection was first attributed to the gravitational buoyant forces due to the concentration and temperature gradients. However, later theories have argued that the convection was not due to the gravitational instability in CP zones. Dukhin et al. [13] suggested the mechanism for mixing to be electroconvection. The type of electroconvection present in the overlimiting regime was revealed as the electroosmotic flow of the second kind. As discussed in the previous section, the induced space charges in the depletion zone (see Fig. 2c) under the action of the electric field results in the EOF of second kind and this convective instability tends to destroy the DBL leading to overlimiting currents as shown in Fig. 2b. Experiments by Kim et al. [10] also revealed the nonlinear currents due to the nonequilibrium EOF in the ion-selective micro/nanochannels. Similar physics was also observed in the permselective membranes and ion-selective particles [3]. In spite of all these postulations, the physics behind the extended space charge layer still remains largely unclear and there are a lot of potential research opportunities to fully understand this complex physics.

Propagation of Concentration Polarization

In this section, the conditions and the scenarios which can lead to the propagation of CP in micro/nanofluidic devices are highlighted. Zangle et al. [14] highlighted the phenomena of concentration polarization propagation using a simplified model of charged species transport and validated the same by conducting experiments and by comparing with other experimental results. The CP phenomenon was found to be governed by a

type of Dukhin number, relating the bulk and the surface conductance. The inverse Dukhin number, for a symmetric electrolyte was specified as:

$$\frac{G_{bulk}}{G_\sigma} = \frac{Fhzc_0}{\sigma} \tag{12}$$

where G_{bulk} is the bulk conductance, G_σ is the surface conductance, c_0 is the concentration outside the EDL, and σ is the wall surface charge density. Zangle et al. postulated that CP depends on Dukhin number and not on the ratio of channel height to the Debye length $\left(\frac{h}{\lambda D}\right)$. Using their simplified model, they showed that both the enhancement and the depletion regimes at the interfaces of micro/nanofluidic channels propagate as shock waves under the following condition:

$$c^*_{o,r} h^*_n < \max\left(\upsilon^*_2, 2\upsilon^*_2 - 1\right) \tag{13}$$

where $c^*_{o,r} h^*_n = \frac{(\upsilon_1 z_1 - \upsilon_2 z_2) F h_n c_{o,r}}{-2\upsilon_1 \sigma}$ is an inverse Dukhin number describing the ratio of bulk to surface conductance as mentioned before. $\upsilon^*_2 = \frac{\upsilon_2 z_2 F_\eta}{\zeta_n \in}$ is the mobility of the co-ion nondimensionalized by the electroosmotic mobility. $c_{o,r}$ is the reservoir electrolyte concentration, h_n is the nanochannel height, υ_1 and υ_2 are the mobilities, and z_1 and z_2 are the valences of the positive and negative ionic species, respectively. ζ_n is the nanochannel zeta potential, $\in$ is the permittivity and η is the viscosity. Elaborate details of the model can be referred in [14]. From this model, they proposed a thumb rule to avoid propagation of CP and it was found that $c^*_{o,r} h^*_n \gg 1$. This condition for CP propagation was compared with 56 sets of experimental literature values and was found to give a sufficient first-hand prediction with regard to the concentration polarization propagation.

Though the model considers the effects of surface charge and the electrolyte concentration, the finite *Pe* effects which also play a critical role in the concentration polarization were not considered. Further, the experiments of Kim et al. [10] and the numerical studies performed by Jin et al. [9] also revealed that the applied potential also plays a pivotal role in the concentration polarization generation and propagation apart from the inverse Dukhin number. The shortcoming of the model was also highlighted by Zangle et al. in their work. Thus, still a clear and complete understanding of the CP regimes is yet to be reached and continuous efforts are being made to understand the physics at the micro/nanofluidic junctions to design advanced and novel devices.

Applications

In this section, various applications that have been developed utilizing the concentration polarization phenomenon are addressed. The applications range from preconcentrating biomolecules to fluid pumping and mixing and also in water desalination. A brief discussion of the aforementioned applications is presented below.

Preconcentration

Wang et al. [15] used the depletion region observed at the micro/nanojunction to preconcentrate proteins. The energy barrier created at the depletion region (due to the large voltage drop induced at this junction) prevents the entry of charged molecules into the nanochannel. This results in an increase in the concentration of the molecules near the depletion region. In their experiments, Wang et al. used two anodic microchannels which were independently controlled so that the direction of EOF can be aligned perpendicular to the axis of the nanopore. An increase of about 10^6–10^8 fold in the concentration of the protein was reported in their study. Over the past couple of years, similar preconcentration devices utilizing the CP effects were experimentally fabricated [3, 14]. Wang et al. [16] also presented an experimental approach to improve the binding kinetics and the immunoassay detection sensitivity using concentration polarization in micro/nanofluidic devices. The antigens were preconcentrated at the depletion region due to the strong electric field gradients resulting in the enhancement in the binding rates with the antibody beads.

Seawater Desalination

The phenomenon of concentration polarization witnessed in ion-selective membranes was successfully implemented to address the freshwater shortage issue by providing energy-efficient solution to water desalination. A microfluidic device was fabricated which provides 99 % salt rejection at 50 % recovery rate at a power consumption of less than 3.5 Wh/L [17]. The CP depletion layer acts as a barrier for any charged species and these species were diverted away from the desalted water using suitable pressure and voltage fields. Their design also ensured salt ions and other debris to be driven away from the membrane thereby preventing any membrane fouling which is often observed in other desalination techniques.

Mixing, Pumping, and Other Applications

As discussed earlier, the induced space charges observed at the depletion region of micro/nanochannel along with the large electric field gradients at this region result in strong vortices. Kim et al. [18] enhanced the mixing efficiency of microfluidic devices using the vortices created at this interface. Further, as the electroosmotic flow of the second kind observed at the depletion region is directly proportional to the square of the applied electric field, Kim et al. [19] was able to pump fluids using the nonequilibrium EOF and observed a fivefold increase in the volumetric flow rates compared to similar devices utilizing equilibrium EOF. Yossifon et al. [20] used an asymmetric microchannel in conjunction with the nanochannels. The application of forward and reverse bias (at the overlimiting regime) voltage led to an asymmetric space charge polarization which resulted in the rectification of the current. Such membranes have potential applications in selective species separation.

Summary

The origin and the underlying physics that is present at the interfaces of micro/nanofluidic devices were discussed. The complex phenomenon of concentration polarization (CP) leading to the enrichment and depletion of ions near the micro–nano junctions and the concepts of induced space charges and nonlinear electrokinetic transport were briefly discussed in this chapter. Further, the various controversies surrounding the physical mechanism for nonlinear current characteristics have been highlighted. The criteria for concentration polarization propagation and the various applications that have been developed utilizing the concentration polarization phenomenon were discussed. Though, a lot of extensive work has been carried out to understand the CP physics, a clear and complete understanding of the CP regimes and the induced space charge dynamics is yet to be reached and efforts need to be directed in this area to understand the physics at the micro/nanofluidic junctions to design novel devices.

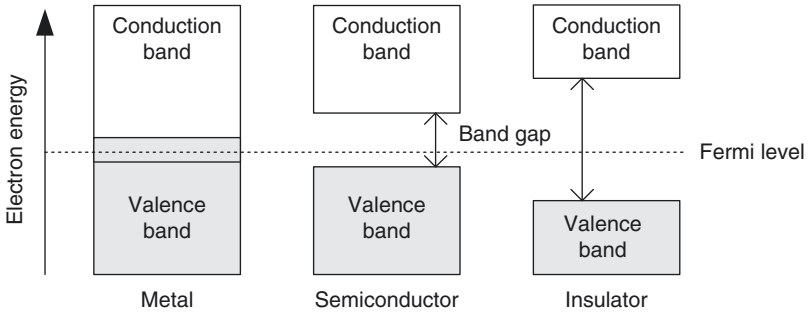
Conduction Mechanisms in Organic Semiconductors



Weicong Li and Harry Kwok
Department of Electrical and Computer Engineering, University of Victoria, Victoria, BC, Canada

Definition

Conduction mechanisms in organic semiconductors refer to the means by which electronic charges move through organic semiconductors under external stress particularly under the influence of an electrical field.

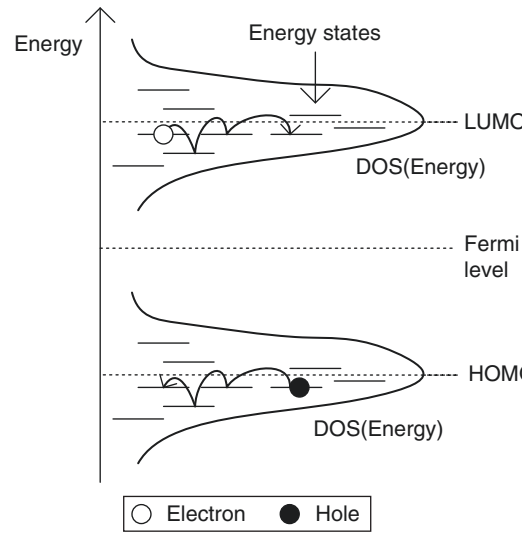
Overview

In order to understand the conduction mechanisms in organic semiconductors, it is necessary to first introduce the concept of *band theory*, which is well established in solid-state physics. Solids in general are made of atoms, each of which is composed of a positively charged nucleus surrounded by negatively charged electrons. In quantum mechanical terms, these electrons effectively reside in discrete energy states in orbits. When a large number of atoms (of order 10^{20} or more) are brought together to form a solid, the discrete energy states are so close together that energy bands begin to form. At the same time, there will be gaps between the energy bands which are known as the *band gaps*. Because of the presence of these energy gaps, there will be some energy bands that are almost fully occupied (known as the *valence bands*) and energy bands that are almost unoccupied (known as the *conduction bands*). Based on the band theory, solids are typically divided into the following three categories: *metals*, *semiconductors*, and *insulators*. In metals, there is an overlap between the energy bands so that the energy bands are partly filled by electrons at any temperature (even $T = 0$ K), while both the semiconductors and the insulators have fully filled

Conduction Mechanisms in Organic Semiconductors, Fig. 1 Band structures of metal, semiconductor, and insulator

valence bands and empty conduction bands at $T = 0$ K. To further study the distribution of electrons occupying the energy states in solids, it is also necessary to introduce the concept of Fermi level into the band theory, which represents the maximum energy of states that electrons can occupy at $T = 0$ K. Accordingly, all the allowed energy states below the Fermi level are occupied by electrons, and all the energy states above it are empty. When temperature is above 0 K, the probability that electrons occupy the state with energy E under thermodynamic equilibrium condition is given by Fermi-Dirac distribution function:

$$f(E) = \frac{1}{1 + \exp[(E - E_F)/kT]} \qquad (1)$$



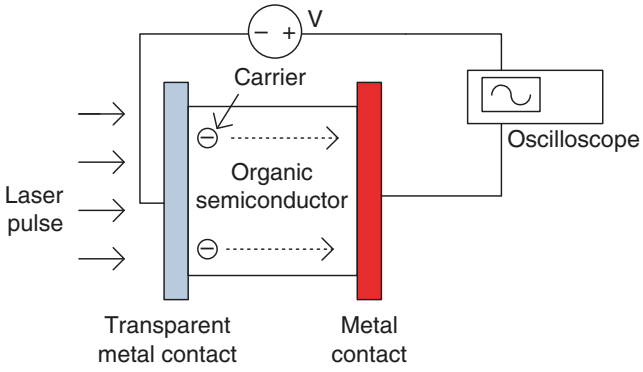
where E_F is the Fermi level, k is the Boltzmann constant, and T is the temperature in Kelvin. As mentioned earlier, in semiconductor and insulator, the valence band is fully occupied by electrons, and the conduction band is empty at $T = 0$ K. Therefore, one can infer that the Fermi level lies in the bandgap, between the valance and conduction bands. On the other hand, in metal, due to the fact that the energy bands are partly filled by electrons at any temperature, the Fermi level lies within the energy bands. The band structures of metal, semiconductor, and insulator, and the position of Fermi level in them are shown in Fig. 1. The distinction between the semiconductors and the insulators appears when temperature rises above 0 K. Because the band gap between conduction and valence bands in semiconductors is much narrower than that found in insulators, a fair amount of electrons can be thermally excited from the valence band to the conduction band in semiconductors at finite temperature, leading to measurable conductivity. This is not found in the insulators due to the larger band gaps even at room temperature, which lead to negligible probability of electrons occupying energy states in the conduction band, according to Eq. 1. The characteristic semiconductor band structure has allowed it to play an important role as the materials of choice in the prosperous electronic industry in the last few decades.

While inorganic semiconductors such as silicon dominated the electronic industry in the twentieth century, tremendous effort has been spent in the research and development of organic electronics in last decade due to the fact that organic semiconductors are usually easier and cheaper to form. Soluble organic materials, such as conjugated polymers, can be deposited in liquid phase (e.g., by printing and spin coating) onto large substrate areas at low processing temperature (below 100 °C). Due to this advantage, organic electronics are particularly attractive in the making of displays, sensors, light sources, photovoltaic panels, radio-frequency identification detectors (RFID), and in devices used in optical communications. As a consequence, research on the charge conduction mechanisms in organic semiconductors and devices is of significant importance.

In general, conduction mechanisms primarily describe how electronic charges (referred to as carriers) move inside the solids under the influence of an external electrical field. The process produces a current. At the macroscopic level, the current density J in solids produced by external electrical field is given by

$$J = env = en\mu F \tag{2}$$

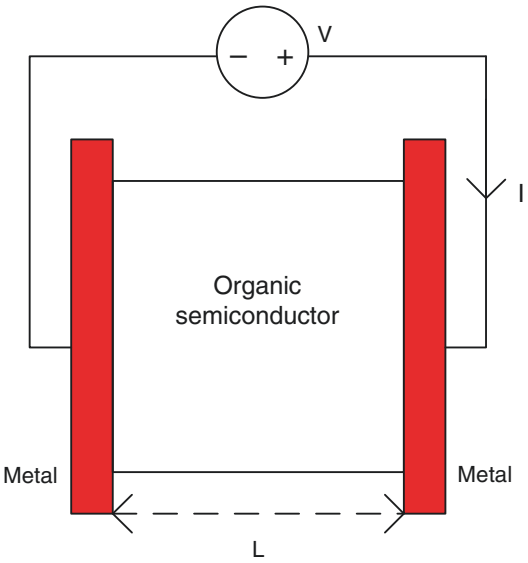
where e is elementary charge of a single carrier, n the charge density, and v is the drift velocity. Furthermore, v can be expressed as the product of the charge mobility μ and the electrical field F. As can be seen in Eq. 2, a large current requires the presence of a substantial number of mobile charge carriers (electrons or holes). In organic semiconductors, mobile carriers are known to be produced from the distributed π-bonds, which are covalent chemical bonds resulting from the overlap of atomic orbitals. Thus, the limited current flow in many organic semiconductors are related to their irregular molecular structures which can result in low charge mobility in comparison to values found in silicon and other inorganic semiconductors. In addition, the more established conduction mechanisms based on band theory normally found in inorganic crystalline semiconductors are absent in the organic semiconductors. As mentioned earlier, band theory states that carriers could only exist and move in either the conduction bands or the valence bands because there are permitted energy states where carriers can reside and their movement between the energy states will produce a current. The use of "energy band" diagrams (see Fig. 1) to explain charge transport in organic semiconductors however is not possible. This is because of the presence of high densities of defects and trap states. Instead, charge transport in organic semiconductors is directly explained in terms of the energy (orbital) states which are termed either the *lowest unoccupied molecular orbital* (LUMO) or the *highest occupied molecular orbital* (HOMO). As such, LUMO and HOMO levels are not genuine energy bands and they are used merely to serve as references to demarcate ground state energy and the next activated state energy [1]. The distribution of these energy states known as the *density of states* (*DOS*) is usually considered to be Gaussian centered at the LUMO and HOMO (see Fig. 2). The width of the Gaussian energy states depends on both the regularity of the molecular structure and the impurities present in the organic semiconductor.



Conduction Mechanisms in Organic Semiconductors, Fig. 2 Density of (energy) states in an organic semiconductor

As expected, in most organic semiconductors both the carrier density n and the charge mobility μ are low and the value of the latter often depends on the strength of the electrical field F in contrast to what is observed in inorganic semiconductors. In some organic semiconductors, the molecular structures can be highly disordered and different conduction mechanisms are found to predominate depending on the associated manufacturing process.

Basic Methodology

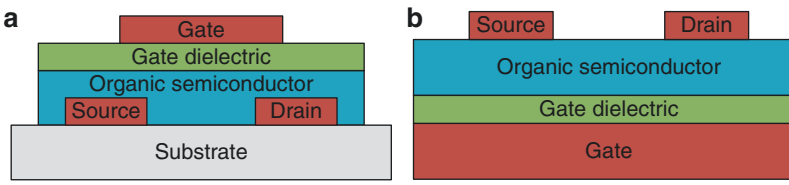


Many useful techniques have been proposed to study the conduction mechanisms in organic semiconductors including time-of-flight (TOF) experiment, space charge limited current (SCLC) measurement, and field-effect measurements using organic field-effect transistors (OFETs). These techniques, combined with the dependence on temperature, provide important information on mobility, trap concentration which are useful to assess the conduction mechanisms. Brief introductions to several different techniques commonly used are given here.

Conduction Mechanisms in Organic Semiconductors, Fig. 3 A schematic of the time-of-flight (TOF) experiment setup

Time-of-Flight (TOF) Experiment

As implied by its name, time-of-flight (TOF) experiment is the method of measuring the time it takes for one or a few carrier to travel a distance through the solid. When TOF experiment is used to study the conduction mechanisms in organic semiconductors (see Fig. 3), two metal electrodes (forming the contact) are deposited on the two ends of the organic semiconductor (one of the two is usually transparent). Initially, a few carriers are generated at one end near the transparent metal electrode using a short laser pulse with energy greater than the energy difference between HOMO and LUMO levels of organic semiconductor. The photo-generated carriers are then drifted toward the opposite end by an external electrical field generating a current pulse. By measuring the time delay of the current pulse, the velocity and the mobility of the charge carriers through the organic semiconductors can be computed.



Conduction Mechanisms in Organic Semiconductors, Fig. 4 A simplified schematic of the setup used for space charge limited current (SCLC) measurement

Space Charge Limited Current (SCLC) Measurement

Due to the low mobility of carriers in organic semiconductors, the measured I–V characteristics usually deviate from Ohm's law (i.e., the linear relationship between current and voltage). This is illustrated in Fig. 4. In this case, if efficient charge injection from the metal electrode is achieved by choosing a suitable metal, the I–V characteristics will follow the space charge limited current equation as given by

$$I = \frac{9}{8}\theta\varepsilon_0\varepsilon_r\mu A\frac{V^2}{L^3} \qquad (3)$$

where θ is a parameter dependent on the traps present in the semiconductors, ε_0 the free space permittivity, ε_r the relative dielectric constant, μ drift mobility of injected charge carrier, A the cross section area of semiconductor, and L the distance between metal contacts. By measuring the I–V characteristics at different temperatures, one can determine the mobility and the trap density of traps. Thus, SCLC measurement is a very useful technique reflecting the conduction mechanisms in organic semiconductors.

Conduction Mechanisms in Organic Semiconductors, Fig. 5 Two device configurations for the OFETs: (**a**) top-gate, (**b**) bottom-gate

Measurement Based on the Organic Field-Effect Transistor (OFET)

Field-effect transistor (FET) is an electronic device widely used in active circuits. It consists of a semiconductor with a conducting channel, an isolated gate controlling charge flow in the channel, a gate dielectric between the semiconductor and the gate, as well as source and drain regions forming the output terminals. Organic field-effect transistor (OFET) is a field-effect transistor formed on an organic semiconductor. The device configuration can have a top-gate or a bottom-gate as shown in Fig. 5.

The basic operation principle of the OFETs is very simple. When a bias voltage is applied between gate and source electrodes, carriers are injected from the source into the organic semiconductor forming an extremely thin accumulation layer ($2 \sim 3$ nm) at the interface between organic semiconductor and the dielectric. The carriers conduct a current across the source and the drain regions, and the current depends on the gate voltage as well as the charge mobility which is also dependent on the gate voltage and the drain-to-source voltage. The operation of the OFETs therefore relies on carrier accumulation in the field-effect structure in contrast to the case of the inorganic FETs which rely on either charge depletion or inversion. Therefore, OFETs are efficient tools to investigate the interfacial conduction mechanisms, while TOF and SCLC measurements are mainly used to study the bulk conduction mechanisms in the organic semiconductors. For example, *I–V* characteristics of OFETs are usually analyzed to determine parameters such as the charge mobility and the threshold voltage both of which are closed related to the density of traps at the interface. In addition, spectroscopic techniques are sometimes used to probe the morphology of the organic semiconductor interface, to look for the potential relationship between regularity of molecular structure and conduction performance.

Key Research Findings

Band-Like Transport

For highly purified and ordered organic molecular crystals, it is possible that band-like charge transport similar to that of the inorganic semiconductors may occur. The main feature found in band-like charge transport is the fact that the temperature dependence of the charge mobility has the following form:

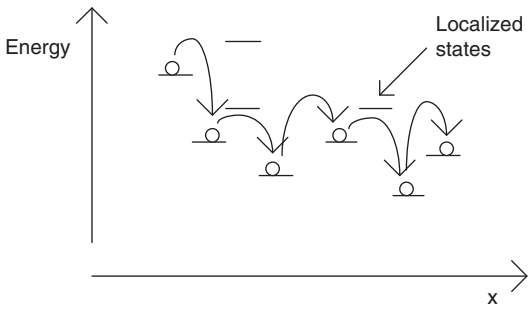
$$\mu(T) \propto T^{-n}, \text{ with } n = 1, 2, 3 \ldots \qquad (4)$$

In practice, n is usually positive which leads to increasing charge mobility when temperature decreases. In general, because the electrons are usually weakly delocalized even in the highly ordered organic crystals, the band widths of the HOMO and the LUMO are small compared to energy bands found in the inorganic semiconductors. As a result, room temperature charge mobilities observed in organic semiconductor crystals can only reach values in the range 1–20 cm^2/Vs [2]. Band-like charge transport has been observed in small-molecules and in single-crystal organic semiconductors (such as rubrene) formed by vapor deposition process. As a matter of fact, in the majority of organic semiconductors, traps and defects are formed during deposition which tends to destroy band-like properties.

Polaron Transport

A polaron is a quasiparticle composed of a charge carrier and its induced polarization field. In many organic materials, due to the low charge

mobilities, carriers tend to polarize their surrounding lattice. As a result, polarization fields are formed around the carriers, which can no longer be considered as "naked." Instead, the carriers will be localized in potential minima created by the so-called molecular deformations [1]. In other words, a charge is trapped by the deformation it induces. Such an entity is known as a "polaron." Polarons can move between molecules similar to the carriers except that they also carry the deformations along. In many disordered molecular organic semiconductors, deformations associated with the trapped charges can be considerable and conduction mechanisms characterizing polaron transport are under intensive research by many research groups across the world.



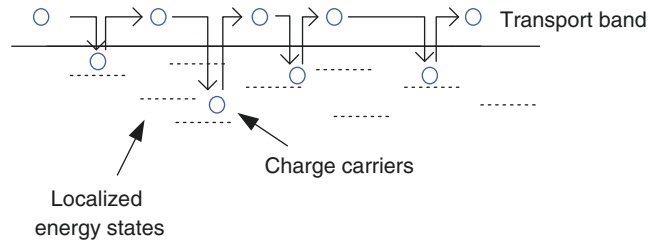
Variable Range Hopping (VRH) Transport

For most organic semiconductors such as polymers and oligomers, their molecular structures are highly disordered and have considerable densities of defects and traps. The energy band diagrams are no longer suitable to describe the densities of states as these energy states are now localized. Furthermore, band-like charge transport can no longer explain the observed low charge mobilities and the fact that their values increase with temperature (as opposed to what is observed in band-like charge transport). One of the widely accepted theories, known as the variable range hopping (VRH) transport, is proved to give a reasonable explanation by describing charge transport in terms of hopping of the charge carriers between localized states as shown in Fig. 6.

Hopping can be used to explain the lower mobility found in disordered organic semiconductors and instead of the power law dependence on temperature as in band-like charge transport, the temperature dependence in VRH charge transport exhibits temperature-dependent activation as well as dependence on the applied electric field as given by [3]

$$\mu(F,T) \propto \exp(-\Delta E/kT) * \exp\left(\beta\sqrt{F}/kT\right) \quad (5)$$

where μ is mobility, F is the electrical field, T is the temperature, ΔE is the activation energy, and β is a parameter related to disorder.



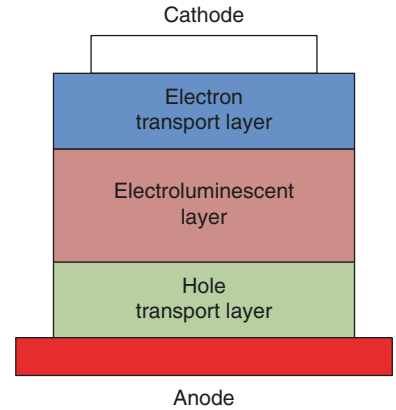
Conduction Mechanisms in Organic Semiconductors, Fig. 6 Hopping transport in organic semiconductors

Multiple Trap and Release (MTR) Transport

Charge transport in OFETs is affected by defects and impurities which exist in the intrinsic part of the organic semiconductors per se and can also be linked to an inferior semiconductor/dielectric interface. As a result, the performance of OFETs is sample-dependent, which is one of the major difficulties in characterizing the properties of OFETs. As mentioned earlier, VRH transport is more suitable to account for charge transport in highly disordered organic semiconductors and, in contrast, another well-established and widely accepted charge transport model known as the "multiple trap and release" (MTR) model is frequently applied to the relatively well-ordered organic semiconductors, such as small molecules and molecular crystals. The basic principle of MTR model includes two important components: (1) a transport band containing delocalized energy states whereby carriers can move freely and (2) the presence of a high density of localized energy states located in the vicinity of the edge of transport band acting as traps. During charge transport, carriers move freely in the transport band with a high probability of being trapped at the localized energy states and then subsequently thermally released into transport band again. The basic illustration of MTR transport process is shown in Fig. 7.

The effective mobility (μ_{eff}) in the MTR model is actually smaller than the "real" mobility (μ_0) in the transport band in the absence of localized energy states and is given by [4]

$$\mu_{\text{eff}} = \mu_0 \alpha \exp(-E_t/kT) \quad (6)$$



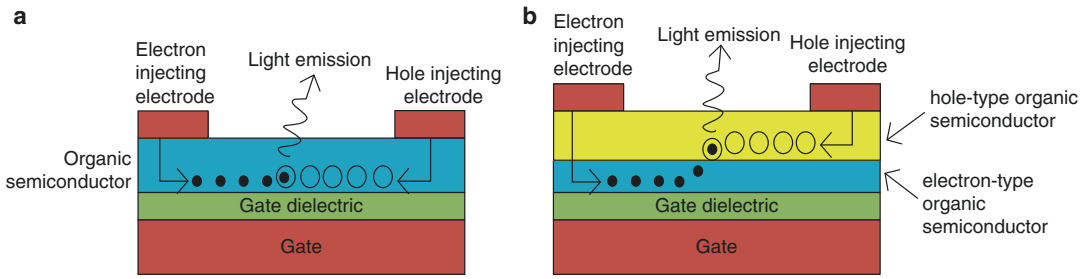
Conduction Mechanisms in Organic Semiconductors, Fig. 7 Multiple trap and release transport (*MTR*) model

where α is the ratio of the effective density of energy states at the edge of the transport band to the density of traps in the localized energy states, and E_t is the energetic distance between the edge of the transport band and the localized energy states. If the localized energy states are energetically dispersive, α and E_t must be recalculated according to the trap distribution.

In the study of OFETs, the MTR model is widely used to account for charge transport due to the fact that it offers a reasonable explanation on the gate voltage dependent mobility usually observed in OFETs. As mentioned above, unlike inorganic semiconductors, organic semiconductors usually have Gaussian density of states (DOS). When a bias is applied to the gate of an OFET, the Fermi level at the dielectric-semiconductor interface will be shifted toward the transport band so that a fair amount of localized energy states near the edge of the transport band will be filled when the Fermi level is located closer to the transport band. As a result, the mobility of the carriers in the MTR model is actually improved because of the reduced density of traps leading to a reduced value of E_t. Therefore, the gate-voltage dependent effective mobility of the carriers in the MTR transport model is given by [5]

$$\mu_{\text{eff}} = \mu_0 \frac{N_c}{N_{t0}} \left[\frac{C_i (V_G - V_T)}{q N_{t0}} \right]^{\frac{T_0}{T} - 1} \tag{7}$$

where μ_0 is the mobility of the carriers in the transport band, N_c the effective density of states at the edge of the transport band, N_{t0} the total density of traps, C_i the capacitance of the insulator per unit area, and T_0 is a characteristic temperature related to the distribution of the DOS.



Conduction Mechanisms in Organic Semiconductors, Fig. 8 Schematic of a typical organic light-emitting diode (OLED)

Devices

Organic Light-Emitting Diode (OLED)

Organic light-emitting diode (OLED) is an electroluminescent diode composed of organic materials serving as the electroluminescent layer and charge transport layer. The typical OLED structure is shown in Fig. 8. During operation of an OLED, a bias voltage is applied between anode and cathode. Holes (electrons) are injected from the anode (cathode) into the electroluminescent layer through the hole (electron) transport layer. Because electrons and holes exist simultaneously in the same layer, there is a high probability that they recombine with each other due to electrostatic forces, leading to radiative emission. Therefore, efficient charge injection from both cathode and anode is requisite for the efficient operation of the OLED and current conduction is dominated by space charge limited current as introduced earlier.

Conduction Mechanisms in Organic Semiconductors, Fig. 9 Schematic illustrations of organic light-emitting field-effect transistors (OLEFETs) with light emission in: (**a**) the single-layer configuration and (**b**) the multilayer configuration

Organic Light-Emitting Field-Effect Transistor (OLEFET)

Organic light-emitting field-effect transistor (OLEFET) is a novel organic device combining the function of current conduction of an OFET with electroluminescence in an OLED. The operation of the OLEFET is actually the same as that of the OFET. However, if proper materials are chosen as the source and the drain to give efficient charge injection and under favorable voltage bias condition, electrons and holes can be injected and transported separately in the OFET channel(s). This type of charge transport is known as ambipolar charge transport, which is unique and only found in an organic field-effect transistor. Furthermore, in ambipolar charge transport if the electrons and holes are allowed to recombine radiatively in an emitter layer to give out light, this type of OFET with electroluminescence functionality is usually called OLEFET. Various device structures have been proposed to realize ambipolar charge transport and light emission in OLEFETs, and, in most cases, the proposed structures fall into two main categories as far as the charge layers are concerned. These are the single-layer OLEFET and multilayer OLEFET as shown in Fig. 9.

Conductivity of Metal Nanowires Studied by Infrared Plasmon-Polariton Spectroscopy, Fig. 1 AFM picture of a typical gold nanowire prepared by EBL on CaF_2. The measured average height of the wire is ca. 60 nm

Definition

Metal nanorods of a few micron length and a much smaller diameter feature strong plasmonic resonances in the infrared region and therefore act rather similar to radio antennas, but the spectral shape of such resonances is related to the conductivity of the nanoantenna material. In the scientific literature, analytic approaches exist which explain the relationship between the electronic conductivity and the resonance spectrum that is due to plasmon polaritons as mixed excitations from free electrons and photons.

Introduction

Metal nanowires are produced, for example, by electron-beam lithography (EBL), electrochemical, and wet chemical methods [1]. Usually they are inspected by scanning electron microscopy (SEM) or atomic force microscopy (AFM) in order to get geometric information; see Fig. 1. But, neither SEM nor AFM can deliver conductivity information of a nanoobject. Electrical measurements are not simple because of the necessary contacts and thus contact resistance comes into play. Nevertheless, because of the importance of the ohmic losses in electronics, many studies already investigated the change of resistivity with the size and the crystalline quality of interconnect structures [2]. The results demonstrate that the two main contributions to the resistivity increase with shrinking height and width of metal interconnects which are surface scattering and grain-boundary scattering. The Matthiessen rule according to which the several contributions add up to the total resistivity [3] was proven to be a valid approximation in most cases.

For plasmonic resonances of nanostructures, increased resistivity leads to higher damping and thus to less-efficient performance of antennas, sensors, and other devices. Vice versa, information on resistivity or conductivity, respectively, is included in the plasmonic resonance spectrum.

Infrared Conductivity of Metals

Below the onset of interband transitions, the infrared (IR) optical properties of metals are determined by the collective oscillations of free-charge carriers called plasmons. The circular frequency (ω)-dependent Drude dielectric function

$$\varepsilon(\omega) = \varepsilon_\infty - \frac{\omega_p^2}{\omega(\omega + i\omega_\tau)} \qquad (1)$$

is a good description of that behavior [4]. Effects from interband transitions on the background polarizability are included in ε_∞. This background permittivity can have values clearly above 1, which becomes important in the near infrared where the negative real part of the Drude term reaches the same order of magnitude. For gold and silver, ε_∞ becomes frequency dependent and complex in the visible, but for other metals like iron, chromium, and platinum, such behavior starts already in the mid-infrared, and the application of the models in this article is then restricted to the far IR below about 1000 cm^{-1} (in wave numbers). The Drude parameters ω_p and ω_τ describe the plasma frequency and the relaxation rate of the free charge carriers, respectively. Frequency-independent parameters (see Table 1) are in reasonable accord with the IR optical

Conductivity of Metal Nanowires Studied by Infrared Plasmon-Polariton Spectroscopy, Table 1 Drude parameters for selected metals at room temperature from the data collection by Ordal et al. [5]. The parameters are given as wave numbers $\varpi = \omega/(2\pi c)$ in cm^{-1} units. They were derived from fits to far and mid-IR spectra of polycrystalline bulk material (ε_∞ was set equal to one)

	ω_τ	ω_p
Gold	215	72,800
Silver	145	72,700
Aluminum	660	119,000

behavior of such metals where only s and p electrons contribute to the conductivity, for example, aluminum, silver, and gold (but not iron). With ω_p much higher than IR frequencies and $\omega_\tau << \omega_p$, the Drude dielectric function has a strong negative real part in the IR. For ω_τ spectrally located in the mid-IR (typical situation occurring for iron or defect-rich noble metals), the skin depth in absorbing region is

$$\delta \approx \frac{c}{\omega_p}\sqrt{\frac{2\omega_\tau}{\omega}}, \qquad (2)$$

but it is $\delta \approx c/\omega_p$ for $\omega_\tau << \omega$ in the reflecting region (c is the vacuum velocity of light). Typical values for skin depths of metals in the mid-IR are of the order of a few 10 nm and thus of the same order of magnitude as the diameters of typical plasmonic structures used in sensing applications. Any increase in resistivity may lead to a strong increase in the skin depth and thus significantly increases the ratio between absorption and reflection [4].

In the dc limit, the Drude parameters determine the dc resistivity $\rho_{dc} = \omega_\tau / \left(\varepsilon_v \omega_p^2\right)$ [3]; ε_v is the vacuum permittivity. Slight deviations from the IR optical parameters may occur due to an anisotropy of scattering [4] and the energy dependence of many body effects [6].

Electron Scattering

From a variety of studies, it is known that, as theoretically predicted, the contribution $\omega_{\tau s}$ of electronic surface scattering to resistivity increases directly proportional to the inverse wire diameter (with a proportionality factor depending on surface roughness and surface chemistry), e.g., [2] and references therein, and, according to Matthiessen's rule, [3] has to be added to the defect scattering rate $\omega_{\tau d}$. Therefore, the total electronic relaxation rate (inverse lifetime) is

$$\omega_\tau = \omega_{\tau e}(t,\omega) + \omega_{\tau p}(t) + \omega_{\tau s} + \omega_{\tau d} \qquad (3)$$

with $\omega_{\tau e}$ and $\omega_{\tau p}$ as the electron–electron and the electron–phonon scattering rate, respectively [2–4].

Above temperatures t of about 10 K, the temperature-dependent term in electron–electron scattering is small compared to electron–phonon scattering [3, 4]. The frequency-dependent term in electron–electron scattering is also negligible for metals with conduction carried by s and p electrons only [5, 6], like, for example, Au in the infrared where the dielectric function follows the simple Drude model with a constant ω_τ. The temperature dependence of ω_τ is almost due to the temperature-dependent number of phonons. With the Debye temperature θ_D, the Debye model for phonons leads to the Bloch–Grüneisen relation [7] for the scattering rate

$$\omega_{\tau p} \propto \left(\frac{t}{\theta_D}\right)^5 \int_0^{\theta_D/t} \frac{z^5}{(e^z - 1)(1 - e^{-z})} dz \qquad (4)$$

for a free electron gas in the dc limit. This relation predicts $\omega_\tau \propto t/\theta_D$ for $t >> \theta_D$, $\omega_\tau \approx \omega_{\tau d} + \omega_{\tau s}$ for $t << \theta_D$, and a transition region with $\omega_\tau \propto (t/\theta_D)^5$ (Bloch relation [3]), respectively. In the infrared, this relation is no more valid since additionally to the electron and phonon, also a photon with energy $\hbar\omega$ is involved, and the scattering rate

$$\omega_{\tau p} = \frac{1}{\tau_0}\left[\frac{2}{5} + 4\left(\frac{t}{\theta_D}\right)^5 \int_0^{\theta_D/t} \frac{z^4}{e^z - 1} dz\right] \qquad (5)$$

derived by Holstein is considered as a better approximation [8]. The rate $1/\tau_0$ depends on the kind of metal and could be approximated by

Holstein's bulk dc-scattering rate at sufficiently low temperature [4].

Granular Metal

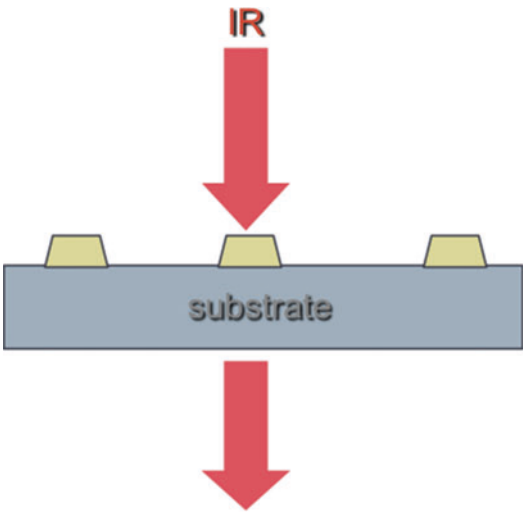
Beyond the percolation threshold, the IR optical properties of conductive but granular metal films can be described by a Drude-type dielectric function ε^* with an effective plasma frequency $\omega_{p,eff}$. The analytic approach to the effective dielectric function ε_{eff} of inhomogeneous media that originally was developed by Bruggeman [9],

$$F\frac{\varepsilon-\varepsilon_{\text{eff}}}{\varepsilon+(D-1)\varepsilon_{\text{eff}}}+(1-F)\frac{\varepsilon_{\text{host}}-\varepsilon_{\text{eff}}}{\varepsilon_{\text{host}}+(D-1)\varepsilon_{\text{eff}}}=0, \tag{6}$$

with the spatial filling factor F, dimension D, and a host medium with ε_{host} can be used to estimate the effective Drude parameters. For a metal-island film $D = 2$ and in vacuum, without adsorbates or cover layers, $\varepsilon_{host} = 1$. With $1/\varepsilon \approx 0$ which is a valid approximation below a certain frequency, it follows $\varepsilon_{eff} = (2F - 1)\varepsilon$. Furthermore, with $\varepsilon_{eff}/F = \varepsilon^*$, a relation that accounts for equal absorption in both the models, the result is $\omega^2_{p,eff} = (2 - 1/F)\omega^2_p$. For $D = 3$ the same approximation leads to $\omega^2_{p,eff} = \omega^2_p(3F - 1)/(2F)$. For $D = 2$, the lowering of the squared-effective plasma frequency is more pronounced than for the $D = 3$ case. So, far-field spectra are especially sensitive to a morphology consisting of one layer of grains, which is mostly relevant for metal nanostructures [10]. The grainy structure of the wire in Fig. 1 could be clearly recognized. Upon annealing the morphology can be changed towards larger grains.

Infrared Plasmonic Resonances

Very similar to radio frequency (RF) antennas, resonantly excited plasmonic nanostructures act as optical antennas that concentrate energy of electromagnetic radiation to a confined volume of sub-wavelength scale. For example, metallic nanorods ("nanoantennas") with μm-sized lengths L show plasmonic resonances in the IR spectral range. Related to the not-negligible skin depth δ, the simple $\lambda/2$-dipole behavior known from RF antennas, where the relationship between L and the resonant wavelength λ_{res} is given by $2\ L = \lambda_{res}$, is not valid for nanoantennas at optical (including IR) frequencies [1]. The modified relation for cylindrical rods



$$2L = \lambda_{\text{eff}} = n_2\left(\lambda_{\text{res}}/\lambda_{\text{p}}\right) + n_1 \tag{7}$$

(for the radius $R << L$) where λ_p denotes the plasma wavelength of the antenna's material better describes the optical antenna behavior in the case $\omega_\tau << \omega_{res}$ and makes clear that $\lambda_{res} \sim 1/\omega_p$ [11]. Thus granularity effects the resonance position; see the lowered effective plasma frequency above. The coefficients n_1 and n_2 depend on R and on the dielectric properties ε_∞ and ε_s, the dielectric constant of the nonabsorbing surrounding medium at the resonance frequency:

$$n_1 \approx R\left\{\left[2\pi\left(13.74 - 0.12\cdot\frac{\varepsilon_\infty + 141.04\varepsilon_s}{\varepsilon_s}\right)\right] - 4\right\},$$
$$n_2 \approx \frac{2\pi R}{\varepsilon_s}\cdot 0.12\cdot\sqrt{\varepsilon_\infty + 141.04\varepsilon_s}. \tag{8}$$

The metal was described as a free-electron gas according to the Drude model with negligible relaxation rate ω_τ compared to photon frequencies ω. Such conditions are fulfilled for perfect, crystalline gold (clearly also silver and copper) nanorods in the mid-IR, but not in case of strong defect scattering when δ becomes frequency dependent.

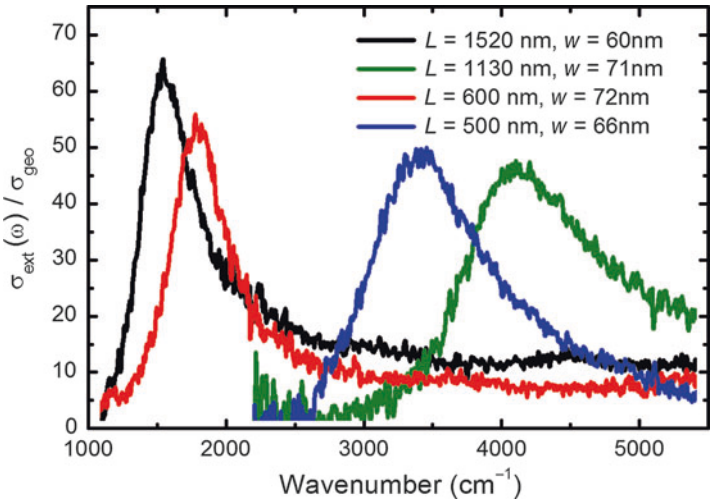
Plasmonic extinction in the IR (e.g., as measured in normal transmittance geometry, see Fig. 2, with polarization along the long-nanowire axis and the nanowire on a substrate that without nanowire is used for the reference spectrum [1]) contains an important contribution from absorption. This contribution becomes smaller (compared to scattering) for larger R (or larger height h and width w) of the antenna. As a rough approximation, these effects can be described within the radiation-corrected

Conductivity of Metal Nanowires Studied by Infrared Plasmon-Polariton Spectroscopy, Fig. 2 Scheme of the IR transmittance measurement at normal incidence of light. For studies of individual wires, the focal plane should be as small as possible but should include the full wire. The reference measurement has to be performed on the identical bare substrate with the same IR optics. The polarization of the IR light is important

quasistatic approximation that allows first-order estimates of resonances also for particles substantially larger than 1 % of wavelength if the incident light is uniform across the object, i.e., for IR antennas at normal incidence of light up to few 10 nm in diameter [12, 13]. In this approximation, for the fundamental resonance and $\omega_\tau << \omega$, the scattering cross section

$$\sigma_{\mathrm{sca}} = \omega_{\mathrm{p}}^2 \frac{Vr}{n_{\mathrm{s}} c} \times \frac{\omega^4 T_{\mathrm{L}}}{\left[\left(\omega_{\mathrm{res}}^2 - \omega^2\right)^2 + \omega^2 \left(\omega_\tau + \omega^2 T_{\mathrm{L}}\right)^2\right]} \tag{9}$$

and the absorption cross section



$$\sigma_{\mathrm{abs}} = \omega_{\mathrm{p}}^2 \frac{Vr}{n_{\mathrm{s}} c} \times \frac{\omega^2 \omega_\tau}{\left[\left(\omega_{\mathrm{res}}^2 - \omega^2\right)^2 + \omega^2 \left(\omega_\tau + \omega^2 T_{\mathrm{L}}\right)^2\right]} \tag{10}$$

differ in their asymmetric frequency-dependent spectral shape; notice the different exponents of ω in the two numerators. $T_{\mathrm{L}} = Vrn_{\mathrm{s}}\,\omega_{\mathrm{p}}{}^2/(6\pi c^3)$ is the Larmor-time parameter (with the vacuum velocity c of light) depending on the volume V (where the electrons are excited in the particle), the refractive index n_{s} of the surrounding medium, and the local-field ratio r [14]. For a spheroid in the quasistatic approximation, $r = \varepsilon_{\mathrm{s}}/[\varepsilon_{\mathrm{s}}+F(\varepsilon_\infty-\varepsilon_{\mathrm{s}})]$ with F as the depolarization factor [15]. For a sphere, for example, $r = 3\varepsilon_{\mathrm{s}}/(\varepsilon_\infty + 2\varepsilon_{\mathrm{s}})$ for an infinitely long needle $r = 1$ which is a reasonable approximation also for nanowires. For a plasmonic dipole of an infinitesimally small volume, T_{L} becomes also infinitesimally small and the damping of the oscillator gets equal to the electronic scattering rate ω_τ. However, related to the scattering of light in case of larger objects with finite V, the radiation damping rate $\omega_{\mathrm{rad}} = \omega^2 T_{\mathrm{L}}$ has to be included in the denominators of both the quasistatic expressions σ_{abs} and σ_{sca}. Typical values of ω_{rad} at $\omega = \omega_{\mathrm{res}}$ for IR nanoantennas from gold (with h and w similar to 50 nm, $n_{\mathrm{s}} \geq 1$) are of the order of the relaxation rate and thus are not negligible.

In experiments, resonances may appear much broader compared to the expectation based on the damping rates if the symmetry of the cylindrical shape is broken due to production errors. Then, for example, the even-order resonances (at 2 ω_{res}, usually not dipole active [1]) can be excited also by normal incidence of light. Further (Gaussian) broadening appears due to random parameter variations in a nanowire ensemble. In ensembles with interwire distances of the order of the resonance wavelength and below, nanowire interaction is an important issue in [16] not presented here.

Infrared Spectroscopy of Metallic Nanowires

With IR microspectroscopy (intense light sources are preferred), the far-field extinction related to a nanowire's plasmonic resonances can be detected well if a small aperture with the wire in its center is used [1, 16]. The IR spectra benefit from a carefully measured reference spectrum from the bare (identical) substrate. The extinction cross section $\sigma_{\mathrm{ex}} = \sigma_{\mathrm{abs}} + \sigma_{\mathrm{sca}}$ of a single nanoparticle

Conductivity of Metal Nanowires Studied by Infrared Plasmon-Polariton Spectroscopy, Fig. 3 Individual nanowire's extinction (normalized to the geometrical shadow) measured at room temperature in normal transmittance for an electric field parallel to the long axis of the wire. The transmittance is normalized to the IR spectrum of the ZnS substrate without any wire. The geometrical parameters (length L and width w) of the electron-beam lithographically produced gold nanostripes are given in the figure. The stripes' height was about 60 nm

(see examples in Fig. 3) on a thick transparent substrate (with refractive index $n_{\text{substrate}}$) can be estimated from the relative transmittance spectrum $T_{\text{rel}}(\omega)$ at normal incidence of light via the relation $\sigma_{\text{ext}} = A_0 \cdot (1 - T_{\text{rel}}) \cdot (n_{\text{substrate}} + 1)/2$ where A_0 is the focal area (with one particle in the center) [1, 16]. If the preconditions mentioned above are fulfilled, a fit based on the Eqs. 8 and 9 can deliver the parameters ω_τ and ω_{res} (and thus λ_{res} that via Eqs. 7 and 8 can be compared to the value expected from the ideal plasma frequency).

Conclusion

Bringing together well-established knowledge on metal optical properties, metallic resistivity, and optical antennas, the strong relationship between electrical conductivity parameters and the fundamental plasmonic resonance of nanowires in the infrared is clarified.

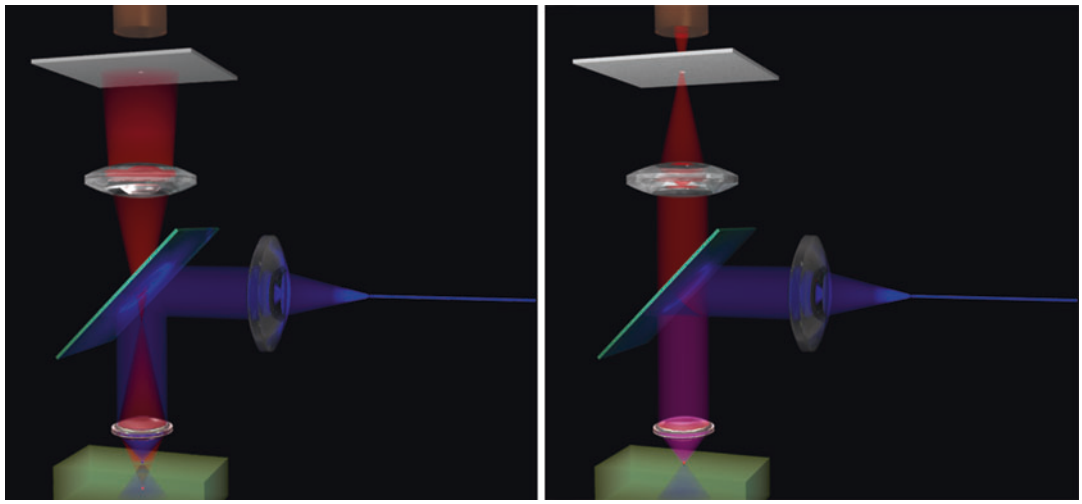
Confocal scanning optical microscopy (CSOM); Laser scanning confocal microscopy



Definition

A confocal laser scanning microscope (CLSM) images a point light source used for excitation onto the sample via the objective lens and images the excited focal volume onto a point detector using reflected, transmitted, emitted, or scattered light. In contrast to conventional microscopes, this scheme permits strong rejection of out-of-focus light and optical sectioning of the sample. In order to obtain an image, the focal volume must be scanned relative to the sample. Scanning can be performed in the lateral as well as in the axial directions, and three-dimensional images of the sample can be generated in this way.

Operating Principle

Figure 1 illustrates the working principle of a fluorescence confocal microscope. A point light source, here the end of an optical fiber carrying the excitation light, is imaged onto the sample by the objective lens via a beam splitter. Emitted light from the focal spot is imaged through the beam splitter onto a pinhole via an auxiliary lens. The light is registered by the detector, because it passes through the pinhole (left-hand side of Fig. 1). Fluorescence from a fluorophore at an out-of-focus position in the excitation cone, on the other hand, arrives at the screen defocused. Therefore, only a small fraction of it passes through the pinhole and reaches the detector. The effect is understated by the schematic figure and actually much stronger in a real microscope because of the short focal length of the objective lens. The optical sectioning capability is the core of confocal microscopy and allows to render the object three-dimensionally under different angles by appropriate software once a stack of images at different depths has been acquired. In addition, the lateral resolution is slightly improved in confocal microscopy, compared to conventional microscopy, when the pinhole is small. On the other hand, an image can be acquired in this way only by serial scanning of the sample or of the excitation beam (for technical improvements in this respect see section "Confocal Microscopy Involving Modified Illumination").

Because a CLSM operates with light, it may be used to image many different physical quantities. These may be simply reflected or transmitted intensity (brightfield confocal microscopy) or the

Confocal Laser Scanning Microscopy, Fig. 1 Principle of confocal laser scanning microscopy, demonstrating the strong rejection of out-of-focus light

intensity of fluorescence excited in the sample (fluorescence confocal microscopy). Other options include polarization and phase of reflected or transmitted light, as well as the intensity, wavelength, lifetime, time correlation, or recovery after photobleaching of fluorescence from the sample or intensity, wavelength, and polarization of inelastically (Raman) scattered light. Moreover, a nonlinear response of the sample to the optical excitation near the laser focus, based, for example, on multiphoton excitation, second harmonic generation, or stimulated scattering processes may be used for confocal microscopy. Some of these options will be discussed in section "Variants of Confocal Laser Scanning Microscopy."

Optical sectioning and three-dimensional image acquisition being the essential feature of confocal optical microscopy, it is worth mentioning here that an alternative (diffraction-limited) brightfield optical microscopy technique with similar capability is digital holographic microscopy, although this technique is far less widely known and used. Here, the object is reconstructed from an intensity camera image and no scanning is necessary. Moreover, a phase image is obtained in addition to an amplitude image. Significant improvements in object reconstruction algorithms have been made in recent years, and lens-based versions with external reference beam as well as lensless versions have been demonstrated. Lens-based instruments with external reference beam are commercially available.

Basic Theory of the Confocal Microscope

The spatial resolution of modern high-quality conventional as well as confocal microscopes is limited by diffraction. This means that within the design spectral range of the objective lens aberrations, such as spherical aberration, astigmatism, coma, field curvature, distortion, and chromatic aberration, have a significantly smaller impact on the resolution of the microscope than diffraction. An important exception to this statement arises from aberrations due to refraction, when sample regions well inside refracting samples have to be imaged.

Most modern microscope objectives are now infinity corrected, that means they are corrected for forming an image at infinity. A tube lens is in this case required to form a real image at finite distance. The limitations by diffraction are, however, in any case dominated by the objective lens and not by the tube lens. This is due to the dependence of the diffraction limit on the opening angle of the rays contributing to the image, which is much smaller for the tube lens than for the objective lens.

Point Spread Function of the Confocal Microscope

The three-dimensional intensity distribution in the image space corresponding to a single-point object, demagnified by the magnification of the optical system, is called the (intensity) point spread function (PSF) of the lens. The PSF of a confocal microscope with an infinitesimally small pinhole is given by [1, 2]:

$$\mathrm{PSF}_{\mathrm{CF}}(x,y,z) = \mathrm{PSF}_{\mathrm{ill}}(x,y,z) \cdot \mathrm{PSF}_{\mathrm{det}}(x,y,z) \tag{1}$$

Here, $\mathrm{PSF}_{\mathrm{CF}}$, $\mathrm{PSF}_{\mathrm{ill}}$, and $\mathrm{PSF}_{\mathrm{det}}$ represent the point spread functions for the confocal imaging and the illumination and detection paths, respectively. Neglecting the contribution from the tube lens, as well as aberrations of the objective lens, the latter two functions are simply the point spread functions of a simple lens, which, in the paraxial and scalar approximation, can be calculated by means of the Huygens-Fresnel principle as [3]

$$\mathrm{PSF}(x,y,z) = |h(x,y,z)|^2 \tag{2}$$

with

$$h\left(\vec{r}\right) = \frac{\mathrm{C}'}{\lambda}\int\int_{A}\frac{\mathrm{e}^{iks}}{s}\mathrm{dA} \approx \frac{\mathrm{C}}{\lambda}\int\int_{\Omega} e^{-ik\vec{q}\cdot\vec{r}}\mathrm{d}\Omega. \tag{3}$$

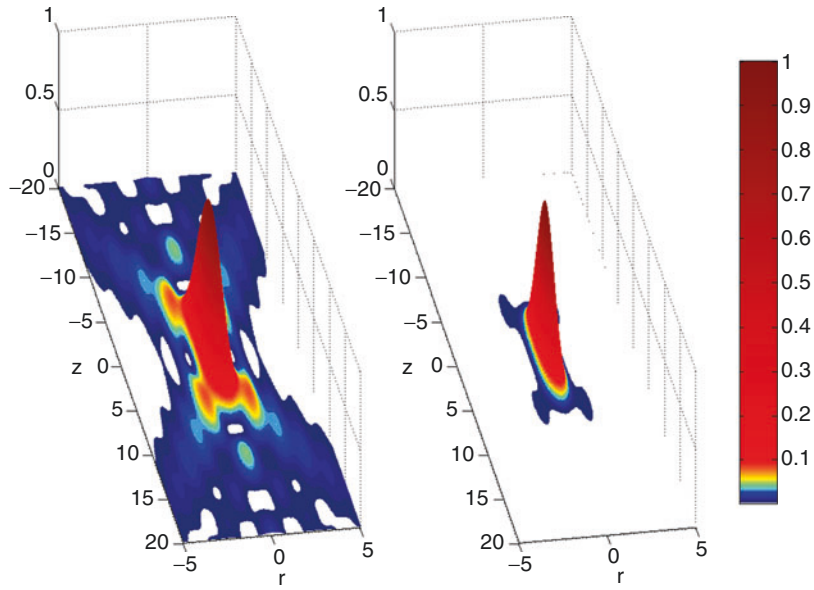
Here, $h\left(\vec{r}\right)$ represents the scalar complex amplitude of the field in the image space at a position $\vec{r} = (x,y,z)$ relative to the location of the geometric focus; λ is the wavelength, $k = 2\pi/\lambda$: s is the distance between the point P at position $\vec{r}$ in the image space and a point Q at position $f\,\vec{q}$ in the pupil A of the lens of focal length f: $\vec{q}$ is a unit vector in the direction of Q: Ω is the solid angle subtended by the aperture of the lens as seen from the origin at the geometric focus, and C and C′ are constants. Equation 3 assumes homogeneous illumination of the lens. Inhomogeneous illumination can be taken into account by multiplying the integrand with a corresponding pupil function (compare section "Apodization"). For a confocal microscope operating in reflection or transmission modes $\mathrm{PSF}_{\mathrm{ill}}(\mathrm{x,\ y,\ z}) \approx \mathrm{PSF}_{\mathrm{det}}(\mathrm{x,\ y,\ z})$, and both functions are then identical to the one given in Eq. 2. This results in

$$\mathrm{PSF}_{\mathrm{CF}}(x,y,z) = |h(x,y,z)|^4. \tag{4}$$

Experimentally, this function would be observed when a point object is scanned through the focus of the instrument in both cases. It should be kept in mind here that the paraxial approximation is contrary to the actual typical situation in optical microscopy. The paraxial approximation, nevertheless, works surprisingly well even for N.A. ≈ 0.5 ($\theta_0 = 30°$ in the case of a dry lens, see below) and gives reasonable estimates of the diffraction limit even for higher numerical aperture objective lenses. Deficiencies of the scalar approximation will be discussed in section "Deficiencies of the Scalar and Paraxial Approximation: Effects of the Vector Character of Light."

Figure 2 displays the three-dimensional intensity point spread function of a conventional (a) and a confocal (b) microscope calculated according to Eqs. 1 and 3. The numerical aperture of the objective lens is N.A. = 0.5. z is the coordinate along the axis of the lens and r the coordinate perpendicular to the optical axis, measured in wavelengths. The drastic reduction in side lobes for a confocal microscope is immediately evident. This also leads to drastic reduction in laser speckle in the case of coherent illumination.

Single-Point Resolution in the Focal Plane



In the focal plane ($z = 0$), the PSF of the conventional microscope, as calculated from Eq. 3, coincides with the well-known Airy pattern

$$\mathrm{PSF} = \left(\frac{2J_1(\mathrm{v})}{\mathrm{v}}\right)^2 \tag{5}$$

with

$$\mathrm{v} = kr \cdot n\sin\theta_0 = kr \cdot \mathrm{N.A.} \tag{5a}$$

Here, r is the distance from the axis; θ_0 is the angle of a marginal ray passing through the aperture

Confocal Laser Scanning Microscopy,
Fig. 2 Intensity point spread function of a conventional (**a**) and a confocal (**b**) microscope in the scalar and paraxial approximations. The numerical aperture of the objective lens is N.A. = 0.5. z is the coordinate along the axis of the lens and r is the lateral dimension, both measured in wavelengths

toward the geometric focus, relative to the optical axis; and n is the refractive index in the image space. From this expression, the lateral full width at half maximum (FWHM) of the PSF of the conventional microscope

$$\mathrm{FWHM} = \frac{0.51\lambda}{\mathrm{N.A.}} \tag{5b}$$

is easily calculated. Equation 3 yields

$$\mathrm{PSF_{CF}} = \left(\frac{2\mathrm{J}_1(\mathrm{v})}{\mathrm{v}}\right)^4 \tag{5c}$$

for the PSF of the confocal microscope in reflection mode, and therefore

$$\mathrm{FWHM_{CF}} = \frac{0.37\lambda}{\mathrm{N.A.}}. \tag{5d}$$

Equations 5b and 5d demonstrate the enhancement in lateral (single-point) resolution for a confocal microscope relative to a conventional one, in the case when the pinhole is closed completely. As an example, for $\lambda = 488$ nm, N.A.=0.9, FWHM = 277 nm, and $\mathrm{FWHM_{CF}} = 201$ nm.

Single-Point Resolution on the Axis: Depth Response

Similarly, the PSF of the conventional microscope on the optical axis is calculated from Eq. 3 as

$$\mathrm{PSF}(u) = \left(\frac{\sin(u/4)}{u/4}\right)^2 \tag{6}$$

with

$$u = nkz\sin^2\theta_0. \tag{6a}$$

It turns out that the definition

$$u = 4kz\sin^2(\theta_0/2) = 2nkz(1 - \cos\theta_0) \tag{6b}$$

which is equivalent to Eq. 6a in the paraxial approximation is more appropriate at higher numerical apertures. The corresponding FWHM of the depth response is therefore

$$\mathrm{FWHM} = \frac{0.89\lambda}{n(1 - \cos\theta_0)} \tag{6c}$$

for the conventional microscope. Correspondingly, for the confocal microscope

$$\mathrm{PSF}_{\mathrm{CF}}(u) = \left(\frac{\sin(u/4)}{u/4}\right)^4 \tag{6d}$$

and

$$\mathrm{FWHM}_{\mathrm{CF}} = \frac{0.64\lambda}{n(1-\cos\theta_0)}. \tag{6e}$$

For the parameters used in the example above, $\lambda = 488$ nm, N.A. $= 0.9$, FWHM $= 770$ nm, and $\mathrm{FWHM}_{\mathrm{CF}} = 554$ nm. The FWHM of the point spread functions on the optical axis of the microscope is therefore about three times larger than the lateral FWHM for the conventional as well the confocal microscope, although the precise value depends on the numerical aperture and although the scalar theory used here is not applicable at large numerical aperture (see section "Deficiencies of the Scalar and Paraxial Approximation: Effects of the Vector Character of Light").

V(z)

A clearer demonstration of the different optical sectioning capabilities of the conventional and confocal microscopes is obtained with planar objects instead of point objects. The depth response of a confocal microscope operating in reflection is often characterized by axially scanning a mirror through the focus position and registering the light intensity behind the pinhole during the scan. The corresponding amplitude function is called $V(z)$, an expression coined originally for the acoustic microscope, which is also a confocal instrument and to which the same scalar theory is applicable. Because the image of the illuminating infinitesimal pinhole is moving by a distance of $2z$ when the mirror moves by a distance z, the intensity detected behind the pinhole is derived from Eq. 6b, by replacing u by $2u$:

$$\begin{aligned} I(z) &= |V(z)|^2 = \left|\frac{\sin(u/2)}{u/2}\right|^2 \\ &= \left|\frac{\sin(nkz(1-\cos\theta_0))}{nkz(1-\cos\theta_0)}\right|^2 \end{aligned}. \tag{7}$$

This equation predicts a central maximum of width

$$\mathrm{FWHM}_{\mathrm{CF}} = \frac{0.44\lambda}{n(1-\cos\theta_0)} \tag{8}$$

which, in paraxial approximation $\theta_0 << 1$ for a dry lens, becomes

$$\mathrm{FWHM}_{\mathrm{CF}} = \frac{0.89\lambda}{\mathrm{N.A.}^2}. \tag{9}$$

Equation 7 also implies symmetric side lobes for negative and positive defocus. As an example, for a dry lens of N.A. $= 0.8$ and an operating wavelength of 488 nm, Eq. 8 yields FWHM $= 537$ nm. In a conventional microscope, on the other hand, the signal received by a large area detector would be independent of the position of the mirror.

The simple theory presented so far predicts a symmetric $V(z)$ function. Whereas the width of the main peak of the $V(z)$ is typically very close to measurements performed with real lenses, the aberrations present in any real objective lens typically lead to deviations as far as the side maxima are concerned and in particular to asymmetry in $V(z)$ for positive and negative defocus. This may be used for quantitative characterization of, for example, the amount of spherical aberration present in the optical system. Interferometric versions of confocal microscopy, however, have been more traditionally used for this purpose.

Two-Point Resolution: Rayleigh and Sparrow Criteria

The single-point resolution of the confocal microscope, as given by the PSF discussed above, is in most cases not the relevant quantity to judge the resolution of the instrument, because what is really desired is the capability to resolve certain details of a microscopic object consisting of various parts. It is therefore important to quantify the two-point resolution of the instrument, which means the capability to resolve two-point objects close to each other. There is some arbitrariness in this definition, because it depends on the subjective judgment, under which conditions two-point objects are resolved in an image. Only the lateral two-point resolution will be discussed here.

The Rayleigh criterion defines two-point sources as resolved, if the image of the second

point lies at the first zero of the image of the first one or at a larger distance. This leads to a lateral resolution

$$d_{\mathrm{R}} = \frac{0.61\lambda}{\mathrm{N.A.}} \tag{10}$$

for the conventional microscope and

$$d_{\mathrm{R,CF}} = \frac{0.56\lambda}{\mathrm{N.A.}} \tag{11}$$

for the confocal microscope, just 8 % less than for the conventional microscope. In the case of coherent sources, d_{R} depends on the phase difference of the sources: whereas two out-of-phase coherent sources can be clearly resolved, because there will be a zero of intensity halfway between the images of the two sources, the sources cannot be resolved, if they are in phase with each other, because the maximum will lie in the middle between the images of the two individual sources.

There is another criterion for the two-point resolution, which is more generally applicable, because it does not refer to a zero of the response function. The Sparrow criterion states that two sources are considered to be resolved, when the intensity halfway between the two images is the same as the one at the individual image locations. For incoherent illumination, this results in

$$d_{\mathrm{S}} = \frac{0.51\lambda}{\mathrm{N.A.}} \tag{12}$$

for *both* the conventional and confocal microscopes.

Coherence in Brightfield and Fluorescence Microscopy

The imaging of extended objects differs significantly for the conventional and confocal microscopes, respectively. For a CLSM operating in brightfield (reflection or transmission) mode, the imaging is spatially coherent, because the illumination generates a spatially coherent field distribution in the focus of the objective lens, as given by the complex amplitude point spread function of the objective lens. For a CLSM in reflection mode, this field distribution has to be multiplied by the reflectance R of the sample, and this weighted field distribution is then imaged onto the pinhole implying convolution with the combined amplitude point spread function of the objective and pinhole relay lenses. Assuming imaging of the object onto the pinhole by the same objective lens that is used for excitation and neglecting contributions to the point spread function from the pinhole relay lens in the second imaging step, the intensity behind the infinitesimally small pinhole can therefore be written as the convolution

$$I = \left| \iiint h(x,y,z) R(x,y,z) h(-x,-y,-z) \mathrm{d}x\mathrm{d}y\mathrm{d}z \right|^2 . \tag{13}$$

Here, $h(x,y,z)$ is the amplitude PSF of the objective lens (compare Eq. 3). For the case of an even PSF, Eq. 13 is equivalent to

$$I = \left| h^2 * R \right|^2 \tag{14}$$

that means the signal is given by the absolute square of the convolution of the amplitude PSF of the confocal microscope, $h^2\left(\vec{r}\right)$, with the local amplitude reflectivity of the sample.

In the case of a conventional microscope, on the other hand, the illumination is approximately incoherent and therefore

$$I = |h|^2 * |R|^2 . \tag{15}$$

In reality, for the conventional microscope, imaging is partially coherent, because the emission from each emitting point on the illumination source is imaged, due to diffraction at the condenser aperture, into a finite spatial region, which is occupied by a coherent field due to that point emitter, and the regions in the image space corresponding to neighboring, incoherently emitting points on the source partially overlap on the sample. This is true for critical illumination, where the spatial region would be given by the PSF of the condenser, as well as for Köhler illumination, where the spatial region is the whole illuminated region of the sample.

Fluorescence Confocal Microscopy

Fluorescence imaging is incoherent. Assuming that the fluorescence intensity is proportional to the excitation intensity, the signal obtained in a confocal microscope with an infinitesimally small pinhole is

$$I = \left(|h(\lambda)|^2 |h(\beta\lambda)|^2\right) * f \qquad (16)$$

where it has again been assumed that, as in standard commercial confocal microscopes, the same objective lens is used for excitation and fluorescence imaging, respectively. Here, f represents the distribution of fluorescent centers in the sample, λ the excitation wavelength, $\beta\lambda$ the fluorescence wavelength, and β the ratio of both wavelengths, the Stokes ratio. In the case of several different types of emitters, f would have to be weighted according to the spectral contribution of each emitter to the detected signal, which depends on the filters employed in detection for rejection of the excitation and also on the wavelength-dependent sensitivity of the detector. For a point emitter placed at the focus, the convolution with a δ function just yields the first two terms on the right-hand side of Eq. 16. For a conventional microscope, on the other hand, because the whole sample is illuminated, the single-point resolution is only determined by the intensity PSF of the objective lens at the fluorescence wavelength, and the excitation wavelength is irrelevant.

Effects of Finite Pinhole Size

A finite size of the pinhole is obviously required in order to obtain a measurable signal. This will reduce the lateral resolution as well as the optical sectioning capability. It can be shown [2] that for a single-point object, the lateral resolution is almost unaffected by the size of the pinhole, if

$$v_P = \frac{2\pi r_p}{\lambda M} \sin\alpha \leq 0.5 \qquad (17)$$

where r_P is the radius of the pinhole and M the magnification of the lens. The maximum value allowed by Eq. 17 therefore sets a reasonable value for the pinhole size, if optimum lateral resolution and reasonable signal are desired. As an example, in the case of a 100×/0.8 N.A. objective lens and $\lambda = 514$ nm, a critical diameter of the pinhole of 10.2 µm is calculated from Eq. 17. The depth discrimination, as measured by moving a mirror through focus, on the other hand, is less affected and is essentially unaltered if

$$v_p \leq 2.5 \qquad (18)$$

It is obvious from these equations that the pinhole size must be adapted when the objective lens is changed.

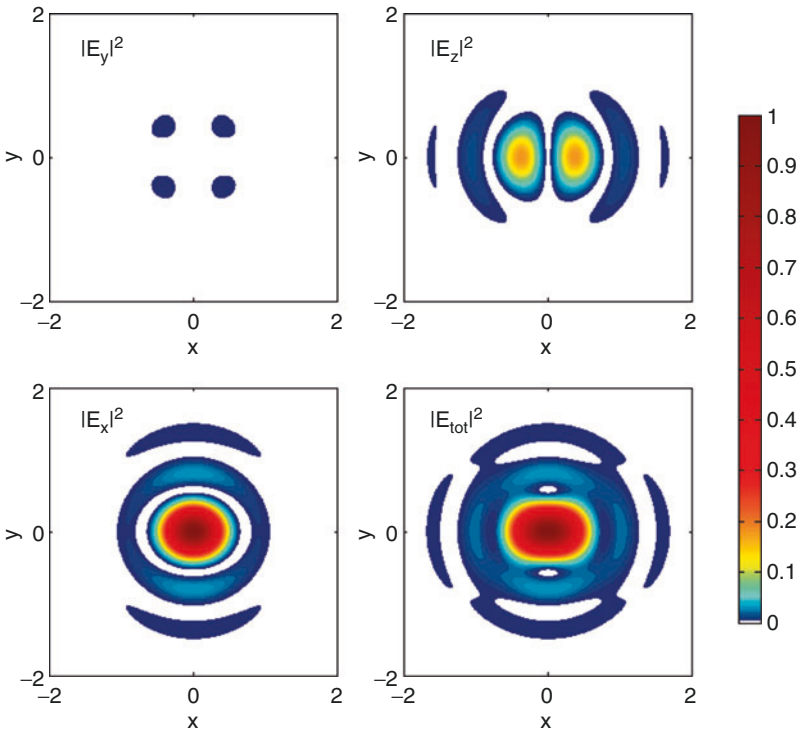
Apodization

Equation 3 assumed rectangular apodization, that is, homogeneous illumination of the lens pupil and neglects reflection losses at the lens. For a given objective lens, rectangular apodization yields the smallest FWHM of the focus in the focal plane, at the expense of larger side maxima, compared to pupil functions falling off toward the edge of the objective lens. It can be achieved only approximately with Gaussian laser beams and is then equivalent to loss of a large fraction of the power of the excitation beam. Gaussian apodization, on the other hand, increases the FWHM, but reduces the side maxima.

Deconvolution

As described by Eq. 16, the image acquisition process in confocal fluorescence microscopy can be modeled as a convolution of the spatially dependent fluorescence of the sample with a point spread function (PSF) of the imaging system. This is true also for conventional non-confocal fluorescence microscopy. In addition, random noise is superimposed on the image. Deconvolution with the PSF would naturally seem the appropriate way to determine the true fluorescence distribution in both cases. Applied to confocal images, the resolution may be improved. In the case of conventional microscopy, optical sectioning and removal of

out-of-focus blur may be achieved by post-processing instead of employing hardware in the optical setup.



In general, the 3D PSF, necessary for this procedure, can be obtained experimentally or analytically. In the experimental methods, images of one or more point-like objects are collected. The problem with this technique lies in the poor signal-to-noise ratio obtainable with very small objects and the fact that the PSF may vary depending on the sample. In analytical calculations of the PSF, aberrations of the optical system are often partially taken into account, whereas, on the other hand, the scalar approximation is most often used and the effects of the vector character of light (compare section "Deficiencies of the Scalar and Paraxial Approximation: Effects of the Vector Character of Light") are neglected.

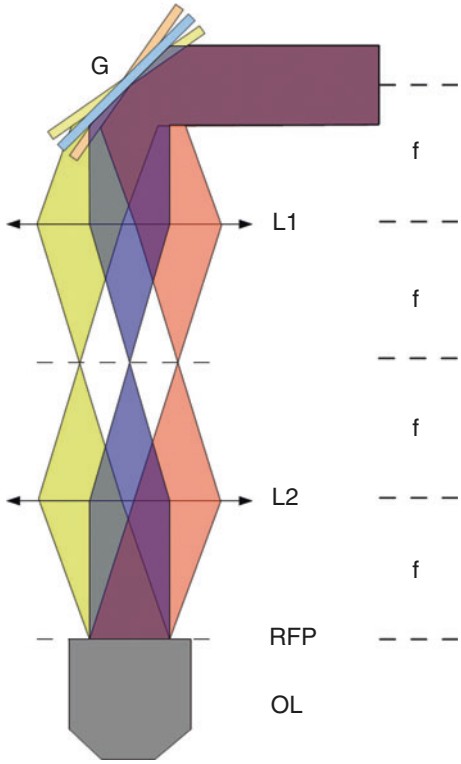
Many 3D deconvolution methods are currently employed and some are available in commercial and noncommercial software packages [4]. The simplest class are *neighboring* methods, in which out-of-focus blur is removed by subtraction of neighboring (filtered) images within a stack. This method does not sufficiently remove noise. In contrast to that, *linear* methods apply deconvolution to the whole stack of images at once. Examples are inverse filtering, Wiener filtering, the linear least squares, and the Tikhonov filtering techniques. The last three methods do not restore high-frequency object components beyond the bandwidth of the PSF, and inverse filtering suffers from noise amplification. All methods are very sensitive to error in the PSF. Therefore, constrained iterative nonlinear algorithms are often employed, in which, starting from a guess for the true object, an error is minimized under certain constraints (positiveness of the image, finite support of the sample, etc.). In cases of strong noise in the image, *statistical* iterative methods (like the maximum likelihood method) are favored. A computational alternative are *blind deconvolution* methods, in which the PSF of the optical system and the "true object" are simultaneously determined in a converging iteration. These methods are, however, computationally demanding and sensitive to noise, and solutions may be nonunique.

Deficiencies of the Scalar and Paraxial Approximation: Effects of the Vector Character of Light

In view of many more recent developments in confocal microscopy, it appears useful to shortly discuss deviations from the simple scalar theory. These deviations become increasingly important with increasing numerical aperture of the objective lens. In the case of linear polarization of the excitation beam, cylindrical symmetry is lost. The field in the focal plane and exactly on axis is then polarized in the direction of the excitation, but, away from the axis, it is elliptically polarized with a longitudinal component pointing in the direction of the optical axis. The intensity PSF becomes elongated and approximately elliptical, with the major axis of the ellipse in the direction of the excitation. Both effects increase with increasing numerical aperture. In the case of linearly polarized excitation, the two-point resolution of an ordinary optical microscope equipped with a well-corrected high numerical aperture objective lens (as well as that of a similar confocal microscope) therefore depends on the orientation of the line connecting the two points relative to the incoming polarization (as well as on the orientation of the dipolar point reflectors or absorbers/emitters). Figure 3 shows the PSF for numerical aperture N.A. = 0.95 and the absolute squares of all electric field components in the focal plane. In the scalar approximation, the lines of constant intensity would, of course, be circles, which is clearly not the case in the figure appearing in the lower-right corner of Fig. 3. Moreover, the maxima of the longitudinal field occur on both wings of the main maximum, along the direction of the incoming polarization (x direction), and the maximum absolute square of E_z is approximately 20 % of that of E_x.

The vector diffraction problem was first solved by Richards and Wolf [5]. A somewhat more physical treatment employs expansion of the field in the image space into vector multipoles centered at the focus [6]. This latter approach is also of interest for matching the focal field distribution to the fields of a dipole via the amplitude distribution and the polarization in the pupil plane. In this way, the coupling of the field to single atoms or molecules can be significantly enhanced, which is of

Confocal Laser Scanning Microscopy, Fig. 3 PSF of a well-corrected microscope objective of a high numerical aperture lens (N.A. = 0.95) for the case of linear polarization of the incoming beam, calculated using the Debye-Wolf integral. A constant pupil function has been assumed here and, correspondingly, reflection losses in the lens have been neglected. z is the coordinate along the axis of the lens and x, y are the lateral coordinates, all measured in wavelengths. The incoming polarization is along the x axis



interest, for example, for quantum optical applications. The vectorial approach is in general also required to treat focusing of other distributions of intensity, phase, and polarization in the pupil plane of the lens. Examples relevant for applications include radially polarized excitation, producing a longitudinally polarized focus, azimuthally polarized excitation, which leads to a doughnut-shaped intensity distribution in the focal plane, or combinations of these distributions with scalar vortices, that means helical phase fronts. A longitudinal focus is essential for tip-enhanced Raman microscopy (TERS, compare section "Confocal Raman Microscopy," ▶ Scanning Near-Field Optical Microscopy), which combines a near-field technique with confocal imaging. Other distributions are relevant for optical tweezers.

Instrumental Details

Scanning Techniques

Whereas scanning the sample is an option, particularly in laboratory setups, many commercial confocal microscopes employ lateral scanning of the laser beam and sample scanning in the vertical direction. Beam scanning is typically achieved using mirrors mounted on galvanometer motors, which allow to vary the angle at which the beam passes the rear focal plane of the objective lens. An example for a telecentric 4f system that allows to vary this angle without displacing the beam in the rear focal plane is shown in Fig. 4.

Recently, resonant galvanometer-based beam scanning systems have become commercially available, which employ torsion spring-based sinusoidal oscillations of the scan mirror with frequencies in the kilohertz range with open-loop operation for the fast scan axis. This permits frame rates on the order of 30 frames per second and in this way allows to study fast processes, such as diffusion in biological cells or to avoid blurring of the image due to movement of organs in in vivo studies. Alternative fast-scanning confocal microscopes are discussed in section "Variants of Confocal Laser Scanning Microscopy."

Excitation Sources and Beam Delivery

Ion lasers, HeNe lasers, diode-pumped solid-state lasers, and diode lasers have all been used as continuous wave light sources in confocal laser scanning microscopy. Argon ion lasers provide a choice of several excitation wavelengths and are therefore still popular in spite of their low efficiency. In order to combine several laser beams, dichroic beam splitters are employed. In many cases, a software-controlled acousto-optic tunable filter (AOTF) selects the excitation wavelength (s) of choice from this combined beam. The AOTF is based on the diffraction of light from ultrasonic waves generated in a birefringent crystal by an ultrasonic transducer. Incident and diffracted waves propagate as ordinary and extraordinary wave in the crystal, respectively, or vice versa and are therefore polarized perpendicular to each other. This allows convenient rejection of the incident light by a polarizer. Because of momentum conservation, the difference in the optical wave vectors of both beams must be equal to the acoustic wave vector. This means that the wavelength of the diffracted beam is controlled by the ultrasonic frequency. In a collinear AOTF, both optical beams and the acoustic wave propagate in the same direction, independent of the optical wavelength.

The optical output of the AOTF is typically fed into an optical fiber, which delivers the beam to the input optics of the confocal scan head of the microscope. In brightfield reflection confocal microscopy, the beam splitter which directs the excitation light toward the objective lens (compare Fig. 1) induces a considerable loss for the excitation as well as for the detected light. This loss is minimized by a 50/50 beam splitter. In fiber-based confocal microscopes, instead of beam splitters, 2 × 2 fiber couplers are typically employed. An improved version would make use of optical circulators, but these are presently not widely available for wavelengths in the visible range. In fluorescence confocal microscopy, the detected wavelength differs from the excitation wavelength and therefore dichroic dielectric beam splitters are used which are highly reflecting (transmitting) at the excitation (detection) wavelength and minimize losses in this way.

Detection

Standard detectors in confocal laser scanning microscopes are photomultipliers, which are in many cases operated in the analogue mode, which means by measuring the anode current and integrating over the pixel dwell time. Photon counting, on the other hand, is typically employed in fluorescence correlation and fluorescence lifetime microscopy (compare section "Variants of Confocal Laser Scanning Microscopy"), where usually avalanche photodiodes with high quantum efficiency and fast response times replace photomultipliers as detectors. Confocal

Confocal Laser Scanning Microscopy, Fig. 5 Tertiary structure of the green fluorescent protein [8]. The fluorescent chromophore, composed of three amino acids is located in the center of the beta-barrel protein cage, length about 4 nm, which prevents quenching of the fluorescence by water

microscopes which allow to spectrally disperse the light passing the confocal aperture often employ a charge-coupled camera (CCD) attached to a spectrograph to register the spectra. Back-illuminated Peltier or liquid nitrogen cooled CCDs provide high quantum efficiency (above 90 % over a wide spectral range) and low background noise, which is important for single molecule detection or when working with less photostable fluorescent probes.

Fluorescent Probes

Many samples are autofluorescent and therefore allow fluorescent imaging without having to introduce additional fluorescent probes. In biological samples, however, autofluorescence is typically weak, and therefore the sample frequently had to be stained with appropriate dyes. The latter, however, are often highly phototoxic in living cells. An important development in light microscopy, including confocal laser scanning microscopy, started in the year 1994 when the green fluorescent protein (GFP, see Fig. 5) from the jellyfish *Aequorea victoria* was genetically expressed in bacteria making them fluorescent at room temperature. In the same way, it is now generally possible to label proteins of interest in biological cells with fluorescent proteins by genetic manipulation, which can be achieved, for example, by injection of a virus vector. The number of fluorescent proteins used in the field has exploded by now and they are widely used in optical microscopy because of their considerably reduced phototoxicity, brightness, and photostability [7]. Genetically modified fluorescent proteins from *Aequorea victoria* now cover the spectral range from the deep blue to yellow and others derived from Anthozoa species (corals and anemones), as well as other sources, span the entire visible spectrum. The tertiary structure and size of these fluorescent proteins are very similar to those derived from *Aequorea victoria*, although the amino acid sequences are quite different. Red-emitting species with correspondingly longer excitation wavelengths are of particular interest because of reduced autofluorescence, deeper penetration, and better resistance toward high excitation density of biological tissue in this spectral region. Research is ongoing to improve brightness and photostability, reduce oligomerization and pH sensitivity, improve the appropriateness for fusion tagging, and reduce the time required for maturation of the protein in living organisms.

Variants of Confocal Laser Scanning Microscopy

Confocal Microscopy Involving Modified Illumination

Slit-Scanning Confocal Microscopes

Scanning a line focus, generated, for example, by a cylindrical lens, over the sample and imaging this line focus onto a slit aperture parallel to the image of the line focus still provides the optical

sectioning capability of the confocal microscope, because the slit rejects out-of-focus light. At the same time, the frame rate is significantly increased, because scanning is necessary only in one direction. A spatially sensitive detector must be used to resolve light passing through different positions along the exit slit. This may be achieved by imaging the exit slit onto a one-dimensional detector array, read out synchronously with the scan, or by scanning an image of the exit slit, synchronously with the scan, across a two-dimensional detector, such as a CCD camera, forming a confocal image in this way. Disadvantages over the single-point scanning technique include reduced lateral resolution in the direction of the line focus, enhanced out-of-focus background, and, in the case of coherent illumination, increased laser speckle.

Spinning Disk Confocal Microscopes

Instead of scanning a single-point focus across the sample, multiple focal spots may be simultaneously generated and imaged each onto a confocal aperture. A white light version of such a confocal microscope based on a spinning Nipkow disk was introduced by Petran and Hadravsky already in the 1960s and later improved by Xiao, Corle, and Kino. The disk contains pinholes arranged in a spiral pattern, which are slightly displaced such that the whole sample is illuminated after the disk has rotated by a certain angle. In more recent versions, light from each focal spot on the sample passes the same pinhole in the disk that was used for excitation. A two-dimensional detector, such as the eye of the observer or a CCD camera, is used to register a confocal image while the disk is spinning. Nipkow disk-based confocal microscopes are now commercially available from several manufacturers and provide fast confocal imaging, but at the cost of reduced flexibility, because the pinhole size cannot be varied and because the beams cannot be steered at will, as it is necessary, for example, in some experiments involving photobleaching. Moreover, cross-talk between the different focal spots may occur. Another version of confocal microscopy with multiple focal spots, *swept field confocal microscopy*, leaves the pinhole array stationary and sweeps the image of this array over the sample. By switching between different pinhole arrays, the pinhole size can be varied.

The light efficiency of Nipkow disk-based confocal microscopes may be significantly improved by adding a microlens array, mounted on a second disk, which is spinning on the same axis as the Nipkow disk and placed on top of the latter. Each microlens focuses incoming light onto one of the pinholes of the Nipkow disk. A dichroic beam splitter between both disks may be used to direct the detected fluorescence onto a camera. Another option is to use slit-shaped apertures on the Nipkow disk, which results in the same advantages and disadvantages as already described in section "Slit-Scanning Confocal Microscopes." For a review of applications of spinning disk microscopes in life science, see reference [9].

Chromatic Brightfield Confocal Microscopy

A chromatic confocal microscope operating in reflection deliberately introduces chromatic aberrations into the imaging system. Scanning in the vertical direction is then replaced by simultaneous detection of different spectral components which encode the depth information, because the depth of the focus depends on the wavelength. A complete stack of images can be acquired in this way in a single two-dimensional mechanical scan of the sample or of the excitation beam. Broadband excitation may be provided by a white light lamp or by a femtosecond laser-generated supercontinuum.

Structured Illumination Microscopy (SIM)

The SIM technique does not employ any pinhole and can be used with white light, but is related to confocal microscopy in its optical sectioning capability [10]. Optical sectioning is achieved by acquiring a sequence of images of the sample with structured illumination. The simplest case of structured illumination is thereby produced by placing a grid of fully transparent and fully opaque stripes of equal width (one half the period L of the grid) into the illumination path and projecting this grid onto the sample. Only sample

structures that are in focus will lead to significant variations of the image when the grid is displaced along the direction of periodicity, because only in focus the image of the grid within the sample is sharp. After acquiring three images with the grid displaced by 0, L/3, and 2 L/3, the optical section can be calculated (in the simplest version of the SIM algorithm) as the root mean square of the three differences between the three images. More sophisticated deconvolution algorithms are available and many other structures for illumination can be used. Movement of a grid illumination pattern across the sample may be replaced by the generation of arbitrary patterns by digital mirror devices (DMD) based on microelectromechanical systems (MEMS) or on spatial light intensity modulators (SLM), based on liquid crystals.

Whereas optical sectioning can be achieved more easily in this way than in a standard confocal system with a single-point focus, there are also some problems related to this approach. SIM works badly in strongly scattering samples, because small differences on a large background have to be determined. This is related to a significant loss in bit resolution and, hence, dynamic range in the final image. Moreover, the optical sectioning capability of SIM is slightly worse than for the standard single focus confocal microscope.

Another version of SIM employs either a grid pattern or random aperture arrays on a spinning disk, which both allow a large throughput of the light from the illumination source of the order of 50 %. Because of cross-talk between the light transmitted through neighboring apertures, the image acquired through the disk will contain a part that is not in focus. This part has to be subtracted from the image. A corresponding conventional image, to be subtracted from the partly confocal image, may be acquired by tilting the disk slightly, reflecting a second light source from the rear side of the disk toward the microscope objective and registering the corresponding image using a second camera. This procedure allows rapid optical sectioning and, hence, in vivo imaging of biological samples with very good signal-to-noise ratio with a comparatively simple instrument. A similar approach of subtracting the conventional image is based on a DMD, instead of a spinning disk, and was termed *programmable array microscope*.

Versions of structured illumination microscopy providing a moderate degree of super-resolution are based on Moiré patterns produced by projecting a high spatial frequency grid onto the sample (high-resolution SIM, HR-SIM). The Moiré pattern arises, because the observed signal is the product of the spatial distribution of the excitation with the concentration of the fluorophore and therefore contains spatial frequencies equal to differences between sample spatial frequencies and the one of the grid. The grid pattern must not only be shifted, but also be rotated, in order to be able to calculate the image. The method is able to increase the resolution by a factor of two beyond the diffraction limit.

Confocal Microscopy Beyond Brightfield and Standard Fluorescence

Confocal Raman Microscopy

In the Raman spectroscopy mode, the inelastically scattered light from the sample is detected, where the frequency shift toward lower (Stokes signal) or higher photon energy (anti-Stokes signal) coincides with an internal vibration of the sample. Raman scattering is typically very weak, and strong rejection of elastically scattered laser light is necessary. Historically, triple monochromators were often used for this purpose and still yield the highest spectral resolution, but in recent years dielectric long-pass filters with ultra-sharp transmission edges and high rejection factors have become available. This simplifies the instruments significantly, increases light efficiency, and in combination with slit-scanning techniques (see section "Slit-Scanning Confocal Microscopes") allows rapid multispectral confocal Raman imaging with acquisition times per pixel in the millisecond range.

Coherent anti-Stokes Raman scattering (CARS) and *stimulated Raman scattering (SRS)* microscopies are nonlinear variants of Raman

microscopy based on stimulated Raman scattering. Both techniques require two short-pulse lasers operating at different frequencies ν_1 and ν_2. The overlapping beams are focused by the microscope objective into the sample. When the difference in the optical frequencies is tuned to the frequency of a characteristic vibrational frequency ν_v of the sample ($\nu_1 - \nu_2 = \nu_v$), it will excite this vibration and at the same time generate anti-Stokes Raman scattered light at a frequency $2\nu_1 - \nu_2 = \nu_1 + \nu_v$ (CARS) or weakly deplete the pump and enhance the Stokes beams (SRS). Stimulated Raman scattering can be several orders of magnitude stronger than spontaneous Raman scattering and therefore allows rapid label-free imaging of a particular molecule in the sample. At least one of the two lasers necessary for CARS or SRS has to be tunable. This requirement maybe fulfilled, for example, by a Ti:sapphire laser or an optical parametric oscillator. Video rate in vivo SRS microscopy has been recently demonstrated and offers a number of advantages over CARS microscopy.

Another variant of confocal Raman microscopy, tip-enhanced Raman scattering (TERS) employs optical near fields of a sharp tip in order to increase the spatial resolution in Raman scattering over the diffraction limit. Confocal excitation and detection thereby reduce elastically scattered background in this setup.

Multiphoton Microscopy

Fluorescence excitation may in general be based on a linear process, in which a single photon excites the emitter into the excited state at energy E_1 from which it fluoresces, or on nonlinear processes, in which the emitter simultaneously absorbs n photons of energy E_1/n. Nonlinear processes are usually much less likely to occur than linear ones, with the probability strongly decreasing with the number of photons. Therefore, pulsed lasers are used for excitation, in which the optical power is concentrated in short pulses of widths in the femtosecond to picosecond range and the intensity during the pulse is very high. In addition, focusing the beam to a submicron spot leads, of course, to strong additional enhancement of the excitation probability.

Multiphoton microscopy has several important advantages over optical microscopy employing linear excitation. First, it is inherently confocal, in the sense that out-of-focus contributions to the detected signal are very small and therefore a confocal pinhole is not required (or the existing pinhole can be opened fully without losing the optical sectioning capability). This is advantageous, in particular for strongly scattering samples, because it yields a higher detection efficiency. Second, the photon energy used for excitation is only one half (for two-photon excitation) or one third (for three-photon excitation) of that used in the linear case, and the excitation wavelength therefore typically lies in the near infrared or even further in the infrared. Because the scattering in biological tissue and other inhomogeneous materials with inhomogeneities on a scale of the wavelength or below decreases strongly with the wavelength (proportional to λ^{-4} for very small inhomogeneities), the penetration depth is considerably larger for multiphoton excitation compared to single-photon excitation of the same fluorophore. This means that three-dimensional imaging deep into tissue becomes possible. Third, photo-induced damage to the sample and the fluorophore is reduced, also because of the lower photon energy.

Instead of making use of multiple photon excitation of a fluorescent chromophore, it is also possible in some samples to detect light due to second harmonic generation (SHG) and to use that for label-free imaging. Other label-free and, in addition, chemically specific, variants of multiphoton microscopy are CARS microscopy and SRS microscopy, as described in section "Confocal Raman Microscopy."

Fluorescence Lifetime Imaging (FLIM)

The lifetime of a fluorophore may vary depending on local pH, oxygen, or ion concentrations, or on intermolecular interactions, for example, fluorescence resonance energy transfer (FRET, see section "Fluorescence Resonance Energy Transfer

(FRET)"). On the other hand, within some limits, it does not respond to the intensity of the excitation light, the fluorophore concentration, or photobleaching. The fluorescence lifetime is therefore a useful physical quantity that can be used for imaging and quantitative analysis of local pH, ion concentrations, or intermolecular interactions. Fluorescence lifetimes are typically in the range of a few picoseconds, when dominated by non-radiative processes, to several tens of nanoseconds, when limited by the radiative transition rate. In some cases it is useful to employ fluorophores with very long lifetimes, in particular when strong autofluorescence is present. Performing a lifetime measurement at each position of the excitation laser focus within the sample and representing the corresponding values as a gray scale or color value from a lookup table yield a confocal lifetime image. At the same time, a standard fluorescence intensity image can be obtained.

A common method of measuring fluorescence lifetime is time-correlated single-photon counting (TCSPC). Here, a correlator, triggered by the short pulse of the exciting laser measures arrival times of fluorescence photons, typically detected by an avalanche photodiode with a short response time, and generates a histogram of delays. Fitting an exponential function to the histogram yields the fluorescence lifetime as the decay time of the exponential. Complications may arise when the decays are actually non-exponential. In the case of relatively long lifetimes in the nanosecond range, instead of TCSPC, a gated image intensifier may be used to measure the number of photons falling into a time window defined by the gate. Both techniques operate in the time domain. When the lifetime is comparatively long, it is also possible to modulate the laser pulses in the MHz range and detect the phase shift of the corresponding modulation in detected fluorescence intensity, which depends in a simple way on the fluorescence lifetime. TCSPC, however, is the most flexible way of measurement, because it is not restricted to long lifetimes and allows to analyze non-exponential decays as well.

Fluorescence Resonance Energy Transfer (FRET)

FRET [11] is a resonant non-radiative energy transfer from a donor to an acceptor fluorophore due to the dipolar interaction. As the dipolar interaction energy is proportional to the third power of the donor-acceptor distance R and because the probability for FRET to occur involves the square of an off-diagonal matrix element of the dipolar interaction, it falls off as R^6 and depends on the relative orientation between the molecules and the spectral overlap between the emission spectrum of the donor and the absorption spectrum of the acceptor. The probability is highest for parallel orientation of the donor and acceptor transition dipoles. Because of the steep fall, off FRET can only occur if R is sufficiently small, that means, if the donor and the acceptor are sufficiently close to each other. Because the critical distance is only 1–10 nm, typically 4–6 nm, in all practical cases, the FRET mechanism provides a *molecular ruler* for measuring the donor-acceptor distance and in this way provides an indirect mechanism for studying structure on the nanometer scale, which cannot directly be resolved by diffraction-limited optical microscopy (superresolution microscopy, compare section "Super-Resolution," might, however, in the future partly supersede FRET studies). This is of particular interest for protein-protein and intra-protein interactions. For this purpose, the proteins of interest have to be labeled by fluorophores with overlapping emission and absorption spectra. In many cases fluorescent proteins (compare section "Fluorescent Probes") are used for this purpose. A sensitive measure for FRET, which can be used for imaging, is the ratio of intensities of the donor and acceptor fluorescence peaks.

A problem with FRET confocal microscopy is that the signal-to-noise ratio is often very poor. Therefore, in many cases only the occurrence or absence of FRET is detected. The signal-to-noise ratio may be improved by measuring the donor lifetime, instead of the acceptor/donor fluorescence intensity ratio. This imaging option is usually known as FLIM-FRET (*fluorescence lifetime imaging-fluorescence resonance energy transfer*).

Fluorescence Recovery After Photobleaching (FRAP)

This microscopy technique, most often performed in a confocal setup, bleaches the fluorescence of a certain sample region, often an intracellular organelle, and registers the recovery of fluorescence due to diffusion of the fluorescently labeled molecules. It may therefore be used to investigate the mobility of the target molecule within the surrounding structures.

Fluorescence Correlation Spectroscopy (FCS)

In contrast to the previous techniques, FCS is usually used not as an imaging technique, but with a fixed position of the confocal volume within the sample. The laser (usually a continuous wave laser) thereby excites fluorescent particles within this volume, and particle movement in and out of the volume produces fluorescence intensity fluctuations. The autocorrelation function of these fluctuations provides information about the concentration, diffusion coefficient, and the mass of the particles. The diffusion coefficient depends on the viscosity of the medium via the Einstein-Smoluchowski relation. It may also depend on interactions of the particles with a microstructured environment.

A variant of FCS is fluorescence cross-correlation spectroscopy, in which the fluorescence intensity fluctuations of two fluorophores, labeling two different molecules, are measured simultaneously in two different channels. If the two molecules are bound in a dimer, the fluctuations will be highly correlated. Otherwise, no cross correlation is expected. The degree of cross correlation then is a measure of how many of the two different species of molecules are bound to each other.

Confocal Microscopy Sensitive to Phase

Interferometric versions of confocal laser scanning microscopy have been reported relatively early in the literature and were based on Mach-Zehnder or Michelson interferometers, for measurements in transmission or reflection, respectively [1]. In this way, it is possible to measure object topography or refractive index variations with interferometric precision. Interferometric confocal microscopes have the advantage over conventional interferometric microscopes that the shape of the wave front of the reference beam and are irrelevant because only phase and amplitude at the pinhole is important. This means that the requirement for matching optics, otherwise necessary in interferometric microscopy, is strongly relaxed.

Often two beam splitters and two detectors, each with its own pinhole, are employed in the detection beam path of interferometric confocal microscopes based on Michelson interferometers. This allows to separate the conventional confocal signal and the pure interference signal as the sum and difference of the outputs of the two detectors. This is based on the fact that two beams at the inputs of a symmetric lossless beam splitter are combined with a $+\pi/2$, $-\pi/2$ phase shift relative to each other at the two outputs of the beam splitter, respectively. A non-interferometric variant of phase-sensitive confocal microscopy, *differential phase-contrast confocal microscopy*, is obtained by omitting the mirror generating the reference beam in the Michelson interferometer and obscuring one half of each of the relay lenses in a complimentary manner [2].

The sensitivity of interferometric confocal microscopes may be enhanced by using a spectrally shifted reference beam (*heterodyne interferometric confocal microscopy*). Topographic resolution of about 0.01 nm using such a heterodyne interferometric confocal microscope has been reported. In addition, the optical sectioning capability of the confocal microscope and the corresponding dependence of the signal on defocus can be used to avoid phase unwrapping ambiguities.

Another variant of interferometric confocal microscopy is called *4π microscopy*. Here, two opposing objective lenses are used for excitation and/or detection. This increases the available numerical aperture and therefore enhances the resolution, in particular, in the axial direction. In addition, because of the coherent excitation, the

technique is inherently interferometric due to the interference of the two counterpropagating excitation beams in the focal region. This generates a standing wave interference pattern which modulates the main lobe of the focus in the axial direction and in this way allows to improve the axial resolution by a factor of about 4.5. The side lobes, due to interference, within the confocal main lobe may be effectively suppressed in the case of two-photon excitation. This suppression is due to the nonlinearity of the excitation process and can be additionally enhanced, if the sample fluorescence is also detected through both objective lenses in an interferometric setup. Because the position of maxima of the PSF for excitation and detection depends on the phase of both beams used for excitation and detection, precise control of the phase of both beams is required.

It should be mentioned here that a non-interferometric technique for phase measurement in optical microscopy is based on the so-called transport-of-intensity equation which can be derived from the paraxial time-dependent wave equation and relates the intensity and phase of a paraxial monochromatic wave to its longitudinal intensity derivative. The technique requires, however, the measurement of very small changes of intensity as a function of small defocus and therefore requires high bit resolution and long integration times.

Superresolution

Historically, the Abbe diffraction limit had been an insurmountable barrier in optical microscopy for many years. Many structures of interest, on the other hand, are significantly smaller than this limit and, particularly in biology, there has been a strong desire to significantly improve the resolution. In recent years, the diffraction limit has been broken in numerous ways, and this is based on some of the most exciting modern advancements in optics, which is still, although very old, a rapidly developing area of physics. The conceptually simplest way to achieve sub-Abbe resolution is by way of deconvolution (compare section "Deconvolution"). This does not, however, allow to achieve resolution enhancements of an order of magnitude, as urgently desired in many cases. One route to satisfy this demand employs non-propagating near fields. These near fields carry all optical information on length scales below the Abbe limit. The fact that these near fields are lost in far-field optical imaging can be viewed as the reason for the limited resolution of standard (including confocal) optical microscopes. Near-field related techniques (compare "▶ Scanning Near-Field Optical Microscopy") will not be discussed here (as an exception, compare TERS, section "Confocal Raman Microscopy"), although some of them may be combined with confocal imaging, for example, *solid immersion lens microscopy* (SIL) or *total internal reflection microscopy* (TIRF). Other routes, however, have opened the way to far-field optical nanoscopy in recent years. They are based on prior knowledge about the sample (PALM/STORM) or on optical nonlinearity (STED, SSIM) [12]. STED uses a specially designed optical excitation and is a scanning microscopy technique. PALM/STORM is non-confocal, because parallel detection using a CCD camera is used. These techniques have reached lateral resolution in the range of 20 nm, and ongoing research attempts to further push the resolution toward the molecular level (1–5 nm). Commercial instruments based on these techniques are increasingly becoming available [13]. The techniques will be shortly described, because of their potential as far-field microscopy techniques to partly supersede standard confocal fluorescence laser scanning microscopy.

Superresolution by Prior Knowledge (Profilometry, PALM/STORM)

In cases where it is known that one and only one sharp interface between two homogeneous materials or one and only one point emitter or reflector in the focus is present, the position of the interface in the z direction or the three-dimensional position of the point emitter/reflector can be determined

with a precision that is far beyond the Abbe limit and is limited only by the total amount of photons detected.

The simplest such technique consists in profiling a surface using a standard non-interferometric CLSM. By adjusting the z position to the wing of the $V(z)$ function, very slight changes in the topography of the sample surface can be measured, if the material and, hence, the reflectivity do not vary. Sub-nanometer depth resolution has been achieved in this way, averaged over the diffraction-limited lateral size of the confocal spot. As discussed in section "Confocal Microscopy Sensitive to Phase," the technique may be combined with interferometry to increase the depth resolution to about 0.01 nm.

In a principally similar way, *photoactivated localization* microscopy (PALM) and *stochastic optical reconstruction microscopy* (STORM) determine the position of single-point emitters with nanometric precision. Because it must be avoided to have more than one molecule in the focal volume and such a sparse distribution of fluorescent emitters would not allow sub-diffraction-limited resolution, it is necessary to separate the contributions from many individual molecules in some way. *Temporal* separation is key to current single molecule-based superresolution techniques. Other options, such as spectral separation, or more sophisticated schemes have also been discussed, however.

Current techniques use *photoactivable* molecules, which can be statistically turned on by another light source. Irreversible or reversible processes may be employed to turn off an activated subset. Determination of the positions of the activated molecules and multiple repetition then results in a software-generated image with nanometric resolution. Typically, thousands of images must be acquired and, correspondingly, imaging is slow, with a trade-off between spatial and temporal resolution. Effective frame rates of reconstructed images of about 1/(3 min) at a Nyquist-limited resolution of about 50 nm have been demonstrated for frames of 50 × 50 pixels. The obtainable resolution depends on the brightness of the fluorophores in the "on" state, as well as on the achievable contrast between "on" and "off" states. Fluorescent proteins as well as fluorescent dyes are currently in use [14].

PALM has hitherto mostly been used in total internal reflection configuration and is then restricted to essentially two-dimensional imaging. Lateral resolution down to ≈20 nm has been achieved. A three-dimensional STORM technique has achieved an image resolution of 20–30 nm in the lateral dimensions and 50–60 nm in the axial dimension in an illuminated sample volume of a few micrometers in thickness. An interferometric variant of PALM employing self-interference of fluorescent photons has improved the axial resolution to <20 nm for optically thin samples.

It may finally be worth noting that, whereas photoswitching is considered by some authors as a kind of optical nonlinearity, an optically nonlinear response is not essential to the breaking of the diffraction limit in the far field in the case of single molecule-based techniques. For example, sub-diffraction imaging due to binding and detachment of diffusing probes has been demonstrated, which obviously does not involve any optical nonlinearity. Moreover, photoswitching and temporal selection of molecules in general represent conceptually only one, although currently the standard and most successful option to ensure that only one molecule is detected within the PSF of the objective lens. It may therefore be said that in this case the breaking of the diffraction barrier is based on the knowledge, however obtained, to have only one molecule within the PSF and on the facts that the center-of-mass position of a diffraction-limited spot can be determined to a much higher precision than given by the size of this spot and that this position corresponds to the position of the fluorescent molecule.

Superresolution Due to Nonlinearity (SSIM, STED)

Some examples of confocal imaging methods employing optical nonlinearity have already

been discussed in sections "Confocal Raman Microscopy"(CARS, SRS), and "Multiphoton Microscopy." By reducing the size of the PSF for photons of the same wavelength, optical nonlinearity is in principle able to enhance the resolution. In multiphoton microscopy, however, because long wavelength photons are used for excitation of fluorophores, the resolution is actually worse than that of its linear counterpart.

Saturated structured illumination microscopy, SSIM, on the other hand, provides resolution enhancement without fundamental limit. This nonlinear variant of SIM (compare section "Structured Illumination Microscopy (SIM)") employs a nonlinear dependence of the fluorescence intensity on the excitation density, which is possible, for example, by saturation of the excited state. In this case, the effective illumination generally contains higher spatial frequency components leading to increased resolution. Optical resolution beyond 50 nm has been reported using this technique.

Stimulated emission depletion microscopy (STED) selectively de-excites fluorescing molecules within the PSF of the confocal microscope by stimulated emission, using a second laser. This laser beam passes a spiral phase mask, which generates a zero of intensity in the center of the beam cross section. Stimulated emission and corresponding deexcitation of fluorophores then occur everywhere within the PSF, except close to the axis of the beam, and the size of the region, from which fluorescence that can be collected depends on the intensity of the deexciting laser. Lateral resolution of about 20 nm has been reported using this setup. If STED is combined with a 4Pi setup, fluorescing spherical focal volumes of 40–45 nm diameter can be generated. STED is currently able to operate considerably faster than PALM. Video-rate STED microscopy with about 60 nm lateral resolution has been reported with a frame rate of 28 frames/s.

Synonyms

Dermal delivery – dermal absorption, skin penetration, cutaneous delivery, skin delivery

Transdermal delivery – percutaneous absorption, transdermal permeation, transcutaneous delivery

Definition

Dermal delivery refers to the process of mass transport of active ingredients applied on the skin to various skin strata.

Transdermal delivery refers to the entire process of mass transport of substances applied on the skin surface and includes their absorption by each layer of the skin, their uptake by microcirculation of the skin, and distribution in the systemic circulation.

Introduction

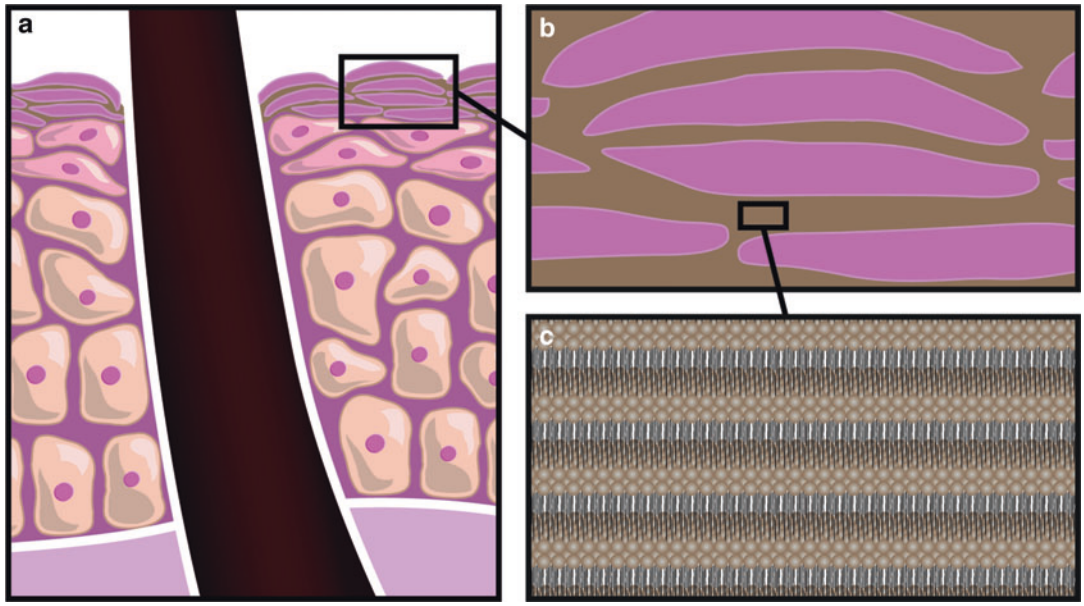
History of Therapeutic Systems Applied on the Skin

The history of skin application of therapeutic substances goes back to ancient times. Numerous carriers, including conventional semisolid bases (creams, gels, ointments), matrix systems (clays, polymers), and liquid systems (solutions, emulsions, suspensions), are being used for cutaneous application of therapeutics for centuries. Transdermal delivery, or delivery of active ingredients across the skin, was actually prototyped in ancient China and Egypt through the use of certain plasters and ointments. Several examples of medications topically applied on the skin to attain regional or systemic effect include the mustard plaster, used as a remedy for severe chest congestion, and Chinese balm or plaster containing menthol and ginger (rich in salicylates) for regional pain relief. In the case of mustard plaster, which later was introduced to the US Pharmacopeia, powdered mustard seeds (*Brassica nigra*) mixed with warm water were applied to the patient's chest with a cloth. Following the application, the change in the conditions to moist and warm activated some ingredients in mustard and particularly an enzyme myrosin. This enzyme is responsible for a hydrolysis of sinigrin and the release of active agent allyl isothiocyanate, which is transdermally absorbed being a low mw (~100 Da) mildly lipophilic substance. Other transdermal formulations recognized by the US Pharmacopeia in the early twentieth century included belladonna plaster (analgesic) and mercury ointment (for treatment of syphilis) [1].

Active development of the transdermal delivery systems started in the mid of the 1970s, exploring only the molecules which could intrinsically permeate the skin. The first transdermal delivery system, the scopolamine transdermal patch for treatment of motion sickness able to deliver the drug for 3 days, was granted with the FDA approval in 1979. The system was developed by the team of Alejandro Zaffaroni, who established ALZA Corporation. Currently, there are more than a dozen marketed transdermal delivery systems containing active ingredients such as nitroglycerin (cardiovascular conditions), nicotine (smoking cessation), various hormone combinations (contraceptives, hormone replacement therapy, etc.), lidocaine (local anesthesia), fentanyl (pain management), oxybutinin (urinary incontinence), methylphenidate (attention deficiency disorder), selegiline (depression), rotigodin (Parkinson's diseases), rivastigmine (dementia), granisetron (nausea and vomiting), and others [2].

Throughout the history, the vast majority of medicaments applied to the skin surface were intended to cure superficial conditions. It can be explained by the intrinsic barrier function of the skin, which efficiently inhibits penetration of

exogenous substances. To enable transdermal absorption or, on the contrary, enhanced accumulation of a therapeutic agent on the skin surface, it is important to thoroughly understand the skin physiology and barrier structure as well as and the physicochemical properties of drug molecules and carrier systems.



Skin Barrier

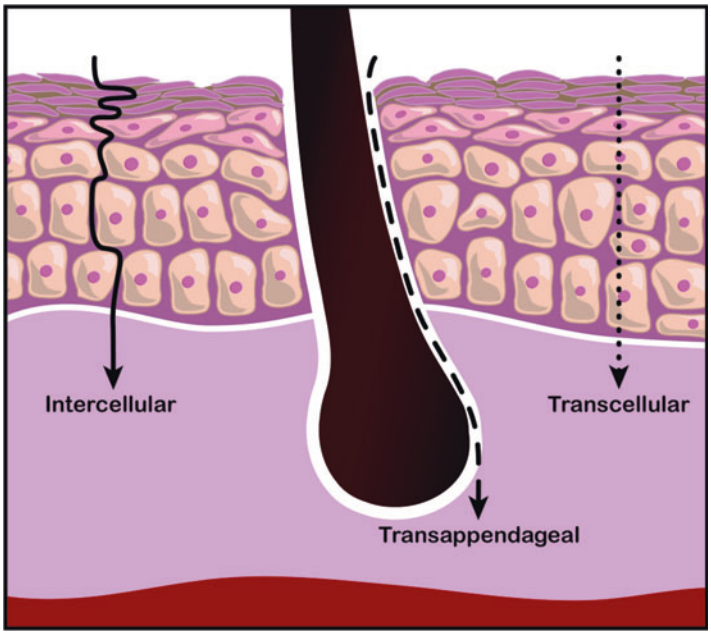
The skin, or integument, is the largest body organ, comprising 15 % of body weight and having a surface area of ~2 m^2. Among the several functions of the skin, the main one is being a physical barrier to the environment; controlling the inward and outward passage of water, electrolytes, and xenobiotics; and providing protection against pathogens, ultraviolet radiation, and mechanical insults. There are three structural layers to the skin: the epidermis, the dermis, and subcutis. Hair follicles and sebaceous, sweat, and apocrine glands are regarded as skin appendages. Epidermal layers of the skin have a dynamic turnover with cells of the outer strata continuously replenished by inner cells moving up to the surface from the basal layer. Epidermis and particularly its outermost layer stratum corneum (SC) represent the most important control elements in the transport of molecules into and across the skin [3, 4]. The actual investigation into the barrier properties of the skin started in the early 1920s. It was initially proposed by Rein that an intermediate layer of cell between SC and viable epidermis is responsible for the resistance to transcutaneous transport of molecules. This hypothesis was further modified by the groups of Blank et al. and Sheuplein et al. who have shown for the first time that SC is the limiting step in the process of passive diffusion across the skin. In 1944, Winsor and Burch have shown that removal of SC by sandpaper dramatically increased permeation of water and solutes into the skin. Nevertheless, in later years, it was demonstrated by Michaels and colleagues that some of the exogenous substances will readily bypass the skin as a function of their physicochemical structure. Great contribution to the understanding of skin barrier structure was done by Kligman and colleagues, who in a series of studies separated the SC membrane and has shown that it consists of well-defined polygonal corneocytes. The composition of intercorneocyte lipid domain [5] of the SC was first described by groups of Elias, Gray, and Yardley [3]. It was shown that the amount of the lipid in keratinocyte as well as the overall composition of the lipid layers in the skin strata is strongly affected by keratinocyte differentiation status. While undifferentiated keratinocytes in basal epidermis contain mainly sphingomyelin and phosphoglycerides, differentiated cells located in the stratum corneum (skin surface) contained mainly ceramides, cholesterol, and fatty acids in approximately equal molar ratios. The key enzymes responsible for the formation of the epidermal permeability barrier are serine palmitoyltransferase for the sphingolipids, β-hydroxymethylglutaryl-coenzyme A reductase (HMG-CoA reductase) for cholesterol, and acetyl-coenzyme A carboxylase [3, 6].

Well along, the widely known model of SC was proposed by Barry and Williams. This model describes SC as a "brick and mortar" structure where the bricks are corneocytes, terminally differentiated metabolically inactive cells of the skin epithelium filled with insoluble keratins, and mortar is the continuous intercellular lipid phase, composed mostly of ceramides, cholesterol, free fatty acids, and cholesteryl esters (Fig. 1). This unique chemical composition of SC and very low water content (∼15 %w/w) impart to this protective layer a highly lipophilic nature. Thus, only low molecular weight xenobiotics with intermediate lipophilicity can cross this intrinsic barrier and be absorbed to the deeper layers of the skin or, through the network of blood capillaries located in the dermis, to the systemic circulation [7, 8]. Efficient administration of substances with distinct physicochemical characteristics (ionic, highly lipophilic, large molecular weight, etc.), aimed to act in the deep viable skin strata, regionally in the immediately underlying tissues (muscles, ligaments, joints, etc.) or systemically, requires various techniques to enable their transport across the SC barrier.

Percutaneous Absorption

The term percutaneous or transdermal absorption refers to the entire process of mass transport of

Dermal and Transdermal Delivery, Fig. 1 (**a**) Schematic presentation of the skin structure. (**b**) Stratum corneum, the outermost layer of the skin and the main barrier for absorption, consists of terminally differentiated anucleated corneocytes filled with proteins and (**c**) intercellular stratum corneum lipids. The overall structure is frequently referred to as a "brick-and-mortar" wall



substances applied topically and includes their absorption by each layer of the skin and finally their uptake by microcirculation of the skin. It can be broken down into a series of sequentially occurring transport events: (i) deposition of a penetrant molecule onto the SC; (ii) diffusion through SC; (iii) diffusion through the viable epidermis; (iv) passage through the upper part of papillary dermis; and, finally (v), uptake into the microcirculation for subsequent systemic distribution. Since the viable tissue layers and the capillaries are quite permeable to solutes, diffusion across the SC is often regarded as the rate-limiting step.

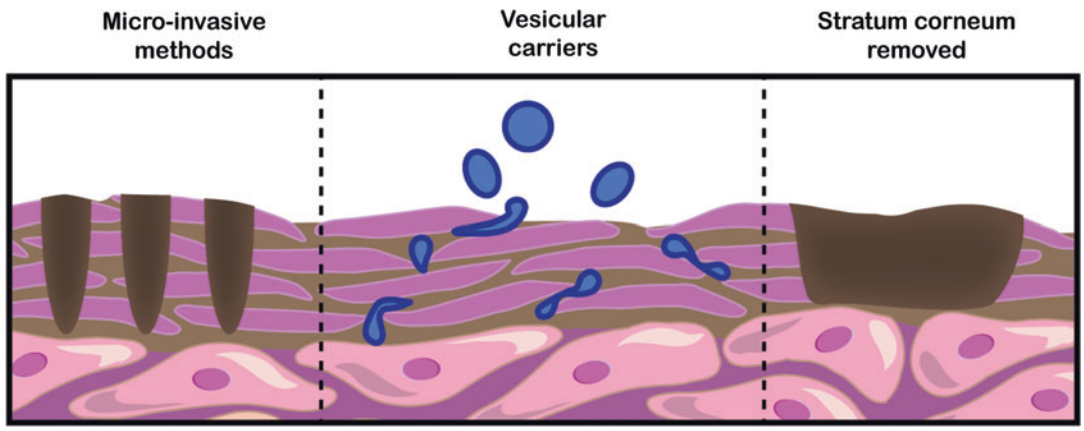
The cells of the SC are anucleated and metabolically inactive; thus, passage through this layer is a passive process governed by classic diffusion laws, and a simple equation for steady-state flux can be used to describe it. When the cumulative mass of a diffusant, m, passing per unit area, A, through a membrane is plotted, at some point the graph approaches linearity, and its slope yields the steady flux, J (dm/dt) (Eq. 1) [7, 8]:

$$J = dm/dt = ADC_0K/h \qquad (1)$$

where C_0 represents the constant donor drug concentration; K, the partition coefficient of solute between membrane (*SC*) and the medium in which the molecule is applied; D, the diffusion coefficient; and h, the membrane thickness. From Eq. 1, the ideal properties needed for a molecule to penetrate stratum corneum are low molecular weight and high but balanced (optimal) partition coefficient and a low melting point, correlating with good solubility. Permeation modifiers can affect various parameters in the equation to tailor the absorption into or across the skin. Skin permeation enhancers, for example, can increase the diffusion coefficient by affecting the partition coefficient to increase the solubility of the substance in SC, decrease the thickness of the membrane, or temporarily reduce/diminish the membrane properties of SC.

A molecule applied on the intact skin surface has three possible routes to reach the viable tissue: intracellular, through SC lipids; intercellular across the corneocytes; and via skin appendages (Fig. 2). The majority of transdermally absorbed molecules are believed to permeate the skin

Dermal and Transdermal Delivery,
Fig. 2 Schematic presentation of the routes for permeation of the agent applied to skin surface to the viable layers of the skin and across the skin: intercellular, transappendageal, and transcellular routes



through the intercellular passage, and therefore, skin permeation enhancement methods disrupt or bypass the crystalline, semicrystalline, and liquid crystal domain formed by intercellular SC lipids. Because of the low fractional appendageal area (about 0.1 %), this pathway usually adds little to steady-state drug flux, with the exclusion being highly polar molecules or macromolecules that struggle to cross intact SC. However, appendages may function as shunts important at short times prior to steady-state diffusion. Some nanovectors can enhance accumulation of bioactive materials in skin appendages, thus benefiting conditions such as acne and alopecia.

Successful transdermal delivery aims to achieve the balance between attaining therapeutic levels of the drug in the required tissue and safety to the skin. Some of the transdermal delivery technologies assume that relatively large, micron-scale defects in the upper skin strata can be well tolerated if the viable strata of the skin (viable epidermis and dermis) are not majorly damaged [2]. In the case of microinvasive techniques, the permeation of the molecules occurs across the physically created channels in the skin barrier.

Nano- and Microtechnologies in Dermal and Transdermal Delivery

The main goal of formulating the active agents in a carrier system is to achieve delivery of therapeutically relevant levels at the target tissue lowering the incidence of systemic adverse reactions. The desired site of action can vary from the skin surface to various body organs/systems. With a very few exceptions, the ultimate destination of the molecule applied on the skin will depend on the vehicle or vector system.

In the past three decades, the research focus in the area of cutaneous and transcutaneous delivery largely shifted toward the application of micro- and nanotechnologies to affect the permeation behavior of active agents applied on the skin surface. These technologies range from systems which enhance the transport of bioactives across the skin barrier (e.g., specially designed vesicles, microinvasive methods) to those impeding skin penetration of small and mildly lipophilic molecules [9, 10]. There are several nano- and microtechnology-based mechanisms/carriers by which an enhanced dermal and transdermal systemic delivery can be achieved as schematically

Dermal and Transdermal Delivery, Fig. 3 Nano- and microtechnology-based methods to enhance skin absorption of active materials: microinvasive techniques (e.g., microfabricated needles, jet injectors), specially designed vesicular carriers (e.g., ethosomes, transfersomes), electrically assisted methods to temporarily remove SC barrier (e.g., radiofrequency ablation, electroporation)

presented in Fig. 3. These techniques are used when the systemic effect is desired or when the applied agent should affect viable strata of the skin or beneath tissues and can be broadly categorized to specially designed nanovectors that temporarily affect SC barrier properties and/or passively deliver drugs across the SC (e.g., ethosomes, transfersomes, surfactant-based elastic vesicles), minimally invasive techniques that actively birch SC and beneath strata (e.g., microneedles), and methods for removing portions of the SC (e.g., microporation, microabrasion) [10]. On the other hand, to maximize the effect of the drugs for alleviating superficial conditions and to minimize whole-body distribution and related side effects, increased concentration and contact time of an active ingredient with skin surface/upper epidermis, while minimizing its absorption, are required. In this case, nano- and microtechnology-based approaches can be useful for preventing transcutaneous absorption of low molecular weight mildly lipophilic agents which intrinsically cross the skin barrier (e.g., corticosteroids, sunscreens, retinoids). Large multilamellar liposomes, nonionic surfactant vesicles (niosomes), solid nano- and microparticles, dendrimers, and dendritic-core multi-shell nanotransporters are being investigated in this essence.

Further in this entry, main techniques for skin application of drugs aiming at different purposes are described.

Nano- and Micro-vectors

There is a great versatility of the nano- and microvectors suitable for topical, regional, and transdermal drug delivery of various active agents with distinct mechanisms of actions. These include phospholipid- and surfactant-based systems (liposomes, niosomes, ethosomes, transfersomes, elastic vesicles, micelles, etc.) and solid nano- and microparticles (solid lipid nanoparticles [SLN], polymeric nano- and microparticles, solgel particles, etc.) [10–15]. Several of these technologies were successfully tested in clinical trials and/or clinically used. Design considerations, structures, and modes of actions of the nano- and microvectors are further discussed with examples of therapeutics/nutraceutics that were shown to benefit from skin application by means of a particular carrier.

Vesicles

Most early reports on traditional *liposomes*, containing phospholipids, water, and cholesterol, were published by Mezei and colleagues in the beginning of 1980s. These and further studies have shown that when applied to the skin,

liposomes enable localized effect, depositing the encapsulated molecule in the SC. In vitro and in vivo studies in various animal models (from mice to rabbits) confirmed the local delivery behavior of liposomes [11, 12, 15, 16]. While corticosteroids and retinoids were the most investigated drugs for liposome-based delivery, reports on xanthines, local anesthetics, proteins, enzymes, tissue growth factors, immunomodulators, and other biologically active substances have also been published. Results from a clinical study on a corticosteroid betamethasone dipropionate encapsulated in liposomes have shown that an anti-inflammatory effect was more pronounced in patients with superficial skin inflammation (eczema) and not in patients with psoriasis, a condition involving deep skin strata [6, 17]. A few in vivo studies and clinical trials with liposomally encapsulated retinoids confirmed enhanced topical localization with improved tolerability [3, 10, 11]. The mode of action of traditional liposomes was investigated by a number of scientists in the area of dermal and transdermal drug delivery. Starting from Junginger and colleagues who provided valuable insights on the understanding of the interactions taking place on the liposome-stratum corneum interface using freeze-fracture electron microscopy, groups of Weiner, Touitou, Barry, Puglisi, Downing, Cevc, and others investigated mechanisms involved by a variety of microscopy techniques, radiolabeled vesicle distribution studies, and physicochemical analyses. It was shown that the ultrastructure of the intercellular lipid domains in SC is not affected by the liposomal application; no permeation of the liposome components to the deep layers of the skin is observed, and in general, liposomes do not penetrate SC and appear as stacks on the skin surface [3, 6, 11, 13, 16, 18, 19]. This can explain the formation of drug reservoir in the SC and lack of penetration into the deeper layers of the skin. In general, liposomes are recognized as a safe delivery system and approved for the last two decades by the regulatory agencies for skin application of pharmaceuticals (e.g., for acne and actinic keratosis) and cosmetic active ingredients as well as for other routes of drug administration (e.g., antifungal and anticancer intravenous medications) [11, 16, 17].

More recent efforts on the front of the *phospholipid-based vesicles* shifted toward systems that can enhance the transport of active ingredients across the SC barrier. Ethosomes and ultradeformable bilayer vesicles, also called transfersomes, represent the two systems most investigated in this endeavor.

Ethosomes, mainly composed of phospholipids, relatively high concentrations of ethanol, and water, were introduced by Touitou et al. [14, 20]. The action of this vesicular system is generated by the presence of phospholipid vesicles and ethanol in the system. The presence of ethanol in the vesicle's structure enables malleability required to cross the "mortar" domain of the SC. On the other hand, ethanol also temporarily fluidizes the lipid phase in the SC, thus providing a background for permeation of the soft vesicles. The mode of action, proposed by Touitou et al. in 2000, can, thus, be denominated into three main simultaneously occurring processes: (1) fluidizing effect of ethanol on SC lipid domain and on phospholipid membrane in the ethosome, (2) entry and passage of the soft ethosomes across the SC lipid "mortar" phase, and (3) fusion of the ethosomal vesicles with phospholipids in the viable skin strata and release of encapsulated components beneath the SC barrier. Moreover, the presence of alcohol enables encapsulation of molecules with a wide spectrum of physicochemical features. In vitro, in vivo, and clinical studies have shown that the composition of the system can tune their behavior in terms of delivery to various deep skin strata or transdermally. Numerous reports on ethosomal systems with various active ingredients were published by Touitou et al. and other research groups. These include antimicrobial and antiviral agents for deep skin infections, acne medications, anti-inflammatory agents, cannabinoids, anti-alopecia therapeutics, anti-parkinsonian trihexyphenidyl HCl, antianxiety drug buspirone HCl, antipyretic paracetamol and ibuprofen, large molecular weight compounds such as insulin, and many others [14, 18, 21, 22]. Ethosomes are safe carriers, and no skin adverse effects were reported with ethosomal products or in clinical studies. They are marketed for treatment of herpes simplex infection and used in cosmeceutical products.

Highly deformable bilayer vesicles, also called transfersomes, were introduced by Cevc as deformable liposomes mainly composed of phospholipids, an "edge activator," such as sodium cholate and water [23]. The inventors argue that due to the presence of a polar substance in the lipid phase of the aggregate, the resulting vesicle can squeeze when the osmotic gradient is applied and enters through the SC pores with less than one tenth of its diameter. In the proposed mechanism of action, two features are claimed to be important: (1) nonoccluded conditions and (2) presence of the hydration gradient from the anhydrous SC (10–15 % water) to the viable skin strata (~70 % water). When applied to the intact skin, the ultradeformable transfersome vesicles can cross a nanoporous barrier essentially intact despite the extreme bilayer vesicle deformation and appreciable intra-pore friction. This is enabled by the self-controlled local bilayer composition adjustment to the shape and overall curvature imposed by the pore on a vesicle. Later, Barry and colleagues evaluated in vitro skin transport of molecules from transfersomes vs. traditional vesicles. Both types raised maximum flux and skin deposition compared to saturated aqueous drug solution (maximum thermodynamic control) under a nonoccluded environment, but results were not as dramatic as detailed in earlier work. Transfersomes were proven in in vitro and in vivo studies transdermally to deliver steroids, NSAIDs, and large molecules (e.g., insulin, interferon alpha, serum albumin) across human skin [23, 24]. A transfersome-based therapeutic, Diractin® or ketoprofen in Transfersome® gel developed by Idea AG, was approved for clinical use. However, phase III clinical studies in Europe and the United States comparing Diractin® with the locally applied ketoprofen-free vesicles (used as an "epicutaneous placebo"), for the treatment of osteoarthritis of the knee, were discouraging and revealed no statistically significant difference between Diractin® and the placebo.

Vesicles based on *synthetic surfactants* were also suggested for skin application of active ingredients. In this category, niosomes and elastic vesicles are further briefly described as carriers for topical or systemic drug delivery, respectively.

Niosomes, proposed by Handjani-Vila et al., are nonionic surfactant vesicles comprised of bilayer assemblies formed from certain synthetic amphiphilic molecules in aqueous medium. Niosomes can contain various surfactants generally used in pharmaceutical preparations, including polyoxyethylene alkyl ethers, sorbitan esters, polysorbate-cholesterol mixtures, alkyl glycerol ethers, and others. Similarl to liposomes, these carriers initially developed in L'Oréal for cosmetic applications [25] enable enhanced retention of active agents within the superficial SC strata, as confirmed by various microscopy techniques. Various cosmetic products currently contain niosomes.

Synthetic surfactant-based *elastic vesicles*, introduced by Bouwstra's research group, were designed according to similar principles as phospholipid-based transfersomes [26]. The most frequently reported "edge activator" in the formulation of these vesicles is octaoxyethylene-laurate ester (PEG-8-L) [27]. The molar concentration of PEG-8-L directly affects the bilayer elasticity. Elastic vesicles were investigated for enhanced percutaneous transport of a number of drugs such as pergolide, rotigotine, estradiol, immune modulators, and ketorolac. As of today, no clinical studies with these systems have been reported.

Microemulsions

Microemulsions typically contain two phases (aqueous and organic) and surfactant/co-surfactant and, due to a very low surface tension between the components, form spontaneously [28, 29]. Cyclodextrins were also used as a component in microemulsions. In general, the type of emulsion (w/o vs. o/w emulsion), the droplet size, the emollient, the emulsifier, as well as the surfactant organization (micelles, lyotropic liquid crystals) in the emulsion may affect the cutaneous and percutaneous absorption. This system was used mainly for solubilization of lipophilic agents for skin application, thus increasing the concentration gradient and enabling skin deposition of higher concentrations of therapeutics. In some cases, this can allow for mild increase in percutaneous penetration as reported in several in vitro and in vivo studies.

Solid Nano- and Microparticles

This category of drug vectors includes such nanovectors as solid lipid nanoparticles (SLN), solgel particles, polymeric nano- and microparticles, metal- (gold, silver, iron) and metal oxide (titanium oxide, zinc oxide, silica)-based particles, and microsponges [30]. As it was mentioned above, efficient penetration of intact skin by nondeformable particles (organic or inorganic nanoparticles, conventional liposomes, micelles, etc.) is both elusive and unlikely. Best evidence for this comes from skin penetration studies with incompressible inorganic nanoparticles which lack any direct ability to affect the cutaneous barrier. Various sizes of inorganic and metallic particles were tested for skin delivery (30–200 nm), and all were found confined to the skin surface. Consistent with the notion, it is a general agreement in the field that solid particles with diameters of >30 nm accumulate on the skin surface and cannot transport across the skin, except through hair follicles. On the other hand, when the skin barrier is breached, as in the case of psoriasis, solid particulates can be of benefit, providing controlled release of substances in the skin [31].

Solid lipid nanoparticles (*SLN*), initially designed to enable extended release of intravenous therapeutics, are relatively large on the nanoscale (<500 nm) dispersions of melted and solidified lipids [32]. Among the common SLN constituents are triglycerides, partial glycerides, fatty acids, steroids, and waxes which are formulated into solid particles by methods such as high-pressure homogenization and microemulsion formation. Diffusion of the active ingredients through the solid matrix is a slow process that enables prolonged release of the molecule on the superficial skin layers. Due to the low concentrations of the free active molecules present on the surface at each time point, the diffusion gradient and thus the driving force for passive diffusion are considerably low than when the actives are applied in liquid formulation. This prevents transdermal absorption of an active ingredient making SLN, and other solid particles, attractive carriers for substances that have to act on the skin surface but possess intrinsic physicochemical characteristics to be absorbed to the viable strata and from there to systemic circulation [13]. Sunscreens, perfumes, and insect repellents belong to this category. Being solid and opaque, SLN also possess an inherent ability to act as a physical sunscreen.

Polymeric carriers are another category of the solid nano- and micro-vectors for topical delivery [33, 34]. There are a plenty of structures and building blocks that can be used for the design of polymeric vectors. The polymers currently investigated and used for preparations of particles in biomedical applications range from natural polymers, such as chitosan and tyrosine derivatives and biocompatible and biodegradable poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and their copolymers (PLGA) to other representatives in the class, such as polymethyl methacrylate (PMMA), polycaprolactone, polyalkylcyanoacrylates, polyvinyl acetate (PVA), and polystyrene [9]. Skin application of polymeric nano- and microscale systems represents a less explored venue comparing to the knowledge of their physicochemical properties and design variables accumulated in the drug delivery field. The first patent on polymeric particles related to skin delivery by Nuwayser was approved soon after the appearance of the first transdermal systems. The inventor proposed to use polymeric particles as a controlled release component in the formulation of transdermal patches. Since then, several, mostly lipophilic drugs were incorporated into the polymeric particles applied on the skin, including steroids, minoxidil, and sunscreens such as octyl methoxycinnamate and benzophenone-3. Studies have shown that based on their shape and structure, polymeric particles can either accumulate in hair shafts enabling intrafollicular depot or retard skin permeation of active ingredients. A *microsponge delivery system* (MDS) [11] is based on porous nondegradable polymeric microspheres, typically 10–25 μm in diameter. MDS can entrap various active ingredients and then release them onto the skin over a time and in response to trigger (e.g., rubbing, temperature, pH change), while remaining on the skin surface. The technology is being used in cosmetics,

over-the-counter skin care, sunscreens, and prescription products. MDS was formulated with benzoyl peroxide (acne medication), hydroquinone (bleaching cosmetic agent), fluconazole (antifungal), and retinoids (acne).

Solgel systems, introduced by Avnir in 1984, are highly porous, reactive organosilicates formed based on the hydrolytic polycondensation of silicon alkoxides with a general formula $Si(OR)_4$or R_0 $nSi(OR)_4$Àn where R_0 contains vinyl, methacryl, or epoxy groups. A flexible network of inorganic oxide or hybrid nanocomposites can be produced through reacting R_0 with additional groups. As a result, the characteristics of solgel nanocomposite are halfway between those of polymers and silica-based glasses. Solgel-based systems were successfully clinically tested (phase II) for treatment of rosacea and acne and are used in sunscreen formulations [35].

Microinvasive Techniques for Enhanced Skin Absorption

Several microinvasive techniques are under investigation for transdermal delivery applications. Principles of ballistic high-velocity needle-free particles, microneedles, and skin microporation methods are described below.

Ballistic Needle-Free High-Velocity Particle System

Ballistic needle-free high-velocity particle system or PowderJect system was invented more than half a century ago for military use. Pulsed microjet injectors could be used to deliver drugs for local as well as systemic applications without using needles. The technology is based on transporting solid nanoparticles or liquid nanodroplets across the SC layer into the viable tissues, driven by a supersonic shock wave of helium. These systems are currently in use for delivery of proteins and vaccine. Jet-based noninvasive vaccination [36] involves shooting suitably coated gold particles into the skin. The injectors in clinical use contain compressed gas that can discharge the contents across the skin barrier. Among the claimed advantages for these delivery systems are freedom from pain and needle phobia, improved efficacy and bioavailability, controlled release, accurate dosing, and safety. However, the reported problems with bruising and particles bouncing off skin surfaces are the main reasons for the PowderJect uncommon use. Another disadvantage is the use of extremely small volumes, lowering the application to very potent therapeutics. Nanoliter-volume pulsed microjets comprised of 10–15 nL droplets were created to minimize the pain associated with this microinvasive transdermal drug delivery. To control the depth of jet penetration into the dermis, thus minimizing the pain, parameters such as velocity and volume of the microinjections can be tuned: a high velocity (>100 m/s) of microjets allows their entry into the skin, whereas the extremely small volumes (from 2 nL) limit the penetration depth. Due to the local adverse effects, the technology is generally proposed for acute usage, as in the case of skin immunization. Among currently used ballistic devices are Antares (insulin delivery), Mini-Jet, Biojector, Inject, and Penjet.

Microneedles (MN)

Microneedles are microinvasive tools to overcome the skin barrier and are currently one of the most vibrant domains of transdermal delivery research by active means [2, 26, 37, 38].

MN were proposed by Prausnitz and coworkers in 1998 for transdermal delivery of high molecular weight bioactives [2]. MN consist of an array of microprojections, ranging from 20 to 2,000 μm in dimensions, and smaller arrays are being developed. Application of MN to the SC surface creates transport pathways of micron dimensions that allow for transport of macromolecules and aggregates such as supramolecular complexes and even nanoparticles. A variety of techniques and designs of MN have been proposed. MN can be produced by microfabrication and laser-based micromolding; can be saw diced and/or etched; can be biodegradable (polymer or nanoporous semiconductors based) or non-dissolving (metallic, silica), solid, or hollow; and can be designed for sampling or drug/vaccine delivery. The design of MN can involve various geometries, which have a direct impact on the diameter and the depth of the pores produced in the skin. As an example, MN can be blunt or possess a very high aspect ratio, can incorporate

the active ingredient into the hollow structure, or can be coated with the substance to deliver. Another key parameter in the design of efficient MN-based delivery system is the application and driving pressures. Generally, due to the skin elasticity, the average diameter of the transepidermal pores left in the skin after microneedle extraction equals to roughly only half of the needle diameter at the base. Microneedles were proven to be efficient in transcutaneous immunization and delivery of opiates and proteins; the long-term safety still remains an open question. There have been a number of clinical studies, which involve mainly metallic MN. Safety of MN especially for chronic administration of therapeutics still holds a question mark. For the last decade, the technology has been under development by several industrial companies mainly for the purpose of vaccination, including Zosano Pharma (Macroflux), 3M Corporation (3 M hollow microstructured transdermal system, hMTS), Corium International Inc. (MicroCor), NanoPass (MicronJet), and BD Technologies (Soluvia™ prefillable microinjection system).

Radiofrequency or Electroporation

Generally, there is less data in the literature related to the methods of *upper skin layer removal* for enhanced percutaneous absorption. Only the main principles of the techniques are given below. *Radiofrequency or electroporation*-based removal of the superficial skin strata is based on microelectronic devices which use high-voltage currents [39]. Further, *lasers* with different wavelengths and types, including the erbium:yttrium-gallium-garnet laser, the neodymium-doped yttrium-aluminum-garnet laser, and the CO2 laser, are studied to increase skin transport of the drugs [2, 40]. This means to create a single or multiple (an array) microchannels across the stratum corneum deep into the viable epidermis. The efficacy of transport depends on the electrical parameters and the physicochemical properties of drugs. When applied in vivo, high-voltage pulses are reported to be well tolerated, inducing only muscle contractions; however, since the techniques may involve viable tissue, the safety for acute and chronic administration of actives yet remains the major question. A few studies reported in the literature show improved skin permeation of ionic molecules such as granisetron hydrochloride and diclofenac sodium, using the above techniques. Enhanced delivery of proteins has also been reported.

Summary

Extensive research during the past few decades has focused on various strategies utilizing nano- and microscaled delivery systems to enhance skin transport of dermal and systemic therapeutics or to retard cutaneous absorption of agents that should primarily act on the skin surface. This entry focused on suitable techniques for delivery of therapeutics either from the skin surface to the deep viable layers or to the systemic circulation. While currently available methods for administration of therapeutics onto the skin span over a wide range of micro- and nanotechnologies, new methods are being introduced in this dynamic research area. In many cases, the safety of chronic or acute use on the skin will determine the fate of the proposed method.

Detection of nanoparticle biomarkers in blood

Definition

Detection of nanoparticulate biomarkers in blood is the ability to find nanoparticles in blood.

Overview

Challenges with Isolating and Detecting Nanoparticles in Blood

While the potential applications of nanotechnology in medicine are rapidly growing, a number of issues still need to be resolved before nanomedicine translates from the lab to the bedside [1]. Two important challenges will be the monitoring of drug delivery nanoparticles and the detection of cell-free-circulating (cfc) DNA nanoparticulate biomarkers [2, 3]. Presently, considerable research efforts are being carried out on the development of new drug delivery nanoparticle therapeutics [4]. For both research and clinical applications, it will be important to develop rapid, sensitive, and inexpensive monitoring techniques for determining levels of drug delivery nanoparticles directly into the patient's blood [2, 5, 6]. In another related area, the ability to detect cfc-DNA, cfc-RNA, and other cell-free-circulating nanoparticulate biomarkers directly into blood would represent a major advance for early cancer screening [7], residual disease detection [8], and chemotherapy monitoring [9].

Unfortunately, present methods for isolating nanoparticles and nanoparticulate biomarkers in the 10–500 nm range from blood are complex, expensive, and time consuming [5–9]. Adding even more challenge is that relatively large blood samples (1–10 ml) are needed when assaying for very low levels of nanoparticles or biomarkers. Thus, sample preparation is more often the weak link in monitoring and diagnostic assays than is the intrinsic sensitivity of the downstream detection technology. The sample preparation process for blood often involves centrifugation, filtration, washing, extractions, and a number of other steps before the analyte(s) can be identified [5–9]. The extended amount of time between blood drawing, cell separation, analyte extraction, and the final analysis also leads to

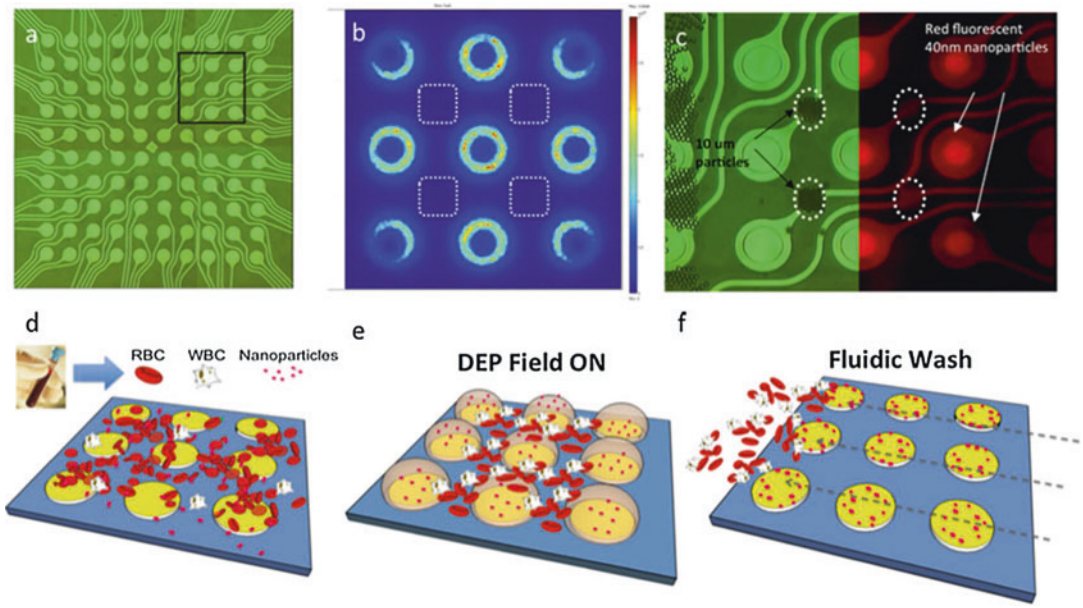
significant loss of sensitivity and selectivity and to the degradation of the analytes [7–9]. Thus, there is a critical need for a novel robust technology, which will allow a variety of nanoscale entities to be manipulated, isolated, and rapidly detected *directly* from whole blood and other biological samples. Meeting this challenge will be required before therapeutic monitoring can be carried out in cost-effective point-of-care (POC) settings.

Dielectrophoresis as an Isolation Method

Dielectrophoresis (DEP) is an intrinsically powerful technique for separating cells and nanoparticles [10, 11]. DEP is the induced motion of particles produced by the dielectric differences between the particles and media in an asymmetric alternating current (AC) electric field [12]. For spherical particles, the DEP force equation is given by:

$$F_{DEP} = 2\pi\varepsilon_m r^3 \mathrm{Re}[K(\omega)]\nabla E^2_{RMS} \qquad (1)$$

where



$$\mathrm{Re}[K(\omega)] = \mathrm{Re}\left(\frac{\varepsilon^*_p - \varepsilon^*_m}{\varepsilon^*_p + \varepsilon^*_m}\right) \qquad (2)$$

where ε^*_p and ε^*_m are the complex dielectric permittivities of the particle and medium respectively, defined by $\varepsilon^* = \varepsilon - j\sigma/\omega$, where $j^2 = -1$, ε is the dielectric constant and σ is the conductivity. If a particle has a positive Re[K(ω)], it will migrate to the high-field regions, and if it has a negative Re[K(ω)], it will migrate to the low-field regions. Unfortunately, the use of DEP for practical applications has been limited by the need to carry out the process under low conductance (ionic strength) conditions [13, 14]. Thus, blood or any other high ionic strength sample has to be significantly diluted before DEP separations can be carried out [14]. Recently, a high conductance (HC) DEP method that allows both nanoparticles and cfc-DNA nanoparticulates to be manipulated, isolated, and detected under high ionic strength conditions has been developed [15–17]. HC-DEP sets the stage for new "seamless" sample to answer systems, which will allow a variety of drug delivery nanoparticles and other nanoscale biomarkers to be rapidly isolated and analyzed from clinically relevant amounts of complex undiluted biological samples.

Basic Methodology

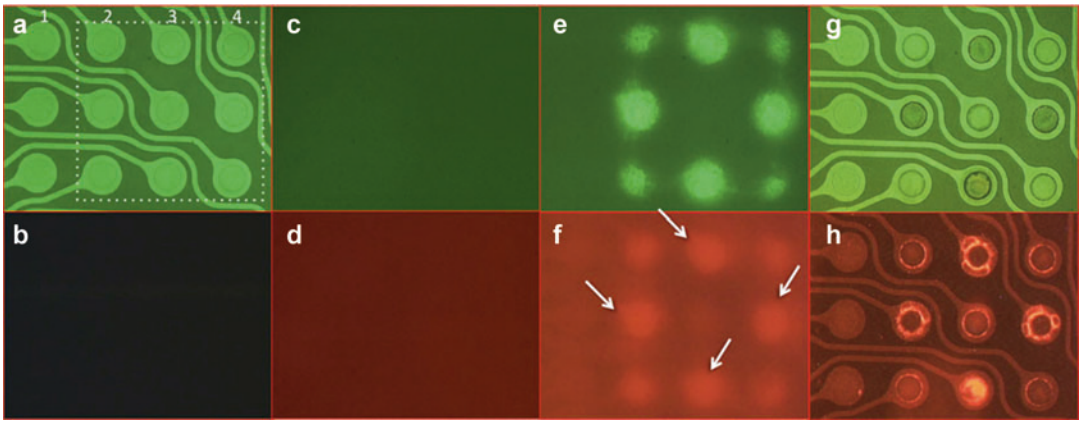
Microelectrode Array Device Used for Dielectrophoresis

In these studies, all HC-DEP experiments were carried out using an electronic microarray device with 100 circular platinum microelectrodes 80 μm in diameter (Fig. 1a). The microarray is overcoated with a 10-μm thick porous polyacrylamide hydrogel layer and enclosed in a microfluidic cartridge, which forms a 20 μL sample chamber. While only a 3 × 3 subset of microelectrodes was used for the DEP experiments, all 100 microelectrodes can be used if desired. AC electric fields were applied to the nine microelectrodes in a checkerboard-addressing pattern where each microelectrode has the opposite bias of its nearest neighbor. Figure 1b shows the asymmetric electric field distribution, which produces DEP positive (high-field) regions on the microelectrodes and the DEP negative (low-field) regions between the microelectrodes [15–17]. At AC frequencies in the 5,000–10,000 Hz range, nanoparticles, cfc-DNA, and other cellular nanoparticulates from about 10 to 500 nm in size will concentrate in the DEP high-field regions over the microelectrodes, while micron-size particles and cells will concentrate in the low-field regions. Figure 1c shows a composite half bright field/half fluorescence image for a prior DEP separation of 10 μm polystyrene particles and 40 nm red fluorescent nanoparticles carried out in 1× TBE buffer. The 10 μm particles are isolated into the low-field regions, and 40 nm red fluorescent nanoparticles are concentrated into the high-field regions. Detailed procedures for high conductance (HC) DEP separations were described earlier [15–17]. The general scheme for the HC-DEP separation of nanoparticles from whole blood (red and white cells) is shown in Fig. 1d–f. When the DEP field is applied, the nanoparticles (red dots) concentrate into the high-field regions where they

Detection of Nanoparticulate Biomarkers in Blood, Fig. 1 Microarray device and flow diagram for the separation of nanoparticles from blood. (**a**) Shows the electronic microarray device with 100 circular platinum microelectrodes 80 μm in diameter. (**b**) Alternating current (*AC*) electric fields were applied to a subset of nine microelectrodes in a checkerboard-addressing pattern. The electric field model for this geometry shows the DEP field maxima or high-field regions exist on the microelectrodes and the DEP field minima or low-field regions exist in the areas between the electrodes (*white dotted square*). (**c**) Shows a composite *half bright field*/*half red* fluorescence image for a prior DEP separation where 10 μm particles are isolated into the low-field regions and red fluorescent 40 nm nanoparticles are concentrated into the high-field regions (**d**) Shows the diagram of the microarray with *red* and *white* blood cells and *red* fluorescent nanoparticles before the DEP field is applied. (**e**) Shows the microarray after the DEP field is applied, with *red* fluorescent nanoparticles moving to the microelectrodes and the larger *red* and *white* blood cells moving between the microelectrodes. (**f**) Shows fluidic wash removing the blood cells, while the nanoparticles remain in the high-field regions

are held firmly on the microelectrodes, and blood cells move into the low-field regions between the microelectrodes where they are held less firmly (Fig. 1e). A simple fluidic wash easily removes the blood cells while the nanoparticles remain in the high-field regions (Fig. 1f). The highly concentrated fluorescent nanoparticles can now be easily detected.

Preparation of Buffy Coat Blood and Whole Blood Experiments

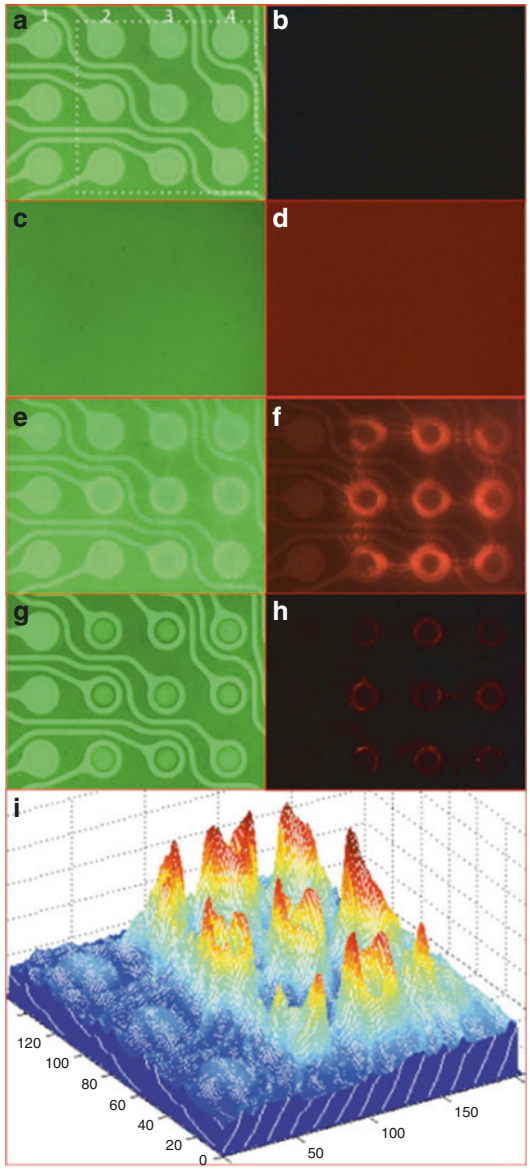


For the HC-DEP experiments, concentrated 5× Tris Borate EDTA (TBE) buffer solution was obtained from USB Corporation (Cleveland, Ohio, USA) and diluted to 1× concentration and Dulbecco's phosphate buffer saline (1× PBS) solution was obtained from Invitrogen (Carlsbad, CA, USA) and diluted to 0.5× concentration. Human buffy coat blood was obtained from San Diego Blood Bank (San Diego, CA). Buffy coat blood contains ~1/10 the number of red blood cells as whole blood. Whole blood samples were obtained from adult female Sprague Dawley rats using proper protocols. Conductivity measurements were made with an Accumet Research AR-50 Conductivity meter using 2 cell (range: 10–2,000 μS) and 4 cell (range: 1–200 mS) electrodes. Buffer conductivities were: 1× TBE: 1.09 mS/cm; 0.5× PBS: 7.6 mS/cm; buffy coat blood: 8.6 mS/cm, whole rat blood: 5.2 mS/cm (nanoparticle experiments). Fluorescent polystyrene nanoparticles (FluoSpheres) with NeutrAvidin were purchased from Invitrogen (Carlsbad, CA). The nanoparticles were 0.04 μm (40 nm) in diameter and red fluorescent (e × 585/em605). For human buffy coat blood

experiments and rat blood experiments, 10 μL of the 40 nm red fluorescent nanoparticles was added from the stock solution to 300 μL of either buffy coat blood or whole rat blood. For comparison purposes, the number of nanoparticles in an Abraxane dosage [18] was calculated by using the recommended dosage of 260 mg/m^2 combined with an average estimated body surface area of 1.92 m^2 leading to a value of approximately 0.5 g of Abraxane per dosage. Since the mean diameter of an Abraxane nanoparticle is 130 nm, and estimating a density of ~1 g/mL, the number of circulating nanoparticles was calculated to be approximately 7.5×10^{10} nanoparticles per ml of blood (assuming 6 L of blood). The red fluorescent nanoparticles were thus serially diluted to the following amounts: 9.5×10^9, 9.5×10^{10}, and 9.5×10^{11} per mL in human buffy coat blood. The microarrays were controlled using a custom-made switching system that allows individual control over the voltage applied to each microelectrode. The microelectrodes were set to proper AC frequency and voltages using an Agilent 33120A Arbitrary Function Generator. AC frequencies ranged from 1,000 to 10,000 Hz, at 20 V peak to peak (pk-pk). The DEP field was generally applied for about 10–20 min. The DEP separations were visualized using a JenaLumar epifluorescent microscope (red fluorescence nanoparticles E × 585 nm, Em 605 nm). Both bright field and red fluorescent images were captured using an Optronics 24-bit RGB CCD camera. The image data was processed using a Canopus ADVC-55 video capture card connected to a laptop computer with Adobe Premiere Pro and Windows Movie Maker. The final fluorescence intensity data images were created by inputting fluorescent image frames of the video into MATLAB.

Key Research Findings

The initial HC-DEP experiment demonstrates the separation and detection of 40 nm red fluorescent nanoparticles in human buffy coat blood (0.86 S/m). Buffy coat blood was used in this experiment because it allows the complete DEP separation process to be observed. The DEP experiment was carried out at 10,000 Hz and 10 V pk-pk. Figure 2a, b shows the microarray in bright field and red fluorescence before the buffy coat blood sample was applied. Twelve microelectrodes are seen in the bright field image (Fig. 2a), and the red fluorescence image is dark (Fig. 2b). *All images show 12 microelectrodes, with the three control microelectrodes in column 1 not activated, and nine microelectrodes in columns 2, 3, and 4, which are activated*. Figure 2c, d shows images of the microarray in bright field and red fluorescence after 20 μL of buffy coat blood containing 300 ng/μL of 40 nm red fluorescent nanoparticles was added. The microelectrodes are not visible in the bright field image because of the high cell density (Fig. 2c), but a red fluorescent background is now seen in the fluorescent image (Fig. 2d). Figure 2e, f shows the microarray after the DEP field has been applied for 12 min to the nine microelectrodes. The bright field image shows the microelectrodes becoming more visible as the blood cells move into the low-field regions (Fig. 2e), and the fluorescent image shows the red fluorescent nanoparticles concentrating in the high-field regions around the microelectrodes (Fig. 2f). Finally, Fig. 2g, h shows the microarray after washing with 0.5 × PBS buffer to remove the blood cells. The bright field image shows the microarray is clear of cells (Fig. 2g), while the red fluorescent image shows intense fluorescence from the concentrated nanoparticles (Fig. 2h). The overall time from sample application to detection was less than 30 min.

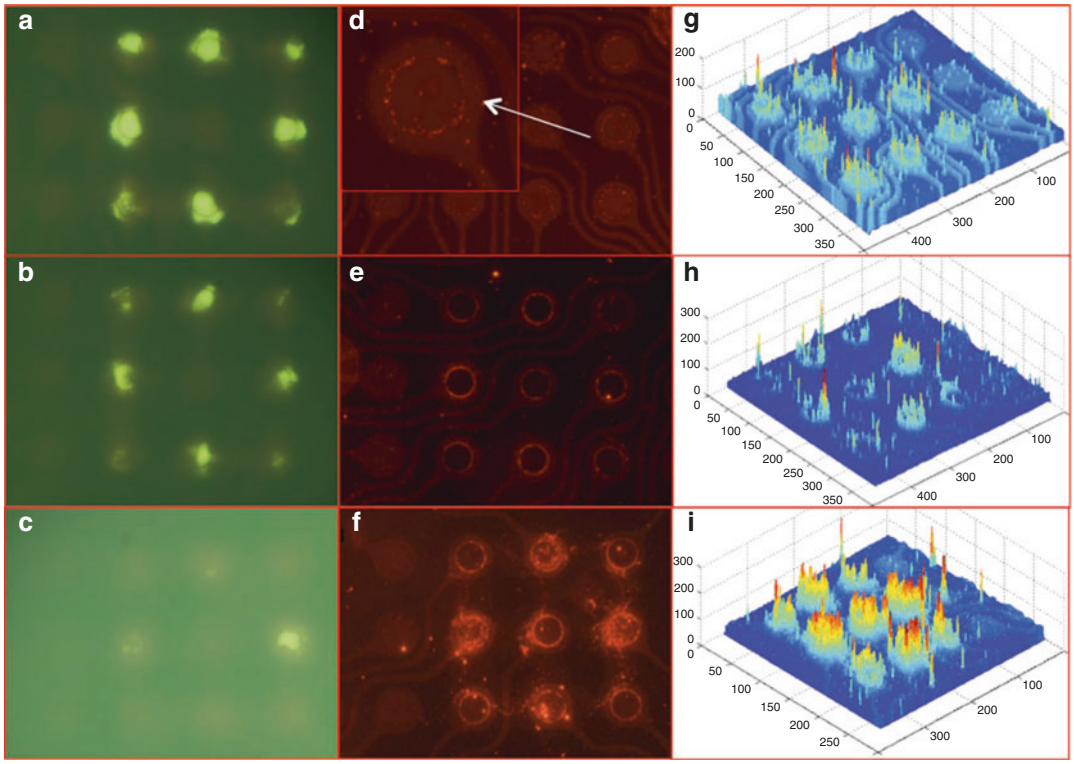


The second HC-DEP experiment demonstrates the separation and detection of 40 nm red fluorescent nanoparticles in undiluted whole rat blood (0.52 S/m). This experiment was carried out at 10,000 Hz and 10 V pk-pk. Figure 3a, b shows the microarray before the whole blood sample was added. Figure 3c, d shows images of the microarray after 20 μL of whole blood containing 300 ng/μL of 40 nm red fluorescent nanoparticles was added. The DEP field was then applied for 11 min. Because of the very high cell density of

(**c**) Shows the microarray in bright field after 20 μL of buffy coat blood containing 300 ng/μl of 40 nm *red* fluorescent nanoparticles were added to the microarray. (**d**) Same as (**c**) in *red* fluorescence. (**e**) Shows the microarray after the DEP field has been applied to a set of nine electrodes (columns 2, 3, and 4), while the three electrodes in the column 1 remained un-activated. The blood cells move away from the microelectrodes. (**f**) Same as (**e**) in *red* fluorescence where the *red* fluorescent nanoparticles can be seen concentrating on the microelectrodes. (**g**) Bright field image shows the microarray after it was washed with to remove the buffy coat blood cells (**h**) *Red* fluorescent image now shows the fluorescent nanoparticles concentrated on the microelectrodes

whole blood, the movement of cells into the low-field regions and concentration of fluorescent nanoparticles into the high-field regions was not observable (while blood cells are present). After one fluidic wash with 0.5× PBS, the bright field image shows the microelectrodes with only a few cells present (Fig. 3e), and the red fluorescent image shows intense fluorescence from the nanoparticles concentrated around the microelectrodes (Fig. 3f). The microarray was then washed five times with 0.5× PBS, and the final images show no cells present (Fig. 3g), with significant red fluorescence remaining on the microelectrodes (Fig. 3h). Figure 3i is a 3D fluorescent intensity image (after the first wash) showing the relative levels of fluorescence on the activated microelectrodes versus the un-activated microelectrodes. The overall time from sample application to detection was less than 30 min.

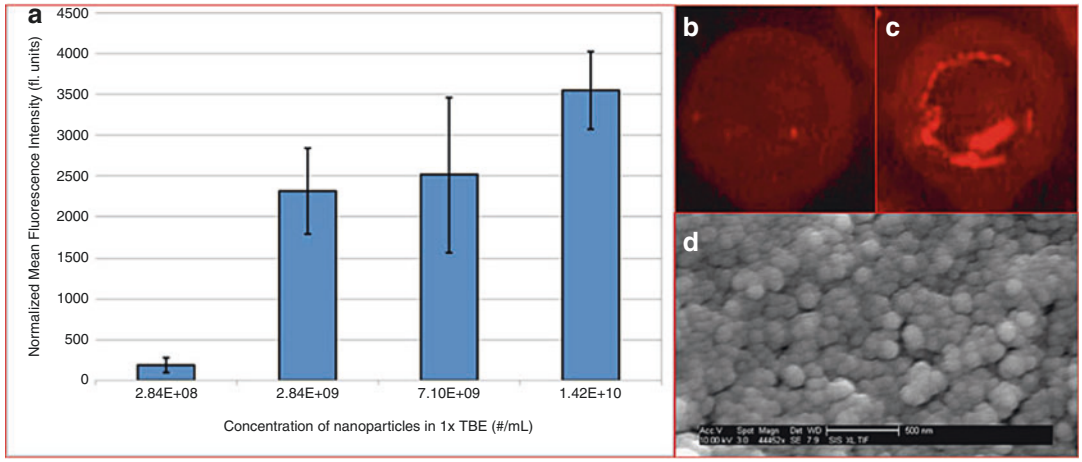
HC-DEP experiments were now carried out in order to determine if nanoparticles could be detected in blood at the basic dosage range used for present drug delivery nanoparticles. By way of example, the dosage for Abraxane drug delivery nanoparticles is approximately 7.5×10^{10} particles/mL blood [18]. Red fluorescent 40 nm nanoparticles at 9.5×10^{9}, 9.5×10^{10}, and 9.5×10^{11} particles/mL were made up in buffy coat blood, and HC-DEP was carried out at 10,000 Hz and 10 V pk-pk for 20 min. Figure 4a–c shows the bright field image for the three different concentrations of nanoparticles, where the blood cells can be seen moving away from the activated microelectrodes into the low-field regions. Figure 4d–f now shows the red fluorescent images of the three different concentrations of nanoparticles after the microarray was washed with 0.5× PBS. Figure 4d shows the nanoparticles at the lowest concentration (9.5×10^{9} particles/mL), with the enlargement of the microelectrode clearly showing fluorescence from the concentrated nanoparticles. Figure 4g–i shows the 3D fluorescent intensity images showing the relative levels of fluorescence on the activated microelectrodes versus the un-activated microelectrodes. These results demonstrate the intrinsic ability of HC-DEP to detect nanoparticles in blood at dosage levels now used for drug delivery nanoparticles.



Detection of Nanoparticulate Biomarkers in Blood, Fig. 3 Separation and detection of 40 nm *red* fluorescent nanoparticles in whole blood. (**a**) Bright field image before the whole blood sample was added. (**b**) Same as (**a**) in *red* fluorescence. (**c**) Bright field image after 20 μL of whole blood containing 300 ng/μL of 40 nm *red* fluorescent nanoparticles was added. (**d**) Same as (**c**) in *red* fluorescence. (**e**) Bright field image after DEP field was applied to a set of nine microelectrodes (columns 2, 3, and 4), and the blood was removed. The bright field image shows the underlying microelectrodes with some blood cells scattered across the surface. (**f**) Same as (**e**) where *red* fluorescent image shows the fluorescent nanoparticles concentrated over the microelectrode structures (columns 2, 3,

Further experiments were carried out to determine the detection levels for the red fluorescent 40 nm nanoparticles in 1× TBE using dilution series of nanoparticles, which ranged from 2.8×10^8 to 2.8×10^{10} particles/mL. HC-DEP was carried out at 10,000 Hz and 10 V pk-pk for 15 min. The results are presented in Fig. 5a (graph) and show that the nanoparticles can be detected down to the 2.8×10^8 particles/mL level. Because only a 1 μL volume of solution is actually being affected by the DEP field (on nine microelectrodes), the true number of nanoparticles being detected on each microelectrode is $<3 \times 10^5$ particles per microelectrode. A final experiment was now carried out to verify by scanning electron microscopy (SEM) that the 40 nm nanoparticles are truly being deposited into the high-field regions on the microelectrodes. For these experiments, a microelectrode array without a hydrogel layer was used. Figure 5d shows a red fluorescent image of one of the microelectrodes before the DEP field is applied. Figure 5e shows an image of the microelectrode after the DEP field was applied at 10,000 Hz and 10 V pk-pk for 4 min. Red fluorescence can be clearly seen concentrated around and on the microelectrode. Finally, Fig. 5f shows the SEM image of the same microelectrode with clusters of the 40 nm nanoparticles clearly visible. In previous work, similar SEM results for HC-DEP using 200 nm nanoparticles were shown [17].

Future Directions for Research



The ability to rapidly detect and monitor the concentration of drug delivery nanoparticles will be important for future nanomedicine applications. HC-DEP has now been shown to be able to rapidly

Detection of Nanoparticulate Biomarkers in Blood, Fig. 3 (continued) and 4). (**g**) Bright field image after washing five times with 0.5× PBS – no cells remain. isolate and detect 40 nm nanoparticles from whole blood and buffy coat blood at clinically relevant levels, $\sim 9 \times 10^9$ particles/mL. Further studies in buffer show that even lower detection limits can easily be achieved, 2.8×10^8 particles/mL. The fact that the isolation of nanoparticles can be carried out directly in whole blood, with no sample processing, means that HC-DEP holds considerable promise for being a viable and cost-effective method for point-of-care applications. At the AC frequencies being used (5,000–10,000 kHz), HC-DEP provides a powerful nanoscopic tool that will allow a variety of important nanoscale entities in the 10–500 nm range to be manipulated and isolated relative to larger cells (red and white blood cells) and numerous smaller proteins and metabolic biomolecules. In addition to having high conductance (0.5–0.9 S/m) [19], whole blood is also one of the most complex of biological samples. Other important nanoscale entities that could be isolated using HC-DEP include: nanoparticle imaging agents, virus, prions, chylomicrons, large antibody and immunoglobulin complexes, and other cellular nanoparticulate biomarkers (nuclei, mitochondria, ribosomes, lysosomes, and various storage vacuoles). It should also be kept in mind that at higher AC frequencies (>10,000 Hz), DEP has the intrinsic ability for the higher resolution separation of different nanoparticles based on their AC crossover frequency and dielectric

Detection of Nanoparticulate Biomarkers in Blood, Fig. 5 Detection levels for the *red* fluorescent 40 nm nanoparticles in 1× TBE buffer. (**a**) Graph shows results after HC-DEP for a dilution series of nanoparticles, ranging from 2.8×10^8 to 2.8×10^{10} particles/mL. Nanoparticles could be detected down to the 2.8×10^8 particles/mL level. (b) *Red* fluorescent image before DEP field is applied. (**c**) *Red* Fluorescent image after the DEP field is applied. properties [20]. A final advantage for HC-DEP is the fact that the entities being isolated do not have to be labeled. The ability to post-label a specific biomarker or analyte will prove to be a significant advantage for future drug monitoring and diagnostic applications. Thus, numerous molecular biological detection techniques including PCR, immunochemistry, specific fluorescent dyes, and in situ hybridization can be easily carried out in the same sample chamber. Overall, the results of this study have shown that HC-DEP has enormous potential for a number of new "seamless" sample to answer nanomedicine applications.

Definition

Nanodiamonds have excellent mechanical and optical properties, large surface areas and tunable surface structures. The nanodiamonds have very broad applications and, since they are nontoxic, also biomedical ones. So far, these artificial diamonds are mainly created by energy-consuming high-pressure and high-temperature methods. Recently, the spark plasma sintering technology proved to be an energy-saving method to generate nanometer and micrometer-sized diamond grains in short processing times.

Introduction

About six decades ago, the first artificial diamonds were synthesized. Since then, diamond particles and diamond films have been successfully obtained by various methods including high pressure and high temperature (HPHT) under static and shock pressure, combustion flames and chemical vapor deposition with radio frequency plasma and microwave plasma. For the synthesis of diamonds, the HPHT is still the most popular commercial method and it is applied to graphite, fullerenes, and carbon nanotubes. The achieved

Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering,
Fig. 1 Pressure-temperature carbon phase diagram (Redrawn from [1] with permission of John Wiley and Sons ©)

materials show properties close to the ones of natural diamonds. Excellent surface coatings are achieved by ultrafine diamond grains with sizes of 5 nm–10 nm synthesized by explosives. Figure 1 shows the pressure-temperature phase diagram of carbon [1]. Generally, the HPHT synthesis of diamonds is applied at pressures above 5.0 GPa and at temperatures above 1300 °C.

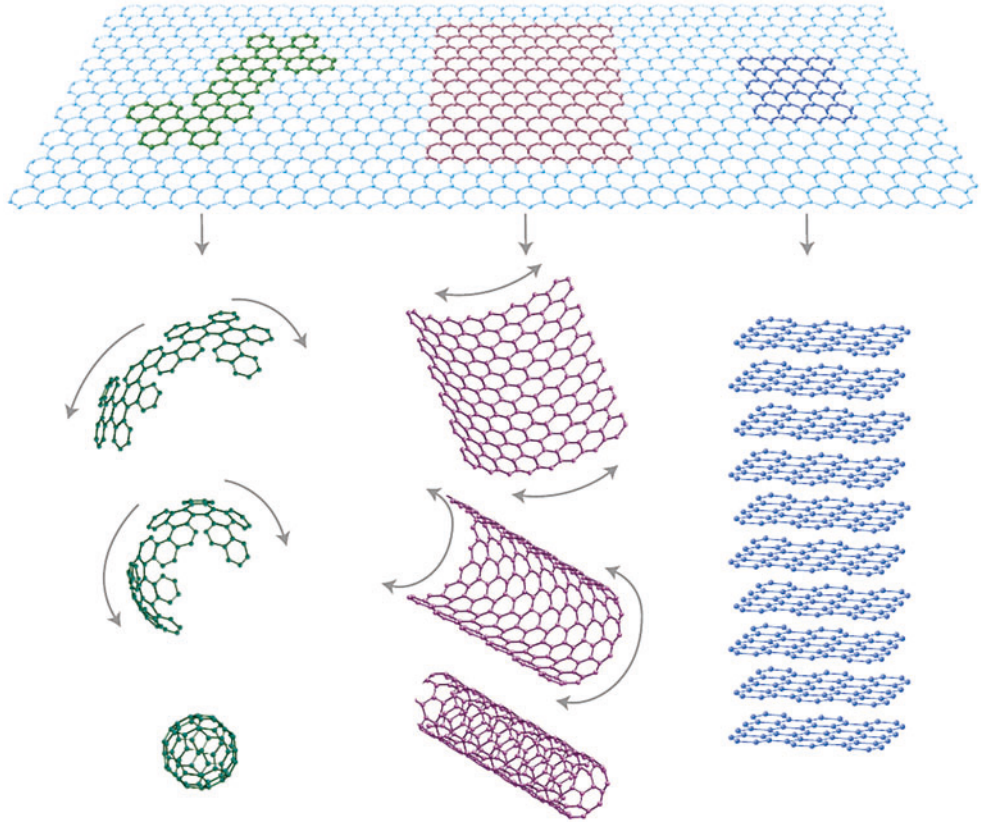
However, C60 fullerenes are also compressed under non-hydrostatic pressures up to 30 GPa at room temperatures and transformed to small diamond crystallites at 20 GPa and 2000 °C using a multi-anvil cell achieving nanocrystalline cubic diamond with crystal sizes of 5 nm–10 nm [2]. In addition, the incorporation of solvent catalysts such as Ni, Co, Fe, and other transition metals and their alloys is a crucial point as aid for the diamond synthesis in the HPHT method.

About one decade ago, it was observed that, during spark plasma sintering (SPS) already at pressures of 80 MPa and temperatures of 1500 °C, carbon nanotubes became unstable and transformed to diamonds without any catalysts being involved [3]. Spark plasma sintering, also known as field-assisted sintering (FAST) or pulsed electric current sintering (PECS), is an electric field-assisted sintering procedure utilizing pulsed direct currents [4]. During this process, the necessary energy required in the diamond transition is delivered. The studies indicate that the SPS has a potential to be used as an alternative method for the diamond generation.

The Innovative Spark Plasma Sintering Technology

The science and technology of new materials is in the focus of ongoing research and development efforts worldwide. One main focus is directed toward the synthesis, characterization and applications of nanostructured and composite materials. The multifunctionality of such materials is caused by their internal structures of micro- and nanometer-sized units. However, the physical, chemical, and mechanical properties of

nanomaterials change not only due to the pure size reduction but also due to the dominant influence of boundary effects and the appearance of quantum mechanical phenomena. The size and surface/interface effects specific to nanostructured solids are nowadays best exploited in the development of new magnetic and lightweight materials. Significant progress has been achieved for hard and soft magnetic materials and exchange-spring composite magnets as well as for nanostructured alloys with improved mechanical properties. Nanomaterials can be metals, ceramics, polymeric materials or their composites. In the last years, innovative processing technologies like the spark plasma sintering have emerged. This high-speed powder consolidation technology has a broad application potential. During SPS, pulsed electric currents and mechanical pressure are applied on precursor powders in a graphite die. Pulsed electrical direct currents through the die and through the powder compacts, directly, in case they are conductive, lead to rapid heating while uniaxial pressure is applied on the powder. The Joule's heating effects can be strongly enhanced. Due to small gaps and small contact points of neighboring particles, plasma discharges and rapid local heating can occur and will lead to surface activation diffusion processes [5–7]. During the SPS synthesis, uniaxial pressure and pulsed currents allow to separate the densification of powders from the grain growth and, thus, to influence the internal structure of the materials. The essential advantages of SPS over conventional sintering methods like pressureless sintering, gas-pressure sintering, hot-pressing or hot isostatic pressure (HIP) are lower sintering temperatures, shorter exposure to elevated temperatures and no need for binder or additives as well as important improvements in the properties of the sintered materials. Processing under extreme pressure and temperature conditions leads to important changes of the density, electron configuration and free energy of the constituent phases. The resulting chemical equilibrium changes allow the access to a wide range of new compounds. External pressure can further induce reactions between chemical components at much lower temperatures, thus facilitating the synthesis of metastable phases with valuable modified properties. SPS has already demonstrated its potential as an energy-saving sintering method, for nanotechnology, for rapid manufacturing of monophasic materials and composites, for biomedical applications and for energy-saving and energy-harvesting materials [8]. This core technology has recently attracted high interest in the fields of material manufacturing, energy, health care, automotive and aeronautics.



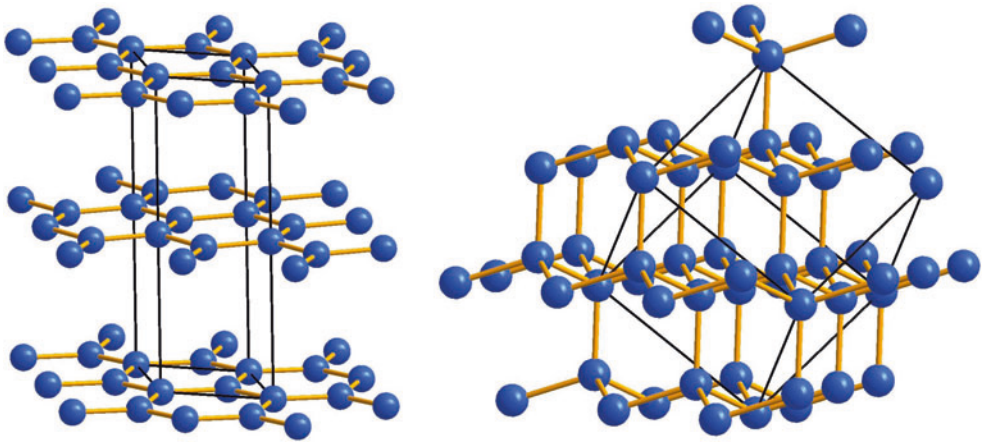
D

Nanocarbons

The nanocarbon materials include fullerenes like C60, carbon nanotubes (CNTs), graphene and nanodiamonds. These allotropes arise since carbon atoms with their original 6 electrons in the states $1s^2 2s^2 p^2$ are able to form various hybrid orbitals due to the energies of the 2 s and 2p states having almost similar energies allowing not only the simple states but also linear combinations of them to be solutions of the Schrödinger equation. Four equal bonding orbitals are formed in the sp^3 state, two in the sp^2 state and one in the sp state, forming localized and directed σ bonds. The other electrons are delocalized, forming the so-called π bonds.

The fullerene C60 is a carbon allotrope that consists of 60 carbon atoms, arranged as 12 pentagons and 20 hexagons. The shape resembles the one of a soccer ball. The discovery of C60 has stimulated strong activities in chemistry and opened with the fullerene chemistry a branch studying a new family of molecules based on fullerenes. The 1996 Nobel Prize for Chemistry has been awarded to H.W. Kroto, R.F. Curl, and R.E. Smalley for their discovery of C60 in 1985 as a new allotrope of carbon.

Carbon nanotubes have attracted many scientists worldwide. The small dimensions, strength and remarkable physical properties of these structures make them a unique material with a whole range of promising applications. Carbon nanotubes were discovered accidentally by Sumio Iijima 1991 while studying the surfaces of graphite electrodes used in an electric discharge. Carbon nanotubes with an incredible



Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 2 Schematic of carbon allotropes (Reprinted from [9] with permission of Nature Publishing Group ©)

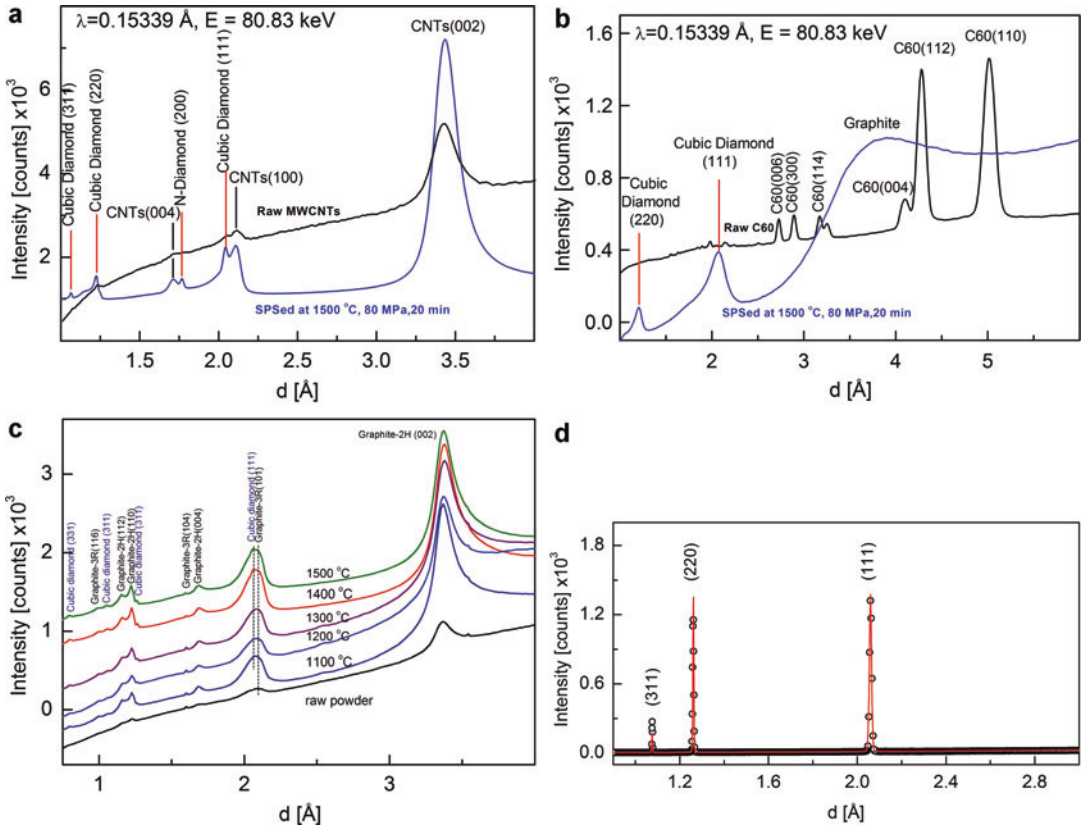
strength and fascinating electronic properties appear to be ready to overtake fullerenes in the race to the technological marketplace.

Graphene is the name given to a monolayer of carbon atoms tightly packed into a two-dimensional (2D) honeycomb lattice which is the basic building block for carbon materials of other dimensions, as shown in Fig. 2. It is bound by σ bonds that are sp^2 hybridized. Each carbon has one π orbital which contributes to a delocalized network of electrons. It can be wrapped up into 0D fullerenes, rolled into 1D nanotubes, or stacked into 3D graphite (Figs. 2 and 3). Recent years have witnessed many breakthroughs in research on graphene and significant advance in the mass production of this material. This one-atom-thick net of carbons uniquely combines extreme mechanical strength, exceptionally high electronic and thermal conductivities, impermeability to gases and many other supreme properties all of which make it highly attractive for numerous applications [9].

Nanoscale diamond particles were first produced by detonation in the USSR in the 1960s, but they remained essentially unknown to the rest of the world until the end of the 1980s. Then a number of important breakthroughs led to wider interest in these particles which are known as nanodiamonds. Nanodiamonds have excellent mechanical and optical properties, large surface areas and tunable surface structures. The nanodiamonds have very broad applications and, since they are nontoxic, also biomedical ones [10].

In diamond, the carbon atoms are bonded in a tetrahedral structure with sp^3 hybridization. Since there is no π orbital, there is no delocalized network of electrons which makes diamond an

Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 3 Structure of graphite (*left*) and diamond (*right*) with the indicated bonds and unit cells



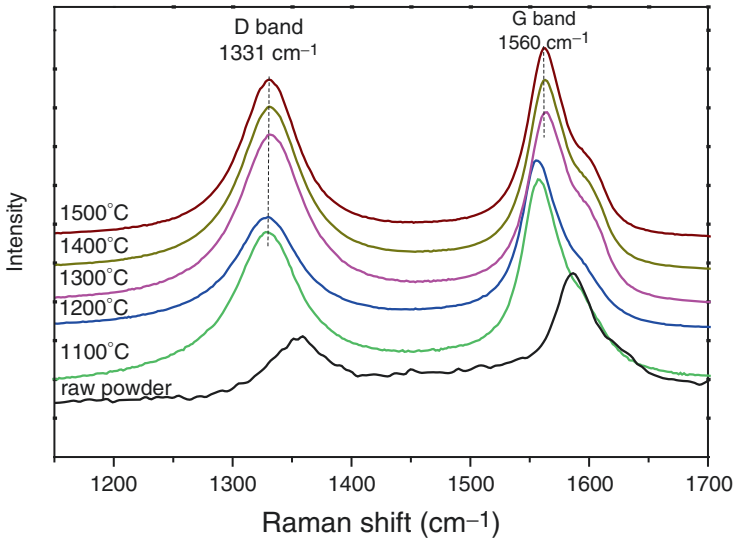
insulator. The diamond structure can be seen as two interpenetrating face-centered cubic structures displaced by one fourth of the cube diagonal. Figure 3 shows the structure of graphite (left) and the structure of diamond with indicated bonds and unit cells. The diamond lattice is rotated to make the similar staple of carbon planes visible.

Stability of Nanocarbon Under SPS

As already discussed, the widespread method to prepare diamonds is the HPHT method with pressures in the GPa region. Therefore, it is important to analyze the behavior of nanocarbons under the low pressures of a few MPa during the SPS treatment and to confirm the suitability of this method for a successful diamond synthesis. A variety of carbon allotropes, such as carbon nanotubes, C60, graphene nanoplatelets and graphite were investigated with respect to their thermal stabilities under SPS conditions [11, 12].

In these experiments, multiwall carbon nanotubes (MWCNT, 10–20 nm), graphite powders (about 10 μm) and graphene nanoplatelets (C-750) were used. The nanoplatelets consisted of short stacks of graphene sheets having platelet shapes with an average thickness of 2 nm and a lateral diameter of less than 2 μm. For the SPS treatment, the carbon powders are usually pressed into a graphite die to form a disk-shaped sample of 20 mm diameter and 5 mm thickness. A heating rate of 100 K min^{-1} was adopted and the sintering process lasted typically 20 min. The sintering temperatures were varied up to 1500 °C. The axial pressure has been 80 MPa and the sintering process was performed under vacuum condition. The applied pulsed direct current for SPS was 1000 A–2000 A. The sintered carbon samples were etched in a solution of concentrated H_2SO_4 (90 vol.%) and HNO_3 (10 vol.%). The etched samples were washed using deionized water repeatedly and dried in an oven.

The phase identification of the raw nanocarbon material and of the SPS sintered samples can be performed by diffraction experiments using high energetic synchrotron radiation X-rays. Figure 4 shows the exemplary spectra already as functions of the lattice spacings. The raw C60 shows diffraction peaks corresponding to spacings of C60 as given in the Fig. 4a. After SPS sintering, diffraction peaks of cubic diamond at spacings 2.06 Å and 1.23 Å appear, as well as a broad graphite peak. Since the C60 diffraction peaks disappeared, this indicates that the C60 was transformed into diamond and graphite during the SPS process. The raw MWCNTs (Fig. 4b) show a main diffraction peak corresponding to the CNT (002) spacing and weaker ones, corresponding to the (100) and (004) spacings. After the SPS process, the MWCNT diffraction peaks are still present with increased intensities



Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 4 X-ray diffraction patterns of (**a**) the raw C60 and the spark plasma sintered C60 at 1500 °C and 80 MPa for 20 min, of (**b**) the raw MWCNT and sintered MWCNT at 1500 °C and 80 MPa, and (**c**) the raw and sintered graphene nanoplatelets at 1100–1500 °C and 80 MPa and (**d**) of the purified diamond crystals

and reduced halfwidths indicating that the crystallinity improved. However, more important, new peaks corresponding to cubic diamond (111), (220) and nanodiamond (200) appear demonstrating the successful synthesis of diamond.

The diffraction peaks of the raw graphene nanoplatelets (Fig. 4c) are very weak and broad indicating their low crystallinity and their nanostructures. The raw graphene nanoplatelets have characteristic peaks corresponding to the graphite-2H (002) and graphite-3R (101) plane spacing. The intensities of the peaks increase continuously with the sinter temperature and the graphite-3R (104), (116) and graphite-2H (004), (110), (112) peaks are visible at temperatures from 1100 °C to 1500 °C. This shows that the crystallization and graphitization of the graphene nanoplatelets depend on the SPS temperatures. In addition, peaks corresponding to cubic diamond (111), (220), (311) and (331) planes can be identified in this temperature range. Figure 4d shows the diffraction pattern of extracted micrometer-sized grains of diamond after the SPS synthesis and purification with the typical diamond reflections.

Raman spectroscopy is another valuable tool to study the phase changes by analysis of typical dynamical features of the materials. Figure 5 shows the Raman spectra of the raw graphene nanoplatelets and the sintered samples at 1100 °C up to 1500 °C and at 80 MPa with typical modes. Here, the so-called graphite-like G-band peak gives information on the inplane stretching of the sp^2-bonded carbon in a two-dimensional

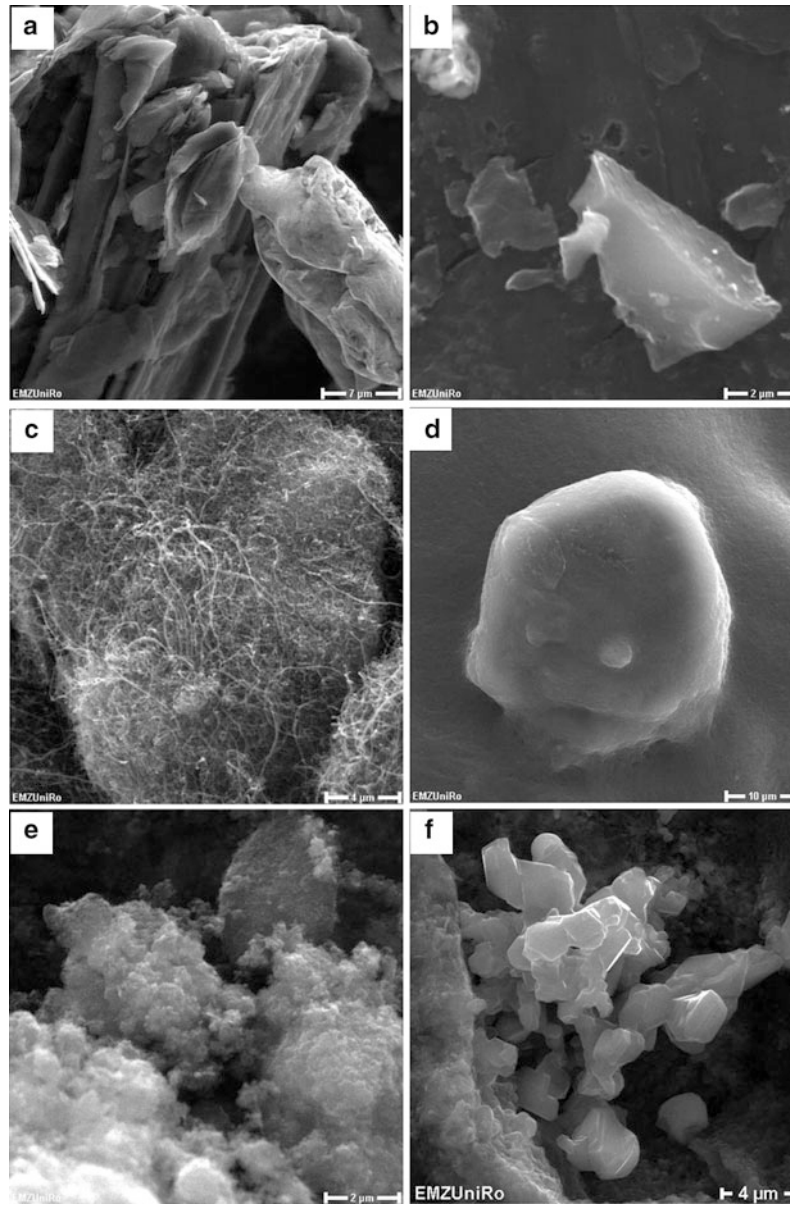
Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering,
Fig. 5 Raman spectra of the raw and sintered graphene nanoplatelets at 1100–1500 °C and 80 MPa

graphitic hexagonal lattice and the disorder D-band peak gives information on the internal crystalline defect densities within the structure. The spectrum of the raw graphene nanoplatelets shows lower intensity in the D-band at 1355 cm^{-1} than in the G-band at 1585 cm^{-1} which indicates defects in the initial nanoplatelets. After SPS processing, the D-band shifted to 1331 cm^{-1} for the samples sintered at 1100–1500 °C. This value is typical for cubic diamond and its sp^3 hybridization, thus, proving a structural change to diamond introduced by the SPS process. The main peak of the G-band has shifted to 1556 cm^{-1} at temperatures of 1100 °C and 1200 °C and to 1560 cm^{-1} at 1300 °C–1500 °C with roughly unchanged contributions at 1585 cm^{-1} of the raw nanoplatelets. The shift of the G-band indicates a major change in the inplane C-C bond stretching proving the formation of sp^2-bonded carbon vibrations in graphite. It is because of the densification and graphitization of the graphene nanoplatelets during the SPS. Some graphene nanoplatelets are bonded together when the stackings match and are formed into nanographite stacks at higher temperatures. The Raman spectra of SPS sintered fullerenes and carbon nanotubes also confirmed the formation of nanodiamonds.

