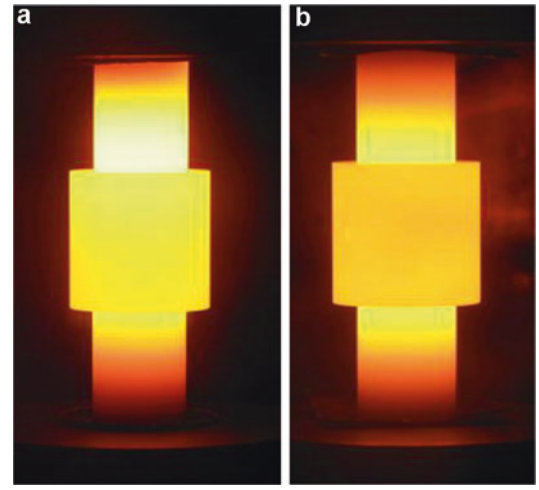
Definition

Nanoceramics	Defined as ceramics with the average grain size at least in one dimension less than 100 nm.
Spark Plasma Sintering	Defined as a sintering process during which the powders or green bodies are loaded in a die and are pressed under a uniaxial pressure. Instead of conventional use of an external heating source, a pulsed DC current is allowed to pass through the electrically conducting pressure die and, in appropriate cases, also through the sample.
Kinetic window	Defined as a temperature interval in which the grain growth and densification process can be separated during sintering.
Grain sliding	Defined as sliding of grains over one another through grain boundaries.

Spark Plasma Sintering



Spark plasma sintering (SPS) is a sintering process similar to conventional hot pressing, in which the samples are loaded in a die and a uniaxial pressure is applied during the sintering. However, instead of using an external heating source, a pulsed direct current is allowed to pass through the electrically conducting pressure die and, in appropriate cases, also through the sample. This implies that the die also acts as a heating source and that the sample is heated from both outside and inside, as outlined in the schematic drawing shown in Fig. 1a. Thus, the unique features of the process are the possibilities of using very fast heating rates and very short holding times to obtain fully dense samples. Three factors that contribute to the rapid densification process can be discerned: (i) the application of a mechanical pressure, (ii) the use of rapid and efficient heating, and (iii) the use of pulsed direct current, implying that the samples are also exposed to an electrical field [1].

During spark plasma sintering the temperature is measured and regulated either by a pyrometer focused on the outer wall of the graphite die or by a thermocouple inserted into the graphite dies. This implies that the real temperature the sample

Nanoceramics by Spark Plasma Sintering, Fig. 1 Schematic figures of the die setup in (**a**) normal spark plasma sintering (*SPS*), (**b**) high-pressure spark plasma sintering (*HP-SPS*), and (**c**) pressureless spark plasma sintering (*PL-SPS*)

experienced during the sintering process is different from what is indicated by the temperature measurement. Such temperature difference is determined by the geometry and size of the die, the thermal and electrical conductivity of the sample, the assembly of the die and punches, the level of applied pressure, and the applied heating rate. Moreover, the contact resistance shows important influence on the temperature distribution during spark plasma sintering. As shown in Fig. 2, the same die set can result in dramatically different temperature distributions when the contacting surfaces of the punches are smooth (a) or rough (b). Since the temperature in most cases is collected from only one spot on the outer wall of the die, it is extremely important to keep the same die configuration for a series of experiments in order to make the results repeatable and comparable [2].

Nanoceramics by Spark Plasma Sintering, Fig. 2 Images of the temperature distributions resulted from (**a**) smooth and (**b**) rough contacting surfaces

The SPS setup can be modified and combined with established sintering technologies to generate further variations. For instance, by using the conception of matryoshka doll, a high uniaxial pressure of up to 1 GPa can be applied with a modified setup as schemed in Fig. 1b [3]. This variation of high-pressure SPS allows further reduction of the sintering temperature. On the other hand, the uniaxial pressure may be totally removed by placing the two oppositely moving punches on the die, with the setup as scheduled in Fig. 1c [4]. In such a case of pressureless SPS, the graphite die acts as a graphite crucible, in which the specimen is not subjected to any external pressure, but only to fast heating. The SPS process may also be used only for gaining close packing of particles at a temperature lower than what was demanded for full densification. Such a process step known as warm pressing in combination with the conventional pressureless sintering and/or hot isostatic pressing for completing the final-stage sintering is beneficial for retaining the nanostructures in densified bulks [5].

The idea to compact metallic materials by an electro-discharge process was originally proposed in the 1960s. Based on this concept, three sintering processes have been developed and commercialized, named as "spark plasma sintering" (SPS), "plasma activated sintering" (PAS), and "electroconsolidation." The characteristics of the three processes are as follows: (i) In the SPS process, a pulsed DC (3.3 ms pulses of 0.5–10 kA intensity) is applied from the beginning to the end of the sintering cycle; (ii) in the PAS process a pulsed DC is normally applied at room temperature for a short period of time and then a continuous DC during the remainder of the sintering process. This procedure is often referred to in the literature as a "single pulse cycle process," with a typical 30–60 ms pulse current of ~1000 A intensity during 60–90 s. In a few cases, the pulsed DC procedure is repeated during the sintering process, and the procedure is then referred to as a "multiple pulse cycle process"; (iii) in the electroconsolidation process, various types of currents (DC, pulsed DC, or AC) can be used, i.e., the system is designed to be flexible in terms of power supply. These processes have now been developed beyond the production of small objects with simple shapes, and a continuous production of compacts of complex geometry and of pieces with diameters larger than 150 mm has been achieved. Despite the fact that a uniaxial pressure is applied, green bodies of complex geometry can be exposed to a "pseudo-isostatic" pressure when being embedded in free-flowing electrically conducting particulates that act as pressure-transmitting medium inside the die. The SPS technology can be combined with various forms of existing production and automatization concepts and technologies. Thus, besides batch-type setups commonly used in laboratory scale, robotic continuous production by SPS is also possible [6–10].

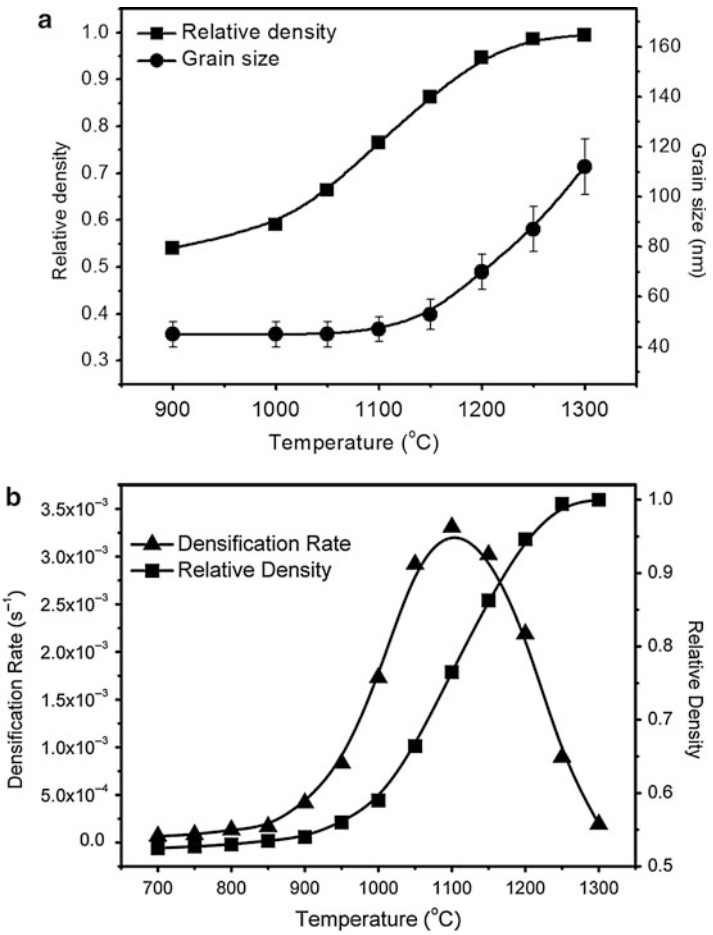
Demand of Separating Grain Growth from Densification for Sintering of Nanoceramics

Nanoceramics, by definition, are ceramics with the average grain size (GS) at least in one dimension being less than 100 nm. A major obstacle for retaining nanostructure in bulks encountered during the bottom-up approaches of sintering of nanoparticles is to separate the grain growth from the densification. It is very challenging to overcome this obstacle, as both the densification and grain growth use the same driving force of reducing the total surface energy of the nanoparticles and the same mass transportation mechanism of interfacial atomic diffusion. Applying high temperatures required for fully densifying ceramic nanoparticles often results in grain growth due to Ostwald ripening when traditional sintering techniques are used. The presence of agglomerates in powders with very fine particle sizes that often leads to an inhomogeneous density distribution in green compacts would contribute further to local grain coarsening during final-stage sintering and would produce nonuniformity in the resulting microstructure.

To minimize grain growth, two strategies are often implemented with a common aim of defining a kinetic window, i.e., a temperature interval in which the grain growth and densification process can be separated: (i) optimizing the packing of nanoparticles and (ii) performing the densification at a temperature as low as possible but just high enough to allow sufficient interfacial atomic diffusion for both the particle sliding and the interfacial atomic diffusion promoting densification. The packing of nanoparticles can be optimized already in the green body stage by involving, for instance, a wet chemical process to increase both the homogeneity and the density of the green body, and/or by applying a pressure to assist the particle rearrangement via particle sliding. Quantitatively, it is well known that the closest sphere packing density is 74.05 %, but, in practice, depending on the particle size and size distribution, presence of agglomerate and applied pressure, etc., dry pressing of nano-sized powders often approaches green body densities around 40–50 % of the theoretical density (TD). Densities up to 60–70 % TD have been achieved by processes such as slip casting, gel casting, and pressure filtration. It was found that the coarsening of particles via surface diffusion is inevitable when pressureless sintering is applied to achieve a

critical density of ~77 % TD from the initial green body with density of 40–50 % TD. To the extent that the starting powder is agglomerated, it is often difficult to de-agglomerate it only by applying high pressure at room temperature. However, when the green body is heated to a temperature that is below the temperature where the grain growth is initiated and is subjected to uniaxial pressures, there it is possible to achieve a packing density in the vicinity of 80 % without any major change of the grain size [11, 12].

Typical Sintering Behaviors Observed During Spark Plasma Sintering



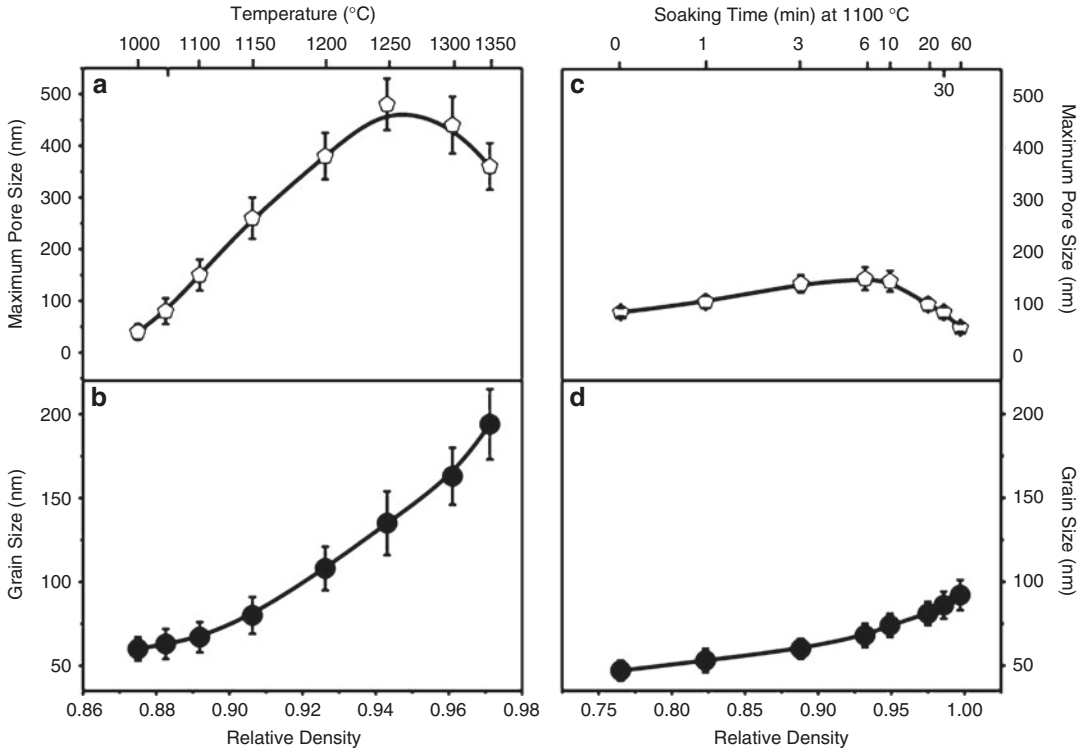
Dramatic Change in Densification Rate

A general observation is the unusual high densification rate achieved in the early and intermediate stage of SPS. The sintering behavior of 3Y-TZP is illustrated as an example presented in Fig. 3. As shown in Fig. 3a, the density rapidly increases from 50 % to ~90 % TD accompanied with rather limited grain growth. The maximum densification rate achievable during this stage of sintering is often in the order of 10^{-3}/s for solid-state sintering and up to 10^{-2}/s in liquid-phase sintering conditions [13]. However, the densification rate dramatically decreases by one order of magnitude during the final stage of sintering. It was reported that the calculated effective activation energies for early stage densification in SPS, based on four classic pressure-assisted models, were considerably lower than those expected by any classical diffusion-related process [14]. This indicates that possible mechanisms beyond the classic interfacial atomic diffusion-related processes may be involved in SPS process. The radical change of the densification rates might reflect the switching of different densification mechanisms that dominate different sintering stages.

Refinement of Pore Structure

When ceramics are viewed as composites of solid and pore phases, densification can be regarded as a process during which pores are gradually replaced by solid grains. It was reported that the enlargement of pores in the intermediate stage of sintering was suppressed during spark plasma sintering which, otherwise, is a phenomenon commonly observed in conventional pressureless sintering. This refinement of pore structure is beneficial for facilitating subsequent densification in the final-stage sintering [15]. Figures 4 and 5 illustrate the evolution of the grain and pore structures against the relative densities of the sintered bodies in the high-density regimes for 3Y-TZP nanoceramics. The samples densified by SPS at 1100 °C for 3 min under 100 MPa achieved a density of 87 % TD which was further densified either by a follow-up SPS at 1100 °C under 100 MPa up to 60 min or by conventional pressureless sintering up to 1350 °C. It can be noticed that the maximum pore size experiences a dynamic enlargement with one order of magnitude increase in size to more than ~480 nm when the sample is pressureless sintered to 1250 °C. Thereafter, the maximum pore size slowly decreases upon further sintering, whereas rapid grain growth was observed resulting in an average grain size larger than 200 nm in the fully densified body. On the contrary, the pore size in samples further SPS processed is suppressed to less than ~150 nm. The easy elimination of small pores during prolonged soaking yielded a final grain size less than 100 nm in spark plasma sintered dense body.

Figure 5a shows an SEM micrograph taken on the partially densified 3Y-TZP samples of 87 % TD, in which both the average grain size (GS) and the maximum pore size measured by linear interception are ~50 nm. Figure 5b shows an SEM micrograph taken on a sample with 94.3 % TD obtained by further pressureless sintering at 1250 °C, revealing the destruction of the microstructural homogeneity due to the local formation of large pores. The removal of those large pores needs much higher temperature which will result in rapid grain growth during the final-stage sintering. On the contrary, the microstructural homogeneity and the fine grain structure can be preserved in a condition as shown in Fig. 5c by SPS at 1100 °C for 10 min under 100 MPa, as the SEM micrograph shown in Fig. 5c revealed. The remaining small pores homogenously distributed at triple junctions in this sample can be eliminated

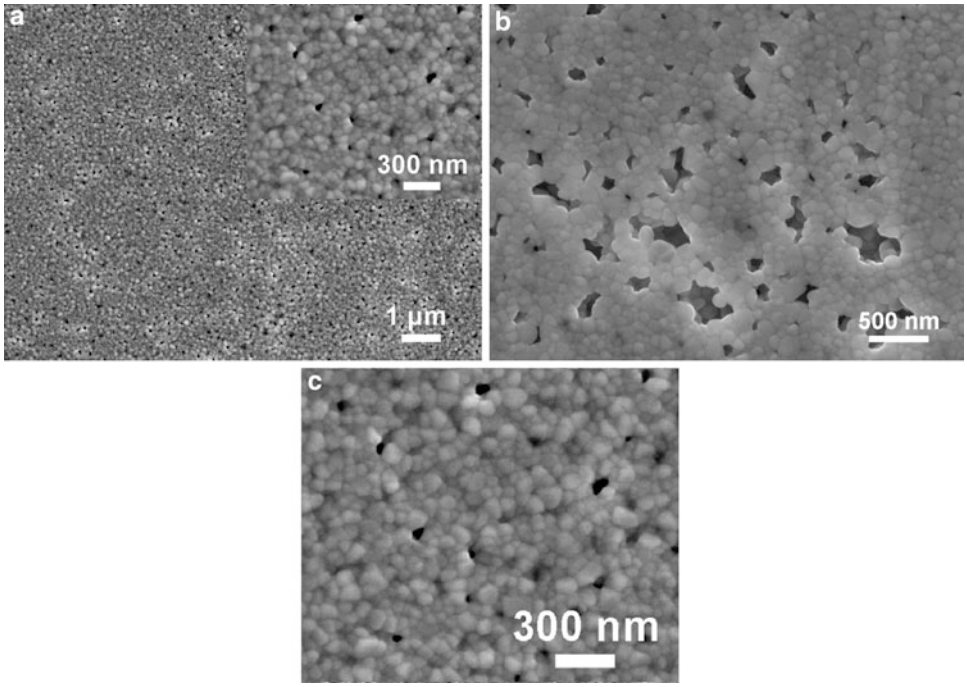


Nanoceramics by Spark Plasma Sintering, Fig. 3 (**a**) The evolution of density and grain size and (**b**) densification rate at elevating temperature of 3Y-TZP nanoceramics by spark plasma sintering under 100 MPa pressure at 100 °C/min heating rate

easily via interfacial atomic diffusion without any extensive grain growth [16].

Grain Sliding as a Dominating Densification Mechanism During the Early and Intermediate Stage of Spark Plasma Sintering

Grain sliding is a phenomenon defined as sliding of grains over one another through grain boundaries which is often observed during pressure-assisted sintering processes. It usually facilitates rapid mass transport and it is responsible for superplastic deformation of nanoceramics. Grain sliding and atomic diffusion-based mass transports are not independent mechanisms. They occur sequentially, implying that the slower mechanism controls the time required for achieving the full densification. Although, it has been reported that during the pressureless sintering of nanocrystalline oxide powders, a sintering mechanism based on particle repacking that occurs concurrently with particle coarsening may be active until ~84 % TD [17]. The active region of particle rearrangement enabled by grain sliding can possibly be further extended to ~93 % TD in SPS conditions [18, 19]. The rapid and efficient heating and the higher pressure that is inherently applicable during SPS appear to be important parameters that bear strong positive influences on the densification of ceramic powders, particularly nanopowders, through grain sliding.



In case of spark plasma sintering of a nano-sized $BaTiO_3$ powder, with the application of a low pressure of 25 MPa, a pressure that normally

Nanoceramics by Spark Plasma Sintering, Fig. 4 Comparisons of the grain size and maximum pore size evolution in two post treatment processes of (**a, b**) by pressureless sintering up to 1350 °C and (**c, d**) by spark plasma sintering soaked at 1100 °C under 100 MPa constant pressure

is used during conventional hot pressing, the maximum shrinkage rate is observed when the sample achieves ~70 % TD. By applying a higher pressure, the shrinkage rate increases and reaches the maximum at higher relative density. Thus, under a pressure of 100 MPa, the maximum shrinkage is achieved at ~90 % TD, implying after that only 10 % of porosity needs to be removed by involving the interfacial atomic diffusion mechanism. The sintering period before the sample reaches the maximum shrinkage can be empirically defined as the initial and intermediate stage during which the densification is enhanced by the smash of agglomerates, the rearrangement of particles, and the close packing of particles, while mechanisms based on power law creep and volume diffusion would probably be excluded. Under high pressures very high strain rates are generated above a critical temperature where an atomic relaxation process in interfacial regions is activated that favor the densification through grain sliding [1, 12].

This shift of the maximum shrinkage rate toward higher relative density minimizes the necessary involvement of the interfacial atomic diffusion mechanisms for densification, thus increases the possibility of reducing the grain coarsening commonly associated with the densification. Accordingly, a large number of nanoceramics and ceramic nanocomposites have been prepared during the last decade [19]. The success in retaining nano-grained microstructure and in reducing the residual pore size down to less than 10 nm has made many dense nanoceramics appearing optically transparent or translucent [20]. It has also drawn attention to spark plasma sintering as a versatile tool for preparing nanoceramics.

Synonyms

Nanofluidic channels; Nanopores; Nanoslits

Definition

Nanochannels or nanoslits are defined as channels with at least one physical dimension equal to or less than 100 nm. The term has, however, been loosely applied to cover channels with a critical dimension as large as 500 nm. Nanopore is a term sometimes used interchangeably with nanochannels. Here, nanochannels refer to channels where fluid flow is on the surface of the substrate, while nanopores are referred to as channels where flow is through the substrate. Another important concept in the field of nanochannels is 1D and 2D nanochannels. A 1D nanochannel can be classified as a channel with both physical dimensions in the nanometer regime, while a 2D nanochannel is defined as one with only one dimension in the nanometer range. These terms, however, have been used interchangeably by some researchers leading to confusion. A better parameter is aspect ratio, that is, the ratio between the height and width or between the diameter and length (e.g., in case of nanotubes). A ratio of more than 100 would represent a high aspect ratio. Nanofluidics refers to study and manipulation of fluid flow in nanochannels. This is the area where nanochannels are finding most promising applications and the following discussion will only focus on applications of nanochannels to nanofluidic technologies.

Overview

Nanochannels are defined as channels that have at least one physical dimension that is less than or equal to 100 nm. The area of research that deals with the behavior of fluids, particularly ionic fluids in nanochannels is called nanofluidics. While nanofluidic encompasses analysis of liquid, gas, or super critical fluid in nanochannels, it is the study of ionic liquids and charged particles in nanochannels that has generated the most interest. This is because of the unique nanoscale electrostatic interactions, entropy, electrodynamics, and steric phenomenon observed in nanochannels that are not observed in microchannels [1]. In nanochannels, the Debye screening length that defines the extent to which surface charge of the nanochannel walls interacts with the bulk fluid is now comparable to the critical dimension of the nanochannel [2]. This proximity allows the wall surface charge to interact with charged particles such as ion, proteins, or DNA in fluid inside the

nanochannel, and surface charge effects can no longer be ignored as is the case in microfluidics. The dominance of ionic interactions leads to unique transport phenomenon caused by complex electrical double layer-electrical double layer (EDL-EDL) interactions, dominant streaming potentials, and particle/biomolecule-EDL interactions [1].

This behavior of fluids in nanochannels is now being exploited for applications targeting biomolecule separation and detection. Some of the techniques used include *co-ion exclusion*. Here the concentration of co-ions is highly depleted in the nanochannel compared to the bulk solution. Electrokinetic flow causes other interesting phenomenon like *concentration polarization* where ions of opposing charges are concentrated at the anode and cathode [3]. Using this approach DNA was shown to be depleted at one end and concentrated at the other end of a nanochannel. These features of nanofluidics have led to extensive fundamental studies and they are now being exploited for biological applications [1]. Biosensing using nanofluidics is beneficial because the small length scales and electrostatic interactions can be leveraged for facile separation of biomolecules, increasing the speed and sensitivity of bioassays. Many applications have targeted DNA separation, concentration, and detection.

Nanochannels are also relevant to cellular organisms. Every living cell is host to a broad collection of nanochannels that traverse the cell membrane and take part in active transport of ions and key nutrients. The most important ones are ion channels; they are central to balancing the intra- and extracellular concentrations of the physiological ions Na^+, K^+, Ca^{2+}, and Cl^- [4] maintaining the cell membrane potential. Also important are aquaporins that nonselectively transport water, ions, and metabolites through the cell. These naturally occurring macromolecular protein-based nanochannels play other significant roles including cell signaling and are the target of many therapeutic drugs. It is no coincidence that the first attempts at nanochannel synthesis involved the naturally occurring protein nanopore – α-hemolysin, a 10-nm long and 1.4-nm internal diameter protein that was involved in lipid bilayer membrane. The setup was used to study DNA translocation through the nanopore in the presence of an electric field, and was promoted as an extremely sensitive single molecule detector. Since then many efforts have focused on fabricating nanopores as small as 2 nm that can be employed for unique applications in single molecule detection and DNA sequencing.