Scanning electron microscopy (SEM) images are shown in Fig. 6a, b for the raw and the sintered C60, in Fig. 6c, d for the raw and sintered MWCNT and in Fig. 6e, f for the raw and sintered graphene nanoplatelets, all sintered at 1500 °C and 80 MPa. The raw C60 powders are nanoparticle agglomerates and show bundles of C60 (Fig. 6a). Some diamond crystals with sizes from 2 μm to 8 μm can be observed (Fig. 6b). The fibrous structures of the raw MWCNTs are very obvious in Fig. 6c. After sintering, the fibrous structures disappear and some diamonds are found. Figure 6d shows one diamond crystal with a particle size of around 35 μm. In the background, there are no longer any MWCNTs visible. The raw powder of graphene shows many agglomerates with platelet shapes and particle sizes from nanometers to several micrometers (Fig. 6e). Some bright diamond particles ranging from 2 μm to 4 μm are found in the 1500 °C sintered samples (Fig. 6f). A larger diamond particle with size about 20 μm is found in the 1400 °C sintered sample (Fig. 6c). The diamond particle sizes are ranging from 2 μm to 4 μm in the 1500 °C sintered sample (Fig. 6d).

In addition, transmission electron microscopy (TEM) can give further information on the structure. The result of a C60 sample that was spark plasma sintered at 1200 °C is presented in Fig. 7 showing a diamond crystal and some C60 particles. The particle sizes of the C60 in this sintered sample lie in the range of 40 to 100 nm which is

Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering,



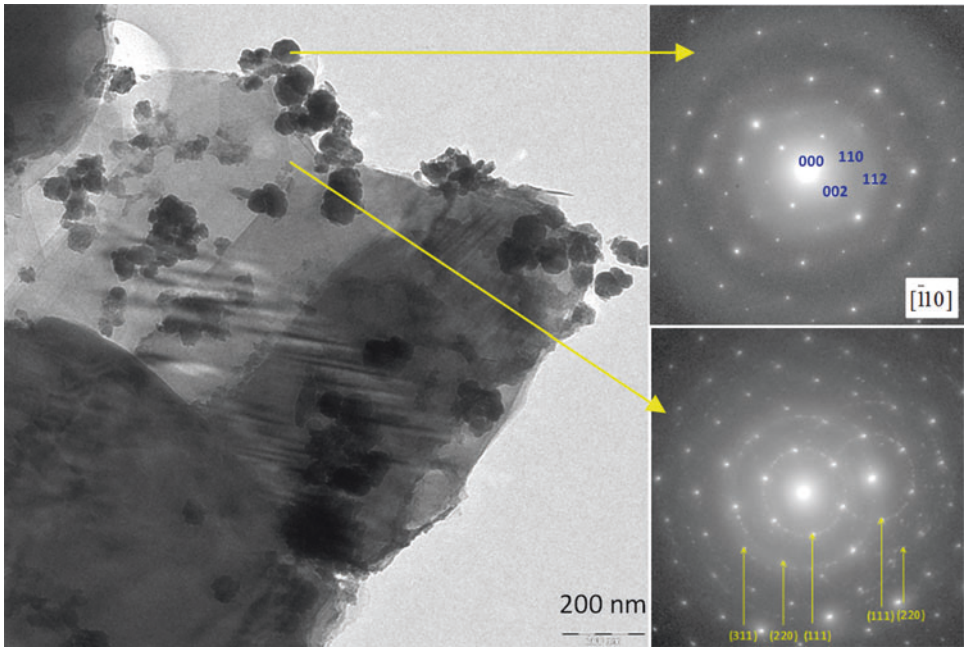


Fig. 6 SEM images of the raw and the spark plasma sintered C60, of (**a**, **b**) the raw and sintered MWCNT and of (**c**, **d**) the raw and sintered graphene nanoplatelets (**e**, **f**), all sintered at 1500 °C and 80 MPa

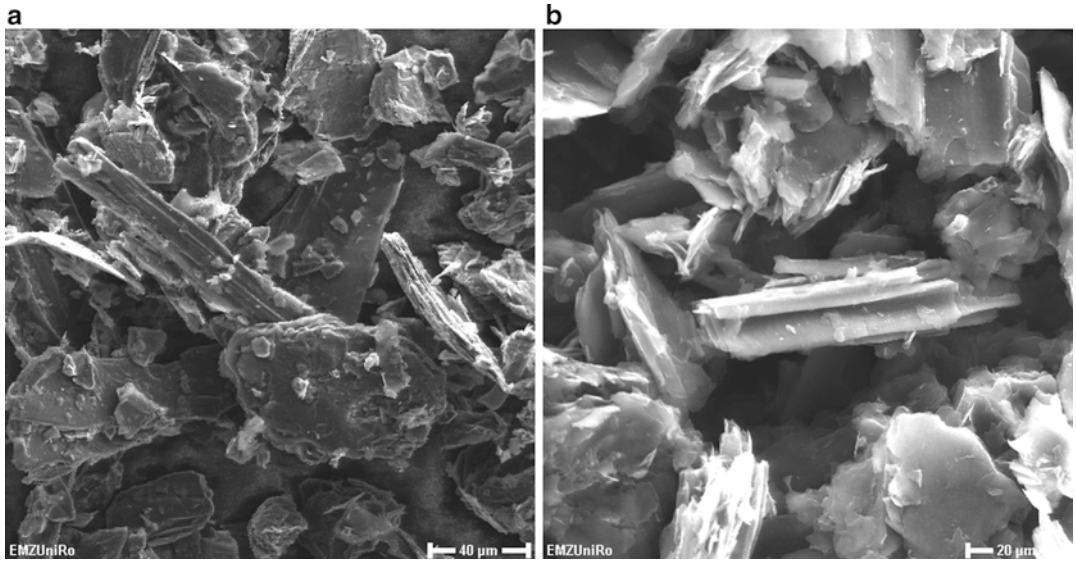
identical to the sizes of the raw C60. The C60 particles are present with the diamond crystal together. This clearly indicates that the diamond is transformed from these C60 particles, directly. The selected area diffraction patterns show the diffraction rings for C60 in the top one and for diamond with cubic polycrystals in the bottom one. No formation of an intermediate phase can be detected. The transformation from C60 to diamond is seen as a direct carbon transformation process with structural reconstruction without intermediate phase [13].

The particle size of the diamond crystals did not increase continuously but decreased again at the temperature of 1500 °C. Nevertheless, the degree of diamond crystallinity at 1500 °C is higher than the one at the lower temperatures. In a pressure-temperature diagram, the best

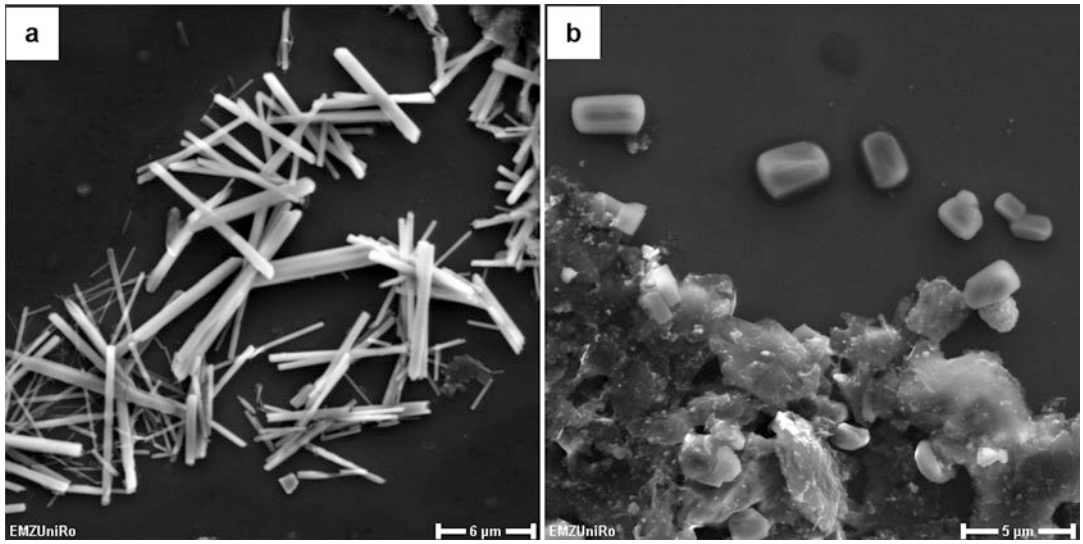
Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 7 TEM image of the C60 to diamond with selected area diffraction patterns of C60 (*top*) and diamond (*bottom*)

transformation of graphene nanoplatelets to diamond occurs in the temperature range of 1300 °C–1400 °C at the pressure of 80 MPa.



Stability of Graphite Under SPS

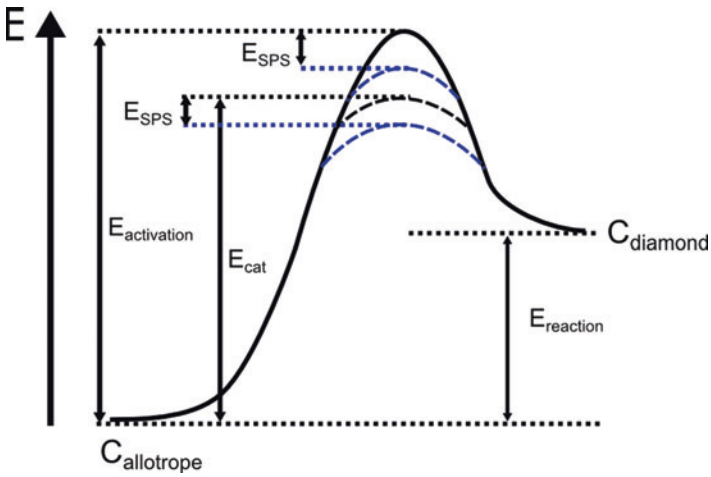
Figure 8 shows the SEM images of a raw and a spark plasma sintered graphite sample, prepared at 1500 °C and 80 MPa for 20 min. The raw graphite shows the typical layered structure (Fig. 8a). After the SPS treatment at similar conditions as for C60, MWCNTs and graphene, no diamond is present in the sample. Still, the typical structure of the raw graphite is visible in Fig. 8b. X-ray investigations and Raman spectroscopy confirm that there is no diamond formation if a pure graphite sample is processed by SPS at these mild conditions. The graphite is the most stable crystalline modification of carbon among the MWCNTs, graphene, C60 and graphite allotropes under the SPS.



Diamond Formation from Graphite with Various Catalysts Under SPS

Pure graphite is the main carbon source for the diamond synthesis with the HPHT method. As mentioned before, the discussed conditions of modest temperatures and pressures in the SPS technology are not sufficient to transform pure graphite into diamond.

However, adding catalytic materials like Ni or quasicrystalline Al-Cu-Fe powders to pure graphite powders allows the transformation of graphite into diamond during a SPS treatment at 1300 °C and 50 MPa for 20 min [14]. Figure 9 shows the SEM images of the diamonds obtained after etching the sintered samples. The Ni catalyst supported the growth of nano- and microrods from graphite (Fig. 9a). The diameter of the diamond rods ranges from 80 nm to 2 μm. Therefore, the SPS method is suited for the synthesis of diamond nano- and microrods. Quasicrystalline Al-Cu-Fe powder used as catalyst allows the

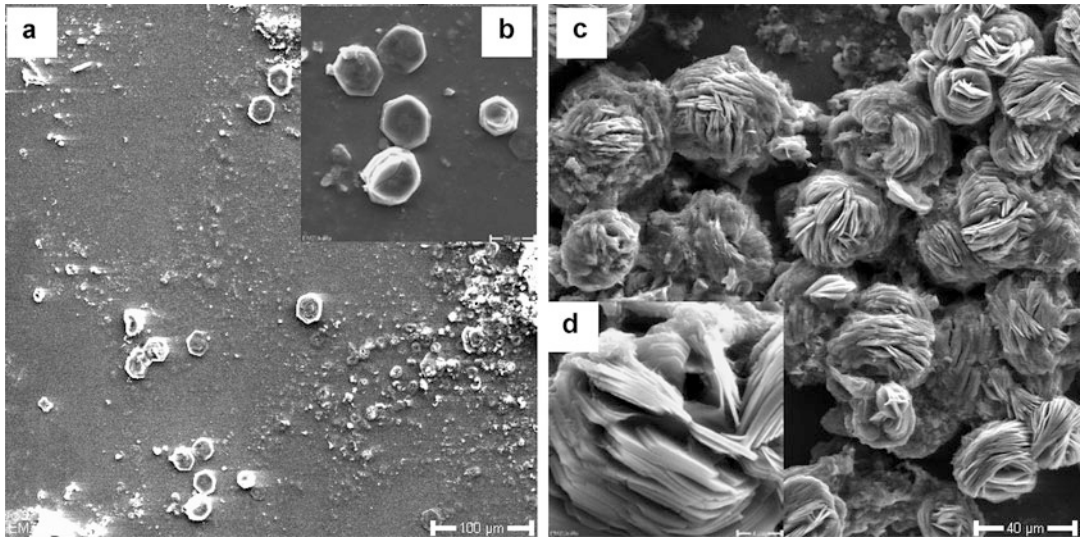


Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 8 SEM images of the raw graphite (**a**) and the spark plasma sintered graphite (**b**) at 1500 °C and 80 MPa for 20 min

Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 9 SEM images of the diamonds gained from the spark plasma sintered graphite samples at 1300 °C and 80 MPa mixed with Ni (**a**) and Al-Cu-Fe quasicrystal (**b**) as catalytic materials

conversion of graphite to well-shaped diamond grains from 1 μm to 3 μm (Fig. 9b). Figure 10 demonstrates schematically the energy barrier between diamond and various carbon allotropes. In the case of graphite, for instance, the high-energy barrier of the activation energy, $E_{activation}$, compared with the real reaction energy, $E_{reaction}$, can easily be crossed with HPHT. With the

Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering,
Fig. 10 Schematic view of the energy barrier for the transformation of various carbon allotropes into diamond



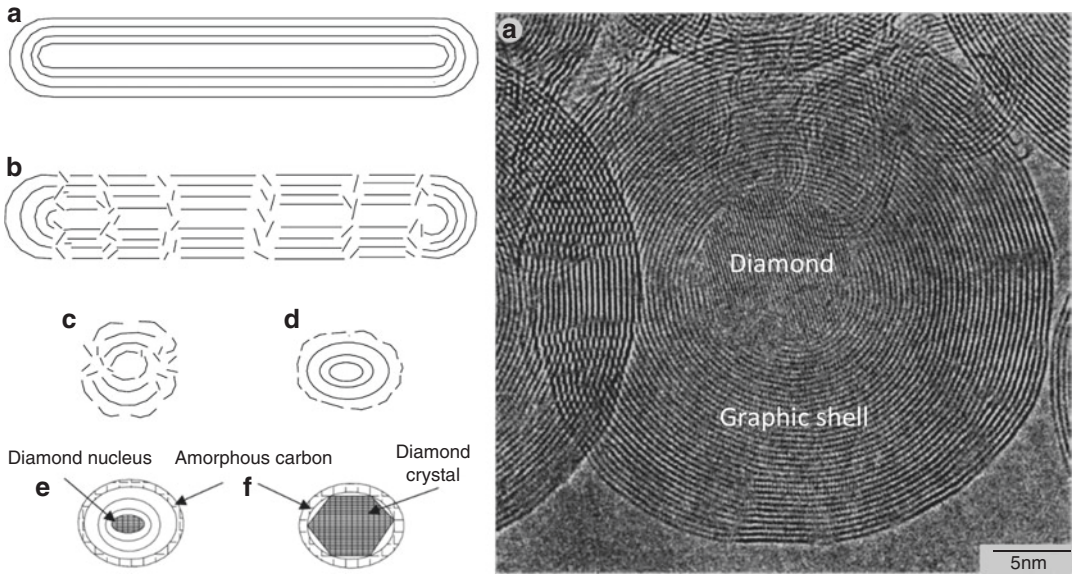
application of a catalyst, the energy barrier is reduced (marked by E_{cat}) and the SPS treatment delivers the necessary energy, E_{SPS}, to cross the barrier, even for graphite. For the other allotropes, the SPS treatment alone can deliver the necessary energy for the barrier crossing. However, the application of catalysts can promote the transition, further.

Diamond Synthesis from Carbon Nanotubes with Solvent Catalysts

In the diamond synthesis with the SPS method, the atmospheres (vacuum or argon gas), the pulsed direct current intervals, and the use of catalysts have a direct influence on the diamond sizes and the transition rates that can be achieved [15, 16]. For a demonstration, MWCNTs/NiFe and graphite/NiFe mixtures were used as raw materials. The microstructures and diamond phases were analyzed by X-ray diffraction, Raman spectroscopy and scanning electron microscopy. It was proven that diamond can be synthesized by SPS in an argon gas atmosphere with a minimum pressure of 9.5 MPa from both mixtures, MWCNTs/NiFe and graphite/NiFe. High-quality diamond crystals with hexahedron structures can be found in the sample (Fig. 11a). A high-magnification SEM micrograph of such diamond crystals obtained by SPS is shown in Fig. 11b. The flowerlike structured carbons visible in the sample (Fig. 11c, d) are seen as a proof that sparking plasmas occurred leading to such carbon flowers. The diamond shapes and sizes increase by the use of Ar gas. This indicates that the Ar gas increases the plasma effects in the SPS. The variations of the pulsed current intervals lead also to changes in the structures and the sizes of the synthesized diamond grains. This demonstrates that the localized temperatures can be varied by the pulse intervals thus influencing the growth of the diamond nuclei.

The Role of SPS in the Transformation from Carbon to Diamond

For further understanding of the nucleation of the diamond grains, in situ diffraction experiments using synchrotron radiation were performed at a pressure of 80 MPa up to a temperature of 1500 °C using standard steady current heating [12]. The diffraction patterns indicated clearly that the graphene nanoplatelets are stable under these conditions which can be attributed to the lack of current pulses being present in the SPS treatment. In these experiments, not the powder but only the sample container was heated by Joule's heating. It was demonstrated that similar pressure and temperature conditions and only steady current heating did not allow the nucleation of diamond grains. Therefore, it is concluded that the pulsed current heating has an important influence. In the



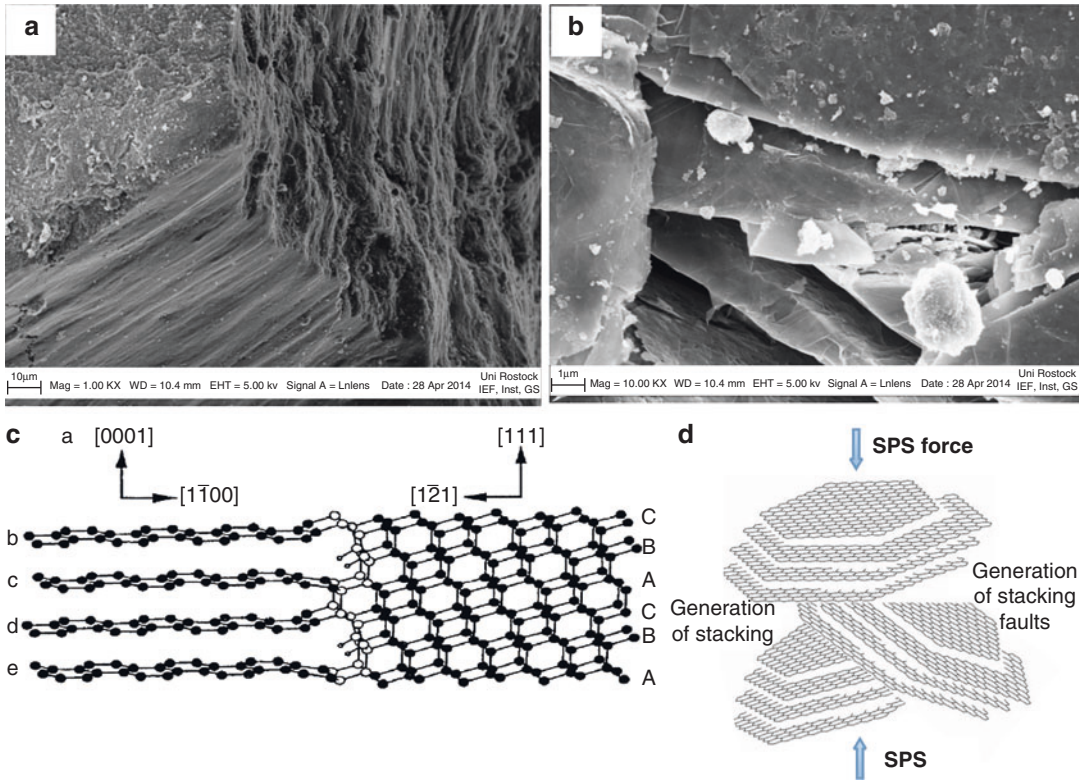
Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 11 SEM micrographs of the spark plasma sintered MWCNTs/FeNi at 1200 °C and 9.55 MPa in Ar gas atmospheres with various magnifications showing the diamond crystals (**a**, **b**) and carbon flowers (**c**, **d**)

SPS method, the electric direct current employs on-off pulses with high current values up to 6000 A at low voltages up to approximately 5 V which can generate highly localized Joules heating up to a few thousand degrees Celsius between particles, within minutes. The current density in the SPS is typically on the order of 10^3 A/cm^2 and it is highly concentrated at the intergranular contacts or interfaces [17], thus leading to localized high temperatures. Momentary plasmas can be generated at the intergranular contacts or interfaces of the powder particulates by the pulsed direct current. There exists a certain activation barrier from the graphene (sp^2) to diamond (sp^3). Bonds have to be broken and rearranged with a different hybridization. The energy of the occurring plasmas allows to pass the activation energy barrier from graphene to diamond, as sketched in Fig.10. The plasmas generated by the pulsed direct current increase the entropy of the whole carbon system thus promoting the diamond formation. The generation of plasmas during the SPS is the main thermodynamic reason for the diamond nucleation. However, the graphite itself cannot be transformed into diamond at the same SPS conditions. This means that graphene nanoplatelets, fullerenes and MWCNTs behave really different than graphite. The graphene nanoplatelets are nanometer-thick graphite with an average particle thickness of 2 nm consisting of less than 10 sheet stacks of graphene. The properties of the graphene nanoplatelets are similar to the properties of the single-layer graphene but not to the ones of graphite.

The model of CNT transformation into diamond in SPS was proposed in [18]: CNT fracture to form an intermediate phase of bulky onions and the diamond nucleates at the cores of onions as sketched in Fig. 12 (left) inspired by the TEM observations in Fig. 12 (right) [13].

From this model, it is predicted that the diameter of CNTs determines the transformation rates to diamond crystals. It was found that the sizes of the achieved diamond particles can be increased if the sizes of the used CNTs are reduced. These results match with the theoretical assumptions. The transformation of C60 to diamond is a direct solid-state phase transformation without intermediate phase (see Fig. 7). It is a SPS-induced phase transformation with a new arrangement of

Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 12 The model of CNT transformation into diamond in SPS [18] and TEM observation (Reprinted from [19] with permission of Nature Publishing Group ©)

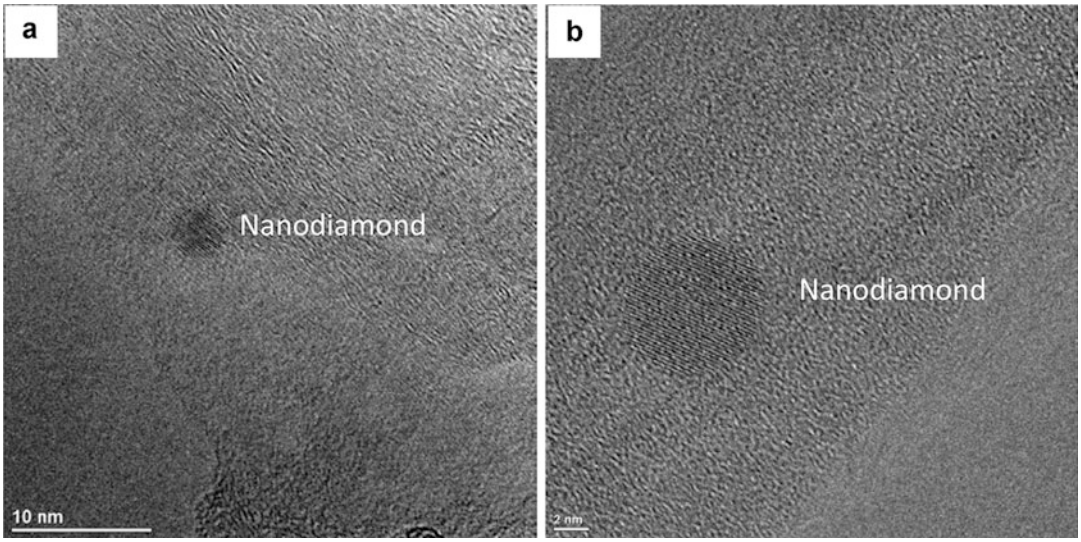


carbon atoms in this extreme physical field during the SPS process.

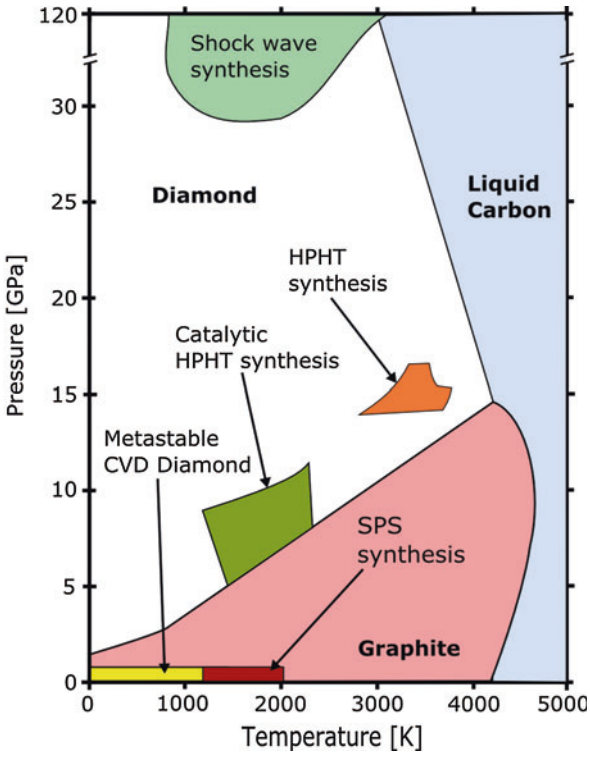
As demonstrated, diamond can be directly synthesized by SPS from graphene nanoplatelets at a very low pressure of 80 MPa without any catalysts being involved. The diamond is observed in all the graphene samples treated at 1100 °C up to 1500 °C with SPS. The particle sizes of the diamonds (up to 20 μm) obtained from the graphene nanoplatelets are much smaller than those from carbon nanotubes (up to 150 μm) and from fullerenes (up to 250 μm) at the same pressure and temperature range. Whereas graphene is a pure sp^2-hybridized material, carbon nanotubes and fullerenes have fractions of sp^3 hybridization due to angular strains.

Figure 13 shows a SEM micrograph of a bulk sample of graphene nanoplatelets treated by SPS at 1400 °C with a fracture surface in the right part. The fractured surface and the sample wall (Fig. 13a) show a clear layer structure perpendicular to the direction of the uniaxial pressure of the SPS almost similar to graphite [12]. The layers are stacks parallel to the top and bottom surfaces of the compacted and sintered graphene body. Etching the fracture surface reveals additional insight into the fine structure. During the SPS, the layered graphene nanoplatelets were packed randomly at the uniaxial pressure of 80 MPa. The fracture surface in Fig. 13b clearly shows that the graphene nanoplatelets are not only pressed parallel to each other but that they are folded and bent causing also a large amount of stacking faults in such SPS-treated bulk graphene solid. Therefore, during the SPS treatment, planar stacks of graphene nanoplatelets are pressed together to form graphite stacks. Hereby, the bent and tilted graphene nanoplatelets create also a considerable amount of stacking faults that are able to trigger the diamond nucleation (visible in the center of Fig. 13b) confirming the findings in Fig. 4a.

High-resolution TEM analysis of the SPS-treated nanoplatelets clearly shows a diamond nucleus with a lattice spacing of 2.06 Å ± 0.02 Å within the compacted, bent and tilted nanoplatelets (Fig. 14).



Already, Lambrecht et al. [20] found that the diamond formation will just become possible through the formation of stacking faults in graphite (Fig. 13c). Based on this, a schematic



Diamond Formation in Graphene Nanoplatelets, Carbon Nanotubes, and Fullerenes Under Spark Plasma Sintering, Fig. 13 SEM micrographs of a fracture surface of the spark plasma sintered graphene nanoplatelet bulk sample before etching showing the stacks (**a**) and a fracture surface after etching with folded nanoplatelets and a diamond grain in the center part (**b**), a schematic with the proposed nucleation mechanism of the diamond nuclei formation at graphite layers (**c**) (Reprinted from [20] with permission of Nature Publishing Group ©) and an illustration indicating the generation of stacking faults during SPS of the layered nanoplatelets (**d**)

illustration of the mechanism for the transformation from graphene nanoplatelets to diamond during the SPS is sketched in Fig. 13d. During the SPS consolidation, the contact areas of tilted and bent graphene layers give rise to a considerable amount of stacking faults and locally high dislocation densities. Due to the applied pressure, diffusion will occur and new interlayer covalent bonds among the graphene nanoplatelets are created. The interlayer covalent bonds will lead to the formation of regions of sp^3-hybridized carbon atoms that are then serving as diamond nucleation sites. In pure graphite, however, there are not enough stacking faults created at the low pressure of 80 MPa applied in the SPS which inhibits the diamond formation as described before.

In conclusion, graphene nanoplatelets can be transformed to diamond without any catalysts being involved at the low pressure of 80 MPa and at temperatures from 1100 °C to 1500 °C in a SPS process. Due to the pulsed current, the locally extremely high temperatures along with possible plasma formation support the creation of new bonds in the regions of high densities of stacking faults serving as nucleation centers for the diamond growth. Thus, the pressure-temperature carbon phase diagram (Fig. 1) can be expanded to the SPS method leading to Fig. 15.

Definition

Dielectrophoresis (DEP) is defined as the motion of polarizable particles under the influence of an applied *nonuniform* electric field, with the force arising from the interaction of the field and the dipole moment induced in the particle.

Introduction

Dielectrophoresis is a second-order effect arising from the net effect of the dielectric force acting on interfaces between different dielectrics. It is second order in that the field generates a charge on the interface due to the different polarizability of the dielectrics and then acts on that charge to produce a force. The second-order nature also means that the time average of the force in an AC field is nonzero. Where the interface is a closed surface surrounding a volume such as a particle or a droplet which is free to move, the net force results in motion where the field is nonuniform. This dielectrophoretic motion is due to the fact that the charge on the interface forms a dipole across the particle and the force on the two poles of the dipole is different since the electric field is nonuniform.

The phenomenon of dielectrophoresis was first recorded in the late nineteenth century as an effect arising in the behavior of soil samples. The term dielectrophoresis was coined by Herbert Pohl in 1951 to describe the motion of biological particles under the influence of nonuniform electric fields [1]. Pohl went on to study the effect in detail and in 1978 published the seminal work on the subject [2]. With the application of semiconductor fabrication methods allowing researchers to easily build field-generating electrodes on the scale of biological cells, dielectrophoresis gained traction in the late twentieth century. Applications followed for manipulation, characterization, and separation of micrometer-sized particles such as cells and bacteria down to nanometer-scale particles such as viruses and proteins.

Interfacial Polarization of Dielectric Materials

The forces which give rise to dielectrophoresis are general in that a force is generated on any surface between materials or any internal discontinuity in a material. Understanding of the force starts with an understanding of dielectric materials: materials which possess bound charges which *polarize* under the influence of an applied electric field. The bound charges can only move minute distances under the influence of an externally applied electric field.

Polarization

In electrostatics, the force acting between charges or the force on a charge in an electric field can be written as $\mathbf{F}_c = q\mathbf{E}$, where q is the charge and $\mathbf{E}$ is the electric field. When positive and negative charges are placed in an electric field, they are therefore displaced in opposite directions. If those charges are bound to atoms or molecules, they will move a short distance and then be held in displaced positions, producing a dipole moment in the atom/molecule.

The dipole moment is a fundamental object in electrostatics consisting of two equal and opposite charges, $+q$ and $-q$ for example, displaced by a vector distance $\mathbf{d}$. The dipole moment in this case is given by $\mathbf{p} = q\mathbf{d}$. Many molecules possess fixed dipole moments, and in the case of dipoles arising from an applied electric field, the molecule then has an *induced* dipole moment. The process of this happening in a dielectric material, with all the molecules developing dipole moments, is referred to as *polarization*. In a dielectric, consisting of N molecules per cubic meter, the electric polarization $\mathbf{P}$, or the average vector dipole moment per molecule, is given by $\mathbf{P} = N\mathbf{p}$.

There are three basic polarization processes. Under an applied electric field, the center of charge of the electron cloud in a molecule moves slightly with respect to the center of charge of the nucleus; this is referred to as electronic polarization. In a solid such as crystalline potassium chloride, the ions of different signs move in different directions when subjected to an electric field; this

is referred to as atomic polarization. If the molecules possess a permanent dipole moment, the material is described as polar, and the molecules both align with and become further polarized in an applied electric field; this is referred to as orientational polarization.

Charge Movement in Materials

Polarization causes charges to gather, either at points within the dielectric or at the surface [3, 4]. Differences in polarization on either side of an interface mean that there is a net charge at that interface. This charge can be generated by bound charges from polarization as described above or in real rather than ideal dielectrics by free charge associated with electrical conduction. In water-based biological systems where dielectrophoresis is typically applied, there is generally a fairly high conductivity arising from the ions and salts suspended in the solutions.

The important relationships can be derived simply by looking at charge densities and the relationship with polarization and the electric field. In a material, the bound volume charge density is related to the polarization by

$$\rho_b = -\nabla \cdot \mathbf{P} \tag{1}$$

and the total charge, which is the sum of the free charge density ρ_f and the bound charge density, is related to the electric field by Gauss's law:

$$\nabla \cdot \mathbf{E} = \frac{\rho_f + \rho_b}{\varepsilon_o} \tag{2}$$

where ε_o is the permittivity of free space. Substituting Eq. 1 into Eq. 2 gives

$$\nabla \cdot (\varepsilon_o \mathbf{E} + \mathbf{P}) = \rho_f \tag{3}$$

This is generally written as

$$\nabla \cdot \mathbf{D} = \rho_f \tag{4}$$

where $\mathbf{D} = \varepsilon_o \mathbf{E} + \mathbf{P}$ is termed the electric flux density. For a linear isotropic dielectric, $\mathbf{P}$ is proportional to $\mathbf{E}$ such that $\mathbf{P} = \varepsilon_o \chi \mathbf{E}$ where χ is the electric susceptibility of the dielectric. Therefore, for a linear and isotropic dielectric, from Eq. 3:

$$\mathbf{D} = \varepsilon_o \mathbf{E} + \mathbf{P} = \varepsilon_o (1 + \chi)\mathbf{E} = \varepsilon_o \varepsilon_r \mathbf{E} \tag{5}$$

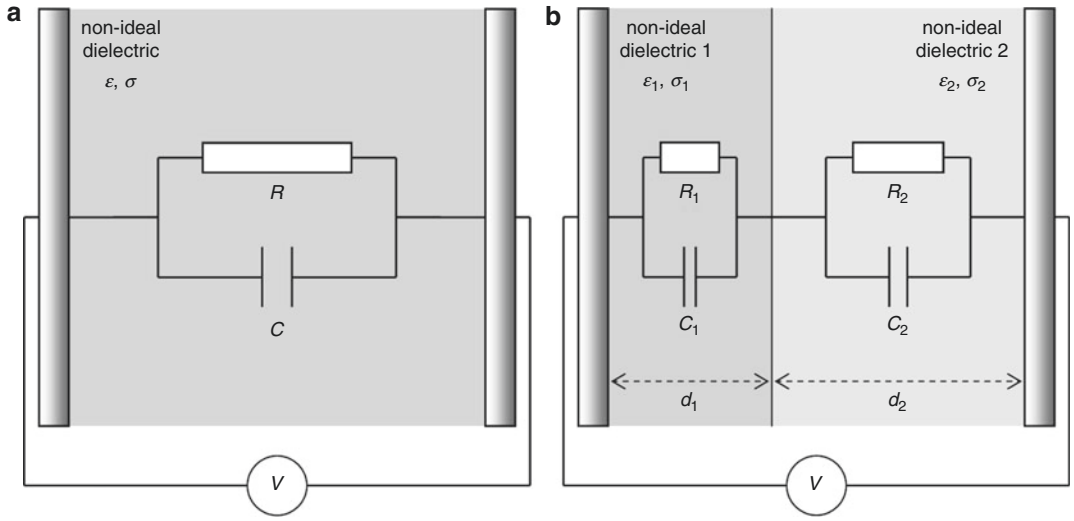
where $\varepsilon_r = (1 + \chi)$ is the relative permittivity of the dielectric.

Frequency-Dependent Charge Processes

The extension of the simple electrostatic model to incorporate polarization effects and processes which depend on frequency can be illustrated using some simple models [3]. The most basic aspect of charge processes which involve frequency is that of conduction from the movement of free charges. This can be illustrated using a model parallel plate capacitor of area A and plate separation d, connected to an alternating potential ϕ of angular frequency ω, as shown in Fig. 1a. With an ideal dielectric filling the capacitor, the impedance is

$$Z = \frac{1}{i\omega C} \tag{6}$$

where $i^2 = -1$ and the capacitance C is given by



$$C = \varepsilon_o \varepsilon_r \frac{A}{d} \tag{7}$$

Most real dielectrics have a nonzero conductivity, and the permittivity is dependent on the frequency of the applied electric field. With the ideal dielectric replaced with a real dielectric of conductivity σ, the current in the circuit is the same as if the circuit were replaced with a capacitor (capacitance C from Eq. 8) representing the ideal dielectric and resistance in parallel given by

$$R = \frac{d}{\sigma A} \tag{8}$$

The total impedance of the circuit is then

$$Z = \frac{1}{1/R + i\omega C} = \frac{1}{\sigma \frac{A}{d} + i\omega \varepsilon_o \varepsilon_r \frac{A}{d}} = \frac{1}{i\omega \left(\varepsilon_o \varepsilon_r - i\frac{\sigma}{\omega}\right)\frac{A}{d}} \tag{9}$$

Dielectrophoresis, Fig. 1 (**a**) Parallel plate capacitor of plate separation d and area A containing a dielectric of permittivity $\varepsilon = \varepsilon_r \varepsilon_o$ and conductivity σ has the same impedance as the parallel circuit shown. (**b**) The same parallel plate capacitor completely filled by two dielectrics, with permittivities ε_1, ε_2, conductivities σ_1, σ_2, and widths d_1 and d_2 has the equivalent circuit shown, comprising that of the individual dielectrics in series

The real dielectric therefore behaves as a capacitor:

$$C = \tilde{\varepsilon}\,\frac{A}{d} \tag{10}$$

with a *complex polarizability* given by

$$\tilde{\varepsilon} = \varepsilon_o \varepsilon_r - i\frac{\sigma}{\omega} \tag{11}$$

This gives the frequency-dependent behavior of a basic homogeneous dielectric material. In general, the behavior of a dielectric is more complicated. Polarization mechanisms have a frequency-dependent nature, and the material has additional frequency dependencies due to relaxation mechanisms.

Since polarization mechanisms involve the movement of charge to create dipoles and the rate of this movement is finite, each mechanism therefore has an associated characteristic time constant which is the time necessary for the polarization to reach its maximum value. As the frequency of the applied alternating field increases, the period over which the dipole moment is able to "relax" and then follow the field decreases. Therefore, there is a frequency at which these two periods are the same and beyond which the polarization no longer reaches its maximum. At much higher frequencies, no polarization occurs and a relaxation or dispersion has occurred in the polarizability.

Of the three basic polarization mechanisms outlined previously, orientational polarization has the longest relaxation time. Atomic and electronic polarization will align with the field up to frequencies of the order of 10^{14} Hz and from the perspective of dielectrophoresis, which typically operates only up to 10^8 Hz, can be considered constant, i.e., $\mathbf{P}_a = \varepsilon_o \chi_a \mathbf{E}$. The orientational polarization is given by a complex expression which accounts for the frequency variation:

$$\mathbf{P}_{or} = \frac{\varepsilon_o \chi_{or} \mathbf{E}}{1 + i\omega\tau_{or}} \tag{12}$$

where τ_{or} is the *relaxation time* and χ_{or} is the low-frequency static limit for the orientational polarization mechanism. The total frequency-dependent polarization is then

$$\mathbf{P} = \varepsilon_o \left(\chi_a + \frac{\chi_{or}}{1 + i\omega\tau_{or}} \right) \mathbf{E} \tag{13}$$

At the low-frequency limit, $\chi = \chi_a + \chi_{or} = \varepsilon_s - 1$, where ε_s is the relative permittivity measured in a static electric field. At the high-frequency limit, $\chi = \chi_a = \varepsilon_\infty - 1$, where ε_∞ is the relative permittivity at sufficiently high frequency that there is no orientational polarization. χ_{or} is therefore given by $\varepsilon_s - \varepsilon_\infty$ and the total polarization given by

$$\mathbf{P} = \varepsilon_o(\varepsilon^* - 1)\mathbf{E} \tag{14}$$

where

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + i\omega\tau_{or}} \tag{15}$$

This description gives the frequency-dependent polarization of a dielectric material and is normally written in separate real and imaginary components as the Debye formulations:

$$\varepsilon^* = \varepsilon' - i\varepsilon'' \text{ where } \varepsilon' = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + \omega^2\tau_{or}^2} \text{ and } \varepsilon'' = \frac{\omega\tau_{or}(\varepsilon_s - \varepsilon_\infty)}{1 + \omega^2\tau_{or}^2} \tag{16}$$

Interfacial Polarization

As stated previously, experimental systems are further complicated by the presence of many dielectrics with differing properties, and the difference in polarizability causes charges to build up at the discontinuities or interfaces between the dielectrics [3]. As the polarizabilities of each dielectric are frequency dependent, so the surface charge density at the interface is also frequency dependent. As a result, the permittivity and conductivity of the whole system exhibit additional dispersions due solely to the polarization of the interfaces. The study of such heterogeneous dielectrics was first discussed by Maxwell and extended by Wagner, and the dispersion in permittivity arising because of an interface is referred to as Maxwell-Wagner interfacial polarization. This can be illustrated by reference to a simple parallel plate capacitor as shown in Fig. 1b where there are two dielectrics with different properties. The two dielectrics have permittivities ε_1 and ε_2 and conductivities σ_1 and σ_2, respectively, and they can be represented as two resistor/capacitor parallel circuits in series. The impedance of the equivalent circuit is given by

$$Z = Z_1 + Z_2 = \frac{R_1}{1 + i\omega R_1 C_1} + \frac{R_1}{1 + i\omega R_2 C_2} \tag{17}$$

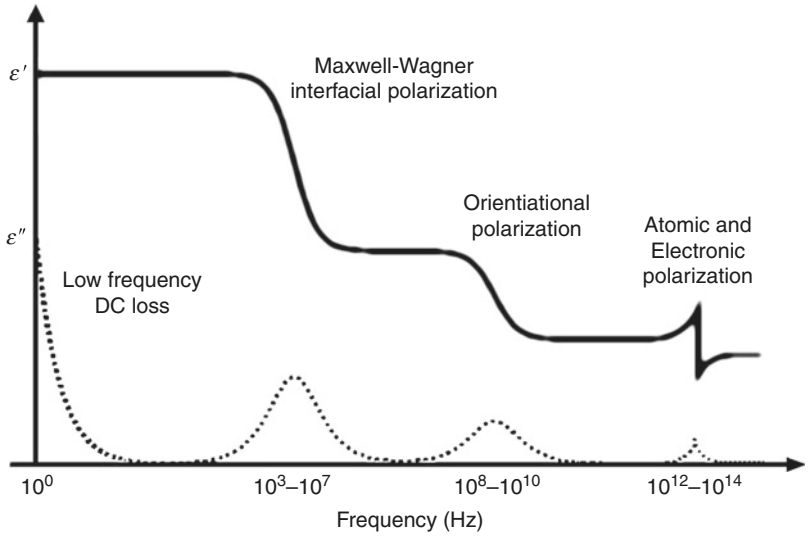
This can be reworked as Eq. 10, with complex permittivity given by

$$\tilde{\varepsilon} = \varepsilon_o\varepsilon' - i\varepsilon_o\varepsilon'' - i\frac{\sigma}{\omega} \tag{18}$$

ε' and ε'' are given by the Debye formulations (Eq. 16) with

$$\varepsilon_\infty = \frac{d\varepsilon_1\varepsilon_2}{d_1\varepsilon_2 + d_2\varepsilon_1}$$
$$\varepsilon_s = \frac{d\left(d_1\varepsilon_1\sigma_2^2 + d_2\varepsilon_2\sigma_1^2\right)}{\left(d_1\sigma_2 + d_2\sigma_1\right)^2} \tag{19}$$
$$\tau = \varepsilon_o\frac{d_1\varepsilon_2 + d_2\varepsilon_1}{d_1\sigma_2 + d_2\sigma_1}$$

σ is the conductivity of the whole system, given by



$$\sigma = \frac{d\sigma_1\sigma_2}{d_1\sigma_2 + d_2\sigma_1} \tag{20}$$

The resulting permittivity of the whole material in the capacitor has a Debye-type relaxation solely due to interfacial polarization. The frequencies for interfacial polarization occur at lower frequencies than for orientational polarization, and a plot of the complex permittivity of the system as a whole would look something like Fig. 2.

Dielectrophoresis

Interfacial Polarization of Particles

A particle suspended in a liquid is a special case of a multi-dielectric system with a closed surface surrounding a volume of a dielectric material (the particle) [3]. Some particles have a more complicated internal structure, which introduce

Dielectrophoresis, Fig. 2 The frequency variation of the complex permittivity of a dielectric, taking into account the typical relaxation mechanisms

additional interfaces to the model. Under the influence of an applied electric field the particle/liquid interface is charged by Maxwell-Wagner interfacial polarization.

A schematic diagram of the resulting effect on the particle is shown in Fig. 3. The difference in polarizability results in a surface charge density around the interface at the surface of the particle. This charge has an opposite sign on either side of the particle in line with the electric field, therefore producing an induced dipole in the particle. The direction of the dipole is either with the electric field if the particle polarizability is greater than the fluid or against the field if the particle polarizability is smaller. The dipole magnitude and direction in general depend, by inference, not only on the particle internal properties but also the properties of the suspending fluid medium.

Determining an expression for the dipole moment of a spherical particle is an exercise in solving Poisson's equation using spherical harmonics which can be found in references [5]. The solution of the electrical potential in spherical polar coordinates is

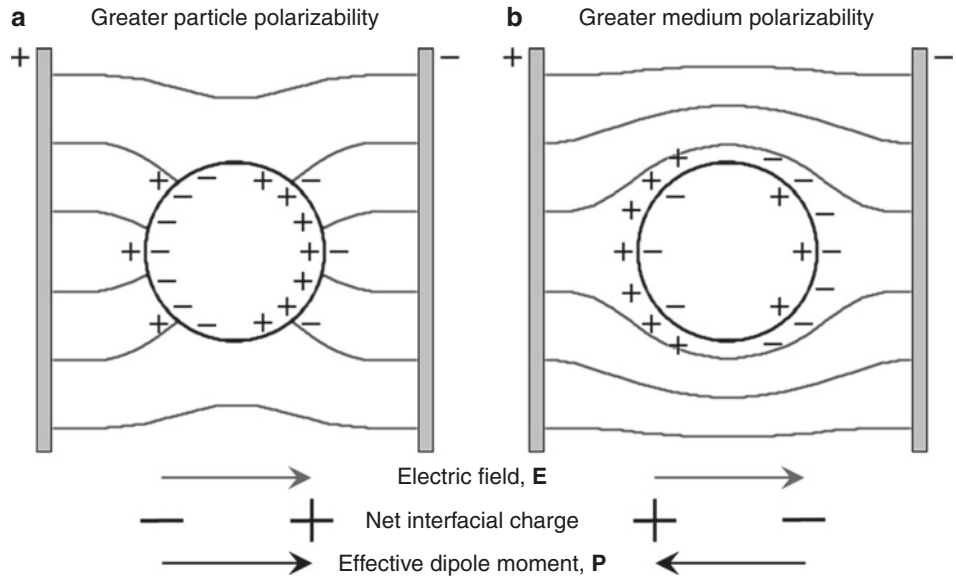
$$\phi_m = Er\cos\theta\left[\frac{a^3}{r^3}\left(\frac{\tilde{\varepsilon}_p - \tilde{\varepsilon}_m}{\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m}\right) - 1\right] \qquad (21)$$

in the fluid medium (indicated by the subscript m) and

$$\phi_p = -\frac{3\tilde{\varepsilon}_m}{\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m} Er\cos\theta \qquad (22)$$

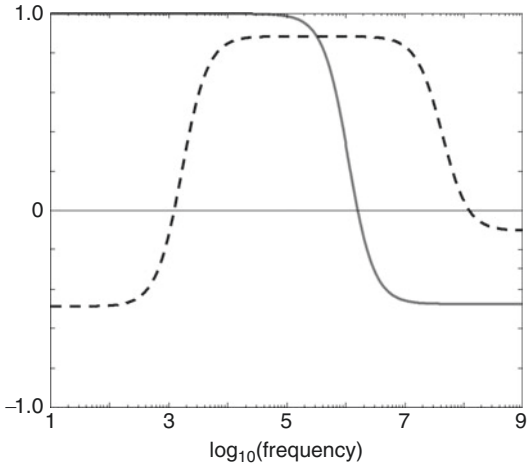
inside the particle (indicated by subscript p). Here, a is the radius of the particle. Comparison of Eq. 21 with the potential of a dipole:

$$\phi_{\text{dipole}} = \frac{qd\cos\theta}{4\pi\varepsilon_m r^2} \qquad (23)$$



shows that the electrical potential in the medium is the sum of the original uniform field and a dipole moment $\mathbf{p}$ where

$$\mathbf{p} = 4\pi\varepsilon_m\left(\frac{\widetilde{\varepsilon}_p - \widetilde{\varepsilon}_m}{\widetilde{\varepsilon}_p + 2\widetilde{\varepsilon}_m}\right)a^3\mathbf{E} \qquad (24)$$



This is the effective dipole moment of the sphere, with a size that is frequency dependent and undergoes a dispersion because of Maxwell-Wagner interfacial polarization. The effective polarizability of a spherical dielectric particle is

$$\tilde{\alpha} = 3\varepsilon_m\left(\frac{\widetilde{\varepsilon}_p - \widetilde{\varepsilon}_m}{\widetilde{\varepsilon}_p + 2\widetilde{\varepsilon}_m}\right) \qquad (25)$$

and the frequency dependency of the dipole and the effective polarizability is described by the Clausius-Mossotti factor:

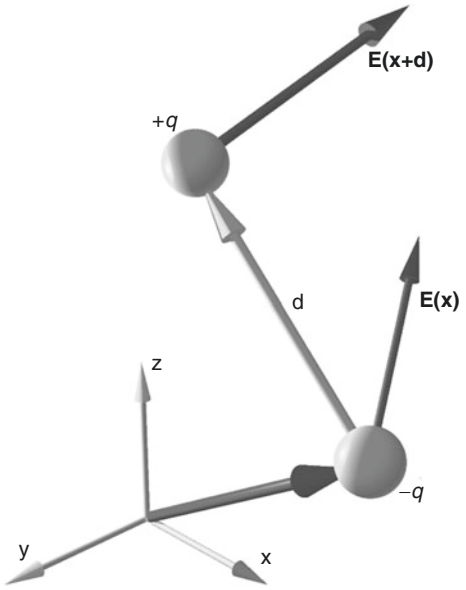
Dielectrophoresis, Fig. 3 Electric field lines, charges (distribution and net) at dielectric interfaces, electric fields, and effective dipole moment vectors for when a dielectric particle in suspension is subjected to a uniform electric field. The effective dipole moment will be aligned (**a**) with or (**b**) against the applied electric field, depending on whether the particle is more polarizable or less polarizable than the suspending medium

Dielectrophoresis, Fig. 4 Variations with frequency of the Clausius-Mossotti factor for two different particle types. Dispersions are due to Maxwell-Wagner interfacial polarization

$$\tilde{f}_{CM} = \frac{\tilde{\varepsilon}_p - \tilde{\varepsilon}_m}{\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m} \tag{26}$$

The variation with frequency of the Clausius-Mossotti factor for two different particle types is shown in Fig. 4.

Translational Force on a Dipole in a Nonuniform Field



The simplest way to assign a force to a particle in a field is to consider the force exerted on a dipole by a nonuniform electric field [3, 4]. The dipole, shown in Fig. 5 (where the two equal and opposite charges $+q$ and $-q$ are separated by the vector $\mathbf{d}$), experiences a net force due to the nonuniform electric field $\mathbf{E}$ due to the fact that the field at and therefore the force on the two poles of the dipole are not equal. The force can be represented as a sum of the forces on the two charges:

$$\mathbf{F} = q\mathbf{E}(\mathbf{x} + \mathbf{d}) - q\mathbf{E}(\mathbf{x}) \tag{27}$$

where $\mathbf{x}$ can be taken to be the position vector of $-q$ without loss of generalization. This equation can be simplified if $|\mathbf{d}|$ is much smaller than $|\mathbf{x}|$ by expanding the electric field using a Taylor series about $\mathbf{x}$ to give

$$\mathbf{E}(\mathbf{x} + \mathbf{d}) = \mathbf{E}(\mathbf{x}) + d \cdot \nabla\mathbf{E}(\mathbf{x}) + \ldots \tag{28}$$

where all terms of order d^2 or higher have been neglected. If the dipole moment $\mathbf{p} = q\mathbf{d}$ remains

Dielectrophoresis, Fig. 5 The charges of the dipole $\mathbf{p} = Q\mathbf{d}$ in a nonuniform field $\mathbf{E}$ experience a different value of the electric field and as a result a different Coulomb force

finite in the limit $|\mathbf{d}| \rightarrow 0$, then substituting Eq. 28 into 27 gives the first order force on an infinitesimal dipole as

$$\mathbf{F} = \mathbf{p} \cdot \nabla \mathbf{E} \tag{29}$$

Only in a nonuniform field does this force have a nonzero net value.

Dielectrophoretic Force

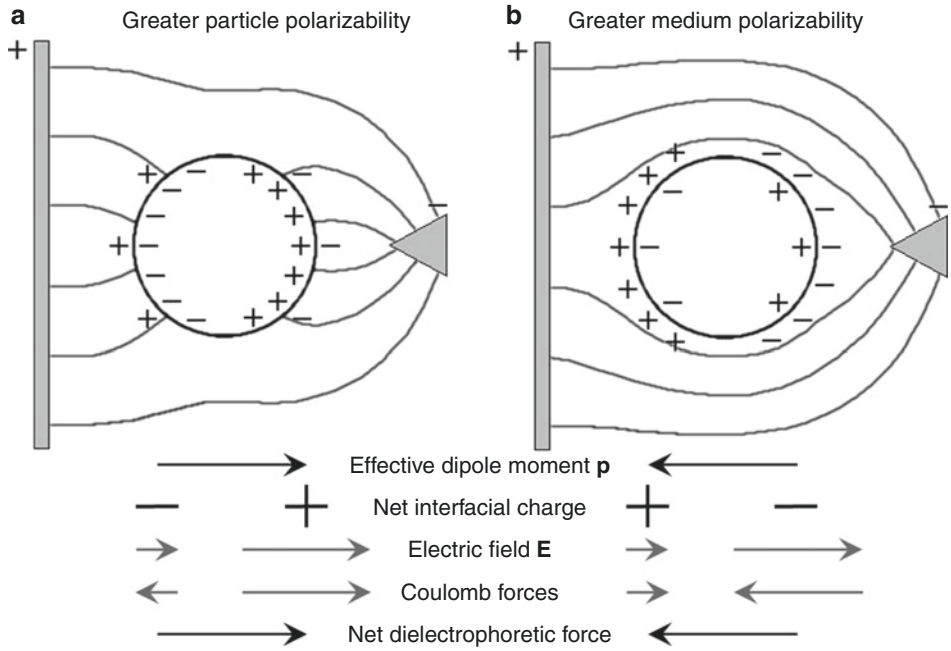
The resulting movement of particles is referred to as dielectrophoresis (DEP) and the force referred to as the dielectrophoretic force [3, 4]. Equation 29 is restricted to cases where the gradient of the field across the particle can be assumed to be constant, often referred to as the dipole approximation. In cases where the field is very nonuniform across a distance comparable in size to the particle, the higher order terms can no longer be ignored.

In the dipole approximation, the dielectrophoretic force on a particle is found by substituting the effective dipole moment, Eq. 24 into Eq. 29 to give

$$\mathbf{F}_{DEP} = \upsilon\alpha \mathbf{E} \cdot \nabla \mathbf{E} \tag{30}$$

where υ is the volume of the particle and α is the effective polarizability (in this initial case, a static polarizability). This can be rewritten using a vector identity as

$$\mathbf{F}_{DEP} = -\frac{1}{2}\upsilon\alpha\nabla(\mathbf{E} \cdot \mathbf{E}) = -\frac{1}{2}\upsilon\alpha\nabla|\mathbf{E}|^2 \tag{31}$$



Since the effective polarizability of the particle can be either positive or negative, the dielectrophoretic force can act either in the direction of increasing field strength or in the opposite direction. Where particles are attracted toward regions of high field strength, the movement is referred to as *positive dielectrophoresis*. The opposite situation, where particles are repelled from high field regions, is called *negative dielectrophoresis*. The difference in the physical mechanism is illustrated in Fig. 6, where Coulomb forces on the two poles of the induced dipole are different owing to the nonuniform electric field. The force on the pole in the strongest electric field is the strongest but is toward high fields when the particle polarizability is greater (positive DEP) and away from high fields when the medium polarizability is greater (negative DEP).

Dielectrophoresis in an AC Field

Equation 31 is derived for a static electric field [3]. Deriving the force for an AC field requires an extension to account for the frequency and phase aspects associated with the time varying charging. This extension also exposes additional force terms that produce related movement in particles.

Assuming an applied potential of a single frequency ω, then the time-dependent values in the system can be represented using phasors. An arbitrary, harmonic potential can be defined as $\phi(\mathbf{x}, t) = \mathrm{Re}\left[\tilde{\phi}(\mathbf{x})e^{i\omega t}\right]$ where the tilde indicates the complex phasor $\left(\tilde{\phi} = \phi_R + i\phi_I\right)$ and Re[...] indicates the real part of. The electric field is then given by $\mathbf{E}(\mathbf{x}, t) = \mathrm{Re}\left[\tilde{\mathbf{E}}(\mathbf{x})e^{i\omega t}\right]$ where the vector $\tilde{\mathbf{E}} = -\nabla\tilde{\phi} = -(\nabla\phi_R + i\nabla\phi_I)$ is the corresponding phasor. The dipole moment of the particle is therefore $\tilde{\mathbf{p}} = \upsilon\tilde{\alpha}\mathbf{E}e^{i\omega t}$ and the time-averaged force on the particle is

$$\langle \mathbf{F}_{DEP} \rangle = \frac{1}{2}\mathrm{Re}\left[(\tilde{\mathbf{p}} \cdot \nabla)\mathbf{E}^*\right] \tag{32}$$

Dielectrophoresis, Fig. 6 Electric field lines, charges (distribution and net) at dielectric interfaces, directions of the applied electric field, effective dipole moment, Coulomb forces, and net dielectrophoretic force for when a dielectric particle in suspension is subjected to a nonuniform electric field. (**a**) When the particle is more polarizable than the suspending medium, the effective dipole moment is aligned with the applied electric field and the DEP force acts to move the particle toward the region of highest electric field intensity. (**b**) When the particle is less polarizable than the suspending medium, the effective dipole moment is aligned against the applied electric field and the DEP force acts to move the particle away from the region of highest electric field strength

where * indicates complex conjugate.

If the phase is constant across the system, the field phasor can be assumed to be real without loss of generality (i.e., $\tilde{\mathbf{E}} = \mathbf{E} = -\nabla\phi_R$). The time-averaged force is then

$$\langle \mathbf{F}_{DEP} \rangle = \frac{1}{2} \upsilon \mathrm{Re}[\tilde{\alpha}](\mathbf{E} \cdot \nabla)\mathbf{E} \tag{33}$$

Using vector identities and the fact that the field is irrotational gives

$$\langle \mathbf{F}_{DEP} \rangle = \frac{1}{4} \upsilon \mathrm{Re}[\tilde{\alpha}] \nabla(\mathbf{E} \cdot \mathbf{E}) \tag{34}$$

This is the dielectrophoretic force, which is commonly written as

$$\langle \mathbf{F}_{DEP} \rangle = \frac{1}{4} \upsilon \mathrm{Re}[\tilde{\alpha}] \nabla |\mathbf{E}|^2 \tag{35}$$

Often the field is quoted using *root-mean-square* (*rms*) values so that Eq. 35 becomes

$$\langle \mathbf{F}_{DEP} \rangle = \frac{1}{2} \upsilon \mathrm{Re}[\tilde{\alpha}] \nabla |\mathbf{E}_{rms}|^2 \tag{36}$$

This is also the expression for the force in a DC field. The field term in Eq. 35 is the magnitude of the phasor and the difference between the two equations is the factor of a half. When using AC fields, it is therefore extremely important to understand whether you are using amplitude or RMS values for the electric field. Inspection of these equations shows that the dielectrophoretic force depends on the volume of the particle and the gradient of the field magnitude squared. The force also depends on the real part of the effective polarizability.

This can be quantified for a spherical particle, where again the variation in the magnitude of the

force with frequency is given by the real part of the Clausius-Mossotti factor. By substitution of the effective polarizability of a sphere (Eq. 25), the full expression for the time-averaged DEP force on a spherical particle is

$$\langle \mathbf{F}_{DEP} \rangle = \pi \varepsilon_m a^3 \mathrm{Re}\left[\frac{\widetilde{\varepsilon}_p - \widetilde{\varepsilon}_m}{\widetilde{\varepsilon}_p + 2\widetilde{\varepsilon}_m}\right] \nabla |\mathbf{E}|^2 \qquad (37)$$

Examination of this equation shows that the magnitude of the force depends on the particle volume (a^3), the permittivity of the suspending medium, and the gradient of the field strength squared. The real part of the Clausius-Mossotti factor defines the frequency dependence and direction of the force. Expanding on the previous description, positive DEP occurs if the polarizability of the particle is greater than the suspending medium ($\mathrm{Re}\left[\tilde{f}_{CM}\right] > 1$) and the particle moves toward regions of high electric field strength. Negative DEP occurs if the polarizability of the particle is less than the suspending medium ($\mathrm{Re}\left[\tilde{f}_{CM}\right] < 1$) and the particles are repelled from regions of high field strength.

Dielectrophoresis in a Field with a Spatially Dependent Phase

For a general AC field, such as that generated by the application of multiple potentials of different phase, the derivation of the dielectrophoretic force is more involved [3]. The electric field in this case is $\mathbf{E}(\mathbf{x}, t) = \mathrm{Re}\left[\tilde{\mathbf{E}}(\mathbf{x}) e^{i\omega t}\right]$, where the vector $\tilde{\mathbf{E}} = -\nabla\tilde{\phi} = -(\nabla\phi_R + i\nabla\phi_I)$ is the corresponding *complex* phasor. The expression for the time-averaged force on the particle can then be derived from Eq. 32 with the vectors now consisting of complex components. The equation for the force is

$$\begin{aligned}\langle \mathbf{F}_{DEP} \rangle &= \frac{1}{2}\mathrm{Re}\left[(\tilde{\mathbf{p}} \cdot \nabla)\tilde{\mathbf{E}}^*\right] \\ &= \frac{1}{2}\upsilon \mathrm{Re}\left[\tilde{\alpha}(\tilde{\mathbf{E}} \cdot \nabla)\tilde{\mathbf{E}}^*\right]\end{aligned} \qquad (38)$$

Again, using vector identities and the facts that the electric field is irrotational and has zero divergence (Gauss's law), the force expression becomes

$$\begin{aligned}\langle \mathbf{F}_{DEP} \rangle = &\frac{1}{4}\upsilon \mathrm{Re}[\tilde{\alpha}]\nabla\left(\tilde{\mathbf{E}} \cdot \tilde{\mathbf{E}}^*\right) \\ &- \frac{1}{2}\upsilon \mathrm{Im}[\tilde{\alpha}]\left(\nabla \times \left(\tilde{\mathbf{E}} \times \tilde{\mathbf{E}}^*\right)\right)\end{aligned} \qquad (39)$$

where Im [. . .] is the imaginary part of the function. This can be rewritten as

$$\begin{aligned}\langle \mathbf{F}_{DEP} \rangle = &\frac{1}{4}\upsilon \mathrm{Re}[\tilde{\alpha}]\nabla\left|\tilde{\mathbf{E}}\right|^2 \\ &- \frac{1}{2}\upsilon \mathrm{Im}[\tilde{\alpha}]\left(\nabla \times \left(\mathrm{Re}\left[\tilde{\mathbf{E}}\right] \times \mathrm{Im}\left[\tilde{\mathbf{E}}\right]\right)\right)\end{aligned} \qquad (40)$$

where $\left|\tilde{\mathbf{E}}\right|^2 = \left|\mathrm{Re}\left[\tilde{\mathbf{E}}\right]\right|^2 + \left|\mathrm{Im}\left[\tilde{\mathbf{E}}\right]\right|^2$. If there is no spatially varying phase, the phasor of the electric field can be taken to be real (i.e., $\mathrm{Im}\left[\tilde{\mathbf{E}}\right] = 0$), the second term on the right-hand side of equation is then zero, and the expression for the force becomes that of Eq. 35. However, if there is a spatially varying phase, as in the case of traveling wave dielectrophoresis, the complete force expression must be used. The first term in the force expression depends on the frequency in the same manner as Eq. 35. The second term in the force equation depends, however, on the imaginary part of the effective polarizability or rather the imaginary part of the Clausius-Mossotti factor. This force is zero at high and low frequencies, rising to a maximum value at the Maxwell-Wagner interfacial relaxation frequency.

A general statement would then be that the *general* dielectrophoretic force is divided into two components, one of which is the DEP force and another that depends on the phase of the field:

$$\begin{aligned}\langle \mathbf{F}_{DEP} \rangle = &\underbrace{\frac{1}{4}\upsilon \mathrm{Re}[\tilde{\alpha}]\nabla\left|\tilde{\mathbf{E}}\right|^2}_{\text{Dielectrophoresis}} \\ &\underbrace{- \frac{1}{2}\upsilon \mathrm{Im}[\tilde{\alpha}]\left(\nabla \times \left(\mathrm{Re}\left[\tilde{\mathbf{E}}\right] \times \mathrm{Im}\left[\tilde{\mathbf{E}}\right]\right)\right)}_{\text{Travelling Wave Dielectrophoresis}}\end{aligned} \qquad (41)$$

Generally, for traveling wave dielectrophoresis to be effective, a frequency must be chosen where both the real part is substantially high **and** the imaginary part, which only has a value close to the relaxation frequency, is nonzero.

Applications of Dielectrophoresis

The critical feature of dielectrophoresis is that it requires field nonuniformities in order to create movement. The rapid development of dielectrophoresis as a method was made capable by the production of microelectrodes using semiconductor fabrication methods [3, 4].

In addition to this, as most biological particles are dielectrics, dielectrophoresis is particularly fitted to lab-on-a-chip applications where multiple processes involving characterization, manipulation, and separation of bioparticles are integrated onto a single chip. Dielectrophoresis is advantageous over other means of inducing particle motion in its noninvasive nature and easy integration onto micro-devices, not relying on any moving parts. Early biomedical applications of dielectrophoresis were limited to studying the response of cells to electric fields for characterization purposes. Nowadays, the technique has found widespread use for a variety of biotechnological and diagnostic applications. Examples include separation of human breast cancer cells from blood and trapping and manipulation of DNA – of importance to the development of point-of-care devices for detection and identification of pathogenic microorganisms, aggregation of hemispherical cells as a first step toward the creation of artificial stem cell microniches in vitro, and creation of engineered skin with artificial placodes of different sizes and shapes in different spatial patterns [6].

Dielectrophoresis has established its status as a versatile technique for separation of dielectric – biological and otherwise – particles in suspension. Through the frequency-dependent characteristics of dielectric particles, DEP has access to a wide range of particle properties and can be modified by the choice of suspending medium. Factors such as double layer and electro-convective effects can complicate DEP separation of dielectric particles [7]. Yet it has been shown that once these phenomena are correctly identified and incorporated in the design process, they can take their part in the toolbox of electrokinetic techniques for separation applications [8, 9].

Advances in fabrication technology have broadened the applicability of dielectrophoresis through realization of micro- and nanoelectrode geometries that are capable of generating electric fields strong enough to move nanoparticles such as viruses and chromosomes [10]. At the nanoscale, effects such as thermal and hydrodynamic forces find increased significance. Yet it has been shown that the "nuisances" are controllable and not significant enough to hinder nanoparticle motion due to dielectrophoresis [11].

Applications of dielectrophoresis are not limited to the realm of diagnostics involving biological particles. As early as 1924, Hatfield achieved separation of minerals using DEP; interestingly, the work has been pursued by other research groups up until very recently. Other examples where dielectrophoresis has been used for industrial applications include construction of a current-limiting fuse using DEP collection of conductive particles between two electrodes, depositing a patterned coating of a nanostructured material onto a substrate using positive DEP, and the fabrication of nanoscale devices, composed of movable components brought together in a fluid medium by exertion of the dielectrophoretic force – among other interactions [4].

With further developments in the design of suitable electrode geometry and in the modeling of phenomena that occur alongside dielectrophoretic motion of particles, DEP applications are expected to advance further, enabling manipulation and characterization of a yet wider range of particles.

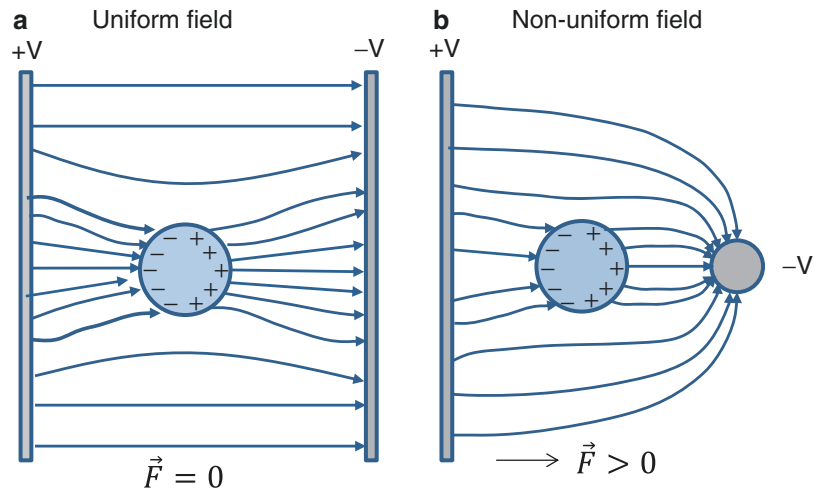
Definition

Dielectrophoresis (DEP)-directed assembly is an electrokinetic manipulation process, in which a force exerted on a particle subjected to a nonuniform electric field is employed to localize the particle in space with micro- or nanoscale precision. DEP force originated from the interparticle interaction due to the induced dipoles on the particles subject to the spatial gradient of the electric field. DEP is applicable for any particles, charged or uncharged, which makes it advantageous over electrophoresis that requires a net charge on the particle for Coulombic interaction to drive the particle in an applied electric field.

Background

DEP was first adopted as a term to describe the motion of particles under nonuniform electric fields in the 1950s by Pohl, who defined this effect as "the motion of suspended particles relative to that of the solvent resulting from polarization forces produced by an inhomogeneous electric field" [1, 2]. In 1966, Pohl and Hawk made the first demonstration of the use of DEP in the collection of living cells [3]. Despite the initial breakthrough, at that time the DEP technique was limited within the manipulation of cells and other microorganisms of the size in the micrometer scale due to the limitations in achieving high field gradients. For submicrometer-sized particles, a strong field gradient of the applied electric field is required in order to overcome the randomization of particles due to Brownian motion (or to provide sufficient energy to overcome the counteracting influence of diffusion). Thus, it was until the 1970s after the advancement of photo and electron beam lithographic techniques for fabricating microdevices [4] the DEP manipulation of submicrometer-sized particles was employed in sufficiently large field gradients by using microelectrodes. The use of microelectrodes also possesses two additional advantages: (1) low voltages can be effectively used to generate high electric field strengths across a wide range

of frequencies; and (2) due to the high surface-to-volume ratio of nanocolloids, Joule heating system can be easily and quickly dissipated.



The early studies using microelectrode-based DEP were still largely concentrated on biotechnology and biomedical applications, including the responses of cells to DEP forces, cell sorting, bacterial manipulation, tissue engineering, and biosensors [4, 5]. Despite the early interest, there was little further attempt to work with nanomaterials until Washizu and co-workers demonstrated the manipulation and collection of biopolymers such as DNA and protein near planar microelectrodes in the 1990s [6, 7]. Since then, a wide range of nanocolloids such as viruses and submicrometer latex spheres have successfully been collected in microfluidic devices combined with DEP [8–13].

In the past decade, the application of DEP has been widely extended to a broad range of fields from biotechnology to materials science. Of particular interest, various materials in the nanometer scale, including polymer and lipid vesicles, carbon nanotubes, graphene, metal and metal oxide nanoparticles, and semiconducting nanowires and nanorods, have been manipulated and assembled into well-defined structures using the DEP technique [14–23]. DEP has been proven to be an efficient and versatile method for the directed assembly of various functional nanomaterials, thus providing a bridge connecting the top-down and bottom-up approaches that are the two independent basic methods used in the nanotechnology. The versatility, precision, and speed of DEP-directed assembly over the traditional bottom-up assembly approaches also impose great potentials to fabricate various nanodevices, such as microminiature biomedical device for diagnosis and electronic transistors.

Theory

DEP is a phenomenon in which a force is exerted on a polarizable particle in the nonuniform electric field. In an electric field, the particle is polarized to bear a dipole on its surface, thereby yielding a transient Coulombic attraction between the polarized particle and the electric field. As illustrated in Fig. 1, in a uniform field, the forces experienced by the positive and negative poles are balanced so that the time-averaged net force is zero. However, in a nonuniform field, the forces become imbalanced across the particle, leading to the time-averaged nonzero net force executed on the particle.

As particles are generally suspended in a medium, the polarization and resulting DEP response of the surrounding medium need to be taken into account for the DEP-driven motion of the particle in suspension. When the suspended particle has the higher polarizability than that of the medium, the induced dipole of the particle lies in the same direction as the electric field so that the resulting DEP force drives the particle toward the

Dielectrophoresis Directed Nanocolloidal and Supramolecular Assembly, Fig. 1 Schematic illustration of dielectrophoresis (*DEP*)

region of higher field strength, which is the so-called *positive* DEP (pDEP). On the contrary, if the polarizability of the particle is lower than that of the medium, the particle is driven toward the region of weaker electric field, which is the so-called *negative* DEP (nDEP). Between these two situations, the DEP force executed on the particle is zero if the particle has the same polarizability as the medium.

In an alternating-current (AC) electric field, the dipole moment of a particle can be written as

$$\tilde{\mathrm{p}} = v\tilde{\alpha}Ee^{i\omega t}, \tag{1}$$

where v is the particle volume, $\tilde{\alpha}$ is the polarizability, and E and ω are the magnitude and angular frequency of the electric field, respectively. As the time-averaged DEP force on the dipole is described as

$$\mathrm{F}_{DEP} = \frac{1}{2}Re[\,(\tilde{p}\cdot\nabla)E], \tag{2}$$

the DEP force is obtained as

$$\mathrm{F}_{DEP} = \frac{1}{4}vRe[(\tilde{\alpha})]\nabla|E|^2. \tag{3}$$

For a spherical particle, the effective polarizability in the medium is given by

$$\tilde{\alpha} = 3\varepsilon_m\tilde{f}_{CM}, \tag{4}$$

where

$$\tilde{f}_{CM} = \left(\frac{\widetilde{\varepsilon}_p - \widetilde{\varepsilon}_m}{\widetilde{\varepsilon}_p + 2\widetilde{\varepsilon}_m}\right) \tag{5}$$

is the Clausius-Mossotti (CM) factor and determined by the difference between the complex permittivity of the particle, $\widetilde{\varepsilon}_p$, and the medium, $\widetilde{\varepsilon}_m$. Substituting $\tilde{\alpha}$ for the effective polarizability of a sphere into Eq. 3, the full expression for the time-averaged DEP force is

$$\mathrm{F}_{DEP} = 2\pi\varepsilon_m a^3 Re\left[\left(\tilde{f}_{CM}\right)\right]\nabla|E|^2. \tag{6}$$

Apparently, the DEP force directly depends on the CM factor and the electric field gradient. As the complex permittivity of both the particle and the medium is frequency dependent as

$$\widetilde{\varepsilon} = \varepsilon - i\left(\frac{\sigma}{\omega}\right), \tag{7}$$

the real part of the CM factor reaches a low-frequency limiting value of $\frac{\sigma_p-\sigma_m}{\sigma_p+2\sigma_m}$, which relies solely on the conductivity of the particle, σ_p, and the medium, σ_m. Conversely, the high-frequency limiting value of the CM factor is $\frac{\varepsilon_p-\varepsilon_m}{\varepsilon_p+2\varepsilon_m}$, which is dominated by the permittivity of the particle, ε_p, and the medium, ε_m. Therefore, the CM factor and a spherical particle can vary between the low-frequency and high-frequency limiting values of 1 and -0.5, respectively. Apparently, pDEP occurs at $Re\left[\left(\tilde{f}_{CM}\right)\right] > 0$, while nDEP occurs at $Re\left[\left(\tilde{f}_{CM}\right)\right] < 0$.

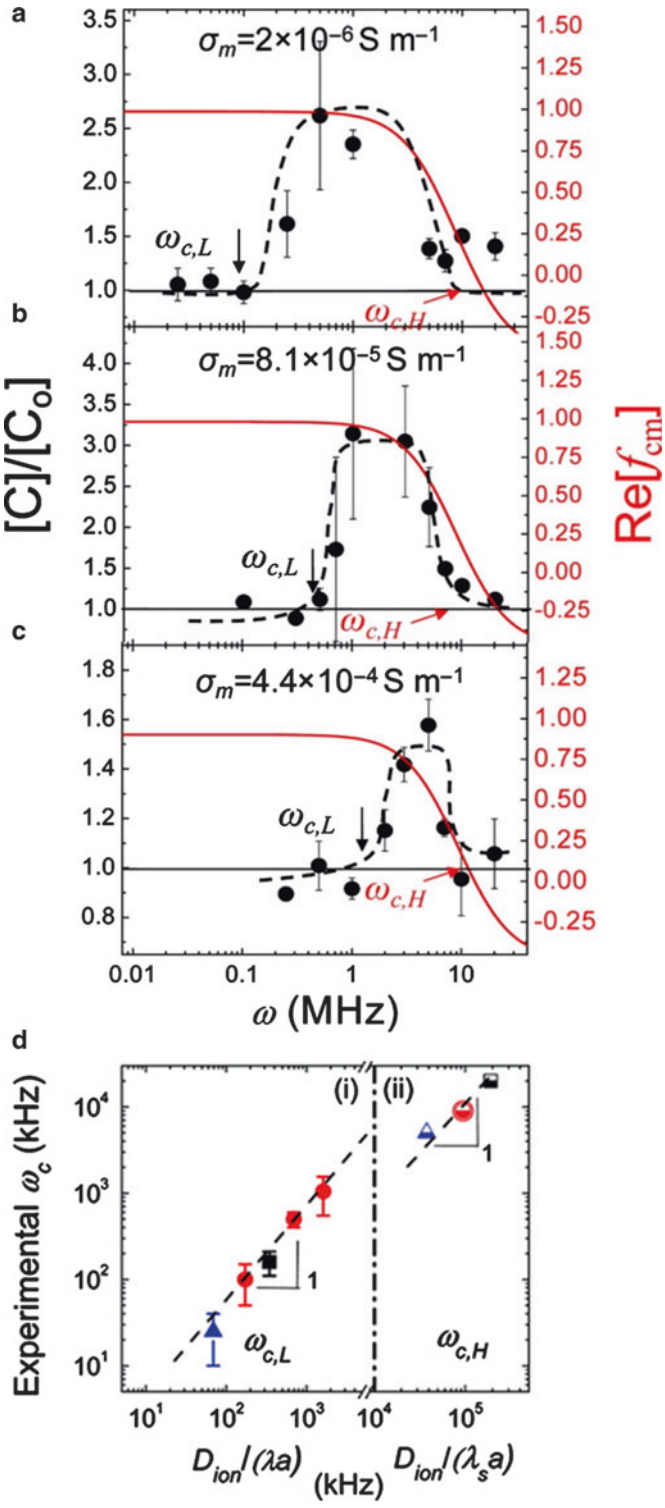
In addition to the DEP force, a particle suspended in the medium also undergoes Brownian motion that can be treated as an effective randomizing force, which can be approximately described as

$$\mathrm{F}_{\mathrm{thermal}} = \frac{k_B T}{v^{\frac{1}{3}}}, \tag{8}$$

where k_B is the Boltzmann constant, T is the temperature, and v is the particle volume [4]. In order to precisely control the DEP-directed motion and particle assembly, the imposed DEP force must overcome the random thermal fluctuation. As F_{DEP} is proportional to v while F_{thermal} is inversely proportional to $v^{1/3}$, the thermal motion is especially more prominent for smaller particles so that a larger field gradient is required to direct their assembly. In addition to the thermal fluctuation, there are several other electrokinetic effects on the particle, which resulted from the motion of the solvent molecules under an electric field, such as electrothermal and electroosmotic forces [24]. These forces are also frequency dependent and occasionally need to be taken into account in the DEP assembling of particles.

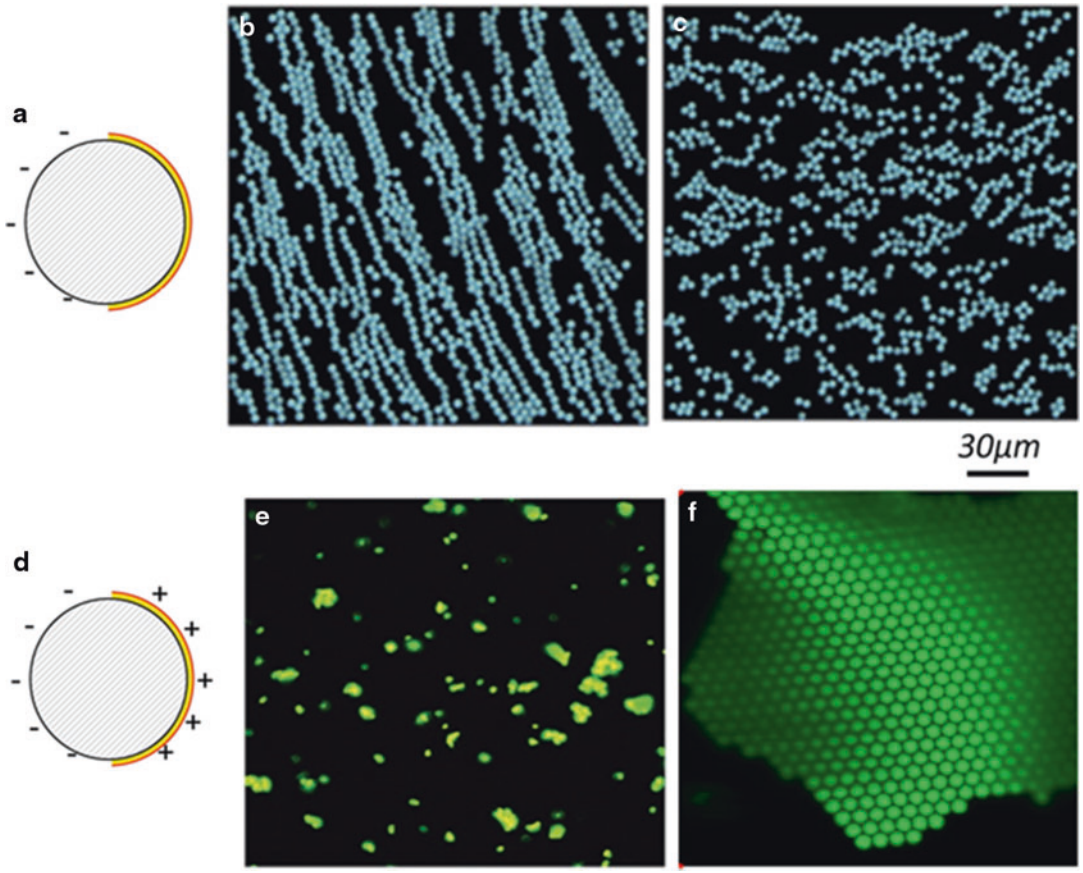
In some practical situations, many particles of interest may not be simply in the symmetric spherical geometry and could also carry charges on

their surfaces. For particles of nonspherical shapes, several methods have been proposed to modify the derivation of the polarizability as well as the resulting DEP characteristics [25–28]. For charged particles in aqueous media, the DEP behavior can be greatly influenced by the relaxation and conduction of counterions in the electric double layer at the particle-water interaction [29]. The effect of the polarized double layer could become prominent for nanoparticles (NPs), where the thickness of the double layer can be comparable to or even larger the particle size. Consequently, Eq. 5 needs to be modified to take the charging of the electric double layer into account and describe the polarizability of the charged particle in aqueous media.



With the advancement of microfluidic technology and DEP theory, DEP has been recently employed to directly assemble various nanocolloids in addition to the traditional targets of cells, viruses, biopolymers, or microsphere particles. Below several representative examples with key findings in the progress of DEP-directed assembly are described.

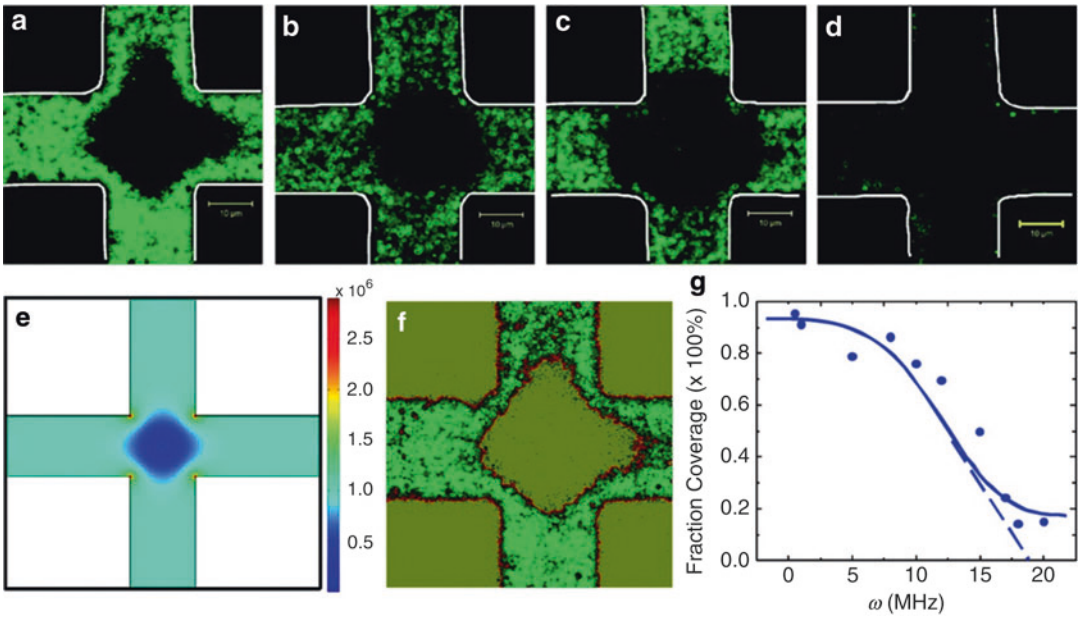
Examples and Key Findings



DEP Manipulation and Assembly of Nanoparticles and Janus Nanoparticles

Classical theories have predicted that due to the severely weakened F_{DEP} with reduced size, the deterministic DEP force on nanoparticles could hardly overcome Brownian motion; as a result, DEP becomes nearly inapplicable for colloidal manipulation and directed assembly at nanoscales [5]. However, recent experimental studies have demonstrated the assembly of functional nanowires and many other hierarchical nanostructures from nanoparticles in suspensions by DEP [22, 30–32]. Recent theoretical studies have endeavored to elucidate the induced dipole and intriguing DEP behaviors of submicrometer colloids of 50–500 nm in diameter by accounting the electric double layer effect for the interfacial polarization mechanism [29, 33]. It was suggested that submicrometer particles experience a DEP force stronger than that predicted by the classical Maxwell-Wagner (MW) theory, because AC field-induced tangential ionic currents in the Stern and diffuse layer result in high surface conductivity of dielectric colloidal particles. Moreover, when the particle radius, a, is further decreased to become comparable to the Debye length, λ (i.e., $a \approx \lambda$), the normal conductive field due to counterion migration in the diffuse layer cannot be negligible any more. As a consequence, nanoparticles should appear different DEP behaviors from micrometer or submicrometer particles.

To enable the in situ characterization of the nanoparticle assembly under nonuniform AC electric fields, fluorescence correlation spectroscopy (FCS) is employed, thanks to its high sensitivity and temporal resolution ($\sim 10^{-6}$ s). The typical concentration of fluorescence-labeled species is 10^{-12}–10^{-9} M in molar concentration or $\sim 10^{-3}$–1 particle or molecule over the ~ 1 μm [3] focal volume, which is 2–3 orders of magnitude lower than the common concentration limit required for microscopic visualization [34]. By employing FCS to detect fluorescence-labeled nanocolloids between microelectrodes, the DEP characteristics of nanoparticles of $a = 5$–25 nm were investigated, surprisingly showing a strong dependence on frequency of the applied AC electric field [35]. As shown in Fig. 2a–c, the nanoparticles surprisingly exhibit two distinct crossover frequencies in response to applied nonuniform AC electric fields between microelectrodes, one corresponding to the transition from zero or nDEP to pDEP and the other one corresponding to the transition from pDEP to nDEP, in contrast to one single characteristic DEP crossover frequency of micrometer-sized particles in suspensions. The results imply two distinct dipole relaxation time scales of a polarized nanoparticle under nonuniform AC fields. By examining the dependence of the two crossover frequencies with particle size and medium conductivity in Fig. 2d, it is found that the two distinct crossover frequencies resulted from the normal space charging in the diffuse layer and the counterion adsorption in the Stern layer, respectively. Because the normal conductivity and electric current in the diffuse layer are negligible for particles



Dielectrophoresis Directed Nanocolloidal and Supramolecular Assembly, Fig. 2 The normalized concentration profiles, C/C_0, plotted on the left coordinate axis, against the frequency of the applied AC electric fields for PS latex nanoparticles of diameter of 20 nm suspended in aqueous media of varied medium conductivity, $\sigma_m = 2 \times 10^{-6}$ (**a**), 8.1×10^{-5} (**b**), and 4.4×10^{-4} (**c**) S/m. The theoretically estimated real part of the CM factor, $f_{CM}(\omega)$, is plotted in the red solid lines on the right coordinate axis. The dashed line is a guideline only and provides comparison with the theoretical $Re[f_{CM}(\omega)]$. (**d**) Schematic illustration of zwitterionic JPs. (**e**) Micrograph of zwitterionic JPs in deionized water in the absence of applied AC field, exhibiting small aggregates formed in the bulk suspension. (**f**) Micrographs demonstrating that zwitterionic JPs with opposite surface charges on each hemisphere can rapidly form irreversible crystalline assembly in deionized water under the applied nonuniform AC fields (Reproduced from Zhang and Zhu [37], with permission from American Chemical Society)

of $a \gg \lambda$, only the tangential conductive current in the double layer is often accounted, leading to one single crossover frequency for micrometer particles. It was also demonstrated that the DEP force imposed on nanoparticles could be stronger than that predicted by classic theory. The assembly of nanoparticles using DEP is therefore practical and has great potential applications for the fabrication of nanoparticle clusters or arrays.

The advanced DEP theory, which has considered the double layer polarization effect, can be also applied to understand and control the DEP behavior of anisotropic nanocolloids in suspensions. One of the simple model anisotropic particles is the Janus particles (JPs), which are biphasic colloids with two hemispheres of distinct chemical and physical properties. It is recently demonstrated that Janus latex particles, the half hemisphere of which is coated with a thin gold layer, experience positive DEP at all the frequency ranges from 25 kHz to 20 MHz and can form pearl chains of JPs by imposed DEP forces in nonuniform AC electric fields [36]. It is also found that the pearl chaining of JPs strongly depends on the medium conductivity [37]. As shown in Fig. 3a–c, shorter pearl chains of JPs

Dielectrophoresis Directed Nanocolloidal and Supramolecular Assembly, Fig. 4 Fluorescence micrographs of the DEP-induced assembly of liposome under applied AC field of constant amplitude, $V_{pp} = 5$ V, and varied frequency of (**a**) 500 kHz, (**b**) 3 MHz, (**c**) 15 MHz, and (**d**) 18 MHz. Panels (**a**–**d**) indicate the decreased liposome coverage between microelectrodes with increasing AC frequency, where the transition from positive to negative DEP takes place; (**e**) simulated AC electric field gradient between the quadruple microelectrodes by using Gauss's law with COMSOL; (**f**) the illustration of image analysis corresponding to the original fluorescence micrograph shown in panel (**a**) to determine the liposome coverage between microelectrodes based on the total areas of fluorescence intensity; (**g**) liposome surface coverage against the applied AC frequency for a plain liposome. A crossover frequency, ω_c, is thereby defined as the frequency extrapolated from the liposome coverage frequency plot where liposome coverage decreases to reach the saturation of typically less than 20 %. The determined ω_c herein for a plain liposome is ~18 MHz (Reproduced from Fronde and Zhu [39], with permission from American Chemical Society)

are assembled from the suspension at low medium conductivity of 0.015 S/m, in sharp contrast to random aggregates at higher medium conductivity of 0.06 S/m. It is interesting to observe that at high medium conductivity, JPs can undergo a transition from nDEP to pDEP, which is opposite to the pDEP to nDEP transition typically observed for the homogeneous particles. This unique DEP response is resulted from induced charge electroosmosis (ICEO) flow due to the imbalanced polarizability of two hemispheres in the JPs.

In addition to form one-dimensional chain-like assembly of JPs, zwitterionic JPs that bear opposite charges on two hemispheres can be driven to assemble into closely random packed crystals in large area by DEP as shown in Fig. 4d–f; in contrast, only small aggregates exist in the suspension in the absence of AC fields. The DEP-directed assembly of JPs with tunable surface chemistry can be used to guide the rapid synthesis of highly hierarchical structured materials from anisotropic building blocks.

DEP Manipulation and Assembly of Surfactant Micelles and Lipid Vesicles

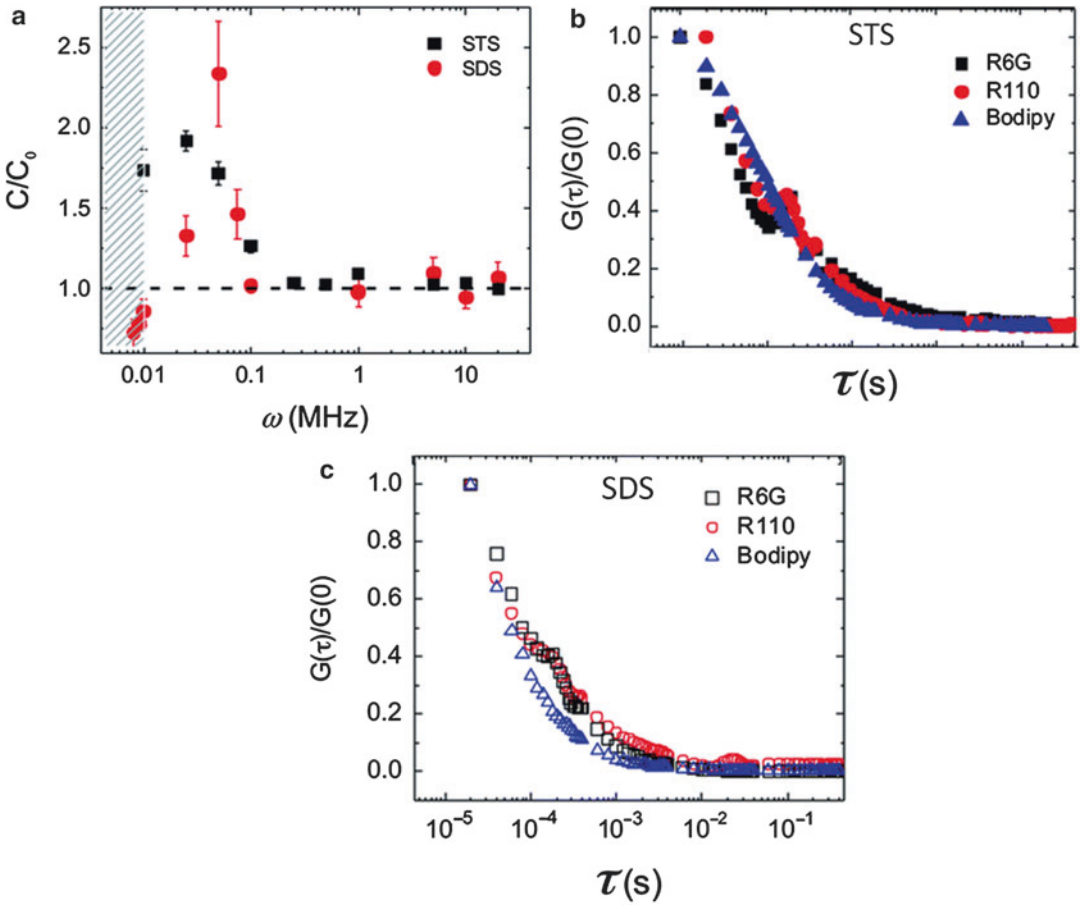
DEP is applicable to manipulate complex nanocolloids, such as lipid and surfactant assemblies in the vesicle or micelle forms. In this session, the application of DEP on two model demonstrative systems, lipid unilamellar vesicle (liposome) and surfactant micelle, is discussed.

Liposome is a synthetic spherical vesicle composed of a unilamellar lipid bilayer, which has been widely used to administrate nutrients and

pharmaceutical drugs by utilizing their hollow, aqueous interior core capable of encapsulating various molecules [38]. The DEP assembly of liposomes of different surface treatments for suspension stability was recently investigated [39]. To prevent liposomes from fusion, two strategies, using charged nanoparticles and calcium phosphate coating, were employed, giving rise to distinct surface chemistry and topology.

Theoretically, for the complex structure of liposomes, the CM factor needs to be modified by considering the polarization across different regions of distinct permittivity and conductivity in each layer. Using the multi-shell model [25], the dielectric property of liposome is described as

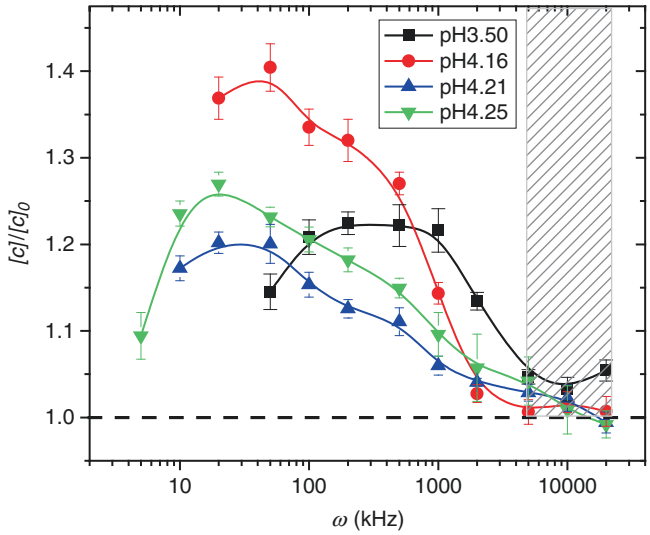
$$\widetilde{\varepsilon}_{lip} = \widetilde{\varepsilon}_{LB} \frac{{\gamma_{12}}^3 + 2\left(\frac{\widetilde{\varepsilon}_{IM} - \widetilde{\varepsilon}_{LB}}{\widetilde{\varepsilon}_{IM} + 2\widetilde{\varepsilon}_{LB}}\right)}{{\gamma_{12}}^3 - \left(\frac{\widetilde{\varepsilon}_{IM} - \widetilde{\varepsilon}_{LB}}{\widetilde{\varepsilon}_{IM} + 2\widetilde{\varepsilon}_{LB}}\right)}, \tag{9}$$



where $\widetilde{\varepsilon}_{LB}$ is the permittivity of the lipid bilayer, γ_{12} is a ratio of the outer to inner radius of the spherical shell, and $\widetilde{\varepsilon}_{IM}$ and $\widetilde{\varepsilon}_{LB}$ are the permittivity of the interior medium (IM) and lipid bilayer (LB), respectively. Using the classical MW theory, the CM factor for liposome could be deduced as

$$\tilde{f}_{CM} = \left(\frac{\widetilde{\varepsilon}_{lip} - \widetilde{\varepsilon}_{m}}{\widetilde{\varepsilon}_{lip} + 2\widetilde{\varepsilon}_{m}}\right). \tag{10}$$

It appears that in this shell model each interface separating the dielectric regions would contribute to the ultimate DEP behavior of the liposome in the suspension.



The key DEP behaviors of liposomes in aqueous buffer suspension between microelectrodes in a quadruple configuration are summarized in Fig. 4a–d. As the applied AC frequency is increased from 100 kHz to 20 MHz, collected liposomes at the microelectrode interfaces repel away from the microelectrode and diffuse into the aqueous suspension as indicated by the reduced fluorescence intensity. The consistence of fluorescence intensity with the simulated AC electric field gradient between the quadruple microelectrodes shown in Fig. 4e confirms the pDEP response of liposomes at low AC frequency but zero DEP at high frequency as a hallmark of a shell structure. The crossover frequency for the transition from pDEP to zero DEP is found to be ~18 MHz. The good agreement between the measured crossover frequency and the theoretical prediction using Eqs. 9 and 10 indicates that the electrokinetic behavior of the liposome can be well described by the multi-shell model. In addition, based on the study of the role of surface coating chemistry and structure on the DEP response of liposomes, it is found that the liposome surface construct, rather than surface conductivity, plays a critical role in the DEP characteristics of a shelled nanocolloid, which is much different from that of a solid dielectric particle. It is noted that when the liposome particle has a highly conductive interior, surface conductivity changes exhibit little effect on the DEP behavior of the liposomes even in the conductivity-controlled low-frequency region. Changes in the permittivity of multilayer coatings, on the other hand, can be used to effectively tune the polarizability of the shelled particle to a much greater extent, significantly altering the high-frequency DEP response of liposomes in suspension.

Surfactant-assembled micelles, which have been used in many chemical, cosmetic, and pharmaceutical products, represent another complex nanocolloidal construct. With micelles composed of sodium tetradecyl sulfate (STS) or sodium dodecyl sulfate (SDS) and fluorescence probe encapsulated in the interior hydrophobic core, the structural dynamics and assembly of micelles by DEP in nonuniform AC electric field were recently reported [40]. In response to applied electrical fields of frequency of 10–500 kHz, both micelles exhibit a pDEP behavior with increased micelle concentration in the strong field regions, as indicated in Fig. 5a. The estimated DEP crossover frequency from pDEP to nDEP is found approximately in the range of 200–500 kHz and agrees well with the advanced DEP theory in which the Stern layer conductance is accounted, indicating that the micelles have similar DEP behaviors as the charged nanoparticles. Most surprisingly, at a further

Dielectrophoresis Directed Nanocolloidal and Supramolecular Assembly, Fig. 5 (**a**) The normalized concentration profiles, C/C_0, plotted on the left coordinate axis, against AC frequency for STS-R6G (*black squares*) and SDS-R6G (*red circles*) micelles in salt-free aqueous suspension under applied AC field of constant amplitude, $V_{pp} = 10$ V, across microelectrodes in a quadruple configuration. Normalized autocorrelation curves, $G(\tau)/G(\tau = 0)$, for STS micelles (**b**) and SDS (**c**) micelles encapsulated with R6G (*black squares*), R110 (*red circles*), and Bodipy (*blue triangles*), both in salt-free aqueous suspensions under AC fields of $V_{pp} = 10$ V and $\omega = 5$ kHz. The autocorrelation curves obtained with micelles encapsulated with R6G or R110 exhibit the similar unusual "double plateau," indicating the existence of the free encapsulated molecules in solution but not with the ones encapsulated with Bodipy (Reproduced from Goodrich et al. [40], with permission from Royal Chemical Society)

low-frequency range of 5–10 kHz, a unique DEP response behavior of the micelle was observed: the correlation curves recorded by FCS manifest the existence of two distinct species of fluorescent entities in the suspension as indicated in Fig. 5b and c, suggesting the release of encapsulates from micelles induced by AC fields; in addition, such field-driven release of encapsulates exhibits a strong dependence on the chemistry of its encapsulated molecules. When charged molecules, for instance, Rhodamine 6G or Rhodamine 110, are encapsulated in the micelles, the anomalous release of the probe encapsulated in the micelle is observed but no release is found with neutral probes, such as Bodipy, encapsulated in micelles. Considering the difference between the charged and neutral molecular encapsulates, it is speculated that the conductivity of the interior regime of the micelle is the determining factor for the field-controlled release due to electromigration of charged probes. A future study with quantification, which also demands the advancement of

Dielectrophoresis Directed Nanocolloidal and Supramolecular Assembly, Fig. 6 The normalized concentration profiles, C/C_0, of a synthetic polyelectrolyte, poly(2-vinyl pyridine) (P2VP), against AC frequency in salt-free aqueous solutions of varied pH under applied nonuniform AC fields of $V_{pp} = 20$ V across a pair of planar microelectrodes separated by 30 μm. The dashed zone highlights the DEP behaviors of P2VP at AC frequencies higher than the crossover frequency (Reproduced from Wang and Zhu [41], with permission from American Institute of Physics)

molecular AC polarization theory, is desired to fully understand this intriguing AC electrokinetic characteristic in the complex micelle system.

DEP Manipulation of Synthetic Polyelectrolytes

The last demonstrative case involves synthetic polyelectrolytes, which are polymers bearing charged groups in their repeating units. By employing FCS, the DEP behavior of a synthetic and positively charged polyelectrolyte, poly (2-vinyl pyridine) (P2VP), was investigated at varied frequency of applied AC electric fields [41]. As P2VP is an annealed polyelectrolyte whose charge density is not constant but tunable by pH or applied electric fields, the local proton concentration in the vicinity of a PE chain can be significantly different from that in the bulk due to counterion condensation and thereby can be modified by external electric fields. In response to a homogeneous AC field, an induced swollen coil-to-collapsed globule conformational transition is observed and reversible upon AC frequency sweep when applied field strength exceeds a critical value, yet a hysteresis in AC frequency-dependent conformation is also observed [42]. However, no conformational change of P2VP is observed by imposed DEP force in response to spatially nonuniform AC fields of similar electric field and frequency, and instead a net flow and an accumulation of P2VP toward high field regions near two microelectrodes are observed, in sharp contrast to the response of P2VP under uniform AC fields that cause isotropic depletion of counterions and subsequent polarization normal to a P2VP chain. As shown in Fig. 6, in nonuniform AC fields within the frequency window of 100 kHz to 5–10 MHz, P2VP exhibits the pDEP response and becomes concentrated at the microelectrode interface. It is thus postulated that due to the field-driven net motion of both P2VP chains and localized counterions, the depletion of localized counterions away from a P2VP chain is significantly weakened or suppressed, resulting in negligible counterion concentration-induced dipolar energy on a P2VP chain, leading to no conformational transition. Nevertheless, the DEP behavior of P2VP at high frequencies above 10 MHz shows a strong dependence on the pH of the solution: at lower

pH, a zero to positive DEP transition appears as increasing the frequency across 10 MHz; however, no clear transition is observed at higher solution pH. The abnormal pDEP behavior for the synthetic polyelectrolyte at high frequencies is unpredicted by the classical MW theory. However, this abnormal pDEP of the synthetic polyelectrolyte is found similar to the reported DEP response for DNAs with short chains [43]. It is argued that the flexibility of the polymer chain could be an important factor for its electrokinetic properties in solutions. The distinct conformational and transport behaviors of a single annealed PE chain under varied microelectrode layouts can be further exploited in lab-on-chip device design to effectively manipulate and transport polyelectrolytes including DNA and protein under the application of varied AC fields.

Perspectives

Over the last decades, rapid and continuous development of lithography techniques has made enormous progress in the fabrication of metal and/or insulator structures. Nowadays, the fabrication of complex and custom designed microelectrodes to generate strong electric field gradient as well as tunable field distributions becomes feasible and nearly a routine job in the lab. On the other hand, nanomaterials, with their vast diversity in chemical composition, structure, and functionality, have been developed incredibly fast and reshaped the landscape of materials today. It turns out that the assembly of nanomaterials into hierarchical structure becomes a critical step to transfer their fascinating properties to advanced devices or products for broad applications. As a bridge linking between the top-down and bottom-up approaches, DEP has been demonstrated to be a robust method with the potential for the large-scaled integration of nanomaterials into nanoscaled functional devices. Future research could be considered along the following directions. First, DEP-directed assembly of various nanomaterials to fabricate functional devices is still of great interest, especially for the anisotropic and heterogeneous nanomaterials. To achieve the high controllability and efficiency of DEP-directed nanomaterial assembly, particular efforts, including the innovative design of microelectrode arrays and optimal operational parameters, need to be taken care of. Second, theoretical modeling on the electrokinetics of nanomaterials is further advanced. The complexity arising from the polarization of condensed counterions, asymmetry and heterogeneity in surface chemical composition, structure, and geometry of nanomaterials, needs to be addressed explicitly to predict the DEP characteristic of structured nanomaterials. Finally, the scaled-up nano-manufacturing based on DEP and other electrokinetic effects could be promising. The integration of DEP with the current micro- and nano-fluidic device could lead to further accelerating the nanomaterial assembly process toward practical industrial applications.

Dielectrophoresis of Nucleic Acids

David J. Bakewell
Department of Electrical Engineering and Electronics, University of Liverpool, Liverpool, UK

Synonyms

Translational movement of polynucleotides in a nonuniform electric field

Definitions

1. **Dielectrophoresis** (DEP) is the translational motion of an electrically polarizable body by the action of an externally applied, spatially nonuniform, electric field. DEP can occur with an electrically neutral body in a spatially nonuniform field and depends on the *dielectric* properties of the body relative to the surrounding medium. The word *dielectrophoresis* derives from the Greek word "*phorein*" where a particle "is *carried* as a result of its *dielectric* properties" [1]. DEP is distinguished from **electrophoresis** that requires a net charge on the body for Coulombic movement to occur in an externally applied, spatially uniform, electric field. DEP is also distinguished from **electrorotation** (EROT) that refers to *rotational* motion of a body in a spatially inhomogeneous electric field.
2. **Nucleic acids** (NAs) are responsible for information storage, distribution, translation, and control throughout a living system, such as a cell. There are two types of NAs central to life: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA, discovered more than a century ago by Friedrich Miescher, is called a nucleic acid because it was extracted from the nuclei of cells (originally called "nuclein") and showed acidic chemical properties [2, 3]. Nowadays, it is known that DNA can also be extracted from organelles in a cell, e.g., mitochondria, or other life forms, e.g., viruses; nonetheless, the term "nucleic" remains. Both DNA and RNA are comprised of nucleotides that consist of a nitrogenous base, a pentose sugar, and a phosphate link. A third type of NA is not naturally occurring; rather it is a synthetically made NA, e.g., peptide nucleic acid (PNA).

Introduction

The first main exposition of dielectrophoresis (DEP) as an important method for moving an electrically neutral body was by Herbert Pohl [4], although the phenomenon was known as far back as 600 BC. DEP of a body suspended in a medium is usually achieved by applying an electric potential between electrodes immersed in low conductivity electrolyte medium. Application of an electric potential can yield an electric field that induces dipoles in the body. If the field is sufficiently nonuniform, the interaction of the dipole charges yields a net force on the body and causes it to move. Dependence on the dielectric polarizability of the body, rather than reliance on net electrical charge, is a key reason for considerable interest in using DEP for noncontact movement of micro- and nanosized bodies. A corollary of the motion based on dielectric properties is that radio-frequency (RF) electric fields can be used to move bodies by DEP and hence avoid problematic hydrolysis at the electrode-medium interface. Developments in microfabrication methods that allow the generation of high electric field nonuniformities using RFs and low voltages have

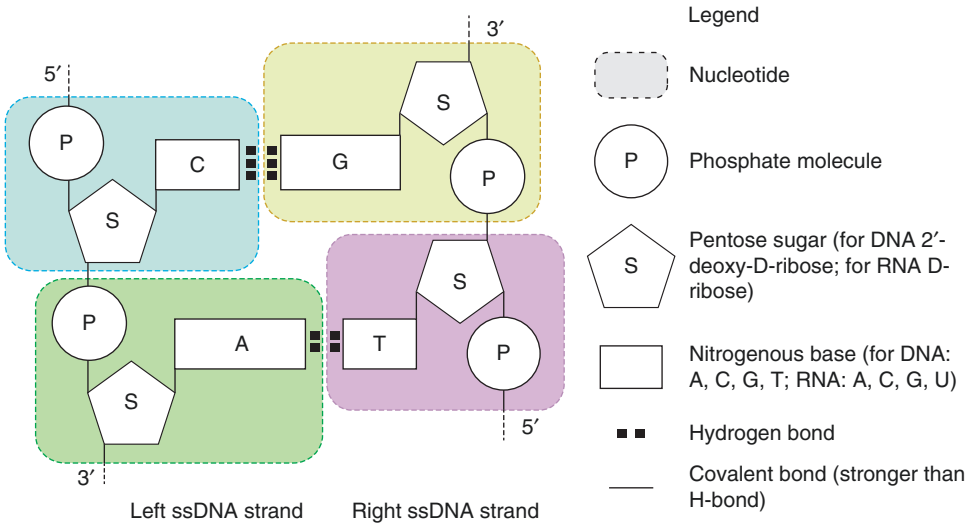
enabled DEP to become a popular method for moving bodies in microenvironments, e.g., lab-on-chip (LOC) and micro-total analysis system (μTAS).

There is considerable interest in using DEP for moving nucleic acids (NAs) which are large molecules that play a central role in life. Both types of naturally occurring NAs, DNA and RNA, possess net negative electrical charge, and electrophoresis is a commonly used tool in molecular biology laboratories today. DEP is less well known in current biology laboratories so that the focus of this entry lies with the DEP motion of these NAs in their native suspension at room temperature (25 °C), i.e., water. Research into DEP in general, and in particular DEP of DNA, has dramatically increased in recent years, forming about 10 % of the several hundreds of journal articles published per annum on DEP. A database search (Web of Science™ v.5.16, 2015, Thomson Reuters), for example, shows that in the last decade there are more than thirty journal publications per annum involving DEP of DNA. The topic is of interest to nanotechnologists due to the central role DNA plays in life sciences and its properties as a nano-construction material. Progress in this field has been discussed in highly informative reviews [1, 5, 6].

Conversely, there are comparatively little published data on DEP of RNA and no journal reports solely on DEP of PNA. This is perhaps because this RNA is more complicated to prepare and handle than DNA; for instance, RNA is easily degraded (e.g., by an enzyme, RNase) without extra laboratory precautions and facilities. This is somewhat unfortunate because RNA, for many scientists and technologists, is more important than DNA (see also "RNA world" hypothesis [3]). The following sections discuss fundamental structural, chemical, and physical properties of NAs for DEP. This is followed by a DEP of DNA application example and a summary of broader contributions including a reference to the use of PNA in experiments. A brief summary of DEP of RNA follows. Due to a need for concise referencing, many of the names of individual authors and groups are referred to as listed in reviews and books, rather than individual citations.

Fundamentals

This section describes the fundamentals of NAs, their structural and electrical properties in water, their inducible polarizability, and the basic principles of DEP. The focus is on DNA since there are far fewer DEP studies on RNA and PNA and it is likely similar electrokinetic principles apply.



Nucleic Acids

The basic chemical building blocks of natural NAs are nucleotides, outlined in Fig. 1, and consist of three characteristic components:

- A nitrogen-containing base, indicated by each rectangle in Fig. 1, that is either:
  - Purine with two possibilities: adenine (A) or guanine (G)
  - Pyrimidine with three possibilities: cytosine (C), thymine (T), or uracil (U)
- A pentose sugar ring (denoted by S within each pentagon in Fig. 1):
  - For DNA the sugar is 2′-deoxy-D-ribose (with "′" read as "prime").
  - For RNA the sugar ring is D-ribose.
- A phosphate (denoted by P within each circle in Fig. 1)

In DNA and RNA, the nucleotides are covalently linked together with the phosphates acting as bridges between the pentose sugars. The 5′ phosphate group of one nucleotide is linked to the 3′ hydroxyl group of the next nucleotide. The linkages between the nucleotides, on each of the left and right strands in Fig. 1, are often referred to as the "sugar-phosphate backbone." DNA is principally distinguished from RNA by the pentose sugar rings; in DNA the hydroxyl (OH) group on the 2′ carbon atom in the D-ribose ring is replaced by hydrogen (H) [3] so that the oxygen atom can be said to be "removed." The "removal" of the oxygen atom is encapsulated by the prefix "deoxy"; so the prefix followed by "ribonucleic acid" can be helpful for remembering the long name for the acronym "DNA."

The schematic arrangement, i.e., two dimensional (2D) of the three constituents for each of the four nucleotides that comprise DNA, is shown in

Dielectrophoresis of Nucleic Acids, Fig. 1 Ladder sketch of dsDNA nucleic acid showing the constituents of each nucleotide containing a base (*rectangle*), sugar ("*S*" inside a *pentagon*), and phosphate ("*P*" inside a *circle*) and pairing of *left* and *right* strands. Not to scale; for twist and writhe angles between molecules in 3D, see text for references

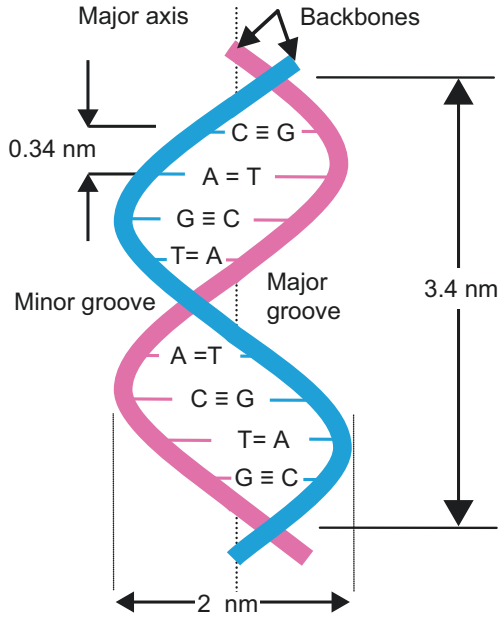


Fig. 1. A key property of NAs is that a single strand of linked nucleotides can form *complementary* pairs with another strand. That is, each base of a nucleotide on one strand can form hydrogen (H) bonds with the base of a nucleotide on the opposite strand according to rules given below. This occurs for all bases on each strand with purines pairing with pyrimidines according to the following rules:

- DNA contains A, C, G, and T and they pair as A with T and C with G.
- RNA contains A, C, G, and U and they pair as A with U and C with G.

DNA and RNA are distinguished not only by their pentose sugars; they differ by one of the bases (T rather than U). Only very rarely do exceptions to these rules occur. There are a number of different structures of DNA; two of the most common are single-stranded DNA (ssDNA) and double-stranded DNA (dsDNA). Figure 1 shows complementary base pairing where A and C on the left ssDNA strand form H-bonds with T and G, respectively, on the right strand. There are different forms of dsDNA, namely, A, B, and Z [7]. The standard double-helical DNA is usually referred to as (Crick and Watson) B-form.

Figure 2 shows a very short length of dsDNA as it occurs in aqueous (or water) solution, that is, in the energetically favorable state as a three-dimensional (3D) double helix. The sugar-phosphate double-helical backbones are shown as thick lines. Structural "backbone" is somewhat of a misnomer as it is the stacking of the nitrogen bases that gives the molecule its mechanical stiffness [7]. The sugar-phosphate backbones are hydrophilic and lie on the exterior of the macromolecule. The hydrophobic nucleotide base pairs (bp) lie within the macromolecule, away from the polar water molecules. They are represented symbolically (A – T, C – G pairs) with, respectively, double and triple H-bonds. The displacement along the major helical axis between base pairs is shown as 0.34 nm, so that the length between repetitive positions of the double helix is about 3.4 nm (10 bp). The diameter is about 2 nm.

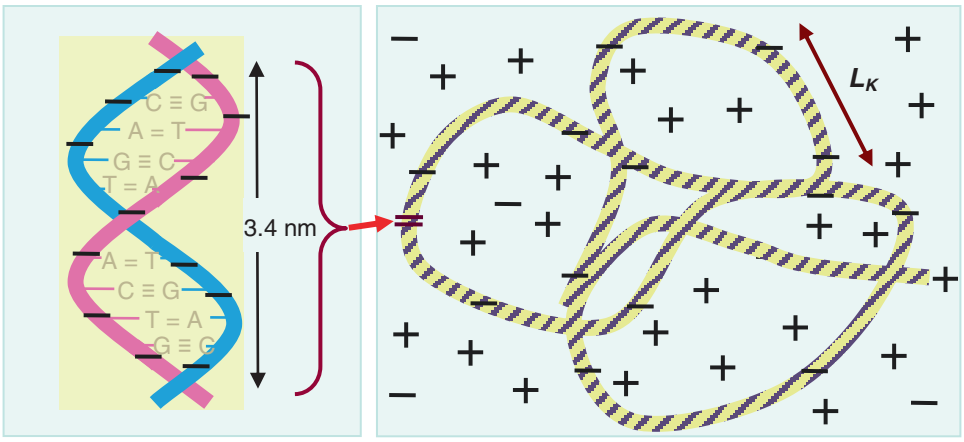
Importantly, the H-bonds shown in Figs. 1 and 2 are weaker than the covalent bonds. Consequently, by moderate heating or by using a different medium, each dsDNA macromolecule can be reversibly separated into two complementary ssDNA strands. These ssDNA strands, in a solution

Dielectrophoresis of Nucleic Acids, Fig. 2 A short fragment of dsDNA in 3D double-helical B-form showing basic dimensions (2 nm diameter and 0.34 nm per base pair length) and exhibiting major and minor grooves of the "backbone." Sketch only, not to scale; see text for references and details

with available nucleotides bases, can act as templates, thus enabling copying, or *replication*. ssDNA also enables *detection* whereby a particular sequence of nucleotides will pair up with another strand with the complementary sequence. In a situation where a particular base does not match (e.g., A – A) and the others do is called a *mismatch*. These fundamental properties underpin the emergence of new technologies, such as nanospheres and microarrays, where applications of DEP are being explored for enhancing concentration and other developments – as described in section "Dielectrophoresis of DNA: General."

RNA is mainly involved with reading of DNA, called *transcription*, and its *translation* into proteins and other macromolecules associated with cellular information. There are a number of different types of RNA that perform different functions inside a cell:

– Messenger RNA (mRNA) is concerned with the transfer of genetic "blueprint" information that codes for proteins. There are 20 different amino acids (AAs) found in nature [3]. Fragments of DNA that code for a sequence of AAs that constitutes a protein, using the A, C, G, and T base alphabet, are called *genes*. A triplet of bases is required to sufficiently code for 20 AAs. That is, four bases to choose independently for first (base) position, four bases for the second, and so on yield a total of $4^3 = 64$ possible AAs. This is more than enough to code for the actual 20 AAs needed to make proteins so the genetic code is said to be "*degenerate*" [3]. The triplet of bases that codes for each AA (and also DNA reading instructions) is called a *codon*.
– Transfer RNA (tRNA) reads or decodes each mRNA codon and transfers an appropriate AA onto a polypeptide chain that is being synthesized during the production of a particular protein. tRNAs are small RNAs (about 80 nucleotides) with a characteristic clover leaf shape and act as adapters.
– Ribosomal RNA (rRNA) constitutes part of the ribosome. These are located in the cytoplasm of a cell and are responsible for catalyzing the synthesis of AA peptides and hence protein, by decoding mRNA.
– Noncoding RNA (ncRNA) is an RNA that does not code for protein (i.e., not mRNA) and includes rRNA, tRNA, and other forms of RNA involved in modification, splicing, and regulation [3]. For example, RNA interference (RNAi) is a process involving gene expression silencing, i.e., preventing part of the genetic code being read. ncRNAs include small interfering RNA (siRNA) and microRNA (miRNA) that have been involved with developmental timing [3]. There are many applications of ncRNA and the variety of functions is continuing to be discovered.



If RNA is extracted, for example, from fish liver cells, the dominant amount of RNA is rRNA with the other amounts of RNA being much smaller. Consequently, mRNA needed for understanding protein production, e.g., for each gene, has to be carefully separated from the total amount of RNA. DNA and RNA are both

biological *polymers*, or biopolymers, with each nucleotide being the smallest subunit (or "mer"). For example, a short strand of 20 nucleotide ssDNA can be referred to as a 20-*mer*. A short strand of up to 50 nucleotides of ssDNA, or ssRNA, can be generally referred to as an *oligonucleotide, oligos* being Greek for "few" [3], and they are often made synthetically. Strands of NAs greater than 50 nucleotides are referred to as *polynucleotides*.

Electrical Properties of Nucleic Acids

DNA is classified as a biological polyelectrolyte. These are biomolecules with a large number of charged chemical groups. An electrolyte or aqueous environment with salts acts as a supply for dissociated ions, for example, Na^+, Mg^{2+}, OH^-, and Cl^-. DNA and RNA possess a net *negative* charge so they attract ions of the opposite charge, or *counterions*, by Coulombic forces to restore charge neutrality. The positive counterions, or cations, form a cloud around the NA and electrically screen the negative charge. Further away from the macromolecule, the counterions are more diffuse and the screening occurs in such a way as to attract other negative ions, or anions, with the same charge as the NA, and they are called *coions*.

The double-helical structure for DNA is shown to be straight in Fig. 2 but this only applies for relatively short lengths. The mechanical properties of DNA are partly determined by its chemical composition and the composition of the solvent or suspending *medium*. In an aqueous medium with low counterion concentration, there is little electrostatic screening so the polyelectrolyte repels itself and it tends to be straight. Conversely, in solvents with high counterion concentrations, there is considerable electrostatic screening so the DNA repels itself less and it is more flexible. A measure of straightness is known as the persistence length, L_p, as sketched in Fig. 3. Typically for standard biological conditions for dsDNA, $L_p = 50$ nm [6]. The behavior of dsDNA in water can be modeled as a wormlike chain with each straight link equal to the Kuhn length that is twice the persistence length, $L_K = 2L_p$ [8]. In this chain, due to thermal motion, the next link is independently and randomly oriented from the previous link. Each link is about 100 nm or about 300 bp. The persistence lengths of ssDNA are much shorter than dsDNA, with a minimum of about 1 nm. The following discussion on dielectric polarization mechanisms includes both of the NAs but focuses on DNA since the literature, reviewed in [6], is much more extensive.

Dielectrophoresis of Nucleic Acids, Fig. 3 dsDNA (or DNA) as a negatively charged polyelectrolyte in solution attracts counterions (mostly cations). These form around the polyelectrolyte to electrically screen the charge of the DNA. Wormlike chain model of dsDNA, with close-up inset, in aqueous suspension, showing relatively straight segments of Kuhn length L_K. Not to scale

In addition, dielectric spectroscopic measurements of the electrical properties of rRNA are often confounded by the presence of ribosomal proteins (see the work by Bonincontro et al. (1997), cited in [9], and references to other work therein).

Dielectric Polarization Parameters

Polarization is a term that describes how charges, within a dielectric, respond to an externally applied electric field. Charges that are free to move over a long range reveal their movement on a macroscopic scale as conduction. If the movement of the charges is restricted, they are said to be "polarized" [4]. In this respect, polarization is the "capability" of the charges to move in response to an applied electric field. The polarization can be expressed, in terms of an equivalent circuit with permittivity parameters, as the real (in-phase) permittivity ε' or *dielectric constant* [10] and the free movement of charges as the imaginary (out-of-phase) permittivity ε'' or *dielectric loss*. The permittivity parameters are frequency dependent, $\varepsilon \equiv \varepsilon(\omega)$. In addition the conductivity (or low-frequency Ohmic loss) of the electrolyte solution σ is included [11]. The complex permittivity ε is the combination of these:

$$\varepsilon(\omega) = \varepsilon'(\omega) - j[\varepsilon''(\omega) + \sigma/\omega] \tag{1}$$

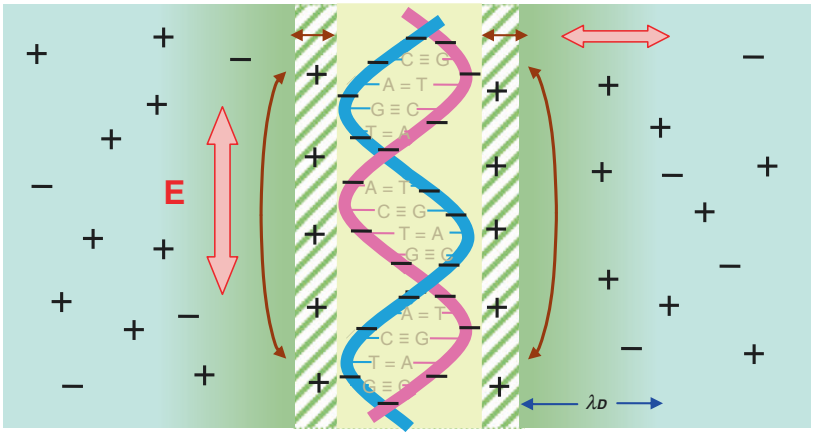
where $j = \sqrt{-1}$; the angular frequency is $\omega = 2\pi f$ (rad s^{-1}) with frequency f (Hz). Often $\varepsilon'' << \sigma/\omega$, the superscript $'$ notation is omitted in the literature and the complex permittivity is written:

$$\underline{\varepsilon}^* = \varepsilon - j\sigma/\omega \tag{2}$$

where the underscore denotes a complex quantity, "*" denotes complex conjugate, and ε is the permittivity (real part of $\underline{\varepsilon}^*$) that is assumed constant for the frequencies of interest.

A quantitative measure of the responsiveness of a body to an applied external electric field is the polarizability, α. A highly polarizable body, for example, features many charges that are responsive to an electric field and their movement is in some way restricted. An important parameter for experimentally determining the value of the polarizability of a NA, such as DNA, is the dielectric increment, or decrement [10–13]:

$$\Delta\varepsilon' = \varepsilon'_{rl} - \varepsilon'_{rh} \tag{3}$$



where ε_{rl} and ε_{rh} are the low- and high-frequency relative permittivities, or limiting dielectric constants, respectively. The predicted polarizability, α_m, for a macromolecule determined using the experimentally measured dielectric decrement, $\Delta\varepsilon'$, is given by

$$\alpha_m = \frac{3\varepsilon_o \Delta\varepsilon'}{C_m} \tag{4}$$

where ε_0 is the permittivity of free space, C_m is the number density (m^{-3}) of macromolecules, and the factor "3" accounts for random macromolecular orientation. Using dielectric mixture theory, the polarizability of each DNA, or RNA, macromolecule can be determined from the suspension by calculating the volume fraction of the NA. Another parameter is the relaxation time constant, τ_R(s) that is the time duration for charges to redistribute or "relax" after being perturbed by an electric field. The charges resonate at a dispersion frequency, f_R, or angular frequency ω_R:

$$\tau_R = \frac{1}{f_R} = \frac{2\pi}{\omega_R} \tag{5}$$

Dispersions arise when the oscillating cloud of charges can no longer follow the alternating electric field, and this effect is observed in both real and imaginary parts of the complex permittivity. NAs can have more than one dielectric dispersion characterized by a decrement and associated time constant. Commercial time-domain dielectric spectrometers can be used to estimate the dispersion decrement $\Delta\varepsilon'$ and time constant τ_R using a sample, e.g., 150 μl, of macromolecules suspended in a medium, such as water. Characteristics of dielectric permittivities and losses for calf-thymus DNA, a macromolecule used in many dielectric spectroscopy studies, versus frequency

Dielectrophoresis of Nucleic Acids, Fig. 4 Counterion polarization on a short segment of DNA: a negatively charged sugar-phosphate double helix attracts mainly counterions. Components of an applied AC electric field (*red filled bidirectional arrows*) cause counterion movement in the longitudinal direction – along the DNA backbone – and transverse direction (*brown bidirectional line arrows*). The counterion movement tends to be within the "cylindrical" condensed layer (*green shaded* ////). The diffuse layer has characteristic length, λ_D, as shown and is referred to as the Debye screening length – see text for details

are compiled and shown in [6]. Although there are variations in the experimentally measured permittivity, ε', they all tend to decrease with an increase in frequency and the polarizability follows the same trend.

The types of polarization include electronic, atomic, molecular, interfacial (or space-charge), and counterion polarization. The first three are attributed to the displacement, or orientation, of bound charges; the latter two concern movement on a larger scale. Of the first three types of polarization, only molecular dipole polarization tends to feature in the literature concerning dielectric properties of NAs. The asymmetric distribution of electrons in molecules gives rise to *permanent* dipoles. The interaction of such a dipole with an externally applied electric field causes a torque that attempts to orient the molecule in the field direction. The polarization is appropriately called *orientation*, or *dipole*, polarization. Water is an example of a molecule with a permanent dipole and manifests permittivity values, via ε and σ, that are practically frequency independent up to 17 GHz [11].

The last two kinds of polarization, interfacial and counterion, involve large-scale charge movement. Currently, there is no universal consensus in the literature on the high-frequency polarization mechanisms for macromolecules, such as DNA or RNA. At present, the emphasis tends to favor Maxwell-Wagner interfacial polarization for molecular structures with well-defined interfaces with water molecules and counterion fluctuation polarization, along the longitudinal axis, for DNA and similarly for RNA.

Counterion Fluctuation Polarization for DNA

It is the response of the counterions to an externally applied AC electric field that results in counterion polarization. Since there is Coulombic attraction between the charged body and the counterion layer, the counterions attempt to pull the charged body along with them as they follow the electric field. The counterion polarization mechanism is due to solution counterions (such as Na^+, Mg^{2+}, etc.) interacting with negatively charged phosphate groups along the DNA or RNA polyion backbone. The counterions move freely along the lengths of the macromolecule in response to the component of the external electric field parallel to the major axis or "backbone" (Fig. 4). Their migration results in an induced dipole moment and, hence, an identifiable polarizability.

A popular model of counterion polarization is the "Mandel-Manning-Oosawa" model developed in various stages by these authors cited in [6, 13, 14]. In this model, the counterions move

freely along macromolecular "subunit lengths" and are permitted to cross from one subunit to a neighboring subunit only by overcoming "potential barriers." The *subunit length*, L_s, is described as the length along the average macromolecular conformation between "breaks," or "potential barriers," resulting from perturbations in the equipotentials due to conformational processes, folding, etc. Counterions moving along these *subunit* lengths, under the influence of an external electric field, manifest *high*-frequency dispersion that is molecular weight *independent*. This polarization contrasts with *molecular-weight-dependent* counterion movement along the entire macromolecular contour length that results in *low*-frequency dispersion and may account for the static permittivity. A proportion of the counterions are so strongly attracted to the polyelectrolyte that they are said to "condense" onto the polyion backbone. Essentially there are three distinct phases:

(i) *Condensed* counterions – these are sufficiently, but non-locally, bound (or "delocalized") to the phosphate groups of the DNA and thereby neutralize a fraction of the DNA charge. In many respects the condensed counterion layer is similar to the Stern layer of the double-layer model for colloids.
(ii) *Diffuse* counterions which are responsible for neutralizing the remainder of the DNA charge, with a density which decreases exponentially with distance from the axis.
(iii) *Bulk* ions or "added salt" ordinary aqueous solution ions.

In terms of their contribution to polarizability, the condensed counterion phase is the most important. A feature of the condensed state is that the local concentration of counterions around the DNA does not tend to zero when the suspending medium or bulk electrolyte concentration does. Condensation occurs when the condition $\xi \geq 1/|z|$ is satisfied where z is the valence of each counterion and the charge density parameter, ξ, is given by

$$\xi = q^2/(4\pi\varepsilon_m k_B T b) \tag{6}$$

where q is the elementary charge, $\varepsilon_m = \varepsilon_0\varepsilon_{rm}$ is the permittivity of the bulk electrolyte medium, ε_{rm} is the relative permittivity, k_BT is the Boltzmann temperature, and b is the average distance between charged sites; for B-DNA double helix, $b = 1.73$ Å. The "Manning-Mandel-Oosawa" model yields a generalized expression for scalar longitudinal polarizability, α_s, per subunit length:

$$\alpha_s = \frac{z^2 q^2 {L_s}^2 n_{cc} A_{st}}{12 k_B T} \tag{7}$$

where A_{st} is the stability factor of the ionic phase and includes mutual repulsion between fixed charges on the backbone and the effect of Debye screening,

$$A_{st} = [1 - 2(|z|\xi - 1)\ln(\kappa_s b)]^{-1}. \tag{8}$$

Referring to Eq. 8, the reciprocal of the Debye screening length, shown in Fig. 4, $\lambda_D = \kappa_s^{-1}$ (m) is given by

$$\kappa_s = \left[\left(\frac{N_{Av} q^2}{\varepsilon_m k_B T}\right)\left(\sum_i C_i z^2 + \frac{C_p}{\xi}\right)\right]^{0.5} \tag{9}$$

where N_{Av} is Avogadro's number and C_i and C_p are the respective molar concentrations of ions in the bulk and diffuse phase and phosphate groups. In the simplified case where $C_p = 0$, Eq. 9 reduces to the standard formula for the Debye reciprocal length of a balanced electrolyte [4, 12, 13]. In Eq. 7, n_{cc} is the number of condensed counterions that can be predicted theoretically:

$$n_{cc} = \phi_c L_s/|z|b \tag{10}$$

where the fraction of condensed counterions is $\phi_c = 1 - |z^{-1}|\xi^{-1}$. Equations 6, 7, 8, 9, and 10 are equated with Eq. 4 that determines the polarizability from a dielectric spectroscopy experiment. The relation, $\alpha_m C_m = \alpha_s C_s$, where the number density of subunits is $C_s = N_{Av} C_p b/L_s$, is useful to bridge the theory and experiment. An expression for L_s based on the measured dielectric decrement $\Delta\varepsilon'$ is thus derived (see Bakewell et al. (2000) cited in [13, 14]):

$$L_s = \sqrt{\frac{9\Delta\varepsilon'}{\pi\varepsilon_{rm}(|z|\xi - 1)A_{st}N_{Av}C_p b}}. \quad (11)$$

Assuming, for example, $T = 298$ K (25.0 °C), $\varepsilon_{rm} = 78.4$, and $z = 1.00$ for monovalent cations and $C_p = 2.72$ (mol/m^3) and $C_i = 1.10$ (mol/m^3), then $\xi = 4.13$, $\kappa_s = 9.754 \times 10^7$ (m^{-1}), $A_{st} = 3.76 \times 10^{-2}$, and $L_s = 3.31 \times 10^{-8}\sqrt{\Delta\varepsilon'}$ (m). An expression for the relaxation time in terms of the subunit length can be also derived:

$$\tau = \frac{{L_s}^2 q}{\pi^2 \mu k_B T}. \quad (12)$$

Assuming the mobility value $\mu = 8.00 \times 10^{-9}$ (m^2 V^{-1} s^{-1}) at 25 °C, $L_s = 1.42 \times 10^{-4}\sqrt{\tau}$ (m). A sample of dsDNA with measured values, $\Delta\varepsilon' = 9.0$ and $\tau = 500$ ns, has predicted subunit lengths from Eqs. 11 and 12 that approximately concur with each other, $L_s \cong 100$ nm. Physically, this value is close to the wormlike chain Kuhn length for dsDNA. In the framework of the counterion model, the result would support the notion that equipotentials arise from natural curvature of the dsDNA suspended in solution.

Maxwell-Wagner Polarization for DNA

Interfacial, or *space-charge*, polarization arises from electrical charges being restricted in their movement at the interfaces between layers of different dielectric materials. Interfacial polarization results in dielectric dispersions when the aggregate of dissimilar materials is exposed to AC electric fields [4, 10–13]. Maxwell-Wagner (MW) polarization models for DNA suspensions have been undertaken by a number of researchers (see Grosse (1989) and Saif et al. (1991) and their respective coworkers cited in [13, 14]).

MW interfacial polarization models the DNA macromolecule with the amino acid sugar-phosphate double helix as a 2 nm diameter, long cylindrical insulating core with low conductivity and permittivity. The insulator core is surrounded by a highly conducting sheath that represents the bound counterions on the negatively charged sugar-phosphate backbone. The conductive sheath interfaces with an electrolyte medium with low conductivity. The dielectric decrement for MW dispersion for DNA is predicted to be

$$\Delta\varepsilon' \cong 8\varepsilon_{rm}v_f/3 \quad (13)$$

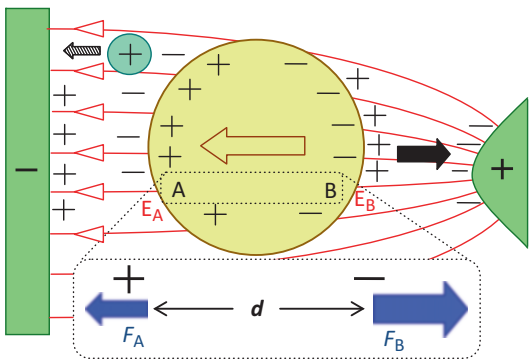
where v_f is the volume fraction. Similarly, the high-frequency relaxation is approximated in terms of the DNA *suspension* conductivity, σ_s (or conductivity of the electrolyte medium, σ_m) and fraction of condensed counterions, ϕ_c,

$$f_R = \sigma_m\phi_c/\left(4\pi\varepsilon_o\varepsilon_{rm}v_f\right) \quad (14)$$

where $\sigma_m = \left(1 - v_f\right)\sigma_s/(1 - \phi_c)$. For example, using $\sigma_s = 8.5 \times 10^{-3}$ (S/m) at 25 °C, $v_f = 0.20\,\%$, and the fraction of condensed counterions, $\phi_c = 0.25$, Eqs. 13 and 14 yield $\Delta\varepsilon' = 0.42$ and $f_R \cong 160$ MHz.

An alternative approach that mimics the rod-shaped DNA macromolecule with conducting sheath by a randomly oriented shelled, prolate ellipsoid with a very short minor axis and an extremely long major axis, predicted a very high relaxation frequency of hundreds of MHz (see Bone and Small (1995) cited in [6, 14] and other reports by their group). The MW interfacial polarization model tends to predict high relaxation frequencies in the order of 100s of MHz and it is a less successful model for explaining the dielectric behavior of DNA than the counterion fluctuation model. This is perhaps because relatively dilute suspensions of DNA exist as wormlike entanglements with a poorly defined interface compared with the well-defined spherical, or rod-like, boundaries of colloids or some viruses.

Other Polarization Mechanisms



A variety of other polarization mechanisms include counterion polarization transverse to the DNA axis, rotation of water-bound molecules along and across the grooves of the DNA, and relaxation of DNA polar groups. These polarization mechanisms tend to predict very high-frequency dispersions up to hundreds of MHz. Also the relaxation times have temperature dependence that predicts much higher activation

energies than measured and tend to have received less significance in the literature (see works by De Xammara Oro, Mashimo, and Takashima referenced in Bone and Small (1995) and others cited in [6, 14]).

Dielectrophoresis

The principles of DEP are often described for an electrically neutral body although in practice the body, such as DNA, is often charged. Application of an electric field external to a neutral body induces an uneven spatial distribution of electrical charge, or *dipoles*, as shown in Fig. 5.

The external electric field also acts on the displaced charges themselves, so that the electric field can be said to act *twice* on the body. If the electric field is uniform, the field flux acting on electrical charges within each localized region yields Coulombic forces that cancel each other and the net force is zero. On the other hand, in a *nonuniform* electric field, Fig. 5, the density of the electric flux varies spatially between regions within the body, so that there is an imbalance of Coulombic forces and they sum to a nonzero net force. If the body is *more* polarizable than the surrounding medium, it moves *toward* the region of highest field nonuniformity. This is the case in Fig. 5; the body moves to the right, as shown, and the movement is called *positive* DEP (pDEP). Conversely, if the body is *less* polarizable than the surrounding medium, it moves *away from* the region of highest field nonuniformity (i.e., to the left, not shown) and it is called *negative* DEP (nDEP).

Dielectrophoresis of Nucleic Acids, Fig. 5 Dielectrophoresis: a neutral body (*yellow circle*) in a nonuniform electric field (*red unfilled arrows*) experiences a net force depending on the spatial distribution of electric field strength. In this example, where the polarizability of the body is greater than the surrounding medium, it moves to the right (*black arrow*). The field lines near the body are simply sketched; see the literature, e.g., [13], for a more accurate description. A positive test charge (\\\\\\\ *arrow*) moves to the left according to the direction of the electric field flux. **Inset**: charges at A and B displaced d apart interact with the electric field, E_A and E_B, generating Coulombic forces, F_A and F_B, that act in opposite directions (*blue-filled white-dot patterned arrows*), as shown. The force at B is greater than at A, $F_B > F_A$, so the neutral body moves to the right (*black-filled arrow*)

The imbalance of forces on the neutral body can be modeled by considering two elementary charges $+q$ and $-q$ at A and B, distance d apart, shown in Fig. 5 inset. The electric field at B is stronger than at A, $E_B > E_A$. Assuming the forces are acting in the horizontal direction, the sum of the Coulombic forces approximates with a Taylor series:

$$\begin{aligned} F_{total} &= F_A + F_B = qE_B - qE_A \\ &= q\,[E(x+d) - E(x)] \cong q\,d\frac{dE}{dx} \\ &\cong p\frac{dE}{dx} \end{aligned} \tag{15}$$

where $p = qd$ (C m) is the induced (or effective) dipole moment. This can be written as

$$p = \alpha v E \tag{16}$$

where α is the induced polarizability, or effective dipole moment, per unit volume, v, in unit electric field and has units Farad per meter (Fm^{-1}). It is assumed, for the force to be proportional to the derivative of E in Eq. 15, that the dimension of the dipole p is small compared with the characteristic length of the electric field nonuniformity. Any spatial electric field phase variation is considered to be negligible and so that consideration is confined solely to the in-phase component of the DEP force, and the polarizability is real. Combining Eqs. 15 and 16,

$$F_{DEP}|_{DC} = \alpha v E\frac{dE}{dx} = \frac{1}{2}\alpha v\frac{dE^2}{dx} \tag{17}$$

where the subscript signifies that this equation is applicable for a constant (DC) signal applied to electrodes and is positive (i.e., acting toward the right). Expressions for the net force acting on a neutral bioparticle in a nonuniform electric field have also been developed using the energy variation principle and Maxwell stress tensor approach (see discussion and reference to Wang et al. (1997) cited in Chap. 4 of [13]). The effective moment method is the most straightforward and can accommodate situations where there is dielectric loss.

Since the electric field acts twice, *inducing* and *acting on* dipoles within the body, the DEP force predicted by Eq. 15 is proportional to the *square* of the magnitude of the electric field. The body moves in accordance with the strength and inhomogeneity of the electric field, the volume and dielectric polarizability of the body, and also the dielectric properties of the suspending medium. Importantly, the net movement of the body does *not* depend on the direction of the electric field or on the electrode polarity. Consequently, time-varying alternating current (AC) electrode voltages can be used to move the body rather than constant time direct current (DC) potentials. This feature, in turn, avoids problems of hydrolysis reactions occurring between electrode surfaces and bulk medium. AC radio frequencies above a few kHz applied to electrodes in moderately salty electrolytes, for example, do not incur hydrolysis. This enables DEP to be implemented using microelectrodes with micron to submicron features for miniaturized applications.

Since AC signals are more useful than DC, the response observable of macromolecules moving in liquids implies that the small time-averaged DEP force is considered. It is evaluated as half the DC value. Generalizing to three dimensions,

$$\left\langle \vec{F}_{DEP}(\underline{x},t)\right\rangle_t = \vec{F}_{DEP}(\underline{x}) = \frac{1}{4}\alpha(f)v \vec{\nabla}\left|\vec{E}(\underline{x})\right|^2 = \frac{1}{2}\alpha(f)v \vec{\nabla}\left|\vec{E}_{rms}(\underline{x})\right|^2 \quad (18)$$

where $\vec{\nabla}$ is the gradient operator and "→," $\langle\rangle_t$, and "*rms*" denote vector quantity, "small time" average over a RF electric field oscillation period, and root mean square, respectively. The frequency dependence of the polarizability is made explicit and the DEP force is understood to be "almost instantaneous." In terms of understanding and computing the DEP force, the electric field gradient for realistic geometric electrode designs can be determined analytically for simple cases or by electromagnetic simulation software. The frequency-dependent polarizability, α, is inferred from dielectric measurements using Eq. 4 or predicted from Eq. 7, and the volume is usually known or can be approximated.

Note that for a sphere with radius r with MW polarization, $\alpha = 3\varepsilon_m \mathrm{Re}\{f_{CM}\}$ where f_{CM} is the frequency-dependent Clausius-Mossotti factor and "Re" denotes real part. The time-averaged force given by Eq. 18 becomes

$$\vec{F}_{DEP}(\underline{x}) = 2\pi\varepsilon_m r^3 \mathrm{Re}\{f_{CM}\}\,\vec{\nabla}\left|\vec{E}_{rms}(\underline{x})\right|^2 \quad (19)$$

which is the starting formula in many scientific publications, e.g., [1, 4–6]. In terms of scaling relations used in nanotechnology, a simple and effective way of considering the DEP force is to recall that E is determined by Poisson's or Laplace's equation, so

$$F_{DEP} \propto \frac{r^3}{d^3}V^2. \quad (20)$$

In Eq. 20, d represents the characteristic length of the structure, or feature, size generating the nonuniform electric field and V is the voltage across the electrodes. This means that if r and d decrease by the same amount, e.g., by 1/1000 from μm to nm, in body and feature size, the DEP force remains the same. This principle of invariance to scale enables DEP to be an attractive means of moving biomolecules on the nanoscale even if earlier work was on the micron scale or larger. It also remains proportional to the square of the voltage across the electrodes.

Dielectrophoretic Transport

NAs have little inertial force compared with viscous drag force so that the former can be neglected. The latter can be approximated in the first instance if a charged macromolecule and associated counterions and coions, moving in a medium (e.g., DNA in water), behave hydrodynamically as if it is a semirigid body, such as a sphere or an ellipsoid. As discussed in section "Electrical Properties of Nucleic Acids," the rationale for this is that DNA behaves as a wormlike chain retaining a roughly spherical (or ellipsoidal) shape due to ions and water molecules being attracted and dragged along with it. The complex of DNA, ions, and water can be made equivalent to a body with a hydrodynamic radius, r_h, and an effective drag force is approximated.

As a consequence, the concentration flux of a population of single, noninteracting NAs or an ensemble of experiments of single NAs, arising from a DEP force, can be expressed in a very simple way as

$$\vec{J}_{DEP}(\underline{x},t) = c(\underline{x},t)\vec{F}_{DEP}(\underline{x})/\zeta \qquad (21)$$

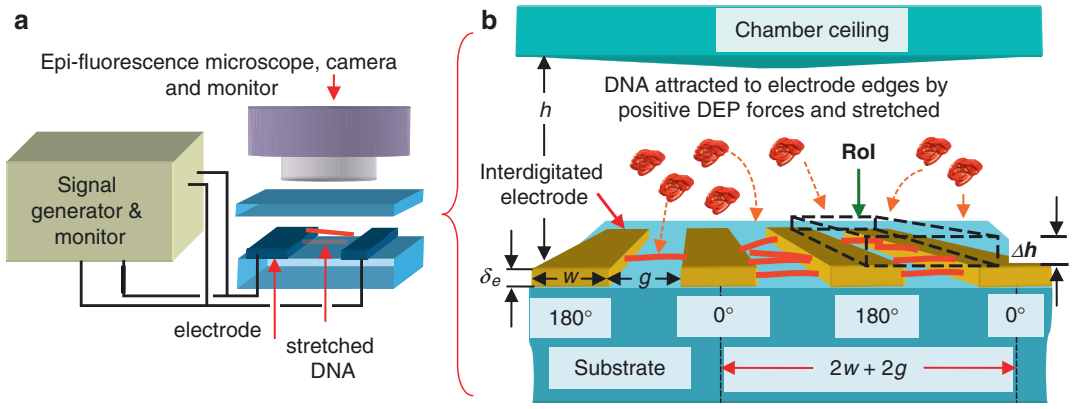
where the drag coefficient for a sphere is $\zeta = 6\pi\eta r_h$ where η is the dynamic viscosity of the medium. The incessant collisions of water molecules on the NA give rise to Brownian motion and hence to a thermally driven diffusion flux:

$$\vec{J}_{Diff}(\underline{x},t) = -D\ \vec{\nabla}\, c(\underline{x},t) \qquad (22)$$

where the Einstein diffusion coefficient is $D = k_B T/\zeta$ and all symbols have been defined. The contributions from DEP and diffusion can be combined into a continuity equation, also known as the modified diffusion equation (MDE) or Fokker-Planck equation:

$$\frac{\partial c(\underline{x},t)}{\partial t} = -\vec{\nabla}\cdot\left(\vec{J}_{DEP}(\underline{x},t) + \vec{J}_{Diff}(\underline{x})\right). \qquad (23)$$

The evolution of Eq. 23 is a starting point for very simple analytical and numerical simulations of DEP-driven transport of NAs.



Applications

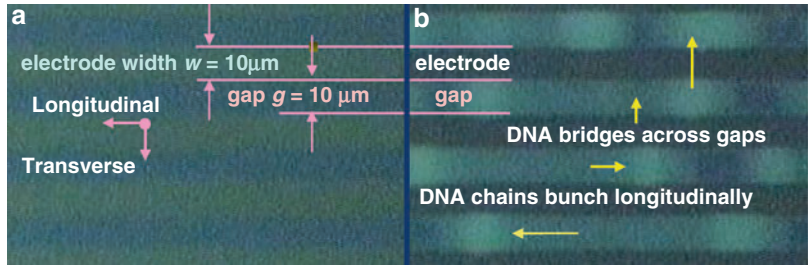
There is much interest in controlling the movement of DNA in microfabricated environments for two general application areas: first, DNA base sequence and gene expression analyses in LOC and μTAS microdevices and related biotechnological and biomedical applications and, second, using DNA as nano-scaffolds or constructing material, in molecular electronics. A key motive for this application is that "top-down" fabrication approaches are limited on the nanoscale so there is strong technological interest in alternative "bottom-up" approaches. Although there is considerable research on DEP of DNA, there is very little work reported so far on DEP of RNA or PNA.

This section starts with an introductory example of DEP of DNA. Investigations indicate DNA macromolecules tend to exhibit pDEP, i.e., their induced polarizability is greater than the surrounding medium. As discussed in the previous section, the pDEP could be due to the dilute suspensions of DNA existing as wormlike entanglements involving the aqueous medium so that there is a poorly defined polyelectrolyte/medium interface. The behavior contrasts with model colloids, e.g., polystyrene nanospheres, or viruses that can exhibit both pDEP and nDEP – depending on the applied RF, medium conductivity, and other experimental factors. The section discussion continues on to address wider contributions from the scientific community to DEP of NA.

Positive Dielectrophoresis of DNA: An Introductory Example

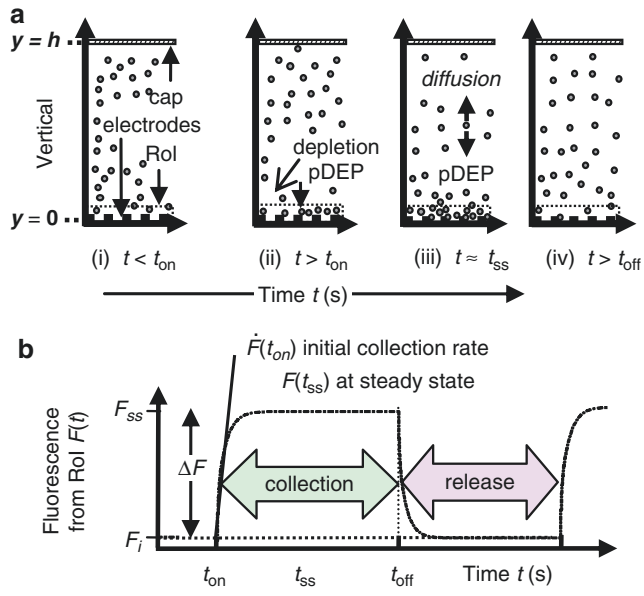
DEP of DNA is typically accomplished with a standard RF signal generator, signal monitoring oscilloscope, and measurement apparatus. A wider range of RFs and conductivities can be used but a benchmark RF is 1 MHz with reverse osmosis (RO) water or buffer with conductivity less than 1 millisiemen per meter (mS/m). The measurement process often involves imaging using fluorescence microscopy with modifications that enable recording and data processing. An experimental arrangement for observing DNA transport is shown in Fig. 6a. Tracking of DNA

Dielectrophoresis of Nucleic Acids, Fig. 6 Scheme of DEP experimental apparatus: (**a**) AC signal generator, monitoring oscilloscope, epi-fluorescence microscope, camera, monitor, DEP of DNA collection experiment. (**b**) Detailed inset of DEP collection showing interdigitated electrodes (fabricated with width w, interelectrode gap g, and thickness δ_e – not to scale) with electrical potential phases 180° apart and housed in a chamber with height h. DNA molecules (*red*) are attracted to the electrode edges and across the interelectrode gaps by positive DEP and stretched, as shown. An example of a region of interest (*RoI*) volume (height Δh), for DEP collection quantification, is shown on the *right* by the *box outlined* by *black dashes*



macromolecules as they move in real time is achieved by labeling them with a fluorescent dye and observing their micron-scale movement with an epi-fluorescence microscope with typically 200 × or above magnification, as shown. Often an anti-strand-breaking agent is used with the fluorescent dye and a camera is used to record and display DNA movement on a PC/TV screen.

A perspective close-up view of the microelectrode interdigitated "finger" electrodes that are responsible for generating electric fields that drive DEP macromolecule transport is shown in Fig. 6b. The thickness of the electrodes, δ_e, has been exaggerated for illustration and is typically much less than the transverse width, w, and interelectrode gap, g, $\delta_e << w, g$. Typical standard microfabrication methods are used: UV patterned resist on glass or other suitable substrates, evaporated with metal, developed, and lifted off. The AC potentials to the electrodes are 180^0 apart so the potential pattern is repeated in the transverse direction every $2w + 2g$ so from Eq. 18 the DEP force repeats and is symmetric about each center of the electrode. The regions of the planar array with the highest nonuniformity are the electrode edges so switching on the DEP attracts the DNA to that region. The DNA is shown in Fig. 6b to be coiled in the suspension; plasmid DNA, for example, has a shape similar to a rubber band that has been, cut, twisted, and rejoined again. If the DEP force is sufficiently strong, the coiled DNA collected by the pDEP forces becomes stretched by the electric field and builds up to form bridges, parallel to the field lines, that span between adjacent electrodes, as shown.



Quantification of pDEP collections of plasmids can be achieved using fluorescence spectroscopy, in a similar manner to nanoparticles, by designating a three-dimensional (3D) volumetric region of interest (RoI) (see [1, 14] and references therein to Bakewell and Morgan (2004)). As illustrated on the right of Fig. 6b, the 3D RoI involves assignment of a 2D planar area parallel to the substrate and encompassing the electrode edges, with a small height, Δh, e.g., that is within the micron-scale depth of focus of the microscope objective. Within the RoI volume (V_{RoI}), for sufficiently low concentrations, the fluorescence is proportional to the plasmid concentration:

$$F(t) \propto \int_{V_{RoI}} c(\underline{x}, t)\, d\underline{x}. \tag{24}$$

Consequently, the fluorescence can be used as a measure of the amount of DNA within an RoI.

Dielectrophoresis of Nucleic Acids, Fig. 7 DAPI-labeled DNA plasmid suspension: half-frame width images: (**a**) before the onset of DEP and (**b**) 0.13 s after the onset of DEP with $V_o = 4.5$ V, $f = 100$ kHz. See text for further details

Dielectrophoresis of Nucleic Acids, Fig. 8 Cartoon showing DNA collection under the action of positive DEP force and release after the DEP force is switched off. (**a**) Cartoon showing DNA concentration within the chamber with RoI (*side view*, not to scale) shown by the *dotted box outline* near the array at the *bottom* of the chamber; (**b**) fluorescence quantified within RoI as a function of time, $F(t)$, showing DNA collection and release

An example of a part video-frame microscope image of 12 kilo-bp (kbp) plasmid DNA, stained with fluorescent dye, 4′,6-diamidino-2-phenylindole (DAPI), taken from a similar study to [14], is shown in Fig. 7a before DEP was applied. The electrodes comprised 10 nm titanium onto glass substrate, 10 nm palladium, overlaid with 100 nm gold, and with dimensions $w = g = 10$ μm. The negatively supercoiled plasmid DNA strands, suspended in low conductivity medium, cannot be seen individually but they were known to be about 4 μm in contour length or 2 μm looped end to end. Figure 7b shows the DNA has collected into the interelectrode gap 0.13 s after pDEP was applied. One plasmid alone cannot bridge the interelectrode gap, so it is thought that the strands elongate and link to each other, similar to a pearl chain, as they position between the electrodes. The medium has started to evaporate so the transversally stretched DNA strands have tended to bundle longitudinally in places, as shown. After the pDEP force is switched off, Brownian motion is responsible for the DNA strands being released (image not shown) and moving away from the planar array into the bulk solution.

Quantification of pDEP collection and release of plasmid DNA, [1, 14], were achieved by exploiting the geometric properties of the electrodes. The longitudinal length, l, of the electrodes, $l >> w + g$, enabled symmetric and periodic patterns of the DEP to be efficiently image processed that resulted in collection and release time profiles. A simplified side-view cartoon of pDEP of plasmid DNA, suspended in an aqueous medium within a chamber, is shown in Fig. 8a. Accompanying collection and release fluorescence profiles are shown in Fig. 8b, as the

pDEP is switched on and off, or time modulated. Near the electrodes at the bottom of the chamber, the RoI is indicated by the box-dotted outline shown in Fig. 8a stages (i) to (iv). The DNA plasmids are initially uniformly suspended, Fig. 8a(i), with a concentration that, within the RoI volume, yields the *initial* fluorescence, $F_i = F(t_{on})$, as shown in the corresponding plot in Fig. 8b. After pDEP is switched on at $t = t_{on}$, the plasmids are attracted toward a planar interdigitated electrode array by pDEP, particularly near electrode edges where the DEP force is strong. As the plasmids rapidly collect near the electrode edges, the concentration increases so that the fluorescence of the plasmids within the RoI region above the array is shown to increase for a short time afterward, $t > t_{on}$, as shown in Fig. 8b. The concentration of the plasmids above the RoI becomes depleted, and over time, the depletion zone progresses toward the microdevice cap, Fig. 8a(ii). Eventually the pDEP flux becomes balanced by thermally driven diffusion and the concentration reaches steady state (SS) at $t = t_{ss}$, shown in Fig. 8b(iii), with fluorescence, $F_{ss} = F(t_{ss})$, shown in Fig. 8b.

Switching off pDEP at $t = t_{off}$ releases the plasmid DNA so the fluorescence of the plasmids, within the RoI, is shown to decrease in Fig. 8b. The plasmids continue to diffuse from the array and return to the bulk solution, Fig. 8a(iv). Two quantification summary parameters, shown in Fig. 8b, are (i) the initial collection rate and (ii) the change from initial to SS concentration. The former assumes, initially, diffusion is negligible in Eq. 23. Consequently, from Eq. 24, to a first approximation, the rate of change of fluorescence is proportional to the DEP force, $\dot{F}(t_{on}) \propto F_{DEP}$ where the overhead "$\cdot$" denotes time derivative. The relation for the initial collection rate enables a comparison of DEP forces for different experimental parameter values, e.g., voltage and frequency. The latter parameter, initial to SS fluorescence change, $\Delta F = F(t_{ss}) - F(t_{on})$, can also be compared for different experimental parameters.

The results in [14] indicated that the strength of collections also decreased with increasing frequency from 100 kHz to 5 MHz, and these trends concurred with dielectric polarizability measurements for the same DNA plasmid. The results also showed that for these electrodes, the predicted pDEP force is lower than that expected from theory. A number of reasons were presented including the possible effects of AC electroosmosis (EO) (also called electroosmotic flow (EOF)), polarization saturation, and distortive effect of the DNA on the electric field itself.

D

Dielectrophoresis of DNA: General

There have been many variations and advancements on the basic arrangement in the previous section. The literature indicates that Washizu's group in Japan pioneered most of the early and novel experiments on DEP of DNA, starting in the 1990s with their fluid-integrated circuit (FIC). The details of their work, e.g., Washizu and coworkers (1990–2007), can be found in several very comprehensive reviews [1, 5, 6], along with many important and recent contributions from newly emergent groups around the world. The state of the art and advancement for nanotechnology can be summarized into a couple of general categories:

1. Generation of DEP force, microfabricated environment, and DNA preparation:
   (a) The length of DNA that can be moved by DEP depends on many factors including the smallest feature size of the electrodes, position of the DNA macromolecules within the nonuniform electric field, and ranges from 20 bp to tens tens of kbp and upward; it is limited by the practicalities of sample preparation, e.g., a 1000 kbp or 1 Mega-bp (Mbp) of DNA has a contour length of 340 μm, long enough to be sheared in a micropipette tip during preparation.
      - Many experiments have used 48.5 kbp (contour length 16.5 μm) λ-phage dsDNA and more recently short sequences (e.g., 20-mer) of ssDNA that are commercially available.
      - Other types of DNA and including chemical modifications and attachments are discussed later in this section.

(b) Methods for measuring DEP movement:
- Fluorescence microscopy, as described in the introductory example, has been the standard method for visualizing and measuring DEP of DNA. Suitable dyes for visualization with fluorescence microscopy include DAPI, YOYO, TOTO, acridine orange, and PicoGreen.
- Methods that do not require attachment of a fluorescence dye, i.e., are label-free; these include electrical impedance spectroscopy and special optical techniques, e.g., surface-enhanced Raman spectroscopy (SERS). In the former, the presence of the DNA alters the capacitance between the measurement electrodes. An ingenious arrangement is to use the same electrodes for DEP as for impedance measurement and quantification, as reported by Bier, Hölzel, and coworkers in Germany [15].

(c) Voltage and frequency range:
- Most DEP experiments use standard RF signal generators that range from 0 to 20 MHz and up to 30 V peak to peak. Investigators have tended to use a low-frequency range from 30 to 1 kHz or high-frequency, e.g., 20 kHz to 20 MHz. In principle there are no restrictions except to avoid hydrolysis at low RFs and this, in turn, depends on experimental factors, e.g., solution conductivity. The high-frequency response is influenced by impedance characteristics of the electrodes and supply buses.

(d) Direct DEP force:
- "Traditional" DEP uses metal electrodes that connect directly with buses to the AC supply. The electrodes have often been microfabricated using standard photolithographic methods as described for Figs. 6b and 7. Consequently, planar metal electrodes are typically up to a few hundred nanometers in thickness and are essentially quasi-two dimensional (~2D) with designs that are castellated, corrugated, triangular, sinusoidal, polynomial, etc., to optimize DEP response. The metals used are inert or, at least, biocompatible and can be single- or multilayered. They include gold, aluminum, titanium, platinum, palladium, etc. There are variations on the use of traditional metals; examples are:
  - Metal oxides, such as indium tin oxide (ITO), have become popular to use as material for electrodes in more recent years due to high electrical conductivity combined with optical transparency (e.g., see early work by Fiedler et al. (1998) and Suehiro and Pethig (1998) cited in [1]).
  - To avoid chemical reactions that are likely to occur if low frequencies and high medium conductivities are used, electrode surfaces exposed to the medium are coated with thin layers that act to electrically insulate, e.g., porous hydrogel. An example is given later in this section.
- Carbon nanotube (CNT) end features with diameters as small as 1 nm can achieve high gradients of the square of the electric field magnitude, and their nanosized scale is similar to the diameter of DNA. Consequently, single- or multi-walled carbon nanotubes (SWCNT or MWCNT) are attractive candidate electrodes since their nanoscale features are capable of yielding high DEP forces (see Tuukkanen et al. (2005–2007) cited in [6, 16]).

(e) Other methods for generating DEP forces do so *indirectly*, i.e., use metal electrodes connected to the ac signal supply to generate a potential difference across the space between them. The *supply* electrodes are located sufficiently far away from the nonuniformity, or RoI, so any electrochemical reactions that may occur at the metal/solution medium interface do so without interfering with DEP transport.
- Floating-potential electrodes (FPEs) are microfabricated metal electrodes

positioned between the supply electrodes but *not* directly connected to them. Instead, submerged in electrolyte, they assume the value of the electrical potential according to their position between the supply electrodes and subsequently act to distort the electric field near and around each of them (see authors Asbury and van den Engh (1998), Washizu et al. (1995), and Washizu (2005), cited in [5, 6]).

- Electrodeless DEP (eDEP) or insulating DEP (iDEP), mainly developed during the last decade, uses *insulating boundaries* between the supply electrodes to distort the electric field. Without needing metal microfabricated electrodes to create electric field nonuniformities, metallic degradation near the RoIs is of little concern, so that iDEP enables much lower frequencies, down to 0 Hz (DC), to be applied. Consequently, higher inducible polarizabilities, and hence, higher DEP forces, can be used to move DNA. Typically, device boundaries are made from 3D microfabricated insulating posts made from quartz, polydimethylsiloxane (PDMS), or polymethyl methacrylate (PMMA) (see Chou et al. (2002, 2003), Tegenfeldt et al. (2004), and Swami et al. (2009), cited in [1, 5, 6], [5, 17], and [1, 15], respectively). The relative advantages of iDEP, including the use of plastics that enables injection molding or hot embossing, and opportunities for mass fabrication are described in a very informative review by Regtmeier et al. (2011) cited in [17]. A summary of materials, underlying principles of operation, and applications is also reviewed. Variations of iDEP include:
  - "Liquid electrodes" whereby the electric potential difference across the supply electrodes is taken up by the electrolyte medium, and cross-sectional variations between the insulating walls, housing the medium, govern the shape of the electric field nonuniformity. This method includes involving insulating membranes that capacitively couple adjacent liquid electrodes, thus circumventing joule heating problems that can occur with iDEP. See Regtmeier et al. (2011) cited in [17] that refers to the work by Demierre et al. (2007, 2008) and Shafiee et al. (2009, 2010) and associated groups that introduced the term "contactless" DEP (cDEP), i.e., DEP motion that avoids direct contact of biological specimens with the electrodes.
  - Nanoscale pipettes, or nanopipettes, are used for material transport and nanolithography. Ying et al. (2004) and others of Klenerman's group in the UK, cited in [1, 5, 6], describe, in an elegant series of experiments, DEP combined with EP and EO that enables high-precision pulsatile, in-and outflow of 40-mer ssDNA and dsDNA from the end of a borosilicate glass nanopipette. Other NAs (1 kb ssDNA and a single-nucleotide triphosphate) were also studied. See further, recent, work by the Klenerman group referred to by Regtmeier et al. (2011) cited in [17] for their important contributions to miniaturized biological analysis.
- Optically induced DEP (ODEP) or optoelectronic tweezers (OETs) – as distinguished from "optical laser tweezers" – have been developed where an optical pattern, e.g., from a commercial photo-projector, illuminated onto a photoconductive layer of amorphous silicon, gives rise to a localized DEP force. The optical image has the benefit of acting as an electrode and being able to change position and shape in real time; consequently, it can be titled "virtual electrode." Chiou et al. (2005) initially presented this

important work; it is cited in [18] that describes developments of the method and includes other relevant optical manipulation techniques.

2. DEP of DNA purpose or outcome:
   (a) Electrostatic stretching and trapping of DNA to electrodes using DEP:
      - Temporary positioning: since DNA is flexible on the micro scale, most reported DEP experiments, one way or another, involve trapping and positioning DNA for the duration DEP force is switched on.
      - Semipermanent positioning or immobilization: use of chemical modification to bind the DNA to the electrode or substrate so that it remains tethered after the DEP force is switched off, e.g., avidin binding (by complementary biotin-linked DNA) and thiol labeling of gold electrodes (complementary thiol labeling of DNA strands) (see works by Germishuizen et al. (2003, 2005) and coworkers of Burns in the USA (2002, 2006) that modified DNA stretching with polymer enhanced media, cited in [1, 5, 6]).
      - Applications of stretching and positioning of DNA, typically along electric field lines, include:
        – Measuring the lengths of stretched and oriented dsDNA prepared using restriction enzymes and simple cutting of stretched DNA using a UV laser (see works by Washizu et al. (1990, 1995) cited in [5]).
        – Measuring the conductivity of DNA for molecular electronics (see the work by Burke and coworkers (2003, 2004) cited in [5]).
        – Probing and modeling the mechanical, elastic properties of DNA (see Dalir et al. (2009) cited in [1]).
        – Molecular visualization and elucidation: elegant and important work by Kabata et al. (1993), cited in [6, 13, 15], used pDEP to provide *direct* experimental evidence that RNA polymerase *slides* along DNA. Previously, only indirect evidence had been available and the putative sliding process contrasted with other possible mechanisms, e.g., intersegment transfer, association, and dissociation. Pulsed pDEP (1 MHz, 1 s duration) was used to attract and stretch strands of DNA, with biotin attached at both ends, between 80 and 100 μm apart parallel edges of aluminum electrodes that had been vacuum deposited onto a glass substrate. After the pDEP was switched off, stretched (λ or T7) DNA strands remained anchored onto the glass substrate at both ends by the biotin linkages that had coupled with avidin that had been adsorbed onto the glass surface. The strong avidin-biotin anchoring allowed *E. coli* RNA polymerase to move along the DNA strands and be imaged using a microscope/camera and subsequently analyzed.
        – Molecular surgery: optical tweezer control of a nanosphere coupled to an enzyme, e.g., DNase I, with cutting the bases of electrostatic stretched DNA was demonstrated by Yamamoto et al. (2000) in Washizu's group as cited in [1, 5, 6]. These elegant experimental examples highlight that DNA base information can be used for sub-nanometer position-dependent function in conjunction with DEP.
        – DNA scaffolds: there is a large corpus of literature on DEP of CNTs, metals, their oxides, and fabrication of field-effect transistors (FETs) (see the review by Zhang et al. [16]). In addition to the current protocols on attachment of metal colloids to DNA, e.g., by Mirkin and coworkers or in situ growth on substrates, DEP

has been proposed for a solution-based method of metallized DNA.
  - DNA origami, which often entails folded long ssDNA strands being paired with oligonucleotide ssDNA, has been structured into 2D sheets that can be used as "nanobreadboard" with 6 nm resolution. Examples of 2D sheets, rectangular and "smiley," have been manipulated by DEP and optimal experimental parameters comprehensively reported (see Kuzyk et al. (2008) cited in [6, 16] followed by a review, Kuzyk (2011), cited in [18]).

(b) Separation and purification of DNA:
  - DEP chromatography has been used to separate large (e.g., 48.5 kbp λ-phage dsDNA) and small (22 base ssDNA oligonucleotide) and also medium-large (2 kbp DNA) (see Kawabata and Washizu (2001) cited in [1, 5, 6]). Described simply and referring to the introductory example in Fig. 6b and descriptions [13, 16], the chromatograph is a type of field-flow fractionation (FFF) where the DNA solution, externally driven by a pump, flows with the fluid lateral to the array (in the direction parallel the array-substrate surface) and interacts with the vertically DEP-driven force generated by the electrode array. Large DNA macromolecules with strong polarizability and pDEP force are pulled down onto the array, whereas small DNA fragments with weak polarizability and pDEP force continue to flow though the chamber, hence, separating the mixture.
  - The separation of comparably sized DNA by pDEP is difficult; however, it has been made possible with nanosphere technology. Called "DEP enhancement," Kawabata and Washizu (2001), cited in [1, 5, 6], described the mixing and subsequent DEP-driven separation of 35 kbp T7-DNA with 48.5 kbp λ-DNA (contour length 16.5 μm) that had been linked to 2 μm diameter polystyrene microspheres. Using low conductivity medium (less than 20 mS/m) and energizing frequency 2.5 MHz, the T7-DNA was moved by pDEP, whereas the λ-DNA-bead complexes underwent nDEP, thus separating the mixture. The reason for the λ-DNA-bead complexes being moved by nDEP was attributed to the bead dominating the movement; on their own, microspheres at these experimental conditions undergo nDEP. In contrast, both types of DNA, on their own, are attracted by pDEP so as to span the shortest portions of the interelectrode, corrugated gaps – in a similar manner to the plasmid DNA described in Fig. 6b and 7b.
  - Recently, continuous-flow separation of linear 2.686 and 6.0 kbp DNA, circular topological variants, e.g., parental (6.766 kbp), *mini-circle* 2.247 (kbp) DNA, and DNA complexes (cancer drug and protein) on a microfluidic chip has been reported by Anselmetti's group in Germany [17]. Building on previous work by this group and others, the results are important for advancing the development of gene vaccines and other investigations where DNA macromolecular shape and topology play a significant biological role.
  - Circulating cell-free (ccf) DNA, an important biomarker for cancer and other diseases, has been recently separated from blood and plasma by Heller's group in the USA [19]. In advancing earlier work cited in [19], problems with using high conductivity medium that arises from using blood were circumvented by using planar platinum electrodes that had been coated with a 20 μm layer of porous

hydrogel. The DNA captured by DEP was reported to be compatible to genomic DNA isolated using current clinical "gold standard" methods – thus demonstrating the practical utility of DEP of DNA that could save resources in healthcare.

(c) DEP of DNA has been combined with other biological, chemical, and electrokinetic methods, e.g., EROT, EP, EO, or EOF, and electrostatic liquid actuation. In addition to the work by Klenerman's group mentioned above, three recent and notable examples include:
- Development of DNA concentrators (see Yokokawa et al. (2010) cited in [9, 15]). In that work, the DEP of 48.5 kbp λ-DNA was compared with low-level DC EP (i.e., electrode voltage was sufficiently low, less than a few volts, so that electrolysis did not occur). It was found that low-level DC EP concentrated the λ-DNA better than DEP but the medium conductivity was low (2 mS/m) and possible degradation to the electrodes by using a DC voltage over time is unclear.
- iDEP, achieved by using insulating constrictions, has resulted in a ten-fold enhancement of DNA hybridization kinetics down to 10 p-molar concentration sensitivity using relatively high ionic buffer strengths (see Swami et al. (2009) cited in [1, 15]).
- DEP has also been combined with nanosphere technology to significantly improve the hybridization kinetics of DNA with savings in the use of reagents and with lower ionic strength and simpler protocols than current microarray and Southern blot methods (see Cheng et al. (2010) cited in [1, 9]). This offers a molecular-scale DEP enhancement and offers promising new advances in detection sensitivity, speed, etc., for genomics research and diagnostics.

(d) DEP of DNA in "packages" or as "linked":
- Viruses contain DNA or RNA encapsulated with a protein coat. Viruses have been intensively studied for DEP response, particularly at RFs where the DEP changes from being positive to negative, thus optimizing virus separation (see works by separate groups, e.g., Morgan in the UK and Führ in Germany, and their respective coworkers reviewed in [1, 5, 6]).
- Chromatin that constitutes chromosomes and contains DNA wrapped around histones and other protein has been lysed from bacteria (*E. coli*), transported by DC EP, and trapped by iDEP at 500 Hz, as described by Prinz et al. (2002) cited in [1, 5, 6].
- DNA ligated with PNA and nanospheres showed that DNA could be maneuvered to a unidirectional orientation by DEP and moreover imaged using a fluorescence microscope without the need for intercalating dyes (see Hölzel et al. (2003) cited in [1, 5, 6]).

Dielectrophoresis of RNA

DEP has been used to rapidly collect RNA from the nucleus of a living cancer cell using atomic force microscope (AFM) [20]. The AFM cone-shaped probe tip had been structurally modified to form nanometer-scale concentric electrodes that enabled mRNA to be attracted and subsequently extracted from the cell nucleus. This novel and promising application of DEP may pave the way for enhanced analysis of single-cell extracts with many applications, particularly, as mentioned in section "Nucleic Acids," the mRNA forms only a small proportion of the total RNA in a cell.

Time-dependent DEP collections on of 16S and 23S subunit rRNA, extracted from *E. coli*, onto planar interdigitated electrodes over a wide RF range, 3 kHz – 50 MHz, have been reported by the Pethig group in the UK [9]. The in-depth study used total internal reflection fluorescence (TIRF) microscopy with an aqueous suspension of 13 mS/m conductivity. The study revealed a positive to negative DEP transition above 9 MHz and confirmed a quadratic dependence of pDEP force with respect to voltage for low values ($3V_{rms}$) – as

predicted by Eq. 19. Being the first demonstration of fast capture and release of rRNA, DEP shows considerable promise for application in rRNA-based biosensing devices.

Other reports at present have involved DEP of RNA in context, i.e., not as the main focus of study but in conjunction with DEP of DNA, or of cells, e.g., the lysing of cell contents (Cheng et al. (1998) cited in [6, 14]) where cells undergo DEP positioning, or investigations on the effect of DEP on gene expression in cells, etc.

Outlook and Concluding Remarks

There have been many achievements and DEP of NAs, particularly DNA, continues to be an active and promising research field with a scope that has advanced with new materials, e.g., PDMS, PMMA, ITO, CNTs, etc., and technologies, e.g., microfluidics, nanospheres, microarrays, electronic nanodevices, and scanning probe microscopes. Detection methods have also advanced, be it either electrical, e.g., impedance spectroscopy, or optical, e.g., SERS and TIRF. There is substantial opportunity for advancing theoretical understanding of polarization mechanisms that underpin DEP-induced motion of NAs; at present, current models favor counterion fluctuation. There is also considerable opportunity for advancement of nanoscale DEP applications, whether it is directed toward nano-construction or advancing DNA hybridization kinetics that is needed in genomics and sensor research. DEP of RNA appears to be research field open for investigation, particularly with the worldwide drive for single-cell analysis and quantitative systems biology. There is also much to be accomplished in terms of integrating DEP-based methods with other electrokinetic, LOC, and μTAS miniaturization technologies and establishing reliable and quantifiable measures of functionality and performance.

Definition

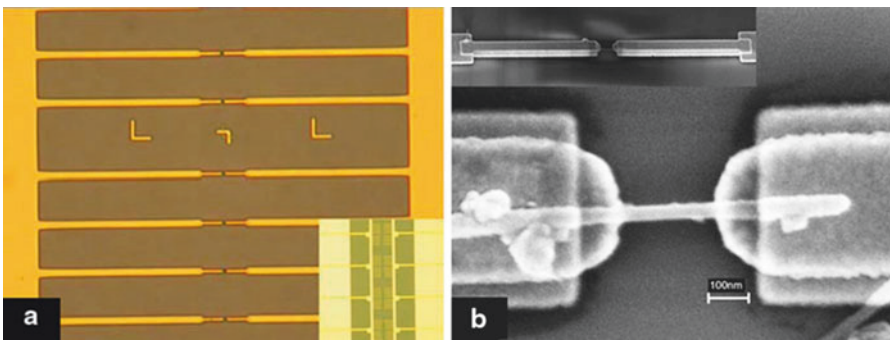
Dielectrophoreis is an electrokinetic manipulation process where the interactions of a nonuniform electric field with a polarizable particle are employed to localize the particle in space with nanoscale precision. The nonuniform field strength around the particle exerts a dielectrophoretic (DEP) force on the dipole induced within the polarizable particle, which drives the particle toward the electric field maximum or minimum. In addition, the resulting torque aligns the particle along the direction of the applied electric field.

Dielectrophoretic assembly has been widely used for high precision assembly of carbon nanotubes (CNTs) in order to overcome disadvantages such as the need for a complex setup and poor controllability, which are associated with other techniques to integrate CNTs onto functional nanostructures. Since this technique is performed at room-temperature, in a noncorrosive fluidic environment, and at low voltage, the electric field-based method is compatible with further postintegration nanostructuring steps such as those used in the Integrated Circuit (IC) industry.

Overview

Functional nanostructures, which incorporate an individual multiwalled carbon nanotube (MWNT) as the fundamental electromechanical transduction element, can be used to create tubular switches, memories, sensors, and resonators/oscillators with improved performance. This entry highlights two key unit processes that enable the fabrication of such constructs and provides an overview of potential applications using recently demonstrated nanomechanical switches. The first unit process relates to dielectrophoretic nanoassembly of single MWNTs onto arrays of nanoelectrode pairs fabricated on silicon chips [1, 2]. Appropriately optimized electrode designs insure that the assembled MWNT bridges the nanoelectrodes at its distal ends while remaining fully suspended and flat in the region between them (Fig. 1).

The second unit process involves the modification of the nested-shell, native MWNT geometry using Joule-heating-induced vaporization of carbon atoms at specific locations on the nanotube [2–4]. By engineering heat sinks along the NT length to modulate thermal dissipation and Joule-heating-induced temperatures, the vaporization of carbon atoms within the NT has been controlled with atomic-to-nanoscale [5]. This technique to selectively modify the NT geometry with control over location, length, and shells has provided us with the capability to create structures where some shells can axially translate or rotate with respect to others. Nanoelectromechanical systems (NEMS) devices based on such intershell displacement mechanisms have been demonstrated to be ultrafast, fatigue-free constructs with very low friction.



Basic Methodology

DEP Assembly Technique

Based on Pohl's theory [6], dielectrophoretic forces F_{DEP} and torques T_{DEP} can be calculated as

$$F_{DEP} = (p \cdot \nabla)E \tag{1}$$

$$T_{DEP} = p \times E \tag{2}$$

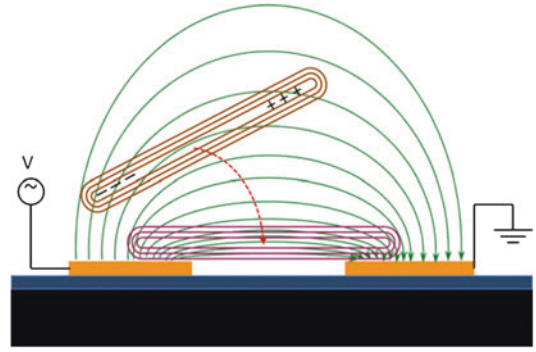
Dielectrophoretic Nanoassembly of Nanotubes onto Nanoelectrodes, Fig. 1 Dielectrophoretic assembly of MWNTs. (**a**) Nanoelectrode array design with a lower magnification image in inset. (**b**) SEM images of an assembled MWNT nanostructure at high and low magnification (Reproduced with permission from Ref. [2], Copyright 2007 IOP)

where p is the induced dipole moment of the particle and E is the electric field.

Because both DEP forces and torques are dependent on multiple parameters, such as particle and suspending medium properties and the applied electric field, the nanotube (NT) is modeled as a prolate ellipsoid with homogeneous dielectric properties. The large aspect ratio of NTs results in a needle-shaped particle with $l \gg r$, so the governing equations in dielectrophoresis could be simplified as [7, 8]

$$F_{DEP} = \frac{1}{2}\pi r^2 l \varepsilon \mathrm{Re}\left(\frac{\widetilde{\varepsilon}_p - \widetilde{\varepsilon}_m}{\widetilde{\varepsilon}_m}\right)\nabla|E|^2 \qquad (3)$$

$$\langle T_3 \rangle = \frac{1}{2}\pi r^2 l \varepsilon_m E^2 \sin\theta\cos\theta \mathrm{Re}\left(\frac{\left(\widetilde{\varepsilon}_p - \widetilde{\varepsilon}_m\right)^2}{\widetilde{\varepsilon}_m\left(\widetilde{\varepsilon}_m + \widetilde{\varepsilon}_p\right)}\right) \qquad (4)$$



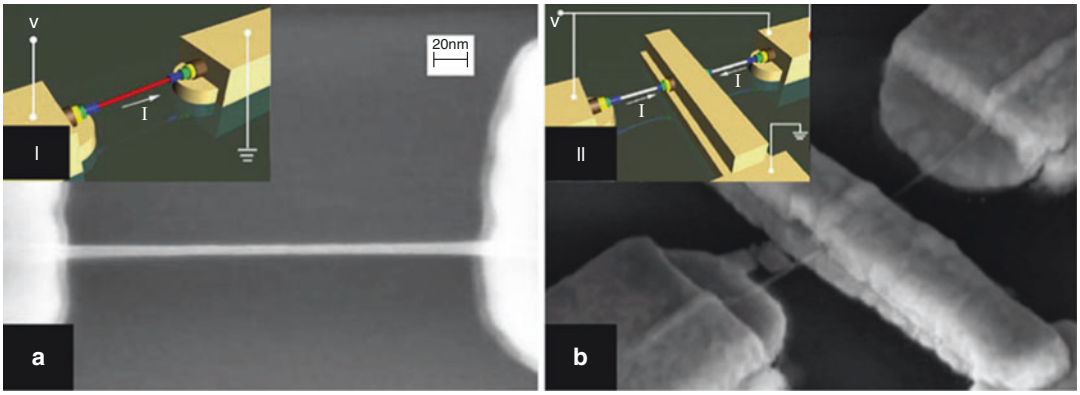
where $\widetilde{\varepsilon}_p$ and $\widetilde{\varepsilon}_m$ are complex dielectric permittivities of the particle and the suspending medium, r and l are the radius and length of the CNT, and the angle between the electric field and the longest axis 1 is θ.

Another important aspect influencing the motion of CNTs is the viscous drag force, which is proportional to the relative velocity, retards the CNT in all directions. If gravity, Brownian motion, electro-osmosis, etc., are all negligible during DEP process, the instantaneous translation velocity is proportional to the instantaneous dielectrophoretic force [3, 4]. Similarly, the rotational friction factor of the CNT rotating about its center in x–y plane can also be calculated by hydrodynamic equations [9]. The schematic is shown in Fig. 2.

$$v_T \approx \frac{\boldsymbol{F}_{DEP}}{f} \qquad (5)$$

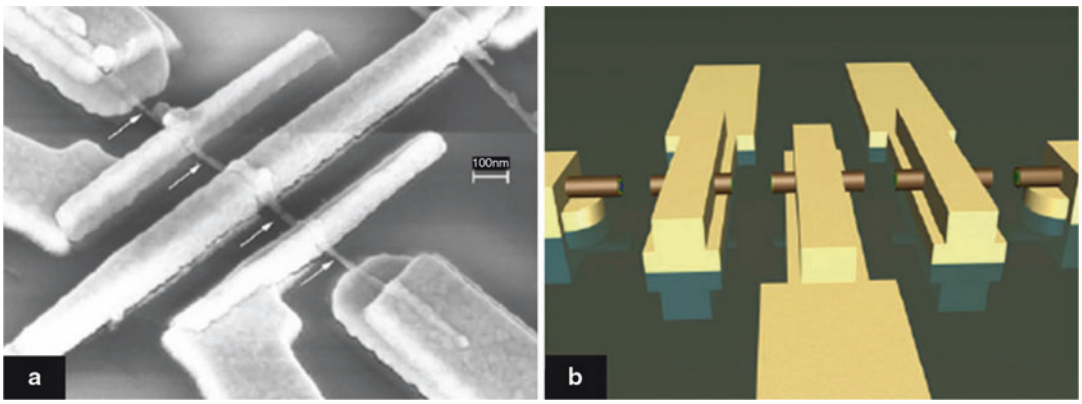
The constant f is the translation friction factor and depends on a range of parameters such as size, shape, and fluid viscosity.

The standard operation procedure of DEP assembly is as follows. First, the MWNTs are suspended and sonicated in ethanol (at a concentration of 5 μg/ml) for 10 h to insure homogeneity.



Dielectrophoretic Nanoassembly of Nanotubes onto Nanoelectrodes, Fig. 2 Dielectrophoresis concept

The chip is then immersed in a reservoir containing this suspension and a nonuniform electric field is applied with a high frequency function generator. After deposition, the chip is removed from the reservoir, rinsed in clean ethanol, and brown-dried with nitrogen. The assembly parameters related to the target nanomaterial and nanoelectrode structure such as the AC/DC voltage components, polarizing frequency, and deposition time are modulated to optimize device deposition yields.



Current-Induced Shell Engineering of MWNT

Current driven shell engineering is useful in cases to employ Joule heating to vaporize carbon atoms and thin the NT between device contacts in order to tune its electrical resistance, mechanical stiffness, and clamping configuration [2]. A typical DEP assembled MWNT is sandwiched between two layers of metal at each end to improve electrical contact. The metallic contacts serve as heat sinks, and shell removal due to thermal stress occurs in the suspended segment, starting from the outermost and proceeding towards the inner ones. During current-induced vaporization, NT temperatures are estimated to be as high as 2,000 K. It is proven that at these elevated temperatures, defects such as kinks and holes are initiated at MWNT mid-lengths and result in individual shell removal in the region between contacting electrodes [3, 4]. An SEM image of a shell-structured nanotube is shown in Fig. 3a.

Modulation of Joule heat dissipation along NT lengths using additional heat sinks can be

[2], Copyright 2007 IOP)

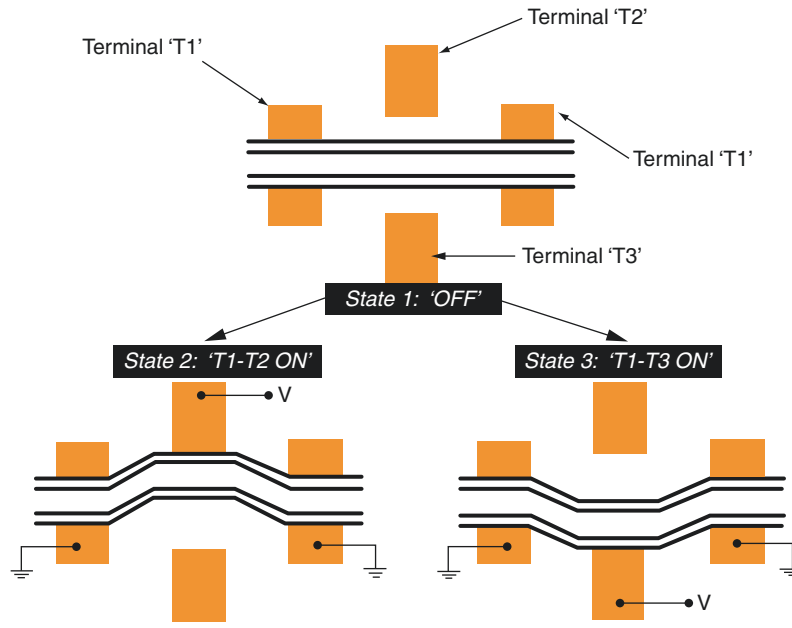
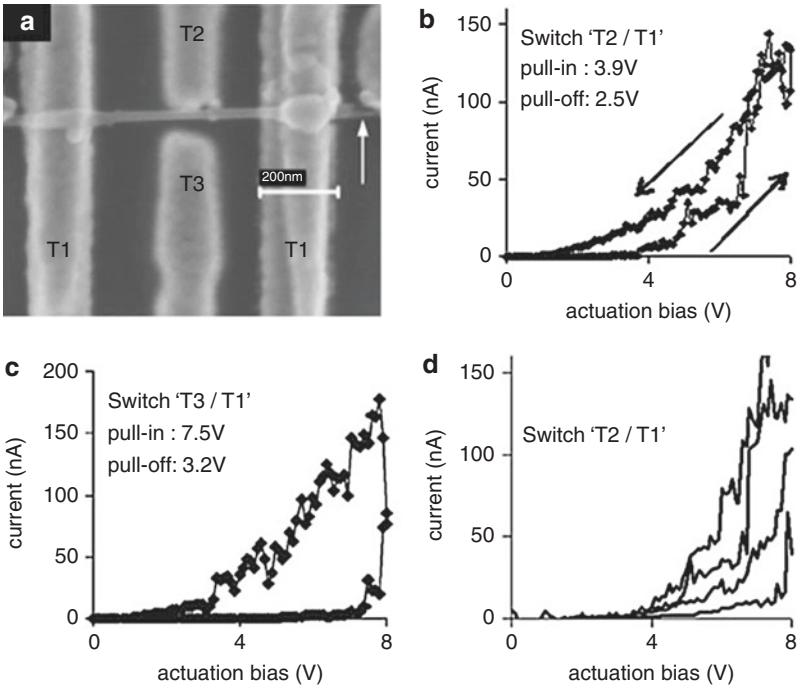
employed to achieve atomic-to-nanoscale control over shell etching locations on a MWNT [5]. It is found that the electric breakdown position can be controlled in MWNTs by introducing additional metallic contacts located at different segments of a NT. A nanotube assembled onto three contacts is shown in Fig. 3b, and a schematic is shown in its inset. By applying a bias to the electrodes at distal ends and grounding the central metal contact (Fig. 3b), currents are driven through both suspended segments of the NT simultaneously and remove its outer shells in the respective segments. Detailed information on this technique can be found in references [2] and [5].

Key Research Findings



Nanotube Bearings

High bearing densities can be achieved through Joule-heat-driven vaporization of different segments of a NT, that is, a NT is assembled onto multiple metallic contacts using floating electrode DEP [2, 10]. Figure 4a shows independent,



bidirectional nanobearings engineered at different locations along the length of a single MWNT bridging five electrodes. With a 220 nm device length, these constructs represent the smallest bearings reported to date and are expected to exhibit lower friction forces and faster response times during telescoping core movements. Each of the three NT segments in the central part of the fabricated device is anchored to the metal at only its outer shells, with inner shells capable of sliding inside the outer housing in both directions. An illustration of this shell structure is shown in Fig. 4b. This structure has a number of potential applications. One possible application involves resonators based on shell displacements, where neighboring nanotube segments electrically excite oscillations. The configurational stability and frequency spectrum of these constructs have been investigated. The most significant conclusion that emerges from the analysis of these open-capped structures is that, for a given NT (in terms of the number of shells and outer diameter), there exist only a finite number of configurations that are energetically stable. For an 11 shell 8 nm outer diameter CNT, resonant frequencies from 1.4 to 4.9 GHz for various stable inner shells exist [11]. Using these constructs, ultralow power electromechanical switches can be realized by electrostatically controlling the movement of NT cores and thereby, modulating the intersegment conductivity [10].

Nanotube Switch

Another energy-efficient, three-state NEMS switch which has been realized using the DEP assembled nanostructures is shown in Fig. 5 [12]. In this device, the contacts at the NT's distal ends are held at a common, ground potential and form the first terminal, T1, of the NEMS switch. The gate electrodes, which are located on either side of the NT in close proximity, represent terminals "T2" and "T3," respectively. In the device "off-state," the NT is not in contact with the gate electrodes on either side. When a voltage is applied to one of the gate electrodes, it induces an attractive electrostatic force on the nanotube and deforms it elastostatically. Beyond a threshold bias, which is characteristic of the NT Young's modulus, diameter, number of shells, length and device actuation gap, the NT comes in the contact with the gate electrode and the switch is turned "ON." Thus, the circuit between terminals T1_T2 and T1_T3 can be turned ON by applying the pull-in voltage at the respective actuation electrodes.

The *arrows* point to the increasing and decreasing voltage parts of the curve. (**c**) I-V characteristics of the switch between terminals "T3-T1." (**d**) Device operation over four cycles shown to demonstrate the repeatability in device behaviors (Reproduced with permission from Ref. [11], Copyright 2009 ACS)

An SEM image of a representative device is shown in Fig. 6a, and its operational characteristics are shown in Fig. 6b–d. The *I-V* curves during the switching transition initiated by a bias applied to terminal T2 is shown in Fig. 6b. One important characteristic that emerges from these curves is the hysteresis in device operation. This is due to the impact of van der Waals forces between the NT and gate electrode, which is onset at pull-in and opposes the subsequent pull-off event. The switching characteristics of the device constructed between terminals T3 and T1 can be seen in Fig. 6c. The pull-in voltage for this terminal was found to be higher as compared to that at terminal "T2" due to the larger NT-electrode gap at this terminal. The repeatability of these devices is highlighted in Fig. 6d using results from four cycles of switching induced by terminal T2. It can be observed from this plot that the turn-on bias remains repeatable.

Future Directions for Research

Results highlighted in this entry provide interesting pointers toward future nanodevices based on single MWNTs with novel performance regimes. Though significant progress has been made, future avenues for research and development exist in each of the following thrust areas: nanofabrication, device engineering, and characterization. For instance, though DEP-based assembly has been demonstrated to be a robust method to assemble diverse materials with nanoscale precision, further improvements in assembly yields are required before these could be used within industrial processes. This is an important challenge that requires the identification of optimum deposition parameters within the multi-variable process.

In the area of device development, a number of different engineering embodiments can be

realized using nanofabrication processes outlined in this report. These include microwave resonators based on elastostatic deformations and inter-shell displacements within MWNTs. These devices have the potential for use in near-term industrial applications such as mass, force, and resonant-pressure sensors. Another possible area of future research relates to developing integrated MEMS/NEMS platforms for probing the electromechanical properties of nanomechanical elements. For instance, appropriately designed constructs realized using a combination of DEP assembly and shell engineering can be used to understand the electromechanical coupling between individual shells within a MWNT and to provide insights into its suitability for use as piezoresistors in nanotransducers.

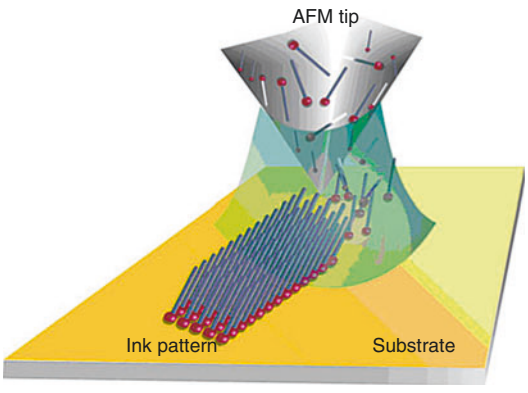
Definition



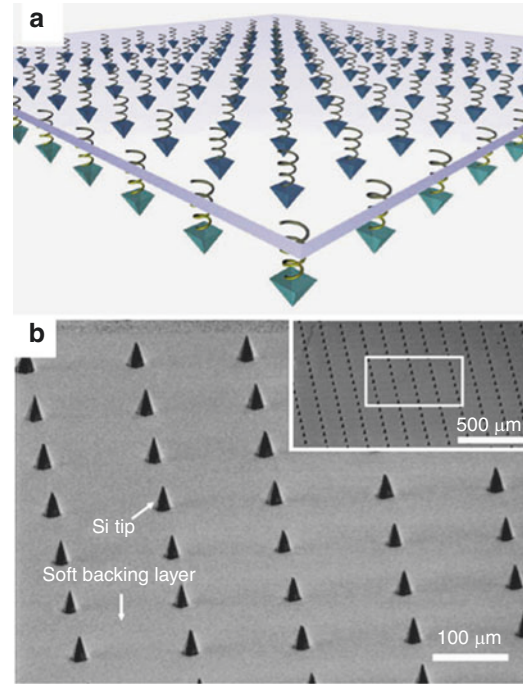
Dip-pen nanolithography (DPN) is an atomic force microscope (AFM) [1]) based patterning technique in which molecules are transported from a sharp tip to a surface [2, 3]. With DPN, the molecules to be deposited are first loaded onto the tip by dipping the tip into a melt or solution of the substance to be deposited. Similar to a pen which people use to write notes on a paper, the atomically sharp tip is scanned in contact with a sample surface. The ink molecules are transported to the surface driven by capillary forces normally generated by the condensed water or melted ink when tip contacts surface. Typically, DPN allows surface patterning with a feature size on scales of less than 100 nm [4]. DPN is a quite unique method for patterning because it depends on the delivery of molecules to surfaces rather than energy (in the form of light, force, heat, or electricity) to make patterns. The DPN principle can be called a positive lithography technique in the sense that material is added rather than removed.

The History of DPN

The research on the deposition of organic materials by the AFM tip to a solid surface can be dated back to 1995 [2]. However, the first use of the term "dip-pen nanolithography" and the fast development of the DPN technique started in 1999 [3] in Prof. Chad Mirkin's lab in Northwestern University. Since then the excellent attributes of the DPN, such as direct-write capability, ultrahigh resolution, molecular ink and substrate general, and programmable abilities, have attracted researchers all over the world. Currently, several tens of groups are employing DPN technique for their researches and contributing on the development of the DPN technique at all aspects. In the last 5 years, a constant value of around 60–70 articles per year was published under the term "DPN." This value characterizes DPN to be a method of scientific importance and not to be a scientific niche. Meanwhile, commercialized instruments for parallel patterning of ink materials have been developed in early 2000s.

Description of the Method

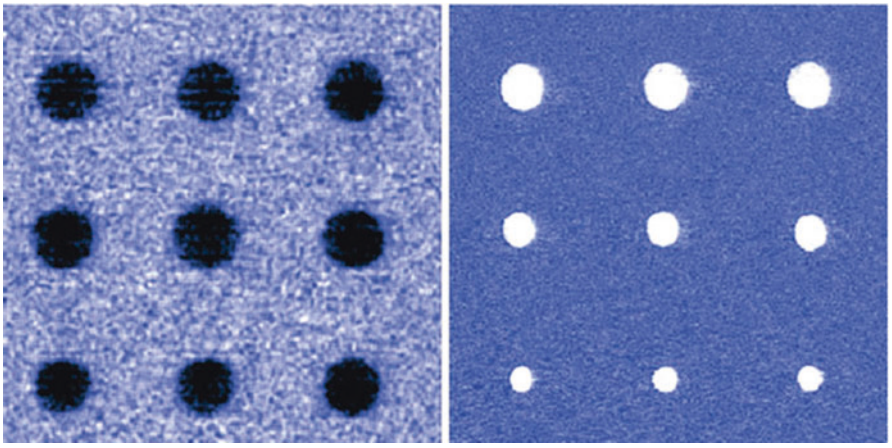
The pens. Conventional DPN utilizes an AFM probe to transport ink materials from an ink-coated tip to a surface when the tip is engaged (Fig. 1). The size of AFM tip is on the scale of tens of



Dip-Pen Nanolithography, Fig. 1 Schematic drawing indicating ink transporting from an AFM tip onto a solid substrate (Image was reprinted from [5] with permission)

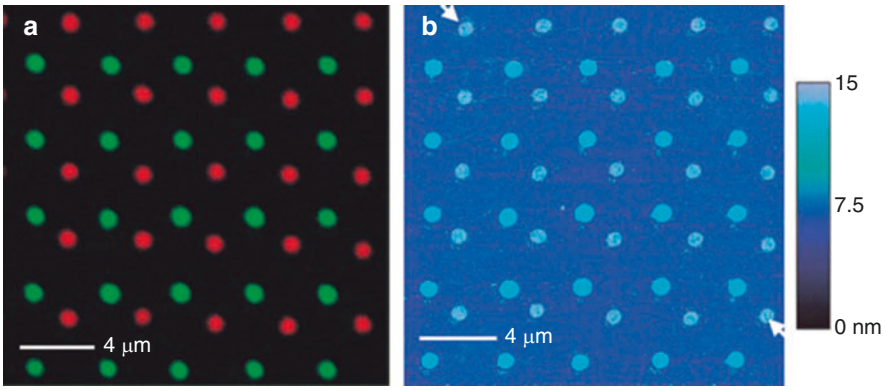
nanometers to several micrometers. Accordingly, the feature size fabricated by the tip can be controlled in the range from about 10 nm to several micrometers by selecting suitable tips and depositing parameters. The motion of the AFM tip on the surface can be precisely controlled by the AFM system, which makes it convenient to fabricate programmed patterns. The same AFM tip also serves as an imaging tool for characterizing written nanoscopic features on a surface.

In order to control the deposition of molecules, specialized AFM tips were fabricated. For example, AFM cantilevers terminated with poly(methyl methacrylate) (PMMA) colloids have been used to pattern molecules by allowing the polymer on the tip to swell under different humidity conditions [6]. Even hollow tips connected with a reservoir were used for controlling the droplet size for liquid nano dispensing applications [7]. New procedures based on novel probes boost the potential of DPN into different research areas.



As a patterning technology, throughput is the biggest limitation of the single-probe DPN. Thus, parallelization capabilities must be developed in order to be competitive with standard lithographic techniques [8]. A possible solution to DPN parallelization is to develop, to fabricate, and to use two-dimensional (2D) tip arrays [9]. Linear and 2D arrays carrying more than 10,000 tips have been developed [8] and are commercially available. These tools allow one to fabricate molecule-based structures over long distances (centimeters) or large areas (square centimeters) with high efficiency. Moreover, the pens in a tip array can be independently actuated and used to make a different nanostructure, which provides more flexible control in DPN. The material that makes up the parallel tip arrays can be soft polymers [10]. The most recent development in this field indicated that a hard silicon tip array on a soft baking layer can overcome the throughput problems of conventional DPN and the resolution limits imposed by the use of soft polymer tips (Fig. 2) [11].

Ink materials. With DPN, "ink" substances are patterned to endow surfaces with predesignated functions at specific locations. Small molecules such as alkanethiols were first used as ink materials to be patterned on gold surface. Alkanethiol molecules deposited on gold surfaces normally undergo a self-assembly process and form a closely packed monolayer. Then DPN has been developed to pattern a variety of "ink–substrate" combinations. Inks studied to date include many types of small molecules, metal salts, nanoparticles, polymers, oligonucleotides, peptides, and proteins, while the substrates used include gold, glass, quartz, silicon, mica, germanium, and so on. In addition, researchers also have developed DPN techniques to pattern different chemical [12] or biological ink molecules on one substrate, so that multiple chemical or biochemical functionalities are integrated [4].



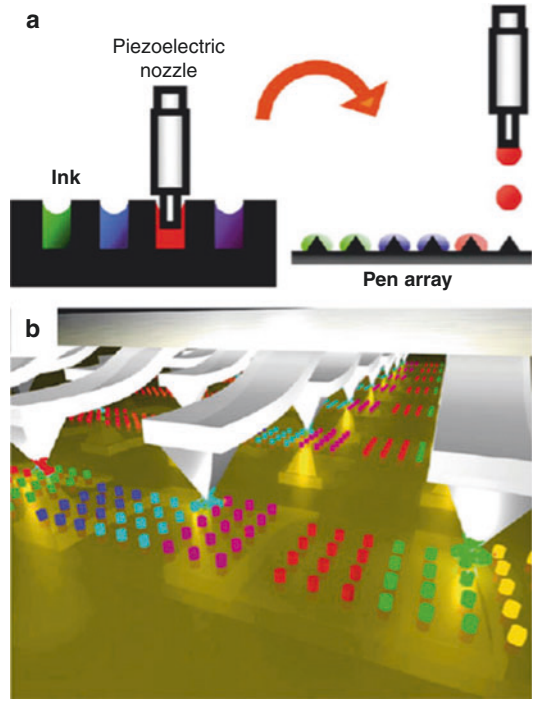
Dip-Pen Nanolithography, Fig. 2 (**a**) Schematic illustration of a hard tip array on a soft baking layer (the springs). (**b**) An SEM image of a real silicon tip array on a SiO_2/PDMS/glass substrate. The *inset* shows a large area of the array (Image was reprinted from [11] with permission)

Alkanethiols were the first type of chemicals [1, 12] that were directly patterned on gold surface with DPN (Fig. 3). Alkanethiol molecules are important because they can be used to conveniently tailor the local chemical properties of the substrate by selecting appropriate tail group of the molecule. In addition, alkanethiols are easy to

Dip-Pen Nanolithography, Fig. 3 Lateral force microscopy images of two dot arrays made by two alkanethiols, 1-octadecanethiol (*left*) and 16-mercaptohexadecanoic acid (*right*), respectively, on thermally evaporated gold films on silicon oxidized substrates

Dip-Pen Nanolithography, Fig. 4 Direct patterning of multiple-DNA inks by DPN. (**a**) Fluorescence image of two different DNA arrays. The arrays were made in two steps, each with an AFM tip that was coated with one DNA ink. After the first array was completed, the AFM tip was retracted and replaced with the second one coated with another DNA ink. The second tip was then relocated to the region of the first DNA array and fabricated the second array in-between the dots of the first array. (**b**) AFM image of the two DNA arrays shown in (**a**) decorated with gold nanoparticles. The DPN arrays were treated with a solution containing two different particles that were modified with DNA complementary to the first and second arrays, respectively. The two particles selectively assembled on the correct arrays (Image was reprinted from [14] with permission)

handle during tip coating and can be repeatable patterned on gold surface. Since then, alkanethiols have been widely explored as a model system for DPN to investigate the ink transport through AFM tip, molecular diffusion on the substrates, and phase separation of mixed ink molecules.

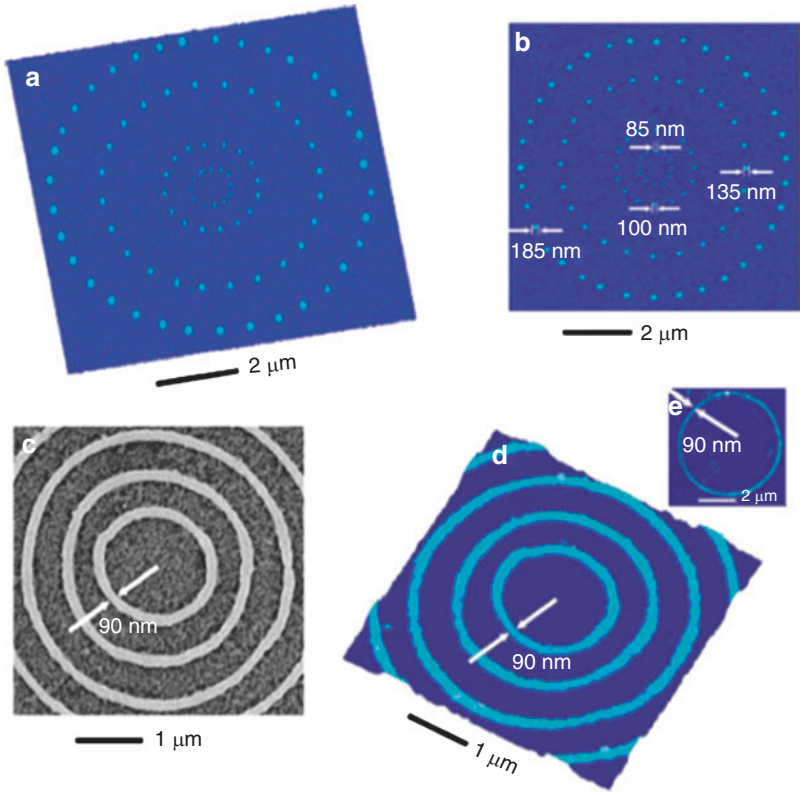


Patterning of biomolecules on various surfaces with DPN is particularly attractive [13]. The biomolecules can be patterned in a direct-write manner in either ambient or inert environments without risking cross-contamination. Since DPN has a very high spatial resolution, it is capable of fabricating high-density micro- or nano-arrays (Fig. 4) for biomolecular assays, including DNA and protein detection. The high spatial resolution that DPN brings to this field would allow an assay to screen for a correspondingly larger number of targets, or allow a fixed number of targets to be screened with a correspondingly smaller sample volume in a shorter period of time.

Tip coating. Tip coating is an important step of a DPN process. Researchers have developed a series of methods to coat AFM tips with molecular inks. For soluble ink materials, one can dip the tips into a dilute solution containing the ink molecules. When the tip is taken out from the solution, the solvent should be removed, normally with a gas flow, prior to deposition. Coating of the tip may be conducted by placing the tips in the ink vapor and by cooling the tip. For liquid inks, tip coating is relatively simple, and dip-coating is normally adopted.

To facilitate tip inking and to increase the quantity of adsorbed ink, researchers have developed novel tip modifications methods. For example, AFM tips made of or coated with poly (dimethylsiloxane) (PDMS) can load more ink than bare AFM tips. Nowadays, researchers have developed microscopic inkwells as well as inkjet printing (Fig. 5) techniques that could be used to ink the different pens in a tip array for simultaneous DPN patterning of multiple inks [15].

Ink transport. Ink molecules transport from coated tip to solid substrate driven by a capillary force. It is a complicated process and is influenced by a lot of parameters. These include the chemical makeup of the ink, the substrate, and the tip, which affect the distribution and mobility of the ink on the tip and substrate, and the environment conditions under which the experiment is carried out. Since the ink-coated tip contact the substrate during DPN, a water meniscus would normally condense between a hydrophilic tip and a hydrophilic surface under room temperature and ambient conditions. It has been found that relative humidity of the environment affects ink transport [16], and today most DPN is conducted in a humidity-controlled chamber that helps to regulate ink transport. In a water-free or solvent-free environment, molecule transfer is hampered but not impossible. It is evident that different molecules are transported to the surface by fundamentally different mechanisms, which may be attributed to the different size, shape, solubility, and diffusion constant of the ink molecules.

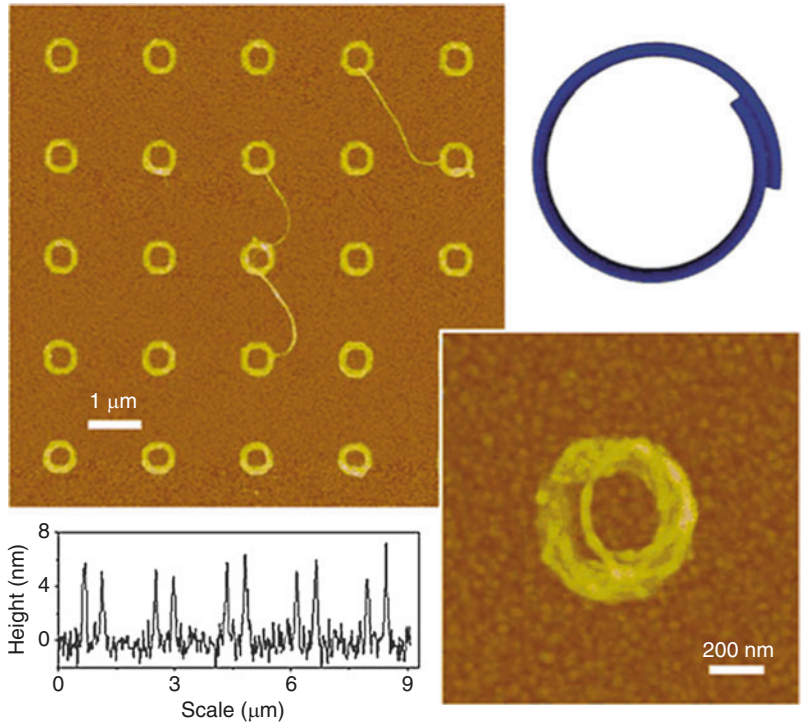


To a better control over the ink transport, researchers have developed approaches that use ink chaperones to overcome the solubility and surface interactions that previously inhibited uniform pattern formation by DPN. One approach uses poly(ethylene glycol) (PEG) as a matrix to facilitate the transport of inks with different sizes and solubilities to an underlying substrate. Some others use viscous liquids such as glycerol, dimethylformamide, and so on, to assist ink transport. In some cases, the use of a liquid will also benefit biomolecule inks to keep their biological functions during DPN process.

Dip-Pen Nanolithography, Fig. 5 Schematic drawings for (**a**) inking of pen arrays by inkjet printing and (**b**) multiplexed dip-pen nanolithography. After the nozzle of the ink jet printer was inked, the arrayed pens were independently addressed with different inks using the inkjet printer. The inked pens then make patterns containing multiplexed compositions on the surface (Image was reprinted from [15] with permission)

Applications of DPN

By depositing ink molecules to surfaces, DPN has the ability to create architectures with controlled chemical composition and physical structure. With significant advances in the parallel printing



Dip-Pen Nanolithography, Fig. 6 AFM images (**a**, **b**, **d**, **e**) and SEM image (**c**) of Au nanostructures on a silicon substrate (Image was reprinted from [18] with permission)

capabilities in the context of DPN with arrayed tips, it has shown great potential to increase the throughput of DPN. Moreover, state-of-the-art DPN allows the individual control of the movement of single pens within a pen array. Therefore, further development of parallel DPN would dramatically increase the complexity and sophistication of the structures one can fabricate with DPN. These capabilities make DPN a unique and highly desirable tool for depositing ink materials on a variety of surfaces, which is important for fundamental studies and direct applications ranging from molecular electronics to materials assembly, and for investigating biological recognition [13].

Generating hard nanostructures. One approach is to write inorganic ink materials that are dispersed in a solvent by DPN. Then the solvent will be removed from the patterned features by post-DPN treatments such as heating or light curing, resulting in well-defined hard inorganic nanostructures [13]. The DPN fabricated hard nanostructures can serve as catalysts, nanoscale conductive circuits, and so on. For example, carbon nanotubes were synthesized on DPN-patterned nanoparticle catalysts [17].

Another approach is the combination of DPN with wet chemical etching. Using such an approach both metal and semiconductor nanostructures were fabricated (Fig. 6). DPN-generated alkanethiol monolayers can be employed as resists for creating solid-state structures by standard wet-etching techniques. By using this method, nanometer-sized complex features can be generated.

Generating templates for hierarchical assembly of materials. DPN-generated chemical templates of various sizes, shapes, and compositions have been used for the directed assembly of a lot of nanoscale building blocks such as carbon nanotubes (Fig. 7) and nanoparticles. In addition, DPN was found useful in bridging the nano-gaps between nanoscale building blocks, which should

Dip-Pen Nanolithography, Fig. 7 (*Upper left*) AFM image and (*lower left*) height profiles of single-walled carbon nanotube (SWNT) rings assembled on a DPN-generated nanoarray. (*Upper right*) A model and (*lower right*) a zoom-in AFM image of a coiled SWNT ring. To achieve the assembly of SWNT, a gold substrate was first patterned with rings of 16-mercaptohexadecanonic acid (MHA). The bare gold regions of the substrate were then passivated with 1-octadecanethiol (ODT). The substrate was treated with a drop of 1,2-dichlorobenzene containing SWNTs. Because 1,2-dichlorobenzene wets the MHA rings but not the ODT passivated regions, SWNTs were selectively assembled on the MHA rings of the substrate (Image was reprinted from [19] with permission)

find broad applications, such as integration of nanocircuits, nanosoldering, and repair of failed nanoelectronics.

Fabricating biological nanoarrays. One can either directly fabricate nanoarrays of biological molecules on surfaces via DPN, or generate biological nanoarrays on a template fabricated with DPN methods. A variety of biological molecules, including DNA, peptides, proteins, viruses, and bacteria, have been patterned using direct-write or indirect adsorption approaches. With biological nanoarrays, a larger number of targets can be screened rapidly in an individual experiment with small amount of sample. For example, DPN-generated nanoarrays of the antibody have been used to screen for the HIV-1 virus antigen in serum samples [20].

Variants of DPN

Researchers constantly extend the basic capabilities of DPN beyond the range of patterning via a coated AFM tips (reviewed by Salaita et al. [13]). For example, researchers have employed heatable AFM tips to achieve melting and afterward patterning of some ink materials that are solids at room temperature and do not have appreciable solubility in a carrier solvent. For another example, by combining DPN with electrochemistry, a surface can also be electrochemically modified and then rapidly coupled to ink material transported from the tip. To facilitate tip inking and ink transporting, several research groups have developed so-called nanofountain or nanopipet as AFM tips to deliver reagents directly to a

substrate. These innovative variations of DPN have significantly expanded its capabilities.

Future Directions

Comparing with other lithographic techniques, DPN has unique properties and advantages. DPN is a positive lithography method. Therefore DPN is complementary to other scanning-probe-based, negative patterning methods [9]. DPN is superior over printing techniques in terms of patterning resolution, while still holds the capability of massive parallelization. The development on the independently actuated pen-array techniques, including software and hardware, is still underway. Further development in this direction would not only provide more flexible control and higher parallelization in DPN process, but also benefit other scanning-probe-based lithography techniques. Then DPN should also find broader applications especially in industry of biotechnology.

In addition, DPN is very attractive for basic research. DPN is an appealing method to deposit a variety of organic molecules on surfaces. The zoo of organic molecules covers a variety of special functionalities, e.g., electrical conductivity, optical properties, and wetting properties. Thus, the behavior of small entities of molecules in respect to these properties can be studied on a nanometer lengths scale with ultrasmall amounts of material.

Disjoining Pressure and Capillary Adhesion

Adsorbate adhesion; Liquid condensation; Liquid film; Liquid meniscus; Meniscus adhesion

Definition

Disjoining pressure, introduced by Derjaguin in 1936, may be defined as the difference between the thermodynamic equilibrium state pressure applied to surfaces separated by a thin film and the pressure in the bulk phase with which the film is in equilibrium [1]. Capillary adhesion refers to the adhesion due to a liquid meniscus bridging two solid surfaces which are wetted partially or completely by the liquid film. A curvature of the liquid meniscus induces a pressure difference across the meniscus, which depends on the liquid surface tension and the shape of the meniscus. The pressure difference as well as the surface tension of the liquid result in a net attractive force if the liquid wets the solid surface.

Occurrence

If you have been at a beach, you would have experienced capillary adhesion whether you recognized it or not. Walking on wet sand is easier than walking on dry sand. The wet sand can support your body weight, while the dry sand cannot and your feet sink into the sand. To build a sand castle the sand has to be wet. Wet sand can be shaped because particles adhere to each other. The strong adhesion is caused by liquid menisci, which form around the contact areas of two neighboring particles [2]. The force caused by such a liquid meniscus is called "capillary force" also termed meniscus force. Capillary adhesion phenomena are found and involved in various technical and biological systems. Capillary forces must be taken into account in studies of the adhesion between particles or particles to surfaces which are involved in processing powders, soils, and granular materials [3] and friction and wear of two contacting solid surfaces. They are also important at technological interfaces such as heads on magnetic hard disc memory and microelectromechanical system (MEMS) devices where they cause stiction [4]. Capillary forces play important roles in adhesion of insects, spiders, frogs, and geckos [5].

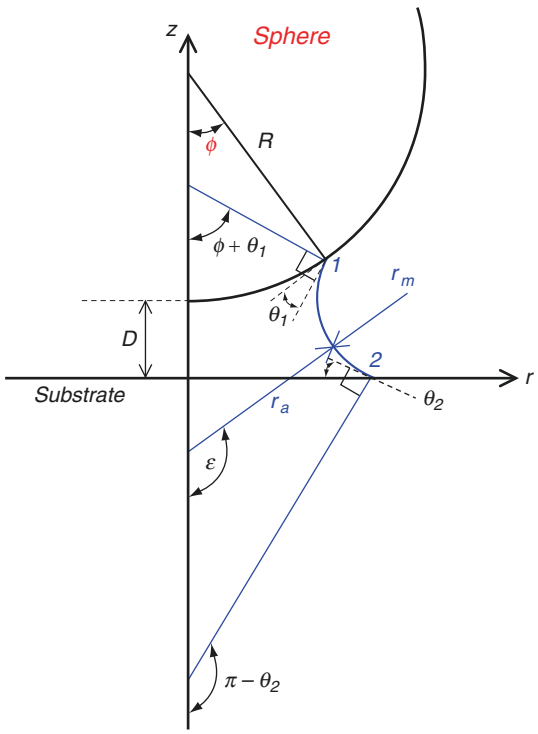
A liquid meniscus at the solid contact surface is readily formed if the solid surface can be wet with liquid. For example, if the solid surface is covered with a thin liquid film such as nonvolatile lubricants used for magnetic hard discs, the meniscus can be formed by flowing the liquid from the thin

film into the contact region when an opposing surface comes into contact. Even if the solid surface is not covered with preloaded liquid films, the meniscus can be formed around the solid contacting point if the vapor in the surrounding medium is readily adsorbed on the solid surfaces. This phenomenon is called capillary condensation and it is quantified by Kelvin's equation (see below).

Key Research Findings

Disjoining Pressure

The disjoining pressure, Π, is the difference between the pressure of the interlayer on the surfaces confining it and the pressure in the bulk phase, the interlayer being part of this phase and/or in equilibrium with it [1]. Π can be attractive or repulsive. For example, in the case of two plates immersed in a liquid, Π is the pressure that must be applied to the liquid between the plates, in excess of the external pressure to the liquid, to maintain a given separation. The concept can be applied to soap films. In the case of the adsorbed layer at the solid–vapor interface, Π can be thought of as a mechanical pressure that must be applied to a bulk substance to bring it into equilibrium with a given film of the same substance.



Various methods exist to measure the disjoining pressure of liquid films. These include thin film balance [6], contact angle studies [7], and atomic force microscopy (AFM) [8]. The disjoining pressure can be regarded as a net of several components including dispersion interactions, overlapping of diffuse double layers in the case of charged surfaces, overlapping of adsorbed layers of neutral molecules, and alteration of solvent structure in the discrete region (such as salvation or hydration) [1]. The dispersion (van der Waals) interaction contribution can be estimated using the Derjaguin approximation, $\approx A/6\pi h^3$, where A is the Hamaker constant (typically ~10^{-20} J) and h is the film thickness. Any deviation from this approximation must be due to specific chemical interactions such as ionic and covalent bonding of liquid molecules or structuring of liquid layers in the vicinity of solid surfaces.

Young–Laplace Equation

In the continuum model, the governing equation for the surface curvature of a liquid meniscus bridging two solid surfaces is the Young–Laplace equation [1, 3]. A curved liquid–vapor interface supports a pressure difference called Laplace pressure:

$$\Delta P_L = \gamma\left(\frac{1}{r_m} + \frac{1}{r_a}\right) = \frac{\gamma}{r_e} \qquad (1)$$

Here, γ is the surface tension of the liquid, r_m and r_a are the meridional and azimuthal radii of curvature of the surface, respectively, as shown in Fig. 1, and re is the effective radius of curvature. The curvature defined by r_m is in the plane of the paper and that defined by r_a is normal to the plane. Since the radius center of r_m is outside the meniscus, it has a negative value. The liquid surface is isobaric, meaning that r_e is constant along the meniscus surface, while r_m and r_a vary along

Disjoining Pressure and Capillary Adhesion, Fig. 1 Geometrical presentation of a liquid bridge between a sphere and a flat substrate [13]

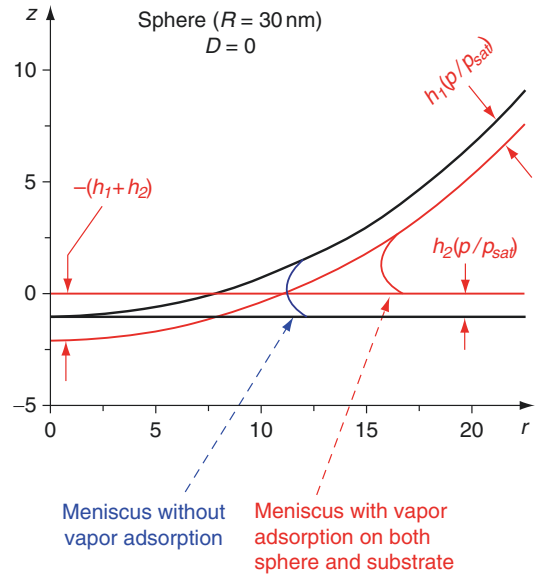
the surface. Figure 1 also shows the contact angles of liquid with the sphere and the substrate surfaces (θ_1 and θ_2), which arise from the solid–liquid equilibrium (Young equation). The exact solution of the differential Young–Laplace equation for this geometry can be found in references [3] and [9].

Liquid Meniscus Formation Due to Vapor Adsorption

Thermodynamic equilibrium requires the chemical potential of the liquid meniscus to be equal to that of the vapor. Assuming the molar volume (V_m) of the liquid substance to be constant and applying the Young–Laplace equation, (1), the Gibbs free energy of the liquid meniscus at a constant temperature is expressed as $\Delta G_{liq} = \int V_m \mathrm{dP} = V_m \Delta P_L = V_m \gamma / r_e$. The Gibbs free energy of a vapor with respect to its saturation state is $\Delta G_{vap} = R_g \mathrm{T} \cdot \ln(p/p_{sat})$. Setting ΔG_{liq} equal to ΔG_{vap} and replacing r_e with r_K gives the Kelvin equation [1, 3]:

$$V_m \Delta P_L = V_m \frac{\gamma}{r_k} = R_g T \mathrm{1n}(p/p_{sat}) \qquad (2)$$

$$r_k = \frac{\gamma V_m}{R_g T} = \frac{1}{\mathrm{1n}(p/p_{sat})} = \frac{\lambda_k}{\mathrm{1n}(p/p_{sat})} \qquad (3)$$



Consider that the solid surface is covered with the adsorbate film which is in equilibrium with the vapor phase (Fig. 2). Then, the isothermal Gibbs energy relationship between the adsorbate and the vapor is as follows [10]:

$$V_m \Pi(h) = R_g T \mathrm{1n}(p/p_{sat}) \qquad (4)$$

where $\Pi(h)$ is the disjoining pressure of the adsorbed layer with a thickness h. The $V_m \Pi(h)$ term represents the molecular interactions of the adsorbate molecules with the solid surface [11]. From (2) and (4), it is obvious that the meniscus should be in equilibrium with the adsorbate film.

Capillary Force Calculation

The capillary force from the liquid meniscus depends on two components – the axial

Disjoining Pressure and Capillary Adhesion, Fig. 2 Meniscus profiles for a sphere with a radius of 30 nm without (*blue line*) and with (*red line*) considering the equilibrium thickness of the adsorbate layer on the sphere, $h_1(p/p_{sat})$, and the thickness on the flat substrate, $h_2(p/p_{sat})$. The meniscus contact angle is set to $\theta_1 = \theta_2 = 0°$ [13]

components (along the z-axis) of the surface tension force F_{st} and the Laplace pressure force F_{pl} at the point where the meniscus and the sphere meet (at the upper boundary point 1). For the geometry shown in 1, the two components can be calculated with the following equations:

$$F_{st} = 2\pi R \sin(\phi) \times \gamma \sin(\theta_1 + \phi) \qquad (5)$$

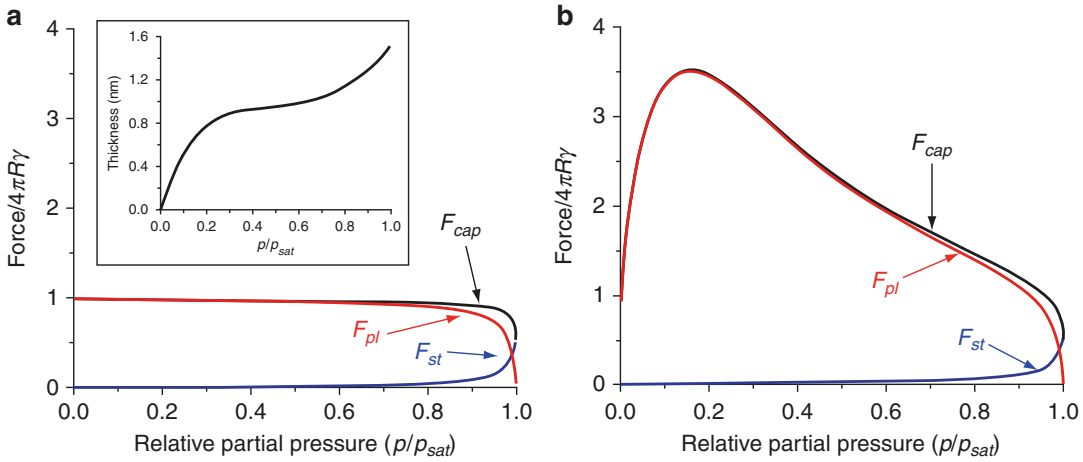
$$\begin{aligned} F_{pl} &= -\pi R^2 \sin^2(\phi) \times \frac{\gamma}{r_k} \\ &= \pi R^2 \sin^2(\phi) \times \frac{R_g T}{V_m} \mathrm{1n}(p/p_{sat}) \end{aligned} \qquad (6)$$

Here the positive sign is chosen for the attractive force. The term ϕ is often called a filling angle. The total capillary force is then the sum of these two components:

$$\begin{aligned} F_{cap} &= F_{st} + F_{pl} = 2\pi\gamma R \\ &\times \left[\sin(\phi) \sin(\theta_1 + \phi) - R \sin^2(\phi)/(2r_k) \right] \end{aligned} \qquad (7)$$

Since the meniscus is in equilibrium, the force at the boundary point 1 is the same as the force at any point on the meniscus.

Simple Approximation



One of the widely used equations to describe the capillary force is $F_{cap} = 4\pi R\gamma \cos\theta$ [10]. This equation is derived from the Young–Laplace equation which contains two unknowns (principal radii of the meniscus) through several assumptions. One assumption is that the meniscus shape can be approximated to be circular. It also assumes that the radius of the tip is much larger than the cross-sectional radius of the liquid meniscus which, in turn, is much larger than the meridional curvature (external curvature) of the meniscus surface. This approximate form describes many macroscopic capillary phenomena; however, it does not work well as the contacting solid system gets smaller.

More Accurate Calculations

Figure 3 shows the capillary force (F_{cap}) and its two components (F_{pl} and F_{st}) for R = 100 nm calculated using the exact solution of the Young–Laplace equation, (1) [12, 13]. The force scale is normalized with $4\pi R\gamma$. The calculation shows a drastic difference in the p/p_{sat} dependence of F_{cap} due to the vapor adsorption. When the solid surface is assumed to be free of adsorbates (Fig. 3a), the capillary force decreases monotonically but insignificantly with p/p_{sat} until p/p_{sat} approaches the saturation point [14]. In contrast, the calculation including a type-II adsorption isotherm (inset in Fig. 2a) shows a large partial pressure dependence (Fig. 3b) [12, 13]. *Fcap* reaches a maximum value at p/p_{sat} ~0.15 and then decreases upon further increase of p/p_{sat}. Note that the maximum p/p_{sat} range coincides with the knee point of the type-II adsorption isotherm which corresponds to the completion of the monolayer thickness. The result calculated with the adsorption isotherm is in good agreement with experimental measurement data [15]. The capillary force exerted by the meniscus formed by vapor adsorption and condensation is strongly affected by the structure of the adsorbate layer [16] as well as the geometry of the contacting solid surfaces [17].

Meniscus Stretch and Liquid Film on Solid

When the vapor adsorption from the environment is negligible (e.g., water does not adsorb readily on hydrophobic surfaces), the Laplace pressure of the meniscus ($P(h)$) under equilibrium conditions is equal to the disjoining pressure ($\Pi(h)$) of the

Disjoining Pressure and Capillary Adhesion, Fig. 3 Total (*black*), Laplace pressure component (*red*), and surface tension component (*blue*) of the capillary force for a sphere with R = 100 nm on a flat surface (**a**) without and (**b**) with taking into account the adsorption isotherm of ethanol. The forces are normalized with $4\pi R\gamma$, where γ = surface tension of liquid [13]. The inset in (**a**) shows the model adsorption isotherm used in this calculation. The isotherm curve is produced by fitting the experimental data reported in reference [15]

liquid film deposited on the solid surface. Mate et al. demonstrated the use of AFM in calculating $r_{eff}(h)$ for a liquid lubricant film [18]. By slowly retracting an AFM probe in contact with a liquid film, the meniscus is stretched in a quasi-equilibrium state (the stretch rate is slow enough to allow for the change in the meridional and azimuthal radii in a manner that $r_{eff}(h)$ remains constant throughout the meniscus stretching). Then, $r_e(h)$ is obtained by fitting the force-distance curve data to the following equation:

$$\frac{F(d)}{4\pi R\gamma} = \left(1 + \frac{d}{2r_e(h)}\right) \tag{8}$$

where $F(d)$ is the force measured by AFM, R is the radius of the AFM probe tip, and d is the tip-sample separation distance. The $r_e(h)$ is extracted from the slope of the linear portion of the retraction curve where the meniscus is stretched from the AFM tip.

Bowles and White later proposed a numerical solution to calculate the shape of the retraction curve based on the shape of the meniscus with a given $r_e(h)$ [19]. The White method analyzes this retraction curve based on a given $r_e(h)$ and the cantilever spring constant k. The White method fits the experimental data with the following equations:

$$\frac{F(d)}{4\pi R\gamma} = \frac{\lambda}{4\alpha^2} \tag{9}$$

where $\lambda = \frac{r_e(h)}{R}$ and $\alpha = \frac{r_e(h)}{r_0(d)}$ are two parameters for the numerical solution of the shape of the meniscus on the AFM probe and $r_0(d)$ is a moving boundary where the lower edge of the meniscus meets the unperturbed liquid film of thickness h. Once $r_e(h)$ is determined, the disjoining pressure of the liquid film and the Laplace pressure of the liquid meniscus can be calculated using the surface tension of the liquid film.

Definition

Dissipative particle dynamics (DPD) is a stochastic mesoscopic simulation technique that describes *clusters* of molecules moving together in a Lagrangian fashion subject to simplified pairwise conservative, dissipative and random forces.

Introduction

Natural systems can be described at different scales based on both spatial and temporal size. In general, there are three different scales, i.e., micro-, meso-, and macroscales. A microscopic event occurs at nanometers in length and nanoseconds in time or, even less, governed by quantum mechanics or classical laws. Macroscale describes physical objects or phenomena that are measurable and visible directly with the naked eye, and thus, the mean free path of molecules is far smaller than the characteristic length of the geometry. A macroscopic event is usually described by continuum partial differential equations (PDEs), such as Navier-Stokes equations for fluid dynamics. Mesoscale is somewhat in between, which is typically in order of micrometers and microseconds. Examples of such mesoscopic systems include colloidal suspension, polymer solution, and biological membranes. Since the behaviors of such systems can be much more complex than that of a simple fluid, they are usually called complex fluids. There exist broad applications of complex fluid systems in industrial technologies, especially in the field of biological and biomedical sciences such as biochemical lab-on-a-chip systems, separation devices, and drug delivery systems.

Computer simulations have become an essential part of mathematical modeling of many natural systems in modern science and technology, serving as a bridge between theories and experiments (see Fig. 1). Molecular dynamics (MD) has emerged as one of the first and yet widely used simulation methods in many areas of physics and chemistry starting from the 1950s. However, the classical MD is practical only for simulations up to microscales. It is difficult to simulate larger and more complex systems because of prohibitively expensive computations. Meanwhile, sophisticated computational and numerical discretization techniques have been developed over the past decades for the solution of PDEs at macroscale,

Dissipative Particle Dynamics, Overview, Fig. 1 Illustration of the length scales in "soft" materials. MD, DPD, and PDE stand for molecular dynamics, dissipative particle dynamics, and partial differential equations, respectively, and eDPD and SDPD indicate energy-conserving DPD and smoothed DPD, respectively

such as various computational fluid dynamics (CFD) methods. However, these PDEs are inadequate to capture mesoscopic events in complex fluids, since these PDEs are based on simple constitutive equations, while the dynamics of a complex fluid is fundamentally affected by its microscopic structure. Furthermore, the standard PDE formulations often ignore the stochastic nature of a system observed at mesoscale, which is a characteristic feature for many physical phenomena.

Mesoscopic simulation methods have been developed to overcome the aforementioned problems, aiming at modeling complex fluids with efficient computational costs. Dissipative particle dynamics (DPD), which describes *clusters* of molecules moving together in a Lagrangian fashion, is a typical mesoscopic simulation method for the dynamic and rheological properties of simple and complex fluids [1]. DPD combines Lagrangian features from MD and coarser spatial-temporal scales from lattice-gas automata (LGA), and, therefore, it is faster than MD and more flexible than LGA. The first form of DPD was reformulated by Espanöl and Warren such that it produces a correct thermal equilibrium state [2]. This is considered as the standard form of DPD. Several improved DPD models [3–6], which are capable of representing complicated fluid properties more accurately, as well as efficient algorithms have also been developed. Rigorous foundations of DPD methodology have also been investigated by both top-down (from macroscopic description to mesoscopic description) and bottom-up (from microscopic to mesoscopic) approaches.

Theoretical Formulation

In a DPD simulation, a particle represents a cluster of molecules, and the position and momentum of the particle are updated in a continuous phase space at discrete time steps. The equation of motion and pairwise interacting forces of particles read

$$\dot{\mathbf{r}} = \mathbf{v}_i,\ m_i\dot{\mathbf{v}}_i = \sum_{j\neq i}\left(\mathbf{F}_{ij}^C + \mathbf{F}_{ij}^D + \mathbf{F}_{ij}^R\right), \quad (1)$$

where $\mathbf{r}_i$, $\mathbf{v}_i$, and m_i are position, velocity, and mass of particle i, respectively. $\mathbf{F}_{ij}^C$ is referred to as conservative force obtained from a prescribed potential between particles i and j. It is repulsive and leads particles to be evenly distributed in space. Roughly speaking, it can be understood as a pressure force; $\mathbf{F}_{ij}^D$ has a negative sign and is proportional to the velocity difference of two particles. Therefore, it is dissipative and resists velocity difference of any interacting pair of particles. Hence, $\mathbf{F}_{ij}^D$ dissipates the kinetic energy of the system. This amount of energy must be put back into the system, to keep the system at a constant temperature. $\mathbf{F}_{ij}^R$ is exactly for this purpose. It is a random force and injects kinetic energy back into the system. Effectively, $\mathbf{F}_{ij}^D$ and $\mathbf{F}_{ij}^R$ implement a thermostat so that thermal equilibrium is achieved. The magnitudes and functional forms of the two forces are related by the so-called *fluctuation-dissipation theorem*. The typical forms of the three forces are as follows [2, 7]:

$$\mathbf{F}_{ij}^C = a_{ij}\omega^C\left(r_{ij}\right)\mathbf{e}_{ij}, \quad (2a)$$

$$\mathbf{F}_{ij}^D = -\gamma\omega^D\left(r_{ij}\right)\left(\mathbf{e}_{ij}\cdot\mathbf{v}_{ij}\right)\mathbf{e}_{ij}, \quad (2b)$$

$$\mathbf{F}_{ij}^R = \sigma\omega^R\left(r_{ij}\right)\theta_{ij}\delta t^{-1/2}\mathbf{e}_{ij}, \quad (2c)$$

where a_{ij}, γ, and σ reflect, respectively, the strength of conservative, dissipative, and random forces. Here, θ is a *Gaussian white noise* ($\theta_{ij} = \theta_{ji}$), and $\mathbf{e}_{ij}$ is the unit vector pointing from particle j to i; also, ω^C, ω^D, and ω^R are unspecific weighting functions of relative distance r_{ij}. A common choice of the weighting functions is

$$\omega^C\left(r_{ij}\right) = \begin{cases}\left(1 - r_{ij}/r_c\right)^s, & r_{ij} < r_c,\\ 0, & r_{ij} \geq r_c,\end{cases} \quad (3)$$

$$\omega^R\left(r_{ij}\right) = \begin{cases}1 - r_{ij}/r_c, & r_{ij} < r_c,\\ 0, & r_{ij} \geq r_c,\end{cases} \quad (4)$$

where $s = 1$ is the most widely adopted for the classical DPD method. However, other choices (e.g., $s = 0.25$) for the envelopes have also been used. Also, r_c is the cutoff radius, which defines the extent of the interaction range.

To satisfy the fluctuation-dissipation theorem, two conditions must be further enforced [2]:

$$\omega^D\left(r_{ij}\right) = \left[\omega^R\left(r_{ij}\right)\right]^2, \quad \sigma^2 = 2\gamma k_{\mathrm{B}}T, \quad (5)$$

where k_{B} is the Boltzmann's constant and T is the absolute temperature.

Two important implications of the DPD forces in Eq. 2 must be explicitly noted: firstly, DPD is considered as a reduction model of the underlying microscopic dynamics. By construction, it focuses on the coarse-grained properties and intentionally ignores irrelevant degrees of freedom on the microscopic level. As a result, interparticle potential (the derivative of which is $-\mathbf{F}_{ij}^C$) is much softer than that of MD method; hence, it can potentially access longer time and length scales than are possible using conventional MD simulations. Furthermore, $\mathbf{F}_{ij}^D$ and $\mathbf{F}_{ij}^R$ together account for the lost microscopic information. Secondly, by design, all three forces act along the line of particle centers $\mathbf{e}_{ij}$ and are symmetric by interchanging particle indices. Therefore, the momentum is locally conserved. The fulfillment of the conservation laws guarantees that a DPD system approaches the PDEs of fluid dynamics, such as Navier-Stokes equations, at the macroscopic scale.

For the purpose of modeling simple and complex fluids, α, γ (or σ), and s are free parameters to calibrate so that the desired properties of a target system can be achieved. The time evolution of velocities and positions of particles is determined by Newton's second law of motion similar to the MD method, which is usually integrated using a modified velocity-Verlet algorithm [7].

Extensions of DPD

The classic DPD method is a minimal working version for mesoscopic simulations of fluids. Due to the lack of necessary degrees of freedom, it cannot model some specific problems, e.g., heat flow in non-isothermal systems and liquid-vapor interface in two-phase fluid systems. To this end, extra degrees of freedom, such as an internal energy variable and freedom to alter the equation of state, have been introduced to DPD system for particular applications [8]. In this section, several extensions of the DPD method will be described briefly.

Energy-Conserving DPD

The classic DPD method is limited to isothermal systems and is not valid for modeling non-isothermal processes because the energy is not conserved in particle interactions. To extend the standard formulation of DPD with application to heat flow in non-isothermal fluid systems, the conservation of energy was applied to DPD by introducing the particle internal energy ε_i as an additional variable [3]. Along this new variable, a local entropy function $s(\varepsilon_i)$ and the temperature $T_i = (\partial s_i/\partial \varepsilon_i)^{-1}$ are defined for each particle. The energy-conserving DPD model is known in the literature as eDPD or DPDE, where for interacting particles, the dissipation induced by the dissipative forces is utilized in raising the internal energy of the particles through viscous heating. Moreover, the temperature differences between particles produce variations in the internal energies through heat conduction.

The key aspect of eDPD is that the temperature T_i is defined on each particle, and the fluctuation-dissipation theorem is applied locally based on the particle temperature T_i rather than the thermodynamic temperature of the system. As a result, eDPD allows temperature gradients and can be used in non-isothermal problems, where thermal transport plays a critical role.

Many-Body DPD

The conservative force $\mathbf{F}_{ij}^{C}$ is responsible for the thermodynamic behavior of the DPD system and has the form shown in Eq. 2. For a single-component DPD fluid, the equation of state (EOS) of the system can be approximated as $p = \rho k_B T + \alpha a_{ij} \rho^2$, which is a quadratic function of the particle density ρ. This monotonic function of EOS does not contain a van der Waals loop and excludes the possibility of simulating phenomena involving vapor-liquid coexistence or free surface.

To model vapor-liquid coexistence, the many-body DPD (MDPD) was developed by modifying the expression of the conservative force [5]. A direct way to produce higher order terms in EOS is making the conservative force in MDPD dependent not only on the interparticle distance but also on the instantaneous local particle density. Therefore, the conservative force in MDPD is effectively a many-body force and it generally includes both attractive and repulsive components. With higher order terms in EOS, MDPD has been successfully applied to simulations of droplet- and wetting-related phenomena.

Fluid Particle Model

The fluid particle model (FPM) is a generalization of the classic DPD method [4]. FPM considers both linear and angular momenta of the particles and includes both central and noncentral forces between particles, while the classic DPD method considers only linear momentum and includes only central forces. By introducing torques and angular velocities of the particles, both linear and angular momenta of FPM are conserved. Also, the dissipative and random forces in FPM satisfy the fluctuation-dissipation theorem, and they together act as a thermostat to maintain the temperature of the FPM system at a constant.

Since the rotational motion of individual particle is included, FPM shows high computational efficiency in studying the dynamical and rheological properties of colloidal suspensions in simple fluid solvents. The reason is that each colloidal particle can be represented by a single FPM particle rather than a cluster of particles. FPM has been used to investigate a range of rheological behaviors and volume fractions of the colloidal suspensions and shows good agreement with experimental and theoretical results.

Smoothed DPD

The classic DPD model is a bottom-up approach and it is usually considered as a coarse-grained MD model, in which particles are governed by a coarse-grained force field. Similarly to the MD method, the inputs of DPD are the particle interactions, while the macroscale quantities, such as viscosity, diffusivity, compressibility, and EOS, are output properties. As a result, DPD has no restrictions on constitutive equations, which provides flexibility in modeling complex materials and multicomponent systems. However, a shortcoming of DPD is that it employs empirical expressions for the particle interactions, and its parameters are not related in a straightforward way to usual macroscale quantities. Therefore, in practice, the DPD units have to be mapped to physical units based on output properties.

Alternatively, *smoothed* DPD (SDPD) is a top-down approach [6]. It was developed from smoothed particle hydrodynamics (SPH). In fact, SDPD is a Lagrangian discrete model for simulating Navier-Stokes hydrodynamics that includes thermal fluctuations consistently. Unlike the classic DPD method, the parameters in the governing equations of SDPD have clear physical meaning. The inputs are the viscosity, equation of state, temperature, and other parameters required by the fluctuating Navier-Stokes equations. However, since the constitutive equations and macroscale properties of the system must be given as inputs, SDPD works well with simple fluids but loses its effectiveness in modeling complex materials.

Applications in Different Fields

In the past decade, the DPD method has been successfully extended to many applications including simple fluid hydrodynamics, polymer solutions and melts, biological membranes, colloidal suspensions, and blood flow [9, 10]. A few examples are presented in the following:

Polymer Solution

A polymer is a large molecule composed of many repeated subunits bonded together. In DPD, a polymer can be represented by linking collections of particles into chains with appropriate spring forces expressed as $\mathbf{F}_{ij}^{S} = k_{\text{bond}}\left(1 - r_{ij}/r_0\right)\mathbf{e}_{ij}$ [9]. Numerous simulations have testified that the DPD model is capable of capturing many essential physical phenomena of the polymer systems. For example, the DPD model has been applied to polymers in solution to study effects of solvent quality on the conformation and relaxation of polymer chains [11]. The dynamics of polymer chains in simple shear flow such as Couette and Poiseuille flow have also been simulated. Simple shear flows are commonly generated by imposing a constant driving body force (Poiseuille flow), or a driving velocity on the boundary shear planes (Couette flow). The static and dynamic properties of polymer chain under shear, such as radius of gyration, diffusivity, and viscosity, were computed and compared to experimental results [12]. The conformational changes and translocation dynamics of polymer and DNA molecules through microfluidic channels have also been investigated by DPD [13].

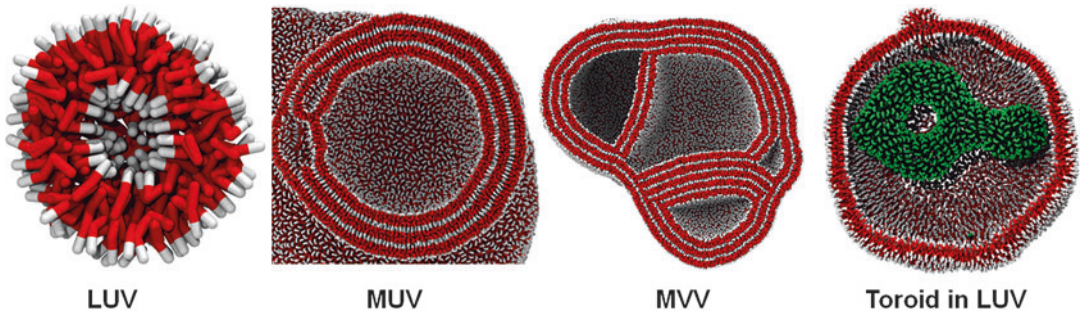
Amphiphilic Systems

Amphiphilic molecules, which contain hydrophilic head and hydrophobic tails, can be synthesized with various structures of the block type. In a selective solvent of one of the blocks, they can self-assemble into a wide variety of morphologies. A typical model of amphiphilic molecules is the two-letter ("black-and-white") H-T model, composed of a single head particle (denoted by H) and a linear chain of tail particles (denoted by T). The amphiphilic molecules are then immersed in solvent bath (denoted by W).

To model the amphiphilic nature of amphiphilic molecules, the hydrophobic and hydrophilic interactions emerge from the relative interaction strengths. In theory, the functional dependence of the Flory-Huggins parameter χ [14] on DPD repulsion parameter a_{ij} places the simulation results in the proper context. The relationship between a_{ij} and χ has been established by Groot and Warren [15]: $a_{ij} = a_{ii} + 3.27\chi_{ij}$ at particle density $\rho = 3$ and $a_{ij} = a_{ii} + 1.45\chi_{ij}$ at $\rho = 5$. Typically, for simplicity, the repulsive parameter related to the interaction between two alike DPD particles (H-H, T-T, W-W, and H-W) is

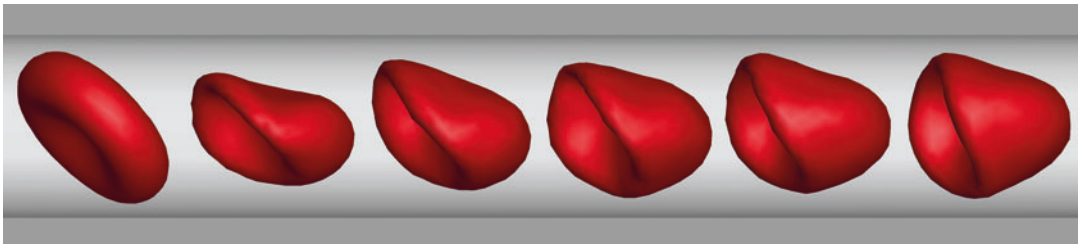
treated the same, while the parameter related to the interaction between the hydrophilic and hydrophobic particles (H-T and T-W) is made larger than the repulsion parameter between two similar particles, which ensures that the hydrophobic tails of amphiphilic molecules are sufficiently shielded from the hydrophilic head and solvent. Various morphologies, such as spherical and cylindrical micelles, toroids, bilayers, and vesicles, have been observed depending on the selectivity of solvents, amphiphilic concentration, and the structure of the amphiphilic molecules [16]. A selection of vesicle shapes obtained from the DPD simulations is displayed in Fig. 2.

By adding a bond-bending potential to the hydrophobic tails, a rod-coil amphiphilic molecule can be modeled. Based on the functionality of the rigid-rod blocks, there is growing interest in amphiphilic systems with rod-coil structures, and a number of intriguing phases, including wavy lamellae, zigzags, and hollow spherical micelles, have been observed through self-assembly from DPD simulations [17]. These simulations have shown the applicability of DPD method to study the self-assembly process of amphiphilic systems.



Blood Flow

Blood is primarily composed of microscopic cellular particles such as red blood cells (RBCs), leukocytes, and platelets. The most abundant cells in vertebrate blood are RBCs. A human RBC is a nucleus-free cell with a biconcave shape when not subject to any external stress and is approximately 8.0 μm in diameter and 2.0 μm in thickness. The RBC membrane consists of a lipid bilayer supported by an attached spectrin-based cytoskeleton, and its extreme deformability allows the RBC to squeeze without any damage when passing through narrow capillaries in microcirculation. A multiscale RBC (MS-RBC) model [18], which is based on spectrin-level RBC model [19], has been developed for blood simulations.



In the MS-RBC model, the membrane of RBC is represented by a two-dimensional triangulated network with a collection of DPD particles, while constraints on the area and volume conservation of RBC are imposed to mimic the area-preserving lipid bilayer and the incompressible interior fluid. The RBC membrane interacts with the fluid particles through DPD forces, and the temperature of the system is controlled through the DPD thermostat. The internal and external fluids are modeled by collections of free DPD particles, and their separation is enforced by bounce-back reflections of these particles at the RBC membrane surface. The MS-RBC has been successfully applied in RBC simulations, such as RBC dynamics in Poiseuille flow (see Fig. 3), RBC thermal fluctuations, and RBCs in diseases like malaria and sickle cell anemia [20].

Outlook

As a coarse-grained molecular dynamics method, dissipative particle dynamics has been

demonstrated to be a promising mesoscopic method for simulating the dynamic and rheological properties of simple and complex fluids. The classical DPD method and its extended models have already been applied successfully to a wide variety of phenomena occurring at the mesoscales. However, there remain many open questions both with regard to the foundations of the method and in various applications. For example, the issue of memory effects and the scaling up of DPD in even bigger spatiotemporal scales are two important open questions.

Definition

DNA is the acronym of deoxyribonucleic acid, also known as the molecule of life. It is the basic constituent of the genetic code. Although genetic studies date back to the activities of Gregor Johann Mendel in the 1860s, the three-dimensional (3D) structure of the genetic molecule was disclosed by James Watson and Francis Crick only about a century later in 1953, after the pioneering X-ray crystallization experiments of Rosalind Franklin and Maurice Wilkins. A canonical DNA molecule is a right-handed double helix with a pitch of 3.4 nm and a diameter of 2.1 nm, made of two strands running in opposite directions. Each strand is a sequence of four different nucleotides (guanine = G, cytosine = C, adenine = A, and thymine = T) separated from each other along the strand by 0.34 nm and connected through a deoxyribose backbone. The two strands are connected by Watson-Crick hydrogen bonding between the bases: guanine pairs specifically to cytosine and adenine pairs specifically to thymine. Guanine and adenine are purines, formed by two coplanar heterocycles (one penta-ring and one hexa-ring); cytosine and thymine are pyrimidines, formed by one heterocycle (hexa-ring). The structure of the double helix and of the base pairs (bp's) is illustrated in Fig. 1 [1].

The electronic structure of materials is at the core of their response to the environment and external stimuli (e.g., light) and of their exploitation for practical purposes: DNA is a biological material that does not violate this rule. In DNA, the response to the environment, as well as the inherent properties, is a crucial factor for its biological role, including normal function and disease; the exploitation for practical purposes includes nanomechanical machines, molecular electronics, and molecular computing devices.

Computational approaches to DNA target both the structure and the electronic properties (the latter include optical excitations and mobile charges). They can be either "parameterized" or "from first principles": the former quality means that the methodology contains external information from experiments or theories, and the latter

DNA from First Principles, Fig. 1 Structure of canonical double-stranded DNA (dsDNA). (**a**) 3D structure in a ribbon representation of a canonical B-DNA molecule, the Drew-Dickerson dodecamer with palindromic sequence 5'-CGCGAATTCGCG-3' (pdb code 1BNA). quality means that the methodology does not contain any information external to the investigated system, but only the chemical nature of the constituent atoms and a viable initial atomic structure. First-principle calculations are feasible only for small fragments because they are too cumbersome for entire DNA molecules: in fact, since they do not require external parameters, they must solve the quantum states of the electrons in a self-consistent manner. Yet, knowledge of the double-helical structure of entire oligomers is required as a viable starting point of first-principle computational procedures: this can be either obtained from the nucleic acid database (a structure is identified by a 4-letter code in a file with extension "pdb"; http://www.rcsb.org/pdb/home/home.do) or from empirical simulations (e.g., classical molecular dynamics or Monte Carlo). At odds with inorganic materials, the electronic properties of a soft DNA molecule are intertwined with the conformational fluctuations. Therefore, first-principle calculations of the electronic structure should address a variety of conformations in order to have a relation with reality. Electronic structure calculations of DNA bases, base pairs, and small fragments of stacked base pairs can be performed with wavefunction-based methods and density-based methods. This entry briefly defines the methodologies, presents milestones achieved with representative methodologies, and discusses the intimate relation between atomic and electronic structure.

First-Principle Methods that Have Been Used to Study DNA

The title "DNA from first principles" refers to computational studies of the physicochemical properties of DNA fragments and oligomers.

Such properties are primarily the 3D atomic structure, the ground-state electronic energy and density, and the response of the electrons to light and external voltage. More complicated spectroscopic features may also be determined but are omitted from this entry. First-principle studies can be conceptually organized in two categories: (fp1) determination of electronic structure for one (or several) frozen atomic configuration(s) and (fp2) determination of the structure and structural motions.

The first problem is tackled with a variety of computational methods that solve for the properties of the electrons, either in the ground state or under the influence of optical and electrical excitations, at constrained atomic positions. The second problem is tackled with ab initio molecular dynamics (MD) or molecular mechanics (MM) simulations, which evolve the atomic geometry in the effective potential of the on-the-fly computed electron density. Molecular dynamics simulations solve second-order equations of motion and give the evolution of the system in time. Molecular mechanics, in the most popular nuance, consists of solving first-order equations of motions for the search of equilibrium configurations, namely, a number of local minima that are closest to trial structures.

For a system of N electrons and K nuclei with exclusively Coulombic interactions, the total Hamiltonian is:

$$H = -\sum_{i=1}^{N} \frac{1}{2}\nabla_i^2 - \sum_{I=1}^{K} \frac{1}{2M_I}\nabla_I^2 - \sum_{i=1}^{N}\sum_{I=1}^{K} \frac{Z_I}{r_{iI}} + \sum_{i=1}^{N}\sum_{j>1}^{N} \frac{1}{r_{ij}} + \sum_{i=1}^{K}\sum_{j>1}^{K} \frac{Z_I Z_J}{R_{IJ}}. \quad (1)$$

In Eq. 1, atomic units are used, for which Planck's constant is 2π, the mass of the electron is 1, and the charge of the electron is 1; M_I is the ratio of the mass of nucleus I to the mass of the electron; Z_I is the atomic number of nucleus I. Electrons and nuclei are labeled by lower- and upper-case subscripts, respectively. The additive terms in Eq. 1 from left to right are the kinetic energy of electrons, the nuclear kinetic energy, and the electron-nucleus, electron-electron, and nucleus-nucleus Coulomb interactions. Within the Born-Oppenheimer approximation, based on the fact that nuclei are much heavier and therefore much slower than electrons, the many-body wavefunction is factorized into a wavefunction for the electrons that depends parametrically on the nuclear coordinates and a nuclear wavefunction. In such conditions the many-body Schrödinger equation can be separated in the electronic and nuclear problems. In the solution of the Schrödinger equation for electrons, the nuclear kinetic energy is zero and the nuclear Coulomb interaction enters as an external potential: this is category (fp1) in the introduction above, namely, the search for the electronic structure of frozen systems. On the other hand, the ground-state electronic Hamiltonian can be used to determine the Hellmann-Feynman forces and evolve the nuclear coordinates either in time or toward the local minimum: this is category (fp2) above. The nuclei are treated as classical particles because of the heavy mass, relative to the electron mass. In many first-principle approaches, a nucleus is replaced by an ion core, which is the nucleus plus the core electrons, which are not explicitly included in the solution of the electronic Schrödinger equation. Electrons are inherently quantum particles, namely, their behavior cannot be explained or determined with the laws of classical physics. Therefore, first-principle methods are based on a quantum mechanical (QM) formulation.

The electronic problem is solved either by wavefunction-based methods, in which the Schrödinger equation for the many-electron wavefunction is solved, or density-based methods, in which the total energy is written as a functional of the electron density whose minimization produces the ground state. In all approaches summarized in the next three subsections, the single-electron wavefunction (a molecular orbital) needs to be expanded in a basis set. Popular basis sets are Gaussians (Pople and Dunning sets) and

plane waves. Gaussians are localized on atoms, while plane waves are delocalized and offer a convergence criterion. Localized basis sets are mostly used for molecules; plane waves are more appropriate for periodic crystals. Localized basis sets may cause a basis set superposition error (BSSE) for systems composed of multiple components, which must be corrected to predict meaningful formation energies [2].

Wavefunction-Based Methods

The many-electron wavefunction is antisymmetric for the exchange of any two electrons. Its most general form is an expansion of Slater determinants. In any computer implementation, this expansion is truncated to one (single-determinantal approaches) or more (multi-determinantal approaches) Slater determinants. In the first case, the many-body problem is reduced to many one-electron problems in which the potential energy in a single-electron Hamiltonian is the sum of the electron-nucleus Coulomb interaction and the Hartree and exchange terms of the electron-electron Coulomb interaction. The Hartree term is the energy of electrostatic interaction of an electron with all electrons. The exchange term removes the unphysical interaction of each electron with itself (i.e., the so-called electronic self-interaction energy) that is inherent in the Hartree term, by an exchange (or Fermi) hole surrounding each electron. This is a manifestation of the Pauli exclusion principle that forbids two electrons with the same spin to have the same spatial localization (namely, to occupy the same molecular orbital). This is the Hartree-Fock (HF) method, which neglects all (dynamical) correlations among electrons apart from the static correlation established by the Pauli principle. In fact, the correlation energy is defined, in computational chemistry and physics, as the difference between the exact energy and the HF ground-state energy of a system. The HF method is solved by a self-consistent field (SCF) procedure starting from guess single-particle orbitals and changing them iteratively under the orthonormalization condition until the energy change between two iteration steps is below a prefixed threshold, and it is assumed that the minimum system energy is thus achieved.

Electron correlation is included in the configuration interaction (CI) scheme by keeping more than one Slater determinant in the many-body wavefunction expansion. This procedure is computationally very cumbersome, because many Slater determinants should be included to respect physical conditions, such as the extensive nature of the energy: all approximate forms of CI, except for full CI (which is exact in the limit of complete basis set), do not have this property. Methods beyond HF (or post-HF methods) that recover this property are coupled cluster (CC) approaches and Møller-Plesset (MP) perturbation theory. The most affordable of such methodologies, which have given satisfactory results for DNA bases and base complexes, are CC with single and double excitations (CCSD) and MP to the second order (MP2). Other successful post-HF methods are the complete active space self-consistent field (CASSCF) approach and its second-order perturbation formulation (CAS-PT2): these methods yield reliable results in complex chemical situations.

All these methods, along with semiempirical treatments (INDO, ZINDO, and similar), are efficiently described in standard quantum-chemistry textbooks [2].

Density-Based Methods

Wavefunction-based methods reach a great accuracy and therefore predictive power. However, their use is limited to few-atom systems due to their big computational cost and bad scalability with the size of the system. A viable way to solve, even if in an approximate way, the many-electron problem relies on density-based methods, where the electronic density instead of the wavefunction is used as the fundamental variable. Density functional theory (DFT) is based on the Hohenberg-Kohn (HK) theorems (1964) [3] and permits, via the solution of the Kohn-Sham (KS) ansatz (1965), to afford the calculation of the ground-state properties of systems of many electrons with reasonable accuracy and predictive power.

The first HK theorem proves that the ground-state properties of a many-electron system, subject to an external potential $V_{ext}(r)$, are uniquely determined by its electronic charge density. In the second HK theorem, an energy functional of the density is defined:

$$E[\rho] = F[\rho] + \int V_{ext}(r)\rho(r)dr, \quad \text{with} \quad F[\rho] = T[\rho] + V_{ee}[\rho],$$

where T is the electron kinetic energy and V_{ee} is the electron-electron interaction. $F[\rho]$ is a universal functional, in the sense that it is the same in all physical systems. The theorem proves that the exact ground-state energy is a global minimum of this functional and the density that minimizes the functional is the exact ground-state density ρ_0.

The HK theorems reduce the complexity of the many-electron problem from 3N spatial degrees of freedom of the wavefunction (N number of electrons) to just three spatial degrees of freedom of the density. This is an exact reformulation of the many-body Schrödinger equation, but its effective exactness is limited because the form of the universal functional $F[\rho]$ is unknown.

Practical applications of DFT are doable in the KS ansatz, whose basic idea is to replace the interacting many-electron system with a fictitious system (the KS system) made of noninteracting electrons that generate the same ground-state density ρ_0 of the real system. For the KS system, the energy functional is

$$E[\rho] = Ts[\rho] + \frac{1}{2}\int \frac{\rho(r)\rho(r')}{|r-r'|} drdr' + \int V_{ext}(r)\rho(r)dr + E_{xc}[\rho], \quad (2)$$

where $T_s[\rho]$ is the kinetic energy of the noninteracting system. The second term is the classical electron-electron repulsion (Hartree term), and $E_{xc}[\rho]$ is the "exchange-correlation" functional, which contains all the many-body effects of the system. The wavefunctions of the KS system can be then expressed as a single Slater determinant, as the system is composed of independent particles. Minimizing Eq. 2 with respect to the density brings to the KS equations, a set of N coupled single-particle Schrödinger-like equations:

$$\left(-\frac{1}{2}\nabla^2 + \int \frac{\rho(r)}{|r-r'|}dr' + V_{ext}(r) + \frac{\partial E_{xc}[\rho]}{\partial \rho}\right)\psi_i^{KS} = \varepsilon_i^{KS}\psi_i^{KS}, \quad (3)$$

in which the subscript i labels each of the N electrons.

The total density can then be written as a sum over all electrons of the single-particle electron densities in terms of the single-particle wavefunctions:

$$\rho(r) = \sum_{i=1}^{N} f_i \left|\psi_i^{KS}\right|^2 \quad (4)$$

where f_i is the occupation number and $\frac{\partial E_{xc}[\rho]}{\partial \rho}$ is the exchange-correlation potential, $V_{xc}[\rho]$. It is clear that the complexity of the problem is strongly reduced, but the dependence of the E_{xc} functional on the density is not known, and therefore, the solution of Eq. 3 requires approximations. Various approximations have been proposed since the early days of DFT, and development of exchange-correlation functionals is still an active field of research.

The simplest family of E_{xc} functionals derives from the local density approximation (LDA), according to which the functional depends on the electron density only at each point. The LDA was successfully used for several years for periodic crystals and is reliable in cases in which the electron density resembles that of a homogeneous electron gas: this condition poorly describes the situation in molecules, and this is why traditionally the electronic structure of molecules was computed with wavefunction-based methods. The first level of improvement relative to the LDA is constituted by the GGA (general gradient approximation) functionals, where an explicit dependence on the density gradient is also considered: popular examples are PBE and BLYP.

GGA functionals gave the earliest acceptable results of DFT on molecular systems. More recently, hybrid functionals were developed: these are not pure functionals of the density, but they also depend on the KS wavefunctions, including fractions of the exact exchange term from the Hartree-Fock (HF) theory and exchange-correlation terms from other approximations, for instance, GGA. Several hybrid functionals were developed, differing from each other essentially for the amount of exact exchange. Hybrid functionals yield a better description of molecular properties with respect to "pure" density functionals. It is important to note that these functionals have a dependence on empirical parameters, usually assigned by fitting procedures on atomic and molecular experimental data. The most popular and successful hybrid functionals that have been considered for studying DNA from first principles are B3LYP (20 % of HF exchange), PBE0 (25 %), BHH (50 %), M05-2X (57 %), and the M06 family with different percentages of exact exchange. BHH and the M06 family are now considered the most accurate for DNA, at least for spectroscopy and electron transfer predictions. Another important set of functionals for the study of DNA is the VdW-DF family, designed to include in DFT the description of Van der Waals interactions, which are entirely missed from "pure" density functionals.

Kohn-Sham energies and wavefunctions computed by DFT can be used as a starting point for Green function-based many-body perturbation theory (MBPT) methods, as the GW approximation for the computation of quasiparticle energies and the Bethe-Salpeter equation for absorption spectra. MBPT methods correct DFT eigenvalues for estimating quasiparticle energy levels as measured, e.g., by photoemission experiments.

The basic idea of the DFT, i.e. the possibility to consider the electronic density as the fundamental variable to solve the many-body problem, has been extended in 1984 to time-dependent phenomena (TDDFT) [4]. TDDFT is based on the Runge-Gross theorem, and the time-dependent KS (TDKS) equations allow calculations of the dynamical properties of many-electron systems in the presence of time-dependent potentials. TDDFT, as DFT, is an exact theory and in principle can be used for any time-dependent situation; it is mostly used for the computation of photoabsorption cross-section spectra and excitation energies of molecular systems. Exchange-correlation potentials in TDKS equations are much more complex than in static DFT, because at each time, they depend on the value of the density at all previous times. Most TDDFT calculations are done with potentials derived in the adiabatic approximation, which consists of considering the ground-state exchange-correlation potential evaluated at the instantaneous time-dependent density, i.e. discarding all the memory effects:

$$V_{xc}^{A}(r,t) = V_{xc}^{gs}[\rho_0](r)\big|_{\rho_0(r)=\rho(r,t)}. \qquad (5)$$

Despite its crudeness, the approximation in Eq. 5 gave reliable results for the optical absorption and circular dichroism (CD) spectra of DNA bases and fragments of stacked and H-bonded pairs. CD spectroscopy is particularly powerful to discriminate between various helix motifs, and the possibility of computing this property opens the way, by comparison to experimental data, to resolve DNA structures that cannot be resolved by conventional methods such as X-ray and nuclear magnetic resonance (NMR).

The quality of TDDFT results is strongly dependent on the choice of the exchange-correlation functional; in particular, charge-transfer excitations are poorly described by local or semilocal functionals.

Ab Initio Molecular Dynamics

Molecular dynamics (MD) simulations solve the equations of motion of each atom in a target system in three dimensions:

$$\vec{F}_i = m_i \vec{a}_i, \qquad (6)$$

where i is a running index over all atoms in the system, m_i its mass, $\vec{a}_i$ its acceleration, and $\vec{F}_i$ the force acting on it at a given instant of time. In turn, the force is expressed as the first derivative of the potential with respect to the atomic coordinate and the acceleration as the second derivative of the

atomic coordinate with respect to time, which results in the second-order differential equations:

$$\frac{m_i d^2 \vec{r}_i}{dt^2} = -\frac{dV}{d\vec{r}_i}. \quad (7)$$

The numerical solution of Eq. 7 yields the ith atomic coordinate at time $t + \delta t$ given its value at times t and $t - \delta t$. When continued in time, this procedure gives the time evolution of the structure. Necessary ingredient to implement this procedure is the knowledge of the interatomic potential $V\left(\vec{r}_i\right)$.

The most widely used implementation of MD is a classical version in which information about the electrons in the system is not necessary, because the potential is parametrized from experimental or theoretical data: this is not a first-principle approach; we mention it here to highlight, by comparison, the crucial aspect of ab initio MD. With the available computer power, classical MD simulations of 10–20 bp DNA molecules can routinely cover a time span of the order of 1 microsecond. The timescale of 1 millisecond is presently attainable only with a special hardware, the computer Anton, donated to the University of Pittsburgh by David E. Shaw and available to the research community by proposal submission and evaluation.

Ab initio MD does not use empirical parameters to express $V\left(\vec{r}_i\right)$. Each atom is composed of a nucleus and a certain number of electrons. In the spirit of the Born-Oppenheimer approximation, the motion of nuclei and electrons occurs on very different timescales, because their masses differ by three orders of magnitude. Consequently, the solution of the many-body problem nuclei + electrons can be separated: (i) at frozen atomic coordinates, the electronic ground state of the system can be determined with the electronic structure self-consistent methods summarized above; (ii) the ground-state energy of the electronic system, along with the ion-ion interaction, defines the instantaneous potential for that atomic configuration and can be used to solve Eq. 7; (iii) the new instantaneous coordinates are found. Then the cycle goes on giving the time evolution of the system. This is also known as Born-Oppenheimer molecular dynamics. This approach is rather cumbersome because it requires at each atomic configuration the attainment of the exact ground state of the electrons, which may require many self-consistent cycles. It was unfeasible 30 years ago, when in 1985 Roberto Car and Michele Parrinello invented the first practical solution of ab initio MD, now known as the Car-Parrinello (CP) method [5]. CP MD does not search for the instantaneous electronic ground state at each atomic configuration and rather evolves nuclei and electrons simultaneously in a Lagrangian formulation, keeping the electrons very close to the ground state by a suitable choice of the integration time and effective mass. The time step for solving Eq. 7 with classical MD is of the order of 1 femtosecond. The time step for solving Eq. 7 with quantum MD (either Born-Oppenheimer or CP) is of the order of attosecond, because of the resolution necessary to probe the electron dynamics, which is about three orders of magnitude faster than the nucleus dynamics. Consequently, the early ab initio MD simulations were limited to few picoseconds and nowadays can reach the order of nanoseconds.

Another approach to solve the quantum MD problem is based on the density functional tight-binding (DFTB) MD, in which the electronic problem is formulated as a tight-binding approach with parameters derived from DFT: this approach is not fully first principle.

Examples of applications of CP and DFTB MD to DNA oligomers are included later.

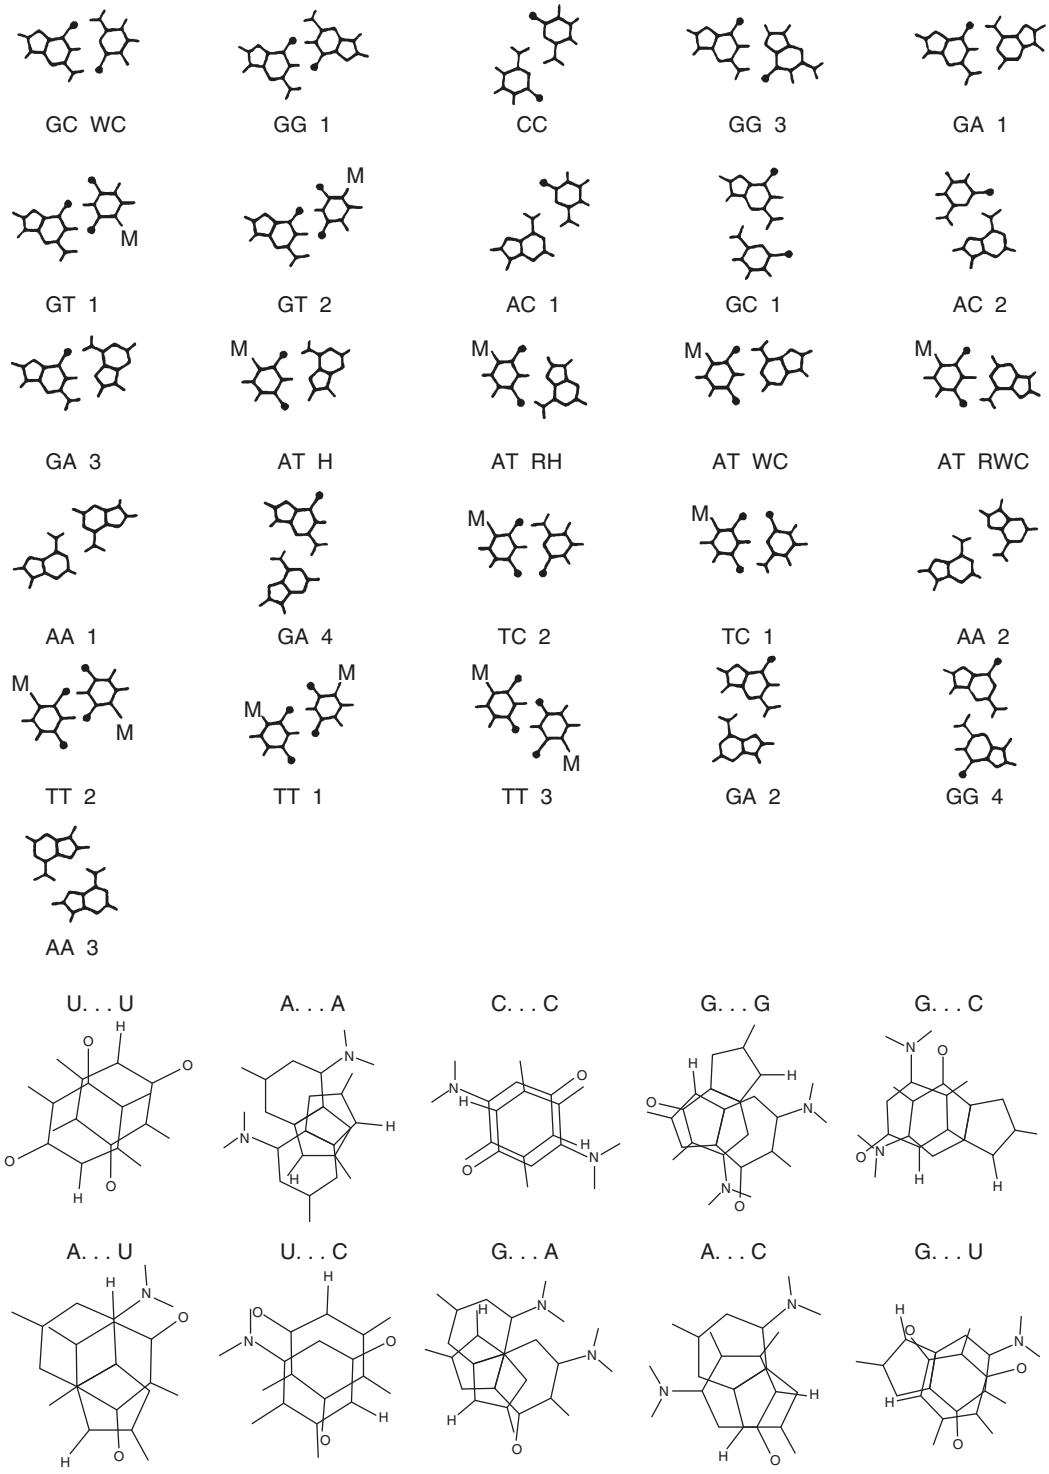
Electronic Structure Calculations of DNA Fragments

The field of "DNA from first principles" evolved from addressing individual components to larger fragments and then entire oligomers, as the methods became more efficient and the computers more powerful. Particularly, crucial achievements were from the hardware point of view, the attainment of efficient parallel scaling of electronic structure and molecular dynamics codes, and from the methodological point of view, the

development of gradient-corrected and hybrid density functionals in DFT.

Structure, Electronic Structure, and Optical Properties of Bases and Base Pairs

Quantum mechanical studies of DNA bases and base pairs were initially driven by the need of knowing the structure of nucleic acids to a high degree of accuracy, for implications in biology and medicine.



Ab initio methods were applied since the late 1980s to investigate equilibrium structures of isolated, stacked, and H-bonded bases, as well as the pairing energies. These studies had the twofold objective of studying the structure and determining interaction energy parameters to enable classical simulations. The early calculations were performed without inclusion of electronic correlations, while calculations done in the mid-1990s started to include a consistent treatment of electronic correlations, which substantially enhanced the accuracy and predictive power.

An early work that still remains a landmark was done in the 1990s by Hobza, Leszczynski, Sponer, and collaborators [6]. The individual bases were investigated at the MP2 level with medium-sized polarized basis sets of atomic orbitals, to disclose the energetics of tautomers, finding that for each base the most favorable tautomer is the one that occurs in nature. The results also disclosed the internal structure of each base, which was later an important input knowledge for studies of base pairs. Other properties of interest in the studies of single bases were the protonization energies, the electrostatic potential, the polarizability, the gas-phase electron affinities and ionization potentials, and the nonplanarity. In the past decade, individual bases were also the object of coupled cluster, multiconfigurational perturbation, and DFT + GW methods, with comparable results.

The first reliable data on the geometry and binding energy of all possible H-bonded base pairs (Fig. 2) was obtained by relaxing the structure at the HF level and determining for the optimized bases the stabilization energies at the MP2 level, using a minimal basis set with diffuse polarization functions and including the BSSE. The results revealed that the Watson-Crick GC pair is the most energetically favorable, while the most unfavorable is an AA pair. It was found that the number of H-bonds is not the only factor that controls the energetics of H-bonding; the dipole interaction is another major determinant. Several pairs were found to be not exactly planar, especially due to rotations of the NH_2 group because of partial sp^3 N hybridization. Later on, canonical and noncanonical H-bonded base pairs were computed with higher-order wavefunction-based methods and DFT, with particular attention to noncanonical pairs with a biological relevance (e.g., methylated cytosine).

The computation of stacked base pairs (called dinucleotides in genomic contexts, Fig. 2) presents more difficulties than that of H-bonded pairs, because stacking implicitly involves dispersion interactions, which are accounted for in the correlation part of the Coulomb electron-electron interaction, which is absent in HF and difficult to grasp in post-HF methods with limited basis sets and in DFT. Thus, the early studies were done without structural relaxation, because the optimized structure could not be trusted. Alternatively, researchers performed single-point (frozen-structure) calculations of several structures for each dinucleotide, varying the internucleotide distance, angle, and inclination and determining the minimum energy geometry for each dinucleotide. For the most favorable pair, the stabilization energy could then be computed at the MP2 level. In a second stage, MP2 was applied for full gradient optimizations of the stacked pairs. Results indicated that the stacking energies for the various pairs span approximately the same range as H-bonding energies. More refined calculations including a better description of the correlation (coupled cluster method in the complete basis set limit) started in 2002, and nowadays, available results from wavefunction-based calculations for the stacking energy of DNA bases are very accurate, indicating energies in the range of 0–15 kcal/mol depending on the context, with an accuracy of around 3 %.

The application of DFT methods to DNA base pairs became credible only with the advent of hybrid functionals that include a part of exact

DNA from First Principles, Fig. 2 H-bonded and stacked base pairs found from first principles. H-bonded (*top*) and stacked (*bottom*) base pairs that have been computed by various first-principle methods in the 1990s (Adapted with permission from Hobza and Šponer [6]; copyright 1999 American Chemical Society)

exchange and after 2008 the VdW-DF family of functionals. However, not all functionals perform well. Specialists in the field can now find in the literature an assessment of which functionals are reliable and which are not, so that basic tests are less mandatory than in the past, though it is always a good idea to carry out tests of the functional and of the basis set before undertaking any prediction of structural, optical, and electronic properties (including electron transfer parameters) of DNA bases and their pairs. DFT methods have become increasingly important with increasing the size of the target system, because correlated wavefunction-based approaches become unfeasible beyond a small size.

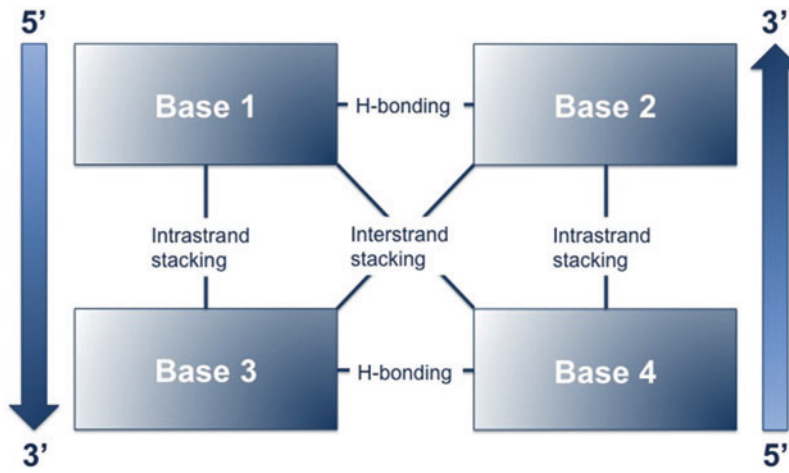
Computation of the optical properties of nucleobases and base pairs is an important tool for understanding the interaction of DNA with sunlight. Excited states of nucleic acids are the first step of chains of events responsible for UV photodamage, leading to photocarcinogenesis; they also play a role in the mechanisms of ultrafast non-radiative decay pathways and DNA photoprotection. Both wavefunction-based methods and TDDFT approaches have been used to study optical properties of DNA bases [7]. There is a good agreement between different computational methods in the calculation of the bright $\pi\pi^*$ transitions (from a bonding orbital π to an antibonding orbital π^*), also relative to experimental findings. Such a good agreement is not found for the "dark" $n\pi^*$ transitions (from a nonbonding state to an antibonding orbital π^*). The discrepancies are partially due to the lack of reliable experimental data for these transitions, because of the very weak oscillator strength. Despite the difficulty of predicting $n\pi^*$ transitions from first principles, they are intensely studied because of their biological relevance. In fact, detailed knowledge of the relative energies of $n\pi^*$ and $\pi\pi^*$ excitations is of paramount importance in understanding the processes of dissipation of the electronic energy by internal conversion and prevention of photochemical reactions.

Gas-phase calculations carried out at the CIS, CAS-PT2, and TDDFT levels agree in assigning the energy order between $\pi\pi^*$ and $n\pi^*$ transitions: the lowest-energy excitation is $\pi\pi^*$ in guanine and cytosine and $n\pi^*$ in thymine and uracil. The situation is more controversial for adenine: wavefunction-based methods predict the lowest-energy excitation to be $\pi\pi^*$, while TDDFT(B3LYP) results indicate the lowest-energy excitation to be $n\pi^*$, very close in energy to a $\pi\pi^*$ excitation.

Some excited-state calculations have been done with the inclusion of solvent effects either implicitly with dielectric models or explicitly (mostly water), allowing comparison with solution-phase experiments. It has been found that the presence of the solvent destabilizes the $n\pi^*$ transitions (blueshift), while the $\pi\pi^*$ transitions are almost unaffected. The different sensitivity of the $n\pi^*$ and $\pi\pi^*$ excited states to the solvent environment leads to a reversal of the ordering of these transitions in thymine, uracil, and adenine, as computed by TDDFT.

Besides the interpretation of spectroscopy experiments, a thorough knowledge of the excited-state properties of DNA bases is of crucial importance for the rationalization of the observed non-radiative decay of the excited states to the ground state. Several computational studies have been dedicated to this issue by looking at the excited-state potential energy surfaces along a reaction coordinate, and different mechanisms have been proposed, involving nonadiabatic coupling between low-lying excited states and conical intersections between excited- and ground-state energy surfaces.

Calculations of the optical excitations of Watson-Crick base pairs revealed that both $\pi\pi^*$ and $n\pi^*$ transitions could be identified as excitations of the monomeric units, leading to an absorption spectrum very similar to the sum of the monomeric spectra. While the $\pi\pi^*$ excitations are only slightly affected by H-bonding, the $n\pi^*$ excitations reveal a consistent blueshift. Different calculations also showed the appearance of excited states of charge-transfer (CT) character (excitations formed by a transition from an electron in a moiety to a virtual state in the complementary moiety). These excitations are particularly interesting for implications in proton-transfer reactions between bases upon light excitation [8]. They have higher energies than the first $\pi\pi^*$ and $n\pi^*$, except for TDDFT



calculations with local or semilocal functionals, which poorly predict CT excitations.

The most evident effect of stacking interactions in the optical properties of nucleobases is the hypochromism, namely, the reduction of the absorption intensity upon stacking: the intensity of a peak for stacked bases is lower than the sum of the intensities for individual bases. This effect is routinely used in experiments to monitor denaturation of the DNA double helix. TDDFT calculations on stacked bases correctly predict hypochromicity, as well as some measured sequence-dependent shifts. Combining computational affordability and reliability, TDDFT is now considered a reference framework to study the optical absorption properties of nucleic acid fragments, except for CT excitations that rigorously still need higher first-principle methods (or calibrated exchange-correlation functionals). Despite this limitation, in the last years, TDDFT has also been applied to elucidate decay mechanisms of stacked base pairs, trying to explain the observed long lifetime in terms of possible decay channels that involve CT states. Long-lived excited states are potentially responsible for DNA photodamage, which is a relevant target in biomedical research.

Structure, Electronic Structure, and Optical Properties of Stacked Base-Pair Dimers

Calculations on stacked base-pair dimers (Fig. 3) constitute a step toward more realistic systems in which both H-bonding and stacking interactions are present and influence each other in a sequence-dependent manner. The results of quantum chemical calculations based on CCSD(T) theory produced an energy ranking for ten possible dinucleotides that appear in base-pair dimers with idealized structures. Individual intrastrand stacking energies are in the range of −10.8 to −1.6 kcal/mol, and individual interstrand stacking energies are between −4.8 and 3.1 kcal/mol, with a total stacking energy for the stacked dimers in the range between −17.3 (CG step) and −11.2 (GG step) kcal/mol. Cooperativity between stacking and H-bonding was revealed in vertical ionization energies in a dimer of two AT pairs with the purines on the same strand.

It was also recognized that the magnitude of the intrinsic gas-phase stacking energy could not be determined unambiguously using a single geometry for each sequence, because of the strong dependence of the interaction energy on the structural configuration. Sequential multistep procedures, based on pruning base-pair dimers from different snapshots from a molecular dynamics simulation and computing the electronic structure of such dimers, have been used to have quantitative estimations of relative energies between different structures. These calculations showed that the sequence dependence of the thermodynamic stability of DNA cannot be explained in terms of intrinsic interactions between stacked base pairs only.

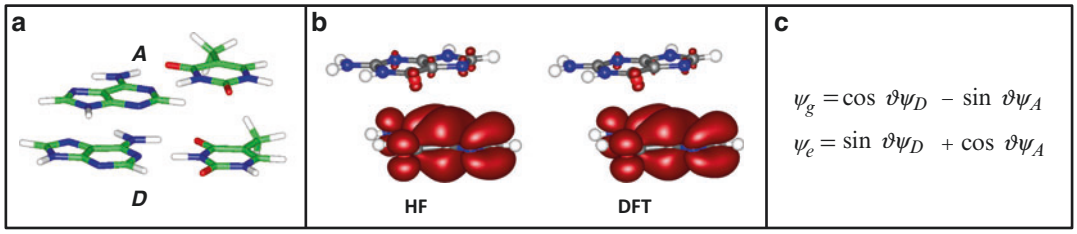
DNA from First Principles, Fig. 3 Scheme of bp dimers. Cartoon of a base-pair dimer with indication of H-bonding and interstrand and intrastrand stacking interactions. Each of Bases 1 and 3 can be G, C, A, or T; Bases 2 and 4 will be the complementary base

Sequence-dependent conformations of DNA base-pair dimers have been also the subject of study using DFT methods. These studies have provided additional information on the sequence-dependent DNA stability, for instance, highlighting the role of the binary interaction between adjacent sets of base pairs in the twist variability observed in high-resolution experiments and identifying the role of the methyl group of thymine in the stabilization of the base-pair dimers.

Calculations of optical properties and excited-state energy profiles on stacked base-pair dimers appeared in the first decade of the twenty-first century and were performed by TDDFT. Using the adiabatic local density approximation, it has been shown that the absorption spectra of stacked bp dimers reveal the fingerprints of both H-bonding (spectral shifts) and stacking (hypochromicity) [9]. TDDFT calculations performed using the M05-2X functional and including solvent effects via a continuum model on stacked AT dimers identified dark CT states that involve both interstrand and intrastrand effects. By relaxing the lowest bright and dark excited-state geometries, Vincenzo Barone and collaborators were able to disclose the specific role of H-bonding and stacking in the excited-state decay and in emission processes in stacked bp dimers. These calculations showed that the optical absorption in DNA fragments is a concerted activity of all bases, while emission occurs essentially from individual monomers, mainly thymine. It was shown that the ultrafast excited-state relaxation channel exists in the $(A:T)_2$ dimer and that CT states between stacked adenines are responsible for the long living states observed experimentally in A-rich DNA. The dynamics of excited states was related to femtosecond pump-probe measurements in single-strand poly-A and double-strand poly(dA)-poly(dT) fragments by Bern Kohler and coworkers.

Electronic Coupling Parameters Between Stacked Bases and Base Pairs

Charge (electron or hole) transfer in DNA, which can involve either electrons or holes, is an important property that has been studied for both biomedical research (oxidative damage and repair, biosensors) and nanotechnology (electrical materials and devices).



All information required to investigate a charge-transfer system can be derived from the wavefunctions for its ground state and for the excited states that correspond to the charge localizations before and after the transfer process. Such wavefunctions can be obtained by DFT, HF, or post-HF methods.

Diverse models have been proposed to describe hole transfer through DNA depending on the chain length: ballistic transport, superexchange, hopping, and phonon-assisted polaronic hopping. Whatever the mechanism for charge propagation through the DNA chain, the electronic coupling between adjacent nucleobase pairs is a critical determinant of charge-transfer efficiency.

Since hole transfer through the π-stacked nucleobases dominates the charge propagation, the electronic couplings can be computed for the fundamental DNA unit shown in Fig. 4, where D (A) is the electron donor (acceptor) group. The inter-pair electronic coupling V_{DA} may be obtained from the adiabatic ground (ψ_g) and first-excited (ψ_e) wavefunctions. The diabatic (localized) electronic wavefunctions with the excess charge (an electron hole) on $A(\psi_A)$ and $D(\psi_D)$ are linear combinations of ψ_g and ψ_e. A master approach to computing the coupling from the adiabatic wavefunctions is the generalized Mulliken-Hush (GMH) method, where

$$V_{DA} = \frac{\mu_{ge}\Delta E_{ge}}{\sqrt{\left(\mu_g - \mu_e\right)^2 + 4\mu_{ge}^2}}. \qquad (8)$$

In Eq. 8, μ_{ge} is the adiabatic dipole transition moment, i.e., the matrix element of the dipole moment operator between ψ_g and ψ_e; $\mu_g(\mu_e)$ is the mean dipole moment in state $\psi_g(\psi_e)$; and $\Delta E_{ge} = \langle\psi|H|\psi_e\rangle - \left\langle\psi_g|H|\psi_g\right\rangle$ is the adiabatic vertical excitation energy (H is the electronic Hamiltonian). This method has been mostly implemented by using HF one-electron wavefunctions. In the HF approach, ψ_D and ψ_A may be obtained as symmetry-broken diabatic wavefunctions. Symmetry breaking means that

DNA from First Principles, Fig. 4 Charge transfer through DNA. (**a**) Adenine-thymine dimer. A base pair is the donor (*D*) group and the other is the acceptor (*A*) group. (**b**) A reduced model for hole transfer between the two adenines. In a one-electron picture, the HOMO of the base couple represents the ground-state charge density. HF and DFT calculations produce very similar HOMO distributions for this system. (**c**) The adiabatic and diabatic sets of electronic states are related by a rotation of an angle ϑ in the system state space. $\psi_D(\psi_A)$ is not an electronic wavefunction for the $D(A)$ group, but a wavefunction for the total *D*-*A* system with the hole essentially localized on $D(A)$

the wavefunction has a lower symmetry than the nuclear framework [2]. This error in the HF calculation of a wavefunction is exploited to obtain generally nonorthogonal wavefunctions whose asymmetry implies charge localization in *A* or *D*.

Related to the above approach is the fragment charge difference method, which writes the electronic coupling as

$$V_{DA} = \frac{\Delta q_{ge} \Delta E_{ge}}{\sqrt{\left(\Delta q_g - \Delta q_e\right)^2 + \left(\Delta q_{ge}\right)^2}}. \qquad (9)$$

Here, $\Delta q_g(\Delta q_e)$ is the difference between the excess charges on the *D* and *A* fragments in state $\psi_g(\psi_e)$; $\Delta q_{ge} = \sin 2\vartheta$, where ϑ is the rotation in the system state vector space that brings from the adiabatic to the diabatic states under the condition of maximum *D*-to-*A* CT (see Fig. 4). The fragment charges are well defined in a DNA dimer or in other systems with well-separated *D* and *A* groups, for which Eq. 9 is then isomorphic to Eq. 8. Equation 9 has been evaluated using the HF Koopmans approximation, which allows estimating ΔE_{ge} as the energy difference between the highest occupied molecular orbital (HOMO) and the HOMO–1 for the neutral DNA system. These electronic orbitals become the lowest unoccupied molecular orbital (LUMO) and the HOMO in the cationic CT system, and changes in the orbitals are neglected.

Applications of this method to DNA dimers with all possible combinations of nucleobases showed secondary effects of the backbone and high sensitivity of the inter-pair coupling to DNA step parameters, thus corroborating that thermal fluctuations can produce significant changes in the electronic couplings, hence failure of the Condon approximation (which neglects the coupling dependence on the nuclear coordinates *Q*). This conclusion was confirmed by coupling calculations on molecular dynamics (MD) snapshots via an INDO/S implementation of the GMH method and via a method that estimates the coupling from the overlap between the nonorthogonal HOMOs of individual bases.

Indeed, in most real situations, the initially produced charge localization and its transfer to a neighboring site amount to initial and final states with non-negligible spatial overlap, and the effective electronic coupling or (generalized) transfer integral or ET matrix element (or, also, electronic coupling matrix element) that enters the CT rate constant is [10]

$$V_{DA}(Q) \equiv \frac{1}{1 - S_{DA}^2(Q)} \left| H_{DA}(Q) - S_{DA}(Q) \frac{H_{DD}(Q) + H_{AA}(Q)}{2} \right|, \qquad (10)$$

where $H_{IF} = \langle \psi_I | H | \psi_F \rangle$ $(I, F = D \text{ or } A)$, $S_{DA} = \langle \psi_D | \psi_A \rangle$, and the Q dependence is explicitly shown. Given physical localized electronic states, a good orthogonal diabatic set needs to be related to the nonorthogonal one by the Löwdin transformation [10], which imposes a constraint on the rotation angle ϑ.

The fragment charge difference method, using HF wavefunctions, neglects the dynamic electronic correlation, which is instead included, albeit with approximations, in DFT. The use of DFT faces two technical issues: the inaccuracy in the description of the adiabatic excited state and unphysical electronic self-interaction [2]. The first problem was solved by a recent approach that avoids using ψ_e [10] by writing the effective electronic coupling in Eq. 10 as

$$V_{DA} = \left| \frac{\alpha\beta}{\alpha^2 - \beta^2} \Delta E_{DA} \left(1 - \frac{\alpha^2 + \beta^2}{2\alpha\beta} S_{DA} \right) \frac{1}{1 - S_{DA}^2} \right| \tag{11}$$

where $\alpha \equiv \left\langle \psi_D | \psi_g \right\rangle, \beta \equiv \left\langle \psi_A | \psi_g \right\rangle$, and $\Delta E_{DA} = \langle \psi_D | H | \psi_D \rangle - \langle \psi_A | H | \psi_A \rangle$. This formula can be used in any computational setup, but has been mainly implemented with DFT and hybrid-DFT approaches, defining the many-body electronic states as Slater determinants of KS orbitals. Despite a long-standing debate on the use of these orbitals, several studies have shown that the "the KS molecular orbital model is physically well-founded and has certain advantages over the HF model" [11] because it includes electronic correlations.

Equation 11 can be used for any Q and S_{DA} values, except for the transition-state coordinate Q_t (where $\Delta E_{DA} = 0$; note that ΔE_{DA} can be used as a reaction coordinate [12]). At $Q = Q_t$, Eq. 11 has an eliminable discontinuity. The condition $Q = Q_t$ defines a zero-measure subset of a molecule conformational space, and Eq. 11 can be used with high accuracy also in the close proximity of Q_t (as measured by $\Delta E_{DA}/V_{DA} \ll 1$), where the Condon approximation is valid.

Hybrid DFT implementations of Eq. 11 using the BHH hybrid exchange-correlation functional and the Minnesota hybrid meta-functionals M06-Hf and M06-2X led to descriptions of DNA electronic properties (including V_{DA} and ΔE_{gs}) in agreement with post-HF results from CASSCF and CAS-PT2. Knowledge of the ground-state wavefunction of the CT system, in addition to the diabatic states where the hole is localized on the donor or on the acceptor, offers the best description of a CT system insofar as this state is properly described. In this regard, functionals such as B3LYP, PBE, and B97 do not allow for suitable implementations of Eq. 11, because they poorly describe electron density tails. For example, even a slight delocalization of the excess charge in the ground state can lead to a significant overestimation of the electronic coupling for weakly coupled off-resonance D and A groups. The diabatic CT states can be obtained from fragment approaches or from constrained DFT (CDFT), which provides the most "natural" approach to charge localization within DFT [10].

The fragment-orbital approach is adopted (i.e., CT between the HOMOs of neighboring DNA bases is considered) in DFTB methods, which are based on the expansion of the DFT energy with respect to charge density fluctuations. DFTB uses simplifications that enable relatively fast electronic coupling estimates in entire DNA oligomers.

Larger Fragments

Electronic properties of DNA fragments larger than dimers of base pairs have been studied using high-accuracy first-principle methods. Particular attention has been devoted to CT through trimers of bases and base pairs.

In the case of superexchange, the electronic coupling involved in the CT rate constant is

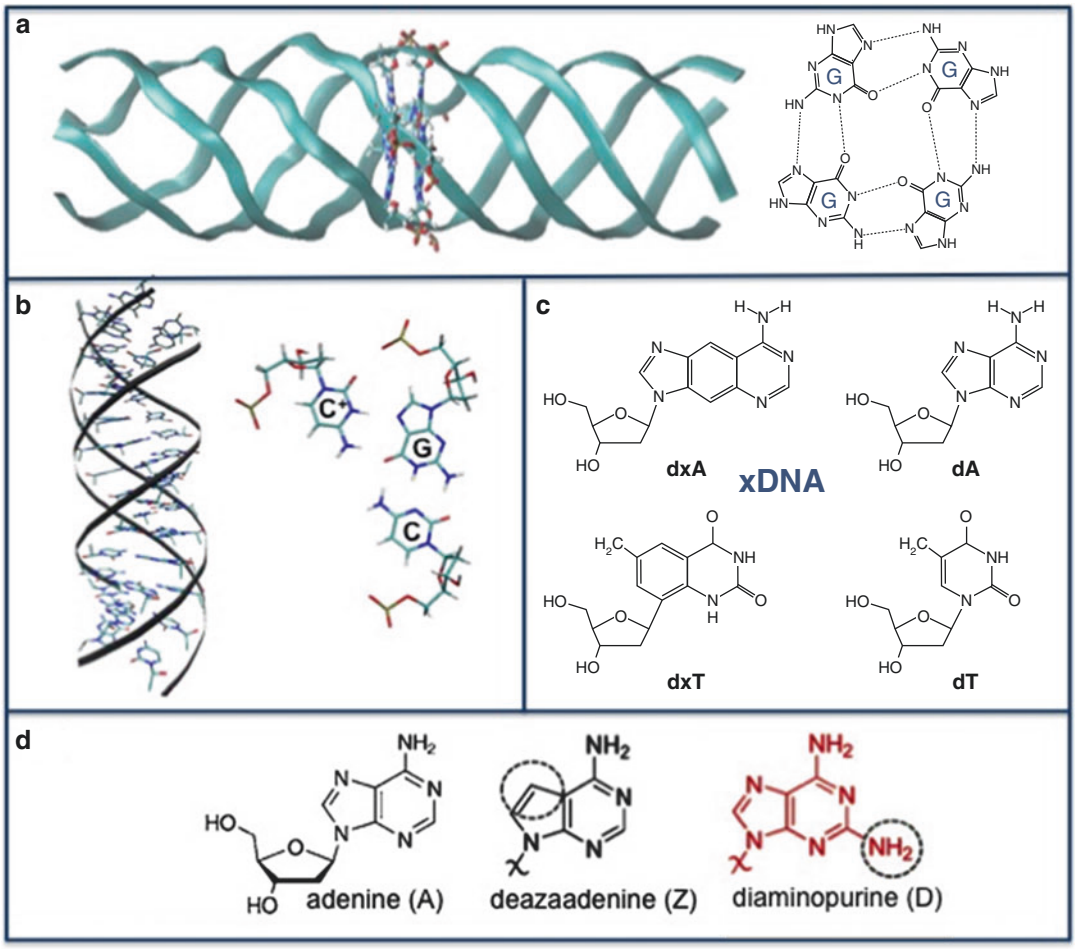
$$V_{\text{superexchange}}(D, A) = \frac{V(D, \mathrm{B}_1) V(\mathrm{B}_n, A)}{\Delta E(D, \mathrm{B}_1)} \prod_{j=1}^{N-1} \frac{V(\mathrm{B}_j, \mathrm{B}_{j+1})}{\Delta E(D, \mathrm{B}_{j+1})}, \tag{12}$$

where N (for a trimer, $N = 1$) is the number of nucleobases bridging the D and A base pairs (or bases, when full localization of the transferring

charge on bases is assumed to reduce the computational cost); $V(D, B_1)$, $V\left(B_j, B_{j+1}\right)$, and $V(B_n, A)$ are the couplings between adjacent base pairs; and $\Delta E(D, B_j)$ are the respective energy gaps. Equation 12 represents a tight-binding bridge model, where electronic couplings between nonadjacent sites are neglected, and assumes that the localization of the transferring excess charge on a bridge site would imply much higher system energy than its localization in *D* or *A*. Hence, the bridge levels correspond to virtual states, that is, superexchange is bridge-mediated *D*-*A* tunneling. Equation 12 is derived using the Green's function formalism [13] and reduces to Larsson's formula for a single bridge.

The hole transfer matrix elements involved in Eq. 12 have been computed by using molecular orbitals from semiempirical (CNDO/S) computations, HF wavefunctions, DFT wavefunctions constructed from the HOMOs of individual bases, CASSCF on base trimers, and full-electron hybrid-CDFT computations on base-pair trimers.

Tunneling through the coupling in Eq. 12 shows an approximately exponential decay with the *D*-*A* distance, and charge hopping (i.e., transient real occupation of bridging bases by the transferring excess charge) takes place at sufficiently large *D*-*A* distances. Each hop amounts to a superexchange process. The hopping mechanism is expected to produce an approximately inverse relation between the number of hopping sites (namely, *D*-*A* distance) and *D*-to-*A* arrival rate. A different inverse-power law is observed in highly nonlinear DNA chains, such as DNA hairpins. The transition from coherent tunneling to incoherent hopping has been predicted theoretically and experimentally. First-principle evaluation of this mechanism transition is nowadays enabled by supercomputers that allow DFT computations on hundreds of atoms.



An alternative interpretation of the experiments that showed the coherent-to-incoherent transition of the hole transport mechanism at sufficiently long *D*-*A* distances is based on the phonon-assisted polaron hopping mechanism. Thermal nuclear motions (phonons) support the propagation (hopping) of the geometry distortion and environmental charge polarization that accompanies and promotes the hole localization over some bases (which is a "delocalization" compared to the hole localization on a single base). Hence, the charge transport proceeds through hopping of the quasiparticle made of the electron hole and surrounding polarization field (polaron). The delocalization of the polaron is limited by the environmental charge polarization, the internal reorganization of the base pairs, and the same continuous nuclear fluctuations.

The delocalization of the hole on more base pairs can lead to an intermediate mechanism, distinct from both superexchange and hopping, where coherence is not completely lost during the hole motion. Experimental evidence reported by Barton's group at Caltech points to transport via DNA domains that form transiently, irrespective of the charge and therefore distinct from the DNA segments implied in a polaron. This interpretation might be related to recent theory on resonant enhancement of charge transport efficiency: fluctuations to transient geometries that bring multiple nucleobases into electronic energy degeneracy may support band-like transport during the resonance lifetimes.

Exotic Helical Conformations and Modified Bases

Nucleic acid conformations are not limited to the canonical Watson-Crick double helix. Topological and chemical modifications are viable, either naturally or through (bio)chemical synthesis. The most relevant modifications in biology and medicine are the G-quadruplex (topological) and methylated cytosine (chemical). Other nucleic acid motifs that have been studied from first principles include triplex DNA (a triple helix mediated by protonated cytosine), xDNA (in which each base can be expanded by an aromatic cycle), and duplex DNA where natural bases are modified with the insertion or removal of functional groups or oxidation. These motifs are illustrated in Fig. 5.

The G-quadruplex (Fig. 5a) is a quadruple helix constituted of only the guanine base. The stacking unit is the G-tetrad, composed of

DNA from First Principles, Fig. 5 Modified DNAs that have been studied from first principles. Structure of selected hexotic nucleic acids. (**a**) The G-quadruplex, with formula of the stacking unit on the right. (**b**) The C^+GC triplex, with atomic structure of the stacking unit on the right. (**c**) Size-expanded bases dxA and dxT, compared to dA and dT. (**d**) Chemical modifications of adenine that have been used in charge-transfer experiments

four guanines fortified by eight H-bonds. G-quadruplexes can form from genomic sequences (only 2–4 G-tetrads, ~1–2 nm long including edge loops) or be produced by enzymatic synthesis (several tetrads, up to 1 μm long): in both cases, the folding results in several different polymorphs. The rigidity of this nucleic acid motif, the high density of stacking sites that give $\pi-\pi$ electronic coupling, and the possibility of controlling the length and the folding process make it appealing for nanotechnologies. Indeed, a special G-quadruplex constituted of four parallel strands connected by biotin-avidin recognition is the only form of nucleic acids that has so far supported significant electrical currents over lengths of up to 100 nm when deposited on an inorganic substrate. First-principle DFT calculations of the electronic coupling parameter between two adjacent G-tetrads in a frozen configuration, extracted from a MD trajectory of a parallel G-quadruplex at room temperature, revealed a much higher value than all published values for duplex DNA and for other G-quadruplex polymorphs. Furthermore, the ab

initio electronic coupling was used to validate a multi-hopping model that successfully fits the measured current-voltage characteristics. Earlier work on the ground-state electronic structure of G-quadruplex was done on two stacked tetrads and on a periodic wire: for the latter, channels in which electrons can move with high mobility were found. Dynamical approaches to the G-quadruplex are mentioned in the next section.

CT parameters have been computed from first principles for frozen xDNA base-pair dimers with different structures, revealing that this variety can be more conducive to charge transfer than natural dsDNA. However, a strong dependence on the structural details was also revealed, to an extent that should be analyzed in a dynamical fashion in order to have predictive power for real measurements.

M-DNA is another possible modification that is not illustrated in Fig. 5: it is obtained by doping duplex DNA with transition metal cations. There is no three-dimensional atomic structural resolution for M-DNA. Hypothetical models, which are supported by high-level DFT calculations by Di Felice and coworkers of the ground-state electronic structure and optimized geometries, consist of a metal ion that breaks the hydrogen bonds within a natural base pair and forms partially chemical bonds with the bases. M-DNA mimics have been obtained experimentally and simulated from first principles also using hydroxypyridone instead of the natural bases.

Other DNA modifications illustrated in Fig. 5d are described below with a combination of classical MD and DFT.

Relation Between Atomic and Electronic Structure

It was already noted in the preceding sections that the atomic structure and electronic structure are intertwined. In particular, excited-state electronic properties, including CT, are very sensitive to structural details. Because in reality the conformation of nucleic acids is dynamic and not static, it is important to compute the electronic and optical properties not for just one conformation but for several of them. The average of the electronic properties for several viable dynamical conformations, or the weighted average over few representative structures that embody the whole trajectory, can be taken as a good estimate of the real situation. The dynamics should be computed for stable oligomers or wires in a solution environment. This computational program has become feasible only in the twenty-first century and more effectively in the past few years. Two possible strategies of doing such calculations are summarized, along with salient results, in the next two subsections.

We note that the backbone has been neglected in most of the QM calculations on frozen atomic configurations, guided by the fact that charge-transfer and optical excitations involve electronic orbitals of the bases. However, dynamical calculations, which target the determination of the structure and structural fluctuations, cannot omit the backbone because this is an integral part of the structure. Hence, in ab initio MD, the backbone is directly included in the quantum dynamics, while in a combined multistep approach, it must be included in the classical MD step and can be included or excluded in the QM step. The environment must also be included in molecular dynamics, and usually, it has been included as explicit solvent molecules and counterions. QM calculations can be done in the gas phase or solution phase: most solution-phase QM calculations on DNA have been done with implicit solvent models.

Ab Initio Molecular Dynamics Simulations

The straightforward approach is to perform MD simulations in which the potential energy to evolve the motion of the nuclei, instead of being parametrized, is given by the ground-state electronic energy at that instantaneous configuration. The nuclei are evolved with Newton's classical equations of motions, but with forces that encompass the full quantum information for the electrons.

The group of Michele Parrinello published in 2002 in *Physical Review Letters* a report on the

electronic structure and optical conductivity of wet Z-DNA, a periodic d(GpC) obtained from a quenched CP MD simulation. In 2005, the same group published in the same journal a dynamical simulation of the same periodic polymer at both room temperature and low temperature, on the timescale of 1 picosecond. In both letters, the BLYP functional was used: we have pointed out above that BLYP is not capable of catching subtle correlation effects; yet, the ground-state electronic structure is qualitatively correct. These works excluded a strict relationship between helix distortions and charge localization and suggested a proton-coupled charge-transfer mechanism.

Marcus Elstner, Gianaurelio Cuniberti, and coworkers simulate charge transfer through DNA with DFTB simulations: the methodology has been published in the *Journal of Physical Chemistry* in 2008. This approach can directly compute the electronic couplings, in a structurally sensitive manner. Only the relevant part of the system, where one wants to evaluate CT, is treated with a quantum method, while the rest of the system is classical (QM/MM). The structure influences the charge-transfer parameters simultaneously in two ways: (i) by computing the transfer integrals for many instantaneous configurations and (ii) through a coupling term between the QM and MM parts. The method is very efficient and enables simulations of realistic oligomers. However, it is based on a simplified description of both the ground-state electronic structure and electronic couplings. It has been applied to a variety of duplex DNA sequences and a G-quadruplex, taking into account chemical modifications of the bases. For the G-quadruplex, this methodology revealed superior charge-transfer efficiency than in duplex DNA.

Intrinsic limitations of these methodologies are the short time over which the dynamics can be sampled, which is generally of the order of picoseconds, and the restricted precision on the electronic structure.

Combined Multistep Procedure

The multistep procedure consists of these four steps: (I) performing classical molecular simulations in explicit solvent of stable oligomers over timescales that can reach 1 ms and are routinely hundreds of nanoseconds; (II) extracting bp dimers or G-tetrads or C^+GC triads (Fig. 5), including or not the backbone, from several dynamical snapshots at regular time intervals or from representative structures obtained by clustering the trajectories or by physicochemical principles; (III) computing the ground-state electronic structure and/or electronic couplings and/or optical properties for such small fragments of stacked units; and (IV) evaluating the desired property as a time average or weighted average.

Uzi Landman, Gary Schuster, and coworkers published in *Science* in 2001 quantum mechanical calculations for native and oxidized configurations of the 4-bp B-DNA duplex d(5'-$G_1A_2G_3G_4$) with an intact sugar-phosphate backbone including Na^+ ions and a hydration shell. The quantum calculations were performed, in the framework of DFT with a gradient-corrected functional, for several configurations extracted from a classical MD simulation of the same oligomer at room temperature. This work proposed an ion-gated mechanism for charge transport through DNA, based on the fact that the dynamical distribution of ions and water molecules controls the charge delocalization through the stack. In this early work, the electronic coupling parameters were not explicitly computed.

Troisi and Orlandi in 2002 published a similar approach but including the explicit calculation of electronic couplings as a function of time. The work included classical MD simulations of some duplex DNA oligomers over 40 ps, followed by quantum chemical calculations between all the pairs of adjacent bases extracted from the dynamical snapshots at regular time intervals of 10 fs. Overall, couplings between adjacent bases showed an oscillatory behavior and a large variance.

The hybrid multistep approach was applied by Di Felice and collaborators to duplex and triplex DNA, with publications appearing in 2012–2013. In all cases, the classical MD simulations were of the order of 20–50 ns. For duplex DNA and

G-quadruplex, the target property was charge transfer, while it was optics for triplex DNA. Overall, these studies proved that the methodology is powerful and sufficiently manageable to be applicable to many different structures.

Alexander Voytiuk, in collaboration with the groups of Anh Tuan Phan and Maria-Elisabeth Michel-Beyerle, applied the procedure to compute transfer integrals for many different G-quadruplex motifs, for identifying which topology yields high inter-tetrad electronic coupling and which geometrical parameter of the helix mostly affects the electronic coupling. In this study, published in 2013, the MD simulations were conducted for 200 ns each, for various quadruplex topologies. The electronic structure was simplified at the semiempirical INDO/S level, and the fragment charge difference method was used for the computation of the electronic coupling parameter. The study pointed out a remarkable dependence of CT rates on the G-quadruplex structure, while it could not identify a single helix parameter that by itself correlates strongly to the inter-tetrad electronic coupling. This negative conclusion is a hint to the cooperativity of the entire quadruplex structure to determine the electronic coupling. Rigorously, this study is not from first principles, because INDO/S is a semiempirical treatment of the QM problem, but we mention it here because it is very similar in spirit to combined MD + QM studies in which the QM part is from first principles.

The groups of George Schatz and Jiry Sponer applied a similar methodology to investigate the optical excitations and the relative stability of DNA duplexes with various sequences, respectively. A combination of MD and quantum chemistry was also applied, in a somewhat different spirit, to compute the optical conductivity of wet DNA and physical approaches to DNA sequences: for the optical conductivity, the full time dependence was not studied; for DNA sequencing, the study was actually not from first principles because a parametric tight-binding model was employed for the electronic structure.

Conclusion

The investigation of DNA from first principles has undergone a terrific progress since the first applications in the mid-1980s. The early studies could only be done for individual bases in frozen configurations and at a relatively low level of theory (missing or poor description of electronic correlations). Nowadays, it is possible to compute entire oligomers at high levels of theory (good description of electronic correlations) including structural fluctuations. Results of first-principle calculations of DNA bases, base pairs, base-pair dimers, larger fragments, and entire oligomers have contributed to our understanding of the structure, electronic and optical properties, charge-transfer efficiency, and structure-electronic relationships in a variety of nucleic acid motifs, including duplex and triplex DNA and the G-quadruplex. This knowledge is fundamental to control oxidative damage and repair of the genetic material and to manipulate DNA derivatives for nanotechnology applications. Yet, we still need to develop the link from fundamental properties to principles of operation, as well as the rules for controlling the structure to obtain a desired function. We expect that in the near future, this gap will be filled if the enthusiasm in DNA from first principles will be sustained: the available information will be largely expanded and will be much more accurate, because of the present possibility of computing real systems with high accuracy, enabled by theoretical, software, and hardware developments. Ultimately, studies of DNA from first principles will have a huge impact not only on fundamental science and technology but also on society through health-care and commercial products.

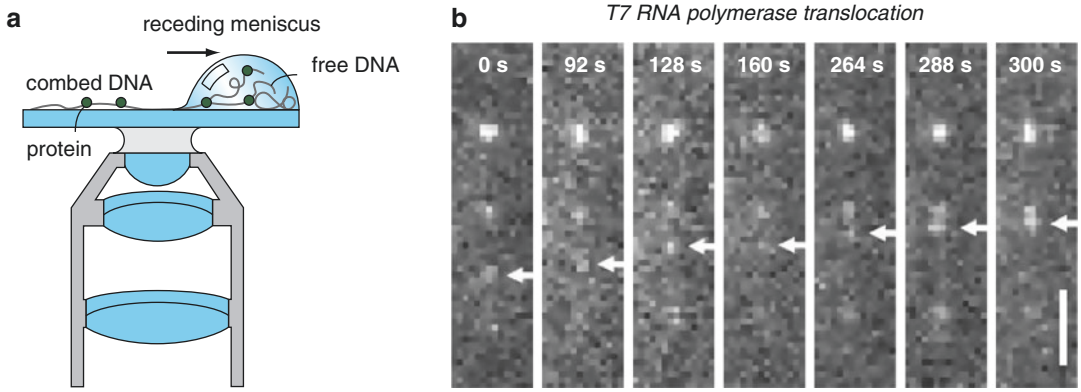
Definition

DNA manipulation based on nanotweezers is the handling of DNA molecules using very small-size tweezers for characterization purpose.

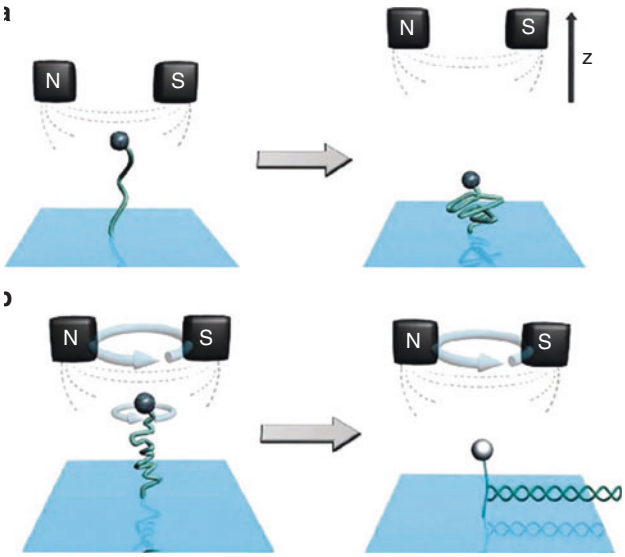
Introduction

Since the 1990s, studies on single-molecule biophysics have brought a large amount of information on DNA properties. The development of manipulation techniques and especially the emergence of new tools have allowed direct measurement of physical and chemical properties of DNA molecules. These properties turn out important for cell machinery understanding as structural modifications in the molecule induce changes in the interaction properties with proteins, and conversely.



For example, topoisomerase enzymes unwind and wind DNA in order to facilitate DNA replication. A helicase protein moves along the unwound DNA, separating the two annealed nucleic acid strands of the double-stranded DNA. Polymerase enzymes reproduce new strands against the single-stranded DNA templates. During all the replication process, the physical properties and the biological functions of the DNA change according to the interactions with the proteins allowing (or proscribing) the sequence of events [1–4].

Large advances in fluorescence microscopy have been achieved enabling single-molecule visualization. Scientists developed powerful manipulation techniques where the DNA is attached to a substrate and observed by fluorescence [5, 6]. For instance, polymerase enzymes were fluorescently labeled to monitor their activity on a single molecule of DNA previously combed onto a surface (Fig. 1) [7]. Meanwhile, new approaches were developed to directly interact with the molecules, e.g., optical tweezers, magnetic tweezers (Fig. 2), atomic force cantilevers (known as AFM), and microfibers [8–10]. The response of single DNA molecules to a stretching or a twisting stress gives direct access to the physical properties of the molecule. Remarkable mechanical properties of DNA were discovered, and protein interactions with DNA were measured by the changes in the mechanical properties of the strands [11, 12].



However, all these new techniques, providing remarkable access to the biophysical properties of the molecules, still have a low throughput since the setup preparation and the experimentations are quite long and done one at a time. To move toward systematic biological or medical analysis, micro- and nano-electromechanical systems (known as MEMS or NEMS for Micro/Nano-Electro-Mechanical Systems) are more appropriate tools. They can be easily integrated into biological manipulation systems. Furthermore they are produced at low cost by an efficient microfabrication process. In [13], DNA molecule bundles are trapped, stretched, and characterized in solution by silicon nanotweezers (Fig. 3).

Working Principle

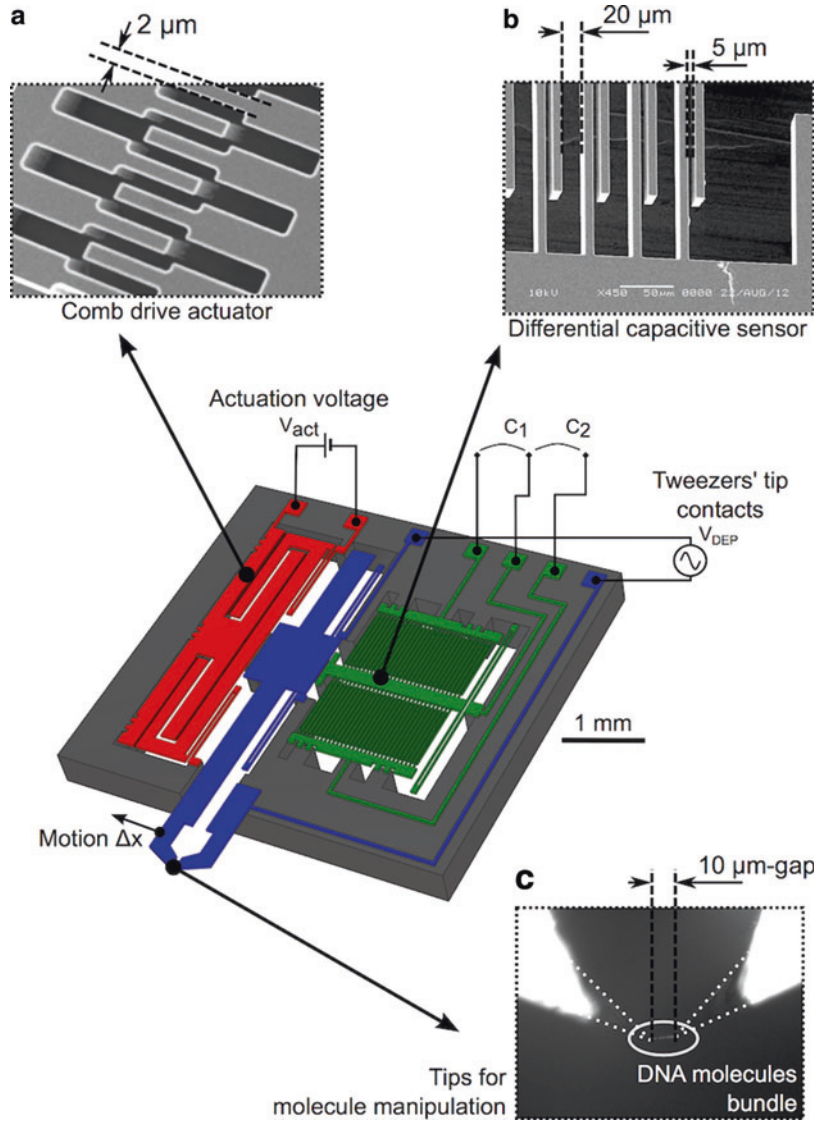
Figure 3 shows a three-dimensional illustration of the nanotweezers. Two sharp tips are used as electrodes for either dielectrophoresis trapping (cf. "Trapping of DNA molecules" section) or conductivity measurements on the molecules. One tip is fixed when the other one can be moved through an electrostatic actuation. The gap between the electrodes can be sensed through

DNA Manipulation Based on Nanotweezers, Fig. 1 Attachment of single DNA molecules on a glass surface. (**a**) DNA is stretched and immobilized using hydrophobic glass substrate and a receding air-water interface. After rehydratation of the sample the DNA stays firmly attached to the glass slide [5]. (**b**) Real-time visualization of the motion of RNA polymerase along combed DNA strands. The directional movement of the RNA polymerase along a DNA molecule is observed using the incorporation of fluorescent into RNA strand (Scale bar = 2.5 μm) (Image from Ref. [7])

DNA Manipulation Based on Nanotweezers, Fig. 2 Schematic sketch of the magnetic tweezer technique. (**a**) The setup consists of a DNA molecule to a magnetic bead and to a glass surface, for instance. A pair of magnets above the bead produces a magnetic field gradient (*dashed lines*) along the axial direction, which results in a force on the bead directed up toward the magnets. The magnets can be lowered (raised) to increase (decrease) the stretching force acting on the DNA. Magnet north and south poles are labeled N and S, respectively. (**b**) Thanks to the magnetic properties of the bead, torque forces can also be applied to the sample. Starting from a relaxed configuration, the DNA molecule becomes more and more tangled as the magnets rotate, and eventually loops of helices (plectonemes) are formed. The formation of plectonemes induces a progressive linear decrease in the DNA extension, which is analogous to the decrease in extension of a twisted and tangled telephone cord (Image from Ref. [20])

a differential capacitor that measures the relative displacement of the moving electrode. Thus, the device consists of three parts:

- Two sharp tips (Fig. 3c)
- A series of electrostatic comb-drive actuators (Fig. 3a)
- A differential capacitive sensor (Fig. 3b)



Since [14], laterally driven electrostatic comb drive architectures are commonly used in MEMS devices with many industrial applications (e.g., microresonators, switches, micromirrors, accelerometers). When a voltage is applied between the two electrodes, the mobile parts move along the electric field paths tending to reduce the gap between the electrodes.

A differential capacitance sensor measures the tip displacement. This sensor is well adapted for bulk micromachining and compact integration [15]. The sensor consists of a series of central plates that move relatively to fixed external plates, forming two variable capacitances C_1 and C_2. The values of the capacitances change inversely with the gap between the electrodes. However, the measurement is linear for small displacements (<100 nm) compared to the capacitance gap (5 μm). Hereafter, the capacitance variations are measured with an electronic read-out allowing static or dynamic displacement measurements.

The micromachining of the device and of the sharp tips is explained in the next section, and the role of the sharp tips is discussed in the DNA trapping section.

Microfabrication of the Nanotweezers

The silicon nanotweezer with sharp tips is fabricated using standard micromachining from a

DNA Manipulation Based on Nanotweezers, Fig. 3 3D schematic of the silicon nanotweezers for DNA manipulation and characterization. Overall dimensions are 4.5 × 4.5 × 0.5 mm. The tweezers consist of an electrostatic actuator in red, a capacitive sensor in *green,* and sharp tips in *blue*. Applying a voltage V_{act} moves the mobile tip, and the displacement changes the sensor capacitance values C_1 and C_2, which are measured with an adequate electronic read-out. On the other hand the tips are also electrodes that allow applying an electric field in between the tips for molecule trapping. (**a**), (**b**), and (**c**) are respectively close-up views of the actuator comb, the sensor capacitances, and the sharp tips with a bundle of DNA molecules

silicon-on-insulator (SOI) wafer [16]. The SOI wafer is based on a standard 400 µm-thick handle silicon wafer, 2 µm-thick buried oxide (BOX) layer, and 30 µm-thin silicon device layer. The crystalline orientation of the top silicon layer is <100>. The BOX is used both as a stopper for the deep reactive ion etching (DRIE) of the top and the backside silicon and as an electrical insulation layer between the comb drive actuator, the tips, and the capacitive sensor. Controlling the device thickness using SOI wafers and the in-plane dimensions using highly anisotropic etching (i.e., DRIE) allow getting uniform tweezers' characteristics and performances.

The sharp tips are fabricated by wet anisotropic etching along the <111> crystallographic planes. The tips engineering needs a sacrificial silicon nitride patterning, a local oxidation of silicon (LOCOS), and wet etching in TMAH.

Finally the process only requires three lithographic masks: one for defining the area of the sharp tips with silicon nitride (mask #1), one for microstructuring the top silicon layer (mask #2),

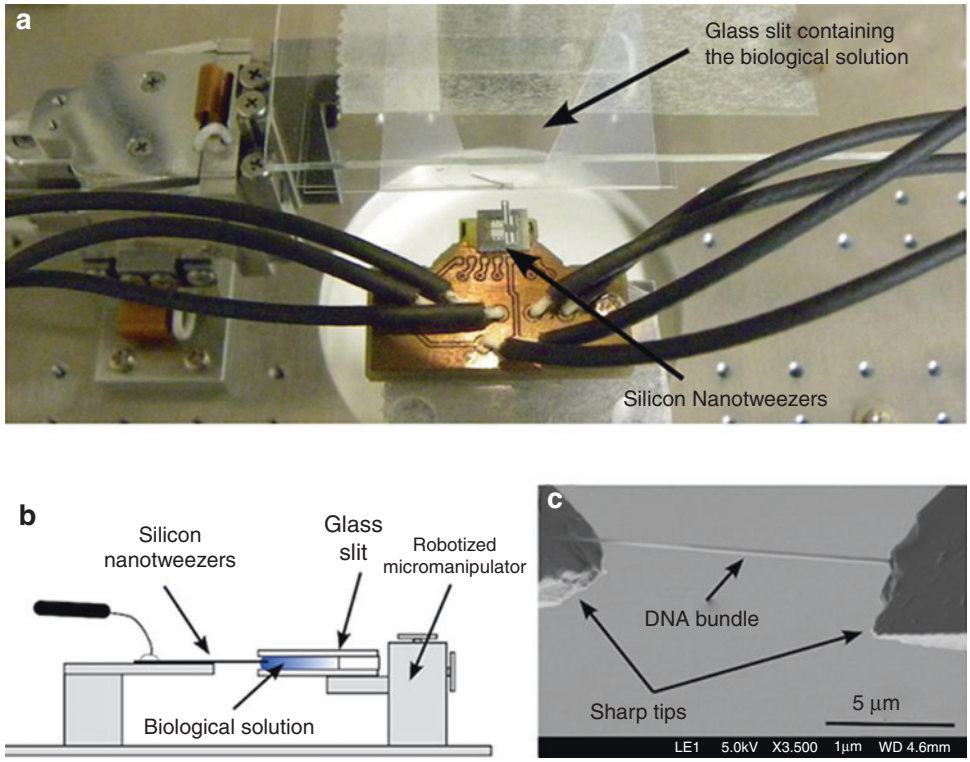
and one for the backside etching of the handling substrate (mask #3).

Here is the process flowchart:

1. Deposition of silicon nitride (SiN, 30 nm) by Low-Pressure Chemical Vapor Deposition (LPCVD)
2. Lithography along the <100> plane (mask #1) and Reactive Ion Etching (RIE) of SiN
3. Lithography of the top silicon structures (mask #2)
4. DRIE of top silicon, stopping on the BOX layer
5. Cleaning in "piranha"solution (called SPM) and slightly in buffered HF (10 s)
6. LOCOS of 300 nm
7. RIE of SiN 30 nm (sharp tips area)
8. TMAH wet anisotropic etching of silicon in order to obtain {111} facets (the other structures are protected by the 300 nm-thick oxide)
9. Cleaning in SPM and in buffered HF (until removing the 300 nm oxide layer)
10. Protection oxide growth (100 nm-thick)
11. Lithography on the backside of the wafer (double side alignment, mask #3)
12. DRIE of the backside 400 μm-thick silicon, stopping on the BOX layer.
13. Releasing of the movable structures in vapored HF
14. Deposition by evaporation of aluminum (Al, 100 nm) on the top side for enhancing DNA trapping.

Trapping of DNA Molecules

Figure 4c shows a scanning electron microscope (SEM) image of a DNA bundle anchored between the tips of nanotweezers. The trapping of molecule bundle with silicon tweezers is achieved when an AC electric field causes positive dielectrophoresis (called in the literature DEP): the DNA molecules elongate along the electric field lines and move toward the regions where the field is higher [17]. Furthermore, it is known that DNA molecules adhere to several electrochemically active metals such as Al or Pt. Sharp aluminum-coated electrodes create high electric gradients that cause the ends of the DNA strands to be attracted to the edges of the electrodes and become attached, resulting in the permanent formation of a bridging structure. Indeed, the adhesion of DNA molecules is strong on the metal as the molecules can be grafted (covalent bounds) on the metal and the metal oxide by its biphosphate function, present on the phosphate-deoxyribose backbone of the DNA, creating P-O-Metal link by hydrolysis reaction.



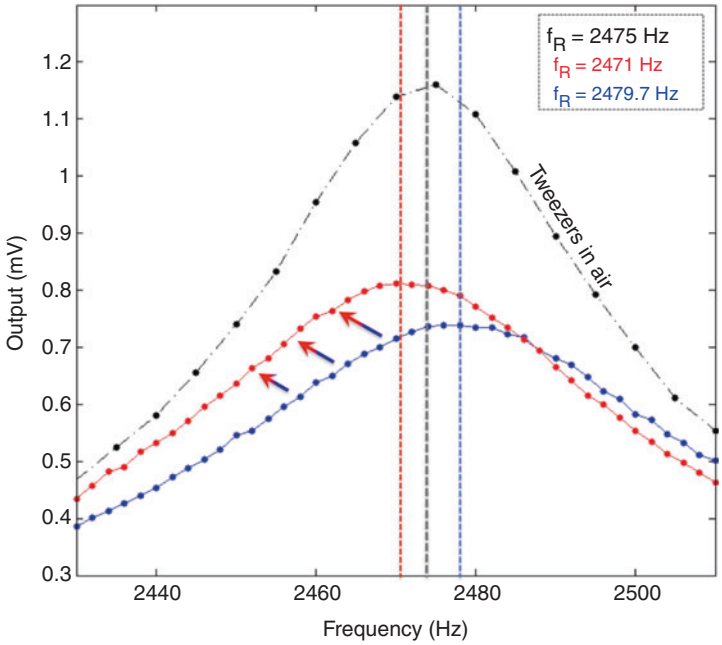
The method can be used to trap single DNA molecules by tuning the parameters appropriately. Two approaches for single-molecule studies are currently investigated:

- A double-stranded λ-DNA molecule can be isolated by DC electrophoresis and consecutively trapped by AC DEP in a microfluidic device.
- Using pulsed DEP, silicon tweezers can be used to trap a single DNA molecule in an aqueous solution.

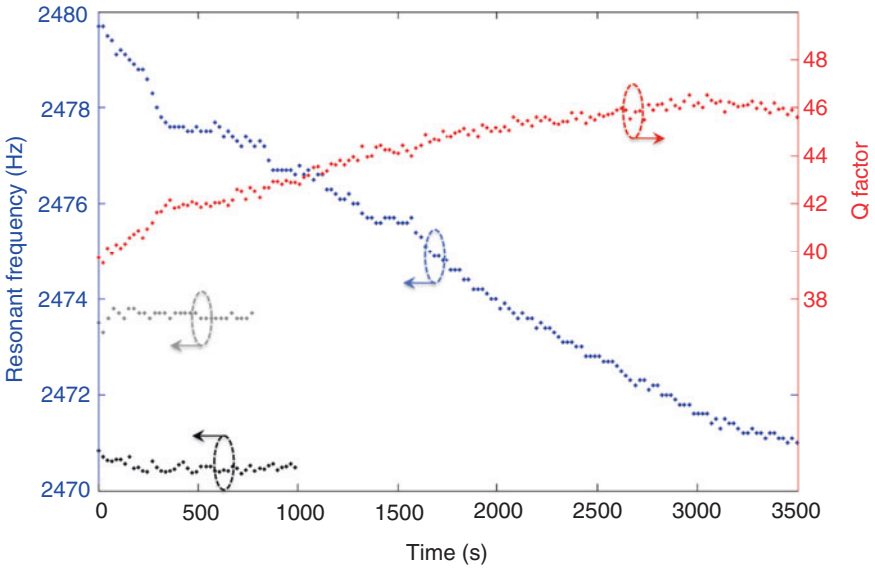
For all the biological experiments, a solution of double-stranded λ-DNA (48,502 base pairs, 16 μm-long) was used. Double-stranded λ-DNA is the DNA of a bacteriophage known as Enterobacteria phage λ or λ-phage. After dilution in deionized water, a small droplet of the solution was deposited on a glass slide. The tweezers were mounted on an optical microscope and brought in contact with the surface of the droplet with a 3D precision micromanipulator (Fig. 4). Then, a high AC electric field (2 MV/m or 2 V/μm at 1 MHz frequency) was applied for few seconds in order to capture DNA molecules. After the experiments, the bundle could be broken and removed by blowing air and rinsing the tips with water. The DEP experiment could be repeated as long as the aluminum coating remained on the silicon tips.

Biocharacterization on DNA Molecules

The characterization of biological samples is done through the mechanical response of the system {tweezers + DNA bundle}. The frequency response of the tweezers being well identified,



DNA Manipulation Based on Nanotweezers, Fig. 4 Trapping of DNA molecules with silicon nanotweezers by dielectrophoresis (*DEP*). (**a**) The experimental setup consists of the nanotweezers on its PCB with the electrical connections and a glass slit containing the biological solution. (**b**) The schematic shows the importance of the micromanipulators, on which are mounted the nanotweezers and the glass slit, for an accurate insertion of the tips in the DNA solution. (**c**) is a scanning electron microscope (*SEM*) image of a trapped molecule bundle. An AC voltage (V_{DEP}) applied between the two tips of the tweezers allows the attraction and the stretching of dielectric molecules as DNA



the changes in the frequency response are attributed to mechanical properties of the molecules. Recently, the real-time monitoring of the number of trapped DNA molecules during the dielectrophoresis was proven. During the trapping, the resonant frequency of the system increases resulting from the addition of the bundle stiffness to the sole tweezers' one. Simultaneously, the quality factor tends to decrease as the viscous loss increases with the bundle formation. In Fig. 5, a clear difference can be observed between frequency responses of the nanotweezers with and without trapped DNA molecules.

The DNA physical properties change with protein interactions, inducing changes of the whole system frequency response. Consequently nanotweezers emerge as a relevant tool even for characterization of DNA-protein interactions. In a recent study, the digestion of the bundle by restriction enzymes was monitored in real time through the frequency response of the nanotweezers. HindIII proteins are known as restriction enzymes for DNA. Indeed HindIII recognizes a specific sequence in the DNA code where to cleave the molecule [18].

As for the trapping of molecules, the resonance of the system {Tweezers + DNA bundle} is monitored. Conversely, the resonant frequency decreases till the initial resonant frequency of the sole tweezers when the digestion of the bundle is finished. The quality factor increases (Fig. 6). The evolution of the number of the molecules in the bundle, deduced from the single molecule stiffness ($k_{\lambda\text{-DNA}} = 30$ µN/m), shows an exponential decay

DNA Manipulation Based on Nanotweezers, Fig. 5 Tweezer resonance evolution during digestion of the DNA bundle. *Blue dots* are the frequency response of the tweezers with a bundle (in solution). *Red dots* are the response of the tweezers after digestion of the bundle (without any bundle in solution). For comparison, the resonance of the sole tweezers in air is plotted in *black* [19]

DNA Manipulation Based on Nanotweezers, Fig. 6 Time evolution of the resonance properties of the system {Tweezers + DNA bundle}. Resonant frequency (in *blue dots*) decreases with the digestion of the bundle by the restriction enzymes, when the quality factor (in *red dots*) increases. For comparison, resonant frequency of the sole tweezers is shown in deionized water (in *black dots*) and in a buffer without restriction enzymes (in *gray dots*) [19]

with time, the extracted time constant depending inversely on the enzyme concentration [19].

The minimum number of molecules that can be sensed using such silicon nanotweezers (about 20 molecules) depends on the minimum frequency variation that can be experimentally measured. In recent works dynamic control strategies have been developed to improve the overall

system sensitivity to the variation of the number of DNA molecules. The objective of such control strategy is the detection of a variation on a single molecule of DNA.

Outlook

Since the 1990s, remarkable techniques and tools were developed in order to perform single-molecule manipulation. Although these recent technological advances had a significant impact on the understanding of the interactions between DNA and the molecular machinery they present some drawbacks that open new research issues.

Indeed, in most of the biological experiments on DNA, manipulations rely on complex systems as optical or magnetic tweezers. These techniques have a low throughput since their implementation is quite long and difficult. Furthermore the molecule preparation is done one at a time. Here the direct sensing of biomolecular reactions is demonstrated using silicon nanotweezers. The experimental results obtained with the integrated MEMS nanotweezers showed the efficiency of such devices for DNA characterization. Nevertheless the main drawbacks of MEMS stem from the large size and high stiffness of the system relatively to the biological molecule properties. Control strategies that are currently under development aim at reducing the tweezer stiffness using feedback to improve the sensitivity of the whole process toward single DNA molecule variation.

The improvement of resolution in DNA sensing brought new perspectives and questions to address. The complexity of the DNA machinery is still far from being elucidated. More complex techniques or technologies are under development with, for instance, combination of different tools with fluorescent visualization, in order to follow multiprotein multienzyme complexes. Lastly, new developments on magnetic tweezers have recently achieved first results inside the nucleus of living cells. Performing such in vivo experiments inside cells will provide inestimable knowledge of molecule functions in their inherent environment.

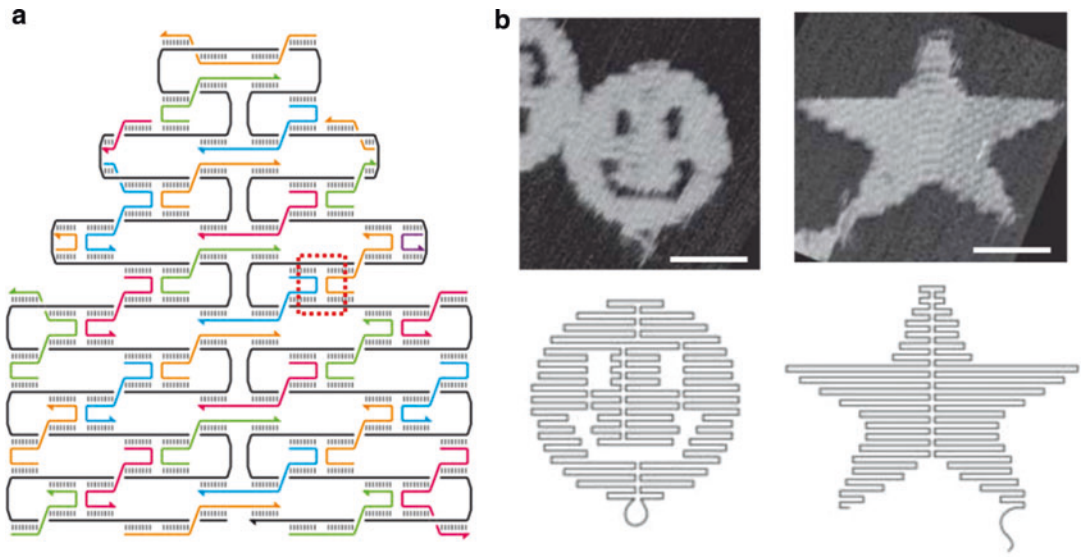
Structural DNA nanotechnology

Definition

DNA origami is a self-assembly technique, where a long single-stranded DNA (scaffold), usually from the genome of a bacteriophage, is folded into a designed path with the help of a set of synthetic oligonucleotides (staples). This bottom-up nanofabrication approach is capable of generating large numbers of identical DNA structures with designed geometry. The structures can be further functionalized or decorated to produce versatile nanostructures.

Introduction

Apart from being the genetic material for various forms of life, DNA has also emerged as a promising engineering material for nanotechnology. Based on its excellent ability to recognize its complementary sequence, the binding of DNA can be programmed by sequence design. This idea gave birth to the field of structural DNA nanotechnology. Carefully designed oligonucleotides have been demonstrated to assemble into polyhedrons [1], 2D lattice [2], and 3D crystals that facilitate X-ray crystallography [3]. The DNA origami method, first introduced in 2006 [4], marked another important development in structural DNA nanotechnology. This method significantly increased the available complexity of self-assembled DNA structures because of the increased number of synthetic oligonucleotides involved. Importantly, the method also relaxed the rather stringent requirement for stoichiometry and oligonucleotide purification [4], and thus, it simplified the procedure and made custom DNA structures more accessible to the science and engineering community.



DNA origami technique uses double-stranded B-form DNA [4] as building blocks to construct a programmed structure through self-assembly. A rather complex geometry of hundreds of double-stranded structural units can be programmed by designing the sequence of hundreds of staples. An eight-base-long

double-stranded basic unit is only about 2 nm in diameter and 3 nm long. Such small size means that features as small as a few nanometer can be generated, which is not easy even for advanced lithographic techniques. The ability of DNA origami technique to controllably generate complex structures with nanometer accuracy has made it a valuable nanofabrication tool for research purposes. The parallel, bottom-up nature of the method also makes large-scale production possible. This essay focuses on the fabrication of various nanostructures using DNA origami. The fabrication strategies are described along with the unique properties and applications of the resulting structures.

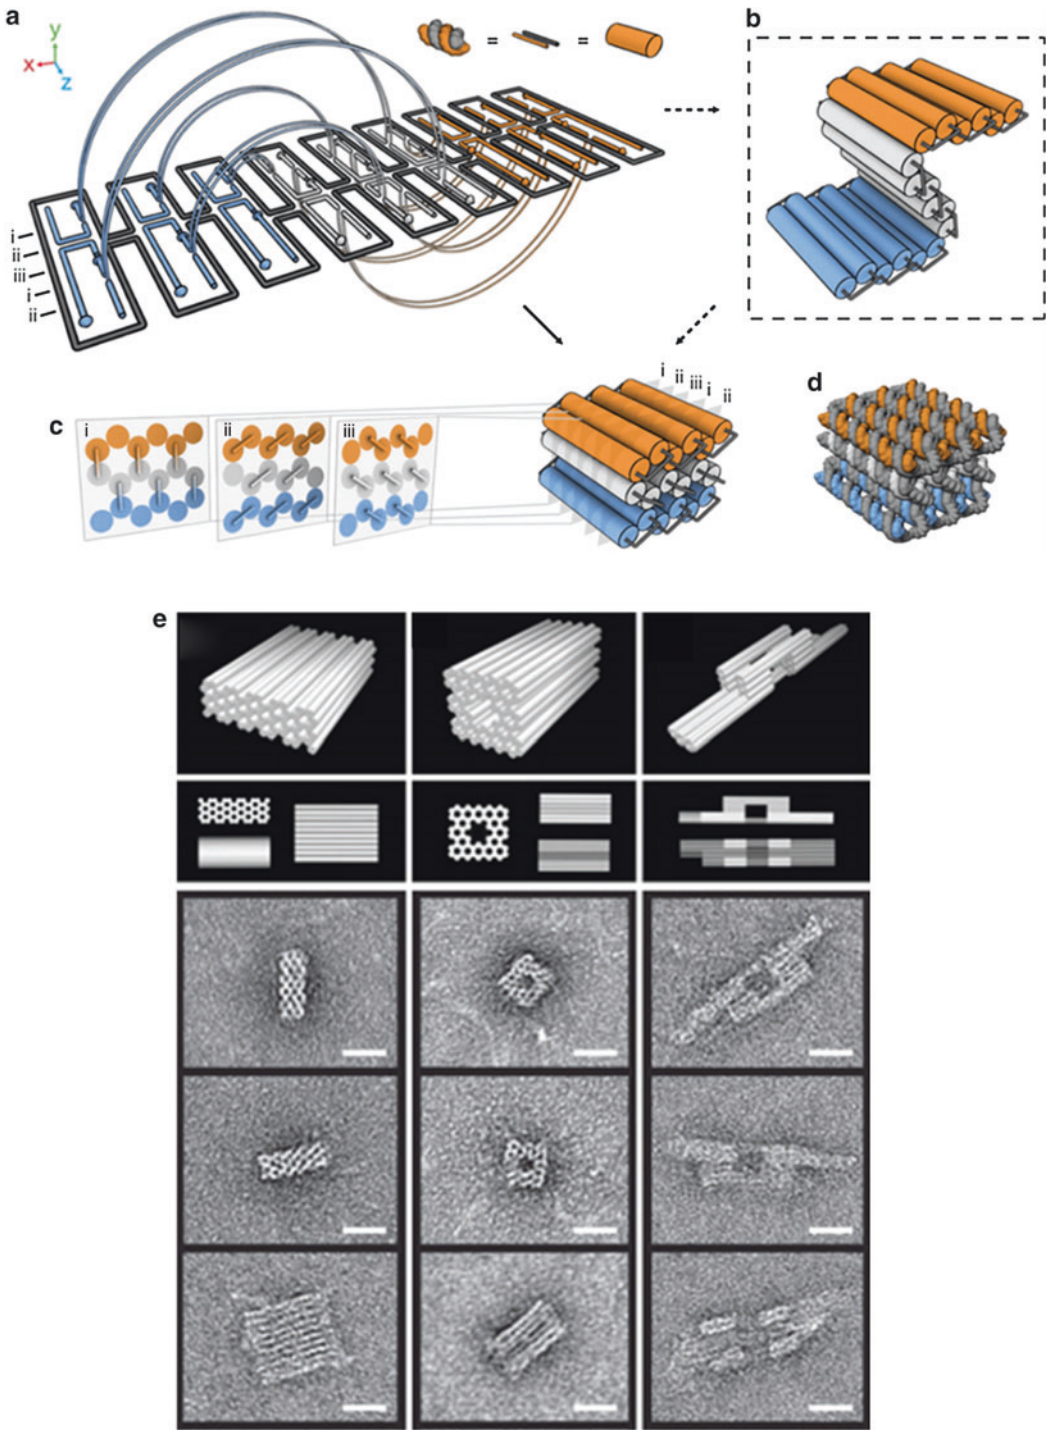
Design Strategies for DNA Origami of Versatile Geometric Shapes

The synthesis/fabrication of DNA origami typically involves mixing the scaffold with the appropriate excess of a designed staple set and thermal annealing of the mixture in one pot. During annealing, the mixture is briefly heated to 75–95 °C to disrupt any secondary structure and then slowly cooled down to let complementary domains hybridize in a thermal cycler [4]. It is also possible to substitute the thermal annealing process with chemical annealing by controlling the concentration of denaturant such as formamide [5]. Since the synthesis procedure is rather established, the development of new DNA origami structure is usually centered on designing the folding path and staple sequences. As with all other design strategies, one should first choose the scaffold to be used because the length of the scaffold will determine the maximum size (area) of the final structure. The single-stranded genome of m13mp18 phage is the most widely used scaffold, while other DNAs of known sequence (such as PhiX174 [6] and lambda DNA fragment [7]) can be used as well. Two established design strategies for 2D and 3D structures will be discussed below.

DNA origami of arbitrary 2D shapes can be designed with an established procedure. As illustrated in Fig. 1a, the folding path of the long scaffold (colored in black) is first laid out in a raster fill pattern to approximate the target geometry. Then, the staples are added to the design diagram to connect adjacent rows of the scaffold by forming crossovers (circled in dotted red).

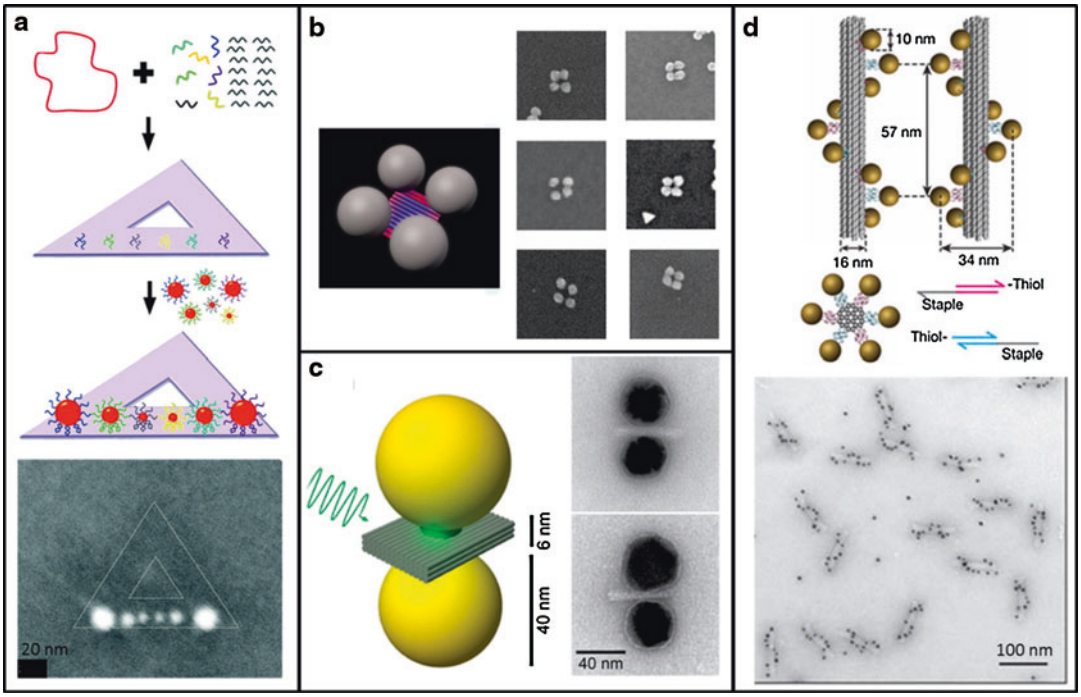
DNA Origami as Programmable Nanofabrication Tools, Fig. 1 Design schematics of DNA origami. (**a**) Scaffold and staple layout for a 2D DNA origami design based on raster fill. A *red* dotted box circles one crossover that interconnects two double helices. (**b**) AFM images of 2D DNA origami with complex geometry, along with the corresponding folding paths [4]. Scale bar: 50 nm

The positioning of the staples should follow certain rules to minimize the strain of the resulting structure by allowing each DNA double helix to make integers of full turns between crossovers. A common practice is to place staples into a staggered periodic array where the crossovers in the same row are 32 bases apart from each other [8, 9]. Finally, the sequence of each staple is determined based on the complementary scaffold domain that it is designed to bind. A software package has been offered to generate a sequence design from a bitmap graph of the target shape [10]. 2D DNA origami has demonstrated its usefulness in 2D self-assembly and nanolithography as will be discussed in later sections.



By extending the folding path of a scaffold out of plane, 3D DNA origami can be designed. Figure 2a–d illustrates a standardized strategy for folding a scaffold in 3D. Similar to the 2D origami design strategy, the scaffold only travels along one direction (Fig. 2a). Therefore, when the scaffold is hybridized with staples, the resulting DNA double helices will all be parallel to each other. The staples are placed to connect the double helices into a hexagonal array as shown in Fig. 2c. The staples form three sets of crossovers that connect every helix with three adjacent neighbors and stabilize the hexagonal array [11]. Based on this framework, various designs such as shown in Fig. 2e can be generated by specifying the length and starting position of each double helix in the array. For efficiently implementing this design strategy and preventing errors, an open-source computer-aided design tool, caDNAno [11], is available.

Besides the standardized design strategies, there are also specialized strategies for designing special structures such as wire frame-like tensegrity [12] or gridiron [13] structures. New structures may also be created by modifying the standard designs. For example, curvature and twist can be generated by deliberately introducing strain in a 3D structure. By controlled inserting and deleting of bases between crossovers in a minimally strained standard design, the new structure will be strained and change to a new conformation in response [14]. In summary, the design of DNA origami is rather flexible. While standard procedures lead to fast and low-error designs, there is also an ample room for creative twists and novel structures. The ever increasing library of available geometry illustrates the versatility of the DNA origami method.



DNA Origami as Nanobreadboards

One of the most powerful abilities of DNA origami is to enable the organization of nanocomponents with a few nanometer accuracy [4]. As governed by sequence complementarity, each staple has a unique position in the assembled DNA origami structure. By functionalizing selected staples, modifications and decorations can be specifically added to predefined positions. The DNA origami template functions as a nanobreadboard where each staple is addressable as a decoration site for attaching nanocomponents including inorganic nanocrystals and functional biomolecules [4]. This approach is useful in inducing novel properties by controlling distance-dependent interactions between nanocomponents.

The accurate spatial control of DNA origami has been demonstrated to facilitate efficient construction of plasmonic structures. By controllably patterning gold or silver components in close proximity, the collective motion of the free electrons can yield novel optical effects such as large enhancement of electrical field in the near field [15] or even negative refractive index [16]. DNA origami has been used as an effective template in organizing gold nanoparticles (AuNPs) into plasmonic structures. The general assembly strategy is illustrated in Fig. 3a [17]. Selected staples are extended with sticky ends (unhybridized single-stranded domains), while the AuNP surface is conjugated with thiolated single-stranded DNA complementary to the sticky ends. The DNA origami structure formed after annealing the scaffold-staple mixture displays sticky ends on its surface, while excess free staples are removed via filtration [4, 18] or gel electrophoresis [11]. Finally, the DNA origami and AuNPs are incubated in an appropriate ratio to allow the sticky ends to hybridize with the DNA on AuNP surface, hence anchoring the AuNPs to the origami.

(**b**) SERS antenna consists of 4 AuNPs on four corners of a DNA origami tile [19]. (**c**) SERS antenna consists of 2 AuNPs on opposite side of a three-layered DNA origami [20]. (**d**) AuNP helices templated by columnar DNA origami [21]

To make the anchorage robust, three or more neighboring staples are usually extended with the same sticky ends so that the AuNPs can be anchored by multiple strands (i.e., multivalency). It is worth noting that one DNA origami structure can express multiple groups of distinct sticky ends. Correspondingly, multiple types of AuNPs (or different kinds of nanoparticles) may be respectively conjugated with corresponding thiolated DNA strands. The heterogeneous AuNP chain shown in the TEM image of Fig. 3a demonstrates the versatility of DNA origami-based AuNP assemblies.

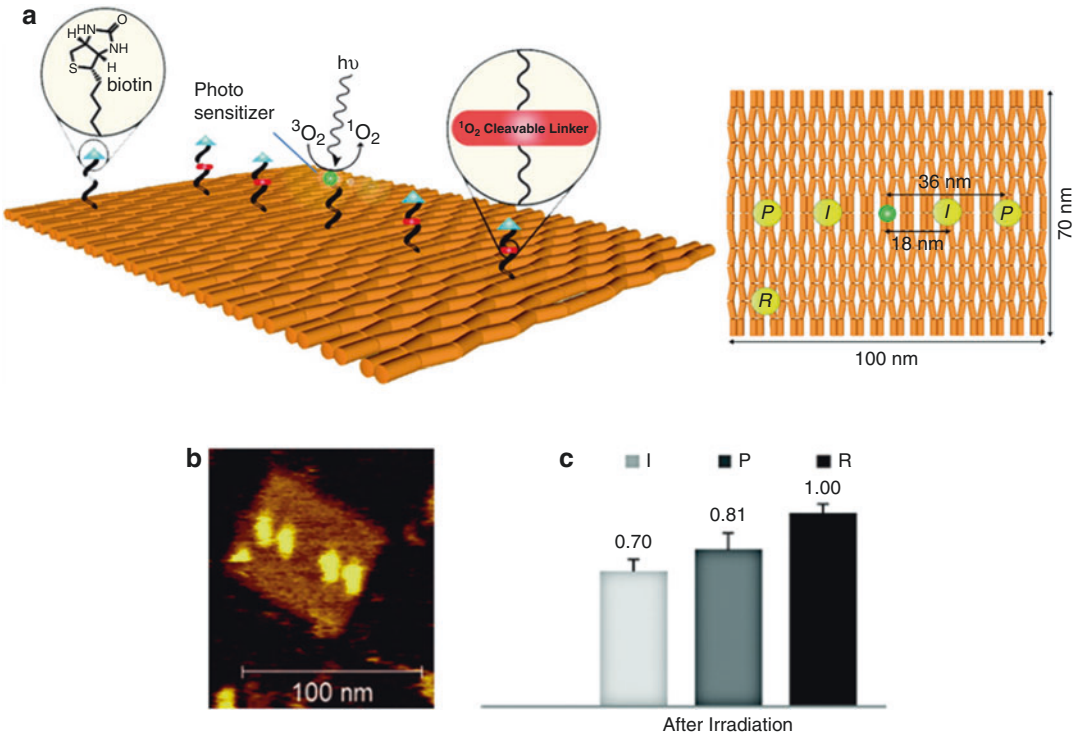

Figure 3b shows a plasmonic antenna fabricated by placing AuNPs on the four corners of a rectangular DNA origami [19]. The nanoparticles are then enlarged through electroless plating of silver. As the growing particles squeeze down the gaps between them, hotspots are created for surface-enhanced Raman scattering (SERS) measurements. The Raman fingerprint signals produced by four-particle assemblies are reported to be 100 times stronger than those of single particles. Figure 3c presents a different plasmonic antenna construction, where two gold nanoparticles are placed on opposite sides of a multilayered DNA origami [20]. The separation was accurately controlled by the thickness of the DNA template and can be tuned by changing the number of layers. When DNA-binding analytes were introduced into the hotspot, a SERS enhancement factor of 3.1×10^5 was observed. Figure 3d shows the arrangement of 9 AuNPs on each DNA origami rod into a helix, demonstrating DNA origami's capability in 3D nanofabrication. The helical arrangement generates chiral optical response near the plasmonic resonance wavelength in the visible range [21]. This plasmonic property can be drastically magnified by enlarging the particles through electroless plating. The resulting solution

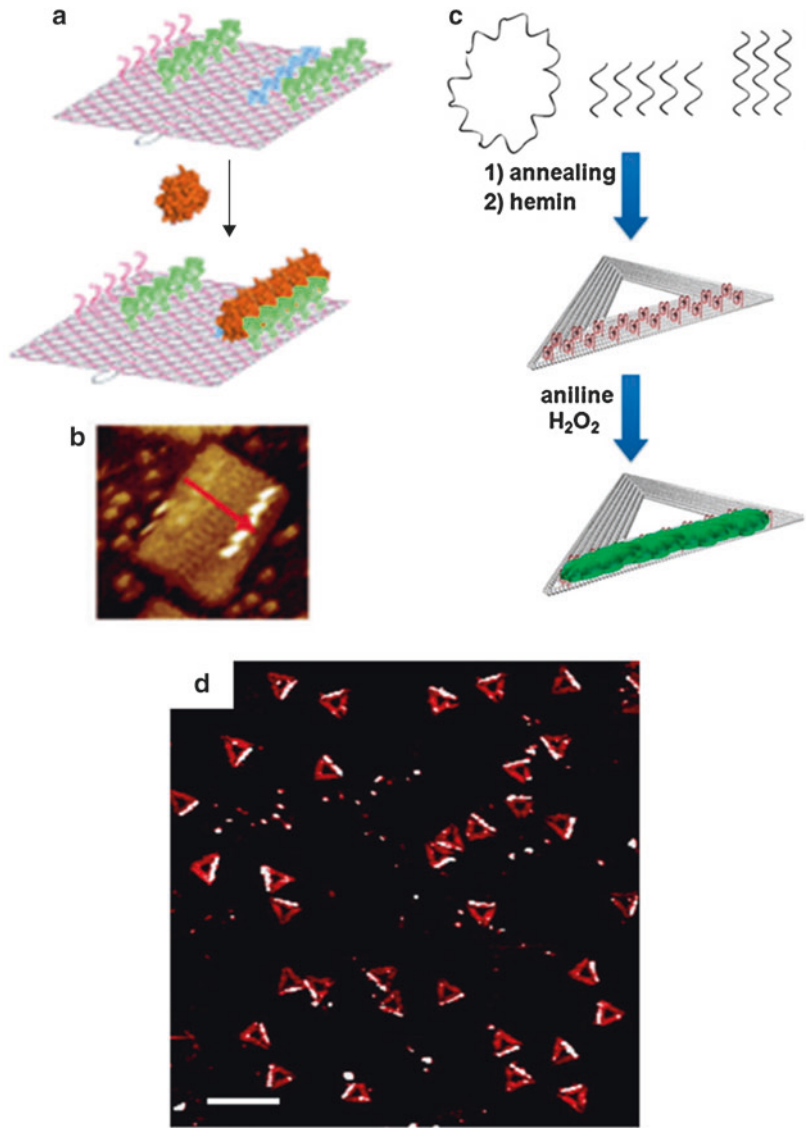
produces strong optical rotary dispersion that can be detected by even naked eyes.

Semiconductor quantum dots (QDs) are another class of important optical nanocomponents that have been used to decorate DNA origami platforms. Given their excellent photo-properties such as high fluorescence quantum yield and long-term photostability [22], the ability of organizing QDs should increase their utility in various engineering applications. Liddle et al. have reported the assembly of QD and AuNP on the same DNA origami [23]. By controlling the distance between the particles and their relative number ratio, the fluorescence lifetime of the QD was engineered. The QD assembly onto DNA origami was first achieved via the high-affinity interaction between biotin and streptavidin [23]. To facilitate the assembly, a set of selected staples were replaced with biotinylated strands. After one-pot annealing, the resulting DNA origami had biotins exposed in designed positions, which conjugated with streptavidin coated on the QD surface [24], thereby anchoring the QDs on DNA origami. As with AuNPs, multivalent binding with several neighboring biotinylated staple strands makes the anchorage robust and increases the assembly yield. When compared to DNA base pairing on origami, however, the biotin-streptavidin interaction is not information rich and facilitates the assembly of homogeneous QDs only. Thus, DNA hybridization is a more powerful approach to graft various kinds of QDs on origami, although it requires special attention and extra efforts to conjugate DNA on QDs, because QDs are usually synthesized with small organic ligands, and the transfer to aqueous solution for DNA conjugation requires multistep ligand exchange and/or encapsulation processes. Such procedure often introduces unwanted sample heterogeneity and surface defects. To overcome these limitations, Choi et al. proposed an alternative approach of using DNA for the dual purposes of particle capping and targeting recognition [24]. This strategy has been further explored and is now generalized by several groups where phosphorothiolated, single-stranded chimera DNA is employed for dual purposes: the phosphorothiolated part is used as the capping domain, while the rest of the sequence binds to its complementary strand as the recognition domain [25, 26]. This scheme allows one to directly synthesize various kinds of QDs (e.g., CdS and PbS) that express distinct sequences (with size tunability and material composition variability) and assemble them on a DNA origami in a highly controlled manner.

Besides various nanoparticles, the conjugation with small molecules brings a variety of functionalities to DNA origami structures. By incorporating modified phosphoramidite building blocks during oligonucleotide synthesis, various chemical groups including biotin, thiol group, and fluorescent dyes may be incorporated to a staple oligonucleotide. The well-defined distance between the staples with functional moieties in a DNA origami structure can be exploited for sub-diffraction imaging calibration standard [27] or as research platforms for investigating distance-dependent molecular interactions. Figure 4a illustrates one of the latter examples where one photosensitizer and five biotinylated extensions are placed precisely on a 2D DNA origami [28]. The biotin moieties are conjugated with streptavidin to produce a height contrast for AFM imaging, and four of the biotin extensions have singlet-oxygen cleavable linkages. Upon irradiation, the photosensitizer at the center of the origami tile starts to generate singlet oxygen molecules which diffuse and cleave the linkage. With this setup, the cleavage efficiency was probed as a function of distance, and information about the diffusion length and lifetime of singlet oxygen was obtained.



DNA origami may be used as a template to organize functional DNA strands such as aptamers, which are identified from in vitro selection for high binding affinity toward given target molecules (typically, small proteins and organic compounds) [29]. By expressing aptamer sequences on the surface, DNA origami can mimic the function of antibodies. This is shown to be a useful mechanism for molecular diagnostics and for organizing nanomaterials. Figure 5a illustrates a DNA origami with extensions of thrombin-binding aptamers [30] which capture thrombin, a serine protease involved in the blood clotting process. The capture event can be clearly

observed with AFM (Fig. 5b). This example demonstrates that combined with AFM, DNA origami can serve as a platform for immunoassay at the single-molecule level. In Fig. 5c, triangular DNA origami tiles are extended with a 17-nucleotide hemin-binding aptamer, which contains a guanine (G)-rich sequence [31]. This aptamer forms a G-quadruplex secondary structure in the presence of potassium ions which facilitates recognition of hemin [32]. The hemin-containing extension was shown to behave as a peroxidase-mimicking enzyme and subsequently catalyze the polymerization of aniline through facilitating its oxidation into aniline radical by H_2O_2. Because the catalysis is limited in a short range, the polymer forms only in the vicinity of an aptamer extension. Therefore, by designing the spatial placement of aptamer extensions, polyaniline can be controllably formed in specified locations on DNA origami (Fig. 5d). Such spatial control of conjugated polymers holds a great promise for organic nanoelectronics.

Finally, the ability to arrange proteins on DNA origami implicates an access to enormously rich biochemical functions. With the maturation of the conjugation strategies, endless possibilities could unfold. For example, the assembly of proteins may result in more effective biochemical catalysis. Figure 6a illustrates the spatially controlled enzyme cascade reaction on a DNA origami. In this example, glucose oxidase and horseradish peroxidase were conjugated to thiolated oligonucleotides via *N*-[(ε-maleimidocaproyloxy) sulfosuccinimide ester] (sulfo-EMCS) bifunctional linkers. They were subsequently anchored onto the origami structure via DNA hybridization [8]. By assembling the two enzymes close to each other (Fig. 6b), the intermediate product was more effectively transferred between them, resulting in a significantly increased overall

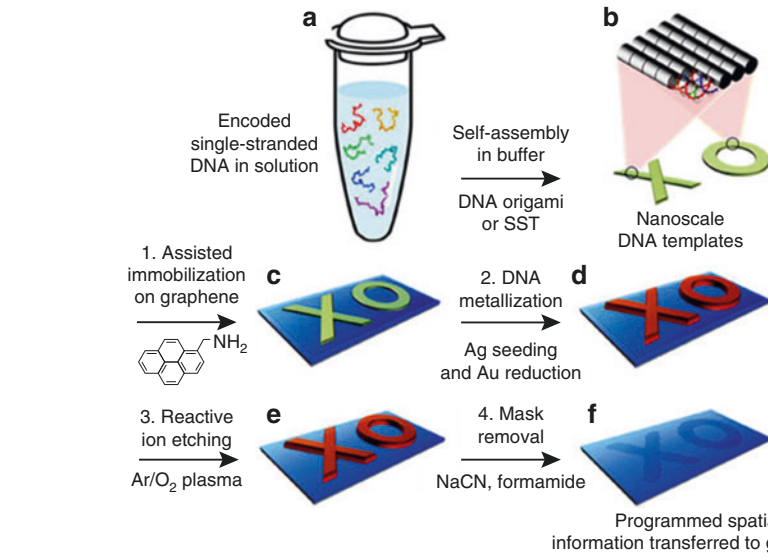
reaction rate. DNA origami was demonstrated to further increase the catalytic efficiency by forming a semi-closed tube around the enzyme cascade (Fig. 6c), which reduces dissipation of an intermediate product and creates a higher local concentration.

DNA Origami as Nanostencils for Fabricating Inorganic Materials



The ability of DNA origami to produce arbitrary 2D geometry with nanometer accuracy makes it a potential nanolithography tool. Compared with optical lithography, the small feature size of DNA origami enables it to achieve much better resolution. Given the nature of its synthesis and deposition, DNA origami is a scalable and parallel process that is faster in fabricating large quantities of nanostructures, which is advantageous over other high-resolution methods such as electron beam lithography (EBL) and focused ion beam (FIB) milling. Several successful demonstrations of nanopatterning with DNA origami have been reported [18, 33, 34].

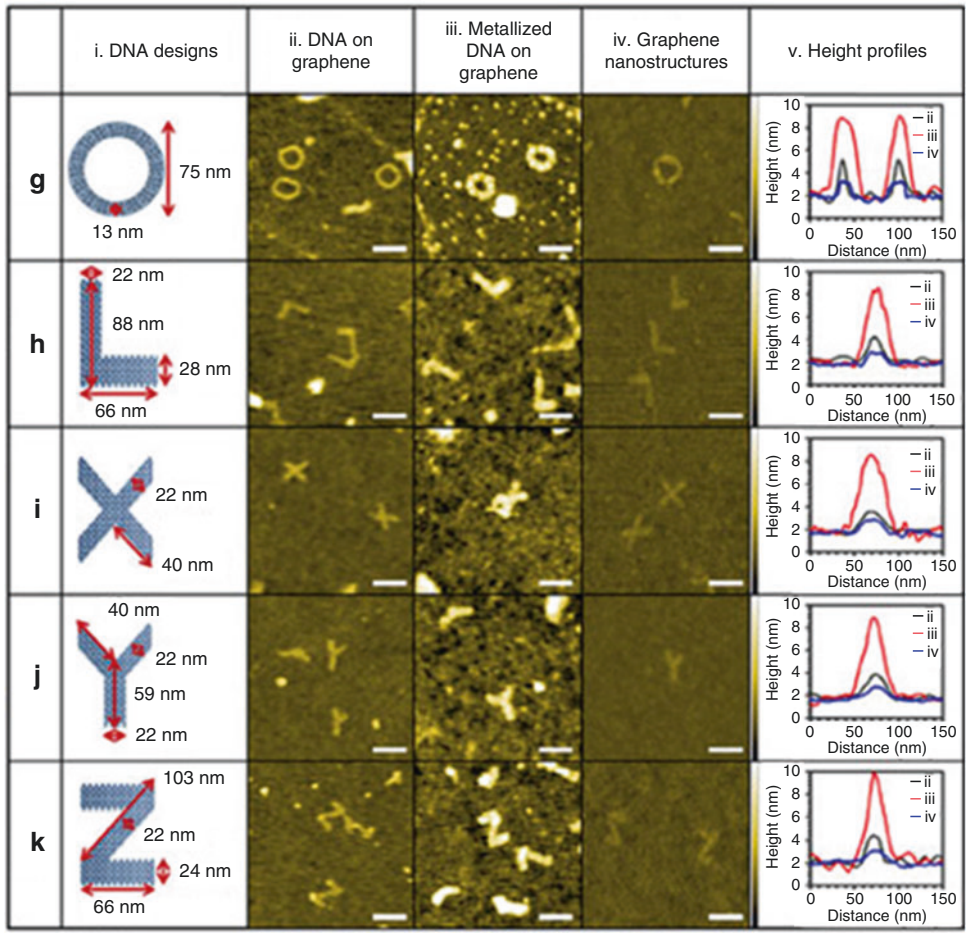


Figure 7 illustrates the process of transferring programmed DNA origami geometry to

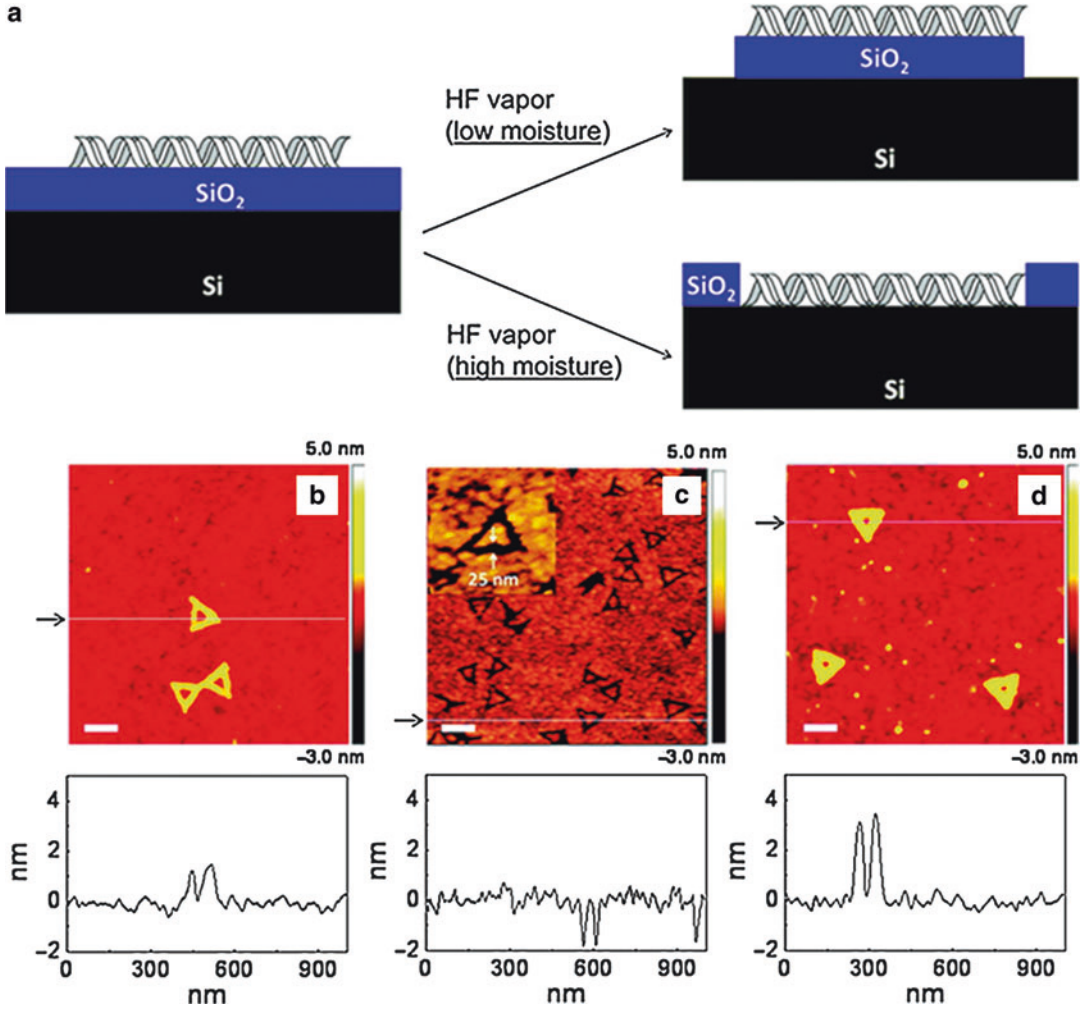
DNA Origami as Programmable Nanofabrication Tools, Fig. 6 Conjugation of proteins on a DNA origami tile. (**a**) Schematic of glucose oxidase and horseradish peroxidase assembled into enzyme cascade on DNA origami. (**b**, **c**) AFM images of the enzyme cascade on flat DNA origami (**b**) and semi-closed DNA origami tubes (**c**). (**d**) Catalytic kinetics of the enzyme cascades compared to control [8]

underneath graphene [18]. Briefly, DNA origami templates are incubated with glutaraldehyde to adsorb the molecule onto the surface. Then the templates are immobilized onto graphene surface with the assistance of 1-pyrenemethylamine, which adsorbs onto graphene by π-π stacking and aids the adhesion of DNA origami. After deposition, the DNA template is metalized by a sequential treatment with silver nitrate and gold enhancement solution. The adsorbed glutaraldehyde reduces silver ions into metal seeds on DNA skeleton. Gold then deposits around the silver seeds, resulting in a fully metalized mask, which protects graphene during the subsequent Ar/O_2 etching. Finally, the metal mask and DNA residue are removed by $NaCN/H_2O$ and deionized formaldehyde, leaving only the patterned graphene. This example illustrates two key challenges for pattern transfer from DNA template: the effective attachment of the template and the strengthening of that template. Atomically thin materials such as graphene are probably the best suited for DNA origami-based molecular lithography because they need only a limited exposure to plasma etching and do not require thick masks which generally have a lower resolution.

DNA Origami as Programmable Nanofabrication Tools, Fig. 7 (**a**–**f**) Step-by-step illustration of the pattern transfer process. (**g**–**k**) Schematics, AFM images, and height profiles at different processing stages. Scale bars: 100 nm [18]

Oxides from chemical vapor deposition (CVD) can be a good alternative to metal in preparing the etching masks [33]. Compared with metalized masks, which show significant grains and extra particles (Fig. 7g–k), CVD oxides are potentially smoother with less uncontrolled nucleation. For CVD-based oxide growth, a substrate with deposited DNA origami is placed in a glass desiccator with two open vials of precursor and ammonia. Tetraethyl orthosilicate (TEOS) and titanium isopropoxide are the respective precursors that hydrolyze to yield SiO_2 and TiO_2. The hydrolysis reaction is catalyzed by water. Therefore, the different amount of adsorbed water results in different rates of oxide growth. Overall, CVD can convert a DNA template into a hard mask from vapor phase and circumvent several possible issues related with liquid-phase methods, such as fouling and DNA desorption.