Nanofabrication is a key enabler of nanofluidic research and like microfluidics, the area of nanochannel fabrication has greatly benefitted from the rich knowledge in silicon processing available from the microelectronics industry. Silicon and silicon oxide are, therefore, the most commonly used substrates for nanochannel fabrication. Recently, other cheaper materials such as polydimethylsiloxane (PDMS) and polymethylmethacrylate (PMMA) are becoming popular alternatives for creating nanochannels.

Nanochannels can be fabricated using either top-down approach or bottom-up approach. The top-down approach involves selective deposition and removal of material from substrates generally using classical nanofabrication methods such as photolithography, wet and dry etching, and substrate bonding. This is currently the dominant approach and complex features can be fabricated with relative ease. The equipment and protocols used for top-down fabrication are however expensive, which can drive up the cost of nanochannel devices substantially. In the bottom-up approach, nanochannels are either created through self-assembly or through electrochemical treatment of a suitable substrate such as alumina. This approach can be more affordable and a large array of nanochannels can be created very easily, though spatial control is difficult. Therefore, it is not easy to fabricate complicated geometries and interfacing with the macro-world might also be a challenge.

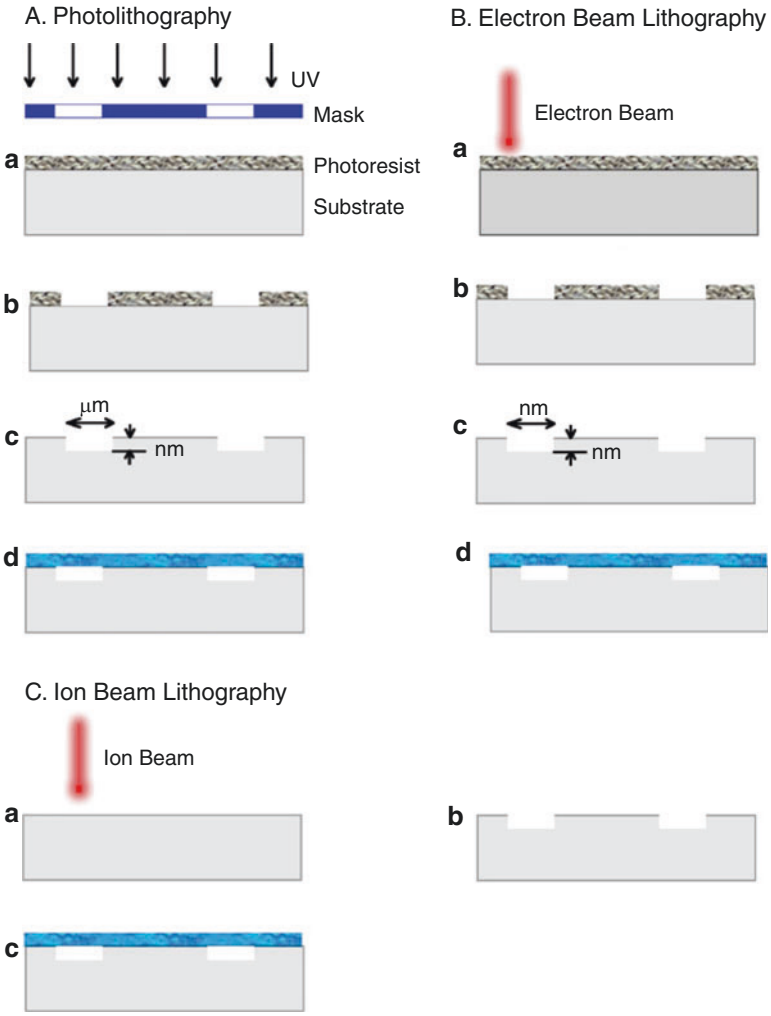
Historical Perspective

In 1939, bacterial gramicidin, a naturally occurring antibiotic and a nanochannel were isolated by Rene Dubos. The nAChR ion channel was the first naturally occurring ion channel to be isolated. In 1996, α-hemolysin was incorporated into a lipid bilayer and in a first, the possibility of using

nanochannels for performing a practical application – DNA sequencing was demonstrated [5]. Fabrication of tunable nanopores in SiO_2 and SiN with minimum dimensions ~1.8 nm using ion beam sculpting was first reported by Golovchenko and colleagues at Harvard in 2001. Dekker's group at Delft demonstrated the patterning of 20-nm diameter pores in Si, SiO_2, and SiN with electron beam lithography (EBL) and then shrinkage of these pores under tunneling electron microscope (TEM). Nanoimprint lithography was developed in 1996 by Chou and colleagues [6] and in 1997, Stern et al. [2] demonstrated the fabrication of 50-nm high nanochannels by etching a buried interfacial amorphous silicon sacrificial layer.

Basic Methodology and Key Findings

Fabricating Nanochannels with the Top-Down Approach



Generally the top-down techniques used for fabricating nanochannels employ fabrication protocols borrowed from the microelectronics industry. These include photolithography, physical deposition, and wet and dry etching, to name a few.

Photolithography

The simplest and most convenient method of fabricating nanochannels is through conventional UV photolithography. A UV-sensitive photopolymer or photoresist is spun coat on silicon, SiO_2, glass, or other appropriate substrate and then exposed to a UV light source through a glass mask. This mask has the nanochannel pattern defined in it. The pattern can also be exposed serially using a UV laser writer. The photopolymer is developed in a chemical developer that removes the unexposed or exposed resist (depending on the resist tone) and transfers the pattern in the photoresist. This is followed with a wet or dry etching step that etches the channel in the substrate. The resolution of conventional UV photolithography used in academia is generally in the micron range (1–3 μm). With advanced photolithography techniques using deep UV, extreme UV light source, or X-rays and expensive diamond masks, resolution below 100 nm can be obtained. These instruments and techniques are, however, very expensive and not readily available in the academia. Therefore, fabrication of nanochannels by photolithography is generally achieved by controlling the etch depth. Nanochannels fabricated using conventional photolithography are, therefore, 2D nanochannels. The channels are closed by bonding silicon, glass, or PDMS cover on the substrate. High aspect ratio nanochannels with depth as small as 2 nm have been fabricated with this method [7].

Electron Beam Lithography (EBL)

In EBL, a high-powered electron beam is used to transfer the pattern into an appropriate e-beam-sensitive resist. This is a maskless process as the pattern is directly written into the resist with the e-beam. The most commonly used e-beam resist is polymethylmethacrylate (PMMA), but now more advanced resists such as ZEP and Hydrogen Silsequioxane (HSQ) that provide better resolution are becoming increasingly popular. Beam diameter smaller than 10 nm are possible; so theoretically line widths of that order can be directly patterned onto the e-beam resist. Practically however, this is a tough task as inelastic scattering often causes over exposure of the resist. Also at very small dimensions over development of the resist is always a concern. This can be overcome using cold development processes at sub-zero temperatures [8]. The patterns can then be transferred in the underlying substrate (Si, glass etc.) with a wet or dry etching process. EBL combined with RIE has also been used to fabricate nanopores that have diameters in the tens of nanometers in Si, SiO_2, and Si_2N_3 membranes. In an interesting discovery made by Dekker's group [9], exposure of nanopores formed in silicon membranes to high-energy electron beams was found to fluidize the silicon and cause shrinkage of the nanopores. Switching the beam off quenches the shrinkage process and the new reduced diameter pore retains its shape. Using this method single-nanometer size pores were fabricated successfully. The central advantage of EBL is the higher degree of control and the possibility of obtaining channels with varying widths in the nanometer

Nanochannels for Nanofluidics: Fabrication Aspects, Fig. 1 (**A**) Nanochannel patterning using photolithography; (*a*) Photoresist spun coat on the nanochannel substrate and exposed to UV light through a photomask that has the nanochannel pattern defined in it. After development of the photoresist (*b*) the substrate is etched with RIE to the desired nm depth. A second substrate is bonded on this substrate to close the nanochannel. (**B**) Nanochannel definition with EBL; (*a*) An electron beam is used to directly write the nanochannel pattern on an e-beam-sensitive resist spun coat on the substrate. After photoresist development (*b*) RIE is used to etch nanochannels in the substrate. (**C**) With IBL an ion beam is used to directly etch the pattern in an appropriate substrate

regime. The key drawback of EBL is that due to its serial patterning nature, it is a slow technique and thus throughput is very low. It also requires highly trained staff and is relatively expensive.

Ion Beam Lithography (IBL)

Similar to EBL, Ion Beam Lithography is a serial patterning technique that uses a focused beam of ions such as protons, or heavy ions such as gallium, to directly write the pattern. The heavier ions scatter less and therefore, IBL is assumed to yield better resolution compared to EBL. It can be used for directly etching and fabricating nanochannels in substrates like silicon and glass without the need of a photoresist, a major advantage over EBL. Nanochannels down to 20 nm were directly milled with IBL in silicon and glass, and proton beams were also used to fabricate nanochannels in polymers such as PMMA. Nanopores in silicon oxide and silicon nitride membranes as small as 5 nm have been reported with IBL [10]. This technique, however, suffers from the same drawbacks as EBL – it has very low throughput, requires highly skilled researchers for operation, and is expensive. The doping of the substrate with the heavy metal ions is also a concern (Fig. 1).

Sacrificial Technique

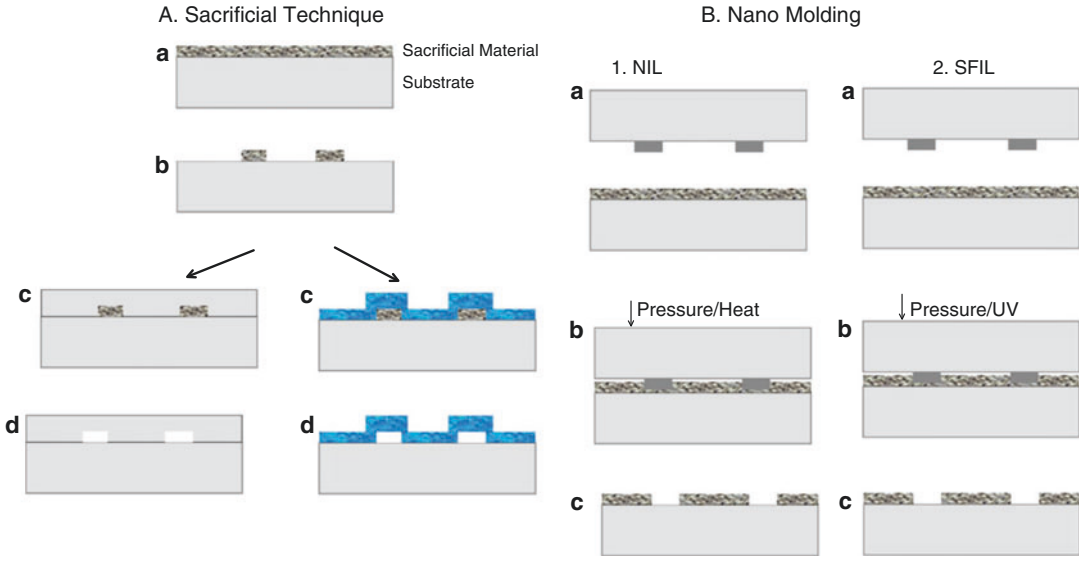
In sacrificial techniques, an intermediate sacrificial layer is generally used between the two substrates that will be bonded to form the

nanochannels. A less than 100 nm thick layer of a sacrificial material in the pattern of the nanochannel is first deposited on the nanochannel substrate in the desired thickness. This thickness later defines the depth of the nanochannel. For this reason it is important that a sacrificial material is chosen that can be deposited at a thickness below 100 nm with high uniformity. Commonly used sacrificial materials include amorphous silicon, polysilicon, and even metals such as chromium and gold. The deposited sacrificial layer is first patterned generally using photolithography and dry or wet etching into the desired nanochannel shape. The second nanochannel substrate is then bonded with the substrate that was patterned with the sacrificial layer. The two substrates bond only in places where they come in direct contact with each other and do not bond with the sacrificial layer. In another variation, a structural layer can also be deposited on the sacrificial layer. The sacrificial layer is now wet etched in an appropriate etchant that selectively etches the sacrificial layer, but does not or minimally affects the substrates, leaving behind nanochannels. Using this approach it is possible to make high aspect ratio channels, and nanochannels that were 20-nm deep, 0.5 to 200-μm wide and up to 4-mm long were reported [2]. Since wet etching of the channels is solely based on diffusion inside the channel, this is a slow approach. It can take a couple of days to etch through the entire sacrificial layer. Also because selectivity of etchant toward sacrificial layer versus the substrate is not always 100 %, tapering is often observed in nanochannels fabricated using this technique.

Nanomolding Techniques

Micromolding of polymer elastomeric materials provides a cheap and easy way for rapid prototyping of devices and therefore occupies widespread popularity in the microfluidics arena. Polydimethylsiloxane (PDMS) is by far the most popular material used for micromolding of fluidic channels because it can retain the features of the mold with up to 99 % accuracy. Nanochannel fabrication in elastomeric materials is much more difficult mainly because at nanometer dimensions, they tend to deform and collapse [6]. This inhibits direct molding of nanochannels in PDMS using molds of the nanochannels. If designed properly, however, this deformation and collapse can actually be used for fabricating nanochannels. One method is crack-induced generation of nanochannels in PDMS. When a slab of PDMS is surface oxidized, for example, in an oxygen plasma, the surface hardens creating an elastic modulus mismatch between the surface and the bulk PDMS. Application of a uniaxial tensile force generates cracks in the slab forming triangular nanochannels. The nanochannels can be sealed by oxygen plasma bonding with another PDMS slab, glass, silicon or by using this slab as a mold for transferring the nanochannel pattern into another PDMS layer. Nanochannels with heights of 80 nm have been fabricated with this technique. In an alternative approach, thinner and thicker PDMS slabs that have both been surface oxidized in oxygen plasma are bonded together and a uniaxial tensile force is applied. This causes crack generation at the weak oxidized bonding interface producing diamond-shaped nanochannels. In both these cases, tuning of the tensile force controls the depth of the nanochannels. In a similar approach called wrinkle nanochannels (WNC), a stretched slab of PDMS is exposed to an oxygen plasma or UV light source and then relaxed. This creates wrinkle patterns along the PDMS surface. The wavelength of this sinusoidal wave pattern is controlled by the difference in elastic moduli of the PDMS slab and the substrate on which it is bonded, while the amplitude depends on the applied strain. With this technique nanoslits with widths and heights in the tens of nanometers have been fabricated.

Other researchers have used the inherent elasticity of PDMS that allows it to deform around structures to fabricate nanochannels. In the first method, shallow beams were fabricated on a silicon substrate using reactive ion etching (RIE). A thin film of oxygen plasma–treated PDMS is bonded on this silicon substrate. The PDMS film deforms in the crevices of the substrate in a wave like pattern and bonds to the top of the beams and part of the base of the crevice. Nanosized gaps at the edge of the beams and the point where PDMS bonds at the base of the crevice result in the



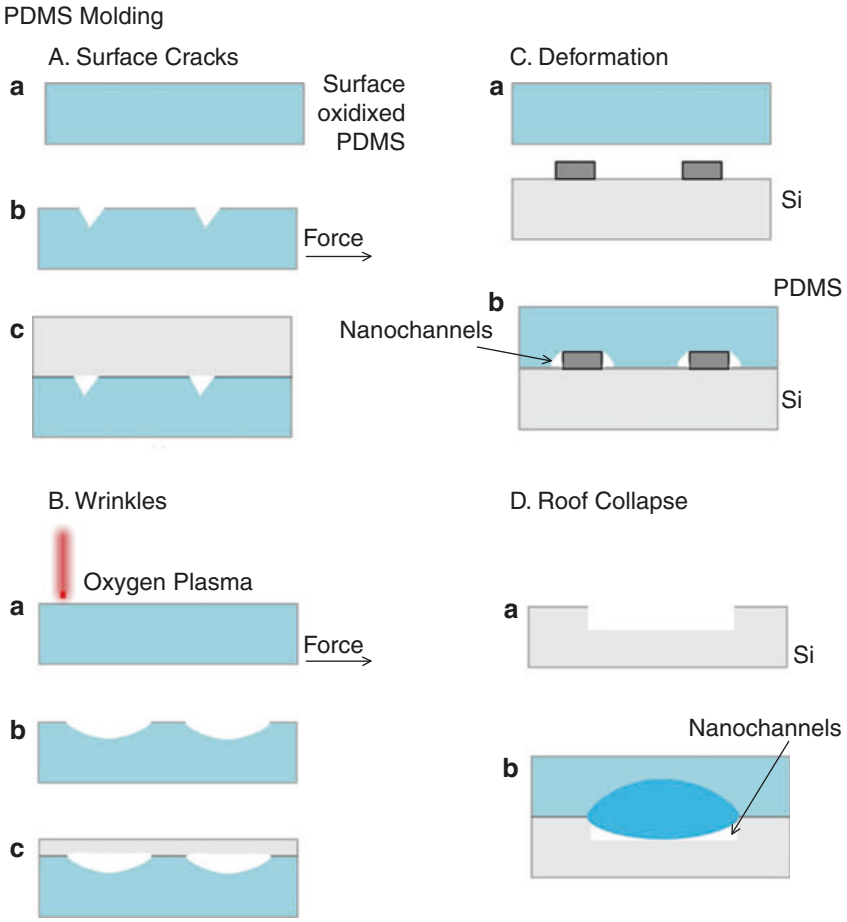
formation of nanochannels. In a similar technique called roof collapse technique, precision steps with strictly controlled height-to-width ratio of 0.2 were fabricated [6]. These are then used to mold microchannels in PDMS. When this PDMS slab is bonded to a substrate, the roof of the microchannel collapses. While the bulk of the channel is sealed nanoslits still remain open at the edges of the microchannels. With this technique nanochannels with heights as small as 60 nm have been fabricated. This technique is particularly applicable for creating variously shaped nanochannels.

Unlike elastomers, thermoplastics such as poly (methyl methacrylate) (PMMA), cyclic olefin co (polymer) (COC), and poly(ethylene terephthalate) (PET) deform negligibly and can retain their shape on direct imprinting with nanoscale features. This is the principle behind nano imprint lithography (NIL) pioneered by Chou et al. [11, 12]. A nanomold or template is first created generally using EBL followed by RIE in silicon or glass, or by direct writing using focused ion beam (FIB). A thermoplastic resist is spin coated on another substrate such as silicon and heated above its glass transition temperature (T_g). The template is now pressed on the spun coat thermoplastic under vacuum and the thermoplastic is allowed to cure. The template is released and a short RIE is performed to remove the residual thermoplastic leaving the nanochannel patterns embossed in it. The thermoplastic can itself be used as the material for the nanochannels or the thermoplastic can be used as a mask for etching the underlying substrate with RIE. With this technique 20-nm deep nanochannels that are centimeters in length were fabricated for nanofluidic applications. In a similar technique called step and flash imprint lithography (SFIL), a UV curable polymer is spun coat on an appropriate substrate. A template of the nanochannel pattern is fabricated in a transparent substrate as discussed before and pressed on the photoresist. The photoresist is exposed to UV light through the transparent template curing it and embossing the pattern in it. The template is removed and a short RIE step is performed to remove the residual photoresist layer. Another embossing technique is called reversal imprint. Here, a liquid polymer or prepolymer is spin coated directly on the template that is previously surface treated with fluorosilanes or other adhesion inhibitors. The template with liquid polymer is now transferred on another substrate and hardened. The template is removed such that the hardened polymer is left on the substrate. In a novel technique, silica nanowires were used as the nanochannel template. Silica nanowires, produced by tapering single-mode optical fibers in an alcohol flame [6], were positioned on a glass substrate using a scanning tunneling microscope (STM). The nanowire was hot embossed in a polycarbonate substrate and then etched away with hydrofluoric acid yielding the nanochannel in polycarbonate. The polycarbonate nanochannel was closed with PDMS. The need for STM position makes this technique very slow. Also this nanowire molding is confined to straight nanochannels.

The greatest advantage of nanomolding techniques is that they can yield high throughput and are relatively inexpensive. Particularly, NIL is very popular since equipment and materials for nanomolding using this technique are now available commercially through NanoNex®. The real expensive part in nanomolding techniques is the template that still has to be fabricated with EBL or FIB, but once the mold is machined it can be reused to imprint multiple devices (Fig. 2).

Miscellaneous Top-Down Techniques

Edge Lithography takes the advantage of asymmetry at the edge of a structure to fabricate nanochannels. In one example, polysilicon was deposited at the edge of a step on SiO_2 film. This was followed with anisotropic etching of polysilicon and the SiO_2 film such that the thickness of the polysilicon is converted into the width of the nanochannel. In another example, a 10-nm thick SiO_2 film was deposited on a Si_2N_3 substrate and then further coated with another Si_2N_3 masking layer. With controlled under etching 20 nm high and 200 nm wide nanochannels were fabricated. *Phase shift lithography* (PSL) is also considered as an edge lithography technique [2] that uses phase-shift photomasks to beat the diffraction limit of UV light. These are transparent



Nanochannels for Nanofluidics: Fabrication Aspects, Fig. 2 (**A**) Nanochannel patterning with sacrificial technique; (*a*) An appropriate sacrificial material is deposited on a substrate and the nanochannel pattern defined with photolithography (*b*). Then either a second substrate is directly bonded on top of this substrate or another structural material is deposited (*c*). The sacrificial material is then etched leaving the nanochannels. (**B**) A thermoplastic (*1a*) or a photosensitive (*2a*) polymer is spun coat on a substrate and embossed with a mold of the nanochannels. The polymer is then applied to heat and pressure (*1b*) or UV light (*2b*) curing the polymer. The mold is removed (*1c*, *2c*) leaving the nanochannels defined in the polymer

masks that include trenches with depth $d = \lambda [2(n - 1)]$ where λ is the wavelength of light and n is an integer. The phase shift in light caused by the trenches result in destructive interference, and interference patterns that are below 100 nm resolution down to 30 nm have been reported with this technique. *Interference lithography* (*IL*) is another interference pattern–based lithography technique. Here, the photoresist is exposed to the interference pattern produced by two coherent laser beams whose fringe period is given by $T = (\lambda/2)\ sin\ (\theta/2)$ where θ is the angle between the two light waves. IL is difficult and the setup to produce the interference patterns is complex but it can yield a dense array of nanochannels at a high rate without a mask. There is, however, limited flexibility in the number of shapes that can be patterned with this technique.

A novel technique was demonstrated by Han's group using *junction gap breakdown* to fabricate nanogap nanochannels in PDMS [13]. Two chevron-shaped microchannels were fabricated on either side of a horizontal microchannel such that there was a 40 μm gap between the tip of the chevron channels and the central horizontal channel. The channels were filled with an ionic buffer and a high voltage was applied with the horizontal channel as the anode while the chevron channels as cathode. This caused a junction gap breakdown at the tip of the chevron channels resulting in nanogap nanochannels. Pulling optical fibers and capillaries that are heated above their glass transition temperature can also be used to fabricate nanochannels. Co-axial fibers that were a mixture of silica sol–gel and motor oil were extruded to yield silica nanochannels with an inner diameter of 20 nm after annealing and removal of the oil. Only vertical nanochannels shaped like venturies can be fabricated with this technique (Fig. 3).

Atomic Force Microscopy (AFM) Nanolithography has also been used to create nanoscale features and depressions on substrates. Using high aspect ratio Si tips 80-nm wide and 30-nm deep channels were fabricated in PMMA [6]. AFM nanolithography like EBL and FIB is a

Nanochannels for Nanofluidics: Fabrication Aspects, Fig. 3 Fabrication of nanochannels in PDMS using (**A**) production of nanochannels through formation of cracks and (**B**) formation of wrinkles. Both techniques use surface oxidation of PDMS and application of a tensile force to create these nanochannels. Bonding with a second PDMS, silicon or glass layer closes the nanochannels. Nanochannels can also be formed in PDMS using deformation around pillars patterned in a substrate (**C**) or collapsing of the roof (**D**) of a PDMS microchannel that yields nanochannels at the bottom corners of the pillar

serial technique and is in fact even more tedious and slower than the beam-based techniques. While throughput can be increased using multiple probe tips such as on Dip Pen Nanolithography systems available from NanoInk®, limitations in scan area and the collateral damage around the indentation site reduce the practicality of this technique.

An attractive method of fabricating nanochannels is the fabrication of microchannels in a substrate followed by anisotropic deposition of another material. Controlled deposition converts the microchannel to a nanochannel. Using this approach parylene was deposited in microchannels etched in silicon. The parylene deposited preferentially at the top of the channel compared to the base. This caused the channel to close at top forming parylene nanotubes. As parylene is biocompatible these nanotubes can find biomedical applications such as in implants or as synthetic arteries or veins. A layer-by-layer polyelectrolyte multilayer deposition approach and non-conformal deposition was also used to convert microchannels to nanochannels [14]. Microchannels 1 μm wide and 15 μm deep were fabricated in silicon with photolithography

and deep RIE. Plasma Enhanced Chemical Vapor Deposition (PECVD) was then used to deposit silica on the device. The silica deposited preferentially on the top of the channels reducing its width at that location. Next conformal Low Pressure Chemical Vapor Deposition (LPCVD) of polysilicon was deposited that closed the microchannel at the top. After thermal oxidation to reduce the channel width to the desired level, layer-by-layer deposition of polyelectrolyte films was performed to reduce the channel width to 200 nm.