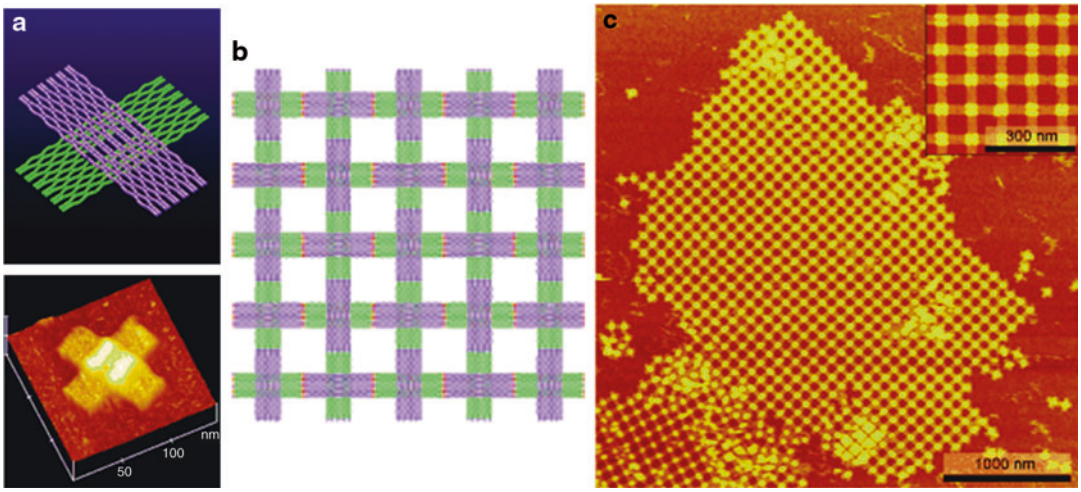


DNA origami also has been reported to directly template the etching of SiO_2 substrates without using any hard masks [34]. Similar to the oxide precursors, etching by vapor phase HF needs water as a catalyst. Therefore, the differential adsorption of water in various areas produces a contrast mechanism (Fig. 8a). Compared to DNA, SiO_2 surface has higher water adsorption at low relative humidity, but lower water adsorption at high relative humidity. Therefore, etch rate in DNA region is slower at low humidity and faster at high humidity. Figure 8a illustrates that both positive and negative tone patterns can be produced, depending on the relative humidity. In either scenario, a height contrast of about 2 nm has been demonstrated (Fig. 8c, d). This strategy may be applied for etching thin oxides, such as those grown by atomic layer deposition (ALD).

The fragile nature of DNA generally does not allow it to directly function as an etch mask. Novel contrast mechanisms such as presented above are needed for effectively transferring programmed DNA geometry to other materials. DNA origami has been demonstrated to template the deposition of metals and oxides. However, more diverse chemical strategies should be established to enable DNA-templated growth of a wider range of materials. Then, DNA origami structures may either provide functionality on their own or serve as hard masks for etching other functional materials. The graininess and fidelity of the processes also need to be optimized in order to fully exploit the high spatial resolution of DNA origami.

Scaling Up DNA Origami Structures

Most DNA origami designs use the 7 kb m13 genome and about 200 staples. As a result, a 2D structure typically covers an area less than 100 × 100 nm [35]. While DNA origami represents a breakthrough in the complexity and size for molecular self-assembly, further scaling up is sought after for organizing nanocomponents into more sophisticated systems and better integration with top-down fabrication methods. One possible route for scaling up is through the use of larger scaffolds. However, the increased number of staples for folding such a scaffold also means increased similarities between binding domains and increased misfold rates. In addition, very long single strands are fragile and may result in more fragmented partial structures. An alternative strategy is to hierarchically assemble preformed DNA origami into larger and more complex structures, as discussed below.

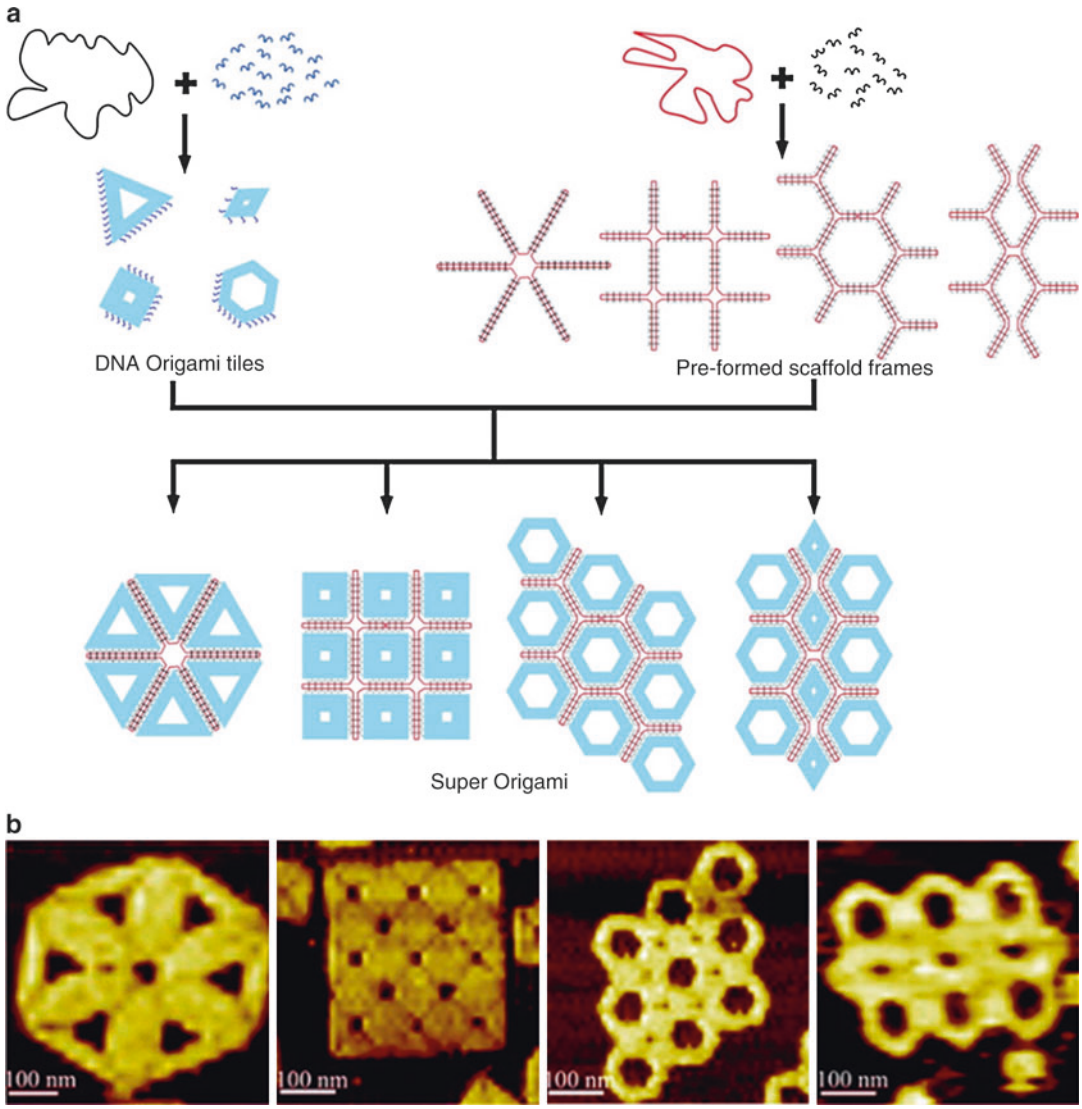


A hierarchical assembly strategy has been shown to create microscale structures from preformed DNA origami monomers. Figure 9 shows a 2D array of interconnected, cross-shaped DNA origami. Because DNA origami are observed to connect more effectively in the direction parallel to DNA helices [36], the cross-shaped DNA origami was designed in order to let the 2D array propagate effectively in both directions. As illustrated in Fig. 9a, the cross consists of two rectangular subunits connected perpendicularly, and all of the four edges are perpendicular to the DNA strands to facilitate effective linking. Eight sticky ends extend from each edge. Their programmed hybridization to the sticky ends on another edge will connect two DNA origami structures in an exactly predesigned fashion. Figure 9c presents the resulting crystalline 2D array which exceeds 2 × 2 μm. Such size adequately matches the feature lengths of

DNA Origami as Programmable Nanofabrication Tools, Fig. 8 (**a**) Schematic of the two etching regimes that result in positive and negative tones. (**b**–**d**) AFM images of DNA origami and the corresponding etched patterns of negative/positive tone. Depending on the moisture condition, the presence of DNA either promotes etching of adjacent silicon oxide (**c**) or hinders the etching (**d**). Height profiles are presented below the corresponding AFM images. Scale bar: 100 nm [34]

photolithography. However, the assembly mechanism does not actively limit the expansion of the 2D array. As a result, its overall size and shape is not well controlled. Moreover, DNA origami units in this periodical array cannot be distinguished from each other; hence, they cannot be addressed individually.

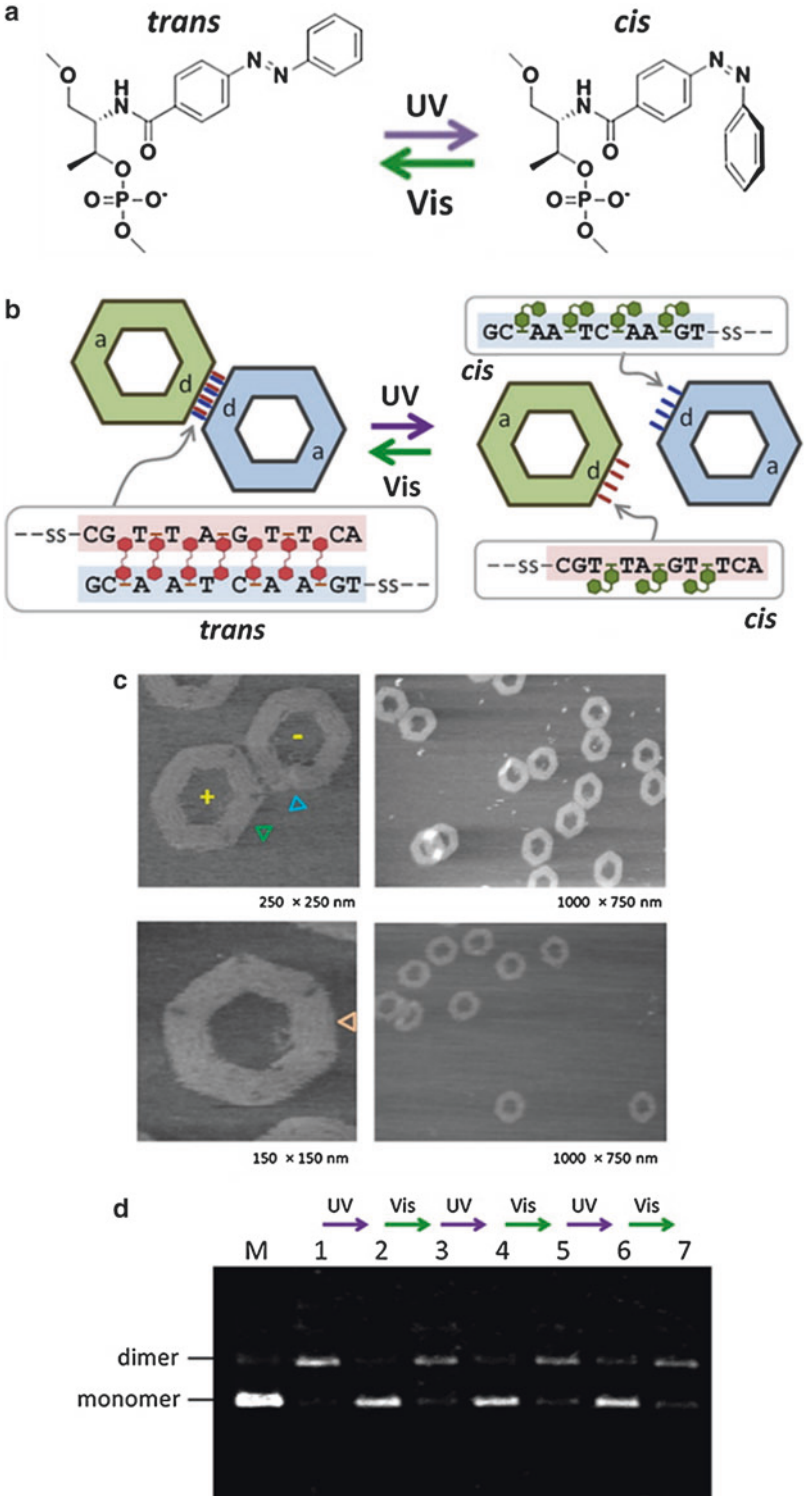
An "origami of origami" strategy has been proposed to produce well-defined DNA origami assemblies, where each origami unit can be addressed. Figure 10a illustrates this strategy: two kinds of scaffolds are utilized, one for constructing the normal DNA origami units and another for constructing a loose framework [6]. The normal origami tiles have specially designed sticky ends for directing them to a predetermined location in the framework. Collectively, the framework and the unit tiles form a much larger structure of a predesigned geometry. It is worth noting that each tile in the assembly is unique because of their unique set of sticky ends. This allows every point in the assembly to be individually addressed;



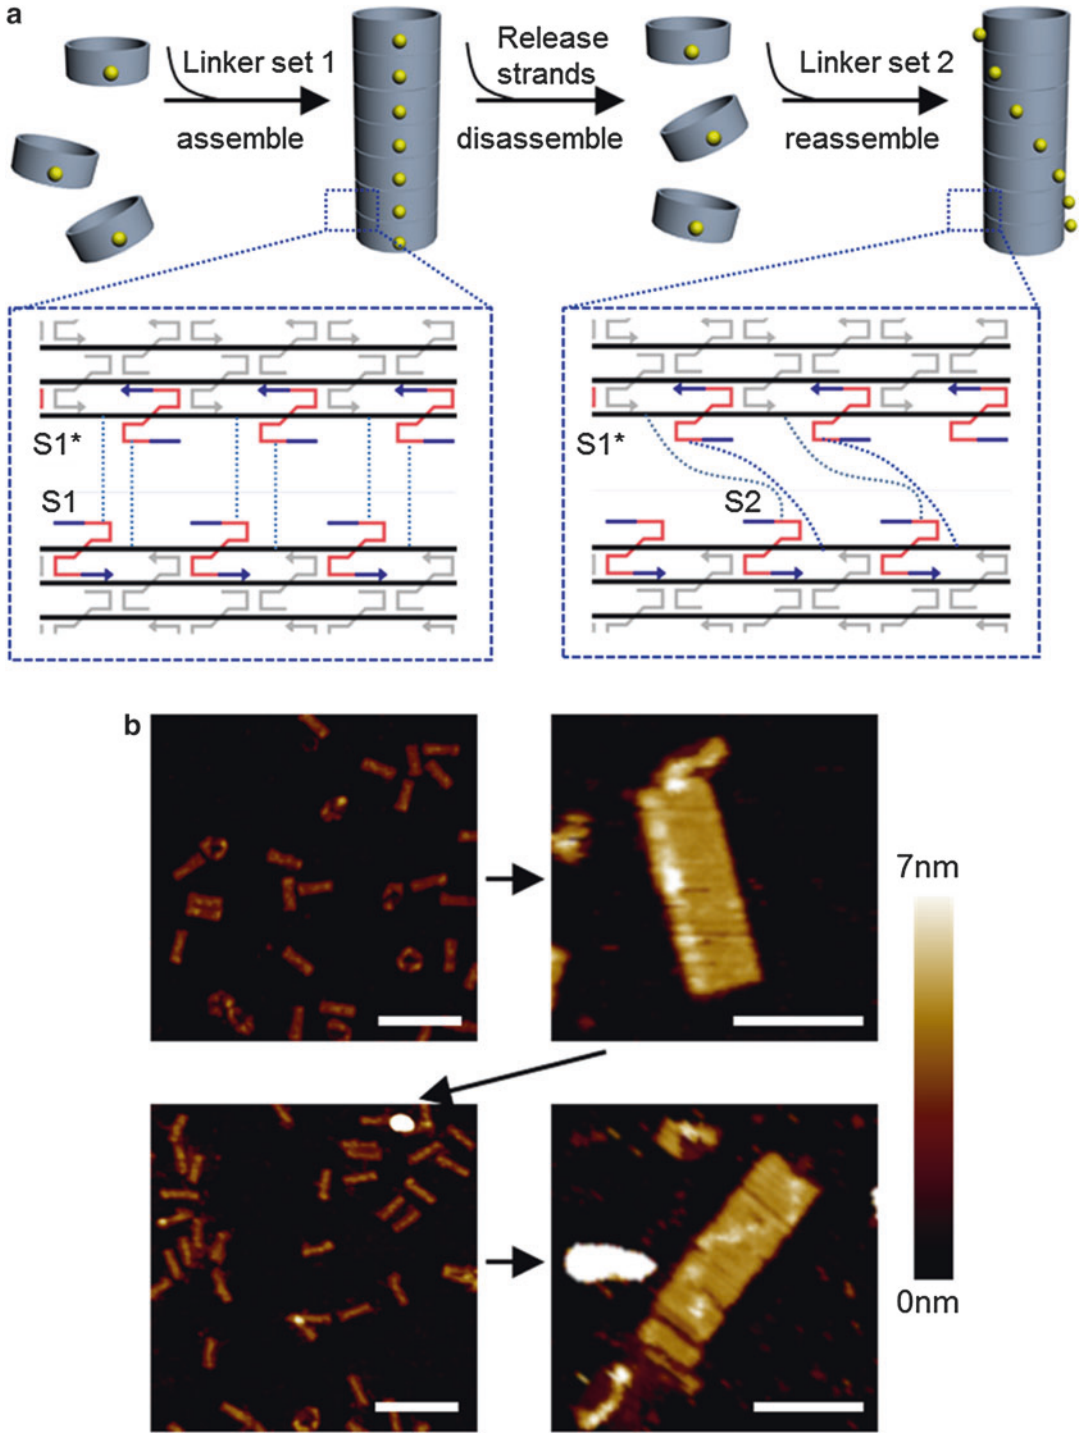
DNA Origami as Programmable Nanofabrication Tools, Fig. 9 (**a**) Schematic and AFM image of individual cross-shaped DNA origami. (**b**) Schematic for connecting individual cross origami into a crystalline 2D array. (**c**) AFM image of a 2D array about 2 × 3 μm in size [36]

to decorate a point, one only needs to functionalize the point on the corresponding DNA origami tile. After assembling the tiles, the functionalization will be automatically carried to the predetermined position in the superstructure. With this strategy, about ten DNA origami tiles can be grouped together, and therefore, an approximately ten-time scale-up has been achieved without compromising addressability.

In the hierarchical assembly strategy, reversible linkage between DNA origami units provides the larger systems with dynamic properties. Figure 11 presents such an example that uses azobenzene, a chemical moiety that undergoes reversible photo-isomerization in response to illumination of different wavelength [37]. Azobenzene can be incorporated into DNA to facilitate photo-controlled hybridization: planar *trans* isomer stacks with the nucleobases and stabilizes the double helix, whereas out-of-plane *cis* isomer destabilizes the duplex due to steric hindrance (Fig. 11a) [37]. By switching azobenzene moiety from *trans* to *cis* isomers, base pairing can be disrupted, while switching from *cis* to *trans* form promotes the hybridization (Fig. 11b). Therefore, by extending DNA origami with azobenzene-functionalized sticky ends, the linkage between DNA origami can be controlled by light of different wavelengths [38]. Figure 11d demonstrates the dynamic switch of DNA origami between monomer and dimer forms within the time frame of a few minutes. Such remote control capability should prove a valuable tool for regulating various processes at the nanoscale.



Reversible linkage during the hierarchical assembly can also be realized by DNA hybridization. Compared with azobenzene that has only two available conformations, DNA is information rich and allows the assembled structure to switch between multiple linking configurations. Figure 12 shows such a versatile strategy. Short cylindrical DNA origami monomers are designed to have unhybridized binding domains on both upper and lower edges (Fig. 12a). The linkers that simultaneously hybridize to binding sites on both edges stack the short cylinders into an elongated tube. Different linker sets that pair up the binding sites differently cause a variation in the relative rotation between two connected DNA origami units and thus result in tubules of chosen chiral angles [9]. Moreover, the linkers may also be extended with unhybridized domains (the so-called toeholds) in order to allow disassembly via toehold-mediated strand displacement [39]. For disassembly, a set of single strands (i.e., release



DNA Origami as Programmable Nanofabrication Tools, Fig. 10 (**a**) Schematic of the process for creating "origami of origami" structures. (**b**) AFM images of the assembled super origami structures corresponding to respective designs [6]

strands) are introduced to the solution. The release strands are exactly complementary to the linkers. They first hybridize to the toehold domain of the linkers and then bind more and more bases of the linkers via random branch migration [39]. Because of the increased number of base pairs, the release strands eventually hybridize with the linkers completely and disengage them from linking the two neighboring origami units together, thereby releasing the linkages and causing disassembly. The disengaged linkers leave unhybridized binding sites intact which are available for another round of assembly. In Fig. 12b, the hollow ring-shaped DNA origami units are assembled into a nonchiral tubule, disassembled, and then reassembled into a chiral tubule (the chosen helical angle of ~45°), demonstrating the dynamic nature of the assembly strategy.

The hierarchical assembly strategy has been demonstrated to produce structures that exceed

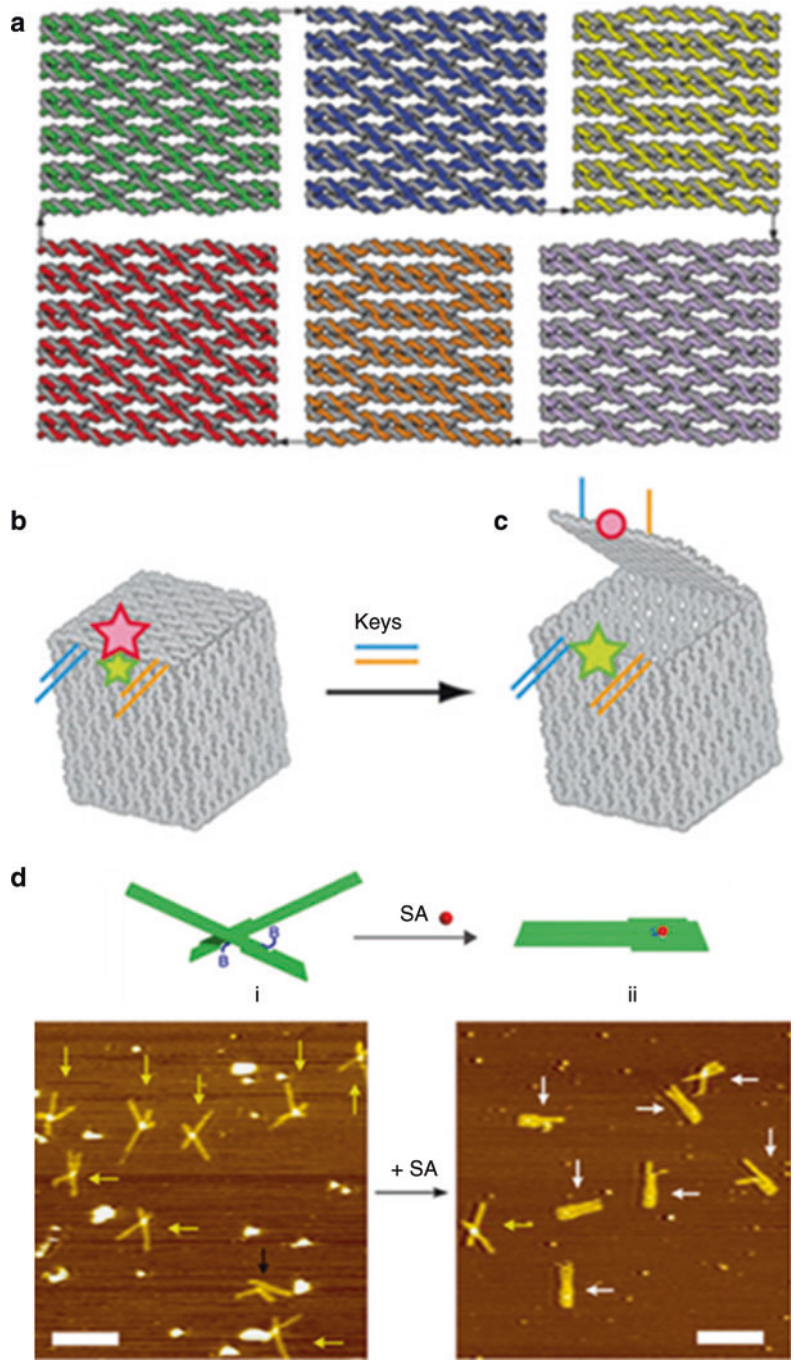
the size limit of a single DNA origami while retaining the spatial accuracy. The increased size and complexity combined with reversible and photo-responsive assembly mechanisms should open up new possibilities of sophisticated nanosystems.

DNA Origami for Constructing Dynamic and Tunable Structures

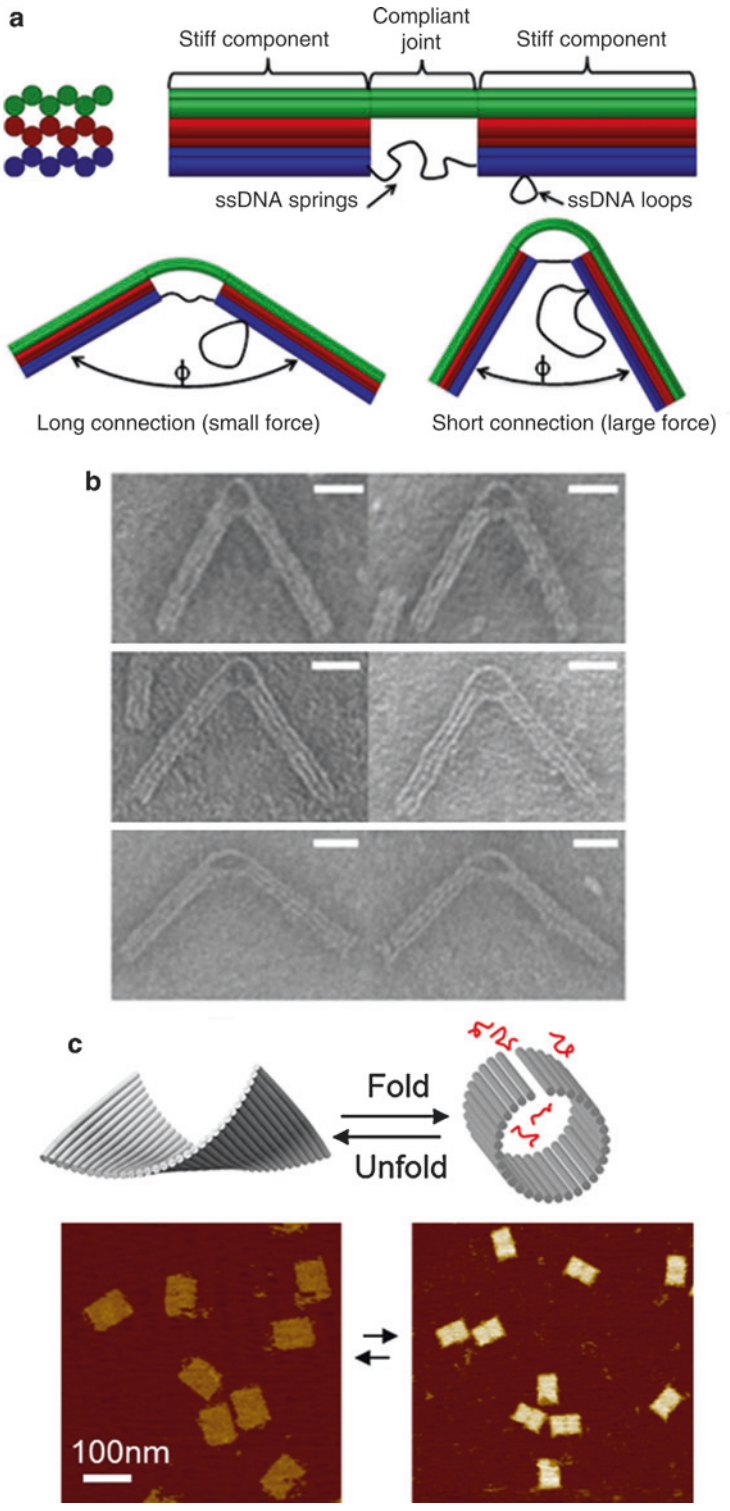
DNA is much more compliant compared to many other materials commonly used in nanotechnology such as silicon and gold – this is especially the case for single-stranded DNA. As a result, DNA-based structures can be designed to significantly change their configuration in response to environmental cues, similar to many conformation-changing proteins. This unique property opens up broad possibilities for dynamic structures and novel functions.



Highly compliant single-stranded DNA has been used as free hinges for creating dynamic structures. Figure 13a, b illustrates a DNA origami box that uses such mechanism [40]. By design, the scaffold folds into a box formed by six interconnected rectangles. One top side of the box (the lid) is hinged by several staples with a four-base-long single-stranded flexible domain. The lid is locked closed by two pairs of partially hybridized extensions (Fig. 13b). A "key" DNA can disrupt the hybridization through toehold-mediated strand displacement. When the two pairs of locking extensions are both disrupted, the lid is free to open (Fig. 13c). Douglas et al. have further demonstrated that a similar structure can open in response to other chemical analytes such as platelet-derived growth factor (PDGF) if the corresponding aptamer sequences are used as locking strands [41]. As an application, drugs may be loaded inside the structure, which are accessible from the outside only when it is opened by target analytes. Such dynamic structure has been shown to sense environmental signals and expose payloads accordingly. This responsive behavior makes dynamic DNA structures promising drug delivery carriers.

Figure 13d illustrates a molecular forceps that pinches its target analyte [42]. This DNA origami structure consists of two single strands connecting two rigid arms. Both arms contain a chemical group for recognizing a molecular target. The forceps normally assumes the most relaxed open conformation. Upon addition of a target, the recognition groups on both arms bind to the target and cause the structure to pinch close. This conformation change can be clearly visualized with AFM and offers a target-sensing mechanism with high sensitivity and selectivity.

While single-stranded DNA behaves much like free hinges, double-stranded DNA can be used to construct springlike connections that are able to generate considerable restoring forces. The structure shown in Fig. 14a has a thin (one corrugated layer) double-stranded joint [43], and another single-stranded connection is placed away from the joint. The natural tendency for single-stranded DNA to coil up produces the tensile force that bends the joint. The tensile force may be tuned by changing the length of the single strand. Figure 14b shows that the bending angle responds to the changing force, clearly demonstrating the elastic nature of double-stranded DNA.



A similar elastic behavior has been demonstrated for 2D DNA origami in solution. As illustrated in Fig. 14c, a 2D rectangular DNA origami has considerable flexibility, which causes the structure to frequently bend over and close the two opposite edges at 40 °C or higher [44]. After introducing linkers that connect the two edges, the majority of the DNA origami structures fold into short tubules as they are frozen in the bent-over conformation. By investigating the kinetics of such a folding process, Chen et al. calculated the bending flexibility of inter-helix crossovers in DNA origami and explained the elastic behavior of the origami structure [44]. They were also able to accelerate folding kinetics by up to 20 times through tuning the structural elasticity by introducing structural defects (i.e., intentionally excluding several staple strands in the origami structure).

The examples discussed here have introduced reconfigurable structures based on the compliance of single-stranded DNA and the elasticity of double-stranded DNA. In analogy, many proteins undergo constant conformational fluctuations [45]

DNA Origami as Programmable Nanofabrication Tools, Fig. 13 (**a**) Folding path of the origami box. (**b**) Schematic of the origami box locked by two pairs of hybridizing extensions. The two pentagrams represent two fluorophores on opposite edges that form efficient FRET (fluorescence resonance energy transfer) pair. (**c**) The box is free to open when the hybridizations are disrupted by strand displacement. The FRET pair is disrupted as the lid opens and can be used to monitor the origami configuration [40]. and experience drastic structural changes in response to environmental stimuli such as light irradiation and chemical binding. A better understanding of the mechanical properties of DNA will enable more dynamic structures with tailored conformations and well-controlled kinetic properties and may even result in transformable structures that emulate proteins in functionality.

Outlooks

While novel properties and promises for applications have been demonstrated, DNA origami technique is still in the phase of rapid development, growing as powerful, programmable nanofabrication tools. Novel geometries generated by innovative design schemes are likely to bring new applications. The development of robust linking schemes will facilitate more versatile assemblies of nanocomponents with higher yields and enable novel functionalities. New chemical strategies will allow the transfer of versatile DNA origami geometries into wider varieties of materials with increased fidelity. Further breakthroughs in scaling up are needed to match the size of DNA origami structures to the feature length scale of lithographic techniques. When the DNA origami is developed as a viable, bottom-up manufacturing technology and integrated with traditional top-down methods, there would be little limit on the complexity and accuracy of the achievable nanostructures and could revolutionize a wide range of industries. Finally, the ability to fabricate compliant dynamic structures is a rather special feature of the DNA origami method. With increased understanding of the fundamental properties of DNA, combined with advances in chemistry, highly functional DNA origami that emulates proteins may be possible, and DNA nanotechnology may join force with synthetic biology.

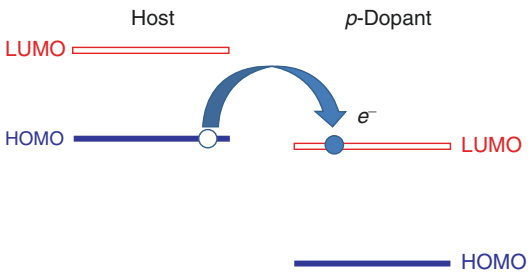
Doping of organic semiconductors

Definition

There are two major ways to dope an organic semiconductor: chemical doping and electrochemical doping. Because of the additional complexity due to the presence of an electrolyte solution in the case of electrochemical doping, the focus is placed on chemical doping. In chemical doping, dopant molecules (typically a few weight percent) are introduced into an organic semiconducting host material, either by co-evaporation in vacuum or spin casting from solution.

Operation Principles



Doping in organic semiconductors can be rationalized based on energetics, i.e., charge carriers (electrons or holes) "flow" from the higher energy levels of host molecules to the lower energy levels of dopant molecules to minimize the total energy. It is known that the energy levels in atoms are discrete and narrow in width. On the other hand, as a large number of atoms are brought to proximity to form solids with an ordered crystal structure, the energy levels evolve to continuous bands.

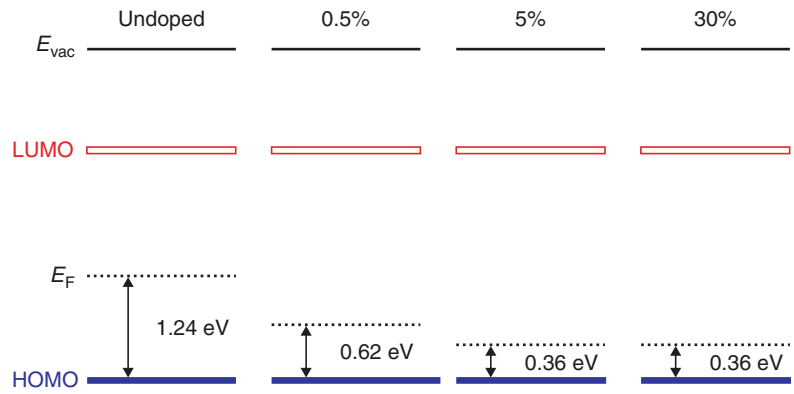
Doping in Organic Semiconductors, Fig. 1 Schematic drawing of energy levels in molecules

Energy levels in molecules are somewhere between these two extremes, not as discrete as those in atoms, but also not as continuous as those in crystals. Figure 1 illustrates the energy levels in molecules. The highest energy levels that are occupied by electrons are the so-called highest occupied molecular orbitals (HOMO). Any energy level below HOMO is occupied by electrons. The lowest energy levels that are not occupied are the so-called lowest unoccupied orbitals (LUMO). Any energy level above LUMO is unoccupied. The energy required to excite an electron in HOMO of a molecule to the vacuum level is defined as the ionization energy (IE). The energy gain for an electron falling from the vacuum level to fill LUMO is electron affinity (EA). The energy difference between the Fermi level and the vacuum level is work function (WF).

In order to efficiently *p*-dope a host material, the EA of the dopant molecules needs be comparable to or even greater than the IE of the host molecules (see Fig. 2). Vice versa, an efficient n-type dopant is expected when the dopant molecules have an IE comparable to even lower than the EA of the host material. As an example, α-NPD (*N*,*N*′-diphenyl-*N*,*N*′-bis (1-naphthyl)-1,1′-biphenyl-4,4′-diamine) is a widely used hole transport material in organic light emitting diodes

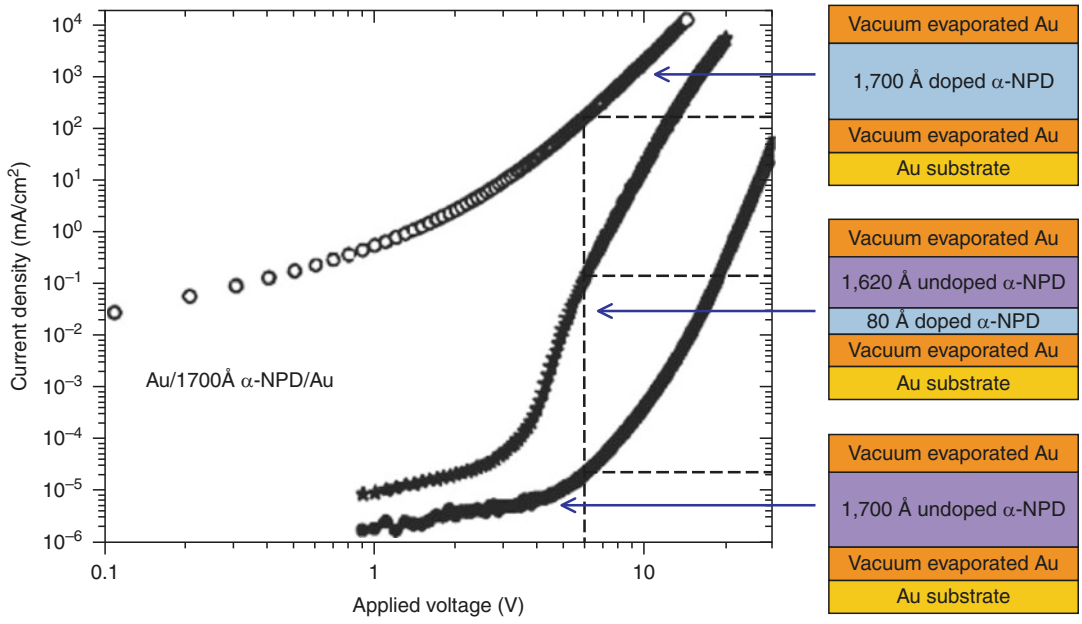
Doping in Organic Semiconductors, Fig. 2 Schematic drawing of charge transfer for p-type doping

(OLEDs). The ionization energy and electron affinity of α-NPD are 5.4 and 1.4 eV, respectively [3, 6]. An efficient p-type dopant for α-NPD should have an EA comparable to 5.4 eV. F_4-TCNQ (2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane) has an EA of 5.24 eV, which has been shown to efficiently *p*-dope α-NPD [2]. It is worthwhile to note that in Fig. 2 an organic molecule dopant is assumed, although materials other than organic molecules have been used as dopants. For example, alkali metals have been used as p-type dopants and halogens have been used as n-type dopants.



Basic Methodology and Key Research Findings

Experimental techniques that have been commonly used in doping studies of organic semiconductors include ultraviolet photoemission spectroscopy (UPS), inverse photoemission spectroscopy (IPES), x-ray photoelectron spectroscopy (XPS), Rutherford backscattering (RBS), charge transport measurements, and scanning tunneling microscopy (STM).



The first set of measurements for a typical doping study are usually UPS and IPES measurements on neat films of host and dopant molecules, which provide fundamental information such as IE and EA. With such information for both materials, a crude judgment can be made whether doping can take place between these two materials. While electrochemical measurements combined with optical absorption measurements are also often cited in literature to yield values of IE and EA, it should be noted that (1) electrochemical measurements are usually performed in solution where intermolecular interaction is rather weak and (2) optical gap values need to be corrected for exciton binding energy in order to be compared with the HOMO–LUMO gap (= IE − EA) measured by UPS and IPES.

In order to accurately assess effectiveness of doping, more direct measurements are required, one of which is to study the Fermi level position change by UPS as a function of doping concentration. When organic materials are not intentionally doped (so-called intrinsic), the Fermi level is often close to the mid-gap position. A Fermi level shift from the near mid-gap position to HOMO is expected for the p-type doping. For the n-type doping, on the other hand, the Fermi level shifts toward LUMO. Figure 3 schematically depicts the Fermi level shift toward HOMO as the concentration of F_4-TCNQ in α-NPD increases from 0 % to 0.5 %, and then to 5 % [2]. It is worthwhile noting that as the doping concentration increases further to 30 %, the Fermi level remains at approximately the same position, and is pinned at ∼ 0.4 eV above HOMO. This is a result of the tail of density of states extended into the HOMO–LUMO gap. It has been proposed that various types of static and/or dynamic disorder in organic films are responsible for these states.

0.019w?>The second direct way to visualize the doping effect is to measure charge transport properties of undoped and doped films. Bulk conductivity enhancement and charge injection improvement at organic–electrode interfaces are two major doping-induced advantages, both of which can be verified via charge transport measurements. These two features are demonstrated in Fig. 4, where the current–voltage (I-V) characteristics are compared for undoped α-NPD, 0.5 % F_4-TCNQ interface–doped α-NPD, and 0.5 % F_4-TCNQ bulk–doped α-NPD samples [2]. Detailed structures of the three types of samples are schematically shown on the right in Fig. 4. Due to the amorphous nature of α-NPD films, charge carrier hopping is believed to be the main conduction mechanism in α-NPD. The first sample is an undoped sample (represented by solid circles in Fig. 4). For this

Doping in Organic Semiconductors, Fig. 3 Position of the Fermi level in the HOMO–LUMO gap of ***α***-NPD as a function of doping concentration of F_4-TCNQ. The values are taken from Gao and Kahn [2]. Reprinted with permission. Copyright 2003, American Institute of Physics

Doping in Organic Semiconductors, Fig. 4 I-V curves of undoped α-NPD, 0.5 % F_4-TCNQ interface–doped α-NPD, and 0.5 % F_4-TCNQ bulk–doped α-NPD samples. sample, the I-V curve basically follows a straight line with the slope approximately equal to 1 at low applied voltages (between 0.9 and 4 V). The electrical current in this region is dominated by ohmic conduction due to free charge carriers. As the applied bias increases to 6 V, the current begins to climb up with a much steeper slope. This rapid increase is called injection onset, caused by charge carrier injection at the organic/electrode interfaces. The steep slope is most likely caused by the filling-up of trap states in α-NPD, which in turn facilitate charge carrier hopping in α-NPD. Doping can be used to improve injection, which is demonstrated by the interface-doped α-NPD sample (represented by stars in Fig. 4). I-V characteristics at low applied voltages (between 0.9 and 2 V) share the same features as those of the undoped sample, i.e., linear on log-log scale with a slope of 1.

The current in this regime is within a factor of 5 of that of the undoped one, which is expected from the fact that only a small portion of the film is doped. On the other hand, injection properties are significantly improved, and the injection onset occurs at a much lower bias (~3 V). For the bulk-doped sample (represented by open circles in Fig. 4), the low bias conductivity (i.e., in the ohmic conduction region) is 5 orders of magnitude higher than that of the undoped sample. Along the same line, doping has been implemented in organic field-effect transistors (OFETs) to tackle the contact resistance issue, which is one of the common problems. Studies have shown that contact resistance in pentacene OFETs has been reduced by sevenfold by inserting a 10-nm-thick doped interface layer [4]. It is important to note that the stability of the devices was not affected significantly by doping of the contacts [4].

In some cases, as dopant molecules donate (or accept) electrons from the host material, oxidation states of some specific atoms in the dopant molecules change. This change can be used as an indicator for doping. Oxidation states can be determined by XPS. For example, such a change is revealed in an XPS study on cobaltocene and cobaltocene-doped tris(thieno)hexaazatriphenylene derivative [1].

Future Directions for Research

In the past decade or so, applications involving organic semiconductor (especially OLED-based products such as OLED lighting, OLED TV, OLED cell phone, etc.) have been commercialized successfully. Meanwhile, there is a rapidly growing interest in using doping to improve performance of these organic based devices [5]. Despite increased interest and research efforts along this direction to make doping a process readily applicable in organic based devices, several key issues need to be addressed appropriately. First of all, air stability of dopants and doped films are crucial. This is particularly true for n-type dopants, because with a high-lying HOMO n-dopants are prone to oxidation when exposed to air. Secondly, to cut down fabrication cost, it is highly desirable to be able to introduce dopants via ambient pressure, low-temperature, and high-throughput techniques such as spin coating, spary pyrolysis, inkjet printing, etc. Thirdly, to ensure reliable operation of organic-based devices, dopants need to be spatially confined within the targeted region. Therefore, diffusional stability of dopants in the host matrix is of great value. Last but not least, systematic research is necessary to search for new dopants that are of low cost and high performance.

Definition

In dry etching, substrate material is removed by impinging radicals in plasma or by etchant gases. The reaction that takes place can be done utilizing high kinetic energy of particle beams, chemical reaction, or a combination of both.

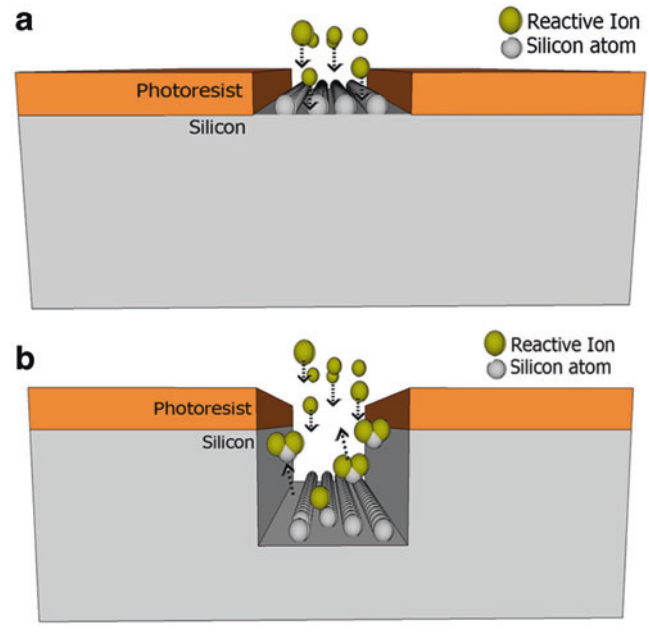
Physical Dry Etching

Physical dry etching requires high energy kinetic energy (ion, electron, or photon) beams to etch off the substrate atoms. When the high-energy particles knock out the atoms from the substrate surface, the material evaporates after leaving the substrate. There is no chemical reaction taking place and therefore only the material that is unmasked will be removed. The physical reaction taking place is illustrated in Fig. 1.

Dry Etching Processes, Fig. 1 The plasma hits the silicon wafer with high energy to knock off the Si atoms on the surface. (**a**) The plasma atoms hitting the surface. (**b**) The silicon atoms being evaporated off from the surface

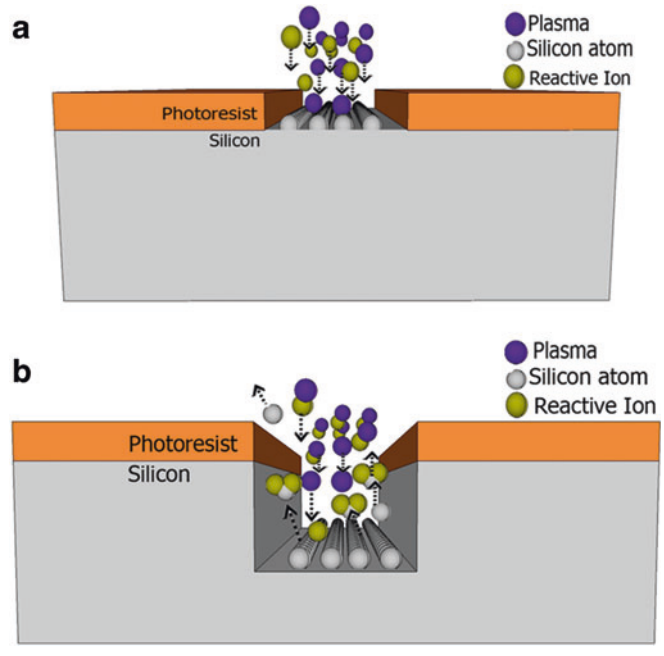
Chemical Dry Etching

Chemical dry etching (also called vapor phase etching) involves a chemical reaction between etchant gases to attack the silicon surface or the substrate. The process does not use liquid chemicals or etchants. The chemical dry etching process is usually isotropic and exhibits high selectively. Anisotropic dry etching has the ability to etch with finer resolution and higher aspect ratio than isotropic etching. Due to the directional nature of dry etching, undercutting can be avoided. Figure 2 shows a rendition of the reaction that takes place in chemical dry etching. Some of the ions that are used in chemical dry etching is tetrafluoromethane (CH_4), sulfur hexafluoride (SF_6), nitrogen trifluoride (NF_3), chlorine gas (Cl_2), or fluorine (F_2).



Reactive Ion Etching

Reactive ion etching (RIE) provides high level of resolution using both physical and chemical etching mechanisms. RIE is one of the most diverse and most widely used processes in semiconductor industry and research settings. Since the process combines both physical and chemical interactions, the process is much faster. The high-energy collision from the ionization helps to dissociate the etchant molecules into more reactive species.



In the RIE process, cations are produced from reactive gases which are accelerated with high energy to the substrate and chemically react with the silicon. The typical RIE gases for Si are CF_4, SF_6, and $BCl_2 + Cl_2$. As seen in Fig. 3, both physical and chemical reactions are taking place. Table 1 shows some commonly used gases for etching semiconductor and dielectric thin films.

Deep Reactive Ion Etching (DRIE)

Major challenges toward fabricating high-aspect-ratio structures with dry etching include (a) low etch rates, (b) inability to maintain high-aspect ratios for etching depths of 10 μ or more, and (c) weakness of photoresist masks to survive extended etching runs [1]. Deep reactive ion etching (DRIE) provides a viable solution to these problems and successfully etches structures as deep as the thickness of a silicon wafer with extremely high-aspect ratios of 20–30:1 [1]. The DRIE process is

comprised of two steps. In the polymerization or passivation step, a thin 10 mm layer is deposited on the side walls and bottom of a trench etched in the previous etching step. The (plasma) etching step following the passivation step removes the polymer from the bottom of the trench and proceeds with etching of silicon while the side walls remain protected by the polymer. In this way high anisotropy is achieved through repeated succession of etch and passivation sequence.

DRIE works on the mechanism of plasma etching in the presence of process gases (SF6 for

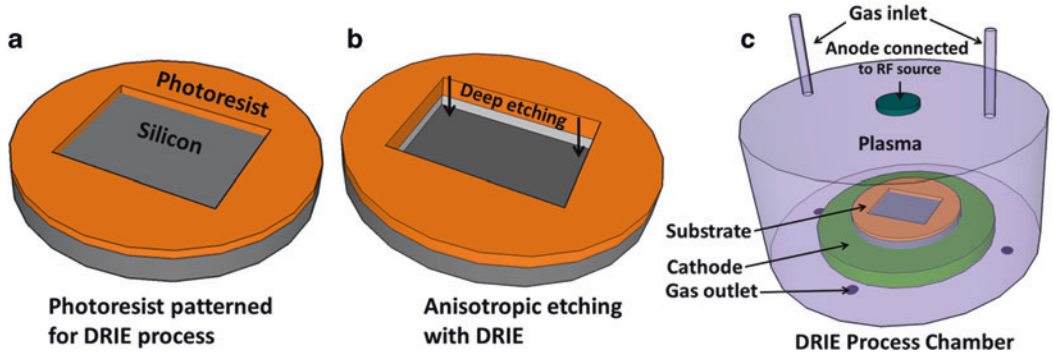
etching and C4F8 for polymerization) in the etching chamber. Like any plasma etching, DRIE requires the presence of sustained plasma through the generation of secondary elections after the initial plasma-generating electrons have been consumed. These secondary electrons are emitted by the cathode when struck by the ions inside the plasma. Collection of positive ions around the substrate (cathode) forms a sheath or a dark space. This sheath ensures further accumulation of positive ions responsible for etching. When the substrate placed on cathode is a conductor, the sheath is maintained with its positive polarity and the bombardment of substrate is sustained.

In case of an insulating substrate, however, the substrate accumulates the positive charges nullifying the field in chamber (between anode and cathode). The plasma ceases and etching process stops. In DRIE process the process chambers are operated with high frequency RF source. The rapidly alternating polarity of electrodes prevents the positive charges from accumulating on the substrate which are neutralized in the second half cycle by the impinging electrons (substrate acts as anode in the second half cycle).

Process Issues

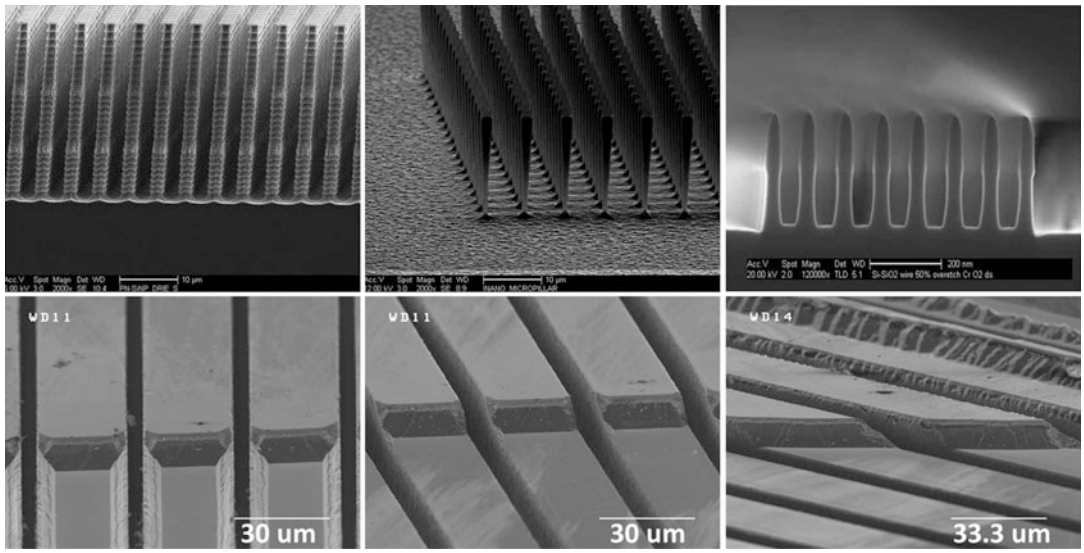
Bull's eye effect: The phenomenon by which edges of wafer etch faster than the central regions [2].

Microloading: The phenomenon by which isolated features etch faster than those located in a dense array.



Aspect ratio dependent etch (ARDE): The occurrence of smaller features etching slower than those with larger dimensions.

Inductively Coupled Plasma: Reactive Ion Etching (ICP-RIE)



Although plasma etching provides high etch rates at low chamber pressure for increased directionality, the plasma density is low due to low chamber pressure. Low plasma densities not only degrades selectivity but also renders inability to maintain high-aspect ratios [1]. High-density plasma etchers, namely, ICP-RIE, provide a solution to abovementioned problems by producing high-density plasma at low pressure. ICP-RIE comprises of magnetic coils that create a magnetic field to control the ion-producing electrons. The magnetic field ensures electrons are prevented from colliding with electrodes or chamber walls. This increases the probability of electrons for successful ion creating collisions, thus increasing the plasma density at low pressure.

Applications

Dry etching is used to etch some selective areas of a semiconductor surface in order to form recesses

Dry Etching Processes, Fig. 4 (**a** and **b**) Wafer preparation for deep reactive ion etching (**c**) Inside the DRIE process chamber

Dry Etching Processes, Fig. 5 Silicon nanopillars [3], nanowalls [4], and nanoridges fabricated using deep, ICP, and regular reactive ion etching

in material, such as mesa, contact holes, or via holes, to otherwise remove portions of semiconductor or dielectric layers where predominantly vertical sides are desired. Along with semiconductor manufacturing, micromachining, and display production, the removal of organic residues by oxygen plasmas is also described as a dry etch process. Dry etching is particularly useful for materials and semiconductors, which are chemically resistant and could not be wet etched, such as silicon carbide or diamond.

Logeeswaran et al. [3] fabricated high-aspect-ratio vertically oriented silicon micro-pillars using deep reactive ion etching (DRIE) to develop highly efficient portable and flexible electronic devices for future applications. As shown in Fig. 4, a highly doped p-type Si (100) substrate with a doping concentration of $\sim 10^{19}$ cm^{-3} was patterned with a 2-μm dot etch mask. The substrate was kept at 10 °C with SF_6 and C_4F_8 flows of 300 and 150 sccm, respectively, a source RF power at 1,800 W and a substrate power at 20 W for a total etching time of ~6 min. These high-aspect-ratio structures were etched using a special DRIE recipe called Bosch process. The Bosch process is a pulsed-multiplexed etching technique which

alternates between two modes to achieve extremely long and vertical micro-scaled nanostructures (Fig. 5).

Chen et al. [5] carried out an extensive study to determine the dependence of the etching performance. Factors such as applied coil or electrode power, reactant gas flow rates, duty cycles, and chamber pressures were considered. These process parameters were modeled and experimentally determined to see the effect on the surface morphology and the mechanical performance of the silicon structures.

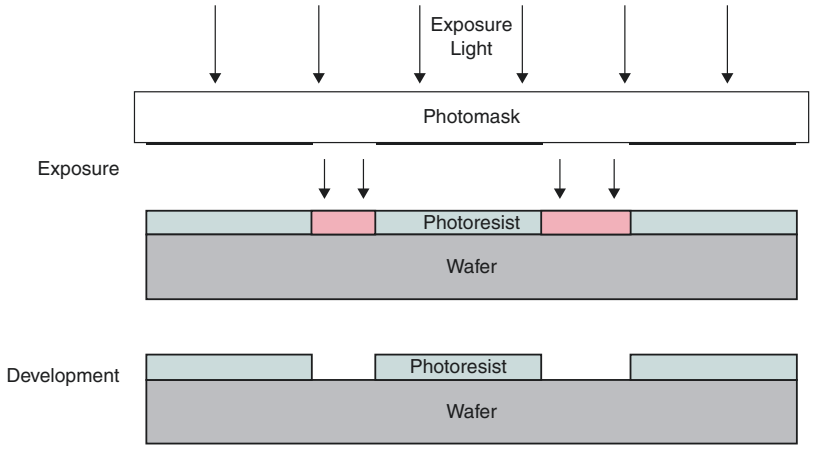
Definition

Deep ultraviolet (DUV) photolithography is the process of defining a pattern in a thin photosensitive polymer layer (photoresist) using controlled 254–193-nm light such that the resulting polymer pattern can be transferred into or onto the underlying substrate by etching, deposition, or implantation. The exposing light is passed through a chrome-on-quartz photomask, whose opaque areas act as a stencil of the desired pattern. The exposed polymer is then subjected to a chemical development process where the unwanted areas of polymer are removed, leaving the target areas unprotected from subsequent processing.

In semiconductor manufacturing, the light sources used are typically excimer lasers and produce either 248-nm or 193-nm light. The light is usually passed through the photomask and then through a reduction lens which reduces the pattern size by a factor of 5 or 4 times.

Introduction



The process of photolithography has been performed since at least the 1950s in the

manufacturing of circuit boards and discrete electronic devices, initially using cyclized rubber-based photoresists as the patterning medium in the process of contact lithography, where the photomask is brought into contact or near-contact with the substrate for direct 1:1 patterning, using mask-aligning exposure tools. Modern DNQ-novolac (diazonaphthoquinone) photoresists were developed in the early 1970s allowing features smaller than 2 μm to be printed and opened the door to the age of mass-produced silicon-based integrated circuits. The resulting economies of scale eventually led to the development of the personal computer for the mass market. The growth of this market, in turn, drove the development of advanced photoresist materials and exposure tools to satisfy the demands of the market for faster, smaller, and cheaper technology products.

The process of UV (ultraviolet, 436–365 nm) photolithography as performed for the last 30 years remains basically unchanged in that time. A design pattern is generated using computer-aided design (CAD) software. The pattern data is converted into a standardized file format, usually GDSII or, more recently, OASIS. This data is then converted by specialized software into the format needed for the specific mask-writing tool to be used and then sent to the mask writer. The mask writer exposes the pattern on a thin resist film (100–500 nm) coated on top of a thin chrome layer (1,000 Å typ.), which has been deposited on top of the photomask substrate, which is most often fused silica or quartz, but can be other types of glass. The exposed pattern is then chemically developed, revealing the chrome layer underneath in the shape of the desired pattern. Next, the uncovered chrome is etched away with an acid, removing the designed pattern from the chrome layer. The end result is an opaque stencil made from thin chrome on a transparent plate, which is suitable for use in either a mask aligner for contact photolithography or a projection photolithography tool. The photomask can then be used many times, particularly in projection photolithography, where the pattern area of the mask never contacts the wafer or the tool.

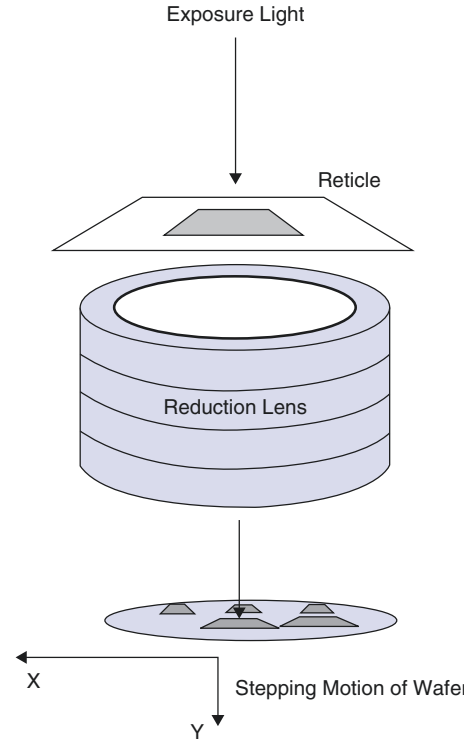
The device substrate, usually a silicon wafer, is spin coated with a thin photoresist layer and baked at a temperature near the glass-transition temperature of the resist to remove most of the solvent. Exposure of the mask pattern into the resist is then performed, either by bringing the wafer and mask together before exposure (contact or proximity photolithography, 1:1) or by mounting the mask in front of a (usually reduction) lens and projecting the image onto the wafer (projection photolithography, 4:1 typ.). Production tools currently are virtually all reduction projection printers, and they are what the remainder of this discussion will focus on. The DNQ-novolac chemistries used in UV photolithography today are substantially the same as when they were first formulated, with some tweaking of wavelength absorption properties and sensitivities. The exposure light causes a chemical reaction within the photoresist, forming acid (for DNQ resist, indene carboxylic acid) in the exposed areas. An aqueous base solution (developer) removes these acidic areas of the resist, creating a three-dimensional replica of the pattern seen on the photomask. Positive-tone photoresists such as this are dominant in usage, but negative-tone versions, where the exposed areas *remain* after development, also are available. The high-pressure mercury (Hg) arc lamp light sources used still possess the same output spectrum characteristics as before, and the exposure tools using them, while more sophisticated and automated than before, are essentially the same (Fig. 1).

The emergence of modern-day DUV (deep ultraviolet, 248–193 nm) exposure tools and chemistry has profoundly changed this established process. What was once a comparatively forgiving series of process steps has now become a critically controlled time and temperature ballet with incredibly complex machinery and computerized systems. The development of DUV photolithography has caused engineers to push the boundaries of our understanding of the behavior of light, as well as our concepts regarding mechanical and chemical systems, beyond

DUV Photolithography and Materials, Fig. 1 Basic photolithography process

what we once considered the limits of our abilities. Most remarkably, it is done on a daily basis in high-volume manufacturing (HVM) and with great success.

History



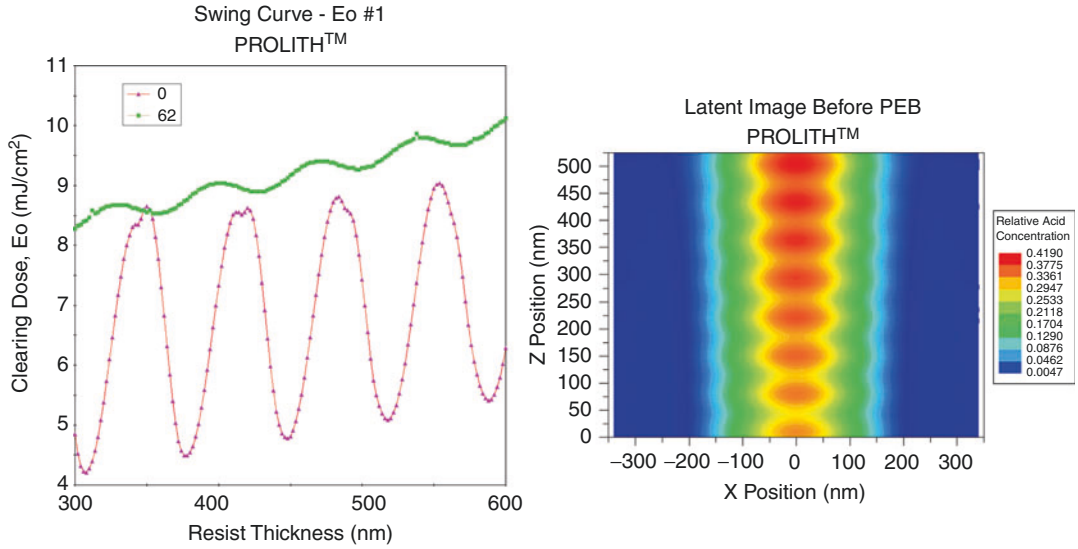
Modern DUV lithography had its beginning in the early 1980s at IBM with Frechet, Willson, and Ito and their development of chemically amplified resists. The drive toward ever-smaller features in the structures that make up the electronic devices in the marketplace required the use of ever-shorter-wavelength exposure light, which in turn required new photoresists with appropriate sensitivity to these new wavelengths. Unfortunately, the existing photoresist materials were too absorptive and insensitive in the DUV wavelength regions to be practical. New polymer systems were developed with sufficient transparency at these wavelengths, but their sensitivity to exposure was still far too low. Chemically amplified (CA) resists overcame this by using a complex heat-activated de-protection method that multiplied the acid formed by exposure, which increased the material's DUV sensitivity by some orders of magnitude, leading to today's superior performers with resolution capabilities far better than DNQ-sensitized materials could ever achieve.

However, this was not an overnight success story. Although these resists began to appear in the early 1980s, and IBM had a small production line in Burlington, Vermont, in the late 1980s, HVM using 248-nm photolithography did not begin until the late 1990s. There were two primary reasons for this: a lack of adequate photoresists and delayed tool development. The CA resists described previously would take another 10 years to reach the stage of development where they were robust enough to survive the rigors of mass production with reasonable cost. Problems with airborne contamination and etch resistance also took years to overcome, but in the end DUV resist performance surpassed expectations, with etch resistance nearly equal to DNQ materials and with much better sensitivity and resolution. The exposure tooling also encountered many roadblocks during development, including difficulty in identifying suitable fused silica material for lenses and masks, developing suitable 248-nm light sources, and, perhaps most importantly, finding funds to research all of these issues. The SEMATECH consortium played a vital role in this by helping to organize and direct efforts and funding in these matters. Industry-university collaborations also played key roles in areas like materials and chemical engineering. They reprised these roles during the similar progression in the development of 193-nm materials and tools in the 1990s. Thankfully, lessons learned in resist

development and material qualification during the run-up to 248-nm HVM shortened the 193-nm development timeline by about 50 %. This learning was also important in later investigations into the viability of 157-nm (F_2) photolithography, a technology that was ultimately rejected.

DUV Processing

DUV photolithography is at its core the same as UV photolithography. The two methods share many of the same basic processing steps: photoresist is spin coated onto wafers, baked, exposed, post-baked, and developed. Similar tools are used for both technologies in HVM: spin coaters, hot plates, step-and-repeat systems (steppers), and aqueous developers. However, there are important differences in these processes besides the minimum value of the resulting pattern's critical dimensions (CD). The devil is, as usual, in the details (Fig. 2).



DUV Photolithography and Materials, Fig. 2 Wafer stepper schematic

Wafer Preparation

Photolithographic processing always begins with cleaning of the wafer surface. Depending on the state of the wafer (new or in process), the cleaning process can take many forms and be either dry or wet. Final results depend heavily on the cleanliness of the wafer surface, so the importance of this step should not be minimalized. Typical new wafer cleaning may include the "standard cleans," SC1 and SC2, which derive from the well-known "RCA clean" originally used in vacuum tube manufacturing. SC1 is a 5:1:1 solution of water, ammonium hydroxide, and hydrogen peroxide heated to ~75 °C. SC2 is a 6:1:1 solution of water, hydrochloric acid, and hydrogen peroxide heated to ~75 °C. Both baths are usually performed for ~10 min each, and an additional step consisting of a dip in dilute hydrofluoric acid is sometimes included as well. Cleaning of wafers which are "in process" (partially completed) can take many forms, each dependent on the previous processing steps performed on the wafer, as specific residue will need to be addressed.

Once a clean surface is achieved, the paths of the two processes differ: UV wafers typically undergo a "priming" step, where the wafer surface is dehydrated using heat and sometimes vacuum and then coated with a chemical primer, hexamethyldisilazane (HMDS), to maintain the dehydrated state and optimize adhesion of the photoresist to the wafer surface [1]. Dehydration is necessary as photoresist will preferentially attach to water on the surface, causing serious degradation of resist adhesion. HMDS application will contain any remaining water and greatly increase the wetting angle of the surface, rendering it hydrophobic. DUV wafers, on the other hand, typically do not undergo this priming step.

In DUV lithography, a bottom antireflective coating (BARC) is usually applied to the surface of the wafer by spin coating. During exposure, light penetrates progressively deeper into the photoresist until complete exposure is achieved. At that point, the light reaches the bottom of the resist and is reflected by the wafer surface. BARC is a thin polymer layer which is designed, when applied at the proper thickness, to absorb the

DUV Photolithography and Materials, Fig. 3 Standing wave dose swing of 63 % reduced to 1 % by BARC; 248 nm on Si

light which would otherwise be reflected back into the resist by the wafer. BARC is also used in some UV processing where topography of the wafer surface can cause "notching" or unwanted exposure due to reflected light, particularly in the case of metal lines on the wafer. Light can be reflected randomly by irregularities in the surface, especially by features that have been etched into the wafer, or by deposited material on top of it, creating a background dose which can affect feature sizes. In some cases, the reflected light can be focused onto an area of resist, exposing it and creating unexpected patterns. BARC is necessary in most DUV processing due to the high reflectivity of silicon (or almost any material) at DUV wavelengths. This reflectivity, in combination with additional internal reflections caused by the refractive index mismatch at the air-resist interface, forms a standing wave within the bulk of the resist. The resulting constructive or destructive total effect of this wave on the exposure dose makes CD control increasingly difficult as feature sizes shrink, and the impact on the dose becomes more significant. Therefore, BARC is used in most 248-nm processing and in all 193-nm processing. In fact, in advanced 193-nm processing, multilayer BARCs are common (Fig. 3).

Antireflective coatings are comprised of various polymer materials, usually linked to dyes to give them the desired wavelength absorbance. The polymers can be acrylic, vinyl, polyether, polyurethane, polysaccharide, or polystyrene, among others. The polymer is dissolved in a photoresist bowl-compatible solvent to allow easy integration into the processing line. There must be no intermixing with the photoresist applied after bake and no chemical interactions that might cause footing or undercut at the base of the resist feature. Some BARCs can be developed away with the resist (D-BARC) to simplify processing or for applications such as metal lift-off.

There are two important benefits of this step: the internal reflective interference is greatly reduced or eliminated, allowing better process control, and the adhesion of the photoresist to the surface (now BARC) is greatly improved, negating the need for any priming [2]. The inevitable trade-off is that the process requires an additional spin-and-bake step at elevated temperature (∼180–220 °C), and sometimes an

additional dry etch step after development to open the ARC at the bottom of the resist before the actual process step is performed. The etch chemistry can be O_2 plasma, or the same process that will be used in the following wafer etch step, but characterization of the etch rate is necessary. The thickness of the BARC must be adjusted to optimize performance with the existing film stack on the wafer at the time of exposure due to the interaction of the light with each of the layers and must be re-optimized for any changes in the films during each step in the process. Photolithographic computer modeling can be of great help here, narrowing the empirical testing parameters to acceptable size.

Another type of antireflective coating, top-layer ARC, or TARC, is also used in some situations. This layer works in much the same manner as BARC but is applied to the top of the resist layer. This layer can serve two purposes: it can act as an absorber for light reflected back from the wafer surface, reducing the standing wave intensity, and it can serve as a protective barrier layer for the photoresist, keeping any harmful chemicals from reaching it. In many immersion lithography applications (see DUV Exposure), it is used for this second function, preventing the immersion fluid, usually water, from leaching chemicals from the surface of the resist and degrading the resulting image.

Wafer Flatness

One important difference between UV and DUV processing is the flatness requirement of the wafer substrate. Silicon wafers start as slices from a long single-crystal ingot, called a boule. These slices are polished to the required thickness and flatness on either one side or both sides. The surface polish is usually required to be <1-nm RMS, with <0.5 nm being more desirable. Wafers polished on both sides (double polished) typically have the flattest surfaces and least thickness variation. As will be shown, flatness is important for successful DUV lithography.

The most stringent requirement for wafer flatness in UV lithography is 2-μm TTV (total thickness variation). The *least* stringent requirement for projection DUV lithography wafer flatness is 2-μm TTV and is 0.5-μm TTV for many critical processes. This more demanding requirement is due to the properties of projection optics outlined below.

The resolution of a reduction lens is calculated based on the Rayleigh criterion:

$$R = \frac{k_1 \lambda}{NA}$$

where

R = resolution of the system (1/2 of the smallest printable pitch)
λ = wavelength of exposure light
NA = numerical aperture of the lens
k_1 = process-dependent factor ($\geq$0.8 typ. DNQ, $\leq$0.6 typ. DUV)

However, the depth of focus of the same system is similarly calculated:

$$DOF = \frac{k_2 \lambda}{NA^2}$$

where

DOF = depth of focus (usable focus range on axis)
λ = wavelength of exposure light
NA = numerical aperture of the lens
k_2 = process-dependent factor ($\leq$1 typ.)

The first equation shows that smaller-wavelength light sources result in smaller features being printed (λ is directly proportional to R). It also shows that larger NA lenses result in smaller features being printed (NA is *inversely* proportional to R).

The second equation shows that smaller-wavelength light sources result in a smaller depth of focus (λ is directly proportional to DOF). It also shows that larger NA lenses result in a *much* smaller depth of focus (NA is *inversely exponentially* proportional to DOF) [3].

From the information above it is clear that the same mechanisms that produce smaller features also decrease the depth of focus, which is typically the most important limiter of process latitude. The

DUV Photolithography and Materials, Table 1 Various exposure wavelengths and their production capabilities at the time of the next wavelength technology introduction to HVM

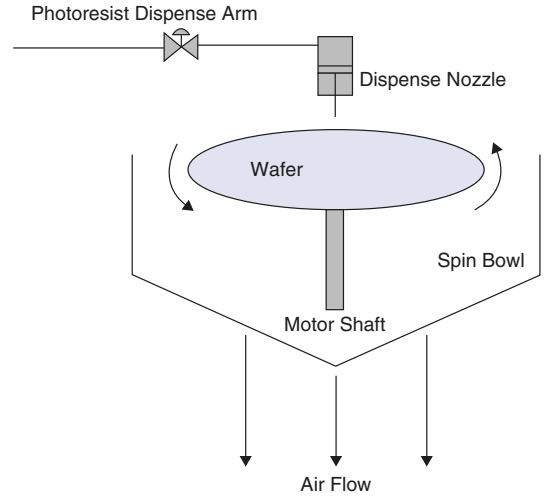
λ (nm)	NA	Resolution (μm)	Total depth of focus (μm)	Overlay (nm)
436	0.38	1.000	3.020	±0.120
365	0.60	0.350	1.010	±0.050
248	0.75	0.130	0.340	±0.025
193	0.93	0.065	0.220	±0.012
193i[a]	1.35	0.038	0.106	±0.005

[a]Immersion, currently the leading-edge technology

DOF is the tolerance of the system to vertical variations in the target surface, which can include resist nonuniformity, chuck non-flatness or contamination, focus system noise, and physical vibrations, as well as wafer thickness excursions. In other words, the *difficulty* of printing features increases *exponentially* as the minimum pitch decreases linearly. If the parameters for the first generation of HVM 248-nm exposure tools ($\lambda = 248$ nm, NA $= 0.7$, $k_1 = 0.6$, $k_2 = 1$) are substituted into these equations, the following values result: resolution $= 213$ nm and depth of focus $= 506$ nm. Since the DOF figure represents the total available focus latitude, this might also be stated as ±253 nm. At the time of these tools' introduction, the typical *minimum* photoresist thickness was ~600 nm, which already exceeded the focus capabilities of the new DUV systems.

This loss of latitude in processing caused a paradigm shift in the lithographic process flow: from then on, photoresists would have to be increasingly thinner, and all surfaces requiring DUV exposure would have to be very flat regardless of their current state of processing. The industry would come to depend on chemical mechanical polishing (CMP) to provide the flat surfaces required for successful patterning of critical layers. CMP is a wet wafer polishing technique, where a slurry containing etch chemistries specific to the wafers to be polished is introduced to large rotating polishing pads. The polishing is performed using controlled pressure, continuous slurry flow, and constant motion of the wafer and pads to yield a uniformly flat surface across the wafer. Contamination is a constant issue in CMP processing, as any material left behind, such as copper, can contaminate an entire processing line. Post-CMP cleaning is, therefore, a critical step in the process flow. One example of innovative processing fostered by this flatness requirement is damascene metallization, where insulating material is deposited, patterned, and etched; then metal is deposited to overfill the etched features and finally CMP polished back down to the insulator, leaving a flat surface with metal in the previously etched areas. Many other variations exist, but the goal is that every process performed must result in a flat surface for the next lithography step.

Another important observation to be made from the above calculation is the powerful resolving ability of the photoresists used in DUV processing. The factor k_1 is an empirically derived number based on actual processing results. It can be influenced by many elements of wafer processing, such as uniformity, resist contrast, and development. The k_1 factor has a direct linear relationship to the system resolution. Note that the k_1 value is much smaller for DUV resists than for typical UV resists. This is due to the chemical amplification process described earlier. The above k_1 value is higher than typical values found in HVM today, which are often less than 0.4. This remarkable property of DUV photoresist enabled the printing of features *smaller* than the wavelength of the light used for exposure. In fact, 193-nm exposure tools were first introduced to HVM at around the 110-nm node, almost *one half* the exposure wavelength, a feat deemed impossible only a few years earlier (Table 1).



Photoresist Coating and Development

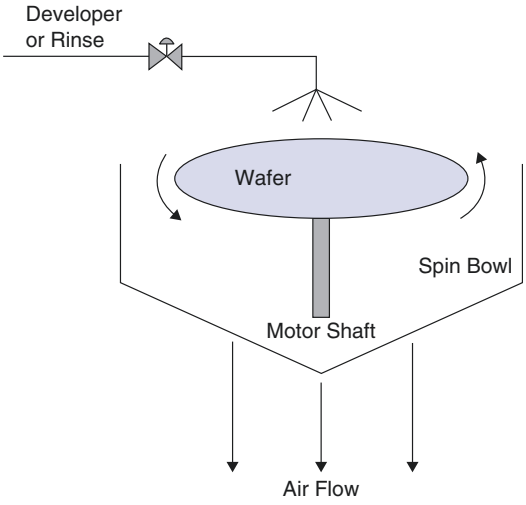
Spin coating of photoresist is universally performed due to the efficiency and uniformity achieved with this process. Other methods exist,

such as spray coating or meniscus, but they are reserved for special applications and do not typically appear in DUV processing. Wafer coating is performed by large, complex machines using precise control of dispense volume, spin speed, acceleration, and temperature parameters, to name only a few. While the tools used in UV processing are similar, the DUV versions are more tightly controlled in all parameters, have airborne chemical filtration (CA resists are sensitive to airborne contamination, e.g., ammonia and NMP), and require higher uniformity of hot-plate surface temperatures.

DUV photoresists are comprised of various materials including polyhydroxystyrene (PHS), acrylic polymer, and phenolic resin. The three general types of 248-nm photoresists are t-BOC PHS, ESCAP (PHS t-butyl acrylate), and acetal resin [4]. 193-nm resists can be polyacrylate, polymethylmethacrylate, or silsesquioxane resin, to name a few. The solvents used are primarily propylene glycol monomethyl ether acetate (PGMEA) and ethyl lactate, along with anisole and butyl acetate. Other materials are added to act as acid generators, acid inhibitors, and base quenchers, as well as surfactants to eliminate streaking during spin coating.

A typical resist coating process for DUV lithography has two primary steps: BARC coating and resist coating. Beginning with a properly cleaned surface, the wafer is spin coated with BARC, usually using a dynamic (wafer spinning) dispense process: a nozzle is moved out over the rotating wafer, and resist is released onto the wafer surface at a precise position, sometimes with continuous motion of the nozzle across the wafer, with a carefully controlled rate and amount. The wafer's rotation is then ramped up at a high rate of acceleration (5–30-k rpm/s) to the final casting speed of 2–6-k rpm, although usually the maximum is 3-k rpm for 200-mm or larger wafers. The volume of exhaust air from the spin bowl is adjusted to obtain the maximum film thickness uniformity across the wafer and to simultaneously obtain the fewest number of defects. The wafer is then baked on a hot plate at 170–210 °C for 60 s to remove solvent from the film and is then moved to a chill plate for 20–30 s (Fig. 4).

DUV Photolithography and Materials, Fig. 4 Resist coating schematic



A hot-plate bake is analogous to baking in a convection oven but has some important benefits. The hot plate can bring the wafer into intimate contact for uniform thermal transfer across the wafer, often using vacuum for better contact between the wafer and the plate, and the process drives the solvent out of the film from the inside at a high rate. Oven baking causes the resist to form an outer skin, which thickens as the drying process continues at a decreasing rate due to the increasing skin thickness. A typical hot-plate bake time is 60 s, while an equivalent oven bake process may take 30 min or more and cannot maintain similar uniformity across all wafers in a batch.

The BARC thickness can be anywhere from 40 to 120 nm depending on the application. After cooling, the wafer is coated with photoresist using the same methods as before, but this time it is baked at 110–140 °C for 45–90 s to remove most of the casting solvent from the film, and then moved to a chill plate for 20–30 s to stop the bake process in a controlled way. All wafers must be baked for exactly the same length of time at exactly the same temperature for wafer-to-wafer repeatability to be maintained. The final thickness of the resist can be anywhere from <100 nm to >1 μm depending on the application. All of these process steps are performed by

automated modules utilizing tight control of dispense volume and bake time and temperature, as well as the temperatures of the chemicals and the individual parts of the tool.

After exposure, DUV wafers must be postexposure baked (PEB) to activate the acid amplification process. The PEB is a critical step, as the time and temperature both have a strong impact on the final CD and sidewall profile of the resist. Exposure of the resist by the tool creates a small amount of acid in the film but not enough to cause well-developed features to form. The PEB activates the acid amplification process, which greatly multiplies the volume of acid in the exposed areas, making the resist soluble in the developer solution. The acid profile in the resist is sensitive to both the time and temperature of the PEB, as they determine the final acid diffusion length as well as the final acid concentration in the resist. Once the wafer cools it is placed on a spin chuck, and a developer solution, usually tetramethylammonium hydroxide (TMAH) or recently tetrabutylammonium hydroxide (TBAH), is applied to the spinning surface by stream, spray, or other methods to form a puddle on the entire (now stationary) wafer. The developer remains in place for 30–60 s and is then rinsed off with deionized water as the wafer ramps up to speed and continues to spin until dry. There have been recent reports of using alcohols as the developer to produce a negative-tone image in the resist, which is very useful in 193-nm processing as there are no negative-tone 193-nm resists currently available. The amount of water and the length of the rinse time are crucial to minimizing the creation of defects on the wafer from this process. Uniformity and repeatability are also key components of a successful development process (Fig. 5).

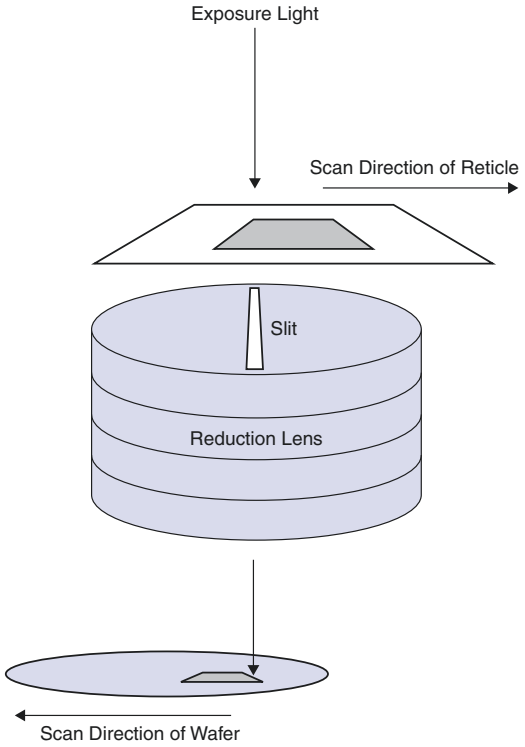
Because of the remarkable sensitivity of CA photoresists, any variation in temperature at any position on the wafer can cause a change in the final CD at that location. It is not uncommon for a DUV resist to have a CD change of 1 nm/°C. That may not seem like much, but it can make up more than 2 % of current device CDs, which sometimes have a total error budget of 5 % or less. Such CD variations can wreak havoc with the performance of multi-gigahertz devices and significantly

DUV Photolithography and Materials, Fig. 5 Development schematic

reduce yields in the fab (fabrication facility or semiconductor factory). The uniformity of DUV hot plates is usually specified to be $\leq$0.5 % variation across the surface, which can be larger than a 300-mm square. DNQ resists used for UV processing are not nearly as susceptible to these variations as engineers typically only perform PEB to reduce standing wave profiles in the resist sidewall.

DUV resist processing spurred the introduction of proximity hot-plate baking, a method where instead of pulling the wafer into close contact with the surface using vacuum, the wafer is suspended a few tens of microns above the hot-plate surface using, for example, ceramic beads at the wafer edge. The purpose of this spacing is to eliminate across-chip line-width variations (ACLV) due to local changes in the bake temperature of the wafer that might be caused by contamination or other nonuniformity of the hot-plate surface. Longer bake times are required for this, but the resulting increase in across-chip and across-wafer CD control makes it worthwhile. Any variations in the CD from one area of a chip to another can decrease the maximum working speed of the device by skewing clock timings or even cause the device to fail completely.

The uniformities of the spin-coated film thicknesses are very carefully controlled. With 193-nm



resist film thickness on the order of 100 nm and feature sizes reaching below 30 nm, there is no room for error. Any variation in the resist thickness (or the BARC thickness) will cause a measureable change in the CD at that location. For this reason, thickness variation across a 300-mm wafer is targeted to be <5 nm. Perhaps an even more difficult control issue is the level of defectivity. Defects are irregularities in the resist film which act to distort the exposed image. Some examples are particles on top of, underneath, or imbedded into the resist film. If defects are in the same location as device features, they can cause incorrect imaging of the pattern, leading to poor device performance or failure. They can be caused by many things, including the resist itself. Defect control is important in all photolithography, but because the CDs are so small in DUV processing, the problem is exacerbated. The allowable defect level for ≥30-nm defects on a 300-mm wafer is about $0.01/cm^2$. The introduction of immersion lithography (see DUV Exposure), where water is used between the exposure lens and the wafer surface, has created entirely new types of defects. Some of these have been solved by hardware engineering, while others have required material and chemical solutions. Some solutions include modification of the wafer coating system and the use of protective top coating layers.

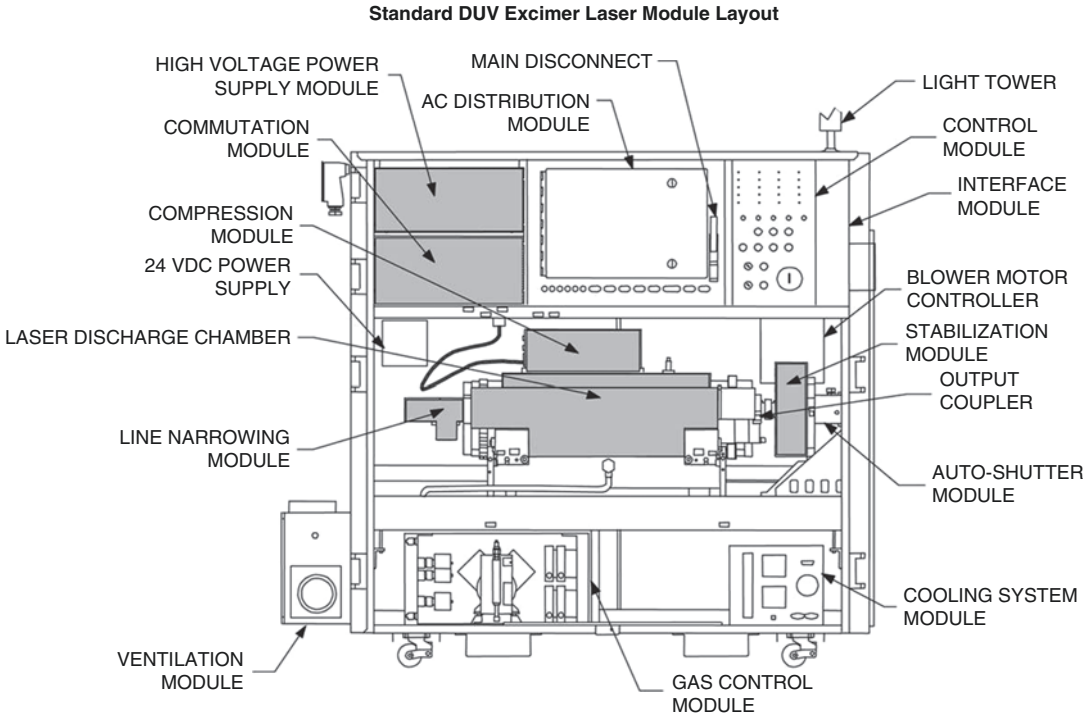
Considering that many wafer fabs start more than 10,000 new wafers each week and that each wafer will undergo as many as 30 or more photolithography steps during the approximately 45-day process, it should be apparent that complete control of the coating process is essential to keeping CDs in spec and production profitable.

DUV Exposure

The tools used for DUV exposure are by and large the same as those used for g-line (436-nm) and i-line (365-nm) UV exposure. Economical HVM is only made possible by using the ubiquitous wafer stepper. This high-throughput, high-yield, high-uptime platform enables the incredible economies of scale that today supply the marketplace with billions of transistors at a cost to the end user of < $0.0000002 each. These aforementioned qualities are indeed required as the tools can cost anywhere from $7 M to more than $40 M each. Steppers use computer-controlled automated systems to load and pre-align wafers, compensate for environmental conditions, load and align reticles (photomasks used in projection exposure tools), step the wafers to each programmed location for alignment and focus measurements, expose the wafers, and unload the wafers to start the process again. The pattern image on the reticle is projected through the reduction lens and focused onto the wafer to print each image, which may contain multiple devices or die. Each die will eventually be cut from the wafer and packaged into a chip for use in an electronic system. The placement accuracy of each die is measured by a laser interferometry system which monitors the wafer stage position. The wafer is leveled at the start to maximize the available focus range across the surface. Each die location on the wafer is measured for focus before each exposure using grazing-angle light beams, and the individual die locations can be measured for accurate overlay of layer-to-layer patterns using through-the-lens grating comparison or off-axis diffraction systems. The location of each stepper is scrutinized with regard to environmental factors such as electrical noise and vibration, as these can have a detrimental impact on the printed images. All of these systems must work together at high speeds and with high accuracy while remaining operational >95 % of the time. This is, of course, a simplification of what have been described as the most complex machines ever built.

DUV steppers utilize additional systems to level the wafer for *each exposure location* to maximize available DOF, correct focus error to a few tens of nanometers, and correct individual exposure lens element positions to reduce distortion within the field. Air filtration systems remove airborne contaminants from the atmosphere within the tool to prevent degradation of the resist profile and damage to the optical elements. Motors are used to generate motion opposite to the motions of the tool caused by the stage jumping from die to die. Alignment tolerances for both the wafer and the reticle are tighter due

DUV Photolithography and Materials, Fig. 6 Wafer stepper-scanner schematic



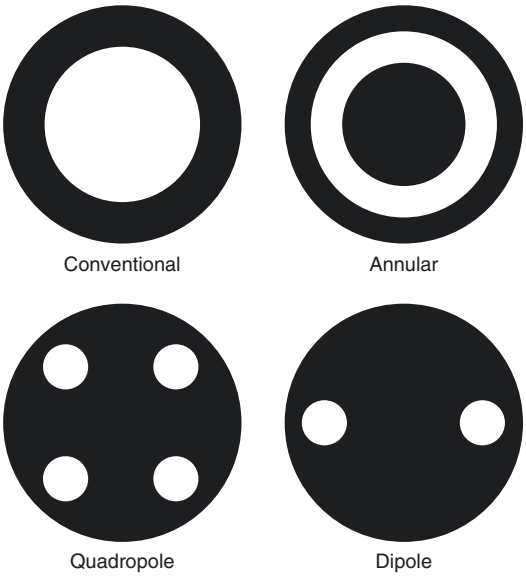
to shrinking feature sizes. At the same time, stage speeds and field sizes are increased to enhance productivity (Fig. 6).

The ever-increasing demands on DUV lithography for better alignment and lower distortion led to the introduction of the stepper-scanner systems now widely used in HVM. Scanners use a limited slit of the reduction lens for exposure, in order to optimize the best parts of the lens assembly. The reticle is scanned across this slit from end to end, while the wafer die location is scanned in the opposite direction under the lens. The result is a larger die than would be possible with a static system, with better distortion control and better overlay performance. The stage steps to the next die position and the scanning repeats in the reverse direction. Wafer stages can move at up to 700 mm/s, requiring counterbalances to move opposite the wafer and reticle stages to offset recoil, reduce stress on the factory floor, and dampen vibrations. Scanner throughput has reached 250 aligned and exposed 300-mm wafers per hour using two wafer stages in tandem: one performs wafer focus and alignment mapping, while the other steps and scans the wafer under the exposure lens.

Light Sources

Illumination systems for DUV exposure no longer use mercury arc lamps as the source, as the output intensity at DUV wavelengths is too low. Instead, excimer lasers provide high-power illumination with up to 90 W at 6-KHz pulse frequency and sub-half picometer bandwidth. Excimer lasers have proven to be very reliable, and constant improvements have made them increasingly powerful and cost effective. The laser can be located remotely from the tool, as far away as 20 m. The beam delivery systems utilize automated aiming mirrors in the nitrogen-purged beam line to maintain optimum positioning at the tool. A complex system of lenses, expanders, and homogenizers shape the beam and ensure uniformity across the reticle and from exposure to exposure. The laser uses a fluorine gas-filled chamber (KrF for 248 nm, ArF for 193 nm) with high-voltage electrodes to create the illumination source. The chamber gas depletes over time, and new gas can be injected to replenish the mix, until the chamber must eventually be flushed and refilled. These laser gas injections and refills are monitored and performed automatically by the stepper software to keep laser power and bandwidth within specifications. Laser maintenance is usually one of the less troublesome aspects of DUV lithography (Fig. 7).

The ramp-up of DUV photolithography also marked the acceptance of shaped illumination into HVM. Though proven for some time, this resolution enhancement technique (RET) was not often implemented in production environments. With the advent of sub-wavelength printing, shaped sources became a cost-effective enhancement to the wafer stepper. By using annular (off-axis) illumination, smaller features can be printed with greater depth of focus, albeit at the expense of (sometimes) throughput and printability of certain other feature sizes. Even greater enhancement is possible using quadrupole or, in the extreme, dipole illumination. One-



DUV Photolithography and Materials, Fig. 7 Two hundred and forty-eight-nanometer DUV excimer laser diagram

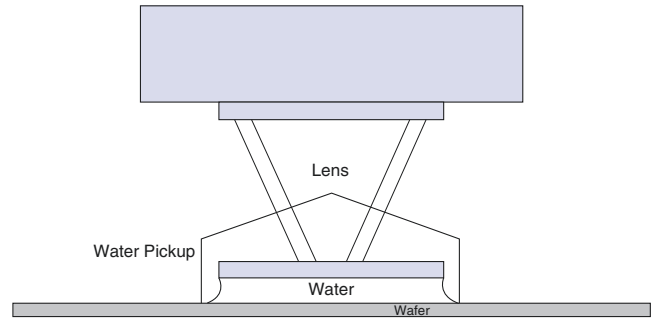
dimensional gratings can be printed at the diffraction limit of the system using binary masks, simply by inserting a shaped source. Programmability also was introduced, allowing any size annulus to be formed from keyboard commands and source shapes to be called up automatically. Today these mechanisms have been developed to the point of "free-form" source-shape capability. Arrays of thousands of mirrors are used to create any random shape calculated to optimize the process with any particular mask. The forms of both the source and the mask are calculated together in a technique called source mask optimization (SMO). Using free-form sources, the engineer is allowed almost limitless flexibility in process optimization (Fig. 8).

Polarization of the illumination is now one of the variables the operator can manipulate to optimize tool performance with regard to particular pattern orientations. Because of the high angles of incidence of the exposure light to the resist surface, light is transmitted or reflected by the photoresist depending on its polarization. Polarization can be set in orthogonal directions or in circular ones. Controlling the polarization of the exposure light can assist the engineer in controlling the printability of the resulting pattern.

Immersion Systems

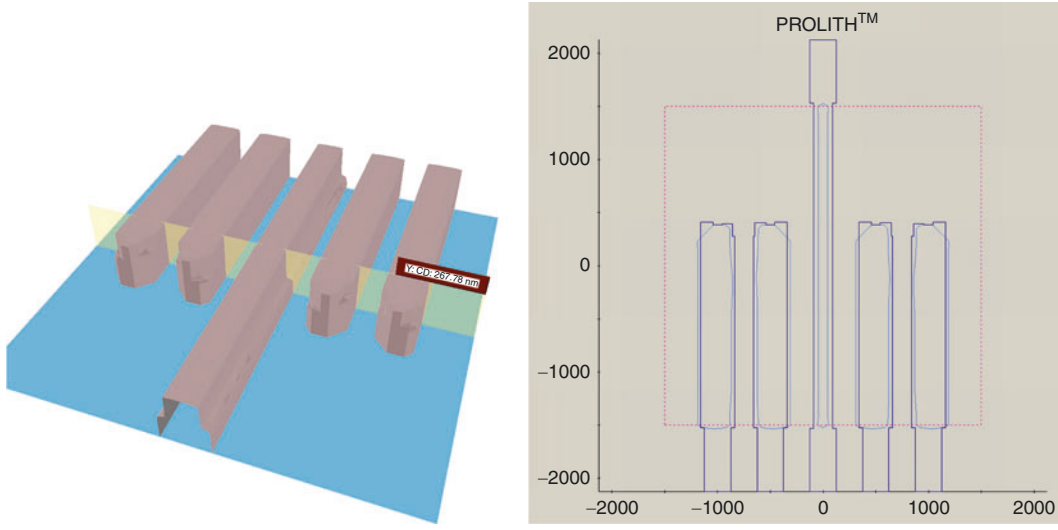
The NA of exposure lenses has become so high, 0.93 in air, that the angles of light exiting the lens are as high as 70° from normal, leading to reflection of the light at the resist surface. The two polarizations of the light (TE and TM) will behave differently with one polarization reflecting away more than the other, and the penetrating light polarizations focusing at different depths within the resist. To overcome this, current leading-edge system vendors have implemented immersion systems at 193 nm, where purified water is used as the transport medium between the exposure lens and the resist. The water fills the space between the

DUV Photolithography and Materials, Fig. 8 Illumination source-shape examples



lens and the wafer surface, creating a higher index medium for the light to pass through. The higher index of the water is a better match to the indexes of both the lens glass and the photoresist, reducing both the exit angle of the light leaving the lens and the angle of incidence of the light entering the resist, thus reducing the reflectivity and polarization losses. The water must be injected into the space without wetting any other parts of the system and must be kept only in the lens-wafer space throughout the exposure process. At the end of the exposures, it must be removed from the wafer without leaving any residue. To prevent defects the water must be bubble-free and leave no droplets behind on the surface, even though the wafer moves at very high speeds. Elaborate systems consisting of de-gassers, showerheads, and pickup rings are used to inject and remove the water from the moving wafer surface (Fig. 9).

This additional complexity, introduced by immersion and polarization, drives the cost of tooling up but also allows features to be printed on a half pitch as small as 38 nm in a single exposure. No smaller pitch can be resolved using these wavelengths unless a significantly higher refractive index medium can be found to replace the water currently in use, a doubtful prospect.



Mask Making

During the 1980s, mask making for the newly introduced reduction UV steppers initially relaxed the requirements for mask making compared to contact lithography, leading to what has been called the "mask makers' holiday," which lasted for some years. With features five times the size of the wafer CD, and only one field to make instead of the entire wafer, making acceptable masks presented a relatively simple task. With the introduction of DUV exposure at 4 × reduction, this holiday was abruptly ended. The industry struggled to meet increasingly demanding specifications for feature size and placement, line-edge roughness, and defects. Shortly thereafter, even greater pressure was brought to bear by the inclusion of optical proximity correction (OPC) features, which are assist features on the reticle sized below the resolution of the system, and phase-shift masks (PSM), which have some clear areas of the mask etched to a depth that causes the light passing through them to exit the mask 180° out of phase with the rest of the light. OPC may include assist features such as scattering bars or serifs, which are sub-resolution shapes that act to force the diffracted light into desired shapes on the wafer. Phase-shifting areas can be used either to define features or to improve the fidelity of the printed pattern. By placing out-of-phase light at the edge of a feature, the location in the resist can be precisely defined. Critical level masks can today have features nearly as small as the wafer CDs, making masks very difficult and expensive to manufacture.

The addition of OPC and PSM to a mask can cause the volume of the data necessary to write the masks to explode, making file size and data rates problematic. The tools used to write the masks, laser and e-beam writers, can cost $10 M or more and can take many hours to complete each mask. Inspection and repair add more time and effort to the task. Using these RETs in manufacturing, one single mask can cost $60 K or more. Given that a mask set for a device may require 30 or more masks, with perhaps 10 critical levels, mask costs can surpass the $1 M per set mark. Frequent revisions in production, sometimes known as "re-spins," can

DUV Photolithography and Materials, Fig. 9 Immersion scanner schematic

DUV Photolithography and Materials, Fig. 10 Computer model output of resist profile and mask OPC

obviously get very expensive. This in turn has driven the use of modeling in manufacturing.

Computer Modeling

Simulation of photolithography has been ongoing for around 30 years, initially in an effort to better understand and explain the process and then later as a way to optimize processing parameters. It has today evolved to the point where models can quickly and accurately predict not only the resulting resist pattern but also the optimum illumination shape and mask pattern corrections. By modeling the process, expensive hours of DUV tool time are saved by greatly reducing the on-wafer testing required to explore the process parameter space. Dose, focus, and illumination settings can all be determined before even making the mask. Simulation of the process over the entire chip can be done to locate problems and optimize yield before "tape out" of the mask design (submission of final data to the mask vendor), saving enormous time and effort and thus cost. Current applications of computer power leverage the enormous data volumes generated in manufacturing to model systems and extract error contributions from individual system components such as the reticle, the lens, and even the wafer chuck. Once these values are measured, corrections can be applied to reduce or eliminate them (Fig. 10).

The resolution of DUV exposure systems has now been pushed so far into previously unknown,

nonlinear regimes that the accepted concepts regarding refractive imaging systems cannot predict their behavior. The patterns that need to be exposed on the wafer cannot be defined in traditional ways due to previously unseen phenomena. Modeling and simulation have now allowed lithographers to reverse engineer the optical image, creating a new approach called inverse lithography technology (ILT). A mask made using ILT may look nothing like the final printed pattern, but it is a collection of shapes which will, when used in conjunction with the complementary illumination source shape, cause a diffracted pattern that will ultimately form the desired image in the photoresist. The SMO approach combines ILT with variable shaping of the light source, in some cases with single pixel addressing. These techniques have allowed engineers to push the resolution of exposure systems to the limits of diffraction with acceptable control.

One of the major mask-making issues that came to light in DUV lithography has to do with an unexpected effect that occurs when printing feature sizes below the wavelength of the exposure light. During exposure processes with low k_1 values, where the process becomes nonlinear, defects on the mask are printed on the wafer at dimensions larger than would normally be expected. This mask error enhancement factor (MEEF) can in some cases exceed 4 × or more, magnifying any error into a potential "killer" defect. Modeling these potential errors has led to better mask inspection methods focusing on the conditions particular to creating MEEF in order to prevent unexpected pattern failures. Simulations are also used to compute full-chip OPC to maximize the process window and increase yield. Without this computational modeling power, the advancement necessary to maintain "Moore's law" would have lost momentum long ago.

Inspection

One of the most difficult aspects of DUV processing is the inspection process. Trying to determine exactly what is on the wafer after lithography is much more difficult than in typical UV patterning, due to the much smaller feature sizes and overlay requirements. DUV lithography has driven the rapid advancement of optical inspection tools utilizing actinic (248-nm, 193-nm) illumination for both wafers and masks. Scanning electron microscopes (SEM) are routinely used in HVM to check in-line wafers, which can then feedback and feed forward data to other line processing tools. The information is then used to adjust processing parameters to compensate for measured results and improve yield. Atomic force microscopy (AFM) is also useful for determining surface characteristics and resist profiles. In recent years, a new method, called scatterometry, has gained popularity for measurement of dimensions which are difficult to resolve using standard tools. This method has the advantage of not requiring the formation of an image of the target to calculate its dimensions, something which can be impossible to do with light and is increasingly challenging with any tool at the scale of leading-edge devices. SEM inspection also has an unfortunate side effect on DUV resist: shrinkage. The area under inspection by the electron beam will actually change size through the process of inspection, making any resulting measurements questionable.

Another unique issue has also appeared in 193-nm DUV: the formation of a haze on the chrome side of reticles is causing new inspection techniques to be investigated. This haze can, over time, reduce transmission of the reticle affecting CD and even causing placement errors. New cleaning techniques are under investigation in order to counter this problem. Reticle inspection in general has undergone rapid development as 248- and 193-nm tools have advanced, in the quest to keep pace with shrinking CDs and exploding data sets.

Future Issues

One recurring theme in the descent to molecular-scale devices has been the battle against line-edge roughness (LER). LER may become the ultimate limiter of photolithography as the actual feature sizes approach the magnitude of the roughness. It

manifests as small variations in sidewall linearity or smoothness, either vertically or horizontally. These variations affect the line width of device structures after pattern transfer, making control of the performance of the device difficult or impossible. When the uniformity of the printed line width is beyond the control of the lithographer, working devices become unreliable or unattainable. The operational speeds and the timing of events within the devices depend on the uniform size of its structures. Once this uniformity is compromised, delicate timings are changed and device operations may fail.

The root cause of these variations in the sidewall plane has not definitively been explained by modeling, and ongoing work includes both investigations into the causes of LER and the development of new materials and techniques to reduce or eliminate it. Materials such as molecular glass are intended to reduce the size of the polymer molecules in an effort to reduce the width variations. New methods and materials for development of the resist after exposure are also possible solutions. LER can be reduced by decreasing the sensitivity of the resist, thus increasing the required dose, but this would result in an unacceptable decrease in throughput.

High-index immersion materials have been investigated as a way to extend the usefulness of 193-nm tools. Replacement of the water used in immersion lithography systems with higher index fluid could extend 193-nm exposure resolution for another node or two at most. Possible candidates have usually included fluorinated liquids, but most have been dismissed as not having high enough index to be worth the investment to make them viable.

Current work is focused on double-patterning scenarios, where two mask patterns are exposed in the same layer. The use of two separate patterns solves the problem of shrinking pitch values but requires either a resist that "forgets" the unwanted effects of the first exposure by "freezing" the image or that an etch step be performed before the second mask is exposed. The latter method places demanding overlay requirements on the scanner as well as a heavy burden on the mask makers. This level of precision is unprecedented, with error tolerances in the range of 2–3 nm for layer-to-layer registration. Another effort is concentrating on "spacer" patterning, also known as pitch splitting. This is a method of self-aligned patterning where the wafer is exposed and developed, a new layer of material is deposited, and then the material is etched back to form the new structures. This produces a pattern with about ½ the original pitch. This technique has been used by memory chip manufacturers for some time and has now evolved to triple and quadruple versions as the industry waits for EUV to finally reach readiness for HVM.

Conclusion

DUV photolithography is a dynamic and rapidly advancing technology. The race between manufacturers to make the smallest, fastest, and cheapest devices is seemingly endless. However, they may be approaching the end of their abilities to make things smaller. EUV lithography (13.5 nm) is preparing to enter the production phase by the 10-nm node, but some uncertainty still exists. Even if it does come into the fab, how long will it be useful? Current predictions are that it could last until the 5-nm node, if it is ever reached. At the same time, multiple e-beam and imprint technologies, as well as directed self-assembly, are still in the running. If they do work, will anyone be able to afford these technologies?

One thing is certain: as soon as this entry goes to press, it will become outdated. The latest advancements will change the direction of the industry, probably in unforeseen ways. In order to ascertain the current implementations of DUV lithography, the reader should investigate the SPIE Advanced Lithography Conference proceedings published since this entry was updated (2014), as well as search the publications of SEMATECH, ITRS, IEEE, BACUS, and IEDM. DUV photolithography will likely remain in favor longer than many would imagine, but the leading edge will eventually pass it by.

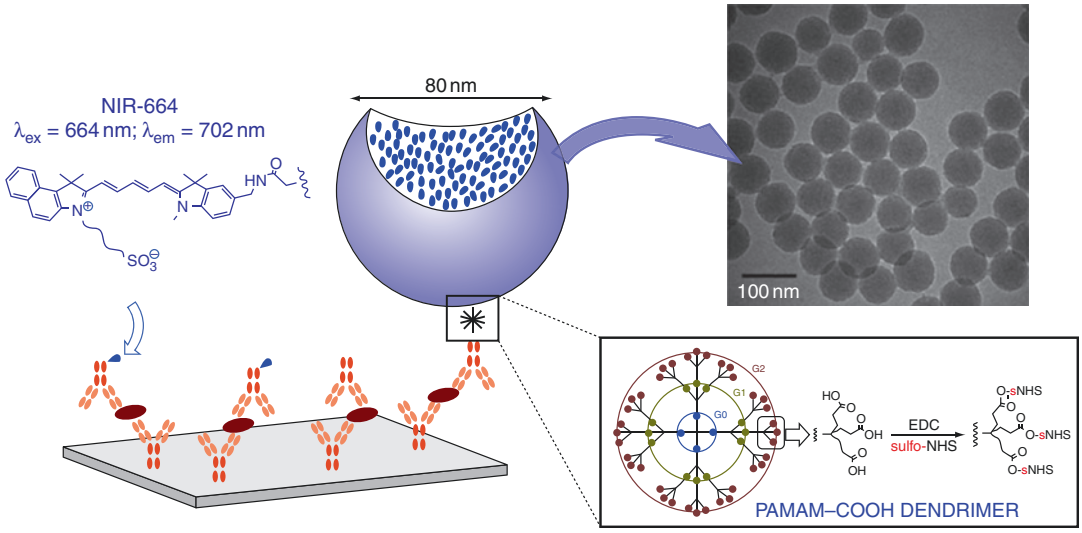
Dye-doped nanospheres in biomedical diagnostics

Definition



Dye-doped nanoparticles are new class of fluorescent labels. They are typically made of silica or polystyrene with tens of thousands of fluorescent dyes entrapped in the pores of its polymer matrix.

Overview and General Concept

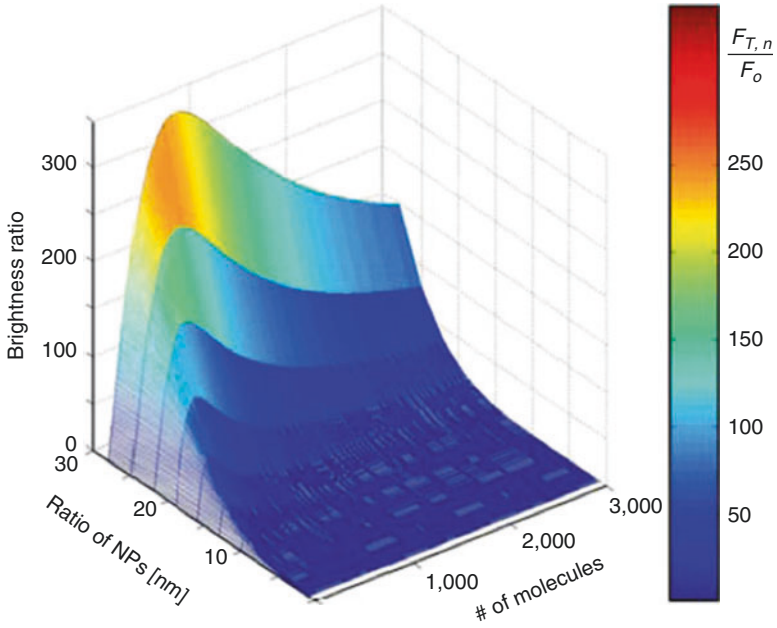
When designing devices for biomedical diagnostics, it is essential to maximize the signal to noise ratio to achieve clinically relevant sensitivity and limits of detection. Simple assay designs involve first capturing an antigen onto a surface using one antibody, then measuring the surface concentration by visualizing the captured antigen through its reaction with a second, labeled antibody. There is increasing interest in fluorescence-based array sensors (biochips) for biomedical applications. While fluorescence detection offers high sensitivity, there is generally a low level of fluorescence signal from the biochip due to a monolayer of fluorescent labels, hence the importance of enhancing the fluorescence. In antibody-based assays, the measured signal can be amplified through the replacement of molecular luminophore with doped nanoparticles (NP) (Fig. 1).

Fluorescent labels are used for a range of applications including immunosorbent assays [1], immunocytochemistry [2], flow cytometry [3], and DNA/protein microarray analysis [4]. Current research in biomedical diagnostics is moving to inexpensive devices, using biochips that often have to measure biomolecule concentrations at the picomolar level in blood sample volumes on the microliter scale, without the possibility of any user manipulation of the sample. This is exceptionally challenging to achieve in a miniature bioassay device. First, the active biomolecules (antibody or nucleic acid) must be immobilized at the appropriate surface density while maintaining its reactivity. Second, the measured signal should be maximized relative to noise and background contributions. In antibody-based assays, nonspecific binding (NSB) controls the background response and often results in a detection limit that is much higher than that defined by the equilibrium constants for the binding events.

To meet these new demands, fluorescent labels with improved physical and chemical properties are required: for example, high photostability and fluorescence intensity, with a reproducible signal under a variety of chemical and biological conditions. Excellent photostability and significant

Dye-Doped Nanoparticles in Biomedical Diagnostics, Fig. 1 A cartoon illustrating the concept of fluorescence-linked immunosorbent assay using the detection antibody labeled with molecular fluorophore (NIR-664 in this particular case) and 80 nm nanoparticles, doped with tens of thousands of molecular dye molecules, thus significantly increasing the brightness of the label. The TEM image shows the high monodispersity and size-uniformity of 80-nm silica nanoparticles doped with NIR-664, prepared by reverse microemulsion method. Inset with PAMAM dendrimer highlights a unique modification of the NP surface that ensures high colloidal stability and efficient bioconjugation to biomolecules of interest

reductions in photobleaching is required for applications where high intensity of prolonged excitations are applied, such as intracellular optical imaging. Dye-doped nanoparticles (typically silica or polystyrene) stand out as excellent candidates as it is possible to dope silica NPs with a large number of fluorophores, increasing the total fluorescence of the label significantly. Despite the effect of fluorescence quenching phenomena within an NP with a large amount of dye incorporated in a small volume, the goal of producing a particle with brighter fluorophores protected inside an organic matrix, thereby increasing photostability and quantum efficiency is largely successful. Owing to their intense signal, fluorescent nanoparticles (NP) are useful as labels since they can be measured directly, without the need for any amplification step.



How to Select Appropriate Dye-Doped NPs for Your Application?

Dye-doped NPs are currently offered in a wide range of sizes, with entrapped fluorophores covering most of the useful spectrum of UV/V radiation and with a surface modification to contain chemically reactive groups, usually –COOH and $–NH_2$. Most of the scientists using dye-doped NPs will make their decision based on the characteristics of the instrument (e.g., excitations source and emission filters) and the type of application.

Typically, at least three parameters should be defined when selecting the appropriate dye-doped NP:

(a) What is the desired fluorescence property of the NP for your application?

The choice of the luminophore, particularly its excitation and emission wavelengths, obviously depends on the capacity of the instrument that is used to excite the fluorophores and collect the emitted light. However, it also depends on the application. At near infrared wavelengths there is low background interference from the fluorescence of biological molecules, solvent, and substrates. For example, whole blood has a

Dye-Doped Nanoparticles in Biomedical Diagnostics, Fig. 2 A computer model showing the correlation between the brightness ratio and the radius and number of dye molecules entrapped inside NP

weak absorption in the NIR region, thus reducing the need for whole-blood filtering for assays using whole blood. NIR light can also penetrate skin and tissue to several millimeters and this can enable fluorescence detection in dermatological or in vivo diagnostic devices. When preparing dye-doped NPs, it is also important to remember that not every readily available dye can be doped into the NP matrix. This will be further discussed later in this entry.

(b) What is the desired size of the NP for your application?

In case of bioassays, the answer to this question is specific to the design of the assay. While it is tempting to think that the brightness will increase with increased size of the NP, one must also consider the increased surface area and different monolayer packing arrangement of larger NP when compared to smaller ones.

It is not necessarily true that by increasing the diameter of NP say by an order of 2, the fluorescence will also increase by the same order (Fig. 2). In general, dye-doped NPs in the range of 20–200 nm were successfully used in bioassays in the wider research community. As for optical imaging, the rate of uptake of nanoparticles by mammal cells depends on the particle size and shape. A number of articles emerged recently reporting that the optimum size of nanoparticles to enter the cells is around 50 nm. The cellular uptake of $\sim$ 50 nm NP is typically the highest and the NPs were shown to be trapped inside vesicles in the cytoplasm; however they did not enter the cell nucleus. Shape also plays an important role, with spherical nanoparticles being taken in larger numbers than rod-shaped nanoparticles. This is presumably due to the difference in curvature affecting the contact area with the cell membrane receptors.

(c) What is the desired surface modification for efficient conjugation with biomolecules?

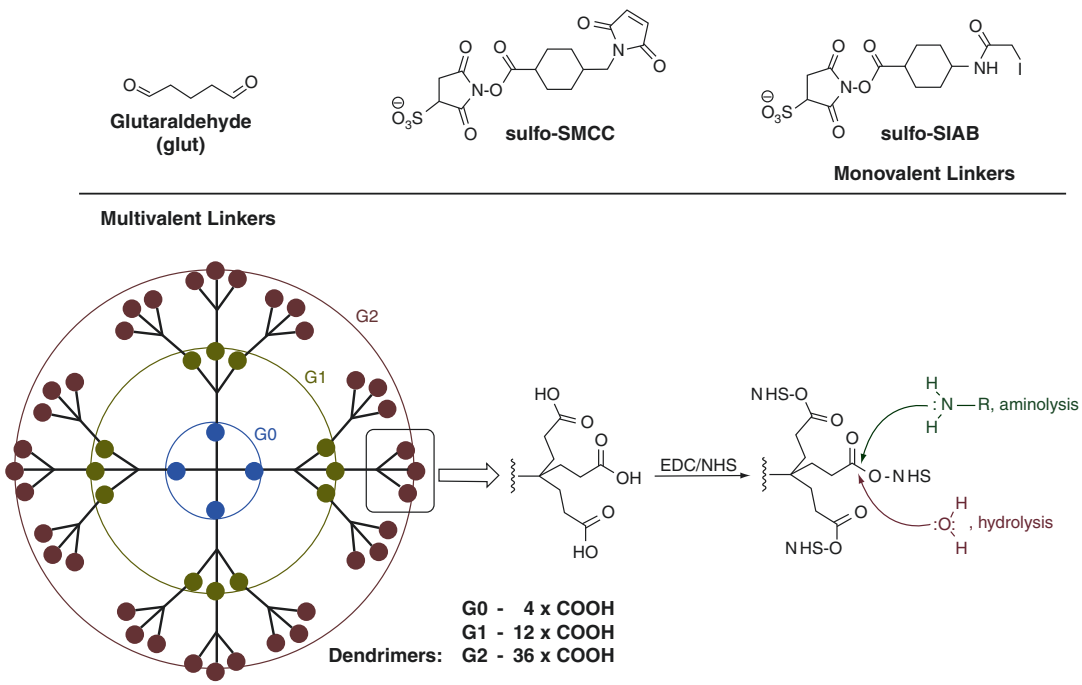
It is relatively easy to functionalize silica or polystyrene NPs with reactive groups that enable bioconjugation. However, each step in the conjugation process modifies the zeta potential of the NP, thus affecting colloidal stability. Proteins are usually immobilized on the surface of polystyrene beads by physical

adsorption. It is a relatively fast method for formation of reasonably homogeneous protein layer. For better results, it is often desirable to block the non-active surface area with bovine serum albumin or similar blocking agents. In case of silica particles, the colloidal stability and the density of the active molecules on the surface can be fine-tuned by carefully executed surface chemistry. Some aspects of the surface modification strategies of dye-doped silica NP will be discussed later in this entry.

Basic Methodology

Synthesis of Dye-Doped Silica Nanoparticles

One obvious advantage of using silica particles as opposed to polystyrene is the significantly higher density of fused silica (2.2–2.6 g/cm^3), which facilitates the manipulation and purification of samples (centrifugation at 15,000 rpm for 1–2 min is usually sufficient to separate the beads from supernatant). Also, silica NPs are relatively nontoxic and chemically inert. They can be prepared in a range of sizes and the post-synthetic surface modification can be achieved with good reproducibility.



There are two main methods for synthesis of dye-doped silica particles.

1. Sol–gel technique via Stober method, which consists of the hydrolysis of a silica alkoxide precursor (such as tetraethylorthosilicate, TEOS) in an ethanol and aqueous ammonium hydroxide mixture.
2. *Reverse microemulsion* method based on a water-in-oil reverse microemulsion system.

Both methods have certain advantages and disadvantages. For example, the former method is comparatively simple and both organic and inorganic dyes can be incorporated in the silica matrix. A modified Stober method has been used to produce highly fluorescent dye-doped core–shell silica NPs with narrow size distribution by the Wiesner group at Cornell University (NY, USA) [5]. The latter technique is using stabilized water nanodroplets formed in the oil solution. Silane hydrolysis and the formation of NPs with the dye trapped inside occur inside such small microreactors. The size of the NP is determined by the nature of surfactant, the hydrolysis agent, and other parameters, such as the reaction time, oil/water ratio, etc. The resulting NPs usually show a high degree of uniformity and water dispersity. One of the limitations of this method is that, in most cases, it works well with inorganic dyes, some of which have lower quantum yields compared to organic fluorophores. By both techniques, the dye molecule can be either physically adsorbed inside the pores of NP or covalently linked to its matrix. The second option is preferred, as the non-covalently attached fluorophores can eventually diffuse or "leach out" into a solution over time, thus reducing the overall brightness of the NP.

Surface Functionalization of Dye-Doped NPs

In general, the benefits of using dye-doped NPs can only be realized if they are efficiently coated with biorecognition elements (in most cases antibody, oligonucleotides, etc.), have good colloidal stability, and the ratio of specific to nonspecific binding (NSB) is sufficiently great. The colloidal stability of NPs can be modulated by carefully executed surface modification. Sufficient separation of NPs can be achieved by increasing either steric or electrostatic repulsions between two or more adjacent NPs. Current approaches to prepare colloidal solutions with low polydispersity index are mostly based on electrostatic interactions. In polystyrene particles, the introduction of charge on the surface can be done by copolymerization reaction of polystyrene monomer and its charged analogue. And even then, a longer-term colloidal stability is guaranteed only after addition of polar surfactants into the sample. Quite often, this surfactant must be removed prior the immobilization of the antibody or DNA. On the other hand, the flexible silica chemistry provides versatile routes for surface modification. Different types of functional groups can be easily introduced onto the NP surface enabling conjugation with biomolecules of interest. The post-synthetic modification of the particle surface with charged species (e.g.,

Dye-Doped Nanoparticles in Biomedical Diagnostics, Fig. 3 Structures of the most popular monovalent linkers and a cartoon illustrating the multivalent feature of a Newkome-type dendrimer, activated by a dehydrating agent (This figure was reprinted with permission of Elsevier)

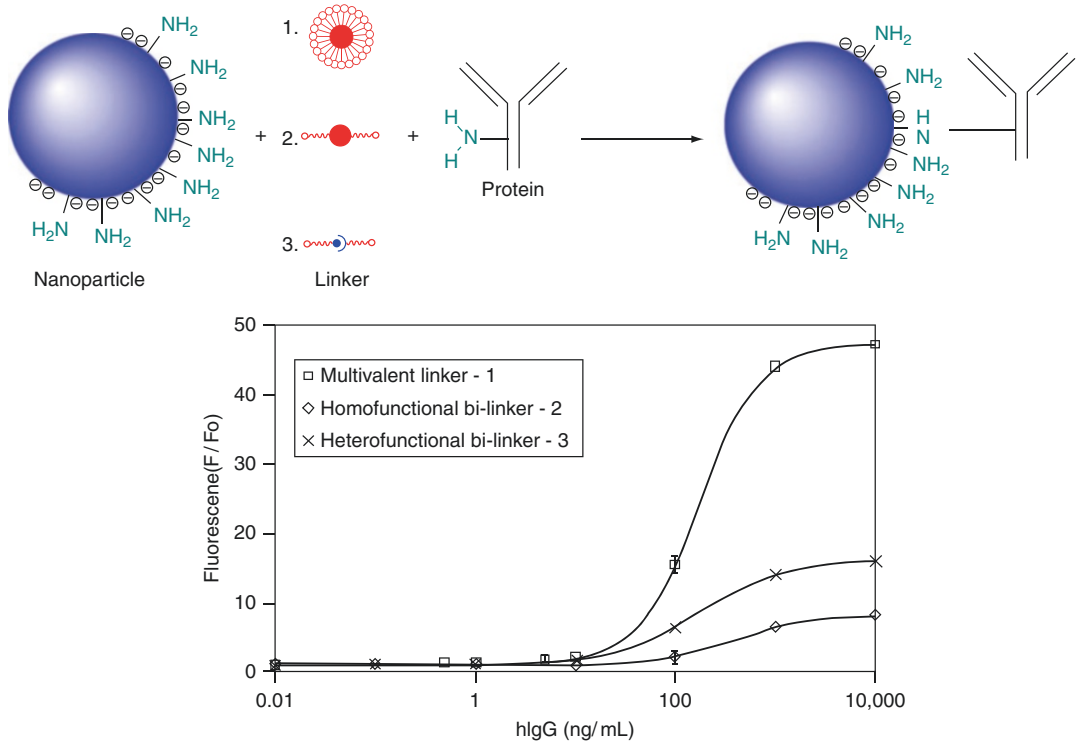
phosphates, carboxylic acid, etc.) is not only aimed to reduce particle aggregation but also to provide some sort of reactive handle, where the reaction with antibodies takes place. Most of the biomolecules used as molecular recognition elements are charged species (proteins, DNA, etc.) and contribute positively toward the decrease of the polydispersity index of the sample.

One of the most elegant and efficient methods to achieve good colloidal stability of silica NPs is to introduce a mixture of charged precursors on the particle surface. The first one is usually chemically inert with low pKa value, assuring that the charge is present when working at physiologically relevant pH (7.0–7.4). The second one, typically at much lower quantity provides reactive group for the reaction with biomolecules or other cross-linking agents. In 2006, Tan and colleagues [6] proposed a way of improving the colloidal stability of silica NPs through the addition of a negatively charged, nonreactive alkoxysilane with phosphate group along with its counterpart carrying a reactive amine. Other very common groups that can be used as reactive "handles" include carboxylic acids, isothiocyanates, and epoxy group. Normally, the ratio between the nonreactive and reactive groups is relatively high (10:1) in order to maintain the suspension stability. As a consequence, the number of attachment sites on the NP surface is therefore limited. For this reason, it might be quite difficult to achieve high protein coupling ratios. Gubala et al. [7] overcame this disadvantage by using multivalent linkers such as dendrimers as antibody scaffolds (Fig. 3).

Bioconjugation Strategies

As mentioned previously in this entry, the most straightforward method to immobilize large biomolecules like antibodies is through physical adsorption [8]. This method is very popular with polystyrene beads; however, it does not offer direct possibility of modulating the density of the captured protein on the NP surface. The

control over the active surface area, which is the area of the NP surface covered with antibodies, can be achieved by using cross-linking reagent.



There is a great choice of commercial hetero- or homo-functional linkers available; however, their effect on NP stability, aggregation, solubility, and efficiency of bioconjugation was until recently poorly documented. This was striking, particularly when considering that this is the actual layer "sensed" by the molecule to be labeled.

In a sensitive and functional bioassay, one obvious issue in the use of NPs as labels is the fraction of the coupled antibody that is in fact active or available for reaction with antigen. This fraction can be rather small, which in turn can lead to diminished sensitivity and increased nonspecific binding. The minimization of NSB is essential for sensitive detection in an assay. Thus, it is clear that the strategy used to attach an antibody to NP surface is a key element that affects the activity of the bound antibody, the nonspecific binding, and the surface binding of particles.

Improved colloidal stability of silica NPs has been previously achieved by the addition of negatively charged nonreactive organosilanes in addition to organosilanes with functional groups available for bio-immobilization. The number of attachment sites on the nanoparticle surface is limited in order to maintain the suspension stability of the NP system. For this reason it is difficult to achieve high protein coupling ratios. Gubala [7] and colleagues at Biomedical Diagnostics Institute have recently demonstrated some advantages of using multivalent molecules such as dendrimers as antibody coupling scaffolds as illustrated in Fig. 3. Dendrimers are monodisperse, nano-sized, hyperbranched "starburst polymers," with growing numbers of terminal functional groups with increasing generation number that have been extensively investigated for a variety of biomedical applications. By changing the generation of dendrimers, the authors were very efficiently able to control the surface area populated by biomolecules. The authors demonstrated that antibody-sensitized NPs prepared by using a multivalent linker showed a significantly lower limit of detection and higher sensitivity than with the homo- and hetero-functional cross-linkers (Fig. 4). The difference in performance was remarkable, particularly when compared with glutaraldehyde, one of the most common cross-linker still employed by many research laboratories. They reasoned that the multivalency of the dendrimers is one of the most significant factors behind the increase in the detection sensitivity. Dendrimers had a positive effect on NP stability and aggregation, were more reactive with biological materials, and were capable of immobilizing antibody at the appropriate surface density while maintaining its activity to the analyte of interest. Moreover, the multivalency of the dendrimer is a significant factor responsible for the improvement in the reaction yields even at lower protein concentration. This is very important, particularly when considering the cost of the bioorganic material that is used in bioconjugation reactions.

Dye-Doped Nanoparticles and the Implications on Assay Kinetics

A surface capture immunoassay can be considered in two ways: either incubation of antibody-sensitized particles with antigen followed by capture onto an antibody-sensitized surface of those particles that have bound antigen; or capture of antigen onto an antibody-sensitized surface followed by capture of antibody-sensitized particles onto the surface-bound antigen. In either case, the kinetics of reaction of a sensitized particle with a sensitized surface is a key element of the description of the process and hence of the assay design. The size of the particles and the fraction of the particle surface that is active for the antibody–antigen reaction are the important parameters. A simple kinetic model was developed for particle capture onto an antigen-loaded assay surface by means of an antibody–antigen reaction. This is similar to kinetic formulations treating single molecules, but also accounts for the fact that each particle has a multiplicity of antibodies present on its surface. The NPs-surface-bound antibodies can be considered as active binding sites. Depending on the coverage of such active sites on the particle, a collision of the particle with an antigen may or may not lead

Dye-Doped Nanoparticles in Biomedical Diagnostics, Fig. 4 Bioconjugation strategies that rely on the use of cross-linking agent. The content of $–NH_2$ (or $–NH_3^+$) groups on the surface of the NP is typically limited to ~ 10 %. Higher amount of amines can cause aggregation. The lower density of reactive amines is offset by the multivalency of dendrimers. Their effect is threefold: (**a**) the use of dendrimers positively affects the colloidal stability of the NPs, (**b**) the reactivity of each amine on the surface is amplified by the number of dendrimers' surface groups, hence significantly improving reaction efficiency with usually expensive biomolecules, (**c**) dendrimers, due to their size, not only serve as linkers but also as spacers between the surface of the NP and the captured recognition elements, thus maintaining the activity of antibodies, oligonucleotides, etc. The net result is more sensitive assays when compared to the monovalent linkers and also improved assay kinetics

to reaction, with a probability proportional to the surface coverage of active sites on the particle and the surface coverage of antigen in the reaction well.

The capture reaction, of antibody-functionalized NPs onto the assay surface, can be written as:

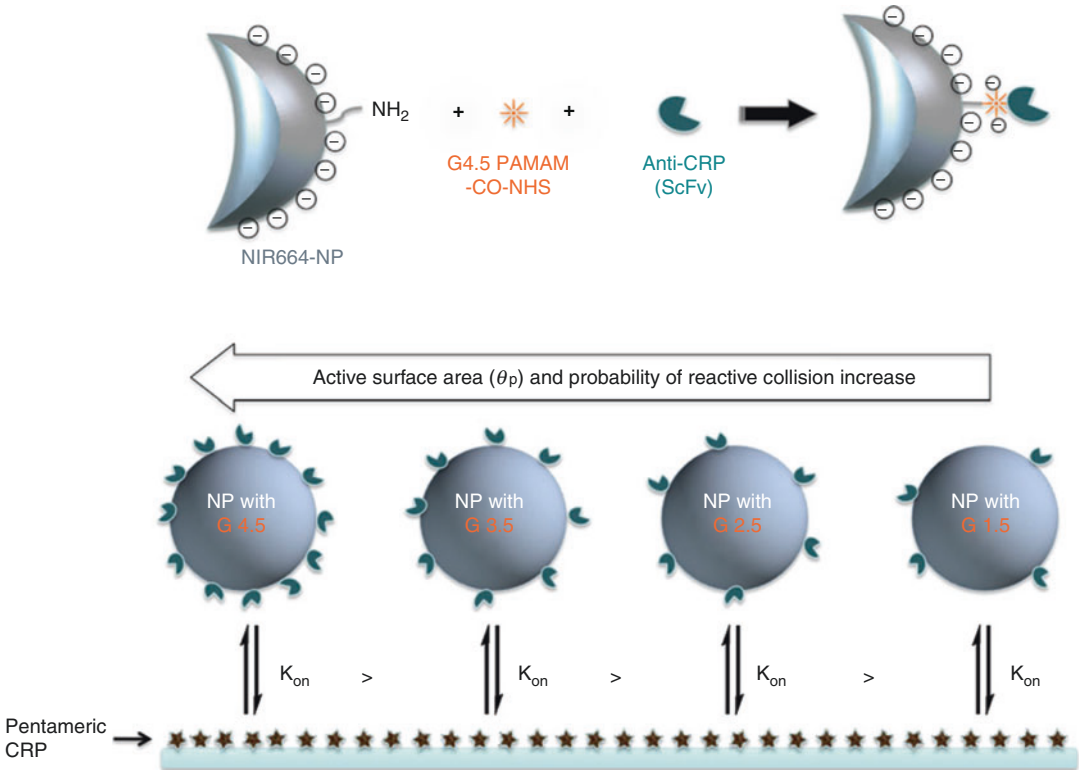
$$P + S \rightleftarrows PS \qquad (1)$$

with forward rate constant k_{on} and reverse rate constant k_{off}. Here, S denotes an active antigen site on the assay capture surface. If the NP is bound to the surface by a single antibody–antigen interaction, then k_{off} will simply be the dissociation rate constant for the antigen–antibody complex. The association rate, k_{on}, will be determined by the probability of a reactive collision between an antibody-functionalized NP and an unoccupied reactive antigen site on the assay surface. A reactive collision, leading to coupling of the NP to the assay surface, would occur when a reactive part of the NP surface (an antibody, oriented with the binding site exposed) collides with a reactive part of the assay surface (an antigen, oriented with the epitope exposed). NPs are in a continuous state of collision with the assay surface, at a rate determined by the diffusion coefficient of the NPs (hence by their radius and the viscosity of the

reaction medium) and by their concentration. As the NP concentration on the assay surface builds up, particles not only occupy sites but also physically block the assay surface area, on account of their size. The probability of obtaining a successful reactive collision between particle and capture surface also depends on the fraction of the capture surface that is active for reaction. Therefore, the probability that the collision will be with an active site on the assay capture surface will be a product of the following:

- The fraction of the total assay capture surface that is covered by accessible antigen with the binding epitope correctly exposed to facilitate antibody binding
- The fraction of the total assay surface that is unblocked by bound NPs
- A coverage-dependent factor that expresses the requirement that a NP requires a space whose smallest dimension is at least as large as the NP diameter, in order that the NP can fit into the space

The considerations of reaction probability are embedded in the capture rate constant, k_{on}, which depends on both the fraction of the surface of the antigen-loaded capture plate that is in fact active for the capture reaction (i.e., it depends on the surface state of the adsorbed antigen) and on the fraction of the surface of the antibody-sensitized NP that is active for reaction. It can be written as:



$$k_{on} = k_D \varepsilon \theta s \theta p \tag{2}$$

where k_D is the diffusion-limit rate constant for NP consumption by the antigen-surface, dependent on the NP radius and the viscosity of the medium; ε is the reaction efficiency for a reactive collision; θ_S is the fraction of the capture surface area (here the antigen-loaded capture plate) that is active for the capture reaction, which in this case is dependent on the surface coverage of active adsorbed antigen on the prepared capture surface; and θ_P is the active fraction of the NP surface, in this case dependent on the surface coverage of active antibody attached to the NP. Therefore, the central objective of surface functionalization with is to increase θ_P, which can be achieved by using dendrimer as a linker (Fig. 5).

Gubala et al. have shown how the use of dendrimers as multivalent linkers effectively controls and maximizes the active fraction of the particle surface. Dendrimers have been presented as efficient coupling agents to conjugate antibodies to the surface of dye-doped silica nanoparticles. The protein-binding capacity of the dendrimer-sensitized NPs increased by the same factor as the number of surface carboxylate groups on the dendrimer used. The highest generation of the dendrimers (G4.5) used in their study showed the highest surface binding rate and the highest signal in the direct-binding FLISA. The effect of increased active antibody loading significantly outweighed any effect of a decreased NP diffusion coefficient compared to that of a molecular dye-labeled antibody. The practically important parameter, the ratio of the equilibrium fluorescence (offset corrected) to the nonspecific offset, or signal to background ratio, increased by a factor of ~ 4 for the G4.5 dendrimer-conjugated NPs compared to the molecular dye-labeled antibody.

Future Directions

Successful detection devices for biomedical diagnostics frequently require high sensitivity and low LOD. Moreover, a device for point-of-care diagnostics must be both inexpensive and reliable under a variety of experimental conditions. In this entry the advantages of employing dielectric, dye-doped NPs have been highlighted for the purpose of enhancing the performance of fluorescence-based assays. The objective of this entry was to discuss the versatility of silica (or eventually polystyrene) as a host material for fluorescent dyes for many applications, specifically in the fields of nanobiotechnology and the life sciences. Silica as a host material represents an ideal scaffold for encapsulation of organic dyes in a silica matrix thus enhancing their stability and performance.

Dye-Doped Nanoparticles in Biomedical Diagnostics, Fig. 5 *Top* – A cartoon illustrating a bioconjugation reaction between single-chain fragments of C-reactive protein antibody (ScFv) and dye-doped silica NP. By varying the dendrimer generation, it is possible to vary the density of ScFv fragments on the surface of NP, hence modulate the active surface area of NPs. The net outcome is increased probability of reactive collision and hence association K_{on} constant. The effect of increased active antibody loading significantly outweighed any effect of a decreased NP diffusion coefficient compared to that of a molecular dye-labeled antibody

It is obvious from the growing literature on this topic that this area is still in a growth phase and that significant new developments are likely to emerge in the coming decades. Although co-doping of NPs with multiple dyes of distinguishable spectral properties has been demonstrated, the application of such barcoding NPs in multiplexed assays is expected to grow significantly. Similarly, the use of high-brightness NPs as labels in flow cytometry applications is attracting considerable interest. The versatility of silica as a host material and the feasibility to modulate the core–shell architecture provide a unique environment for innovative research toward creating integrated nanomaterials with highly fine-tuned functionality in the field of nanotechnology and beyond.

Definition

Dynamic clamp is a method of introducing simulated electrical components into electrically active biological cells using a fast real-time feedback loop between the cells and a computer.

The Dynamic Clamp Concept

Traditionally, neurophysiologists have used current and voltage clamp protocols to assess the electrical properties of neurons. In the current clamp technique, a current (typically a pulse) is injected into the neuron while the membrane potential is being recorded. In voltage clamp, the membrane potential is kept at a controlled value while the transmembrane current is being recorded. Both techniques have contributed to the understanding of the biophysical properties of excitable cells and allowed the design of conductance-based models of neurons.

The dynamic clamp technique operates in a cyclic way (see Fig. 1). An electrode is inserted into a neuron, and the membrane potential is recorded, amplified, and digitalized into a computer that calculates a current to inject into a postsynaptic neuron. This postsynaptic cell can be the same or a different one from which the membrane potential is being recorded. The injected current is calculated after solving a model that describes ionic or synaptic conductances or simulates the dynamics of individual neurons or neural networks. This process is repeated indefinitely with a fixed frequency. The time between two consecutive membrane potential acquisitions is known as the update rate. The correct selection of the update rate is critical for the proper function of the application. The maximum update rate is usually determined by the data acquisition board. A slow update rate can prevent the correct simulation of conductances and a realistic stimulation. On the other hand, a realistic update rate may require a fast computer, depending on the computational load of the models which can consist of several differential equations that need to be solved online. Depending on the goals of the experiment,

Dynamic Clamp, Fig. 1 The general dynamic clamp setup. The dynamic clamp system forms a closed observation-stimulus loop in which the measured and amplified membrane potential is input to the dynamic clamp hardware/software (dynamic clamp workstation), which calculates a corresponding transmembrane current according to a model specified by the user. The software then issues an appropriate current command, which is converted into a physical current injection by the amplifier. A second, independent, analog to digital (A/D) converter and PC with standard electrophysiology recording software monitors and saves all aspects of the experiment (electrophysiology workstation). The measurement-injection loop is repeated at 10–20 kHz, making the interaction essentially instantaneous for the target neuron

hardware or real-time software implementation may be required to achieve a realistic closed loop.

Through the closed-loop interaction, the dynamic clamp technique can simulate the addition of new ionic and synaptic conductances into a living neuron. Modelers and experimentalists have used dynamic clamp to design new experiments on excitable cell properties which were impossible or difficult to carry out with classical techniques. For example, dynamic clamp has been used to simulate the effects of introducing or removing conductances, simulating drug effects, increasing or decreasing neural activity, simulating in vivo conditions, and modifying or building neural dynamics with artificial synapses and artificial neurons in hybrid circuits (see below).

The dynamic clamp allows for a large variety of activity-dependent experiments to address complex information processing and learning in neural systems [1, 2]. The closed-loop interaction can reveal dynamics hidden under traditional electrophysiological protocols. Dynamic clamp can also be used to control neural dynamics under normal or pathological conditions and to induce specific types of neural activity in circuits whose targets are under investigation.

History of Dynamic Clamp

Dynamic clamp was independently invented by Sharp et al. [3] at Brandeis University and Robinson and Kawai [4] at Cambridge. The term "dynamic clamp" was coined by the former group, while Robinson and Kawai originally referred to the technique as "synthesized synaptic conductance transients." The two systems also differed in their technical implementation.

Sharp et al. used a generic data acquisition board and developed the Microsoft DOS-based

Dynamic Clamp, Table 1 Common dynamic clamp implementations

Name	Technology	URL/publication	Comments
RTXI (Real-Time eXperiment Interface)	Real-Time Linux, Comedi	http://www.rtxi.org/ [13]	Based on RTLDC, MRCI, and RTLAB
StdpC	Windows based, custom DigiData driver, NI-DAQmx	http://sourceforge.net/projects/stdpc/ [11]	Partially based on Dynclamp 2/4
G-clamp	LabVIEW RT, NI-DAQmx, embedded RT hardware subsystem	http://www.hornlab.neurobio.pitt.edu/ [15]	
SM-1, SM-2 amplifiers by Cambridge Conductance1	Custom analog hardware and DSP board	[4,17]	
Dynamic Clamp in CED signal	Uses DSP capabilities of CED DAQs	http://www.ced.co.uk/	Offers a subset of models in StdpC; released in Fall 2010
QuB	Windows based, NI-DAQmx	http://www.qub.buffalo.edu/wiki/index.php/Dynamic_Clamp [14]	
RTBiomanager	Real-Time Linux, Comedi	http://www.ii.uam.es/~gnb [16]	

dclamp software to emulate artificial ionic and synaptic conductances.

Robinson and Kawai followed the "hardware route" and built analog circuitry (the SM-1 amplifier) to inject dynamic clamp conductances into neurons.

The MS DOS-based dclamp was later replaced by other solutions, the main developments being real-time Linux-based (RTLDC, RTLAB, MRCI) solutions [5–8] and the Windows-based Dynclamp 2/4 [9].

Dynclamp 2/4 was further developed by Nowotny et al. since 2003 and under the name StdpC [10, 11], including for the first time plastic synapses, in particular spike-timing-dependent plasticity (STDP). Other additions included experimental automation through a scripting mechanism, a modern GUI based on QT (Trolltech, now Nokia), and most recently active electrode compensation [12].

The real-time Linux-based projects RTLDC, RTLAB, and MRCI merged in 2004 into the common RTXI (real-time experimentation interface) project [13]. A major step forward for the usability of this system was the recent release on live CDs.

Besides these longer-term projects, independent other implementations of dynamic clamp have been developed over the years. These include QuB [14], g-Clamp [15], and the dynamic clamp subsystem of the commercial CED Signal software.

One of the more recent systems (RTBiomanager; [16]) now promises another step change in dynamic clamp research in systematically extending the concept of closed-loop real-time experimentation beyond the realm of pure electrophysiology.

The currently available dynamic clamp systems and their characteristic features are summarized in Table 1. They can roughly be categorized into hardware- (SM-1, SM-2) and software-based solutions. The latter category roughly divides into Windows-based (StdpC, QuB, g-Clamp) and real-time Linux-based (RTXI, RTBiomanager) solutions. The hardware-based and real-time Linux-based systems guarantee hard real-time constraints, whereas the Windows-based solutions work in a soft real-time framework.

Dynamic Clamp Applications/ Configurations

Since its inception, dynamic clamp has seen several different extensions and modifications. The most common types of experiments are the following.

Simulated Chemical Synapses

The simulation of chemical synapses reaches back to the original publications of Sharp et al. [3] and Robinson and Kawai [4]. It involves measuring the membrane potential of two neurons and injecting current into one of them – the designated postsynaptic cell – in order to simulate the action of a nonexisting synapse or increasing the conductance of existing ones. Some researchers have also compensated existing synapses by using a negative conductance value. Further extensions of this protocol include:

1. Short-term depression of the simulated synapse
2. Spike-timing-dependent plasticity of the simulated synapse
3. Using a simulated model neuron as the presynaptic and/or postsynaptic neuron
4. Using an electronic circuit for the presynaptic neuron

A typical description of a chemical synapse is given by

$$
\begin{aligned}
I_{\text{syn}} &= g_{\text{syn}} S\left(V_{\text{post}} - V_{\text{rev}}\right) \\
\frac{dS}{dt} &= \alpha\left(V_{\text{pre}}\right)(1 - s) - \beta_0 s \\
\alpha\left(V_{\text{pre}}\right) &= \left\{ \begin{array}{ll} \alpha_0 & 0 \le t - t_{\text{spike}} \le t_{\text{release}} \\ 0 & otherwise \end{array} \right\}
\end{aligned}
$$

where I_{syn} denotes the postsynaptic current, g_{syn} the maximal synaptic conductance, S the fraction of active transmitter, V_{rev} the reversal potential of the synapse, and α_0 and β_0 are rate constants of synaptic transmitter activation and removal, t_{release} the duration of transmitter release in response to a presynaptic spike, and t_{spike} the time of the last occurrence of such a spike.

Simulating Electrotonic Connections (Gap Junctions)

A gap junction is essentially an Ohmic conductance between two cells through which current can flow in two directions. In dynamic clamp, a simulated gap junction is achieved by monitoring the membrane potential of two cells and injecting the appropriate currents into both cells according to Ohm's law and the observed membrane potential difference.

$$
\begin{aligned}
I_1 &= g_{\text{gap}}(V_2 - V_1) \\
I_2 &= g_{\text{gap}}(V_1 - V_2)
\end{aligned}
$$

where I_1 and I_2 are the currents injected into the two neurons, V_1 and V_2 are their respective membrane potentials, and g_{gap} the constant conductance of the gap junction.

A common extension are asymmetric or rectifying gap junctions, in which current can preferentially or exclusively flow in one direction.

Simulating Voltage-Dependent Ion Channels (Hodgkin–Huxley Conductances)

Voltage-dependent ion channels allow current flows into and out of a cell depending on its own membrane potential. For a simulated voltage-gated ion channel, the membrane potential of a cell is monitored, and the current of the simulated ionic conductance is injected into the same cell. Commonly, the conductance is described in the Hodgkin–Huxley formalism, for example, the sodium current is given by

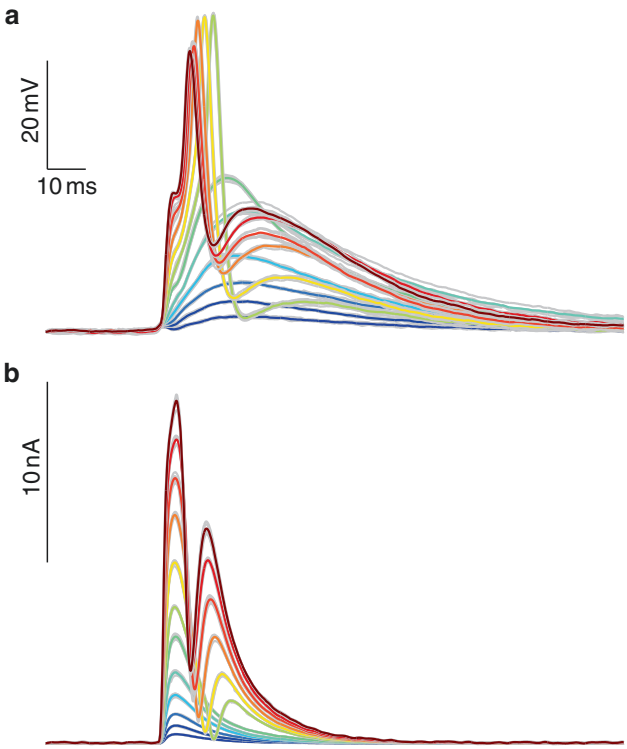
$$
\begin{aligned}
I_{\text{Na}} &= g_{\text{Na}} m^3 h (V - V_{\text{Na}}) \\
\frac{dm}{dt} &= \alpha_m(1 - m) - \beta_m m \\
\alpha_m &= \frac{(-35 - V)/10}{\exp((-35 - V)/10) - 1} \\
\beta_m &= 4\exp((-60 - V)/18)
\end{aligned}
\qquad
\begin{aligned}
\frac{dh}{dt} &= \alpha_h(1 - h) - \beta_h h \\
\alpha_h &= 0.07\exp(-60 - V)/20 \\
\beta_h &= \frac{1}{\exp((-30 - V)/10) + 1}
\end{aligned}
$$

where I_{Na} denotes the sodium current, m and h are the so-called activation and inactivation variables, V denotes the membrane potential of the neuron, and V_{Na} is the sodium reversal potential.

Pattern Clamp

Pattern clamp is the simple combination of simulating a presynaptic neuron and a strong unidirectional gap junction. It nevertheless deserves a separate discussion because if the gap junction conductance is large, the electrical activity of the target neuron will be almost identical to the simulated presynaptic activity pattern, allowing the experimenter to virtually control: "clamp" the neuron to a particular activity pattern (hence the name "pattern clamp"). While quite simple from a theoretical point of view, this mode of dynamic clamp is very powerful as it allows the experimenter to interact with the rest of the neuronal system through the clamped neuron's natural synapses. This can include the release of neuromodulators and synaptic plasticity of the neuron's synapses.

Hybrid Circuits of Real and Artificial Neurons



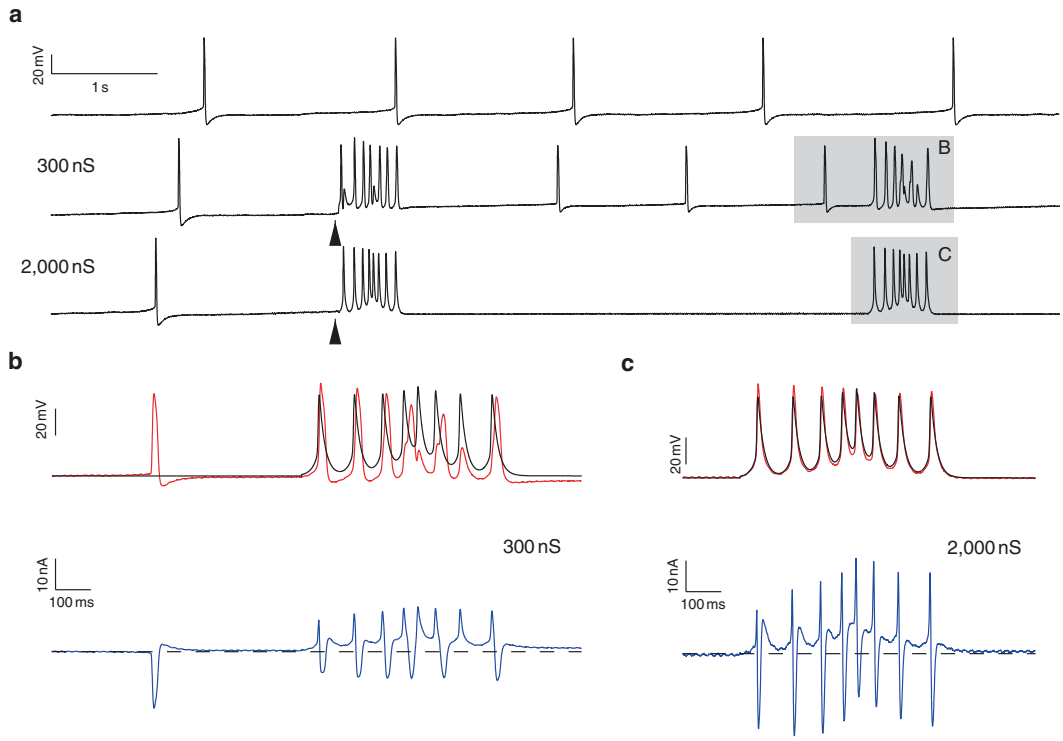
Hybrid circuits of multiple living and artificial neurons implemented with dynamic clamp protocols provide a unique way to test model neuron and network dynamics within a realistic cellular and synaptic environment [18]. A hybrid circuit can be used to bridge between different description levels and allows precise changes in single cellular or synaptic parameters in order to assess their direct participation in the collective output. In this way, hybrid methods can result in more physiological ways of stimulating networks, creating direct links between experiments and modeling, and providing new tools and validation methods for neural network analysis.

Examples of Dynamic Clamp Results

Typical results from standard dynamic clamp applications are illustrated in Figs. 2, 3, and 4. They were obtained using the StdpC dynamic clamp software on Windows XP and using a National Instruments M series PCI-6229 data acquisition board (Figs. 2 and 3) and the real-time Linux system RTLDC on Fedora Core using a National Instruments PCI-MIO-16E-4 data acquisition board (Fig. 4).

Figure 2 illustrates results from simulating an excitatory chemical synapse between two cells of the mollusk *Lymnaea stagnalis* in an in vitro whole brain preparation. The cerebral giant cell (CGC) and the motoneuron B1 were impaled with sharp microelectrodes. A second sharp electrode was inserted into the B1 neuron for the purpose of current injection. The dynamic clamp was configured to use the tonically firing CGC as the presynaptic cell and the quiescent B1 neuron as the postsynaptic cell. The synapse was configured with reversal potential 0 mV, activation threshold −20 mV, activation slope of 25 mV, and time scale of 10 ms. The maximal synaptic conductance was varied, taking values 10, 20, 30, 50, 80, 120, 170, 230, 300, 390, 490, and 600 nS (encoded by line color in Fig. 2). Note, how the simulation of a chemical synapse in dynamic clamp is different from injecting a predefined EPSP, in particular if a postsynaptic spike is evoked (current reversal during the spike).

Figure 3 illustrates the results of performing pattern clamp on the CGC neuron in the mollusk *Lymnaea stagnalis*. An accelerating-decelerating burst pattern was defined using the StdpC spike generator facility. The pattern was imposed onto the CGC neuron using a high conductance-simulated gap junction. Figure 3 shows the results for gap junction conductances of 300 nS (B) and 2,000 nS (C). For the lesser conductance, pattern clamp is only partially successful, and some spikes of the pattern are displaced or missing. At 2,000 nS, the pattern clamp is almost flawless, including exact timing of all spikes in the burst pattern. Interestingly, even though the gap junction conductance is almost seven times higher in C than in B, the injected currents are only two to three times stronger due to the better control achieved. It is also important to note that the spikes in the CGC are of higher amplitude than the spikes of the target activity pattern (Fig. 3d, e). This indicates that the CGC spikes are genuine and will travel down the axon rather than being merely strong deflections of the membrane potential at the soma.

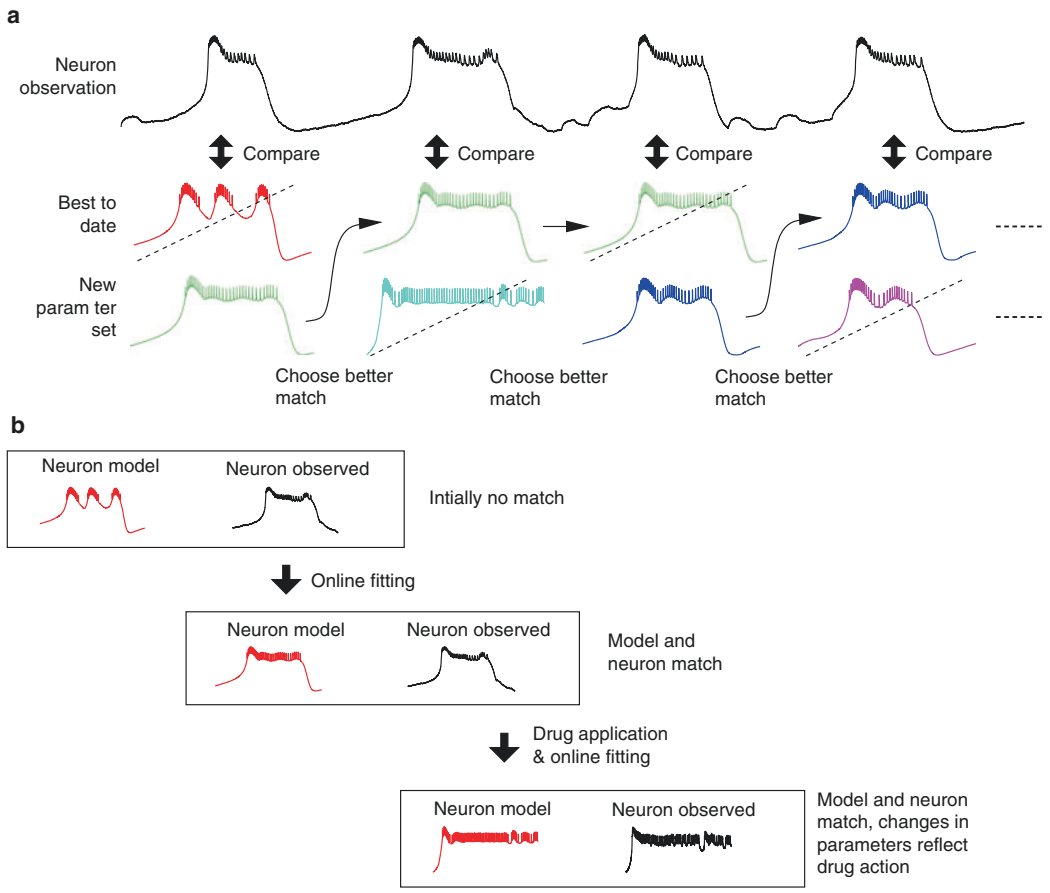


Dynamic Clamp, Fig. 2 Excitatory postsynaptic potentials (EPSPs) and excitatory postsynaptic currents (EPSCs) of a simulated, excitatory, chemical conductance introduced into a molluskan cell. (**a**) EPSPs for simulated maximal synaptic conductance of 10, 20, 30, 50, 80, 120, 170, 230, 300, 390, 490, and 600 nS aligned to the occurrence of the presynaptic spike. For each maximal conductance, five individual EPSPs (*thin gray lines*) and their average thick lines (*colored online*) are shown. (**b**) Corresponding EPSCs. The *colors* of **a** and **b** are matched to mark the corresponding data sets. Note how the introduction of a simulated synaptic conductance is different from injecting a fixed current waveform: When a postsynaptic spike is elicited (*yellow to red traces (color online)*), the current through the simulated ion channel shows a marked dip and almost reverses (Figure modified from Kemenes et al. [19])

A somewhat more unusual example of dynamic clamp is shown in Fig. 4. Here, dynamic clamp is used to synchronize a model neuron and a real cell in order to fit the properties of the cell online and in real time. Within the dynamic clamp software, two copies of a neuron model with slightly different parameters are simulated together with a simulated coupling to a real cell impaled with two electrodes. Through the simulated coupling, the cell and the model cells synchronize (partially) which allows to assess how much the dynamics of each of the model cells differs from the real cells'. After a fixed testing period, the model cell with the more appropriate dynamics is retained and further compared to a new model. Through this iterative process, the model cells become increasingly similar to the real cell allowing indirect deduction of cell properties.

Limitations

Like any other electrophysiological technique, dynamic clamp has practical and principal limitations. The main principal limitation is that dynamic clamp simulates the electrical effect of simulated channels in the cell membrane, not the flow of specific ions. Where the presence of the ions is important as, for example, with calcium ions that act as second messengers, simulating an ion channel will have a different effect than the actual channel would have. A second principal limitation is related to the position of the electrode(s) used.

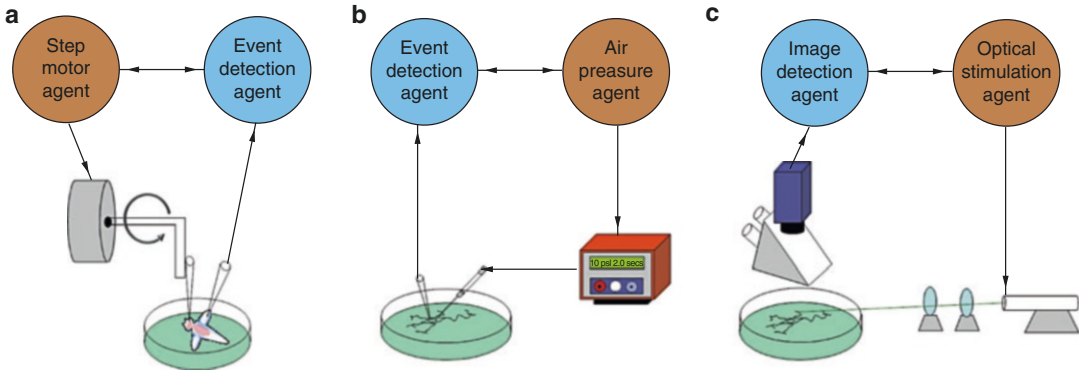


Dynamic Clamp, Fig. 3 Results of a pattern clamp experiment. The target cell spikes tonically when the pattern clamp is off (*panel a, top*). When the gap junction coupling in pattern clamp is not strong enough (gap junction conductance of 300 nS), the target neuron will only be clamped partially (*panel a, middle*), but sufficient conductance (gap junction conductance of 2,000 nS) leads to a complete clamp (*panel a, bottom*). Pattern clamp is switched on at the *black arrowheads*. Panels b and c are detailed views of the episodes shaded in *gray* in panel a. The *gray* (*red online*) trace was recorded from the target neuron; the *black* trace shows the desired pattern. Currents injected are shown in the *bottom panels of b and c.* With 300 nS conductance, the pattern clamp is not able to prevent intrinsic spiking (*panel a, middle and panel b*). This is readily achieved at 2 μS maximal conductance, even though the currents injected for this >6 times larger conductance are only two to three times larger owing to the better match achieved (From Kemenes et al. [19])

If electrodes are far from the locus in the cell where real channels would be located, the effect of the injected current can be quite different from the current that flows through the channels directly. If, for example, the current injecting electrode is inserted into the soma, a Na current is simulated that normally would be located at the axon hillock, and the axon hillock is electrically far removed from the soma; the dynamic clamp experiment may be difficult to interpret.

Practical limitations depend on the dynamic clamp implementation and the used hardware.

Dynamic clamp protocols rely critically on the update rate used for the closed-loop interaction. In many applications, this update rate must be strictly accomplished, requiring precise timing and no jitter. Specific hardware, fast DSP systems, or real-time software technology can overcome these problems. Software implementations are more suitable than hardware approaches as they are easier to program, generally inexpensive, and more flexible to modify and customize to a particular experiment. A common problem in electrophysiology, and more so in dynamic clamp, is the series resistance and capacitance of electrodes. Common techniques such as bridge series resistance compensation and capacitance compensation are generally not suitable for dynamic clamp due to the rapidly changing current injections. Most dynamic clamp experiments have, therefore, been conducted with two separate electrodes in the same cell, one for membrane potential



Dynamic Clamp, Fig. 4 Dynamic clamp used for online fitting. (**a**) Two model neurons with slightly differing parameters are simulated alongside a real cell (a lateral pyloric (LP) cell of the lobster) to which they are coupled through a simulated electrical coupling. After a test period, the better matching model cell is retained and compared to a model with a new, slightly different, parameter set. (**b**) Initially, the model cells' dynamics can be quite different from the dynamics of the real cell. After some time, the models fit the cell increasingly better and eventually should be able to track slow changes within the cell. The data shown in this figure are illustrative excerpts from experiments with a prototype system programmed in RTLDC and used with a lobster LP cell (Levi and Nowotny 2005, unpublished)

measurements and one for current injection. Others have used low-resistance patch clamp electrodes to avoid the problem.

A recent alternative solution to the electrode artifact problem was introduced by Brette et al. [12], who used a sophisticated calibration method to estimate series resistance and capacitance artifacts with a digital model of the electrode and subtract them digitally and in real time. Using this new active electrode compensation (AEC) allows experimenters to conduct dynamic clamp experiments with a single high-resistance electrode.

Future Directions

The dynamic clamp concept has an enormous potential to precisely control the spatiotemporal aspects of a stimulus and to build activity-dependent stimulus–response loops to interact with neural systems beyond the realm of electrophysiology. Establishing these loops can be an essential step toward understanding the dynamics of many neural processes and can bridge between traditionally disparate levels of analysis (e.g., subcellular, network, and system dynamics).

Dynamic Clamp, Fig. 5 Generalization of the dynamic clamp concept for different stimulation and recording techniques. Computer algorithms implemented as intelligent agents monitor neural activity to exert goal-driven closed-loop stimulation. Panel **a**: activity-dependent mechanical stimulation. Neural activity is measured with intra- or extracellular recordings. Specific events detected in this activity are used to control a step motor for mechanical stimulation of sensory systems. Closed-loop interaction can be used to automatically find receptive fields of cells that react to the sensory stimulation throughout the nervous system [15]. Panel **b**: activity-dependent drug microinjection. A microinjector delivers a timely and precise amount of neurotransmitter or neuromodulator to achieve a desired type and level of neural activity. Panel **c**: closed-loop optical recording with real-time event detection used to drive laser stimulation which can go down to nanoscale precision

The same principles used in the dynamic clamp technology can be generalized to develop new techniques of activity-dependent stimulation by enhancing or going beyond the electrophysiological realm in a broad spectrum of research in nervous systems (see Fig. 5).

For example, a generalization of the dynamic clamp concept has been used to find receptive fields throughout the sensorimotor transformation by implementing activity-dependent mechanostimulation [20]. In this protocol, a step motor is controlled to exert mechanic stimulation as a function of neural events recorded with microelectrodes throughout this transformation. The protocol can explore different motor angles and speed until neural activity correlated with the stimuli is found. Another dynamic clamp extension has implemented activity-dependent real-time drug microinjection to stimulate neural circuits [21] as a function of specific patterns recorded in the electrical activity. This protocol is used to constrain neural activity within specified limits and to produce robust temporal patterns. Other protocols can include closed-loop optical recording and stimulation, for example, in two-photon microscope setups which can lead to highly realistic experimental conditions that overcome the dynamic clamp limitations discussed above. Further extensions of the closed-loop interaction with neural systems will lead to novel brain–machine interfaces and prosthetic devices.

Amplitude-phase-distance (APD) curves; Dynamic force spectroscopy

Definition

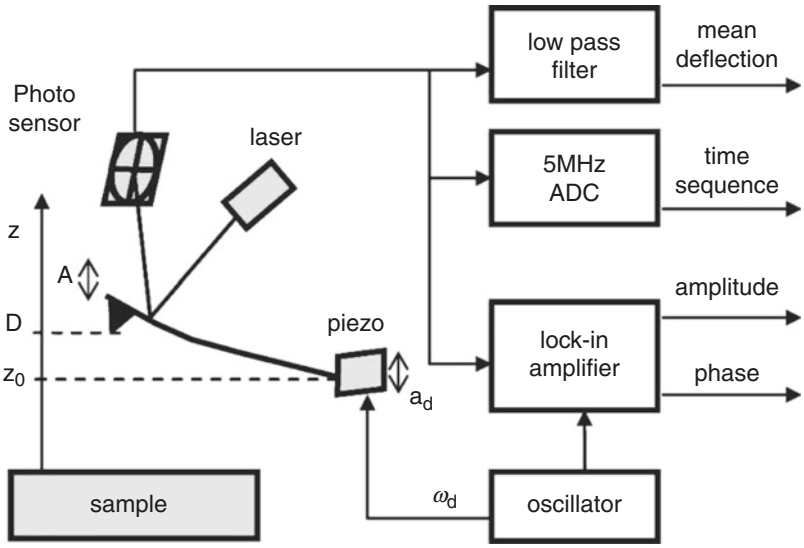
Dynamic force measurement is a variation of the force spectroscopy mode of an Atomic Force Microscope (AFM), where the amplitude and phase response of an oscillating AFM probe are used to detect the interaction forces between the probe and the sample or substrate of interest. In contrast to quasi-static force measurements where the micro-cantilever's deflection signal can be directly related to the interaction force between the AFM tip and sample surface using Hooke's law, the interpretation of amplitude and phase data in dynamic force measurement often requires detailed analysis of a micro-cantilever's vibration

using dynamic models. When applied at solid/water interfaces, dynamic force measurement is sensitive to solvation forces, van der Waals forces, electric double-layer forces, and viscous damping forces. Dynamic force measurements therefore lead to a useful technique for characterizing chemically modified surface in electrolyte solutions.

Introduction to Force Spectroscopy

Shortly after the invention of AFM by Binnig and Quate [1], surface scientists began to use AFM as a tool not only for high-resolution topography imaging but also for quantitative measurements of interaction forces between the AFM tip and a sample surface [2, 3]. The tip-sample interaction forces provide valuable information on local material properties such as elasticity, hardness, Hamaker constant, adhesion, and surface charge densities [4]. The application of the AFM in measuring the tip-sample interaction force is called force spectroscopy. Force spectroscopy has wide applications in surface science, materials engineering, and biology.

Most force spectroscopy is done with a quasi-static force measurement. In quasi-static force measurements, the cantilever-based AFM probe is brought into contact with a solid surface at a constant speed. The deflection at the free end of the micro-cantilever beam due to tip-sample interaction force is detected using the optical lever technique, where a laser light reflects off the end of the cantilever and strikes a detector. For small deflection (with respect to the length of the beam), the cantilever can be modeled as a linear spring with spring constant k_c. Assuming static equilibrium during the approaching and/or retracting process of the cantilever, the balance between the tip-sample interaction force and the spring force gives the expression of the measured interaction force via Hooke's law:



$$F_i = k_c \cdot h \tag{1}$$

where h is the deflection of the cantilever beam. Typically, the deflection and the vertical position of the cantilever are monitored during the entire process of approaching and retracting the AFM tip to and from the sample surface. As the result, a curve of measured force versus tip-sample distance can be constructed.

Dynamic Force Measurement

The interest in dynamic force measurements started when tapping-mode AFM became a dominant imaging mode for AFM applications [5, 6]. During a dynamic force measurement, the micro-cantilever is driven by an excitation signal at the resonance frequency of the micro-cantilever. The amplitude of the oscillation and the phase lag of the cantilever response with respect to the excitation signal are measured as a function of tip-sample distance. Analogous to quasi-static force-distance curves, the data from dynamic force measurements are called amplitude-phase-distance (APD) curves. An example of a dynamic force measurement setup is shown in Fig. 1. In Fig. 1, the excitation of the cantilever is done acoustically, i.e., via exciting a piezo-ceramic at the base of the micro-cantilever. There are other means to drive the cantilever, including magnetic [7] and photothermal excitations [8].

Most of the early work in dynamic force measurements was done for better understanding of the cantilever dynamics in tapping-mode AFM, especially with the goal of providing the interpretation of the phase signal in tapping-mode AFM [9–11]. Consequently, early work on dynamic measurements focused on large-amplitude oscillation (on the order of a few tens of nanometers) to match the typical operation condition of tapping-mode imaging. These types of APD curves are useful to correlate experimental observations such as attractive versus repulsive imaging regions in tapping mode with theories on cantilever dynamics [11]. Since the tip goes through almost the entire force field from attractive to repulsive region in every cycle of oscillation, large-amplitude dynamic force measurements fall short in capturing the detailed dependence of tip-sample interaction forces as function of

Dynamic Force Measurements on Modified Surfaces with AFM,
Fig. 1 Schematic diagram showing the experimental setup dynamic force microscopy. The tip oscillates with an average distance, *D*, from the sample surface with amplitude, *A*. The piezo provides the force needed to oscillate the micro-cantilever

tip-sample distance as in quasi-static force measurement.

In the late 1990s, researchers started to use small-amplitude dynamic force measurements in detecting the solid/liquid interfacial forces [12, 13]. Previously, there had been a lot of work on using quasi-static force curves to study solid/liquid interfacial forces [4, 14, 15]. When using either dynamic or quasi-static force measurements to study solid/liquid interfacial force, the micro-cantilever and the AFM tip are typically immersed in liquid to avoid the influence of forces from liquid/air interface. Compared with quasi-static force measurements, there are several advantages of using small-amplitude dynamic force measurement in liquid environments: first, the cantilever deflection signal tends to pick up greater thermal drift noise in liquid environment than in air, which allows much better error minimization in dynamic force measurements in a liquid environment since the force is not directly calculated from the cantilever deflection signal. The noise due to thermal drift can be rejected by modulating the deflection signal with an oscillating cantilever and selecting only the signal at the modulating frequency. Second, the viscous damping force is much stronger in a liquid than in air. It is hard to separate the conservative forces such as van der Waals force and electric double-layer force from dissipative viscous damping force in quasi-static force measurements. In dynamic force measurements, however, conservative forces and dissipative forces produce in-phase response and out-of-phase responses in the APD curves, respectively, making it possible to decouple the two kinds of forces. Dynamic force measurements can be done on the same location where tapping-mode scan is performed without losing the spot because there is no need to change the AFM probe. This is convenient when the nature of application demands tapping-mode imaging, for example, soft biological membranes or surfaces with nano-bubbles.

It is important to keep the oscillation amplitude small when conducting dynamic force measurements in a liquid. In addition to the fact that the large-amplitude oscillation is not sensitive to small changes in force fields, large-amplitude oscillation excites higher modes of vibration of the cantilever beam simultaneously in liquids [16]. The energy transfer from fundamental vibration mode to higher vibration mode complicates the analysis of cantilever dynamic response in order to obtain the tip-sample interaction force. For small-amplitude oscillation, the complicated cantilever beam dynamics can be simplified using point mass model with the dominant vibration mode being the fundamental mode of the cantilever.

Dynamic Model for Small-Amplitude Dynamic Force Measurement in Liquids

The equation of motion of an oscillating cantilever in a liquid, shown in Fig. 1, can be approximated in low Reynolds number, Re, flow to the first order by a point mass versus beam system [17]:

$$m\ddot{z} = -b\dot{z} - k_c(z - z_0) + k_c a_d \cos(\omega_d t) + F_i \tag{2}$$

where z is the position of the tip at any time and z_0 is the position at zero cantilever deflection. The coefficient, m, is the effective mass of the cantilever, including the additional fluid mass being accelerated, and k_c is the spring stiffness of the cantilever. The tip-sample interaction force, F_i, includes the electrical double-layer force and van der Waals force. The hydrodynamic damping, b, and the tip-sample interaction force, F_i, are all tip-sample distance dependent. Including the higher harmonic modes, the steady-state solution of Eq. 2 for the oscillation of the cantilever tip can be approximated as

$$z = D + \sum_{n\geq 1} A_n \cos(n\omega_d t - \phi_n) \tag{3}$$

where D is the mean value of the tip-sample distance, and A_n and ϕ_n are the amplitude and phase shift of the oscillation at the n^{th} harmonics, respectively.

In typical dynamic measurements, Re ranges from 10^{-6} (at the tip radius) to 10^{-3} (at the widest beam width). For Re $<<$ 1, the flow around the tip and the beam of the cantilever is classified creeping flow, with standard solutions existing for many different conditions. If the oscillation amplitude is small compared to the range of the conservative interfacial forces including the van der Waals force and the electric double-layer force, we can assume the total tip-sample interaction force, F_i, is a single value function of tip position z and can be approximated by

$$\begin{aligned} F_i(z) &\approx F_i(D) + \frac{\partial F_i}{\partial z}(z - D) \\ &= \langle F_i \rangle - k_i(z - D) \end{aligned} \tag{4}$$

where $< F_i >$ is the averaged interaction force over one cycle and k_i is the force gradient or the effective stiffness of the tip-sample interaction. For low Reynolds number flow, the forces arising from interactions between the AFM tip, liquid, and surfaces can be superimposed, and the virial theorem [18] can be used to estimate the time averaged forces. Note that in Eqs. 2 and 4, F_i represents the summation of all conservative interfacial forces in aqueous medium including van der Waals force, electric double-layer force, hydration force, and others. At steady state, the virial theorem for the point mass model is $(1/2)m\langle \dot{z}^2 \rangle = -(1/2)\langle F_i z \rangle$ and the power balance at steady state, $\langle k_c a_d cos(\omega_d t)\dot{z} \rangle + \langle -b\dot{z}^2 \rangle + \langle F_i \dot{z} \rangle = 0$, giving

$$\frac{a_d \cos\phi_1}{A_1} = \left(\frac{k_i}{k_c} + 1\right)\frac{1}{{A_1}^2}\sum_{n\geq 1} {A_n}^2 - \left(\frac{\omega_d}{\omega_r}\right)^2 \frac{1}{{A_1}^2}\sum_{n\geq 1} n^2 {A_n}^2 \tag{5a}$$

and

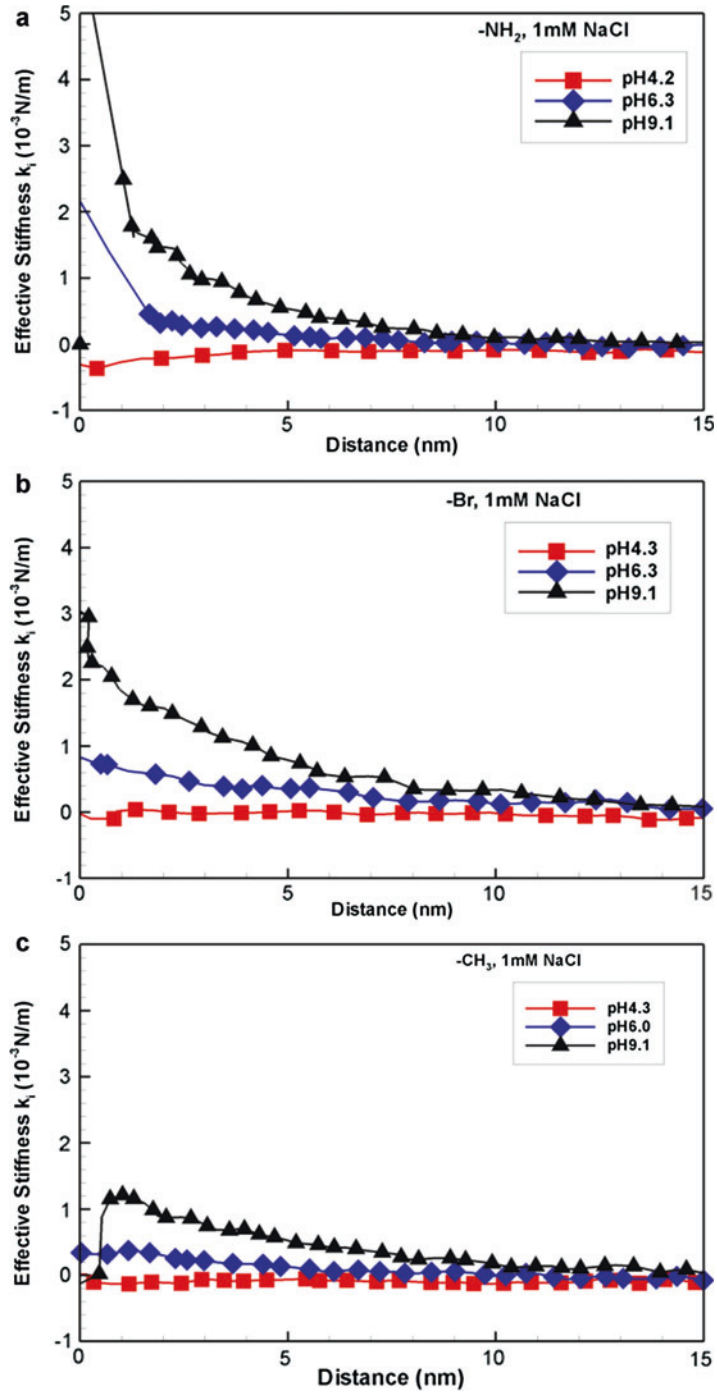
$$\frac{a_d \sin\phi_1}{A_1} = \frac{b\omega_d}{k_c {A_1}^2}\sum_{n\geq 1} n^2 {A_n}^2 \tag{5b}$$

where ω_r is the cantilever's resonance frequency, and it equals $(k_c/m)^{1/2}$. Equation 5a shows that the in-phase component of the APD curve, $\cos\varphi_1/A_1$, is related to the conservative interaction (the gradient of the single valued interaction force, k_i), and Equation 5b shows the out-of-phase component, $\sin\varphi_1/A_1$, is related to the dissipative interaction (hydrodynamic damping, b).

If the amplitudes at higher harmonics are negligible, Eq. 5 can be simplified to

$$k_i = \left(\frac{\cos\phi_1}{A_1} - \frac{\cos\phi_\infty}{A_\infty}\right) a_d k_c \tag{6a}$$

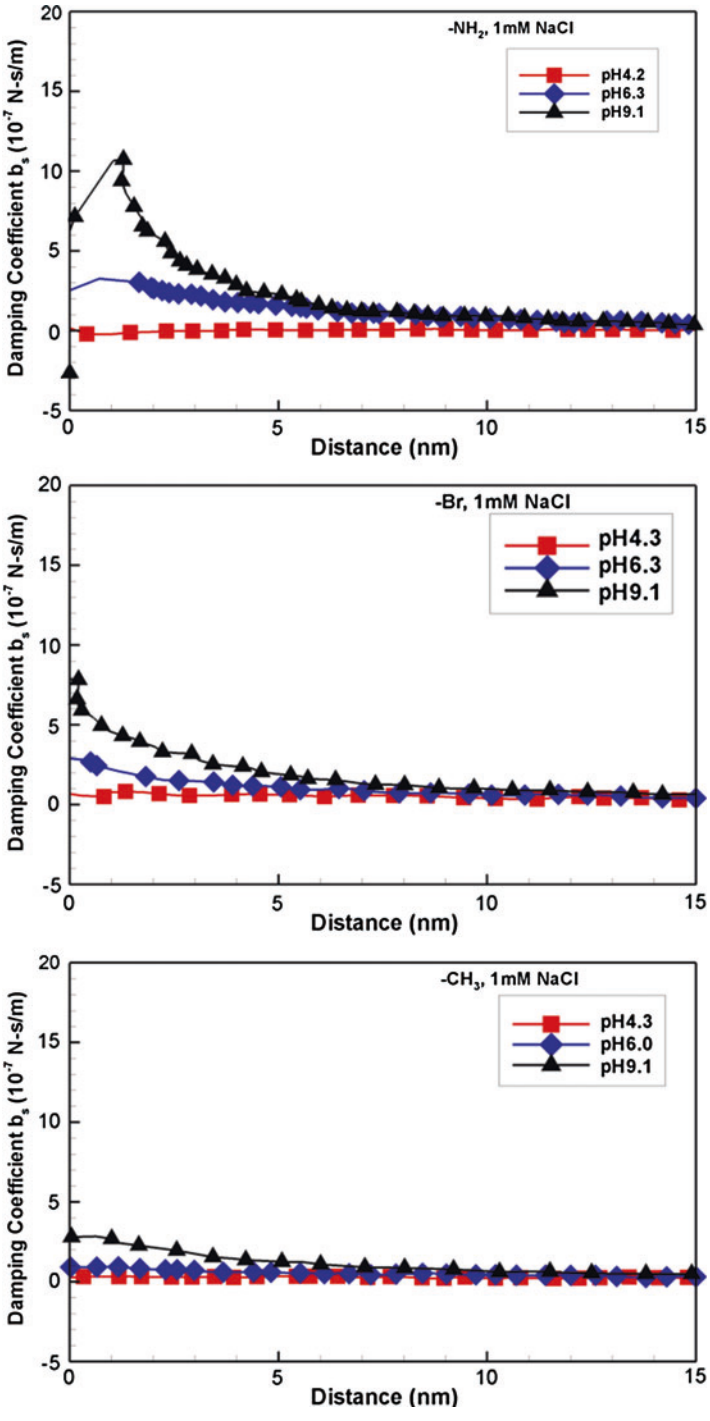
and



$$b_s = \left(\frac{b}{b_c} - 1\right) b_c = \left(\frac{A_\infty \sin\phi_1}{A_1 \sin\phi_\infty} - 1\right) b_c \quad (6b)$$

where A_∞ and ϕ_∞ are fundamental mode amplitude and phase when the AFM probe is far away from the solid/water interface. In dynamic force curve measurements, A_∞ and ϕ_∞ are obtained experimentally by measuring the amplitude and phase signal when the oscillating tip is at least a few microns away from the sample surface. The hydrodynamic damping coefficient, b, sensed in the dynamic measurements consists of a term associated with the damping of the cantilever, b_c, that stays relatively unchanged when the tip-sample distance is in the tens of nanometer range and the cantilever beam is at least several microns away from the sample surface and a distance-dependent term, b_s, which arises due to the squeeze film damping between the tip and sample surface [19]. Equation 6 translates the measured data in dynamic force measurements, A_1 and ϕ_1, to physical quantities, k_i and b_s, at the solid/liquid interface. The rest of parameters in Equation 6 can be measured independently from APD curves. Both k_c and b_c can be determined by the thermal noise spectrum of the cantilever when the tip is far away from the surface [20, 21]. The amplitude of acoustic excitation, a_d, can be approximated to be A_∞/Q_∞, where Q_∞ is the quality factor of the cantilever resonance curve measured at a distance far away from the surface.

Equation 6 shows that the dynamic force curve can be used to calculate the effective stiffness of the electric double-layer interaction and hydrodynamic damping at solid/water interfaces if the contribution of the higher harmonics to cantilever oscillation is negligible. In general, the following two conditions are necessary if we can safely neglect the higher harmonics without losing much insight to the physics of the interaction. First, the mechanical stiffness of the cantilever needs to be much greater than the effective stiffness of the tip-sample interaction. Second, the oscillation amplitude needs to be small compared to the characteristic range of the interaction, which is the thickness of the electric double layer and is usually taken to be equal to the Debye length of the electrolyte solution [17], but can vary to 3–4 times the Debye length [22, 23].



Applications of Dynamic Force Measurement on Modified Surfaces in Liquid

The understanding of solid/liquid interfacial forces is fundamental to a variety of fields, including tribology, colloidal systems, electrochemical cells, biomolecular interactions, and electrokinetic transport through micro- and nanofluidic devices [22, 24]. Dynamic force measurements have shown to be sensitive to conservative interactions such as the electrostatic double-layer force and dissipative interactions from hydrodynamic damping in aqueous solutions. An application of particular interest is to characterize modified surfaces or engineered surfaces in micro- and nanofluidic devices. Due to the high surface-area-to-volume (SA/V) ratio in micro- and nanofluidic devices, the material properties of channel walls such as surface charge density, surface roughness, and surface hydrophobicity become dominating factors in determining the fluidic transport inside the channel [24, 25]. For example, macroscale fluid mechanics assumes a no-slip condition at the wall, which implies that the velocity of the fluid layer in contact with the walls is the same as that of the walls. In micro- and nanofluidic channels, however, finite slip of fluid flow can be achieved by using hydrophobic material for channels or modify the surface of channel wall to be hydrophobic [26]. The unique surface-mediated flow in micro- and nanofluidic channels opens the possibility to control fluidic transport characteristics by systematically engineering the surface properties of channel walls [22, 24]. Dynamic force measurement has proven to be a useful tool in characterizing the modified surfaces for micro- and nanofluidic devices because it provides information not only on the electric double-layer interaction but also on hydrodynamic damping coefficients at

Dynamic Force Measurements on Modified Surfaces with AFM, Fig. 2 Plots of effective stiffness versus tip-sample distance for functionalized silica surfaces immersed in 1 mM NaCl solutions titrated at three different pH values

solid/liquid interfaces. Hydrodynamic damping coefficients are important in micro- and nanofluidic devices as they can provide insights into the physical implications of surface-fluid interactions. One particular surface-fluid interaction of interest is the drainage velocity of the liquid thin film confined between two surfaces approaching one another. The drainage is related

Dynamic Force Measurements on Modified Surfaces with AFM, Fig. 3 Plots of hydrodynamic damping versus tip-sample distance over functionalized silica surfaces immersed in 1 mM NaCl solutions titrated at three different pH values

to the surface properties of the confining surfaces. For example, the drainage rate (or fluid drainage velocity) is often related to the equilibrium surface forces or can be used to determine interfacial properties for both Newtonian and non-Newtonian fluids. Fluid drainage between surfaces with different combinations of hydrophilicity and hydrophobicity [27] has been used as an

indirect way to characterize the boundary slip effect, with the underlying mechanisms for slip being the subject of continued debate among the scientific community.

In the following, an illustrative example for the application of dynamic force measurements on modified surfaces is described [28]. In this example, silica surfaces were chemically modified yielding surfaces with –Br, -NH_2, and –CH_3 functional group terminations, respectively, using previously reported methods comprising self assembly and "click" chemistry [29]. The dynamic force measurement data were obtained using gold-coated silicon nitride probes (Biolever, Olympus) with a rectangular cantilever (nominal spring constant of 0.03 N/m). The cantilever oscillation amplitude was less than 2 nm when the tip was within 15 nm distance from sample surface. Once the APD curves were measured, the effective interaction stiffness and hydrodynamic damping can be calculated based on Eq. 6. Figure 2 shows the effective interaction stiffness between the AFM tip and the chemically modified surfaces with –Br, –NH_2, and –CH_3 functional groups in 1 mM NaCl solutions at different pH values, respectively. Assuming electric double-layer interaction is dominating in the tip-sample distance range of interest (1–15 nm) in this study, the effective interaction stiffness, k_i, can be approximated to be the derivative of electric double-layer force over distance in this case, as expressed in

$$k_i \approx g\sigma_s\sigma_T \exp\left(-\frac{D}{L_D}\right) \tag{7}$$

where σ_S and σ_T are the surface charge densities of the sample and the AFM tip, respectively, L_D is the Debye length of the electrolyte solution, and g can be considered as a geometry constant when z is of the same order of magnitude of the tip radius. Equation 7 assumes small surface potentials (smaller than or of the order of kT/e, i.e., around 25 mV) and that D is large enough compared to L_D. A higher absolute value of effective stiffness indicates a stronger double-layer interaction force and stronger surface charge density at the sample surface. One can compare charge densities between different modified surfaces, evaluate the effect of changing pH value in the solution on surface charges, and find out the electric double-layer interaction ranges from the results in Fig. 2.

The distance-dependent hydrodynamic damping at the modified surfaces sensed by the micro-cantilever is shown in Fig. 3. Figure 3 shows that there are distinct hydrodynamic damping responses among the silica surfaces with dissimilar functional groups. For example, there is a significant increase in the damping factor of the –Br surface as the distance between the probe and sample decreases, but by contrast there is almost no change for the –CH_3-terminated surface under similar test conditions. With each kind of surface, the solution pH value also has an impact on the damping curves, most likely due to the fact that pH acts as a control variable to modulate the effective surface charge density, thereby changing the interaction forces between the tip and the surface.

The example shows dynamic force measurement is a powerful tool to probe solid/liquid interfacial forces. When the oscillation amplitude of a micro-cantilever is much less than electrical double-layer interaction range, there are distinctive dynamic responses to chemically modified surfaces in aqueous electrolyte solutions within a few Debye lengths from the surfaces. The effective interaction stiffness is highly dependent on the surface charge. The hydrodynamic damping also shows strong dependence on the surface hydrophobicity.

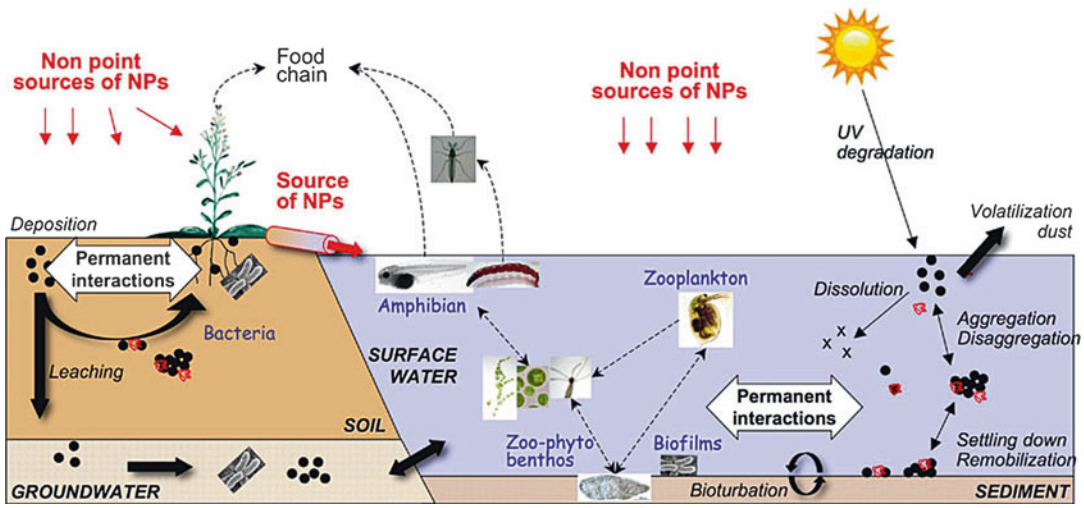
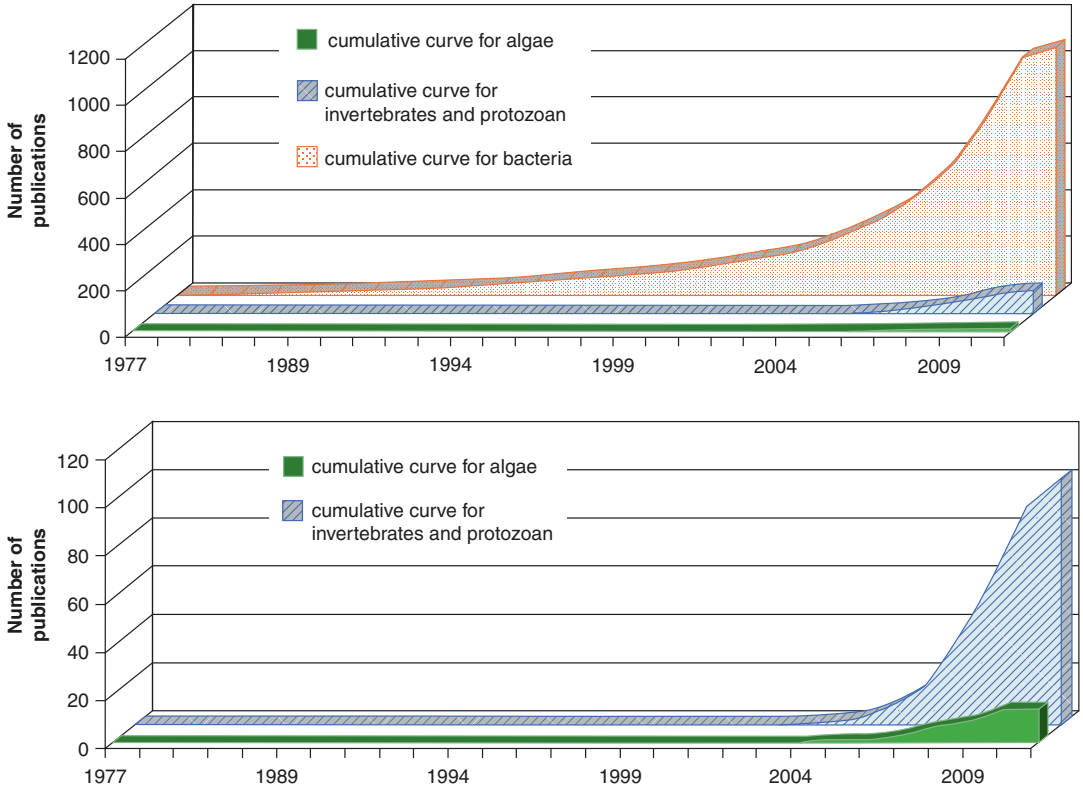
Definition



A toxic product is a chemical compound that harms the environment by affecting the biological organisms. Due to their novel properties, nanoparticles (NPs) cannot be considered as other organic and inorganic xenobiotics in the environment, e.g., pesticides, HAPs and PCBs dissolved metals, or also medicines. NPs have a mass, a charge, and above all a surface area. They are subject to phenomena of classical and quantum physics. Their reactivity means that their surface atoms are labile, easily change their redox state, and highly reactive with respect to compounds in the environment. Considering the huge range of applications using NPs, it seems reasonable to expect their dissemination in the environment at each step in their life cycle, from design through production to use and disposal of finished products. To date, the data available show that NPs can cross biological membranes and distribute themselves within different compartments of living organisms, or can also induce a remote toxicity. Consequently, there is a need to elucidate how the NPs can lead to adverse effects on organisms in their natural environment, considering not only their effects on target organs and life traits, but also their fate and transfers within the food webs (Fig. 1) (Box 1).

Box 1: Ecosystem and Food Chains



An ecosystem is the basic functional unit in ecology, as it includes both organisms and their abiotic environments (Fig. 1). It represents the highest level of ecological integration based on energy and biomass transfers. It is defined as a specific unit of all the organisms occupying a given area that interacts with the physical environment producing distinct trophic structure, biotic diversity, and material cycling.

Overview

The number of available publications (Fig. 2) dealing with the environmental impacts of NPs (called nano-ecotoxicology [1]) is presented in Fig. 2. Studies regarding algae, protozoa, and invertebrates are more recent (since 2006) than the ones regarding bacteria (which started in the 1980s) (*ISI Web of Knowledge source*) (Box 2). As a consequence, researches on bactericidal effects are more advanced (already at the scale of biofilms and the microbial community

Ecotoxicity of Inorganic Nanoparticles: From Unicellular Organisms to Invertebrates, Fig. 1 Fate and transport of nanomaterials within aquatic and terrestrial ecosystems and the relationships with the living organisms

Ecotoxicity of Inorganic Nanoparticles: From Unicellular Organisms to Invertebrates, Fig. 2 Evolution of the nano-ecotoxicology studies focused on the algae, invertebrates and protozoan, and bacteria since the 1980s (based on the ISI Web of Knowledge database)

structures), while for the other models nano-ecotoxicology is still in its infancy (at the individual scale).

About 30 species of invertebrates are studied regarding the three main ecosystemic domains: freshwater, marine, and terrestrial. For each domain, the Crustacean Cladocera Daphniidae (freshwater), the Mollusks Bivalvia Mytilidae, and Annelids Polychaetes (marine) are the most studied invertebrates, while the terrestrial (earthworms and isopods) examples are scarce.

Considering the three-domain system that divides cellular life into archaea, bacteria, and eukaryote domains (based on differences in 16 S rRNA genes), the studied models are mostly Eukaryotes belonging to Opisthokonts Animals, Alveolata (Ciliata), Plants Chlorophyta (green algae), or Prokaryotes with planktonic bacteria. Following the Whittaker's model distinguishing the differences in nutrition, most of the studied invertebrates belong to the ingestion nutrition group (active suspensory feeders (Daphniidae), suspension feeders (Mytilidae), or carnivorous (Cnidaria, Polychaeta)), others are detritivorous (*Blaberus*), deposit feeders (*Eisenia*), or fluid suckers (*Caenorhabditis elegans*), and most of the autotrophic organisms are the eukaryotic photosynthetic green algae (Chlorophyta). Protozoa are unicellular heterotrophic organisms, belonging to the Ciliophora group, feeding by phagotroph.

Box 2: Bacteria as a Good Model for Ecotoxicology

Life on earth evolved from bacteria and life on earth depends on bacteria, as they make the essential elements oxygen, carbon,

(continued)

nitrogen, and sulfur available for other life forms on our planet. They play important roles in the global ecosystem. They are key players of the breakdown of dead organisms, and the release of nutrients back into the environment. Each human body hosts ten microorganisms for every human cell. Microbes inhabiting humans have been recently identified and shown to play a beneficial role in health by contributing to human metabolism while in turn they benefit from the nutrient-rich niche in the intestine. Since bacteria constitute the largest biological surface, nanoparticles (NPs) may encounter in different ecosystems from air, soil, water to insect and animal bodies. Their contribution to NPs fate in different ecosystems has to be taken into account, as they may be involved in NPs transformation, sequestration, solubilization, or aggregation.

The biology and functional ecology of bacteria in different ecosystems make them good models for NPs toxicity studies. NPs may show deleterious effect on microbial physiology and survival, altering hence ecosystems functioning. It is hence worth investigating NPs effects of exposure and subsequent bioaccumulation to determine their toxicity on microbial communities and model bacteria.

Key Principles

Not intended to be an exhaustive list of results, this article discusses the relationships between the potential ecotoxicity of NPs with respect to their physicochemical properties, the organism functions, and the relationships between species. It has been recently shown that the surface reactivity and the chemical destabilization of metallic and metal oxide NPs were involved in their potential toxicity. NPs reactivity can be spontaneous (e.g., adsorption, oxidation, or reduction) or induced by an external event (e.g., the photocatalytic activity of TiO_2) [2]. Chemical destabilization can lead to redox changes within the lattice structure, the generation of reactive oxygen species (ROS), and to the release of ions in solution (e.g., Zn ions). The dissolution can be either reductive (e.g., the reduction of $Ce^{4+}O_2$ NPs into Ce^{3+}) or oxidative (e.g., Ag^0 NPs oxidation into Ag^+, Cu^0 NPs oxidation into Cu^{2+}) [3]. All these modifications can be critical events if the protective mechanisms of unicellular or pluricellular organisms are overwhelmed by a strong affinity with NPs. To highlight the relationship between surface reactivity and the ecotoxicological effects, this article is focused on metallic and metal oxide NPs.

Key Research Findings

Photocatalytic NPs: The Example of TiO_2

TiO_2 NPs (anatase and rutile) are the most used photocatalytic NPs as self-cleaning, opacifying, antimicrobial, antifouling agents, or UV-absorber in cosmetics, paints, etc., (see [4] and references therein). Recent studies have shown that they can be disseminated in the environment. For instance, the leaching out of TiO_2 NPs from exterior facades releases few $\mu g.L^{-1}$ of TiO_2 into stream water [5].

Bacteria

The ecotoxicity of TiO_2 NPs has been studied on rod-shaped *Escherichia coli*, *Pseudomonas fluorescens*, *Vibrio fischeri*, *Salmonella typhimurium*, bacillus-shaped *Nitrosomonas europaea* Gram-negative bacteria, and *Bacillus subtilis* Gram-positive bacteria [6, 7].

The mechanisms of ecotoxicity of TiO_2 mainly rely on a photocatalytic process at the surface of NPs generating ROS. The toxicity requires a contact between bacteria and TiO_2 NPs leading to the loss of membrane integrity and an increase in outer membrane permeability. The concentration of TiO_2 affecting bacterial survival in photocatalytic conditions varies between 10^{-3} and 5×10^3 $mg.L^{-1}$ [8]. For *E. coli*, the antimicrobial activity depends on biological parameters such as physiological state, generation, and initial concentration of bacteria [9] as well as the

chemical structure and the shape of the TiO_2 NPs. Surprisingly, membrane damages were also observed in the absence of light, e.g., [10].

The uptake of well-dispersed TiO_2 NPs was observed by transmission electron microscopy in *S. typhimurium* [7] treated with 8 and 80 ng.mL^{-1} of TiO_2 for 60 min. This induced a weak mutagenic potential in *S. typhimurium* strains (TA98, TA1537). Mutagenic effects were also observed toward *E. coli* (WP2uvrA) [7, 11].

Size-dependent toxicity of TiO_2 NPs is controversial. Studies have shown that particle size did not affect antibacterial activity [12, 13]. However, Ivask et al. have shown that whereas nano and bulk TiO_2 both decrease viability of bacteria at high concentrations (>4,000 mg.L^{-1}), the TiO_2 NPs were the only ones inducing bioluminescence of the superoxide anion sensing bacteria from 100 mg.L^{-1} [14]. Another size effect regards the size-dependent point of zero charge (PZC) of TiO_2, with a PZC of 4.8 for the smallest particles (∅ 3.6 nm) and higher PZC values (6.2, 6.5, 6.8) for the largest ones (∅ 8, 25, 200 nm) [6]. Since many experiments are performed at pH 5.5–6.8, exposure to bacteria and the adsorption onto their walls will be sensitive to this change in PZC [13]. Moreover, initially agglomerated TiO_2 NPs can be dispersed by bacteria as *P. fluorescens*. Such phenomenon can enhance the transport of NPs in the environment [15].

Algae

Since 2006, less than 20 papers illustrate the effects of NPs on marine and freshwater primary producers (algae). Overall, these studies demonstrate that primary producers (algae) are among the more sensitive forms of aquatic life to metallic NPs. The most studied freshwater green algae are *Pseudokirchneriella subcapitata*, but the results are controversial. Warheit et al. [16] observed acute effects with EC_{50} values of 21 mg.L^{-1} for TiO_2 NPs (∅ 140 nm), and 72 h EC_{50} of 5.83 mg.L^{-1} for TiO_2 NPs (∅ 25–70 nm). However, no toxicity was found at concentrations up to 100 mg.L^{-1} for TiO_2 NPs (∅ <40 nm) [17]. The absence of ecotoxicity is attributed to the rapid aggregation/coagulation [17], whereas the toxicity is related to entrapping of algal cells by aggregated TiO_2 NPs [18]. Such controversy highlights that many studies address the question of ecotoxicity but very few concern the mechanisms of toxicity or internalization.

The effects of particle size and UV photoactivation were assessed using TiO_2 (anatase, ∅ 25 and 100 nm) on freshwater green algae *Desmodesmus subspicatus* [19]. The EC_{50} value was 44 mg L^{-1} for the 25 nm NPs and greater than 50 mg L^{-1} for the 100 nm-TiO_2. UV photoactivation caused no additional effects. In some cases, the presence of TiO_2 NPs can also be beneficial. It increases the dry weight, chlorophyll synthesis and metabolism in photosynthetic organisms.

Finally, in a recent study [20], the toxicity of TiO_2 NPs was assessed for the first time on marine diatoms, chlorophyceae, and prymnesiophyceae. Ninety six hours NOEC were observed on all species in presence of TiO_2 NPs (anatase, ∅ 15–20 nm, 10–1,000 µg.L^{-1}).

Invertebrates

Terrestrial Invertebrates Ecotoxicological studies on terrestrial invertebrates are limited. They mostly regard the crustacean isopod *Porcellio scaber* [21, 22], the model *C. elegans*, and the earthworm *Eisenia fetida* [23, 24]. TiO_2 NPs (∅ from 15 to <50 nm) spread over the surface of dry leaf (1 mg TiO_2.g^{-1} of food for 14 days) did not induce effect on mortality, weight change, or feeding behavior toward *Porcellio*. However, *E. fetida* exposed to artificial soils containing more than 1 g.kg^{-1} of TiO_2 NPs for 7 days bioaccumulates and exhibit significant mitochondria damage. Moreover, a strong inhibition of the cellulase activity of *E. fetida* occurred that directly impacted the digestion. However, it has not been clarified whether cellulase originates from the earthworms or the symbionts.

Freshwater Invertebrates The adverse effects of TiO_2 NPs on aquatic invertebrates have been more studied than other inorganic NPs. In freshwater crustaceans, only branchiopods have been tested: the cladocerans *Ceriodaphnia dubia*, *Chydorus sphaericus*, and the anostracans

Thamnocephalus platyurus, as well as the brine shrimp *Artemia*.

Daphniid *Daphnia magna* are the most tested animals. TiO_2 NPs were mostly detected in their gut, but no clear conclusions can be drawn on the size-dependent toxicity of NPs. However, the aggregation state is important to consider [16]. Variable 48 h EC_{50} and LC_{50} ranging from 5.5 to 20,000 $mg.L^{-1}$ have been reviewed [1]. Others studies regard *Hydra attenuata*, the Gastropod *Physa acuta*, and midge larvae *Chironomus riparius*. For instance, sublethal doses of alumina coated-TiO_2 NPs reduced embryo growth rate and hatchability, and induced developmental deformities of the embryos on the freshwater snail *Physa acuta* [25]. Embryonic growth and hatchability tests are useful endpoints to assess chronic toxicity and toxic thresholds of NPs in sediment environment. Although no snail mortality was observed significant change in antioxidant levels were observed at 0.05 or 0.5 $g.kg^{-1}$. In this study, the exposure duration appeared as a significant factor. Consequently, long-term exposure has to be taken into account since alterations of ecological populations and ecological functionality are possible.

Marine Invertebrates A significant decrease in casting rate, increase in cellular and DNA damage in coelomocytes was measured toward the sediment dwelling marine Polychaetes *Arenicola marina* [26]. Using Raman Scattering Microscopy, TiO_2 aggregates of diameter >200 nm were located in the lumen of the gut and attached to the outer epithelium. On the bivalve *Mytilus galloprovincialis*, 24 h in vivo tests highlight that TiO_2 NPs (∅ 22 nm, 51 $m^2.g^{-1}$) induced lysosomal membrane destabilization in the hemocytes and digestive gland [27]. TiO_2 also increased the catalase and glutathione transferase activity in the digestive glands (not in the gills) which implies an oxidative stress mechanism.

Chemically Unstable NPs

Bacteria

Metallic Ag NPs have antimicrobial properties, and are the most commonly used nanomaterials in consumer products (see [28, 29] and references therein). The widespread use of Ag NPs will increase the load up of silver into wastewater treatment plants. Predicted environmental concentration (PEC) for Ag NPs are 0.5–2 ngL^{-1} in surface waters, 32–111 ngL^{-1} in sewage treatment plant effluents, and 1.3–4.4 $mg.kg^{-1}$ in sewage sludge. Recently, silver sulfide NPs have been evidenced in the reducing and sulfur-rich environment of sewage sludge.

A wide range of Ag NPs sizes, shapes, crystal structure, and surface chemistry were exposed to bacteria at different pH and ionic strength. The toxicity proceeds through release of free silver ions associated with specific effects of Ag NPs. Ag ions inhibit the oxidation of endogenous substrates by *E. coli* and cause efflux of accumulated phosphates and metabolites. Ag^+ interferes with the respiratory chain, induces the collapse of the proton motive force, the de-energization of the cell, the disruption of DNA replication, and disturbs phosphate uptake. Silver binds to proteins or enzymes and also competes for cell surface binding sites of bacterial cells with metal ions, such as copper. Ag NPs attach to the surface of the Gram-negative membranes, can penetrate inside the bacteria, and drastically disturb the cell permeability and respiration, dissipate the proton motive force, collapse the plasma membrane potential, and deplete intracellular ATP levels. The mode of action of Ag NPs (∅ 9.3 nm) 0.4 nM is similar to that of Ag^+ ions 6 μM. Free silver and Ag NPs generate ROS and cell membrane damage. Using superoxide anion sensor *E. coli* [14] showed that generation of ROS by Ag NPs contributed to the toxicity. Interestingly, extracellular polymeric substances produced by bacteria, neutralized free silver ions, and decreased the toxicity of Ag NPs [30]. River humic acids also mitigated the bactericidal action on *P. fluorescens*.

Size-, crystallinity-, and shape-dependent effects were observed in terms of antibacterial activity and ROS production. Direct interaction with the bacteria preferentially occurred for NPs ranging within 1–10 nm. Among tested Ag NPs sizes (10, 30–40, and 100 nm), only the 10 nm NPs inhibited methicillin-resistant *S. aureus* (the main cause of nosocomial infections worldwide) [31].

Quantum dots (QDs) are colloidal semiconductors with composition- and size-dependent absorption and emission. They are used as biological probes cellular imaging, tumor targeting, and diagnostics. The minimum inhibitory concentrations of ZnO NPs against *E. coli*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus* were found between 125 and 500 $\mu g.mL^{-1}$ [32]. ZnO NPs induce toxicity via the dissolution and release of Zn^{2+} ions [6, 33]. The toxicity depends on the media composition (pH, ionic strength) and the illumination conditions. Both Gram-negative and Gram-positive membranes are disorganized after interactions with ZnO NPs [6, 34]. The increase in membrane permeability leads to the internalization of NPs [34]. A study using mutant strains has shown that CdSe and CdSe/ZnS QDs (∅ <5 nm) can penetrate into *B. subtilis* and *E. coli* upon purine-processing mechanisms [35]. Extracellular polymeric substances excreted by bacteria prevent NPs internalization and decrease the toxicity observed [36]. Interestingly, ZnO NPs inside the cell are less crystallized than the initial NPs [34]. This raises the question of whether there is a direct internalization of the NPs, or a dissolution/precipitation within the cells.

CdTe QDs also induce toxicity toward Gram-positive methicillin-resistant *Shewanella aureus* and *B. subtilis*, with EC_{50} concentrations tenfold higher than toward Gram-negative strains *E. coli* and *P. aeruginosa* [37]. CdTe NPs bind to bacteria and impair the antioxidant system by photogeneration of ROS [37]. In that case, the release of Cd^{2+} has little or no role in toxicity of CdTe NPs [37], but the formation of TeO_2 and CdO by surface oxidation may cause cytotoxicity [38].

CeO_2 NPs are used as diesel fuel additives, polishing surface agents, as well as in coating and microelectronics. CeO_2 are nonstoichiometric NPs with cerium atoms in +4 and +3 oxidation states, and oxygen vacancies [39]. EC_{50} was near 5 mg L^{-1} for *E. coli* and ranged from 0.27 to 6.3 $mg.L^{-1}$ for *Anabaena* in pure water [40]. Under exposure to CeO_2 NPs, *N. europaea* cells have shown larger sedimentation coefficient than the control [6]. The toxicity of CeO_2 NPs is exerted by direct contact with cells [40], membrane damages [6], cell disruption [40], and release of free Ce^{3+} [41]. Even if free Ce^{3+} is toxic for *Anabaena* in pure water, it could not explain by itself the cytotoxicity observed. However, the reduction of the Ce^{4+} into Ce^{3+} at the surface of the CeO_2 NPs correlates with the cytotoxicity toward *E. coli*. No oxidative stress response was detected with *E. coli* or *B. subtilis*, but CeO_2 NPs and $CeCl_3$ alter the electron flow, and the respiration of the bacteria [42]. Pelettier et al. [42] also observed the disturbance of genes involved in sulfur metabolism, and an increase in the levels of cytochrome terminal oxidase (*cydAB*) transcripts known to be induced by iron limitation.

Algae

The short-term toxicity of Ag NPs (∅ 25 nm) and $AgNO_3$ was tested toward the freshwater algae *Chlamydomonas reinhardtii* [43]. The toxicity measured by EC_{50} for Ag^+ was 18 times larger than for Ag NPs and much higher than those determined to inhibit algal growth in other studies. The toxic effects observed here reflect toxicity to photosynthesis. TEM showed no aggregation of Ag NPs. However, the measured Ag^+ concentration in the suspension of Ag NPs by itself cannot account for the observed toxicity since only 1 % of the Ag had been oxidized [43]. Interestingly, once normalized by the concentration of dissolved Ag^+, the toxicity of Ag NPs was more important than that of $AgNO_3$. This suggests the importance of interactions between the surfaces of Ag NPs and algae cells.

In contrast, Ag^+ released from the oxidative dissolution of Ag NPs (∅ 60–70 nm) severely suppressed cell growth, photosynthesis, and chlorophyll production in marine diatom *T. weissflogii* [44]. In both studies [43, 44] Ag NPs were not found to be toxic to either freshwater or marine unicellular algae at concentrations that could be expected in contaminated water bodies.

Regarding ZnO NPs, their toxicity toward the freshwater algae *P. subcapitata* was solely attributed to rapid dissolution at pH 7.6 with a saturation solubility in the range of 1 mg L [45]. Toxicity of ZnO NPS (∅ 20–30 nm) was assessed on marine phytoplankton (diatoms, chlorophytes, and prymnesiophytes) [20]. Even in saline water,

the toxicity was related to dissolution, release, and uptake of free Zn ions.

Protozoa

Studies on adverse effects of NPs against unicellular eukaryotes are scarce. The toxicity of Ag NPs (Ø 30–40 nm) on the Ciliate Protozoa *Paramecium caudatum* was reported by Kvitek et al. [46]. No toxicity was observed below 39 $mg.L^{-1}$, whereas ionic silver induced toxicity above 0.4 $mg.L^{-1}$. The authors noticed that the surfactant/polymer modification strongly affected the toxic behavior of Ag NPs.

The toxicity of CuO NPs (30) was investigated on Protozoans *Tetrahymena thermophila* [47]. A clear accumulation of the CuO NPs was observed in their food vacuoles. In all cases toxic effects of Ag and CuO NPs to protozoa were caused by their solubilized fraction. Interestingly, experiment performed in natural water versus artificial water remarkably (up to 140-fold) decreased the toxicity of CuO NPs depending mainly on the concentration of dissolved organic carbon.

Invertebrates

Terrestrial Invertebrates The effects of Cu NPs (∅ 20–40 nm, and <100 nm) and Cu ions were assessed on *Eisenia* in artificial soil [48]. Both Cu ions and NPs are bioaccumulated suggesting a route of entry into terrestrial food chains. No subchronic toxicity of Cu NPs was observed at concentrations up to 65 $mgCu.kg^{-1}$ soils. Increases in metallothionein expression occurred from 20 mg kg^{-1} of Cu NPs to 10 mg kg^{-1} of $CuSO_4$. An oxidized and amorphous layer at the surface of the Cu NPs appears immediately in the soil and depends on particle size (XANES-based experiment). This highlights the necessity to consider the surface chemistry of Cu NPs during nano-ecotoxicology studies since the toxicant is likely to be more reflective of CuO than metallic Cu. *Eisenia* was also exposed to $AgNO_3$ and Ag NPs (PVP-coated) [49]. *Eisenia* consistently avoid soils contaminated with Ag NPs or $AgNO_3$ with faster avoidance for $AgNO_3$. In natural soil, *Eisenia* accumulated significantly higher concentrations of Ag than in artificial soil. Ag NPs incubated in the soil were 10–17 % Ag(I), suggesting that Ag ions may be responsible for the effects observed with Ag NPs (EXAFS-based experiment). The earthworm *Lumbricus terrestris* was exposed to Ag NPs. Increased apoptotic activity was detected in a range of tissues both at acute and sublethal concentrations (down to 4 $mg.kg^{-1}$ soil). Comparing exposure in water and soil showed reduced bioavailability in soil reflected in the apoptotic response [50]. Toxicity of Ag NPs was also observed on *Drosophila melanogaster* in terms of egg development and pupae hatching. Ahamed et al. [51] show that coated-Ag NPs induce heat shock stress, oxidative stress, DNA damage, and apoptosis toward *D. melanogaster*.

C. elegans is a good model to assess the toxicity of chemically instable NPs at low doses. For Ag NPs, growth inhibition occurs at concentrations in the low $mg.L^{-1}$ levels [52], and the metallothionein-deficient strain exhibited greater sensitivity than wild-strain. Both Ag and ZnO NPs release Zn and Ag ions that are responsible for most of the toxicity, but the NPs themselves did also cause toxicity on the nematode [52, 53]. CeO_2 NPs (∅ 8.5 nm) also affect *C. elegans* at low doses inducing a decrease in the lifespan (−12 % at 1 nM), ROS accumulation, and oxidative damage [54]. The best developed paradigm to explain these toxic effects are an oxidative stress and the ROS generation when the CeO_2 NPs reversibly alternate between $Ce_{(3+)}$ and $Ce_{(4+)}$ [54]. To date, further studies are needed to demonstrate whether the surface reactivity of CeO_2 NPs could trigger the generation of ROS or not.

Freshwater Invertebrates Heinlaan et al. [55] compared the toxicity of Cu and ZnO NPs between two branchiopods, *Daphnia magna* and an anostraca *Thamnocephalus platyurus*. The L $(E)C_{50}$ values of Cu NPs (90–224 $mg.Cu.L^{-1}$) are greatly higher than ZnO NPs (1.1–16 $mg.L^{-1}$). The toxicity of Cu NPs was also compared to Ag NPs [56] on *Ceriodaphnia dubia*. Whatever the water matrix tested, Ag and CuO NPs were highly toxic to the water flea. The lower toxicity of Ag NPs is explained by the silver complexation with dissolved organic compounds naturally present in the tested waters [57].

A TEM histological study on *Daphnia magna* observed the dispersion of Cu NPs in the midgut [58]. Questions raised on the respective localization of NPs between the peritrophic membrane and the midgut epithelium microvilli. This was completed by a study on the biokinetic uptake and efflux [59] showing that more than 70 % of Ag NPs accumulate in the daphnids through ingestion. This highlights the importance of NPs transport along the aquatic food chain.

One study focused on *Hydra attenuata* has shown that CdSe/Cd QDs induced non-synchronous tentacle retraction. The tentacle-writhing behavior is related to the position of metal core inside the QDs [60]. The organic coated QDs were able to enter into the head after 1 h, and the entire body within 24 h. The freshwater mussels, *Elliptio complanata*, are also disturbed by CdTe QDs: decrease in viability, lipid peroxidation of the gills and gut, and fall down of the immune activity of hemocytes [61]. The toxic effects are linked to the toxicity of their metal core, the coating, and dissolution rate. However, Velzeboer et al. [17] do not observe clear effects at concentrations up to 100 $mg.L^{-1}$ toward the cladoceran *Chydorus sphaericus* exposed to CdSe/ZnS QDs. This lack of toxicity is explained by the aggregation of the NPs that decreases the bioavailability.

Ag NPs are efficient larvicides for mosquitoes involved in malaria fever. Sap-Iam et al. [62] found that 90 % of *Aedes aegypti* larvae died after 3 h contact with 5 $mg.L^{-1}$ of Ag NPS (∅ 10 nm, PMA-coated). The involved mechanism is the penetration of Ag NPs through the larval membrane. Ag NPs in the intracellular space can bind to sulfur-containing proteins or phosphorous-containing compounds like DNA, leading to the denaturation of organelles and enzymes. However, Ag NPs had no effects on the hatchability of mosquito eggs due to the chitinized serosal cuticle that prevents the penetration within the eggs.

Marine Invertebrates A comparison between CuO NPs and the soluble form of Cu was done on *Scrobicularia plana* and *Nereis diversicolor* [63]. The annelid and bivalve organisms showed different behaviors and biochemical responses, but oxidative stress was observed for both species (increase in catalase and glutathione transferase activities).

Toxicity of QDs was also assessed on a coastal marine and salt lake rotifer, *Brachionus manjavacas* [64]. Population exposed to 0.3 $\mu g.mL^{-1}$ of QDs (∅ 37 nm) exhibited 50 % of decrease in the growth rate while larger particles (∅ up to 3,000 nm) caused no change. These larger particles remained confined in the gut, indicating NPs sizes as a critical factor in the internalization by tissue. Moreover, transfer of the F_1 offspring from NPs-exposed maternal females into NPs-free media demonstrated that NPs are cleared from the animals without residual adverse effects [64].

Chemically Stable NPs: The Example of Gold

Metallic Au NPs are used as contrast agents in electron microscopy, optical sensors, catalysts, and for therapeutic uses. Au metal is extremely resistant to oxidation, and essentially insoluble under ambient conditions. Although Au is resistant to oxidative dissolution, excess Au ions can remain in the suspension at the end of the synthesis process. Therefore, the possibility that Au associated with organisms was taken up as Au ions cannot be discounted without a determination of the speciation of Au in the exposure media [65].

Bacteria

Toxicity of Au NPs has been studied on *S. typhimurium*, *Salmonella enteritidis*, *Streptococcus mutans*, *E. coli*, and *Listeria monocytogenes*. Ammonium functionalized Au NPs (∅ 2 nm) showed 3.1 ± 0.6 μM LC_{50} on *E. coli*. The toxicity is related to the strong electrostatic attraction between the negatively charged bilayer and the positively charged NPs [66]. This affinity for the surface was also observed with *S. typhimurium* strain TA 102 [67]. No toxic or mutagenic effects were observed. However, Au NPs demonstrated a Minimum Inhibitory Concentration (MIC) at 97 $\mu g.mL^{-1}$ on *S. mutans*, which is a possible infectious etiology in dental caries. As a comparison, silver showed an average MIC of 4.86 $\mu g.mL^{-1}$.

E

Algae

One study focused on the impacts of Au NPs (∅ 10 nm, amine-coated) toward the marine algae *Scenedesmus subspicatus*. LD_{50} value was reached at 1.6 10^5 Au NPs $cells^{-1}$ (∼2.4 mg. L^{-1}). Au NPs were strongly adsorbed onto the cell wall leading to progressive intracellular and wall disturbances [68].

Invertebrates

Terrestrial Invertebrates Few in vivo studies document the interactions between Au NPs and terrestrial organisms. One recent paper evidences that Au NPs are bioavailable from soil to the model detritivore *Eisenia fetida* and have the potential to enter terrestrial food webs [65]. They are distributed among tissues, and affect the earthworm reproduction. Using several sizes of Au NPs, it was found that primary particle size (∅ 20 or 55 nm) did not influence accumulated concentrations on a mass basis, while on a particle number basis the 20 nm NPs were more bioavailable. Differences in bioavailability can be related to the aggregation behavior in porous media [65].

The impacts of Au NPs (Ø 50 nm) on the central nervous system (CNS) of male cockroach *Blaberus discoidalis* was assessed [69]. Negatively charged Au NPs interacted with the roach, transferred inside the nerve cord within 17 days, and encapsulated by the proteins of the CNS. No major impact on the life expectancy was observed after 2 months, whereas the locomotion was affected.

The effects toward *Drosophila melanogaster* wild-type (Oregon R+) were also studied using Au NPs (citrate-capped) [70]. Ingested Au NPs induced a strong reduction of the lifespan and fertility, DNA fragmentation, and overexpression of the stress proteins HSP_{70}. Au NPs were homogeneously distributed through the deep layers of the enteric tissue and in the reproductive organs. Most of them were in the endosomes near the lamellar structures of the rough endoplasmic reticulum. In the germinal tissues, Au NPs were homogeneously distributed in the spermatocytes and flagella, but only in the cytoplasm of the ovarioles. No data are available on the motility of spermatozoids [70].

Freshwater Invertebrates The impacts of Au NPs (amine-coated, ∅ 10 nm) was investigated on the freshwater benthic bivalve *Corbicula fluminea* [68]. Contamination via trophic exposure (7 days with *Scenedesmus subspicatus*) induced internalization through the bronchial and digestive barriers. The histological penetration of Au NPs in the stomach cells (cytoplasm and nucleus), or in epithelial cells of digestive gland (lysosomal vesicles) depended on the speed and intensity of the digestion. Strong bioconcentration factors were obtained in gills and visceral mass, respectively. Interestingly, dose-dependent genetic expressions were observed on the gills of *Corbicula* but not in the visceral mass [68]. At low doses [1.6 10^2 Au NPs.$cells^{-1}$], there was an overexpression of genes associated to oxidative stress, while for [1.6 10^4 Au NP.$cells^{-1}$], there was also decrease in the mitochondrial activity and respiratory rate. For the highest concentration [1.6 10^5 Au NPs.$cells^{-1}$], biochemical mechanisms of detoxification were activated (changes in the glutathione transferase expression and metallothionein concentrations).

Marine Invertebrates Relatively little is known about how Au NPs nanoparticles interact with marine organisms. Au NPs (∅ 15 nm) incubated with *Mytilus edulis* were detected in the digestive gland due to impaired feeding [71]. This suggests that Au NPs cause a modest level of oxidative stress sufficient to oxidize thiols in glutathione and proteins but without causing lipid peroxidation or induction of thioredoxin reductase activity. However, the mechanisms by which Au NPs might cause oxidative stress are still poorly understood.

Interspecies Relationships

Effects on Biofilms and Bacterial Communities

Effects of NPs were assessed toward biofilms and communities. In these complex systems, the microbial responses do not always correlate with results from studies performed on monocultures in vitro. For instance, TiO_2 NPs from wastewater and seawater sludge have low toxicity on *V. fischeri* (see [4] and references therein).

However, low concentration (5.3 $mg.L^{-1}$) of TiO_2 NPs added to a stream microcosm under ambient UV radiation [72] damaged the cell walls of planktonic microorganisms due to intercellular action of ROS and accumulated in the benthic biofilms. Cell membrane damages were more pronounced in free-living cells than in biofilm cells, indicating the protective role of cell encapsulation against TiO_2 NPs. In biofilms, the surface properties of NPs govern their mobility, diffusion, and distribution, and structural parameters such as roughness and cell distribution of biofilm can be affected. Ag NPs also induced sloughing of *P. putida* biofilms. The presence of fulvic acid (which could play the role of a natural surfactant) reduced sloughing but increased uptake and bioaccumulation of the NPs [28]. Au NPs were also aggregated within flagella or biofilm network made from *Salmonella enteritidis* and *Listeria monocytogenes*. While bacterial cell walls and cytoplasm membrane were disintegrated, Au NPs did not penetrate into the bacteria [73].

Nitrifying bacteria are main players in wastewater treatment plants and in soil. Ag NPs concentrations lower than 1 $mg.L^{-1}$ inhibit nitrifying organisms taken from a nitrifying reactor. This decrease correlates with the fraction of Ag NPs less than 5 nm, the intracellular ROS concentrations, but not with the photocatalytic ROS fractions (see [29] and references therein).

Soil bacterial communities were also studied after exposure to ZnO NPs (0.05, 0.1, and 0.5 $mg.g^{-1}$ soil) in microcosms over 60 days. An alteration of the community structure and a decrease in the microbial biomass were observed [74]. The effects were higher than that of TiO_2 NPs, as reflected by lower DNA and stronger shifts in bacterial community composition, and modification of the soil enzyme activities [75]. However, while Ag NPs are bactericidal agents, bacterial community of estuarine sediments exposed to Ag NPs (for 20 days, 1 $mg.L^{-1}$, ∅ 58 nm) did not exhibit significant changes. This is related to the chloride amount in estuary water that alters the physicochemical behavior of Ag NPs [76] and the speciation of ionic silver.

Moreover, engineered NPs can be transferred from prey to predator. One study focused on bare CdSe QD accumulated in the *P. aeruginosa* bacteria, and transferred to and biomagnified in the *Tetrahymena thermophila* protozoa that prey on the bacteria. Cadmium concentrations in the protozoa predator were five times higher than their bacterial prey. However, QDs-treated bacteria affect the protozoa without lysing them. Consequently, intact QD remain available to higher trophic levels [77].

Effects of Invertebrate Assemblages

Land application of biosolids from wastewater treatment will be a major pathway for the introduction of manufactured NPs to the environment. The model organisms *Nicotiana tabacum* L. cv *xanthi* and *Manduca sexta* (tobacco hornworm) was used to investigate plant uptake and the potential for trophic transfer of Au NPs (∅ 5, 10, 15 nm) [78]. This study presents the first evidence of trophic transfer of NPs from a terrestrial primary producer to a primary consumer as well as the first evidence of biomagnification of NPs within a terrestrial food web by mean factors of 6.2, 11.6, and 9.6 for the 5, 10, and 15 nm treatments, respectively.

Recent studies focused on freshwater simplified food webs. The first one regards carboxylated and biotinylated QDs transferred to rotifers *Brachionus calyciflorus* through dietary uptake of ciliated protozoans *Tetrahymena* interacting with *E. coli* [79]. QDs accumulation was limited in the ciliates and no enrichment was observed in the rotifers. The contaminated *E. coli* formed aggregates that were not eaten by *Tetrahymena*. No toxicity was observed in single cells *Tetrahymena* nor in *Brachionus calyciflorus*. Another study regards the trophic transfer of TiO_2 NPs in the food chain including *Daphnia magna* and its predator, the zebra fish *Danio rerio* [80]. Eight-day-old *D. magna* were exposed to TiO_2 (∅ 21 nm, 0.1 and 1 $mg.L^{-1}$) and transferred to the 3-month-old *D. rerio* tanks. No biomagnification of TiO_2 NPs from *Daphnia* to zebra fish was found, but the dietary intake was found to be one of the main NPs exposure route for higher trophic level aquatic organisms.

However these studies regarding short trophic links do not take into account important

parameters such as the colloidal destabilization of the NPs, the interaction between the surface of the NPs and (in)organic molecules naturally occurring or bio-excreted, or the flux between compartments of the ecosystems (aqueous phase, sediments, biota). To work under more realistic scenarios of exposure, few studies are performed on mesocosms. Ferry et al. [81] were the first to study the fate of positively charged Au NPs (65 × 15 nm) in estuarine mesocosms containing sediments, biofilms, primary producers, filter feeders, grazers, and omnivores. While water and sediments represented 99 % of the total mass of the system, on a per mass basis the filter feeders and biofilms were the most effective sink of Au NPs. The estimated mass of biofilms was less than 0.5 % but they recovered 60 % of NPs. This high affinity is related to the negative surface charge of the biofilm interacting with the positively charged Au NPs and to the large surface area developed by the biofilms. These results are interesting since biofilms offer (1) a route into the food web through grazing by detritivores and (2) a route for mineralization through biofilm calcification.

Conclusion: Future Directions

Past experience with chemicals (e.g., methyl mercury, DDT, and PCBs) revealed dietary uptake at lower trophic levels and accumulation up the *food chain* to be an important route of contaminant exposure. All the observations that NPs can biomagnify highlight the importance of considering *dietary uptake* as a pathway for NPs exposure and raises questions about potential *ecoreceptor and human exposure* to NPs from long-term land and chronical exposure.

Ecotoxicity studies carried out at concentrations much higher than would ever be expected in the environment provide necessary data regarding the mechanisms of NPs toxicity. However complementary studies on the impact of NPs at concentrations comparable to those encountered in an environmental situation are required. To date, one challenge is to combine data from bioindicator organisms reflecting environmental health, and suitable biomarkers enlightening physiological processes [82].

They also acknowledge financial support from the French National Agency (ANR) in the frame of the PNANO/NANAN, and P2N/MESONNET projects. We also apologize to the authors whose work was not cited. Due to the limitation of the number of references, we favored the citation of reviews and the most recent articles.

Glossary

EC_{50} The half maximal effective concentration referring to the concentration that induces a response halfway between the baseline and maximum after some specified exposure time.

EXAFS Extended X-ray absorption fine structure.

IC_{25} The inhibition concentration 25 % is the statistical analysis used in chronic whole effluent toxicity tests to estimate the sublethal effects of the effluent sample. IC_{25} estimates of the concentration causing 25 % reduction in growth or reproduction of test organisms.

LC_{50} The lethal concentration 50 % is the dose required to kill half the members of a tested population for a test duration. It is a general indicator of a substance's acute toxicity.

LD_{50} The median lethal dose 50 %.

MIC Minimum inhibitory concentration.

NOEC No observed effect concentration, also called a no observable effect level (NOEL).

PEC Predicted environmental concentration.

ROS Reactive oxygen species.

TEM Transmission electron microscope.

XANES X-ray absorption near edge structure.

Definition

Ecotoxicity is generally defined as the subject in the field of ecotoxicology which studies the potential for biological, chemical, or physical stressors to affect ecosystems. The study of ecotoxicity of nanoparticles focuses on the toxic effects of nanoparticles on wildlife and their ecosystems and uncovers the natural uptake and toxic mechanisms of nanoparticles in organisms. It also investigates the influences of environmental factors on bioavailability and toxicity of the nanoparticles to the organisms. Nanoparticles are defined as particles having one or more dimensions between 1 and 100 nm that show distinct properties from their bulk counterparts of the same materials [1]. The use of nanoparticles in manufactured products has grown dramatically in the last decade. The continuously growing market for zinc oxide nanoparticles (ZnO-NPs), driven mainly by increasing demand for cosmetics and sunscreens, has grown to over 30,000 t annually [2]. ZnO-NPs are transparent ultraviolet (UV) absorbers providing a long-term and broad-band protection from UVA (320–400 nm) and UVB (290–320 nm) radiation. ZnO-NPs are also being used for their antimicrobial, anticorrosion, and catalytic properties in industries such as paints, coatings, textile, and electronics. Due to the widespread use of ZnO-NPs, coastal waters and the ocean would become an ultimate sink of these environmental contaminants. It is, therefore, essential to understand and investigate the fate and behavior of ZnO-NPs in the marine environment and examine their biological effects on saltwater organisms.

This review aims to discuss the behavior and transport of ZnO-NPs, describe the latest methods for characterizing their physicochemical properties, and highlight the environmental impacts of ZnO-NPs on various marine organisms and their potential toxic mechanisms. Influences of various environmental factors on the bioavailability and toxicity of ZnO-NPs to marine organisms are also examined. Based on these findings and knowledge gaps, we recommend some future research directions for better understanding the ecotoxicity of ZnO-NPs in marine ecosystems.

Fate and Behavior of ZnO-NPs in the Marine Environment

Since only very few studies had quantified the concentration of ZnO-NPs in the marine environment, the environmental concentrations were usually calculated based on mathematical modeling methods [3, 4]. Owing to the lack of analytical instruments able to characterize nanoparticles in complex matrices (e.g., surface water, wastewater treatment plant effluents, biosolids, sediments, and soil), the expected environmental concentrations have to be modeled based on the market penetrations of nano-products and the known usage of these products [5] or a life-cycle model to quantify the release of ZnO-NPs into the environment [4, 6, 7]. The modeled concentrations of ZnO-NPs in different environmental compartments are summarized in Table 1. The estimations vary greatly among different modeling methods, indicating a high uncertainty in the estimated concentration.

Nevertheless, the estimated concentrations of ZnO-NPs in the environment can be used as preliminary guidelines for developing analytical methods and forming the basis for risk assessment of ZnO-NPs [3].

The physicochemical characteristics of nanoparticle, together with the conditions of the surrounding environment (e.g., temperature, ionic strength, oxygen level, and natural organic matter), determine the behavior and transport of nanoparticles in the environmental system of concern [5]. The physicochemical properties of nanoparticles can be characterized by various microscopic and spectroscopic techniques (Table 2). The particle size and shape, aggregation/agglomeration, surface chemistry (e.g., functionalization), chemical composition, and dissolution are among the key parameters of physicochemical characteristics of ZnO-NPs. Several state-of-the-art analytical techniques, namely, transmission electron microscopy (TEM), atomic force microscopy (AFM), and dynamic light scattering (DLS), are widely applied to characterize nanoparticles. The advanced microscopic methods (e.g., TEM, AFM, etc.) can generally provide accurate dimensions of nanoparticles that are free from artifacts, but these techniques suffer from low sample numbers and high operating costs [8]. Since the scattering varies with particle radius, aggregates of the particles and the contaminants (e.g., dust) in the sample might mask the signal of the nanoparticles when using DLS techniques [8].

It is important to understand the persistence and distribution of nanoparticles in the environment in order to examine their exposure pathways and estimate their exposure concentrations. Once being released into the marine environment, ZnO-NPs are expected to have different behaviors. In general, the nanoparticles can stay in suspensions as individual particles, dissolve in the seawater, aggregate and form larger particles and subsequent deposit on sediment, adsorb onto the constituents in marine waters (e.g., dissolved organic matter, DOM), and transform chemically based on reduction-oxidation (redox) reactions or transform biologically in the presence of biota (e.g., microorganisms) in the marine environment [9] (Fig. 1).

Persistence

Elemental zinc is able to accumulate in water, sediment, and organisms in two different forms,

namely, zinc ions and ZnO-NP. However, they have completely different properties in terms of their persistence in water. Zinc ion itself is intrinsically persistent, although it can be converted into other species (i.e., speciation) and can form zinc complexes, such as zinc-chloro complexes or zinc hydroxide with chemicals present in natural seawater. In contrast, ZnO-NPs are not necessarily persistent. ZnO-NPs can dissolve or aggregate, losing the properties of the single nanoparticle. Various researchers have been studying the factors affecting the dissolution or aggregation ability of ZnO-NPs in the marine environment. Fairbairn et al. [10] demonstrated that uncoated ZnO-NPs were soluble in seawater and the release of zinc ions from ZnO-NPs was dependent on time and concentration of ZnO-NPs. Specifically, at low initial concentration of 0.1 mg L^{-1} ZnO-NPs, the dissolution reached 100 %; whereas at high initial concentration of 10 mg L^{-1} ZnO-NPs, the dissolution decreased to 60 % after 6 h. Furthermore, Bian et al. [11] also showed that decreasing pH or in the presence of humic acid at pH 9–11 enhanced the release of dissolved zinc ions in water. Also, it has been shown that small ZnO-NPs (4 nm) dissolved more readily than larger ZnO-NPs (15 and 240 nm) at 1,000 mg L^{-1}, and such size effects on dissolution of ZnO-NPs can be explained by the Noyes-Whitney equations and Ostwald-Freundlich equations [11]. As some types of ZnO-NPs in commercial products have surface coatings (e.g., silica and polymer) to ensure their dispersion in aqueous media, these coated ZnO-NPs generally have a greater persistence in the marine environment than uncoated ZnO-NPs [12].

Particle Aggregation

Once the nanoparticles enter the water, they form homoaggregates according to the combined effect

Ecotoxicity of Zinc Oxide Nanoparticles in the Marine Environment, Fig. 1 Schematic illustration of the behavior and transport of ZnO-NPs in the marine environment

of van der Waals and double layer force (DLVO) theory, which describes the forces between charged surfaces of particles interacting in a liquid medium. The combined effects of van der Waals attraction and the electrostatic repulsion due to an electric double layer of counterions that surround ZnO-NPs in an aqueous medium determine the stability of the ZnO-NP suspension. ZnO-NPs carry an electrical charge, which produces a force of mutual electrostatic repulsion between adjacent particles. If the charge is high enough to overcome the van der Waals attraction force, the ZnO-NPs will remain separate and are stabilized in suspension. However, the marine environment with a high ionic strength causes compression of the electric double layer, reduces the electrostatic repulsion forces between the nanoparticles, and consequently promotes the nanoparticles to aggregate and settle out of the suspension [11]. The degree of aggregation (homoaggregation and heteroaggregation) depends on the properties of the nanoparticles (e.g., particle morphology, size, surface area, and surface charge) and characteristics of the environmental system [8], as well as exposure protocols.

The translocation of nanoparticles depends largely on their size. Aggregates of nanoparticles usually have greater likelihood to deposit on sediments, and thus they are usually less mobile than individual nanoparticles. Nonetheless, there are other processes, such as dissociation or resuspension of nanoparticles due to changes in aquatic chemistry of the surrounding environment and the activity of aquatic organisms, that could complicate the deposition action of aggregated nanoparticles. The elimination of aggregates from the water column through deposition or sedimentation decreases the concentration of bioavailable ZnO-NPs for pelagic species. Although these ZnO-NP aggregates become less mobile, uptake by sediment-dwelling organisms or filter feeders is still possible.

Adsorption

Because of their high surface-to-volume ratio and their high surface reactivity, ZnO-NPs can adsorb onto pollutants or DOMs in the marine environment. DOMs such as humic acids and fulvic acids derived from algae or higher plants are ubiquitous in the environment. These plant materials are typically highly functionalized with carboxylic acid groups and/or phenolic groups; they are negatively charged at neutral pH and may also contain chromophores that absorb sunlight [13]. The absorption of light by chromophoric groups can lead to formation of short-lived reactive oxygen species (ROS), for example, singlet oxygen, $^1O_2$, which may increase the toxicity of ZnO-NPs or chemically transform them. The adsorption of DOMs onto ZnO-NPs can alter their surface charge and inhibit aggregation/agglomeration, thereby enhancing their mobility in the environment. For example, adsorption of humic acids onto ZnO-NPs has been shown to decrease the particle zeta potential, suggesting humic acid-coated ZnO-NPs could be more easily dispersed and suspended than uncoated ones because of their enhanced electrostatic repulsion [14]. Some studies have also shown that ZnO-NPs with humic acid coatings enhanced sorption of organic pollutants such as polycyclic aromatic hydrocarbons on the nanoparticles' surface [15].

Transformation

Transformation of ZnO-NPs in the environment will significantly influence their size, shape, and surface chemistry, and this process will affect their ultimate distribution, persistence, and toxicity in the environment. Redox reactions occurring on the surface of ZnO-NPs can lead to the production of ROS, which are in turn able to oxidize organic compounds in the environment. For instance, ROS released from nanoparticles can induce oxidative stress in vivo and in vitro on cell cultures of bacteria [16].

The effects of ZnO-NPs on microbial populations in the natural environment were well studied. Conversely, further examinations are needed to fully understand the contribution of bacteria and fungi in water or sediment to the degradation of engineered ZnO-NPs. Uptake of ZnO-NPs might also happen in higher organisms, and the biological fate of ZnO-NPs depends on the balance of four processes: absorption, distribution, metabolism, and excretion. Up to now, the process of biotransformation of ZnO-NPs by organisms in the natural environment and how such transformation affects the toxicity of ZnO-NPs are still unclear.

In summary, the environmental fate of ZnO-NPs depends on physical and chemical properties of ZnO-NPs and can be further influenced by environmental conditions. Modification will greatly influence the behavior and transport of ZnO-NPs and their interaction with organisms in the marine environment.

Toxic Effects of Zinc Oxide Nanoparticles on Marine Organisms

Over the past decade, there have been a growing number of studies to reveal the relationship between physicochemical characteristics and toxicity of ZnO-NPs to saltwater organisms in seawater. These studies not only examined the effects of ZnO-NPs to marine organisms at various levels of biological organization (e.g., molecular, cellular, developmental, and behavioral responses) but also investigated the potential uptake route, fate, and transport of ZnO-NPs in the marine ecosystem. This section provides an up-to-date summary and critical analysis on the documented information related to the exposure effects of ZnO-NPs on marine organisms from different taxonomic groups, including microalgae, molluscs, crustaceans, and fish (Table 3). Microalgae and crustaceans, which are the common test taxa, are more sensitive than molluscs. Fishes are comparatively less sensitive to ZnO-NP exposure. Growth and mortality were the general toxicity endpoint, while the common test duration was 96 h (Table 3).

Microalgae

Microalgae, primary producers in the marine environment, are particularly sensitive to a wide

Ecotoxicity of Zinc Oxide Nanoparticles in the Marine Environment, Table 3 Toxicity of zinc oxide nanoparticles (ZnO-NPs) to marine organisms: an overview of available literature data

range of pollutants [17]. They are, therefore, often used as model organisms in standard toxicity tests for environmental risk assessment of chemical substances. The majority of studies on microalgae focused on the development of concentration-response relationships using algal growth inhibition or photosynthesis inhibition as the toxicity endpoint [17].

In general, toxic effects of ZnO-NPs varied significantly among different algal species (i.e., species dependent). A less silicified marine diatom *Phaeodactylum tricornutum* was shown to be less sensitive to ZnO-NPs than a more silicified diatom *Thalassiosira pseudonana* [18]. A significant decrease in cell-division rate was observed in *T. pseudonana*, which was suggested to be caused by the disruption of silicon uptake and frustule formation in the presence of zinc ions dissolved from the ZnO-NPs [18].

The toxic mechanisms of ZnO-NPs have been suggested to be dependent on physicochemical properties of the particles, such as size, shape [18], amount of dissolved free zinc ions [18, 19], and production of ROS [20, 21].

The median inhibition concentrations (IC50; concentrations caused 50 % growth inhibition when compared with the control group) of ZnO-NPs to *T. pseudonana* and *Skeletonema costatum* to ZnO-NPs were found to be 4.56 and 2.36 mg L^{-1}, respectively [20]. An exposure to bulk ZnO resulted in significantly higher IC50s at 6.65 and 2.97 mg L^{-1} for *T. pseudonana* and *S. costatum*, respectively, indicating that ZnO-NPs were more toxic to the test diatoms [20]. Studies suggested that dissolved zinc ions released from ZnO-NPs, rather than the nanoparticles themselves, have been demonstrated as the sole cause of toxicity in studies conducted on *T. pseudonana* [19]. Comparable IC50 values were obtained upon exposure to zinc ions or to ultrafiltrate of the ZnO-NPs smaller than <0.22 μm [19]. On the contrary, Peng and colleagues [18] argued that not all the observable toxicity in an exposure of *P. tricornutum* to ZnO-NPs of varying sizes and shapes could be attributed to bioavailable zinc ions, but morphology and aggregates of the nanoparticles played a part as well. They found that one-dimensional rod-shaped ZnO-NPs were more toxic than the spherical ones, whereas the size of nanoparticles was less influential to their toxicities to the microalgae [18]. The presence of ZnO-NP aggregates on the cell surface may also have inhibited algal growth through the release of zinc ions or mechanical damage by the nanoparticles. Based on the above studies, both ZnO-NP aggregates and soluble zinc ions can be attributable to their toxic effects to marine microalgae.

Miller et al. [22] explained that toxic effects of free zinc ions on marine algae *T. pseudonana*, *S. marinoi*, *Dunaliella tertiolecta*, and *Isochrysis galbana* were coupled with the nanoparticle-associated effects. For instance, adsorption of particles onto cell surfaces may facilitate damage because of both the production of ROS and dissolution of free zinc ions and, thus, disrupt cellular metabolic activities. Unless these activities occurring on the cell surface and the concentrations of the free zinc ions can be quantified throughout the experiments, the release of free zinc ions as the sole cause of ZnO-NP toxicities cannot be unequivocally judged.

Several studies [20–22] suggested that the generation of ROS can be a toxic pathway of ZnO-NPs to the marine organisms; however, none of those studies measured the ROS released by ZnO-NPs or quantified the intracellular ROS produced by the diatoms. The photocatalytic activity of ZnO-NPs in seawater is still unknown as is the associated phototoxicity to the marine algae. Further studies are required to confirm the ROS production and photocatalysis as toxic mechanisms of ZnO-NPs in the marine environment.

Molluscs

ZnO-NPs form aggregates rapidly in seawater and deposit on the sediment surface over the time [23]; therefore, benthic invertebrates, especially filter feeders and suspension feeders, have a higher risk of exposure to ZnO-NPs. Several studies had been conducted to study the bioaccumulation of ZnO-NPs in bivalve molluscs including clams, oysters, and mussels.

Exposure of ZnO-NPs (about 30 nm) to the oyster *Crassostrea gigas* caused an accumulation of zinc in gills and later in their digestive gland, which resulted in mitochondrial damage and oxidative stress [24]. The zinc burden could occur by both endocytosis of ZnO-NPs and uptake of soluble zinc. However, the exposure concentration used for the experiment (4 mg L^{-1}) [24] was much higher than the predicted environment concentration of ZnO-NPs in natural surface water (1–10 ng L^{-1}) and in effluents from sewage treatment plants (300–432 ng L^{-1}) [6]. At an environmental realistic concentration of 3 mg kg^{-1} ZnO-NPs in sediments, the marine intrasedimentary clam *Scrobicularia plana* was exposed to isotopically labeled ZnO-NPs (21–34 nm) for 16 days and consequentially showed behavioral disturbance and an increase in catalase activity in their tissues [25]. However, the authors could not distinguish whether the zinc uptake in the tissues of *S. plana* was resulted from nanoparticles or the soluble zinc or a combination of both.

A coastal marine mussel *Mytilus galloprovincialis* was found to have accumulated zinc when it was exposed to 1–10 mg L^{-1} ZnO-NPs for 4 days. Instead of excreting the ZnO-NPs in form of nanoparticles, they actually excreted them as pseudofeces [26]. Once settled on the seafloor, zinc-containing pseudofeces may be consumed by other marine benthic suspension feeders (e.g., clams), deposit feeders (e.g., polychaete worms, amphipods), and grazers (e.g., sea urchins); in this way, ZnO-NPs could be biotransformed in the marine ecosystem and significantly affect their fate and transport [26].

A chronic exposure of *M. galloprovincialis* to 2 mg L^{-1} ZnO-NPs (20–30 nm) for 12 weeks resulted in zinc accumulation in their somatic tissues and gonadal tissue, an increase in respiration rate, a reduced shell growth rate, and an increased mortality [27]. Moreover, the same study also demonstrated that ZnO-NPs exerted greater effect on mortality of small mussels. The removal of small individuals which serve as prey for various predators in the marine ecosystem could cause a cascade impact on the food web and energy flow and might lead to a change in the marine benthic community composition and structure in the long run [27].

Crustaceans

Small crustaceans, such as copepod, amphipods, and brine shrimp, are filter feeders and thus are especially susceptible to many pollutants compared with other pelagic marine animals

[17]. They are sensitive to metal stresses and are, in turn, used routinely as biomonitors for monitoring pollution in aquatic systems and as test species in standard toxicity tests. Exposure of these zooplanktons to ZnO-NPs has been associated with a number of harmful effects which are often linked to the physicochemical nature of the nanoparticles, such as size, dissolution, and aggregation of the nanoparticles. For example, ZnO-NPs of 10–30 nm were shown to be significantly more toxic to the brine shrimp *Artemia salina*, causing 26 % mortality at a concentration of 100 mg L^{-1}, when compared with ZnO-NPs of 200 nm which caused 18 % mortality at the same test concentration and duration (96 h) [28]. In other words, ZnO-NPs having smaller primary particle sizes can cause a higher toxicity than those with a large particle size, even though they will aggregate. The authors suggested that main causes of the toxic effects were due to the release of free zinc ions and the accumulation of ZnO-NPs in the gut of the brine shrimps [28]. They observed that the *Artemia* were unable to excrete the ingested particles that formed massive aggregates inside the guts after accumulation and such gut congestions could significantly affect the food uptake and assimilation leading to weight loss and illness. Wong et al. [20] also found that the mortality of marine copepod *Tigriopus japonicus* might be caused by mechanical injury due to the attachment of the ZnO-NP aggregates to their exoskeleton. In addition, these authors also found that the toxic effect was also dependent on the exposure concentration of ZnO-NPs and correlated well with the concentration of dissolved zinc ions in the exposure medium [20].

Limited work has been carried out on the effects of the dietary transfer of nanoparticles along the food chain. However, an exposure of the copepod *Acartia tonsa* to ZnO-NP-dosed diatom *T. weissflogii* at the highest concentration of 263 μg L^{-1} Zn showed a significant reduction in survival and reproduction by 52 % and 50 %, respectively, after 7 days of exposure [29]. These authors confirmed the transfer of ZnO-NPs to *A. tonsa* from the dosed algae, illustrating their potential for trophic transfer [29].

Toxic effects of ZnO-NPs were also tested with sediment-dwelling zooplanktons. Growth and reproduction of the amphipod *Corophium volutator* decreased after exposed to ZnO-NPs (35 nm) via both the water and sediment exposure routes [30, 31]. Zinc uptake by the amphipod was proved to be via the aqueous phase and ingestion of the zinc-adsorbed sediments.

In summary, effect assessments for ZnO-NPs on marine crustaceans are species dependent. Copepods and amphipods seem to be more sensitive to ZnO-NPs than brine shrimps. Toxic effects of ZnO-NPs to these small crustacean species are associated with the primary particle size, the concentration of free zinc ions, and the aggregates of the ZnO-NPs. More importantly, some studies reported that toxic effects of ZnO-NPs may also be occurring at environmentally realistic concentrations [29, 31].

Fish

Potential uptake routes of ZnO-NPs in fish include ingestion from water or sediment for demersal species, via the gill or the gut epithelial cells or through the chorion pore channel by diffusion for embryos [32]. Studies of toxicities of ZnO-NPs on marine fishes are scarce. The marine medaka fish *Oryzias melastigma* larvae, after exposure to ZnO-NPs of 4 and 40 mg L^{-1} ZnO-NPs for 96 h, showed an upregulation of a heat shock protein (HSP70) only. The *O. melastigma* larvae exposed to $ZnSO_4$ at the same zinc ion concentrations exhibited a significant increase in the protein expression of both HSP70 and superoxide dismutase (SOD). The results implied that the test medaka larvae exposed to ZnO-NPs were under non-oxidative stress, and the toxic effect of ZnO-NPs was mainly due to ionic zinc released from the nanoparticles [20].

In contrast to marine fishes, toxicity of ZnO-NPs to freshwater fish has been comparatively well documented, in particular for the zebra fish *Danio rerio*. Different adverse effects, including reduction in hatching rate of embryos, oxidative stress via intracellular ROS production, malformation of larvae [33], and inhibition of

SOD and catalase (CAT) activities in liver and gill tissues of zebra fish adults [34], have been observed in the literature. Across the studies, toxicity of ZnO-NPs to freshwater fishes was mainly sublethal and caused by oxidative stress. However, more relevant information on marine fish species is required before a robust conclusion can be drawn.

In summary, the recent exposure studies of marine organisms have demonstrated that ZnO-NPs can induce a wide range of toxic effects (including both acute lethal or chronic sublethal effects) in marine algae and invertebrates, but limited toxicity data were found in either embryonic or adult marine fish, possibly because fishes are generally more tolerant to ZnO-NP exposure [35]. A number of possible causes of ZnO-NP toxicities in aquatic organisms have been proposed by previous studies, including the ionic zinc dissolved from ZnO-NP into the exposure media, the bioaccumulation of ZnO-NPs, the interaction between the nanoparticles' aggregates and the target cells of the organisms, and oxidative stress associated to the production of extracellular and intracellular ROS.

Toxic Mechanisms of Zinc Oxide Nanoparticles

The mode of toxic action of ZnO-NPs involves at least three major mechanisms [36]. First is the dissociation of ZnO-NPs into toxic and bioavailable zinc labile (free Zn ions or weakly complexed forms with inorganic and organic ligands) forms in the exposure media. Second is the direct interaction between the nanoparticles and the cell or organisms that may cause mechanical damage, for instance, adhesion of the nanoparticles or their aggregates onto the cell may cause mechanical abrasion and damage, as well as onsite release of ROS on the cell surface, resulting in membrane lesions. Accumulation of the nanoparticles in the cell or body tissues may also trigger toxic effects when the concentration of nanoparticles reaches an effect threshold or when the amount of accumulated nanoparticles is greater enough to cause interruption or impairment of cellular and physiological processes. Third, ZnO-NPs may generate more ROS under ultraviolet (UV) radiation and disrupt the biological activities of the organisms in the vicinity.

Dissolved Ionic Zinc

Toxic effects of dissolved ionic zinc released from ZnO-NPs have been extensively proven in toxicity studies across a wide range of test species and summarized in a number of recent review articles [35, 36]. Most of the studies reported that ionic zinc dissociated from ZnO-NPs contributes solely or at least partially to the observed toxicity of ZnO-NPs [36]. Demonstration of ionic zinc as a cause of ZnO-NP toxicity is usually based on the findings that ZnO-NPs show comparable toxicity to the zinc salts ($ZnCl_2$ or $ZnSO_4$) or the filtrate portion of ZnO-NPs, together with a direct measurement of the concentration of dissolved Zn ions in the experimental medium.

Similar to ZnO-NPs, toxic effects of zinc ions also varied greatly among different marine species as zinc is an essential element to most marine organisms and the requirement of zinc varies among species [37]. Soluble Zn ions can inhibit growth and reduce photosynthesis ability in the marine diatom *T. pseudonana* after 48 h exposure [20], cause abnormal morphology in embryos of the sea urchin *Lytechinus pictus* embryos after 96 h of exposure at low μg L^{-1} range [10] and hinder growth, delay sexual maturation, and reduce reproduction in the amphipod *C. volutator* at concentrations ranging between 0.2 and 1 mg L^{-1} in a chronic exposure for 100 days [30].

Despite the wide recognition of the toxicity of the dissolved zinc ions, it is still uncertain about the extent of contribution of ionic zinc to ZnO-NP toxicity and its underlying mechanisms. As a typical aquatic exposure system contains both nanoparticles and zinc ions released from particle dissolution, the observed toxicity is usually a combination of both of the components [22, 36].

A recent study showed that ZnO-NP toxicity from nanoparticle-dependent effects and from dissolved zinc ions has distinct modes of toxic action as revealed by differential gene expression profiles in the freshwater water flea *Daphnia*

magna after exposure to ZnO-NPs or $ZnSO_4$ [38]. Therefore, expression of specific suits of biomarker genes can be useful to identify environmental exposure of ZnO-NPs and differentiate the exposure and toxic effects between the nanoparticle and ionic component [38]. Similar molecular or omics' approaches can be readily applied to reveal toxic mechanisms of ZnO-NPs and the dissolved zinc ions in marine organisms.

Direct Cellular Interaction and Bioaccumulation in Organisms

Particle dissolution and the release of zinc ions cannot always fully explain the toxicity of ZnO-NPs [22], while the particle-induced effect is suggested to be another important toxic mechanism of ZnO-NPs [18, 21, 30]. When the marine diatoms *P. tricornutum* were exposed to 40 mg L^{-1} of ZnO-NPs, there were obvious attachments of ZnO-NP aggregates onto their walls (as shown by TEM images), suggesting that growth inhibition was likely associated with the physicochemical interaction between the aggregates and the algal cell [18]. Similarly, exposure of nauplii of the marine copepod *T. japonicus* to ZnO-NPs showed physical injury when the ZnO-NPs attached onto the exoskeleton of the nauplii and hence hampered their movement [20]. Larvae of the brine shrimp *Artemia salina* were unable to excrete the ingested nanoparticles under waterborne exposure to ZnO-NPs [28]. After the marine oysters *C. gigas* were exposed to ZnO-NPs, they accumulated the nanoparticles inside vesicles in their gills and digestive gland tissues [24]. The adsorbed or the ingested ZnO-NPs could continuously release zinc ions and/or ROS, causing oxidative stresses, or biotransformation of the nanoparticles inside the organisms [24]. Although there is no systematic study on such a mode of toxic action up to now, these particle-induced mechanisms cannot be ignored.

The Generation of ROS

In addition, toxicity of ZnO-NPs to marine organisms may also be attributed to their photocatalytic activity under UV radiation, resulting in the generation of ROS in aquatic media [36]. Photochemistry behavior of ZnO-NPs is governed by the band gap which is the energy difference between the valence band (highest occupied molecular orbitals, HOMO) and the conduction band (lowest energy unoccupied molecular orbitals, LUMO) [39]. Light absorbed at wavelength less than or equal to the bandgap energy of ZnO will result in the excitation of an electron from the valence band to the conduction band; consequently, a hole or vacancy in the HOMO state of the molecular orbitals is created. Both the excited electrons and holes can migrate to the surface of ZnO and subsequently react in aqueous solution to form ROS such as superoxide (O_2^-) and hydroxyl radical (·OH). The superoxide (O_2^-) in aqueous solution can form oxygen and hydrogen peroxide by self-reaction (i.e., dismutation)
($O_2^- + O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$). This process often occurs in living cells in the presence of superoxide dismutase (SOD) [39]. ZnO-NP, with band gap energy 3.37 eV (equivalent to 368 nm), can generate ROS under UV irradiation with energy at wavelength 368 nm or below, which comprises approximately 6 % of the sunlight energy reaching the earth's surface [36]. This toxicity pathway for ZnO-NPs is seldom studied because the majority of toxicity studies were conducted under laboratory fluorescence lighting which contains negligible or no UV radiation.

Photoinduced toxicity was suggested to be caused by natural sunlight but not laboratory lightings. For example, the 2-h LC50 of the nematode *Caenorhabditis elegans* was found to be 25 mg L^{-1} under the exposure of ZnO-NPs (60–100 nm) and natural sunlight, whereas same concentrations of ZnO-NPs induced no adverse effects under laboratory lighting or dark conditions [40]. In contrast, no significant growth inhibition was induced in the green algae *Pseudokirchneriella subcapitata* when exposed to UV pre-irradiated ZnO-NPs (<100 nm) under visible, UVA and UVB irradiation conditions at a concentration range between 0.05 and 0.3 mg ZnO-NP L^{-1} [41]. Most documented studies on photoinduced toxicity of ZnO-NPs were conducted with bacteria and freshwater species [34, 40]; the photocatalytic activity of ZnO-NPs

is less known in marine species. Thus, future research studies are needed to uncover the photocatalytic activity of ZnO-NPs in the seawater environment and its effects on ZnO-NP toxicity to marine organisms.

Influences of Environmental Factors on Toxicity of ZnO-NPs in the Marine Environment

ZnO-NPs under different environmental conditions can exhibit different toxicities to aquatic organisms [36]. Changes in temperature, salinity, and pH of seawater may change the physicochemical properties of ZnO-NPs, the physiology of the marine organisms, and the interactions between the nanoparticles and the organisms. Hence, the exposure pathway and the toxic effects of ZnO-NPs on organisms would be modified by the environmental condition accordingly. Since temperature, salinity, and pH are the key environmental variables and they vary significantly in marine ecosystems, this section specifically explores their effects on the toxicity of ZnO-NPs to marine organisms.

Temperature

Most aquatic organisms are ectotherms (animals whose regulation of body temperature depends on an external source). As a consequence, temperature is an important environmental factor governing their physiological processes. It is a well-known fact that temperature can influence all kinds of physiological processes. At the same time, temperature can alter properties of a chemical and hence its bioavailability and toxicity to marine organisms. In other words, temperature can influence the metabolic rate, movement, and feeding activity of an organism, causing changes in the toxicokinetics of contaminants (i.e., the rate of chemicals enter the body of an organism and the behaviour of the chemicals in the body), and thus the uptake, elimination and detoxification rates of the contaminants can be affected. In general, organisms living near to their thermal tolerance limits (in particular upper ones) exposed to a chemical toxicant would exhibit a greater combined toxicity than did organisms living under optimal conditions [42]. Up to now, there is only one comprehensive study to investigate the interacting effect of temperature and ZnO-NPs to marine organisms [43]. The results of this study indicate that zinc ion dissolution from ZnO-NPs increases with decreasing temperature and the interacting effect of temperature and ZnO-NPs varies among different species. First, Wong and Leung [43] found an increase in growth inhibition of the marine diatom *S. costatum* at both ends of its thermal tolerance limits at 15 °C and 28 °C based on IC10 values (IC10 = inhibitory concentration of 10 %) when exposed to ZnO-NPs for 96 h. Second, the amphipod *Melita longidactyla* mortality was positively correlated with temperature from 10 °C to 30 °C because they entered dormancy at low temperatures [43]. Third, the growth rate of larvae of the marine medaka fish *O. melastigma* was only reduced by temperature but not by the ZnO-NP exposure at 10 mg L^{-1}, probably because zinc is an essential trace element for fish [43]. Nonetheless, combined effects of temperature and ZnO-NPs on other marine organisms such as filter and deposit feeders like bivalve molluscs and polychaetes are still virtually unknown.

Salinity

Salinity fluctuations are common in estuaries and marine pollution often occurs mainly in coastal areas, where organisms would experience the interacting effect of salinity fluctuation and exposure to chemical pollutants. This interaction is complicated because salinity affects both the physiological processes of the organisms and the physicochemical characteristics of nanoparticles. An increase in salinity generally increases the degree of metal complexation due to the presence of chloride, sulfate, and organic matters in natural seawater. Salinity increase can reduce the ion dissolution from metal-oxide-based nanoparticles and thus lower the toxicity of the nanoparticles associated with the release of free metal ions [44].

However, studies on salinity effect on toxicity of ZnO-NPs are relatively scarce. A study on the salinity-dependent toxicity of ZnO-NPs showed that increasing in salinity from 5 to 35 PSU (practical salinity unit) decreased the dissolved

zinc ion concentration due to precipitation of the metal ions and consequently reduced the toxicity to the marine copepod *T. japonicus* [45].

pH

Changes in ion dissolution and aggregation size of ZnO-NPs can occur following from a change in pH. Miao et al. [19] compared the toxicity of ZnO-NPs on the marine diatom *T. pseudonana* at different pH levels (i.e., pH 7–9) and attributed the elevated toxicity of ZnO-NPs at low pH to an increase in the release of zinc ions from ZnO-NPs in the exposure medium. Similar findings were also reported by Bian et al. [11] that dissolution of ZnO-NPs increased with decreasing pH from pH 11 to pH 1. Moreover, maximum aggregate sizes of ZnO-NPs were observed at pH 9, where the pH level was close to the zero point of charge for ZnO (i.e., the repulsion interactions between nanoparticles decreased to a minimal point), and therefore there was a rapid sedimentation of ZnO-NPs.

Conclusions and Future Research Directions

The toxicity of ZnO-NPs can occur in certain species (e.g., the clam *S. plana*) under the exposure at environmentally realistic concentrations, suggesting that some marine organisms can be at risk in the natural environment with elevated levels of these nanoparticles. The major possible toxic mechanisms of ZnO-NPs, a the environmental factors affecting the behavior of ZnO-NPs and their toxicity to the organisms in the marine environment have been summarized and highlighted above. Based on our comprehensive review of relevant literature, we have identified several knowledge gaps which are needed to be filled for improving our current understanding on the ecotoxicity of ZnO-NPs for environmental risk assessment and management for this group of highly popular, commercialized nanoparticles.

1. Molecular toxic mechanisms to marine organisms should be thoroughly examined using advanced transcriptomic, proteomic, and metabolomic approaches in order to differentiate different modes of toxic action between the nanoparticles of ZnO-NPs and their associated dissolved zinc ions and between waterborne and dietary exposure.
2. Given that ZnO-NPs are highly photoactive, research focus should be laid on understanding the photoinduced toxicity under environmentally relevant UV radiation to an array of different marine species from different taxonomic groups. Tools and techniques should be developed to quantify the ROS released from ZnO-NPs and the intracellularly induced ROS in the environmental compartments and within the test marine organisms.
3. There are insufficient data on chronic effects of ZnO-NPs to marine organisms, and thus more chronic toxicity studies such as life-cycle studies are required to improve our understanding on the long-term and low-dose effect of these nanoparticles on selected marine species. Benthic organisms such as bivalves and polychaetes should be placed on a high priority as a subject of study, since ZnO-NPs have a high potential to aggregate and settle on the sediment in marine environment and bottom filter feeders and deposit feeders have a great potential to consume the nanoparticles associated with organic matter.
4. More toxicity data should be generated from marine fish species so as to reveal the sublethal toxic effects and associated toxic mechanisms of ZnO-NPs in this important group of higher-level organisms in the marine ecosystem.
5. Further ecotoxicological study of ZnO-NPs should also concentrate on bioaccumulation, cellular localization or tissue distribution, biotransformation, and trophic transfer of the nanoparticles in selected, typical marine food chains.
6. Combined effects of environmental stressors such as temperature, salinity, pH, UV radiation, and presence of DOM and combined toxic effects of ZnO-NPs and other pollutants to marine organisms should be investigated to better understand the behavior and toxicity of ZnO-NPs under environmentally realistic scenarios.

By filling up these knowledge gaps, our understanding on the ecotoxicology of ZnO-NPs in the marine environment could be significantly improved, while the information could also be used to derive environmental quality benchmarks such as water and sediment quality guidelines for regulating the use and release of ZnO-NPs, and hence offering better protection to marine ecosystems [46].

Definition

According to Truhaut [1], ecotoxicology is defined as the branch of toxicology concerned with the study of toxic effects, caused by natural or synthetic pollutants, to the constituents of ecosystems, animals (including human), vegetables, and microbial, in an integral context. Carbon NanoTubes (CNT), a man-made allotrope of carbon, are considered as emergent potential contaminants into the environment. The aim of the ecotoxicology is then to evaluate the potential toxicity of CNT toward living organisms. Amphibian's larvae are used as biological models to study the potential toxicity of CNT.

Carbon NanoTubes (CNT) are a man-made allotrope of carbon (1D). They were discovered in 1991 by Iijima [2] and are intensively studied since 20 years by the scientific community. Their structure can be described as a graphene sheet rolled up to form a hollow cylinder. CNT properties depend on their structure. Two main types of CNT are distinguished [3, 4]: Single-Walled CNT (SWNT) consisting of a single sheet and Multi-Walled CNT (MWNT) consisting of several concentric layers, having a larger diameter (Fig. 1). CNT may be closed by half-fullerene-like molecules. Among the MWNT, Double-Walled CNT (DWNT) are at the frontier between SWNT and MWNT, with morphology and properties very close to SWNT. CNT have a diameter from 1 to 100 nm and a length from less than one µm up to tens of µm or more (Fig. 2). Due to their exceptional physical (mechanic, electronic, thermal) and chemical properties particularly because of their nano-size, interest in CNT has grown rapidly and application areas are very wide: nanocomposites, electron transmitters, electromagnetic shielding, batteries, supercapacitors, gas storage (including hydrogen), and nano-medicine [5]. Their current applications in the daily life of developed society are numerous as prototypes (flat-screens, tyres, sport equipments, etc.) and some others are emerging (paints, technical clothes, pharmaceutical products, etc.). Global CNT production capacity was estimated in 2002 over 2.5 t per day, and the correspondent market was estimated at $12 millions for 2002 and was expected to grow up to $700 millions by 2005 [6]. The recent analysis of John Oliver [7] reports that the global market for CNT grades based on committed production reached $103 millions in 2009. This market is projected to reach $167.2 millions in 2010 and $1 billion in 2014 at a compound annual growth rate of 58.9 %. This same analyst states that MWNT grade market was nearly $103 million in 2009 and projected to reach $161 million in 2010 and $865.5 million in 2014, for a 5-year compound annual growth rate (CAGR) of 53.1 %.

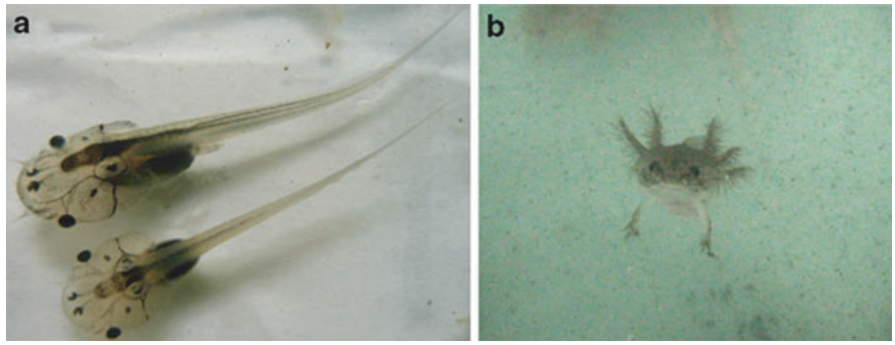
Ecotoxicology of Carbon Nanotubes Toward Amphibian Larvae, Fig. 2 TEM images of MWNT (**a**, **c**) and DWNT (**b**, **d**)

In respect to this economical context and the exponential production of CNT, it is likely that some of them will get into the environment by numerous ways (Fig. 3), during each step of their life cycle, from their production until the end of their life cycle, especially in the aquatic compartment which concentrates most pollutions. Indeed, CNT releases into the environment might come from different sources. Point sources may be the release of CNT at the production site, during manufacturing (via accident of release, landfills or wastewater effluents, etc.) or during their transport from the production site to industrial users. Nonpoint sources may be the dissemination of

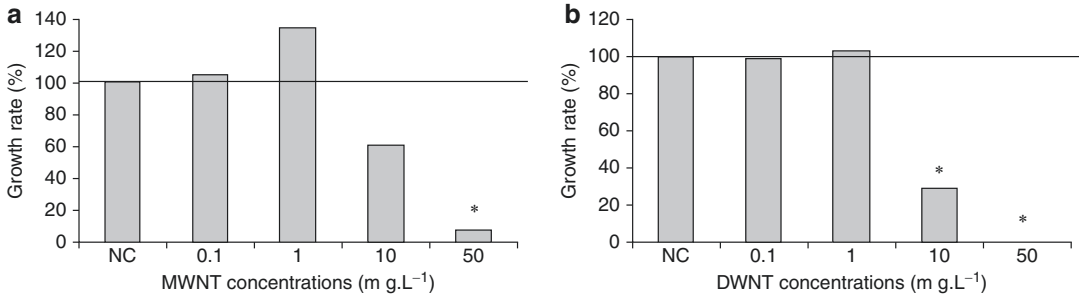


Ecotoxicology of Carbon Nanotubes Toward Amphibian Larvae, Fig. 3 Environmental context of the CNT contamination toward the environment

CNT during the use of products containing CNT, via numerous ways such as wear of products, until the end of their life (wet deposition from the atmosphere, storm-water runoff, surface water leakage with the waste disposal in dumps, etc.) Contamination by CNT, as for the case of all chemical substances, may involve biogeochemical cycles, i.e., transport, dispersion, transformation, and/or concentration into compartments of the environment, but also may involve biological systems due to the potential ingestion, uptake, and excretion mechanisms of living organisms.

In this context, CNT could be classified as emergent contaminants and must receive considerable attention as new, unknown, and potentially hazardous materials. To date, several main questions are established by the scientific community about the quantities of CNT disposed into the environment, their distribution into the environmental compartments, and their preferential areas of accumulation in these compartments, and finally their persistence or potential degradation in relation with some particular environmental conditions. On top of these geochemical concerns, the biological effects at molecular, sub-cellular, and cellular level from organism to ecosystem are of great concern and constitute the ecotoxicity area.

One strategy is to evaluate the potential ecotoxicological risk of CNT in the same way that risk assessment method is carried out during the assessment of the potential risk of a contaminant (e.g., chemical substances as pesticides or heavy metals) into the environment. This approach uses standardized methods in laboratory studies to determine biological effects using biological models, for example, amphibian larvae. Indeed, amphibians are well-known environmental health warning organisms due to their biphasic life cycle, permeable and sensitive eggs, skin, and gills [8]. Their specific physiology makes them particularly sensitive to the presence of contaminants in the water, which influences their behavior [9, 10]. In the same way, the huge quantity of DNA shared in a small number of chromosomes makes them good models for cytogenetic studies.



Ecotoxicology of Carbon Nanotubes Toward Amphibian Larvae, Fig. 4 *Xenopus laevis* (**a**) and *Ambystoma mexicanum* (**b**) larvae

Among amphibian species, *Xenopus* and axolotl models (Fig. 4) were used to evaluate the potential ecotoxicity of CNT in laboratory conditions [11–14] consist in exposing amphibian larvae to different concentrations of CNT in water using standardized methods or adapted ones if necessary. The nature of CNT depends on the synthesis method used (Catalytic Chemical Vapor Deposition (CCVD), Electric–arc discharge, and Laser ablation are the most commonly used), and on their physical–chemical state (e.g., functionalization, dispersion). Three biological endpoints were investigated in amphibian larvae: the acute toxicity (mortality), the chronic one according to the growth of larvae, and the genetic toxicity according to the induction of micronuclei in erythrocytes in the running blood as the expression of the clastogenic and/or aneugenic effects. Among toxic effects, genotoxicity may durably affect the aquatic ecosystems. The interaction between genotoxic compounds and DNA initially may cause structural changes in the DNA molecule. Unrepaired damage can generate other cell lesions and thus lead to tumor formation [15]. The evaluation of genotoxicity is particularly relevant because its assessment constitutes a warning system at short term to measure long-term effects at infra-lethal concentrations. Genotoxicity may be a useful biomarker as an intermediate endpoint in carcinogenesis, for example. This genetic toxicity represents the hidden risk because of its expression at long and very long term in the environment, contrary to the acute toxicity, for instance, which constitutes the visible risk. In the case of genetic toxicity, measured criteria will be DNA damage whereas in the case of acute toxicity, criteria will be mortality. In amphibian larvae, genome mutations may result in the formation of micronuclei, which are a consequence of chromosome fragmentation or malfunction of the mitotic apparatus.

Acute, chronic, and genetic toxicities are the endpoints which were being investigated in amphibian larvae according to the French national [16] and international [17] standardized methods of the MicroNucleus Test (MNT). The MNT has been widely used with many amphibian species: *Pleurodeles waltl*, *Ambystoma mexicanum*, and *Xenopus laevis* [8, 9, 18–20]. The sensitivity and reliability of the MNT to detect chromosomal and/or genomic mutations make it a good method to analyze the potential cytogenetic damage caused by pure substances [21–23]. The use of MNT may provide an important tool for the prediction of the potential long-term effects on amphibians in the environment. One of the key functions of such biomarkers (micronucleus) is providing an "early warning" signal of significant biological effects (changes at the genetic/molecular level) with sub-organism (molecular, biochemical, and physiological) responses preceding those occurring at higher levels of biological organization such as cellular, tissue, organ, whole-body levels and *in fine* at population level.

In this objective, two amphibian species were exposed to different kinds of CNT synthesized by

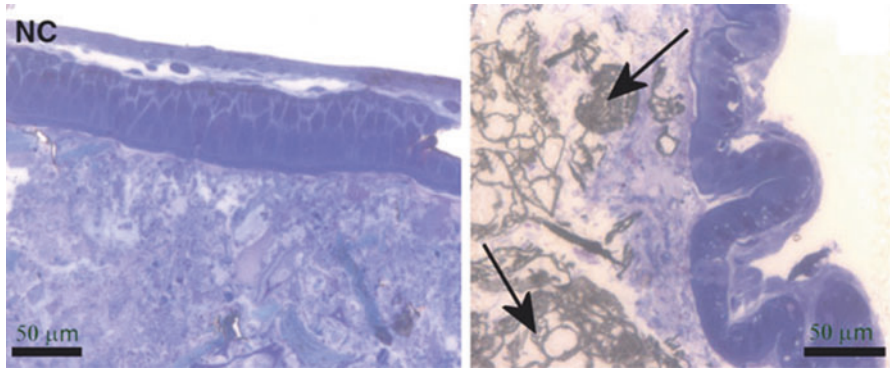
different CCVD synthesis processes: DWNT [24] and MWNT. The three endpoints, described before, were investigated and analyzed. Moreover, the presence of CNT was investigated in the larvae using traditional microscopy methods, but also transmission electron microscopy (TEM) and Raman spectroscopy. This theme around CNT localization in biological matrix is a delicate point in this kind of work. Raman spectroscopy is an optical technique. Monochromatic light (laser) is focused on the sample. The scattered light, composed of the elastic scattering (Rayleigh) and the inelastic scattering due to an interaction with some quanta of energy like phonons (Raman), is analyzed through a spectrometer. With SWNT or DWNT, one-dimensional resonance phenomenon increases strongly the Raman signal, while with large MWNT, the Raman signal is broadened and weaker.

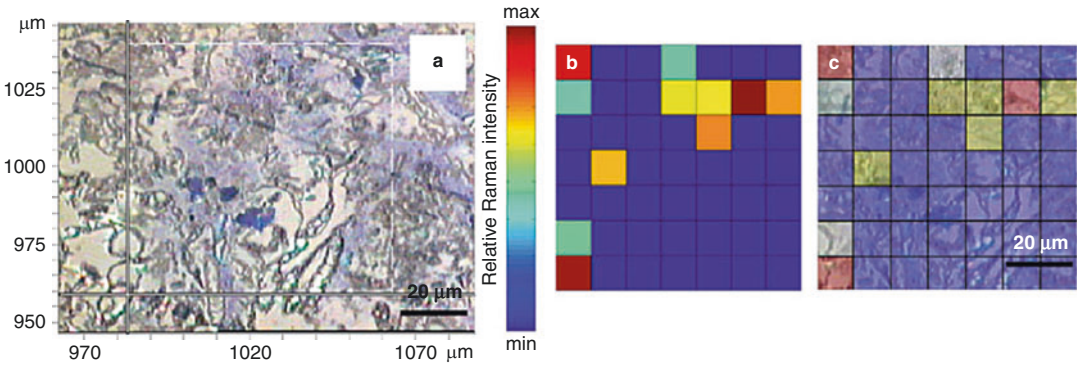


In axolotl, Mouchet et al. [11] exposed the amphibian larvae under adapted standardized conditions to raw DWNT. The results obtained demonstrated that raw DWNT are neither acutely toxic nor genotoxic to larvae whatever their concentration in the water (ranging from 1 to 1,000 mg. L^{-1}). Nevertheless, visual observation under binocular showed that inside the gut there were large black masses of ingested CNT even at the lowest concentration tested.

Mouchet et al. [12–14] exposed *Xenopus* larvae under standardized conditions to raw DWNT or MWNT in water (ranging from 1 to 50 mg. L^{-1}). The results showed no genotoxicity in erythrocytes of larvae. In contrast, results showed chronic toxicity at 50 mg L^{-1} of MWNT (Fig. 5a) and from 10 mg L^{-1} of DWNT (Fig. 5b). A visual inspection of the larvae under binocular after exposure showed that internal gills were black-colored and seemed to be blocked up in the case of DWNT (Fig. 6c) but not in the case of MWNT (Fig. 6a), compared to larvae exposed without CNT (Fig. 6b). In the same way, the visual inspection of the digestive tract in larvae exposed to DWNT or MWNT revealed the presence of black masses into the intestine lumen suggesting that the larvae may have absorbed CNT present in the exposure medium (Fig. 6). In amphibian larvae, xenobiotics could enter in the body of larvae by two principal ways: the dermal route and the digestive route leading to potentially high ingestion rates of particles, especially particles of food susceptible to vehicle agglutinated CNT bundles and water containing suspended particles.

Using microscopic observations of intestine cross-sections in control and exposed larvae (Fig. 7), black masses were clearly identified within food intake in the intestine lumen in exposed larvae, but black masses were not observed in epithelial or in chorionic tissues. It is not possible to identify CNT in the black masses of the intestine lumen by optical microscopy. Using TEM, the intestinal lumen, villi, and intestinal cells can be observed in detail. Figure 8 shows fibers in the intestinal lumen of larvae exposed to DWNT, near the villi but some of them are also observed in the control (not showed). These observations did not lead to the

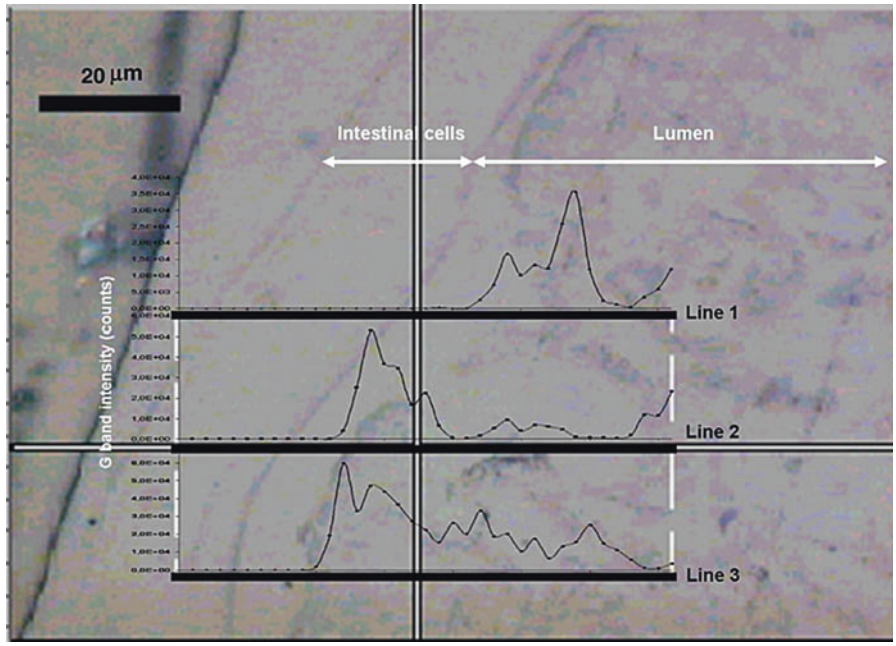
White arrows indicate the presence of CNT in gills in the case of DWNT exposure (**c**) and in the intestine in the case of both CNT (**a**) and (**c**)



Ecotoxicology of Carbon Nanotubes Toward Amphibian Larvae, Fig. 7 Optical microscopy photographs of histological thins of intestine of *Xenopus* larvae exposed to 10 mg/L of DWNT (on the *right*) compared to the control group (on the *left*). *NC* Negative control. Black arrows indicate the presence of black fibrous structures in the intestine lumen of CNT-exposed larvae. Sections showed were stained with methylene blue

confirmation of the presence of CNT in the digestive tissue at cellular level. Fibers were then observed at higher magnification (Fig. 8b, c). Discrimination of these fibers was realized under High-Resolution TEM. Figure 8d shows isolated CNT. At this magnification (Fig. 8e, f), it was possible to show the presence of CNT in exposed larvae. Nevertheless, TEM is a local technique, also leading to possible ambiguity in terms of identification between CNT and biological compounds (ribosomes, organelles, etc.). Another method such as Raman spectroscopy is thus necessary to discriminate between them.

Two kinds of Raman analysis were performed on *Xenopus* intestine. The G or G'2D band can be used to identify and localize CNT in a biological matrix [12]. (1) Raman mapping is presented in Fig. 9 showing the optical microscopic image (slide) of an intestine sample of animal exposed to DWNT (Fig. 9a) and the corresponding Raman image from the same area (Fig. 9b). The superposition (Fig. 9c) clearly shows that, on the one hand, some of the black structures visible in optical microscopy do not contain any DWNT, but that, on the other hand, CNT are present in some other places although optical microscopy does not



Ecotoxicology of Carbon Nanotubes Toward Amphibian Larvae, Fig. 8 Observation of area containing black fibrous structures in the intestine lumen of CNT-exposed larvae using Transmission Electron Microscopy (TEM) and 50 nm High-Resolution Transmission Electron Microscopy Electron micrographs (HRTEM) of *Xenopus* larvae intestine in animals exposed to DWNT. show any clear evidence. (2) Figure 10 presents Raman line analysis in intestine, evidencing the presence of both kinds of CNT (DWNT and MWNT) in the intestine lumen, whereas no CNT were localized in the intestinal cells. Indeed, a sharp drop in intensity of the specific CNT band was observed. Raman spectroscopy analysis of different tissues of the larvae did not evidence

Ecotoxicology of Carbon Nanotubes Toward Amphibian Larvae, Fig. 10 Location of DWNT by Raman spectroscopy. The G band intensity extracted from Raman spectra is characteristic of the CNT. By acquiring spectroscopic lines, we follow the DWNT profile. Disappearance of the DWNT signal at the intestinal cell barrier is observed

the presence of CNT neither in blood (results not shown), nor in liver of amphibian suggesting that CNT do not cross the intestinal barrier.

To summarize, results showed different responses between the two amphibian species, *Xenopus* (anouran) and axolotl (urodeles) in relation with their different biology, larval growth, behavior, etc. A difference in sensitivity was generally observed in response to chemical pollutants, and *Xenopus* larvae are often found more sensitive than urodelian species to environmental substances [8]. Results highlight the potential risk of the studied CNT since acute and chronic toxicities were observed in larvae exposed to raw CNT. In *Xenopus*, exposure to CNT leads to toxicity usually above 10 mg. L^{-1}, which corresponds to a high concentration. This level of contamination seems to be probably unrealistic in the global environmental context, except in the case of an accident at the production site, for example. Since CNT are ingested by larvae, one cannot exclude the possibility that CNT may be found later in the food chain, once released into the environment. In contrast, no genotoxicity was observed in larvae exposed to raw CNT in these conditions. Acute toxicity observed in *Xenopus* larvae may be mediated by several biological mechanisms: (1) branchial obstruction and/or gas exchange perturbation and/or anoxia, (2) and/or intestinal obstruction, (3) and/or competition between CNT and food. The presence of CNT was evidenced in the larvae using both electron microscopy and Raman analysis. The Raman imaging technique is very sensitive and thus allows assessing without doubt that the intestine of CNT exposed larvae contains CNT, as already suggested by the simple visual inspection of the larvae and the TEM observation. However, the image superposition analysis using Raman spectroscopy (Figs. 9 and 10) clearly sharpened the first interpretation obtained by microscopy. Indeed, some of the black spots observed by optical microscopy do not contain any CNT, whereas CNT are clearly identified in some other places, although this technique does not show any clear evidence. Moreover, the abrupt vanishing of the

intensity of the specific CNT bands in Raman spectroscopy when crossing the intestinal cell wall strongly suggests that raw CNT do not cross the intestinal barrier of amphibians.

Effect of Surface Modification on Toxicity of Nanoparticles

Malgorzata J. Rybak-Smith
Department of Engineering Science, University of Oxford, Begbroke, UK

Synonyms

Influence of surface engineering on toxicity of nanoparticles; Influence of surface functionalization on toxicity of nanoparticles

Definitions

Nanoparticles – particles having at least one dimension between 1 and 100 nm.

Toxicity of nanoparticles – undesirable consequence of interactions of nanoparticles with human or mammalian cells (cytotoxicity), organs, such as lungs (pulmonary toxicity), spleen (splenic toxicity), liver (hepatotoxicity), kidneys (nephrotoxicity), immune system (immunocytotoxicity) and the nervous system (neurotoxicity).

Surface modification of nanoparticles – changing of physicochemical or biological characteristics of surface of nanoparticles by introducing chemical functional groups to the surface via creation of covalent bonds (covalent modification) or adsorption of biologically active molecules, such as proteins, surfactants, enzymes, antibodies, nucleic acids (non-covalent modification). Surface modification of nanoparticles can change their physicochemical properties, charge, size, hydrophobicity and make them more biocompatible for biomedical applications.

Nanoparticles are interesting novel materials which have a potential to be effectively used in nanomedicine and biotechnology. Their nano-sized character and exceptional physicochemical properties attract a lot of scientific attention. However, the size of nanoparticles allows them to penetrate various biological barriers within the body and cause toxicity. The potential toxicity of nanoparticles may also arise from interactions of various nanoparticles with biological systems and is highly undesirable. Toxicity of nanoparticles is a major obstacle for their use as potential drug or gene carriers, vaccines, or as biomedical devices. Medina et al. overviewed different classes of nanoparticles, including liposomes, carbon nanotubes (CNTs), gold shell nanoparticles, polymers, metallic nanoparticles, quantum dots (QDs), and carbon nanomaterials [1]. Nanoparticles can be used as biomarkers in molecular diagnosis or in drug delivery [1]. In the same entry, the pharmacological and diagnostic applications and potential toxicity of different classes of nanoparticles have been presented [1].

To minimize the toxicity of nanoparticles, surface engineering and functionalization can be

applied. Surface of nanoparticles, also surface charge, can be modified in numerous ways. Non-covalent modification of the surface of nanoparticles can be achieved by coating or wrapping with biological molecules which may diminish the toxicity of nanoparticles and therefore make them more biocompatible. Coating with proteins, peptides, surfactants, polymers or wrapping with nucleic acids are commonly used approaches. Another approach involves creation of chemical bonds between functional groups present on the surface of nanoparticles and other biological molecules attached to the surface, and is called covalent modification. In this case, the covalent attachment of polyethylene glycol, PEG (PEGylation), carbohydrate or peptide conjugation, and acetylation may be applied. Functionalization of surface of nanoparticles can significantly improve their utility in biomedical applications as long as the functionalization is not toxic for cells and tissues by itself.

The unique physicochemical properties of CNTs make them of great interest for many biomedical applications. However, the presence of structural defects on their surface, metal impurities, length, hydrophobicity, and surface roughness can significantly affect CNT utility in biomedicine. Moreover, CNTs have a large surface area to mass ratio. The greater surface allows the greater interaction of CNTs with human plasma blood proteins, cellular membranes, and adsorption of biological molecules [2]. Smart et al. reviewed biocompatibility aspects of CNTs interactions with fibroblasts, osteoblasts, neuronal cells, ion channels, cellular membranes, antibodies, and the immune system [3].

Yu et al. presented that chemical modifications of surface of nanoparticles may improve their biocompatibility and can change their human plasma protein binding patterns, cytotoxicity, influence Reactive Oxygen Species (ROS) generation and immune responses [4]. Numerous modified MWCNTs showed lower immune responses than their precursor-carboxylated MWCNTs (MWCNT-COOH) [4]. Magrez et al. presented in vitro toxicity studies of carbon-based materials, like multiwalled carbon nanotubes (MWCNTs), carbon nanofibers and carbon nanoparticles on lung tumor cells [5]. All of the tested nanomaterials were toxic. Furthermore, enhanced cytotoxicity was observed after functionalization of the nanoparticles after an acid treatment [5]. The effect of various chemical functionalizations of CNTs on their biocompatibility has been reviewed by Foldvari et al. [6]. Covalent functionalization using 1,3-dipolar cycloaddition is commonly used approach and results in formation of CNT intermediates with amine groups present on the surface which can be further used to attach bioactive molecules such as streptavidin, G-family proteins, or various peptides [6]. Moreover, the CNT intermediates can be used to attach small molecules, like amphotericin B (AmB), an effective antibiotic for treatment of chronic fungal infections [6]. Diminished toxicity and increased antibiotic activity of CNT-AmB conjugate was observed in Jurkat cells [6]. PEGylation is another commonly used approach which can improve the solubility and biocompatibility of CNTs [6]. Some bioactive molecules, for example, Cys-DNA or short interfering RNA (siRNA), can be non-covalently bound to single-walled carbon nanotubes (SWCNTs) [6]. The effect of functionalization of carbon nanoparticles such as SWCNTs, MWCNTs, carbon nanofibers, carbon graphite, carbon black, on cell toxicity was also discussed in the same review [6]. In general, the toxic effect of CNTs depends on their concentration, dose, purity, and surface properties of the CNTs (surface area, topology, presence of functional groups, presence of residues and impurities). SWCNTs and other carbon-based materials (e.g., carbon black, active carbon, carbon nanofibers) seem to be more toxic than MWCNTs [6]. The functionalization of CNTs can increase their dispersibility in biological media and therefore diminish their toxicity, compared with non-functionalized ("pristine") CNTs. "Soluble" functionalized CNTs may either enhance or decrease the toxicity compared with "pristine" CNTs. Possible enhanced toxicity of functionalized DWCNTs (oxidized) has been recently reported by de Gabory et al. [7]. SWCNTS and MWCNTs can cause cellular toxicity (apoptosis and necrosis were observed) [6]. The toxic effect depends on concentration of

CNTs and time of incubation. It was concluded that the smaller the diameter of CNTs and the greater the aspect ratio, the greater toxic effect is observed [6]. In vivo oral, dermal, and pulmonary toxicity of CNTs were also described in this review [6].

Currently, little is known about interactions of nanoparticles with human lungs [8]. Engineered nanoparticles can cause pulmonary toxicity in humans, experimental animals and cell culture [8]. The increased ratio of surface area to mass of nanoparticles means that more potentially reactive groups present on their surface may interact with the lung cells and therefore impact their pulmonary toxicity [8]. Clearance of inhaled nanoparticles from the lungs depends mostly on particle size and surface charge [9]. Charged nanoparticles bind to lung tissues more effectively than non-charged ones [9]. Various surface coatings (albumin, lecithin, polysorbate 80, peptide attachments, PEG) were also found to influence nanoparticle cellular uptake and fate [9]. Nanoparticles associate with proteins or biopolymers present in human plasma or other biological fluids and form a dynamic protein corona [10]. A long-lived protein corona formed from human plasma was studied on 50 and 100 nm sized, unmodified, carboxyl- and amine-modified polystyrene nanoparticles (PS) [10]. Surprisingly, both size and surface properties of the nanoparticles had a very considerable role in determining the nanoparticle coronas on the different particles of the same materials [10]. The size and surface modification of nanoparticles can impact the reactivity of biologically active proteins in the corona and likely have biological consequences [10].

Toxicity of various engineered nanoparticles, including CNTs, fullerenes, dendrimers, QDs, gold nanoparticles, silica, in vivo and in vitro, was summarized by De Jong et al. [11]. Some of the nanoparticles can cause lung inflammation, progression of plaque formation in vivo and oxidative stress in vitro and in vivo. Studies in vitro revealed that some of nanoparticles can cause platelet aggregation, inhibition of macrophage phagocytosis, and affect function of mitochondria [11]. Nevertheless, surface modification of QDs with *N*-acetylcysteine resulted in reduction of toxicity, compared to non-modified quantum dots, which can cause oxidative stress to plasma membranes and cellular compartments [11]. The effect of PEGylation on gold nanorod cytotoxicity was also presented in the same review [11]. Composition of nanoparticle formulation may influence interactions of the nanoparticles with tissues or cells and their potential toxicity [11]. Functionalization of nanoparticles may make them more specific for drug delivery purposes, diminish their toxicity to non-targeted organs, change their therapeutic effect, and make them safer and more biocompatible [11]. Coating of nanoparticles may prevent their agglomeration. For example, the use of polymers, like PEG, poly(vinylpyrrolidone) (PVP), chitosan, dextran, or surfactants as coatings, can keep nanoparticles separated in colloidal suspensions [11]. Crossing of the blood–brain barrier (BBB) by nanoparticles is especially challenging in drug delivery. Nanoparticle surface charges can affect the BBB crossing and must be considered for the brain toxicity. Neutral nanoparticles were found to be not toxic for the BBB unlike cationic nanoparticles [11]. The toxicity of anionic nanoparticles was concentration dependent [11].

In vitro and in vivo toxicity studies on engineered gold nanoparticles (GNPs), including atomic clusters, colloidal particles, nanorods, gold nanoshells, and nanowires, were reviewed in great detail by Khlebtsov and Dykman [12]. Surface functionalization of GNPs can significantly influence their biodistribution in blood, liver, kidney, lung, spleen, muscle, brain, and bone [12]. Some of tested GNPs were coated with PEG, albumin, maltrodextrin, tumor necrosis factor (TNF), PEG-SH, IgG, maltose among many, and biodistribution studies on various animal models were summarized [12]. Interestingly, the adsorption of apolipoprotein on GNP surface may make possible for them to cross the BBB [12]. Also, cytotoxicity studies in vitro with cell cultures like human leukemia (K562), human breast carcinoma (SK-BR-3), human hepatocarcinoma (HepG2) and many more were presented in the same review [12]. The influence of a variety of surface coatings, such as DNA/transferrin,

triphenylphosphine, cyclodextrin, cysteine, folic acid polyvinylpyrrolidone, glycolipid on GNP cytotoxicity was summarized [12].

Chemical modification of nanoparticles can impact their cellular uptake and cellular localization. The functionalization can change the binding of biological molecules, antibodies, etc., to the surface of nanoparticles and may have impact on drug delivery. Polymer-based nanoscale sized materials such as polymer micelles, nanogels, liposomes, polymer-DNA complexes can be of use in pharmacology. Batrakova and Kabanov broadly reviewed the biological activity of Pluronic block copolymers consisting of PEO and poly(propylene oxide) (PPO) blocks [13]. The amphiphilic character of these copolymers allows the interactions with hydrophobic surfaces and biological membranes [13]. These copolymers can self-assemble into pluronic micelles in aqueous solutions [13]. The core of these micelles is made up of hydrophobic PPO blocks while the shell consists of hydrophilic PEO chains [13]. The PEO shell can not only provide increased solubility, but also prevent the unwanted interactions with cells or plasma components. Pluronics have an ability to incorporate into plasma membranes followed by translocation into the cells which has an effect on various cellular functions [13]. Interestingly, the composition of the block copolymers can affect their biological functions. Block copolymers with intermediate lengths of PPO block and quite hydrophobic structure (such as Pluronic P85 or Pluronic L61), were the most efficiently transported into the cells [13]. On the other hand, hydrophilic block copolymers did not incorporate into the lipid bilayers and were not transported into the cells [13].

Fluorescent nanocrystals, also called quantum dots (QDs), can be utilized in drug delivery or cellular imaging [14]. The core of the QDs is usually a semiconductor like cadmium-selenium (CdSe), cadmium-tellurium (CdTe), indium-phosphate (InP), or indium-arsenate (InAs). Zinc sulfide (ZnS) is commonly used as the shell to stabilize the core of the QDs [14]. The structure of the QDs allows of the coating of the QDs and conjugation of biologically active molecules, such as antibodies, peptide ligands, which may reduce their toxicity and increase bioactivity [14]. Toxicity of cadmium and core material was widely discussed in this review [14]. Encapsulation of QD core with ZnS can not only stabilize the core of QD, but also improve their optical properties and bioavailability [14]. Toxicity studies of various QDs in vitro and in vivo were summarized by Ghaderi et al. [14]. In most of studies, CdSe and CdFe were the cores and ZnS was the shell [14]. The majority of tested QDs were not coated and were found cytotoxic for some of cell lines [14]. The size of QD plays an essential role in the observed cytotoxicity. In general, the smaller size the higher toxicity [14]. In one of the studies, preincubation of cells with *N*-acetylcysteine and bovine serum albumine (BSA) considerably reduced the cell death caused by QDs [14]. In some studies, generation of ROS caused the QDs toxicity [14]. Results of QD toxicity studies on mice and rats were also presented in the review [14]. CdSe/ZnS were coated with PEG and BSA and the latter were shown to be distributed to the liver, spleen, and other tissues [14]. Little is currently known about crossing of QDs through the BBB [14].

Jain et al. reviewed dendrimers toxicity in detail [15]. Positively charged dendrimers can interact with negatively charged biological membranes and cause the membrane destruction via nanohole formation and further cell lysis. Cationic dendrimers were shown to be less cytotoxic than anionic or PEGylated dendrimers [15]. Jain et al. summarized the cytotoxicity of positively charged dendrimers, polypropyleneimine (PPI), and polyamido amine (PAMAM) against several cancer cell lines, including B16F10, CCRF, HepG2, COS-7, and Caco-2 [15]. In the same review, results of cytotoxicity and membrane disruption studies were presented for PPI dendrimers, PEG conjugated PPI dendrimers and PPI dendrimers with neutral acetamide groups on cultured Human Umbilical Vein Endothelial Cells (HUVEC) [15]. Moreover, hemolytic and hematological toxicity of dendrimers, including PPI and PAMAM, were presented [15]. The effect of various types of dendrimers, including glycine-, lactose-, mannose-, phenylalanine-coated PPI dendrimers on different blood parameters like

white and red blood cells, hemoglobin, hematocrit, were summarized in the review [15]. It was concluded that the cationic dendrimers might show significant destruction of the hematological parameters [15]. However, immunogenicity has not been yet confirmed for dendrimers [15]. Results of biocompatible and surface engineered dendrimers, such as polyether imine dendrimers, SN-38 complexed G4-PAMAM dendrimers, glycine-coated PPI dendrimers, phenylalanine-coated PPI dendrimers, lactose-coated PPI dendrimers, PPI dendrimers with peripheral neutral acetamide groups, carboxylic acid-terminated PAMAM dendrimers, anionic PAMAM dendrimers, lauroyl- and PEGylated PAMAM dendrimers, and PEGylated PPI dendrimers, on various cell lines were summarized [15]. It was concluded that modification of the surface of dendrimers can diminish their toxicity [15]. Coating of surface of dendrimers with glycine, lactose, mannose, and galactose, PEG can also improve their hemolytic toxicity profile [15]. Surface engineering makes dendrimers more biocompatible for clinical applications. It allows them to mask the cationic charge on their surface which can be achieved by PEGylation, acetylation, peptide conjugation, and make them neutral. Also, introducing of negative charge on the surface of dendrimers makes them more biologically compatible [15]. Chemical modification of the surface of dendrimers can also allow them to be used as drug carriers or DNA and gene conjugates [15].

So far little is known about the interactions of nanoparticles with the central nervous system [16]. Hu et al. summarized results of recent in vitro studies on various cell lines, including cultured neuronal phenotype (PC12), brain cultures of immortalized mouse microglia (BV2), rat dopaminergic neurons (NR7), primary cultures of embryonic rat (Sprague–Dawley) striatum, and mouse neural stem cells (NSCs) [16]. Zinc oxide (ZnO) and anionic magnetic nanoparticles, for example, were neurotoxic to NSCs and PC12 cells, respectively [16]. Results of in vivo studies showed that the presence of charge on nanoparticles can have an influence on their neurotoxicity [16]. Changing the physicochemical properties of nanoparticles by conjugation of, for example, wheat germ agglutinin or coating with polysorbate surfactants, can impact the BBB transport mechanism [16]. Coating of nanoparticles with surfactants (Tween) may influence brain toxicity [16]. Cationic nanoparticles (gold, polystyrene) were shown to cause hemolysis and blood clotting whilst anionic particles were usually non-toxic [16].

Nanomaterials when placed in contact with human or mammalian body fluids and tissues are recognized by the immune system. Modification of nanoparticle surface with hydrophilic agents can influence their potential toxicity in vivo and in vitro. Coating or wrapping of nanoparticles can modify their interaction with blood proteins and cells. Dobrovolskaia et al. reviewed on how surface modification of various nanoparticles can change plasma protein binding and influence the nanoparticles interactions with red blood cells and platelets [17].

Functionalized nanoparticles can be unrecognizable by the immune system or can enhance the immune responses. Zolnik et al. presented how manipulation of physicochemical properties of nanoparticles can change their interactions with the components of the immune system [18]. The interactions may be undesirable and cause immunostimulation (interaction of nanoparticles with the complement system, cytokine secretion, immunogenicity) or immunosuppression. Nanoparticles can be recognized as foreign material entering the body. This may lead to toxicity. If nanoparticles (like carbon nanotubes) are too long they cannot be digested by macrophages and can cause granuloma formation. Modification of the surface properties of nanoparticles by changing their hydrophobicity and/or surface charge, may have a positive influence on compatibility of nanoparticles with the immune system. Immunosuppression may lower the body's defense against infection or may improve the therapeutic benefits of treatments for allergies and autoimmune diseases [18].

Nanoparticles can bind to coagulation proteins, blood plasma components, and cell-surface proteins. Binding of immune system complement proteins activates the complement system and

results in strong binding of several complement proteins to the CNTs [2]. Such complement activation may influence subsequent interaction of the CNTs with cells and tissues and induce potential toxicity. Protein binding occurs when CNTs are placed in contact with human blood or lung fluids and can have biological consequences [2]. Interactions of various CNTs with human plasma proteins and pulmonary surfactant proteins were reported [2]. Pre-coating of CNTs with bovine serum albumin (BSA), human serum albumin (HSA), human fibrinogen (FBG) or the detergent Tween 20 did not prevent the complement activation [2]. Frequently the surface of CNTs is not completely covered by the coating molecules, so some of potential binding sites on the surface of CNTs stay unobstructed and available for binding of various complement proteins [2].

The major limitation of nanoparticles in drug delivery is their rapid uptake by the mononuclear phagocyte system (MPS). However, the presence of PEG chains on the surface of nanoparticles can significantly change their interactions with blood proteins. Prolonged circulation of nanoparticles in the bloodstream is crucial for drug delivery purposes (e.g., particles should not be cleared by the liver and spleen before reaching their target). Moghimi et al. presented protein-binding processes to poly(ethylene glycol)–phospholipid (PEG-PL) engineered nanoparticles and the influence of surface PEGylation on complement activation and the fate of these engineered nanoparticles [19]. The effect of PEGylated liposome composition and size on complement activation in human serum was presented [19]. Anionic liposomes were shown to activate complement more than the methylated conjugates without charge [19].

Stable dispersion of nanoparticles in biological media is a necessary step toward their biomedical applications. It can be achieved by functionalization of CNT's hydrophobic surface with various chemical groups or adsorption of biologically active molecules. Although coating of CNTs with PEG_{5000}-phospholipid conjugates improves their stability in a biological buffer, the PEG-PL-coated CNTs can still activate the human complement system via the lectin pathway [19]. Complement activation by SWNTs in human serum with addition to *N*-acetylglucosamine, D-galactose, non-specific antibody, and Anti-MASP2 antibody in C1q-depleted serum was investigated by Moghimi et al. [19]. Interestingly, PEG-phospholipid conjugates which form stable micellar structures with the size about 30 nm did not activate complement [19]. PEGylated liposomes with the size from 100 to 120 nm activated complement via classical and alternative pathway [19]. The lectin pathway was shown to be activated by 2–5 nm diameter CNTs with a length of 250 nm [19].

Effect of surface PEGylation of various liposomes on complement activation was presented by Moghimi et al. [20]. Anionic liposomes were shown to activate complement in vitro. However, incorporation of phosphatidylethanolamine-methoxypoly(ethylene glycol) (PE-mPEG) into the liposomal bilayer abolished the complement activation and was shown to be liposome-concentration dependent [20]. The drug Doxil®, commonly used in cancer therapy, is a negatively charged PEGylated liposome with doxorubicin enclosed. The drug is a strong activator of the human complement system and even its surface modification with PEG does not suppress complement activation [20]. However, the length of PEG can be an important factor in this as shown in some in vivo studies. Longer PEG chains were much more effective in preventing of complement activation than the shorter chains [20]. Other nanoparticles, very similar in structure to Doxil®, like hydrogenated soy phosphatidylcholine (HSPC) and cholesterol with the size of 100 nm, were shown not to activate the complement system in vitro. However, the presence of PEG_{2000}-conjugated distearoyl phosphatidylethanolamine, can cause significant complement activation in vitro [20]. Also, introduction of hydrogenated soy phosphatidylglycerol causes significant complement activation in vitro measured by an increase of SC5b-9 levels in human serum [20]. The negative charge plays a crucial role in the activation and the surface density of methoxypoly(ethylene glycol), mPEG, cannot prevent complement activation by liposomes as they cannot mask the negatively charged phosphodiester moieties [20].

Assessment of nanoparticles toxicity in vivo is a necessary step if the nanomaterials are to be used in biomedicine as efficient drugs or gene carriers. Functionalization of their surface by changing the surface charge and chemical composition can have a considerable impact on their toxic effect in vivo. Some nanomaterials can initiate oxidative stress in cells and release of ROS. This can initiate inflammation processes and cellular damage. Moreover, organs like the liver, spleen, kidney, and lungs can be affected by the oxidative stress [21]. Nanomaterials can also interact with mitochondria and nucleus, and such interactions are thought to be the main source of their toxicity [21]. Primary causes of various nanomaterials toxicity in vivo were summarized by Aillon et al. [21]. The authors discussed the influence of physicochemical properties of dendrimers, CNTs, QDs, and gold nanoparticles on their toxicity [21]. Examination of nanoparticle toxicity in vivo is still very limited. For most nanoparticles, their nano-size can cause their toxicity. Additionally, the surface charge on dendrimers, the length of CNTs, and the shape of gold nanoparticles can enhance their toxicity in vivo. Functionalization of the surface of the nanomaterials can diminish their toxicity. Chemical modification of the dendrimers surface can mask their charge, CNT hydrophobic surface can become more hydrophilic, and they can also become shorter by cutting using sonication. Hydrophobicity of "pristine" CNTs is a main obstacle in their biomedical applications. Moreover, they have a tendency to aggregate which can cause slow clearance from the body and oxidative stress in organs like liver, spleen, or lungs. Their length causes inefficient phagocytosis and damage of macrophages [21].

Studies on mice revealed that PEG-polyester dendritic hybrids did not cause any pathological changes in the liver, kidney, heart, lungs, and intestine of animals [21]. Similarly, PEGylated melanine dendrimer administration into mice did not cause liver and kidney toxicity [21].

Cadmium and selenium, heavy metals mostly used in QD cores, can be toxic in vivo [21]. Cadmium not only can accumulate in human tissues but also cross the BBB. However, electrostatic charge modification, adsorption, covalent modification, or chelation can have a considerable impact on the QD biocompatibility in vivo. As mentioned earlier, ZnS is commonly used as stabilizer of the QD surface, but also secondary coating of the QD can be applied to diminish its toxicity [21]. However, there is still a debate between researchers if the secondary coating of QD can prevent the cadmium leakage from their core [21]. Stability of the QD complex which consists of core, shell, and secondary coating is a very important factor in their toxicity [21].

Various covalent and non-covalent modifications of the surface of nanoparticles are essential approaches that allow to overcome the toxicity problems associated with nanomaterials. Surface functionalization gives an excellent opportunity to design novel nanoparticles with desirable physicochemical properties and biological activity. Nevertheless, it is essential that the functionalization is not damaging for cells or tissues by itself. Ideally, the functionalization should diminish nanoparticles toxicity and make them more biocompatible. This can significantly enhance their chances to be used in pharmacology and biomedical fields. The modification of surface properties of the nanoparticles can change their reactivity and have considerable impact on their cytotoxicity, ROS generation, immunocytotoxicity, pulmonary toxicity, and neurotoxicity. It can also influence their interactions with human and mammalian blood proteins and their adsorption on the surface. However, as the interactions with biological environments are quite complex, achieving the desirable biological or therapeutical responses of nanoparticles may be time consuming and not always work out. Sometimes quite opposite outcomes can be observed and the functionalized nanoparticles can be even more toxic either in vivo or in vitro than non-functionalized ones [2, 5, 19, 20]. Nevertheless, functionalization of nanoparticles surface can be considered as a useful tool for researchers and may reduce nanoparticles toxicity by making them more suitable for various biomedical applications.

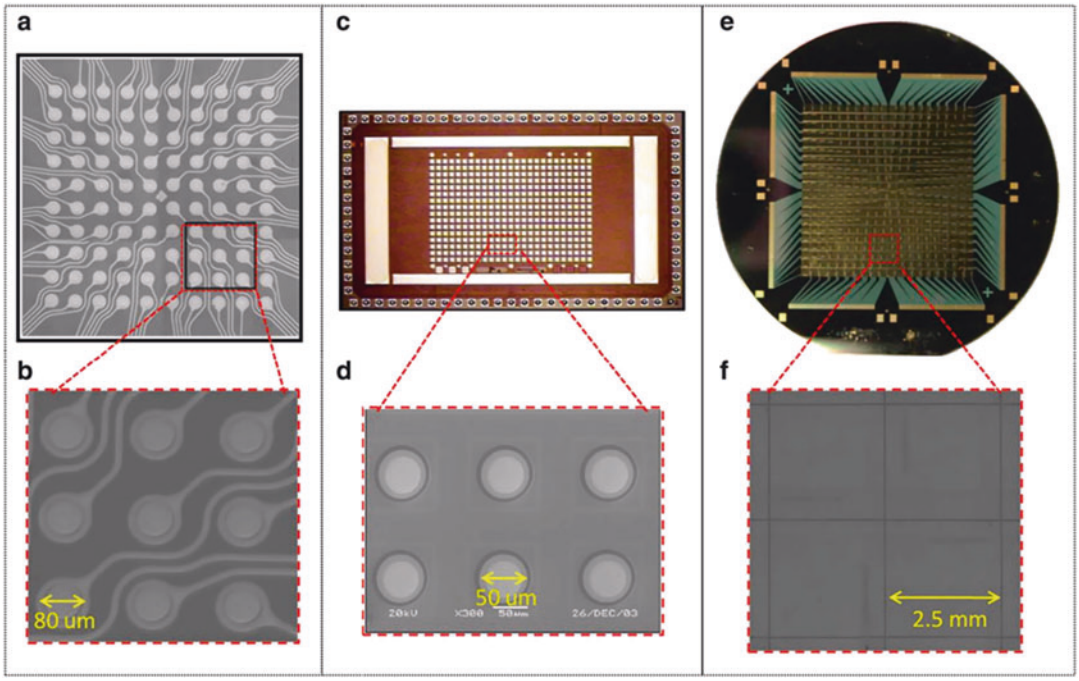
Definition

Use of DC electric field microarray devices and electronic techniques to carry out the directed self-assembly of bioderivatized nanoparticles into high order structures.

Overview

Electronic microarray devices which produce reconfigurable electric field patterns can be used to control the self-assembly of nanocomponents into higher order structures. These devices allow the hierarchical assembly of nanocomponents to be carried within microscale geometries of electronic circuitry. Such nanofabrication devices and technologies have the potential for producing highly integrated nano/micro/macrostructures including nanophotonic-based large-scale arrays and displays; high-efficiency multiple band gap photovoltaics; fuel cells with nanostructured intermetallic catalysts and integrated fluidic channeling; smart-morphing nanocomposite materials; in vivo biosensor and mother-ship drug delivery devices. Electronic microarray devices that were originally developed for molecular diagnostic applications allow DNA, proteins, and almost any charged nanostructure to be rapidly transported and specifically bound at any site on the array surface. Microarray devices that have onboard integrated CMOS circuitry also allow rapid switching and precise control of the currents/voltages sourced to the microarray. Such microarray devices have been used to carry out the rapid highly parallel assisted self-assembly of biotin- and streptavidin-derivatized fluorescent nanoparticles and DNA-derivatized nanoparticles into multilayer structures. Electric field–directed assembly has major advantages over more classical passive layer-by-layer (LBL) self-assembly processes, which are generally one order of magnitude slower, nonparallel, and not reconfigurable in real time. The use of electronic microarray devices for assisted self-assembly represents a unique synergy of combining the best aspects of "top-down" and "bottom-up" technologies into a potentially viable nanomanufacturing process.

It also enables a more bio-inspired logic to be followed for the hierarchal self-assembly of nanostructures into higher order structures, materials, and devices.



Nanotechnology Top-Down and Bottom-Up Processes

Nanotechnology includes a wide range of new ideas and concepts that are likely to enable novel applications in electronics, photonics, materials, energy conversion processes, biosensors, and biomedical devices. Some of the many challenges and opportunities in nanotechnology were discussed in the early National Nanotechnology Initiative meeting [1, 2]. One of the more important challenges is the area of nanofabrication, in particular the development of technologies which will lead to cost-effective nanomanufacturing processes. Enormous efforts are now being carried out on refining the more classical "*top-down*" photolithography processes to produce silicon-integrated (CMOS) electronic devices with nanometer scale features. While this goal has been achieved, the process requires billion dollar fabrication facilities and it does appear to be reaching some fundamental limits. So-called *bottom-up* self-assembly processes are also being studied and developed as possible new ways for producing nanodevices and nanomaterials. While there are now numerous examples of promising nanocomponents such as organic electron transfer molecules, quantum dots, carbon nanotubes, and nanowires, their assembly into higher order structures has been limited [3, 4]. Thus, the development of a viable cost-effective bottom-up self-assembly nanofabrication process that allows billions of nanocomponents to be assembled into a higher order structure still remains a considerable challenge.

Living System and DNA Self-assembly – Living systems represent the best example of self-assembly processes that can be used for developing strategies for bottom-up nanofabrication. Living systems contain many types of biomolecules which have high fidelity recognition properties including deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins. Proteins serve as structural elements (collagen, keratin, silk, etc.), as binding recognition entities (antibodies) and as efficient catalytic macromolecules (enzymes). The nucleic acids DNA and RNA are involved in the storage and transfer of genetic information. All these biomolecules are able to interact and organize into higher order nanostructures which translate genetic information and perform biomolecular syntheses and energy conversion metabolic processes. Ultimately, all these biomolecules and bionanostructures are integrated and organized within membrane structures to form the entities called cells. Cells in turn can then replicate and differentiate (via these nanoscale processes) to form and maintain living organisms. Thus, biological systems have developed the ultimate "bottom-up" nanofabrication processes that allow component biomolecules and nanostructures with intrinsic self-assembly and catalytic properties to be organized into highly intricate living organisms. Of all the different biomolecules that could be useful for nanofabrication, the nucleic acids (DNA and RNA) with their high fidelity recognition and intrinsic self-assembly properties represent a most promising material for creating nanoelectronic, nanophotonic as well as many other types of organized nanostructures [5–7]. DNA, RNA, and other synthetic DNA analogues are programmable molecules which through their base sequence have intrinsic molecular recognition and self-assembly properties. Short DNA sequences, called oligonucleotides, are readily synthesized by automated techniques and can be modified with a variety of functional groups such as amines, biotin moieties, fluorescent or chromophore groups, and with charge transfer molecules. Additionally, synthetic DNA molecules can be attached to quantum dots, metallic nanoparticles, carbon nanotubes; as well as to surfaces like glass, silicon, gold, and semiconductor materials. Synthetic DNA molecules (oligonucleotides) represent an ideal type of "Molecular Legos" for the self-assembly of nanocomponents into more complex two- and three-dimensional higher order structures. At a first level, DNA sequences can be used as a kind of template for assembly on solid surfaces. The technique involves taking complementary DNA sequences and using them as a kind of selective glue to bind other DNA-modified macromolecules

or nanostructures together. The base pairing property of DNA allows one single strand of DNA with a unique base sequence to recognize and bind together with its complementary DNA strand to form a stable double-stranded DNA structures. While high fidelity recognition molecules like DNA allows one to "self-assemble" higher order structures, the process has some significant limitations. First, for in vitro applications (i.e., in a test tube), DNA and other high fidelity recognition molecules like antibodies, streptavidins, and lectins work most efficiently when the complexity of the system is relatively low. That is as the complexity of the system increases (more unrelated DNA sequences, proteins, and other biomolecules), the high fidelity recognition properties of DNA molecules are overcome by nonspecific binding and other entropy-related factors, and the specific hybridization efficiency for the DNA molecules is considerably reduced. Under in vivo conditions (inside living cells), the binding interactions of high fidelity recognition molecules like DNA are much more controlled and compartmentalized, and the DNA hybridization process is assisted by structural protein elements and active dynamic enzyme molecules. Thus, new bottom-up nanofabrication processes based on self-assembly using high fidelity recognition molecules like DNA should also incorporate strategies for directing and controlling the overall process.

Electronic Microarray DNA Hybridization Technology – A variety of electronic microarrays have been designed and fabricated for DNA genotyping diagnostic applications [8–11]. An early 100 test-site electronic microarray which has been commercialized (Nanogen) has an inner set of 80-μ diameter platinum microelectrodes (Fig. 1a, b). Each microelectrode has an individual wire interconnect through which current and voltage are applied and regulated. The microarrays are fabricated from silicon wafers, with insulating layers of silicon dioxide, platinum microelectrodes, and gold connecting wires. Silicon dioxide/silicon nitride is used to cover and insulate the conducting wires, but not the surface of the platinum microelectrodes. The whole surface of the microarray is covered with several microns of hydrogel (agarose or polyacrylamide) which forms a permeation layer. The permeation layer is impregnated with streptavidin which allows attachment of biotinylated DNA probes or other entities. The ability to use silicon and microlithography for fabrication of the DNA microarray allows a wide variety of devices to be designed. More sophisticated higher density electronic microarrays with 400 test-sites have on-chip CMOS control elements for regulating the current and voltages to the microelectrode at each test-site (Fig. 1c, d). These control elements are located in the underlying silicon structure and are not exposed to the aqueous samples that are applied to the chip surface when carrying out the DNA hybridization reactions. DNA hybridization reactions are carried out on these electronic microarrays by first applying a positive DC bias of ~2–4 V to address or spot specific DNA molecules to the selected test-sites on the array. These DNA molecules are usually oligonucleotide "capture" probes or target DNA sequences that have been functionalized with biotin molecules. These biotinylated DNA molecules become strongly bound to streptavidin molecules which are cross-linked to the hydrogel layer covering the underlying microelectrode. In the next step, a positive DC electric field is applied to specific microelectrodes directing the hybridization of the other DNA molecules to the DNA sequences attached to the selected test-sites. (During the addressing and hybridization processes, other microelectrodes on the microarray are biased negative.) Electronic addressing also allows DNA probes to be spotted onto the array in a highly reproducible manner. Electronic microarrays can be formatted in a variety of ways that include reverse dot blot format (capture/identity sequences bound to test-sites), sandwich format (capture sequences bound to test-sites), and dot blot format (target sequences bound to test-sites). DNA hybridization assays involve the use of fluorescent DNA reporter probes designed to hybridize to specific target DNA sequences. The reporter groups are usually organic fluorophores that have been either attached to oligonucleotide probes or to the target/sample DNA/RNA sequences. After electronic addressing and hybridization are carried out, the microarray is analyzed using the

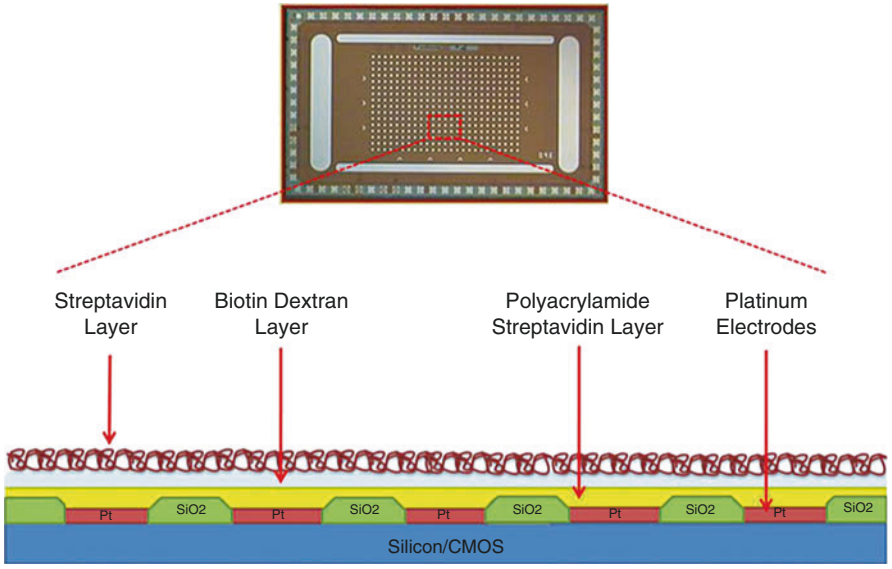
fluorescent detection system. Reference [12] provides a good example of single nucleotide polymorphism (SNP) genotyping analysis that has been carried out on using electronic microarrays.

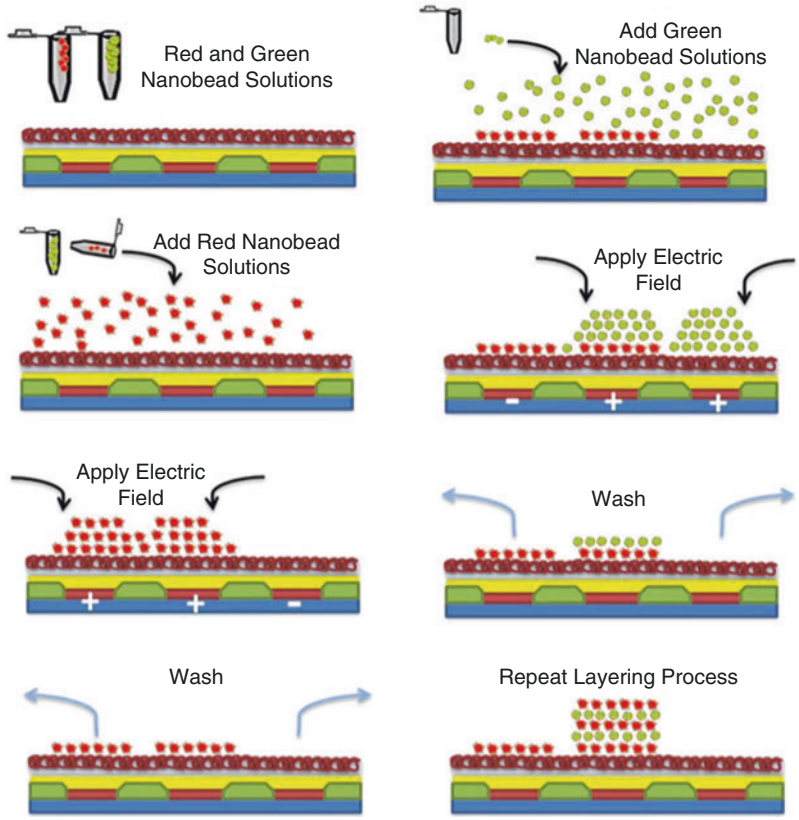


Electric Field–Directed Nanofabrication

While electronic microarray devices were originally developed for DNA genotyping diagnostic applications, the resulting electric fields are able to transport any type of charged molecule or structure including proteins, antibodies, enzymes, nanostructures, cells, or micron-scale devices to or from any of the sites on the array surface. In principle, these active devices serve as a "motherboard" or "host-board" for the assisted assembly of DNA molecules or other entities into higher order or more complex structures. Since the DNA molecules have intrinsic programmable self-assembly properties, and can be derivatized with electronic or photonic groups, or attached to larger nanostructures (quantum dots, metallic nanoparticles, nanotubes), or microstructures, this provides the basis for a unique bottom-up nanofabrication process. Thus, electronic microarray devices can serve as motherboards that allow one to carry out a highly parallel electric field "pick and place" process for the heterogeneous integration of molecular, nanoscale, and micron-scale components into complex three-dimensional structures. Electric field–directed self-assembly technology is based on three key physical principles: (1) the use of functionalized DNA or other high fidelity recognition components as "Molecular Lego" blocks for nanofabrication; (2) the use of DNA or other high fidelity recognition components as a

"selective glue" that provides intrinsic self-assembly properties to other molecular, nanoscale, or micron-scale components (metallic nanoparticles, quantum dots, carbon nanotubes, organic molecular electronic switches, micron and submicron silicon lift-off devices and components); and (3) the use of an active microelectronic array devices to provide electric field assistance or control to the intrinsic self-assembly of any modified electronic/photonic components and structures [13, 14].

Electric Field–Directed Self-assembly of Bioderivatized Nanoparticles – In addition to the more classical top-down processes such as photolithography, so-called bottom-up processes are being developed for carrying out self-assembly of nanostructures into higher order structures, materials, and devices [15]. To this end, considerable efforts have been carried out on both passive and active types of layer-by-layer (LBL) self-assembly processes as a way to make three-dimensional layered structures, which can have macroscopic x-y dimensions [16]. In cases where patterned structures are desired, the substrate material is generally pre-patterned using masking and a photolithographic process [17]. Other approaches to patterning include the use of optically patterned ITO films and active deposition of the nanoparticles. Nevertheless, limitations of passive LBL as well as active assembly processes provide considerable incentive to continue the development of better paradigms for nanofabrication and heterogeneous integration. Of particular importance to self-assembly processes involving biomolecular-derivatized nanoparticles is the prevention of nonspecific binding. Nonspecific binding due to cooperative hydrophobic, hydrogen bonding and ionic interactions between nanoparticles and the assembly substrate may often be as strong as the specific ligand binding interactions. Thus, once a nanoparticle has been bound nonspecifically, it is often difficult to remove it without perturbing or damaging the more specific nanoparticle interactions and structures. Nonspecific binding is often a concentration-dependent problem, whose probability increases when large amounts of derivatized nanoparticles interact with a physically and/or chemically complex substrate. Alternatively, trying to carry out stringent self-assembly at very low concentrations of biomolecular-derivatized nanoparticles is a slow process, and may still result in nonspecific binding to unprotected areas of the substrate. Therefore, there is a clear need for a rapid, directed assembly process which utilizes low concentrations of nanocomponents and reduces nonspecific interactions throughout the repeated multistep processes that will be required for fabricating complex higher order structures.



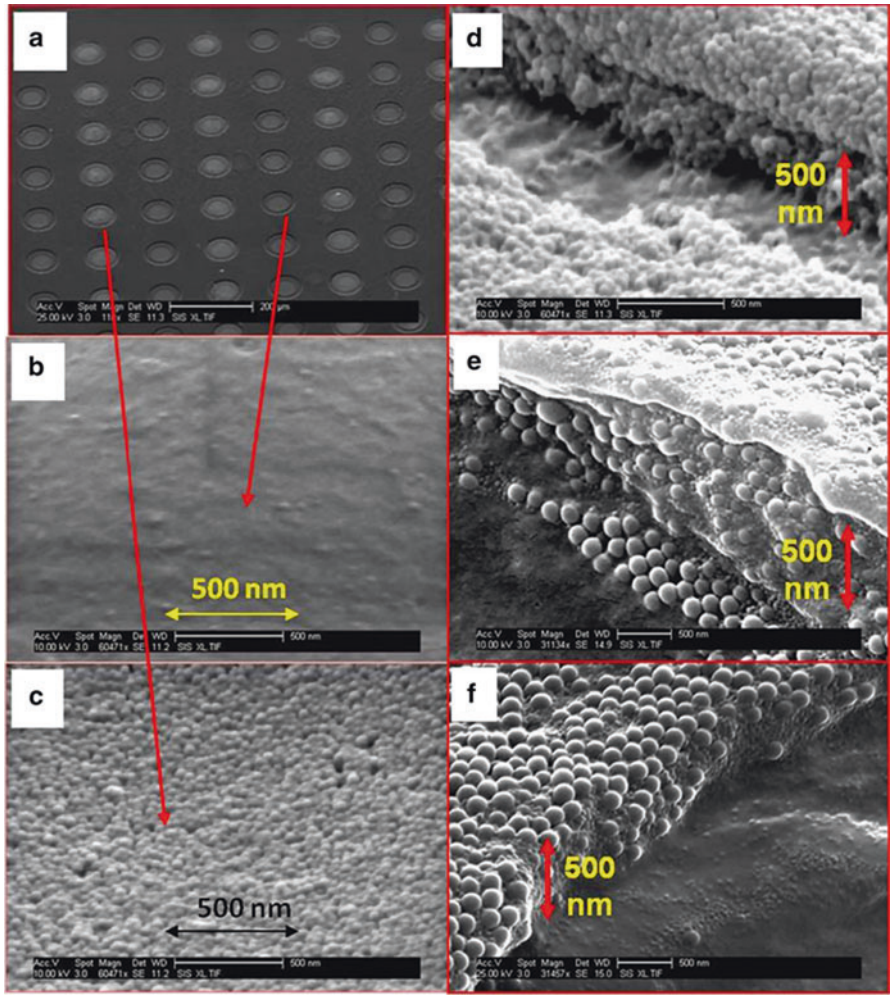
Electronic Microarrays and Techniques – Electronic microarrays and electric field techniques have now been used to carry out the highly parallel directed self-assembly of biomolecular-derivatized nanoparticles into multilayered higher order structures. The rapid and highly parallel assembly of biotin-, streptavidin-, and DNA-derivatized nanoparticles into structures with over 40 layers has been achieved [18–20]. The optimized electric field process allows nanoparticles at very low concentration in the bulk solution to be rapidly concentrated and specifically bound to the activated sites with minimal nonspecific binding. The electric field device used to obtain such results was an ACV 400 CMOS electronic microarray (Nanogen). This CMOS-controlled electronic microarray contains 400 50-μm diameter platinum microelectrodes in a 16 × 25 grid arrangement (Fig. 1c). The device has four additional large rectangular counterelectrodes on its perimeter. Each of the 400 microelectrodes is capable of independently producing from 0 to 5 V at up to 1 μA per microelectrode. The 400 microelectrodes on the array can be biased positive, negative, or left neutral in basically any combination; however, all four of the perimeter electrodes must be biased at the same polarity (positive or negative) or left neutral. The electronic microarray device can be set to source either current or voltage, and the activation time for each microelectrode can be controlled independently. The microarray device uses platinum electrodes as they present an inert interface to the solution. Additionally, the platinum electrodes do not degrade or disintegrate from the electrolysis reactions which occur at the voltages (>1.2 V) necessary to produce rapid electrophoretic

Electric Field–Directed Assembly of Bioderivatized Nanoparticles, Fig. 2 *The 400 test-site CMOS electronic microarray device*. The 400 test-site device, with a cross-sectional diagram showing the silicon base, the CMOS control circuitry, the platinum microelectrodes, the silicon dioxide insulating structures between the microelectrodes, the overlaying polyacrylamide/streptavidin permeation gel layer, the biotin–dextran layer, and the final layer of streptavidin (the drawings are not to scale)

transport of nanoparticles in the bulk solution. The ACV 400 site microarray comes coated with a 10-μm thick (hydrated) porous permeation layer composed of polyacrylamide impregnated with streptavidin (Fig. 2). This permeation layer is designed to prevent analyte molecules (DNA, proteins, etc.) and nanoparticles from contacting the microelectrodes, and to ameliorate the adverse effects of the electrolysis products on the binding reactions. In order to improve nanoparticle binding density, the microarray surface was overlayered with a biotin–dextran layer and a high density streptavidin layer (Fig. 2). The basic scheme for the electric field–directed self-assembly of biotin and streptavidin nanoparticles is shown in Fig. 3, and a full description of the actual procedure is given in Ref. [19].

Procedure for Deposition of First Nanoparticle Layers – The microarray is first washed with a 100 mM solution of L-histidine to remove any excess streptavidin. The bulk of the liquid on the chip is then removed, and 20 μL of a 4 nM solution of biotinylated 40 nm red fluorescent nanoparticles in 100 mM L-histidine buffer is deposited onto the microarray surface. Because most of the derivatized nanoparticles used in the experiments have a net negative charge, microelectrodes used for deposition are biased positive, with the outer perimeter counterelectrodes being biased negative. A number of microelectrodes on the array are often left unbiased (not activated) and served as overall controls for nonspecific binding. Immediately after addition of the nanoparticle containing solution, the directed electrophoretic transport and deposition of nanoparticles to the specific array sites is carried out. In initial experiments, the microarray can be set up in a combinatorial fashion to test a variety of currents, voltages, and activation times to determine optimal deposition conditions. Generally, a current ramp from 0 to 0.4 μA in 0.025 μA increments is programmed along rows of microelectrodes on the array. Activation times from 0 to 20 s in 5 s intervals are programmed across groups of columns on the microarray. Several columns of microelectrodes are also left inactivated to serve as controls. Following directed electrophoretic transport of the biotinylated 40 nm nanoparticles, the microarray is washed six times with 100 mM L-histidine, and then all liquid is removed from the

Electric Field–Directed Assembly of Bioderivatized Nanoparticles, Fig. 3 *The electric field–directed nanoparticle layering process*. The initial step involves adding a solution containing the biotinylated 40 nm *red* fluorescent nanoparticles onto the microarray device. The next step involves applying a positive DC biased to the desired test-sites on the microarray which attracts and concentrates the negatively charged biotinylated nanoparticles to the surface. The biotinylated nanoparticles become bound to the streptavidin layer, and the unattached nanoparticles are then washed away. In the next step, a solution containing streptavidin 40 nm *yellow-green* fluorescent nanoparticles is placed onto the microarray; the positively biased test-sites on the microarray attract and concentrate the negatively charged streptavidin nanoparticles which now become bound to the biotinylated nanoparticle monolayer. The unattached nanoparticles are then washed away. The alternate addressing, binding, and washing of biotin and streptavidin nanoparticles are repeated to form the multilayer nanoparticles structures



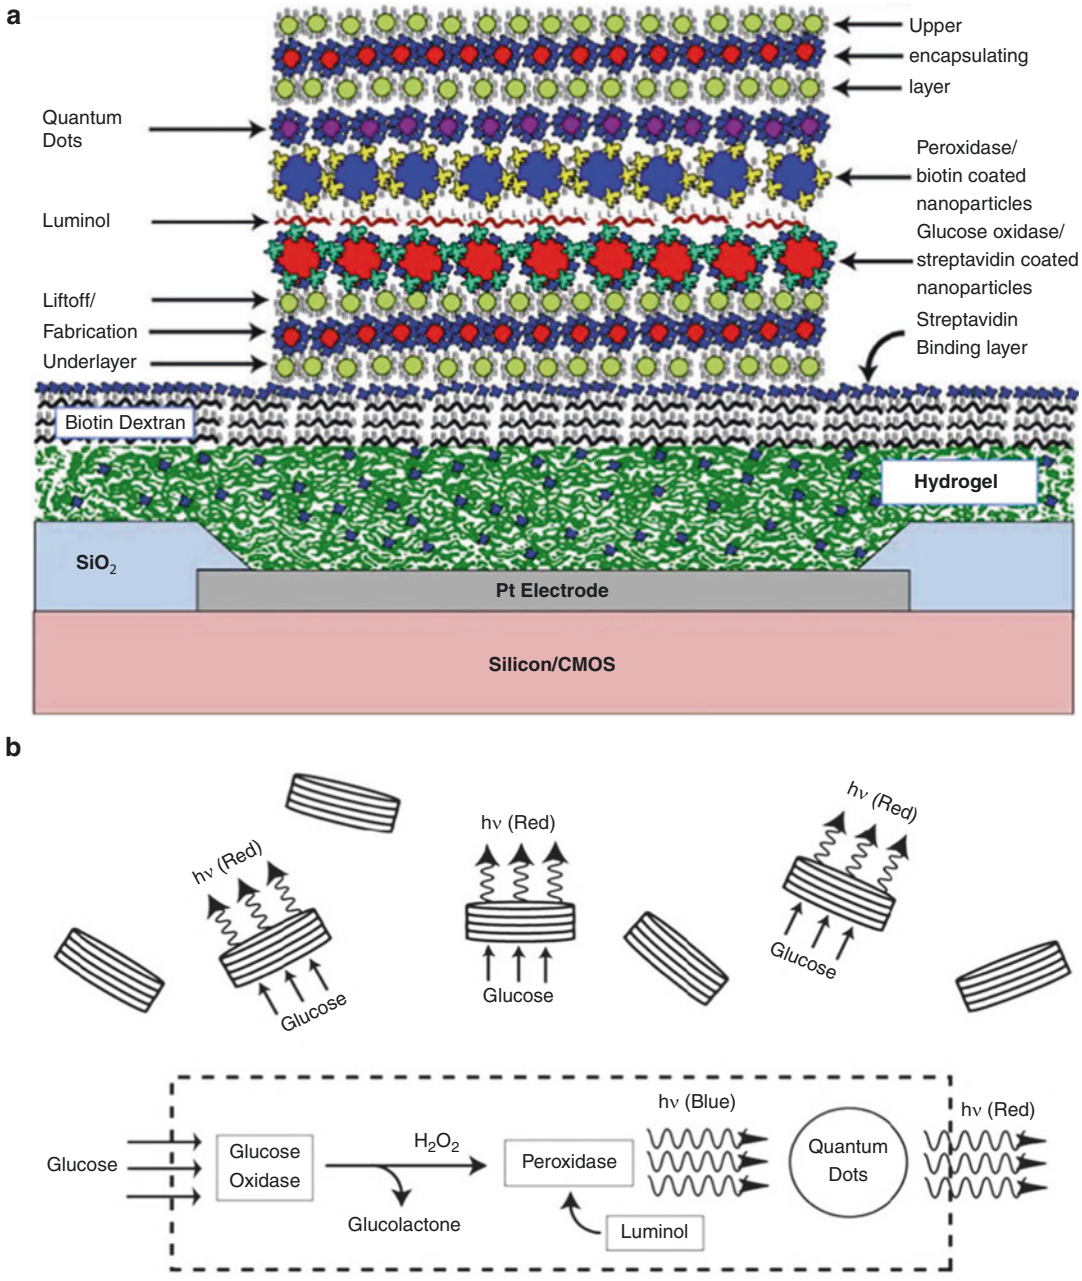
microarray to prevent crystallization of the histidine upon drying [19].

Procedure Multilayer Nanoparticle Depositions – The basic combinatorial directed deposition procedure is repeated in order to determine optimal conditions (current, voltage, and activation time) for producing best quality alternating layers of biotin and streptavidin nanoparticles. Template experiments can be used for determining nanoparticle layering conditions (which could be run on the same microarray in highly parallel manner). The first template experiment involves alternating the deposition of biotin 40 nm red fluorescent nanoparticles and streptavidin 40 nm yellow-green fluorescent nanoparticles in a grid type format. In this format, groups of columns of microelectrodes are set to different activation times (typically between 0 and 30 s), and the rows of microelectrodes are set to different current levels (0.025–0.4 μA in 0.0.025 μA increments). Several repeats of the combinatorial pattern are done across the whole microarray, and intervening columns of microelectrodes are left inactivated to serve as controls. This combinatorial approach allows for a relatively quick determination of the optimal time and current conditions necessary to achieve the best

deposition and layering. A second type of template experiment is used to determine the level of self-adhesion (nonspecific binding) between similar nanoparticles (biotin to biotin and streptavidin to streptavidin). This is carried out by having regions on the microarray only activated on alternate deposition cycles, when the same type of nanoparticle solution is exposed to the microarray. This experiment tests if the same type of nanoparticle would accumulate without the presence of its specific ligand binding partner. In these experiments, a single column per template is activated during every deposition to serve as a positive control for biotin-to-biotin nanoparticle binding and streptavidin-to-streptavidin nanoparticle binding. Additional columns of microelectrodes are not activated throughout the experiment, and serve as overall controls for more general nonspecific binding to the microarray. All of these experiments are monitored in real time and imaged by an epifluorescent microscope set at 540 nm emission for the yellow-green fluorescent nanoparticles and 610 nm emission for the red fluorescent nanoparticles. Imaging was carried out using a Hamamatsu Orca-ER camera [19].

Multilayer Biotin–Streptavidin Nanoparticle Structures – One of the main advantages of the electric field–directed self-assembly fabrication process is the ability to direct the streptavidin–biotin ligand binding to only occur on the specific microelectrodes which have been positively biased. Figure 4a shows a section of the 400 site CMOS microarray device where alternate rows of microelectrodes were used to carry out biotin–streptavidin nanoparticle layering. Rows with bright circular spots had 40 layers of alternating 40 nm red fluorescent biotin nanoparticles and 40 nm yellow-green fluorescent streptavidin nanoparticles deposited by applying a DC electric field. Rows with lighter circular spots had no electric field applied. Figure 4b shows a scanning electron microscope (SEM) image of a microelectrode which had no DC field applied. It can clearly be seen that no biotin nanoparticles have bound to this surface, despite the fact that it contains a streptavidin binding layer and has been exposed to the biotin nanoparticles 20 times. Figure 4c shows an SEM image of a microelectrode to which the DC electric field was applied. Nanoparticles have clearly been deposited on this surface. Multilayer nanostructures were verified by using SEM to image fractured cross sections of the 40 layer structures of alternating 40 nm red fluorescent biotin nanoparticles and 40 nm green fluorescent streptavidin nanoparticles (Fig. 4d). In other work, multilayer layers structures containing alternating 40 nm biotin nanoparticles and 200 nm streptavidin nanoparticles were fabricated. Figure 4e, f show the SEM image of cross sections of 40 layer structure of alternating 40 nm biotin nanoparticles and 200 nm streptavidin nanoparticles.

Multilayer DNA Nanoparticle Structures – In other work, electric field–directed hybridization was used to produce 20 layer nanostructures composed of DNA-derivatized nanoparticles [20]. Using the same CMOS electronic microarray device, DNA nanoparticles could be directed and concentrated such that rapid and specific hybridization occurs only on the activated sites. Nanoparticles layers were formed within 30 s of activation, and 20 layer structures were completed in under an hour. The results of this work carry significant implications for the future use of DNA nanoparticles for directed self-assembly nanofabrication of higher order structures. Advantages for using electric field directed fabrication of DNA nanoparticles include the following: First, the electric field process for the directed hybridization of DNA nanoparticles was significantly faster than the passive process; second, the electric field–directed process requires the use of only minimal concentrations of DNA nanoparticles, which would not be viable for passive hybridization process which requires much higher concentration of nanoparticles; third, the integrity of the biomolecular binding reactions (hybridization) and the ionic flux was maintained throughout the large number of process steps (20 depositions). Thus, high fidelity DNA hybridization and a large number/variety of unique DNA binding sequences can be used for nanofabrication; fourth, the higher order layered DNA nanoparticle structures can ultimately be removed from the microarray by a relatively simple lift-off procedure. Thus, an electric field array device can serve as a manufacturing platform for



Electric Field–Directed Assembly of Bioderivatized Nanoparticles, Fig. 4 *Results of electric field–directed nanoparticle assembly/layering on a microarray device*. (**a**) Shows a section of the 400 site CMOS microarray device where alternate rows of microelectrodes were used to carry out nanoparticle layering. making higher order 3D structures; and fifth, the overall process demonstrated the nanofabrication of higher order structures from a relatively heterogeneous group of materials, that is, biotin–dextran polymers, streptavidin, and two different sets of DNA nanoparticles.

Future Work

Some important potential future applications for the electric field–directed nanofabrication process include miniaturized chemical and biosensor devices, "micron-sized" dispersible chemo/

Electric Field–Directed Assembly of Bioderivatized Nanoparticles, Fig. 5 *Future glucose micro-biosensor device fabricated by electric field–directed assembly.* (**a**) The basic glucose micro-biosensor structure would include a bottom (lift-off) layer of biotin–streptavidin nanoparticles; a layer of glucose oxidase–streptavidin nanoparticles; a layer of luminol–dextran–biotin; a layer of streptavidin, a layer of peroxidase–biotin nanoparticles, a layer of *red* fluorescent streptavidin quantum dots, and a final upper capping layer of biotin–streptavidin nanoparticles. (**b**) When placed in a sample containing glucose, the glucose would diffuse into the micro-biosensor device and react with the glucose oxidase to produce hydrogen peroxide. The hydrogen peroxide and luminol diffusing to the peroxidase layer would catalyze the chemiluminescence (*blue light*). The *blue light* via fluorescent energy transfer to *red* fluorescent quantum dots would now produce detectable *red* fluorescence signal

biosensors for environmental and bioagent detection, lab-on a-chip devices, and in vivo diagnostic/drug delivery systems. Figure 5 shows the scheme for a future glucose micro-biosensor device fabricated using electric field–directed nanoparticle assembly. The basic glucose micro-biosensor structure would include a bottom (lift-off) layer of biotin–streptavidin nanoparticles; a layer of glucose oxidase–streptavidin nanoparticles; a layer of luminol–dextran–biotin; a layer of streptavidin, a layer of peroxidase–biotin nanoparticles, a layer of red fluorescent streptavidin quantum dots, and a final upper capping layer of biotin–streptavidin nanoparticles. When placed in a sample containing glucose, the glucose would diffuse into the micro-biosensor device and react with the glucose oxidase to produce hydrogen peroxide. The hydrogen peroxide and luminol diffusing to the peroxidase layer would catalyze the chemiluminescence (blue light). The blue light via fluorescent energy transfer to red fluorescent quantum dots would now produce detectable red fluorescence signal. This demonstrates that different fluorescent color responses could be created. Electronic array devices have other advantages including that they can be designed in a wide variety of shapes and sizes. To this end, larger "macroarray" devices have now been fabricated which can produce layered nanostructures with macroscopic dimensions. Figure 1e, f show a 4 in. silicon wafer size electric field array device. The total active deposition area for this device is 5 cm^2 with 200 platinum electrodes which are 2.5 × 2.5 mm with 8 μm gaps. Such "macroarray" devices will have applications for producing advanced fuel cells and photovoltaic materials. Overall electric field–directed nanofabrication using electronic array devices represents a unique synergy of combining the best aspects of "top-down" and "bottom-up" technologies into a viable nanofabrication process. It also represents a bio-inspired logic for self-assembly and hierarchal scaling of nanocomponents into integrated microscopic structures.

Definition

Electrical impedance cytometry is a technique whereby the dielectric or impedance properties of biological cells are measured. An externally applied electric field is used to probe the cell or sample of cells. This can be achieved either through the application of one or more discrete excitation frequencies or via broadband frequency measurement techniques. Typically, a potential is applied between a pair of electrodes and the resulting current flowing through the system is measured. The impedance of the system is the ratio of the voltage to the current passing through the system. The dielectric properties of the cells can be derived from this measurement through the use of appropriate models. The development of microfluidics and lab-on-a-chip type devices has allowed single cell impedance measurements to be performed with high sensitivity and high throughput.

Overview

The electrical measurements of biological samples has a long history dating back over a century to the pioneering work in the 1910s by Höber, who measured the low and high frequency conductivity of suspensions of erythrocytes [1]. A decade later Fricke described the electrical

properties of dispersive systems building on the work of Maxwell. Fricke was the first to measure the capacitive properties (8.1 mF/m^2) and thickness (3.3 nm) of the cell membrane – measurements which have subsequently been shown to be remarkably accurate [2]. The first single cell measurements were performed in the 1930s by Curtis and Cole [3].

Schwan [4] pioneered the field of biological impedance analysis; and was responsible for identifying the three main dielectric dispersions (α, β, γ) for suspensions of cells. These dispersions occur across a range of frequencies. The α-dispersion occurs at low-frequencies (~1 kHz) and arises from the polarization of the double layer around the particle. The β-dispersion occurs at intermediate frequencies (MHz) and arises from interfacial charging of the cell membrane. The γ-dispersion arises from the dipolar relaxation of water and occurs in the GHz range.

Experimental instrumentation and theoretical understanding have progressed in tandem, with highly sensitive techniques being developed, which allow the measurement of the dielectric properties of biological particles in fluid suspension. The majority of these techniques are however limited by the fact that they only provide an average value for the dielectric properties of a collection of particles. More recently, with the advent of micro- and nanofabrication techniques and the lab-on-a-chip, it has been possible to perform dielectric spectroscopic experiments on single biological particles suspended in physiological media.

This entry presents theory and models, which can be used to calculate the dielectric properties of cellular structures from impedance measurement. A practical realization of a single cell impedance measurement system is also presented along with data describing the electrical properties of single cells flowing in fluid suspension. Electrical measurement of cells growing on substrates and other more traditional bulk dielectric spectroscopy techniques (which measure the averaged properties of 100,000 s of cells) is not covered; much theoretical and experimental data is available for these techniques. Such techniques are robust and well characterized with a number of commercial systems available.

Theoretical Background

Maxwell Mixture Theory

The single-shelled spherical model can be used to describe a cell in suspension. Figure 1a shows the spherical model of a cell comprising a single shell; the dielectric and geometrical parameters are shown.

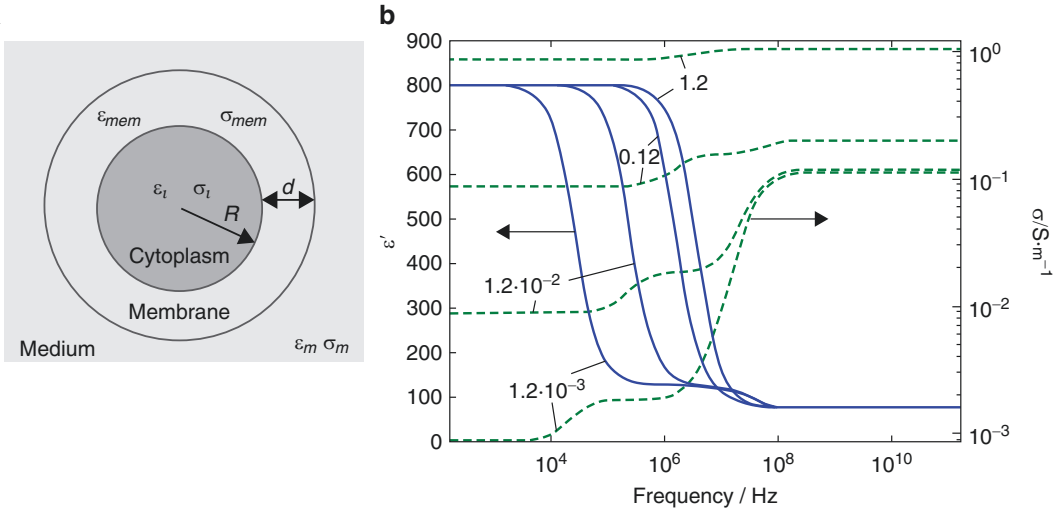
The impedance of a dilute suspension of particles in a uniform electric field can be calculated in terms of individual particle dielectric properties by Maxwell's mixture theory; where the equivalent complex permittivity $\tilde{\varepsilon}_{mix}$ of a mixture of particles and suspending medium is given by:

$$\tilde{\varepsilon}_{mix} = \tilde{\varepsilon}_m \frac{1 + 2\Phi\tilde{f}_{CM}}{1 - \Phi\tilde{f}_{CM}} \tag{1}$$

where

$$\tilde{f}_{CM} = \frac{\tilde{\varepsilon}_p - \tilde{\varepsilon}_m}{\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m} \tag{2}$$

and $\tilde{\varepsilon} = \varepsilon - j\sigma/\omega$ is the complex permittivity, the subscripts m and p refer to the medium and particle respectively, $i^2 = -1$, ω the angular frequency, $\tilde{f}_{CM}$ is the Clausius-Mossotti and Φ is the volume fraction.



The complex permittivity of the cell, $\tilde{\varepsilon}_p$ is a function of the dielectric properties of membrane and cytoplasm, cell membrane $\tilde{\varepsilon}_{mem}$ and internal properties $\tilde{\varepsilon}_{cyto}$, and cell geometry (where R is the inner radius and d the membrane thickness) given by:

$$\tilde{\varepsilon}_p = \tilde{\varepsilon}_{mem} \frac{\gamma^3 + 2\left(\frac{\tilde{\varepsilon}_{cyto} - \tilde{\varepsilon}_{mem}}{\tilde{\varepsilon}_{cyto} + 2\tilde{\varepsilon}_{mem}}\right)}{\gamma^3 - \left(\frac{\tilde{\varepsilon}_{cyto} - \tilde{\varepsilon}_{mem}}{\tilde{\varepsilon}_{cyto} + 2\tilde{\varepsilon}_{mem}}\right)} \tag{3}$$

where

$$\gamma = \frac{R + d}{R} \tag{4}$$

This is only valid for dilute suspensions ($\Phi < 10$ %). Interaction between the particles

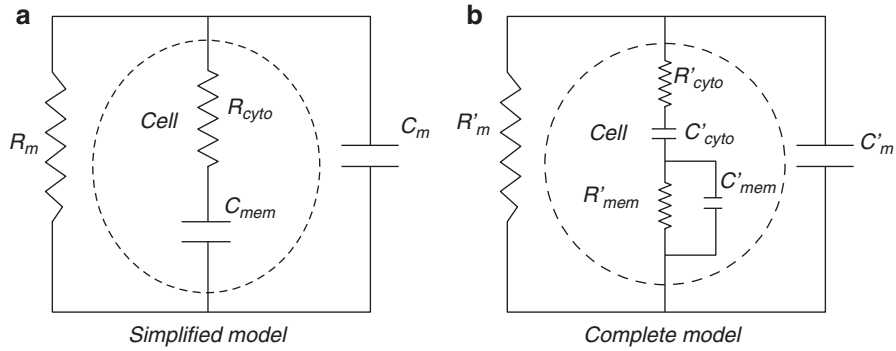
Electrical Impedance Cytometry, Fig. 1 (**a**) Single-shell electrical model of the spherical cell in suspension. (**b**) Plot showing the real and imaginary parts of the CM. The following parameters were used: $\varepsilon_o = 8.854 \times 10^{-12}$ F.m^{-2}, $R = 3 \times 10^{-6}$ m, $d = 5 \times 10^{-9}$ m, $\varepsilon_m = 80 \times \varepsilon_o$, $\varepsilon_{mem} = 5 \times \varepsilon_o$, $\sigma_{mem} = 10^{-8}$ S.m^{-1}, $\varepsilon_\iota = 60 \times \varepsilon_o$, $\sigma_\iota = 0.4$ S.m^{-1} and the medium conductivity varied between $\sigma_m = 1.2 \times 10^{-3}$ S.m^{-1} and 1.2 S.m^{-1}

must be taken into account for higher particle concentrations. The mixture theory can be extended to high volume fractions:

$$1 - \Phi = \left(\frac{\tilde{\varepsilon}_{mix} - \tilde{\varepsilon}_p}{\tilde{\varepsilon}_m - \tilde{\varepsilon}_p}\right)\left(\frac{\tilde{\varepsilon}_m}{\tilde{\varepsilon}_{mix}}\right)^{1/3} \quad (5)$$

The impedance of the system is related to the complex permittivity as follows:

$$\tilde{Z}_{mix} = \frac{1}{j\omega\tilde{\varepsilon}_{mix}} G_f \quad (6)$$



where G_f is a geometric constant, which for an ideal parallel plate electrode system is simply the ratio of electrode area to gap A/g (m). Combining Eq. 6 with Eq. 1 allows the complex permittivity of a suspension of cells to be determined from the frequency-dependent impedance measurements. Typically, a cell suspension is measured using macroscopic planar or cylindrical electrode geometries where G_f can be easily defined. This is not the case for single cell impedance analysis, where the cell is located between a pair of microelectrodes of comparable size to that of the cell (ca. 10–20 μm). In this case the electric field is not uniform and the effect of the divergent field (fringing field) must be considered to correctly model the impedance. This involves detailed analysis of the field geometry and a modification to G_f [5, 6]. It is possible to use more complex electrode geometries, incorporating guard electrodes to confine the electric field and simplify the analysis; however, this requires careful electrode design and complicates the fabrication process.

Equivalent Circuit Model

For simplified analysis of the system, an electrical circuit analog is often used. Such an approach was first developed by Foster and Schwan [7]. The cell can be described in terms of an equivalent circuit model, as shown in Fig. 2.

Simplified Circuit Model

To a first level of approximation, the cell can be modeled as a resistor that describes the cytoplasm in series with a capacitor for the membrane as shown in Fig. 2a. The cell membrane resistance is generally much greater than the reactance of the membrane and can therefore be ignored. Likewise, the capacitance of the cell cytoplasm can be ignored when its reactance is small compared to the cell cytoplasm resistance. The values of the

Electrical Impedance Cytometry, Fig. 2 Foster and Schwan's simplified circuit model for a single cell in suspension. (**a**) The cell is modeled as a resistor R_{cyto} (cytoplasm) and a capacitor C_{mem} (membrane) in series, with the suspending medium modeled as a resistor R_m and capacitor C_m. (**b**) The complete circuit model for a single-shelled particle in suspension. The particle is modeled as a resistor $R'c_{yt}$o and a capacitor $C'c_{yto}$ in series (cytoplasm) in combination with a resistor R'_{mem} and a capacitor C'_{mem} in parallel (membrane) (Adapted with permission from Sun et al. 2012, © 2010, Springer) [12]

electrical components in the simple model circuit are given below. The suspending medium is described by:

$$R_m = \frac{1}{\sigma_m(1 - 3\Phi/2)G_f} \tag{7}$$

$$C_m = \varepsilon_\infty G_f \tag{8}$$

The simplified cell components are given by:

$$C_{mem} = \frac{9\Phi R C_{mem,0}}{4} G_f \tag{9}$$

$$R_{cyto} = \frac{4\left(\frac{1}{2\sigma_m} + \frac{1}{\sigma_{cyto}}\right)}{9\Phi G_f} \tag{10}$$

with specific membrane capacitance (per unit area)$C_{mem,0} = \varepsilon_{men}/d$. The limiting high frequency permittivity of the suspension is related to the suspending medium permittivity according to:

$$\varepsilon_\infty \simeq \varepsilon_m \left[1 - 3\Phi \frac{\varepsilon_m - \varepsilon_{cyto}}{2\varepsilon_m + \varepsilon_{cyto}}\right] \tag{11}$$

This simplified circuit model has been used to interpret single cell impedance measurements providing good agreement with experiments (e.g., see Fig. 4).

Complete Circuit Model

For cases where the cell membrane conductance and cytoplasm capacitance values vary widely and cannot be ignored (e.g., during electroporation or cell lysis), a complete equivalent circuit model is required. This includes the resistance of the membrane and the capacitance of the cytoplasm. The complete circuit model is shown in Fig. 2b and the equations are given below. The suspending medium is described by:

$$R'_m = \frac{1}{\sigma_0 G_f} \tag{12}$$

$$C'_m = \varepsilon'_\infty G_f \tag{13}$$

The complete model cell components are described by:

$$R'_{mem} = \frac{1}{G_f}\left[\frac{\tau_1 + \tau_2}{\Delta\varepsilon_1 + \Delta\varepsilon_2} - \frac{1}{k_2 + k_3} - \frac{\tau_1\tau_1(k_2 + k_3)}{(\Delta\varepsilon_1 + \Delta\varepsilon_2)^2}\right] \tag{14}$$

$$C'_{mem} = \frac{\tau_1\tau_2(k_2 + k_3)}{(\Delta\varepsilon_1 + \Delta\varepsilon_2)R'_{mem}} \tag{15}$$

$$R'_{cyto} = \frac{1}{(k_2 + k_3)G_f} \tag{16}$$

$$C'_{cyto} = (\Delta\varepsilon_1 + \Delta\varepsilon_2)G_f \tag{17}$$

where R'_{mem} and C'_{mem} are the resistance and capacitance of the cell membrane, respectively. R'_{cyto} and C'_{cyto} are the resistance and capacitance of the cell cytoplasm, respectively. Full details of the above equations can be found in [8, 9].

Coulter Counter

Resistive pulse sensors are a specific case of the impedance cytometer. More commonly known as the Coulter counters, the technique measures the DC resistance between two electrically isolated fluid-filled chambers and the change in this current as a particle passes through a small connecting orifice [10]. Two large electrodes are positioned at either side of the orifice. As a particle passes through the orifice it displaces the conductive fluid and alters the resistance, this change results in a current pulse, the magnitude of which is proportional to the cell size. A simplified analysis of the Coulter counter was presented by Deblois and Bean [11]. The resistance of a tube, diameter D_t, length L_t, filled with electrolyte of resistivity ρm is:

$$R_t = \frac{4\rho_m L_t}{\pi D_t^2} \tag{18}$$

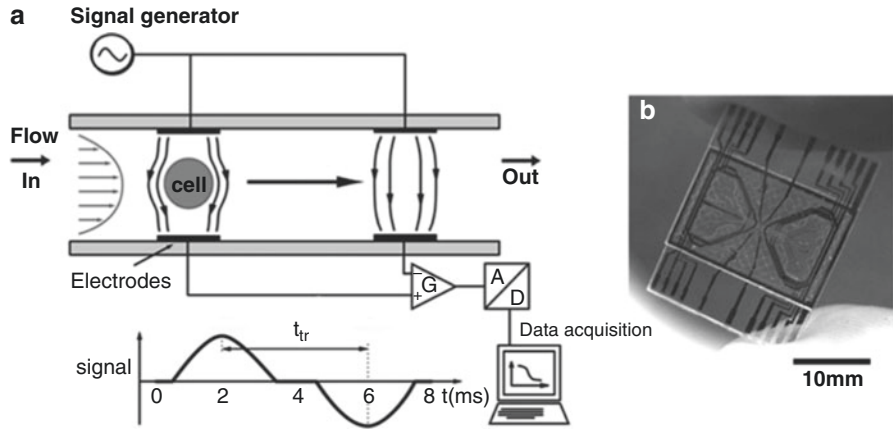
Sun et al. [12] showed that Maxwell's approximation can be used to evaluate the resistance of the tube containing a spherical particle (diameter d_p), giving an expression for the resistance, R_{mix} of a particle suspension:

$$R_{mix} = \frac{4\rho_{mix} L_t}{\pi D_t^2} = \frac{4\rho_m L_t}{\pi D_t^2}\left(1 + \frac{d_p^3}{D_t^2 L_t}\right) \tag{19}$$

The resistance change ΔR due to the particle is given by:

$$\Delta R = R_{mix} - R_t = \frac{4\rho_m d_p^3}{\pi D_t^4} \tag{20}$$

This expression is based on the assumption that the particle diameter is small compared with the tube (i.e., $\Phi << 1$), but ignores other issues such as access resistance to the tube. A solution with applicability over a broader range was given by Deblois and Bean [11]:



$$\Delta R_{(D_t/L_t<<1)} = \left(\frac{4\rho_m d_p^3}{\pi D_t^4}\right) \cdot F\left(\frac{d_p^3}{D_t^3}\right) \tag{21}$$

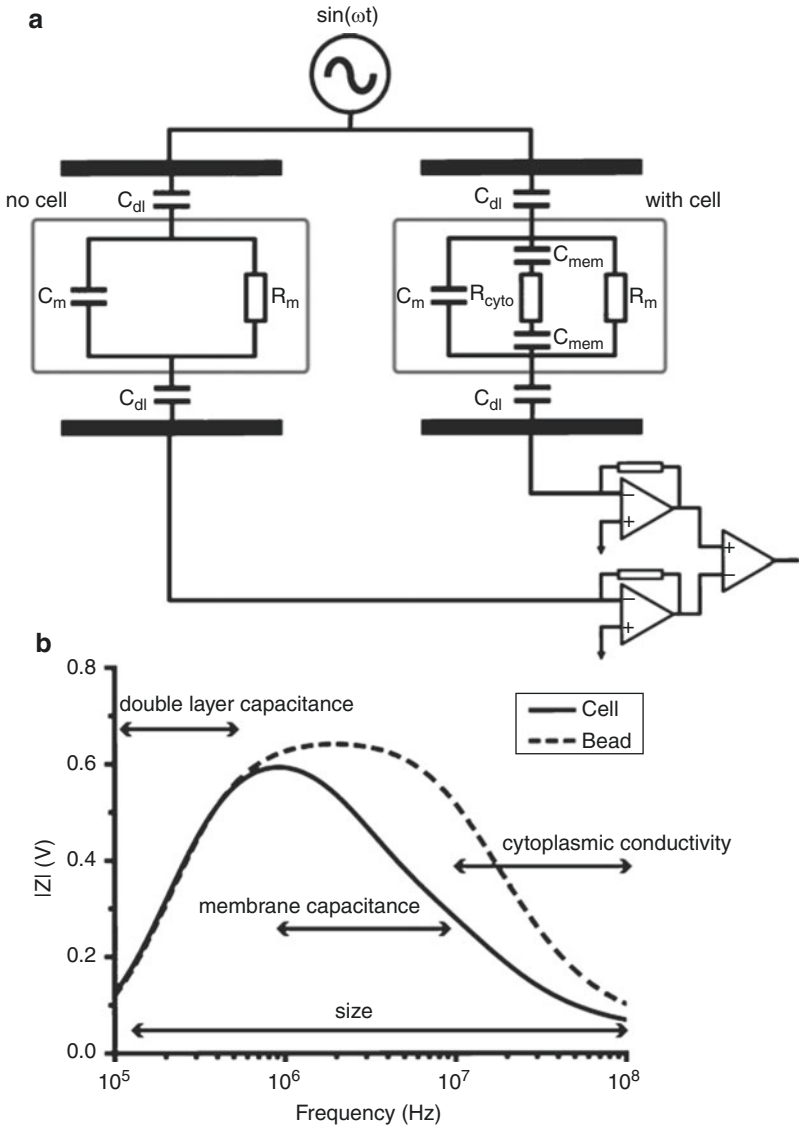
where $F(d_p{}^3/D_t{}^3)$ is a correction term that accounts for the nonuniformity of the current density within the tube.

Basic Methodology

The most successful implementation of a microfluidic impedance cytometry chip, in terms of measurement sensitivity and accuracy, is that of the facing electrode geometry as proposed by Gawad [13]. Other geometries have been implemented such as planar electrode geometries [14] and the so-called liquid electrodes [15]. The facing electrode implementation of a single cell impedance measurement system is shown in Fig. 3a. Electrodes on the upper and lower walls of the microfluidic channel are connected to an AC voltage source, which provides excitation signals at one or more frequencies. To minimize signal noise and drift a differential measurement is performed. The current flowing in the system is measured as a cell passes from one arm of the sensing circuit (two electrode pairs) to the other. The transit time between peaks, *ttr* allows the particle velocity to be monitored, giving information about particle position within the channel and sample flow rates. An example of a microfluidic impedance cytometry chip is shown in Fig. 3b; the chip is constructed from glass substrates with platinum microelectrodes and channel sidewalls formed in polymer. The upper and lower channel walls (glass) allow for microscope observation of cells flowing though the device.

A simplified schematic of the impedance detection system is shown in Fig. 4. A differential detection circuit is used. The electrode pair on the left of Fig. 4a illustrates the equivalent circuit model for the detection region with no cell between the electrodes, the right electrode pair

Electrical Impedance Cytometry, Fig. 3 (**a**) Schematic diagram showing the implementation of a single cell impedance measurement system. Electrodes on the upper and lower walls of the microfluidic channel are connected to an AC voltage source (providing excitation at one or more frequencies). The differential current flowing in the system is measured as a cell passes from one arm of the sensing circuit to the other. The transit time between peaks, t_{tr} allows the particle velocity to be monitored. (**b**) Photograph of a microfluidic impedance chip



has the cell between the electrodes. As described above, R_m and C_m are the equivalent resistance and capacitance of the medium, respectively, C_{mem} is the equivalent capacitance of the cell membrane, and R_{cyto} is equivalent resistance of the cell cytoplasm. C_{dl} represents the electrical double layer capacitance at the electrode–liquid interface. The impedance magnitude from a polymer bead (i.e., an insulating particle) and a cell of the same diameter are shown in Fig. 4b including a graphical indication of the frequency ranges over which the different structures of the cell have an influence on the impedance signal [16].

Key Research Findings

Single Cell Impedance Cytometer for Blood Analysis

One of the most commonly ordered tests in the doctor's office is complete blood count (CBC). Although simple and relatively inexpensive, this test is a very effective screening tool for a wide range of conditions. For example, a lower number of red blood cells could indicate anemia. A higher number of neutrophils could indicate an infection in progress, while changes in the number of lymphocytes could reveal diseases. Current standards for CBC follow stringent requirements for quality control and other regulations and rely on automated machines located either in hospitals or centralized laboratories. Impedance-based counting of white blood cells and differentiating the major subtypes has been demonstrated and has the potential to replace the bulky hematology analyzers, currently only available in hospitals and centralized research labs.

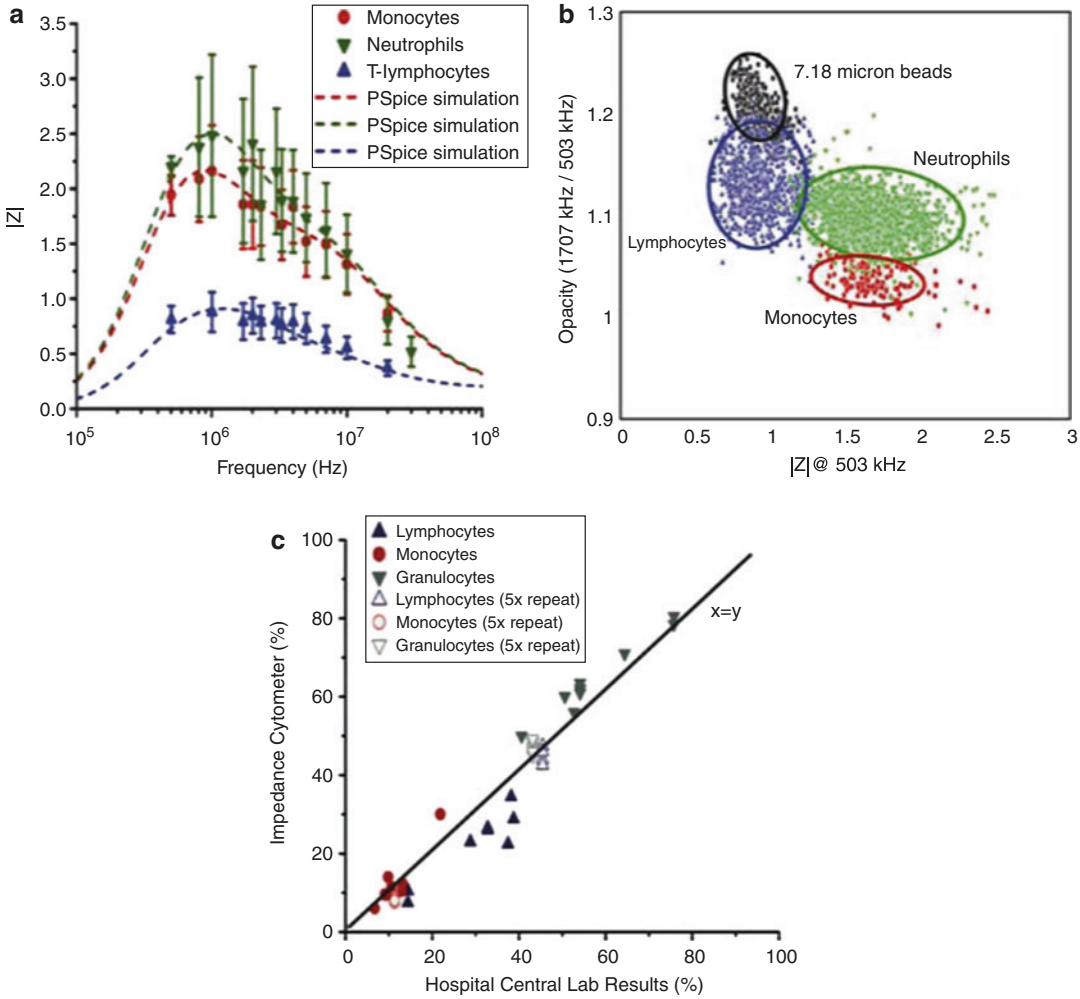


Figure 5a shows the impedance magnitude versus frequency for purified leukocyte subpopulations (T-lymphocytes, monocytes, and neutrophils). The mean and standard deviation of ~1,500 cells is plotted at each frequency point. The dashed lines in the plot show the best-fit circuit simulation (using PSPICE) incorporating the equivalent circuit model, electrical double layer, and differential amplification electronics of the system. Figure 5b shows the impedance-based analysis of clinical samples; the lymphocyte, neutrophil, and monocyte populations are clearly visible. Tests with patient samples are presented in Fig. 5c and show 95 % correlation against commercial (optical/Coulter) blood analysis equipment, demonstrating the potential clinical utility of the impedance microcytometer for a point-of-care blood analysis system [16].

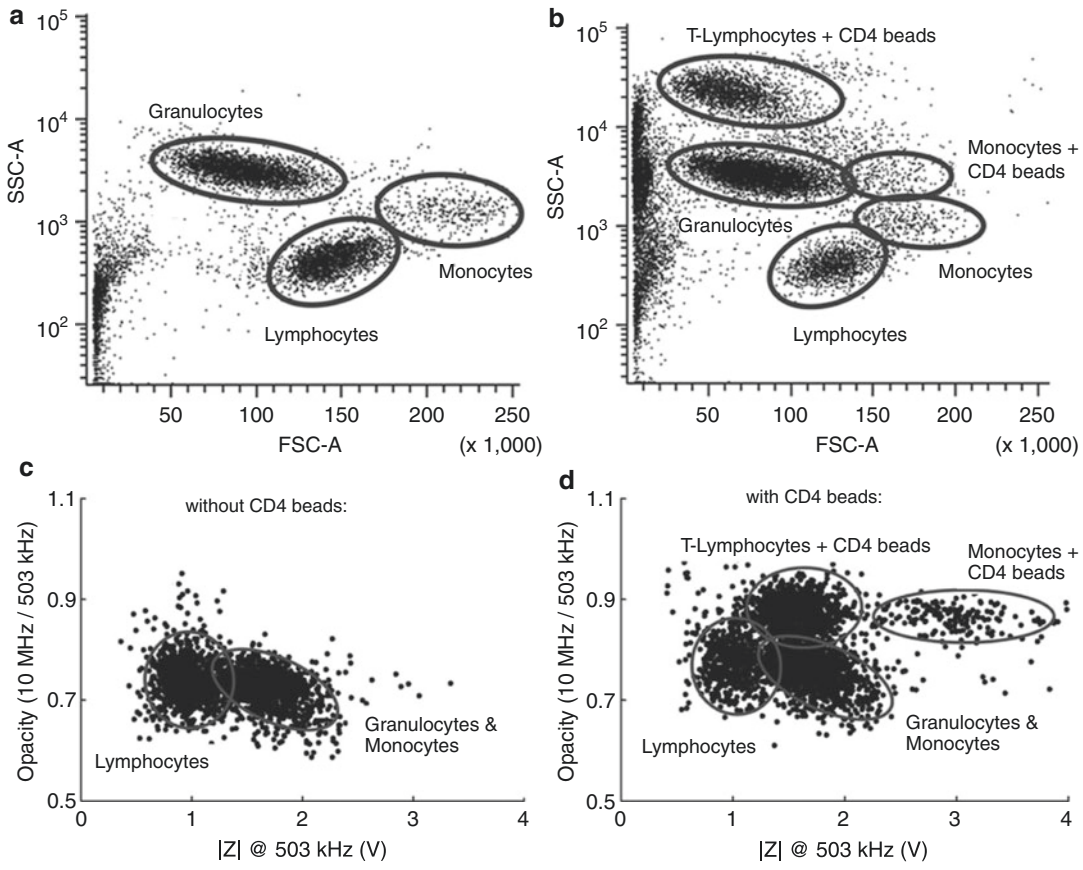
Electrical Impedance Cytometry, Fig. 4 (**a**) Simplified schematic of the impedance detection system shows the differential detection system. The electrode pair on the *left* illustrates the equivalent circuit model with no cell between the electrodes; the *right* electrode pair has the cell between the electrodes. R_m and C_m are the equivalent resistance and capacitance of the medium, respectively, C_{mem} is the equivalent capacitance of the cell membrane, R_{cyto} is equivalent resistance of the cell cytoplasm. C_{dl} represents the electrical double layer capacitance at the electrode–liquid interface. (**b**) The frequency-dependent impedance magnitude from a polymer bead (i.e., an insulating particle) and a cell of the same diameter (Adapted with permission from Holmes et al. 2009, copyright © 2009, RSC) [16]



Impedance Labeling for Impedance Discrimination Based on Antigenic Expression

Electrical impedance cannot detect different antigen expressing cell subtypes with similar morphology; however, a method analogous to fluorescent antibody labeling was recently demonstrated which allows the discrimination of antigenically specific white blood cells [17].

Electrical Impedance Cytometry, Fig. 5 (**a**) Data showing the impedance magnitude versus frequency for purified leukocyte subpopulations (T-lymphocytes, monocytes, and neutrophils). The mean and standard deviation of ~1,500 cells is plotted at each frequency point. The *dashed lines* show the best fit circuit simulation incorporating the equivalent circuit model, electrical double layer, and differential amplification electronics. (**b**) Data showing discrimination of leukocyte subpopulations from clinical blood sample. (**b**) Comparison of impedance-based blood analysis with hospital central lab analysis using a traditional hematology analyzer (Adapted with permission from Holmes et al. 2009, copyright © 2009, RSC) [16]

This was demonstrated through the impedance identification of lymphocyte subset expressing the CD4 surface protein. A suspension of blood cells was mixed with micron sized polymer beads coated with an antibody that specifically recognizes the CD4 antigen. The beads bind to the CD4 expressing cells (T-lymphocytes and monocytes), and in doing so change the impedance properties of these cells. Figure 6 shows the same blood sample with and without the addition of CD4 impedance labels. The bead complexed cells can be clearly seen as separate population on the scatter plot. The T-lymphocyte and monocyte populations are easily discriminated from one and other due to the larger size of the monocytes. The use of labels to selectively alter the impedance properties of certain cell subpopulations brings the molecular specificity of antibody labeling techniques to electrical cell discrimination.

Electrical Impedance Cytometry, Fig. 6 (**a**) FACS data for saponin-lysed whole blood showing the three dominant leukocyte subpopulations. Some debris from the *red* cells is also visible, but the granulocyte and lymphocyte populations can be clearly identified, together with the smaller monocyte population (note axis on log scale). (**b**) The same blood sample complexed with CD4 beads, showing two new populations, the CD4+ T-lymphocytes and the subpopulation of monocytes that bind the beads. (**c**, **d**) show scatter plots from the impedance cytometer. The x-axis shows impedance measured at 503 kHz, which is a measure of cell size, and the y-axis shows the opacity (ratio of impedance at 10 MHz and 503 kHz). The CD4+ cell subpopulations are clearly visible in the impedance plot shown in (**d**) and are comparable with (**b**) (Adapted with permission from Holmes et al. 2010, copyright © 2010, ACS) [17]

Future Directions of Research

Impedance measurements represent a powerful noncontact method of analysis, with the potential to extract a wealth of information relating to the physiological and morphological properties of cells and other microscopic particles. The fact that the technique can probe cellular structures and extract information without the need for labeling makes it appealing for a range of diagnostic and other metrology applications where labeling can be expensive and may modify the cells under investigation (e.g., cell labeling can lead to activation).