Bottom-Up Nanochannel Fabrication Techniques

Bottom-up fabrication of nanochannels involves processes where nanochannels are created electrochemically, through controlled atomic synthesis and assembly of synthetic nanochannels/nanopores and through self-assembly of polymers or naturally occurring nanochannels.

Electrochemical Synthesis

Thin sheets of aluminum can be anodized in acid solutions such as oxalic acid, sulfuric acid, or phosphoric acid with application of voltage/voltage cycles to produce aluminum oxide nanochannel arrays. These alumina nanochannel arrays called anodic aluminum oxide (AAO) or porous anodic alumina (PAA) have been around for a long time and are primarily used as nanofilters. Recently interest in using AAO as nanotemplates for ordered carbon nanotube (CNT) or nanowire growth and in nanofluidic applications has grown considerably. The anodization process involved the growth of an initial oxide layer on the surface of the aluminum film. Oxygen molecules then penetrate and oxidize the aluminum only at sites that provide low electrical resistance. The oxide dissolves in the acid resulting in pore nucleation and growth at these sites. The applied electrical field causes the pores to penetrate perpendicular to the aluminum surface until they traverse the entire alumina film. The pore radius, lengths, and densities can easily be tuned by controlling the number of the anodization voltage cycles and the applied voltage [15]. NIL was also used to produce dimples on the aluminum film that act as anodization nucleation sites [2].

Nanotubes: Carbon Nanotubes and Nanowires

With advances in physical vapor deposition techniques and catalysis it is now possible to synthesize nanotubes and nanowires with excellent control. Among these, carbon nanotubes (CNTs) have enjoyed great attention. CNTs are rolls of graphene, an atomic layer of carbon arranged in classic honey comb pattern. They can be single-walled (SWCNTs) and multi-walled (MWCNTs) and can have diameters from a couple of nanometers to hundreds of nanometers. They have excellent mechanical and electrical properties (tensile strength in the GPa range) and can be conducting or semi-conducting. They can easily be functionalized with biomolecules, leading to their vast use in bio-applications. CNTs can be synthesized using arc discharge, laser ablation, and chemical vapor deposition (CVD and MOCVD) methods. In the arc-discharge process, carbon atoms are vaporized in helium plasma ignited by an electric arc produced by applying high currents between a carbon anode and cathode. This process produces MWCNTs. To produce SWCNTs a metal catalyst such as iron or cobalt is added to the system. Laser ablation is similar to arc discharge, that is, it involves evaporation of a carbon target but now high-intensity laser pulses are employed for ablation. The process is generally performed in a tube furnace heated to 1,200 °C. The furnace is flushed with an inert gas that blows the synthesized CNTs downstream where they are collected. The CVD process involves synthesis of CNTs by the decomposition of a hydrocarbon such as acetylene in the presence of an appropriate catalyst. After nanotube synthesis the reactor is cooled down and the CNTs collected. By controlling the temperature and pressure inside the reactor, careful selection of precursor hydrocarbon and catalyst SWCNTs and MWCNTs can be produced in the same reactor. The CVD process is particularly advantageous for growing ordered arrays of CNTs on substrates that have been appropriately seeded with a catalyst.

An MOCVD process was used to fabricate CNT array in a PAA template that has found applications in CNT transistors and as a glucose biosensor [15]. While CNTs are readymade nanopores, their application is tricky mainly because of integration with the macro-world. CNT nanopores were fabricated in by trapping CNTs with dielectrophoresis and then spin coating SU-8 on top of it that is patterned to produce fluidic reservoirs.

Nanowires can also be used as templates for the fabrication of nanochannels. Nanowires can be synthesized using various techniques such as electroplating (for metallic nanowires), chemical vapor deposition, vapor–liquid–solid method, etc. Bottom-up fabrication of SiO_2 nanochannels was demonstrated with Si nanowires. The Si nanowires were surface oxidized via a timed oxidation process such that the core was still Si. Isotropic etching of the Si core was performed with XeF_2 gas that yielded SiO_2 nanochannels with hollow cores.

Block Copolymers

Block copolymers are soft materials that are composed of two or more immiscible macromolecules. These macromolecules can self-assemble into nanoscopic arrangements with each macromolecule comprising the block polymer maintaining its original properties [16]. Block copolymers can be used to form nanoporous membranes that have ordered nanopores. Polystyrene-block-PDMS (PS-PDMS) was spin coated on a silicon substrate. The block copolymer self-assembled to form ~16 nm diameter vertical cylinders of PS arranged uniformly at a pitch of ~23 nm in a PDMS block. Exposure to oxygen plasma etched the PS leaving nanopores in the unetched PDMS. The PDMS was later used as a mask for etching the underlying substrate. More recently efforts are being made to arrange long channel like arrays of block copolymers. One of the block copolymer phases can then be selectively etched to form long nanochannels. Misalignment over long distances limits the maximum feature length.

Self-Assembly of Naturally Occurring Nanochannels

Naturally occurring protein nanochannels are present in the cell phospholipid bilayer and the intracellular membranes of all eukaryotic and prokaryotic cells. They perform critical cellular functions from maintaining the ion balance, transport of metabolites to cell signaling, communication, and balancing osmotic pressure. Particularly important are ion channels that are also the target of therapeutics. Efforts have been directed toward isolating ion channels and using them as nanochannels for other applications. Porin MspA, a 3.1 nm internal diameter *Mycobacterium smegmatis* channel protein selective for hydrophobic nutrients, was self-assembled inside highly ordered pyrolytic graphite using hydrophobic interactions [17]. In another approach 1.4–4.6 nm nanopores were fabricated by self-assembly of α-hemolysin monomers in a lipid bilayer. Thus far demonstrations of self-assembled isolated naturally occurring nanochannels or their monomers are limited and practical applications are nonexistent. This is mainly because of difficulty of integrating such nanochannels with complex nanofluidic devices. Nonetheless, this represents a very interesting area of research and applications are expected to grow as better ways of integrating the top-down and bottom-up approaches are developed.

Future Directions

Nanofluidics is a frontier area of science today, and ease and affordability of nanofabrication can be key attributes to the broader embrace of the technology. Nanochannel fabrication on substrates like silicon and glass has its advantages such as high fidelity, but fabrication in such cases can suffer from high fabrication costs and low throughput. Advances in polymer-based nanofabrication can offset some of these disadvantages. However, polymer-based fabrication techniques can suffer from the inherent lack of mechanical rigidity of the material, leading to deformation issues. As advances in

nanofabrication are made, the quest for customized surface modification of channel walls and integration of various components into nanochannels will also increase.

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm

Umberto Anselmi-Tamburini and
Ilenia G. Tredici
Department of Chemistry, University of Pavia, Pavia, Italy

Synonyms

Crystallite; Densification; Massive; Nanometric; Nano-sized; Nanostructure; Sintered

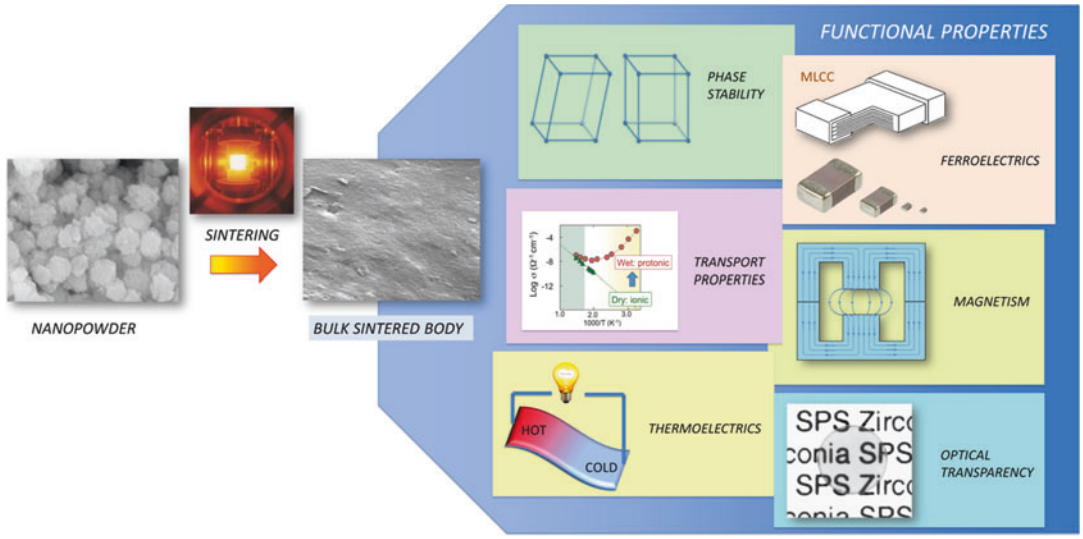
Definition

Crystalline materials are defined as solid materials in which constituents (atoms, ions, molecules) are organized in space following a regular, symmetric long-range ordered lattice.

Functionality refers to typical chemicophysical properties owned by materials, which provide them the possibility to be exploited in technological applications, as in electrical conductors, thermoelectrics, ferroelectrics, magnets, and transparent optical devices.

Nanocrystals are characterized by at least one dimension under a critical value, generally 100 nm, below which peculiar properties related to the nanostructure tend to emerge.

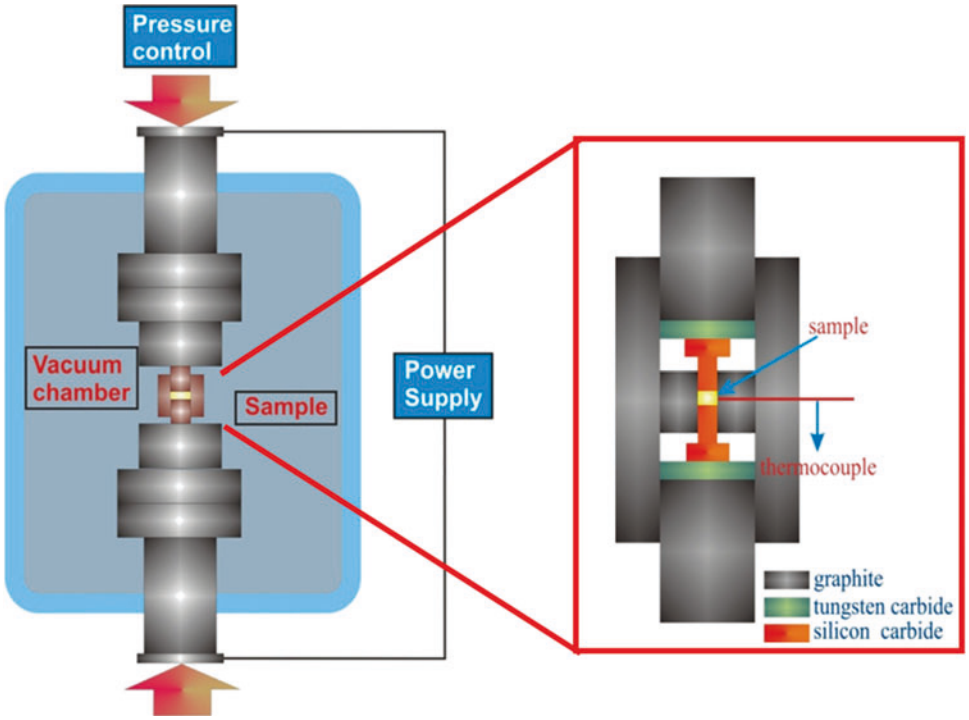
Bulk form refers to materials presenting a macroscopic massive body, in contrast to loose powders.



Overview

Nanostructure has a significant influence on the physical properties of functional materials, and the study of this influence has been the focus of a large research effort in the last two decades. Although some effects can be observed in all the range of nanometric dimension (below 100 nm), most of these modifications became evident only when the materials present at least one dimension falling in the low nanometric range, below 50 nm. These extreme dimensions can routinely be obtained for materials in the form of nanoparticles, thin films, or even more complex nanostructures but represent still a serious challenge in the case of materials in bulk form. On the other hand, several technological applications require materials to be in bulk form, and this justifies the interest toward their synthesis [1].

In the case of functional materials the only practical approach toward the synthesis of bulk nanostructured samples is represented by the densification of nanopowders. However, traditional densification techniques, such as pressureless sintering and hotpressing, are generally accompanied by such a significant grain growth that in most cases the nanostructure of the starting powders is lost. For this reason the synthesis of bulk nanometric functional materials has been obtained almost exclusively using nonconventional sintering methods. These methods will be introduced and described briefly in the following section. The influence of nanostructure on some physical properties of functional materials, with particular emphasis on phase stability, electrical and thermal transport, and optical and magnetic properties of nano-oxides, will be discussed in some detail in the subsequent sections (Fig. 1).



Synthesis Methods

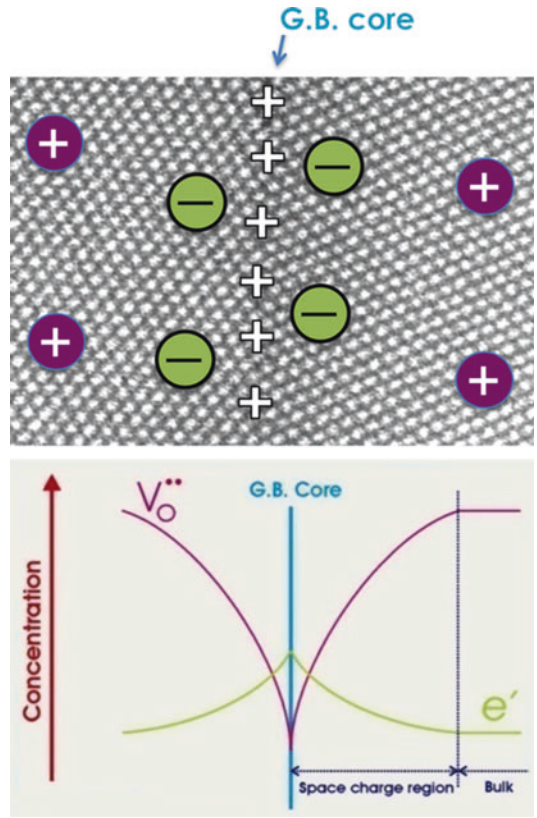
As mentioned before, bulk nanocrystalline functional materials are generally obtained through the sintering of nanopowders. Other methods proposed over the years cannot generally be applied to functional materials. Severe plastic deformation methods, such as Equal-Channel Angular Pressing (ECAP) or High-Pressure Torsion (HPT), are limited to metallic materials, while the controlled crystallization of amorphous precursors can be successfully applied only to a very

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 1 Nanostructure and functional properties. The schematics depict the main functional properties reviewed in the present essay

limited number of systems. The sintering of nanopowders presents the great advantage, at least in principle, of being applicable to almost any system, as the progress in the synthesis methods experienced in the last two decades allowed to obtain nanopowders of almost all the technologically relevant functional materials. Sintering, however, is always accompanied by a significant grain growth. The two processes, in fact, share the same mechanisms. For this reason the traditional sintering techniques, represented by pressureless sintering and hotpressing, have been largely unsuccessful in producing bulk materials characterized by high values of relative densities and grain size in the low nanometric range. These methods, in fact, involve the use of long annealing times (several hours) at high temperatures (usually around 2/3 of the melting point) and are mostly driven by bulk and grain boundary (GB) diffusion processes. In such conditions the nanostructure of the starting powders is usually lost. A further difficulty derives from the fact that most nanopowders present a relevant degree of agglomeration, particularly when they derive from solution methods. Agglomerates with dimensions in the range of micrometers or even tens of micrometers are not uncommon, resulting in green pellets characterized by the presence of macroporosity that can be eliminated only with great difficulty. To overcome these limitations, in the last decades nonconventional sintering methods have been actively investigated. Fast firing and two-step sintering have been first considered and produced some interesting results, but the real breakthrough has been obtained using a group of techniques that are known in the literature with the names Field Assisted Sintering (FAS), Spark Plasma Sintering (SPS), or Field Assisted Rapid Sintering (FARS) [2]. These techniques share the use of elevated uniaxial pressures combined with extremely rapid sintering cycles, resulting in a marked decrease in the associated grain growth. The reference to field and spark effects appearing in their name derives from the use of pulsed electric fields, although the relevance of this effect is still debated. Pressure, on the other hand, has been demonstrated to enhance drastically the densification of nanopowders. High pressures, in fact, can induce nanoparticle rearrangement, plastic and superplastic deformation, particle sliding, and pore shrinkage, allowing densification to be realized at lower temperatures. Figure 2 presents the schematics of a typical SPS apparatus [2]. The sample is usually contained in a die made out of an electrically conducting material (usually graphite, but high-strength steel and

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 2 Schematics of the HP-FAST apparatus. Uniaxial pressure and electric current are applied to a graphite die, placed in a vacuum chamber. The inset shows an enlarged detailed view of the die setup: the high-pressure components are made of SiC or WC, while the dies and the low-pressure components are made of graphite. The temperature is recorded through a thermocouple inserted in the wall of the die

tungsten carbide have also been used), which is placed between two hydraulic rams acting also as electrodes. No furnace is present in these systems, but the die is heated up directly by joule heating. This is obtained through a low-voltage, high-intensity current flowing through the ram/electrode assembly. Current intensities of several thousands of amperes are usually employed. The absence of a real furnace, the low thermal inertia of the die, and the presence of an intimate contact between the sample and the die offer the possibility to realize very high heating rates. Values between 100 °C/min and 300 °C/min are commonly used, although values as high as 1000 °C/min have been reported. Commercial SPS apparatuses generally employ pulsed currents, with waveform that in most systems can be controlled over a wide range. In order to reduce even further the grain growth, high-pressure modification of the technique has been proposed. At higher pressures, in fact, densification is obtained at even lower temperatures, resulting in an even further decrease in the grain growth. Since the compressive strength of the graphite does not generally allow pressures higher than 140 MPa, double-stage dies, presenting a high-pressure section made out of a high-strength material, such as SiC or unbound WC, are usually employed (Fig. 2). Pressures as high as 1 GPa can be easily obtained using this setup [2]. Bulk, almost fully dense materials characterized by a grain size just above 10 nm and by a relative density (r.d.) above 98 % have been obtained with this approach, even in the case of ceramic and badly agglomerated nanopowders. This technique represents at the moment the best and more versatile approach toward the synthesis of bulk nanocrystalline functional materials.

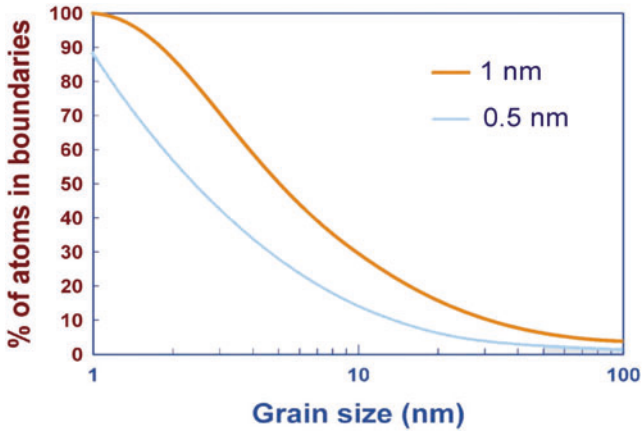


Effect of Nanostructure on Bulk Properties of Functional Materials

As in other class of materials, the nanostructure has a profound influence on the physical properties of bulk nanostructured functional ionic materials. In analogy with the term "nanoelectronics" used for semiconductors, the term "nanoionics" has been proposed for the study of this influence in ionic materials [3]. In some cases, nanostructuring simply enhances features that are already present in the material, while in other cases it introduces new features. Maier introduced the terms "trivial" and "real" (or "true") size effects to describe these two conditions [4]. In ionic materials most of the typical phenomena associated to the nanostructure fall in the first group. "True" size effects that are usually associated to confinement effects [5] are fairly uncommon in these materials.

The first, most obvious effect of nanostructuring is represented by a dramatic increase in the number of interfaces. In anionic materials this might produce some peculiar effects. In these materials, in fact, surfaces and interfaces are associated to a net electrostatic charge (Fig. 3). This charge interacts with the charged point defects present in the bulk of the materials, producing, in proximity to the interface, accumulation or depletion of point defects. The regions in which this accumulation or depletion takes place is generally named "Space Charge Region" (SCR) and typically extends for few nanometers around the GBs. In this region the defect concentration and distribution might vary considerably in respect to the one observed in the bulk of the material (Fig. 3) [4].

While in micrometric materials the effect of SCRs is negligible, in nanostructured materials, where the fraction of atoms located within these regions might become relevant, their influence might become significant and can produce macroscopically evident modification of the physical properties (Fig. 4) [6].



In the following we will discuss some example of effects associated to the nanostructure in functional ionic materials, focusing in particular on the ones related with phase stability, electrical conductivity, dielectric, ferroelectric, piezoelectric, magnetic properties and optical transparency.

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 3 GB core and defect concentration in the SCR. In ionic oxides such as Ceria and Zirconia the GB core is positively charged and attracts negatively charged defects (such as electrons), while it repels positively charged ones (such as oxygen vacancies), producing an altered point defects distribution

Phase Stability

The modification of phase equilibria in polymorphic materials represents one of the best-known and more interesting effects of the nanostructure. Table 1 reports some examples in the case of functional oxides [7]. In all these cases the nanostructure tends to stabilize the high-temperature form of the material. In coarse-grained materials the same effect can only be obtained through alloying with doping elements. In the early

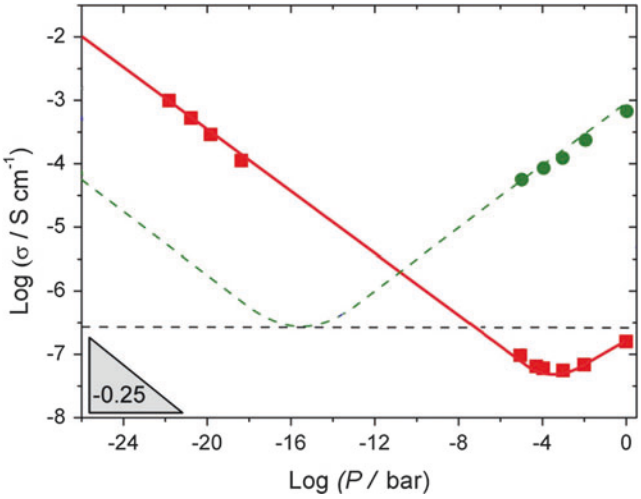
Material	Lattice type	
	Standard conditions	Nanomaterials
ZrO_2	M	T (C?)
TiO_2	Rutile	Anatase
Al_2O_3	Hex (α-Al_2O_3)	C (γ-Al_2O_3)
Y_2O_3	C (α-Y_2O_3)	M (γ-Y_2O_3)
$BaTiO_3$	T	C
$PbTiO_3$	T	C

literature it was suggested that the effect of the nanostructure was to stabilize kinetically metastable crystalline forms. There is now a general consensus that in most cases the crystallographic form observed in nanomaterials represents indeed the most thermodynamically stable form of the material in these conditions. The contributions driving toward this inversion in thermodynamic stability are various. The most important is surely represented by the contribution of the surface or interfacial energy. When materials with a grain size of few nm are considered a significant excess of free energy is introduced in the material. As a result, below a critical grain size the difference in free energies between two polymorphs might vanish [8]. Other contributions, however, must be considered, such as presence of strain energy, external and internal hydrostatic pressure, presence of structural similarities between the polymorphs, surface contamination (such as adsorbed water), bulk contaminants (particularly anions), and point defects (oxygen vacancies). As a result, only in few cases a general consensus exists on the conditions required for the observation of phase stabilization effects induced by the nanostructure. In the case of pure Zirconia, for instance, the size stabilization of the metastable tetragonal phase over the monoclinic form is known since early 1960, but it was observed only in nanopowders and thin films. Only recently it has been possible to produce size stabilization also in bulk sintered bodies. On the basis of surface energy alone, the critical grain size can be predicted in this system to be around 10 nm. However, agglomeration, strain energy, and presence of adsorbed molecules (water in particular) modify significantly this value. Agglomeration and densification increase the limit value. In fact, tetragonal Zirconia has been obtained in bulk form even with grain sizes around 30 nm (95 % tetragonal phase), when strongly agglomerated nanopowders were used to obtain fully dense sintered bodies in HP-FAST. On the contrary, when soft, nonagglomerated powders were sintered in the same conditions, a relevant transition to the monoclinic phase was detected [1]. Strain energy, on the other hand, can significantly reduce the critical grain size, justifying the experimental evidences of lack of stabilization even in loose powders characterized by extremely small grain size (even 5–6 nm). Concerning the presence of adsorbed water, in the case of Zirconia



Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 5 Grain size and point defects distribution in ionic oxides. Decreasing the grain size from micrometric to nanometric produces a relevant alteration in the ratio between the extents of the SCR and of the bulk, regular material. As long as the bulk material is predominant, the interfaces and the SCRs are distant enough and the defect concentrations reach equilibrium in the bulk. When the grain size approaches the size of the SCR no more regular bulk material is availabble and significant modification in the electrical properties are expected

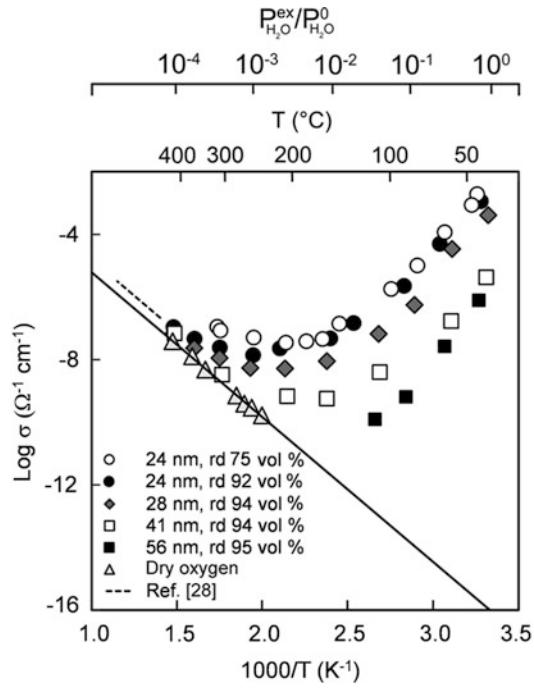
the exposure of the nanopowders to a moist environment drastically reduces the stability of the tetragonal phase, even in presence of extremely small grain sizes.

For titanium oxide, the transition from the anatase to the rutile form is generally believed to happen at a critical grain size of about 50 nm. It is generally quite difficult to keep this material in the anatase form during sintering: grain growth occurs at very low temperatures in Titania (between 400 °C and 700 °C), resulting in a transition to rutile structure. Also in this case many experimental parameters can influence the stabilization; one of the most important is the pressure applied during sintering, since the transition from anatase to rutile involves a reduction of the molar volume. Optimization of the sintering conditions allowed the synthesis of Titania in anatase form with high r.d. (>90 vol.%) with an average grain size of about 30 nm. The samples were obtained by hotpressing, at temperatures as low as 490 °C, under a pressure of 450 MPa, applied for 2 h. Even higher r.d. (above 95 vol.%) has been obtained using shorter sintering times with HP-FAST at 700 °C, under a uniaxial pressure of 620 MPa for 5 min. In this case the final samples were characterized by a grain size around 50 nm.

Electrical Conductivity

The bulk conductivity of functional ionic materials is generally interpreted on the basis of the SCR model described previously. In ionic conductors, in fact, a significant fraction of the overall resistivity is associated to the grain boundaries that are characterized by a "blocking" behavior toward the ionic charge carriers that are usually depleted in proximity of the SCR. Nanostructuring greatly increases the number of GBs, resulting in an even further decrease in the conductivity of the material. On the other side, when the scaling down reaches a value for which the grain size is comparable with the size of the SCR, a significant change in the defect equilibria is expected, as the "regular" bulk material tends to disappear (Fig. 5) [4].

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 6 Effect of nanostructure on the conductivity of $SrTiO_3$ at different oxygen partial pressures. Conductivity was measured at a temperature of 544 °C. *Green dashed line*: microcrystalline $SrTiO_3$; *solid red line*: nanocrystalline $SrTiO_3$ with a grain size of ~30 nm (Adapted from Ref. [11])



An experimental evidence for these phenomena has been firstly reported in the case of CaF_2/BaF_2 heterolayers [9]. When thickness of the alternating layers of CaF_2 and BaF_2 was decreased from 500 to 16 nm, an increase in the ionic conductivity of 2 orders of magnitude was observed and was interpreted on the basis of the model described in Fig. 5. In polycrystalline materials such relevant effect on the ionic conductivity has not been found even in materials characterized by a grain size well below 50 nm. In the case of Zirconia, reduction of the grain size down to 10 nm resulted only in an overall decrease in conductivity, although a small increase in the specific GB conductivity has been observed. However, this enhancement is not enough to increase the overall conductivity, as the GB conductivity remains more than one order of magnitude lower than the bulk conductivity. Guo argued recently that in order to observe a significant increase in conductivity due to size effects, the grain dimension should be decreased to less than 5 nm, since the typical SCR dimension is, for Zirconia, around 2.5 nm [10]. Such grain size, however, has never been reported for bulk Zirconia.

In the case of pure and doped Ceria the situation is complicated by the possibility of mixed conduction. Ceria, in fact, is not generally a pure ionic conductor and might present some electronic conductivity as well, particularly for low doping contents. Since the GB cores in Ceria are positively charged they tend to attract the available free electrons within the SCR, resulting in a further enhancement of the electronic conductivity in nanometric materials, where the free energy required for the formation of free electrons is even lower than in the micrometric counterpart.

Since the dimension of the SCR depends on the dielectric constant of the material, ionic materials characterized by high values of dielectric constant present a particular interest, as they are characterized by wider SCRs. $SrTiO_3$ represents a typical example. This oxide, in effect, shows striking modification in its conduction mechanism even for grain size in the range of 50 nm [11]. $SrTiO_3$, in fact, is a semiconductor that presents a transition between *p* and *n* conductivity when the oxygen partial pressure is modified. In micrometric $SrTiO_3$ this transition falls at an oxygen partial pressure around 10^{-16} bar (Fig. 6). Samples prepared by SPS with grain size of ca. 30 nm, however, show a dramatic change in the position of this transition, which shifts more than 12 orders of magnitude, up to 10^{-4} bar. In respect to coarse-grained counterparts, nanometric samples showed also an oxygen vacancy conductivity (*p*-type) depressed of 6 orders of magnitude and an *n*-type conductivity increased of 3 orders of magnitude (Fig. 6) [11]. This behavior can be considered as one of the most striking examples of modification in the electrical properties due to the nanostructure in ionic functional materials.

Another phenomenon evidencing the influence of the nanostructure on the mechanism of conduction of functional materials is represented by the dramatic increase in the low-temperature conductivity manifested by oxides such as Yttria-Stabilized Zirconia (YSZ), Gadolinium- or Samarium-doped Ceria and Titania, at temperatures below 300 °C, in presence of a moist environment. These oxides present generally a high-temperature ionic conduction, due to the movement of oxygen. However, when produced in bulk nanometric form they present a low-temperature conductivity that can be associated to the movement of protons. None of these oxides, however, is generally recognized to be a typical protonic conductor, particularly in the low-temperature regime. Surprisingly, relatively high conductivity values have been observed also in almost fully dense materials [12]. The most remarkable feature, however, is represented by the strong dependence of this phenomenon from the grain size of the material: it becomes particularly evident for grain sizes below 50–80 nm and increases drastically when the grain size is further decreased. No significant dependence on the crystal structure and on the degree of doping of the material has been observed. Even the degree of porosity resulted to have a limited influence [12].

The typical characteristics of this phenomenon are summarized in Fig. 7 in the case of Titania. The figure reports the temperature dependence of conductivity for five different samples characterized by grain size between 24 and 56 nm and r.d. ranging between 75 and 95 vol.%, when exposed to a dry ($p_{H_2O} < 3$ ppm) or a moist environment. The solid line here indicates the ionic conductivity of Titania in a dry oxygen atmosphere. It appears evident as in nanocrystalline samples the low-temperature conductivity under humid atmosphere is increased of several orders of magnitude over the extrapolated high-temperature ionic conductivity. The figure also shows the strong dependence of conductivity on grain size: for temperatures $\leq$200 °C the conductivity increases more than 3 orders of magnitude, as the grain size is reduced from 56 to 24 nm.

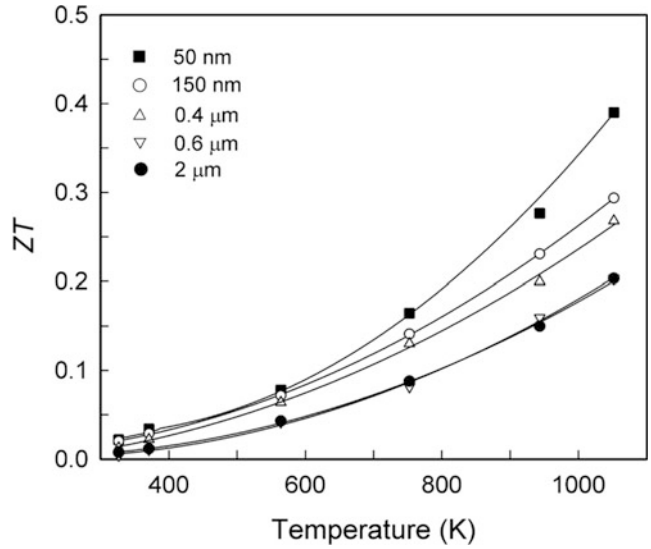
Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 7 Influence of grain size and porosity on total conductivity of nanostructured bulk Titania. $P^{0}_{H_2O}$ is the equilibrium water partial pressure at a given T; $P^{ex}_{H_2O}$ is the water partial pressure used in in our experiments ($P^{ex}_{H_2O} = 32$ mbar) [12]

The transport mechanism responsible for this phenomenon has been object of some debate. In the earlier investigations the movement of protons along the GB of the material was considered as a possible conduction mechanism. This seemed to fit well with some of the observed characteristics, such as the very limited dependence on the sample porosity and the strong dependence on the grain size. Further subsequent investigations, however, have evidenced the presence of water molecules within the material, even in high-density samples. This suggested the possibility of a conduction mechanism based on hopping of protons within a percolating network of water molecules, located in the residual nanoporosity of the material [12]. This conclusion has been supported by several observations, particularly by the low value of the activation energy, which is incompatible with any kind of solid-state process, and by ^{1}H-NMR and DSC analysis that evidenced the presence of

free water molecules within the sample, confined in narrow pores. The presence of a percolating porosity seems to be in contrast with the high values of r.d. reported in most cases, but this result can probably be justified considering some characteristics of the nonconventional sintering methods used for the densification of the materials. This point is particularly interesting as it suggests the possibility that the morphology of these bulk materials obtained by low-temperature high-pressure sintering techniques might differ significantly from the one based on the classical sintering theory. Since the densification does not derive primarily from bulk or grain boundary diffusion but from plastic deformation, a network of open percolating nanoporosity might remain present ever for very high values of relative density, producing eventually unexpected behavior in the material. This point must be better clarified in the future, particularly in the case of materials that are sensitive to liquid- and gas-phase interactions [12].

Thermal Conductivity

Thermal conductivity is another physical property that is significantly modified by the nanostructure. This effect finds direct application in thermal protection coatings. However, wide attention has been given recently to the possibility to exploit the influence of nanostructure on thermal conductivity to improve the efficiency of thermoelectric materials. Thermoelectric devices allow a direct conversion of stable temperature gradients in electric power. In order to achieve the maximum efficiency, thermoelectric materials must present a high electrical conductivity and a low thermal conductivity, to guarantee the maintenance of the thermal gradient. The efficiency of these materials is generally characterized on the basis of a figure of merit, defined as



$$ZT = \frac{\alpha^2 \sigma}{k} T$$

where T indicates the temperature, α the Seebeck coefficient, σ the electrical conductivity, and k the thermal conductivity. The term $\alpha^2\sigma$ is called the power factor, PF. It is evident from this relation as an increase in the figure of merit can be achieved not only through an increase in the intrinsic thermoelectric power of the material, α, but also through a decrease of the thermal conductivity. Nanostructure is known to produce a decrease in electrical conductivity, but the decrease of thermal conductivity is expected to be even higher, resulting in an overall increase of ZT.

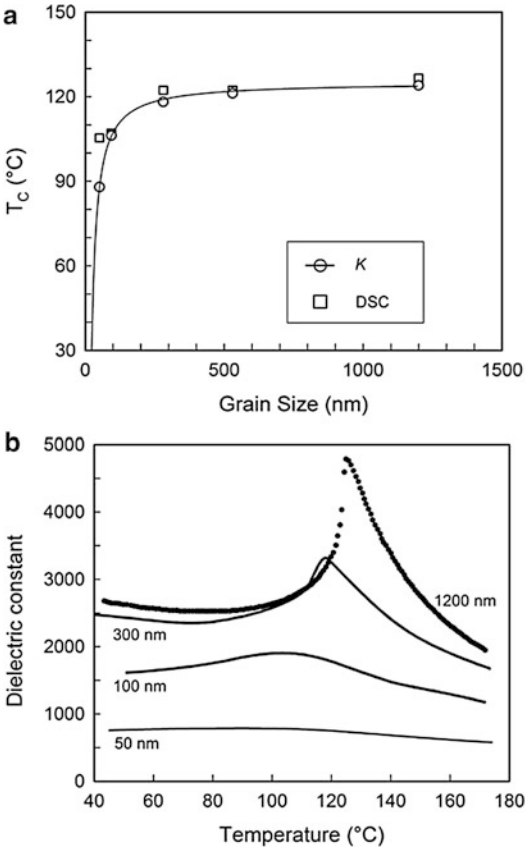
According to the kinetic theory of heat transfer, the thermal conductivity is proportional to the product of specific heat, sound velocity, and phonon mean free path. While nanostructure has not a relevant effect on the first two quantities, it greatly affects the phonon mean free path, which is shortened when the grain size is reduced. The mean free path is also heavily dependent on the density of lattice defects (foreign atoms, cation and anion vacancies, etc.). As a result, the reduction of k in the nanosized samples is attributed to the combined effect of high concentration of GBs and to the presence of nanopores. The phonon scattering produced by the GB introduces an intrinsic interfacial resistance to heat transfer, generally known as Kapitza resistance. When the grain size is reduced to the low nanometric range this contribution is expected to become particularly relevant, opening the possibility to obtain interesting ZT values even in materials characterized by a modest thermoelectric effect [13, 14].

Common thermoelectric materials are usually represented by semiconducting alloys, based on rare and toxic elements, such as Lead, Cadmium, Tellurium, Antimony, and Germanium, and are generally characterized by fairly high values of thermoelectric coefficient. To allow a widespread application of the thermoelectric conversion, however, other classes of material have been recently investigated. Metal oxides represent a promising alternative, thanks to their high thermal and chemical stability, low cost, and low environmental impact. Their Seebeck coefficient, however, is usually low. For these materials a reduction in the grain size in the low nanometric range would be particularly beneficial.

Most of the nanostructured bulk ceramic oxides investigated for their thermoelectric

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 8 Temperature dependence of *ZT* for $In_{1.92}(ZnCe)_{0.08}O_3$ bulk samples with different grain sizes (Adapted from Ref. [15])

properties have been realized using FAST techniques, but only in few cases it was possible to obtain grain sizes below 50 nm. In samples of Ga-doped ZnO with grain size reduced to 30 nm, thermal conductivity is indeed reduced, but also electrical conductivity is decreased significantly and the resulting *ZT* is not improved over the analog micrograined material. On the opposite, nanostructuring of In_2O_3, doped with Ce and Zn, shows a noticeable increase in *ZT*, in respect to coarse-grained counterpart. Samples with grain size of 50 nm, obtained by SPS, have a *ZT* of 0.40, i.e., twice the value of the corresponding micrometric material (Fig. 8) [15]. Anatase TiO_2 shows a decrease of 10 % of thermal conductivity when the grain size is reduced to 20 nm. $SrTiO_3$ represents another good candidate for thermoelectric applications, since at room temperature it shows a high PF value. When its grain size is reduced to 50 nm, thermal conductivity at r.t. is halved, in respect to coarse-grained samples, while at 1000 K the reduction is around 24 %. La-doped $SrTiO_3$ shows an even more relevant effect; when the grain size is reduced to 24 nm, *k* is in fact reduced of one order of magnitude in respect to single-crystal analogues, even though electrical conductivity is depressed as well.



A further decrease of grain size, possibly down to 10 nm, seems to be necessary for a real breakthrough in the reduction of the thermal conductivity. Moreover, a better control over defects and density of scattering sites should help in improving the achievable efficiency even further. However, the results so far obtained confirm that a reduction of the thermal conductivity can indeed be realized in bulk nanometric thermoelectric materials.

Ferroelectric Nanoceramics

Ferroelectric ceramics, such as $BaTiO_3$ and Pb(Zr, Ti)O_3, are largely used in the electronic industry as a key component of ferroelectric memories, multilayer ceramic capacitors (MLCCs), pyroelectric systems, and piezoelectric transducers/actuators. Due to the continuous trend toward the miniaturization of these components, the interest toward the influence of the nanostructure on the ferroelectric properties of these materials has grown considerably. In the case of barium titanate a loss of the ferroelectric properties in extremely fine-grained materials has been repeatedly reported, although the threshold for this phenomenon was difficult to define. In order to clarify this point, bulk nanometric titanate ceramics with extremely small grain size have been produced and investigated. These materials have been generally prepared using high-pressure sintering, as small amounts of residual porosity

produce a decrease of the relative dielectric constant [11, 16].

The loss in the ferroelectric characteristics is strictly associated, in these materials, with the modification in the phase stability produced by the nanostructure. Ferroelectricity in $BaTiO_3$ is produced by the displacement of the Ti ion in its tetragonal structure. The cubic polymorph, on the other hand, does not present ferroelectricity. The transition between the two polymorphs takes place at the Curie temperature, T_c, which falls at 403 K in the single crystal. As mentioned previously, the nanostructure can modify the relative stability of the polymorphs. In the case of $BaTiO_3$, this results in the stabilization of the cubic form, with a consequent decrease of T_c with the grain size (Fig. 9) [16]. The complete stabilization is predicted for particles characterized by a dimension between few nanometers and few tens of nanometers. A further effect is associated to the increase in the GB density, as the regions in proximity of the GB are considered not ferroelectric. Despite these theoretical previsions, a clear and unequivocal threshold for the disappearance of the ferroelectricy has not been identified. Several authors, in fact, have reported the persistence of ferroelectricity, at least at local scale, even in materials characterized by a size reduced to 8 nm [1]. This behavior can probably be explained considering that in the case of extremely small grain sizes the properties of the material tend to depend strongly not only on the crystallographic structure but also on other features, such as the point defect concentration and distribution, incorporation of foreign atoms and hydroxyl groups, aggregation, porosity, residual stresses, etc.

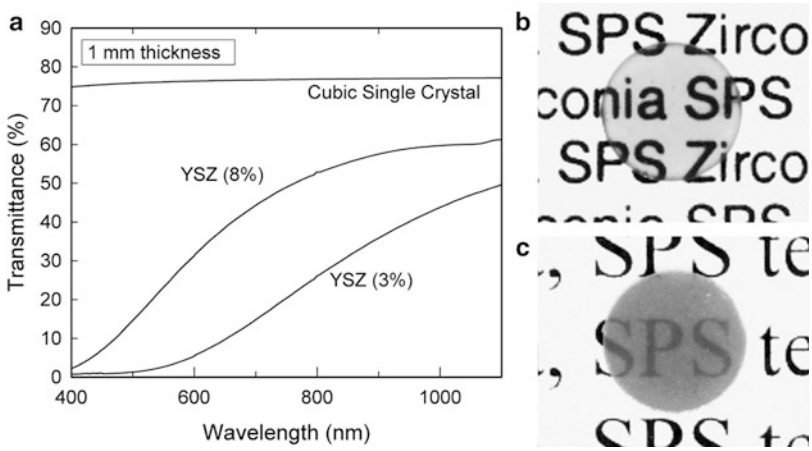
Magnetic Properties

Ferrites represent another group of functional oxides presenting important technological applications [17]. They are in fact largely applied in microwave and radio technology and in computer data storage. New fields of applications are also emerging in the area of biomedical technologies and of thermochemical hydrogen production through water splitting. The general formula of spinel ferrites is AB_2O_4, where A is a divalent metal cation (e.g., Nickel, Cadmium, Zinc, Magnesium, Copper, etc.) and B is Fe. The structural, electrical, and magnetic properties of these materials strongly depend not only on their stoichiometry and on the cationic distributions between the available (A) and (B) sites but also on their microstructure, particle size, and surface-to-volume ratio. As a result, nanostructured materials present significant modification in their magnetic properties. They show, in fact, unusual saturation magnetization and high-coercivity field. Ferrites that are magnetically ordered may also exhibit a

superparamagnetic behavior when in nanocrystalline form. However, only a very limited number of nanostructured bulk materials has been described in the literature. Nanometric $CoFe_2O_4$ ferrite characterized by a grain size of 10 nm and prepared by SPS has been shown to present promising mechanical and magnetic properties [18]. Other examples are represented by $Zn_{0.5}$,$Ni_{0.5}Fe_2O_4$, characterized by a grain size of 60 nm, and by a complex $Ni_{0.4}Zn_{0.4}Co_{0.2}Cu_{0.02}Fe_{1.98}O_4$, presenting a grain size between 38 and 54 nm.

Optical Transparency



Nanostructure has a strong influence on the optical properties of materials. Some of the most evident optical effects are related to confinement, such as in quantum dots or in plasmonic resonators. These effects are well known and are well described elsewhere, but nanostructure might produce other modifications. Particularly interesting in this regard is the effect of nanostructure on the optical transparency of ceramic materials.

Applications requiring optical transparency in bulk materials usually employ single crystals of oxides, such as sapphire. But single crystals are difficult to make and can be produced only in relatively small dimensions. Polycrystalline ceramics represent an appealing alternative, thanks to their lower costs and improved mechanical properties. The degree of transparency of a ceramic polycrystalline material depends on two main parameters: residual porosity and GB density. The former should be kept in the range between 10^{-2} and 10^{-3} vol.% or less, while the latter is usually kept as low as possible, especially when the material presents an anisotropic refractive index. The scattering efficiency of spherical pores, however, decreases drastically when their dimension becomes smaller than the radiation wavelength [19]. Consequently, it has been suggested that materials presenting residual porosity in the low nanometric range should be transparent, even in presence of a significant amount of residual nanoporosity.

Usually low sintering temperatures and very high pressures, sometimes exceeding 1 GPa, have been employed, in order to obtain transparent materials characterized by a uniform nanoporosity and by a grain size in the low nanometric range [1]. The spinel $MgAl_2O_4$ was successfully sintered, reaching optical transparency, under pressures between 2 and 5 GPa. At 4 GPa, for sintering temperatures as low as 600 °C, the spinel showed a high transmittance level (>70 %) for a large wavelength range (600–2000 nm). The sample had a grain size of 40 nm. The same material, with a grain size reduced to 30 nm, was prepared by a two-step sintering at higher temperatures (795 °C), reaching a higher level of optical transmission (80 % for 1000–2000 nm and 70 % for 375–2500 nm) [20]. An even smaller grain size (ca. 25 nm) was obtained by increasing the pressure up to 5 GPa and with no need of heating: the ambient temperature densification provided a material that was transparent for IR and visible radiation. Transparent Y_2O_3 doped with Eu was obtained under even higher pressures, up to 8 GPa, at relatively low temperatures (200 °C), reaching 60 % of transmission in respect to the analogous single crystal [1]. Other nanocrystalline bulk materials showing a good level of transmission were $Lu_{2-x}Ho_xO_3$, $Y_3Al_5O_{12}$, and $Y_3Fe_5O_{12}$ [1]. To obtain the required level of nanoporosity at lower sintering pressures, the corresponding temperatures applied during the densification process need to be remarkably increased: only at temperatures as high as 1000 °C sufficiently transparent YSZ samples were produced by HP-FAST. The sintering cycles however were very short, reduced to only 5 min. Samples 1 mm thick, characterized by a transmittance between 70 % and 80 % of their maximum theoretical value, have been obtained (Fig. 10) [20].

Future Direction for Research

The investigation on possible use of the nanostructure in controlling the physical properties of functional materials in bulk form is still in its early stage of development. Only recently it has been possible to produce these materials in amounts

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm, Fig. 10 (**a**) Optical spectra of two samples of 8 mol% YSZ and 3 mol% YSZ, sintered at ~1000 °C under a pressure of ~800 MPa, for 5 min. (**c**) Optical micrograph of the sample of 1 mm thick 3 mol% YSZ (Adapted from Ref. [20])

large enough to allow a systematic study of their characteristics. In the area of ceramic functional materials, particularly oxides, high-pressure spark plasma sintering and other high-pressure field assisted sintering techniques have emerged as the only approaches allowing a fairly simple and reproducible way for their synthesis. However, the microscopic mechanisms involved in the densification of the nanopowders using these techniques are still poorly understood, and the determination of the experimental conditions required for each system is still largely based on an empirical approach. Furthermore, very limited information is generally available on the details of the obtained nanostructures, as the characterization of bulk ceramic materials with such a small grain size is quite problematic. Despite all this, it has been possible to evidence as the nanostructure represents a powerful tool for the modification of the bulk characteristics of functional materials. It has been demonstrated, in fact, that through a careful control of the nanostructure, phase stability, electrical, magnetic and optical properties of bulk materials can be altered significantly. In this regard, the nanostructure is emerging as an alternative to the traditional methods, represented by alloying with doping elements and control of point defect equilibria, for determining the bulk properties of functional materials. The traditional methods present limitations generally due to thermodynamic constraints. The use of nanostructured materials can in some cases overcome these limitations, as the prevalence of interfacial processes might overshadow the properties of the bulk. Of course, since the nanomaterials characterized by extreme nanostructures are generally thermodynamically unstable, the stability of the produced materials in the long term represents a point of concern.