Extension of the frequency range of the current impedance cytometry techniques to both higher and lower frequencies will allow probing of surface and internal properties of cells. Low-frequency (~1 kHz) measurement of the α-relaxation of cells is an important area of research, which has been poorly investigated to date due to the lack of experimental tools. High frequency (<50 MHz) measurements will allow probing of the intracellular compartment; current

methods rely upon suspending cells in buffer of low conductivity to enhance the signal response and shift the membrane relaxation to lower frequencies (i.e., within the frequency response of the experimental apparatus). Impedance measurement of the cytoplasmic compartment will allow label-free monitoring of cell cycle, intracellular parasite detection (e.g., malaria), and a host of other biophysical measurements. Broadband frequency measurements have been implemented allowing full impedance spectra to be obtained rapidly and accurately [18].

Scaling down of impedance detection systems to allow measurements to be performed on viruses and other nanoparticles may be possible. A number of nonmammalian cell types have been measured using impedance cytometry (e.g., bacteria [19], marine algae [20]), and this combined with the integration of powerful sample preparation techniques and particle focusing will lead to the development of a range of powerful, robust, and portable devices, which will have relevance to a broad range of environmental, clinical, and life science applications.

Definition

Electrical impedance tomography (EIT) is an imaging technology that spatially characterizes the electrical properties of an object. It is an inverse problem: Given an object with unknown electrical properties, reconstruction of an image requires determination of the internal conductivity (or permittivity) profile of the object from a finite number of boundary measurements (current/voltage).

Introduction

The integration of mechanical elements, sensors, actuators, and electronics on a common substrate is known as Micro-Electro-Mechanical-Systems (MEMS). BioMEMS is a multidisciplinary subject across science and engineering and includes mathematics, biophysics, biochemistry, electrochemistry, microfluidics, micro/nano fabrication, integration, materials and surfaces, synthesis and detection technologies, accepted as a new concept – "Lab-On-a-Chip." For quantitatively understanding the functioning of the tissue and organisms, working at the cellular level is of prime interest for biomedical and clinical applications. Cellular analysis requires a combination of biophysical and biochemical approaches. Traditional analysis is performed with bulk techniques. However, measurements on large populations of cells can only provide average information. Individual cells, which look identical in appearance, generally have heterogeneous behavior. Moreover, the limitations of bulk techniques for studying the cell-to-cell and cell-to-surface interactions are apparent. Therefore, considerable attention is now paid to single cell analysis using microfluidic technologies [1].

Electrical impedance spectroscopy [2, 3] is a high-speed, noninvasive technique that is used to characterize the dielectric properties of biological cells. In the simplest sense, a biological cell consists of a conducting cytoplasm (with nucleus) covered by an ultrathin insulating cell membrane. When exposed to an ac electric field, at low frequencies the cell behaves as an insulating object. The cell membrane is equivalent to a capacitor and prevents the electric field lines from penetrating the cell. Therefore, information concerning cell size (and shape) can be obtained by measuring the electrical properties of the cell at low frequencies. At higher frequencies, the cell membrane electrically becomes short-circuited. Thus, the internal properties of the cell (i.e., cytoplasmic resistance) can be probed. For adherent cells, the kinetics during culture, such as cell growth, differentiation, and the effect of drugs can be monitored using electrical impedance. Cells are grown on the surface of an array of electrodes and the impedance is monitored as a function of time. This technique is termed electric cell-substrate impedance sensing [4].

In electrical impedance tomography (EIT) [5], measurements of a sample are made between multiple electrodes. The technique generates images of the conductivity distribution inside an object. Although, the spatial resolution of EIT cannot be compared with magnetic resonance imaging, the technique is harmless, less costly, and has good temporal resolution.

Electrical Impedance Tomography

EIT is an inverse problem: Given an object with unknown electrical properties, reconstruction of an image requires determination of the internal conductivity (or permittivity) profile of the object from a finite number of boundary measurements (current/voltage). The theory of EIT is composed of two parts: the forward problem and the inverse problem. The forward problem corresponds to the calculation of the potentials on the electrodes for a known injected current and conductivity distribution. Solving the forward problem involves constructing the global Jacobian (sensitivity) matrix of the system, which is required for image reconstruction and the solution of the inverse problem. For EIT, the electric field distribution in considered quasi-electrostatic. If only low frequency ac is used, the analysis is restricted to mapping the conductivity distribution of the object. Therefore, the electrical potentialϕ, satisfies Laplace's equation:

$$\nabla \bullet \sigma \nabla \phi = 0 \tag{1}$$

Equation 1 gives a unique solution for the electric potential distribution, if the boundary conditions are defined. The forward problem is well-posed in terms of existence, uniqueness and stability. However, in the case of EIT, since the potential distribution is dependent on the conductivity distribution, it cannot be solved analytically for arbitrary values of σ. Therefore, a general approach is to set up a numerical model that can simulate the potential values on the electrodes as close as possible to the measured voltage data in an experiment. The numerical model discretizes the domain into small elements so that an approximate solution can be obtained. Using the finite element method (FEM) with the defined boundary conditions, the governing equation of the system is:

$$\mathbf{A}\begin{bmatrix}\phi_p \\ V_l\end{bmatrix} - \begin{bmatrix}0 \\ 1\end{bmatrix} \text{ with } \mathbf{A} = \begin{bmatrix}\mathbf{A}_C & \mathbf{A}_E \\ \mathbf{A}_E^T & \mathbf{A}_D\end{bmatrix} \tag{2}$$

where $\mathbf{A}$ is the global admittance matrix of the system. The expressions of the compartments $\mathbf{A}C$, $\mathbf{A}E$, and $\mathbf{A}D$ can be found in [6]. The potential on every node ϕp in the finite element model and the voltage on every electrode Vl can be obtained by solving Eq. 2.

Image reconstruction requires the knowledge of the conductivity distribution. In EIT, the changes in conductivity σq within the domain, and the changes in the potential distribution ϕp are linked by the Jacobian (sensitivity) matrix $\mathbf{J}p,q$:

$$\mathbf{J}_{p,q} = \frac{\partial \phi_p}{\partial \sigma_q} \tag{3}$$

The inverse problem corresponds to calculation of the conductivity distribution when the injected current is known and the voltages are measured. It is "ill-posed" since the solutions of the inverse problem are not unique. The process of solving the inverse problem requires finding a stable value of σ, so that the difference between the numerical simulations $\phi(\sigma)$ and the measured voltage V is minimized.

$$f(\sigma) = \frac{1}{2}(\phi(\sigma) - V)^*(\phi(\sigma) - V) = \frac{1}{2}||\phi(\sigma) - V||^2 \tag{4}$$

To find the minima of the objective function $f(\sigma)$, a Taylor series is used to expand $f(\sigma)$, neglecting higher-order terms in Eq. 6:

$$f(\sigma + \Delta\sigma) = f(\sigma) + f'(\sigma)\Delta\sigma + \frac{1}{2}f''(\sigma)\Delta\sigma^2 \tag{5}$$

Using the Newton–Raphson method to search for a step $\Delta\sigma$, such that $f(\sigma + \Delta\sigma) \cong 0$, the iterative solution of Eq. 5 is:

$$\sigma_{n+1} = \sigma_n + \Delta\sigma \quad n > 0 \tag{6}$$

$$\Delta\sigma = -[Hf(\sigma_n)]^{-1}\nabla f(\sigma_n) \tag{7}$$

where $Hf(\sigma n)$ is the Hessian matrix and $\nabla f(\sigma n)$ is the gradient, given by:

$$\Delta f(\sigma) = f'(\sigma) = \phi'(\sigma)^*(\phi(\sigma) - V) \tag{8}$$

$$Hf(\sigma) = \phi'(\sigma)^*\phi'(\sigma) + \phi''(\sigma)(\phi(\sigma) - V) \tag{9}$$

For simplicity, the second-order derivative term in Eq. 9 can be neglected. Therefore, the expression for the adjusting step $\Delta\sigma$ becomes Eq. 6:

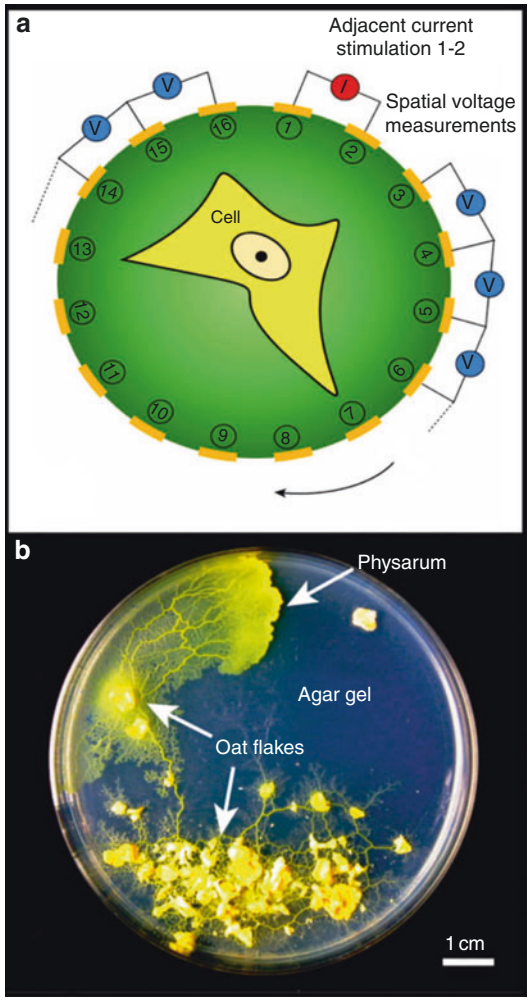
$$\begin{aligned}\Delta\sigma &= -[\phi'(\sigma)^*\phi'(\sigma)]^{-1}\phi'(\sigma)^*(\phi(\sigma)-V)\\ &= \phi'(\sigma)^{\dagger}(V-\phi(\sigma))\end{aligned} \tag{10}$$

where $\phi'(\sigma)^{\dagger}$ is the Moore–Penrose pseudo-inverse of $\phi'(\sigma)$, which is the inverse of the Jacobian matrix (Eq. 3).

The solutions given by Eqs. 6 and 10 are based on the Gauss–Newton algorithm. Other algorithms can be used to minimize Eq. 4. For example, the linear generalized Tikhonov regularization can be encapsulated into the Gauss–Newton algorithm, which gives calculation of $\Delta\sigma$ as:

$$\Delta\sigma = \left[\phi'(\sigma)^*\phi'(\sigma)+\lambda^2R^*R\right]^{-1}\left(\phi'(\sigma)^*V+\lambda^2R^*R\sigma\right) \tag{11}$$

where R is either the identity matrix or other regularization matrix including certain *image prior* assumptions about σ for reconstruction. λ is a positive scalar regularization parameter.



Over the past 20 years, a large number of reconstruction algorithms have been developed to improve the computational efficiency, reconstruction sensitivity, and image fidelity. Examples include the modified Newton–Raphson method, back-projection algorithm, variational method, maximum a posteriori approach, Monte Carlo sampling method, and direct reconstruction algorithms. Most biomedical and clinical uses of EIT are in vivo and used to detect disease such as breast cancer [7] or to monitor brain function [8]. Interest has centered on in vitro applications, e.g., Davalos et al. [9] proposed using EIT for detecting and imaging electroporation of cells in tissue in real time. Recently, there has been an interest in miniaturizing the technology. Hou et al. [10] patterned 32 electrodes in a rectangular configuration to provide a two-dimensional map of the conductivity of carbon nanotube thin films. Chai et al. [11] fabricated a set of 4 × 4 complementary metal oxide semiconductor microelectrode array to image a cell culture environment. Linderholm et al. [12] used an array of interdigitated electrodes to monitor the migration, stratification, and influence of detergent on cells in culture.

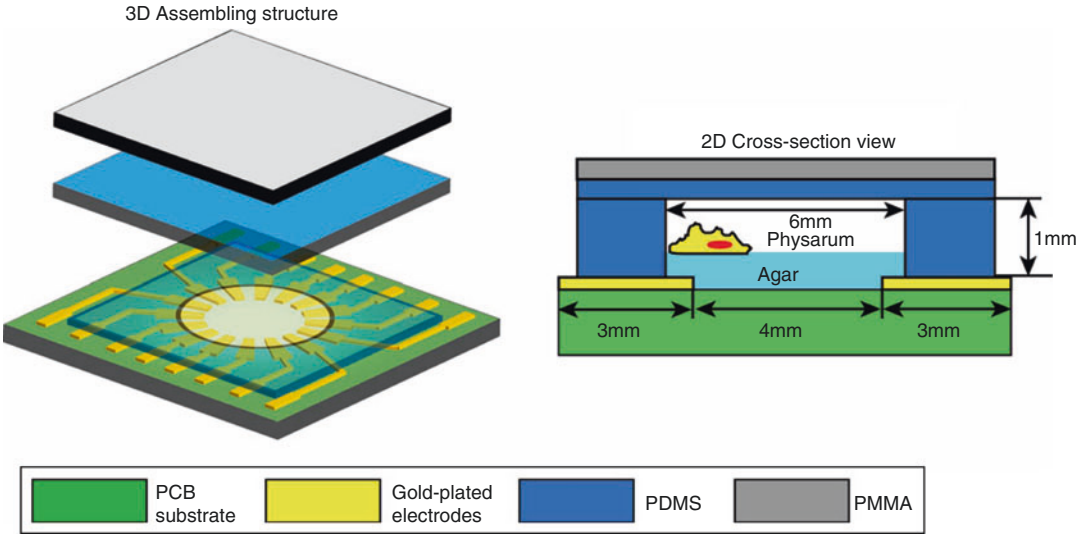
EIT for Single Cell Imaging

Individual cells can be identified from differences in size and dielectric properties using electrical techniques. Recently, an on-chip two-dimensional cell imaging technology using EIT was developed [13]. The cell can be cultured at any position within the circular array for imaging (Fig. 1). To perform EIT, a stimulating signal is injected through one pair of electrodes and the voltage across all sequential electrode-pair combinations measured. The electrical stimulations and measurements are noncontact to the cell. The perturbation in the conductivity distribution in the system is characterized by the voltage data, and images the cell are reconstructed using software termed "Electrical Impedance Tomography and Diffuse Optical Tomography Reconstruction Software," EIDORS [14]. The first step toward single cell impedance tomography was demonstrated by imaging a large multinuclear single-cell organism – the amoeboid plasmodium of the slime mold *Physarum polycephalum*, Fig. 1b.

EIT Chip Fabrication

The EIT chip contains 16 electrodes positioned in a circular pattern, and made from a printed circuit board (PCB). The electrode length and spacing are identical, the electrodes are 35 μm thick and the area of an individual electrode is 2.06 mm^2. A thin gold layer was galvanostatically plated onto the surface of the copper electrodes using a three-electrode potential station (PGSTAT128N, Autolab electrochemical instruments, the Netherlands) with a platinum-coated metal mesh counter electrode and Ag/AgCl electrode (REF321, Radiometer Analytical S. A., France) reference electrode. The thickness of the gold layers was 500 nm and controlled by adjusting the deposition time. To culture the plasmodium, a

Electrical Impedance Tomography for Single-Cell Imaging, Fig. 1 (**a**) Diagram showing the principle of electrical impedance tomography (EIT) for imaging single cell in culture in a circular electrode pattern. (**b**) Photograph showing *Physarum polycephalum* cultured (fed with oat flakes) on the surface of agar gel



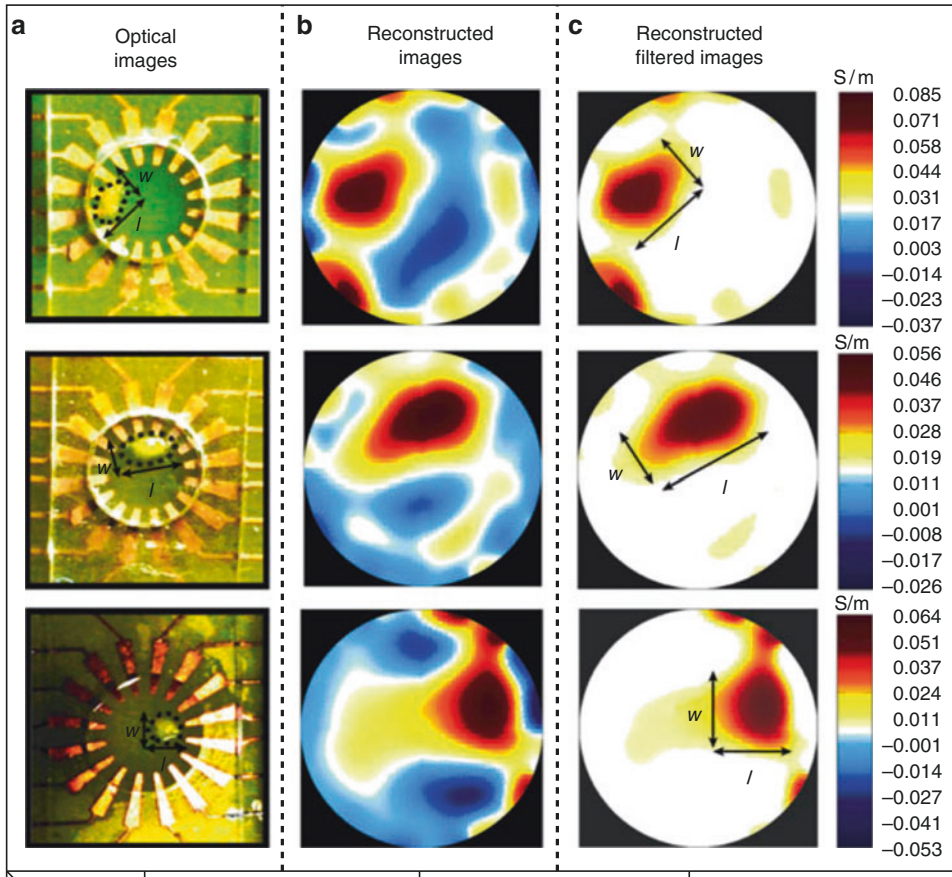
polydimethylsiloxane (PDMS) sheet (1 mm thick) with a 6 mm diameter hole was clamped over the EIT chip. A thin layer of agar gel was deposited over the surface of the electrodes, within the PDMS chamber, over which, the *Physarum polycephalum* was cultured. This avoids direct contact between the electrodes and the *Physarum polycephalum*. To eliminate evaporation, a second PDMS sheet and a polymethylmethacrylate (PMMA) plexiglass lid was used, as shown in Fig. 2.

System Instrumentation

Signal stimulations and measurements were performed using an Alpha-A impedance analyzer (Novocontrol Technologies, Germany) operating in four-electrode impedance measurement mode. A custom-designed electronic platform was built for multiplexed measurements, switching the pattern of stimulating signal and measuring voltages on different combinations of electrode pairs. Analogue chips, consisting of 16×8 crosspoint switches (Intersil CD22M3494) were used as multiplexers. The impedance analyzer and the multiplexing board were both controlled by a Linux PC through a GPIB-PCI interface (NI PCI-GPIB, National Instruments, USA) and a USB controller (FT2232D, FTDI Ltd. UK), respectively. Custom software was used for automated real-time measurements. The software sets the amplitude and frequency of the stimulating signal, the digital signals to the address lines of the multiplexers and controls the data acquisition. The highest temporal resolution of individual voltage measurement is 100 ms, which is limited by the data rate of the impedance analyzer.

EIT Measurement Scheme

The adjacent method was used for signal stimulation and voltage measurements. This method is more sensitive to variations in the impedance of objects near the electrodes than in the center of the chip. The stimulating signal is first applied through electrodes 1 and 2 (Fig. 1a) and the voltage measured from successive electrode pairs: 3–4, 4–5, . . ., 15–16, giving 13 voltage measurements. Note that voltages across electrode pair 16–1, 1–2, and 2–3 cannot be measured since the stimulating signal is injected from electrode pair 1–2. Then a second set of measurements is made with the current applied through electrodes 2 and 3 giving a further 13 sets of voltage data. This process is repeated, generating a total of $16 \times 13 = 208$ voltage measurements, which requires approximately 20 s for a full scan. Owing to reciprocity, only half of the measurements are linearly independent, all the data are used in the image reconstruction.



Electrical Impedance Tomography for Single-Cell Imaging, Fig. 2 Diagram showing the structure and cross section of the EIT chip used to image *Physarum* in culture

Physarum polycephalum in Culture

The plasmodium of the slime mold *Physarum polycephalum* is an amoeboid multinucleated single cellular organism. It consists of fanlike advancing fronts connected by tubular structures found in the posterior region (Fig. 1b). This organism has been long used as a model organism for the study of mitosis, membrane potential, and protoplasmic streaming. A *Physarum* plasmodium can extend to over several centimeters in diameter; nevertheless, it still maintains itself as a single cell by protoplasmic flow. Being a multinucleated cell, even if a cell is split into pieces, each piece can keep alive and act as single cell. It can be regarded as an autonomous distributed system and recently, its oscillatory behavior has been utilized directly for robotic control applications.

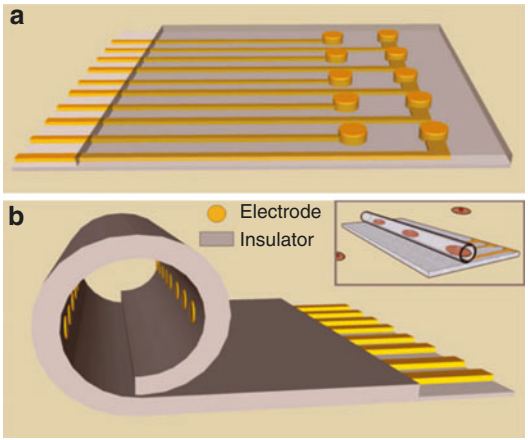
Results and Discussions

Different shapes of *Physarum polycephalum* were grown on the surface of the agar in different positions within the chip as shown in Fig. 3a. Two sets of voltage data were measured using the adjacent method (stimulating signal = 100 mV @ 200 kHz). One set of data was taken for pure agar gel in a closed EIT chip, providing a homogeneous background. The second set of data was measured after *Physarum* was grown on the agar. Images were reconstructed using 5,184 elements in the forward model. The initial value of *hyper-parameter* was set to 0.1 and adjusted in the range between 0.05 and 0.2 for smooth boundaries between *Physarum polycephalum* and the background. Figure 3b shows the corresponding reconstructed images from the voltage data. Brighter (*red*) corresponds to higher conductivity and darker (*blue*) to lower conductivity. The brighter region where the *Physarum* cell locates (positive values in the reconstructed differential conductivity) can be clearly seen. The mirror ghost images are equivalent to regions of lower conductivity (negative values in the reconstructed differential conductivity), and produce variations in the reconstructed conductivity values. Because the ghost images are low conductivity regions, and the difference between *Physarum* and the background is positive, the ghost images were eliminated by setting a threshold in the reconstructed conductivity, as shown in Fig. 3c. There are other artifacts, exhibiting both high and low conductivity regions, distributed along the edges of the

	Top physarum sample			Middle physarum sample			Bottom physarum sample		
	Optical	Electrical	Relative difference	Optical	Electrical	Relative difference	Optical	Electrical	Relative difference
Width (*w*)	1.41 mm	1.45 mm	2.8 %	1.61 mm	1.64 mm	1.8%	1.76 mm	1.82 mm	3.4%
Length (*l*)	2.47 mm	2.54 mm	2.8 %	3.19 mm	3.27 mm	2.5%	1.76 mm	1.82 mm	3.4%

Electrical Impedance Tomography for Single-Cell Imaging, Fig. 3 (**a**) Optical images of *Physarum polycephalum* on the agar gel in the EIT chips, (**b**) Corresponding reconstructed images. The *Physarum* cell is more conductive than the agar gel, exhibiting as bright (*red*) region in the reconstructed images. (**c**) Filtered images, the ghost images are eliminated by filtering the low conductivity regions

reconstructed images, which may come from the incompleteness of the one-dimensional segment model of the electrodes in the forward model.



To analyze the resolution of the reconstructed images, the dimensions (the width and the length) of the *Physarum* cell from the optical and electrical images were compared. Dimensions of three samples (from top to bottom) are listed below the images in Fig. 3. The absolute difference in the dimensions between the optical and the reconstructed images ranges from 30 to 80 μm. The relative difference, calculated as the ratio of the absolute difference to the dimension in the optical image, shows that the minimum is 1.8 % and the maximum is 3.4 %. The average size of a single *Physarum* cell is approximately 2 mm in one dimension.

Conclusion and Outlook

The developed system would be useful in diagnostic and biomedical applications, such as cancer and cancer treatment monitoring for characterizing the spatial electrical properties of tumor cell colonies. Understanding the tumor growth is essential for screening programs, clinical trials, and epidemiological investigations. Skourou et al. [15] demonstrated the feasibility of using electrical impedance technique to detect small tumors (<3 mm) and tumor-associated changes. The tumor growth varies but is generally from a few mm to tens of mm [16], which falls into the imaging scale and resolution of the developed system. It can be expected that electrically mapping the electrical properties of tumor spatially will benefit the study in the dynamics in tumor cells spreading and proliferation.

Although impedance-based microfluidic cytometry [2, 3] has been widely used for cell manipulation and characterization using various approaches, the microfabrication of the devices leads to the difficulties in bonding the top and bottom of the microchannels, aligning the microfeatures (i.e., microelectrodes) exactly where they are required, fabricating the microelectrodes on the sidewalls of the microchannels, etc. A neat and smart technology is required to effectively address these problems in order to develop novel applications and push microfluidic cytometry into commercial markets, advocating point-of-care and on-side analysis.

A promising route is to use rolled-up microfabrication technology [17] to compensate the conventional microfabrication process. By using this technology, microchannels can be fabricated with a smooth inner/outer surface and a near to perfect circular cross section. Also, the microelectrodes can be located where they are needed with good control in position and alignment, thus offering the opportunities to address the above problems. Furthermore, the rolled-up technology can be applied to many materials and material combinations and thus it is easy to fabricate microchannels with customized surface chemical properties provided by the appropriate rolled-up materials.

Electrical Impedance Tomography for Single-Cell Imaging, Fig. 4 Schematic illustration of the proposed structure of rolled-up microspectroscope, integrated with pairs of microelectrodes for single cell imaging

However, up to now, only few reports can be found to apply this technology toward bio-applications. Very recently, researchers fabricated rolled-up transparent microtubes as confined culture scaffolds for individual yeast cells [18]. Good biocompatibility of rolled-up microtubes has been demonstrated by monitoring the growth of yeast cells inside the microtubes. It would be interesting to explore the rolled-up microtubes from microfluidic approaches in single cell analysis applications, where different patterns of microelectrodes will be integrated into the inner surface of the rolled-up microtubes for single cell manipulation and characterization under laminar microflow. Cells will be flown and trapped inside the microtube. Rolled-up multiple layers of circular electrode-arrays allows performing 3D single cell imaging [19], as shown in Fig. 4. The dimensions (diameter and length) of the microspectroscopes can be easily controlled by lithography, etching, and deposition techniques. Therefore, the tubular microspectroscopes can be designed for analyzing different sizes of biological cells to obtain the optimal signal. The microelectrodes can be fabricated exactly at the desired positions and also desired shapes; hence, by using conventional photolithography, different cell analyzing functions can be fabricated on a single chip that integrates

multifunctions for cell manipulation, identification, and imaging. Particularly, compared to the conventional microfluidic cytometry, the microelectrodes can be fabricated in a circular pattern inside the tubular microchannels. This allows many cell analysis applications to be extended from 2D to 3D, such as 3D single cell imaging using EIT by fabricating multiple sets of electrode-arrays inside the microtubes. Very recently, Caselli et al. [20] reported the simulation work of single cell imaging in a microfluidic cytometry using EIT. The authors reported detailed finite element modeling and numerical simulation results to demonstrate the feasibility of the device and method to extract information on cell morphology and to discriminate normal biconcave erythrocytes, spherocytes, and echynocytes. However, no device fabrication and experimental result has been reported yet. In summary, high-throughput and high-resolution microfluidic single cell impedance tomography is an important area that will continue to develop. It would be expected that 3D single cell imaging can lead to integrated point-of-care systems for biomedical and diagnostic applications.

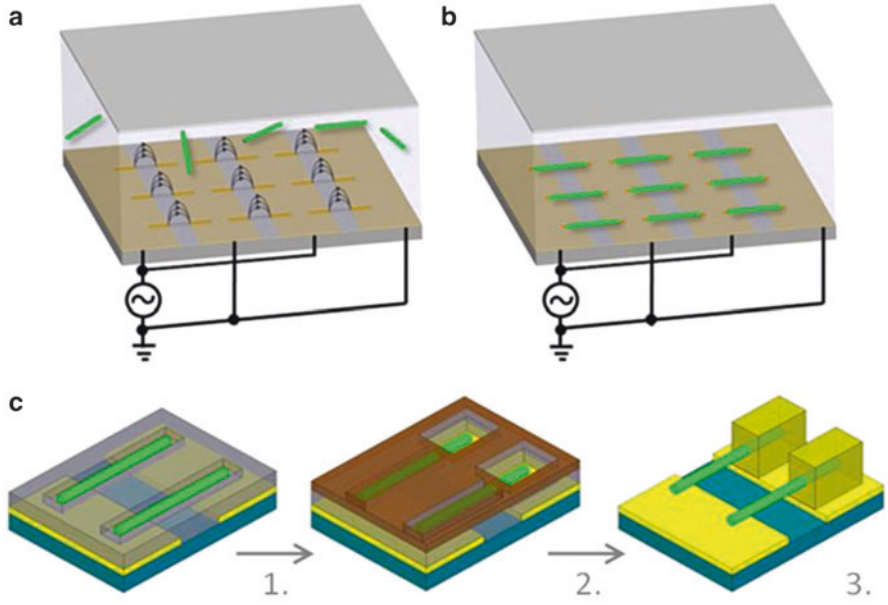
Definition

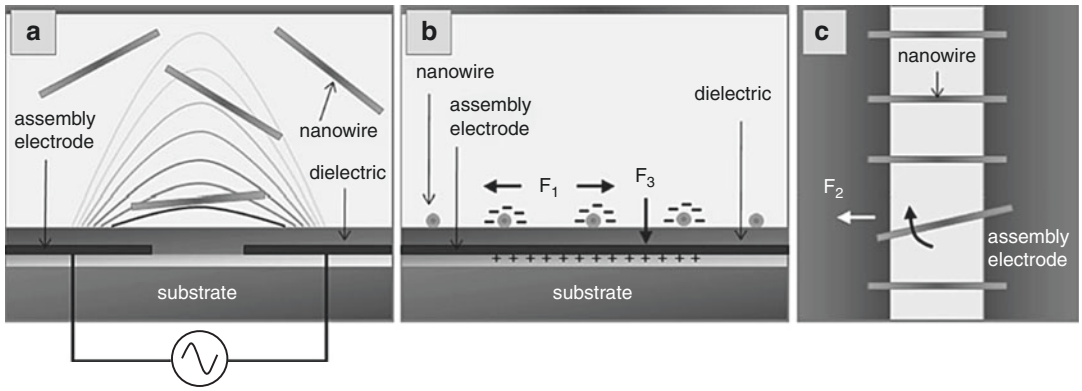
Electric-field-assisted deterministic assembly uses the force induced on individual nanowires by a nonuniform electric field to position each nanowire with submicron registration accuracy relative to previously defined nanodevices on a substrate.

Overview



The electric-field force induced on solution-suspended, polarizable nanowires by a nonuniform alternating electric field can be used to attract, align, and position individual nanowires at predefined locations on a patterned substrate (e.g., Si integrated circuit) [1–4]. The magnitude and direction of the spatially varying electric-field force, which together control the final position and orientation of the nanowires, are determined by electrode structures on the substrate, bias voltages applied to the electrodes, the geometry and material properties of the nanowire, and material properties of the solution (Fig. 1a). The force field can be tailored to provide submicron registration (overlay) accuracy between each assembled nanowire and a specific nanoscale feature on the substrate at integration densities $>10^6$ nanowires/cm^2 and with yields >95 % [5]. Additionally, different nanowire populations (e.g., materials, coatings, etc.) can be directed to particular regions of the substrate by synchronizing the sequential delivery of each population with a unique electric-field force pattern [6]. Once assembled, the nanowires can be converted into one of many different device types – nanomechanical, electronic, optoelectronic – by adding mechanical and/or electrical contacts using conventional lithographic, deposition, and etching processes (Fig. 1b) [5, 6].

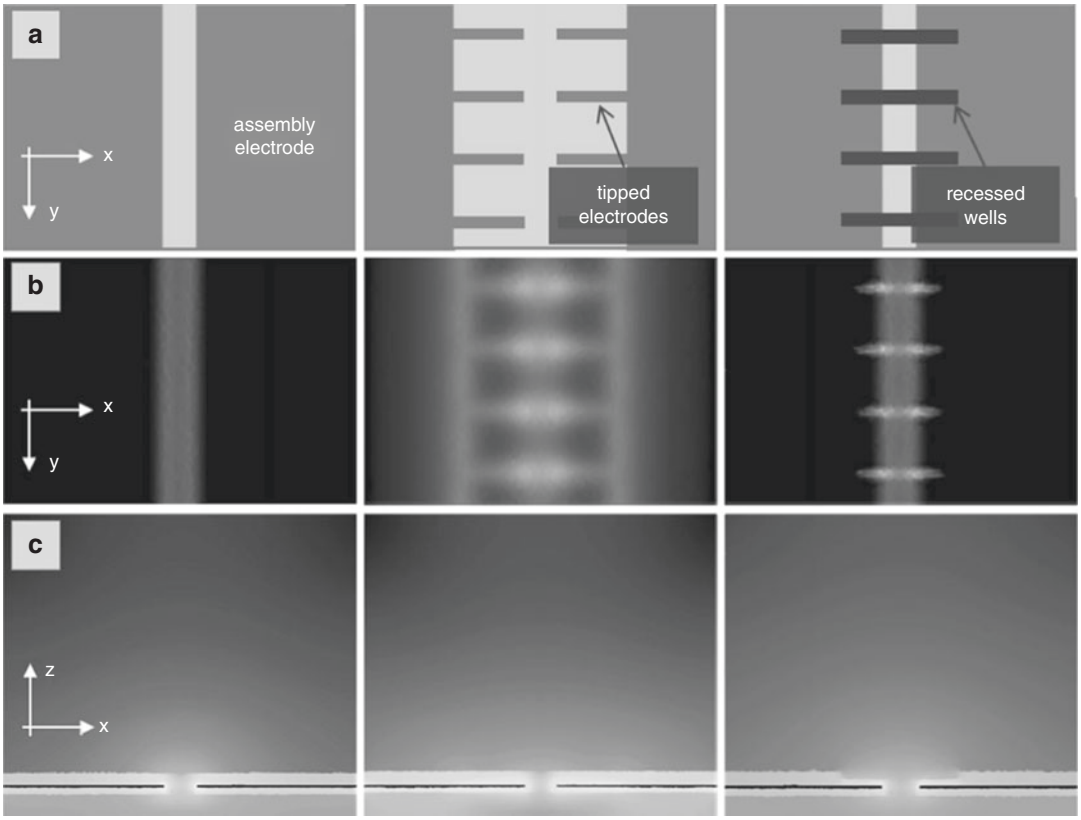
Basic Methodology



The electric-field-assisted deterministic nanowire assembly process can be divided into two phases: (1) attraction of the solution-suspended nanowires to a predefined area on the substrate and (2) alignment and positioning of the nanowires relative to other assembled wires or lithographic features on the substrate. In the first phase, the nanowires are suspended in the fluid far above the dielectric-coated substrate in a region where the gradient of the alternating electric field produced by the biased electrodes is relatively small but sufficient to polarize the individual nanowires. Each of the polarized nanowires experiences a force that is well modeled using the dielectrophoretic (DEP) force equation [7]:

$$\vec{F}_{DEP} = \left(\vec{p}.\nabla\right)\vec{E}\ ,$$

where $\vec{p}$ is the effective dipole moment of the particle resulting from its polarization by the electric field $\vec{E}$. More specifically, numerical solutions of the force using the Maxwell stress tensor (MST) method show that it is proportional to $\nabla\left|\vec{E}\right|^2$ [8], which is the same field dependence as $\vec{F}_{DEP}$ for a spherical dielectric particle analyzed by Pohl [7]. In general, the force is significantly larger than the other hydrodynamic, gravitational, and Brownian forces acting on the nanowires, and causes the wires to

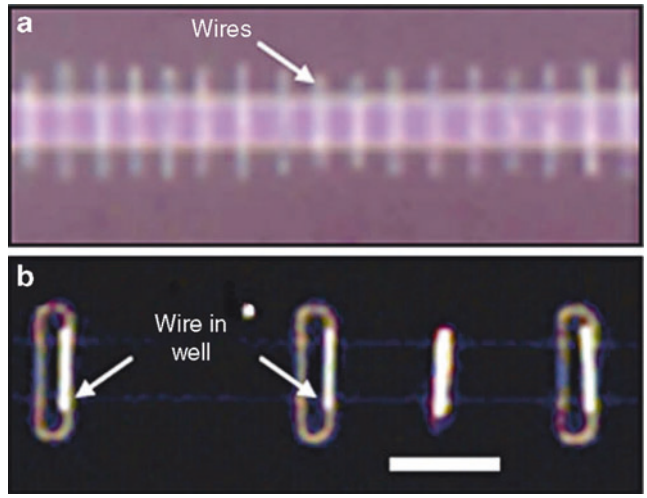


Electric-Field-Assisted Deterministic Nanowire Assembly, Fig. 1 *Deterministic nanowire assembly.* (**a**) Nonuniform electric fields originating from electrically biased electrode structures on the substrate extend into the fluid medium. (**b**) Electric-field forces acting on the solution-suspended nanowires are used to position individual nanowires within lithographic wells on the substrate. (**c**) Nanowires assembled in the wells are converted into cantilever devices by patterning windows to contact one end of each wire (*step 1*), electroplating metal clamps (*step 2*), and dissolving the sacrificial photoresist (*step 3*) (After Ref. [5])

Electric-Field-Assisted Deterministic Nanowire Assembly, Fig. 2 *Deterministic nanowire assembly.* (**a**) Cross section of interdigitated electrode structure showing electric field lines. *Dark gray* designates the highest and light gray the lowest electric field magnitude. The nanowires align tangent to the field lines and are attracted to the high field region in the gap between the electrodes. (**b**, **c**) Electric-field forces due to like charge on the wire tips (*F1*), opposite charge on the wires and on the biased metal electrode (*F2*, *F3*). Together these forces form uniformly spaced, aligned nanowire arrays

align tangent to the electric field lines and to move in the direction of the highest field gradient. For a simple interdigitated electrode structure, the nanowires are attracted from solution and are aligned such that they span the gap separating the biased electrodes (Fig. 2a).

In the second phase of the assembly process, the nanowires are on the substrate, and the

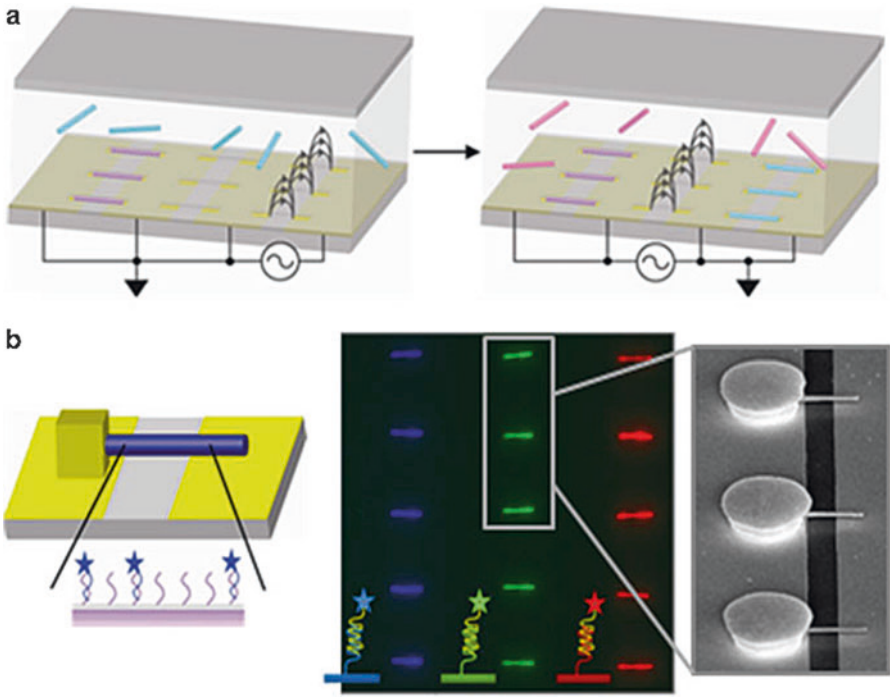


Electric-Field-Assisted Deterministic Nanowire Assembly, Fig. 3 *Electrode structures*. (**a**) *Top and cross-sectional views* of the three different electrode structures all having a gap width of 5 μm. The sharp tipped electrodes and recessed wells are 1 μm wide and 10 μm long. (**b**) *Top view* of the electric field magnitude measured at the dielectric coating/solution interface. (**c**) *Cross-sectional view* of the electric field magnitude (plotted on a log scale) measured along the *center* of the tipped electrodes and recessed wells. *Dark gray* designates the highest and *light gray* the lowest electric field magnitude

induced charge distribution and electric field are more complex, resulting in forces between neighboring wires as well as between these same wires and the buried electrodes (Fig. 2b, c). In the first case, the like charge on the nanowire tips gives rise to a net repulsive force between neighboring wires. This results in the formation of uniformly spaced arrays at high wire concentration. In the second case, if an aligned nanowire is offset from the center of the gap, the opposite charge on the wire and on the metal electrodes produces a lateral restoring force and torque. This causes the wires to align, centered across the gap, with end-to-end registration. It also fixes the position of the wires on the substrate when the solution is removed. As described in the next section "Key Research Findings," by tailoring the electrode structure design, the electric-field profile and forces the can be optimized to position individual wires with submicron registration accuracy relative to previously defined nanodevices on the substrate.

Key Research Findings

Assembly Electrodes and Electric-Field Profiles



The electric-field forces used for nanowire assembly are defined by the nonuniform field originating from the electrically biased electrode structure. Three different structures are presented in Fig. 3 to illustrate the range of field profiles that

Electric-Field-Assisted Deterministic Nanowire Assembly, Fig. 4 *Nanowire assembly.* Dark field optical microscope images of 200 nm diameter, ~7 μm long Rh nanowires assembled on electrodes with (**a**) a uniform-width gap, and (**b**) recessed wells that span a uniform-width gap. The wires were suspended in isopropanol for assembly, and a 10 kHz, 7 V_{rms} sinusoidal voltage was applied across the interdigitated assembly electrodes. Uniformly spaced, well-aligned nanowire arrays were assembled using the uniform-gap electrode structure. Deterministic positioning of individual nanowires was achieved using recessed wells. Scale bar = 7 μm

can be realized: (1) electrodes with a uniform-width gap and a planar dielectric coating, (2) electrodes with sharp tips and a planar dielectric coating, and (3) electrodes with a uniform-width gap and a dielectric coating patterned with wells that span the gap. Figure 3 also shows simulations of the electric field magnitude (COMSOL Multiphysics) measured at the interface between the dielectric coating and the solution (x–y plane, Fig. 3b) and through the cross section of the structure (x–z plane, Fig. 3c). For the first structure, the field strength is highest at the edge of the electrodes, and it is uniform along the length of the gap. This gives field lines that radiate outward from the gap, with a field gradient that is the largest near the substrate surface. Optical microscope images taken after electric-field-assisted assembly of template-synthesized Rh nanowires (200-nm diameter, 7-μm long wires; Fig. 4a) demonstrate that this field profile leads to the formation of parallel wire arrays along each gap. The spacing between adjacent nanowires is uniform, but the absolute position of each wire in the array is not well controlled. This limits the registration accuracy of the assembled wires relative to existing device features on the substrate.

The next two electrode structures overcome this limitation by producing spatially confined regions of high field strength using lithographic features. For the sharp-tipped electrode structure, the electric field magnitude is the strongest in the region surrounding the tips, with a field gradient that is the largest in the gap between the tips. This results in individual nanowires preferentially assembling across the gap, with additional wires aligning in the fringing field at an angle relative to the gap. A similar field profile can be obtained by defining an array of recessed rectangular wells in the dielectric coating that separates the metal electrodes from the solution [5]. This structure has the advantage that it suppresses the lateral field between adjacent high field regions, which ensures that individual wires align to span the gap within the well (Fig. 4b). It is also possible to minimize the assembly of multiple wires on the sharp-tipped electrodes by adjusting the fluid flow to control the hydrodynamic forces acting on the wires during assembly [4]. Importantly, submicron registration accuracy between the assembled nanowire and features on the substrate can be achieved with both of these electrode structures.

Electric-Field-Assisted Deterministic Nanowire Assembly, Fig. 5 *Programmed nanowire assembly.* (**a**) Scheme illustrating programmed deterministic assembly of different populations of bioprobe-coated nanowire. Each population is directed to the recessed wells in the electrically biased regions of the substrate. (**b**) Following programmed assembly of three populations of bioprobe-coated wires, nanomechanical cantilever devices (*left*) were fabricated as described in Fig. 1. Fluorescence images (*center*) show that the fluorescently labeled targets hybridized selectively to their complementary probes. The field emission scanning electron microscope image (*right*) shows the fabricated nanocantilever devices (After Ref. [6])

Programmed Assembly of Different Nanowire Populations

Electric-field-assisted assembly can be used to deterministically position more than one type of nanowire on the same substrate. As illustrated in Fig. 5a, this is accomplished by synchronizing the sequential delivery of each nanowire population with a unique electric-field profile obtained by biasing a specific set of assembly electrodes. As a proof of concept, this programmed assembly approach was applied to create nanowire arrays containing three populations of wires, each functionalized with different nucleic acid probe molecules and positioned in different columns in the array [6]. Following assembly, the three types of wires were converted into nanomechanical cantilevers using conventional lithography and metal deposition processes. The probe-coated nanocantilever devices were incubated with a mixture of all three fluorescently labeled nucleic acid targets. Fluorescence microscopy images of the three column array (Fig. 5b) confirmed that the target molecules selectively hybridized to their complementary targets and that the assembly process positioned each nanowire population in the correct array column.

Examples of Applications

Adding heterogeneous populations of nanowire devices onto Si integrated circuits (ICs) will enable new and diverse functions ranging from energy harvesting to chemical and biological sensing [9]. Deterministic assembly offers a flexible and customizable alternative to traditional top-down nanofabrication because it completely decouples the nanowire synthesis process from

the IC manufacturing process. This allows the use of emerging template, solution, and catalyst-based protocols for inexpensive batch synthesis of diverse materials such as metals, semiconductors, metal oxides, conducting polymers, and molecule-coated wires [10]. Off-chip wire synthesis also removes the constraints of thermal budget and chemical compatibility imposed by top-down manufacturing methods. This permits the integration of nanowires with properties optimized for a specific function.

Future Directions for Research

Advancing the electric-field-assisted deterministic assembly technique for use in practical applications will require ongoing research to develop new and scalable nanomanufacturing strategies that can provide high-yield integration of nanowire devices with the required registration accuracy over large substrate areas. For Si-based systems-in-a-package (SiP), the nanowires should be assembled at the back end of the Si IC process. This involves a highly integrated, interdisciplinary research effort. For example, the availability of batch-synthesized nanowires with uniform properties (i.e., dimensions, microstructure, etc.) is essential to the success of this approach. Similarly, scalable methods should be developed to deliver aggregate-free, solution-suspended nanowires to large-area substrates with controlled and reproducible concentration. Additional research aimed at developing a comprehensive theoretical and experimental understanding of the electric-field forces will enable the design of new and more effective assembly electrode structures with patterns customized for different circuit applications. Finally, innovative nanofabrication methods should be applied to convert the assembled nanowires into high-performance electronic, optical, and sensing devices that can be monolithically integrated with the Si circuitry.

Definition

Under equilibrium conditions, a bulk electrolyte is an electroneutral, isotropic, and homogeneous solution, and there are no electric fields along any preferential direction. However, at the frontier with another material with mobile free charges (ions or electrons) and a different chemical potential – e.g., the electrode – some anisotropy in the forces experienced by the particles arises, and charge redistribution occurs. Although the interfacial region remains overall neutral, either side of the boundary becomes charged to an equal and opposite extent, forming the so-called electrical double layer or electrified interface. This gives rise to a potential difference across the interface. This potential difference is usually not large (~1 V); however, the dimension of the interphase region is very small ($\sim 10^{-7}$ cm) with the consequence that the field gradient is enormous ($\sim 10^{7}$ V/cm). The potential difference across the electrified interface and the structure of the double layer are intimately related. The fundamental problem in electrochemical studies is to unravel this functional relationship and the effect of the field at the electrode–electrolyte interface.

Introduction

Electrochemistry represents the general framework for a wide variety of processes and phenomena, playing a crucial role in biology, materials science, and technology. The attention it receives from the scientific community is rapidly increasing because of its crucial role in a variety of energy generation and storage devices such as fuel cells, batteries, solar cells, and supercapacitors.

A vast amount of empirical data on electrochemical (EC) systems have been accumulated during the more than 150 years since Faraday's groundbreaking work. Not surprisingly, electrochemistry and its general applications in electron transfer reactions have given origin to a number of fundamental theoretical and computational models, such as the Debye–Huckel and Marcus theory.

The unifying motif of almost all (EC) systems – such as fuel cells, batteries, solar cells, and supercapacitors – is the coupled flow of matter and charge across the electrified interfaces (EI) between electrode and electrolyte. EC reactions, which usually produce or are driven by an electric current, ultimately dictate the behavior of most EC devices. Microscopic processes of this kind occur, for instance, in electrolytic cells, where water can be split into hydrogen and oxygen due to an electrical energy supply, or in batteries and fuel cells, where an electrical energy is derived from chemical reactions taking place within the cell. Understanding the microscopic details of these interfaces and of the processes taking place in their proximity, therefore, is a key to their optimization, enabling them to fulfill their promises for cleaner, cheaper, and safer energy technologies.

Experimental methods such as STM (scanning tunneling microscope), AFM (atomic force microscopy), SFG (sum frequency generation), and NF (near-field) spectroscopy sometimes achieve atomistic resolution. Most experiments, however, can only observe the macroscopic manifestation of EC conversion processes while the detail of their microscopic behavior remains vague. This implies that computer simulations,

which have the power to resolve processes atom by atom, are required to magnify our view of EC systems and should be used to validate experimental results, to design new experiments, and to predict exciting new effects of potential technological interest.

However, in EC systems, there is still a wide gap between theoretical understanding of microscopic phenomena and the macroscopic outcome of experiments.

Most of the current computational models target a single aspect of EC systems or phenomena, such as the electrostatic double layer (DL), the electronic structure at the electrode–electrolyte interface, the electron or ion transfer processes taking place at the electrode, the ion diffusion in electrolyte, etc. A unifying approach, able to cover the statistical mechanics and thermodynamics as well as material science or electronic structure of these complex systems, is still missing.

Such a comprehensive description can in principle be provided by ab initio simulations, relying on density functional theory (DFT) in the Kohn–Sham (KS) formulation [1] and able to simultaneously account for thermal motion, along with the changes in the electronic structure of the system. The full exploitation of this approach in electrochemistry, however, is still hampered by substantial difficulties [2].

Open issues and problems in electrochemistry target different levels of theory and applications, requiring the modeling of:

1. Inhomogeneous systems, with ionic species in solution and a variety of chemical bonds, from metallic or covalent to hydrogen bonding and nonbonded interactions going from long-range Coulomb to short-range but still important dispersion forces. The correct reproduction of the quantum chemistry of energy alignment at EI for this variety of interactions may require the introduction of correction terms to local or semilocal DFT potentials or the adoption of schemes beyond standard DFT. Moreover, in current materials used in already commercialized lithium-ion batteries and emerging photovoltaic cell technologies, for example, the charge conduction is governed by polarons, which are difficult to describe with standard DFT methods.
2. Complex adsorption, catalytic, and charge and mass transfer phenomena, occurring at the electrode–electrolyte interface. Liquid electrolytes require evaluation of the surface free energy rather than simple internal energy. Dynamical techniques, with their associated computational cost, are thus needed.
3. Double-layer formation/dynamics and the effect of varying the electrode potentials, affecting structure and phenomena occurring at EI. These include effective mass and charge dynamical reorganization, work function modifications, and energy flow at the electrode surfaces. Moreover, phase transition and volume changes are often induced by the EC process. In general, when complex forms of organization are the result of nonlinear interactions between their basic building blocks, the development of multiscale approaches, combining atomistic modeling with a continuum description, is advantageous.

All these aspects together imply large simulation samples and long equilibration times for finite temperature simulations and, in the case of charged electrodes, may require rather artificial assumptions on the distribution of charge in the system.

Theoretical Surface Science Approaches

There is a long history of theoretical, DFT-based surface science [3] – often in combination with experiments – resulting in a deep insight into the structure and reactions on metal and oxide surfaces as well as comprehensive studies on electronic, structural, and dynamical properties in energy materials [4].

An established and very popular model to predict reactivity and catalytic performance of different electrodes by means of simple descriptors was proposed by Hammer and Nørskov in 1995 [5]. In this model, adsorption energies are related to *d*-band position in the metal and to barriers in catalytic reactions. For instance, oxygen reduction

activity – which can be calculated in terms of activation energies, using the concept of Sabatier analysis – was related in a volcano plot to oxygen binding energy on different metal surfaces. The position of the center of *d*-electrons density with respect to metal Fermi level in some cases correlates linearly with oxygen atom chemisorption energy. However, this is only true if the metals under consideration are very similar. Even with this caveat, this approach has proven to be extremely useful, especially when oxygen binding energy is used as a parameter in describing the catalytic performance. However, it has to be said that using this approach, the complicated processes governing EC conversion are oversimplified and electrolyte presence is not considered explicitly.

Unraveling the atomistic structure and dynamics of metal–water interfaces is of crucial interest from both a fundamental and an applied point of view, in phenomena and technological processes such as corrosion, lubrication, heterogeneous catalysis, and electrochemistry. The established picture for water at this interface is of an icelike structure with enhanced density close to the electrode. These metal–water interfaces have been traditionally modeled statically, using the water bilayer model, with every second water molecule oriented parallel to the surface and the other molecules pointing one H atom either toward (H-down configuration) or away from the surface (H-up configuration). More recent studies [6] have shown that a remarkably rich variety of equilibrium structures, including dissociated or not hexagonal water rings, can form at the interface with even simple, flat surfaces, depending on the strain acting on the water layer and, in general, on the nature of the substrate. To address the open issues in electrode/electrolyte interface modeling, the theoretical surface science community has followed a stepwise approach based on first principles by considering systems with increasing complexity [7]. For instance, chemical trends in adsorbed halides- and water-induced work function changes have been correlated with water–metal interaction strength, charge redistribution at the interface, and metal electronegativity.

While an important progress has been achieved due to these static approaches, the equilibrium structure of metal–electrolyte interfaces in ambient condition is yet to be unraveled.

To take into account the effect of temperature in the modeling of the interface between electrode and water, numerous molecular dynamics (MD) studies [7, 8] used empirical and classical force fields models. The main limitation of most of these studies is that they do not explicitly include charge polarization effects as well as do not describe breaking and formation of chemical bonds and charge transfer at interfaces and in bulk electrolytes.

The only approaches suitable to describe the subtle interplay of electronic, ionic, and thermal effects are those based on first principles, especially when coupled with MD. Among those, DFT represents a very good compromise between accuracy and numerical efficiency. Recently, the increased availability of computational resources allowed a few first-principles MD studies to treat explicit water [8].

More recently, a method was devised to investigate coupled proton–electron transfer reactions [9]. This approach is based on ab initio MD but relies on foundations that might be seen as intermediate between simulation and theory. The half-reactions consisting of the addition/removal of protons/electrons are simulated in a homogeneous solution environment. Quantitative contact with electrochemistry is established by measuring free energies with respect to a common reference point, corresponding to the free energy of an aqueous hydronium ion H_3O^+. Once the thermochemical corrections are applied, free energy differences obtained by this method do correspond to the ΔG_0 measured with respect to the normal hydrogen electrode (NHE). This method is sophisticated and powerful in describing the thermodynamic bulk properties, but it lacks a comprehensive description of the metal/electrolyte interface that is central to electrochemistry. Perhaps more importantly, it does not provide a description of the overpotential related to the transfer of species to, from, or across the interface, which generally could be useful in determining the efficiency of the electrode and catalyst.

Finally, the method cannot be extended easily to real-time, real-space formulations of time-dependent DFT, which will be eventually required to describe the full kinetics of the system.

First-principles methods and MD are crucial for describing fundamental aspects of EC conversion, where chemical and electronic structure transformations occur. However, the complexity of these approaches and their high computational cost still restrict most of the existing studies to short simulation times and relatively small simulation cells, reducing the statistical validity of their conclusions.

A primary example of the currently limited ability to describe atomic and electronic scale processes at EI is our limited knowledge of the structure of the equilibrium DL and the effect of an external bias applied to the electrolyte through the electrodes even for the most basic metal–electrolyte interfaces. Secondly, the computed activation barriers for charge transfer at interfaces are usually not accurate (see however Ref. [4]) due to neglecting the effect of the environment.

In the following, we will present in some detail the methodological open issue of modeling the effect of the application of an external potential on the electrode and some of the proposed solutions.

In the final part of this entry, we will speak about modeling EC devices such as batteries and fuel cells, presenting some recent examples of the *state of the art* first-principles modeling of these devices.

Modeling the Effect of the Variation of the Electrode Potential: Conceptual Overview and Applications

The interest and the challenge in modern simulation of EC processes consist in representing the effect of variation of the electrostatic potential and thus the strong surface charge density redistribution and the fluctuating electric field at the electrode–electrolyte interface.

In principle, to describe an EC process a non-equilibrium approach should be used (such as the non-equilibrium Green's function formalism used in molecular electronics) and the open boundary conditions for describing the electrode, electrolyte, and chemical transformations occurring therein. Moreover, different timescales, ranging from that of slow solvent rearrangements to that of electron transfer up to fast solvent polarization effects, should be treated at the same level. These difficulties are the reason for the delay in advance of theoretical material science in this area, and only recently, the growth of computer power enabled treating such systems using DFT. The extensive computational power when using such approach, however, is still not available for the wide scientific community to be used in ordinary calculations.

The presence of an electrode potential distinguishes electrochemistry from catalysis and affects EC reactions by:

- Determining the chemical potentials of the electrons involved in half-reactions at the electrode surface
- Inducing the formation of a DL at the EI and a very strong electric field affecting the phenomena occurring therein

The simplest models of half-cell reactive processes use atomic clusters in gas phase and external parameters to simulate experimental equilibrium potential. To take into account the effect of an electric field on adsorption behavior at electrodes, a homogeneous electric field is sometimes applied perpendicularly to the cluster surface. The electrode potential is tuned by varying the external applied field; yet the relation of the EC potential to a known reference remains unclear.

Most of the *standard* simulation methods resort to periodic boundary conditions (PBC) to speed up the computation and minimize the effect of finite sample sizes, thus mimicking an infinite perfect crystal. Adopting periodic slabs provides a good description of the electronic and geometric structures, crucial for describing adsorption processes and relevant EC quantities at EI. However, the use of PBC makes it difficult to apply an electric field across the system, as required to

simulate a system under bias. The supercell geometry, coupled with current methods to account for long-range Coulomb interactions (Ewald and variations thereof), implies, in turn, that the system must be globally neutral. Previous models described the charge on the electrode by including additional occupied KS orbitals and/or resorting to fractional occupation numbers. In other cases, neutrality is enforced by adding a judicious distribution of fixed countercharges [7]. These could take the form of a homogeneous background charge uniformly distributed over the simulation cell [10], charged planes [11], a dipole layer into the vacuum region [12], or hydronium ions [13] placed at a fixed distance from the electrode surface in order to charge the electrode.

The conceptual evolution of these approaches will be now critically highlighted in some detail.

In 2004, Norskov demonstrated [13] that even for globally neutral supercells, electron transfer between electrodes can be effectively included in half-cell reaction free energies by adding a term which depends on the applied potential U as follows:

$$\Delta G = G_{\text{products}} - G_{\text{reactants}} - neU,$$

where e is the charge of an electron and n is the number of exchanged electrons between reactants and products. This method was applied for calculating reaction energies for O_2 reduction at fuel cell cathodes as a function of the applied EC potential, by establishing a computational reference to the hydrogen electrode at standard conditions, when hydrogen evolution is at equilibrium ($H_2 \leftrightarrow 2(H^+ + e^-)$). In this approach, similar to the thermodynamic approaches used in electrocatalysis, the electrode potential only affects Fermi level electrons, while the EC environment is considered as the adsorbate reservoir. The charge polarization at the electrode due to the induced electric field and the explicit effect of the EC environment on the interfacial processes is disregarded. Despite this severe limitation, the method is computationally viable and allowed establishing trends in electro-catalysis.

Subsequently, a dipole layer was introduced into the vacuum region to induce electrode polarization – thus accounting for the effect of an external field. The main challenge in this case is to know the strength of the electric field induced by the applied potential. The authors evaluated this contribution assuming plate capacitor behavior, $|E| = U/d$, and guesstimating the Helmholtz layer thickness.

Charging up the slabs leads effectively to a variation in the electrode potential. Since in periodic calculations the unit cell has to be neutral, a countercharge is needed to maintain cell neutrality. We will illustrate this issue in more detail in the following. For the moment, we note that once the slab is allowed to take on a net charge, it is possible to set the electrode charge also implicitly, by fixing the chemical potential of the electrons associated with the slab. Along this line, Lozovoi [11] presented a grand-canonical formulation of charged slabs, where a chemical potential, μ, is defined and kept fixed relative to a reference electrode at finite distance from the slab. However, restraining μ is often less efficient than varying the charge in the slab until the value corresponding to a desired μ is found.

The most important contribution along this line was provided in 2006 by Filhol [10]. In Filhol's approach, a net surface charge q is introduced onto the electrode via the variation of the total number of electrons present in the slab. Cell neutrality is enforced adding a constant countercharge background $-q/W$, where W is the cell volume (this countercharge is by default present in standard DFT codes in case of charged calculations in order to avoid electrostatic divergence). The potential drop at the EI induced by the presence of the charged electrode is quantified by comparing the Fermi level of the system to a reference potential at a defined distance from the metal/water interface.

Two potential references are defined, a vacuum and an aqueous state (double reference method). The first reference is the vacuum level for the uncharged system, giving the zero of the energy scale:

$$\phi_{0\text{bulk}} = \phi_{\text{bulk}} = \phi'_{\text{bulk}} - \phi'_{\text{vacuum}}.$$

The metal/electrolyte potential (no vacuum present) is aligned to this vacuum level by

aligning the bulk potential levels of the systems with and without vacuum. The second reference is the water potential, a fixed region far from the electrode at its position in the calculation at zero charge. Energy levels of the charged and relaxed system are aligned to this fixed water level:

$$\phi_{\text{charged}} = \phi'_{\text{charged}} - \phi'_{\text{water-charged}} + \phi'_{\text{water-uncharged}}.$$

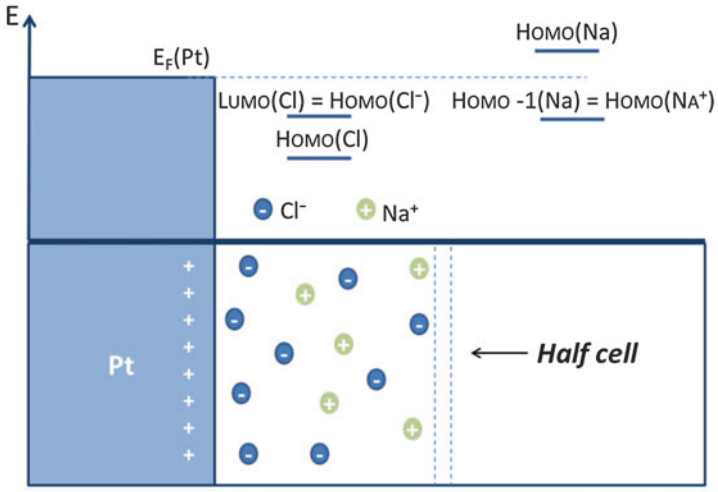
The absolute reference is given by the NHE:

$$NHE = -4.85\text{eV} - \phi_{\text{charged}}.$$

The presence in this model of a constant countercharge background, mimicking the effect of the counterions, introduces a parabolic contribution to the potential outside the electrode. Interestingly, the artifacts arising from this distribution are reduced at the presence of polarizable water layers. However, since the counterions are modeled as uniformly spread in the electrolyte, rather than localized in the vicinity of the electrode surface, the electric field just outside the surface is too small.

An alternative solution was developed in 2007 by Rossmeisl and Norskov [13], who proposed a model where counterions are explicitly considered and the electrode potential is varied by varying the number of protons/electrons in the DL. Excess H atoms are thus included at fixed positions in the water layer, which should result in formation of solvated protons and transfer of electrons to the metal.

Free energies of solid/liquid interfaces with N metal atoms and n protons in the water layer are calculated as



$$G_{\text{int}} = \left(G(N,n) - G(N,0) - n\mu_{H_2}/2\right)/N$$

where μ_{H_2} is the chemical potential of hydrogen. $G_{\text{int}} = 1/2C(U-U_{pzc})^2$ can be plotted as a function of the electrode potential U, calculated from the work function, extracting in this way the interface capacitance C. The potential of zero charge, U_{pzc}, is found by choosing the chemical potential μ_{H_2} in such a way that the G_{int} has its minimum for the configuration with no protons in the water layer. By choosing the μ_{H_2} equal to the free energy of H_2 at standard conditions, the minimum of G_{int} is at another value, representing the NHE. In this way, the work function is directly related to the potential scale of the NHE.

A different approach, proposed by Otani and Sugino [14], relies on performing nonperiodic slab calculations with effective screening medium. Green's function technique is used to solve the Poisson equation with these boundary conditions. The slab is sandwiched by a continuum medium characterized by dielectric constant ε. For instance, to model the structure of a Pt/water interface in acidic conditions, vacuum ($\varepsilon = 1$) is used for the Pt side of the slab and a perfect conductor ($\varepsilon = \infty$) beyond the water side. Changing the number of electrons produces a charge on the slab surface and induces a countercharge in the perfect conductor. A vacuum region is present between water and the perfect conductor. In this model, the countercharge is placed in a layer beyond the water, 15–20 Å far from the electrode. This again represents a fictitious condition because in a real interface, the countercharge is very close to the electrode surface.

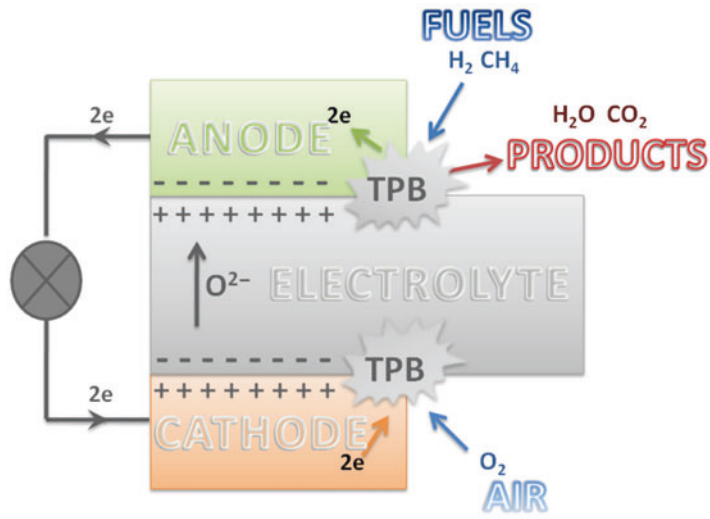
A clever usage and tuning of the methodologies highlighted above [4] led to different applications, simulating half-reactions in electrocatalysis – sometimes including the modeling of kinetic effects [2, 4, 7]. For instance, the thermodynamic approach of Ref. [13] has been used to study equilibrium coverage of metal halides as a function of the electrode potential. H_2 dissociation barrier at water/metal interfaces at room temperature as well as structure and stability of water layers as a function of electrode coverage due to hydrogen and other anions has also been recently addressed. In these cases, the effect of the electrode potential has been included using the approach described in Ref. [7, 8].

Other times, different levels of theory have been combined, for instance, by possible inclusion of the presence of the electrolyte using a polarizable medium [15].

Electrochemical Interfaces for Energy Storage and Conversion, Fig. 1 The standard frozen-levels picture of the single-electron energy levels. A prototypic Pt/electrolyte interface is schematically represented. The electrolyte is water with Na^+ and Cl^- ions in solution. The separation between the filled and empty electronic states is decided by the Pt Fermi energy E_F. Filled molecular levels of water lay well below E_F, while the corresponding empty states are well above E_F. As a result, water is expected to be neutral. The HOMO state of the cation, Na^+ in our case, is above E_F, and thus, this species is expected to be fully ionized. Cl^-, of course, is the complementary case, since its LUMO is below E_F, and it becomes filled in the system under consideration

Single Energy Level Alignment and DFT

The validity of the highlighted theoretical approaches, which charge the electrode to simulate the effect of the application of an external potential, relies on a correct description of the single-electron energies. Charging the electrode surface will occur only provided the KS density of states reflects the ordering shown in Fig. 1. The DFT approach determines self-consistently the charge of each species, filling KS electron states according to their relative energy with respect to the system Fermi energy, determined in this case by the Fermi level of the electrode.



This points out an important methodological open issue to be addressed in view of a realistic description of EC interfaces: the well-known inadequacy of standard DFT in predicting single-electron energies for ions in solution, and for materials currently used as electrodes – such as metals and metal oxides.

In current DFT approximations, the energy of eigenstates depends on the occupation [9], and, as a result, the highest occupied level of cations may fall below the global Fermi energy upon discharging, and the lowest unoccupied level of anions might rise above E_F when accepting the extra negative charge. As a result, the DFT charge on ions in electrolytic solutions might turn out to be a fraction of the electron charge $|e|$, instead of reaching the integer value $\pm n$ as occurs in reality.

To prevent the artificial charge delocalization and improve the description of energy levels, the adoption of exact exchange schemes is required [9]. Such schemes are computationally extremely demanding. The system size and the simulation time become again an obstacle. Alternative, computationally viable solutions would be highly beneficial.

Electrochemical Systems: Batteries and Fuel Cells

One of the greatest scientific challenges of our time is to provide the solution to the dramatic increase in energy demand and costs. Such a solution should be of minimal environmental impact. Energy policies based on capture and sequestration of CO_2 as well as those providing the setting

Electrochemical Interfaces for Energy Storage and Conversion, Fig. 2 Operation of a solid oxide fuel cell (SOFC): At the cathode triple phase boundary (TPB), the oxygen is reduced with charge transfer from the cathode to the electrolyte. The O^{2-} ions diffuse through the electrolyte toward the anode. At the anodic TPB oxidation of the fuel and charge transfer from electrolyte to anode occur

for hydrogen production, storage, and distribution require massive infrastructures and are, at present, beyond the market capacity. In the short to intermediate future, EC devices such as batteries and fuel cells have a great potential for solving key aspects of the energy challenge.

Fuel cells (FCs) are EC devices in which a hydrogen-rich fuel reacts with an oxidizing agent, normally O_2. Fuel and oxygen are split at the opposite sides of an electrolyte, through which, an ion diffuses to combine with an ion with opposing charge, at the opposite side. This process allows the flow of electrons, i.e., electric power (see Fig. 2, which shows how a solid oxide fuel cells works). Like a combustion engine, FCs use a chemical fuel to generate power, but like in Batteries (Bs), the chemical energy is converted directly to electricity by means of an EC process, excluding the combustion step. As a consequence, FCs operate at much higher efficiency and generate fewer pollutants than traditional combustion methods. Bs convert chemical energy directly into electrical power, exploiting the difference in potential between electrodes. Nowadays, Bs power billions of portable electronic devices and are likely to represent the storage technology of choice in the near term for several other applications. The leading Li-based Bs technology represents a $50 billion dollar industry in the USA [16]. Energy storage devices can be utilized together with renewable but intermittent energy sources (like solar or wind) and/or conversion devices. Bs fulfills the need for readily available energy and could provide the means for the vehicle electrification, leading to a reduction of the carbon fingerprint.

Among the various types of FCs, solid oxide fuel cells (SOFCs) are of great interest, because of their ability to utilize, except from hydrogen, a wide variety of commonly available fuels at high efficiency, including waste [17]. Thus, SOFCs do not rely on the development of hydrogen infrastructure and represent a midterm solution to lower both the energy demand and the CO_2 emissions. Typically SOFCs find a natural application as combined heat and power devices for residential applications. They are convenient because they work with the present energy distribution system and potentially could drive the transition toward hydrogen-based economy.

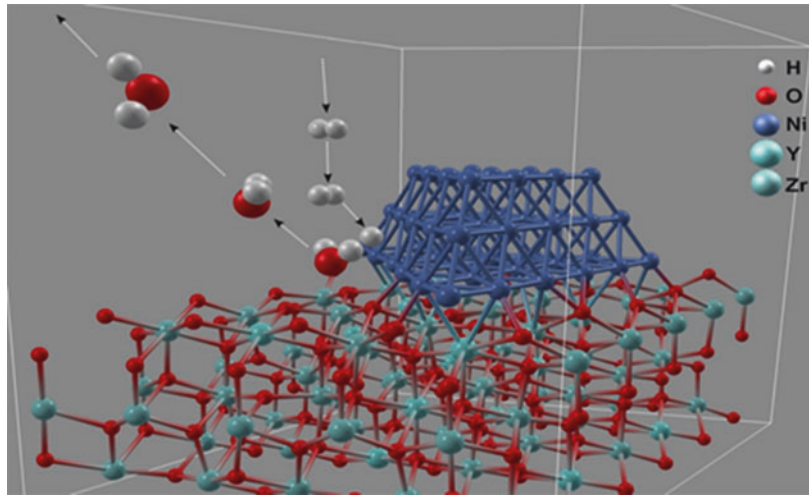
Major factors responsible for the growth of fuel cell market include the ability to integrate fuel cells in stationary, portable, and transportation applications to function as an off-grid power source, with zero emissions. The key concerns in the industry pertain to the high cost of interconnection (mainly in SOFCs, due to their high operating temperature), catalyst for both the cathode and anode compartments, their commercialization, and establishment of fuel cell infrastructure [17].

A broad scientific effort is devoted by both the academic and industrial communities for

improving this energy-related technology; however, the gap separating the actual state of the art of the energy storage and conversion technology from that required for widespread commercialization is still large. On the one hand, increasing the specific energy capacity, the power, the safety, and the life cycle and lowering the cost of various devices remain a challenge, especially when one wishes to power hybrid electric vehicles. Improved electrode materials based on new ideas and advanced electrolytes with higher ionic conductivities and increased voltage stability must be developed. On the other hand, performances, durability, and cost of FCs must be improved. In this area, the major challenges consist of developing new electrolytes, electrodes, and catalyst materials/structures. For instance, while precious catalysts received a great attention and their performance reach the commercialization limit, the non-precious catalysts perform worse, and realization of their full potential is subject to extensive exploratory work.

Applications: Modeling Fuel Oxidation in Commercial Solid Oxide Fuel Cells

Unraveling microscopic processes at the electrode surface remains challenging for both experimental and computational communities [18]. As an example, fuel oxidation at the triple phase boundary (TPB) between Ni electrode, yttria-stabilized zirconia (YSZ) electrolyte, and fuel gas phase in commercial SOFCs was subject to numerous experimental and computational studies. However, in spite of these studies, it was still not clear where water was formed. Impedance spectroscopy measurements identified the rate-limiting step (RLS) with a charge-transfer reaction with an activation barrier in the range 1.04–1.68 eV [19].



Kinetic modeling of impedance spectra had proposed three different assignments of the nature of the RLS, identified either with H^+, OH^-, or O^{2-} spillover.

In H^+ spillover ($H_{Ni} \rightarrow H_{YSZ} + e_{Ni}$), H atoms adsorbed on Ni hop either to a hydroxyl ion or an oxygen ion on the YSZ surface and here combine with oxygen to produce water. In O^{2-} spillover ($O^{2-}{}_{YSZ} \rightarrow O_{Ni} + 2e_{Ni}$), oxygen ions hop from the YSZ surface to the Ni surface, undergoing two charge-transfer reactions that take place before, after, or during the hop. In OH^- spillover, the OH^- formed on YSZ surface after H^+ spillover jumps back on the Ni anode. Following O^{2-} and OH^- spillover, water formation occurs on Ni surface. It has been also shown that the polarization resistance is reduced by a high water partial pressure.

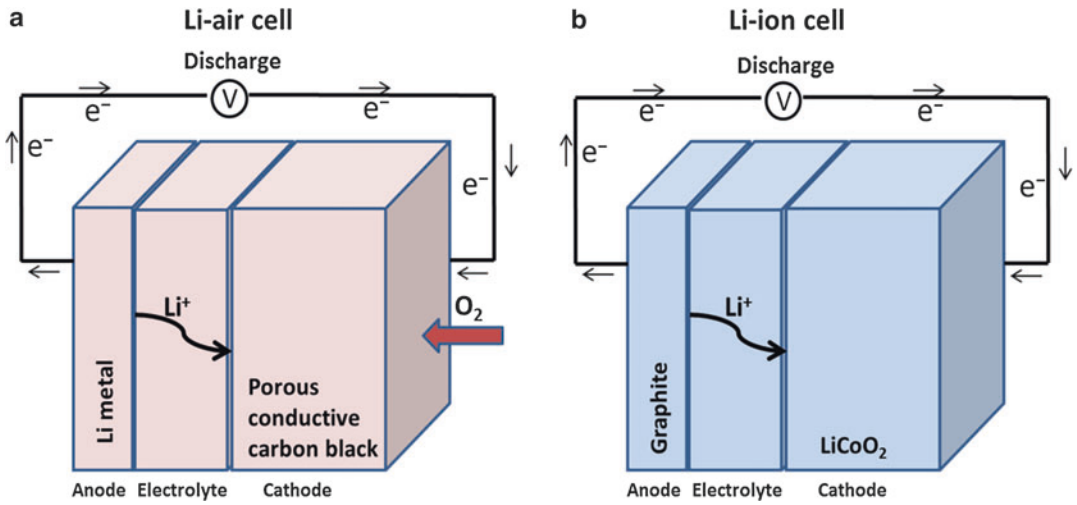
In this respect, ab initio simulations provided crucial insight on the nature of the RLS and the role of adsorbed water. A recent perspective on DFT modeling of three-phase boundary SOFC electrode has been provided by Shishkin and Ziegler [20]. A realistic modeling of these processes implies that electrode dimension and chemical activity allow charge transfer from O^{2-} to Ni, as it results in the potential drop at the DL, during SOFCs operation.

A state of the art model for the Ni/YSZ interface [21] is shown in Fig. 3. This realistic model allowed to study explicitly the different processes which lead to water desorption from the TPB and their dependence on the local defective structure of the YSZ surface moiety. In this study, it has been proven that the most favorable oxidation pathway involves hydrogen spillover from Ni to YSZ surface, which represents the RLS of the process. This study has shown that water formation and desorption take place on the YSZ surface and are mediated by the diffusion of a hydroxyl group on a Zr site close to the Ni/YSZ interface. The process continues with formation of water by the direct transfer from Ni cluster of a second H atom and its subsequent release. The smaller polarization resistance experimentally observed when water partial pressure increases in the anodic chamber is also explained in terms of enlargement of the active triple phase boundary. In the article, it is shown how this is made possible by the presence of water in the environment, in the form of adsorbed hydroxyl groups on the YSZ surface.

Such a detailed mechanistic insight was made possible due to the combination of a variety of DFT-based techniques such as MD (to explore the

Electrochemical Interfaces for Energy Storage and Conversion, Fig. 3 Supercell used to model the triple phase boundary between electrode, electrolyte, and gas phase in the anodic chamber of Ni–YSZ based SOFCs. Graphics by Mario Valle, Swiss National Supercomputer Centre, Lugano, Switzerland

configurational space), metadynamics (often used as an exploratory tool to guess possible reaction pathways), and nudged elastic band approach (to quantify potential energy profiles) for the optimization of those reaction trajectories. It is worth mentioning that this study required extensive computational time. Therefore, the limitation of the computational facilities can play a critical role in mechanistic studies at electrode surfaces.



Cluster Models

An alternative approach for studying surface reactivity related to EC interphases is to use a cluster model of the active catalysts site, instead of periodic cell calculations. This approach has been particularly useful in modeling non-precious oxygen reduction reaction (ORR) catalysts, which were demonstrated to have comparable catalytic activity to that of Pt-based catalysts [22]. In such studies, the reaction paths and barriers are found by locating the all relevant minimum energy structures which represent reactants, products, or stable intermediates, as well as confirmed transition state species (i.e., structures having one imaginary frequency) on the potential energy surface. Usually such computational schemes are not prohibitively computationally expensive for using hybrid DFT potentials as well as post-Hartree–Fock electron correlation schemes, as opposed to slab periodic models. The favorable agreement between the computational data and experimental outcome may be partially attributed to the well-tuned DFT functionals, accounting for various types of interactions, typically found in metallo-organic catalysis [23].

Applications: Modeling Electrode Surfaces in Batteries

Understanding of the EI at the battery electrodes is particularly important due to the formation of the solid electrolyte interphase SEI [24, 25] which represents the actual EC surface during the stable operation of the battery. This intermediate layer could be formed due to the reactivity of the surface of the electrode with the electrolyte in the presence of chemically active species formed during battery operation. Therefore, the modeling of surface reactivity should take into account the non-perfect electrode covered with this additional layer. Only in recent years, DFT studies appeared tackling the formation of this layer or its possible precursors.

The importance of modeling the SEI or its precursors cannot be underestimated in metal–air batteries. Metal–air batteries have the highest energy density because most of the cell volume is occupied by the anode while the cathode active material, i.e., the O_2, is not stored in the battery,

Electrochemical Interfaces for Energy Storage and Conversion, Fig. 4 Schematic representation of (**a**) lithium–air cell and (**b**) lithium-ion cell components and the flow of the positive and negative charge on discharge of the cell

rather adsorbed constantly from air into the porous conductive carbon black (Fig. 4a). If Li metal is used as an anode, the specific capacity can be as high as 3,842 mA h g^{-1}. During the discharge of the cell, an oxidation reaction occurs at the anode, $Li \rightarrow Li^+ + e^-$.

Li^+ ion is moving across the electrolyte while the electrons flow in the external cycle to the cathode where a reduction reaction occurs, $2Li^+ + 2e^- + O_2 \rightarrow Li_2O_2$ (or $Li^+ + e^- + O_2 \rightarrow LiO_2$).

The EC performance of this type of cells strongly depends on the electrolyte. By an example, initially, organic carbonates were used; however, it was found that they are unstable toward the nucleophilic attack by the ORR products. Therefore, the understanding and optimization of the EC cathode electrolyte interface are crucial for battery performance.

Very recent studies tackled the reactivity of the electrode surface by modeling each possible reaction of the surface with electrolyte molecules. As an example, the reactivity of propylene carbonate with basic species derived from the Li_2O_2 molecule in solution (Li_2O_2, LiO_2^-, and O^{2-}) and the (100) surface of Li_2O_2 in the presence of the propylene carbonate solvent was recently studied [26]. A wealth of information is provided on the chemical reactivity of the ORR products with the electrolyte. As much as 15 individual reaction paths were examined, combining classical and DFT potentials together with free and potential energy methods.

The complexity of such studies is increased when taking into account particular electronic features of the bulk and surfaces. Again, for Li–air batteries, it was demonstrated that the stable surfaces of Li_2O_2 could be oxygen rich and have a half-metallic character, while the bulk is an insulator [27].

In rechargeable lithium-ion batteries (LIB), in which both the anode and the cathode are intercalation electrodes, the conductivity depends on the positive and negative charge conduction rate both in the bulk of the electrode and on their surface. Schematic representation of a Li-ion cell, which is typically used in portable devices, is shown in Fig. 4b. Interestingly, $LiFePO_4$ was successfully commercialized as a cathode in rechargeable LIBs. However, its surface characterization and the impact of surface composition on Li transport properties have been almost ignored. Recently, this trend has changed. For instance, NEB calculations on a vacuum slab model have shown that the diffusion of Li on the surface has higher activation barrier (0.52–0.77 eV) than for diffusion barrier in the bulk (0.19–0.29 eV) [28].

Summary and Future Perspectives

Understanding the basic principles of operation of novel materials and devices for energy storage and conversion opens new horizons within theoretical material science. It allows designing new strategies – going beyond a mere trial and error procedure – for improving actual technology, developing new materials, and establishing basic relationships in the electrochemistry of interfaces and electrolytes.

The constant development of computational power and new theoretical methods enabled the modeling of EC phenomena purely on the basis of microscopic information of the atomistic structure and our knowledge of electronic phenomena. In particular, parameter-free approaches such as DFT are unique in providing a comprehensive description of the subtle interplay between thermal, electronic, and ionic effects at EI.

The most important progresses in the simulation of realistic interfaces for energy storage and conversion was achieved by the theoretical surface science community. The studies summarized above demonstrated how DFT simulations can provide crucial insight on the nature of key mechanisms at EC bulk and interfaces in batteries and fuel cells. However, many important methodological issues are still open in electrochemistry. For instance, the disclosure of the functional relationship between DL structure, potential drop at EI, and effect of an applied potential is only in its infancy, especially for complex EI.

In this entry, we have highlighted the recent conceptual evolution leading to the development of the most popular methodologies to describe EC phenomena and processes. We have shown how standard simulation methods – which use periodic boundary conditions and supercells – resort to charging the electrode to simulate the effect of an applied potential to an electrolytic cell and how this approach allowed achieving relevant progress in the last 10–20 years. We illustrated how all these models reach global charge neutrality and how most of them reproduce the localization of the electric field and potential energy drop within a microscopic distance from the metal surface.

However, none of these methods currently provide a fully realistic and self-consistent view of the electrostatic DL characterizing an EI, due to the small size of the samples, the artificial assumptions on charge distribution, the lack of description of the open nature of EC systems, and how their dynamical behavior is affected by an applied external potential. Importantly, the kinetics of redox processes at the electrode fully including the effect of the solvent environment is still mostly disregarded.

More realistic models for EIs are needed, possibly including explicit dynamical description of electrolyte solution at the interface with the electrode and its effects on the complex activated phenomena occurring within the DL.

A combination of classical electrochemistry, electronic structure, and classical surface science knowledge will be essential for addressing the still numerous open issues in this intrinsically multidisciplinary research area. Crucially, a substantial progress will be enabled by the increasing availability of computational power.

Finally, the understanding of atomistic and molecular scale processes that occur in EC devices and their interplay can only be achieved by addressing the relevant questions using theoretical models, experimental techniques, computational methodology, and associated simulations as complementary tools.

Definition

Electrochemical machining is a metal removal–based manufacturing process that depends upon electrochemical dissolution for metal removal mechanism. It is one of the advanced manufacturing processes for producing parts with complex shapes using metals and alloys with low machinability.

Overview

Though electrochemical machining process is of relatively recent origin, the reverse process – electroplating – has been in use since a long time. The basic process is indicated in Fig. 1.

A metallic tool is fed at a constant rate toward the work, and the gap between the tool face and the work surface (in the machining area) is supplied with copious flow of an electrolyte (often brine) at a reasonably high rate. A large direct current at a low voltage (typically 10–15 V) is supplied to the work–tool system, the positive terminal being the work. Electrochemical dissolution causes material to be removed from the work piece and the electrolyte–material combination being such that no deposition takes place on the tool electrode (and the dissolved material and the ohmic heat generated in the tool–work gap are carried away by the electrolyte). The shape of the machined portion of the work conforms to the shape of the tool face as indicated in Fig. 1. Once the desired shape is achieved the tool is withdrawn.

Electrochemical Machining (ECM), Fig. 1 Basic scheme of electrochemical machining

Process Mechanism

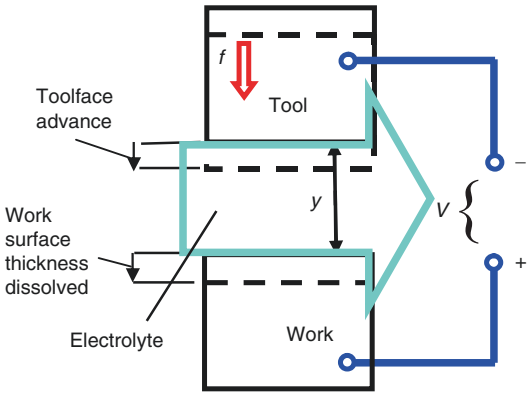
According to Faraday's laws, the amount of material dissolved during an electrochemical process is proportional to the quantity of electricity passed; besides, the amounts of different substances dissolved by the same amount of electricity are proportional to their chemical equivalent weights. Thus,

$$m \propto \in It \tag{1}$$

where m is the weight in gram of a substance dissolved, I is the current in amperes, t is the time in seconds and $\in$ is the gram equivalent weight of the substance (i.e., the work material). Equation 1 can be written in the form of the following equation:

$$m = \frac{\in It}{F} \tag{2}$$

Where F represents the constant of proportionality and is equal to 96,500 C. For ferrous chloride solution (brine) as the electrolyte, the following electrochemical reactions occur at the anode (work) and the cathode (tool); respectively:



$$Fe \rightarrow Fe^{++} + 2e^{-}$$
$$2H_2O + 2e^{-} \rightarrow H_2 \uparrow + 2(OH)^{-}$$

Thus, Fe dissolves at the anode and H_2 is released at the cathode. The reaction in the electrolyte is as shown below:

$$Fe^{++} + 2(OH)^{-} \rightarrow Fe(OH)_2 \downarrow$$

The insoluble $Fe(OH)_2$ is removed with the electrolyte as a precipitate and no deposition at the cathode occurs.

The gram equivalent weight of the work metal, $\in$ is given by A/Z, where Z is the valence

Electrochemical Machining (ECM), Fig. 2 Mechanics of ECM

of the produced ions and A is the atomic weight. If ρ be the density of the work material in gm/cm^3, Eq. 2 yields the following relation for the volume rate of material removal from the work piece:

$$Q = \frac{AI}{96,500\rho Z}\text{cm}^3/\text{s} \tag{3}$$

The magnitude of the current I is given by

$$I = \frac{V - \Delta V}{R} \tag{4}$$

where V is the applied voltage in volts, ΔV represents the combined over voltage due to various effects and should be subtracted from the impressed voltage before Ohm's law can be applied, and R is the overall resistance (but most of it due to the electrolyte layer in the interelectrode gap). Typical electrolytic conductivity is 0.1–1.0 $\Omega^{-1}\text{cm}^{-1}$ whereas that of iron is about $10^5\Omega^{-1}\text{cm}^{-1}$.

Figure 2 shows symbolically the plane-parallel work–tool electrolyte combination with tool being advanced at a constant rate of f toward the work.

If the applied voltage is V and specific conductivity of the electrolyte is k, Eq. 2 yields the following relation for the current density at the work surface:

$$J = \frac{k(V - \Delta V)}{y} \tag{5}$$

Where, y is the gap thickness at the instant under consideration. So, after a short time interval Δt the tool face advances by $f \times \Delta t$. The work surface also recedes because of electrochemical dissolution. If δ be the depth of recession then using Eq. 3

$$\delta = Q \times \Delta t = \frac{AJ\,\Delta t}{96,500\rho Z}$$

Replacing J in the above equation from Eq. 5

$$\delta = \frac{Ak(V - \Delta V)}{96,500\rho Z y} \times \Delta t$$

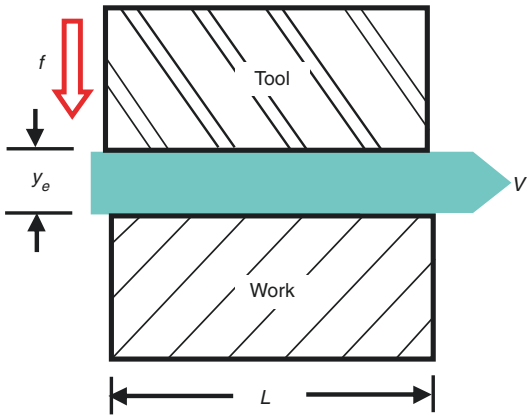
But when the gap is stable the rate of depth of dissolution ($\delta/\Delta t$) and the rate of tool advance (f) must be equal. Hence, under equilibrium condition (i.e., $y = y_e$)

$$\frac{\delta}{\Delta t} = f$$

or,

$$\frac{Ak(V - \Delta V)}{96,500\rho Z y_e} = f$$

or,



$$y_e = \frac{Ak(V - \Delta V)}{96,500\rho Z f} \tag{6}$$

It can be easily seen that this equilibrium condition is stable and for a given electrolyte–electrode combination, the equilibrium work–tool gap, y_e, depends upon the applied voltage and the feed rate.

Since an equilibrium gap is ultimately reached it is possible to arrive at a definite relationship between the tool and work geometries (i.e., a tool can be shaped to generate a desired work shape). This phenomenon makes the process suitable for machining objects with definite shapes.

Machining Force and Electrolyte Flow

At a first glance, it may appear that there is no machining force involved as there is no contact

Electrochemical Machining (ECM), Fig. 3 Electrolyte flow through work–tool gap

between the work and the tool. But, in reality, there exists large force acting on the electrodes due to a large pressure exerted by the electrolyte flowing through the work–tool gap.

Figure 3 indicates symbolically an ECM operation with an equilibrium work–tool gap of y_e. The flow velocity, v, is determined predominantly from the thermal conditions.

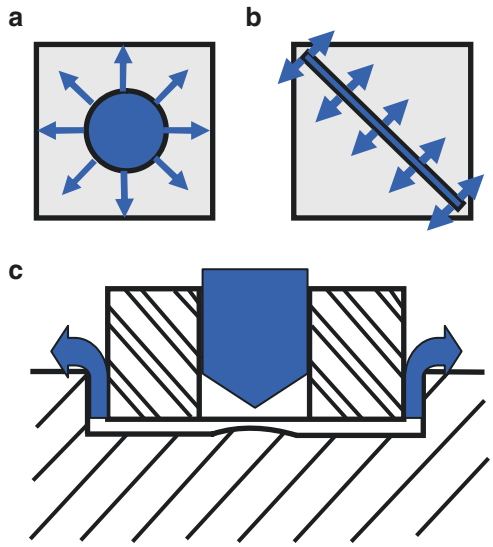
If the variation in conductivity of the electrolyte with temperature is ignored, then the following equation for the required flow velocity, v, of the electrolyte can be obtained [1]:

$$v = \frac{J^2 L}{k\Delta\theta\rho_e c_e} \tag{7}$$

where, J is the current density, L is the length of the flow path, k is the specific electrical conductivity of the electrolyte, $\Delta\theta$ is the allowed temperature rise in the electrolyte, ρ_e and c_e are the density and specific heat of the electrolyte. If the gap is y_e and the viscosity of the electrolyte is η, the total pressure required (assuming turbulent flow) to achieve a flow velocity of v is given by the relation [1].

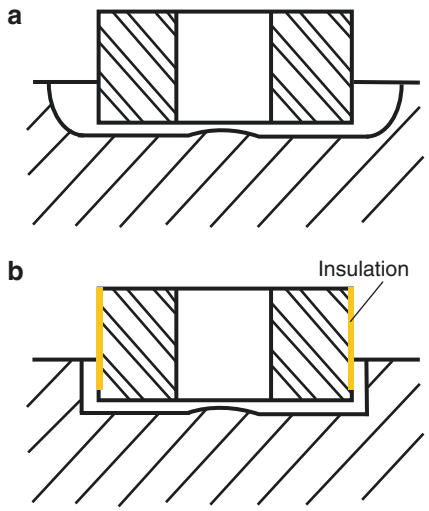
$$p = \frac{0.3164\rho_e v^2 L}{4y_e (R_e)^{1/4}} + \frac{\rho_e v^2}{2} \tag{8}$$

where, R_e is the Reynolds's number. It can be easily demonstrated that to prevent boiling of the electrolyte the pressure for the electrolyte in a typical ECM operation is a few hundred kN/m^2. This can exert a reasonably large force on the tool face depending on the size.



Tool Design

The three primary aspects associated with the tool design for ECM operation are (a) the determination of the geometric shape of the tool that generates the desired work shape, (b) electrolyte flow path design that ensures smooth and ample flow of electrolyte all over the working area, and (c) design from other considerations like strength, insulation of the areas of tool surface which should not take part in the electrochemical process and fixing arrangements.



Since the equilibrium gap y_e can be accurately predicted it is possible to decide upon the required tool geometry that will generate the desired work shape. Design of electrolyte flow path is extremely important as the quality of the surface generated depends very significantly on the uniformity and smoothness of electrolyte flow. A large flow requires a large cross-sectional area of the orifice through which the flow emerges as indicated in Fig. 4a. This leads to a residual bulge on the machined surface of the work as shown in Fig. 4c. To avoid the residual bulge without reducing the flow path opening area, the passage can be in the form of a narrow but long slot as shown in Fig. 4b. Since the flow will be in a direction normal to the slot as shown, the slot geometry should be carefully decided so as to keep the whole machining area with ample and smooth flow of electrolyte.

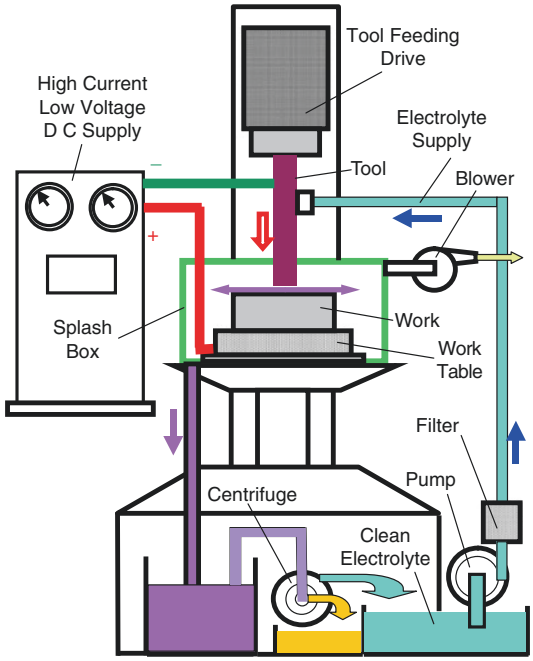
To restrict machining only at the desired locations, it is essential to insulate some portions of the tool surface. Figure 5a, b indicates the result of ECM without and with insulation.

It is obvious that the tool material should be electrically conducting. As the desired shape has to be machined, tool material should have good machinability and reasonable mechanical strength.

Electrochemical Machining (ECM), Fig. 4 Tool face showing the flow exit holes (**a**) normal shape, (**b**) narrow and long passage, (**c**) residual bulge with a flow path as shown in (**a**)

Electrochemical Machining (ECM), Fig. 5 Machined shape (**a**) without insulation, (**b**) with insulation

Electrolytes



The functions accomplished by the electrolyte during ECM are: (a) completing the electrical path allowing passage of large current, (b) sustaining the electrochemical dissolution process, and (c) carrying away the heat and waste product from the machining area. So a good electrolyte should have large electrical specific conductivity. It should be also of such composition that deposition does not occur on the cathode (i.e., the tool) as otherwise the tool geometry can change. Besides, an electrolyte should be inexpensive, safe, and as noncorrosive as possible. Usually, an aqueous solution of inorganic compounds is used as shown below in the list:

Work material	Electrolyte
Ferrous	Chloride solution in water, usually NaCl
Nickel based	HCl or mixture of H_2SO_4 and brine
Titanium based	10 % HF + 10 % HCl + 10 % HNO_3
Co–Cr–W based	NaCl
WC based	Strong alkaline solutions

ECM Unit

The basic components of a typical ECM unit are shown in Fig. 6. It consists of a work table holding the job.

The tool is fed by a low-feed-rate tool feeding drive with a facility to quickly retrieve the tool at a fast rate. The machining zone is enclosed in a box and the collected electrolyte and the precipitate are accumulated in a tank. A centrifuge separates the precipitate as sludge and the clean electrolyte is stoned in another tank from where it is recirculated by a pump through a filter as shown. The H_2 generated by the process is removed using an exhaust blower to prevent the chance of any explosion. A low voltage high amperage DC supply provides the required large current at a low voltage as indicated. All the units must be made of corrosion-free material like stainless steel, polymeric materials, etc. The whole system is supported by a rigid and strong structure as very large electrolyte pressure can generate a large force between the tool and the electrode; and any deformation can jeopardize the operation. All these requirements result in high cost of such machines.

Electrochemical Machining (ECM), Fig. 6 Basic components of a typical ECM unit

Department of Chemistry and Biochemistry, University of Bern, Bern, Switzerland

Synonyms

EC-STM; In situ STM

Definition

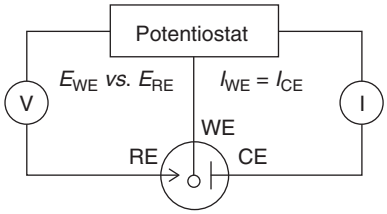
Electrochemical scanning tunneling microscopy (EC-STM) is a conceptional and instrumental extension of scanning tunneling microscopy toward its application to charged solid–liquid interfaces (electrochemical systems).

Introduction

With the invention of scanning tunneling microscopy (STM) by Binnig and Rohrer, a unique new tool for high-resolution imaging of structures and process (dynamics) at conducting surfaces became available. Soon after its application in surface studies under ultrahigh vacuum (UHV) conditions, this method was also adopted to electrochemical systems under potentiostatic or galvanostatic control and "in situ" EC-STM was born. This technique advanced tremendously the knowledge on surface structure and reactivity in electrochemistry because imaging of electrode surfaces was now possible in situ, in real space, and with atomic-scale resolution [1–7].

Examples range from fundamental studies of reconstruction of metal single-crystal surfaces [5], ordered adsorption of anions [3, 6], and organic molecules [7] to the initial stages of metal deposition [8] and up to applications in electrocatalysis, plating, and corrosion [9]. During the last decade, in situ STM investigations were combined with in situ scanning tunneling spectroscopy (STS) to obtain electronic structure information [10] and to explore charge transport in single atom and molecular junctions [11] as well as in tunneling junctions [12]. Besides imaging with atomic-scale resolution, the STM tip has been also employed as a tool in nanostructuring of electrode surfaces with high spatial and chemical resolution [13].

The entry starts with a brief introduction into electrochemistry and EC-STM. Subsequently, the potential of STM in electrochemistry is demonstrated in selected structure studies with bare and adlayer (anions, molecules, metal atoms)-modified single-crystal surfaces and by monitoring simple reactions, such as metal deposition. Finally, single-molecule transport experiments and nanostructuring of surfaces by the STM tip will be addressed.



Overview and Key Principles

Fundamentals of Electrochemistry

Electrochemistry represents chemical reactions that are connected with the transfer of electric charges [14]. Many of these processes occur at electrified solid–liquid interfaces. Typically, the solid phase acts as an electron conductor (metal or semiconductor electrode) and the liquid phase as ionic conductor (e.g., an aqueous electrolyte solution). The interface is composed of electronic and ionic charge carriers and characterized by an electric field as high as 10^9 Vm^{-1}. This region is called "electrical double layer" (EDL). In the absence of electrochemical reactions, no charge transfer across the interface occurs. The latter then resembles a capacitor that can be charged or discharged upon application of an external voltage ("ideally polarizable interface"). In the presence of an electrochemical (Faraday) reaction, charge or, in other words, an electrochemical current passes the interface ("ideally nonpolarizable interface"). The classical route to the study of electrochemical reactions rests on current and voltage measurements. Both quantities can be determined with high precision and are easily accessible, although they lack direct chemical or structural specificity.

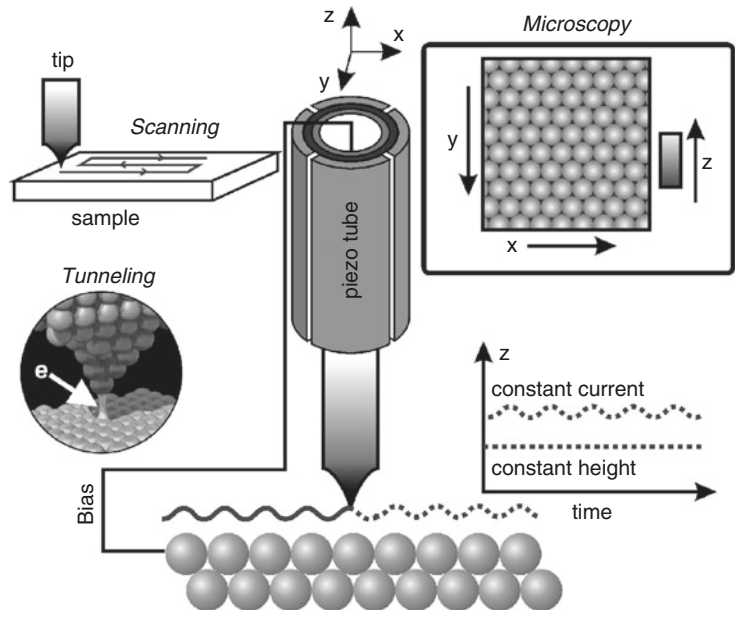
Electrochemical experiments are typically carried out under potentiostatic conditions (i.e., under potential control) in a three-electrode configuration composed of a working electrode (WE), the electrode of interest, a reference electrode (RE), and a counter electrode (CE), respectively (Fig. 1). For the discussion of a relation between the electrochemical and the absolute potential scales, we refer to Ref. [15]. All electrodes are immersed into the electrolyte solution. The setting up of the potential differences and the measurement of the current are controlled by a potentiostat (Fig. 1).

The potentiostat measures current and potential in the CE and RE circuits. Due to voltage drops and polarization effects, the potential difference between WE and RE can be measured precisely only if there is negligible current flowing through the RE. The potential difference between the WE and the CE is adjusted via a feedback loop

Electrochemical Scanning Tunneling Microscopy, Fig. 1 Schematics of a potentiostat and three-electrode electrochemical cell

in such a way that the desired value of the electrode potential E (E_{WE} vs. E_{RE}) is reached. As a consequence, the current flowing in the CE circuit (between WE and CE) is the current flowing at the WE at this electrode potential [14].

Basics of Scanning Tunneling Microscopy



The STM technique is based on electron tunneling, which is well known from quantum mechanics. When a freely moving electron incidents an energy barrier of constant relative height Φ and width z, it may penetrate through it with the probability

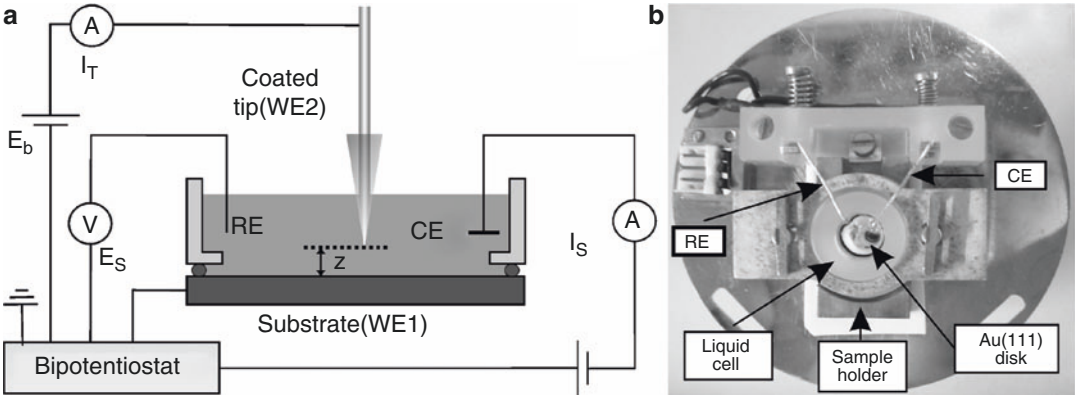
$$P(z) = \exp\left(-\frac{4\pi}{h}\sqrt{2m_e\Phi}\cdot z\right) = \exp\left(-\kappa\sqrt{\Phi}\cdot z\right) \quad (1)$$

Here $h = 6.626 \times 10^{-34}$ J · s is Planck's constant, $m_e = 9.11 \times 10^{-31}$ kg is the electron mass, and $\kappa = 10.12\ \mathrm{eV}^{-1/2} \cdot \mathrm{nm}^{-1}$ is a combination of constants. In STM, a sharp conductive tip (typically metal) is brought up to few nanometers close to a conductive surface (Fig. 2). The potential difference E_b (bias voltage) applied between an atomically sharp tip and the sample causes electron tunneling via the insulating gap, which could be ultrahigh vacuum (UHV), gas, or liquid. In the low-bias approximation, the tunneling current is proportional to E_b and to the electron tunneling probability:

$$I_T(z) \propto E_b \exp\left(-\kappa\sqrt{\Phi}\cdot z\right) \quad (2)$$

The tunneling current I_T is measured by a highly sensitive preamplifier with a typical operational

Electrochemical Scanning Tunneling Microscopy,
Fig. 2 Schematics of an STM. *Upper left*: tip scanning on the sample; *lower left*: electron tunneling between tip and sample; *upper right*: obtained STM image; *lower right*: two operation modes



range of 1 pA to 100 nA. The *x,y,z*-movement of the tip in the nanometer scale is performed by a piezoelectric tube based on ceramics (often lead–zirconium–titanate) exhibiting a piezoelectric effect, that is, expanding or shrinking upon application of a voltage. One may distinguish between two operational modes of the STM (Fig. 2). In constant-current mode, a preset tunneling current I_T is kept constant by adjusting the z position of the tip at every measured point via a feedback circuit. The information on vertical displacement of the tip as a function of the lateral position is recorded as an array of (x, y, z) data and presented as a three-dimensional (3D) or two-dimensional (2D) image of the local density of states, which reflects, in the case of metals, the topography of the substrate surface directly.

In constant height mode the vertical position of the tip is kept constant during the lateral scanning while the value of I_T is recorded as a function of the tip position. The array of (x, y, I_T) data provides information on the surface topography and can be presented in a similar way as results of the constant-current mode STM.

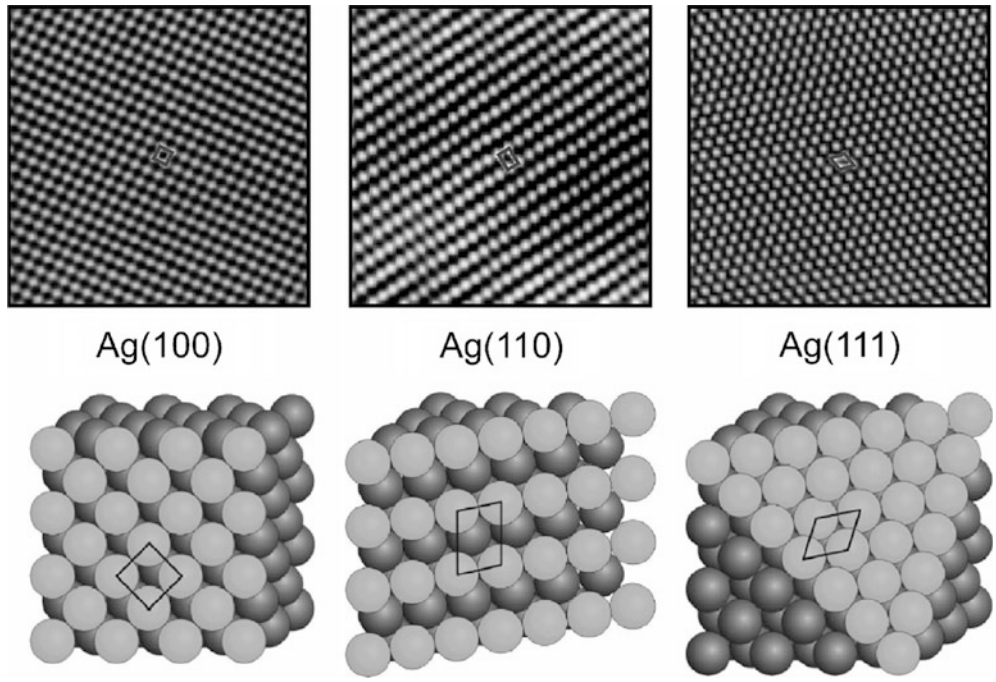
In an STM experiment, one may achieve lateral *x,y* resolution of 0.1 nm and a vertical resolution up to 0.01 nm. This unprecedented capability of STM is due to the strong dependence of the tunneling current on the distance z between tip and sample (cf. Eq. 2). With a typical barrier height of one to a few eV, an increase of z by the size of a single metal atom (0.2–0.5 nm) decreases the tunnel current up to three orders of magnitude. Atomically sharp STM tips are required to avoid artifacts, and in this case, only the most protruding part of the tip acts as a probe. Finally, it is noted that STM per se is not providing "chemical information" on surface (and tip) composition!

Electrochemical (In Situ) Scanning Tunneling Microscopy

Tunneling in an electrochemical experiment takes place in an electrically conducting environment, the electrolyte (aqueous, organic, or ionic liquid as examples). Electrochemical reactions may occur at the tip as well as at the substrate. The resulting electrochemical current I_F is superimposed on the tunneling current I_T. To minimize I_F at the tip relative to I_T, the tip is coated with an inert and insulating layer made of glass, apiezon, polyethylene, or electrophoretic paint [1]. The remaining electrochemically active area of well-insulated tips amounts to 10^{-8}–10^{-7} cm^2 and yields residual electrochemical ("leakage") currents of typically less than 5 pA, which do not interfere with tunneling currents of 0.1–10 nA.

Electrochemical Scanning Tunneling Microscopy, Fig. 3 (**a**) Schematics of an EC-STM setup; (**b**) assembled cell

From an electrochemical point of view, substrate and tip represent two working electrodes (WE1 and WE2 in Fig. 3a), in which potentials E_S and E_T are independently controlled with respect to the RE, and the bias voltage is given by the potential difference $E_b = E_T - E_S$. This functionality is controlled by a bipotentiostat, which represents a potentiostat with two independently adjustable working electrodes (four-electrode potentiostat).



The type of substrate and its potential E_S are determined by the electrochemical problem to be studied. The choice of tip material and potential E_T are dictated by the requests of high mechanical and, in addition, chemical stability to minimize the faradic current I_F at the tip. Atomically sharp tips are typically prepared by electrochemical etching of thin metal wires, such as tungsten, platinum–iridium, or gold.

The choice of the RE depends on electrolyte and electrochemical problem under study. Examples are a Pt wire in acidic electrolytes, reference electrodes of the first kind (Me in Me^{z+}-containing electrolyte such as Cu/Cu^{2+} or Ag/Ag^{+}) or of the second kind (Ag/AgCl, Au/Au_xO_y, etc.). The materials of the CE are less critical. Often Pt or Au wires are chosen. Attempts to remove oxygen and to control the environment during an STM experiment led to the development of various custom-built environmental chambers. Figure 3b illustrates, as an example, a typical EC-STM cell.

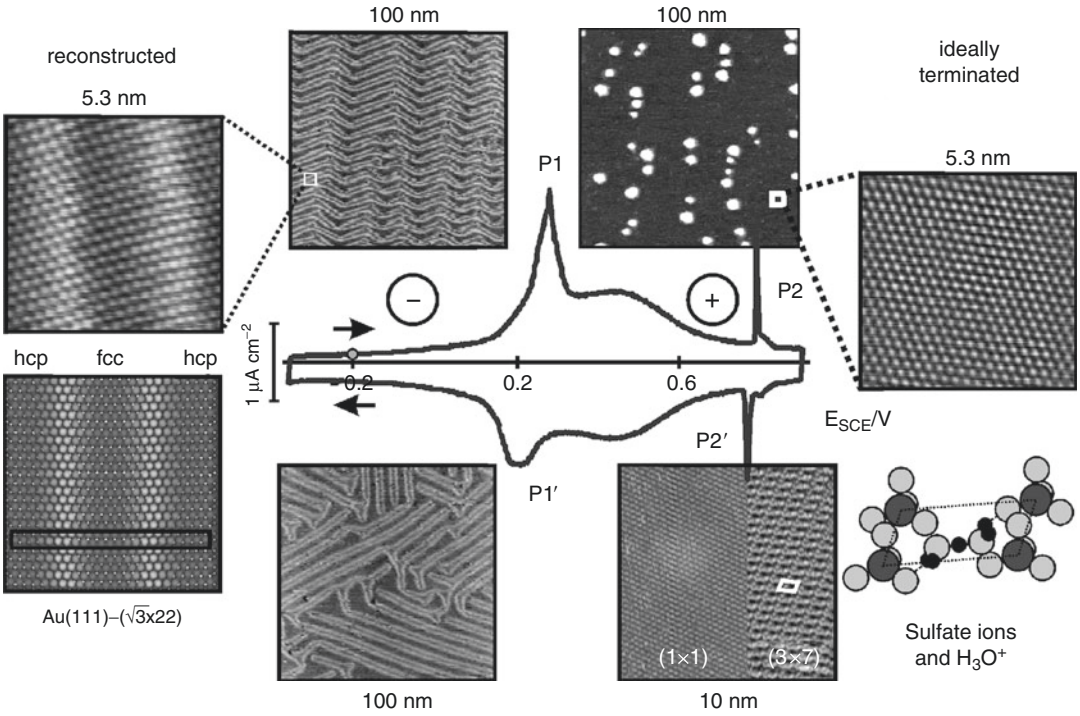
Besides high-resolution atomic-scale imaging, even up to video acquisition rates [16], most EC-STM setups are also capable of performing scanning tunneling spectroscopy (STS) measurements. The latter are carried out at fixed lateral (x,y) position of the tip above the substrate. In *current–distance STS experiments*, the tunneling current is measured at constants E_S and E_T as a function of the vertical tip displacement Δz. The independent control of the potentials of both tip and substrate with respect to the RE allows various modes of *current–voltage spectroscopy* in an electrochemical environment. In *variable bias STS mode*, the potential of one electrode (typically of the substrate WE1, E_S) is fixed, while that of the other (WE2, E_T) is swept over a wide range of potentials. This regime is equivalent to an ex situ current–voltage STS experiment with two electrodes. The *constant bias mode of current–voltage STS* is unique for the electrochemical environment. Here, both E_S and E_T are swept simultaneously, so that their difference E_b is kept constant. Tunneling spectroscopy is an important technique for studies of electronic properties and in particular of electron transfer at electrochemical solid–liquid interfaces [10, 12].

Key Research Findings and Selected Applications

In the following section, the potential of EC-STM is demonstrated in structure studies on bare and adsorbate-modified single crystals and by

Electrochemical Scanning Tunneling Microscopy, Fig. 4 *Top row*: STM images of three low-index faces of silver single-crystal electrodes in 0.05 M H_2SO_4, 7 × 7 nm. *Bottom row*: models of the low-index faces of a FCC metal. The surface unit cells are indicated (Adapted from Ref. [17])

monitoring simple reactions such as metal deposition. Finally, single-molecule electron transport experiments and nanostructuring of surfaces are described.



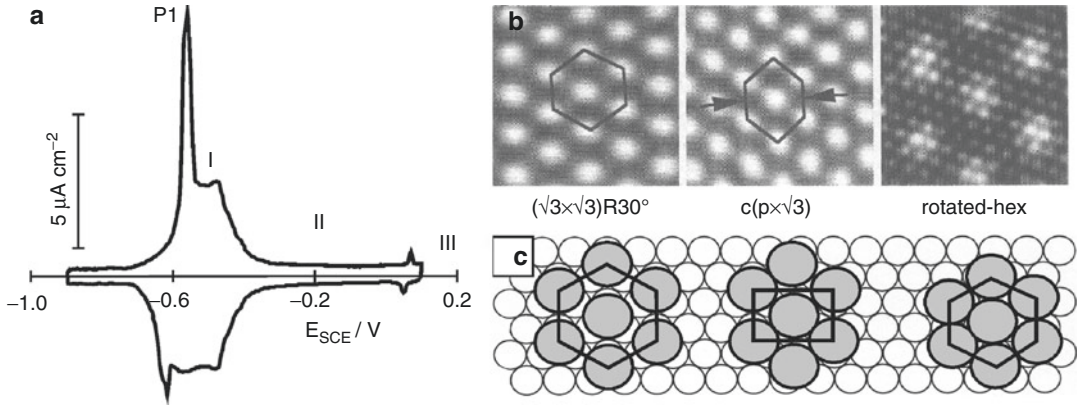
Structure of Single-Crystalline Surfaces

For a detailed understanding of surface processes, the use of single crystals with structurally well-defined surfaces is highly desirable. After establishing high-quality and lab-accessible preparation techniques, such as flame annealing, inductive annealing, and various chemical etching protocols, STM revealed unprecedented microscopic details of electrode surfaces under electrochemical conditions since the early 1990s up to the present [1–5]. The majority of atomic resolution studies was carried out with metals forming face-centered cubic (FCC) crystal lattices, such as Au, Ag, Cu, Ir, Ni, Pd, Pt, and Rh. Selected studies were also reported for Fe-type and semiconductor surfaces. As an example, Fig. 4 shows in situ STM images of the three low-index faces of silver single-crystal electrodes recorded in 0.05 M H_2SO_4 [17], together with schematic models of the respective surface structures.

The high spatial resolution of EC-STM provides access not only to steady-state surface structures, such as the lattice arrangement of surface atoms and defects (holes, steps, kinks, and/or islands) under potential control, but also to dynamic phenomena with a time resolution as high as several tens of milliseconds. Examples are step and island mobility [18] and surface reconstruction [5].

Surface Reconstruction

Experiments on the formation and lifting of surface reconstruction represent classical examples of surface processes driven by electrode potential and solution composition [5]. Surface reconstruction is the rearrangement of surface atoms into a different structure than the one dictated by the crystal plane, as driven by the minimization of the energy for surface atoms with an unsaturated coordination sphere. This phenomenon was first extensively studied in UHV. Conclusive evidence



Electrochemical Scanning Tunneling Microscopy, Fig. 5 Cyclic voltammogram and STM images of Au(111) in 0.1 M H_2SO_4 (Adapted from Ref. [7])

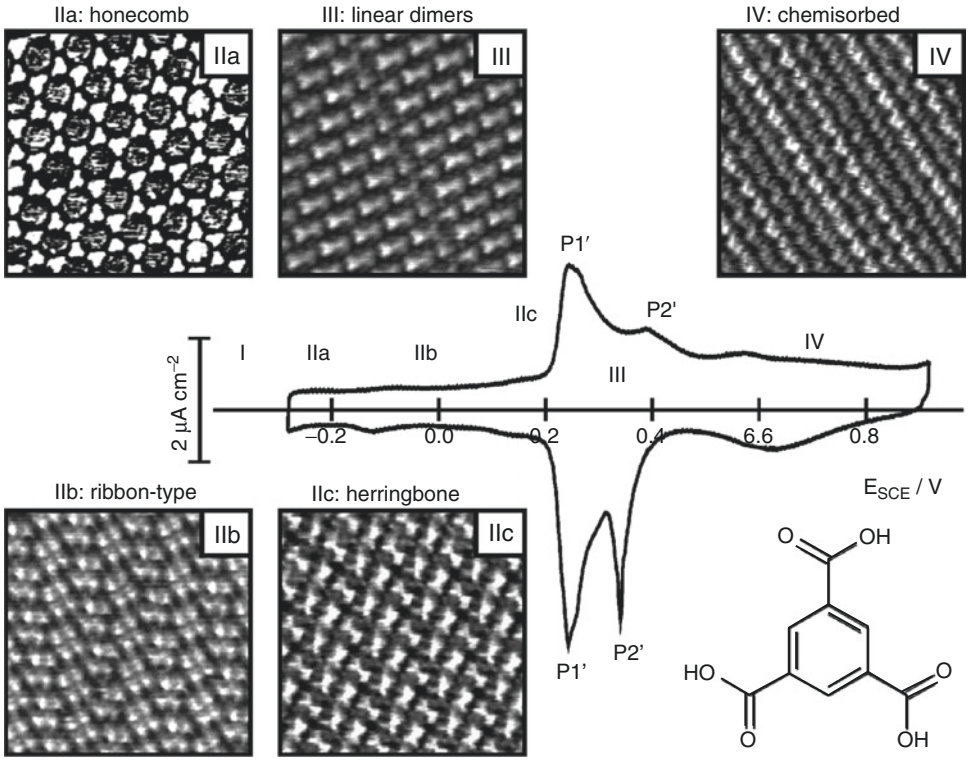
about the existence of reconstructed surfaces under electrochemical conditions was obtained after electrochemists gained access to high-resolution structure-sensitive techniques, such as in situ STM. Examples are the low-index phases of Au (Au(111)-(p × √3), Au(100)-(hex), Au (110)-(1 × 2), and Au(110)-(1 × 3)) and Pt (Pt (100)-(hex), Pt(110)-(1 × 2)) as prepared by sputtering and annealing cycles in UHV or annealing in a Bunsen burner or hydrogen flame. In particular, in situ STM and surface X-ray scattering experiments revealed that the reconstructed surfaces of the three low-index Au single crystals are stable at negative surface charges and are lifted upon positive polarization. The process is reversible. The adsorption of anions was found to assist the lifting of the reconstruction [5].

Figure 5 shows large-scale and atomic-scale resolution images of the thermally induced Au (111)-(p × √3) reconstruction, as obtained after flame annealing in 0.1 M H_2SO_4 at $E_S = -0.20$ V, where the electrode is charged negatively. Changing the electrode potential toward positive charges causes the lifting of the reconstruction into the Au(111)-(1 × 1) structure. The extra amount of Au atoms from the ca. 4 % more densely packed (p × √3) structure forms monatomic high gold islands, which are rather mobile. At sufficiently high potentials, the adsorbed sulfate ions form a 2D-ordered (√3 × √7) adlayer on top of the Au(111)-(1 × 1) surface. Changing the potential back to negative charge densities causes the reconstruction to reappear. However, this so-called electrochemically induced reconstruction is less ordered as compared to the thermally induced reconstruction. For further details the reader is referred to Refs. [5, 7].

Adsorption of Anions

The study of adsorbates is of importance for electrochemistry, as many reactions proceed through intermediate adsorption stages [3, 6]. Anions exhibit a strong tendency to adsorb specifically at metal surfaces, that is, to establish a direct bond

Electrochemical Scanning Tunneling Microscopy, Fig. 6 Adlayers of iodide on Au(111)-(1 × 1). (**a**) Cyclic voltammogram of Au(111) in 50 mM NaI, scan rate 50 mV·s^{-1}. The potential ranges of stability for the different monolayers of I on Au(111) are indicated, (**b**) EC-STM images, and (**c**) models of the I monolayers on Au(111) (Adapted from Ref. [3])



with the metal by partial loss of their solvation shell. The direct contact to the electrode reduces the ionic character markedly, which allows a much higher surface concentration than in the case of nonspecific (purely electrostatic) adsorption. Cyclic voltammograms often reveal sharp current spikes (Fig. 6a), indicative of phase transitions within the anionic adlayers and, hence, of the existence of 2D-ordered phases. Structural aspects of these adlayers have been studied in detail by EC-STM in combination with other structure-sensitive in situ techniques [3, 6].

As an example, Fig. 6 demonstrates interfacial structures formed by iodide adsorbed on Au(111) [3]. The cyclic voltammogram was recorded in 50 mM NaI aqueous electrolyte. The current peak P1 represents the lifting of the reconstruction Au(111)-(p × √3) → Au(111)-(1 × 1), while the potential regions I, II, and III, which are separated by characteristic current peaks, could be identified as the following 2D-ordered iodide adlayers: (√3 × √3)R30°, a compressed c (p × √3) phase, and a rotated hexagonal phase at the highest potential and iodide coverage, just before the onset of adlayer oxidation.

Adsorption and Self-Assembly of Organic Molecules

The adsorption and self-assembly of organic molecules at metal surfaces comprise a growing field of interest for fundamental research as well as technological applications. This is due to the immense importance of organic molecules in applied areas such as additives in plating baths (e.g., for superconformal growth in the Damascene process of Cu deposition [19]) or as corrosion inhibitors [9] and to the growing field of molecular nanotechnology for designing materials and functionalized surfaces with novel electronic, magnetic, photonic, mechanical, and sensing/diagnostic properties.

Employing defined substrate surfaces, such as metal single crystals, and tailored molecules as coded information, molecular recognition pattern, and self-organization as well as local functionalities have been studied by EC-STM under a wide range of conditions [2, 3, 7]. These investigations benefited from the application of concepts of supramolecular chemistry to create modified surfaces in the submonolayer, monolayer, and multilayer regime. Adlayer structure motifs are based, for instance, on hydrogen bonding and hydrophobic and electrostatic interactions, such as dipole, π-stacking, and metal ion–ligand coordination [7]. In the case of an electrochemical system, the substrate electrode WE1 acts as an electron source or sink and, eventually, as an additional coordination center. The electrode potential may be considered as a universal tuning source to fabricate and to address these molecular nanostructures.

Electrochemical Scanning Tunneling Microscopy, Fig. 7 Steady-state voltammogram for Au(111)-(1 × 1) in 0.05 M H_2SO_4 in the presence of 3 mM TMA, scan rate 10 mV·s^{-1}, together with typical EC-STM images of the TMA adlayers (size 10 × 10 nm): (*IIa*) hexagonal honeycomb phase, $E = -0.18$ V; (*IIb*) ribbon-type motif, $E = 0.03$ V; (*IIc*) herringbone motif, $E = 0.21$ V; (*III*) hydrogen-bonded linear dimers, $E = 0.34$ V; (*IV*) ordered chemisorbed striped phase of TMA at $E = 0.80$ V (Adapted from Ref. [7])

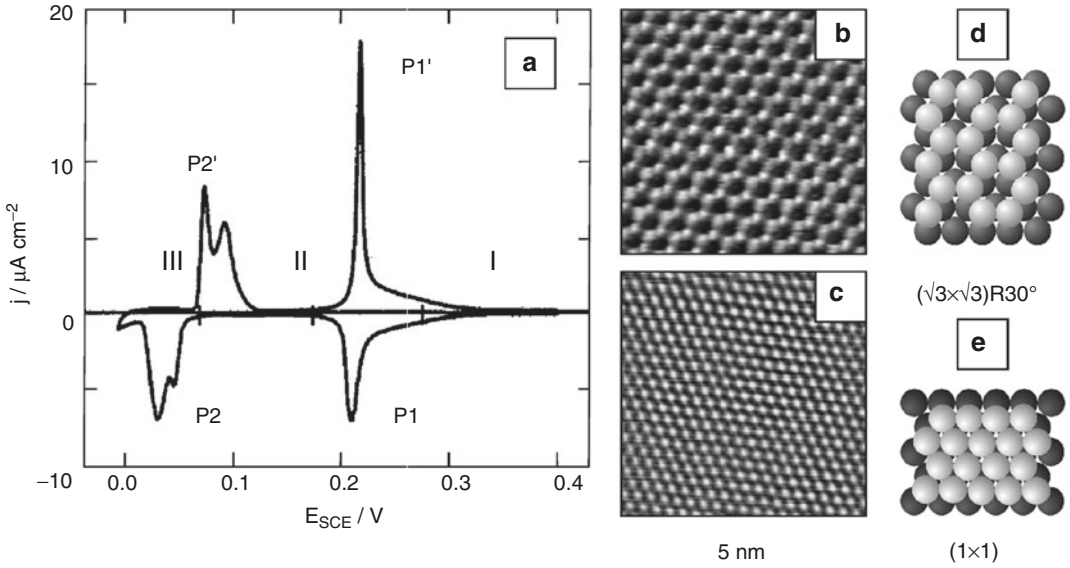
Structure motifs and processes of self-organization at surfaces can be investigated with atomic/molecular resolution employing EC-STM and STS.

A particular fascinating example of tailored molecular self-assembly at an electrified solid–liquid interface is benzene-1,3,5-tricarboxylic acid (trimesic acid (TMA); Fig. 7), a prototype material for engineering molecular nanostructures, on Au(111) in 0.05 M H_2SO_4 [7]. Depending on the assembly conditions and the applied electrode potential, five 2D-ordered molecular adlayers were observed by EC-STM (Fig. 7). At a negatively charged or uncharged Au (111) surface, the molecules are adsorbed flat and assemble with increasing coverage in four distinctly different hydrogen-bonded patterns: the low-coverage hexagonal honeycomb phase (IIa), sometimes even with guest molecules incorporated, a ribbon-type motif (IIb) and a herringbone motif (IIc) pattern, and rows of hydrogen-bonded linear dimers (III). At a positively charged surface, the TMA molecules change their orientation from flat to upright and one carboxyl group deprotonates. The resulting carboxylate group coordinates with the positively charged surface and rows of a new stacking structure are formed (IV). These structure transitions are reversible upon changing the electrode polarization. The detailed mechanisms were explored in a combined EC-STM and infrared spectroscopy study [7].

Concluding this paragraph one should emphasize that the interpretation of EC-STM images of molecular adlayers requires great caution because the observed contrast pattern provides information on the electronic structure of the entire

tunneling junction, and not a straightforward adlayer topography, as often naively assumed in the description of molecular adlayers.

Metal UPD and OPD



The deposition of metals from aqueous solutions has attracted the attention of electrochemists for more than a hundred years. This is related to the importance in many industrial-scale processes such as plating and metal refining. Contemporary frontiers in this field include the optimization of the electrochemical copper deposition in the fabrication of high-quality nanometer-wide integrated circuit interconnects (Damascene process) [19]. A primary characteristic of the metal deposition process is the equilibrium potential E_{eq}, at which the rates of metal deposition and dissolution are equal. The dependence of E_{eq} on the concentration of the metal ions Me^{n+} in a solution, $C_{Me}{}^{n+}$, is described by the Nernst equation:

$$E_{eq} = E^0 + \frac{RT}{nF}\ln(a_{Me^{n+}}) \cong E^0 + \frac{RT}{nF}\ln(C_{Me^{n+}}) \quad (3)$$

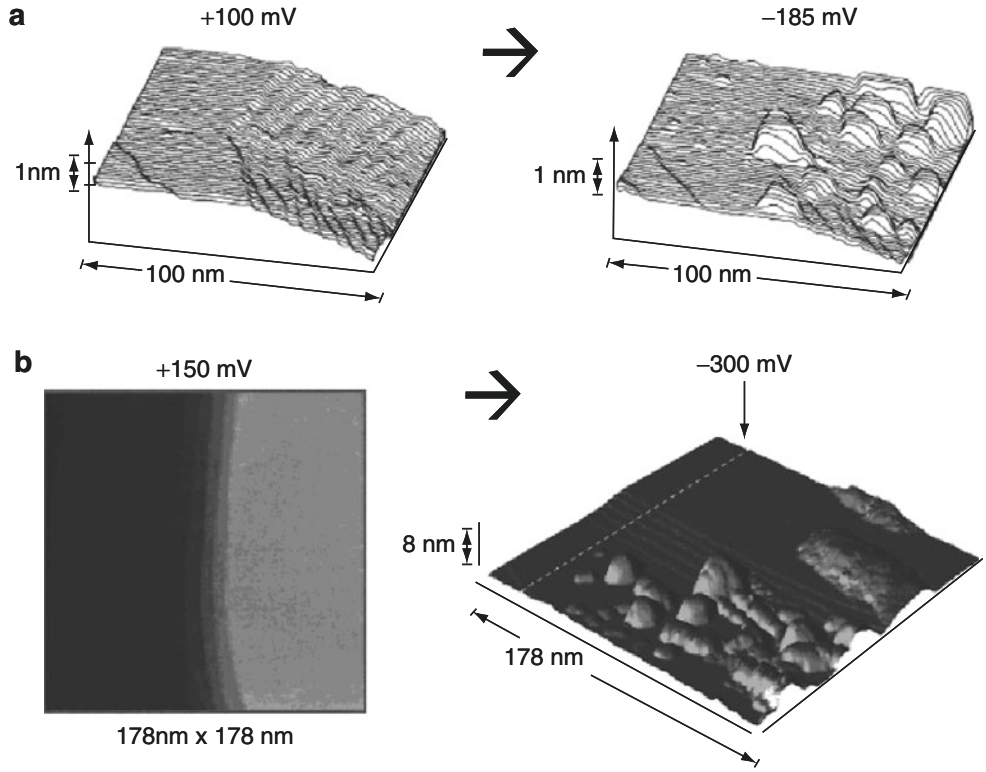
with E^0 being the standard potential of the redox pair Me^{n+}/Me and $(a_{Me^{n+}})$ as the thermodynamic activity of the metal ions in solution. When an external potential $E < E_{eq}$ is applied to the metal electrode, which is in contact with a metal ion Me^{n+}-containing solution, bulk deposition (or overpotential deposition (OPD)) of the metal Me takes place. At $E > E_{eq}$ the bulk dissolution of the metal phase is promoted. However, a (sub)monolayer of metal ions is deposited at $E > E_{eq}$ when the energy of the metal–substrate interaction is higher than that between the atoms of the deposited metal. This process is referred to as underpotential deposition (UPD) [8, 20]. Metal deposition onto a foreign substrate (e.g., Cu on Au) often starts with the formation of a monolayer at underpotentials, that is, at potentials positive to the Nernst potential for the respective bulk phase. UPD of metals is important as the first stage of many metal bulk deposition processes, to tailor electrocatalytic properties of metal surfaces as well as in fundamental electrochemical surface science. The structures and process involved were studied in detail by EC-STM, in combination with classical electrochemical and other structure-sensitive techniques for a wide range of systems and conditions [2, 3, 20].

As an example, Fig. 8 represents the archetype UPD system Cu on Au(111) in 0.05 M H_2SO_4 [20–22]. The cyclic voltammogram shows two well-defined pairs of current peaks P1/P1′ and P2/P2′ corresponding to energetically different adsorption/desorption processes in regions I to III. In the first step (P1), the transition between randomly adsorbed copper ions and (hydrogen) sulfate ions (region I) into an ordered layer of copper ions and co-adsorbed sulfate ions takes place. Among other structure-sensitive techniques, EC-STM revealed a $(\sqrt{3} \times \sqrt{3})R30^\circ$ pattern of bright features (region II) [22]. The correct interpretation of this contrast pattern is based on a surface X-ray scattering study of Toney et al. [23]. These authors demonstrated that Cu ions adsorb in hollow positions of the underlying Au(111) lattice and form a honeycomb-like hexagonal network with a 2/3 Cu coverage. Sulfate ions are positioned in the center of the hexagons with one S-O bond facing toward the electrolyte, which corresponds to a 1/3 sulfate coverage. The pattern resolved by EC-STM represents only the co-adsorbed anion structure. Further decrease of the potential leads to a second interfacial phase transition in this system, as indicated by the peak P2, and a pseudomorphic monolayer of Cu with the same structure as the underlying Au(111) surface is formed (region III). The potential range III is very narrow and limited by the onset of copper overpotential (bulk) deposition (OPD), which proceeds at $E < E_{eq}$ with $E_{eq} = 0.012$ V versus SCE.

OPD of Cu on Au(hkl) was among the first systems studied by EC-STM. The research on Cu-OPD and many other technologically important metals can be divided in three main directions addressing (1) the initial stages of bulk deposition, (2) the growth of the metal phase, and (3) the influence of additives on deposit morphology and deposition rate. Structure and dynamic studies

Electrochemical Scanning Tunneling Microscopy, Fig. 8 (**a**) Cyclic voltammogram of a Au(111)-(1 × 1) electrode in 0.1 M H_2SO_4 and 1 mM $CuSO_4$, scan rate 1 mV·s^{-1} (Adapted from Ref. [24]). (**b**, **c**) (√3 × √3) R30° and (1 × 1) Cu UPD adlayers on Au(111) (Adapted from Ref. [21]). The models of both phases are depicted in panels (**d**) and (**e**)

by EC-STM contributed substantially to the advancement of knowledge in all three target areas [2, 8, 20].



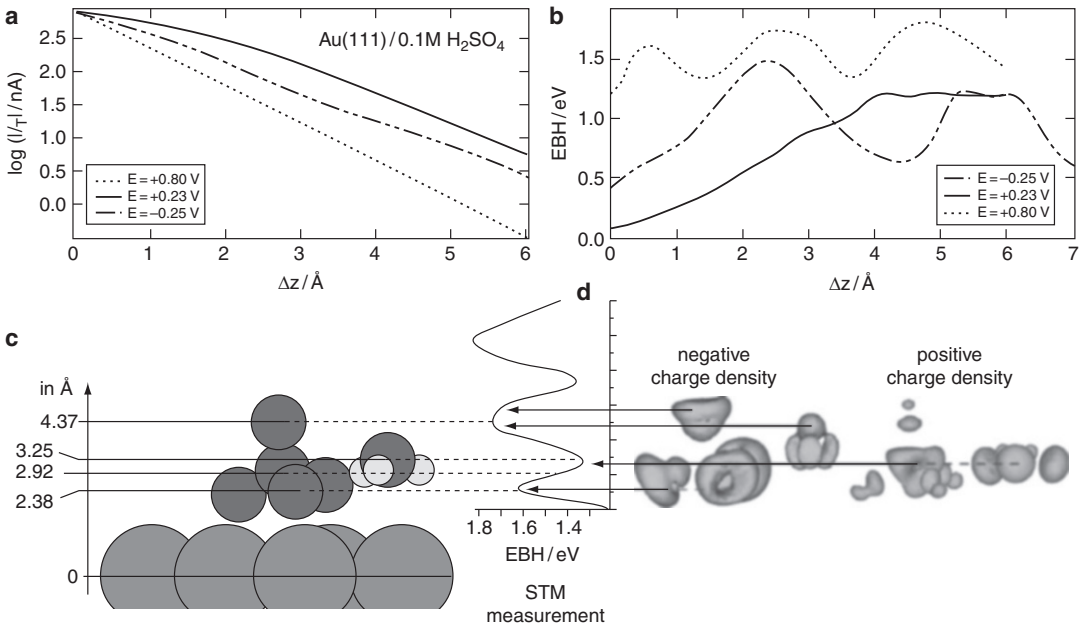
The morphology of the deposit during the initial stages of the OPD process depends on the nature and distribution of surface defects. For example, the deposition of Cu on Au(111) proceeds first by nucleation on surface defects, such as steps, kinks, and screw dislocation, and only at higher overpotentials also on terrace sites (Fig. 9). The nucleation-and-growth behavior leads to inhomogeneous film thicknesses and, hence, to rough metal overlayers. The presence of organic additives such as benzotriazole, thiourea, crystal violet, or polyethylene glycol, which act as so-called levelers and brighteners, modifies the deposition process in such a way that smooth and uniform overlayers emerge. As an example, the addition of crystal violet induces a quasi-two-dimensional growth, which causes the substrate to be quickly covered by a rather uniform Cu film on Au [22]. This particular study gives an illustration on the importance of additives for the optimization of deposition processes, such as that of Cu in the Damascene technology [19].

Current–Distance Spectroscopy: Measurements of the Tunneling Barrier

Current–distance STS represents a complementary approach for the characterization of the normal distribution of electric charges and adsorbates at electrochemical interfaces, as compared to STM imaging [21]. Particularly interesting insights on the electronic structure of adlayers were obtained by comparison of measured and simulated tunneling responses [10]. Figure 10a shows current–distance curves recorded on Au (111) in 0.1 M H_2SO_4 at different potentials. Unlike expected from a simple constant tunneling barrier model (cf. Eq. 1), the log (I)-Δz curves demonstrate pronounced deviations from linear behavior. They were also represented in terms of an effective barrier height (EBH), calculated as

$$\Phi_{\mathrm{eff}} = \kappa^{-2}\left(\frac{\partial \ln I}{\partial z}\right)^2 \qquad (4)$$

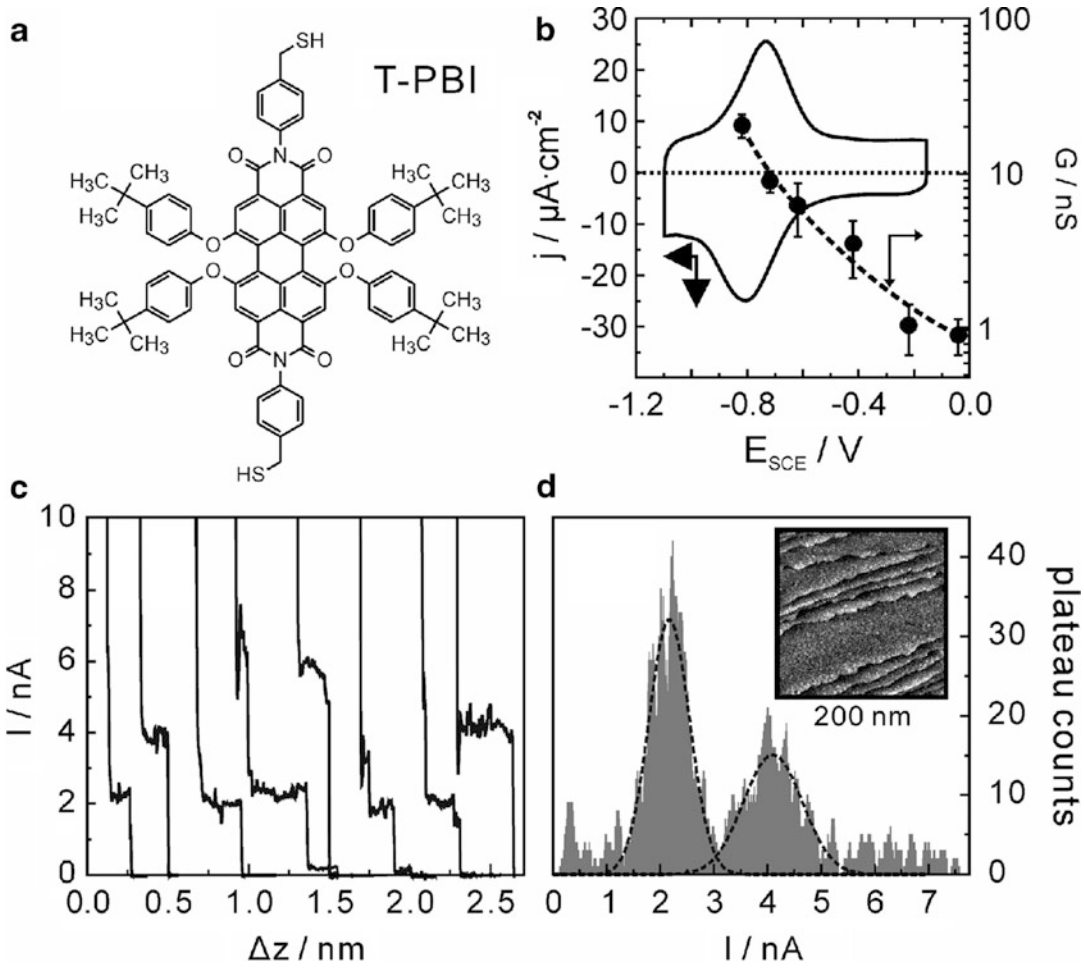
The profiles of the EBH obtained from curves in Fig. 10a are displayed in Fig. 10b. They exhibit minima and maxima with height and position depending on the electrode potential. The distance



Electrochemical Scanning Tunneling Microscopy, Fig. 9 (**a**) STM images of Au(111)-(1 × 1) in 0.05 M H_2SO_4 + 5°10^{-5} M $CuSO_4$ at 0.1 V and −0.185 V versus Cu^{2+}/Cu; (**b**) Au(111)-(1 × 1) in 0.1 M H_2SO_4 + 10^{-3} M $CuSO_4$ at 0.15 V and −0.3 V versus Cu^{2+}/Cu (Adapted from Ref. [22])

scale in Fig. 10a, b is relative due to the experimental uncertainty of the absolute tip separation Δz in the STM experiment. To understand the origin of the variation of the EBH, structure and electron density distribution of the experimentally studied interfaces were modeled in DFT calculations [10]. As an example, Fig. 10c demonstrates the calculated optimal structure of the sulfate adlayer on Au(111) with the well-known (√3 × √7) R19.1° geometry (Fig. 5) and the corresponding distribution of positive and negative charge densities (Fig. 10d). Electron tunneling is facilitated by the positive local charge density and hindered by the negative ones. Therefore, the positions of the maxima and minima in the EBH profile were attributed to the maxima and minima of charge density (Fig. 10d). The distance scale of the experimental curves was shifted so that the features of the calculated charge distribution normal to the surface coincided with the features of the experimental curve. The report published in Ref. [10] demonstrates the power of complementary experimental and theoretical approaches to the study of charged interfaces by EC-STM/STS.

Single-Molecule Charge Transport and Switching



In this paragraph, an advanced application of EC-STM for studies of electrochemically controlled electron transport in single-molecule junctions is described [11]. The latter are formed by a molecule with two chemical anchoring groups trapped to two metal electrodes. The STM tip is used as an active tool for contacting one anchoring group of a molecule bound to the substrate electrode by the second anchoring group. The method is demonstrated for the redox-active molecule of thiol-terminated

Electrochemical Scanning Tunneling Microscopy, Fig. 10 (**a**) Experimental current–distance STS traces. (**b**) Corresponding effective barrier height profiles measured at the Au(111)/0.1 M H_2SO_4 interface at different potentials. (**c**) DFT-optimized structure of the sulfate adlayer adsorbed on Au(111), $E = 0.8$ V. perylene-3,4:9,10-tetra-carboxylic acid bisimide (T-PBI; Fig. 11a). The cyclic voltammogram of a T-PBI-modified Au(111) electrode (Fig. 11b) shows a broad current peak at $E^0 = 0.79$ V, which represents a reversible two-electron reduction/oxidation of the immobilized organic adlayer. A typical EC-STM image of a disordered densely packed T-PBI adlayer on an Au(111)-(1 × 1) surface is shown as inset in Fig. 11d.

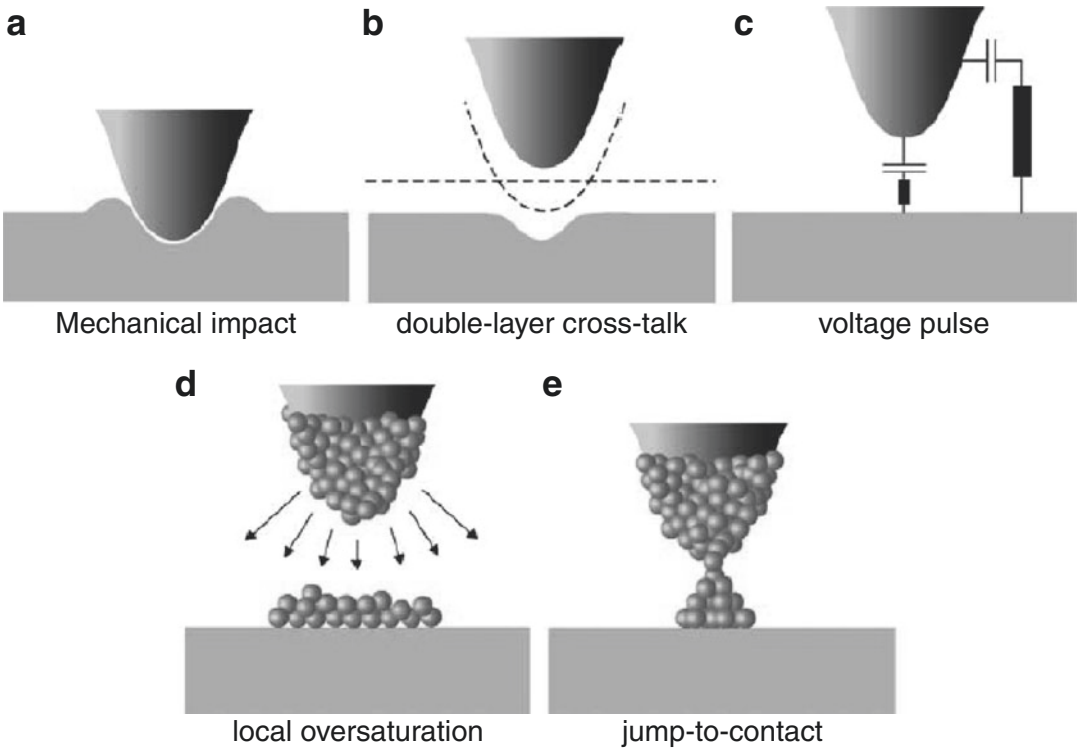
Single Au |molecule| Au junction conductance measurements were carried out according to a "break junction" or "stretching" technique. A sharp Au STM tip, capable of imaging experiments with atomic resolution, was brought to a preset tunneling position. Subsequently, the STM feedback was switched off, and the tip approached the adsorbate-modified substrate surface at constant *x*-*y* position. The approach was stopped at a preset tunneling current of 5–20 μA, which corresponds to a strong tip–adlayer interaction. After a dwelling time of ~100 ms, sufficient to create molecular junctions between tip and substrate, the tip was retracted and the corresponding current–distance traces were recorded. Examples, acquired at $E_S = -0.82$ V and $E_b = 0.10$ V, are shown in Fig. 11c. The traces exhibit characteristic plateaus, which are separated by abrupt steps. These observations are attributed to the stochastic formation and breaking of individual respective multiple Au |T-PBI| Au junctions. Unlike in the case of a tunneling current, the current flowing through a molecular junction is rather constant during the separation of tip and sample electrodes and quickly drops by orders of magnitude when the junction is broken (Fig. 11c). The statistical analysis of several thousands of individual traces leads to conductance histograms, such as plotted in Fig. 11d. The histogram shows two pronounced peaks with positions close to 2 and 4 nA, with the second peak being broader and lower than the first one. The latter is a typical indication of molecular junctions corresponding to one and two molecules bound between electrodes.

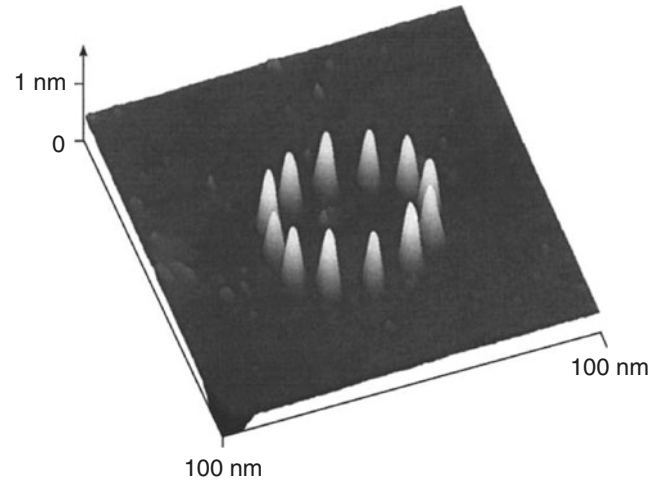


Electrochemical Scanning Tunneling Microscopy, Fig. 11 Single-molecule conductance experiments of T-PBI immobilized on Au(111)-(1 × 1) in 0.05 M $LiClO_4$, pH ≈ 12. (**a**) Chemical structure of T-PBI. (**b**) Cyclic voltammogram of a T-PBI monolayer, scan rate 0.2 $V \cdot s^{-1}$, and single-molecule conductance of T-PBI as a function of the substrate potential. (**c**) Typical current–distance retraction traces for T-PBI molecular junctions at $E_b = 0.10$ V, $E_S = -0.82$ V versus SCE. (**d**) Conductance histogram for T-PBI constructed from curves such as that presented in panel (**c**). The inset shows an STM image of a disordered T-PBI adlayer on Au(111) (200 × 200 nm, $I_T = 0.1$ nA; $E_S = -0.02$ V vs. SCE, $E_b = 0.1$ V) [11]

The single-junction conductance is estimated for this particular experiment at $E_S = -0.82$ V and $E_b = 0.10$ V as $G = 22 \pm 4$ nS. These experiments were repeated at different substrate potentials. Figure 11b illustrates the corresponding single-junction conductance as a function of substrate potential. The reduction of T-PBI upon decrease of the potential leads to an increase of the junction conductance by a factor of 20 over the whole measured potential range.

These experiments illustrate one of the frontier areas in electrochemical nanotechnology. They represent a direct approach toward exploring device-analog functions at electrified solid–liquid interfaces.

EC-STM-Based Nanostructuring



The STM tip can also be used as a tool to actively structure electrode surfaces [4, 13]. Several existing strategies are illustrated in Fig. 12: (a) formation

Electrochemical Scanning Tunneling Microscopy, Fig. 12 Various approaches to nanostructuring of metal electrodes by the EC-STM tip (Adapted from Ref. [13])

of active surface sites by mechanical impact of the tip, (b) local surface dissolution by double-layer cross talk upon application of a steady tip potential, (c) dissolution initiated by short voltage pulses, (d) deposition of metal upon the local oversaturation of solution with metal ions during a "burst-like" dissolution of the metal from the STM tip, and (e) transfer of metal clusters from the tip to the surface. While surface or monolayer defects as created by the mechanical impact of the tip are in general poorly defined and lead to non-reproducible surface features, the more controlled noncontact regimes allow fabrication of much more uniform, stable surface nanostructures with unique electric, magnetic, and catalytic properties. Fast dissolution of predeposited metal from the tip (Fig. 12d) can be used to create a local increase of the concentration of metal ions leading to metal deposition in the close vicinity of the tip (cf. Eq. 3). If the substrate potential E_S is only slightly more positive than E_{eq} as defined by the bulk concentration of metal ions, local metal deposition may occur. The generated metal clusters are metastable, as their dissolution at the substrate potential used is kinetically hindered [8].

In the "jump-to-contact" technique (Fig. 12e), metal predeposited on the tip is transferred to the substrate upon approaching the tip toward the surface without reaching mechanical contact [13]. Jump-to-contact occurs, and a metal bridge is formed between tip and the substrate. When the tip is retracted from the surface, the metal bridge breaks and leaves a small metal or alloy cluster on the surface (Fig. 13). Using this technique, small and uniform clusters of various metals can be generated on metal and semiconducting surfaces with high reproducibility and lateral precision having a wide range of unique properties. The tip potential is always held in the OPD range,

Electrochemical Scanning Tunneling Microscopy, Fig. 13 Cu clusters formed by the "jump-to-contact" technique on a Au(111) electrode in a solution of 0.05 M H_2SO_4 and 1 mM $CuSO_4$. The clusters are 0.8 nm high; the diameter of the circle is about 40 nm (Adapted from Ref. [4])

and provided that the metal deposition is sufficiently fast, the cluster transfer process can be repeated at kHz rates [13].

Definition

Electrode–organic interface physics describes the formation of an electric contact between an organic semiconductor material and an electrode, typically a metal. The alignment of the energy-levels of the organic material with the energy-levels of the electrode dictates the energetic barrier which must be overcome to move electrical charges between the electrode and organic material. Depending on the magnitude of the energetic barrier at the interface, the injection of charge across the interface will be different.

Introduction

Organic electronic devices are electrical devices, such as light emitting diodes, photovoltaics, or thin film transistors, in which the active materials consist entirely of organic materials with semiconducting properties. Since organic materials consist of discrete molecular units, there is no need for long range order between adjacent molecules or polymer chains. Organic semiconductors therefore have the advantage over traditional inorganic semiconductors, such as Si or GaAs, in that they do not require perfect single crystal films to operate in real devices. Complicated multilayer structures with nanometer-scale thicknesses can thus be easily fabricated from organic materials using low-cost roll-to-roll printing or vacuum coating techniques. However, the discrete nature of organic semiconductors also implies that they typically contain almost no *intrinsic* charge carriers (i.e., electrons or holes), and thus act as insulators until electrical charges are injected into them. In electrical device applications this means that all of the holes and electrons within a device must be injected from the anode and cathode respectively. As a result, device stability, performance, and lifetime are greatly influenced by the interface between the organic materials and the electrode contacts.

Energy-Level Alignment

Of particular interest for device applications is the energy-level alignment at electrode–organic

interfaces, or in other words the alignment of the molecular orbitals of the organic to the energy-levels of the electrode (typically the Fermi level). For traditional inorganic semiconductors the energy-level alignment at semiconductor–metal contacts is typically described by the Schottky barrier height, which is the potential barrier between the Fermi level of the metal and the conduction band or valence band edge of the semiconductor. Analogous to the Schottky barrier height at semiconductor–metal interfaces the energy-level alignment at electrode–organic interfaces is also typically represented by an injection barrier height ϕ_B. This injection barrier represents the potential barrier which must be overcome to move an electrical charge from the Fermi level of the electrode into the highest occupied molecule orbital (HOMO) or lowest unoccupied molecular orbital (LUMO) of the organic (or vice versa). Metal–organic interfaces were the first contacts to be extensively characterized in organic electronics, owing to their similarity to Schottky contacts in traditional semiconductors.

Work Function

The work function of a uniform surface of a conductor is defined as the minimum energy required to remove an electron from the interior of the conductor to just outside the surface, where "just outside" refers to a distance that is large enough that the image force is negligible, but small compared to the physical dimensions of the crystal (typically $\sim 10^{-4}$ cm). In other words, the work function is the difference between the electrochemical potential $\overline{\mu}$ of electrons in the bulk and the electrostatic potential energy $-e\Phi_{\text{vac}}$ of an electron in the vacuum just outside the surface [1]:

$$-e\phi_m = -e\Phi_{\text{vac}} - \overline{\mu}. \tag{1}$$

The energy-level corresponding to $-e\Phi_{\text{vac}}$ is referred to as the *local* vacuum level E_{vac} and is not to be confused with the vacuum level at infinity E_0, which represents an electron at rest at infinity (i.e., zero potential energy) [2]. Since the Fermi level E_F relative to the vacuum level at infinity E_0 is the electrochemical potential of electrons in the conductor [3],

$$E_0 - E_F = -\overline{\mu}, \tag{2}$$

the work function given by Eq. 1 is equivalent to the difference in potential energy of an electron between the local vacuum level E_{vac} and the Fermi level:

$$e\phi_m = E_{\text{vac}} - E_F. \tag{3}$$

From Eq. 3 it is clear that if the local vacuum level E_{vac} varies across a sample, as is the case for the different faces of a single crystal, the work function will also vary.

Schottky Contacts

The energy-level alignment at semiconductor–metal contacts has been extensively studied owing to their importance in microelectronics. In the Schottky–Mott limit the vacuum level of the semiconductor and metal align, forming a region of net space charge at the interface. No charge is transferred across the interface and hence the semiconductor bands are forced to bend to accommodate the potential difference. The Schottky barrier height for electrons is then given by the difference between the work function of the metal ϕ_m and the electron affinity of the semiconductor χ (i.e., the conduction band edge). However, the Schottky–Mott limit is rarely observed at most metal–semiconductor interfaces due to charge transfer across the interface (i.e., an interfacial dipole). As a result, the Fermi level cannot move freely in the bandgap of the organic and thus tends to be pinned by the dipole layer. The interface slope parameter is a convenient parameter that quantifies this phenomenon, and is commonly defined in terms of the Schottky barrier height for an electron or hole [4]:

$$S_\phi = \frac{d\phi_{\text{Bn}}}{d\phi_m} = -\frac{d\phi_{\text{Bp}}}{d\phi_m}, \tag{4}$$

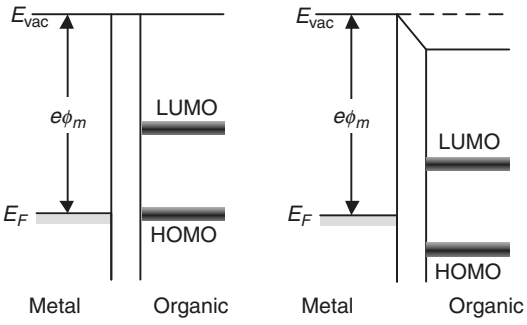
where S_ϕ is the interface slope and ϕ_{Bn} and ϕ_{Bp} are the barrier heights for electrons and holes respectively. In the Schottky–Mott limit $S_\phi = 1$ (vacuum level alignment); and for Fermi level pinning $S_\phi = 0$ (interfacial dipole).

In the case of organic semiconductors many studies have experimentally demonstrated a strong correlation between the metal work function and the barrier height for holes or electrons. In analogy to inorganic semiconductors, in the Schottky–Mott limit the vacuum level of the organic and metal align, forming a region of net space charge at the interface. The barrier height for holes is then given by the offset between the HOMO of the organic E_{HOMO} and the work function of the metal:

$$e\phi_{\mathrm{Bp}} = E_{\mathrm{HOMO}} - e\phi_m. \tag{5}$$

However, since organic semiconductors contain almost no free charge carriers, band bending in the organic cannot fully accommodate the potential difference. Hence, the Schottky–Mott limit is rarely observed at metal–organic interfaces due to the formation of a strong interfacial dipole between the metal surface and organic molecules. Accounting for the effect of an interfacial dipole, the injection barrier for holes is then given by the following:

$$e\phi_{\mathrm{Bp}} = E_{\mathrm{HOMO}} - e(\phi_m - \Delta). \tag{6}$$



From the above equation it is clear that a negative dipole reduces the hole injection barrier, while a positive dipole enhances electron injection. From Eq. 6 an effective metal work function can be defined as the difference between the pristine metal work function and the dipole:

$$\phi_{m,\mathrm{eff}} = \phi_m - \Delta, \tag{7}$$

where $\phi_{m,eff}$ is the effective metal work function (Fig. 1).

Interface Dipole Theory

Deviation from the Schottky–Mott limit was first described by Bardeen [5] as the result of a large density of surface states; charge transfer between the metal and these surface states acts to pin the Fermi level. In fact surface states were first postulated by Tamm and Shockley prior to the Schottky model, but were largely ignored. Heine [6] later

Electrode–Organic Interface Physics, Fig. 1 Schematic diagram of energy-level alignment at the metal–organic interface in the Schottky–Mott limit (*left*) and with an interfacial dipole (*right*)

demonstrated that surface states do not exist in the gap of most metal–semiconductor interfaces, or at least not for modern devices produced by the high vacuum deposition of metal onto a clean semiconductor surface. In Bardeen's time semiconductor–metal contacts were formed by laminating a piece of metal and semiconductor, which inherently results in a "dirty" interface. Heine postulated that for a "clean" interface, gap states are induced in the semiconductor as a result of the rapidly decaying tail of the electronic wave function from the metal. These gap states would also tend to pin the Fermi level same as for Bardeen's surface states. Tersoff [7] later identified the gap states as metal-induced gap states (MIGs), which derive from the virtual gap states (VIGs) of the semiconductor complex band structure.

Regardless of their specific origin, interface states are independent of the energy-levels in the semiconductor, and hence can either be donor like or acceptor like when close to the valence or conduction bands respectively. A charge neutrality level ϕ_{CNL} is defined as the point at which the interface states are equally donor- and acceptor-like (i.e., the transition point from donor to acceptor states). Cowley and Sze [8] applied this notion to derive the dependence of the Schottky barrier height upon the metal work function. They argued that at semiconductor–metal interfaces the charge neutrality level of the semiconductor will tend to align with the Fermi level of the metal as a result of charge transfer between the metal and the interface states, forming an interfacial dipole. In other

words, the redistribution of charge at the interface (dipole) offsets the vacuum level of the metal and semiconductor, resulting in an effective metal work function that is different from the vacuum metal work function:

$$\phi_{m,\mathrm{eff}} = \phi_{\mathrm{CNL}} - S_\phi(\phi_m - \phi_{\mathrm{CNL}}). \quad (8)$$

The interfacial dipole is then the difference between $\phi_{m,eff}$ and ϕ_m:

$$\Delta = (1 - S_\phi)(\phi_m - \phi_{\mathrm{CNL}}). \quad (9)$$

Interface Slope Parameter

In their analysis, Cowley and Sze assumed a constant continuum of interface states across the semiconductor gap. Based on this assumption, the interface slope parameter, which in this context represents the dielectric screening strength of the semiconductor, is given by:

$$S_\phi = \frac{\varepsilon_i}{\varepsilon_i + e\delta D_s}, \quad (10)$$

where ε_i is the interface permittivity, δ is the characteristic thickness of the interface (atomic length), and D_s is the density of interface states. However, since these parameters can only be measured indirectly, accurate determination of the interface slope parameter using Eq. 10 is problematic at best. Luckily, Mönch [9] empirically found that the interface slope parameter (for weakly interacting interfaces) is dependent on the optical dielectric constant:

$$S_\phi = \frac{1}{1 + 0.1(\varepsilon_\infty - 1)^2}, \quad (11)$$

where ε_∞ is the optical dielectric constant (high frequency limit of the dielectric function). One important caveat to consider for Eq. 11 is that it only accurately describes the interface slope parameter for weakly interacting and laterally homogenous Schottky contacts. If interfacial chemical reactions occur, or if the interface is patchy, then S_ϕ often deviates from the ideal theoretical dielectric value.

Recently it was shown that organic semiconductors also follow the same empirical relationship between S_ϕ and ε_∞ described by Eq. 11, same as for Schottky contacts with solid Xenon. However, many organic molecules either interact fairly strongly with clean metal surfaces or do not wet the surface of metals uniformly. The experimentally determined value of S_ϕ for clean metal surfaces is, therefore, often different than the ideal theoretical value described by Eq. 11. For example, the experimental value of S_ϕ for C_{60} is nearly 0, while the theoretical value is 0.53 assuming $\varepsilon_\infty = 4$. In this case it is well known that C_{60} interacts strongly with most clean metal surfaces, which results in complete pinning of the Fermi level (i.e., $S_\phi = 0$). For terminated surfaces, such as an oxidized metal surface (e.g., Al/Al_2O_3), the interaction between the metal and organic is screened by the adsorbed surface termination layer. In this case, S_ϕ approaches the ideal theoretical value for a weakly interacting interface. Metal oxides in particular form ideal contacts with most organics since the first layer of adsorbed molecules tends to wet the oxide surface, forming a laterally homogeneous contact. One important consequence of this is that a clean metal and oxide-terminated metal will behave differently in contact with an organic semiconductor, even if the effective metal work function of the oxide-terminated metal is the *same* as the work function of the clean metal surface. In general, the clean metal will pin the Fermi level stronger than the oxide-terminated metal.

Since the interfacial dipole is indicative of charge transfer between the metal and semiconductor, electronegativity is often used in place of work function to describe the dependence of barrier height on the contacting metal. In this case a linear dependence of the injection barrier on the electronegativity *difference* of the metal and semiconductor is observed:

$$\phi_{m,\mathrm{eff}} = \phi_{\mathrm{CNL}} + S_x(X_m - X_s), \quad (12)$$

where X_m and X_s are the electronegativity of the metal and semiconductor respectively and S_x is

the electronegativity-based interface slope parameter given by:

$$S_x = \frac{d\phi_{\mathrm{Bn}}}{dX_m} = \frac{d\phi_{\mathrm{Bp}}}{dX_m}. \tag{13}$$

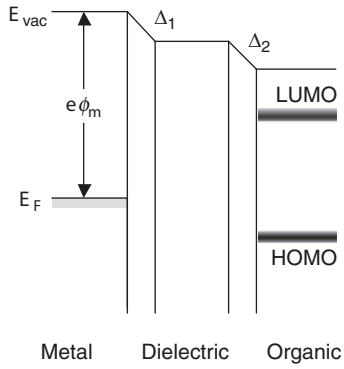
One important distinction between the two different interface slope parameters is that S_ϕ is a dimensionless quantity with an upper limit of 1, while S_x on the other hand is *not* dimensionless and has an arbitrary upper limit depending on the units of electronegativity used. There have been several attempts to link the two interface slope parameters via a constant of proportionality:

$$S_\phi = A_x S_x, \tag{14}$$

where the value of A_x varies depending on the electronegativity scale used. In the case of organic semiconductors, there is no clear definition of electronegativity and hence previous attempts to relate injection barriers at metal–organic interfaces to electronegativity values are in general not very useful.

Metal–Dielectric–Organic Interfaces

Although interface dipole theory can explain the energy-level alignment at metal–organic interfaces in most device applications, the metal contacts are often modified with various dielectric buffer layers to improve charge injection. Dielectric buffer layers, often referred to as electron or hole injection layers (EIL or HIL) since they dramatically enhance carrier injection, typically fall into one of three categories: (1) wide bandgap insulators such as LiF, (2) semiconducting transition metal oxides such as V_2O_5, or (3) organic molecules, such as fullerene (C_{60}). Despite the appreciable difference in material properties for these three different types of dielectrics, one important similarity has been consistently reported in the literature. For all three types of dielectrics, strong interfacial dipoles (i.e., a rapid change in vacuum level across the interface) have been reported at the interfaces formed with metals and organics.



The energy-level alignment at real electrode–organic interfaces will therefore typically depend on the properties of the underlying metal as well as the dielectric buffer layer. A similar situation occurs at metal–oxide–semiconductor (MOS) interfaces used in advanced high-κ dielectric metal gate MOS field effect transistors (MOSFETs). It was discovered that the effective work function of the metal gate was strongly influenced by the properties of the oxide dielectric. Robertson [10] proposed that interface dipole theory could be applied to each of the interfaces (i.e., metal–oxide and oxide–semiconductor) to describe the trend in effective work function, or in other words that Eq. 12 could be applied to both interfaces to describe the net effective work function. A similar approach can thus be applied to metal–dielectric–organic interfaces to describe the energy-level alignment.

In order to calculate the net effect of the oxide layer on the injection barrier, the two interfaces can be considered in series. At the metal–dielectric interface the interaction between the dielectric and the metal creates an interfacial dipole layer that modifies the work function of the pristine metal surface. This results in the organic molecules deposited on top of the dielectric modified metal experiencing an effective metal work function as given by Eq. 12. Treating the metal–oxide as a layered anode structure, the effective metal work function can be plugged back into Eq. 12 to extract the effective work function of the metal–oxide after consideration of the effect of the organic layer:

$$\begin{aligned}\phi_{m,\mathrm{eff}} = &\left(1 - S_\phi^{\mathrm{org}}\right)\phi_{\mathrm{CNL}}^{\mathrm{org}} \\ &+ S_\phi^{\mathrm{org}}\left[\phi_{\mathrm{CNL}}^{\mathrm{ox}} + S_\phi^{\mathrm{ox}}(\phi_m - \phi_{\mathrm{CNL}}^{\mathrm{ox}}\right],\end{aligned} \tag{15}$$

where S_ϕ^{org}, S_ϕ^{ox}, $\phi_{\mathrm{CNL}}^{\mathrm{org}}$, and $\phi_{\mathrm{CNL}}^{\mathrm{ox}}$ are the interface slope parameters and charge neutrality levels of the organic and oxide respectively. The total combined dipole across the interface can then be calculated using Eq. 9. The barrier height for holes is then taken as the difference between this combined effective work function and the HOMO of the organic (Fig. 2).

Dielectrics typically have $S_\phi < 1$, which implies that the Fermi level is not completely

Electrode–Organic Interface Physics, Fig. 2 Schematic diagram of energy-level alignment at a metal–dielectric–organic interface

pinned at most metal–dielectric–organic interfaces. As a result, the barrier height at the interface is partially dependent on the work function of the underlying metal. However, in a few special cases S_ϕ can approach unity, implying that the Fermi level is pinned and hence the energy-level alignment at the interface is independent of the underlying metal. Buckminsterfullerene (C_{60}) is one example of such a dielectric layer. In contact with clean metal surfaces C_{60} can accept up to six electrons from the metal, becoming itself partially metallic. As a result, the optical dielectric constant (ε_∞) of the C_{60} approaches infinity, such that S_ϕ goes to 1 as given by Eq. 11. Therefore C_{60} can be used as a "universal" charge injection layer as it pins the Fermi level of any metal to its charge neutrality level.

Charge Injection and Transport

Up to this point only the barrier height at electrode–organic interfaces has been discussed. However, in real devices what is measured is the flow of current through the device as a function of applied bias. Therefore how the barrier height discussed above affects the injection and transport of charge in real devices is of interest. At traditional semiconductor–metal interfaces the process of charge injection is typically divided into two different regimes, space charge limited current (SCLC) and injected limited current (ILC).

Space Charge Limited Current

The first regime, which represents the maximum current that a semiconductor can sustain in the bulk (i.e., the amount of carriers in thermal equilibrium), is called the SCLC. A semiconductor–metal contact capable of injecting enough charges to sustain the SCLC is called an Ohmic contact. In most traditional semiconductors an Ohmic contact is assumed to represent a zero barrier height. One significant feature of SCLC is that the spatial distribution of electric field is described by $F(x) \propto x^{1/2}$, where x is the distance from the charge-injecting contact. The electric field at the interface of an Ohmic contact is therefore equal to zero. For unipolar transport (i.e., transport of only one type of charge carrier) in a perfect insulator (no intrinsic carriers) without traps the SCLC is given by the Mott-Gurney law [11]:

$$J = \frac{9}{8}\varepsilon_0\varepsilon\mu\frac{V^2}{d^3}, \tag{16}$$

where V is the applied voltage, d is the thickness of the film, and μ is the field-independent mobility.

With further consideration of an exponential distribution of trap states, the trap-charged limited current (TCLC) based on Eq. 16 follows:

$$J \propto \mu\frac{V^{l+1}}{d^{2l+1}}, \tag{17}$$

where l is a parameter derived from the trap distribution. Notice that the injection of charge depends only on the mobility, thickness of the semiconductor, and applied voltage as the barrier height is assumed to be zero.

In the case of organic semiconductors, however, the mobility typically depends on electric field. In disordered organic materials, it is believed that all electronic states are localized and participate in conduction through thermally activated hopping, which yields a Poole–Frenkel-like field dependence of the mobility:

$$\mu(F) = \mu_0\exp\left(\beta\sqrt{F}\right). \tag{18}$$

Under the assumption of a Poole–Frenkel dependence, an approximation to the SCLC for a field-dependent mobility is given by [12]:

$$J_{\mathrm{SCLC}} = \frac{9}{8}\varepsilon\varepsilon_0\mu_0 \exp\left(0.89\beta\sqrt{\frac{V}{d}}\right)\frac{V^2}{d^3}. \quad (19)$$

There has been significant experimental evidence that this model does indeed describe the SCLC in many organic semiconductors. One interesting caveat however due to the hopping-based transport in organic materials is that the barrier height for an Ohmic contact does not have to be zero in the typically operating electric field range of most device applications. Specific criteria for determining this critical threshold barrier height will be discussed in detail below.

Injection-Limited Current

The second regime of charge injection in semiconductors represents the situation where a significant barrier height exists at the interface, such that the transport of charge in the semiconductor is limited by the injection of charge at the semiconductor–metal contact. The ILC at Schottky contacts has traditionally been described by one of two processes. For high electric field strength and large barrier heights, Fowler–Nordheim (FN) tunneling, also known as field emission, dominates the injection current [4]:

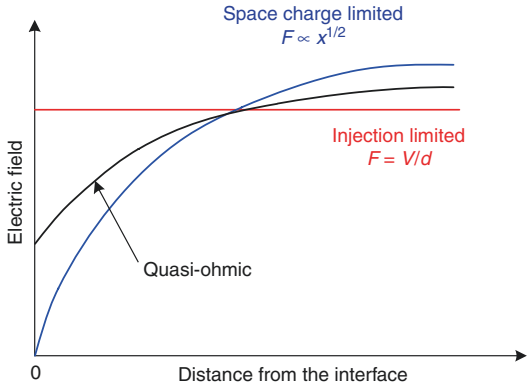
$$J_{\mathrm{FN}} = \frac{q^3F^2}{8\pi h\phi_B}\exp\left[-\frac{8\pi\sqrt{2m^*}{\phi_B}^{3/2}}{3qhF}\right] \quad (20)$$

where F is the electric field strength, ϕB is the barrier height, m^* is the effective mass of an electron or hole in the semiconductor, q is the electronic charge, and h is the Planck constant. For thermally activated processes at lower electric field, Richardson–Schottky (RS) emission, also known as thermionic emission, dominates the injection current [4]:

$$J_{\mathrm{RS}} = A^*T^2\exp\left[-\frac{\left(\phi_B - \sqrt{qF/4\pi\varepsilon}\right)}{k_BT}\right] \quad (21)$$

where A^* is the modified Richardson constant, ε is the permittivity of the semiconductor, k_B is the Boltzmann constant, and T is the temperature.

In the case of organic semiconductors, the ILC was early on modeled as diffusion-limited thermionic emission. However, both FN tunneling and RS emission are derived for delocalized Bloch waves in the semiconductor, whereas the electronic states in most organic semiconductors are highly localized due to their discrete molecular nature. In addition, at room temperature FN tunneling typically requires electric field strengths several orders of magnitude greater than what are observed in real organic devices ($\sim 10^5$ V/cm).



To overcome these deficiencies Scott and Malliaras [13] have proposed a modified thermionic emission model for the ILC in organic semiconductors based on the original solution to the drift-diffusion equation for injection into a wide bandgap intrinsic semiconductor solved by Emtage and O'Dwyer [14]. This model determines the equilibrium contributions to the current density for charge carriers recombining with their own image analogous to Langevin recombination of an electron–hole pair in the bulk:

$$J_{\mathrm{ILC}} = 4N_0\psi^2 e\mu F\exp\left(\frac{-e\phi_B}{k_BT}\right)\exp\left(f^{1/2}\right), \quad (22)$$

where N_0 is the density of chargeable sites in the organic film, ϕ_B is the barrier height, F is the electric field at the charge-injecting contact, μ is the electric field-dependent mobility, k_B is the Boltzmann constant, T is temperature, e is the electron charge, and ψ is a function of the reduced electric field ($f = e^3F/4\pi\varepsilon k_B^2T^2$):

$$\psi = f^{-1} + f^{-1/2} - f^{-1}\left(1 + 2f^{1/2}\right)^{1/2} \quad (23)$$

There has been significant experimental evidence that this model does indeed describe the ILC in many organic semiconductors. Also, under ILC conditions the spatial electric field distribution is assumed to be uniform such that $F(x) = V/d$; whereas for SCLC the value of V/d only gives the average value of the electric field.

Electrode–Organic Interface Physics, Fig. 3 Calculated electric field at the metal–organic interface as a function of the barrier height for a typical organic semiconductor with a mobility of 10^{-4}–10^{-3} $cm^2\ V^{-1}\ s^{-1}$ and a thickness of 1,000 nm

This suggests that SCLC can be distinguished from ILC by the electric field at the electrode–organic interface.

Quasi-Ohmic Contact

The two conditions discussed above, SCLC and ILC, correspond to the upper and lower limits respectively. What about the case in between SCLC and ILC, when the electric field at the electrode contact is $0 < F(x = 0) < V/d$ (see Fig. 3)? This indicates that there is in fact no clear boundary between SCLC and ILC, but rather an intermediate regime in between referred to as "quasi-Ohmic." Since the quasi-Ohmic regime exhibits characteristics of both SCLC and ILC, it is incorrect to apply the models for either case. Moreover, it is important to note that the boundaries of the quasi-Ohmic regime are dependent on the field-dependent carrier mobility μ, the barrier height ϕ_B, the applied voltage V, and the device thickness d. As a result the same electrode–organic contact may display characteristics of ILC, quasi-Ohmic, and SCLC in different ranges of applied bias. A new approach is thus required to properly describe the quasi-Ohmic regime.

As discussed above, the quasi-Ohmic regime in between SCLC and ILC cannot be described using traditional models. As a result a new approach that includes both the injection at the interfaces and the transport in the bulk of the organic is required to deal with this special case. One approach to deal with this situation is to use a time domain simulation under the transport models developed for inorganic semiconductors (i.e., the drift-diffusion and Poisson equations) to describe the distribution of electric field at steady state.

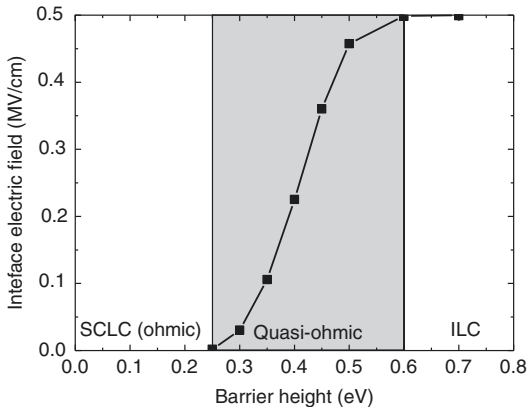
In the simulation, space x and time t are discrete. The injection current density described by Eqs. 22 and 23 serves as a boundary condition at $x = 0,\ t > 0$ (i.e., the charge-injecting contact). The time-dependent continuity equation follows:

$$\frac{\partial p(x,t)}{\partial t} = -\frac{1}{e}\frac{\partial J(x,t)}{\partial x}, \tag{24}$$

where p is the total density of holes and J is the conduction current density. The relation between the electric field and the charge density can be expressed by the Poisson equation as:

$$\frac{\varepsilon_r \varepsilon_0}{e}\frac{\partial F(x,t)}{\partial x} = p(x,t). \tag{25}$$

In Eq. 25, ε_r and ε_0 are the dielectric constants of the organic and the dielectric permittivity in vacuum respectively. The conduction current density can be calculated through the drift-diffusion equation:



$$J(x,t) = ep(x,t)\mu(F)F - eD\frac{\partial p(x,t)}{\partial x}, \tag{26}$$

where D is the diffusion coefficient, which can be obtained from Einstein's relation (as a function of the field-dependent mobility):

$$D = \frac{\mu k_B T}{e}. \tag{27}$$

The other boundary conditions are:

$$\begin{cases} V = \int_0^d F dx \\ F(x, t = 0) = V/d, \\ p(x, t = 0) = 0 \\ J(x, t = 0) = 0 \end{cases} \tag{28}$$

Electrode–Organic Interface Physics, Fig. 4 Calculated electric field at the metal–organic interface as a function of the barrier height for a typical organic semiconductor with a mobility of 10^{-4}–10^{-3} $cm^2\ V^{-1}\ s^{-1}$ and a thickness of 1,000 nm

where d is the thickness of the film and V is the applied voltage. It is noted that the transient current density J_t is contributed by the displacement current and the response of the charge carrier density as:

$$J_t(x,t) = \varepsilon_r \varepsilon_0 \frac{\partial F(x,t)}{\partial t} + J(x,t). \qquad (29)$$

From Eq. 29 the total transient current at $x = d$ can be calculated until the steady state is reached. Also, the spatial distribution of electric field at steady state can be obtained from the simulation.

From these simulation results the boundaries of the quasi-Ohmic regime (i.e., the lower limit of SCLC and the upper limit of ILC) can then be defined as the convergence of the simulation results with the SCLC from Eq. 19 and the ILC from Eq. 22. Also, these boundaries represent the strict limits for SCLC and ILC in terms of the electric field at the charge-injecting contact. Figure 4 shows an example of the calculated electric field at the electrode–organic interface for a typical organic semiconductor with a mobility of 10^{-4}–10^{-3} $cm^2\ V^{-1}\ s^{-1}$. The calculation shows that the interfacial electric field depends strongly on the barrier height in the quasi-Ohmic regime. The interfacial electric field approaches zero and the average values (i.e., $F = V/d$) at low ($< \sim 0.25$ eV) and high ($> \sim 0.55$ eV) barrier height which respectively correspond to SCLC regime and ILC regime.

Future Directions

The energy-level alignment and charge injection at electrode–organic interfaces is based on the classical device physics developed for inorganic semiconductors. It can be applied to a wide variety of different materials and interfaces, even newly developed organic materials.

Definition

Electrokinetic flow in nanostructures involves the study of the behavior, manipulation, and control of fluids that are confined to structures characterized by nanometer scale (typically $\leq$ 100 nm) dimensions. Fluids confined in these structures exhibit behaviors not observed on longer length scales, because characteristic physical scaling lengths, e.g., Debye length, in the fluid are commensurate with the dimensions of the nanostructure itself. A dominant factor in determining the electrokinetic (EK) flow behavior in physical nanostructures is the size of the electrical double layer (EDL) associated with the physical boundaries of the nanostructure and its relation to the channel dimensions.

Overview

Motivation. Although the engineering drivers for reducing the size of laboratory devices are clear (reduced materials costs, reduced power consumption, less waste, lower operating costs, etc.), the case for doing science at reduced dimensions needs to be made more carefully. Factors which justify working at the nanometer scale include: (1) new transport phenomena, (2) exploiting the enhanced surface-to-volume ratio, (3) using diffusion as a viable transport mechanism, and (4) integrating large molecules or molecular complexes with very small (1–10 nm) physical structures. In particular:

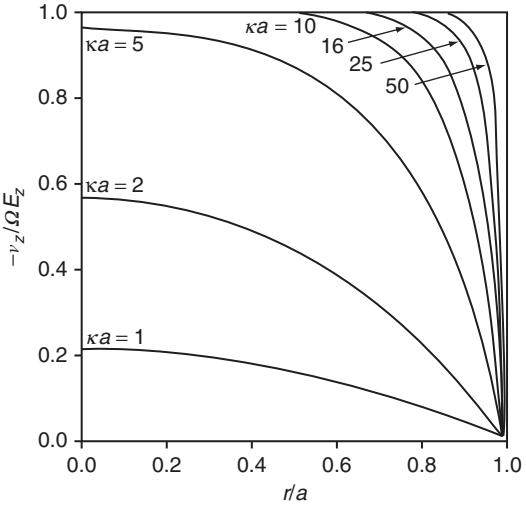
- The similarity of the Debye length, κ^{-1}, and the channel diameter, a, accesses a new electrokinetic flow regime ($\kappa a \sim 1$) that is not available at longer length scales, even in μm-scale capillaries. By changing κ^{-1} it is possible to move from a regime, $\kappa a >> 1$, where flow is dominated by electrophoresis to a regime, $\kappa a \sim 1$, where electroosmotic flow is the dominant transport mechanism. This is possible, because in the nanochannels there is a preponderance of counterions over co-ions; in fact it is easy to achieve conditions where every mobile counterion in the pore is of one polarity, i.e., there are no co-ions.
- The huge increase in surface-to-volume ratio dramatically increases the efficiency of physical partitioning and chemical reactions and reduces Joule heating effects. Comparing a 20 μm open tubular pore featuring a 10-nm thick coating to a 200-nm nanopore with the

same coating, the capacity factor, k', for molecular separations increases by a factor of 117.
- Due to their small size, adjacent nanostructures can be sufficiently close to one another to allow solution emerging from neighboring pores to rapidly mix through diffusion alone. Using the Stokes–Einstein infinite dilution diffusivity for a 1-nm particle in H_2O at 300 K and a structure supporting a pore density of $\sim 5 \times 10^8$ cm^{-2} yields a diffusion time of $\tau_D \sim 450$ μs to achieve full lateral mixing.

Early Studies. All investigations of nanoscale electrokinetic transport ultimately trace their origin to a seminal 1965 study of EK transport in nanometer scale cylindrical capillaries by Rice and Whitehead [1], in which the behavior of electroosmosis, streaming potential, current density distributions, and the electroviscous effect in cylindrical capillaries of nanometer dimensions were described within the Debye–Hückel approximation. Rice and Whitehead began with the Poisson–Boltzmann equation for a narrow cylindrical capillary at small, $\zeta < 25$ mV, zeta potential,

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{d\varphi}{dr}\right) = k^2\varphi \tag{1}$$

Where



$$k = \sqrt{8\pi n e^2/\varepsilon kT} \tag{2}$$

is the inverse Debye length. The solution of (1) is

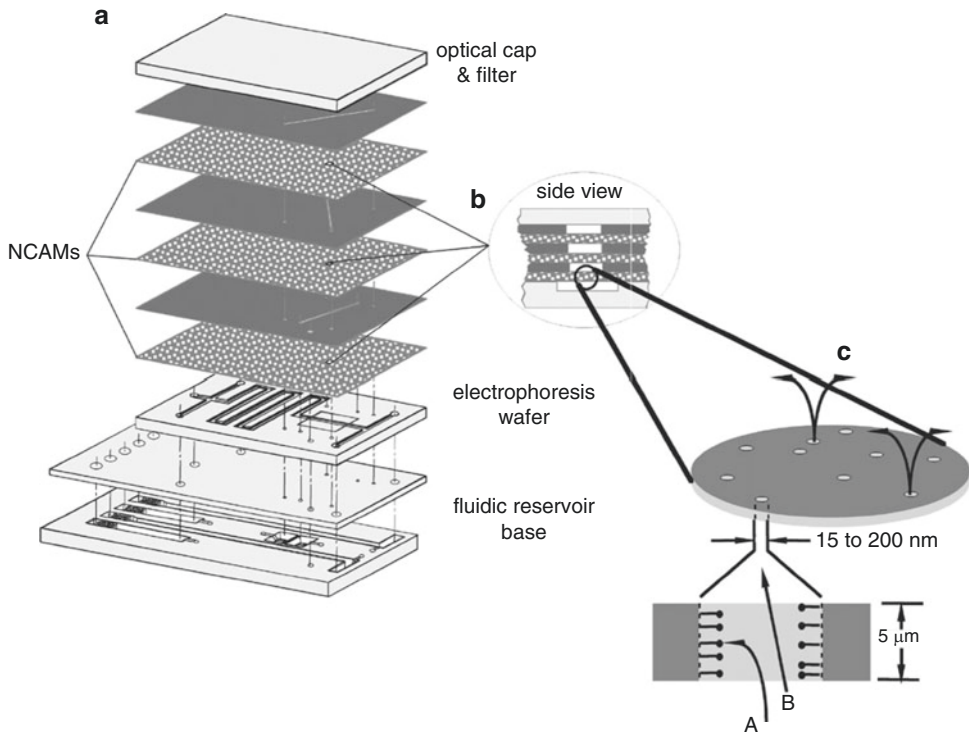
$$\varphi = \varphi_0 \frac{I_0(\kappa r)}{I_0(\kappa a)} \tag{3}$$

where I_0 is the modified Bessel function of the first kind, which allows the charge density to be recovered directly using the Poisson equation. For an infinite cylindrical tube, the equation of motion under a combination of electrical and pressure-driven flow can then be written as

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{dv_z}{dr}\right) = \frac{1}{\eta}\frac{dp}{dz} = \frac{F_z}{\eta} \tag{4}$$

Electrokinetic Fluid Flow in Nanostructures, Fig. 1 EOF velocity profiles in infinite cylindrical capillary (Adapted with permission from Ref. [1])

where the body force, F_z, is driven by the action of the applied field on the net charge density in the double layer, $\rho(r)$. The important result from this analysis is that two flow regimes are established. When $\kappa a >> 1$, the radial velocity profile, $v_z(r)$, reduces to the classical result, except very near the cylinder wall, i.e., the "plug flow" familiar from studies of capillary electrophoresis in μm-scale capillaries is recovered. When $\kappa a \sim 1$, $v_z(r)$ is proportional to $(a^2 - r^2)$, a behavior which is equivalent to the Poiseuille flow at nanometer dimensions, as shown in Fig. 1 and has been verified experimentally [2].



Fundamentals. When $\kappa a \sim 1$ there is significant interaction between the electrical double layers associated with opposing surfaces of the nanostructure. In general, transport across nanofluidic features at $\kappa a \sim 1$ depends on the sum of interactions among charge, electrophoretic mobility, molecular size, nanochannel cross section, ionic strength, and surface charge. A 100 nm × 1 μm nanochannel might exhibit a typical surface charge density ($\sigma \sim 2 \cdot 10^{-3}$ C m^{-2}), resulting in ~4,000 elementary charges on the interior wall of the nanochannel, requiring ≥1 mM counterion concentration in order to balance the surface charge. The ionic strength of the

solution can then be adjusted to control the relative populations of counter- and co-ions in the nanochannel. At low ionic strength, EDL overlap is significant, and counterion concentration and nanochannel conductance are determined purely by surface charge density. For common buffer concentrations (1–100 mM), κ^{-1} can range from 10 to 1 nm. Small molecule diffusion times across such nanochannels are of the order of 10^{-5}–10^{-4} s, which is advantageous if one wishes to implement heterogeneous reactions within nanochannels (*vide infra*). Adsorption (or desorption) of surface monolayers ($\Gamma = 10^{-10}$–10^{-11} mol/cm^2) within nanopores can cause the concentration to change ~1–5 mM, which has important implications for selective capture and subsequent release in purification and concentration applications.