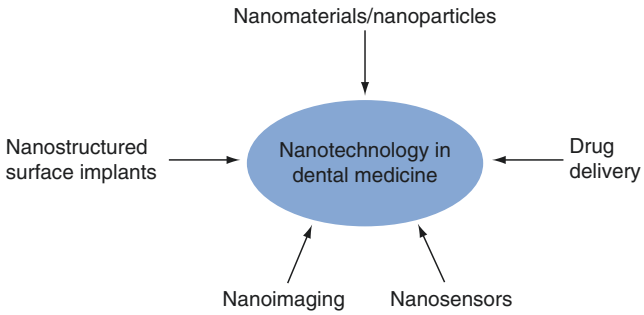
Nanotechnology in dental medicine

Definition

Nanodentistry is defined as the science and technology of diagnosing, treating, and preventing oral and dental diseases, relieving pain, and of preserving and improving dental health, applying materials structured on the nanometer scale [1]. The nanotechnology considers nanostructures between 1 and 100 nm exhibiting properties and functionalities that fundamentally differ from that of other length scales, as the surface of the nanostructures dominates the material properties usually given by the bulk. The nanomaterials are not only promised to improve the properties and functionalities of dental products but also to lead to the development of innovative, novel products for the benefit of patients. In particular,

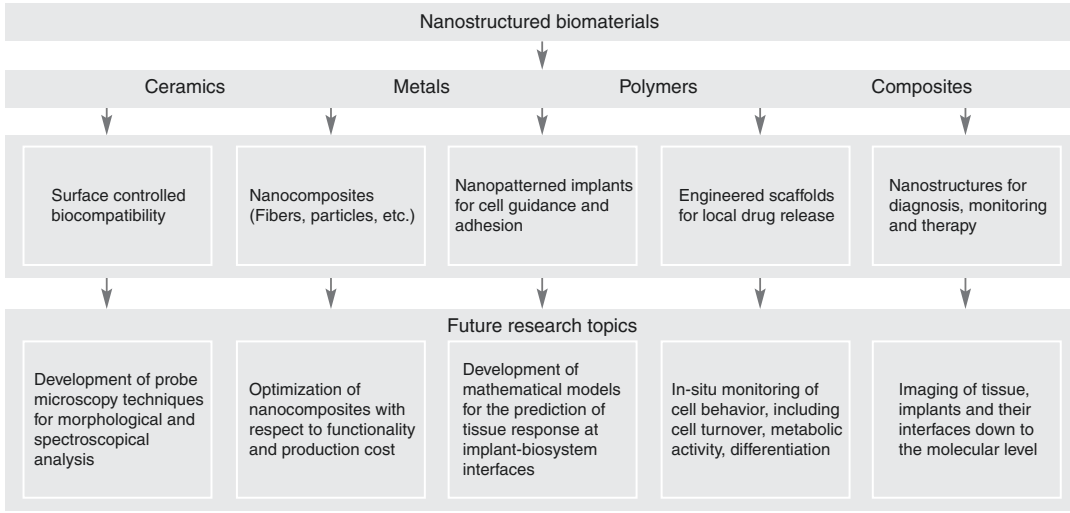
nanomaterials have been part of engineered products, such as implants, dental and surgical instruments, dental care wares, as well as diagnostics tools.

Overview



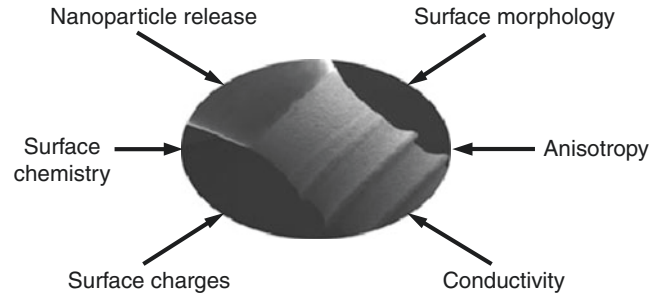
The cover story of R. A. Freitas Jr. in the *Journal of the American Dental Association* more than a decade ago [2] introduced the term *nanodentistry* to a larger community. He developed visions effectively using dental nanorobots for orthodontic realignments, for dentition regeneration procedures and, finally, oral health maintenance. He already elucidated the increasing influence of nanomaterials and the importance of tissue engineering. It has been pointed out that properly configured dentifrobots will recognize and subsequently destroy pathogenic bacteria residing in the plaque and elsewhere.

Although most of Freitas' ideas are still science fiction, today many applications of nanometer-scale components are known in the field of dentistry, which include nanoparticles in sensitive toothpastes, nanostructured surfaces of dental implants to improve osseointegration, and to reduce inflammatory reactions of different kinds of drugs (cp. Fig. 1). Further applications still on the research stage are classified into nanoimaging to reveal the nanometer-sized features in human tissues and man-made implants or nanosensors to quantify physical, chemical, or biological parameters within the oral cavity.



Dental materials are ceramics, metals, and polymers or any combination (cp. Fig. 2). Applying the knowledge and experience of nanotechnology to solve problems in the field of dental medicine, nanometer-sized patterns have been created on surfaces of implants and surgical instruments and incorporated into the bulk of the dental materials to accomplish the dedicated functionality. Nanostructures can improve the biocompatibility of dental implants or carry drugs toward the target within the oral cavity. Reactive nanostructures are going to emerge in diagnosis, monitoring, and therapy to enhance the patient treatments. Diverse activities augment the basic research of bio-nano-materials. Scanning probe microscopy techniques, for instance, enable us to morphologically and spectroscopically analyze hard and soft tissues to understand the structure–-function relationship on the nanometer scale. Sophisticated mathematical simulations allow tailoring the material properties by the combination of nanometer-sized components. The outcome also predicts the tissue response and the self-organization at the implant–biosystem interfaces down to the molecular scale. Highly advanced in vivo measurements support cell biologists to determine the cell behavior with respect to proliferation, differentiation, and metabolism, especially at the interface between the dental material and the surrounding tissues. For this target, high-resolution imaging facilities have become more and more vital to quantify the different kinds of nanostructures with the desired precision.

Biocompatibility



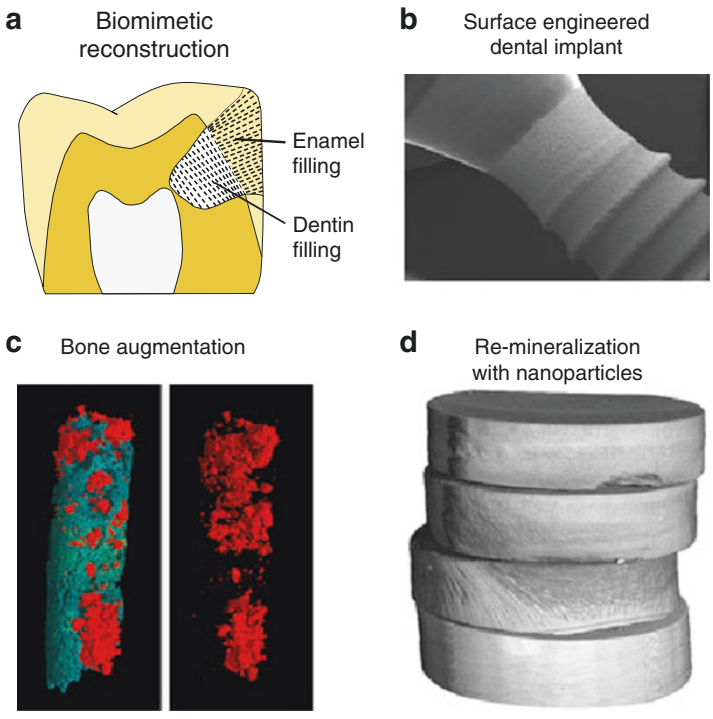
Biocompatibility cannot be simply described as a specific property of the selected biomaterial, as well known from mechanical quantities such as

Nanodentistry, Fig. 1 Key issues currently related to nanotechnology in dental medicine

Nanodentistry, Fig. 2 Materials science for nanodentistry

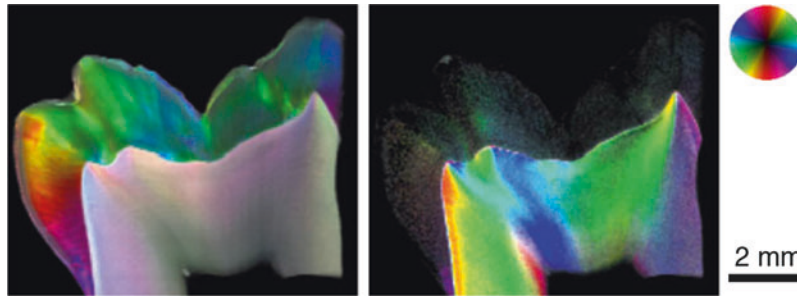
Nanodentistry, Fig. 3 Several parameters allow tailoring the biocompatibility of dental implants

Young's modulus. It is a peculiar term and defined as ". . . the ability of a material to perform with an appropriate host response in a specific application." [3]. This means it not only depends on the material itself but also from the location within the human body where the material is to be placed. Consequently, biocompatibility is not only related to intrinsic material properties. Its classification relies on standards (mainly ISO 10993 [4]). Therefore, the regular updates of these standards may change the status of a material concerning biocompatibility. Natural scientists and engineers are often not familiar with such a practice and, hence, usually terminate their work on such research areas.



The encouraging argument, however, correlates to the experimental observations that biocompatibility of implants can be intentionally manipulated to optimize the clinical outcome. Figure 3 illustrates how some selected phenomena can influence the biocompatibility. For a dental titanium implant, for example, the surface is made rough down to the molecular level by sandblasting and etching procedures to ensure osseointegration and to reduce the inflammatory reactions [5]. Surface morphology can offer certain angles for dedicated protein absorption and activity. In addition, the surface chemistry is commonly tailored concerning oxide thickness, stoichiometry, and normally functionalized to obtain a hydrophilic surface. Further relevant factors are particle and ion release, surface charges, electrical conductivity, and anisotropies as present on patterned surface micro- and nanostructures. The measurement of the surface roughness on real implants is more than challenging, since there is

no single parameter and no single experimental setup, which allow simultaneously determining roughness on the micro- and nanometer scales.



Key Research Findings

Figure 4 shows representative applications of nanotechnology in dental medicine. The fillers of reconstruction materials, the surfaces of dental implants, the different kinds of bone-augmentation ceramics and glass ceramics, as well as the re-mineralization of hard tissues by means of nanoparticles exploit nanotechnology by now and possess enormous growing potential. Nature-analogue, anisotropic restorations will replace today's dental filling and inlay materials as well as artificial teeth [6]. Researchers are still searching how the anisotropy can be introduced to obtain nanostructures similar to the ones present in healthy human teeth.

It belongs to the key impacts to realize that the ceramic components in dentin are orthogonally oriented to the nanostructures of the same size in enamel (see Fig. 5). This finding well observable in scanning small-angle X-ray scattering could explain why the dentin-enamel junction acts as an effective crack barrier. Small-angle X-ray scattering in scanning mode, as performed at the cSAXS beamline (Swiss Light Source, Paul Scherrer Institut, Switzerland) allows uncovering the mean orientation, abundance, and anisotropy of nanometer-sized components in human tissues over macroscopic areas [7]. It is in general difficult to isolate the contribution of specific components to the scattering signal, see entry "► Imaging the Human Body Down to the Molecular Level." The collagen in human dentin, however, yields a characteristic signal related to its 67 nm-wide periodicity. Due to the sensitivity of scattering data to periodic structures, it is possible to extract a signal unequivocally related to collagen, thus allowing gathering component-specific information. Several 400 μm-thin slices from a human third molar were examined. Figure 5 shows the processed scattering signal from the features with sizes between 60 and 70 nm. The mean orientation of the scattering signal is coded according to the color wheel. The brightness relates to the abundance of nanostructures, while

Nanodentistry, Fig. 4 Applications of nanotechnology in dentistry with growing potential

Nanodentistry, Fig. 5 Processed small-angle X-ray scattering data in the range between 60 and 70 nm. The mean orientation of the scattering signal is according to the color wheel. The brightness relates to the nanoparticle abundance, while color saturation codes their degree of anisotropy

color saturation matches the degree of the anisotropy. The orientation of the scattering signal in both enamel and dentin is perpendicular to the crystallite orientation. On the left-hand side, the information from the total scattering signal is shown, which is mainly produced by the ceramic components of the tooth. Enamel and dentin can clearly be distinguished due to their different scattering potential. The strong color in the enamel is related to the high degree of anisotropy, that is, the high degree of orientation of the calcium phosphate crystallites, and their strong scattering potential in this range. In the dentin, the anisotropy is less distinct, and decreases with increasing distance from the dentin-enamel junction (DEJ). Moreover, a perpendicular orientation of the scattering signal, and thus of the nanostructures, between enamel and dentin is observed. While the crystallites are mainly oriented perpendicular to the DEJ in enamel, parallel to the main direction of mechanical load, the dentin structures appear parallel to the DEJ, perpendicular to the mechanical loading. It is well known that the DEJ acts as an effective crack barrier, impeding the propagation of cracks from the enamel into the dentin. The image on the right in Fig. 5 shows only the signal related to the collagen matrix. Due to the distinctive periodicity of 67 nm along the collagen fibrils, the scattering signal is oriented parallel to the fibrils. No significant signal is found in the enamel. The mean scattering orientation of the collagen is found to be mainly perpendicular to that of the total signal on the left-hand image, revealing a parallel arrangement of collagen fibrils with the calcium phosphate crystallites. The collagen abundance is maximal near the DEJ and decreases toward the pulp. Abrupt changes in collagen fibril orientation are found along lines connecting the tooth cusps and the pulp. In this manner, the structure of the human teeth along the entire nanometer range is evaluated.

As pointed out above, the part of dental implants to be fixed in the bone is made rough. It contains nanostructures which resemble the apatite crystallites in human bone and therefore offer nanostructures with angles for suitable protein absorption. The suppliers have their secrets for the surface engineering processing, which includes sandblasting, etching, and electrochemical functionalization. Surface-engineered dental implants are very well established and do have a high success rate. During the next decade, we can expect a significant reduction in price so that a broader community of our aging society can benefit from such surface-engineered implants with dedicated nanostructures.

The calcium phosphate phases for bone augmentation gain more and more importance in our aging population. The resorbable calcium phosphate ceramics or bio-glasses do actively support the bone formation. These bone substitutes are combined with autologous bony tissues to repair larger and larger defects arising from cancer surgery, trauma, or just tooth loss.

There are numerous reasons for the de-mineralization of teeth. The mineral loss,

especially owing to attacks of caries bacteria, has a massive effect on lifetime and function of teeth. Therefore, strategies have been developed to at least partially re-mineralize the enamel and dentin as the robust alternative to mechanical removal and conventional filling the defect. Optimized dental hygiene has reached restricted success in small caries lesions. Researchers all over the world use slices of dentin to explore the re-mineralization capacity of a variety of nanotechnology-based ceramics particles. Using a set of slices, a direct comparison of the different materials and procedures has become possible.

Future Research

The dental nano-biomaterials have to be investigated to judge the toxicity and the biocompatibility and to pursue the personalized medicine with respect to more and more frequent material incompatibilities. The development of nanocontainers for a variety of drugs aims for targeted delivery preventing undesired side effects. For larger caries regions, which grow fast into the dentin, the collagen network might be still available, but the mineral phase is already dissolved. The return of the calcium phosphates and traces of other minerals into the affected region for restoration purposes is challenging but not impossible, as the collagen network could provide nucleation sites for the re-mineralization.

Bio-inspired dental fillings and inlays have to exhibit the anisotropy and orientation of organic and inorganic nanometer-sized components as found in enamel and dentin. Today, the dentists already use different fillings for dentin and enamel but without oriented anisotropic ceramics. Therefore, scientists and engineers have to discover opportunities to incorporate anisotropic nanometer-sized ceramics into the fillers and to carry them into the desired direction. Hence nature-analogue mechanical properties should be obtained. Based on these oriented nanostructures, one should search for self-repairing materials. Here again the human body provides concepts: the remodeling of bone.

Definition

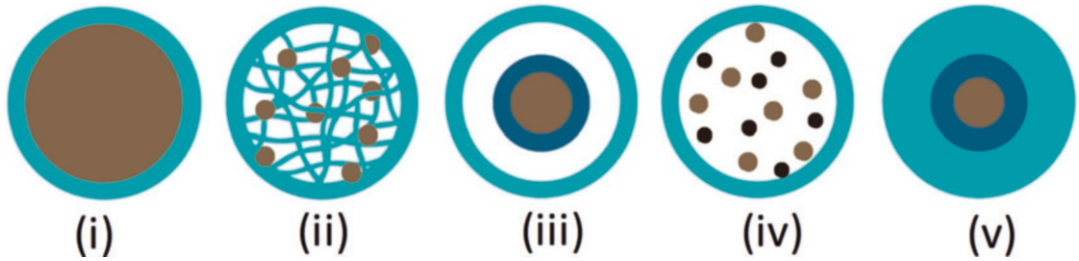
Nanoencapsulation is defined as the entrapping of active ingredients in nanometer sized capsules.

Overview

Nanoencapsulation is defined as the technology of packaging nanoparticles of solid, liquid, or gas, also known as the core or active, within a secondary material, named as the matrix or shell, to form nanocapsules (see Fig. 1) [1]. The core contains the active ingredient (e.g., drugs, perfumes, biocides, vitamins, etc., see Table 1) while the shell isolates and protects the core from the surrounding environment. This protection can be

Nanoencapsulation, Fig. 1 Scheme of a nanocapsule

Nanoencapsulation, Table 1 Core and shell materials more commonly used in different nanoencapsulation applications



Application	Materials
Food	C: acidulants (acetic, sorbic, lactic), flavoring agents (citrus/mint oils, oleoresin, oregan, menthol), sweeteners (sugar, aspartame), colorants (β-carotene), lipids (fish oil, linoleic oil, palmitic acid), vitamins and minerals (vitamin A, D, E and K, folic acid), salts, preservatives (gallic acid), antimicrobials and antioxidants (terpene, limonene, black pepper, catechins), probiotics (lactobacillus, bifidobacteria) enzymes and microorganisms (lipase, invertase, penicillium roqueforti) S: carbohydrates (sucrose, malto- and cyclo-dextrines, chitosan), gums (agar, arabic, gum acacia, sodium alginate, lipids (oils, paraffin, stearic acid, fats, beeswax, phospholipids, Stealth® liposomes), celluloses, proteins (albumin, casein, gelatin, gluten, peptides, zein), synthethic elatomers (polyacrylamide, polyacrylate, polyethylene, polyvinyl alcohol, polyvinyl acetate), synthetic polymers (acrylonitrile, polybutadiene, poly(lactide-co-glycolide), silicon dioxide
Pharmaceutics	C: hormones (insulin), vaccines, oncologic (doxorubicin, cisplatin) and hematology actives (anthracyclines), proteins (bovine serum albumin, globulin, myoglobin,), enzymes (glucose oxidase), antibiotics (amoxicillin), drugs (felodipine, nicardipine, heparin), bacteria (lactobacillus acidophilus) and hepatocytes S: carbohydrates (chitosan, alginate, dextran), proteins (polylysine, polyglutamic, albumin, peptides), synthethic elatomers (poly(alkyl acrylate), poly(ethyleneglycol)), celluloses (ethylcellulose), synthetic polymers (poly(lactide-co-glycolide, polyethyleneglycol), lipids (phospholipids), carbon nanotubes, erythrocytes, gums (alginate), silicon dioxide, phyllosilicate
Agriculture	C: Insecticides (endosulfan), herbicides (fenamiphos), pheromones, fertilizers, pesticides, microbicides S: Polyurea, polyurethane, gelatin, gum Arabic, chitin, chitosan
Textile	C: PCM, emollients (aloe vera, vitamin E, lanolin), dyes, fabrics softeners, flame retardants S: Poly(styrene), urea-formaldehyde, ethylcellulose
Paintings	C: Biocide (OIT), pigments, anti-foulant agents, anti-corrosion agents S: Melamine formaldehyde, gelatine – acacia, silica, zeolite
Personal care	C: natural ingredients, essential oils (menthol, lime, lavender), preservatives, vitamins (A, E, C), retinol and triclosan S: carbohydrates (sucrose, malto- and cyclo-dextrines, chitosan), cellulose, silicon dioxide

C core, *S* shell

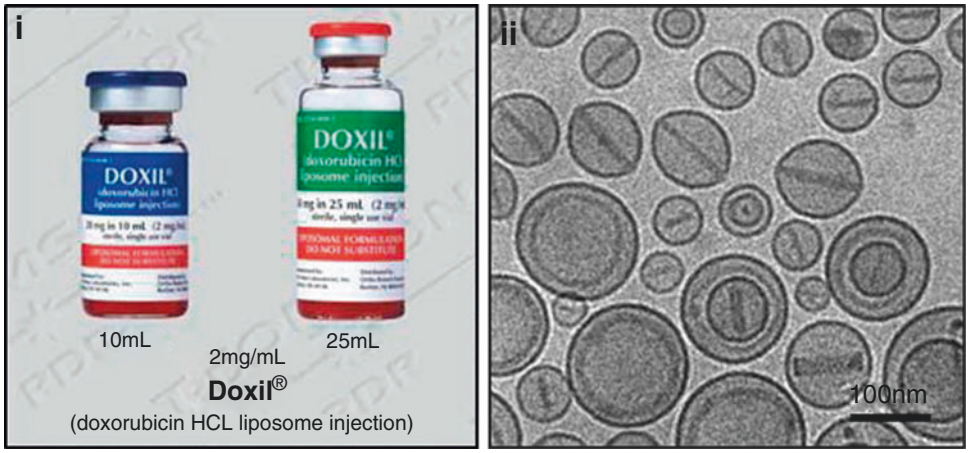
permanent or temporal, in which case the core is generally released by diffusion or in response to a trigger, such as shear, pH, or enzyme action, thus enabling their controlled and timed delivery to a targeted site [2, 3].

Nanocapsules may range from 1 to 1000 nm in size and they have a multitude of different shapes, depending on the materials and methods used to prepare them [2]. The structure of encapsulated ingredients (see Table 1) which largely depend on the selected shell material and nanoencapsulation method can be classified into two main categories (see Fig. 2): capsules with (a) a core that is surrounded by a shell of the matrix material or (b) a core that is entrapped within a continuous network of the matrix material. Variations of these morphologies include capsules with multiple cores or multilayered capsules [1]. However, the most significant feature of nanocapsules is their nanoscopic size that provides a large surface area. The total surface area is inversely proportional to the capsule diameter. This large surface area is appropriate for incorporating recognition species (functionalization with peptides, antibodies, organic polymers, etc.), sites of adsorption and desorption, chemical reactions, light scattering, among others.

Many different materials can be used as encapsulating matrices which must be selected depending on the critical properties needed for each intended application (see Table 1). The majority of these carriers are proteins (lecithin, legumin, gelatin, and albumin), polysaccharides (dextrin, starch, gums, chitosan, and alginates), fats, liposomes [4], biopolymers, co-polymers (poly(lactic-co-glycolic acid), micelles, organogels, dendrimers, solid nanoparticles

Nanoencapsulation, Fig. 2 Morphologies of nanocapsules (from *left* to *right*): (i) single-core capsule, (ii) dispersed core in polymer gel, (iii) multi-layer capsule, (iv) dual-core capsule and (v) single-core-multi-shell capsule

(SLN), polymeric nanoparticles, emulsions-base systems, and metal-organic particles [5].



The main reason for nanoencapsulating species is to ensure that the encapsulated material reaches the area of action without being adversely affected by the external environment through which it passes. Thus, the principal reasons for encapsulation are: (a) separation of incompatible materials, (b) conversion of liquids to free flowing solids [6], (c) increased stability (e.g., protection of the encapsulated against oxidation or deactivation due to reaction in the environment), (d) masking organoleptic properties like color, taste, odor of substances, (e) safe handling of toxic materials, and (f) controlled and targeted release of encapsulated active compounds. In addition, nanoencapsulation allows to modify the release of encapsulated active materials, providing sustained release (maintaining the right concentration), long lasting (and therefore improving effects), target release (improving adhesion, penetration, or recognition of tissues and cells), or triggered release (mainly by environmental changes in pH, temperature). Encapsulation and release modification (sustained, triggered, or targeted release) also reduces doses and, therefore, potential toxicity of drugs. This is of the main interest in medical applications. Moreover, since the encapsulated molecule is not in direct contact with the environment, irritation at the site of administration is commonly reduced.

Because of this wide range of advantages and properties, nanoencapsulation technologies have applications in many industrial sectors, including the medical, pharmaceutical, cosmetics, chemical, textile, construction, agricultural and food industries. In fact, this technique is already commonplace within a range of industries, but it is accepted that only around 10 % of potential applications are currently being exploited. For example, in the case of medicine delivery, the core material (e.g., drugs, vaccines, etc.) can be targeted and released in a controlled manner and at a specific location (see Fig. 3). In agrochemistry, the nanocapsules were proposed for controlling the release of insecticides or pesticides and improve their efficiency and decrease the quantity of active substances for a given application. Or, in the textile industry, durable textile fragrances and skin softeners in the form of nanocapsules have been developed [6].

Basis Nanoencapsulation Techniques

Before considering the fabrication of nanoencapsulated products, one should first determine which are all the characteristics, properties, and capabilities that such products must satisfy for each intended application. For this, the following questions must be taken into consideration before choosing which nanoencapsulation methodology is the more appropriate: [2]

1. What functionality should the encapsulated ingredients (core) provide to the final product?
2. What kind of coating material (matrix) should be selected?

Nanoencapsulation, Fig. 3 (i) Nanoliposomes loaded with the chemotherapeutic agent doxorubicin in commercial product Doxil® (Ortho Biotech) and (ii) SEM image of doxorubicin liposomal in Nuclisomes® formulation (Image taken from Ref. [20], With kind permission from Springer Science+Business Media: Ref. [16], 2010)

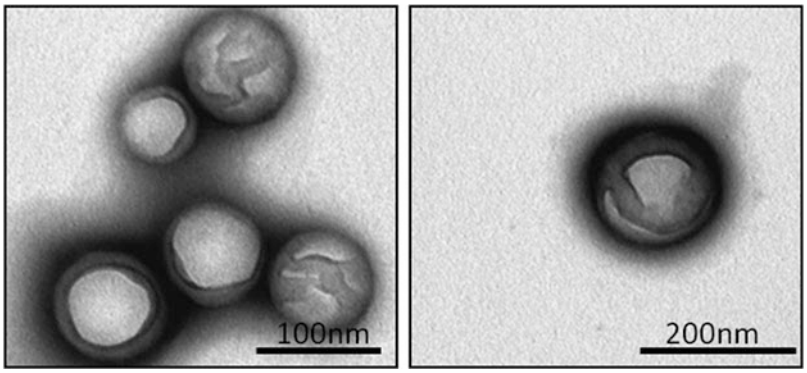
3. What processing conditions must the encapsulated ingredients survive before releasing its content?
4. What is the optimal concentration of the active ingredient in the nanocapsule?
5. By what mechanism the ingredient must be released from the nanocapsules?
6. What are the particle size, density, and stability requirements for the encapsulated ingredient?
7. What are the cost constraints of the encapsulated ingredient?

Similarly, an understanding of the physicochemical properties of the core and factors that control the interfacial and aggregation behavior of the matrix materials is crucial to choose suitable processes for nanoencapsulation [1]. Today, a multitude of techniques are used for nanoencapsulating active species. The more popular techniques can be classified in three main families: chemical, physicochemical, and physicomechanical encapsulation processes [3]. The chemical and physicochemical processes include those methods in which chemical reactions are involved in the nanocapsule formation. In contrast, in the physicomechanical methods, no chemical reactions are involved in the nanocapsule formation and only shape fabrication usually takes place. Some of the techniques that are commonly used are briefly discussed below (see Table 2).

Chemical Processes

The chemical processes are building-up techniques where the nanocapsules are synthesized through the nucleation and growth processes involving elementary building blocks, such as ions, atoms, and molecules. The most important chemical methods include the emulsions, suspensions, precipitations, sol–gels, and polymerizations. The advantages of these chemical methods are that they provide nanocapsules with high purity, high uniformity, small particle size, narrow size distribution, dispersable, good chemical homogeneity, and more reactivity.

The majority of chemical methods are based on the initial formation of an emulsion. An emulsion is a suspension of small droplets (diameters below 1000 nm), usually stabilized by an emulsifier, of one liquid in a second liquid in which the first will not mix. These emulsions are conventional emulsions, multilayered emulsions, microemulsions, nanoemulsions, solid lipid emulsions, or double emulsions. Generally, the "*emulsification*" methods consist on first creating an emulsion of a liquid core in a continuous phase using shaking, stirring, homogenizing, or spray processes. In a second step, a shell is formed via organic polymerization, or the emulsion homogenized by microfluidisers, or the suspension atomized for solvent evaporation. Control over the properties of emulsion-based nanoencapsulation systems



Nanoencapsulation, Table 2 Several nanoencapsulation techniques and the steps involved in each process

Nanoencapsulation technique	Processed involved
Sol–gel	(a) Solution of core and polymer (b) Formation of Sol phase (c) Gelation (d) Solidification
In situ polymerization	(a) Preparation of core solution (b) Addition of droplets of monomer
Coacervation	(a) Formation of a three-immiscible chemical phases (b) Deposition of the coating (c) Solidification of the coating
Rapid expansion of supercritical solution	(a) Preparation of solution of core and shell materials in CO_2 (b) Depressurization through a nozzle
Liposome entrapment	(a) Microfluidization (b) Ultrasonication (c) Reverse-phase evaporation
Inclusion complexes	Preparation of complexes by mixing or grinding
Spray-drying	(a) Preparation of a dispersion (b) Homogenization of the dispersion (c) Atomization of the dispersion
Solvent evaporation	(a) Preparation of solution of polymer and core (b) Solvent evaporation by heating
Electrocoextrusion	(a) Preparation of core solution and wall solution (b) Simultaneous spraying of two solutions from two coaxial capillaries

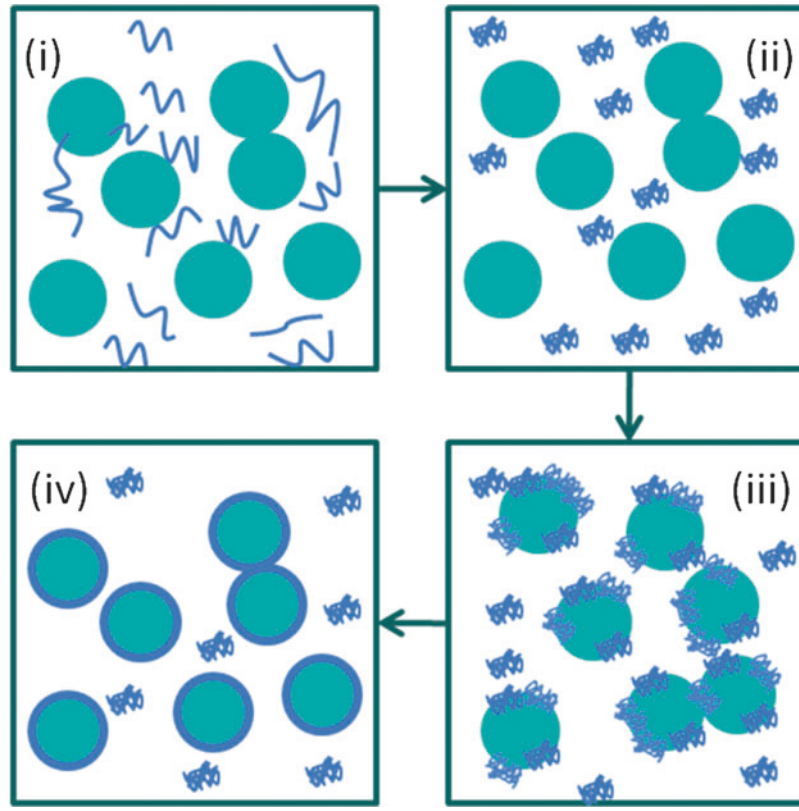
can be achieved by tailoring the dispersed phase as well as the structure of emulsions [1]. In general, the so-called microemulsions are defined as thermodynamically stable transparent or translucent isotropic dispersions of nanodroplets with a size ranging between 5 and 1000 nm, whereas nanoemulsions are metastable dispersions of nanoscale droplets (<100 nm) and optically transparent. This last property is of interest, for example, to the food and beverage industry as it enables the delivery of flavors and bioactive ingredients in clear emulsions. For example, kinetic stable nanoemulsions of triglyceride oils may be achieved using high-pressure homogenizers as the final step [7].

Emulsion encapsulation methods include the "in situ *polymerization*" and the "*interfacial polymerization*" methodologies, among others. In the "in situ *polymerization,*" the monomer is added dropwise to an emulsion which is formed by the aqueous polymerization solution, the active ingredient and an emulsifier, under continuous stirring. Initially, a low molecular weight polymer is formed in the continuous phase, and as the polymerization proceeds, the polymer gradually grows and simultaneously entraps the core material to form the final nanocapsules. For example, insulin loaded poly(alkyl cyanoacrylate) nanocapsules are prepared using this technique [8]. On the other hand, in the "*interfacial polymerization*" technique, the capsule shell is formed at/on the droplet surface by polymerization of the reactive monomers. First, the core material is dispersed into the continuous phase where the monomer is dissolved, forming an emulsion. A coreactant is then added to the mixture, provoking the polymerization at the core interface, thus generating the capsule shell. As an illustrative example, this method is used for the encapsulation of polyaminoacids in PLGA-polaxamer nanocapsules (see Fig. 4) [9].

The "*sol–gel*" method is a process based on the preparation of a solution, sol and gel, followed by the solidification and heat treatment of the organic and inorganic compounds. "*Sol–gel*" encapsulation involves the evolution of inorganic networks through the formation of a colloidal suspension (sol) and gelation of the sol to form a network in a continuous liquid phase (gel). In this method, the capsules can range between submicron sizes to a few tens of microns [10]. The most popular use of this process is the production of immobilized biomaterials, such as enzymes and microorganisms. Its main advantages are the very mild operating conditions as well as the small particle size achievable and the affordable raw materials. From an industrial point of view, this process is easily scaled up even considering the tight cost-in-use constraints characteristics of the food industry. For example, this method can be used for the immobilization of lipase enzymes within a

Nanoencapsulation, Fig. 4 TEM image of a polyaminoacid loaded in PLGA: poloxamer nanocapsules (Image taken from Ref. [9])

phyllosilicate and vinyltriethoxysilane sol–gel matrices and beta-glucosidase in alginate-silicate sol–gel matrices.

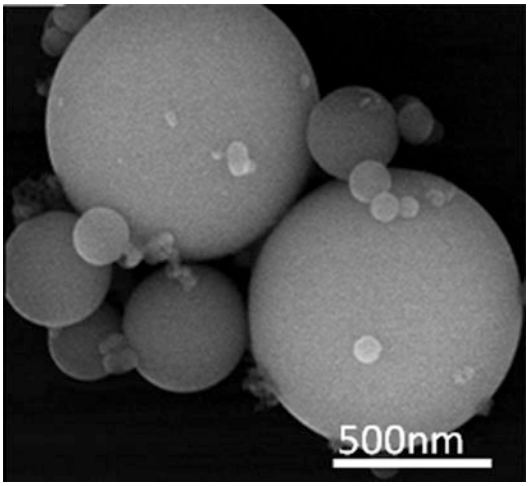


In addition to the chemical nanoencapsulation techniques described above, nanoencapsulation can also be carried out by "*suspension cross-linking.*" This is the method of choice for encapsulating proteins and polysaccharides. This method involves the dispersion of a polymer aqueous solution containing the core material in an immiscible organic solvent to form an emulsion. Droplets are hardened by covalent cross-linking and directly converted to capsules. The cross-linking process is accomplished either thermally or by the use of cross-linking agents. Albumin nanocapsules containing doxorubicin and magnetite particles are prepared by this technique. Salmon calcitonin-loaded chitosan-PEG nanocapsules are prepared with this methodology as well.

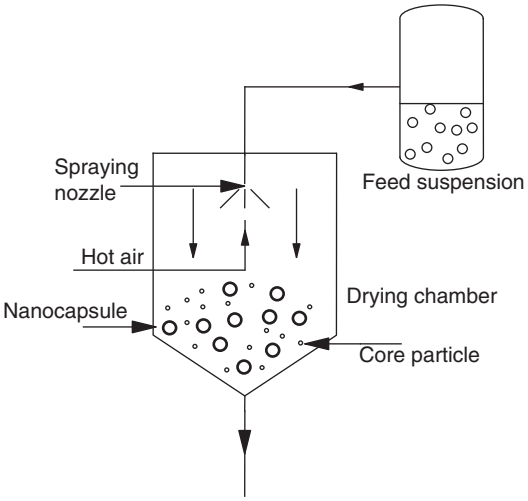
Finally, nanoencapsulation can also be carried out via "*hydrothermal methods*" where chemical reactions in water at high temperatures and high pressures are involved for the nanocapsule formation and via "*oxidation processes*" that oxide and deoxidize directly the raw materials in the liquid phase or quasi-liquid phase state to prepare the nanocapsules.

Physicochemical Processes

Physicochemical methods are the processes that combine both the chemical and physical methods during the nanoencapsulation. For example, "*phase inversion nanoencapsulation*" (PIN) is a method for highly efficient encapsulation of drugs, proteins, or plasmid DNA into biodegradable polymer nanospheres. Capsules are produced with a limited size distribution, ranging from 100 nm to 10 μm in diameter, and labile drugs are efficiently encapsulated without denaturation. In this method, the active compound is added to a dilute polymer solution (normally in methylene chloride) which is then poured rapidly into an unstirred bath of nonsolvent (petroleum) at a solvent to nonsolvent ratio of 1:100, causing nano- and microspheres to form spontaneously. The drug dicumarol, proteins such as bovine serum albumin, hormones such as insulin, and plasmid DNA have been successfully encapsulated using the PIN system in combination with biologically erodible, biologically adhesive polymers like fumaric acid, sebacic acid, poly-lactide-co-glycolide (PLGA), polylactic (PLA) acid, and polystyrene.



"*Coacervation and phase separation*" is another physicochemical method based on the gradual desolvation of a homogeneous polymer solution into a polymer-rich phase (coacervate) and the poor polymer phase (coacervation medium). Phase separation processes are divided into simple and complex coacervation. The mechanism of capsule formation is identical in both processes, except in the way in which the phase separation is carried out (see Fig. 5). In a simple coacervation, a desolvation agent, such as gelatin or ethyl cellulose, is added to the aqueous or organic media for phase separation, whereas complex coacervation involves complexation between two oppositely charged polymers, both soluble in an aqueous media. Nanoencapsulation by coacervation is carried out by preparing an aqueous



Nanoencapsulation, Fig. 5 Schematic illustration of a typical coacervation process, involving (i) dispersion of the core material in a solution of the shell polymer, (ii) initial separation of the coacervate from the solution, (iii) coating of the core material by microdroplets of the coacervate and (iv) coalescence of the coacervate to form continuous shell by reticulation at the interface

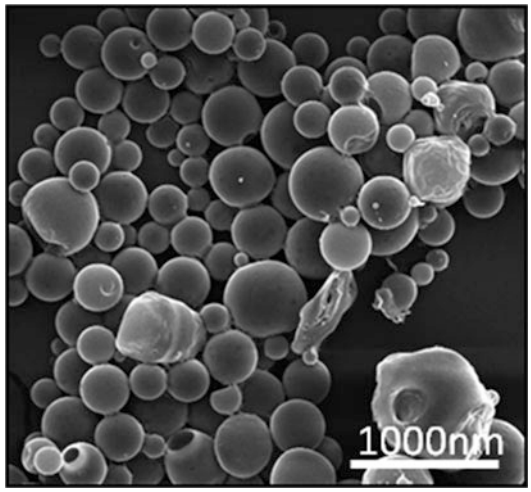
polymer solution (1–10 %) at 40–50 °C where the hydrophobic core material is also dispersed/dissolved. Stabilizers are usually added to the mixture to keep the individuality of the final particles. Then, a suitable desolvating agent is gradually added to the mixture leading to the formation of partially desolvated polymer molecules and, hence, their precipitation on the surface of the core material. Finally, the prepared capsules are stabilized by cross-linking, desolvation, or thermal treatment (e.g., cooling at 5 °C). An illustrative example is the gelatin nanocapsules (840 nm) loaded with the protein/peptide drug bovine serum albumin (BSA) which have been produced by a modified coacervation method free of desolvating agent.

Another common physicochemical approach is the use of molecular systems that self-assemble into capsules at given conditions, such as the aggregation of lipid molecules into spherically closed bilayer structures at low concentrations, the so-called vesicles or liposomes, or molecular inclusion complexes, such as cyclodextrins and dendrimers or hyperbranched polymers. "*Liposomes*" are the smallest artificial vesicles of spherical shape that can be produced from natural nontoxic phospholipids and cholesterol. When phospholipids are dispersed in an aqueous phase, the liposomes are formed spontaneously, thus encapsulating either aqueous or lipid-soluble materials. In general, they are considered very versatile tools in biology, biochemistry, and nanomedicine because they are currently been used for delivery of vaccines, hormones, enzymes, and vitamins (see Fig. 3) [4]. The great advantage of liposomes over other nanoencapsulation techniques is the stability that liposomes impart to water-soluble material in high water activity applications [2]. Recently, it has been published a very interesting nanoencapsulation technology that produced capsules coined "colloidosomes" because of their resemblance to liposomes, while using colloid particles as shell material. Also, the ultimate achievement in enzyme protection and

Nanoencapsulation, Fig. 6 SEM image of PLGA-encapsulated SiO2 powder prepared by rapid expansion of supercritical suspension process (Reprinted with permission from Ref. [11]. Copyright 2009 American Chemical Society)

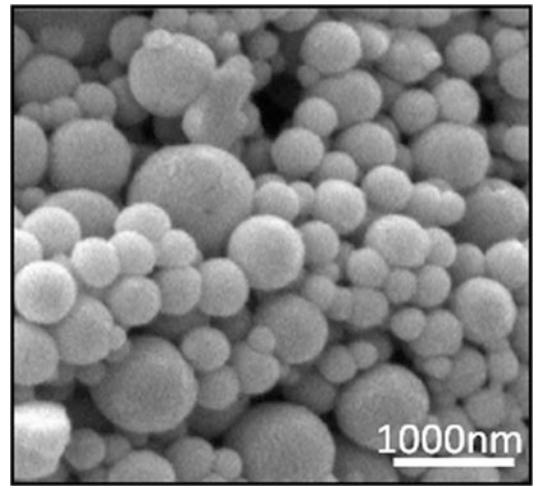
Nanoencapsulation, Fig. 7 Schematic representation of the spray-drying process

delivery is represented by polymeric vesicles which are called polymersomes.



"*Inclusion complexes*" generally refers to the supramolecular association of the encapsulated substance into a cavity-bearing complex or dendrimer (shell). Small organic molecules can displace the water from the inner cavity and form thermodynamically stable complexes. The encapsulated unit is kept within the cavity by hydrogen bonding, van der Waals forces or by the entropy-driven hydrophobic effect. Examples include the encapsulation of hydrophobic vitamins (A, E or K) in cyclic oligosaccharides such as β-cyclodextrins.

Other physico-chemical processes for nanoencapsulation are based on *supercritical fluids*. In these methods, the core ingredient is dispersed in a matrix material solubilized in a supercritical fluid (usually carbon dioxide). Removal of the carbon dioxide results in the core being encapsulated within the matrix material. For example, in *rapid expansion of supercritical solutions* (RESS), the dispersion is sprayed through a nozzle and a particulate material containing the core is formed. Titanium dioxide and silica nanoparticles coated with poly(lactide-co-glycolide) are prepared using the RESS process (see Fig. 6) [11].

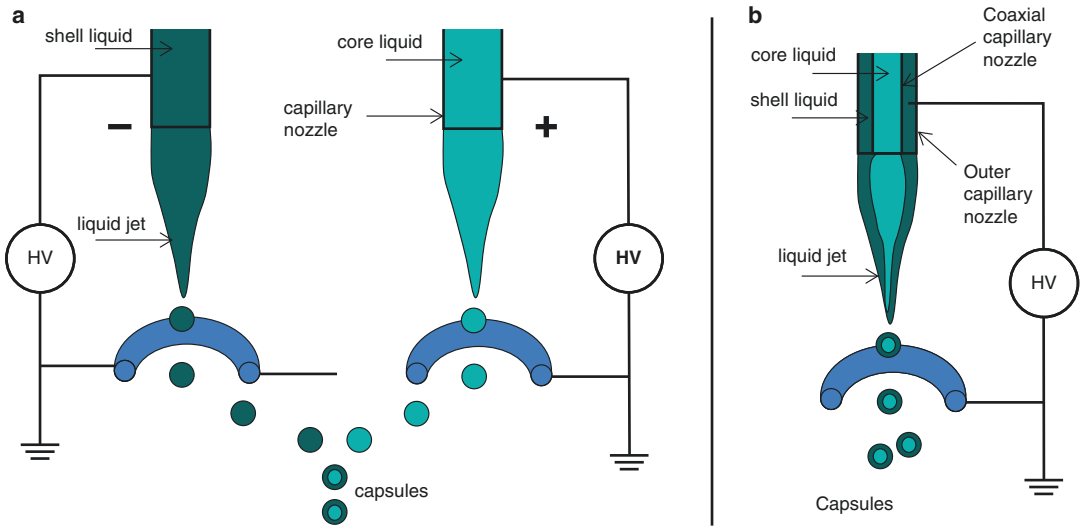


In addition to the nanoencapsulation techniques described above, microfluidic platforms are started to be exploited for the synthesis of nanocapsules because these platforms allow a precise control of their size and shape and, therefore, of their physico-chemical properties [12]. For example, anti-fungal drug itraconazole has been encapsulated in polymethylsilsesquioxane nanospheres with a controlled drug release profile using a V-junction microfluidic device [13]. Also, other physico-chemical processes are "*solid lipid nanoparticles*" (SLN), "*layer-by-layer deposition* (e.g., *encapsulation by polyelectrolyte multilayer*)" and "*controlled precipitation.*"

Physico-Mechanical Processes

The most important physico-mechanical methodologies for encapsulating desired species at the nanometer scale are: (i) spray drying, (ii) solvent evaporation/solvent extraction, and (iii) electroencapsulation-based techniques. Among them, "*spray drying*" is a process widely used in the encapsulation of fragrances, oils and flavors. In a "*spray drying process,*" core particles are dispersed in a polymer solution of wall material and atomized into a hot chamber (see Fig. 7). As the solvent evaporates, the shell material solidifies onto the core particles, obtaining polycore or

Nanoencapsulation, Fig. 8 SEM image of oxaprozin/methylated-β-cyclodextrin-loaded PLGA nanocapsules (Image taken from Ref. [9])



Nanoencapsulation, Fig. 9 SEM image of naproxen-PLGA nanocapsules prepared by solvent evaporation/extraction technique (Reprinted from Ref. [14], Copyright (2010), with permission from Elsevier)

matrix type capsules. The one-droplet-to-one-particle mechanism during the spray drying sets the lower limit of the particle size to 100 nm. For example, this technique is used for preparing 260 nm in diameter amifostine/PLGA nanocapsules.

"*Solvent evaporation/solvent extraction*" is a method based on the dissolution of a polymer in a water immiscible organic solvent, such as dichloromethane or chloroform, where the core material is dissolved or dispersed as well. The mixture is then added dropwise to a stirring aqueous solution to form small polymer droplets containing the encapsulated material, and then, the solvent is eliminated. Here, the coat material shrinks around the core material and encapsulates it. The solvent elimination can be done by simple solvent evaporation (heat or reduced pressure) or by solvent extraction with a third liquid which is precipitant for the polymer and miscible with both water and the solvent. This method is suitable for the preparation of fluorescein-loaded nanocapsules based on PLGA using droplet-based microfluidic platforms. PLGA nanocapsules loaded with naproxen and oxaprozin-cyclodextrin are also prepared using this methodology (see Figs. 8 and 9) [14]. In some cases, the "*solvent evaporation/solvent extraction*" method is also combined with "*freeze drying*" process; for example, in the encapsulation of hypericin in polylactic acid.