Flow rate normalized to cross-sectional area is less in nanochannels than in microchannels and limits translocation velocities. In addition to applied field, molecules are affected by the electric field due to the electrical double layer (EDL). As a result, counterions with larger charge are more attracted to the surface of the nanochannel and their migration is impeded most. Co-ions are repelled from edges of the channel and are transported faster than counterions. Neutral species are not significantly affected by the EDL and exhibit intermediate velocities. This complex interplay between charge and molecular size can have interesting consequences for differential transport and molecular separations, especially of macromolecules. For example, molecules which occupy or sweep out a significant portion ($> a/10$) of the nanochannel can exhibit altered molecular transport characteristics. Smaller molecules, which approach the channel walls more closely, show slower translocation velocities than larger molecules, which present a larger cross section to the higher flow velocities near the center of the nanochannel. This phenomenon mediates Ogston sieving, which has been exploited to effect DNA separations in nanochannels [3]. In addition, macromolecules that are larger than the cross section of the nanochannel undergo entropically disfavored conformational changes upon entering the confined space represented by the nanochannel. Longer DNA strands surmount such entropic barriers more rapidly, because they have a larger contact area at the entrance and larger increase in entropy facilitates faster escape from the constriction, an observation which has been explored to fabricate nanoscale sieving media.

Applications

Electrokinetic Flow Switching. Clearly the special characteristics of nanoscale EK flow present rich possibilities for studying the fundamental physics of fluid transport at this scale. Beyond the interesting fluid physics, nanofluidic architectures present great opportunities for construction of integrated microfluidic architectures exhibiting digital fluidic transfer by exploiting the unique properties of nanocapillary array membranes (NCAMs) as the fluidic analogs of transistors in integrated electronic circuitry, (Fig. 2). NCAMs can be physically realized in a variety of forms, including spatially random distributions of nuclear track-etched nanopores in polycarbonate membranes or focused ion beam milled arrays in poly(methylmethacrylate). Fluid volume elements can be transferred from one microfluidic channel to another by manipulating the bias potential applied across an NCAM. Kuo et al. demonstrated that this fluid transfer is linear in driving potential up to a threshold value, V_{thresh}, beyond which quantitative mass transfer occurs, i.e., at $V_{appl} > V_{thresh}$ all of the analyte species which enter the cross section of the NCAM and the microfluidic channel are transferred quantitatively across the NCAM [4]. In addition, the pore size determines the mass selectivity of fluid transfer; surprisingly, hindered transport is observed for molecular sizes as little as $a/20$, where a is the pore diameter [5]. Integration of nanofluidic components also permits fluidic samples to be handled with discrimination based on molecular size and charge using valves, gates, and other fluidic components, similar to the way that integrated electronic components control information flow in VLSI circuits [6]. In addition, 3D integrated microfluidics constitute a powerful method to enhance fluid handling capabilities, because

Electrokinetic Fluid Flow in Nanostructures, Fig. 2 (**a**) Exploded schematic view of a multilevel vertically integrated μTAS system displaying a fluid input layer (*bottom*), a pre-separation (*electrophoresis*) layer, and three microfluidic layers separated by nanocapillary array membrane-switching layers. (**b**) Side view of the vertically stacked microfluidic channels separated by NCAMs. (**c**) Schematic diagram of a single NCAM with an exploded view of an individual nanopore with chemically derivatized interior. (**a**) and (**b**) denote two species that have been introduced at the mouth of the pore, with (**a**) being sequestered by the molecular recognition motifs lining the pore wall and (**b**) transferred across the pore (Adapted with permission from Ref. [16])

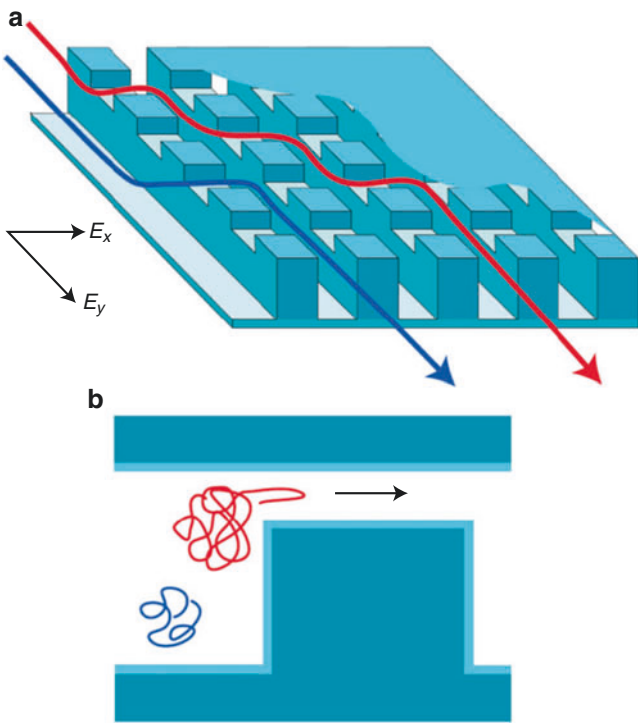
disparate fluidic manipulations such as preparation, concentration, tagging, separation, or affinity recognition may be accomplished in distinct physical locations.

Molecular Separations. Naturally occurring confined nanoscale geometries take advantage of several unique phenomena to produce ionic and molecular separations of remarkable power and utility. For example, transmembrane potassium channels routinely permit the passage of K^+, while excluding smaller, similarly charged Na^+ ions [7]. Such observations in nature have generated an interest in biomimetic nanostructures as tools to separate entities ranging from small molecules to proteins. Although synthetic replication of such complex ion channels has yet to be realized, significant progress in the field has been made.

The simplest form of a molecular separation utilizing nanostructures is filtration using a pressure gradient across a membrane. Provided both the surface charge density, σ, of the enclosing boundary and the ionic strength, I, of the mobile phase are negligible, size-based separation is feasible. Under these conditions, establishing either a pressure or concentration gradient will drive the extraction of appropriately sized analytes across the separation device. However, these options offer limited control, and the separations can be very slow.

Fortunately, EK transport is a powerful alternative. In fact, with the appropriate conditions to ensure $\kappa a \sim 1$ (*vide supra*), nanochannels, nanotubes, and nanopores may become completely perm-selective for counterions (relative to the zeta potential, ζ, of the structural

boundary). Garcia et al. successfully separated charged from uncharged dye molecules in nanochannels using EK transport [8]. In this experiment, the EDL was sufficiently large to localize the charged dye molecules (co-ions relative to ζ of the nanochannel walls) in the center of the nanochannel, while the uncharged molecules interacted with the channel walls. The induced electroosmotic velocity (maximal at the center of channel) eluted the charged dye molecules significantly faster than the uncharged species, essentially inducing radially varying capillary electrophoresis within the nanochannel.



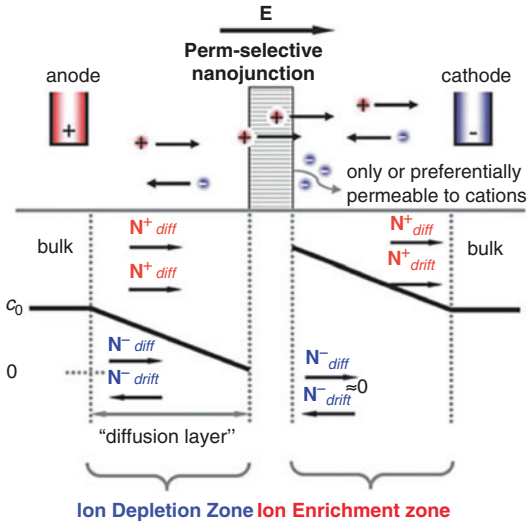
In addition to EK transport, molecular separations can be enhanced by modifying the nanostructure surface chemistry. For example, the perm-selectivity of nanopores (due to $\kappa a \sim 1$) in polycarbonate NCAMs can be enhanced by uniformly functionalizing pores in order to control both the pore size and surface charge density, thereby enabling size- and charged-based separations of small molecules as well as the resolution of mixtures of proteins of similar size but distinct isoelectric points (pI) [9, 10]. Similarly, Lokuge et al. realized actively tuned size-dependent separations of labeled dextrans, by modulating the temperature of NCAMs decorated with poly (N-isopropylacrylamide), thus causing the temperature-responsive polymer to cycle through its lower critical solution temperature, contracting and expanding to open and close the pores, respectively [11].

In order to extend the separation capabilities offered by nature, the screening quality of hydrophobic molecules has been exploited. Unfortunately, the conditions required for EK-enhanced separations typically do not favor hydrophobic molecules. In fact, high charge density regions within nanopores, for example, may act as barriers to entry. Fortunately, surfactants can be added at concentrations above the critical micelle concentration (CMC) to form micelles, which can be used to sequester hydrophobic molecules and transport them across the nanopores. This strategy was used to observe the micelle-enhanced transport of a sparingly soluble local anesthetic dissolved in nonionic surfactant across polymeric nanoporous membranes [12].

The fact that nanostructures can be fabricated to be commensurate with biomolecular scaling lengths also creates new modes for single-molecule manipulation and separation. For example, in bulk solution DNA molecules equilibrate to a spherical shape with a characteristic radius of gyration, R_0 [13]. To enter structures with any cross-sectional dimension less than $2R_0$, the molecule has to deform from its minimal energy state, a process that leads to entropic trapping. Figure 3 shows a periodic nanofilter array used to separate molecules with different mobilities, which are determined by the ease with which they deform from the preferred conformational state, a property that is inversely proportional to molecular size [14]. Additionally, confinement within nanochannels enables study of physical properties of DNA molecules in an uncoiled, linear form [15].

Whether applied independently or coupled, size-, charge-, and hydrophobicity-based molecular separations within nanopores, nanochannels, and nanotubes offer a range of options, especially when they are incorporated into larger microscale geometries and utilized as electrically switchable molecular gates [16]. Such devices have the potential to enhance or augment well-established separation processes, including microdialysis, capillary electrophoresis, and micellar electrokinetic chromatography positioned either upstream or downstream of the nanostructure.

Chemical Interactions and Reactions. Large surface-to-volume ratios and small cross-sectional areas make it possible for molecules traversing nanopores to have numerous interactions with the channel surface [15]. This phenomenon can be exploited to useful effect, for example, to selectively pattern the interior of nanochannels and nanopores in a process known as diffusion-limited patterning. The same phenomenon can be used to manipulate complex mass-limited samples, particularly in microfluidic/nanofluidic hybrid devices. Kim et al. exploited the molecular recognition abilities of antibodies to selectively capture, purify, and release target analytes from a mixture [6]. Gold-thiol chemistry was used to immobilize Fab' onto the electrolessly gold-plated interiors of NCAM nanopores. A mixture containing the target antigen, insulin, was transported through the

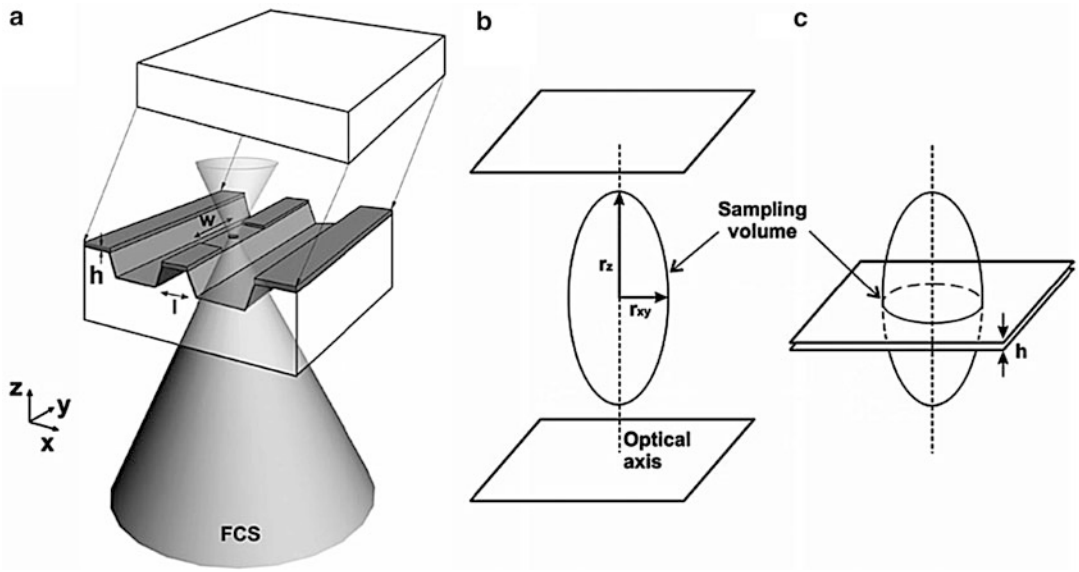


Electrokinetic Fluid Flow in Nanostructures, Fig. 3 (**a**) Orthogonal electric fields, E_x and E_y, serve as driving forces for the molecules and provide the energy needed to deform from their minimal energy states. (**b**) The longer molecule (*red*) has a greater rate of passage through confined regions due to a greater probability of deforming its shape than the shorter molecule (*blue*) (Reproduced with permission from Ref. [14])

NCAM by EK flow, after which, a releasing agent was applied to remove captured analytes. Mass spectra of the releasate showed strong specific retention of insulin – at 23-fold of the control intensity – but no presence of the other species, indicating the specific capture, concentration, and release of insulin. Thus, the high surface area within the NCAM and the increase in wall-collision frequency, Ω_W, render this immobilization strategy applicable to a broad range of analytes, especially those contained within mass-limited samples.

The effects of confinement in nanostructures are also apparent in altering the nature of fluidic transport. De Santo et al. observed sub-diffusive motion in nanochannels exhibiting high degrees of confinement [17]. Using fluorescence correlation spectroscopy (FCS), small, cationic rhodamine 6 G (Rh6G) molecules and charge-neutral labeled macromolecules, dextran and PEG, were observed under no-flow conditions in nanochannels of 30, 20, and 10 nm height. While Rh6G maintains its bulk diffusion coefficient in all cases, both dextran and PEG exhibit hindered diffusion – nearly an order of magnitude smaller at the highest degree of confinement. The decrease in diffusion for macromolecules is explained by anomalous diffusion, the degree of which increases with decreasing channel dimensions, until the theoretical limit for single-file diffusion is achieved. These findings emphasize the importance of surface interactions under confinement.

Concentration Polarization. Aside from direct effects on transport and reactivity inside nanofluidic channels, the presence of nanochannels can affect properties of liquid samples in adjacent microscale structures. Concentration polarization (CP), for example, occurs near ion-selective nanostructures. Surface-charged nanochannels/nanopores show selective permeability to ions due to EDL overlapping at $\kappa a \sim 1$ [18]. At low ionic strengths (<10 mM) the Debye length is comparable to the channel diameter, a, and the nanochannel is occupied entirely by counterions. Figure 4 illustrates CP at a cation perm-selective nanostructure [19]. When a dc bias is applied across the nanochannel, CP develops. On the anodic side, the anions move toward the anode migrating away from the anionic membrane interface where their concentration



Electrokinetic Fluid Flow in Nanostructures, Fig. 4 Concentration polarization observed at the interfaces of a cation perm-selective nanostructure in the presence of current flow. Ion enrichment is observed at the cathodic side, while ions deplete at the anodic side (Reproduced with permission from Ref. [19])

decreases, while only cations can enter and pass through the perm-selective nanostructure. On the cathodic side, anions cannot enter the cation-selective nanostructure, so cations exit the membrane, causing an increase in local concentration. This phenomenon leads to concentration gradients established by the ion-enriched and ion-depleted zones thus created.

When an analyte bears the correct charge to be segregated in the ion enrichment zone, the local concentration can be increased, sometimes by orders of magnitude, thereby enhancing the sensitivity in chemical analysis applications. Han and coworkers observed strong nonlinear electrokinetic flow at the micro-nanostructure interface giving rise to strong CP [20]. The capability to preconcentrate analytes using CP prior to analysis has obvious applications in biosensing, where analytes may be present at concentrations far below available limits of detection (LOD). Wang et al. [21] utilized a nanofluidic preconcentrator and a bead-based immunoassay to enhance binding kinetics, sensitivity, and the dynamic range of detection in immuno-sensing of R-phycoerythrin, achieving a 500-fold sensitivity enhancement and lowering the LOD from 50 pM to <100 fm. Ramsey and coworkers [22] developed a comparable preconcentration system using a highly ion-conductive charge-selective polymer [poly-AMPS (2-acrylamido-2-methyl-1-propanesulfonic acid)]. Such sample preconcentration devices could be potentially integrated to a wide range of detectors, such as mass spectrometers, to improve the detection of low-level proteins.

Resistive Pulse Sensing. Because nanochannels are commensurate in size with macromolecular scaling lengths, they can be used as chemical and biochemical sensors. The translocation of large molecules through nanopores containing high ionic strength electrolyte can produce a transient ionic current simultaneous with the temporary pore blockage [23], which can be used to count and size macromolecules, using the same principles as in commercial Coulter counters. The resulting current transients are termed resistive pulses. The majority of effort has targeted the use of biological ion channels to support DNA or RNA translocation, with α-Hemolysin being the most popular choice due to its well-studied structure, stability, and ability to introduce specific structural modifications. α-Hemolysin is a 293-amino acid protein secreted by *Staphylococcus aureus*. Since the passage of each ssDNA or RNA molecule induces a current transient with a temporal duration proportional to its length, careful characterization of resistive pulse widths can be used to acquire information on molecular size. In favorable cases, these measurements can yield information capable of discriminating oligonucleotide composition [24].

Adding either chemical or geometric asymmetry to nanopores leads to structures with the ability to discriminate among chemical species. Conical nanopores can be produced from track-etched polymer membranes, which are etched in base, while neutralizing the incoming basic solution from the distal side. Conical nanopores display distinct advantages for resistive pulse sensing, including higher sensitivity due to ionic current being focused at the conical tip, larger ion currents at equivalent diameters, and being more resistant to fouling [25]. For example, protein biosensors have been fabricated from surface biofunctionalized nanotubes by electrolessly plating a layer of gold

[28])

onto the interior surfaces of conical nanopores, followed by self-assembly of thiolated biotin derivatives [26]. Streptavidin was subsequently detected, and blockage time was related to streptavidin concentration. This strategy highlights one of the strengths of metal-coated nanostructures – by exploiting self-assembly chemistry a wide range of sensor chemistries can be realized within the same physical structure.

Single-Molecule Manipulations. When coupled with traditional optically based single-molecule detection methods, nanofluidic features enable detection to be performed at more biologically relevant concentrations. The diffraction-limited spot size in a confocal fluorescence correlation spectroscopy (FCS) experiment is on the order of 0.2 fL, requiring nanomolar or lower concentrations for single-molecule analysis [27]. As seen in Fig. 5, nanoscale channels use only a fraction of this volume, decreasing the detection volume by up to more than an order of magnitude, while at the same time allowing a corresponding increase in the fluorophore concentration [28].

At the cost of flow-through experimental capabilities, zero mode waveguides (ZMWs) enable a further reduction in excitation volume beyond that of diffraction-limited techniques [15]. ZMWs are created by making a nanopore or nanopit in an opaque film such as Al or Au. The physical volume of these features confines the sample and excitation volumes to be on the order of 100 zL, (1 zL $= 10^{-21}$ L), more than three orders of magnitude smaller than the lower limit of the diffraction-limited focal volume in FCS experiments. Correspondingly, single-molecule observations can take place at physiologically relevant concentrations, 1 μM $< C <$ 1 mM, even for proteins with μM K_D values. The signal-to-noise is significantly increased, because the electromagnetic field is effectively confined within the ZMW, which enhances the signal relative to the reduced background by eliminating light propagation into the far field.

Conclusions

Realizing EK flow in nanostructures opens up a range of new phenomena that support important new applications. Especially important are those

applications that enable the space-time manipulations of molecular distributions in fluids, such as molecular separations, concentration polarization, and EK flow switching. In addition, new approaches to chemical sensing that exploit novel nanofluidic properties are realized through the scaling of mass transport for specific chemical interactions that in turn supports resistive pulse sensing and single-molecule manipulations.

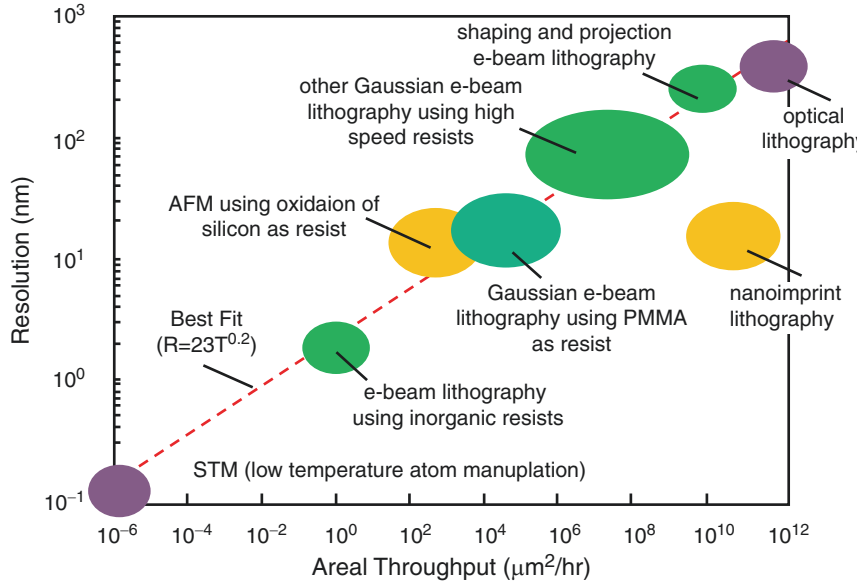
E-beam lithography (EBL)



Definition

Electron beam lithography (often abbreviated as e-beam lithography or EBL) is the process of transferring a pattern onto the surface of a substrate by first scanning a thin layer of organic film (called resist) on the surface by a tightly focused and precisely controlled electron beam (exposure) and then selectively removing the exposed or nonexposed regions of the resist in a solvent (developing). The process allows patterning of very small features, often with the dimensions of submicrometer down to a few nanometers, either covering the selected areas of the surface by the resist or exposing otherwise resist-covered areas. The exposed areas could be further processed for etching or thin-film deposition while the covered parts are protected during these processes. The advantage of e-beam lithography stems from the shorter wavelength of accelerated electrons compared to the wavelength of ultraviolet (UV) light used in photolithography, which allows defining much smaller diffraction-limited features. On the other hand, direct writing of patterns by scanning electron beam is a slow process and results in low throughput. Therefore, EBL is used for preparing photomasks for photolithography or for direct writing of small-area, low-volume patterns for research purposes.

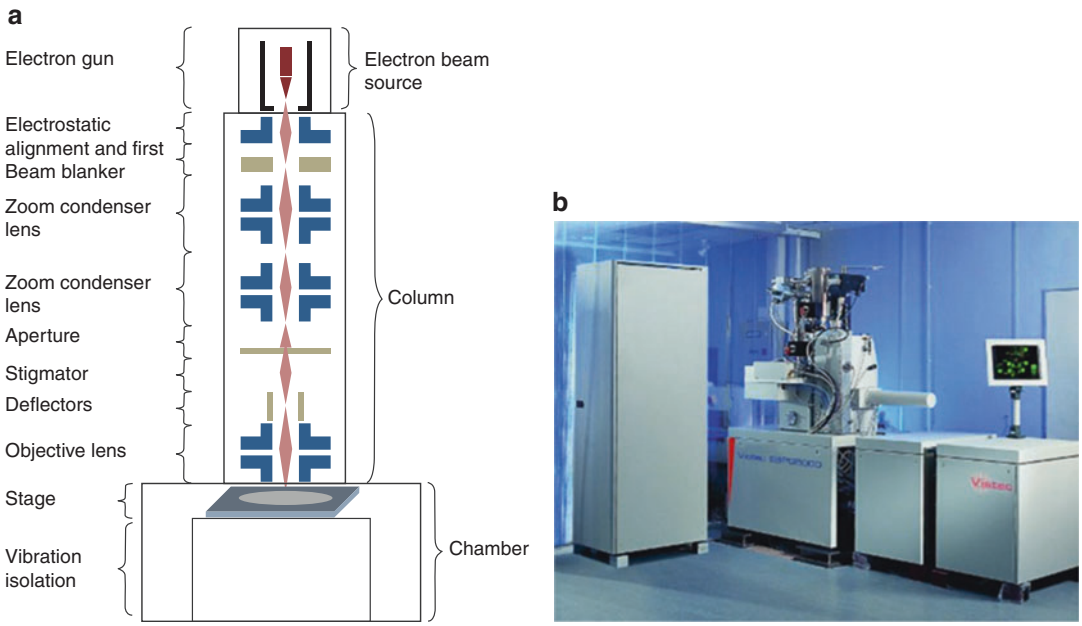
Principles of Electron Beam Lithography

There are two driving forces for the development of electron beam lithography and other patterning technologies (e.g., X-ray lithography) as potential alternatives to the conventional UV-based photolithography: higher resolution (smaller feature size) and cost.

The maximum resolution of an optical system is limited with the wavelength of the beam used. Conventional photolithography systems, which rely on UV light, can therefore achieve a minimum “diffraction-limited” feature size of several hundreds of nanometers. Using resolution enhancement techniques such as phase shifting and immersion lithography, it is possible to

Electron Beam Lithography (EBL), Fig. 1 Resolution of different lithographic techniques as a function of throughput

improve the resolution to some extent. However, the fundamental laws of optics will continue to be a limitation. Moreover, resolution enhancement techniques for photolithography caused both cost and cycle time of masks to steadily increase with the rising level of complexity for every technology node. The cost of an optical mask set for 90-nm technology has surpassed the $1 million mark and exceeds $2 million for the 65-nm node. As a result, prototyping is becoming extremely expensive and time consuming. Mask amortization for low- and medium-volume chip production is becoming all but unaffordable. For this reason, various maskless lithography approaches are being pursued in attempts to solve the cost and cycle time dilemmas. Especially in the framework of nanotechnology, variations of EBL emerge as valid alternatives for lithographic patterning (see Fig. 1).



Electron Optics

The power of electron beam lithography to define nanometer-scale patterns comes from the short wavelength of electrons. In 1924, Louis de Broglie proposed that moving particles could show wave-like properties and therefore can be considered and modeled as waves in an appropriate framework. His theory was fully confirmed with the observation of electron diffraction in crystals in 1929. In his work, de Broglie developed a simple formula for the wavelength of a moving particle:

$$\lambda = \frac{h}{p} = \frac{h}{m \cdot v} \tag{1}$$

where h is Planck's constant (4.135×10^{-15} eV.s), p is the momentum, m is the mass of the electron (9.11×10^{-31} kg), and v is its speed. This neglects special relativity effects, because it is assumed that the electrons are traveling sufficiently below the speed of light. If the electron were traveling at the speed of light, c (2.9979×10^{8} m/s) which is its maximum theoretical speed, it would have a wavelength of 2.43 pm. An electron's velocity can be determined from its kinetic energy, by the formula

$$E_{kin} = \frac{1}{2} m v^2 \tag{2}$$

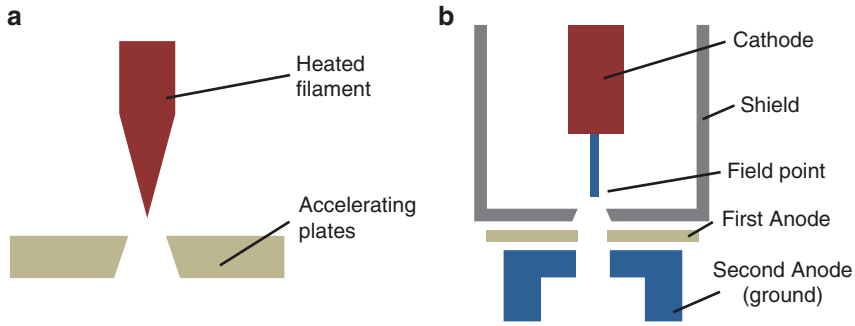
Electron Beam Lithography (EBL), Fig. 2 (**a**) Schematic of a typical electron beam lithography system. (**b**) A typical EBL system (Courtesy of Vistec Electron Beam Lithography Group)

Thus, the de Broglie wavelength for electrons with kinetic energy E_{kin} is:

$$\lambda = \frac{h}{\sqrt{2mE_{kin}}} = \frac{1.23}{\sqrt{E_{kin}}}[nm] \qquad (3)$$

where E_{kin} is expressed in eV. So if an electron were accelerated to an energy of 10 keV, then it would have $\lambda = 0.12$ A. This clearly shows that if lithography could be done with electrons, it would have a huge advantage over current optical lithography systems, which are limited by their wavelength. This is just a theoretical limit, however. EBL systems use projection and with most forms of EBL, no mask is used at all. So except in high-resolution systems (with very low throughput) where electron diffraction can come into play, the resolution of the system is limited by the beam column rather than the wavelength of the electrons. The resist also places limitations on the resolution of the beam, which can be greater than those effects, and in most cases, scattering in the resist places the limiting factor for the resolution.

Equipment



Although modern electron beam lithography systems are quite sophisticated to achieve very high resolution, precision, and repeatability, they all have the same fundamental parts in common. Figure 2 shows the schematic of a typical EBL system with major equipment parts.

Electron Sources

Electron source is the most essential part of any electron beam system. This is where the electrons are generated, which will eventually reach the resist on the sample and expose it. An ideal electron source should have a high intensity (brightness), high uniformity, small spot size, good stability, and long life. Brightness is measured in units of amperes per unit volume per steradian. Higher brightness is desired to have increased reaction rate with the resist and thereby shorter exposure time and higher throughput. High-resolution patterning, on the other hand, requires lower beam intensities. Virtual size of the source is also important since it determines the demagnification needed to be applied to the column. The smaller virtual size

Electron Beam Lithography (EBL), Table 1 Characteristics of different electron sources

Source type	Material	Brightness (A/cm^2rad)	Source size	Energy dispersion (eV)	Vacuum level (Torr)	Emitter temp. (K)
Tungsten Thermionic	W	~10^5	25 μm	2–3	10^{-6}	~3,000
LaB6 Thermionic	LaB_6	~10^6	10 μm	2–3	10^{-8}	~2,000–3,000
Thermal field aided emission	Zr/O/W	~10^8	20 nm	0.9	10^{-9}	~1,800
Cold field emission	W	~10^9	5 nm	0.22	10^{-10}	Ambience

Electron Beam Lithography (EBL), Fig. 3 Simplified cross-sectional schematics of (**a**) thermionic emission (**b**) field emission electron sources

provides smaller beam spot size on the wafer with minimum number of lenses. This makes the column less complicated, and allows a higher resolution to be achieved. Another very important feature of a good electron source is the low energy dispersion of the emitted electrons. An electron beam with a wide energy distribution is comparable to white light, while an energy beam with a narrow spectrum is comparable to a laser source. A narrow electron energy spread is desired as it reduces chromatic aberrations. Characteristics of different electron sources are summarized in Table 1 [1].

In an electron source, electrons are removed from cathode of the gun either by heating the cathode or by applying a large electric field. The first process is called thermionic emission (Fig. 3a) and the latter is called field emission (Fig. 3b). A combination of two, which is called thermal field–aided emission, is also sometimes employed.

For thermionic emission sources, tungsten or tungsten thoriated filaments were commonly used as emitters. In such sources, the filament is heated by passing current through it and electrons are emitted thermionically from a sharp tip. Tungsten filaments allow operation at pressures as high as 0.1 mtorr, but their low current density (~0.5 A/cm^2) results in very low brightness (~2 × 10^4 A/cm^2 sr). Thoriated tungsten cathodes have somewhat lower brightness at the same filament current and require higher vacuum (0.01 mtorr), but their maximum current density can be as large as 3 A/cm^2. Another disadvantage of tungsten sources is the high-energy spread due to the high operating temperature (2,700 K). Lanthanum hexaboride (LaB_6) is a newer thermionic source which can achieve very high current density over 20 A/cm^2 and good brightness of nearly 2 × 10^4 A/cm^2 sr at a lower temperature of 1,800 K. It has a slightly smaller source size than tungsten; however, it requires a better vacuum of 10^{-8} Torr, which can be easily achieved in present systems and must be well protected against sudden vacuum loss.

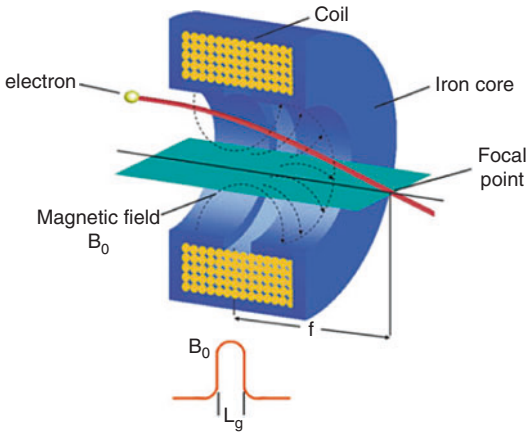
A major concern with all thermionic sources is the finite source size or crossover diameter. Because

a large volume of wire is heated, the thermionic sources produce broad beams. The energy distribution from such a source is also quite broad. This leads to focusing problems similar to those found in large optical partially incoherent sources. For typical LaB_6 sources, the crossover diameter is about 10 μm. Therefore, a demagnification of 100× is required to achieve 0.1-μm spot size. Even though the source has a large current density, the inherent source brightness is greatly reduced in order to achieve deep submicron resolution.

Field emission electron sources are based on application of an electric field high enough to extract the electrons through the surface potential barrier of the emitter (see Fig. 3b). In field emitters, cathode tip should be sharp, made of a material with reduced work function and be placed close to the extraction electrode to operate at a low voltage. Tungsten tips provide the extremely high fields necessary for electron extraction. An example of an electron source and the electrodes is shown in Fig. 3b. Two anodes are normally used. The first anode is the extraction electrode, and is used to extract the electrons from the cathode tip, and the second is used to accelerate the electrons to their full potential. The shield electrode is used to prevent thermally generated electrons from entering the beam. Thus, electrons are only emitted from the tungsten tip. Cold field emission sources have the disadvantage of high short-term noise, which is due to atoms adsorbing onto the tip. This causes fluctuations in the electron current in the short term as well as in the long term. Intensity fluctuations in the beam current caused by tip absorption can be reduced by ultrahigh vacuum environment.

Thermionic field emission sources are the best available electron sources. Thermal field emission sources combine the best of both field and thermionic emission sources. A tungsten needle (with approximately 1-μm tip) is used at only 1,800 K, thus increasing the lifetime of the source. The barrier to field emission of electrons is lowered because the needle is heated. Its brightness, source size, and energy spread are all better than the standard thermionic sources. Recently Zr/W/O tips have become available with crossover diameters as small as 200 Å for thermionic field emission. Such emitters can provide very high current densities up to 1,000 A/cm^2 and beam diameter as small as 100 Å without compromising the brightness. They, however, require a constant vacuum of at least 1×10^{-8} Torr for stable operation.

Once an electron beam is generated, it is focused and steered in the column using lenses, apertures, and deflectors. In the following sections, main components of a typical EBL column will be described.



E

Electron Lenses

The physical principles of electromagnetic lenses can be described by using the basic laws of electromagnetism. Electron motion can be modeled as EM waves, which implies that it can be focused and manipulated analogous to the classical optics systems (geometric optics). At the same time, electrons maintain the characteristic properties of classical charged particles. Therefore, electrons are manipulated in two basic ways: through an external electric field or a magnetic field.

From the second law of Newton, $\mathbf{F} = m \cdot (d^2x/dt^2)$, the trajectory and speed of electrons can be controlled by external forces, more precisely, by electromagnetic forces. According to the Coulomb's law, an electric field will exert a force on a charged particle. An electron will experience a force of $\mathbf{F}_C = -e\mathbf{E}$, where e is the elementary charge of an electron, and $\mathbf{E}$ is the electric field. According to Lorentz's Law, an electron will experience a force when traveling perpendicular to a magnetic field. This force will be perpendicular to the magnetic field and the electron's velocity, and is given by $\mathbf{F}_L = -e.\boldsymbol{v} \times \mathbf{B}$. The contributions could be summed together; however, normally in EBL systems, both magnetic and electric fields are not used simultaneously.

Magnetic lenses are used primarily because the aberrations produced by magnetic lenses are less severe than those produced by electrostatic lenses. A cross section of a magnetic lens is shown in Fig. 4. The radial magnetic fields cause the electrons to experience rotation about the optical axis upon entering the lens. The electrons now have a

Electron Beam Lithography (EBL), Fig. 4 Cross-sectional schematic of a magnetic electron lens [2]

velocity component in the tangential direction about the optical axis. This component now interacts with the axial magnetic field, imparting a force on the electrons toward the optical axis, bringing them close to the axis.

Neglecting the actual aberrations that exist in the beam trajectories, electrons are focused to a certain distance, f, from the center of the lens, determined by the electron mass m, unit charge e, magnetic field B_0, the gap L_g, and V_0 the voltage representing the electron's velocity:

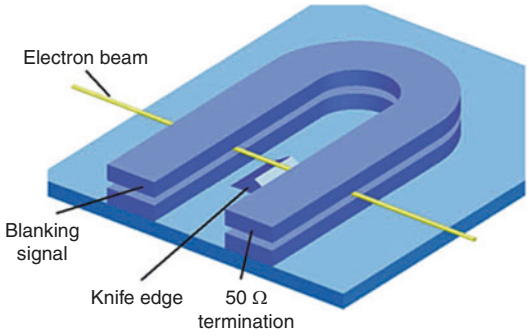
$$f \cong \frac{8mV_0}{eL_gB_0^2} \tag{4}$$

Electrostatic lens operation, to force electrons to converge in some point of the optical axis, is similar to magnetic lens one. The realization is accomplished by three plates provided with a central aperture. Central plate has a variable potential and the first and third plates are connected to the ground. In general, electrostatic lenses are used as condenser lenses of the electron source since the distortions inherent to these lenses are less critical here. The deflection unit is in charge of deviating the beam through the sample surface, within what is called the scan field. Ideally, the minimum degradation of beam is desired, i.e., precise deflection, constant beam size, and no hysteresis.

Beam Deflectors

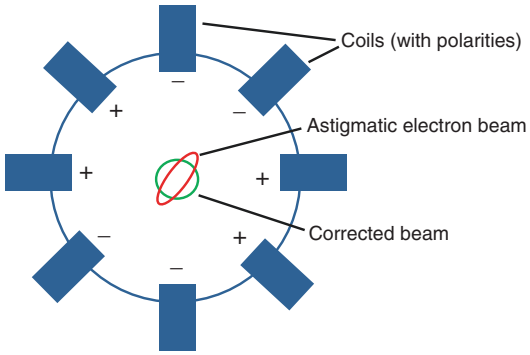
Beam deflectors are used to scan the electron beam over the target, across an area called the scan field. To have a predictable deflection for precise patterning of ultrasmall features, this process must be very linear, with minimal degradation to the electron beam spot size and with no hysteresis. Like in electron lenses, deflection can be done by an electric field or by a magnetic field. Electrostatic beam deflection results in more distortions in the beam, so magnetic deflection is normally used. Beam deflectors are one of the most important components; however, any nonlinearities or problems with beam deflectors can easily be fixed in the software, which drives them.

Apertures



There are a few different types of apertures, blanking apertures, and beam-limiting apertures. Blanking apertures deflect the beam by deflecting the beam away from the aperture hole. Beam-limiting apertures set the beam convergence angle, α, (the angle between the beam trajectory and the normal line to the target) which controls the effect of lens aberrations and resolution but also limits the beam current.

Beam Blankers



Beam blankers are used to turn off or "blank" the beam. This is necessary when doing vector scanning and the beam needs to be moved from one part of the wafer to another. The beam must be blanked in a time, which is very small compared to the time it takes to illuminate one pixel on the array, and the beam cannot move along the substrate while it is being blanked. A common blanker is shown in Fig. 5 and it works by applying a voltage to the upper plate, which deflects the electron beam away from the center of the column.

Stigmators

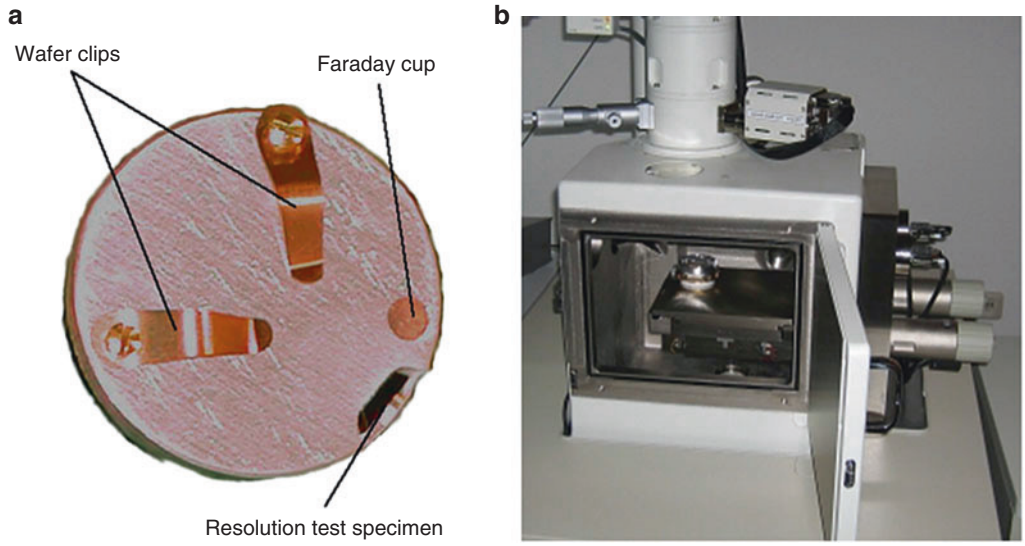
The imperfections in fabrication and assembling of the column cause astigmatism. Astigmatism results in different focusing conditions at different positions on the sample surface. This means that the ideal circular section of the beam becomes elliptic and, consequently distorts the image.

Electron Beam Lithography (EBL), Fig. 5 Schematics of a typical beam blanker

Electron Beam Lithography (EBL), Fig. 6 Schematic of a stigmator with eight poles. Alternate coils are connected in series but have different polarities. Astigmation of the electron beam can be corrected by changing the size of the current through the two sets of coils

Concerning to lithography, beam shape does not correspond to the model used for calculating the exposure dose; therefore, the pattern to be transferred is also distorted from the original design. The stigmator system is responsible for correcting beam shape to be circular again. It consists of four or eight poles that surround the optical axis. Adjustment is performed by the balance of electrical signal of the poles (Fig. 6).

Stage



EBL patterning is performed in a high vacuum chamber. The sample is fixed on a sample holder by screws, spring-loaded mechanisms, double-sided tapes, or silver paint. Wafer holders usually contain a set of test standards for calibration focusing and position. Calibration subroutines can be performed immediately before the actual writing or even during the writing in between different fields as often as desired.

The dimensions and mobility of the stage determine the size and accessibility of the sample that can be patterned. The equipment used can lodge up to 300 mm wafers and movement is possible for XYZ, rotation and tilt (Fig. 7a). The capabilities of the system benefit from precise and motorized controlled displacements. The stage moved by piezoelectric motors and the position is controlled by laser interferometry system to achieve nanometer-scale precision. The stage is also placed on vibration isolation system to reduce the mechanical vibrations, which might affect the spatial precision. At the same time, computer monitors, transformers, and vacuum pumps are kept separate or controlled and shielding is used to avoid interferences. In addition, the chamber may also be equipped with a charge-coupled device (CCD) camera to visualize inside the chamber and to assess the control of sample positioning.

Limitations of the Equipment

Different from conventional optical lenses, electromagnetic lenses are only converging. In reference to aberrations, their quality is so poor that field size and convergence angle (numerical aperture) are limited. From electron source specifications, the beam diameter as a function of virtual source and column reduction is determined. The distortions caused by the column arise as spherical aberrations (astigmatism) and they are originated in both the lenses and the deflectors. Chromatic aberrations appear when electrons present a certain energetic spectra. This may be caused in the beam source itself, but also can be increased by the so-called Boersch and Loeffler effects, where energetic distribution increases as a result of electron collisions. Both phenomena contribute to decrease the precision of lenses and deflectors.

In general, the theoretical effective beam can be expressed as the quadratic sum of each contribution and optimal point is a compromise between all involved factors. For high resolution, the use of high magnification and beam energy is combined with low energetic dispersion and short

Electron Beam Lithography (EBL), Fig. 7 (**a**) A simple EBL sample holder with two wafer clips to hold the sample, a Faraday cup to measure the beam current, and gold on carbon resolution sample for resolution test. (**b**) Wafer chamber of an EBL system with the door open

focal distance. In consequence, write field is smaller and beam current should be reduced, which means that exposure process is slower, throughput is limited, and flexibility is constrained. The final spot diameter on the surface of the wafer is given by

$$d^2 = d_d^2 + d_o^2 + d_S^2 + d_C^2 \qquad (5)$$

where d_s is the spherical aberration, d_C is the chromatic aberration due to the nonzero energy distribution, and d_o is the perfect lens diameter, which is limited by the finite source size and space charge and d_d is the diffraction limit.

Another limitation is called stitching and stems from the limited deflection of the beam. Typically, for very small beam deflections electrostatic deflection "lenses" are used, larger beam deflections require electromagnetic scanning. Because of the inaccuracy and because of the finite number of steps in the exposure grid, the writing field is on the order of 100 μm–1 mm, larger patterns require stage movements. An accurate stage shift is critical for stitching (tiling writing fields exactly against each other) and pattern overlay (aligning a pattern to a previously made one). Large patterns spanning several write fields may suffer from *stitching errors* due to the finite inaccuracies in stage movement.

Resists for Electron Beam Lithography

Interactions between electromagnetic radiation (either UV or electron beam) and polymers, which are used as resists (either for optical or e-beam lithography) result in one of the following two chemical reactions: (1) *cross-linking* (2) *chain scission* (also known as fragmentation). The resists are usually long chains of carbon-based polymers. By interacting with incoming radiation, atoms in adjacent chains may be displaced and the carbon atoms will bond directly. This process is called cross-linking. Highly cross-linked molecules dissolve more slowly in an organic solvent (developer). A material in which cross-linking is the dominant reaction upon exposure is a *negative resist*. Radiation can also disrupt the polymer chains, breaking them up to smaller pieces. This reduces the molecular weight of the resist, which makes it more soluble in developer solution. A material in which chain

Electron Beam Lithography (EBL), Table 2 Commonly used EBL resists

Resist	Tone	Sensitivity @20 keV (μC/cm^2)	Resolution (nm)	Contrast	Etch resistance
PMMA	+	100	10	2.0	Poor
P(MMA-MAA)	+	5	100	1.0	Poor
PBS	+	1	250	2.0	Good
NEB-31	–	30	50	3.0	Good
EBR-9	+	10	200	3.0	Poor
ZEP	+	30	10	2.0	Good
UV-5	+	10	150	3.0	Good
SAL-606	–	8.4	100	2.0	Moderate
COP	–	0.3	1,000	0.8	Poor

scission is the dominant reaction upon exposure is a *positive resist*. The most important resist criteria are contrast and sensitivity for the exposure type and energy and etch resistance.

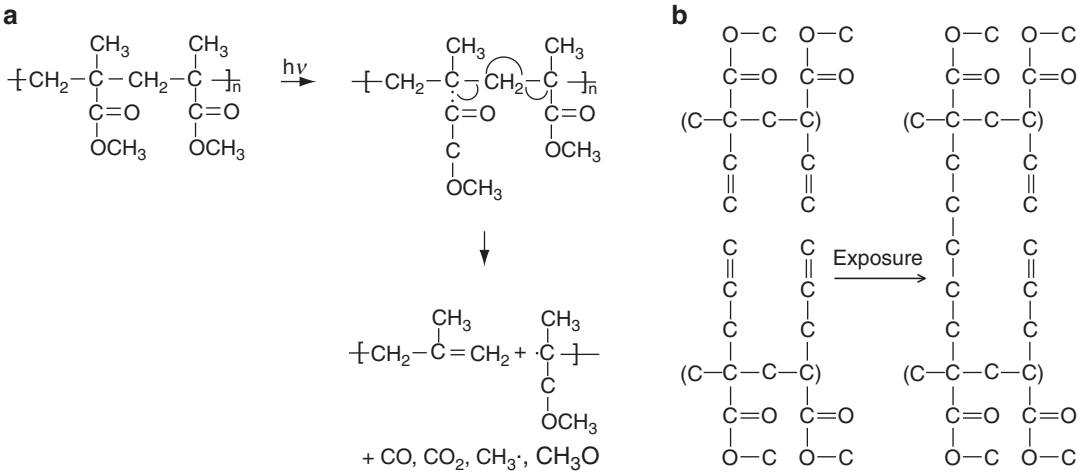
Tone determines the areas that will be removed in the development. For positive tone resists, patterned areas are removed with the developer, whereas for the negative ones, the result is the inverse of exposed features, resist is not dissolved where irradiated.

Sensitivity quantifies the minimum amount of delivered dose that is required to achieve the selective development, where dose is the number of electrons per unit area.

Resolution defines the minimum feature size or the smallest distance between two patterns that can be resolved.

Contrast describes how abrupt is the dependence of thickness on dose, which also has implications upon resolution. It is determined from the linear slope of the sensitivity curves.

Etch resistance determines the resist integrity under chemical (wet) and physical (dry) etching processes.



Other resist variables are adhesion to the different substrates, compatibility with conventional techniques, or shelf life. Table 2 summarizes the properties of commonly used EBL resists.

Positive Resists

Polymethyl methacrylate (PMMA) was one of the first resists developed for EBL and remains the most commonly used positive resist. PMMA has extremely high resolution, and its ultimate resolution has been demonstrated to be less than 10 nm. In PMMA, both cross-linking and fragmenting of the polymeric chains occur (see Fig. 8), but the rate of scission is much larger than that of cross-linking. If PMMA is exposed to ten times the normal critical dose, chain-linking will occur and it will behave like a negative resist; however, its resolution will be degraded to about 50 nm. One of the major disadvantages of PMMA is low sensitivity. PMMA also has poor resistance to dry etching, which makes it limited to mask making where only a thin Cr wet etch on a flat substrate is required. When it is used for direct writing, PMMA is typically used as the imaging resist for a liftoff process. PMMA is available in low-molecular-weight form and high-molecular-weight form, of which the former is more sensitive than the latter. Thus, if two layers of PMMA are used, with the low-molecular-weight form on the bottom, this will cause the resist to develop with an undercut, thus making it suitable for a liftoff process.

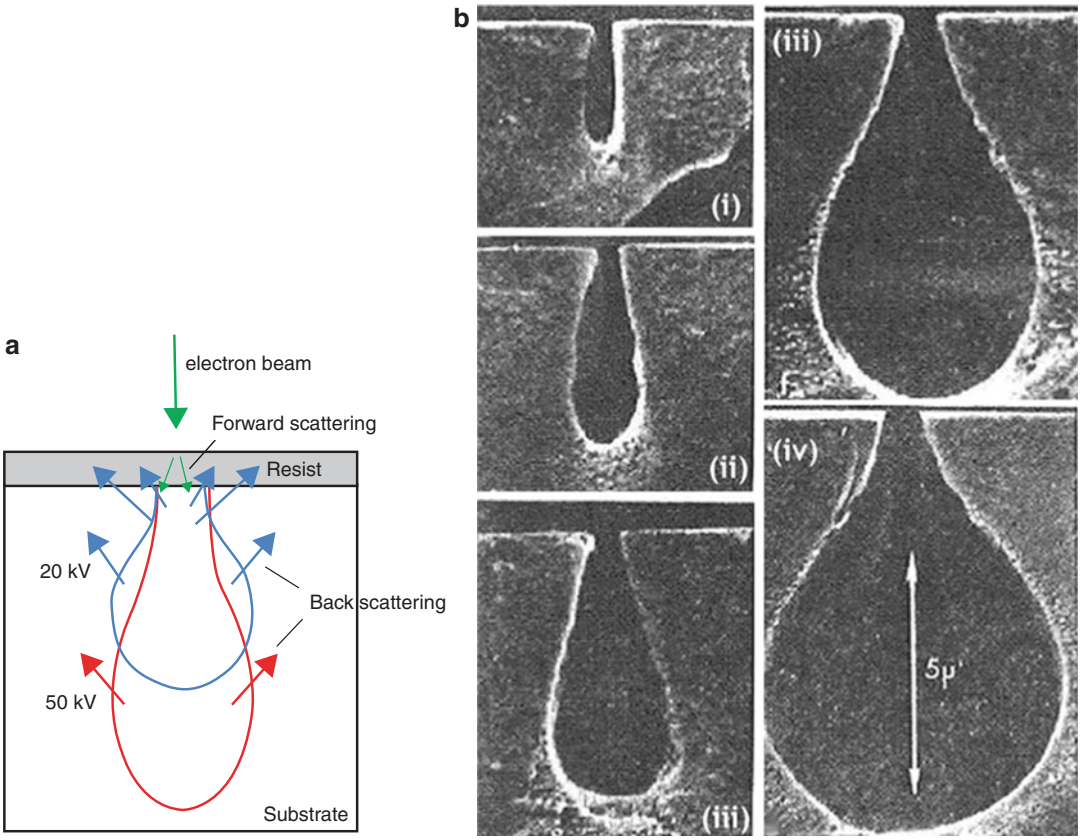
The copolymer, methyl methacrylate and methacrylic Acid (P(MMA-MAA)), provides a three- to fourfold improvement in sensitivity relative to PMMA and image thermal stability of 160 °C. Since P(MMA-MAA) can also be developed in MIBK:IPA solvent as used for PMMA, a single-step development of mixed layers of PMMA and P(MMA-MAA) is possible for enhancing the sensitivity and thermal stability of the resist.

A new resist called ZEP has an order of magnitude improvement in sensitivity versus PMMA and it has 2.5 times better etch resistance compared to PMMA although it is still not as resistant

Electron Beam Lithography (EBL), Fig. 8 (**a**) Mechanism of radiation-induced chain scission in PMMA (**b**) Cross-linking of PMMA structure where it is modified through the addition of a C=C side chain

as novolak-based resists. ZEP has about the same resolution as PMMA of about 10 nm and it has demonstrated an ability to produce lines of width 10 nm with a pitch of 50 nm. Other important positive resists include PBS (polybutene-1-sulfone) and EBR-9 (a copolymer of trifluoroethyl a-chloroacrylate and tetrafluropropyl a-chloroacrylate) which have high sensitivity. It is noted that the desired properties of a resist are high resolution and high sensitivity (high speed). Unfortunately, the resist that has higher sensitivity, including those mentioned here, usually has lower resolution, especially compared to PMMA.

Negative Resists



A number of negative EBL resists are also available. These resists have components on the polymer chain that enhance the cross-linking. Typical cross-linking components include chloromethyl styrene, epoxies, and vinyl groups. Negative resists tend to have less bias but they have problems with scum and swelling during development and bridging between features.

Commonly used negative e-beam resists consist of the Shipley advanced lithography (SAL) product line, an epoxy copolymer of glycidyl methacrylate and ethylacrylate (P(GMA-EA)), also known as COP, and a partially chloromethylated polystyrene (CMS). While COP has high sensitivity, CMS possesses modest resolution at modest sensitivity. The SAL offers many new deep ultraviolet (DUV) resists through the use of chemically amplified resist materials. Fast versions of CAP have demonstrated high-resolution capability with 100-nm lines at sensitivity higher than PMMA. Also, as it was mentioned before, PMMA can exhibit negative tone when exposed to a dose one order of magnitude higher [3].

Electron-Substrate Interactions

Electron beam generation and control technologies allow achieving beam diameters below the nanometer range. However, electrons being massive charged particles undergo interactions with the resist and the substrate and result in larger minimum resolution. Therefore, electron-solid interaction must be carefully taken into account to obtain small feature size by EBL.

Typical electron beam lithography machines use electron beams with 10–100 keV energy per electron. Therefore, the free path of an electron is 10 μm or more, which is at least an order of magnitude more than the resist thickness. Thus, the electrons can easily penetrate the resist layer and reach the substrate. When an electron beam hits the surface of a resist deposited on a substrate, it experiences elastic and inelastic collisions with

Electron Beam Lithography (EBL), Fig. 9 (**a**) Forward and backward scattering in resist and substrate. (**b**) Experimental evidence of pearl-shaped electron trajectories caused by electron-resist scattering. A 5-μm-thick layer of PMMA is developed with increasing times from (*i*) to (*iv*) [4]

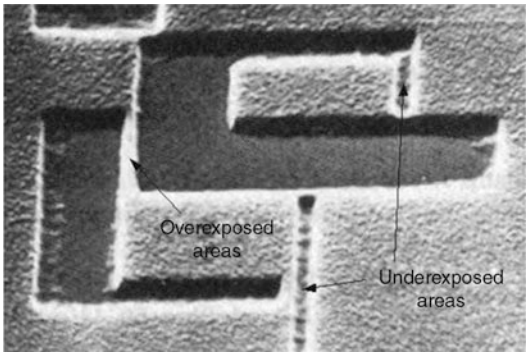
the resist and substrate atoms and molecules. Elastic collisions result in backward scattering whereas inelastic collisions create small angle forward scattering (see Fig. 9). The energetic transfer in the resist mainly causes the resist exposure, whereas interaction with the substrate underneath is manifested as heating and creates more backscattered electrons. Usually, elastic collisions are expressed in terms of the unscreened single electron scattering of Rutherford. It evaluates the process as a probability of interaction that strongly depends on the solid atomic number and the electron energy. Inelastic collisions are the cause of the loss of electron energy and it is typically described by the Bethe's continuous slowing down model. As a result, electron trajectories are mostly dependent on electron energy and the substrate composition.

In the resist, forward scattering is the more probable process, i.e., main parameter is the energy, while the interaction with the substrate comes from backscattering, which is highly dependent on both charge energy and substrate nature. Thus, electron trajectories are typically distributed in a certain 3D interaction volume that reaches few microns in range of 10–20 keV for incoming electron energy. The usual pearl shape of electron distribution in the resists can be easily explained from the low atomic number and density of the resists (Fig. 7b). High-energy electrons initially are just slightly deviated from the incoming direction, since elastic contribution is weak ($\sim Z^2$), but once they slow down, lateral scattering dominates ($1/E^2$). Electron trajectories in resist and substrate are often modeled by Rutherford scattering and simulated using Monte Carlo

techniques. However, resultant increase in the beam diameter can also be estimated by an empirical formula [5]:

$$\Delta d = 0.9\left(\frac{t_R}{V_b}\right)^{1.5} \tag{6}$$

where Δd is the change in beam diameter after entering the resist, t_R is the resist thickness, and V_b is the accelerating voltage of the electron beam. Forward scattering is detrimental if very high resolution is required, and can be reduced by increasing the accelerating voltage. Forward scattering does have one advantage, however; it can be used to create a negative sidewall angle in the developed resist. This is advantageous when doing liftoff process with positive resist, because a slight negative sidewall angle is required. This eliminates the need for using two layers of different resists and simplifies the processing.



The electrons impinging on the resist and substrate have a large energy (typically 10–100 keV). Their forward scattering results in generation of *secondary electrons* with lower kinetic energies (typically 20–50 eV). The major part of the resist exposure is due to these electrons. Since they have low energies, their range is only a few nanometers. Therefore, they contribute little to the proximity effect. However, this phenomenon, together with the forward scattering, effectively causes a widening of the exposure region. This is one of the main limiting factors in resolution of e-beam lithography machines. The distance a typical electron travels before losing all its energy depends on both the energy of the primary electrons and the type of material it is traveling in. The fraction of electrons that are backscattered is roughly independent of beam energy. It does, however, have a strong relation to the substrate material. Substrates with a low atomic number give less backscattering than substrates with high atomic number.

Proximity Effects

As it is mentioned above, as the electrons penetrate the resist and the substrate, they experience many scattering events. In backscattering, an electron collides with the much heavier nucleus, which results in an elastic scattering event. The electron retains (most of) its energy, but changes its direction. The scattering angle may be large in this case. After large angle scattering events in the substrate, electrons may return back through the resist at a significant distance from the incident beam, thereby causing additional resist exposure outside the desired area. This phenomenon caused by electron backscattering is called *proximity effect*. It is important to correct for the proximity effects to avoid erroneous pattern developing.

Proximity effects may be observed in the final pattern in two different forms: intrashape and intershape proximity effects. The intrashape proximity effect causes smaller shapes to be underexposed relative to larger shapes written with the same dose. In this case, each pixel in a smaller shape gets less exposure from scattered electrons, because there are fewer neighboring exposed pixels. In a positive resist, intrashape proximity effects may result in underdeveloping of narrow lines or small features. Intershape proximity effects are the result of the fact that exposed shapes are also affected by other nearby shapes, with electrons scattering through the intervening resist. Densely packed shapes will strongly interact, providing much "cooperative exposure" between the shapes, and will thus require a lower exposure dose than sparse, isolated shapes, which get fewer scattered electrons and will thus be underexposed relative to their cousins with closer neighboring shapes. In a positive resist, intershape proximity effects may result in accidental exposure of narrow fields in between large exposed areas and thereby developing completely. These effects are illustrated in Fig. 10.

The first step of the proximity-effect correction is an accurate knowledge of the energy density profile deposited in the electron-resist layer due to a point or pixel exposure (often called point spread function). In general, this profile is a function of the system setup. An important property of these profiles is that the shape is independent of dose as well as position, assuming a planar and homogeneous substrate. This profile is often

Electron Beam Lithography (EBL), Fig. 10 SEM picture of a positive resist pattern affected by the intrashape and intershape proximity effects [5]

approximated by the sum of two Gaussian distributions:

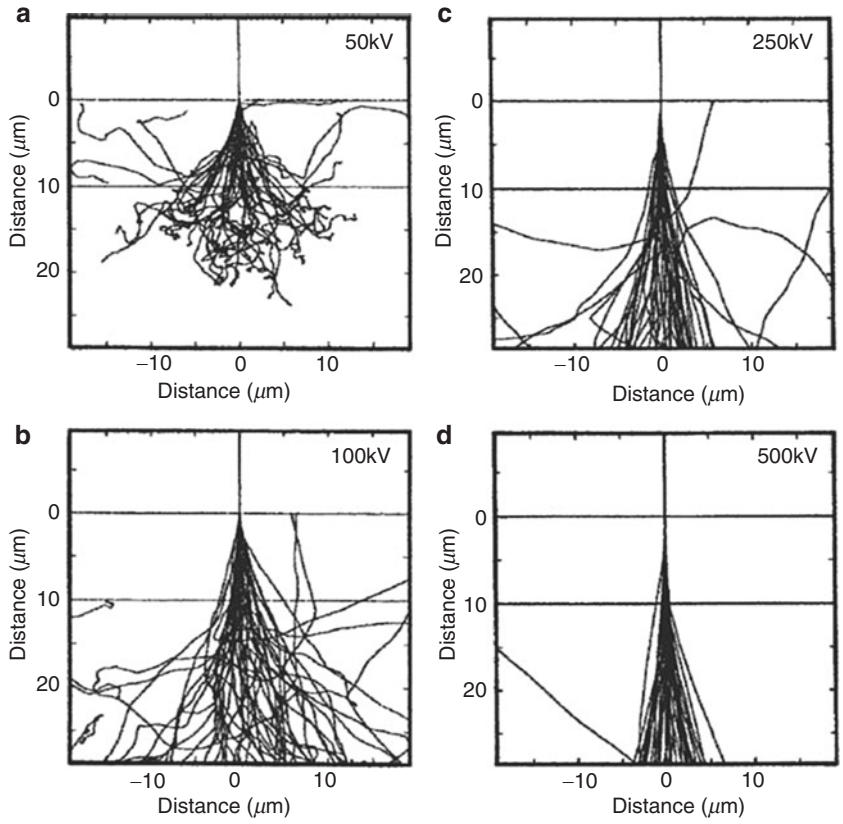
$$f(r) = \frac{1}{\pi(1+\eta)}\left\{\frac{1}{\alpha^2}\exp\left[-\left(\frac{r}{\alpha^2}\right)^2\right] + \frac{\eta}{\beta^2}\exp\left[-\left(\frac{r}{\beta^2}\right)^2\right]\right\} \quad (7)$$

where r is lateral distance from incident beam; α is standard deviation of forward scattered electron distribution; β is standard deviation of backscattered electron distribution; η is ratio of energy deposited by forward scattered electrons to the energy deposited by backscattered electrons. The first term represents the contribution of forward scattered electrons, whereas the second term is related with the backward scattered electrons. Equation 7 is normalized so that

$$\int_0^\infty f(r)2\pi dr = 1 \quad (8)$$

for some substrates and resists, a better match between the experimental results and the model is achieved with the addition of a third contribution. As a matter of fact, deposited energy distribution is not uniquely caused by proximity effects in terms of electron scattering, so, due to this, more accuracy is obtained when an exponential decay modulates proximity function:

$$f(r) = \frac{1}{\pi(1+\eta+v)}\left\{\frac{1}{\alpha^2}\exp\left[-\left(\frac{r}{\alpha^2}\right)\right] + \frac{\eta}{\beta^2}\exp\left[-\left(\frac{r}{\beta^2}\right)^2\right] + \frac{v}{2\gamma^2}\exp\left[-\left(\frac{2}{\gamma^2}\right)\right]\right\} \quad (9)$$



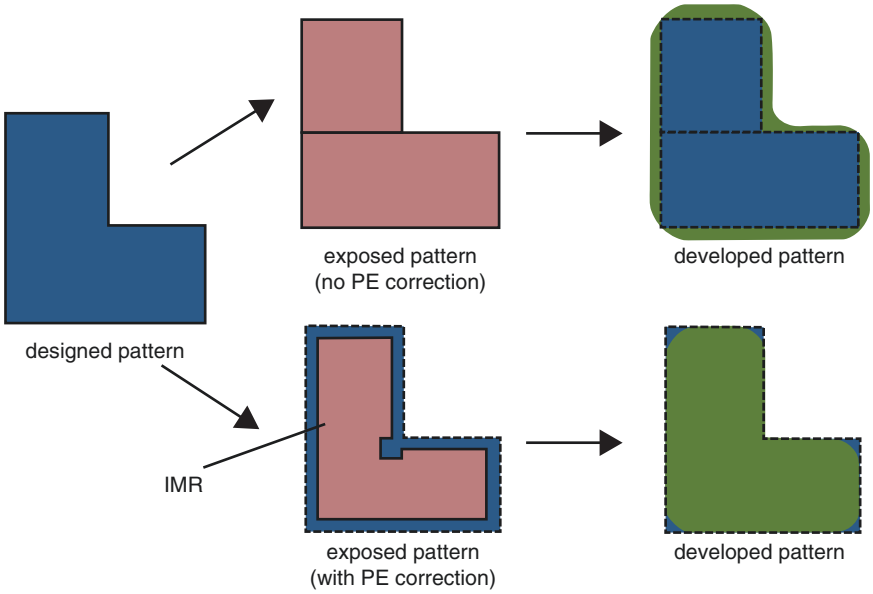
where v is efficiency of exponential function and γ is decay of exponential function.

The models discussed above are two-dimensional versions of an essential three-dimensional phenomenon. In general, the energy profile depends upon depth as well as radius. By averaging out the depth dependence, a two-dimensional profile can be obtained out of a three-dimensional profile. The simplified models allow great reduction in computation time for the exposure estimation and correction. For certain applications, it may be necessary to use a three-dimensional profile. In this case, a Monte Carlo simulation of electron scattering in the resist layer can be used. Electron scattering in resists and substrates can be modeled with reasonable accuracy by assuming that the electrons continuously slow down as described by the Bethe equation, while undergoing elastic scattering, as described by the screened Rutherford formula (Fig. 11).

Once the proximity function is correctly determined with the coefficients, proximity effects can be corrected for by several methods.

Dose modification and its variants are the most common correction. It is based on determination of the required dose for each pixel with a reasonable accuracy while being computationally practicable. Numerous variants of the "self-consistent dose correction" have been developed. In its simplest form, it is basically the reverse of the exposure estimation. Let Q_j be the dose applied to pixel j and let N be the total amount of pixels. The total energy on pixel i will be:

$$E_i = \sum_{j=1}^{N=} R_{ij}Q_j \text{ with } R_{ij} = \frac{\Delta V_f}{t}\left(\frac{1}{\pi\alpha^2}\exp\left(-\frac{r_{ij}^2}{\alpha^2}\right) + \frac{\eta}{\beta^2}\exp\left(-\frac{r_{ij}^2}{\beta^2}\right)\right\} \quad (10)$$

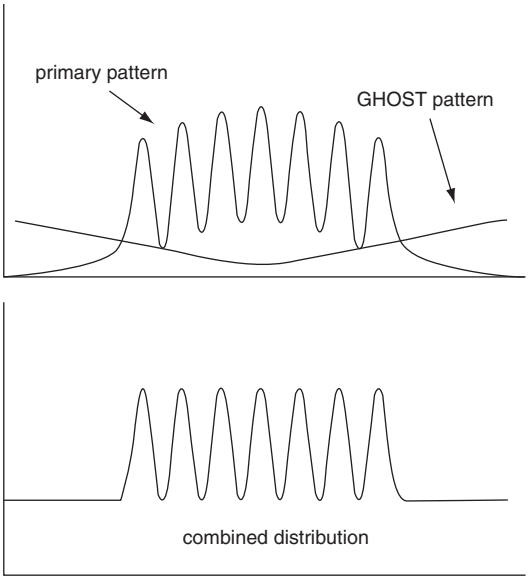


Electron Beam Lithography (EBL), Fig. 11 Electron trajectory simulations using Monte Carlo for 10 mm of resist on a silicon wafer for different electron energies [6]

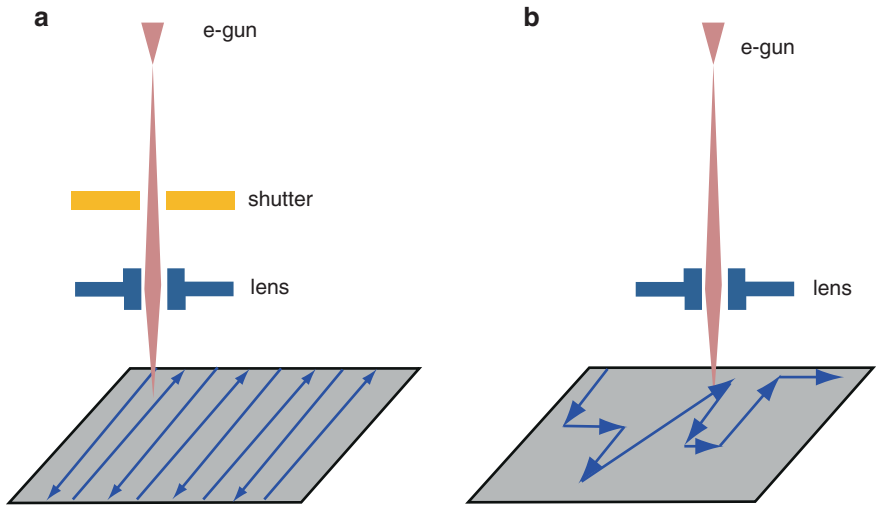
where r_{ij} is the distance between pixel centers of i and j. This equation can be written in matrix notation for all i:

$$[E_i] = [R_{ij}][Q_j] \tag{11}$$

Solving this set of equations with matrix operations will provide a proximity-effect corrected pattern. However, this "self-consistent" scheme will not be a perfect correction since only the exposed pixels are considered in this equation. The problem can be simplified, thereby reducing the calculation time, by splitting the dose modification into a problem of forward scattering and back scattering correction. With dose modification, it is possible to achieve superior proximity-effect correction. The main disadvantage is that with very large circuits, it may require large computation times.



In another correction method, the shapes found in the pattern image are modified in such a way that the developed image will resemble the intended image as close as possible, while a single dose is used for the entire circuit. A good example of a shape modification method is the correction scheme in PYRAMID [7]. PYRAMID takes a pattern with rectangular circuit elements. The circuit is then passed to a correction hierarchy, which adjusts each element via pre-calculated rule tables. This rule table is created using exposure estimation as described earlier. The first step is to replace each rectangle with its inner maximal rectangle (IMR). The second step is to correct the effect of interaction among the different circuit elements. Each edge facing



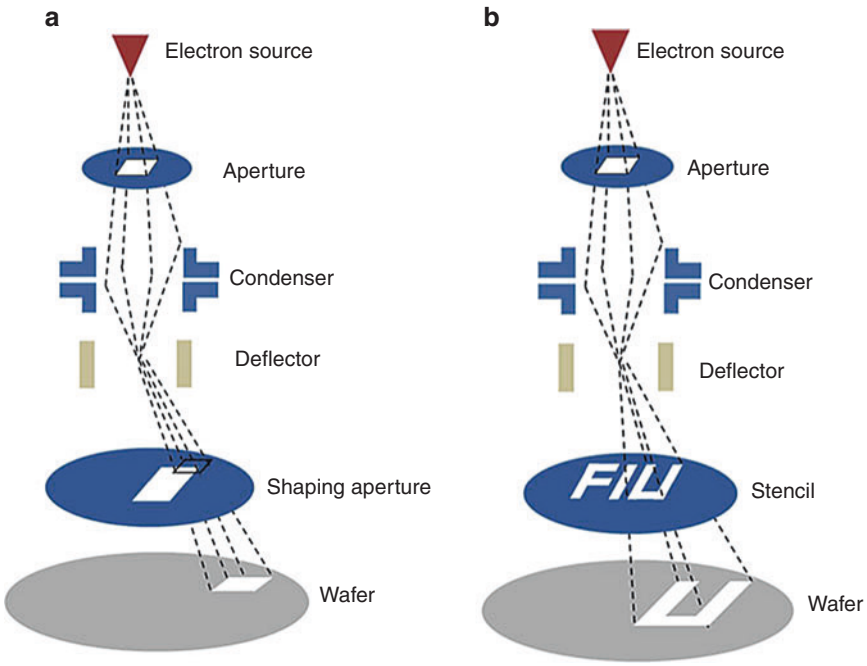
Electron Beam Lithography (EBL), Fig. 12 PE correction by shape modification at critical points

other circuit elements will be adjusted so that the midpoint of the edge will be equal to the experimentally determined development threshold. Even better results can be obtained by bending the edge when appropriate. The final step is to modify the shapes at critical points, that is, junctions between adjacent rectangles (Fig. 12). The major advantage of the shape modification method is that accurate results can be obtained without being computationally expensive and without losing throughput. However, it may not be as flexible as the other methods and experimental data are needed to obtain the necessary rule tables.

Background exposure correction, often referred to as GHOST, works by writing a second exposure, which is the inverse of the intended image (Fig. 13). This is done in such a way that the background dose is brought to a constant level. The main advantage of this method is that it is one of the easiest proximity-effect correction methods found in the literature and can be used with virtually all electron beam machines. However, there are several disadvantages with this method. One problem may be a contrast reduction (although this is true for many other correction types too). However, the main problem is that it only provides correction to the backscattering component, where the forward scattering remains uncorrected. There is also a loss of throughput because of the double exposure.

Electron Beam Lithography (EBL), Fig. 13 The figure on the top shows a pattern of lines, and the GHOST pattern superimposed. The figure on the bottom shows the summed contribution of the GHOST pattern and the line pattern [5]

Electron Beam Lithography (EBL), Fig. 14 Schematic representation of (**a**) raster scan (**b**) vector scan



Electron Beam Lithography Systems

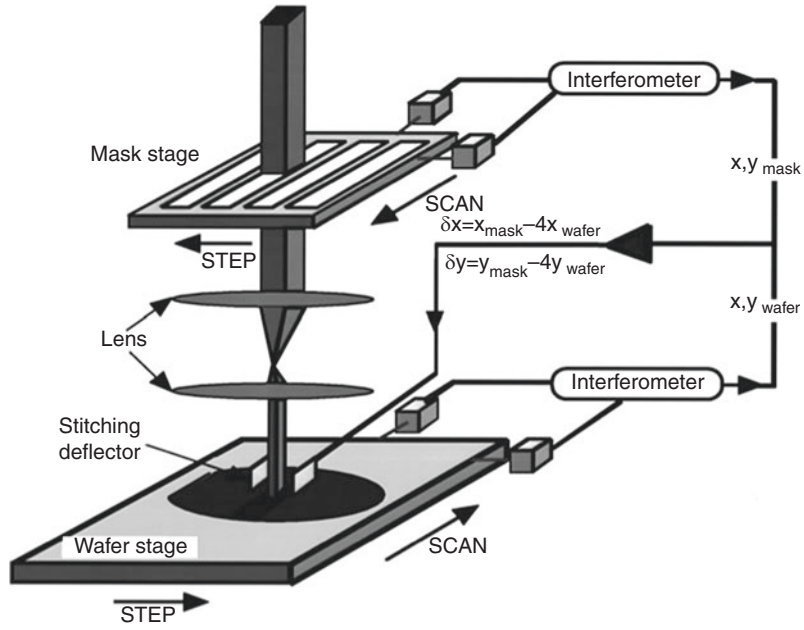
Although they all are based on the same basic principles, different types of electron beam lithography systems are available. These systems as well as some proposed future systems will be briefly discussed in this section.

Gaussian Beam EBL Systems

The most EBL systems today are based on scanning electron microscope (SEM) or scanning transmission electron microscope (STEM) systems since they share the same electron optics column. In fact, the first EBL systems were direct descendents of scanning electron microscopes and for research applications, it is very common to convert an electron microscope into an electron beam lithography system using a relatively low cost accessory (~ $100 k). This provides a huge saving especially for academic research facilities considering that dedicated e-beam writing systems are very expensive (~$4 M). SEMs normally have some lenses to focus the beam on the specimen, a beam-blanking mechanism, and some magnetic deflection coils used to scan the beam across the sample. Controlling these components by a computer allows transfer of any design in digital format to an exposure pattern. Digital-to-analog (DAC) converters are the key components for this transfer. The area to be scanned by the beam is divided into fields and subfields. This makes high speed (subfield) scanning achievable with DAC electronics when the address contains fewer bits (e.g., 12 bits). Then the large-field scanning is performed by tiling together subfields with a high-precision DAC with larger addressing (e.g., 20 bits or larger). For the given DAC sizes and 1-nm address grid, it can be estimated that the maximum subfield size is 2^{12} nm (~4 μm) and the maximum main field is 2^{20} nm (~1 mm) [8]. The scan trajectory is defined as the path, which the beam would be deflected along if every pixel were to be exposed. The actual pattern is written by opening and closing a shutter. The scan method in which the beam scans the entire field by following the bit map data organized serially is called *raster scan* (Fig. 14a). Since every pixel must be scanned serially in raster scan, exposure time is independent of the pattern and longer than the alternative method *vector scan*.

Vector scan method is developed to improve the throughput by directing the electron beam to only those parts of the chip to be exposed (Fig. 14b). The digital address of each area to expose is sent to DAC and the beam scans over only the pixels, which must be exposed. Some systems use two sets of DACs: The first DAC drives a deflector, which directs the beam onto

Electron Beam Lithography (EBL), Fig. 15 Simplified schematics of (**a**) variable shape aperture (**b**) cell projection approach with a stencil mask



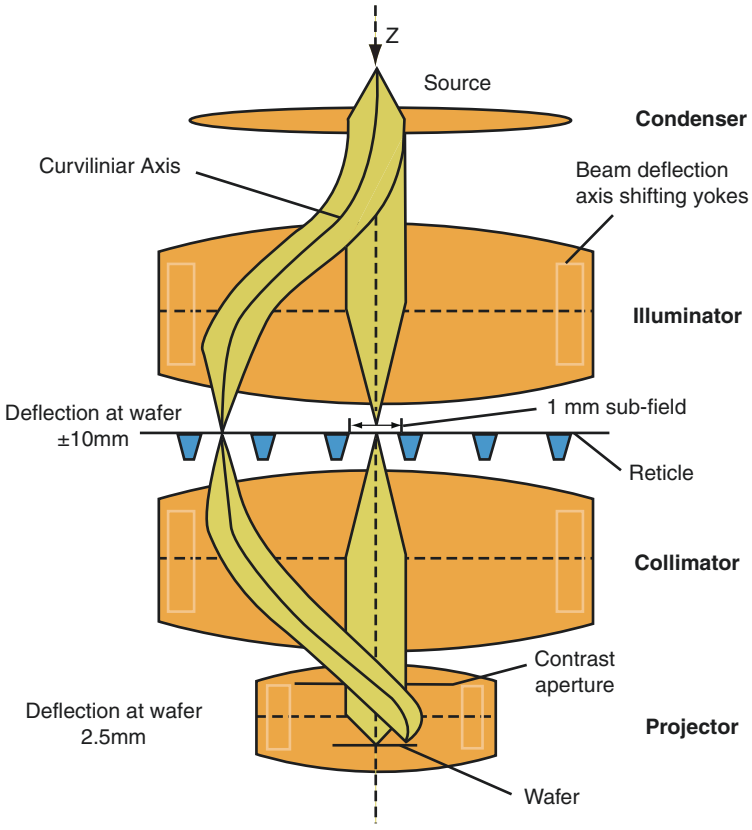
the corner of some primitive shape on the target wafer; the second DAC drives the same deflector or a different deflector in a raster pattern to fill in the shape. A moveable x – y substrate stage is often used, and is normally controlled using a laser interferometer to give accuracy down to the wavelength of the laser being used. Another advantage of the vector scan is the higher precision. Ignoring system aberrations and nonlinearities, the precision of the pattern address is determined by the width of the digital word. Therefore, pixels can be placed on an extremely fine grid if a high-speed, wide word DAC is used.

Variable-Shaped Beam and Mask Projection EBL Systems

As it was explained in detail before, direct write systems use a small electron beam spot that is moved with respect to the wafer to expose the pattern: one pixel at a time. This technique inherently suffers from low throughput to become a major process for economically manufacturing complex ICs. Inspired by the photolithography techniques, special EBL systems similarly have been developed to improve the throughput.

In one approach, the beam is partially intercepted by a square aperture. The electron beam is deflected and rotated electrostatically to adjust the width, length, and angle of the line exposed on the wafer. Since most images are made up of rectangles, hundreds or even thousands of pixels can be exposed simultaneously. Line width is somewhat more difficult to control in this method but for many applications, the increase in throughput is sufficient to compensate for the reduction in line width control (Fig. 15a).

In the cell projection approach, a mask with predetermined geometries similar to the photomasks in photolithography is placed between the wafer and the beam source (Fig. 15b). Since the short penetration length of electrons prohibits the use of a quartz mask, a stencil mask is used instead. Highly repetitive features such as DRAM cells can be transferred at a much higher throughput than conventional EBL. Cell projection has an advantage over shaped beam systems

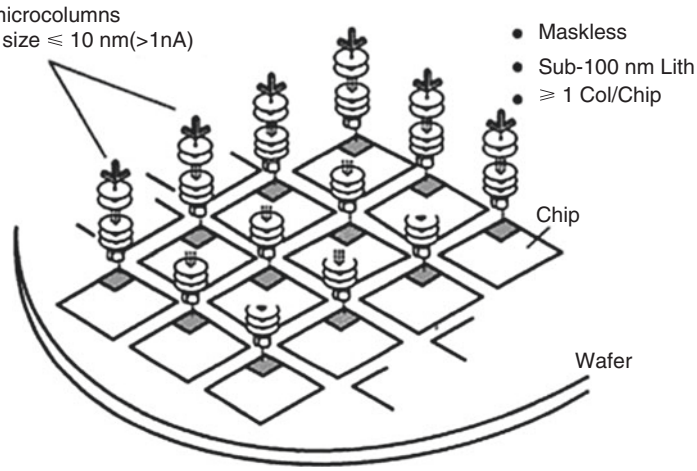


Electron Beam Lithography (EBL), Fig. 16 Schematic diagram of the SCALPEL principle showing the function of the scattering mask in forming image contrast [9]

in that complex shapes can be created on a stencil mask beyond rectangles and triangles, at a modest increase in throughput.

To be able to stop highly energetic electrons, the stencil masks in cell projection method have to be large even to pattern a small area. The energetic electrons absorbed by the mask also heat up the mask, which can significantly alter the size of the features. New projection EBL systems have been developed to solve these problems. SCattering with Angular Limitation Projection Electron-beam Lithography (SCALPEL) system developed by Bell Labs is a noteworthy approach. SCALPEL approach combines the high resolution and wide process latitude inherent in electron beam lithography with the throughput of a parallel projection system and avoids the problems of stencil masks. In the SCALPEL system, a mask consisting of a low atomic number membrane and a high atomic number pattern layer is uniformly illuminated with high-energy (100 keV) electrons (Fig. 16). The entire mask structure is essentially transparent to the electron beam and little of its energy is deposited there. The portions of the beam, which pass through the high atomic number pattern layer, are scattered through angles of a few milliradians. An aperture in the back focal plane of the electron projection imaging lenses stops the scattered electrons and produces a high contrast image at the plane of the semiconductor wafer. The SCALPEL approach separates the pattern formation and energy absorption to maintain pattern fidelity. The pattern is defined by the mask although the energy from the unwanted parts of the beam is deposited on a mechanical aperture [9]. Throughput on the SCALPEL system has been predicted to be approximately 45 wafers per hour. This is ten times higher than raster-scan EBL systems, and only 50 % slower than optical lithography machines. It is estimated by SCALPEL's designers that SCALPEL will be cheaper than optical lithography systems, which use RET and hence, could be used for the sub-100-nm ULSI nodes. However, further development and commercialization of SCALPEL was stopped in January 2001.

IBM has also developed a projection EBL system, which is dubbed projection reduction exposure with variable-axis immersion lenses (PREVAIL). The PREVAIL system increases the throughput by shifting the main optical axis of the electron beam through the use of variable-axis lens designed at IBM. Deflections within each subfield can be superimposed onto the magnetic

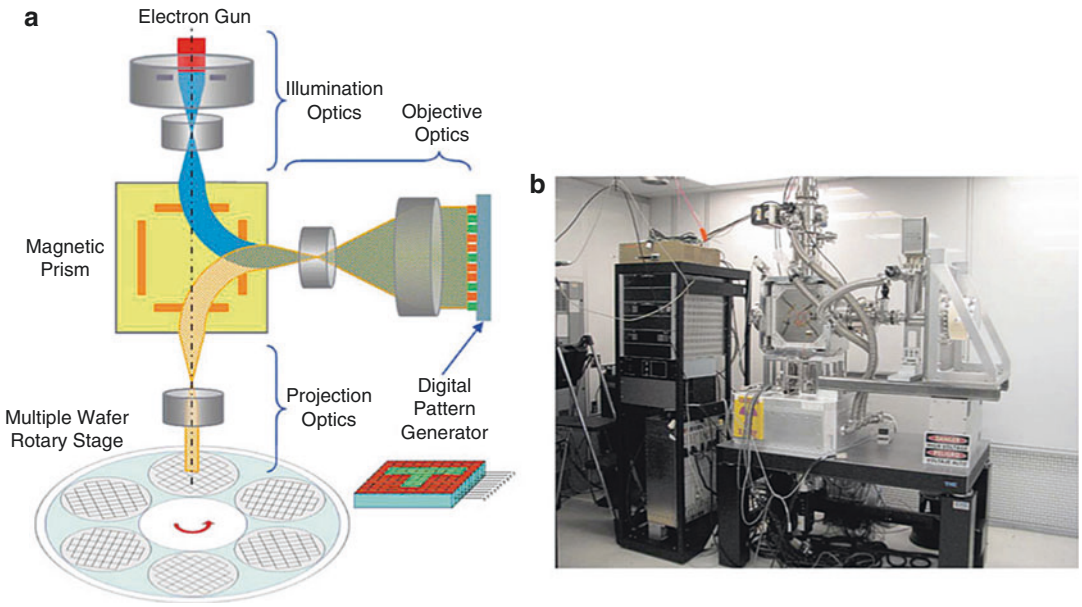


Electron Beam Lithography (EBL), Fig. 17 Core technology of the IBM's PREVAIL EBL system: Curvilinear variable-axis lenses (*CVAL*)

and electric fields used in the variable-axis lens. This variable-axis system allows the beam to be moved quicker from cell to cell on the mask, and reduces the dependence on slower mechanical components (Fig. 17).

Multi-beam EBL Systems

Throughput of EBL can also be increased by employing multiple beams. One way to obtain multiple beams is to use a series of electron sources rather than a single source. With the advancements of nanomanufacturing technologies, micromachined electron gun (MEG) devices have been proposed. A MEG device consists of monolithically integrated lenses feedback resistors and heaters. MEGs operate at much lower voltages (~200 V) than conventional electron guns and yield a spot size of 8.7 nm at a working distance of 20 μm. The lower voltage operation of these emitters mean that the electrons will have negligible backscatter and no proximity-effect corrections will be needed; however, exposure times may be longer due to the low narrow/low current beam. Since this technology is still at prototype stage, some details regarding the sample mounting and possible throughput are not clear. Very similar approach named sTM aligned field emission (SAFE) microcolumn arrays have also been proposed. SAFE technology uses a 2D array of miniaturized electron sources (Fig. 18). Although details of the manufacturing technology have not been fully disclosed, SAFE system is estimated to achieve a resolution of 25 nm and throughput of 60 count 200 mm diameter wafers per hour.



An alternative method proposed to obtain multiple beams is using one large electron beam and then dividing it into smaller beams by using miniature MEMS lenses and apertures. Smaller secondary beams are then focused on the target wafer [11]. This system has a 32×32 array of subelectron beams which cover a total of

Electron Beam Lithography (EBL), Fig. 18 Conceptual drawing of microcolumn array for parallel e-beam lithography Ref. [10]

3:6 × 3:6 mm area. It would require arrays of small lenses, blanking deflectors, blanking apertures, and beam deflectors, all implemented in a silicon substrate. The deflectors only need to deflect the beam in one direction, and a stage can move the sample in the other direction. No prototype of such system has been produced yet.

Recently, a novel maskless EBL system called the reflective electron beam lithography (REBL) has been proposed by KLA-Tencor Corporation [12]. REBL system incorporates six core technologies: reflective electron optics, the digital pattern generator, time domain integration, gray tone exposure, rotary stage, and optical wafer registration. Reflective electron optics enables the use of the digital pattern generator (DPG) chip to independently control 1×10^6 beams for massively parallel exposure. The electron optics ray diagram of the REBL nanowriter is shown in Fig. 19. A large area cathode of relatively low reduced brightness ($Br < 10^4$ Am^{-2} sr^{-1} V^{-1}) generates an illuminating electron beam. The cathode lens forms a crossover at the center of the condenser lens. The condenser lens forms an image of the source at the virtual center of the magnetic prism. The prism is set up to bend the optical axis exactly 90° and establish the focal lengths in the x and y planes to be equal, with equal magnifications in the x and y axes. When these three conditions are satisfied, the prism behaves as a 1:1 imaging lens, imaging the crossover from the center of the condenser lens to the center of the transfer lens. The transfer lens in turn images the source image at the virtual prism center onto the DPG through the DPG lens. The electrostatic DPG lens serves a dual purpose: It forms a virtual image of the crossover at infinity, and it decelerates the electrons to within a few volts of the cathode potential. When a mirror is turned "on" at the DPG, it will reflect electrons from the illuminating beam. These reflected electrons are reaccelerated back toward the prism as they travel through the accelerating field of the electrostatic DPG lens. A crossover is formed at the center of the transfer lens by the DPG lens. The transfer lens images the DPG at the virtual center of the prism but along the diagonal 90° clockwise from the first image formed on the illuminating arm. The reflected electron beam, going in the opposite direction, is therefore bent in the opposing direction. The prism thus bends the reflected beam away from the gun to project it onto the wafer. The prism also forms a crossover at the back focal plane of the demagnification lens, while the demagnification lens focuses the DPG image from the virtual center of the prism onto the wafer plane. The prototype REBL system has demagnification of 50 and DPG pixel pitch of 1.5 μm which produce a pixel pitch at the wafer plane of 30 nm. The system targets five to seven wafers levels per hour on average at the 45-nm node with extendibility to the commercial mainstream lithography market for the 32-nm node and below.

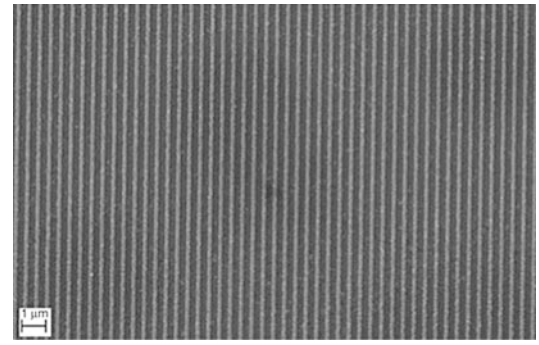
Examples of Application

EBL is arguably the most versatile technique in nanofabrication technologies. Ability of direct writing nanoscale features allows researchers to fabricate experimental proof-of-concept and prototype devices, circuits and systems in diverse fields including electronics, photonics, microelectromechanical systems, and material sciences. Although it is impossible to cover all these applications, selected ones will be presented in this section to give a glimpse of the capabilities of EBL.

Transistors for High-Frequency Applications

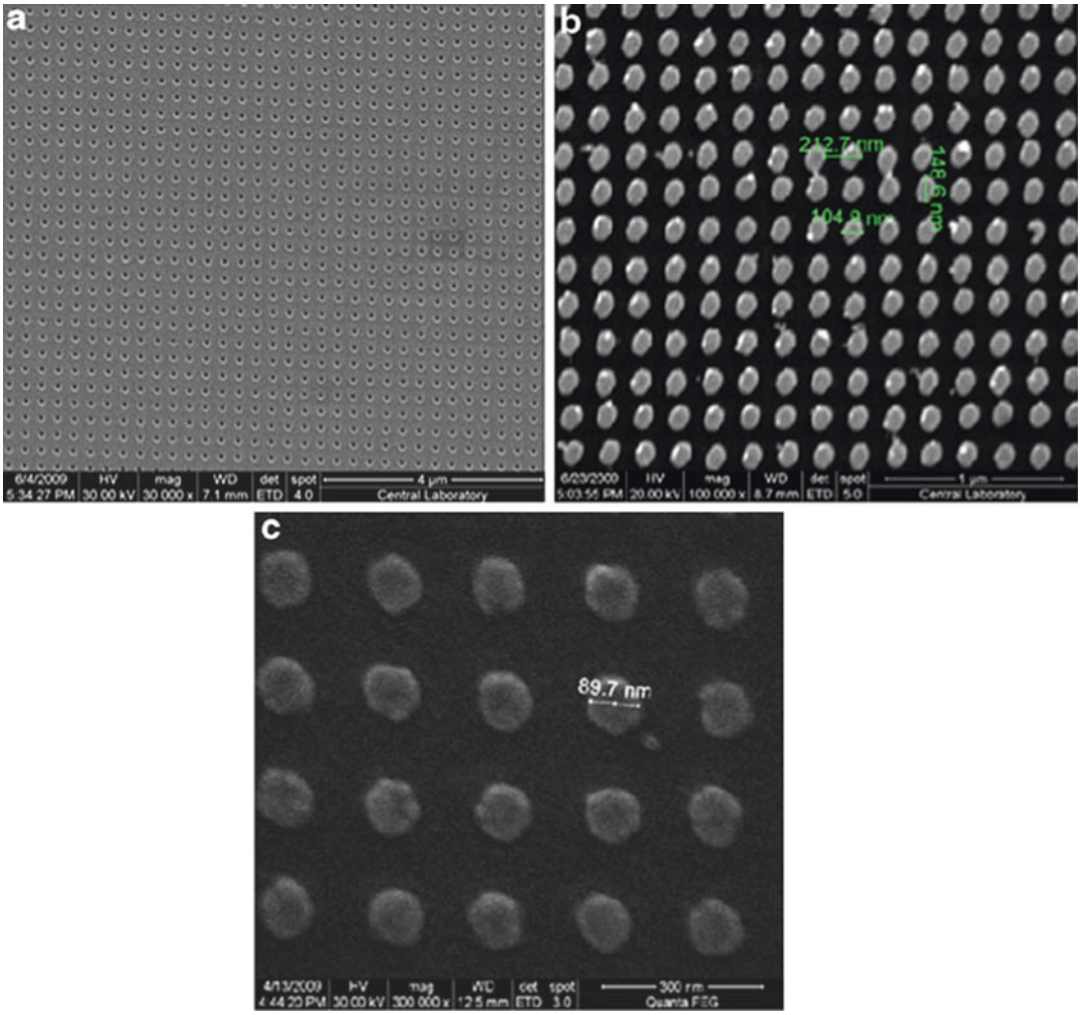
With their high breakdown voltage and large sheet carrier concentrations, nitride-based wide band gap materials and devices attracted great deal of attention in the last decade. Particularly AlGaN/GaN HEMTs have been researched for their potential applications in wireless communication and radar replacing the incumbent GaAs devices. Fabrication of AlGaN/GaN single devices and monolithically integrated microwave integrated circuits (MMICs) involves several nanofabrication steps. Among them, fabrication of transistor gate is particularly important as the gate length is the smallest dimension in the transistors and is the most important parameter that determines frequency response of the transistors. Since the gate resistance is an important parasitic element affecting key parameters like f_{max}, it should be minimized. To minimize the gate resistance for a given gate width, it is essential to have a large cross section. However, a large cross section would mean a long gate footprint affecting frequency response. This problem can be tackled by making a mushroom like (T-gate) structures as shown in Fig. 20. A T-gate is a structure that has a narrow footprint on the semiconductor and large head. The large head of the gate increases the cross-section area of the structure and thereby reduces the gate resistance. To fabricate T-gates one takes advantage of the difference in developing times for a given dose for the two commonly used e-beam resists, PMMA and copolymer (P(MAA-MMA)). This provides sufficient contrast to fabricate the three-dimensional shape required.

The process for fabrication of gates usually involves spinning three-layer stack, consisting of PMMA/copolymer/PMMA. Then, the resist is exposed with three passes: one strong centerline



Electron Beam Lithography (EBL), Fig. 20 (**a**) SEM picture of a 100-nm "T-gate" of an AlGaN/GaN HEMT fabricated by 3-layer resist EBL. (**b**) Typical process flow for "T-gate" fabrication using tri-layer process (Courtesy of MicroChem Corp.)

dose, which helps in clearing the resist to define the foot of the gate first and two light side area doses to help develop a big head. CAD layout is designed accordingly. Patterns are written by an e-beam lithography tool using low current (~1 nA). After developing the resists, a metal stack (e.g., Ni/Au) with adequate thickness is deposited. Liftoff is performed usually in methylene chloride. Figure 20 shows the SEM picture of a T-gate with a footprint of 100 nm.

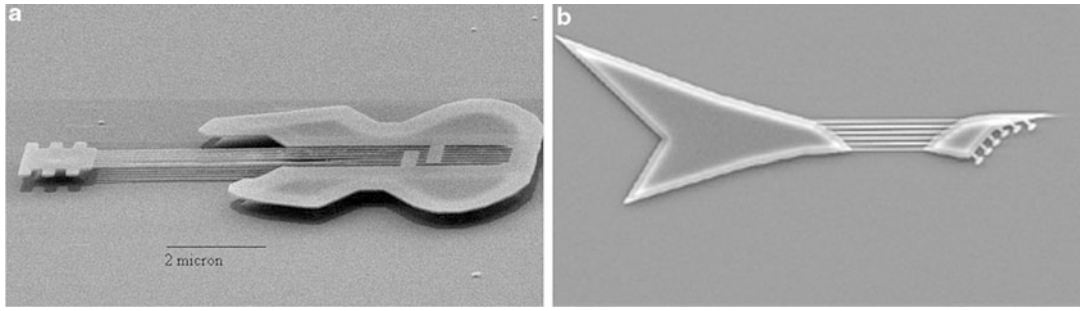


Surface Plasmonic Devices

Surface plasmon polaritons (SPPs) originate from the collective oscillations of conduction electrons coupled with photons propagating at metal-dielectric interfaces. Localization of SPPs can find wide range of applications in technology like SPP-based Bragg reflectors, emitters, and filters. Their massive localized electric fields are used to enhance weak Raman signals. Using surface plasmon enhancement even a single molecule can be detected on plasmonic surfaces. SPP cavity structures can be used as a template in surface-enhanced Raman spectroscopy (SERS) applications. Template supports a localized plasmonic mode that can be excited by the laser to be used in SERS. These templates are created by electron beam lithography. SPP-localized modes are adjusted by tuning the periodicity of the metallic grating. A sample image of metallic grating created by EBL is shown in Fig. 21.

Electron Beam Lithography (EBL), Fig. 21 *Top view* SEM image of a uniform grating fabricated by e-beam lithography with a period of 440 nm

PMMA is used as resist to create a uniform grating by EBL. The line width of the exposed regions depends on the following parameters: dose exposed per unit length, develop time, developer concentration, film thickness of PMAA, baking time and temperature, period of the grating (proximity affect), type of PMMA, silver thickness under PMMA, type of substrate. Correction of proximity effects is extremely important to obtain precise grating spacing, especially for small periods. In addition to using a PE correction software, an empirical "dose matrix" test method

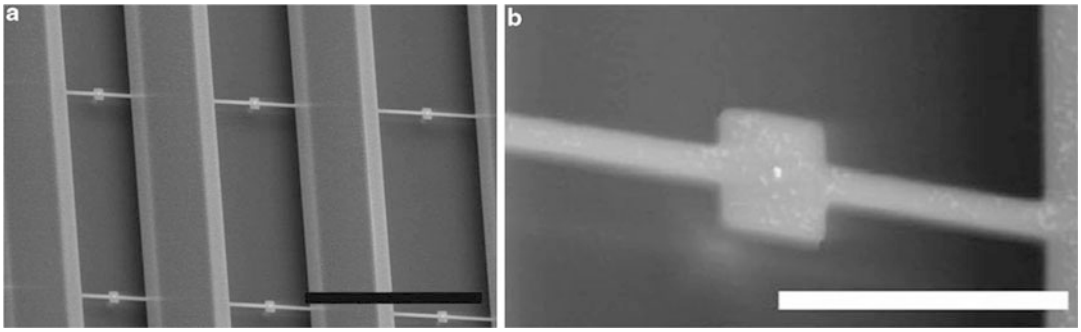


Electron Beam Lithography (EBL), Fig. 22 (**a**) Array of 100-nm diameter nanoholes with a period of 300 nm patterned on PMMA over an ITO-coated microscope slide. (**b**) SEM images of metal nanoparticles patterned over ITO-coated glass with different beam currents. (**c**) Enlarged image of the nanoparticles (Courtesy of Urcan Guler)

is also employed to determine the optimum exposure parameters. In a typical dose matrix test, the exposed dose on the resist is varied and other parameters are kept unchanged. Different fields are exposed with different doses. All fields are processed to the end. After checking the dose matrix with SEM, best exposure doses are selected to create gratings for measurements.

Light Trapping for Solar Cells

Light trapping with metal nanostructures on thin-film photovoltaic solar cells increases the solar cell efficiency. Light is coupled to metal nanoparticles and then coupled to the thin-film solar active layer over a wide range of angles. This procedure enhances the effective path length and absorption in the layer. So, metal nanoparticles can be used to increase efficiency of the devices based on the absorption of light. Enhancement effects of metallic nanoparticles are also demonstrated for dye-sensitized solar cells. Periodically structured metallic nanoparticles can trap the light onto the thin-film solar cell. Such structures can be created by EBL. First, an array of nanoholes is patterned on PMMA over an ITO-coated microscope slide Fig. 22a.



Electron Beam Lithography (EBL), Fig. 23 (**a**) World's smallest guitar, the "nano-guitar" fabricated on silicon using e-beam lithography [13] (**b**) Newer version of the "nano-guitar" which can actually be played by focused laser beams [14]

After standard EBL fabrication process, the desired nanoparticle-coated thin-film solar cell structure can be obtained (Fig. 21b, c). Period and size of the nanoparticles can be tuned for desired absorption spectrum of the incident light.

Micro and Nano Electromechanical Systems (MEMS and NEMS)

MEMS and NEMS were envisioned long time ago and put forward as a challenge by Richard Feynman in his seminal talk "There is plenty of room at the bottom" in 1959. Advancements in the nanofabrication technologies have allowed replication of many mechanical systems in nanometer scale and even creation of novel systems by taking advantage of physics at this scale. Electron beam lithography is one of the key technologies, which made possible the development of MEMS and NEMS. A striking example of the capabilities of MEMS fabrication by EBL is the *nano-guitar* In 1997, Cornell University researchers built the world's smallest guitar – about the size of a red blood cell – to demonstrate the possibility of manufacturing tiny mechanical devices using nanofabrication techniques [13]. It was 10 μm long, with six strings each about 50 nm, or 100 atoms, wide and made from crystalline silicon (Fig. 23a). Six years later the same group fabricated a new version of the nano-guitar, which is about five times larger than the original, but still so small that its shape can only be seen in a microscope [14]. Its strings are really silicon bars, 150 by 200 nm in cross section and ranging from 6 to 12 μm in length (Fig. 23b). The strings vibrate at frequencies 17 octaves higher than those of a real guitar, or about 130,000 times higher. What is unique about the second version is that it is possible to "play" it by sending focused laser beams. Since there is no practical microphone available for picking up the guitar sounds, however, the reflected laser light was computer processed to provide an equivalent acoustic trace at a much lower frequency. Both demonstrate the power of nanotechnology for a new generation of electromechanical devices.

One of the most widely explored application of MEMS and NEMS is sensitive detection of bound mass. With selective binding surfaces, the devices could be exquisitely sensitive to binding of selected chemical or biological species. In the selected case, EBL-supported nanofabrication capability was used to fabricate arrays of both polycrystalline silicon and silicon nitride resonators with evaporated gold contact pads. Circular gold pads 50–400 nm in diameter were deposited on the bridge resonators to serve as anchors for self-assembled thiol monolayer (SAM) for selective binding of target substances (Fig. 24). Detection of the resonant frequency shift allowed the determination of the mass of the adsorbed SAM. Nanoscale resonators presented

Electron Beam Lithography (EBL), Fig. 24 (**a**) SEM micrograph of arrays of bridge oscillators. (**b**) Oblique-angle SEM micrograph of oscillator. The diameter of the gold pad at the center is 50 nm. Scale bars correspond to 2 μm [15]

quality factor of Q = 8,500 and allowed detection of 2.7 attogram (=2.7 × 10^{-18} g) minimum resolvable mass [15].

Definition

The application of ion beam and transmission electron microscopy techniques to image, analyze, and study the 3-D structure and chemistry of nanomaterials inside cells.

Overview

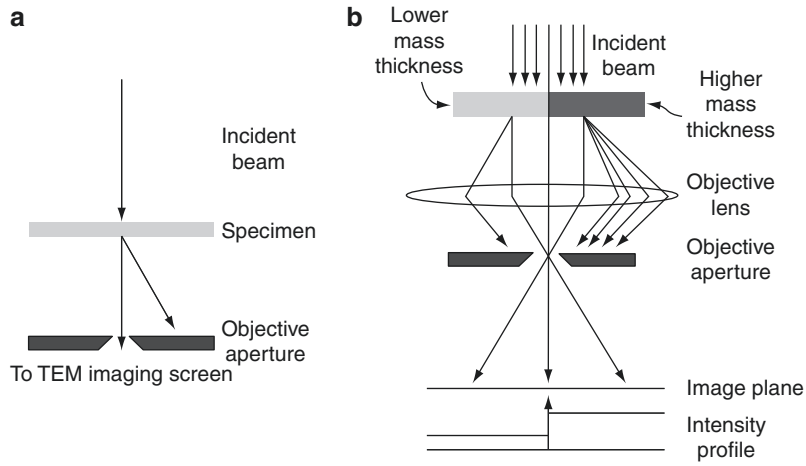
Direct imaging of the structure and chemical analysis of tissues, cells, and biomaterials at the nanoscale is critical for understanding a wide variety nanoscale processes in biological systems. Whether in comprehending the role of amyloid fibrils in Alzheimer's disease or the toxicity of nanomaterials, there is a significant need for such studies to develop the potential for new forms of treatment and to advance the design of bio- and nanomaterials [1–9]. Analytical electron microscopy is an indispensable technique for characterization of the material-biology interface because information can be obtained with very high spatial and energy resolution. However, this field remains wide open due to technical difficulties with sample preparation, particularly of hard-soft interfaces, and in achieving adequate spatial resolution and contrast between individual components within the cells and tissues while preserving them in their near native state and maintaining adequate stability of samples under the electron beam. Traditional preparation methods in electron microscopy use chemically intrusive stains and fixatives to preserve tissue and cell structure; however, these protocols will both distort the structure and modify the chemistry of the material. It is crucial to preserve the chemistry of the bio- or nanomaterial in the biological system as any slight modification in their chemistry or oxidation state caused during processing could make the results ambiguous and liable to misinterpretation which in turn could impact treatment strategies. Furthermore, the electron beam can damage the sample, altering the structure and changing the local chemistry. Methods to minimize this effect include the development of minimal dose methods as well as instruments that can operate at a range of accelerating voltages so that the experiments can be performed under optimum conditions. Once this has been achieved, the only option remaining is to cool the sample to reduce the damage rate. This entry aims to discuss development and application of analytical and 3-D microscopy techniques to analyze a range of bio-/nanomaterials interfaces at medium to high spatial resolution from ~1 μm to 1 nm using a range of techniques, namely dual-beam focused ion beam milling, energy-filtered TEM (EFTEM), high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM), and electron tomography. Traditional methods of sample preparation and using mass-thickness contrast for the imaging of biological samples will be discussed first as these still remain important techniques for both imaging and screening samples.

Sample Preparation

One of the greatest challenges for imaging nanoparticles within cells or biomaterials cell interfaces is in the sample preparation. When preparing samples for TEM, it is essential to induce minimal alteration to cell ultrastructure and also to the distribution and chemistry of nanoparticles within the cell. There are two main techniques available to prepare TEM samples at room temperature: fixation, dehydration, and embedding followed by ultramicrotomy; and focused ion beam milling (FIB). With ultramicrotomy, ultrathin resin-embedded sections containing the

cell–nanomaterial interface are mechanically sectioned using a diamond knife. Here the challenge lies in matching the hardness of the embedding resin with the hardness of the cell/nanomaterial to ensure that the interface does not damage during sectioning [1]. For this reason, choice of embedding resin is crucial. FIB is also an excellent technique for preparing and analyzing interfaces for electron microscopy [6, 9]. A clear advantage of FIB milling is that chemical processing and also mechanical damage can be obviated, thus reducing damage to the specimen prior to examination. The FIB process will be described later in this entry.

Staining



To increase contrast from cell organelles, heavy metal stains are often employed. Stains such as Os, Pb, and U leave heavy metals in specific regions of the structure. For example, osmium tetroxide is a strong oxidant that cross-links lipids; it therefore acts not only as a secondary fixative of membranes, but also increases contrast in TEM images because of the high atomic number of the osmium atoms. These stains can however, obscure visualization and characterization of low contrast nanostructures. To overcome this problem, stained and unstained sections have been compared to correlate distributions of nanoparticles within cell structure [4, 5].

Section Thickness

In ultramicrotomy, standard sample thicknesses for TEM sections can vary from 70 nm to several hundred nanometers. This results in the acquisition of a two-dimensional image containing three-dimensional information which can, in turn, result in the "blurring" of data or loss of information. For electron energy loss (EEL)-based techniques or high-resolution imaging, optimum contrast can be achieved by sectioning ultrathin sections of around 20 nm in thickness. By using these ultrathin sections, two-dimensional slices through cells are obtained, therefore minimizing the three-dimensional information and allowing for high-resolution imaging of nanoparticles within the cell. Contrast from cell organelles can also be significantly improved by sectioning at 20–40 nm or by leaving the section under the electron beam in the TEM to thin. The limitation with ultrathin sections, however, is durability of the section under the beam, thus, when energy or spatial resolution is not critical, thicker sample thickness (~70 nm) will provide sufficient contrast.

Rapid Freezing Techniques

Such as freeze substitution and freeze drying are also available to prepare cell–nanomaterial interfaces. These methods involve rapidly freezing the tissues or cells, typically in liquid propane or liquid nitrogen, either by drastically decreasing the temperature and/or by applying a high pressure. The cells are rapidly frozen to avoid ice crystal formation which would cause mechanical injury to the cells. After the cells/tissues have been frozen, these materials are slowly heated to allow the frozen water in the material to sublime from the solid phase to the gas phase. This process is called freeze drying. Sublimation of the material is required to avoid shrinkage, which would occur when rapidly heating the sample. If ice is not sublimed into the gas phase, the surface tension of the material will increase, and the material could collapse under this tension as the water leaves the liquid specimen. Freeze substitution is based on rapid freezing of tissues followed by solution ("substitution") of ice at temperatures well below 0 °C. For best morphological and histochemical preservation, substituting fluids should, in general, contain both chemical fixing agent and solvent for ice, e.g., 1 % solutions of osmium tetroxide in acetone or mercuric chloride in ethanol. Preservation of structure is generally poorer after substitution in solvent alone. Osmium tetroxide can also act to enhance the contrast acquired from the cell organelles. These techniques have many advantages over traditional room temperature preparation methods, particularly the preservation of structure, chemistry, and the accurate localization of many soluble and labile substances. Both these methods have been used to study the process of the formation of nanoparticles of amorphous calcium phosphate inside osteoblast and also neuronal cells. In these studies, cryo-fixation methods are critical to

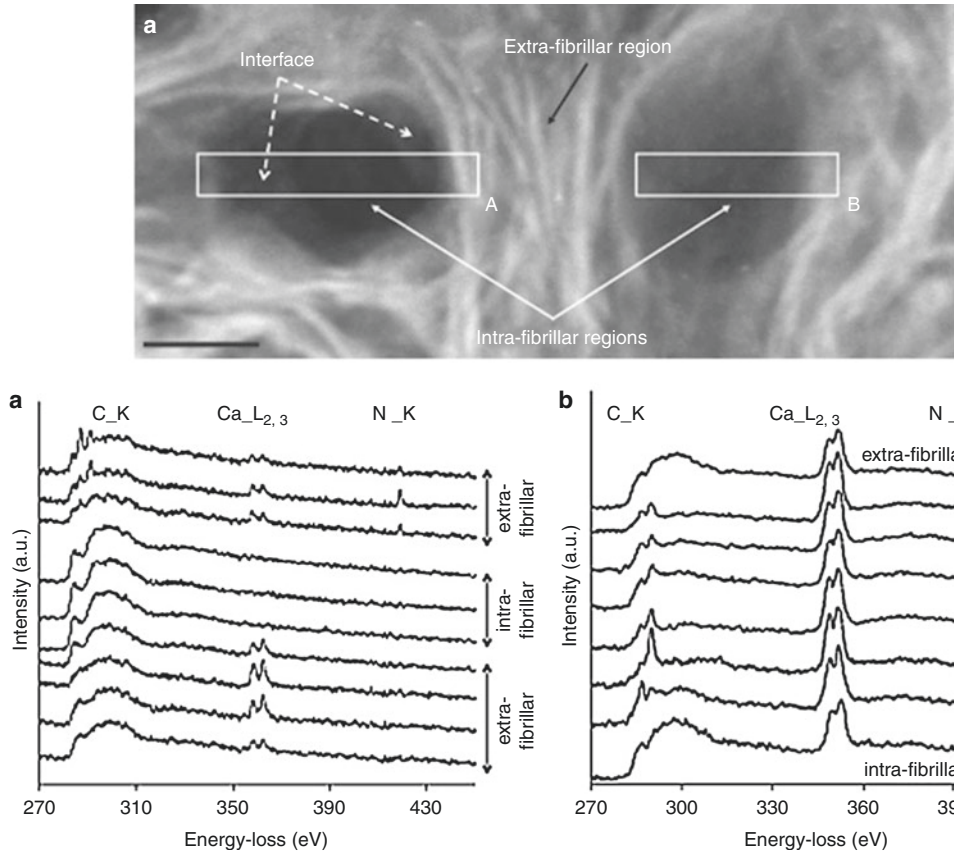
Electron Microscopy of Interactions Between Engineered Nanomaterials and Cells, Fig. 1 (**a**) The insertion of an objective aperture to select the direct beam removes most scattered electrons and may greatly increase image contrast. (**b**) The mechanism by which differences in mass and thickness create image contrast in a bright-field TEM image (Figure adapted from Ref. [11])

preserve both the chemistry of the labile calcium phosphate particles and the structure of the cell [10].

Bright-Field TEM Imaging and Mass-Thickness Contrast

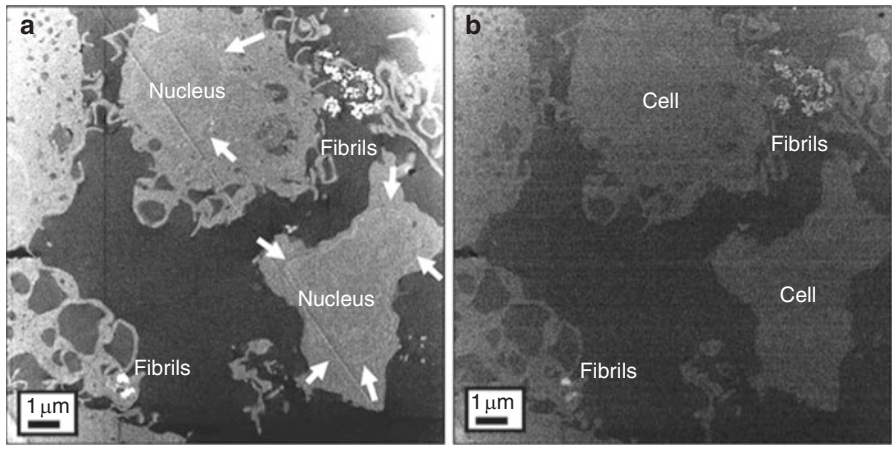
Mass-thickness contrast is the contrast mechanism that is traditionally used for imaging biological samples. As electrons pass through the sample, they are scattered off-axis by elastic scattering events. Electrons that interact with the electron clouds of atoms in the sample are scattered through relatively small angles and may still contribute to the image, but electrons that are scattered due to interactions with an atomic nucleus are scattered through a higher angle and are less likely to contribute to the image generated. The cross section of scattering depends on the atomic number, Z, and on the density and thickness of the sample. In bright-field imaging, the direct beam is used to generate bright-field TEM images. The insertion of an objective aperture selects the angular range of electrons contributing to the image and may greatly improve image contrast as demonstrated in Fig. 1a. The mechanism by which contrast in a bright-field TEM image is formed from differences in mass and thickness is demonstrated in Fig. 1b. The areas of the sample that have higher mass thickness (ρt) produce areas of lower intensity in the resulting TEM image than areas of lower mass thickness. Mass-thickness contrast from cell organelles can be enhanced by staining the cells with heavy metals such as osmium tetroxide.

Analytical Transmission Electron Microscopy



In a TEM, energy loss can either be measured in series, i.e., an image is acquired over a defined energy loss window, known as energy-filtered TEM (EFTEM); or in parallel, where an entire energy loss spectrum is acquired from a point in the specimen, known as electron energy loss spectroscopy (EELS). EELS is a technique where high-energy electrons incident on a sample scatter from, and therefore lose energy to, atoms in the sample. The energy lost in a particular scattering event is lost to an atom's electrons and only takes discrete values (quanta) which are different for every element. The electrons are transmitted through a sample, and then the energy that they lose is recorded in the form of a loss spectrum. The spectrum of each element is comprised of peaks or edges positioned at characteristic energy-losses. The shape and position of each edge also provides information about the bonding environment of the sample being analyzed. Therefore, EELS spectra provide detailed information about the elemental composition and bonding state within a sample with sub-nanometer spatial

resolution. EFTEM is a technique based on EELS which records images taken at different energies. The basis of this technique is that an energy-filter slit is used which only allows electrons through which have lost certain energies. By selecting different energies, elemental EFTEM maps can be produced. Using this technique, it is possible to acquire two-dimensional, elemental maps using electrons with an energy loss characteristic of a core level, interband transition or Plasmon resonance energy. With EFTEM, the EELS spectrum may be extracted by acquiring a series of energy-filtered images, using a narrow energy window (1–3 eV). Image processing software may then be employed to extract the EELS spectra over a given energy range.



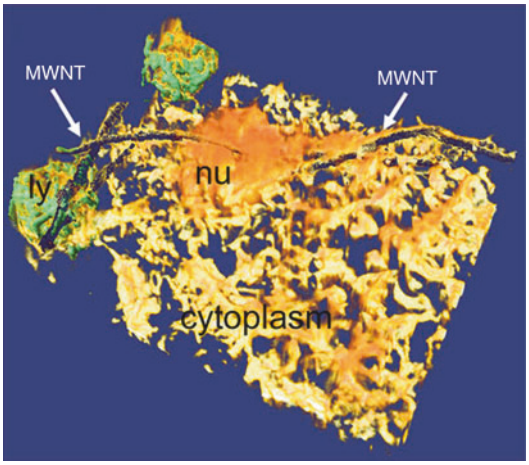
EFTEM is an excellent technique for nanobioscience applications because it can detect low atomic number elements (such as biological constituents) with high sensitivity. Using this technique, maps of the distributions of the elements in the sample can be resolved and, thus, the chemistry of the cell or presence of nanoparticles and their locations in the cells determined [3, 4]. For example, low-loss EFTEM enables clear differentiation between *unlabelled* C_{60}, SWNTs, and the cell cytoplasmic contents [3, 4]. TEM and EELS can be also applied to study intracellular free ion concentrations, the oxidation state of engineered nanoparticles in the cellular environment [12], mineral distributions in osteoporotic bone, or the formation of and the oxidation state of iron storage protein ferritin in the brains of patients suffering from Alzheimer's disease [13].

In scanning transmission electron microscopy (STEM), the incident electron beam is focused to a probe and scanned across the sample. Detectors placed at different post-specimen locations can collect different scattered or unscattered beams. The scattered (or unscattered) electrons are collected serially, and the image is displayed pixel by pixel. Combined with EELS, it can be used to map the chemistry or oxidation state of materials nanoscale resolution. In recent work, Jantou et al. have shown that STEM-EELS can provide new insights into the chemistry and bonding at the collagen-hydroxyapatite interface in ivory dentin and observed fine structure on the carbon K-edge spectra, suggesting that functional groups at the interface between the collagen and mineral phase can be identified [9]. This work potentially provides information on the modification of the surface amino acid groups by the inorganic phase [9]. Such approaches offer enormous potential for improved characterization of the chemistry of nanoparticles within tissues to advance knowledge of how these structures interact with cell organelles (Fig. 2).

HAADF-STEM is an imaging mode that is highly sensitive to the atomic number of the sample. HAADF-STEM relies on collecting electrons which have been scattered to high angles by Rutherford scattering. The HAADF detector has a large central aperture and collects only electrons that are scattered to relatively high angles (e.g., >30 mrad, the exact range of scattering angles is determined by the camera length and the geometry of the detector). The intensity of a HAADF-STEM image is therefore dependent on Z^n ($n \sim 2$). As the detector collection angles are reduced, the contribution of mass thickness (ρt) increases. Thus, it is possible for the user to control the kinds of electron/specimen interactions that contribute to an image (Fig. 3). HAADF-STEM has been combined with energy dispersive x-ray spectroscopy (EDX) to image Amyloid-beta aggregates inside cells using a selenium enhancement technique [7]. The rationale for this study is that a number of challenges arise when attempting to image the interactions between amyloid or other protein aggregates and cells or tissue. The most significant of these is a lack of contrast between the carbon-rich protein aggregate and the carbonaceous cellular environment, making the aggregates extremely difficult to distinguish and identify with confidence. A variety of strategies have previously been employed to overcome this, but these all involve the application of chemically intrusive labeling techniques such as immunogold labeling or tagging the proteins with fluorescent tags [7]. Instead, peptides were assembled from selenium-analogues of the sulfur-containing methionine peptides, and then used HAADF-STEM to detect the selenium-doped species selectively within the carbon-rich background of the cell. The presence of selenium was confirmed by the

Electron Microscopy of Interactions Between Engineered Nanomaterials and Cells, Fig. 2 STEM image of a transverse section of ivory dentine. Fine structure on the carbon K-edge can be seen at the interface between the intra- and extra-fibrillar regions which can be attributed to the molecular amino acid signatures. P L2,3-, O K- (not shown), and Ca L2,3-edges can be used to investigate local variations in mineral chemistry [9]

Bright contrast from the nulclear membrane is enhanced in (**a**). *Arrows* delineate the nuclear membrane



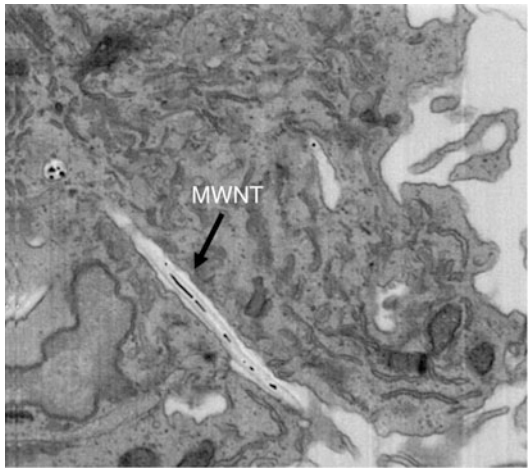
use of energy dispersive X-ray spectroscopy (EDX). The energies of the X-rays generated by the interactions between the electron beam and the atoms in the sample can be examined for peaks at energies characteristic of specific elements.

Electron Tomography

TEM and STEM imaging creates two-dimensional projections of a specimen. One disadvantage of this is that structural details from different depths within the specimen are superimposed on top of one another. Electron tomography (ET) involves collecting a series of images while tilting the specimen in the TEM around a single axis at regular intervals. It is impossible from this projection alone to determine the structure of the original object. For this reason, electron tomography is carried out – the process of taking a large number of two-dimensional electron micrographs of a specimen at different tilt angles and then reconstructing these to generate a volume that represents the original object.

The collection of a tomographic dataset produces a large number of two-dimensional projections of the region of interest which can be reconstructed into a three-dimensional volume that closely resembles the original object. The correlation between the three-dimensional reconstructed volume and the original object is limited by the data collected – the quality of the images and number of images collected – and the technique used to reconstruct the dataset.

Data collection for electron tomography involves tilting the specimen around an axis perpendicular to the electron beam and collecting images at successive angles. Specimen shift must be minimized during data acquisition, in particular in the direction parallel to the tilt axis, as only the area that is in every image can be used for the reconstruction of the data. Images are collected up to as high tilt angles as possible to minimize the size of the missing "wedge" in the dataset. It is impossible to take images of the specimen at tilt angles up to $\pm 90°$; therefore, there will always be some information missing from the dataset.



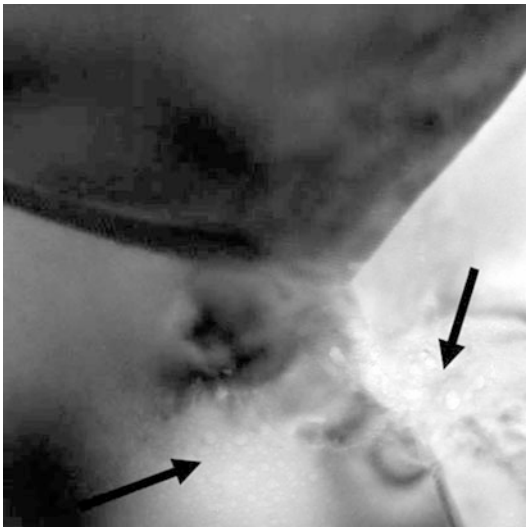
Electron Microscopy of Interactions Between Engineered Nanomaterials and Cells, Fig. 4 HAADF-STEM tomogram of a necrotic macrophage cell illustrating MWNTs penetrating the nucleus (nu) [15]

A three-dimensional structure can then be reconstructed from the series of images collected to give high-resolution structural information about the material being analyzed. ET combined with EFTEM can also be used to yield three-dimensional compositional information [14]. Biological structures frequently need to be determined in all three dimensions because their chemical and physical properties are highly related to their topography. ET reconstructions are crucial to confirm that the nanostructures are localized within cell organelles and not just lying on the surface of the sample (Fig. 4).

Ion Beam Milling

A recent development in three-dimensional imaging is the "slice-and-view (S&V)" method in the dual-beam focused ion beam (DB-FIB). The DB-FIB combines an ultrahigh-resolution field emission gun scanning electron microscope (FEG-SEM) with a precise FIB system. In this system, the SEM uses electrons as a source for imaging and monitoring the milling process, whereas the FIB uses gallium positive ions as a source to ablate the surface of a specimen via the sputtering of substrate. This unique FIB-SEM combination allows the investigator to image the

Electron Microscopy of Interactions Between Engineered Nanomaterials and Cells, Fig. 5 FEG-SEM image of a MWNT internalized inside a phagosome in a macrophage cell (Image taken from an osmicated cell in backscattered electron mode)



architecture of selected specimens by SEM and FIB in parallel. The focused ion beam can be used to mill away a precise volume to reveal the internal surfaces at a designated site in the specimen. The three-dimensional morphology of the sample can then be built up by milling and recording successive image slices (Fig. 5), the entire three-dimensional volume of the sample can then be reconstructed from the serial images to give information about the architecture of the sample. Milling can be performed with a precision of ~10 nm depth and up to 100 μm width allowing for analysis, in three dimensions, of the structure of materials from 0.1 mm to <100 nm. Approximately 500 serial images from a sample can be generated automatically overnight; therefore, both quantitative and qualitative information can be acquired. This technique has successfully been used to study the ultrastructure of mouse cortex tissue in three dimensions [16] and has great potential for mapping the distributions of nanoparticles inside tissues which can otherwise be analogous to the problem of "finding a needle in a haystack." The FEG-SEM method can also be used to prepare site specific lamella regions in the FIB for subsequent analysis in the TEM. More recently, this method has shown to be highly promising for preparing and studying frozen hydrated cells and tissue-material interfaces [17–19]. The advantage here is that this method involves no exposure to toxic or aggressive staining agents and the process induces little or no mechanical damage as would be experienced during cryo-ultramicrotomy.

Electron Beam Damage

Electron beam damage can be the limiting factor in the TEM study of biological materials. Many of the electron/specimen interactions that produce useful signals in the TEM result in damage of the specimen that can lead to structural and chemical changes in the sample [11]. This means that the region of the specimen under examination is no longer representative of the original sample and interpretation of the images and spectra is more difficult. Damage can result from both elastic and inelastic scattering of electrons. There are two main mechanisms of electron beam damage in the TEM: radiolysis and knock-on damage.

Radiolysis or ionization damage results in the breaking up of chemical bonds in the sample [11]. Organic solids, such as polymers and biological materials, are most prone to radiolysis [11]. Incident electrons can break down the main chain of a molecule, resulting in the loss of mass, or can break off side chains which may in turn react with other molecules in the sample and cross-link to form a new structure. Loss of mass results in a thinning of the sample or even the drilling of holes in the sample. Crystalline samples can lose their crystallinity due to ionization damage. The extent of damage due to radiolysis can be minimized by increasing the accelerating voltage as this decreases the interaction cross section. However, this leads to a reduction in image contrast, as less electron scattering takes place on interaction with the sample, and can result in an increase in knock-on damage.

Knock-on or atomic displacement damage occurs when electrons in the beam transfer enough energy to atoms in the sample to knock them out of their atomic sites leading to the creation of vacancies in the specimen [11].

Electron Microscopy of Interactions Between Engineered Nanomaterials and Cells, Fig. 6 Void formation (indicated by *black arrows*) in an hydroxyaptite ceramic implant generated by knock-on damage to the sample under the electron beam

This damage mechanism will generate artifacts, such as amorphization of carbon nanotubes or void formation in calcium phosphate ceramics (Fig. 6). Electrons in the beam must possess enough kinetic energy to knock a specimen atom out of its site; this energy depends on the type of sample and is known as the threshold energy. This type of damage therefore increases with increasing accelerating voltage. Knock-on damage is not expected at an acceleration voltage of 100 kV (unless hydrogen atoms are present), but it is anticipated at higher voltages [20]. Cooling the specimen will not reduce the effects of knock-on damage. Keeping the energy of the electron beam low is the only way to avoid this type of damage. If energies above the threshold energy must be used, the total electron dose should be minimized by minimizing the time the electron beam is incident on the sample.

Heat is also a major cause of damage in the TEM. Much of the energy that is transferred to the sample when beam electrons collide with specimen electrons ends up as heat within the specimen [20]. Organic specimens are particularly susceptible to heat damage as they have low thermal conductivity, and so the region of interest cannot dissipate the thermal energy it gains under the beam. Heat damage can be minimized by using a higher accelerating voltage as this minimizes the interaction cross section.

Future Research Directions

Rapid developments are currently taking place in the field of electron microscopy, both to increase energy and spatial resolution, and also to increase automation of the equipment so that data can become significantly more quantitative and so it can be obtained with less work by the user, a feature that biological electron microscopy has traditionally suffered from. Exciting developments are occurring in the area of dual-beam FIB milling such that it will now be possible to correlate across length scales to link macroscale processes to structure and chemical changes occurring at the nanoscale. These methods will make major advancements in linking the physicochemical properties of nanoparticles to their effect on tissue structure and more generally will guide our understanding of tissue pathologies such as neurodegenerative diseases.

Definition

Electron-beam-induced deposition is a process for growing patterns with different sizes, shapes, and materials in the nanometer or submicron scale. In this process, an energetic electron beam in a vacuum chamber is focused on a substrate surface on which precursor molecules, containing the element to be deposited (e.g., organometallic compound or hydrocarbon), are adsorbed. As a result of complex beam-induced surface reactions, the precursor molecules adsorbed in and near to the irradiated area are dissociated into nonvolatile and volatile parts by the energetic electrons. The nonvolatile materials are deposited on the surface of the substrate to form a deposit, while the volatile parts are pumped away by the vacuum system. The advantage of electron-beam-induced deposition over conventional lithography methods is that two- and even three-dimensional (3D) structures are patterned and deposited simultaneously, making it a fast, one-step technique. Due to the controllability of the electron beam, the fabrication of the position-, size-, and morphology-controllable nanostructures can be easily achieved.

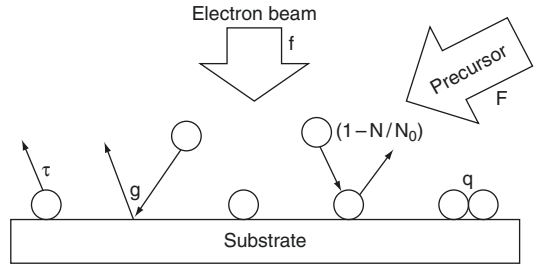
Overview

Originally, electron-beam-induced deposition was known as contamination growth in electron microscopy. Broers et al. [1] used contamination growth patterns as an etching mask to define 8-nm-wide metal lines. In the last decades, electron-beam-induced deposition for maskless nanofabrication has gained more importance as a tool, and it has been studied by many researchers because of its higher resolution due to the smaller beam spot. At an early stage, electron-beam-induced deposition has mainly been performed in scanning electron microscopes (SEMs) for various gases and conditions, and the technique was found to be very successful for a number of applications, making variously shaped nanostructures from metals such as W, Au, and Pt [2, 3]. However, the smallest structures fabricated in scanning electron microscopes have a typical width of 15–20 nm, no matter how small the primary electron beam is [4]. This is usually attributed to the fact that the distribution of secondary electrons, rather than primary electrons, determines the size of the deposits. The profile of the secondary electrons exhibits some spread, particularly for the energy range of scanning electron microscopes. Even for primary electrons of zero diameter, the profile of secondary electrons has a range of more than 15 nm [5]. Hence, it was believed that the resolution limit of electron-beam-induced deposition was at most 15 nm for the fabrication in scanning electron microscopes. Recently, several groups have tried to minimize the secondary electron effect by using transmission electron microscopes (TEMs) and scanning transmission electron microscopes (STEMs). Transmission electron microscopes utilize electrons of higher primary energy than scanning electron microscopes and can produce more focused beams with less secondary electron emission. Mitsuishi et al. [6] fabricated nanodots of 3.5 nm in diameter using a 200-keV field emission scanning transmission electron microscope. They found that the dot size does not depend on the substrate thickness; rather, the deposition period and speed are strongly dependent on the intensity of the electron beam. Tanaka et al. [7] have also fabricated nanodots containing W by electron-beam-induced

deposition in a 200-keV ultrahigh vacuum field emission transmission electron microscope (UHV-FE-TEM). The size of the dots can be controlled by changing the pressure in the chamber. The smallest particle size was about 1.5 nm in diameter.

Physics of Material Supply and Deposition

Aiming at a rate optimization in the electron-beam-induced deposition, one has to know how the deposition rate depends on the various relevant process parameters. Some theoretical analyses about the deposition process have been developed by Scheuer et al. [8, 9] for flood-beam systems and adapted for scanned-beam systems by Petzold and Heard [10]. Following the theoretical approach of Scheuer [8], it is assumed that only those molecules adsorbed at the substrate surface undergo dissociation induced by electron beam irradiation. Thus, only a monolayer of adsorbed molecules can contribute to the layer growth. Figure 1 illustrates the different processes on the surface [8]. The density (N) of adsorbed molecules on the substrate surface varied in time (t) is given by the following equation:



$$\frac{dN}{dt} = g \cdot F\left(1 - \frac{N}{N_0}\right) - \frac{N}{\tau} - q \cdot N \cdot f \quad (1)$$

where f is the electron flux density, q is the cross section for dissociation of the adsorbed molecules under electron beam irradiation, F is the molecular flux density arriving on the substrate, g is the sticking coefficient, N_0 is the molecule density in a monolayer, and τ is the mean lifetime of an adsorbed molecule.

If $dN/dt = 0$, equilibrium is obtained, resulting in an equilibrium density (N_E):

$$N_E = N_0 \cdot \frac{(g \cdot F/N_0)}{(g \cdot F/N_0) + 1/\tau + q \cdot f} \quad (2)$$

This means that $N_E \leq N_0$ for all supply and irradiation conditions, i.e., the maximum surface coverage at any time is one monolayer (ML). The growth rate (R) of the layer is given as follows:

Electron-Beam-Induced Deposition, Fig. 1 Illustration of surface interaction of the deposition process

$$R = v \cdot N \cdot q \cdot f \quad (3)$$

where v is the volume occupied by a dissociated molecule or its fractions. In the equilibrium case, $N = N_E$. From Eqs. 1, 2, 3, the steady-state growth equation is derived:

$$R = v \cdot N_0 \cdot \frac{(g \cdot F/N_0) \cdot q \cdot f}{(g \cdot F/N_0) + 1/\tau + q \cdot f} \quad (4)$$

In practice, the influence of the finite lifetime (τ) of the molecules can be made negligible, e.g., by cooling the sample. It is then worthwhile to note a few properties of the above equation. Obviously, the growth rate increases when the electron flux (f) and/or the molecular flux (F) is increased. In practice, these parameters are limited, e.g., by electron optical constraints, the vapor supply and differential pumping system, or simply the fact that only a limited vapor pressure can be tolerated above the sample before significant electron scattering starts. Under these conditions, the maximum rate obtainable for any given electron flux is

$$R_{\max} = v \cdot N_0 \cdot q \cdot f \quad (5)$$

and choosing

$$q \cdot f = g \cdot F/N_0 \quad (6)$$

yields 50 % of the maximum obtainable growth rate at supply F. This condition can be considered a reasonable compromise of parameters for efficient use of both electron and molecule supply. Increasing either flux to infinity while keeping the other one constant only increases the growth rate by a factor of 2, while decreasing either flux by

one order of magnitude reduces the growth rate by more than a factor of 5.

Key Research Findings

High-quality, intense, and focused electron beams have been used for the fabrication of nanomaterials with controlled position, size, and morphology. Electron-beam-induced deposition was used as an advanced method to fabricate nanostructures in situ by a maskless process. The reaction of precursor gas molecules with electrons near the material surface causes the formation of a solid deposit whose size and shape depend on the substrate materials and the profile of the electrons. Using the electron-beam-induced deposition technique, a variety of nanostructures, such as nanodots, nanowires, nanotubes, nanopatterns, two- or three-dimensional nano-objects, and so on, have been fabricated [2, 11–13].

When precursor gases containing tungsten (W), iron (Fe), and other metals are introduced into the microscope, noble-metal nanostructures can be fabricated in situ by electron-beam-induced deposition. The electron beam controls both the nucleation and growth processes. For the substrate materials, conventionally two kinds of materials, namely, conductive and insulator materials, are used. When the conductive materials, such as silicon, were used as a substrate, two- or three-dimensional nanostructures of W, Pt, Fe compounds, and so on, were fabricated by the electron-beam-induced deposition with the beam-scanning technique [2, 11]. This process is effective for the direct fabrication of nanosized structures by taking advantage of its fine probe of 1–10 nm in diameter. The effect of a vacuum on the size and growth process of the fabricated nanodots containing W was investigated using an ultrahigh vacuum field emission transmission electron microscope (UHV-FE-TEM). The size of the dots can be controlled by changing the dose of electrons and the partial pressure of the precursor. The smallest particle size obtained was about 1.5 nm in diameter at 1.5×10^{-6} Pa pressure, a probe size of 1 nm, and with 5 s irradiation [7]. Furthermore, nanodots, nanorods, and freestanding square frames were also fabricated by the electron-beam-induced deposition in an ultrahigh vacuum field emission scanning electron microscope (UHV-FE-SEM) using the precursor gas of iron carbonyl gas, Fe$(CO)_5$. The typical line width and length of the iron freestanding square frames were 30–50 nm and about 300 nm, respectively [14]. The iron freestanding square frame structures were magnetized by introducing the specimen into a magnetic field of about 1 T under the objective lens of the transmission electron microscope. After that, the objective lens was turned off, and the residual magnetic field was estimated to be less than 100 mT. The application of the magnetic field to iron three-dimensional nanostructures produced an electron hologram from the nanostructures. It was found that the magnetic field leaked from the nanostructure body, which appeared to act as a "nanomagnet" because of the square and ring shapes.

When insulator materials were used as a substrate, inhomogeneous deposition occurred because the charges accumulated on the insulator substrate upon electron irradiation during electron-beam-induced deposition. It has been reported that carbon dendrite-like or filament-like structures were grown on insulator substrates under electron beam irradiation in an electron microscope at a relatively poor vacuum condition [15]. The charging up of the surface of the insulator substrate due to electron beam irradiation and the high concentration of hydrocarbon molecules in the vacuum chamber are considered to be the formed reasons. By using insulator substrates such as Al_2O_3 [16] and SiO_2 [17], characteristic morphologies of nanostructures, such as arrays of nanowhiskers (or nanowires), arrays of nanodendrites, and fractal-like nanotree structures, were fabricated in transmission electron microscopes (TEMs) by the electron-beam-induced deposition. The typical size of the diameter of a nanowhisker, the tip of a nanodendrite, and the tip of a nanotree was about 3 nm and was almost completely independent of the size of the electron beam. The nanostructures with different morphologies can be obtained by controlling the intensity of the electron beam during electron-beam-induced deposition. The process of growth of the nanostructures is based on mechanisms in which the formation of the nanostructures is related to the nanoscale unevenness of the charge distribution on

the surface of the substrate, the movement of the charges to the convex surface of the substrate, and the accumulation of charges at the tip of the grown nanostructure. Furthermore, novel composite nanostructures of Pt nanoparticle/W nanodendrite or Au nanoparticle/W nanodendrite were also fabricated by the decoration of W nanodendrites with metallic elements [18]. The nanostructures have advanced features such as a large specific surface area, a freestanding structure on substrates, a typical size of several nanometers, and high purity. Because there are many possible combinations for the precursor and substrate, it is expected that various nanostructures may be fabricated on various substrates. Therefore, the nanostructures and their fabrication process may be applied in technology to realize various functional nanomaterials such as catalysts, sensor materials, and emitters.

Instead of using thin films of insulator materials, an anodic porous alumina membrane with the ordered nanohole arrays was used as a substrate; ordered array of nanostructures can be fabricated by the selective deposition of the precursor molecules into the ordered nanohole arrays using the electron-beam-induced deposition process. As an example, a porous alumina membrane on an aluminum substrate was prepared by a two-step anodization process, and then the aluminum was removed by etching. The diameter of the holes was about 40 nm, and the interval between the centers of the holes was about 100 nm. The total thickness of the membrane was about 1000 nm, but there were electron transparent regions at the bottoms of the holes (the barrier-layer thickness of the membrane was about 50 nm [19]). Tungsten hexacarbonyl, $W(CO)_6$, was used as a precursor gas source. The gas was supplied through a nozzle placed near the membrane on the side of the pores. The electron beam simultaneously irradiated the membrane from its reverse side. The deposition was carried out at room temperature. The diameter of electron beam during irradiation was about 1900 nm. The irradiation period was 1 min. It was found that the size of the formed pattern was almost the same as that of the electron-beam-irradiated area. Also, the deposition was only conducted in the pores of the electron-beam-irradiated area. Almost all of the pores in the electron-beam-irradiated area were filled with the deposits, while there was no deposit on the places other than the pores. The as-deposited nanoparticles contained many nanocrystallites. The nanocrystallites were identified to be the equilibrium phase of bcc structure metal W at room temperature [20].

Future Directions for Research

The further development of electron-beam-induced deposition requires the application of state-of-the-art electron microscopy technology such as precise positioning of a nanometer-scale electron beam, a high current for the achievement of small structures with a much higher fabrication speed, and an ultrahigh vacuum environment for eliminating contamination of the deposits.

There are many possible combinations for precursor and substrate; therefore, various functional nanostructures or compound nanostructures can be produced by electron-beam-induced deposition. However, the growth conditions for each combination of precursor and substrate should be different, and it should be further investigated. The fundamental processes involved in the interaction of an electron beam with substrates, the adsorption of precursor molecules on a substrate, and the decomposition of molecules by energetic electrons during electron-beam-induced deposition should also be further clarified.

Definition

Ab initio electronic and optical properties of nanostructures.

Introduction

The interaction between oxides and light represents the fundamental process at the base of photocatalysis and solar-to-energy conversion. TiO_2 is one of the most studied oxides as well as testified by a large number of publications [1–4] both at fundamental and applicative levels of research.

Low-dimensional, nanostructured TiO_2-based materials, such as nanocrystallites, nanofibers, nanosheets, and nanotubes, offer the undeniable advantage of an enhanced available surface area that improves their photochemical and photophysical activities, compared with the high-dimensional counterparts.

Accordingly, they are receiving increasing attention as potential candidates for improving device performances. Particular attention has been paid to nanostructures of the anatase phase due to its higher energetic stability at the nanoscale and also to the envisaged superior performances of this phase with respect to rutile in photovoltaics (PV) and photocatalysis [5].

Both from experimental and theoretical points of view, deep research efforts are spent to investigate the role of nanostructuring and the influence of defects and of extrinsic doping to improve chemical and physical properties with respect to pure material.

Since most of the applications involve photoexcitation and the subsequent creation, transport, and dissociation of excitons, it is clear that a microscopic knowledge of their properties is a fundamental prerequisite to rationalize experimental data and improve device performances.

First-principles excited state methods, based on many-body perturbation theory [6] applied on top of density functional theory calculations [7, 8], provide a reliable tool to identify, explain, and predict the specific behavior related to the electronic and optical properties of nanostructures that may result hidden in the experimental processes.

In particular, here, the relationship among structure and electrooptical behavior will be highlighted. Strong excitonic effects, which allow a correct interpretation of the photoexcited processes, are present in all the considered nanostructures.

Theoretical Foundation

Density functional theory (DFT) [9] in the Kohn-Sham formalism [10] is a very powerful computational approach to predict a wide range of chemical and physical properties of materials.

However, it is well known that this mean-field theory does not correctly describe the electronic excited state properties of materials. At variance, within the Green's functions formalism, by means of the so-called Hedin's GW method [11] applied on top of DFT calculations, the calculated quasiparticle band structures result in good agreement with the experiments for a wide range of materials [12, 13]. Furthermore, within the same formalism, the solution of the two quasi-particles Bethe-Salpeter equation (BSE) [6, 14] allows to calculate spectroscopic properties (i.e., absorption, reflectivity, EELS, etc.), including many-body interactions, like local fields and excitonic effects, which result extremely important in systems of reduced dimensionality as those discussed here. While the theoretical framework described in the following is quite general and has been applied to a plethora of systems, inorganic and organic, finite and periodic ones, here the main focus will be on its application to titanium-dioxide low-dimensional structures.

The Kohn-Sham Formulation of the Density Functional Theory

Within density functional theory, the electron charge density $n\left(\vec{r}\right)$, rather than the electron wave function, plays a central role. DFT has been introduced by Hohenberg and Kohn (HK) in 1964 [9]. They demonstrated that the

ground state (GS) energy of a system of N-interacting electrons in an external potential V_{ext} (**r**) is a functional of the electronic density which is minimized at the correct GS density of the system. Kohn and Sham [10], a year later, reformulated the variational problem of the HK functional energy minimization in terms of the solution of a set of one-particle self-consistent equations (Kohn-Sham equations):

$$\left[-\frac{1}{2}\nabla^2 + V_{eff}^{KS}\left(\vec{r}\right)\right] \cdot \phi_i\left(\vec{r}\right) = \varepsilon_i \phi_i\left(\vec{r}\right) \quad (1)$$

where $n\left(\vec{r}\right) = \sum_i^N |\phi_i\left(\vec{r}\right)|^2$ is the electron charge density and $V_{eff}^{KS}\left(\vec{r}\right) = V_{ext}\left(\vec{r}\right) + V_{\mathrm{H}}\left(\vec{r}\right) + V_{xc}\left(\vec{r}\right)$, where the three parts of effective potential are the external, the Hartree, and the exchange-correlation potential. The last term, explicitly defined as the functional derivative with respect to the density of the exchange-correlation energy $E_{xc}[n]$, formally includes all the many-body effects of the system. Most of the drawbacks of DFT reside in the approximation used for the exchange-correlation potential. The oldest is the so-called local density approximation (LDA), where a local dependence on the density of the homogenous electron gas exchange-correlation energy is used [15, 16]. The inclusion of a dependence on the density gradient as in the generalized gradient approximation (GGA) [17] provides a better description of the nonlocality of the exchange-correlation hole [18]. New families of exchange-correlation functionals (PBE0, B3LYP and HSE06, meta-GGAs and hyper-GGAs functionals [8, 19]) have also been introduced in the last decades, giving more refined results for material properties than LDA and GGAs but at higher computational cost. The results shown in the last sections are mainly obtained at the GGA level of DFT, by using the PBE exchange-correlation functional.

Nevertheless, DFT is formally a "ground state" theory, and, as there is not a rigorous justification to interpret the KS eigenvalues ε_i as energy levels of the system, it is not surprising that the calculated electronic band structures, especially for semiconductors and insulators, do not compare very well with experiments. Therefore, in the next sections, a rigorous method to describe the charged and neutral electronic excited states of an interacting N-electron system will be presented.

Electronic Properties Within the Quasi-Particle Formulation of the Green's Functions Theory

The physical quantity which allows to describe the propagation of an electron added or extracted from an N-interacting electrons system is the time-ordered single-particle Green's function within the second quantization formalism [20, 21]:

$$G(1,2) = -i < \Phi_N | T\left(\hat{\psi}_H(1)\hat{\psi}_H^{\dagger}(2)\right) | \Phi_N >. \quad (2)$$

Here $1 = (x, t)$ (where t is a time coordinate, while $x = \left(\sigma, \vec{r}\right)$ indicate the spin and spatial coordinate and a similar definition stands for 2); $|\Phi_N >$ is the GS of the N-interacting particles system; $\hat{\psi}_H$, $\hat{\psi}_H^{\dagger}$ are the field operators in the Heisenberg representation; and T is the Wick time-ordering operator.

The ground state total energy, the expectation value of any single-particle operator, and the charged excitations spectra of the system can be calculated when G is known [20, 21]. Clearly being $|\Phi_N >$ an unknown quantity, Eq. 2 does not provide a practical way to calculate G in an arbitrary N-interacting system.

Nevertheless within the many-body perturbation theory (MBPT), it can be shown that G is connected to the Green's function of the noninteracting system G_0 (corresponding to the solution of the Hartree Hamiltonian) by the so-called Dyson equation:

$$G(12) = G_0(1,2) + \int G_0(1,3)\Sigma(3,4)G(4,2)d3d4. \quad (3)$$

where a nonlocal, time-dependent, non-Hermitian operator, the *self-energy* Σ, is introduced. This can

be thought as the effective potential that the electron or hole added to the system feels due to the change in the charge distribution induced by its own presence.

Using the spectral representation of G, and assuming that its dominant contribution comes from well-defined complex poles ε_i^{QP}, the electronic excitations of the many-body system can be obtained solving the so-called quasi-particle (QP) equation [6, 20, 21]:

$$\left(-\frac{1}{2}\nabla^2 + V_{ext} + V_H\right)\Phi_i^{QP}(x) + \int \Sigma\left(x, x', \varepsilon_i^{QP}\right)\Phi_i^{QP}(x')dx' = \varepsilon_i^{QP}\Phi_i^{QP}(x). \tag{4}$$

Then compared to KS electrons, which are completely independent particles, quasi-particles can be seen as weakly interacting dressed electrons characterized by a finite lifetime which is related to the imaginary part of the complex eigenvalues ε_i^{QP} [6, 22, 23]. It is worth to notice that when $\Sigma = 0$, Eq. 4 reduces to the Hartree approach, when $\Sigma = iGv$ (with v the unscreened Coulomb potential) to the Hartree-Fock, and when $\Sigma = V_{xc}$ to the Kohn-Sham scheme.

Now within the many-body perturbation theory, a set of five integral equations, known as the *Hedin* equations, can be derived, providing a formal scheme to find a suitable expression for Σ [11]. Starting from the equation of motion of the field operator and from the expression of the many-body Hamiltonian in the second quantization formalism, the equation of motion for G can be derived, and it results to depend on the two-particle Greens function. In a similar way, the two-particle Greens function equation of motion turns out to depend on the three-particle Greens function and so on, yielding an infinite hierarchy of equations [24]. It has been shown that this chain of equations can be broken by introducing in the Hamiltonian an external source that couples to the density and that at the end of the derivation is set to zero [11, 25]. In this way, the two-particle Greens function G_2 can be written in terms of a functional derivative of G with respect to this external source, and then G_2 is formally removed from the equation of motion of G [14]. Introducing other characteristic quantities of the system like the screened Coulomb potential $W(12)$, the time-ordered polarization $P(12)$, and the vertex function $\Gamma(123)$, the close set of five *Hedin* equations can be derived (see, i.e., Ref. [6] for their full expression). The *Hedin* equations offer the possibility to analyze the physical meaning of the quantities involved: the polarization P describes the response of the system to the additional particle or hole and the creation of electron-hole couples, and it is related to the dielectric function ε by the following expression $\varepsilon(1,\ 2) = \delta(1,\ 2) - \int\ v(13)P(32)d3$; W is the dynamical screened coulomb potential, and Γ is the vertex function which contains the information that the hole and the electron interact and is formally determined by the change in the potential upon excitation. Interestingly they lead directly to the possibility of a perturbative expansion in terms of the screened Coulomb interaction W. This is very important and physically sound; in fact a direct expansion in terms of the bare Coulomb interaction would be unsuitable due to the strength of this kind of interaction, whereas in many-electrons systems, the Coulomb interaction is usually screened via the polarization of the system, and the effective potential, by which the particles interact, is much weaker.

Since these equations are not exactly solvable, Hedin proposed an iterative approach to their solution. Starting with $\Sigma = 0$, at the end of the first iteration, the following expressions are obtained:

$$G = G_0; \quad \Gamma(123) = \delta(12)\delta(13);$$
$$P(12) = iG(12)G(21);$$
$$\Sigma(12) = iG(12)W(2,1).$$

This leads to an expression for the polarization function where the electron and hole propagators are independent (generally known as the random phase approximation (RPA) [26]) and defines the so-called GW approach for the self-energy calculation. Nowadays this is the most used approximation within the many-body approaches for the calculation of the QP excitation energies. In practical calculations, as the KS equations of the DFT are a better starting approximation than Hartree,

because a certain degree of exchange and correlation is included in V_{xc}, both G and W are calculated starting from the DFT-KS eigenvalues and eigenfunctions. Moreover, since Eq. 1 is formally similar to Eq. 4, the self-energy corrections are evaluated considering the term $\left(\Sigma - V_{xc}^{KS}\right)$ as a perturbation term of the KS equations. Due to the fact that in many systems the KS eigenfunctions are very similar to the GW ones, one may often neglect the off-diagonal terms in the many-body Hamiltonian and calculate the QP energies solving the following equation:

$$\varepsilon_i^{QP} = \varepsilon_i^{\mathrm{KS}} + \left\langle \phi_i^{\mathrm{KS}} \middle| \Sigma\left(\varepsilon_i^{QP}\right) - V_{xc}^{KS} \middle| \phi_i^{\mathrm{KS}} \right\rangle. \quad (5)$$

A further simplification consists in the inclusion of the frequency dependence of the self-energy by a first-order Taylor expansion around $\varepsilon_i^{\mathrm{KS}}$ [27, 28]:

$$\left\langle \Sigma\left(\varepsilon_i^{QP}\right) \right\rangle = \left\langle \Sigma\left(\varepsilon_i^{\mathrm{KS}}\right) \right\rangle + \left(\varepsilon_i^{QP} - \varepsilon_i^{\mathrm{KS}}\right) \left\langle \frac{\partial \Sigma(\omega)}{\partial \omega} \middle|_{\omega=\varepsilon_i^{KS}} \right\rangle + O\left(\left(\varepsilon_i^{QP} - \varepsilon_i^{\mathrm{KS}}\right)^2\right) \quad (6)$$

This approach is generally known as the perturbative G_0W_0 method, and it is the scheme used to calculate the QP self-energy corrections to the KS energies for TiO_2 clusters and sheets described in section "Applications."

Optical Properties By the Solution of the Bethe-Salpeter Equation

Starting from the GW approximation for the self-energy and multiplying the vertex by $-iGG$, a four-point integral equation for a generalized reducible ${}^4\overline{P}(1234)$ can be obtained at the second iterative step of the *Hedin* equations:

$$\begin{aligned} {}^4\overline{P}(1,1';2,2') &= {}^4P_{IQP}(1,1';2,2') \\ &+ {}^4P_{IQP}(1,1';3,3')K(3,3';4,4'){}^4\overline{P}(4,4';2,2') \end{aligned} \quad (7)$$

where the repeated arguments are integrated over and the kernel K contains two contributions [29]:

$$\begin{aligned} K(1,1',2,2') = &-\delta(1,2)\delta(1',2')W(1,1') \\ &+ \delta(1,1')\delta(2,2')\overline{v}(1,2). \end{aligned} \quad (8)$$

The term $\overline{v}$ is the unscreened coulomb potential where the long-range $\left(\vec{G} = 0,\ \vec{q} \to 0\right)$ Fourier transform component is set as zero. When the spin is not explicitly treated, this term gets a factor of two for singlet excitons. The second term, $-W$, is the screened Coulomb attraction between electron and hole. As mentioned before, while it is obtained from the functional derivative of the self-energy, the first term (here $\overline{v}$ to obtain the macroscopic dielectric function instead of the microscopic one) comes formally from the functional derivative of the Hartree potential [14] which enters in the equation for the reducible polarization function.

Using the basis of the KS wave functions ϕ_{nk} the Bethe-Salpeter Equation becomes

$$\begin{aligned} \overline{P} &= \left[1 - P_{IQP}K\right]^{-1}\overline{P}_{IQP} \\ &= \left[H^{exc} - I\omega\right]^{-1}_{(n_1,n_2),(n_3,n_4)}\left(f_{n_4} - f_{n_3}\right) \end{aligned} \quad (9)$$

where an effective excitonic Hamiltonian is introduced, defined as

$$H^{exc}_{(n_1,n_2),(n_3,n_4)} = \left(E_{n_2} - E_{n_1}\right)\delta_{n_1,n_3}\delta_{n_2,n_4} + \left(f_{n_2} - f_{n_1}\right)\times \int d\vec{r}_1\, d\vec{r}_1'\, d\vec{r}_2\, d\vec{r}_2\, \phi_{n_1}\left(\vec{r}_1\right)\phi^*_{n_2}\left(\vec{r}_1'\right) K\left(\vec{r}_1,\ \vec{r}_1',\ \vec{r}_2,\ \vec{r}_2'\right)\phi^*_{n_3}\left(\vec{r}_2\right)\phi_{n_4}\left(\vec{r}_2'\right)$$

Then, using the spectral representation [6] for the inverse of a matrix, the interacting polarization can be obtained solving an effective eigenvalue problem:

$$\sum_{(n_3,n_4)} H^{exc}_{(n_1,n_2),(n_3,n_4)} A_\lambda^{(n_3,n_4)} = E_\lambda A_\lambda^{(n_1,n_2)}. \quad (10)$$

In particular it can be shown that for the calculation of the absorption spectra, (i) one needs to

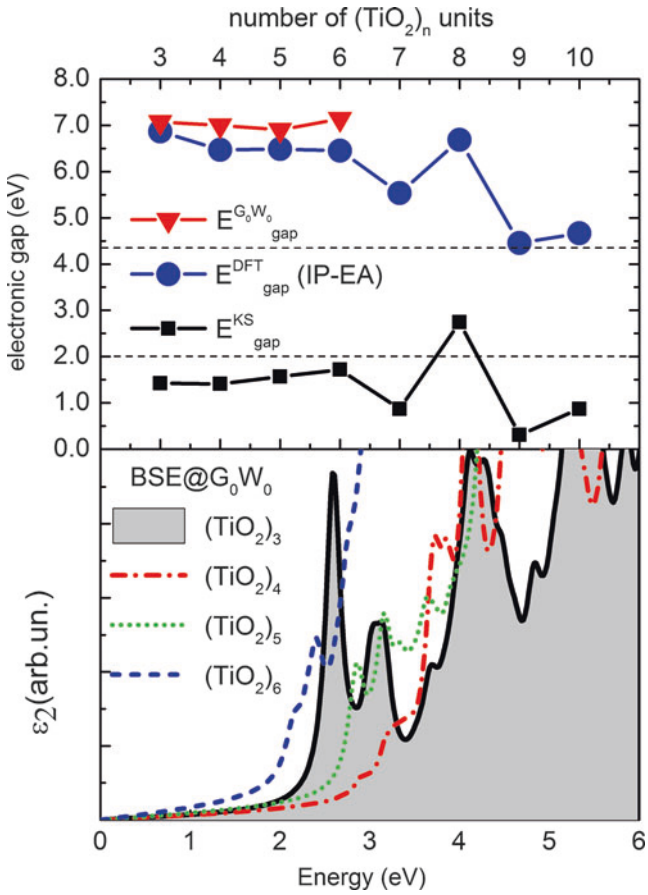
include only transitions with positive frequency [6] (i.e., (n_1, n_2) and (n_3, n_4) are pairs made of one valence and one conduction band, respectively) and (ii) only transitions with the same **k** for the initial and final state can be included. Then the macroscopic dielectric function reads as

$$\varepsilon_M(\omega) = 1 + \lim_{\vec{q}\to 0}\left(\vec{q}\right)\sum_{\lambda}\frac{\left|\sum_{v,c;\vec{k}}\left\langle v,\ \vec{k}-\vec{q}\ \left|e^{-i\vec{q}\vec{r}}\right|c,\ \vec{k}\right\rangle A_{\lambda}^{\left(v,c,\vec{k}\right)}\right|^2}{(E_{\lambda}-\omega)}. \tag{11}$$

The meaning of this equation is clear: instead of a simple sum of independent-particle optical matrix elements, they are weighted by the excitonic eigenstates A_λ. This occurs because the electron-hole Hamiltonian (Eq. 10) is not diagonal due to the presence of the nondiagonal excitonic kernel. This formulation allows to interpret the optical spectra (like absorption, reflectivity, transmission, EELS, etc.) in terms of mixing of single-particle transitions. Moreover the excitation energies in the denominator of Eq. 11 are related to the excitonic eigenvalues E_λ which, especially in low-dimensional systems as those considered here, are smaller with respect to the difference between the quasi-particle energy of occupied and unoccupied states, due to large exciton binding energies.

Applications

As applications of first-principles GS and excited state methods to the class of oxide nanostructures, two examples are discussed in the following: zero-dimensional atomic clusters [30, 31] and two-dimensional nanosheets [32] of titanium dioxide.



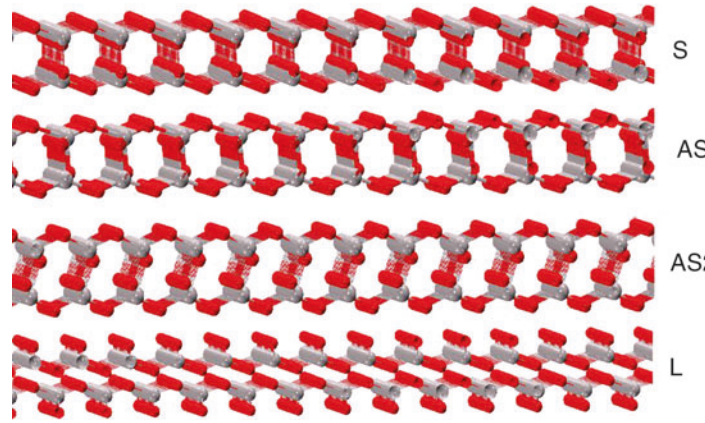
Numerical Details

The KS equations are solved here using a plane wave approach, as implemented in VASP [33, 34] and in the Quantum-ESPRESSO packages [35], while many-body calculations are performed using the plane wave Yambo code [36]. VASP code has been used to relax the structures using projected augmented wave (PAW) [37, 38] potentials for all the atomic species considered with a kinetic energy cutoff of 36.75 Ry and sampling of the Brillouin zone with different meshes according to the size of the system under investigation. Using the optimized geometrical structures, we then performed DFT calculations using Quantum-ESPRESSO package which is interfaced with the many-body code Yambo. Fictitious replica interactions occurring in the repeated cell approach are eliminated by using a vacuum thickness of more than 10 Å. Furthermore a cutoff in the coulomb potential is used both in the GW and BSE calculations, in the nonperiodic directions. Once the solution of the KS equations is obtained, it is possible to calculate several physical quantities of interest for the investigated systems; here the focus is on electronic band structures and optical spectra.

TiO_2-Based Atomic Clusters

Atomic anatase clusters of TiO_2 can be considered as the starting seeds for the synthesis of larger and more complex nanostructures for photocatalysis and photovoltaics. Due to the dimensions of the studied atomic clusters (up to 10 TiO_2 units, between 6 and 10 Å of size), giving finite-size quantization and shape-anisotropy, the electronic properties of these clusters strongly differ from the bulk.

In general, electronic and optical gap values present oscillations at growing size of the clusters, related to the symmetry of the electronic distribution (see Fig. 1, top panel). The largest KS gap (2.8 eV) is obtained for the $(TiO_2)_8$ system, which is the only cluster with a gap larger than the bulk anatase DFT value. The electronic gap, calculated as $E_{\text{gap}}^{\text{DFT}}$ (within ΔSCF, as IP-EA, with (IP) ionization potential and (EA) electron



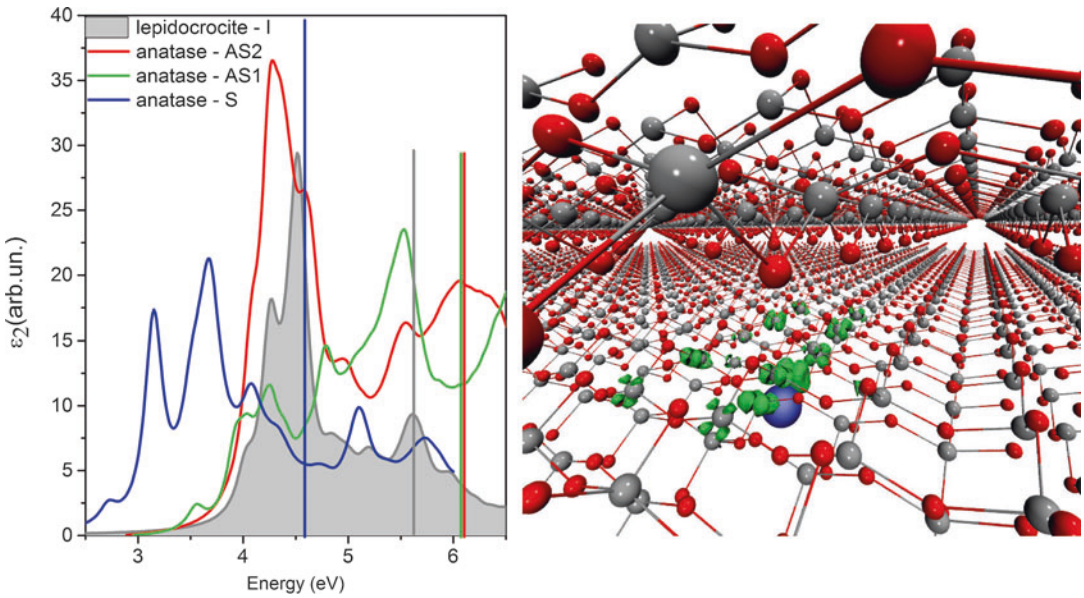
Electronic and Optical Properties of Oxides Nanostructures by First-Principles Approaches, Fig. 1 *Top panel*: Electronic gap, evaluated at KS, DFT, and G_0W_0 level, for atomic clusters of increasing size. G_0W_0 converged results are reported only for smallest clusters ($(TiO_2)_n = 3,6$), due the computational cost of the approach. As reference values, *dashed lines* indicate the KS (1.8 eV) and G_0W_0 (3.8 eV) gap of the anatase bulk. *Bottom panel*: Imaginary part of the dielectric function (proportional to optical absorption) at BSE level, for the four smallest clusters $(TiO_2)_n = 3,6$

affinity) or via G_0W_0, has quite large values (in the range 4.5–7.0 eV), due to the strong quantum confinement of these atomic-size systems, and shows a quite good agreement with experimental data [30]. Because of the strong many-body effects, the electronic gaps of these inorganic molecules are also several eV (about 4 eV) larger of the Kohn-Sham [39] and optical gaps (Fig. 1). This is not surprising, as in localized systems the strong electron-hole interaction induces bound excitonic states, with e-h-binding energies much larger than in the bulk phase [30, 31, 40].

Indeed optical spectra of the smallest clusters, calculated at the many-body level, including the electron-hole interaction (i.e., by solving the BSE equation [6]), show a strong red shift from electronic to optical gap, with BSE gap larger than the KS-PBE gap and quite close to KS-PBE0 values [30].

Even more interesting information comes from the optical transitions analysis. In the quite asymmetric clusters, as $(TiO_2)_3$, the optical transitions described by BSE clearly show a charge transfer effect. With the hole localized on an O atom, the excitonic wave function is indeed localized on Ti atoms, denoting an internal charge transfer under photoexcitation. The first optical allowed transition involves the mixing of several states near the electronic gap and cannot be described simply as HOMO-LUMO transitions. In more symmetric clusters like $(TiO_2)_4$, any admixture of single-particle transitions is present in the lowest energy optical excitation. The first optically allowed, even if not very intense, transition, is at 2.9 eV, given by HOMO-2 → LUMO states. For $(TiO_2)_5$ and $(TiO_2)_6$ clusters, it has been found that an admixture of KS states contributes to optical transitions, but without net charge transfer effects.

Electronic and Optical Properties of Oxides Nanostructures by First-Principles Approaches, Fig. 2 From *top* to *bottom: side view* of for symmetric anatase (*S*), asymmetric anatase (*AS1* and *AS2*), and lepidocrocite (*L*) isolated single-layer sheets

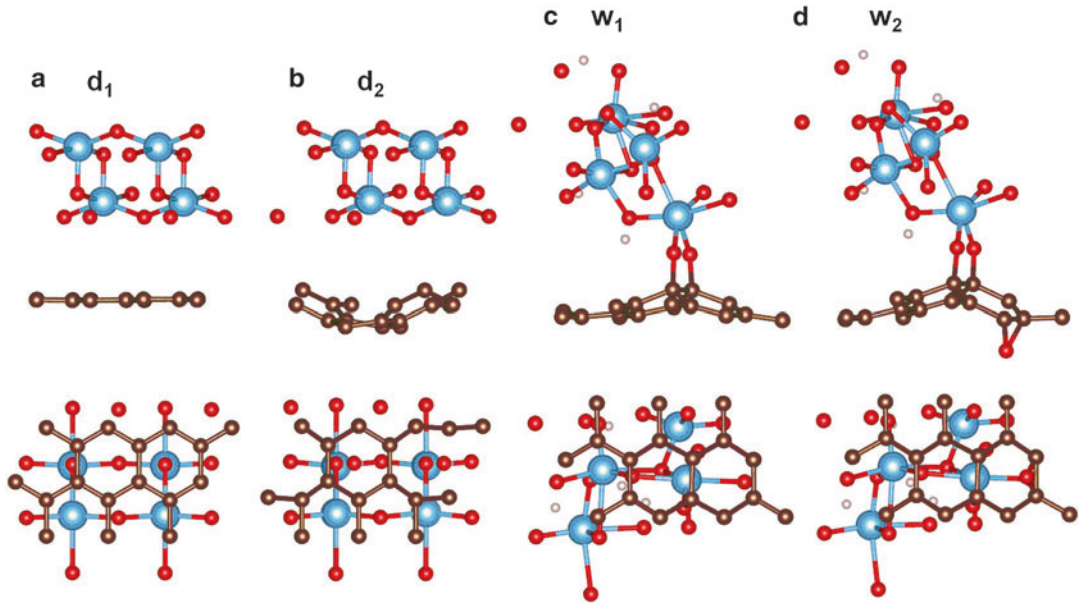


The different optical behavior is reflected on the different spectral shape (Fig. 1, bottom panel). The many-body approach thus offers a representation of optical properties which includes effects related to admixtures of KS states and introduces a refined description of charge transfer phenomena, which could affect excitonic distribution in TiO_2.

Overall, strong excitonic effects are observed, as the optical gaps of atomic clusters (defined from the first optically allowed transition) are in the range 2.0–3.0 eV, quite smaller than the electronic ones (about 7.0 eV). Well-defined optical peaks can be identified in the absorption spectra and may provide a useful tool for establishing the presence of well-determined structures in atomic clusters samples. The use of many-body methods becomes more and more important when the symmetry of the system is lowered, and the effects of point defects or other asymmetries affect the electronic properties of the system.

TiO_2-Based Nanosheets

Among all the possible morphological shapes of TiO_2-derived low-dimensional materials, the study of (001)-oriented nanosheets (NSs) is of broad interest for the enhanced optical activity when a high percentage of these facets are exposed [41]. A double nature characterizes such layered structures: one is the "bulk-cut" face obtained from anatase along [001], and the other is the so-called lepidocrocite [42, 43]. This latter phase can be thought as still derived from the former, but differently resulting from the gliding of the upper layer of the film over the lower along the Ti-O-Ti chain direction. A barrier-less path driven by the stress reduction characterizes the final bilayer. The importance of these NSs is also due to the fact that they are precursors of titania nanotubes (NTs) which in turn can be used for further assembling of nanostructured materials with different morphologies and applications [44]. In details, concerning the anatase (001)-oriented bulk-cut NSs, several structures (see Fig. 2) according to the nature of the Ti-O bond at the surface of the sheets are investigated: (1) a symmetric system (anatase-S) where the bonds Ti-O-Ti are identical (with the lattice cell parameters $a = b = 3.78$ Å) and (2) two asymmetric systems, i.e., with different Ti-O bonds at the surface, where the bulk-optimized lateral parameter is kept (anatase-AS1, still $a = b = 3.78$ Å) and also another structure where the total energy is minimized imposing the constraint of a square unit cell (anatase-AS2, $a = b = 3.51$ Å).

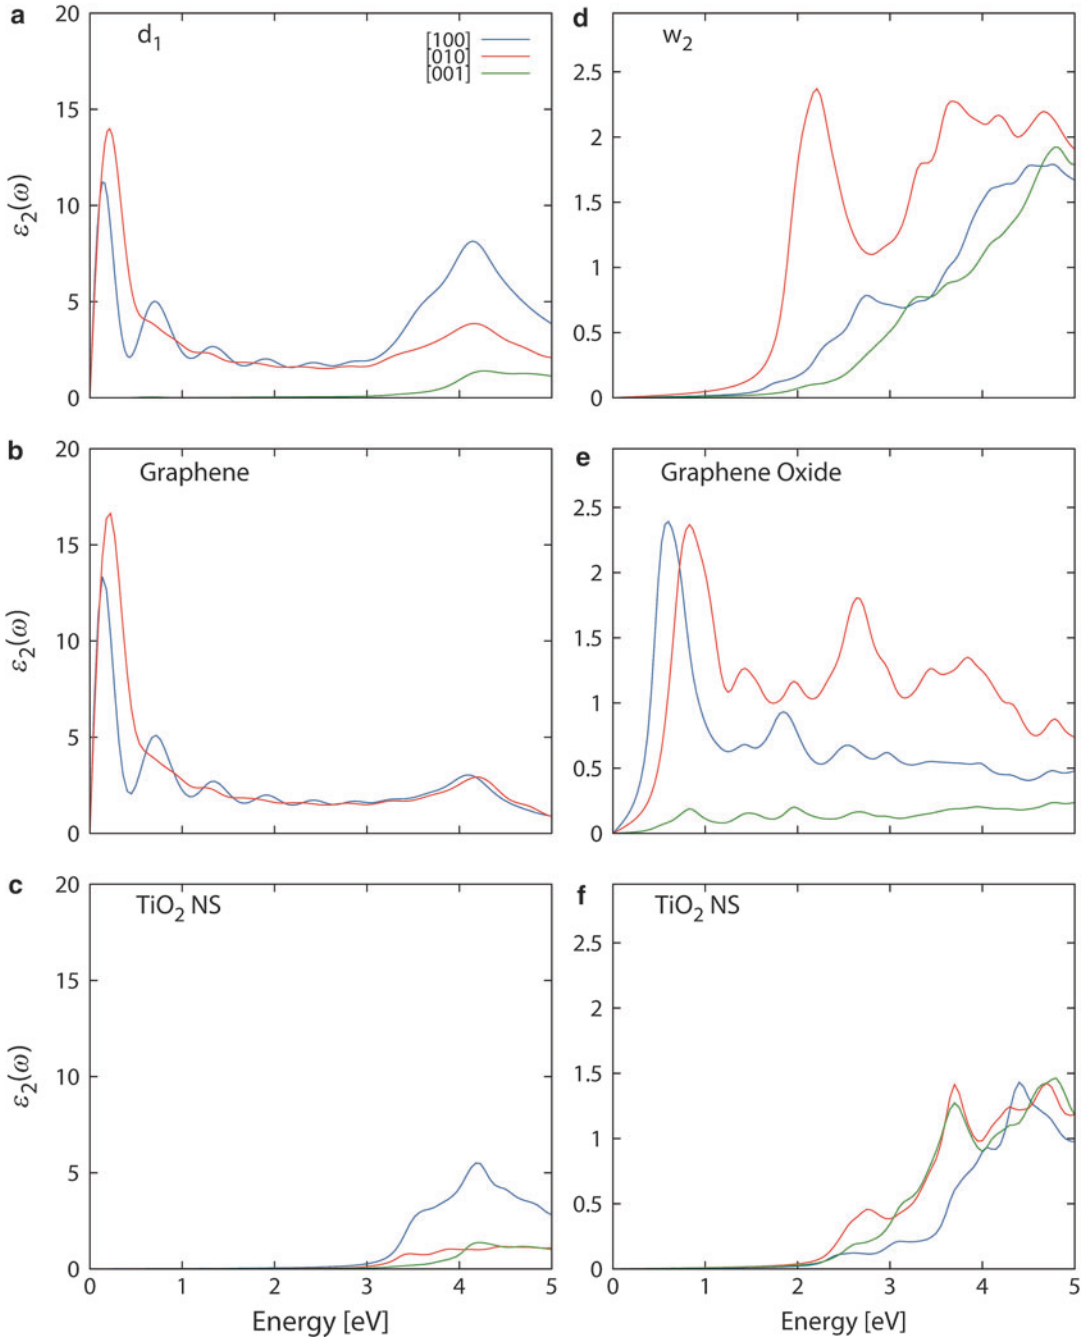


At variance, for the lepidocrocite structure, the system coordinates of Sato et al. [43] has been used as starting point and then accordingly reoptimized to find a structure (lepidocrocite-I, with $a = 3.76$ and $b = 3.03$ Å, respectively $a = b = 3.51$ Å; see Ref. [32] for more details). Ab initio calculations of the QP band structures reveal a change from indirect to direct bandgap when moving from anatase-S to lepidocrocite-I structure. This is an important aspect to be taken into account when evaluating the optical response of these nanostructures because the direct or indirect nature of the electronic and optical gap clearly affects the photoluminescence behavior. For all

Electronic and Optical Properties of Oxides Nanostructures by First-Principles Approaches, Fig. 3 *Left panel*: imaginary part of the dielectric function calculated within the BSE approach, for anatase (S (*blue*), AS1 (*green*) and AS2 (*red*)) and lepidocrocite (*gray*)-isolated single-layer sheets. For each nanosheet, the vertical line indicates the corresponding minimum electronic gap calculated at the QP level of approximation within the G_0W_0 approach. *Right-panel*: plot of the excitonic wave function (*green isosurface*), fixing the hole near an oxygen bridge (*blue ball*) for an isolated double-layer of lepidocrocite

the computed isolated NSs structures, the electronic QP gaps range from 4.5 to 6 eV, while the corresponding optical gaps, calculated at the BSE level, are about 1.5 eV smaller. A systematic blue-shift of the optical gaps is observed going from the symmetric anatase (S) to the lepidocrocite (see the left panel of Fig. 3). The comparison with experimental absorption spectra (not shown here) results quite good in the case of lepidocrocite sheets both for single- and multiple-layer samples [32]. As for nanoclusters, the narrowing of the optical gap with respect to the corresponding electronic gap stems from the nanosheet-reduced dimensionality and from very low dielectric screening which induces a strong attractive electron-hole interaction. As a consequence, the optical spectra presented in Fig. 3 have a clear excitonic nature in the vis-UV region, presenting at the lower absorption edge more peaks than those obtained within the independent-particle treatment [32]. A sensitive oscillator strength redistribution is observed, indicating that, including the excitonic description, not only the energy associated to the transitions varies but also the nature itself of the states involved in the optical absorption changes due to the e-h interaction [32]. The left panel of Fig. 3 also shows a quite different optical response of the various layers. A direct comparison with experimental absorption data available from literature (not reported here) makes possible to establish an unambiguous relationship between atomic structures and optical properties of TiO_2-derived NSs [32]. An example of spatial exciton localization, described as the probability to find an electron when the hole is fixed in a given position, is represented in the right panel of Fig. 3 for the case of bilayer lepidocrocite sheet.

In the last years, the hybrid carbon-titania nanocomposites have been extensively investigated at experimental level for their promising applicability both in photocatalysis and photovoltaics [45–48]. Then the optical properties of graphene/TiO_2-based heterostructures represent a further very interesting field of analysis. The relevance of this class of materials in solar-to-energy



Electronic and Optical Properties of Oxides Nanostructures by First-Principles Approaches, Fig. 4 *Side* and *top views* of graphene TiO_2 bilayer nanocomposite models. Structures (**a**) and (**b**) are the two dry models. (**c**, **d**) mimic the wet experimental environment (Reprinted with permission from Ref. [53]. Copyright 2014 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim)

conversion process stems from the combined nature of the heterostructure that embodies both the semiconducting properties of TiO_2 NS and the unique transport ones of graphene. Its large specific surface area, flexible structure, high transparency, and good electrical and thermal conductibility [49–52] make graphene the most promising materials in nanocomposite systems. It also exhibits excellent mobility of charge carriers, and it is expected to be able to slow the recombination of photogenerated electron-hole pairs contributing to the photocatalytic efficiency improvement of these hybrid materials. The almost complete lack of theoretical knowledge for such systems clearly associated with the different lattice parameter of the two subsystems has motivated to model nanohybrids formed by graphene- and TiO_2-based NSs. The simulations show that the presence of a direct bond (chemisorption) between the two-layered structures plays a crucial role in the electronic and optical properties of the final nanocomposite [53]. Figure 4 shows the atomic structure of the four models investigated in Ref. [53]. Two of them ($\mathbf{d_1}$ and $\mathbf{d_2}$) mimic the dry experimental assembling procedure [54], while the other two ($\mathbf{w_1}$ and $\mathbf{w_2}$) are modeled to reproduce the wet experimental environment. The presence of water makes the anatase NS hydroxylated at both surfaces. Furthermore the oxidized precursor of graphene, i.e., GO, is employed in assembling these wet heterostructures [55].

Structure optimization and calculation of electronic properties have been performed at the DFT level (see Ref. [53] for further details). The large size of the simulation cells did not allow the calculation of optical spectra by means of the GW/BSE approach. As demonstrated for the case of pure TiO_2-based nanosheets, the electronic bandgap opening ascribed to the GW correction is almost balanced by the inclusion of the excitonic effects at the BSE level of approximation. Then it can be fairly said that RPA and BSE optical spectra should be similar at a qualitative level.

Top panels of Fig. 5 report the imaginary part of the dielectric function of the physisorbed

Electronic and Optical Properties of Oxides Nanostructures by First-Principles Approaches, Fig. 5 The imaginary part of dielectric function calculated as the independent level of approximation for the (**a**) $\mathbf{d_1}$ system, (**b**) graphene, and (**c**) TiO_2-NS. Same is reported for the (**d**) $\mathbf{w_2}$ hybrid, (**e**) graphene oxide, and (**f**) the hydrated TiO_2 NS. *Blue* and *red* are the two ordinary rays (x, y) and *green* is the extraordinary ray (z) (Reprinted with permission from Ref. [53]. Copyright 2014 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim)

heterointerface (model $\mathbf{d_1}$) and of one of chemisorbed systems (model $\mathbf{w_1}$). The imaginary part of the dielectric function of the two component layers of these two systems is also reported in the central and bottom panels. As visible from the figure, while the photo-responsivity in the visible region is not enhanced in the physisorbed heterostructure (panel a), in the chemisorbed one, a higher photo-responsivity in the VIS region is predicted (panel d). As discussed in detail in Ref. [53], this is due to the raise of the valence band maximum state which stems from the hybridization between the two-layered subunits.

Conclusions

The recently achieved impressive progress in the experimental investigation and synthesis of optoelectronic and solar energy device oriented oxide nanostructures demands for the use of reliable theoretical/computational simulations able to provide a microscopic understanding of the underlying chemistry and physics.

Not secondarily, theoretical predictions represent fundamental tools to guide designers towards new and more efficient architectures.

Parameter-free-excited state approaches based on the Green's function formalism applied on top of DFT calculations are nowadays successfully employed to investigate the electronic and optical properties of a large class of materials.

The absence of any external fitting parameters offers an accurate and unbiased microscopic description at quantum-mechanical level of the chemical-physical processes involved.

Many-body perturbation theory results obtained on top of mean-field density functional theory calculations have been discussed here with a particular focus on TiO_2-based nanostructures. The inclusion of many-body effects in the theoretical description is of primary importance to obtain a first firm comparison between theoretical and experimental data (when available). The excitonic nature of the main optical peaks clearly comes out from the analysis of the theoretical spectra of these low-dimensional systems.

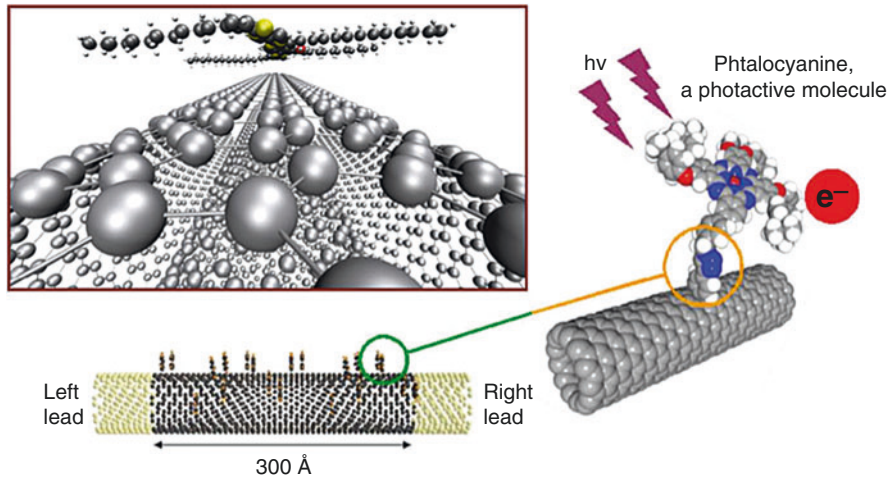
Synonyms

Charge transport in carbon-based nanoscaled materials; Electron transport in carbon nanotubes and graphene nanoribbons

Definition

Electronic transport is the transport of a charge carrier, either an electron or a hole, through a system that is coupled to two or more electrodes which serve as a source and sink for the charge carriers.



Single-walled carbon nanomaterials like carbon nanotubes and graphene nanoribbons are, respectively, tubular and planar arrangements of a one-atom-thick carbon sheet which possess a quasi one-dimensional (1D) geometry.

Introduction

As predicted by the miniaturization roadmap of the microelectronic industry, the gate length in metal-oxide-silicon-based field effect transistors (MOSFETs) has now been downscaled to a few tens of nanometers. This length reduction allows for the massive integration of billions of interconnected transistor devices, while preserving impressive current–voltage characteristics of individual components [1]. However, despite the sustained development of silicon-based nanoelectronics, the search for alternative materials for electronics has motivated the scientific community toward exploring the potential of molecular, organic, and carbon-based electronics such as carbon nanotubes or graphene [2]. The integration of carbon nanotubes (CNTs) and graphene nanoribbons (GNRs) as electron channels in electronic devices has become the focus of significant research and is the topic of this work. It should be stressed at the onset that, to date, carbon-based nanodevices have not been found to outperform silicon devices in mainstream microelectronics. Therefore, other types of applications need to be targeted. Among the wealth of possibilities, (bio)sensing at the nanoscale for medical, optical switches, photovoltaic cells, or nanoelectromechanical devices (NEMS) constitute some of the most promising alternatives [3, 4].

In spite of their promise, the use of such devices will remain elusive without a precise understanding of the intrinsic transport properties of carbon-based materials [5, 6]. Here, the advances made in the use of controlled chemical doping to fine-tune the transport properties of the pristine material as a particularly promising method of fundamental research are reviewed. Both experimental and theoretical studies have considered external agents like adsorbed atoms and molecules, substitutional impurities, and functional groups as possible candidates to introduce new functionalities in pristine carbon nanosystems. For instance, electroactive systems such as π-conjugated polymers display electronic and optical properties that can be tuned by appropriate molecular design. These systems also adopt several conformations with varying physical properties when molecular groups are subjected to oxidation or protonation through doping reactions. These polymers can also form molecular composites with other electroactive components of different chemical composition. Interesting properties emerge from the combination of CNTs and GNRs unique properties with those of the polymers themselves and open up many opportunities for potential applications, such as data storage media, photovoltaic cells, etc. - π-conjugated polymers are also known to strongly interact with a carbon nanotube surface through π-stacking interactions to form supramolecular adducts (Fig. 1a). This type of noncovalent functionalization allows for nanotube modification without the introduction of defects in the original geometry. At the same time, this procedure facilitates the molecular mixing of both composite components [7].

Conjugated π-networks decorate the surface of quasi-one-dimensional structures of CNTs and GNRs and confer to them either semiconducting or metallic properties, in addition to quasi-ballistic transport on micrometer length scales. Some external agents that do not necessarily modify the system geometry can alter the electronic transport features. For example, hole and electron doping chemistry does not significantly modify the position of individual carbon atoms but can create strongly localized states, electrostatic fields, and conduction gaps or localization phenomena. Conversely, the chemical modification of nanotubes or nanoribbons by covalent attachment of functional

Electronic Transport in Carbon Nanomaterials, Fig. 1 Physisorption (*top left*) and chemisorption (*bottom*) of organic molecules on carbon nanotubes. A phthalocyanine (*bottom*) is attached to a carbon nanotube by using a chain of phenyl groups that serve as linkers. This chemical attachment allows the nanotube to evacuate the electrons that result from photoactivation of the phthalocyanine. Modeling the degradation of electron transport abilities of the nanotube upon grafting of the phenyl groups is a fundamentally important task. In contrast, physisorbtion (*top left*) represents a noninvasive type of functionalization. The organic molecule(s) sit(s) in the proximity of the nanotube such that chemical bonds are not established and the electronic structure is only partially affected

groups causes simultaneous geometrical and electronic structure distortions. The alteration of the surface of the carbon nanostructures perturbs the crystal periodicity and modifies the electronic band structure and, in turn, the native quasi-ballistic nature of the electron transport properties [8, 9].

The experimental achievements in the field of nanotube functionalization have been spectacular. For instance, the "Click Chemistry" [10] approach succeeded in functionalizing and characterizing CNTs with zinc-phthalocyanine, with the aim of preparing a nanotube-based scaffold, which would make it easier to fabricate more complex functional structures. The attachment of phthalocyanines to nanotubes and fullerenes has emerged as a superb approach to carbon nanostructure phthalocyanine-based photovoltaic applications and other electronic devices [11]. Phthalocyanines are planar and electron-rich macrocycles characterized by remarkably high extinction coefficients in the red/near-infrared region (which is an important part of the solar radiation spectrum) and outstanding photostability and singular physical properties. These features make them exceptional building blocks for their incorporation in photovoltaic devices. Theoretical and computational studies support the understanding of how molecular states of phthalocyanines or other photoactive species mix with carbon nanotubes extended states (Fig. 1b).

Numerous questions regarding chemical functionalization still remain unsolved, especially since the goal is to develop novel applications. For instance, how does the interaction between nanotube and adsorbate affect their physical properties? What grafting process should be used to minimize the modification of the intrinsic and desirable electron transport capabilities of pristine nanotubes? In this regard, theoretical advances have allowed tremendous progress toward the understanding of some of the physical and chemical issues related to the modification of the electronic structure of carbon-based systems. However, the complexity of the calculations involving modified structures does not always permit a systematic comparison of theoretical modeling at size and timescales relevant to experiments. This complexity arises from the need to include a large number of atoms in the computer

simulation, as well as from the accuracy required to treat systems in a realistic manner. Notwithstanding, DFT-based approaches provide a set of powerful tools for the quantum mechanical investigations of the physical and chemical properties of nanosystems. The self-consistent calculation of the electronic structure of any material is critical whenever charge transfer between two interacting systems plays a major role in the interaction. Examples of this effect include chemical doping [12] or structural alterations introduced by topological defects that force local change in aromaticity [13]. Variations of the charge distribution leads to a number of effects, such as the appearance of local polarization and modification of the local geometry. For instance, when a functional group such as an aryl ring is positioned close to the surface of a CNT or a GNR, a covalent bond between two carbon atoms of both objects is established [14]. The covalent bond corresponds to the archetypical sharing of electrons between the two moieties and creates a dipolar moment that polarizes the charge distribution in the surrounding of the new carbon–carbon σ-bond between the individual molecules. The polarized charge distribution gives rise to an electrical field that perturbs the charge distribution that initially caused the polarization, and so forth in a self-consistent cycle.