Recently, pharmaceuticals, cosmetic or food industries seek for new, more efficient technologies for nanocapsules production which do not degrade the chemical or biological properties of the material. Electroencapsulation-based techniques are excellent candidates to be some of these technologies. "*Electrospraying*" is a straightforward bottom-up method to manufacture capsules of submicrometer diameters. It is a method of liquid atomization by means of electrical forces. In "*electrospraying,*" the liquid flowing out of a capillary nozzle is subjected to an electrical shear stress by maintaining the nozzle at high electric potential which forces the liquid to be dispersed into fine droplets. The nanocapsules are produced by previously dissolving the polymer and the active compound into the solvent(s). With this method, the droplet sizes can range from hundreds micrometers down to several tens of nanometers, and they can be controlled by electrical means, i.e., by adjusting the flow rate and voltage applied to the nozzle. Recently, research in electronanoencapsulation is aimed at developing new drugs delivery systems, medicine

Nanoencapsulation, Fig. 10 Schematic representation of two electro-encapsulation processes: (i) electrospraying of two oppositely charged droplets and (ii) electrocoextrusion

production and ingredients dosage in the cosmetic and food industries since the utilization of electrical forces can increase the effectiveness of nanoencapsulation. As a consequence, some "*electrospraying*" techniques have recently been described. For example," *Impacting of two oppositely charged droplets*" is a method where both of the droplet's streams are emitted from two separated capillary nozzles maintained at opposite potentials, one of the capillaries at positive and the other at negative (see Fig. 10a). The droplets collide due to Coulomb attraction forming a capsule via submerging the droplet of higher surface tension within that of smaller surface tension. Another method is the "*electrospraying/evaporation of colloidal suspension,*" in which a suspension is initially electrosprayed followed by the shell solidification by solvent evaporation. Similarly, in the "*electrospraying/gelatinization of colloidal suspension*" method, a suspension of a core material is electrosprayed into a bath containing a gelatinizing or polymerizing agent. This agent forms a hard envelope on the core material. Among other actives, eletrospraying has been tested for the encapsulation of the drug paclitaxel in PLGA and polycaprolactone. Recently, nanocapsules composed of natural polymers (e.g., chitosan) for ampicillin and elastin-like polypeptides for doxorubicin have also been fabricated using the "*electrospraying*" methods.

The "*electrocoextrusion*" process is another electronanoencapsulation technique based on the simultaneous spraying of two different liquids from two coaxial capillaries that are maintained at the same potential (see Fig. 10b). In this method, the core liquid flows from the central capillary and the envelope liquid flows through the annular nozzle between the capillaries. It is important to note that the core liquid must have a high resistivity and the envelope sufficiently high conductivity in order to be used in this methodology. At the present time, the smallest capsules reported using this methodology has a diameter of 150 nm, and they were produced using a photopolymer (Somos 6120-DuPont) and ethylene glycol.

Besides the formation of spherical nanocapsules, electronanoencapsulation technologies can also allow the encapsulation into nanofibers. Indeed, "*electrospinning*" is a method to produce nanofibers where a suspension of the core material in a polymer solution is supplied from a spinneret and forms a droplet at the spinneret exit. In this methodology, an electric field is

applied to the suspension by immersing an electrode in it and placing the counter-electrode some distance from the spinneret and then jetting sets in. This field provokes an electrically induced bending instability in the solution jet which causes stretching of the bent sections of the jet. The solvent eventually evaporates, the jet dries and solidifies, and the spun nanofibers are deposited on the counter electrode. The nanofibers are collected onto the edge of a grounded collector disc. This method has been used in biotechnology, i.e., for the capturing of living cells (virus and bacteria) in poly(vinyl alcohol) nanofibers.

In addition to the techniques described above, other physicomechanical methods that can be used for encapsulating desired species at the nanoscale are the "*melt-solidification,*" "*centrifugal suspension separation,*" "*vibrating and coaxial nozzle,*" and "*pan-coating*" processes.

Release Mechanisms

Different release mechanisms of encapsulated materials provide controlled, sustained, and targeted release of core materials. There are three main mechanisms by which encapsulated material is delivered from a capsule: (i) mechanical rupture of the capsule wall, (ii) dissolution (impact/shear/pressure) or melting of the wall, and (iii) diffusion through the wall. The desired mechanism depends on the nature of the application. For example, carbonless copy paper and scratch and sniff perfumes rely on mechanical rupture of shell to release the core contents. In these applications, the rupture may be caused by pressure or due to propagation of cracks. In contrast, detergent industry uses dissolution of shell wall of powder detergents for the release of encapsulated protease enzyme in order to remove bloodstains from clothing. Similarly, in pharmaceutical industry, nanoencapsulated products are designed for sustained and controlled release by either degradation or by diffusion through the shell. For example, doxorubicin is encapsulated in liposomes to control its release into the body reducing its cardiotoxicity [15].

Applications

Nanoencapsulation is believed by many scientists and technological fields to be one of the most important scientific topics of the next decade with a huge impact on medicine, pharmacology, construction, cosmetics, chemistry, textile, agriculture and food industry, among others. Nowadays, nanoencapsulation is being used in a diverse range of markets, including, but not limited to agrochemicals, aromatherapy, paints, coatings, colorants, pharmaceuticals, personal care, adhesives, biocides, nutraceuticals, oil and gas, textiles, paper systems, electronics and imaging systems (see Table 3). Depending on the application, the nanoencapsulated product can be delivered as a dry, free flowing powder, as slurry or in the form of a wet filter cake. A brief explanation of some applications in some of the most powerful sectors is given below.

Agriculture

Nanoencapsulation appears to be the most promising technique for short-term application in the field. One of the most important applications of nanoencapsulated products is in the area of crop protection in agriculture. In the case of controlling parasitic plants, encapsulation can be used to solve problems regarding phytotoxicity on the crop of the herbicides used against the parasite. For example, glyphosate, imidazolinones, and sulfonylureas can be encapsulated within a polymeric shell. Germination stimulants can be also delivered into the soil inside nanocapsules protecting them from degradation.

Pharmaceutics and Medicine

Nanoencapsulation currently has the highest potential in the pharmaceutical industry because it allows the possibility to deliver a drug at the right moment, in the right place and at an adequate concentration. One of the simplest examples is the protection of orally applied drugs from the attack of acids in the stomach before they can be adsorbed in the intestine. This problem is solved in many cases by the encapsulation of the active ingredient in chitosan and PLGA (poly(lactic-co-glycolic acid) nanocapsules. In addition, both

polymers are widely used in many aspects of biomedical research ranging from tissue engineering to drug delivery because they are highly biocompatible, easily available, and provide excellent delivery capabilities. For example, ascorbyl palmitate can be encapsulated in a chitosan derivative with an efficiency of 84 % at 56 % drug loading. The nanocapsules display no short-term cytotoxicity against the human skin melanoma. On the other hand, nanoencapsulation is also used for cancer therapy. Indeed, two nanoencapsulated products named as Doxil® and Abraxane® have recently been approved by the European Medicines Agency (EMA). Doxil® is a liposomal system for doxorubicin delivery and treatment of ovarian carcinoma (see Fig. 3) and Abraxane® is an albumin nanoparticle taxol conjugate for the treatment of metastatic breast cancer [16]. More recently, there is also an increasing interest in the preparation of polymeric nanocapsules incorporating vegetable oils (mainly, from linseed, sunflower, grape seed, almond, Brazil nut, olive, and coconut) as a consequence of their antifungal and antioxidant activities [17]. Another tendency is to use nanoencapsulation to enhance the stability, biocompatibility, or efficacy of other type of nanoparticles, such as quantum dots, widely used in multimodal imaging and imaging-guided therapies [18].

Food Industry

Today's food industry makes use of nanoencapsulation to develop "functional foods" with ingredients that improve the nutritional content of food without affecting the taste, aroma, or texture of food and enhance the shelf-life and stability of the ingredient and the finished food product [1]. Nanoencapsulation is used to protect sensitive food ingredients (i.e., flavors, oils, vitamins) as well as to provide viable texture blending, appealing aroma release and taste, odor and color masking. This technology also enables food companies to incorporate minerals, vitamins, flavors, and essential oils [7]. In addition, nanoencapsulation can simplify the food manufacturing process by converting liquids to solid powder, reducing costs allowing low cost handling equipment. Moreover, nanocapsules also help fragile and sensitive materials (oils, vitamins, enzymes) to survive processing and packaging conditions and to stabilize the shelf life of the active compound. For example, there are several commercial nanoencapsulated products in the market that offer specific supplement of Omega-3 DHA and of natural form of folated for pregnant and lactating women, such as VitaDHA™ Materna.

Personal Care

Nowadays nanoencapsulation technologies play an important and growing role in the health and beauty industry. They offer an ideal and unique carrier system for active ingredients aside from an effective protection against photodegradation. Their striking effects can enhance the tactile and visual appearance of a variety of cosmetic and personal care products, including bath gels, lotions, tanning, makeup, aromatherapy, etc. Furthermore, nanoencapsulation can make significant savings for formulator as it can reduce the amount of active ingredients needed. For example, the retinyl palmitate oil which is the most stable form of vitamin A and plays an important role in cellular differentiation and carcinogenesis prevention has been recently prepared as a novel nanocapsule antiaging formulation. Flexible polymeric nanocapsules with retinyl palmitate core and PLA shell as carrier of drugs or simply as a reservoir of vitamin A were prepared. The main advantage of these capsules is that they can easily pass through biological barriers, due to deformability characteristics, reaching deeper layers of the skin and allowing a uniform permeation in the skin. Another example are liposomes as source of magnesium ascorbyl phosphate, a stable derivative of vitamin C, which allow higher effects of vitamin, such as whitening and antioxidants thanks to the targeted activity provided by the liposome.

Other Applications

Besides many classical applications, nanoencapsulation technologies provide a large number of other applications. One of them is the preparation of high-surface area carbon nanocapsules (100 nm) with hollow cores and porous shells. Such mesoporous carbon nanocapsules are of extensive interest for catalysis, separation, gas storage, and fuel cells, among others applications. Another novel application is the nanoencapsulation of phase change materials for energy storage since this class of materials is able to absorb and release energy during its phase change [19]. Nanoencapsulation also plays an important role in the construction industry by improving traditional materials and facilitating the incorporation of nanomaterials. For example, nanoencapsulated corrosion inhibitors have shown good results in protecting steel, and carbon encapsulated nickel and iron nanoparticles have improved cement mortar resistance to compressive strength [20].

Future Directions for Research

The nanoencapsulation of active compounds for controlled release applications is a promising alternative to solve some of the major problems of active ingredients faced by industries. Today, a wide range of encapsulated products have been developed, manufactured, and successfully marketed in the pharmaceutical, medical, and cosmetic industries. However, nanoencapsulation has still found a small market in many other industries such as food, construction, etc. In these potential fields, nanoencapsulation is still far from being fully developed since the development time is rather long and requires multidisciplinary cooperation. For this reason, great advances in nanoencapsulation are highly expected in the near future. These advances will include the development of novel materials to be used as matrices, more stable, efficient and biocompatible nanocapsules and advanced nanoencapsulation technologies as well as their transferring to industrial-scale mass production. Such improvements and novel capabilities will expand the scope of application for nanoencapsulation technologies in many industries, where such innovations will certainly open new opportunities to develop a novel generation of products.

Definitions

What Is Nano-concrete?

Portland cement concrete is a complex nanostructured, multiphase, multiscale composite material that evolves over time [1, 2]. The elementary block calcium-silicate-hydrate (C-S-H), which holds the concrete composite together, is also a nanostructured material (Fig. 1) [3]. The properties of concrete exist in multiple length scales (nano to micro to macro). Processes occurring at the nanoscale ultimately affect the engineering properties and long-term performance of concrete [2].

Nanoengineered Concrete,
Fig. 1 Nanoscale structure of C-S-H crystallized on calcite substrate and revealed by AFM (Ca/Si = 0.9) (Reprinted with permission from the American Ceramic Society Bulletin, 2005, vol. 84, N 11)

The nanotechnology of concrete can be represented by two directions: nanoscience and nanoengineering (or nanomodification) [1, 2, 4]. As defined by Sanchez and Sobolev [2] nanoscience "deals with the measurement and characterization of the nano- and microscale structure of cement-based materials to better understand how this structure affects macroscale properties and performance through the use of advanced characterization techniques and atomistic or molecular level modeling." Nanoengineering includes "the techniques of manipulation of the structure at the nanometer scale to develop a new generation of tailored, multifunctional, cementitious composites with superior mechanical performance and durability potentially having a range of novel properties such as: low electrical resistivity, self-sensing capabilities, self-cleaning, self-healing, high ductility, and self-control of cracks [2]." Concrete can be nanoengineered by the incorporation of nanosized (less than 100 nm) building blocks or objects (e.g., nanoparticles and nanotubes) to control material behavior and add novel properties or by the grafting of molecules onto cement particles, cement phases, aggregates, and additives (including nanosized additives) to provide surface functionality, which can be adjusted to promote specific interfacial interactions.

Introduction

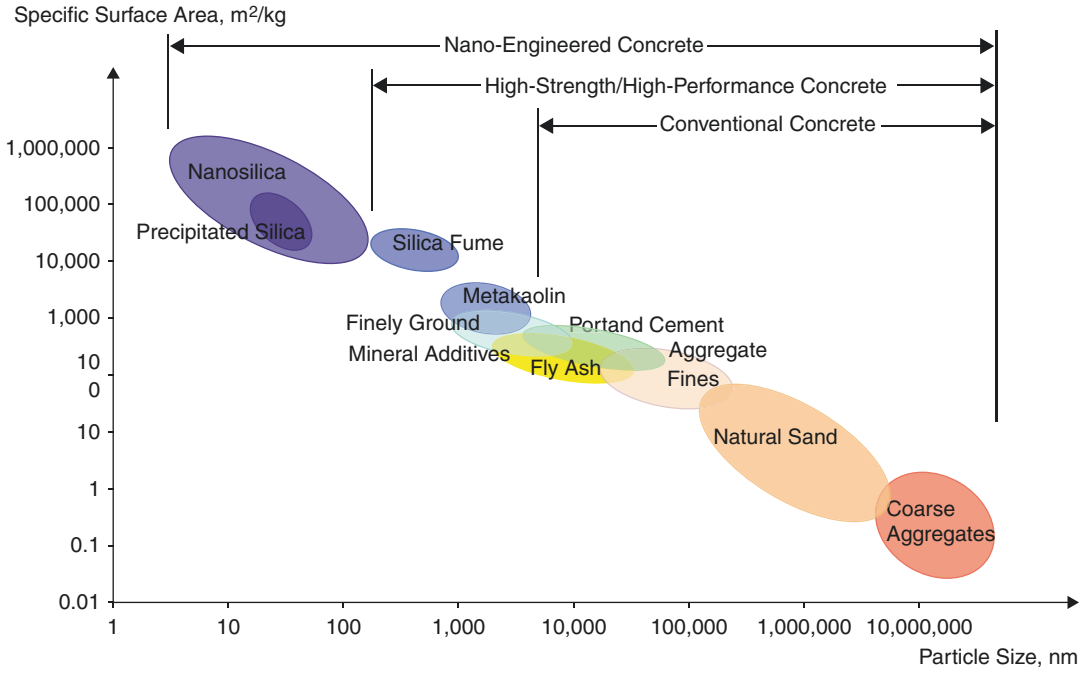
Though nanotechnology is a new emergent technology, nanosized objects have existed for millennia, from ancient times when humans began to use nanosized materials in glass [5] to modern times where "classic" photography employs silver nanoparticles sensitive to light. Natural materials have been shown to exhibit exceptional mechanical properties that are in some cases unmatched by man-made materials. For example, the exceptional performance of biomaterials such as mollusk shells has been attributed to the presence of calcium-based nanocrystals [6]. One of the most promising directions in nanotechnology is a better understanding of the relationship between microstructure and strengthening mechanisms employed by nature with the goal to ultimately mimic nature's design principle and self-organization (bottom-up approach) [5].

The nanoparticle is the elementary building block in nanotechnology and is comprised of up to thousands of atoms combined into a cluster of 1–100 nm. The conditions of the bottom-up production of nanoparticles allow for control of the size and shape of the particle. A reduction in size provides an exceptional surface area-to-volume ratio and changes in the surface energy, surface chemistry, and surface morphology of the particle, altering its basic properties and reactivity [1, 2, 5, 6]. Nanoparticles have been shown to significantly enhance the mechanical performance of a variety of materials, including metals, polymers, ceramic, and concrete composites [1, 5–7].

By far, the most significant development has been the synthesis of fullerenes (C_{60}) and fullerene-like structures such as carbon nanotubes [5]. Since their discovery, carbon nanotubes have

been used in numerous applications varying from superconductors, optical and electronic devices, sorbents, drug delivery systems, and nanostructured materials. The exceptional tensile strength of carbon nanotubes (as much as 20 times higher than that of steel) makes them ideal reinforcing components for structural applications, such as bridges and high-rise buildings. Polymer-based nanofibers and nanotubes [5, 8, 9] are promising nanomaterials that could open the door for new developments and innovative applications in building and construction industry.

Understanding the Structure at the Nanolevel and "Bottom-Up" Design



Most research on nanotechnology in concrete has focused to date on the investigation of the structure and mechanical properties of concrete at the nanoscale [1–4, 10, 11]. Recent advances in instrumentations have made it possible to characterize the structure of concrete at the nanoscale and to measure the local mechanical properties of its micro- and nanoscopic phases [10]. Significant progress in understanding nanoscale processes in cementitious materials has been achieved thanks to the use of nanoscale characterization techniques [1, 2, 10, 11]. These advanced techniques include nuclear magnetic resonance, atomic force microscopy, micro-and nanoindentation, neutron scattering, ultrasonic force microscopy, and focus-ion beam (FIB) nanotomography. For example, the use of atomic force microscopy (AFM) has revealed that, contrary to general thought, nanoscale C-S-H has in fact a highly ordered structure (Fig. 1) [3]. A better understanding of the structure of concrete at the nanolevel will allow for a better control of concrete performance and even the tailoring of desired properties and is expected therefore to affect the method of production and use of concrete.

Another application of nanotechnology in concrete has come from the "bottom-up" possibilities of nanochemistry with the development of new products such as novel superplasticizers and new coating materials [12, 13]. One such superplasticizer was recently developed by BASF and was specifically designed for controlling the slump retention characteristic of the concrete mixture [13]. Another example is the development of coating materials with new self-cleaning properties, discoloration resistance, antigraffiti protection, and high scratch-and-wear resistance. These self-cleaning materials are based on photocatalyst technology [12]. Titanium dioxide (TiO_2) is used as a photocatalyst for the decomposition of organic compounds. TiO_2 is active under exposure to UV light, exhibiting self-cleaning and disinfecting properties. Another aspect of self-cleaning is provided by the hydrophilicity of the surface, which helps to prevent dust and dirt from attaching to it.

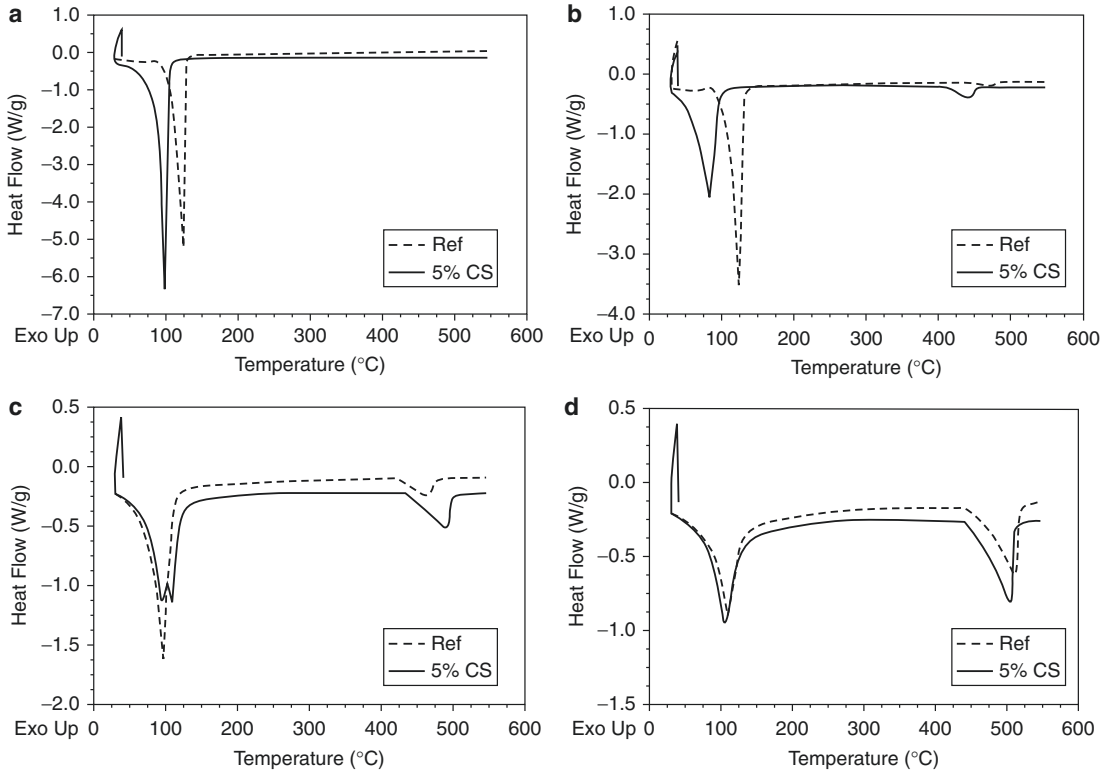
In the past, major developments in concrete technology have been achieved through the use of superfine particles such as fly ash and silica fume. Recent advances in nanochemistry and the development of new methods for synthesis of nanoparticles are now expected to offer a new range of possibilities for improvement of concrete performance [14, 15] (Fig. 2). Incorporation of nanoparticles into conventional construction materials can provide the materials with advanced or smart properties that are of specific interest for high-rise, long-span, or intelligent infrastructure systems [1, 2, 10, 11, 15].

Performance of Concrete with Nanoparticles

The addition of nanoparticles has been shown to improve various performances of concrete [1, 2, 15–20]. For example, nanosilica (silicon dioxide nanoparticles, nano-SiO_2) has been shown to improve workability and strength in high-performance and self-compacting concrete [1, 2, 14, 15]. Improvement in concrete performance has been attributed to several effects of the nanoparticles. Well-dispersed nanoparticles can act as crystallization centers for cement hydrates, thereby accelerating the hydration reactions, and can act as filler, filling the voids between the cement grains, thus reducing the material porosity [15–17]. Well-dispersed nanoparticles have also been shown to promote the formation of

Nanoengineered Concrete, Fig. 2 Particle size and specific surface area related to concrete materials (Adapted from [1])

smaller-sized crystals (e.g., $Ca[OH]_2$ and AFm), thus densifying the microstructure, and to promote crack arrest and interlocking, improving the material mechanical properties.



Most of the research on the addition of nanoparticles to cementitious systems has been performed using nano-SiO_2 [1, 2, 14–20]. Nano-SiO_2 has been found to accelerate the hydration reactions of C_3S, improve concrete workability and early age strength, be more efficient in enhancing strength than silica fume, and improve the bond between the aggregates and the cement paste [14–20]. The following provides a few examples of recent studies in this area highlighting some of the effects of nano-SiO_2 addition.

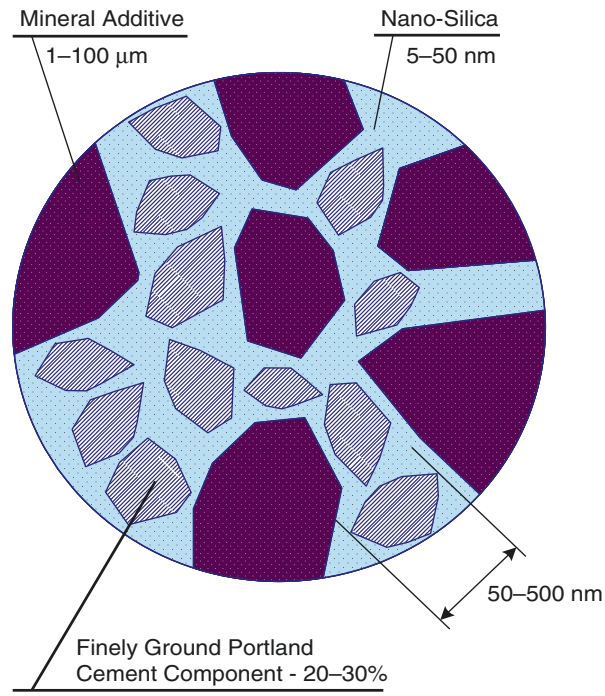
The accelerating effect of nano-SiO_2 (colloidal silica, CS) on the hydration of C_3S (alite, Ca_3SiO_5) has been reported by Björnström et al. [17]. Differential scanning calorimetry (DSC) for samples containing up to 5 % of colloidal silica (Fig. 3) showed the initial dependence of C-S-H formation on the addition of colloidal silica and suggested that colloidal silica mostly affects the initial silica polymerization rates rather than the amount of product ultimately formed [17].

Porro et al. [16] reported that the compressive strength of cement pastes increased with the reduction in particle size of nano-SiO_2. The strength improvement was attributed to the formation of larger silicate chains of the C-S-H gel in cement pastes containing nano-SiO_2.

In contrast to silica fume (SF), the addition of nano-SiO_2 at dosages of 1–5 % has been reported by Qing et al. [18] to increase the thickness and viscosity of superplasticized cement pastes and shorten the initial and final setting times. Nano-SiO_2 significantly improved the compressive strength in the early stages of hardening. After 3 days of curing, the cement pastes with 5 % nano-SiO_2 were 41 % stronger than the reference pastes. At 28 days, the strength was improved by 25 %. Without exception, the strength of the cement pastes containing nano-SiO_2 improved with increasing dosage of the nanoadditive.