The present entry primarily focuses on some recent works toward understanding the surface modification of carbon nanotubes and graphene nanoribbons by chemical doping such as adsorbed functional groups and substitutional doping. Depending on the chemical interaction, the transport properties of the carbon materials can be significantly altered. All the results shown here are based on DFT modeling, as implemented in the SIESTA [15, 16] and NWChem [17] codes. The localized orbital basis set, which constitutes one of the essential features of both codes, along with their reliable and fast calculations, are the main advantages of this approach. The tight-binding-like Hamiltonian obtained from the self-consistent calculation of an electronic structure presents the compactness required to study the transport property within the Green's function formalism.

In order to set the theoretical background to this entry, the principal concepts underlying the Landauer-Büttiker [18–20] theory of coherent electronic transport in low-dimensional systems are presented in section "The Landauer-Büttiker Quantum Transport Theory," along with a detailed description of the decimation technique in section "Green Function," which is particularly well suited for the calculation of long disordered systems. In section "Quantum Transport in Nanostructured Carbon Materials," a study of metallic and semiconducting functionalized carbon nanotubes by exohedral interactions with carbene and phenyl groups, endohedral amphoteric doping, and substitutional doping with N, P, B, S, and heteroatomics such as N–P is presented. In section "Summary and Conclusions," a summary and some conclusions are provided.

The Landauer-Büttiker Quantum Transport Theory

First, the basic ideas of the transport formalism are explored. The electronic transport calculations that will be presented are based on the Landauer-Büttikker formulation of conductance, which is particularly adequate for the study of electron motion along a device channel connected to two semi-infinite leads. The Landauer-Büttikker approach considers the transport properties of a phase coherent system formed by scattering region and leads, providing a simple and powerful framework for quantum transport in 1D mesoscopic systems. A device is defined as a material region where charge carriers spend a certain amount of time during their propagation. The electronic wave packets propagate quantum mechanically along a channel characterized by a cross-section and a longitudinal length. The channel is connected to left and right 1D semi-infinite leads that are in thermodynamical equilibrium with infinitely larger electron reservoirs. The Landauer-Büttikker approach is based on the classical concept of scattering: an incoming electron has a certain probability to be backscattered or transmitted when it crosses the device due to impurities. Material impurities are seen by

charges as attractive or repulsive potential barriers and the mutual interaction leads to various material conductance regimes. This transport model treats electron interferences from a quantum mechanical point of view corresponding to the coherent dynamics of the electron.

In 1957, Rolf Landauer introduced the revolutionary concept that contacts play an important role in transport phenomena, and should therefore be properly treated. In addition to the molecule or device resistance, the intrinsic resistance of the whole system is determined by the coupling of the channel with the electrodes. Landauer's formulation for the quantum mechanical problem of electronic transport consists in establishing a one-to-one correspondence between the conductance of a 1D conductor and the probability of an electron to transmit without reflection.

Landauer's model deals with strictly 1D systems, the conductance of which can be expressed by:

$$G = \frac{e^2}{h}\frac{T}{R},$$

where e is the electronic charge, h is the Planck constant, and T and R are the transmission and reflection probabilities, respectively. This equation has an apparent algebraic limitation: when T = 1 (i.e., perfect conductor) the conductance of the device becomes infinite. This result caused controversy at the time of Landauer's seminal publication since it is clear that no channel has an infinite conductance. Büttiker's work put the controversy to rest by considering the contribution of all the electronic channels of transmission. The resulting Landauer-Büttiker approach states that, in a two-probe system, the conductance per channel is

$$G_n = \frac{e^2}{h}T_n,$$

where T_n is the transmission coefficient for the *n*th channel. In this formula, several assumptions are made: there is no electron–electron interaction and each charge propagates coherently through the conductor with only possible elastic scattering events, since all the inelastic processes take place in the reservoirs. The final expression that takes into account all channel contributions, in addition to spin degeneracy therefore reads

$$G = G_0\sum_{n=1}^{N} T_n,$$

where $G_0 = \frac{2e^2}{h}$ is the quantum of conductance and the sum runs over all the different conducting channels at a given energy. This formula is usually known as the two-probe conductance formula. This description differs from Landauer's original formula in the conductance of a perfect 1D conductor is equal to G_0, which corresponds to maximum value of conductance. Reciprocally:

$$R = \frac{1}{G_0} = \frac{h}{2e^2} = 12.906\,\mathrm{k\Omega}$$

is the quantum of resistance. It is striking that this theory predicts that a perfect conductor has a minimum resistance larger than zero. The actual experimental verification of this theory devised in the 1950s was only achieved in the late 1980s by van Wees et al. [21] and Wharam et al. [22] who unambiguously demonstrated the finite minimum resistance of each individual channel of conductance.

Green Function

In this section, a primer on the use of Green functions in transport calculations is provided. In this work, electronic transport of single-particle problems are solved, the energetic of which is described by a density functional Hamiltonian, H, used in Schrödinger equation as:

$$H\Psi_i = \varepsilon_i\Psi_i \Rightarrow \left[-\frac{1}{2}\nabla^2 + V(r) - \varepsilon_i\right]\Psi_i(r) = 0,$$

where V(r) is a potential and ε_i are the eigenvalues associated to the eigenfunctions $\Psi_i(r)$. The wavefunctions can be expressed by an expansion in a complete set of basis functions $\{\varphi_\nu(r)\}$:

$$\Psi_i(r) = \sum_{v=1}^{N} c_{iv}\varphi_v(r).$$

Truncating the number of basis functions leads to an operational approximation. A sufficient large number of basis functions can reduce the imprecision. The Hamiltonian matrix elements of H in the $\{\varphi_v(r)\}$ basis are defined as:

$$H_{vv'} \equiv \int d3r\varphi_v^*(r)\left[-\frac{1}{2}\nabla^2 + V(r)\right]\varphi_{v'}(r)$$

and the overlap matrix element between two functions is defined as:

$$S_{vv'} \equiv \int d3r\varphi_v^*(r)\varphi_{v'}^*(r)$$

Inserting expression (2) into (1) a generalized eigenvalue problem is obtained:

$$\sum_{v'} H_{vv'}c_{iv'} = \varepsilon_i \sum_{v'} S_{vv'}c_{iv'} \quad \forall v.$$

From this expression, the Green's function is defined as:

$$\sum_{v''} (\varepsilon S_{vv''} - H_{vv'})G_{v''v'}(\varepsilon) \equiv \delta_{vv'}.$$

Within a tight-binding framework, the basis set can be formed by a set of atomic orbitals centered on each atom of the system that confers a compact form to the matrix. Inverting the matrix for a given value of ε is, in principle, the only calculation needed to determine the Green's function of the electronic system. In this work, the Hamiltonian and overlap matrices are provided by a DFT calculation of a system composed of hundred of atoms. Since the SIESTA and NWChem codes employ a basis set of atomic-like orbitals, the Hamiltonian matrix that result from a simulation meets the operational requirements of size and compactness to determine Green's function. Further, an appropriate choice of basis set size leads to a relatively compact set of matrices within the linear combination of atomic orbital model.

In a generalized consideration of the transport problem of a two-terminal geometry, the finite device is sandwiched between two semi-infinite electrodes, and the Hamiltonian of the entire system (i.e., an infinite size Hamiltonian) can be written as:

$$H = \begin{bmatrix} H_L & -\gamma_L & 0 \\ -\widetilde{\gamma}_L & H_0 & -\widetilde{\gamma}_R \\ 0 & -\gamma_R & H_R \end{bmatrix}$$

where H_0 is the device Hamiltonian, $H_{L,(R)}$ are the bulk left (right) electrode Hamiltonians, and $\gamma_{L,R}$ represent the tight-binding-like coupling between the electrodes and the device channel. The Green's function operator of the system can be expressed as:

$$[\varepsilon \cdot S - H]G(E) = \mathrm{I},$$

where I is the identity matrix and ε is the complex energy that imposes causality and is chosen to avoid the real axis poles of the Green's function by extending its domain to the complex plane. Depending on the positive or negative semi-infinite complex plane definition of ε, the Green's function can be labeled as $G_0^{r(a)}(\varepsilon)$,, that is, the retarded (advanced) Green functions of the device channel (fulfilling the relation $G_0^r(\varepsilon) = \tilde{G}_0^a(\varepsilon)$) where $\sim$ denotes the complex conjugated. Physically, these two Green functions represent an incoming and an outgoing wave formed upon the same excitation. It is worth noting that, while the contact function subspaces are semi-infinite, the device subspace has a finite representation. To obtain a finite matrix representation of the electrodes, it is useful to resort to the self-energy representation $\Sigma_{L,R}$ of both the left (L) and the right (R) electrodes:

$$\sum\nolimits_L = \widetilde{\gamma}_L g_L \gamma_L$$

$$\sum\nolimits_R = \widetilde{\gamma}_R g_R \gamma_R$$

Where

$$g_L = [E \cdot S - H_L]^{-1}$$

$$g_R = [\varepsilon \cdot S - H_R]^{-1}$$

are the (surface) Green functions of the left and right contact, respectively. The transformation of these two infinite matrices into two (*N, N*) matrices to obtain a finite expression is usually performed by taking advantage of the semi-infinite lattice symmetry of the two leads, either by analytical or iterative techniques. Once the self-energy terms are calculated, one can obtain the final expression of the Green's function matrix of the whole device as:

$$G_0 = \left[\varepsilon \cdot S - H_0 - \sum\nolimits_L - \sum\nolimits_R\right]^{-1}.$$

From this expression, the self-energies can be interpreted as additive potential terms of the device channel Hamiltonian whose final expression represents an effective Hamiltonian that accounts for the presence of the electrodes. The numerical representation within the chosen basis now corresponds to a matrix of finite rank. This is an undeniable advantage. Note that this standard procedure for the calculation of Green's function of a two-terminal system can be easily extended for multiterminal geometries, since each electrode can be included by a proper self-energy added to the expression of G_0.

Once the Green's function of the device channel is determined, the Caroli formula [23] is applied to calculate the transmission coefficients. In its compact form, the transmission between the right and left electrodes T(ε) is:

$$T(\varepsilon) = tr\left[\Gamma_R(\varepsilon) G_0^r(\varepsilon) \Gamma_L(\varepsilon) G_0^a(\varepsilon)\right],$$

where the contact terms, Γ_L and Γ_R for left (L) and right (R) electrodes are:

$$\Gamma_{R(L)}(\varepsilon) = i\left[\sum\nolimits_{R(L)}^{r}(\varepsilon) - \sum\nolimits_{R(L)}^{a}(\varepsilon)\right].$$

This expression for T(ε) is equivalent to that introduced in section "The Landauer-Büttiker Quantum Transport Theory" for the transmission coefficients.

Quantum Transport in Nanostructured Carbon Materials

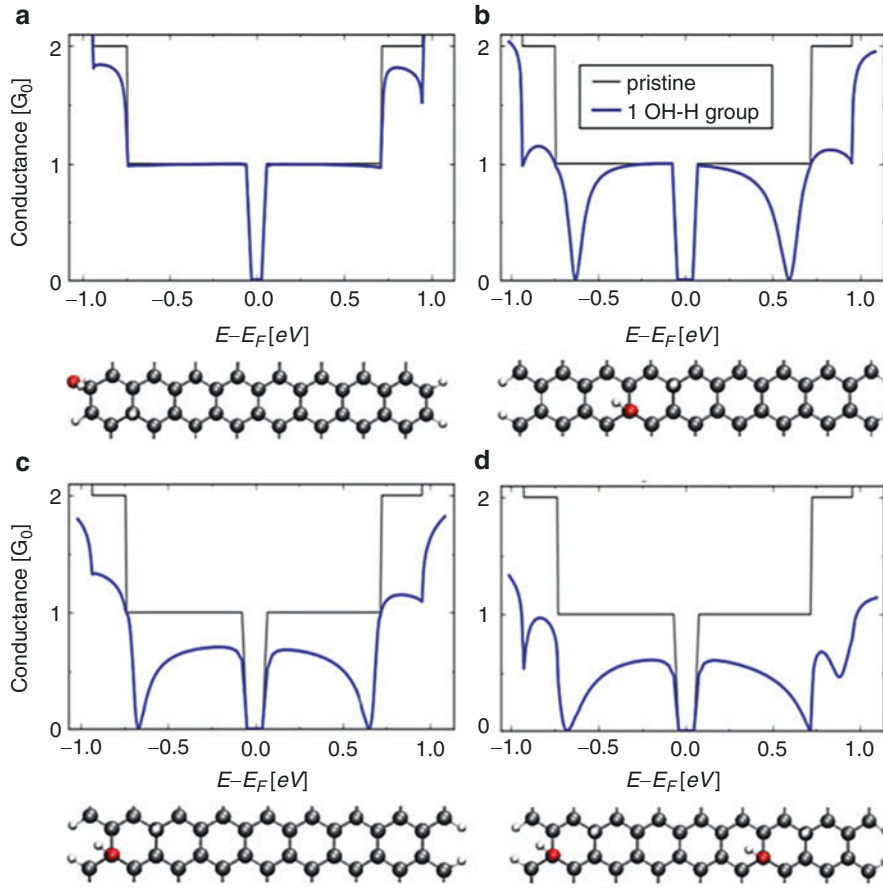
Chemical Functionalization of Graphene Nanoribbons

Graphene is a zero-gap semiconductor and is therefore unsuitable for achieving efficient field-effect functionality with an acceptable ON/OFF states current ratio. One possibility to increase the zero-gap of two-dimensional (2D) graphene single layers is to shrink its lateral dimension. This dimensional confinement effectively opens an electronic bandgap that decreases in magnitude when the nanoribbon width increases. In spite of this, theoretical predictions and experimental observations have reported energy band-gaps far too small or very unstable in regard to edge reconstruction and defects, thus preventing envisioning these graphene-based devices from achieving improved performance relative to the ultimate CMOS-FETs.

To further introduce suitable band-gaps, one can instead recourse to larger width graphene nanoribbons (above 10 nm in lateral sizes) and compensate the loss due to the bandgap shrinking by triggering mobility gaps through doping or surface modification. Mobility gaps are direct consequences of a wide distribution of quasi-bound states over the valence band (for acceptor-type impurities) or the conduction band (for donor-type impurities) in the first conductance plateau when dopants are randomly distributed across the ribbon width because of the strong dependence of the scattering potential with the dopant position in respect to the ribbon edges. The electronic transport properties of GNRs modified by means of substitutional doping with atoms such as boron, nitrogen, or phosphorus and chemical attachment of functional groups have been simulated and has shown promising features [24].

Graphene is an aromatic material: its electronic ground state corresponds to completely delocalized π-electrons. It follows that all conjugated chemical bonds are equivalent. This symmetry is broken when a functional group is grafted onto graphene's surface since it removes a π-bond, thereby inducing an sp^2 to sp^3

rehybridization and a net magnetic moment [25]. However, this situation is not stable and as soon as a second atom is chemisorbed on graphene's basal plane, the unpaired electron participates in a second sp^3 hybridization and the magnetic moment vanishes. This formation of radicals associated with the removal of one p_z orbital in the conjugated graphene network also takes place in nanotube networks. Chemical functionalization of graphene-based materials is a promising strategy to reversibly tune the electronic properties without aggressively reducing the ribbon width. For instance, pairs of hydrogen (H–) and hydroxyl (OH–) functional groups attached on GNRs at opposite positions in a hexagonal graphene ring introduce the simultaneous appearance of two bonds with different charge densities in the system. The oxygen atom of the OH– group is a good acceptor of electrons while H– adopts a donor behavior when it is located in the vicinity of a C atom. The two equivalent bonds can also be treated by considering two phenyl rings covalently attached at opposite sides of a hexagonal ring.

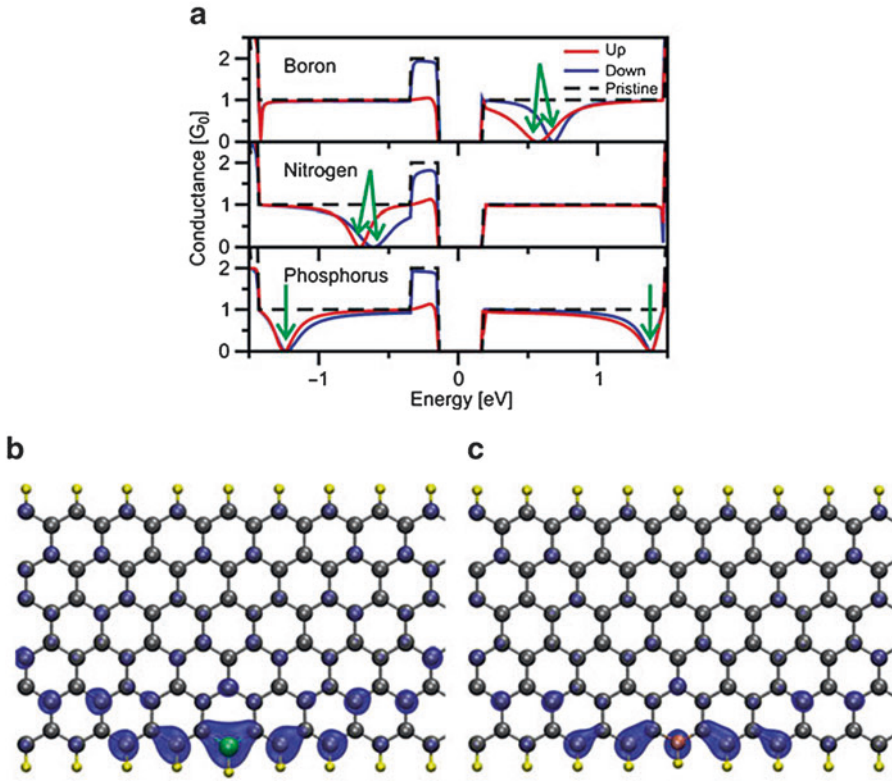


Several chemical groups can be simultaneously attached, which allows for a wide range of conductance and structural modulations depending on the relative positions of the addends. The particular configuration of a nanoribbon with functionalization at the edge is also of special interest. In this case, no localized states are introduced by the functional groups at energies close to the Fermi level and, therefore, the conductance ability of the ribbon is not significantly affected.

As explained in section "Green Function," a complete device can be set up once ab initio calculations are performed to obtain the Hamiltonian and overlap matrices associated with short functionalized nanoribbon sections. To compute the conductance of clean and defected GNRs, the multichannel Landauer-Büttiker technique described in sections "The Landauer-Büttiker Quantum Transport Theory" and "Green Function" is used. The channel is defined between two perfect GNR-based right (left) leads, which impose chemical potentials μ_1 (μ_2). This choice of leads also optimizes the coupling with the channel.

First the properties of an armchair-edged nanoribbon with 17 bonds along its length (hereafter called a17GNR) are discussed. The dependence of the a17GNR conductance as a function of the H– and OH– group position is shown in Fig. 2 for a set of different configurations. If the C–OH bond is located at the GNR edge, no backscattering is observed in the first conductance plateau (Fig. 2a), although some weak conductance decay is seen for higher energy sub-bands. Edge functionalization does not alter the electronic properties of the aGNR in the first sub-band since the impurity states are located far away from the Fermi level. In contrast, when the C–OH bond is shifted out of the edge line, the conductance is more significantly reduced as shown in Fig. 2b or in Fig. 2c. Figure 2b shows similarity with the situation for pair of grafted phenyls, whereas other locations (Fig. 2c) exhibit a larger suppression of conductance in the first plateau, although higher energy sub-bands remain largely unaffected. This dependence of the conductance on the location of the OH/H pair can be rationalized by analyzing the variation of electrostatic screening effects that dictate the effective scattering potential. The conductance decay is driven by backscattering on individual functional groups and by quantum interferences due to the proximity of the defects.

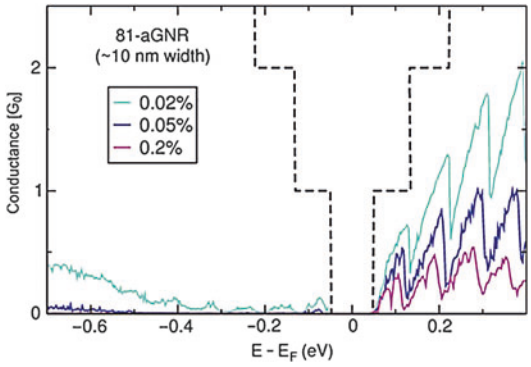
Zigzag-edged GNRs (zGNRs) display a number of different electronic features compared to aGNRs. As opposed to aGNRs, zGNRs present a magnetic ordering at the edges as a consequence of the strong localization of the unpaired π and π^* electrons in the ground state. These edge states are spin-degenerate but both ribbon edge states exhibit different spin orientations as a result of edge–edge interactions, and hence the difference between ferromagnetic and antiferromagnetic spin states disappears gradually for wide enough ribbons. First-principles calculations show that zGNRs are metallic in the ferromagnetic configuration whereas they exhibit semiconducting behavior in the antiferromagnetic state. zGNRs' magnetic properties have interesting implications for the development of electronic and spintronic devices.



The case of GNR substitutionally doped with boron, nitrogen, and phosphorus atoms, which

Electronic Transport in Carbon Nanomaterials, Fig. 2 Conductance of narrow GNRs. Conductance of a17GNR as a function of defect position. The locations of the defects for (**a**–**d**) are illustrated at the *bottom*. The (**d**) case shows the conductance in the case of two pairs of functional groups

modify the electronic and transport properties of the ribbons, is now considered. The presence of a dopant typically induces localized states and a drop in conductance at some particular energies. The dependence of the conductance drop position in the transmission spectrum on the specific doping site was investigated within an ab initio approach. DFT is well suited to calculate the charge transfer between the doping atoms and the GNRs and thus to find the exact position in energy of the bound states. Nitrogen and phosphorus atoms preferentially substitute at the edges of zigzag and armchair nanoribbons, whereas boron atoms preferentially substitute at the edges of zGNRs but next to the edge of aGNRs. Spin-dependent conductance in the most energetically favorable boron-doped and nitrogen-doped zGNRs leads to the possibility of utilizing such structures in spintronic devices. The most favorable configuration of phosphorus atoms does not present a significant degree of spin-dependent behavior, but it displays both a donor-like and an acceptor-like state. The conductance of doped armchair nanoribbon exhibits spin degeneracy for all cases, but in phosphorus-doped zigzag ribbons, spin-dependent behavior can emerge as the doping is placed at particular sites across the ribbon width (Fig. 3).



The large predicted variation of resonant energies with the dopant position with respect to the GNR edges [26] indicates that a random distribution of impurities along the ribbon surface should

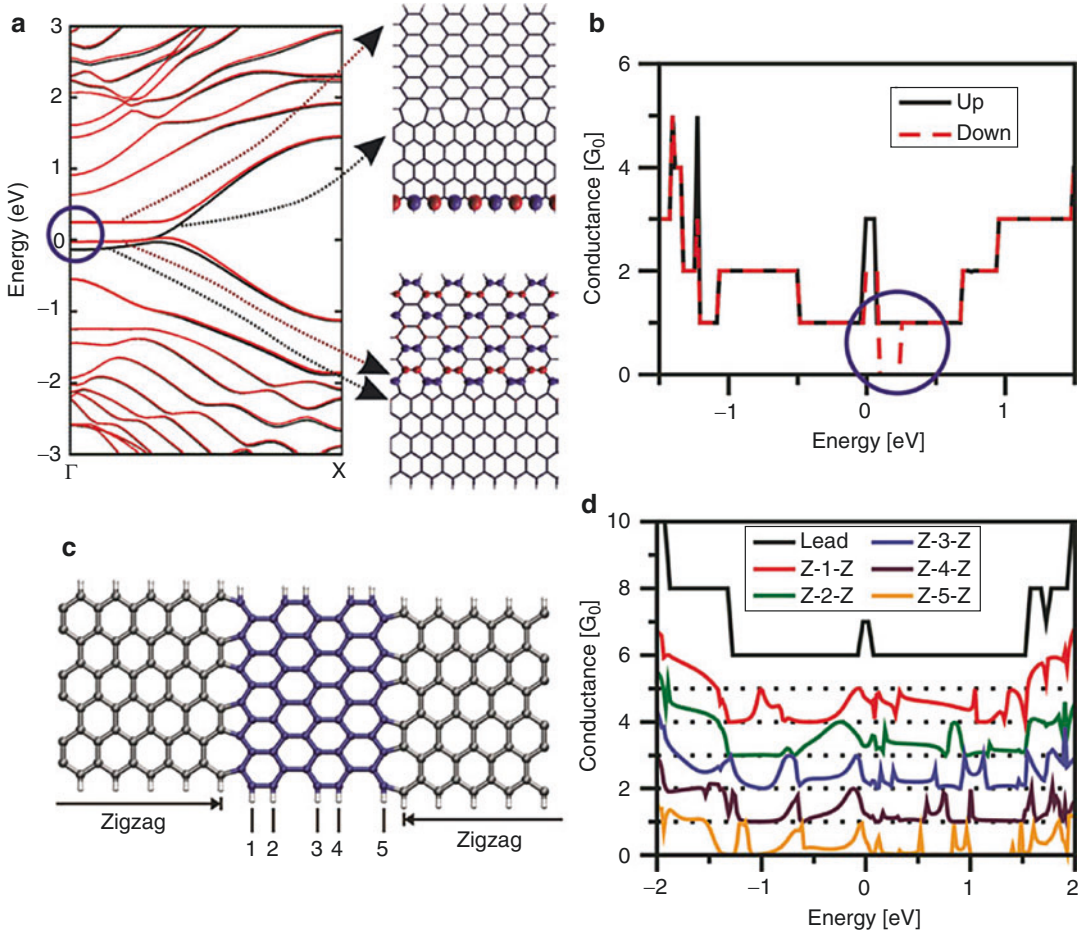
lead to a rather uniform reduction of the conductance over valence states on the first plateau of conductance. Turning to the quantum transport properties of boron doped GNRs up to 10 nm in width, first-principles calculations are combined with tight-binding models to investigate the effect of chemical doping on charge conduction for ribbons length up to 1 μm with randomly distributed substitutional boron impurities. Due to the large size of the corresponding unit cells, a statistical study of the mesoscopic transport using the fully ab initio Hamiltonian is not directly possible. Instead, a tight-binding model parameterized by accurate first-principles calculations is used. In a first step, the scattering potential induced by the dopant is extracted from those obtained with DFT. The analysis of the ab initio onsite and hopping terms around the doping atom obtained from self-consistent DFT calculations within an atomic-like basis, allows a simple nearest-neighbor tight-binding model to be built. The substitutional impurity modifies mainly the onsite terms, creating a potential well on a typical length scale of about 10 Å.

Figure 4 shows the conductance of a 10 nm wide armchair nanoribbon with a low dose for boron doping. For a doping density of about 0.2 %, the system presents a mobility gap of the order of 1 eV. When lowering the doping level to 0.05 %, the mobility gap reduces to about 0.5 eV and finally becomes less than 0.1 eV for lower density. The 0.2 % case is obtained for a fixed nanoribbon width and length, so that adjustments need to be performed for lateral or longitudinal size upscaling, but the method is straightforward once the transport length scales (mean free paths,

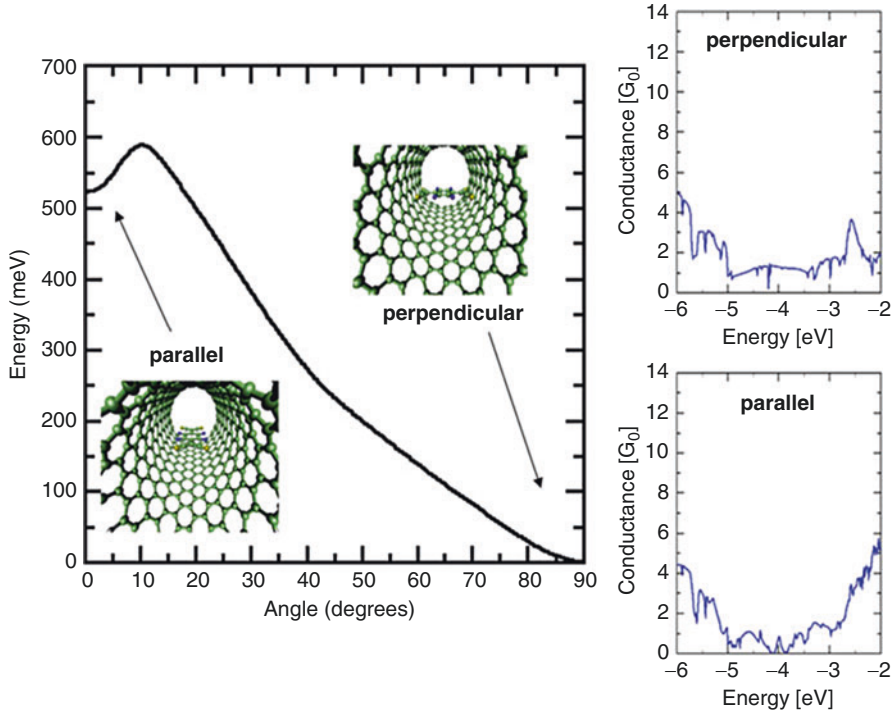


Electronic Transport in Carbon Nanomaterials, Fig. 4 Average conductance as a function of energy for a semiconducting 81-aGNR (*dashed line*) and three selected doping rates (0.02 %, 0.05 %, and 0.2 %, from *top to bottom*)

localization length) have been computed [24]. One notes however that the existence of mobility gaps (with conductance several orders of magnitude lower than the quantum conductance) can hardly allow a straightforward quantitative estimation of resulting ON/OFF current ratio, since this would require computing the charge flow in a self-consistent manner (using a Schrödinger-Poisson solver). This turns out to be critical since accumulated charges inside the ribbon channel screen the impurity potential in an unpredictable way. These types of calculations would need to be performed using nonequilibrium Green functions (NEGF) formalism and deserve further consideration [27].

To summarize the results presented thus far, it is clear that for any graphene-based application to be viable, it is critical to understand the effect of defects and disorder. In the following, junctions of nanoribbons based on an ordered array of structural defects [28] are treated. Such arrays of defects have been observed experimentally and could be visualized as grain boundaries in a graphene sheet [29]. In particular, an array of pentagons and heptagons can be used to join an armchair and a zigzag nanoribbon, as shown in Fig. 5. The spin resolved band structure for a (4, 4) hybrid nanoribbon is shown in Fig. 5a. Note the presence of an energy gap of ~0.2 eV in the minority spin states. For ribbons with an even width, there is a gap in the spin down states, that is, the systems exhibit half-metallicity and these hybrid systems behave as a spin polarized conductor (Fig. 5b). The isosurface plots of the wave functions near the Fermi level are indicated by the arrows on Fig. 5a. Some of these bands (top) are closely related to the zigzag nanoribbon edge states although, unlike zGNRs, there is only one edge state yielding a net magnetic moment. Another interesting case arises when an armchair segment is sandwiched in between two zGNRs electrodes, as shown in Fig. 5c. In this case, the two different lattices can be joined while keeping the threefold connectivity of each inner carbon atoms by introducing a set of pentagon-heptagon defects. The results presented in Fig. 5d indicate that the conductance near the Fermi level is reduced as the armchair section is increased, denoting a tunneling driven transport across the junctions.

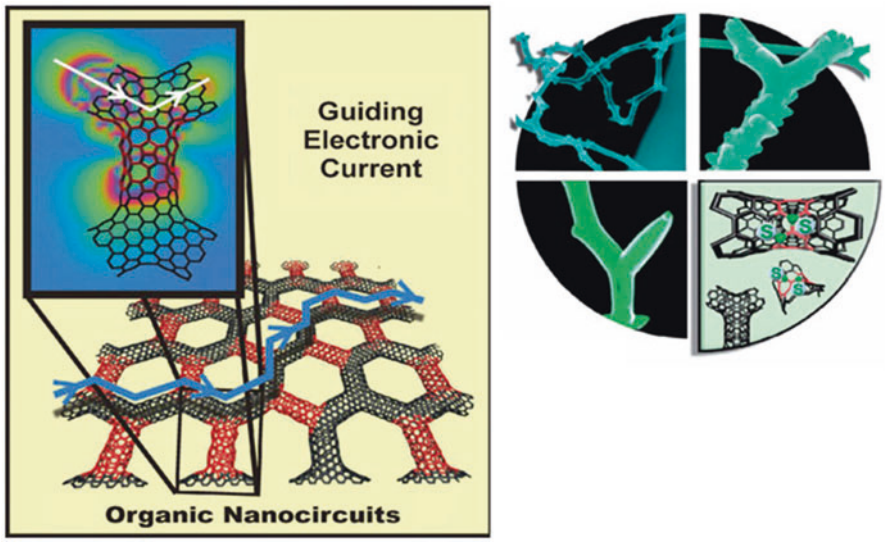
Chemical Functionalization in Carbon Nanotubes



Amphoteric doping: It has been demonstrated that DFT-based transport calculations can be used at the fundamental level to devise a novel nanoelectronic device by exploiting the interplay between the intrinsic properties of pristine nanotubes and those of chemical dopants [30]. Here, a bistability is built in to form a nanoswitch whose conductance state depends on the relative position of a guest molecule inside of a carbon nanotube (see Fig. 6). Depending on the mode of operation, the proposed device is capable of acting as an electrical switch or a nonvolatile memory element. The switching mechanism consists of a significant change in the flow of electrons in a circuit due to different orientations of a molecule relative to the host nanotube. As shown in Fig. 6, one stable position of the molecule yields a high current across the device ("ON" conducting state) while a change in orientation is associated with an important, measurable decrease of the transmission property ("OFF" nonconducting state). The information is therefore stored in the form of the orientation of the molecule (parallel for "OFF" and perpendicular for "ON"), which retains its position even when the external source of energy is switched off

Electronic Transport in Carbon Nanomaterials, Fig. 5 (**a**) Computed spin resolved band structure for a (4,4) hybrid nanoribbon. The energy gap ($E_g = 0.27$ eV) on the minority spin (*red*) is indicated by a *blue circle*. The *arrows* show the wave function plot for the bands close to the Fermi level at the Γ-point. (**b**) Quantum conductance for a typical (4,4) hybrid graphene nanoribbon. The nanoribbon is spin degenerate in most of the energy spectrum, except for the region close to the Fermi level, where spin-polarized conductance is observed. (**c**) Example of a zigzag-armchair-zigzag device joined by 5–7 defects. (**d**) Quantum conductance for a set of these devices. It is observed that the conductance is reduced as the armchair section is increased, revealing a tunneling driven transport

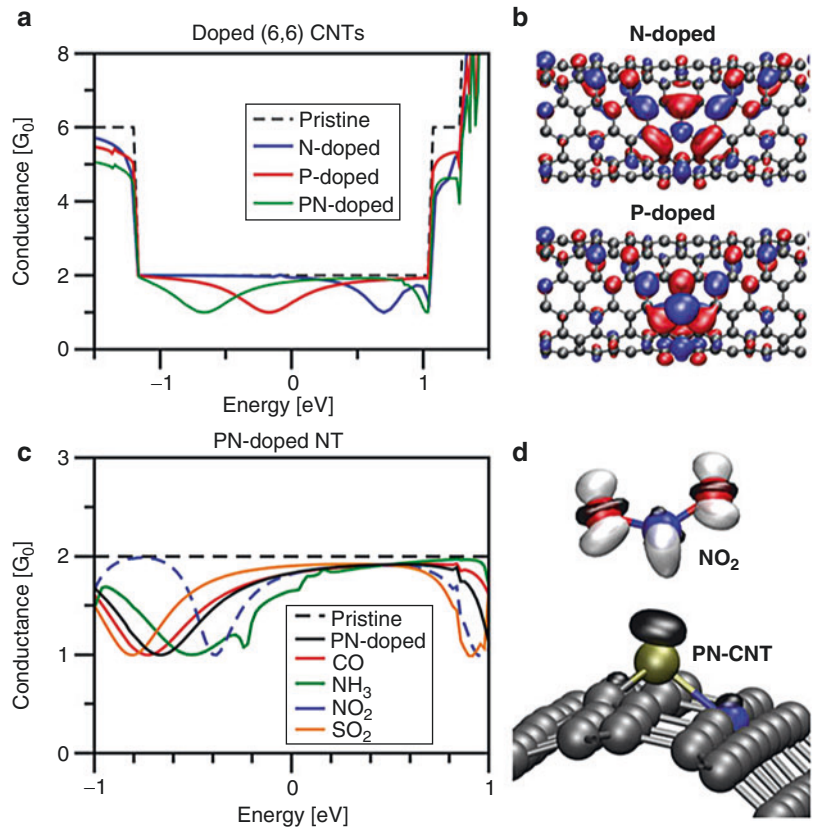
(nonvolatility). In addition, due to the intrinsic mechanical properties of the nanotube, the molecule's orientation can be reliably switched back and forth mechanically. The information storage mechanism remains valid for any molecule–metallic nanotube combination as long as it displays the desired properties of significant charge transfer, and the presence of at least two metastable molecule positions with respect to the nanotube core. In addition, these two positions, in order to present distinct transport properties, must be characterized by clearly different types of interaction (such as different amounts of charge transfer for instance). These are necessary conditions but they are not always simple to guarantee a priori, and computational exploration is needed to properly select the correct combination of systems.



In this regard, it was shown that computational approaches paired with density functional theory studies can be routinely used to identify relevant combinations of molecules and wires/CNTs for realistic applications. In particular, a class of devices where a noncovalently bound molecule

Electronic Transport in Carbon Nanomaterials, Fig. 6 *Left panel*: total DFT energy of a "guest" F_4TCNQ molecule as a function of the angle between the main molecule axis and the "host" nanotube axis (inserts show the orientation). *Right panels*: conductance profile of the two different open systems where the active region is seamlessly connected to semi-infinite (10,10) carbon nanotubes

that acts as a passive gate can be extended to a large number of molecule-nanotube pairs, giving great versatility in the choice of nanotube diameter and doping molecule. Specifically, for a given molecule, it is possible not only to identify a nanotube that displays the characteristics of a memory element device but also to develop a detailed understanding of the criteria governing the functioning of this device.



Nanonetworks: Carbon nanotubes can be combined to create 2D and 3D (three-dimensional) networks. These complex systems can be tailored from nanostructures as building blocks and are the foundations for constructing multifunctional nano- and microdevices. However, assembling nanostructures into ordered micronetworks remains a significant challenge in nanotechnology. The most suitable building blocks for assembling such networks are nanoparticle clusters, nanotubes, and nanowires. Unfortunately, little is known regarding the different ways networks can be created and their physicochemical properties as a function of their architecture. It is expected that, when 1D nanostructures are connected covalently [31], the resulting assemblies will possess mechanical, electronic, and porosity properties that are strikingly different from those of the isolated 1D blocks. In extensive theoretical studies, it has been shown that the properties of 2D and 3D networks built from 1D units are dictated by the specific architecture of these arrays. Specifically, the hierarchy concept as a practical way to design complex nanostructures from basic nano-building blocks was introduced. It was also demonstrated that nanotubes could be joined to make super networks with new properties emerging from those of the individual building blocks (i.e., the nanotubes). In addition to the unusual mechanical and electronic properties, the porosity of these systems makes them good candidates for catalysts, sensors, filters, or molecular and energy storage properties. The crystalline 2D and 3D

Electronic Transport in Carbon Nanomaterials, Fig. 7 *Left panel*: An ordered carbon nanotube network where defects introduced at the intersection of the nanotubes act as electron scattering centers (insert). *Right panel*: some of the different types of carbon nanotube architectures possible by introducing small amounts of sulfur into the precursors for the synthesis

networks are also expected to present unusual optical properties, in particular when the pore periodicity approaches the wavelength of different light sources, such as optical photonic crystals. The power of theoretical calculations in predicting novel materials with enhanced electronic and mechanical properties, using single atoms as building blocks, has been demonstrated repeatedly. These systems were studied by examining how atomic level modification of the networks can be made to tailor the properties of the current flow, a key ingredient for smart and addressable nanoarrays. The electrical current could be efficiently guided in 2D nanotube networks by introducing specific topological defects within the periodic framework. Using semiempirical transport calculations coupled with the Landauer-Büttiker formalism of quantum transport in multiterminal nanoscale systems, a detailed analysis of the processes governing the atomic-scale design of nanotube circuits was possible. When defects are introduced as patches in specific sites, they act as reflecting centers that re-inject electrons along specific paths, via a wave reflection process (see Fig. 7 left panel). This type of defect can be incorporated while preserving the threefold connectivity of each carbon atom embedded within the graphitic lattice. These findings introduce a new way to explore bottom-up design, at the nanometer scale, of complex nanotube circuits that could be extended to 3D nanosystems and applied in the fabrication of nanoelectronic devices.

Using knowledge acquired during the nanonetwork characterization and the behavior of nanostructures relative to local changes in chemistry, it was shown that the actual realization of networks can be obtained by inserting minute amounts of sulfur in precursors used for nanotube formation. This method was found to lead to the creation of a large range of structures, including crossbars and multiterminal junctions (Fig. 7 right panel) [32]. It also clarified the key role of sulfur in nanotube growth. Most notably, it was demonstrated that sulfur not only promotes the C-H separation in the precursor but also triggers the emergence of negative and positive local curvature, which are essential in the development of multiterminal, covalent systems. Here, the dopant's main role is to create nanostructures whose properties emerge from those of the individual components. For instance, sulfur triggers

branching and initiates network creation but does not play a major beneficial role in the electronic transport properties of the resulting object.

Heteroatom Doping: Substitutional doping of carbon nanotubes and graphene clearly offers a practical path to tailor their physical and chemical properties by creating new states that modify their electronic structure [33]. The presence of these states, as discussed above, originates from the different electronic configurations of the doping atoms. These modifications in the electronic structure and surface reactivity can help to achieve new improved materials. Nitrogen and boron are among the most studied substitutional dopants used in nanotube research but phosphorus and phosphorus-nitrogen heteroatomic doping of carbon nanotubes have been successfully realized in experiments by using thermolysis of mixtures of ferrocene and triphenyl phosphine dissolved in benzylamine and ethanol. In order to fully understand the structure and properties of these new types of doped nanotubes, extensive electronic structure and transport calculations were used.

DFT calculations revealed an electronic band structure displaying the presence of localized (P) and semilocalized (PN) states around the doping atoms. In contrast to nitrogen, these states are normal to the nanotube surface and do not modify the intrinsic nanotube metallicity, and therefore semiconducting nanotubes remain so regardless of the doping. However, these electronic states behave as scattering centers for carriers with energies close to the localized state energy. Electronic transport calculations on pristine, nitrogen, phosphorus, and P–N doped nanotubes clarified the different effects of the dopants on their conductance. The dips observed in the quantum conductance (Fig. 8a) correspond to the localized and semilocalized states located around the doping atoms (Fig. 8b). The calculations of the quantum conductance on semiconducting zigzag nantubes showed that phosphorus doping do not modify their intrinsic

semiconducting behavior, as opposed to the effect observed for N-doped nanotubes. Phosphorus and PN doping in a (10,0) nanotube only creates bound and quasibound states around the phosphorus atom, which are dispersionless (flat bands in the band structure), and projected as sharp peaks in the density of states.

Due to the sp^3 hybridization, substitutional P atoms induce highly localized states which modify the chemical properties of the surface of carbon nanotubes. These sites have a strong affinity toward acceptor molecules. On the other hand, it was found that P–N co-dopants not only have a reduced affinity for acceptor molecules, but that the P–N bond can also accept charge, resulting in affinity toward donor molecules because of a partial positive charge at the phosphorus atom. For example, CO and NH_3 were found to adsorb only on PN-doped nanotubes, O_2 was adsorbed only on P-doped nanotubes, while NO_2 and SO_2 were adsorbed on both P- and PN-doped nanotubes. A natural bond orbital (NBO) analysis showed that the P atom has a very different chemical environment in P- and PN-doped nanotubes as a result of variations in charge and local bonding conditions.

The chemical changes at the localized electronic states affect its energy, resulting in different positions for dips in the conductance that are associated with them (Fig. 8c). SO_2 and CO cause only minor shifts in the conductance, while NH_3 causes the suppression of a conductance dip, and NO_2 and O_2 had similar effects in the conductance of P-doped carbon nanotubes. Since changes in the conductance at Fermi energy of about 10 % can be detected experimentally and, in particular, since modifications of the conductance slope near the Fermi energy can be an alternative for experimental measurements, the results of this study demonstrated the potential for a molecular sensor with identifiable selectivity that is based on P- and PN-doped carbon nanotubes.

Summary and Conclusions

At the nanoscale a number of new phenomena resulting from quantum effects and confinement, begin to dominate the processes governing the electron flow across the active device. Understanding those quantum effects is critical in the quest to develop new device concepts or novel mechanisms tuned to desired functionality and performance. Given the inherent difficulty in the integration of nanoscale systems like carbon nanotubes and graphene nanoribbons (e.g., controlled manipulation without agglomeration), into precise arrangements for devices, and the complexity in the assessment of the properties of these devices, a tremendous effort has been devoted in past years toward the development of theoretical methods and computational tools that make it possible to design and test new systems for desired and tailored characteristics. Realistic treatment of the fundamental properties of novel devices at the quantum mechanical level is now becoming a more routine task mainly due to accurate approaches such as density functional theory, nonequilibrium Green function formalism for electron transport in open-systems, and the advent of larger and more powerful computers. Extensive applications of these approaches are beginning to uncover new behavior in cabon-based materials that are uniquely suited for nanoelectronic applications.

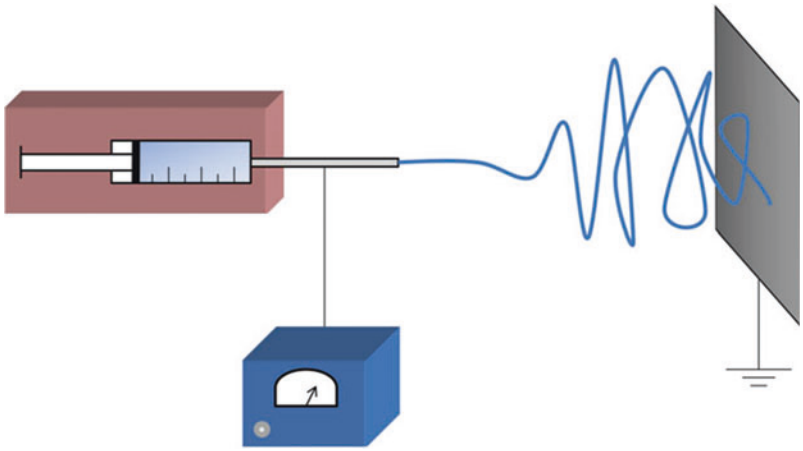
Definition

Electrospinning is a process to obtain polymer, ceramic, metallic, and composite fibers from solutions, dispersions, or melts as a liquid jet accelerates through an electric field.

Introduction

Electrospinning produces long fibers with diameters that range from tens of nanometers to several microns. Despite the nanoscale diameters, the fiber lengths can reach several meters. Figure 1 shows a typical scanning electron microscope image of randomly oriented electrospun nanofibers.

Electrospinning, Fig. 1 Electrospun fibers spun from a titanium butoxide sol–gel and polyvinylpyrrolidone solution



Electrospinning, Fig. 2 Three images showing droplet deformation and eventual fiber ejection as the electric field increases

While initial developments in the technique primarily dealt with polymers, further advances have demonstrated a diverse range of materials including ceramic, metallic, and composite systems. Additionally, this technique also provides control over the fiber structure and orientation.

The study of electrospinning begins with the field of electrohydrodynamics, which describes a range of phenomena that occur as liquids interact with electric fields. A single droplet when placed in an electric field deforms from a spherical droplet into an elongated Taylor cone [1]. With higher voltages, the droplet begins to eject fluid. Figure 2 shows three stages in droplet deformation as the electric field is increased. The droplet was formed from a highly viscous polyvinylpyrrolidone solution dissolved in water. Depending on the solution properties, two related phenomena occur: electrospraying and electrospinning.

Electrospraying forms discrete particles from nanometers to microns in diameter, whereas electrospinning forms long, continuous strands of fibers. However, a range of behaviors exists between these two extremes. In electrospinning, chain entanglements from high molecular weight polymers prevent the fluid from breaking apart. One of the great advantages of this process is that virtually any soluble polymer can be electrospun into nanofibers. As the strand accelerates through the field, it initially travels along a straight path. Due to instabilities in the electric field, its trajectory changes and the fiber whips around, spiraling toward nearby grounded surfaces. Although the study of electrohydrodynamics has existed for some time, electrospinning has only recently garnered much attention.

Electrospinning has several distinct advantages over other fiber processing techniques. Conventional fiber processing techniques are not readily capable of producing fibers with the nanoscale diameters that are characteristic of electrospun materials. Conversely, nanomaterial synthesis techniques can produce structures with similar diameters, but only at significantly shorter length scales. Furthermore, the electrospinning technique is applicable to an extensive range of material systems, while other nanomaterial growth methods are often highly specific to each material. The major drawback of the electrospinning technique is that the production rate of electrospun fibers is significantly slower than conventional techniques, typically on the order of milligrams per hour. Overall, the nanoscale dimensions and high aspect ratio of electrospun fibers creates many interesting avenues for research. The dimensions of these fibers

Electrospinning, Fig. 3 Typical laboratory scale electrospinning setup

greatly improve several of their properties such as porosity, surface area, and grain size (in the case of ceramic fibers). With these enhanced properties, electrospun fibers are applied to a number of disparate fields including filtration, cell growth, catalysis, energy storage and conversion devices, and hydrophobic surfaces.

Historical Developments in the Electrospinning Process

The first published use of the word electrospinning appeared in the literature in 1995. However, the study of charged fluids has existed for far longer. William Gilbert first published on the topic in 1600, where he describes the deformation of liquid droplets in an electric field [2]. Further insights into the field were reported by Lord Rayleigh who modeled the ability of charged fluids to eject liquid in 1882 [3]. The next major publications occurred in the 1964 by Sir Geoffrey Taylor. Taylor was the first to provide detailed descriptions of the deformation of liquid droplets [1]. To his credit, the distinctive shape of the deformed charged droplets has been given the name Taylor cones (or sometimes Gilbert-Taylor cones).

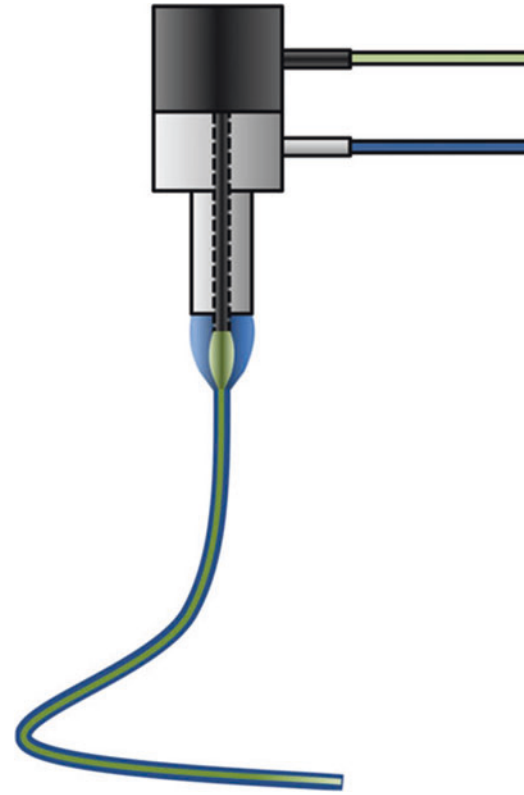
During this time, the industry also took notice of the field. Several important commercial developments in the field began in 1902. At this time, the US patent office recognized two methods for the dispersion of droplets via electrical means [4, 5]. Furthermore, in 1934, Anton Formhals patented the electrospinning process. Two years later, in 1936, the first commercial development of electrospun fibers began. I.V. Petryanov-Sokolov developed filters from electrospun fibers. Today, numerous companies currently manufacture electrospinning equipment and sell electrospun products.

Electrospinning Setup

Figure 3 shows a typical electrospinning setup. An advancement pump controls the flow rate of the polymer inside the syringe. Next, a power supply generates a charge on the liquid droplet. The electric field causes the droplet to deform and eject fluid. As the fluid travels, instabilities in the electric field cause the fiber to undergo a spiraling motion. This motion serves two purposes: It helps to thin the fiber, and it allows the solvent to evaporate prior to collecting on the substrate. The substrate is a grounded, conductive plate typically made from aluminum foil. Although this is the most commonly used setup, numerous modifications exist that can alter many of the properties of electrospun fibers.

Morphology of Electrospun Fibers

Porosity. As the fibers collect in randomly oriented meshes, the space left between fibers



makes a highly porous structure. This porosity is dependent on the fiber diameter, and any alignment techniques that are used. The high surface area exhibited by electrospun mats is also due to the porosity. It is also possible to achieve porosity within individual fibers. Two methods are commonly used to produce porous fibers. One method exploits phase separation in a composite polymer system. Selectively removing one of the polymers after phase separation leaves behind a highly porous structure. Carefully adjusting the solvent, humidity, and molecular weight can also lead to highly porous surfaces with specific polymer systems [6]. In both cases, the fibers themselves are in the micron range, while the pores are on the nanoscale.

Core-shell and hollow fibers. Sun et al. used a novel electrospinning apparatus consisting of concentric capillaries to produce core-shell fibers [7]. Figure 4 demonstrates a typical core-shell electrospinning apparatus. Separate tubes feed material into each compartment of the device. In this case, two different polymers are used. The same device is also used to form hollow fibers. Pumping an immiscible oil through the inner capillary and subsequently removing the oil leaves behind hollow fibers [8].

Beaded fibers. Not all electrospun nanofibers form flat, uniform surfaces. Under certain conditions, large droplets called beads form on the electrospun strands. Several factors influence bead formation: low viscosity, low electric fields, and high surface tension. Therefore, adjusting the solution concentration, solvent, and ions present in the system can greatly influence the presence of beads [9].

Ribbons. These fibers do not have the circular cross section that is characteristic of nanofibers. Under certain conditions, a volatile solvent can induce the formation of a skin on electrospun fibers. As the material dries, the tubular structure collapses in on itself forming flattened ribbon structures [10].

Branched fibers. Short branches protruding from the sides of the nanofibers are reported due to perturbations in the cross-sectional areas of the fibers in polycaprolactone dissolved in acetone. These structures occur more frequently with large diameter fibers produced from highly viscous solutions in strong electrical fields [10].

Electrospinning, Fig. 4 Device for core-shell and hollow fiber production

Aligned fibers. Several different techniques produce aligned electrospun fibers [11]. The techniques either use a novel collection device or modify the electric or magnetic field to prevent the whipping motion. In one method, a high-speed mandrel replaces the standard collection plate. The rotating motion aligns the fibers around the mandrel. Another modification to the collector is to create a long gap in the collection substrate. The conductive sides of the gap attract the fibers, and residual charges within the fibers repel other fibers leading to parallel arrays collecting across the gap. A final technique involves using a magnetic field to prevent the whipping motion of fibers.

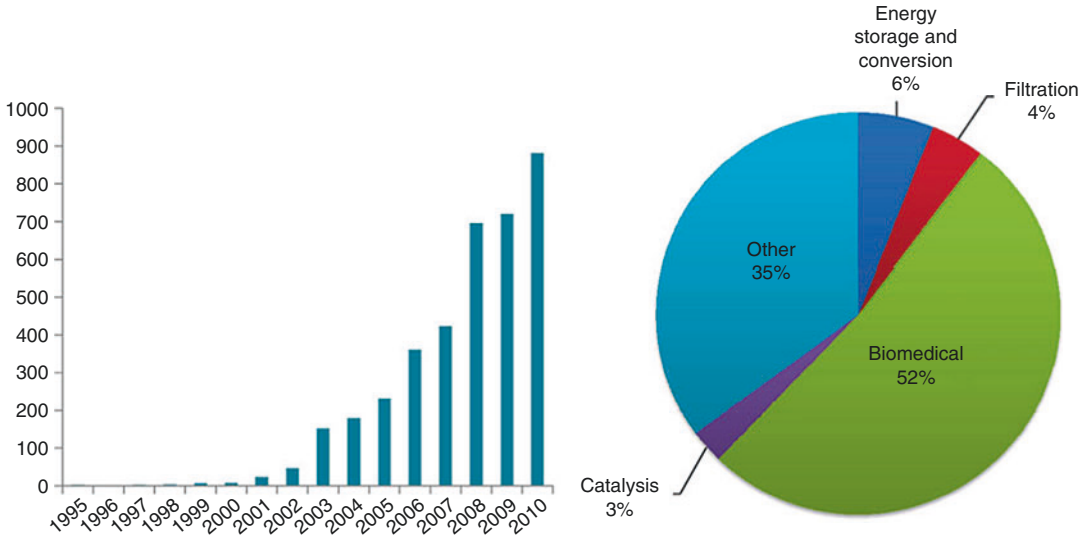
Methods to upscale production. The greatest limitation of the electrospinning process is the slow production rate. Increasing the fiber production output from a single needle is not possible.

However, it is possible to outscale the technique by assembling arrays of spinnerets in close proximity. This can result in numerous complications. Multiple spinnerets in close proximity cause electric field interference, which creates an uneven coating of fibers. Additionally, a single clogged needle in a large array could ruin the uniformity of the fiber mat. Several startup companies have begun developing other novel methods to increase fiber production. Some of these methods bypass the use of needles altogether. However, their efforts are beyond the scope of this entry.

Electrospun Materials

Polymers. The most frequently electrospun materials are polymers. Both synthetic and natural polymers are extensively reported for a variety of applications [12]. Due to the ability to use biocompatible materials and solvents, these materials are particularly interesting for biomedical and filtration applications. However, the electrospinning process is not limited to producing only polymeric fibers.

Ceramics. Several methods are able to produce ceramic fibers. The most common route to ceramic fibers is to incorporate a sol–gel material into a polymer. Heat treatments can burn out the polymer, leaving behind pure ceramic fibers. Similarly, incorporation of ceramic nanoparticles into electrospun polymer fibers followed by calcination is another pathway to ceramic fibers.



Metals. Only a few studies report purely metallic electrospun fibers. One method is to reduce ceramic nanofibers into metallic fibers. Another method uses electrospun fibers indirectly. Polymer nanofibers are coated in a thin metallic layer, and subsequently the polymer core is removed. This process leaves behind hollow metallic nanotubes. The potential advantages of metallic nanofibers for catalysis ensure that research into the area of metallic fibers will continue to expand.

Composites. As long as one of the materials is capable of being electrospun, the entire system will produce fibers. Due to this fact, a myriad of composite systems exist. These systems typically involve the incorporation of nanomaterials into the fibers. By carefully selecting the polymer and heat treatment conditions, the polymer can be turned into a carbon nanofiber support for the nanoparticles. Systems containing multiple polymers are also common. For the few polymers that prove intractable for electrospinning, a second polymer is often added creating a new composite system.

Analytical Models for Fiber Diameter

The unique properties of electrospun fibers stem from their nanoscale diameters. Therefore, it is of critical importance to understand the parameters that influence the fiber diameter. However, a complex relationship exists. The solution properties, Taylor cone shape and size, electric field, and whipping motion of the fiber all affect the fiber diameter. The solution properties (viscosity and surface tension) interact with gravity to form an equilibrium droplet shape. Appling an electric field deforms this shape and, at a sufficiently high voltage, ejects fluid from the droplet. Furthermore, adjusting the flow rate of the liquid through the capillary alters the size of the droplet. Finally, the radius of curvature as the jet whips toward the target further affects the final diameter.

Combining all of these terms, Fridrikh et al. proposed an analytical model to determine the final nanofiber diameter with an error of around 20 % for polymer fibers [13]. Equation 1 shows the relationship between the electrospinning parameters and the terminal fiber radius. The terminal radius depends on surface tension (γ), dielectric constant of the outside medium (ϵ), total current directed toward the lower electrode (I), radius of curvature divided by the diameter of the jet (χ), and flow rate (Q). This equation assumes that all solutions and voltages produce electrospun fibers, which is not the case. However, one can use the equation to determine which parameters have the greatest influence over the terminal fiber diameter. From the equation, it is apparent that flow rate and current are the most influential terms.

Electrospinning, Fig. 5 Electrospinning publications through 2010

$$r_{terminal} = \left(\gamma\varepsilon\frac{Q^2}{I^2}\frac{2}{\pi(2\ln\chi - 3)}\right)^{\frac{1}{3}} \quad (1)$$

Incorporation of ceramic precursors into polymer fibers greatly enhances the electrical conductivity by several orders of magnitude. For these highly conductive solutions, one must consider the conductivity due to the bulk charge and not limit the model to the surface charge alone. The high conductivity invalidates some of the critical assumptions in Eq. 1. Calcination further complicates the prediction of diameters in ceramic systems; fiber diameters shrink as calcination removes the polymeric material. However, the polymer loading and final fiber diameter is linearly related, and can be determined using a correction factor [14].

Properties of Electrospun Fibers

Mechanical properties. The mechanical properties of nanofibers can vary greatly depending on the materials involved and their processing conditions. The most common method to test fiber properties is to generate stress strain curves from large fiber mats. Measuring the properties of individual fibers is more challenging. To this end, several studies report various methods using atomic force microscopy measurements to determine the mechanical properties of individual fibers. The results of these studies suggest that the electrospinning process induces a molecular orientation within the samples, which increases the Young's modulus. The mechanical properties of ceramic fibers introduce special challenges. While polymer nanofibers are typically flexible, ceramic fibers are often extremely brittle. However, reports also exist of flexible ceramic fibers.

Applications and Publication Trends

Electrospinning applications span a range of diverse fields. Figure 5 shows the breakdown of publications according to their field from a title search on ISI web of knowledge. The first publications appeared in 1995, and the number of active researchers in the field has rapidly increased. The first publications in electrospun ceramic fibers appeared in 2003. Along with this development, publications in energy materials began to appear. The list of publications was categorized based on key terms relevant to each field. Papers that did not contain any of these terms are labeled "Other." This category includes research

into the fundamental concepts of electrospinning as well as modifications to the electrospinning setup to produce new structures and morphologies. The following sections outline how researchers utilize electrospun fibers in their respective fields.

Biomedical. Approximately half of electrospinning publications fall under the field of biomedical research. This is a broad area of research that comprises several subfields: scaffolds, wound healing, and drug delivery [15, 16]. Many biocompatible materials are electrospun for these applications. The porous nature of the fibers improves cell proliferation. Furthermore, by orienting the fibers, directed cell growth is possible. Drug delivery utilizes the high surface area to volume ratio of the fibers to increase the loading of drug molecules.

Energy materials. Recent developments in ceramic fiber processing have opened many new avenues in energy harvesting and conversion [17]. The one-dimensional structure of nanofibers confines grain growth, which can improve electrical conductivity. Researchers have assembled batteries, photovoltaics, hydrogen storage materials, capacitors, thermoelectric, and fuel cells from electrospun nanofibers. Some of these devices also make use of polymer fibers such as battery and fuel cell membranes.

Filtration. The highly porous network created by electrospun fibers makes them interesting filtration materials. As air flows through filters, there is a change in pressure. Higher drops in pressure require more energy to force air through the filtration devices. Assembling filters from thinner, uniform fibers, reduces the pressure drop, which lowers the energy requirements to force air through the filters. While most nanofilters are assembled from polymer fibers, ceramic fibers are also investigated due to their chemical and thermal stability [18].

Catalysis. The interconnected structure of electrospun fibers coupled with their high surface area makes electrospun fibers interesting catalyst materials. The connected fiber structure allows facile recovery of the catalytic material. Researchers have explored several methods to use nanofibers in catalysis. The most straightforward method is to embed catalytic nanoparticles in a polymer support material. Other studies have explored photocatalysis using ceramic fibers. Finally, a few researchers have heated polymer fibers embedded with metal salts to produce purely metallic nanofibers [19].

Super hydrophobic surfaces. Water repellent surfaces have many potential industrial applications, particularly due to the self-cleaning effect observed in super hydrophobic surfaces (surfaces with a water contact angle $>150^\circ$). A combination of high surface roughness and chemistry is necessary to achieve super hydrophobicity. By carefully controlling the morphology of electrospun fibers, a variety of super hydrophobic materials are reported [20]. These fibers often make use of the multiple scale of surface roughness created from beaded fibers.

Outlook

Electrospinning is an incredibly versatile nanomaterial processing technique. Using this technique, researchers can generate a wide range of materials and nanostructures from relatively simple, inexpensive equipment. These materials have the potential to purify air, heal wounds, deliver drugs, catalyze reactions, and produce and store clean energy. The full potential of electrospinning is just starting to be realized. As novel techniques are developed to enhance the output of electrospun fibers, industrial usage of the technique will increase. Further developments in this field will continue to unlock the potential of this technique to solve important scientific challenges.

Electrostatic MEMS Microphones

Neal A. Hall
Electrical and Computer Engineering, University of Texas at Austin, Austin, TX, USA

Synonyms

MEMS capacitive microphone; MEMS condenser microphone; MEMS microphone; Silicon microphone

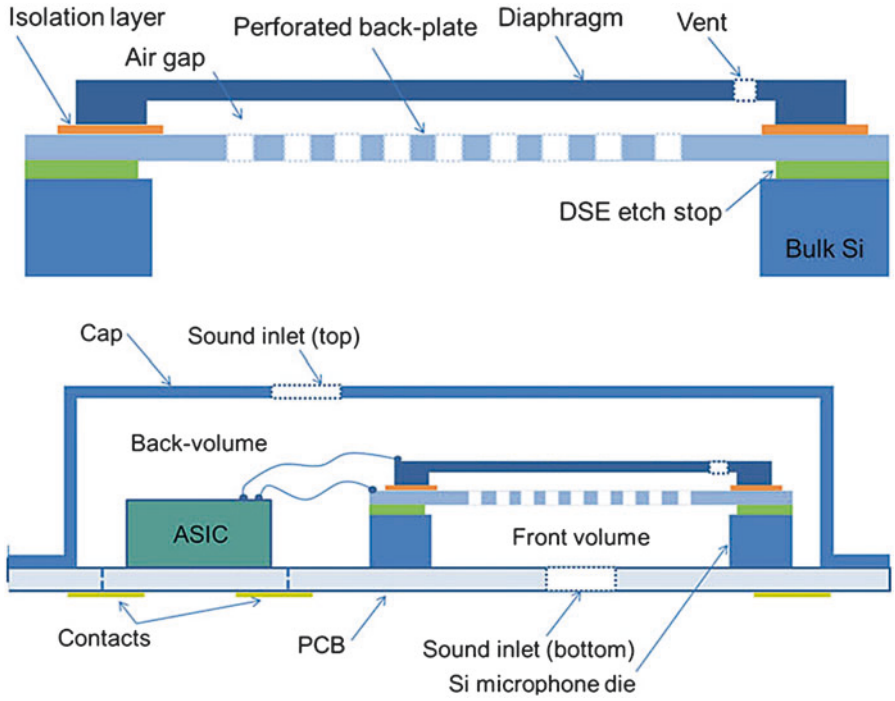
Definition

A microphone fabricated using surface and bulk silicon micromachining techniques and operating on the principle of a variable capacitance.

Applications and Background

Electrostatic MEMS microphones, like their larger counterparts, convert pressure waves in air into electrical signals. MEMS microphones were successfully commercialized in 2003 and began

competing with electret condenser microphones (ECMs) in consumer electronic device markets, most notably in cellular phones. Compared to ECMs which use heat-sensitive electret foils, MEMS microphones have a critical advantage in that they can withstand high temperatures encountered in standard lead-free solder reflow cycles used in automated pick and place manufacturing, and this in turn results in significant cost savings to system integrators [1]. Since their entry into the market, electrostatic MEMS microphones have become one of the highest growth areas for MEMS, growing from less than 300 million units shipped in 2007 to over one billion units shipped in 2011 [2]. Today many major semiconductor companies manufacture and sell electrostatic MEMS microphones including Knowles, Analog Devices, Infineon, and ST Microelectronics. The top four buyers of MEMS microphone in 2011 were Apple, Samsung, LG, and Motorola [3]. Apple's iPhone 4 product alone contains three electrostatic MEMS microphones – two in the body of the phone and a third in the mobile headset.



Operation and Construction

Field variables used to characterize sound include both pressure and particle vibrations. Although some new techniques attempt to measure particle velocity directly [4], the vast majority of microphones including electrostatic MEMS microphones are constructed as dynamic pressure sensors. Generally speaking, the range of sound pressures of interest in most applications is as low as 200 μPa root mean squared (rms) (20 dB) and as high as 10 Pa (114 dB). Electrostatic MEMS microphones must detect these small pressure signals in the presence of a large "DC" background atmospheric pressure, approximately 100 kPa. The frequency range typically of interest is the audio bandwidth, 20 Hz–20 kHz, although only recently have commercial models of MEMS microphones approached these limits. The corresponding wavelength range is 17 m–17 mm. For most of this range, MEMS microphones packages are significantly smaller than the wavelength of sound being measured.

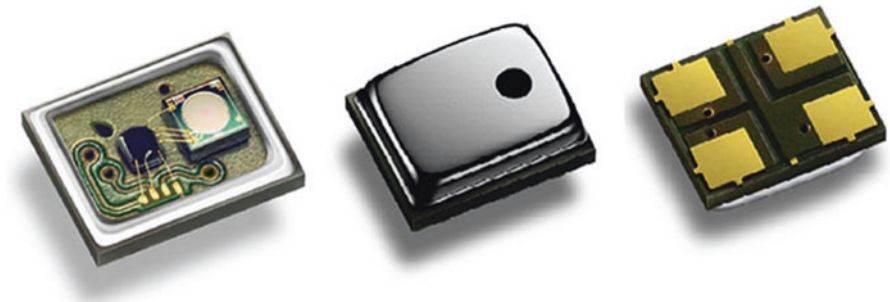


Figure 1 details important features of a silicon microphone die and also a complete surface mount electrostatic MEMS microphone package. Referring to the top image, a compliant, pressure-sensitive diaphragm is suspended over a rigid and perforated backplate to form a variable capacitor. When sound pressure is applied to the diaphragm, the diaphragm moves vertically and the resulting change in the parallel-plate capacitance is detected. The capacitive structure must be electrically biased and loaded with charge, and the high output impedance of the signal must be buffered with an amplifier. These features are implemented by a small application specific integrated circuit (ASIC) as shown in Fig. 1 bottom. To sense sound pressure effectively, one side of the diaphragm must be exposed to the incoming sound pressure while the opposing side must be sealed off from the environment. A common package to accomplish this is also shown in Fig. 1. The MEMS die and ASIC are both mounted on a common printed circuit board (PCB) which contains a small opening on the bottom surface to let sound pressure in. A sealed back volume is created by a cap mounted directly to the PCB. Electrical vias through the PCB lead to contacts on the bottom side to create a complete surface-mountable package.

As a variation to the system shown in Fig. 1 (bottom), the sound inlet is sometimes placed on the cap rather than the PCB to form a "top-inlet" configuration. A second common variation found on the MEMS die is a backplate fabricated above rather than below the diaphragm. Photographs and SEMs of a commercial electrostatic MEMS microphone that implements both of these variations are presented in Figs. 2 and 3, respectively. In the center image of Fig. 2, one can observe the sound inlet on the cap of the device. The SEMs in Fig. 3 highlight the perforated backplate suspended approximately 2 μm above the pressure sensitive membrane.

A final important feature to note in Fig. 1 is the presence of a small low-frequency vent, most commonly fabricated into the microphone diaphragm. The vent provides the device with a high flow resistance leakage path enabling sound pressure to bypass the diaphragm and reach the back volume. This feature creates a lower limiting frequency and prevents the diaphragm from

Electrostatic MEMS Microphones, Fig. 2 Photographs of a commercial MEMS microphone. This device has a footprint of 4.72 × 3.76 mm and a profile of 1.25 mm. The image at *left* is with the cap removed and shows details of the PCB, ASIC, and MEMS die. The figure at far *right* shows the electrical contacts on the *bottom* of the package that interface with a customer's system (Images borrowed courtesy of Infineon and first appearing in Ref. [5])

deforming and responding to DC atmospheric pressure and low-frequency barometric pressure fluctuations, which are orders of magnitude larger than the audible sound pressures that the device is designed to sense.

Although Fig. 1 presents the most common construction of MEMS microphones, single-chip architectures have also been demonstrated combing the MEMS capacitive sensing structure with the CMOS electronics on the same die. At least one commercial embodiment of this approach exists. Figure 4 below presents a photograph of a microphone made by Akustica (acquired by Bosch in 2009) in which one can observe the pressure-sensitive diaphragm structure along with electronics. The total die size is

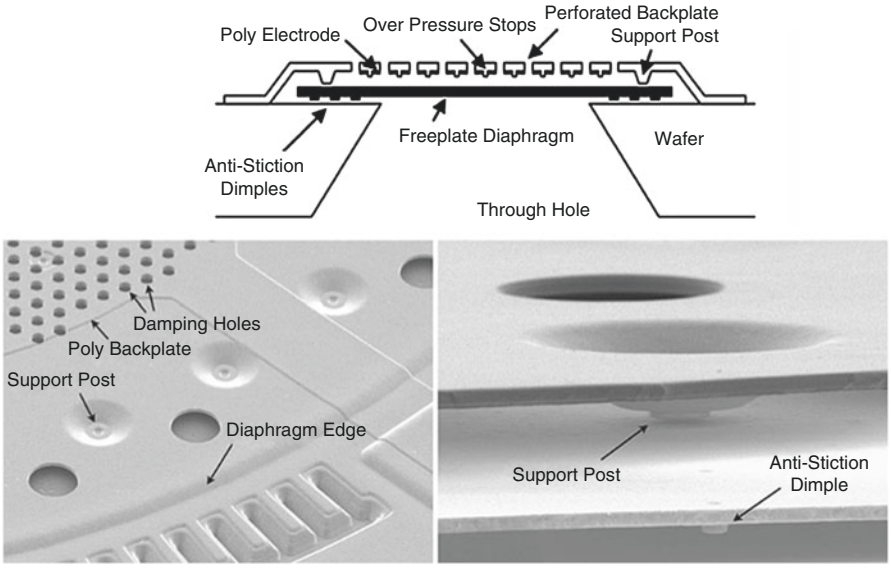
Electrostatic MEMS Microphones, Fig. 4 Micrograph of a single-chip electrostatic MEMS microphone made by Akustica. The sensing diaphragm can be seen in the center of the structure. This die measures approximately 1 × 1 mm (Image borrowed courtesy of Akustica, Inc. [6])

1 × 1 mm. An obvious advantage of this approach is size, with space being a premium in small consumer electronic devices (e.g., cell phones and laptop computers). A second advantage cited is potentially lower per unit cost. The MEMS structure is fabricated in layers already required in the CMOS process, so only few additional processing steps are required for the MEMS. The peripheral packaging requirements are also reduced. A third advantage cited is electronic design flexibility owing to the proximity between the sensing capacitance and the electronics, which reduces parasitic capacitance associated with bond pads and wire bonds that are otherwise required to route signals to off chip electronics as shown in the two-chip embodiment of Fig. 1. This proximity may also be advantageous for shielding against electromagnetic interference created by neighboring electronics in consumer products.

Transduction Principle

The variable capacitance transduction principle is presented in Fig. 5. The capacitive sensing structure is biased through a high impedance resistance, R_L, shown at left. Electrostatic forces pull the diaphragm in toward the backplate to create a standoff distance h_o typically between 1 and 2 μm and a nominal parallel-plate capacitance C_o. A phenomena known as electrostatic collapse of the diaphragm limits the bias voltage that can be applied [7], which is typically in the range of 2–11 V and depends on the design [1]. The instantaneous voltage across the parallel-plate capacitor is given by $v = q/C = qh/(\varepsilon_{oA})$, where C is the instantaneous capacitance, q is the instantaneous charge, h is the instantaneous backplate-diaphragm standoff distance, and A is the area of the structure. Small diaphragm vibrations create small changes in h, and the resulting small signal voltage generated about the bias point is therefore $dv = q_o/(\varepsilon_{oA}) \quad dh = (v_{bias}/h_o)dh$. The output impedance associated with the small signal voltage is the device capacitance itself, C_o, and the small signal equivalent circuit is that shown in Fig. 4 (right), with dh replaced by the product of the incoming acoustic pressure $P(j\omega)$ and the mechanical sensitivity of the device, $S_m(j\omega)$, defined below.



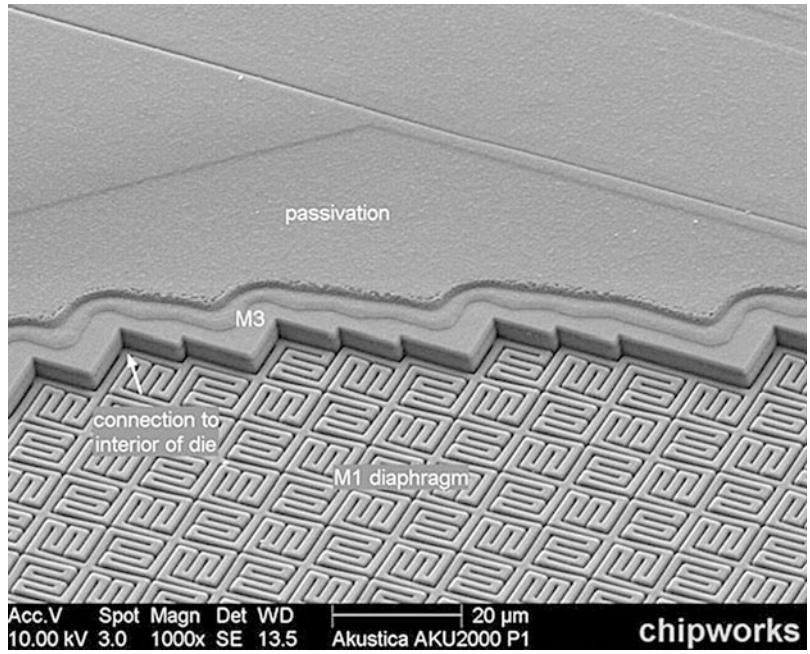
Electrostatic MEMS Microphones, Fig. 5 (*Left*) Circuit schematic for biasing an electrostatic MEMS microphone and measuring changes in capacitance, and (*right*) small signal equivalent circuit about the bias point

vb_{ias}/h_o is commonly referred to as an electrical sensitivity and has units of volts per meter of diaphragm displacement. It is also the electric field in the diaphragm-backplate gap created by application of the bias voltage. $S_m(j\omega)$ is a transfer function relating the displacement of the diaphragm to incoming sound pressure. As shown in Fig. 5 right, the small signal voltage generated is the product of the incoming pressure phasor and the electrical and mechanical sensitivities. The small capacitance of the device creates a high output impedance, and v_{out} in Fig. 4 is therefore followed by an amplifier with high input impedance such as a JFET [8]. Digital microphones are also common, in which case the buffered analog output is followed by a sigma-delta analog to digital converter.

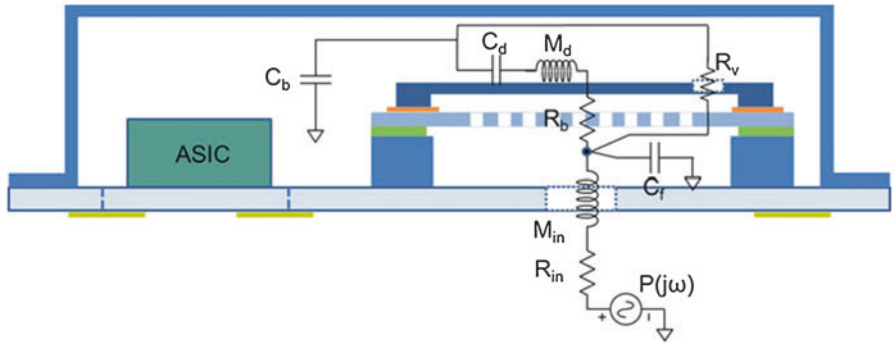
Microfabrication of Sensing Structure

The structure shown in Fig. 1 (top) can be fabricated using many different fabrication process flows with many options for materials. Almost all electrostatic MEMS microphones use thin surface micromachined layers for the backplate and diaphragm, and a deep silicon etch (DSE) bulk micromachining step to form the front volume. The surface machined layers are typically between 100 nm and 2 μm thick. Figure 1 (top) suggests a simple fab flow option, in which the first step is to deposit or grow a material with high selectivity against a silicon deep reactive ion etch (DRIE) process, such as silicon dioxide. The first structural layer is then deposited and patterned to form the backplate. Polysilicon is a common material choice. A thin isolation layer (commonly silicon nitride) is deposited and etched to provide electrical isolation between the diaphragm and backplate, followed by deposition and etching of the sacrificial layer to form what will become the air gap. Low temperature oxide (LTO) and TEOS oxide are common choices for the sacrificial layer. After deposition and patterning of the diaphragm, which is commonly formed using polysilicon, the surface steps are completed and the device is etched through the silicon wafer from the opposing side up to the DSE etch stop. Both isotropic etches (e.g., DRIE) and anisotropic wet etches (e.g., KOH) are used in commercial versions of the technology [1]. The sacrificial layer(s) at the surface are then removed and the wafers are diced to realize completed die. Some commercial processes use a silicon on insulator (SOI) wafer as a starting point and use the epitaxial Si layer for formation of the microphone backplate [9].

As electrostatic MEMS microphones continue to mature into commercial device applications, several innovations at the microfabrication level continue to be driven by reliability and device-to-device repeatability criteria. For thin (1–2 μm thick) clamped diaphragms employed in MEMS microphones, even small residual film stress resulting from the deposition process can have a major influence on the compliance of the sensing diaphragm which in turn directly affects the total sensitivity of the device measured in volts/Pa. Controlling film stress in microfabrication processes to ensure device-to-device repeatability has practical limitations. Further, changing environmental conditions (e.g., temperature) can affect sensitivity output of a single device during the course of day-to-day operation. This has motivated the development of innovative structures designed for immunity of output sensitivity to these variations. Figure 6 presents a device by Knowles in which the sensing diaphragm is not clamped, but rather is freely floating until pulled into contact with the support posts by electrostatic forces upon biasing. By allowing the diaphragm to float freely rather than clamping and anchoring it to the substrate, zero diaphragm tension is achieved regardless of film stresses introduced in the deposition process. The free plate design is achieved by completely surrounding the plate with sacrificial layers rather than anchoring it to the substrate during the processing sequence.



Electrostatic MEMS Microphones, Fig. 6 A schematic and SEMs highlighting a free diaphragm design by Knowles (Image borrowed courtesy of Knowles Acoustics and originally appearing in Ref. [1])

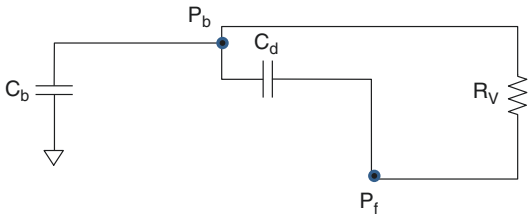


The sensing membrane in the single-chip microphone developed by Akustica is made using metal interconnect layers that are already part of standard CMOS processes [10]. Specifically, a metal layer is patterned to form a perforated screen which becomes buried in oxide layers during the subsequent CMOS processing steps. Upon completion of the CMOS process flow, the oxide on top of the wafer is etched down to the screen. The perforations in the screen then allow silicon etchant to reach the Si wafer beneath the screen to create a cavity behind the screen. This cavity is analogous and identical in function to the back volume labeled in Fig. 1. To create a sealed diaphragm, a conformal polymer is deposited to fill the screen perforations. Figure 7 shows an SEM of the metal screen layer forming the diaphragm. The interesting serpentine pattern of the screen in this design is aimed at removing bowing due to stresses inherent in the metal.

Dynamic Model of Package

More so than many other MEMS and Nanosystems, packaging has a profound effect on the overall dynamics of electrostatic MEMS microphones. The use of impedance-based network analogies such as the one presented in Fig. 8 are pervasive in the study of MEMS microphones [11]. Such models are based on the observation that acoustical and mechanical systems obey rules analogous to Kirchhoff's voltage and current laws. In acoustical impedance networks, pressure is a node variable and the sum of pressure drops across elements in a closed loop is equal to zero. Similarly, volumetric flow of air entering and leaving nodes in the network is conserved. In such models, acoustic pressure is a potential or effort variable and therefore analogous to voltage in electrical circuits. Acoustic volume velocity (with units of m^3/s) flows through various elements in the circuit and is therefore analogous to current. Cavities or volumes in acoustical systems have the ability to store potential energy by storing compressed air and are analogous to capacitors in electrical networks, while small inlets and outlets force air to accelerate upon passage through and therefore store energy by virtue of momentum, analogous to an inductor in an electrical network. Similarly, the mechanical compliance and mass of the diaphragm are represented by capacitors and inductors, respectively, with appropriately computed values. The backplate resistance R_b plays a dominant role in shaping the frequency response of the system and also in the noise analysis as

Electrostatic MEMS Microphones, Fig. 7 SEM showing the diaphragm layer and anchoring in Akustica's CMOS microphone (Image borrowed courtesy of MEMS Investor Journal, Inc. and Chipworks)



Electrostatic MEMS Microphones, Fig. 8 Network model superimposed on the physical package schematic to emphasize the important package dynamics in electrostatic MEMS microphones

discussed below. R_b is a flow resistance generated by the movement of air through the backplate perforations as the diaphragm vibrates relative the stationary backplate. Network models provide a way to combine mechanical, acoustical, and electrical features of the device into a unified model that can be simulated with common circuit simulator tools such as SPICE.

Figure 8 presents a common network model superimposed on the physical device structure. Subscripts *in*, *f*, *b, d* and *v* refer to elements associated with the inlet, front cavity, back cavity, diaphragm, and vent, respectively. The $S_m(j\omega)$ transfer function referenced in Fig. 5 relating an incoming pressure phasor to motion of the diaphragm may be modeled and computed based on the network model in Fig. 8.

Insight into the dynamics of the complete package arises from analysis of the network model in the low-frequency limit, the pass band, and near the fundamental resonance of the system. The model makes clear how the vent feature represented by R_v creates a lower limiting frequency by creating a low-frequency bypass around the diaphragm compliance C_d. To see this further, the section of the model relating the

Electrostatic MEMS Microphones, Fig. 9 Section of the low-frequency equivalent circuit of Fig. 8 relating the front volume pressure to the back volume pressure

front cavity pressure, P_f, to the drive pressure across the diaphragm ($P_f - P_b$) is shown in Fig. 9. A low-frequency approximation is shown and M_d and R_b are therefore not included.

For microphones packaged as shown in Fig. 8, C_b is often significantly larger than C_d. The low-frequency response of the microphone is then characterized by a simple first-order high-pass filter, with a zero at $\omega = 0$, and a pole or break frequency at $\omega = 1/(R_v C_b)$, above which the microphone operates in a flat band with $S(j\omega)$ dominated by the series compliance $C_b + C_d$. A fundamental resonance of the system characterized by two complex conjugate poles is common of electrostatic MEMS microphones. This LRC type resonance arises from the series combination of the inertial elements $M_d + M_{in}$, the compliance elements, $C_d + C_b$, and the loss elements $R_b + R_{in}$. This fundamental resonance is typically designed to be close to or above the desired upper limiting frequency of the microphone.

Dominant Noise Sources, dB(A) Weighting, SNR Definition

Signal-to-noise ratio is an important figure of merit for small acoustic transducers, defining the realm of applications in which a particular device technology is suited. Noise floors for electrostatic MEMS microphones are most meaningful when referred to an input pressure level. The input-pressure-referred-noise spectrum is commonly integrated using an A-weighted filter which takes into account the frequency response of a healthy human ear. The sound pressure level (SPL) of the A-weighted rms pressure level is computed and a dB(A) noise level is reported for the device. Common noise levels for MEMS microphones are around 34 dB(A). Often a signal-to-noise ratio (SNR) is reported, and in these cases the convention is to assume a 1 Pa rms, or 94 dB SPL, input. SNR is then defined by the following expression: SNR = 94 dB − A weighted noise. Additional performance-based figures of merit for MEMS electrostatic microphones include dynamic range, upper limiting frequency, and lower limiting frequency.

Scaling Challenges for Small-Scale Electrostatic Microphones

Electrostatic MEMS microphones face challenges in achieving low noise floors, and this has limited their ability to address applications such as hearing aids which require noise floors in the 20–25 dB (A) range. A fundamental noise limit in miniature microphones is thermal-mechanical noise due to the dissipative mechanisms in the acoustical and mechanical parts of the system [12]. In particular, the backplate resistance R_b labeled in Fig. 5 generates a thermal-mechanical pressure noise contribution that is seen at the input of the device across the pass band of operation and therefore impacts the input-pressure-referred noise directly. P_{tm}, the thermal-mechanical noise due to the mechanical flow resistance R_b, can be computed as:

$$P_{tm} = \frac{1}{A_d}\sqrt{4k_bTR_b} = \frac{1}{A_d}\sqrt{4k_bTR_{ba}A_d} \propto \sqrt{\frac{R_{ba}}{A_d}} \propto \frac{\sqrt{R_{ba}}}{a}$$

where k_b is Boltzmann's constant, T is the ambient temperature, A_d and a are the area and radius of the diaphragm and backplate (assumed to the same), and R_{ba} is the mechanical flow resistance per unit area. R_{ba} is a function of the perforation ratio and perforation geometry [13] but not the size of the backplate itself since R_{ba} is defined on a per unit area basis. For a given backplate design, decreasing the diaphragm radius by a factor of 2 results in a doubling (i.e., 6 dB) in the input-referred thermal noise limit. While backplates can be redesigned to achieve lower R_{ba}, this path faces practical limitations as higher perforation ratios reduce the total active capacitance of the device. Further, the lack of damping in the system can

result in an undesirably high resonance Q (i.e., small damping ratio) at the fundamental resonance of the system discussed above. In the pass band, the device behaves as a second-order system with a damping ratio:

$$\varsigma = \frac{R_{ab}A_d}{2M\omega_n} \propto \sqrt{\frac{R_{ba}}{\rho t \omega_n}}$$

where M is the combined inertia of the diaphragm and sound inlet, ω_n is the fundamental radial natural frequency of the system, and ρ and t are the density and thickness of the diaphragm. Within limits dictated by fabrication robustness, the latter two variables provide a means for achieving a desired damping ratio for an R_{ba} predetermined by noise considerations.

In addition to the above mechanical and acoustical scaling considerations, the lower cutoff frequency of the microphone may also be limited by the high-pass nature of the small signal electrical circuit shown in Fig. 5 (right). This electrical filter is independent of the lower limiting frequency inherent to $S_m(j\omega)$ discussed above due to the package dynamics. For a given bias resistor, the lower limiting frequency of the microphone will increase with reduced device capacitance. Although in principle GΩ bias resistors can be used, preventing leakage across such elements amid all required environmental operating conditions can prove challenging.

Other Techniques and Future Directions

Other types of MEMS microphones include piezoelectric and optical. The former have shown to be advantageous for special applications demanding high linearity and high dynamic range (e.g., aero-acoustic measurement arrays and sensors for wind tunnel testing) [14], while recent work with the later work aims to achieve significantly lower noise floors than that achievable with electrostatic MEMS microphones [15]. Active research is also aimed at demonstrating designs that are inherently directional. An innovation inspired by the directional hearing mechanism of a special parasitoid fly has recently been demonstrated [16]. Until recently, little attention was given to SNR as an important parameter for MEMS microphones in the consumer electronics commercial sector. Recently, however, manufacturers of electrostatic MEMS microphones have started introducing lower noise models, with the lowest noise models to date having input-referred noise levels equal to 29 dBA. This may be driven by a recent trend in smartphone applications: the use of multiple microphones in a single product for implementation of ambient noise cancelation algorithms. As a significant departure from traditional close-talking voice input, hands-free and headset-free application modalities may continue to drive performance increases and new innovations for electrostatic MEMS microphones.

Definition

Making a surface more wetting to a liquid by applying voltages.

Introduction

When a material (typically solid) and a liquid are in contact, the application of an electric potential between them may cause the wettability of the material to increase, which is exhibited by a decrease of the observed contact angle. This phenomenon is called electrowetting – a term reminiscent of the more traditional electrocapillarity. In recent years, the development of various electrode and material configurations for technological applications – mostly in the rapidly expanding field of microfluidics – has given rise to additional terms such as electrowetting-on-dielectric (EWOD). Because technologies relying on the actuation of liquids by applied electrical potentials are still new, the terms used to describe such systems can be difficult to delineate. It will therefore be helpful to introduce a few terms related to electrowetting with a little bit of the history and theoretical background behind each of them. While the basic approaches to utilizing the electrowetting phenomenon to obtain physical results are presented here, applications of electrowetting to manipulate droplets or to develop devices

Electrowetting, Fig. 1 Comparison between electrocapillarity (**a**) and electrowetting (**b**), drawn to maintain the original configurations presented by Beni and Hackwood [2]. and systems are deferred to other related entries as well as other works referenced later in this entry.

Electrocapillarity and Electrowetting

A typical liquid (e.g., water) rises in a vertical glass capillary against gravity by the intermolecular attraction between the liquid and the inner wall of the capillary. A terminal height is reached when the gravity of the liquid column equals the attractive force or, more precisely, the vertical component of the liquid-air interfacial tension. The vertical component is larger if the liquid wets the glass surface better (e.g., the surface is clean). The degree of wetting is expressed by the contact angle θ of the liquid on the solid surface by the Young equation:

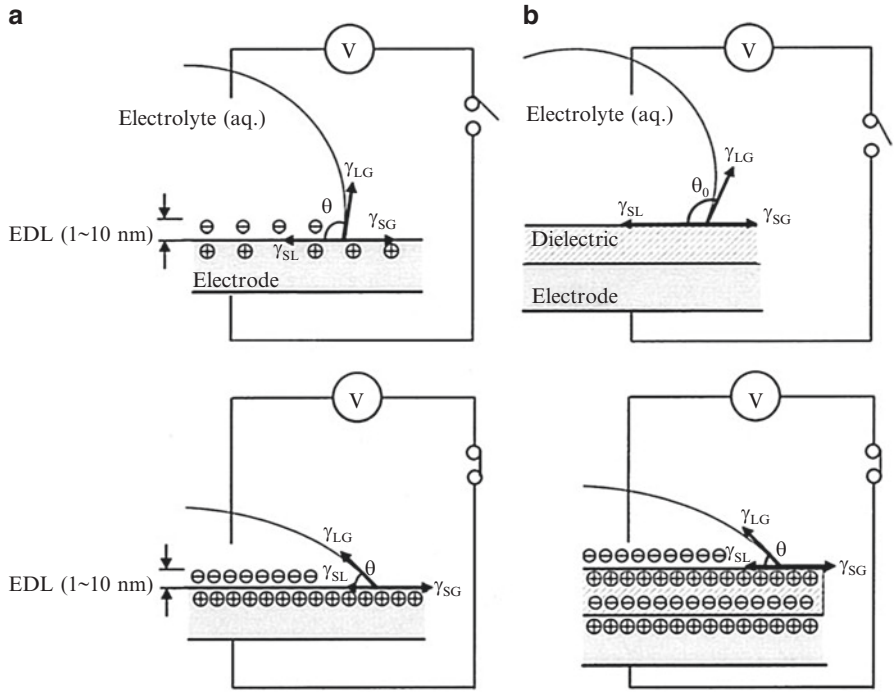
$$\gamma \cos\theta = \gamma_{sg} - \gamma_{sl} \tag{1}$$

where γ, γ_{sg}, and γ_{sl} are the interfacial energy (or interfacial tension, surface tension) between liquid and air (gas), solid and air, and solid and liquid, respectively. On the other hand, if the liquid does not wet the glass (e.g., mercury), i.e., the contact angle is greater than 90°, the liquid falls down in the capillary. A terminal falling depth against gravity is determined by the surface tension and the contact angle.

In 1875, Gabriel Lippmann showed that a mercury column in a glass capillary, which is dipped into an electrolyte bath, rises or falls when a voltage is applied between the mercury and the electrolyte [1]. This experiment, which is called the Lippmann electrometer, demonstrated that the interfacial tension between the mercury and the electrolyte is a function of the electric potential across the interface. Perhaps termed originally to depict the initial experimental configuration involving a capillary tube, *electrocapillarity* nevertheless describes a general phenomenon of interfacial energy changing by electric fields.

In 1981, Beni and Hackwood [2] introduced the term *electrowetting* to describe a manifestation of electrocapillarity that occurs when the configuration of materials and electrodes is somewhat different than that of the classical Lippmann electrometer. Specifically, in the traditional electrocapillarity measurement, voltage is applied between a metallic *liquid* (i.e., mercury) and an aqueous liquid (i.e., electrolyte), while both materials are surrounded by an insulating *solid* (i.e., glass capillary). For electrowetting, on the other hand, voltage is applied between a metallic *solid* and an aqueous liquid surrounded by an insulating *fluid* (e.g., air or oil). Figure 1 schematically illustrates these two phenomena, which operate under the same general principle but are distinguishable by how the materials are configured.

Readers may realize that, despite their apparent differences, electrocapillarity and electrowetting describe essentially the same principle. One can do a mental exercise that involves dictating phase changes of a given material. Rotate Fig. 1a 90° clockwise; remove the right dielectric solid and convert the left dielectric solid into a fluid (i.e., vapor or liquid); and convert the liquid metal into a flat solid metal and duplicate it at the bottom. Now one has Fig. 1b. So, the two terms describe one phenomenon depending on the users' focus of interest. If the interest is a liquid column moving in a solid capillary, electrocapillarity describes the phenomenon well. If the interest is how well a liquid wets a solid surface, e.g., what is the contact angle, electrowetting is a better description.



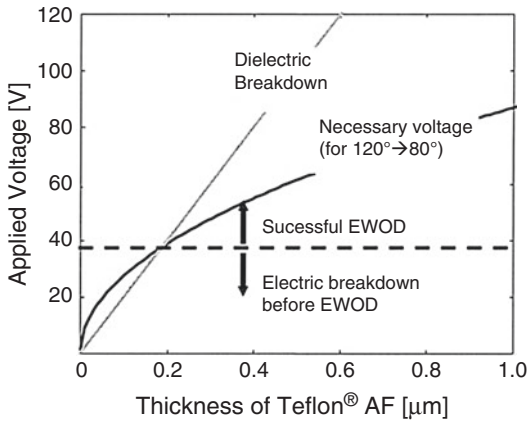
Some readers may raise another question, however. There exists a contact angle of the liquid electrolyte on the solid surface in the electrocapillarity of Fig. 1a, and there exists a column of the liquid electrolyte in a metallic capillary in the electrowetting of Fig. 1b. The confusion may be avoided if one notes that the main interest should be in the interface across which the electric potential is applied. In Fig. 1a, the liquid-liquid interface, across which the voltage is applied, travels in a capillary, exhibiting capillary action. In Fig. 1b, the solid–liquid interface, across which the electric potential is applied, forms a contact angle, exhibiting wetting.

Electrowetting and Electrowetting-On-Dielectric (EWOD)

Historically, for both the electrocapillarity and the electrowetting phenomena, the main interest was the interface between an aqueous liquid and a metal. Whether the metal was a liquid (for electrocapillarity) or a solid (for electrowetting), the electric double layer (EDL) at the interface played a critical role. Since the underlying mechanism for both phenomena was that the free interfacial energy can be modulated by increasing or decreasing the capacitive energy stored at the EDL via an electric potential across it, the mechanism would be valid only while the EDL functions as an insulating capacitor, i.e., below ~1 V range in practice. An applied voltage above such a limit would induce electrochemical reactions, such as electrolytic gas generation, and alter the surface. In the case of electrowetting, it was difficult to induce contact angle changes large enough to be useful without degrading the surface. Promising utilities were limited to the case of a liquid metal in an electrolyte-filled capillary, e.g., [3, 4].

Building on the findings of Minnema et al. [5], in 1993 Berge [6] reported that it is possible to perform electrowetting on a dielectric material when it is placed (as a solid film) between the liquid and the electrode. In a nutshell, the dielectric film functions as the primary energy-storing capacitor, thereby serving the same function as the EDL in conventional electrowetting. Since it required a very high voltage for electrowetting to be noticeable on an insulator, it is fitting that the first such observation was made during investigations of "water trees" (degradation structure grown in a polymer due to humidity and an electric field) in high-voltage cables [5]. Several kV were commonly used in the early reports. Since reducing the operating voltage range was simply a matter of making the dielectric layer thinner and of higher quality materials, the thin-film techniques of microelectromechanical systems (MEMS) played a timely role in helping experimenters reduce the dielectric thickness from the millimeter range [5, 6] to the micrometer range [7]. To distinguish it from the conventional practice of electrowetting on a metal surface and because it provided unprecedented viability for practical applications, Lee [8] and Moon et al. [7] named this new material configuration electrowetting-on-dielectric (EWOD). Figure 2 compares EWOD with conventional electrowetting.

Although a significantly higher voltage is necessary to charge the dielectric capacitor of EWOD than the EDL of electrowetting in order to obtain the same degree of wetting, much higher voltages can be applied to the dielectric for additional wetting. In other words, a larger contact angle change can be achieved with EWOD by allowing high voltages, whereas conventional electrowetting is severely limited by the small breakdown voltage of the EDL. Figure 3 explains the



Electrowetting, Fig. 2 Electrowetting and EWOD [7]. (**a**) Illustration of conventional electrowetting. *Top*: With no external voltage applied, charges are distributed at the electrode-electrolyte interface, forming an EDL. *Bottom*: With an external voltage applied, charge density at EDL changes, and the contact angle decrease or increase. (**b**) Illustration of EWOD. *Top*: With no external voltage applied, there is little charge accumulation at the interface. *Bottom*: With an external voltage applied, charge accumulates at the interfaces, and the contact angle θ decreases

trade-off between dielectric thickness and operating voltage in EWOD, and why it is advantageous to use EWOD (compared to conventional electrowetting) despite the relatively high voltages that are needed. The thick solid curve in the figure shows that the voltage required to induce a specified increase in wetting (i.e., a reduction of contact angle $\Delta\theta$) is proportional to the square root of the thickness of the dielectric layer for a given dielectric material (Teflon AF is assumed in the figure), while the thin solid straight line shows that the breakdown voltage of the dielectric layer is proportional to the thickness. For successful operation, the electrowetting voltage should be smaller than the breakdown voltage. Although the required voltage continues to increase with the dielectric thickness, the margin of safety increases as well.

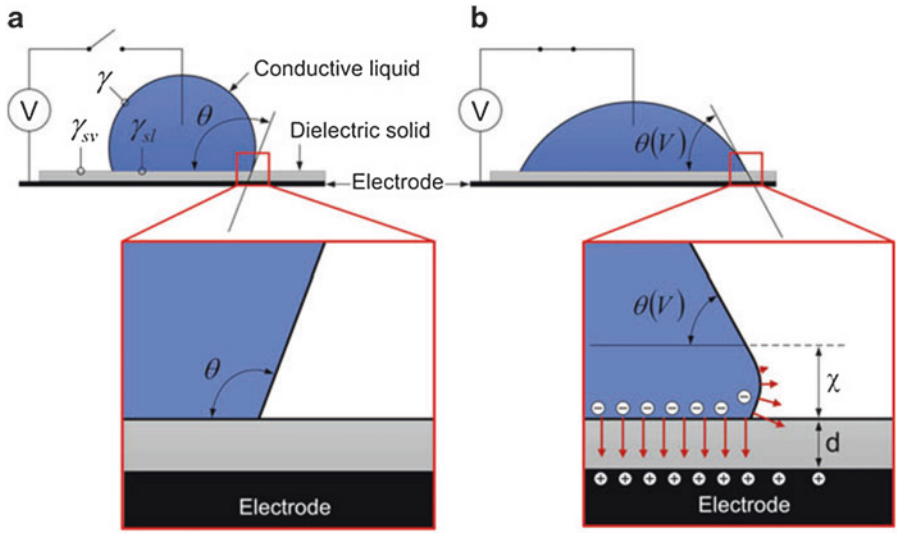
Despite the higher operation voltages, e.g., 15–80 V in air or 10–50 V immersed in oil in present experimental reports, EWOD is preferred over electrowetting on a conductor (which uses less than 2 V) in most cases. One may lower the voltage requirements of EWOD without sacrificing the electrowetting effect by coating the dielectric with a very thin layer of a very hydrophobic material. This strategy works by reducing the contact angle hysteresis, thereby enabling the contact lines (and thus droplets as well) to move more easily. A wide variety of droplet-medium combinations can be manipulated with EWOD, e.g., water in air, water in oil, oil-encapsulated water in air, oil in air, gas in water, etc. To learn more about the fundamentals of electrowetting and EWOD, readers are encouraged to consult [10].

Theories and Equations

The phenomenon of electrowetting can be interpreted (or understood) thermodynamically as well as electromechanically. In the

Electrowetting, Fig. 3 Electrowetting voltage and dielectric thickness [7]. The *thick solid line* represents the voltage required to obtain a certain degree of wetting (drawn for a contact angle reduction from 120° to 80° – enough reduction to slide a water droplet on many nonwetting solid surfaces in air) with Teflon AF as the sole dielectric, and the *thin solid line* represents the breakdown voltage for the same dielectric layer. A desired wettability increase is possible only where the electrowetting curve (the parabolic curve) stays safely below the *breakdown line* (the *straight line*). In other words, the dielectric should be thicker than where the two lines cross (~0.2 μ in the figure), as marked "Successful EWOD." If a smaller degree of wetting (e.g., moving a droplet on a solid surface coated with or immersed in oil) were acceptable, the corresponding electrowetting curve would be drawn lower, allowing lower voltages and thinner dielectrics. For conventional electrowetting, in contrast, the electrowetting curve would be drawn much lower than the EWOD curve in the figure due to the huge capacitance of the EDL (typically only several nanometers thick). Only ~1 V was used to induce enough wetting (70–40° to rough estimations) on gold to draw water in air environment [9]. However, that 1 V, which was the minimum needed to move the interface, was the maximum that could be applied before severe electrolysis. With no margin of safety, the actuation was not reversible

thermodynamic interpretation, assuming conventional electrowetting, the electrical energy accumulated at the solid–liquid interface, $cV^2/2$ (where c is the capacitance per area of the EDL and V the voltage across it), decreases the interfacial energy. For EWOD, the interpretation is slightly modified: the electrical energy accumulated in between the electrode and the liquid, $cV^2/2$, where c is the capacitance per area and V the voltage applied between them, makes the interfacial energy between the solid surface and the liquid decrease. The interfacial energy is exhibited as the contact angle of the liquid on the solid surface θ, which is easily measurable; as the solid–liquid interfacial energy decreases, so does the contact angle. By combining this energy equation with the Young equation and following the thermodynamic principle of energy minimization, the electrowetting equation (often called Lippmann-Young Equation) can be derived and written as follows:



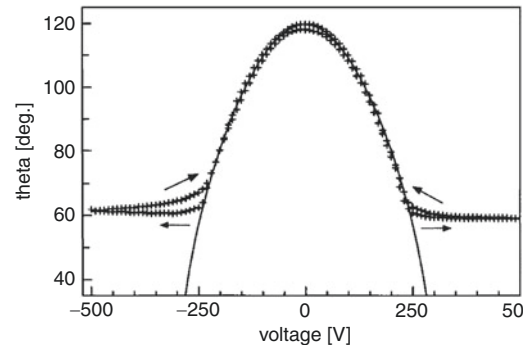
$$\cos\theta = \cos\theta_0 + \frac{cV^2}{2\gamma} \tag{2}$$

where θ_0 is the contact angle when there are no charges at the solid–liquid interface, i.e., no EDL exists, and γ is liquid-fluid (air being a fluid in Eq. 1) interfacial energy. The fluid may be a gas or a liquid that is immiscible with the liquid of interest, to which voltage is applied. For EWOD, where the specific capacitance can be obtained from the dielectric properties as $c = \varepsilon/d$ (ε is the permittivity, and d is the thickness of the dielectric), θ_0 coincides with the contact angle at no applied voltage, i.e., the Young angle, as the EDL has a negligible effect in this case. Considering the wide range of dielectric materials (i.e., representing a wide range of permitivities) and different liquid-fluid combinations used, it is convenient to define the second term on the right side of the equation as:

$$Ew = \frac{cV^2}{2\gamma} \tag{3}$$

The dimensionless Electrowetting Number Ew, defined as Eq. 3, expresses the importance of electrical energy relative to the free energy at the liquid-fluid interface. The liquid-fluid interface can be liquid–gas, liquid–vapor, or liquid-liquid if immiscible liquids. Although a liquid-air system is considered a standard in this essay, liquid-liquid systems of aqueous solution and oil are found in many electrowetting devices.

The importance of EWOD over conventional electrowetting and the growing view of the phenomenon as a physical force have led some researchers to the electromechanical interpretation of electrowetting, as summarized in Fig. 4. Considering the interfaces close to the solid–liquid-fluid



Electrowetting, Fig. 4 Electromechanical interpretation of electrowetting, illustrated for EWOD [10]. (**a**) With no voltage applied, the contact angle of a liquid is the Young angle. (**b**) With voltage V applied, the contact angle decreases by electrowetting. In the figure magnifying the area of solid–liquid-fluid triple point, χ is on the order of the dielectric thickness d, which is on the order of 1 μm in many EWOD devices

triple point as illustrated in Fig. 4b, one can see that the applied voltage produces normal electrostatic forces on the solid–liquid interface. Also, the fringe electric field on the liquid-fluid interface near the triple point exerts electrostatic traction normal to the liquid-fluid boundary right above the contact point (i.e., within χ in the figure), resulting in a net force parallel to the solid surface and causing droplet spreading. These electrostatic forces deform the liquid-fluid interface very close (sub-micron range in most practical cases) to the triple point, and this deformation reduces the slope of the interface away from the region. This reduced slope is the contact angle apparent to the observer. This pure electromechanical interpretation of electrowetting was made by theoretical derivations, e.g., [11, 12], and observed in experiments [13]. Under the electromechanical view, the electrowetting force is not infinitely concentrated at the contact point.

Electrowetting Curve

Since the electrowetting equation (Eq. 2), derived by both the thermodynamic and the electromechanical approaches, matches the experiments

Electrowetting, Fig. 5 A typical electrowetting curve [14] follows the electrowetting equation (Eq. 2) until the electrowetting effect saturates at high voltages (Reprinted with permission from American Chemical Society)

quite well in most cases, it plays an important role in understanding the phenomenon and performing research and development for applications. An example is shown in Fig. 5, which also reveals an important limitation: contact angle saturation. When the voltage is applied above a certain limit, a further increase of voltage does not decrease the contact angle anymore, e.g., not below 60° in Fig. 5. Instead, excessively high voltages only bring about detrimental effects,

such as the liquid-fluid interface becoming unstable and ejecting small droplets. Contact angle saturation is one of the most common sources of frustration for those engaged in research and development involving electrowetting. Despite its importance, however, the origin of saturation is still not well understood.

Summary

While explaining electrowetting, other closely related terms (electrocapillarity and EWOD) have also been described. Based on the same fundamental concept of electric potential affecting the interfacial energy, each portrays the electrowetting phenomenon in a somewhat different material configuration. Depending on the user's interest, one configuration may be more convenient than others, although EWOD is by far the most widely used configuration today. Basic theories of electrowetting have been presented through the conventional thermodynamic interpretation as well as the relatively new electromechanical interpretation, both of which result in the same electrowetting equation. The electrowetting equation is very useful as experimental data usually match the electrowetting curve. Today electrowetting is used in a wide range of applications including optical, biomedical, and even electronic.

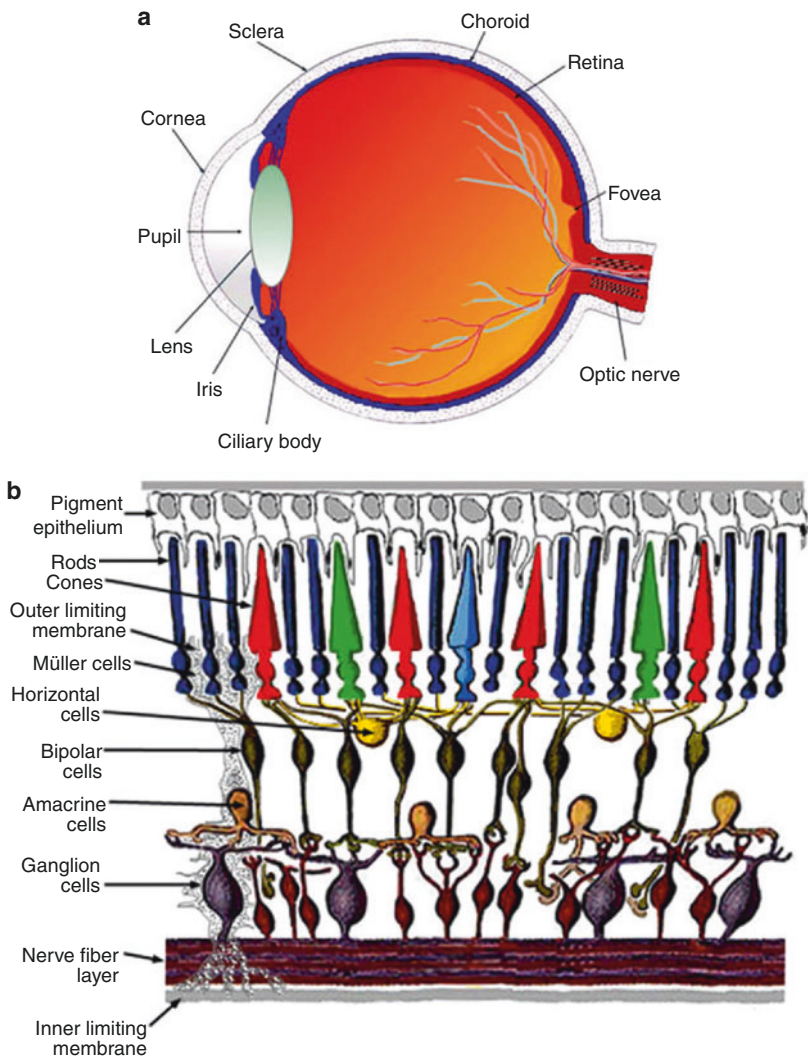
Epiretinal implant; Retinal prosthesis

Definition



Epiretinal prosthesis refers to the device designed to restore partial vision for the blind people by stimulating the retina through electrodes on the retina surface.

Overview

Introduction to Retina

Vision is the main method for people obtaining information from the outside world. Unfortunately, it has been estimated that there are about 250 million blind patients in the world, and the number is increasing year by year. Researchers have tried many ways to address the causes of blindness. Electrical stimulation has been proposed as a means to restore some sight for blind patients. The idea behind this is similar to what has been done in cochlear implants, where electrical stimulation of hair cells in the inner ear has been used to successfully restore the hearing for the deaf people [1]. In retinal prosthesis, electrical pulses are being delivered to the retina, invoking a neural response that corresponds to the information of the image and creating a useful visual perception for the blind patients.

As is shown in Fig. 1, the retina is composed of several neuron cell layers, located in the back of the eye. The innermost layer in the retina that is closest to the lens and front of the eye is called the ganglion cell layer while the photosensors (the rods and cones) lie outermost in the retina against the pigment epithelium and choroid. The photosensors convert light into chemical/electrical signals which are conducted to the ganglion cells through intermediate layers of neurons. The ganglion cell axons form the optic nerve, carrying the image information to the brain. Interestingly, light has to travel through the thickness of the retina before striking and activating the rods and cones where the absorption of photons by the visual pigment of the photoreceptors is translated into a chemical/electrical message that can stimulate the succeeding neurons of the retina. The ganglion cells transmit all the information that has been processed by the retinal layers to the brain in terms of neuronal spikes.

Epiretinal Prosthesis, Fig. 1 Schematic of the human eye (**a**) and the retina-layered structure (**b**) (Adapted from Webvision, http://webvision.med.utah.edu/)

Main Causes of Blindness

Some retinal diseases, unfortunately, disturb the above process and can prevent the patients from getting useful vision. Age-related macular degeneration (AMD) is one of those and the leading cause of blindness in the developed world [2]. It results from abnormal aging of retina. As the cones of the fovea die, the central vision is affected first and thus patients lose the capability of seeing objects in details. Retinitis pigmentosa (RP) is another disease that causes blindness [2]. This is a genetically related disease and refers to a collective name for a number of genetic defects that result in photoreceptor loss. RP affects the rods (used in night vision) first and then the cones (used in ambient daylight levels). There are 100,000 people in the USA affected by retinitis pigmentosa, according to the National Eye Institute.

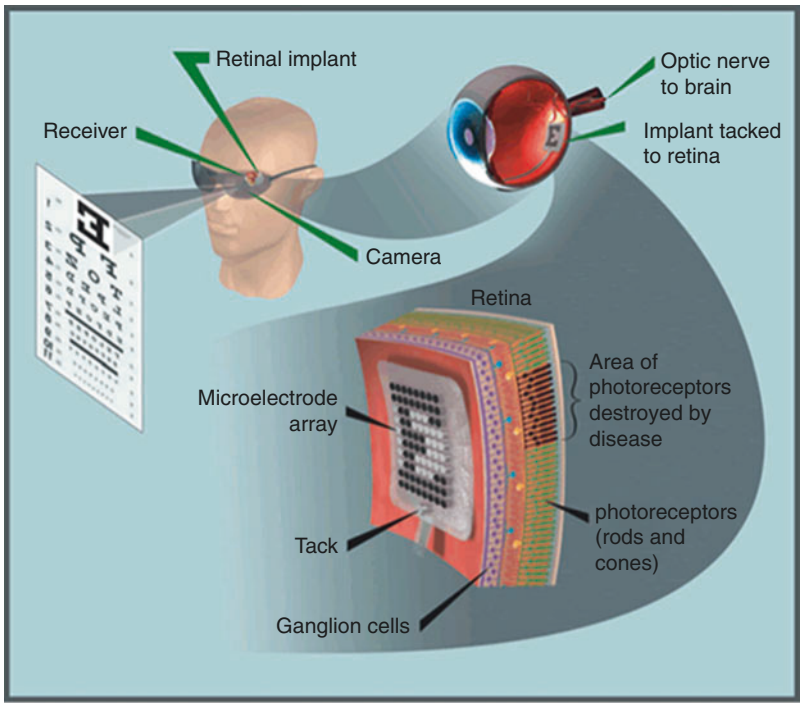
In both RP and AMD, the vision is impaired due to the damage to the photoreceptors that transform photons to neural signals. Postmortem evaluations of retina with RP or AMD have shown that a large number of cells remain relatively healthy in the inner retina compared to the outer retina [3]. This has led to the idea of building a device to electrically stimulate the

remaining viable cells in the retina to restore vision. In other words, the device can function as a replacement for the photoreceptors, converting the light information to electrical signals which can be interpreted by the remaining retinal neuron cells. The remaining ganglion cell neurons can pass the information to the brain, which perceives patterns of light and dark spots corresponding to the electrical signals generated by the device.

Types of Visual Prostheses

Retinal prostheses refer to the devices that mainly aim to fix the vision loss problems through electrically stimulating the retina. Electrodes are used to deliver electrical pulses to the retina. Depending on where the electrodes are placed, there are two leading approaches of retinal prostheses: epiretinal and subretinal. For epiretinal prosthesis, the electrodes are placed inside the vitreous, close to the inner layers of ganglion cells and nerve fibers. In contrast, in the sub-retinal prosthesis, the electrodes are placed under the retina where the rods and cones were. This entry will mainly explain the challenges and progresses associated with epiretinal prostheses. Other types of visual prostheses will be briefly discussed.

If the electrodes are implanted between the pigment epithelial layer and the outer layer of the retina, it is termed subretinal prosthesis. Compared with epiretinal approach, sub-retinal prosthesis has the potential advantage of closer proximity to the natural circuits of the retina and easier fixation of the electrodes since they are kind of sandwiched between the tissue layers. The disadvantages might include a more difficult surgery and more engineering challenges such as heat dissipation and power management. A German team led by the University Eye Hospital in Tübingen was formed in 1995 by Eberhart Zrenner to develop a subretinal prosthesis. Recently, they reported very promising results with acute human studies [4], but creating a reliable long-term subretinal device has proven more challenging. Also, currently the subretinal surgery requires filling the eye with toxic silicone oil. Clearly there are many issues to be resolved with the subretinal approach before it can be a viable practical therapy.



Another group led by Joseph Rizzo at the Massachusetts Eye and Ear Infirmary and John Wyatt at MIT also worked on retinal prosthesis and recently reported a subretinal stimulator with animal implantation results [5].

It is also worthwhile mentioning that similar to retinal stimulation, researchers worldwide have also proposed to electrical stimulation of optic nerve and visual cortex to invoke phosphenes to provide visional inputs to the patients. Among those are Dr. Claude Veraart from University of Catholique de Louvain at Belgium, Dr. Tohru YAGI from Tokyo Institute of Technology, Dr. Palankar from Stanford University, Dr. Nigel Lovell from University of New South Wales at Australia, and Dr. Mohammad Sawan from Ecole Polytechnique de Montreal at Canada. Despite all the challenges ahead, with the great efforts by the scientists, engineers, and entrepreneurs, there is no doubt people will move forward in curing blindness.

Principles of Epiretinal Prosthesis

Figure 2 shows the concept of epiretinal prosthesis. The device can be partitioned into two components, the external unit and the implant unit. The external unit includes the camera, signal processor, and power and data transmitter. The implant unit includes the power and data receiver, stimulator, and electrodes.

The whole device works as follows. An external video camera captures the image in the field of vision. This image is processed by a video signal processing unit that converts this image into stimulation data for the electrical stimulus. This data is then wirelessly transmitted to and received by an integrated circuit chip in the receiver inside the eye. The chip converts the signal to actual electrical stimulus currents which are delivered to the retina through the microelectrode array as shown in the figure. The electrode array is fixated on the retina by a retinal tack.

Image Capture

A digital camera, most likely mounted on the patient's eyeglasses or head, captures the images in the field of vision. The raw data from the camera has to be processed to convert the video information to the format that can be understood by the implant chip to stimulate the retina. For example, the raw data needs to be downsampled, since most cameras today have orders of higher number of pixels than needed for a prosthetic device with only tens of electrodes. To date, Second Sight Medical Products, the leading company in retinal prosthesis, is carrying out a chronic clinical trial for a device with 60 electrodes (The Argus™ II). Devices with more electrodes are also being researched worldwide [6]. Besides downsampling, the video processing has to carry out complex procedures such as image enhancement.

Research is also being conducted to move the camera inside the eyeball. An intraocular camera used for image capturing may include an optical imaging system with an image sensor array, which may be enclosed in an implantable biocompatible housing together with other electronic components. The difficulty lies in the miniaturization of such an optical system in a way that is protected from the harsh corrosive environment of the body. Heat is also a challenge. Leaving the camera outside has the advantages of lower power consumption inside and thus less heat dissipation. In addition, it allows for convenient refinement and upgrades of signal processing algorithms and functionality in the exterior blocks.

Besides the imaging processing capability, the external unit should also provide options for personal customizations. The unit should have an easily accessible user interface that permits the patient to do some necessary image enhancement adjustments on his/her own. An error detection function should also be built in.

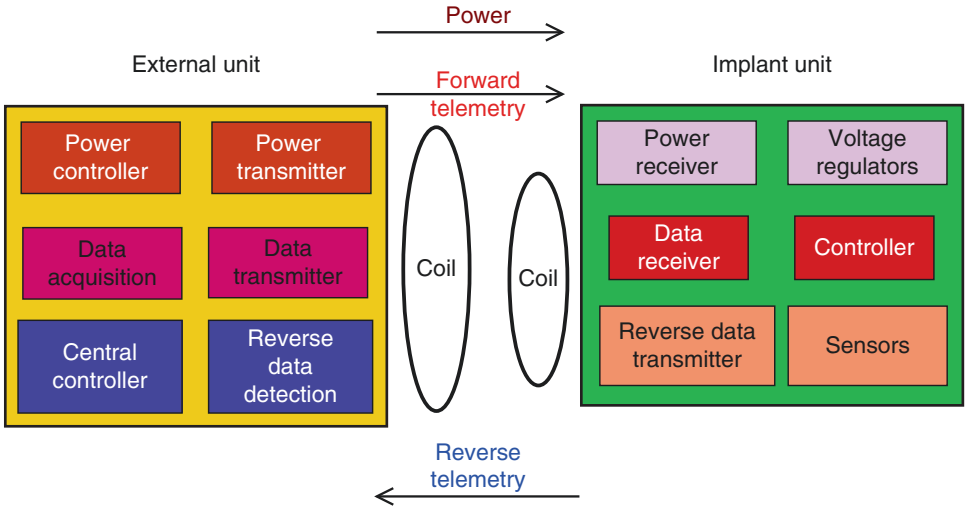
Wireless Telemetry

The implant needs power for the functions of electrical stimulation, image data recovery, and other circuits. The power required by the implant is provided by wireless telemetry. The overall power needed from telemetry is a function of the

stimulation parameters such as stimulation voltage and stimulation current amplitude, which in turn depend on many other parameters, such as the electrodes shape, distance to the retina, and even disease conditions of patients [3]. It has been estimated that a peak power of 250 mW may be needed for 1,000 electrodes stimulation [7]. During stimulation, the actual power needed by the implant may change with the stimulation patterns, which are a function of the image "seen" by the patients.

On the other hand, the maximum power that the implant can consume is governed by the safety issue that the temperature of the implant contacting the tissue should not exceed the normal temperature by a few degrees. Heating effects of RF power and chip operation have been studied experimentally and through modeling [8]. In sum, these studies suggest that wireless data and power transmission will not create a significant thermal effect, while the chip operation may generate a significant amount of heat. However, the liquid environment of the eye acts as a heat sink that is capable of dissipating a significant amount of power. An electronic chip positioned away from the retina can run at considerably higher power than a chip positioned on the retinal surface [9].

The required data rate for transmitting the image data from the external unit to the implant unit depends on the stimulus parameters and the refreshing rate of the stimulation. Assuming a total of 20 bits for one electrode stimulus current definition [10] and a refreshing rate of 50 frames per second, for 100 electrodes, the minimum data rate is $20 \times 50 \times 100 = 100$ kbps (kilobits per second). Obviously higher data rate will be needed if more electrodes are being stimulated.

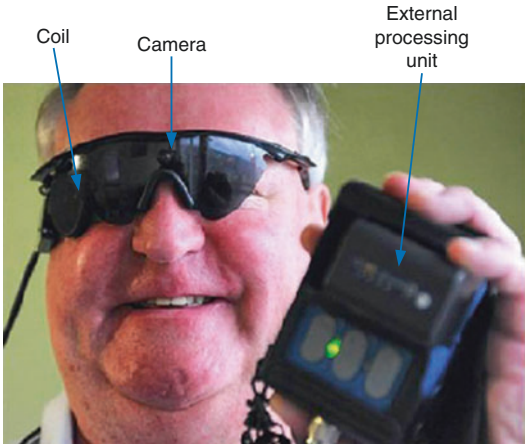


Besides relaying the image information from the external unit to the implant unit, it is also necessary to monitor the implant status for safety and also for optimal control purpose. For example, it is important to know the temperature of the implant and possibly shut down the device when the temperature exceeds a predetermined safety limit. Also, the change of pH value of the solution due to electrical stimulation could potentially be an indicator of tissue damage; thus it should be transmitted to the external unit for safety control [11]. The power level information inside the implant can also be detected and relayed back to the external unit to achieve an optimal power transfer system. The electrode impedance may be another parameter that needs to be transmitted back to the external unit for determining optimal stimulation patterns [12]. In sum, a communication channel is required to monitor the important implant parameters such as the temperature, pH value, power level, and electrode impedance, etc. These physiological signals generally change slowly and thus do not require a high data rate communication channel.

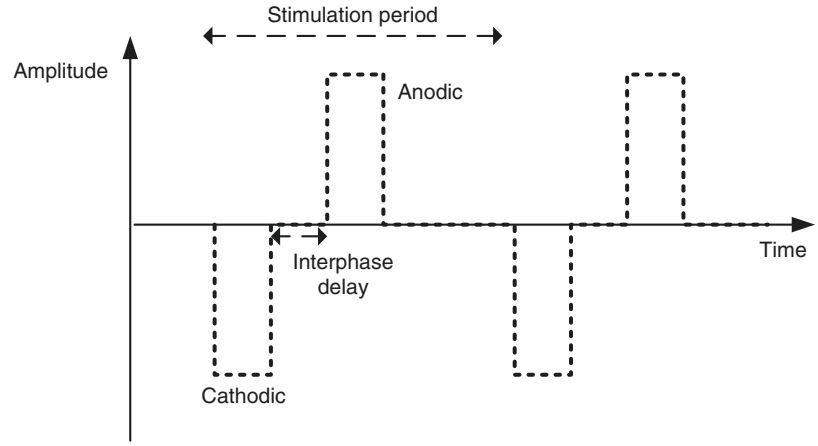
In summary, the telemetry system for retinal prosthesis needs to perform three functions, as shown in Fig. 3:

- Transmitting power to the implant
- Transmitting image data to the implant
- Transmitting data from implant to the external unit

To power the implant unit, the epiretinal prosthesis, like most other implantable applications, use inductive coupling as a means for wirelessly transmitting power. When an electrical current flows through a wire, a magnetic field is generated. A coil is formed when this conducting wire is wound into one or several loops. The magnetic field lines generated by each loop of coil combine with the lines generated by other loops to produce a concentrated field in the center of the coil. When another (receiving) coil is placed close to the transmitting coil, the magnetic field generated by the transmitting coil passes through the windings of the second coil and these two coils are magnetically (inductively) coupled. Further, if the current of the transmitting coil is alternating, by Faraday's law, the time-varying magnetic field generated by the alternating current induces an alternating voltage in the receiving coil, thus enabling energy transfer from the transmitting coil to the receiving coil.



The whole system is powered by a portable battery outside the body with power transmitted to the implant through the coupled coil pair. The power amplifier at the primary side converts the battery DC power into radio frequency



Epiretinal Prosthesis, Fig. 3 Illustration of an inductive power and data telemetry for epiretinal prosthesis

(RF) power to be radiated by the primary coil and thus to be received by the secondary coil. This power is then converted back to DC by the power recovery circuits to operate the implant electronics.

The size and shape of the coils are highly critical for an efficient power transfer and deserves special attention. Firstly, to facilitate the energy transfer, the two coils should be constructed with a shape that can maximize the coupling and be placed as close as possible. Secondly, the wire diameter of the coil should be chosen according to the frequency of the electrical current to minimize the losses associated with electrical resistance. For example, one way to reduce the resistance is to construct the coil with several wires (strands) twisted together (for example, litz wire) to increase the equivalent cross-section conducting area and reduce the resistance. However, the number of strands is normally limited by the maximum allowable size of the coils. Another important parameter of the coil is the number of the loops of the conductor (called number of turns). With the same current in the transmitting coil, more turns can generate higher magnetic field thus inducing a higher voltage across the implanted receiving coil. However, as the number of turns increases, the equivalent resistance of the coil increases too, which causes higher power dissipation on the coil. For a given size of coil, the number of strands trades off with the number of turns, and both should be optimized for a given application to achieve high power efficiency. The coil being implanted should be constructed as small as possible to minimize the patient discomfort and to ease surgery/injection procedure. The external coil, mounted on eyeglasses, however, is usually much larger for better coupling as shown in Fig. 4.

Epiretinal Prosthesis, Fig. 4 Photo of external unit developed by Second Sight Medical Products. Coil is on the side of the eyeglasses

Epiretinal Prosthesis, Fig. 5 Scheme of typical biphasic pulses for stimulating retina

The magnetically coupled coil pair can also be used to transmit data wirelessly from the external unit to the implant unit. By modulating the power carrier (used to transmit power), data can be sensed by the implant unit. Research is also being conducted to transmit data using a different carrier instead of the power carrier, mainly to increase the amount of data that can be transmitted without sacrificing the power transmission efficiency.

Stimulating the Retina

Electrical current is delivered from the electrodes to the retina, and presumably the retinal cells are stimulated, which generate neuronal spikes to be passed to brain. A high-density electrode array is composed of a substrate that provides mechanical support and the conducting material, for instance, a noble metal such as platinum, creating the electrical connection between the stimulator and the tissue. At the electrode/tissue interface, the electronic current is transformed into ionic current which sets up a voltage gradient that then activates the neurons.

It is desirable for the electrodes to be placed on to the macular region and close to the retina as this will create more efficient stimulation. The electrode array, as illustrated in Fig. 2, is fixated onto the retina by a tack. Optimizing this interface is an important area of research.

As shown in Fig. 5, a typical electrical stimulus is biphasic with the pulse of a cathodic phase and an anodic phase. The interphase interval (time between the two phase) separates the pulses slightly to make sure that the next pulse would not reverse the physiological effect of the previous one. The stimulus information contains the amplitude, width, interphase delay, and the repetition rate of the pulses. All this information highly correlates to the image information and the actual stimulation strategy may also be patient-specific. In other words, for the same picture being "seen" by the patient, the stimulation currents may be very different.

The integrated circuit chip is responsible for generating such current according to the commands it receives through data telemetry from the external unit. The stimulator is miniaturized to be accommodated within the constraints of the available space and designed to be controlled with the minimum power to cut down the possible heat dissipation inside the body.

Current Research Progress

In the early 1990s, Humayun and colleagues demonstrated that controlled electrical stimulation of the retina in individuals blind from RP and AMD results in visual percepts in the form of light dots. Experiments using pattern electrical stimulation of a human retina resulted in subjects perceiving

simple forms of vision with the percepts corresponding in time and location to the electrical stimulus. These were short-term tests, with the stimulating devices temporarily positioned on the retina.

In 1998, Second Sight Medical Products was founded to build a retinal prosthesis. A permanent implant, developed by Second Sight Medical Products, with 16 electrodes (4 × 4 array) was implanted in patients starting in 2002. The implanted subjects were able to use a camera to detect the presence or absence of ambient light, to detect motion, read a large letter, count objects, and recognize and differentiate objects such as cup from plate. The longest implant still in use by a patient today is over 7 years to date.

Starting in 2007, Second Sight went on to a clinical trial for its second-generation device, Argus II, which has 60 electrodes. So far there have been more than 30 patients implanted with centers in the USA, England, France, Geneva, Mexico, etc. The patients with such devices, for the first time, could see a series of letters, thus recognizing simple words and even sentences. Some patients could recognize numbers on cards held in their palm.

One natural assumption is that with more electrodes, the epiretinal prosthetic device could provide better vision inputs for the suffered blind patients and thus restore more meaningful vision to the patients, such as face recognition, unaided mobility.

Simulations of prosthetic vision suggest that 600–1,000 electrodes will be needed to restore visual function to a level that would allow blind to read, navigate a room unaided, and recognize faces [13, 14]. But, through the use of scanning, clearly far fewer can make a significant impact. As the number of stimulation outputs increases, the complexity of the stimulator electronics increases, requiring larger amounts of power to provide to the implant and a higher data rate, for transmitting the image information to the stimulating electronics. Protecting these high-channel-count devices from the body is also increasingly difficult as the numbers of electrodes increases. To date, only the Argus I and II from Second Sight have demonstrated long-term reliability in patients.

Future Direction for Research

With the advancement of technologies in the areas of microelectronics, mechanics, materials, there is no doubt that devices with better performance than current state of the art will emerge in the future. Needless to say, this involves a great deal of engineering challenges and trade-offs. Can 1,000 analog drivers be packed into a microchip that can be small enough to be implanted? Can enough data be transmitted into the device without consuming too much power to actually overheat the implant? Can a hermetic package be built to support 1,000 electrodes?

Another important area is to understand the neural response of the retina when stimulated by electrical current. Many experiments have been carried out to find out the relationship between stimulation current (such as the magnitude, waveform, and frequency) and the perception, but more work is needed.

EUV Lithography

Chimaobi Mbanaso and Gregory Denbeaux
College of Nanoscale Science and Engineering, University at Albany, Albany, NY, USA

Synonyms

Extreme ultraviolet lithography (EUVL); Soft x-ray lithography

Definition

EUV lithography is a technology that uses radiation near 13.5 nm wavelength to transfer patterns from a reflective mask to a substrate coated with a light-sensitive material called a photoresist. This patterning technique occurs under vacuum conditions in an all-reflective optics configuration and is used to fabricate integrated circuits with printed features that are smaller than 32 nm. The technology is considered to be the likely next-generation lithography method with the prospect of succeeding the current immersion lithography technique.

Overview

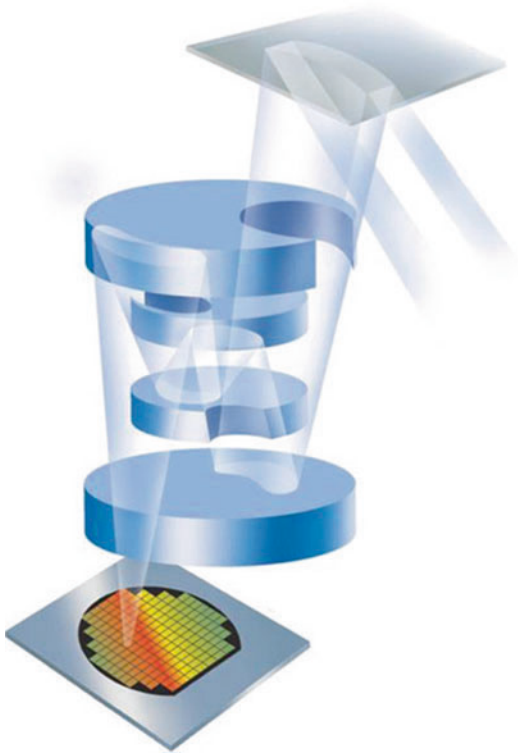
Semiconductor integrated circuits (ICs) which are embedded in various electronic devices are fabricated using a lithography process. As technology has advanced since the invention of the IC in 1958, lithography has played a vital role in patterning smaller features to produce faster and more powerful operating devices. Decreasing the exposure wavelength used for lithography is one of the ways in which the printing of ICs has steadily improved using optical lithography techniques. Extreme ultraviolet (EUV) lithography operating at 13.5 nm wavelength will possibly succeed the state-of-art lithography method as the next-generation technique of choice for continuing the shrinking of ICs [1–9]. Other next-generation lithography methods that have been considered include proximity x-ray lithography, electron projection lithography, ion projection lithography, and multi-e-beam direct-write [6, 10]. Before the adoption of the next lithography technology, important requirements such as throughput, cost of ownership, and image quality have to be considered [6].

In lithography, an optical projection printing system uses light to image a mask pattern onto a wafer substrate that has been coated with a light-sensitive material called a photoresist. The projection lens system typically reduces the mask pattern by a factor of four onto the photoresist [11, 12]. The lithography process defines the

critical dimensions of the printed features while other process steps such as etching and metallization contribute toward the overall fabrication of the device. In EUV lithography, 13.5 nm wavelength of light enables the transfer of patterns from a reflective mask to a photoresist-coated substrate. The short EUV wavelength is easily absorbed by most materials; hence, the lithography process must be operated under vacuum conditions and by using special reflective materials in the optical system in contrast to conventional lithography techniques that use refractive optics [3, 4].

One of the drivers for implementing EUV lithography is the capacity to print high-resolution features by the following fundamental relationships describing the lithographic system with resolution (R) and depth of focus (DOF). Thus,

$$R = k_1 \frac{\lambda}{NA} \tag{1}$$



$$DOF = \pm k_2 \frac{\lambda}{NA^2} \tag{2}$$

where λ is the optical wavelength and NA is the numerical aperture of the projection system [3]. The parameters k_1 and k_2 are determined through empirical means and depend on the critical dimension (CD) tolerance and the size of an acceptable IC manufacturing process window [5]. The printing of smaller features in the semiconductor industry has followed a trend in which the number of transistors in an IC has doubled after approximately every 24 months (Moore's law) [13]. Strategies to improve the optical lithography technique to keep pace with Moore's law have led to modification of the lithography system according to Eq. 1; hence, decreasing the wavelength of light, fabricating high NA optics or decreasing k_1 have led to smaller patterned features [8]. The optical lithography technique that used the 436 nm g-line illumination wavelength during the early 1980s printed features with dimensions of over 2 μm by using a system with an NA of 0.15 and a k_1 of 0.8 [10]. At present, 193 nm lithography uses an immersion liquid along with various resolution enhancement techniques such as phase shifted masks, optical proximity correction, off-axis illumination, and double patterning lithography to print features below 32 nm [10]. Shortening the wavelength by using 13.5 nm is the next practical way to enable the printing of smaller features for future IC devices.

Initial concepts of EUV lithography were introduced in the 1980s from research efforts in Japan and the United States while using a broader radiation wavelength range of about 10–30 nm, referred to as soft x-rays [3, 4]. National laboratories such as the Lawrence Livermore National Laboratories (LLNL), Sandia National Laboratory (SNL), Lawrence Berkeley National Laboratory (LBNL), as well as the AT&T Bell Laboratories performed some of the early research in using EUV radiation in an all-reflective projection lithography system [4]. Since then, research efforts by industry consortia and semiconductor manufacturers have all been instrumental in leading developmental efforts in EUV lithography for high-volume manufacturing. Some of the early EUV development programs which commenced in the 1990s include Extreme Ultraviolet Limited Liability Company (EUV LLC), the European Extreme UV Concept Lithography Development System (EUCLIDES), and the Japanese Association of Super-Advanced Electronics Technologies (ASET). These programs and many others since then [4], have supported the development of light sources, optics, masks, photoresists, and vacuum equipments needed for EUV lithography. The sections that follow discuss these essential components of an EUV exposure tool and their development for this technology (Fig. 1).

EUV Light Sources

Historically, progressively shorter wavelengths in the lithography tools have been used as one of ways to reduce the feature sizes of IC devices. The visible g-line at 436 nm wavelength was used in the early 1980s for the lithography process [11]. Its wavelength successor was the ultraviolet i-line at 365 nm which was used in the late 1980s [11]. Both the g-line and i-line radiation wavelengths were produced with a mercury arc lamp.

EUV Lithography, Fig. 1 Schematic showing the EUV lithography projection optical system based on reflective mirrors (Courtesy of Carl Zeiss SMT GmbH)

With further decrease in feature sizes came the advent of deep ultraviolet (DUV) 248 nm wavelength lithography using a KrF (krypton fluoride) excimer laser in the late 1990s and then in 2001 [11], the ArF (argon fluoride) excimer laser was used for advanced lithography and has been modified to use an immersion liquid. ArF lithography uses light at 193 nm wavelength. The fluorine (F_2) excimer laser, which operates at 157 nm wavelength, was briefly considered to be the next lithography step toward shorter wavelengths but did not proceed to high-volume manufacturing [10, 11]. EUV lithography, operating at 13.5 nm, is considered the next step in shortening the wavelength of light used for lithography to continue the scaling of device features.

To generate high-power radiation at 13.5 nm for EUV lithography, high-temperature plasmas (approximately 30 eV) of a fuel material are used [3, 14]. For high-volume manufacturing applications, these hot plasmas of a target fuel such as xenon, tin, or lithium are generated from either an electrical discharge or by using an intense laser pulse. These two viable commercial solutions for generating EUV radiation are referred to as discharge produced plasma (DPP) and laser produced plasma (LPP). Other sources of EUV radiation such as synchrotrons were used for early demonstrations and pioneer studies of EUV lithography but requirements such as space restrictions limited their practical use for commercial applications [6, 7]. Tin is currently the leading target fuel for high-volume manufacturing EUV sources because of its higher conversion efficiency (CE) compared to xenon and lithium [3, 14]. CE, which is the ratio of the generated energy from the EUV source in the 2 % bandwidth of 13.5 nm wavelength to the energy input to the EUV source, is used to estimate the utility requirements and fuel choice [3].

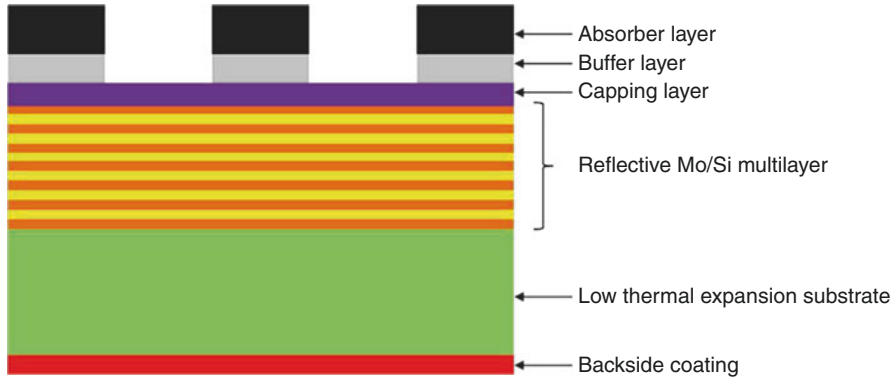
In order to focus the light generated by the EUV source, collector optics that are either grazing incidence or normal incidence are used. The point where the light is focused is called the intermediate focus (IF) and connects the source-collector module to the illuminator and projection mirrors of the EUV lithography scanner. Only a portion of the EUV radiation emitted by sources is collected and transmitted to the IF due to factors such as the geometrical restrictions in the collector design, the efficiency of the collectors to reflect the EUV radiation, absorption of EUV by background gases and spectral purity filters (SPFs) along the propagation path to the IF [3]. SPFs are needed to suppress out-of-band radiation produced outside the 2 % bandwidth of the 13.5 nm wavelength by the plasma sources. The presence of these filters can further attenuate the in-band EUV power. Other filters include debris barriers to mitigate high-energy particles from the plasma source which can otherwise lead to degradation of reflective optics in close proximity to the source [3, 4].

EUV source specifications are determined based on consumer requirements which include throughput, cost of ownership, and image quality. For instance, for high-volume manufacturing, the EUV power generated must be sufficient to ensure

that a high wafer throughput, which is estimated to be about 100 wafers per hour, is achieved. This equates to a power of 115–180 W depending on the sensitivity of the photoresist at 5–10 mJ/cm^2, respectively. Hence, sources that meet the power requirements, while maintaining energy stability and reliability during operation, are needed. EUV sources can also be used for metrology purposes and the specifications for such applications are somewhat different from lithography exposure tools [6].

EUV Multilayer Optics

In contrast to prior optical lithography technologies that use transmission optics for propagating the light to the photoresist, EUV technology needs vacuum conditions and reflective optics to avoid absorption of the short wavelength at 13.5 nm. The optics system used for EUV lithography consists of reflective illumination optics used to effectively allow the mask to be illuminated and reflective projection optics to image the pattern on the photoresist. The reflective optics consist of repeated bilayer pairs to make a multilayer mirror material [3, 15]. The mathematical relationship between the bilayer spacing, d, incidence angle, θ, and wavelength, λ, is shown in the equation below,



$$n\lambda = 2d\cos\theta \tag{3}$$

where n is an integer. The bilayer stack to reflect EUV radiation from a multilayer consists of a metal (high Z material) and a spacer (low Z material) which correspond to materials with high and low atomic numbers (Z). Historically, two of the common multilayers considered for EUV lithography were Molybdenum/Beryllium (Mo/Be) and Molybedenum/Silicon (Mo/Si) corresponding to best reflectivity performance at wavelengths in the 11.3–11.6 and 13.3–13.6 nm range, respectively [3]. The Mo/Si for 13.5 nm is widely used as the metal/spacer material of choice for EUV technology with a typical stack consisting of 40 Mo/Si layer pairs. These mirrors have shown a peak reflectivity of close to 70 % at 13.5 nm [15]. The quality of the multilayer coatings contributes to the reflectivity of the multilayer mirrors and is dependent on the deposition process. Magnetron sputtering [3, 15] is one of the common deposition techniques for EUV lithography mirrors because of the ability to coat large optics, the relatively fast sputtering rate and reproducibility from process to process. Some of the other deposition methods include ion-beam sputtering, electron-beam evaporation, and pulsed laser deposition [3].

Contaminants, which include water and hydrocarbons, in the presence of EUV photons can lead to oxidation or surface contamination resulting in a loss of reflectivity [3, 16]. The operational lifetime of the projection optics used in the EUV system must satisfy greater than 30,000 light-on hours [3, 5]. Thus, degradation at the surface of the optics must be kept at a minimum. Molecular contamination has been attributed to cracking of adsorbed molecules at the mirror surface by EUV-induced secondary electrons [16]. Typical species causing contamination are oxygen-containing molecules and carbon-containing molecules. A small increase in the layer of oxide (less than 1.5 nm) on the surface of these multilayer mirrors leads to a reflectance loss of greater than 1 %, and is unacceptable [3]. Such optics contamination will decrease the throughput of the exposure tool and printing uniformity. Strategies to reduce contamination of the optics include using protective capping layers, such as ruthenium, that are resistant to oxidation [3, 16]. Other strategies to extend the lifetime of the optics and reduce carbon growth include improvement of the vacuum conditions and adopting various cleaning techniques that would efficiently remove the carbon but not damage the underlying mirror. Possible removal methods include the use of molecular oxygen and atomic hydrogen [3].

EUV Masks

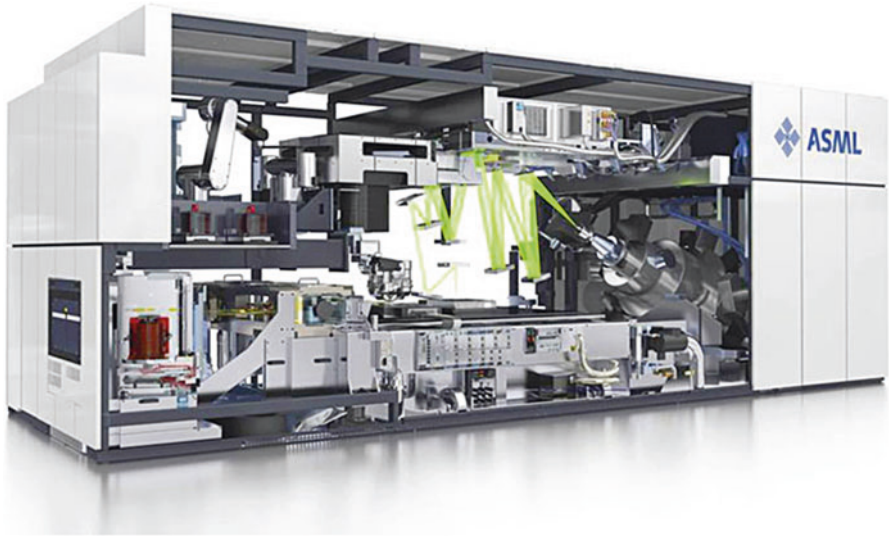
The EUV mask, which contains the pattern to be imaged onto the wafer, has to be reflective to avoid absorption of the short wavelength of light; hence, it is different from conventional

EUV Lithography, Fig. 2 Schematic showing a stacking structure of a reflective mask used for EUV lithography

transmissive optical masks. The EUV mask undergoes two main fabrication processes. These are the development of the mask blank and the patterning of the mask. For the mask blank fabrication, a flat and defect-free substrate with a low coefficient of thermal expansion material maintains the rigidity of the mask with minimum distortion [3, 6]. On this substrate, a reflective multilayer structure consisting of alternating layers of Mo/Si is deposited and covered by a capping layer to prevent oxidation. The multilayer on the EUV mask ensures high reflectivity at the 13.5 nm wavelength and consists of 40 pairs of Mo/Si bilayers as shown in Fig. 2. An absorber layer coating, antireflective coating on the topside of the mask as well as a conductive layer coating on the backside of the mask are all performed as part of the mask blank fabrication process. The absorber layer helps in the pattern-forming process by providing contrast to the reflective multilayer through absorption and minimum reflection, and materials such as tantalum nitride (TaN) are used for this function [3]. To minimize reflectivity during mask inspection using deep ultraviolet (DUV) light, an antireflective coating can be applied to the top of the absorber layer. A buffer layer material such as silicon dioxide (SiO_2) or ruthenium can be used to protect the multilayer structure during the etching or repair of the absorber layer [3]. The conductive backside coating is made to be compatible with the electrostatic chuck used to support and flatten the mask in the exposure tool as well as other process tools. Electrostatic chucking ensures that the clamping forces are evenly distributed over the mask area to maintain flatness. The next step in the fabrication of the EUV masks is the mask patterning by electron beam writing and dry etching. The writing process is similar to that used for conventional optical masks but with tighter restrictions on distortions and thermal specifications.

Mask defects can occur in the absorber layer, the multilayer reflective coating, or in the substrate below the multilayer coating. Substrate defects can propagate through the multilayer coating and cause a phase defect which is the perturbation of the reflected wave front [3]. Amplitude defects can be caused by particles near the top of the multilayer or if there is a flaw in the multilayer. Other defects can occur in the absorber layer where a portion of the absorber is missing from its desired location (clear defect) or if there is absorber material in an undesired location (opaque defect) [3]. Unlike optical lithography that uses a highly transparent membrane (pellicle) to be placed over the mask to provide protection from small particles that can fall and cause defects, the absorption of the short 13.5 nm wavelength makes it unusable in EUV lithography. Nevertheless, during shipping, storage, or handling, various protection schemes have been evaluated such as the dual pod concept [3]. The dual pod is a special mask carrier that gives double protection to the mask by using an inner and outer compartment to maintain a particle-free mask before use in an EUV exposure tool.

To avoid defects from being imaged on the wafer, the EUV mask must go through the manufacturing process defect-free and remain that way during use. Reliable and accurate EUV mask inspection is needed to capture and characterize printable mask defects at various levels of fabrication. Inspection tools that use EUV wavelength (actinic) and DUV wavelengths (non-actinic) have been used for this purpose [3]. However, to meet the requirements for high-volume manufacturing, actinic inspection and imaging tools will likely be needed due to the limits of DUV inspection techniques [3].



EUV Photoresists

Photoresists, which are the light-sensitive materials used in the lithography process, have undergone much progress from the Novolac® photoresists used in the i-line (365 nm) era to chemically amplified photoresists used for 248 and 193 nm lithography [12, 17]. The platform for EUV photoresists, also based on chemical amplification, is similar to those used for 248 and 193 nm optical lithography. These photoresists were first used in the mass production of semiconductor devices during the transition from the i-line of the mercury lamp to the KrF (248 nm) excimer laser [18]. These chemically amplified photoresists have been further employed from KrF (248 nm) to the current ArF (193 nm) immersion lithography and exhibit high sensitivity and resolution [6]. In chemically amplified photoresists, pattern formation occurs through deposition of energy in the photoresist upon exposure to the incident radiation leading to the generation of acids. The acids catalyze the pattern forming reaction at elevated temperatures referred to as the post exposure bake (PEB) step. The image in the photoresist is then developed in an aqueous base to reveal the pattern. The efficiency of these processes depends on the absorption efficiency of the incident radiation, the number of acids generated, and the efficiency of the catalytic chain reaction [12]. In EUV, the mechanism for interaction of radiation with the photoresist is different than exposures using 248 and 193 nm radiation technologies. The high energy of the EUV photon, 92 eV (13.5 nm), ionizes the components of the photoresist film to generate secondary electrons which contribute to the chemical reactions occurring during exposure [17, 18]. The properties of these photoresists depend on the photoacid generator (PAG) and the polymer used in the formulation and affects the specifications for resolution, line edge roughness (LER), and sensitivity [12]. The sensitivity of the photoresist required for EUV lithography is dependent on the power produced by the source. One of the concerns of using EUV photoresists in the vacuum environment with all the nearby reflective optics is the release of hydrocarbon contaminants during exposure, which could decrease the lifetime of the optics [19]. The outgassing of photoresist materials exposed to EUV wavelengths has been studied using various methods [19].

EUV Research Status

EUV technology has undergone rigorous research efforts which began over two decades ago in order to meet the requirements for high-volume manufacturing and cost of ownership. One of the critical areas that needs further development is the EUV source. Currently, the collectable power of EUV is limited and must be improved for EUV technology at high-volume manufacturing throughput levels. For EUV technology to be implemented, demonstrations of the reliability and stability for source power have to be achieved. Defect-free masks with the corresponding inspection infrastructure that can find all the printable EUV mask defects must be developed. SEMATECH (Semiconductor Manufacturing Technology, www.sematech.org) is contributing actively to develop the infrastructure for EUV blank and mask inspection tools. In addition, photoresists that meet the requirements of resolution, sensitivity, and line edge roughness (LER) need to be available as well.

Currently, ASML (ASM lithography, www.asml.com) has developed the semiconductor industry's first EUV lithography production platform (TWINSCAN NXE). The system platform is

EUV Lithography, Fig. 3 ASML NXE:3100 which is the pre-production TWINSCAN system EUV lithography scanners (Courtesy of Bill Pierson, ASML)

based on the learning and achievements from the EUV prototype tools (Alpha Demo Tools – ADT) located at IMEC (Interuniversity MicroElectronics Center, www.imec.be) in Belgium and CNSE (College of Nanoscale Science and Engineering, www.cnse.albany.edu) in Albany, New York [20]. The system architecture is based on a six-mirror lens, and the EUV radiation is generated from a tin-based plasma source [20]. The preproduction TWINSCAN NXE system is the NXE:3100 shown in Fig. 3, with *NA* as 0.25 and resolution of 27 nm, and six of them have been produced [20]. The NXE:3300B will follow the NXE:3100 to target volume production at a resolution of 22 nm and less at an *NA* of 0.32 in 2012 with throughput estimated to be 125 wafers per hour [20].

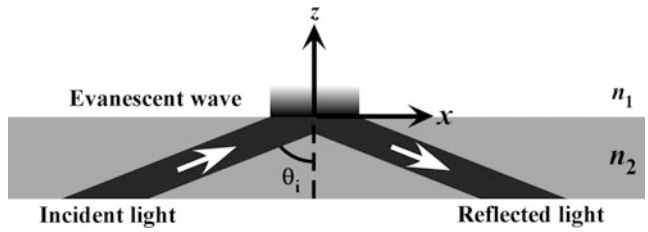
Nano-particle image velocimetry; Total internal reflection (fluorescence) velocimetry

Definition



Evanescent-wave particle visualization is a technique for studying the dynamics of fluorescent colloidal particles, or spheres, of average radii a ranging from about 100 nm to a few μm. These particles, which are typically suspended in an aqueous buffer solution at volume fractions $\varphi < 1$ %, are illuminated by evanescent waves generated by the total internal reflection (TIR) of light at the refractive-index interface between a wall and the buffer, for example. In a flowing suspension, the technique can be used to measure near-wall velocities by tracking the motion of the particles over time. Moreover, the technique can also be used to measure the distribution of, and hence the forces acting upon, colloidal particles near the wall because the particle-wall separation h can be estimated from the brightness of the particle image.

Introduction

Surface forces are significant in the flows typical of micro- and nanofluidic devices with their relatively large surface areas and small volumes. Interfacial transport, specifically transport within the region less than 1 μm from the wall where surface forces are significant, is therefore of interest in the steady, creeping, and incompressible flows found in most micro- and nanofluidic devices.

From a fluid mechanics viewpoint, the most important parameter is flow velocity field. The energy required to drive an aqueous solution through nanochannels and microchannels, for example, is determined by the velocity gradient at the channel wall. Measuring this velocity field requires techniques with a spatial resolution at least an order of magnitude less than the overall dimension of the nanochannel or microchannel.

The most common velocimetry technique used in microfluidic devices, microparticle image velocimetry (μPIV), measures fluid velocity distributions by following the motion of suspended fluorescent polystyrene (PS) particles less than 3 μm in diameter with a density (1.05 g/cm^3) which is very close to that of most aqueous solutions, assuming that the particles follow the flow [1, 2]. Micro-PIV can measure the two in-plane components of the velocity without disturbing the flow by illuminating the entire flow and imaging a single two-dimensional plane of the flow. And, because it can use the same optical path to illuminate and image the flow, μPIV requires only the addition of a single optical window to the microfluidic device.

Evanescent-Wave Particle Visualization in Nano- and Microchannels, Fig. 1 Total internal reflection of light at the planar interface between two dielectric media. The reflected beam is slightly offset along the x-direction by the Goos-Hänchen shift

In the near-wall region, the velocity is mainly parallel to the wall because the fluid cannot penetrate the wall. Imaging the velocity field within 1 μm of the wall in a plane parallel to the wall with μPIV is difficult, however, because the thickness of the plane imaged by the technique, based on the "depth of correlation," is at least 2 μm, and optical interference (e.g., glare, reflections) greatly reduces the quality of the image.

Evanescent waves, however, can (as reviewed later) be used instead to illuminate only the flow within the first 0.5 μm next to the wall. They can therefore be used to visualize, and track, only the particles that are within the region of interest for studying surface forces.

As noted earlier, the particles are assumed to be passive tracers that follow the flow in particle velocimetry. This is not the case for colloidal particles, however, because these particles have significant Brownian diffusion. And near the wall, Brownian fluctuations will not necessarily have a mean of zero because the diffusion varies with distance from the wall.

Furthermore, the particle concentration is not uniform near the wall and varies along the wall-normal direction even in a suspension at rest due to particle-wall electric double layer and van der Waal interactions predicted by the classic Derjaguin-Landau-Verwey-Overbeek (DLVO) theory and additional forces associated with the pressure and voltage gradients often used to drive flows in micro- and nanofluidic devices. These phenomena (discussed in the next sections), which play a significant role for suspended particles within 1 μm of the wall, should be considered when determining the flow velocity field from these particle velocity data.

Key Concepts

Evanescent Waves

From basic optics, it is known that when light of wavelength λ is incident upon the planar interface between two homogeneous dielectric media of refractive indices n_1 and n_2 (where $n_2 > n_1$) at an angle of incidence θ_i exceeding the critical angle $\theta_c \equiv \sin^{-1}(n_1/n_2)$, TIR occurs, where all of the incident light is reflected, remaining in the more dense medium of refractive index n_2 (Fig. 1). The Fresnel conditions for TIR, however, give a nonzero amplitude transmission coefficient, and so there is a wave transmitted into the lower-refractive-index medium that cannot, on average, carry any energy across the interface [3].

This transmitted *evanescent wave*, which propagates parallel to the interface along the x-axis, has a purely imaginary wavenumber, and hence an intensity that decays exponentially as it propagates into the less dense medium of refractive index n_1. The intensity of the evanescent wave is then

$$I = I_o \exp\left\{-\frac{z}{z_p}\right\} \tag{1}$$

where I_o is the intensity of the evanescent wave at the interface, z is the distance normal to the interface measured from the interface, and z_p, the intensity-based penetration depth, is given by

$$z_p = \frac{\lambda}{4\pi}\left[n_2^2 \sin^2\theta_i - n_1^2\right]^{-1/2} \tag{2}$$

The illumination incident upon the interface should be linearly p-polarized to ensure that

Eq. 1 is valid [4]. The intensity of the evanescent wave is maximum at the interface, and this maximum value can be several (more than four) times the intensity of the light incident upon the interface [5]. Based on Eq. 1, the evanescent wave only illuminates the region within a few penetration depths of the wall. Evanescent waves, because they are confined to a region less than 1 μm from the wall, have been used in total internal reflection fluorescence (TIRF) microscopy to visualize cell-substrate contact and measure the binding kinetics of proteins to cell surface receptors in biophysics [5] and measure colloidal forces in surface science [6].

Particle-Wall Interactions in a Dilute Colloidal Suspension at Rest

Even in the absence of flow, it is well known in colloid science that colloidal particles near a wall suspended in a quiescent conducting medium (e.g., an aqueous electrolyte solution) will have a nonuniform distribution along the wall-normal direction, even for a dilute suspension where interparticle interactions are negligible, due to electrostatic interactions between the screening layers of mobile counterions that surround the particle and wall surfaces and van der Waals interactions due to dipole interactions. Gravitational interactions are for the most part negligible for these nearly neutrally buoyant particles.

When the solid surface (e.g., of the wall or the particle) is exposed to an aqueous solution, the surface will become charged, for example, by dissociation of surface groups or adsorption of ions. This charged surface will then in turn attract mobile counterions from the solution to form a charged screening layer, known as the electric double layer (EDL), whose thickness is characterized by the Debye length scale κ^{-1}, which is at most $O(10\text{ nm})$ for most aqueous solutions [7]. For a glass microchannel wall and PS particles, the wall and particle surfaces will become negatively charged for aqueous solutions at moderate pH values, and the particle-wall surfaces, will then have a repulsive interaction between their EDLs over distances of order κ^{-1} that depends upon the particle and wall zeta-potentials, which are also affected by the ionic strength and temperature of the solution.

The particle and wall surfaces will also experience attractive intermolecular van der Waals interactions. The combination of EDL repulsion mediated by van der Waals attraction, described by the DLVO theory [7], leads to a strongly nonuniform particle distribution along the wall-normal direction, with a particle depletion zone immediately next to the wall.

This steady-state nonuniform particle distribution should be a Boltzmann distribution, and so the potential energy of the particle-wall interactions $\phi(h)$ can be written in terms of the particle number density $c(h)$:

$$\frac{\phi(h)}{kT} = -\ln\left\{\frac{c(h)}{c_\infty}\right\} \tag{3}$$

where h is the particle-wall separation (so a particle touching the wall corresponds to a separation $h = 0$), k is Boltzmann's constant, T is the absolute temperature of the fluid, and the particle number density recovers to its nominal value c_∞ in the bulk of the flow far away from the wall, or for $h \to \infty$. The magnitude of the wall-normal "lift" force acting upon the particle is then the (magnitude of the) derivative of ϕ.

Hindered Brownian Diffusion

Colloidal particles with radii $a \leq 0.5$ μm suspended in an unbounded fluid are subject to significant Brownian diffusion due to Stokes' drag and thermal effects. The stochastic fluctuations due to Brownian diffusion are described by the Stokes-Einstein diffusion coefficient:

$$D_\infty = \frac{kT}{6\pi\mu a} \tag{4}$$

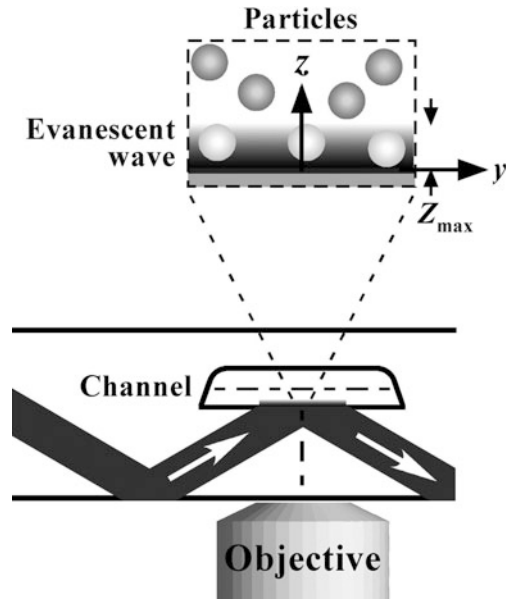
where k is the Boltzmann constant, T is the absolute temperature of the fluid, and μ is the viscosity of the fluid. In the near-wall region, however, the fluctuations in the particle position due to Brownian diffusion are reduced by hydrodynamic interactions with the wall. Moreover, the presence

of the wall hinders diffusion normal and parallel to the wall differently. For a particle whose center is at a wall-normal distance $z = O(a)$ from the wall, the correction factor for diffusion parallel to the wall is given by the Faxén relation [8]:

$$\beta_{\parallel} \equiv \frac{D_{\parallel}}{D_{\infty}} = 1 - \frac{9}{16}\frac{a}{z} + \frac{1}{8}\left(\frac{a}{z}\right)^3 - \frac{45}{256}\left(\frac{a}{z}\right)^4 - \frac{1}{16}\left(\frac{a}{z}\right)^5 \tag{5}$$

where $D_{\parallel}$ is a coefficient for hindered diffusion parallel to the wall. The correction factor for diffusion normal to the wall, which is an infinite series in z/a [9], can be approximated by regression of the series [10] as

$$\beta_{\perp} \equiv \frac{D_{\perp}}{D_{\infty}} = \frac{6h^2 + 2ah}{6h^2 + 9ah + 2a^2} \tag{6}$$



where $D_{\perp}$ is the coefficient for hindered diffusion normal to the wall and $h = z - a$ is the particle edge-wall separation. Near the wall, the diffusion coefficients become functions of the particle wall-normal position. Given that this position will change over time due to diffusion normal to the wall, the near-wall fluctuations of particles due to Brownian diffusion will not have a mean of zero, unlike the fluctuations described by Eq. 4.

The effects of hindered Brownian diffusion have been modeled using Fokker-Planck and Langevin approaches [11, 12], and the discrepancy between the particle and fluid velocities due to Brownian diffusion increases with a dimensionless group $\Pi \equiv D_{\infty}(\Delta t)/Z_{\max}^2$ that compares the displacements due to Brownian diffusion with the wall-normal dimension of the region illuminated by the evanescent wave for $\Pi > 1$. The effects of Brownian diffusion can therefore be reduced by minimizing Δt, the time interval between successive images.

The particles will also lag the flow if a large velocity gradient, or shear, causes the particles to rotate. The velocity of a sphere U near a solid planar wall convected by a simple shear flow rate of $\dot{\gamma}$ will be reduced by 3 % at normalized particle edge-wall separations $h/a = 2$ and by 8 % at $h/a = 0.5$ [13]. Particle rotation therefore only has a significant effect on particle dynamics very close to the wall, where there are relatively few particles due to repulsive particle-wall EDL interactions.

Evanescent-Wave Particle Visualization

Evanescent waves generated by the TIR of a laser beam at the interface between the glass wall of the channel and the flowing aqueous solution can be used to illuminate fluorescent PS particles of radius $a = 50$–500 nm suspended in the flow (Fig. 2). This illumination can be generated either by coupling the laser beam into the channel using a prism or by using a high–numerical aperture TIRF microscope objective. For blue light at $\lambda = 488$ where $n_1 = 1.34$ (i.e., the refractive index of water) and $n_2 = 1.46$ (i.e., the refractive index of fused silica), $\theta_c = 66.6^\circ$ and $z_p \approx 100$–200 nm by Eq. 2 for angles of incidence a few degrees greater than the critical angle. The fluorescence from the particles in the x-y plane parallel to the bottom wall is imaged

Evanescent-Wave Particle Visualization in Nano- and Microchannels, Fig. 2 Sketch of the cross section of flow through a glass microchannel containing suspended fluorescent particles. The particles are illuminated by evanescent waves from the TIR of a laser beam at the glass wall-fluid interface and imaged through the same (*lower*) wall of the channel. The flow and x direction point out of the page

from below through a microscope objective by an intensified or electron multiplying CCD (ICCD and EMCCD, respectively) camera.

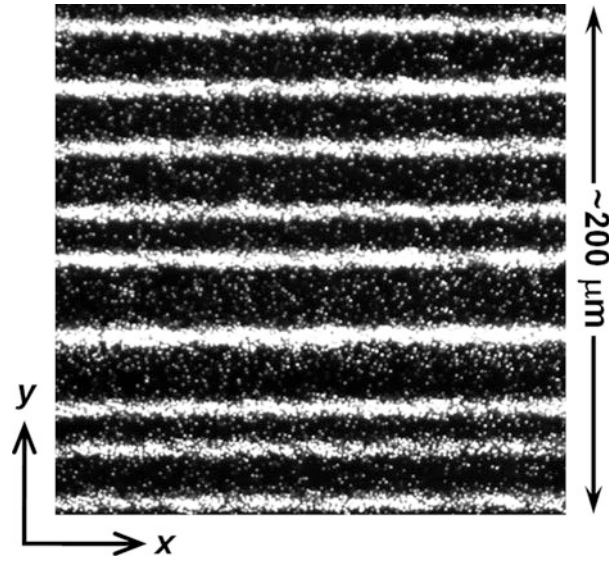
The maximum z-distance from the wall Z_{max} where tracer particles are visible in the images is usually determined by the noise characteristics of the camera. For a 16-bit EMCCD camera image, for example, the background noise can be as great as 8 % of the maximum grayscale value. In this case, $Z_{max} = 3z_p$ based on Eq. 1, since the images of particles beyond that distance cannot be distinguished from the background noise in the images.

The x- and y-locations of the center of any particle image can be determined, for example, with a resolution of ~0.1 pixel by identifying the center of the correlation peak after cross-correlating the particle image with an axisymmetric Gaussian function. Moreover, the wall-normal, or z-, location of the particle can be determined from the grayscale value of the particle image. If the intensity I_p of the image of a fluorescent particle excited by evanescent waves also follows Eq. 1, the particle edge-wall separation is

$$h = z_p \ln\left\{\frac{I_p^0}{I_p}\right\} \tag{7}$$

where I_p^0 is the intensity of the image of a particle touching the wall (i.e., at $h = 0$). Note that particle-to-particle variations can introduce significant variations in I_p^0.

In most cases, the z-component of the velocity is negligible this close to the wall. The two other (x- and y-) components are typically obtained by estimating the displacements between a series of images separated by a time interval Δt using particle-tracking techniques [14] or by simply matching the particles in the first image to their nearest neighbor in the second image in cases where φ and Δt are small enough for the particle displacements to be less than the average interparticle distance. Each particle displacement is then assigned to its average wall-normal position over the two images in the pair.



In multilayer nanoparticle tracking velocimetry (MnPTV) [15], one can obtain a velocity profile, typically consisting of three data points, all still at $z \leq Z_{max}$, which accounts for the nonuniform distribution of the particles. The velocity data from a sequence of images of a steady or periodic flow are divided, based upon their average wall-normal positions, into a few (usually three) layers and averaged over all the velocities in each layer. The wall-normal position of this average velocity is then also the average of the wall-normal positions of all the velocity samples in that layer. By effectively reducing the wall-normal dimension of the velocity data to that of a single layer (vs. Z_{max}), MnPTV should also be less affected by Brownian diffusion.

The particle edge-wall separations determined from Eq. 7 for a large ensemble ($O(10^4)$) of particles also can be used to estimate the steady-state distribution of the particles along the wall-normal direction. One of the more recent applications of evanescent-wave particle visualization in microfluidics entails directly measuring this distribution, quantified by the particle number density profile $c(h)$, and studying the differences in the near-wall distribution of colloidal particles in flowing, versus quiescent, dilute colloidal suspensions to determine the additional lift forces on near-wall particles due to the flow itself.

Examples

Over the past decade, a variety of phenomena have been studied using evanescent-wave particle visualization. A number of groups have studied hindered Brownian diffusion of particles ranging from $a = 100$ nm to 1.5 μm both parallel and normal to the wall [16–18] and for the most part reported results in good agreement with the predictions of Eqs. 5 and 6.

A variety of evanescent-wave particle velocimetry approaches using fluorescent PS tracers have been used to study slip of Newtonian liquids in Poiseuille flow through microchannels. Slip lengths as great as 96 nm have been observed in hydrophobic channels at $\dot{\gamma} = 1800\,s^{-1}$ [19], while other studies have reported smaller values for slip lengths, as great as 23 nm, in hydrophobic channels at $\dot{\gamma} = 2250\,s^{-1}$ [15]. Accounting for the

Evanescent-Wave Particle Visualization in Nano- and Microchannels, Fig. 3 Image of "bands" of $a = 245$ nm fluorescent PS particles suspended in an aqueous solution of 1 mM sodium tetraborate flowing through a ~30 μm deep fused-silica channel at $\dot{\gamma} = 1100\,s^{-1}$ and a dc electric field magnitude of 47 V/cm. The particles in these bands, which are aligned with the Poiseuille and EO flow directions, are illuminated by evanescent waves, and only particles at $h < 360$ nm are visible in this image

nonuniform near-wall distribution tracers significantly reduced the slip lengths estimated in the latter study, which noted that assuming uniformly distributed tracers would have easily tripled the slip length. Most recently, the technique has been used to study transport in nanochannels, with slip lengths as great as 189 nm reported in 410 nm deep hydrophilic channels [20]. Evanescent-wave particle velocimetry has also been used to measure velocity fields in electroosmotic (EO) flows driven by a voltage gradient or electric field [21] and estimate velocity profiles inside the EDL [22].

Other types of particle-like tracers have also been used to study near-wall flow dynamics. Near-wall flow velocities have been estimated from the displacements of both fluorescently labeled λDNA molecules [23] and ZnS-overcoated CdSe quantum dots [24] illuminated by evanescent waves, for example.

Recently, evanescent-wave particle visualization has also been used to study the near-wall dynamics of the particles themselves, versus the convection of these particles by the flow. It has been known for almost two decades that $a \approx 2$–5 μm neutrally buoyant particles in a dilute suspension are subject to so-called electrokinetic (or electroviscous) and hydrodynamic lift forces in shear (e.g., Poiseuille and Couette) flows that drive them away from the wall [25, 26]. More recently, both theoretical and experimental studies have shown that suspended particles are subject to "dielectrophoretic-like" forces due to a steady electric field parallel to the wall in electroosmotic flows [27, 28]. Evanescent-wave visualizations of dilute colloidal suspensions of $a \approx 100$–500 nm fluorescent PS and colloidal silica particles in both Poiseuille and EO flow through fused-silica microchannels have shown that these smaller particles are also subject to repulsive lift forces of O(1–10 fN) [29, 30] and that they can even be self-assembled into "bands" (Fig. 3) using a combination of Poiseuille and EO flow [31].

Definition

Exposure and toxicity are the two variables that are required to assess the risk that a substance poses to an organism or the environment. Exposure determines to which extent an organism enters in contact with a substance, while toxicity measures to which extent an organism is impaired by the substance.

Background

The increasing use of engineered nanomaterials (ENMs) in consumer products is leading to a new type of environmental pollution for which the knowledge related to environmental hazards and risks is very limited. Toxicity and even ecotoxicity have been examined for a range of ENMs, and a majority of the reports conclude that several ENMs have toxic properties under certain conditions. Yet, exposure conditions seem to govern the outcome of such studies which range from instillation into mammalian airways to exposure of ENMs mixed into soil.

Soil is a particular matrix. It is recognized as a major recipient and sink for environmental pollution with ENMs [1], particularly through application of sewage sludge which contains most of the ENMs entering wastewater [2]. But soil is also an environmental compartment that is essential for food production and a number of important ecological and biogeochemical functions. Soil is an extremely complex matrix, with high specific surface area, a large amount of charged surfaces, abundant amorphous colloidal material, and a wide range of dissolved ions and dissolved organic matter, all of which eludes precise characterization. From one soil to another, there may be a large variation with respect to composition and properties due to differences in parent material and the extent and stage of biological and climate-dependent soil-forming processes. The complexity and diversity of soils is a challenge in terrestrial ecotoxicity studies, as soil properties will influence bioavailability and thereby exposure of organisms and ultimately the apparent toxicity to ENMs. Which properties are most important for ENM bioavailability probably depend on the ENM in question, but remains to be examined in detail.

Differences in soil composition translate into differences in soil properties that can be quantified by physical and chemical analyses. Though no systematic examination exist of which soil properties affect the bioavailability of different ENMs, certain soil properties that affect the bioavailability of other environmental pollutants are likely to be important. These are, therefore, reported in soil-based ecotoxicity studies on ENMs and include, or should include, texture (particle size distribution), organic matter content, pH, cation exchange capacity (CEC), and base saturation (BS; quantity of exchangeable Na, K, Mg, and Ca as a percentage of CEC). Even though other parameters may be equally important or provide more detailed information that may be used to explain interactions between a soil and ENMs, these are often too specialized to be available in most soil science labs (e.g., equipment for characterization of specific surface area, clay mineralogy, or soil organic matter quality).

When ENMs are characterized, specific surface area has become a useful parameter believed to predict both surface reactivity, capacity to

interact with dissolved ions and molecules, as well as propensity for dissolution. Small nanoparticles typically have specific surface areas (measured by BET; the Brunauer-Emmett-Teller method) in the order of 30–50 $m^2\ g^{-1}$ [3]. Though impressive it may seem, soil constituents like clay may have BET values an order of magnitude higher, ranging from 50 to 1,100 $m^2\ g^{-1}$. Also humic soil organic matter has BET values in the order of 500–800 $m^2\ g^{-1}$. As soils commonly contain at least 3–5 % organic matter and often at least 10 % clay, there are ample possibilities for interactions between ENMs and the soil matrix, which may affect exposure and toxicity to soil organisms.

Standard OECD and ISO test guidelines for soil organisms like earthworms commonly exclude the use of soil, and those standardized tests that permit the use of soil prescribe the use of soil types that are low in clay and organic matter. Artificial "soils" are frequently used in which weakly transformed peat constitute the organic fraction and sand and low swelling clay represent the mineral fraction. Not only are these "soils" poor as proxies for real soil with respect to surface area and surface charge, but they are also void of organisms which constitute an integral part of natural soils.

To test the impact of environmental toxicants on soil organisms, earthworms have frequently been used due to the ecological importance of their activity related to soil organic matter turnover and their burrowing that ensures soil porosity [4]. Earthworms are also convenient as test animals, as several stress-related and toxicological endpoints may be used in tests of limited duration to assess both acute and chronic effects at different levels (behavioral, physiological, reproductive, and genetic).

Eisenia fetida is a model earthworm used in standardized soil toxicity tests issued by the US-EPA and the OECD. This species has a short generation time and reproduces easily under lab conditions. Part of its genome is also sequenced for use in transcriptomic studies. Yet, the extensive use of this species is often criticized as it is epigeic (living in organic surface layer or compost), rather than endogeic or anecic (living and burrowing in soil, *stricto sensu*).

Exposure

The question of possible risks of ENMs does not depend solely on their toxicity, but also requires information on exposure (Risk = Hazard × Exposure). The latter aspect has, however, received far less attention than toxicity studies, probably due to methodological difficulties, as ENMs are difficult to track and quantify in organisms and their tissues, and even more so in complex media like water, sediments, soil, and waste. Exposure is somewhat differently defined in toxicology and ecotoxicology. In higher organisms in vivo, exposure is often concerned with toxicokinetic aspects of absorption, distribution, metabolism, and excretion (ADME), though the route of exposure is also given (oral, dermal, respiratory, etc.). In ecotoxicology, the perception of exposure is much closer to the colloquial understanding of the word and implies to which extent an organism gets in contact with a toxic compound, ingests it and excretes it. Two earthworm species living in the same soil but having different feeding habits (e.g., anecic vs. endogeic) may thus be exposed to ENMs in surface applied sewage sludge in very different ways. Also, a worm living in a clay-rich soil containing ENMs may be differently exposed compared to the same worm species living in a sandy soil containing the same type and amount of ENMs. This aspect of exposure is closely related to the concept of bioavailability, which is taking into account the interactions between a nutrient or a toxic compound and its surrounding matrix. Studies on earthworm exposure to ENMs have sought to vary both the way ENMs are provided (mixed into soil or feed) and matrix composition (soil vs. water, and soil composition). Also, pure measurements describing uptake and excretion have been made for some ENMs. The few earthworm exposure studies that exist are described under each category of ENM, together with data on ecotoxicity.

Experimental Evidence

Several types of metal and metal oxide nanomaterials have been studied for their

potential bioavailability and toxicity to earthworms, namely, Ag, Au, Co, Cu, Fe, Ni, Al_2O_3, SiO_2, TiO_2, ZnO, and ZrO_2. Most of these studies used the earthworm *E. fetida*, while others used *Lumbricus terrestris*, *L. rubellus*, or *E. veneta*. Also tests using the closely related pot worm *Enchytraeus albidus* have provided relevant data in similar tests, since this species also belongs to the subclass Oligochaeta. A variety of endpoints are reported, from survival, body burden, and reproduction to apoptosis and expression of genes involved in metal homeostasis and oxidative stress. State-of-the-art results are presented for each metal and metal oxide type below.

Ag

A variety of silver nanoparticles (Ag NPs) with a range of sizes (9–50 nm diam.) and coatings (citrate, oleic acid, polyvinylpyrrolidone, or none) have been exposed to earthworms through water, food, or different types of soil at concentrations ranging from 0.3 to 1,000 mg kg^{-1}. Bioaccumulation has generally been higher for $AgNO_3$ than for Ag NPs, and the various sizes and coatings tested have affected bioaccumulation to no or only limited extent. What has made a difference is the soil type used in these tests, so that higher bioaccumulation of Ag NPs has been observed in soil with lower organic matter and higher sand content. In artificial OECD soil, bioaccumulation factors (BAFs, being the concentration ratio of accumulated ENMs/soil ENMs) have been very low and seem to indicate that Ag NPs measured in earthworms merely result from incomplete gut clearance after exposure. In soil with lower organic matter and higher sand content, Ag NPs have been more bioaccessible and BAFs higher (BAF = 0.05–0.08 in sandy loam while <0.03 in OECD soil) [5, 6]. Survival and growth of worms were not affected by Ag NP concentrations as high as 1,000 mg kg^{-1}, contrary to $AgNO_3$, which reduced survival to approx. 3 % at the same concentration [7]. Reproduction measured as cocoon production has been affected at lower concentrations with significant reductions at ≥94 mg kg^{-1} for $AgNO_3$, and at ≥800 mg kg^{-1} Ag NPs in an experiment by Shoults-Wilson et al. [6]. In this experiment, no differences were found between particles of different size or with different coatings. A more sensitive endpoint yet is the measurement of avoidance, as demonstrated in an experiment by Shoults-Wilson et al. [8] where worms given the choice between uncontaminated soil and soil spiked with 7 mg kg^{-1} Ag NPs, avoided the latter when measured after 48 h exposure. A similar concentration of $AgNO_3$ induced the same response, but faster. This concentration is close to predicted environmental concentrations of Ag NPs in sludge from sewage treatment plants in Europe and the United States (1.29–6.24 mg kg^{-1}) [1]. Also enhanced frequency of apoptosis measured in the cuticle, the intestinal epithelium, and the chloragogenous tissue of earthworms (*L. terrestris*) exposed to concentrations as low as 4 mg kg^{-1} in soil indicate that earthworms may be negatively affected by environmentally relevant concentrations of Ag NPs [9]. The two latter reports do, however, not prove any lasting negative impact, but may simply be due to stress from which the worms can recover in time. The studies conducted so far have been based on freshly spiked media. It appears, however, that Ag NPs may become more bioavailable than $AgNO_3$ over time as Ag NPs can act as constant sources releasing ionic and bioavailable Ag. This is indicated, e.g., by the results of Shoults-Wilson et al. [10] who showed that 11–20 % of Ag in 30–50 nm Ag NPs was oxidized after 28 days in OECD soil, and supported by results from sequential chemical extractions of soils spiked with different types of Ag NPs (Coutris et al., unpublished results). Until more sensitive endpoints are examined, e.g., related to transcriptomic analyses, that can confirm or preclude proper toxicity effects of environmentally relevant AgNP concentrations, conclusions must be drawn from the physiological and reproductive endpoints available. Based on such data it seems like Ag NPs have a low toxicity and low bioavailability to earthworms.

Au

Gold NPs (4 and 18 nm diam., coated with citrate) have been found in the gut and the skin of earthworms exposed for 1 week to Au NPs in artificial OECD soil spiked with 3 mg Au kg^{-1}. A similar

body distribution was found in worms exposed 48 h on filter paper to a 10 mg L^{-1} Au NPs suspension [11]. In this study, Au uptake was particle size dependent, with uptake of Au ions being the highest followed by 4 and 18 nm Au NPs. In another experiment with Au NPs (20 and 55 nm diam., 5–50 mg kg^{-1} soil) Unrine et al. [12] confirmed that Au NPs were bioavailable to *E. fetida* through exposure in artificial OECD soil, and that Au ions were taken up to a larger extent than Au NPs. However, in this case, no difference in uptake was noticed between Au NPs on a mass basis (whereas on a particle number basis, more 20 nm Au NPs were taken up than 55 nm Au NPs). Although no effects on survival or growth were noticed, both ions and NPs had negative effects on earthworm reproduction. This response was not purely dose dependent, as e.g., 55 nm Au NPs had no negative effect on reproduction at 50 mg Au kg^{-1}, whereas at 20 mg kg^{-1} a negative effect was observed. Also here, ions were more toxic than NPs, but smaller NPs did not appear more toxic than larger ones, and the two size classes tested formed aggregates of similar size. Finally, none of the earthworm genes related to metal homeostasis and oxidative and cellular stress were expressed differently in control and Au NPs treatments, whereas $HAuCl_4$ at $\geq$2.5 mg kg^{-1} resulted in the upregulation of metallothionein [12].

Co

Cobalt NPs (Co core/Co_3O_4 shell, 4 nm diam.) have been found to be readily bioavailable to *E. fetida* exposed though their diet to 1 mg Co kg^{-1} (BAF = 0.69 ± 0.04 for Co NPs and 0.88 ± 0.05 for $CoCl_2$). Co from both particulate and ionic sources was only slowly excreted from the worms (biological half-life 200 days) and showed a rather similar biodistribution within internal organs of the worms [5]. The highest accumulation was found in the blood and the intestinal tract and the least in the reproductive organs. Still, at high concentrations (87 mg kg^{-1} food), Co from Co NPs have been found in reproductive organs and cocoons produced after the worms had been transferred to a non contaminated environment [13].

Cu

Copper NPs (Cu/CuO, 80 nm diam.) added to artificial OECD soil at 1,000 mg kg^{-1} had no acute effect on the survival of *E. fetida*, but induced a dramatic decrease in reproduction, whereas a similar concentration of $CuCl_2$ had both an acute and chronic effect [7]. The same particles have been tested at 450 and 750 mg kg^{-1} on *Enchytraeus albidus*, and indicated that both $CuCl_2$ and Cu NPs caused oxidative stress damage, yet in different ways and with more pronounced effects in the case of $CuCl_2$ [14]. An experiment by Unrine et al. [15], where *E. fetida* was exposed to artificial OECD soil spiked with Cu NPs (20–40 nm and 100 nm diam.), has showed that the expression of metallothionein genes was upregulated at $\geq$20 mg kg^{-1} Cu NPs and $\geq$10 mg kg^{-1} $CuSO_4$, while no effect on the regulation of other genes related to oxidative and general stress was detected. Synchrotron-based X-ray analyses indicated that both types of Cu NPs had been oxidized within 4 weeks so that they contained a mixture of zero-valent Cu, Cu_2O, and CuO. Smaller particles were also more oxidized than larger ones. The authors concluded that oxidized Cu NPs were able to enter the food chain from soil, but that only concentrations >65 mg kg^{-1} would induce adverse effects.

Fe

Ecotoxicity data for nano zero-valent iron (nZVI) on terrestrial macro- and mesofauna are only starting to emerge. Preliminary studies have shown that earthworms are sensitive to nZVI concentrations of $\geq$100 mg kg^{-1}. Both the compost worm *E. fetida*, used in standardized OECD tests, and the epigeic earthworm *Lumbricus rubellus* showed signs of adverse effects during long-term exposure to 100 mg nZVI kg^{-1}, whereas acute (mortality after 14 days exposure in sandy soil) toxicity was observed only at concentrations $\geq$500 mg nZVI kg^{-1} for both species (El-Temsah and Joner, unpublished results).

Ni

The only published study assessing the potential toxicity of Nickel NPs (20 nm diam.) to *E. fetida* did not reveal any acute effects on the survival or

reproduction. The test featured 28 days exposure in artificial OECD soil containing 1,000 mg kg^{-1} Ni NPs. On the other hand, a similar concentration of $NiCl_2$ induced a high mortality and impaired reproduction dramatically (98 % decrease in cocoon production and none of the cocoons hatched) [7].

Al_2O_3

Al_2O_3 NPs (12–14 nm diam.) added to artificial OECD soil at 1,000 mg kg^{-1} did not show any acute effects on the survival or reproduction of *E. fetida* [7]. Another study with similarly sized Al_2O_3 NPs (11 nm) found that cocoon production was reduced only at concentrations $\geq$3,000 mg kg^{-1}, and that avoidance was apparent when concentrations reached $\geq$5,000 mg kg^{-1} [16]. Although no predicted environmental concentrations are available for this type of nanomaterials, it seems unlikely that such concentrations will be found in the environment.

TiO_2

TiO_2 NPs (21 nm diam., 73 % anatase, 27 % rutile) added to artificial OECD soil at 1,000 mg kg^{-1} had no acute effect on the survival of *Eisenia fetida*, but induced a weak but significant adverse effect on reproduction [7]. TiO_2 NPs (10–20 nm diam., rutile) added to artificial OECD soil induced lipid peroxidation, DNA damage, and mitochondria damage only at very high concentrations (5,000 mg kg^{-1}) [17]. Another experiment with *Lumbricus terrestris* exposed to an aged TiO_2 composite (100–300 nm, 1–100 mg kg^{-1}) through water, food, and soil showed neither effect on survival nor bioaccumulation, but enhanced apoptotic frequency in the cuticle, the intestinal epithelium, and chloragogenous tissue of worms exposed to 100 mg kg^{-1} in water [18]. Similar effects were not observed when exposed in soil or feed.

ZnO

No acute toxic effects of Zn on survival were found in *E. veneta* exposed to $ZnCl_2$ or ZnO NPs ($\leq$100 nm diam.) at 250 and 750 mg ZnO kg^{-1} soil for 21 days [19]. Growth was observed in all worms irrespective of Zn source and dose, but was slightly reduced for $ZnCl_2$ at the highest concentration. Cocoon production was reduced by 50 % at 750 mg kg^{-1} in the case of ZnO NPs, whereas the same Zn concentration led to an almost complete inhibition in the case of $ZnCl_2$. No reduction in immune activity of coelomocytes was found in presence of ZnO NPs, even at the highest concentration tested, whereas a 20 % reduction was observed at 750 mg kg^{-1} for $ZnCl_2$. In another study with 7 days exposure of *E. fetida* to ZnO NPs (10–20 nm diam.) Hu et al. [17] observed increased lipid peroxidation at $\geq$100 mg kg^{-1}, reduced activity of superoxide dismutase and biochemical metabolism (measured as catalase activity) at $\geq$500 mg kg^{-1}, induced DNA damage at 1,000 mg kg^{-1}, and mitochondria damage at 5,000 mg kg^{-1}. This study made no comparisons to ionic Zn. A third study where *E. fetida* was exposed to ZnO NPs in agar for 4 days found close to 100 % mortality of ZnO NPs at 1,000 mg ZnO kg^{-1} [20]. The same authors also used a contact test where worms were exposed to ZnO NPs added as an aqueous suspension to filter paper, but this test showed no dose-dependent toxicity. Both the agar test and the filter paper test did, however, show that environmental conditions can influence toxicity, as lower negative effects were observed when ZnO NPs suspensions were prepared with water containing salts or dissolved humic material, as compared to exposure to ZnO NPs suspended in deionized water.

SiO_2 and ZrO_2

To date, the adverse effects of SiO_2 and ZrO_2 nanoparticles have only been examined one study, which did not reveal any detrimental effects on the survival or reproduction of *E. fetida* when exposed to 1,000 mg kg^{-1} SiO_2 NPs (5–15 nm diam.) or ZrO_2 NPs (20–30 nm diam.) in artificial OECD soil [7].

Concluding Remarks

Testing of metallic and oxide ENMs for adverse effects on soil invertebrates has only been attempted for a few years, and the limited amount

of data available, with respect to tested ENMs, earthworm species, ecotoxicological endpoints, and exposure conditions, calls for cautious conclusions. Still, it seems that ENMs made of elements with known antimicrobial properties, like Ag and Cu, are among those that should be treated with most concern as they have so far shown the lowest adverse effect concentrations. Earthworms may not only be affected by direct toxicity of these ENMs, but will also suffer if microorganisms on which they depend are affected. Earthworms strongly depend on microorganisms living both endosymbiotically in the coelomic cavity and in the digestive tract, and any adverse effects on these organisms are bound to affect the worm's physiology and health. Regarding the specific effects of ENM versus the same elements in a soluble form, there are several indications that the effect of ENMs stems, at least partly, from dissolving ions released by from the surface of ENMs. While free ions often react rapidly with other ions or more complex molecules to form insoluble metal species (e.g., AgCl), ENMs may continue to act in a toxic manner by surface interaction or continued release of ions. In this way, ions may appear more acutely toxic, while corresponding ENM may eventually appear to have more chronic effects.