The addition of nano-SiO_2 has been shown to significantly improve the pozzolanic activity of

Nanoengineered Concrete, Fig. 3 Differential scanning calorimetry of reference (Ref.) and samples containing 5 % of CS at different hydration times: (**a**) 1 h hydration; (**b**) 4 h hydration; (**c**) 8 h hydration; and (**d**) 24 h hydration [20]



N

fly ash. In a study performed by Li [19], the addition of 4 % nano-SiO_2 to concretes prepared using 50 % type F fly ash, a water-to-cement ratio of 0.28, and a superplasticizer dosage of 2 % (by weight of binder) helped to achieve reaction levels typically obtained at 6 months after only 24 days. The pozzolanic reaction of nano-SiO_2 was shown to be very quick, reaching 70 % of its ultimate value (achieved by "common" pozzolans at the age of 2 years) within 3 days and ~95 % in a 2-week period. In contrast, plain fly ash reacted with lime very slowly, reaching a significant hydration degree only at the age of 2 years.

The addition of nano-SiO_2 at a dosage of 1–2 % has been shown by Collepardi et al. [14] to improve the performance of low-heat self-compacting concrete (SCC). The addition of nano-SiO_2 to blended blast furnace slag concretes made the mixtures more cohesive and reduced bleeding and segregation but had little effect on the slump loss measured within the first 30 min. The best performance was obtained for the blended blast furnace slag concrete prepared using ground fly ash (GFA) as mineral additive, 2 % nanosilica, and 1.5 % superplasticizer with a compressive strength of 55 MPa at the age of 28 days, low bleeding, higher slump flow, and very little slump loss.

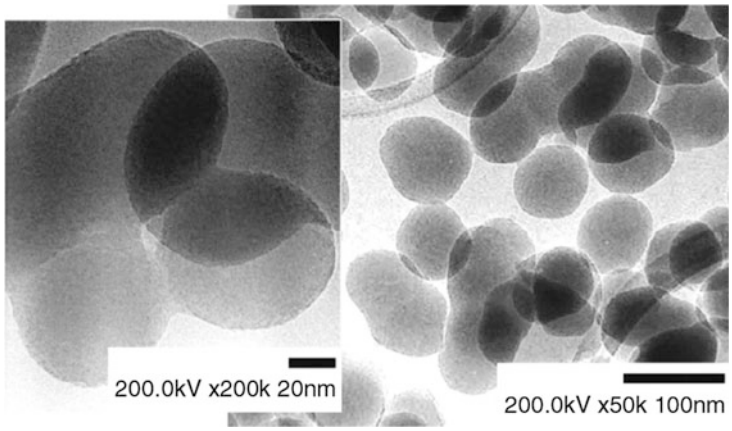
The addition of nano-SiO_2 has also been reported by Hosseini et al. [20] to improve the interfacial transition zone (ITZ) by combining with calcium hydroxide crystals to produce C-S-H leading to a denser, more uniform ITZ. This resulted in a significant improvement of the compressive strengths of recycled aggregate concretes.

As an alternative to nanoparticle addition, the idea of nanobinder was recently proposed to improve concrete performance [1]. In nanobinder, the mineral additives act as the primary components, and nanosized cement is used to fill the gaps between the particles (Fig. 4). The nanosized cement thus acts as a glue to bind the less reactive

Nanoengineered Concrete, Fig. 4 The concept of nanobinder (nanoengineered cement) (Adapted from [1])

mineral additives together. The nanosized cement can be obtained either by colloidal milling of conventional (optionally high C_2S) portland cement clinker (top-down approach) or by self-assembly (bottom-up approach) through mechanochemically induced topochemical reactions [1].

Tailoring of Nanoparticles for Optimal Performance



While small quantities of nanoparticles (less than 1 % by weight of cement) are generally sufficient to improve the performance of composites [2, 14–20], practical application in concrete requires manufacturing a considerable amount of these particles [5–7]. Being able to produce nanoparticles in large quantities at a low cost is, therefore, a paramount. Several technologies have been used for the production of nanoparticles [5–7]. The sol–gel process is the most commonly used for the production of nanosilica (Fig. 5). The chemical procedure consists of the formation of a colloidal suspension (sol) and gelation of the sol to form a network in a continuous liquid phase (gel). The procedure can be summarized as follows [7, 15]:

1. Hydrolysis of the precursor
2. Condensation and polymerization of monomers to form the particles
3. Growth of the particles
4. Agglomeration of the particles, followed by the formation of a network and gel structure
5. Drying (optional) to remove the solvents and thermal treatment (optional) to remove the surface functional groups and obtain the desired crystal structure

Trymethylethoxysilane or tetraethoxysilane (TMOS/TEOS) is typically applied as the precursor in the production of nanosilica, and the following reaction takes place [7, 15]:

$$n\mathrm{Si}(\mathrm{OC_2H_5})_4 + 2n\mathrm{H_2O}\xrightarrow[\mathrm{NH_3}]{\mathrm{C_2H_5OH}} n\mathrm{SiO_2} + 4n\mathrm{C_2H_5OH}$$

pH, temperature, concentration of reagents, H_2O/Si molar ratio, and type of catalyst are important

Nanoengineered Concrete, Fig. 5 The morphology and particle size distribution of nano-SiO_2 (TEM) synthesized by the sol–gel method [15]

Nanoengineered Concrete, Table 1 Design and properties of nano-SiO_2 [15]

Specimen type[a]	Molar ratio TEOS/Etanol/H_2O	Reaction time, hours	Particle size (TEM), nm	Surface area (BET), m^2/kg
1B3	1/24/6	3	15–65	116,000
2B3	1/6/6	3	30, 60–70	145,000
3B3	1/6/24	3	15–20	133,000

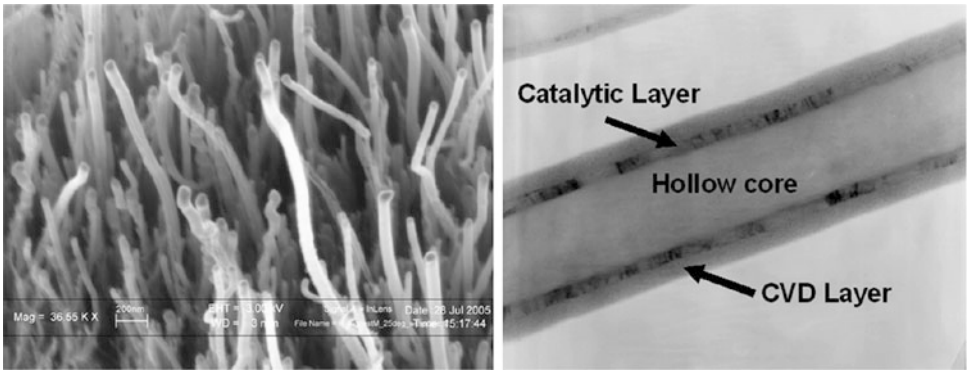
parameters that can affect the production and characteristics of the nanoparticles [7, 15].

Flores et al. [15] used the sol–gel process to synthesize nano-SiO_2 with a size range of 5–100 nm (Fig. 5).

Different experimental conditions were examined as summarized in Table 1. X-ray diffraction study showed that the obtained nano-SiO_2 was a highly amorphous material with predominant crystallite size of 1–2.5 nm [15]. The addition of 0.25 % (by weight of cementitious material) of the synthesized nano-SiO_2 improved the early strength of portland cement mortars with a 17 % strength increase at 1 day. The 28-day compressive strength was improved by as much as 10 % and the flexural strength by as much as 25 % [15]. Proper dispersion of the nano-SiO_2 within the cement paste is critical for improved performance [1, 15]. The use of polycarboxylate acrylic ester (PAE) superplasticizer, ultrasonification, and/or high-speed mixing has proven to be efficient in the dispersion of nano-SiO_2 [15]. The addition of 0.1 % superplasticizer and 0.25 % nano-SiO_2 synthesized using the sol–gel process has shown a 20 % increase in the compressive strength of cement mortars (Fig. 6).

Developing New Functionalities

Photocatalytic TiO_2 has been used in white cement-based concrete, providing the material with self-cleaning and air purification capabilities [12, 21]. It is important for architectural concrete



Nanoengineered Concrete, Fig. 6 Compressive strength of superplasticized mortars with nano-SiO_2 at different ages (NPC and NPC-SP are reference portland cement and superplasticized mortars; nanoparticle specification as per as Table 1, Fig. 5; CB-8 and SF are cembinder-8 and silica fume) [15]

to maintain its aesthetic and decorative characteristics such as color over its entire service life, even in highly polluted urban environments. Photocatalytic materials provide a smart solution to effectively minimize contaminant buildup at the surface of architectural concrete through photocatalytic oxidation. One of the most popular photocatalytic materials used in cement is TiO_2. The anatase polymorph of TiO_2 (especially nanosized) is the most effective TiO_2-based photocatalytic material, outperforming rutile in cement-based materials [12, 21]. Photocatalytic nano-TiO_2 embedded into cement matrix has also been reported to be very effective for NO_x abatement [21].

Application of Carbon Nanotubes and Carbon Nanofibers

Due to extraordinary strength and tensile modulus, carbon nanotubes and carbon nanofibers (CNTs/CNFs) are potential candidates for use as nanoreinforcement in cement-based materials [1, 2, 5, 6, 22–26]. Vapor-grown CNTs are concentric cylinders made from rolled-up planes of hexagonally bound carbon atoms. Vapor-grown CNFs (Fig. 7) exhibit a "herringbone" or cup-stacked structure of nested graphene layers with a hollow core. The production of CNTs on an industrial scale remains expensive. In contrast, CNFs have a lower production cost and can be made at a higher production capacity [27]. The use of CNTs/CNFs in cement remains limited [2]. The proper dispersion of CNTs/CNFs within the cement paste is one of the main challenges [2, 22–26] due to their high hydrophobicity and strong self-attraction. A number of methods have been used to improve the dispersion of CNTs/CNFs in cement, including the use of surfactants, surface treatment with acids, high shear mixing, and sonication [22–26].

To date mixed performance results have been achieved ranging from significant improvements for small addition of CNTs/CNFs to minimal or no improvement. Among the promising results,

Nanoengineered Concrete, Fig. 7 SEM (*left*) and TEM (*right*) image of carbon nanofibers [27]

Makar et al. [23] demonstrated that CNTs can affect early age hydration and indicated the potential of CNTs for crack bridging and enhanced stress transfer. Shah et al. [24] showed that, after dispersion in water using surfactant and ultrasonic energy, small amounts of CNTs (0.048 % and 0.08 %) can result in a significant (∼50 %) increase in the Young's modulus of cement pastes.

Smart Stress-Sensing Composites

The incorporation of conductive nanomaterials (CNTs/CNFs, nano-Fe_2O_3, etc.) into cement-based composites has been reported to provide the materials with self-sensing capability [28, 29]. It has been shown that carbon fiber-reinforced cement may function as a piezoresistive strain sensor [28]. Due to the high conductivity of the carbon fibers compared to the cement matrix, the introduction of the fibers into cement decreases the electrical resistivity of the material. Strain sensitivity (i.e., fractional change in electrical resistance per unit strain) of as much as 700 has been obtained with incorporation of 0.2–0.5 % (by volume) carbon microfibers [28]. Recently, a self-sensing cement material with multiwalled carbon nanotube (MWCNT) has been proposed for traffic monitoring [29]. The piezoresistive properties of the MWCNT-cement composite enabled the detection of mechanical stresses induced by traffic flow.

Future Developments

Concrete science is expected to benefit significantly from the rapidly growing field of nanotechnology. Advances in the characterization of the nanoscale structure of concrete are providing new insights about concrete. New developments are underway in the nanoengineering of concrete. Some of the most promising include the development of [1]

- Highly efficient superplasticizers for concrete and high-strength fibers with exceptional energy-absorbing capacity
- Concrete with self-cleaning properties, discoloration resistance, and antigraffiti protection, based on photocatalytic technology
- Reinforced binders with nanoparticles or nanotubes
- Concrete with smart properties such as temperature-, moisture-, or stress-sensing capability; deformative properties; and nonshrinking and low thermal expansion
- Ecobinders modified with nanoparticles and produced with significantly reduced amount of portland cement
- Ecobinders with nanoparticles based on alternative systems (MgO, phosphate, geopolymers, gypsum)
- Self-healing concrete with controlled supply of internal moisture or solution of repair/bonding agent

Conclusions

Nanotechnology in concrete is still in its exploratory phase, and full-scale applications in the field of construction are to date very limited. Nevertheless, the potential for nanotechnology to help improve the performance and durability of one of the oldest known construction materials is most promising.

Nanostructured hydrogels; Patterned hydrogels

Definition

Nanoengineered hydrogels are soft, high water content, hydrophilic networks with nanoscale topographical or biomolecular patterns for mimicking the extracellular matrix of tissues in order to control cell fate and function.

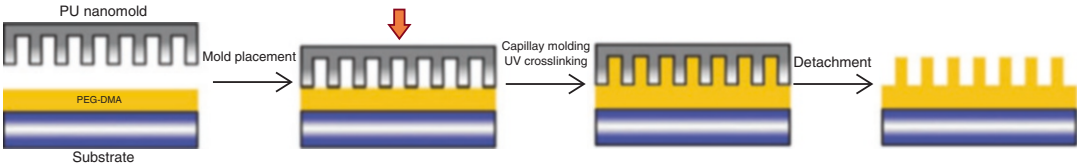
Introduction

Hydrogels are three-dimensional (3D) cross-linked polymeric networks that retain a significant fraction of water in their structure without dissolving when placed in physiological solution. Due to their high water content, biomolecules like peptides and proteins and cells immobilized in hydrogels are more likely to retain their biological activity. Poly(ethylene glycol) (PEG)-based hydrogels, due to minimal interaction of the ethylene oxide repeating unit with biomolecules, do not elicit an immune response. Therefore, PEG hydrogels are used extensively for cell immobilization and encapsulation. Furthermore, PEG networks can be conjugated with bioactive molecules to produce cell-responsive hydrogels for applications in tissue engineering and regenerative medicine [1]. The cell fate including shape, morphology, phenotype, and function is determined by interaction with soluble and insoluble factors in the extracellular matrix (ECM) [2]. These interactions are between the functional motifs of the ECM proteins and binding sites of the glycoproteins embedded in the cell's plasma membrane. The functional motifs as well as geometrical and morphological features of the ECM are ordered at the nanoscale. As a result, synthetic hydrogels patterned with biologically active molecules or topographical nanostructures are important in understanding the role of ECM on cell fate, and the engineering of cell environment at the nanoscale. Patterning of hydrogels at the nanoscale includes surface techniques (2D patterning) and bulk/matrix techniques (3D patterning). The cell-nanostructure interaction is two dimensional for surface-patterned hydrogels while the interaction is three dimensional for matrix-patterned hydrogels. Surface patterning techniques include

Nanoengineered Hydrogels for Cell Engineering, Fig. 1 Schematic diagram for fabrication of a surface nanopatterned hydrogel by micelle nanolithography (Refs. [7, 11])

electron beam patterning, micelle nanolithography, UV-assisted nanomolding, and nanostamping. Matrix techniques include polymer phase separation and multiphoton chemical patterning.

Electron Beam Patterning



Hydrogels are surface-patterned at the nanoscale using a focused electron beam. In this method, a thin layer of hydrogel precursor solution, spin-coated on silicon wafers, is exposed to a focused electron beam using a modified field-emission scanning electron microscope [3]. The extent of cross-linking and density of the pattern can be controlled with this technique by varying the pixel dwell time to irradiation dose and interpixel spacing. After irradiation, the pattern is exposed by dissolving unexposed areas with organic solvents and rinsing in water. Topographical patterns with sizes ranging 50–1,000 nm can be produced with this technique. As an example, poly(sodium 4-styrenesulfonate-co-poly(ethylene glycol) methacrylate) (pSS-co-pPEGMA) with heparin-mimicking thiol groups was patterned with electron beam and the patterned gel is used for localized attachment of vasculogenic proteins bFGF and VEGF [4]. As another example, Boc-protected aminoxy tetraethylene glycol methacrylate was patterned with electron beam, the Boc-protecting group was removed to expose the aminoxy groups for localized grafting of proteins to the patterned hydrogel via oxime ligation [5].

Micelle Nanolithography

Self-assembled array of metal-impregnated diblock copolymers is used for nanoscale surface patterning of hydrogels. In this technique, a monolayer of polystyrene-block-poly(2-vinylpyridine)(PS-b-P2VP) and $HAuCl_4$ micelles is formed on a substrate (glass or silicon wafers) by dip-coating [6]. Next, the micellar array is treated with oxygen plasma to remove the PS-b-P2VP copolymer and exposing the ordered array of gold nanoparticles (NPs) on the substrate, as shown in Fig. 1. The pattern of gold NPs is moved to a nonadhesive fluorosiloxane layer by transfer-molding, followed by transfer to a hydrogel surface as shown in Fig. 1. In a variation of this technique, polystyrene homopolymer, as an ordering interference reagent, is mixed with PS-b-P2VP and $HAuCl_4$ micelles to produce a disordered array of gold NPs on the substrate [7], leading to a disordered nanopattern on the hydrogel surface. In another variation, $PtCl_4$ is used in the place of $HAuCl_4$ to form a nanoscale pattern of platinum NPs on the substrate [8]. The platinum pattern is moved to a PDMS substrate by transfer-molding, as shown in Fig. 2, to produce a catalytic nanostamp for chemical patterning of

Nanoengineered Hydrogels for Cell Engineering, Fig. 2 Schematic diagram for fabrication of PDMS nanostamp (Ref. [8])

Nanoengineered Hydrogels for Cell Engineering, Fig. 3 Schematic diagram for UV-assisted capillary nanomolding (Ref. [12])

hydrogel surfaces. In another interesting approach to generate micro- nanostructured hydrogels, an array of gold NPs on a glass substrate was coated with a photoresist layer [9]. After photolithography and removal of the uncovered gold NPs and the protecting resist layer, the microstructured nanoarray of gold NPs was covered with acrylated PEG hydrogel precursor solution and cross-linked by ultraviolet (UV) radiation. Upon detaching from the glass substrate, a hydrogel surface with microstructured array of gold NPs was generated which could potentially be used to study the modulation of nano- and microscale patterns of biomolecules on cell function.

Nanomolding and Nanostamping

The block-copolymer-templated micelle lithography is used to fabricate stamps and molds in sub-100 nanoscale for patterning [8]. In this approach, a silicon substrate is patterned with platinum (Pt) NPs by micelle lithography and the bare silicon surface is covalently covered with a fluorosiloxane monolayer. Next, a PDMS layer is spin-coated on the patterned substrate followed by curing. Upon peeling the PDMS layer, a Pt nanopatterned catalytic stamp and a silicon nanopatterned mold are produced. The catalytic stamp can be used to print nanoscale biomolecular patterns on hydrogels. The pattern on silicon/glass substrate can be moved to a polyurethane (PU), PDMS, or other soft hydrophobic substrates [10] for subsequent patterning of hydrogel surfaces [11]. As an example, in UV-assisted capillary lithography [12], a nanopatterned PU mold is placed over a thin layer of methacrylated PEG precursor solution to make conformal contact by capillary forces, as shown in Fig. 3. After cross-linking of the PEG layer by UV-assisted photopolymerization, the PU mold is peeled off to produce a PEG hydrogel with a surface pattern ranging 50–500 nm in size. Direct molding of a hydrogel precursor solution with nanotemplated quartz followed by cross-linking can also be used to form hydrogels with nanopatterned surface topography [13].

Copolymer Phase Separation

Phase separation of amphiphilic di- and triblock copolymers at the nanoscale is used to form hydrogels with less than 50 nm matrix nanopatterns. For example, amphiphilic triblock copolymers of poly(ε-caprolactone) and PEG were allowed to self-assemble in aqueous solution to form 30–40 nm ordered cylindrical structures [14]. Following electron beam cross-linking of the microphase separated mixture, the PCL phase was removed by hydrolysis to form a porous hydrogel, which can potentially be patterned in 3D with

cell-responsive functional groups. In a similar approach, microphase separation of a blend of polystyrene-block-poly(ethylene oxide) (PS-b-PEO) and arginine-glycine-aspartic acid (RGD)-conjugated PS-b-PEO was used to form nanoscale domains of RGD integrin-binding peptide in the hydrogel matrix [15]. By manipulating phase separation of the diblock copolymer, domain sizes of 8–14 nm, lateral spacing of 62–44 nm, and island densities of 450–900 per μm^2 were formed. In a related approach, a blend of methacrylated PEG-b-PLA-b-PEG (PLA denotes poly(lactic acid)), methacrylated biotin-PEG, and a self-assembling lyotropic liquid crystalline mesophase as the polymerization template was used to generate biotinylated hydrogels with lamellar matrix morphology [16]. The biotin-avidin chemistry was used to attach integrin-binding RGD peptide to the nanostructured matrix. In a similar approach, a mixture of blank alginate chains and integrin-binding RGD-coupled alginate chains was cross-linked in aqueous solution to form nanopatterned RGD islands in an alginate matrix [17]. Similarly, a mixture of thiol-derivatized hyaluronic acid (HA) and acrylated nanogels was cross-linked to form a uniformly distributed nanostructured HA hydrogel [18].

Cell Engineering with Nanopatterned Gels

When cardiomyocytes were seeded on PEG hydrogels patterned with 50–150 nm nanopillars, cell adhesion was significantly enhanced and formed 3D aggregates, which retained their conductive and contractile properties [12]. Neonatal rat ventricular myocytes (NRVMs) seeded on anisotropically nanofabricated hydrogel substrates, with ridges/grooves in the 50–800 nm range, had perfect alignment with the ridge/groove direction, the direction of cell contraction was closely aligned with the pattern direction, and the action potential direction was anisotropic, when compared to unpatterned hydrogel substrates [19]. The spreading of NIH-3T3 fibroblasts increased from 1,100 to 1,700 μm^2 as 3D lateral spacing of RGD integrin-binding domains in a PS-b-PEO hydrogel matrix was decreased from 62 to 44 nm [15]. The phosphorylation of Y397 focal adhesion kinase, cell spreading, and osteogenic differentiation of MC3T3 preosteoblasts depended on the spacing of RGD islands in an alginate matrix. Closer spacing of RGD islands favored phosphorylation of Y397 and cell spreading while wider spacing favored differentiation, and proliferation was a function of RGD density in the matrix [17]. Block copolymer micelle lithography followed by ligand conjugation was used to form a gradient in the spacing of cyclic-RGD peptide, specifically recognized by $\alpha_v\beta_3$ integrins, on a substrate [20]. The gradient in cyclic-RGD spacing induced cell orientation toward shorter spacing. In another study, integrin clustering on MC3T3-E1 osteoblasts depended on the local order of RGD ligand arrangement on the substrate for average ligand spacings >70 nm [7]. Cell adhesion was lower on substrates with ordered RGD pattern and higher on disordered patterns. Human embryonic stem cells seeded on polyurethane gels with 350-nm grooved arrays, fabricated by UV capillary force lithography, differentiated directly into the neuronal lineage in the absence of differentiation-inducing agents [21]. Submicron pattern of cell-repulsive PEG hydrogel on an adhesive substrate can discriminate between different cell types. At the highest PEG density with overlapping patterns, neither neurite cells nor astrocytes adhered to the substrate [22]. As the spacing between PEG patterns was increased to 2 μm, neurons were able to grow and form long axons while astrocytes were unable to grow. At higher PEG spacing of 10 μm, both neurons and astrocytes were able to grow on the patterned substrates. In an interesting study, poly (vinyl alcohol) (PVA) nanogels were used to form nanoarrays of tethered lipid bilayer rafts (tLBRMs) on a solid substrate to study the effect of cell membrane's lipid rafts on signal transduction [23]. In this work, PVA hydrogel was nanopatterned on a gold substrate using UV nanolithography to form selective nanowells. After covering the gold nanowells with a monolayer of vesicle rupturing promoter, tLBRMs were selectively immobilized on a gold substrate between the PVA nanogels by monolayer-assisted

vesicle fusion. These studies clearly demonstrate that engineered hydrogels can play a major role in understanding the effect of topography and ECM ligands, patterned at the nanoscale, on cell shape, morphology, phenotype, and fate.

Future Direction

A number of techniques such as electron beam patterning and micelle lithography have been developed for nanoscale patterning of hydrogel surfaces. However, there is a need to develop techniques for 3D patterning of hydrogels at the nanoscale, as the interaction of cells with ligands in the ECM is three dimensional. Related to that, the effect of surface pattern of adhesive ligands on cell shape and morphology has been studied extensively but there is a need to conduct similar studies in 3D within a nanopatterned hydrogel matrix. Those studies should be extended to the effect of 3D pattern of ECM ligands on cell differentiation, lineage selection, and fate.

Nanogap Biosensors

J. Tanner Nevill and Daniele Malleo
Fluxion Biosciences, South San Francisco, CA, USA

Definition

A nanogap biosensor is an arrangement of two electrodes separated by no more than 300 nm that is used to electrically detect biologically relevant

materials, reactions, or interactions in solution. The limit of 300 nm is imposed because it represents the practical upper limit of the characteristic thickness of the electrical double layer, which forms at all charged surfaces in aqueous solutions.

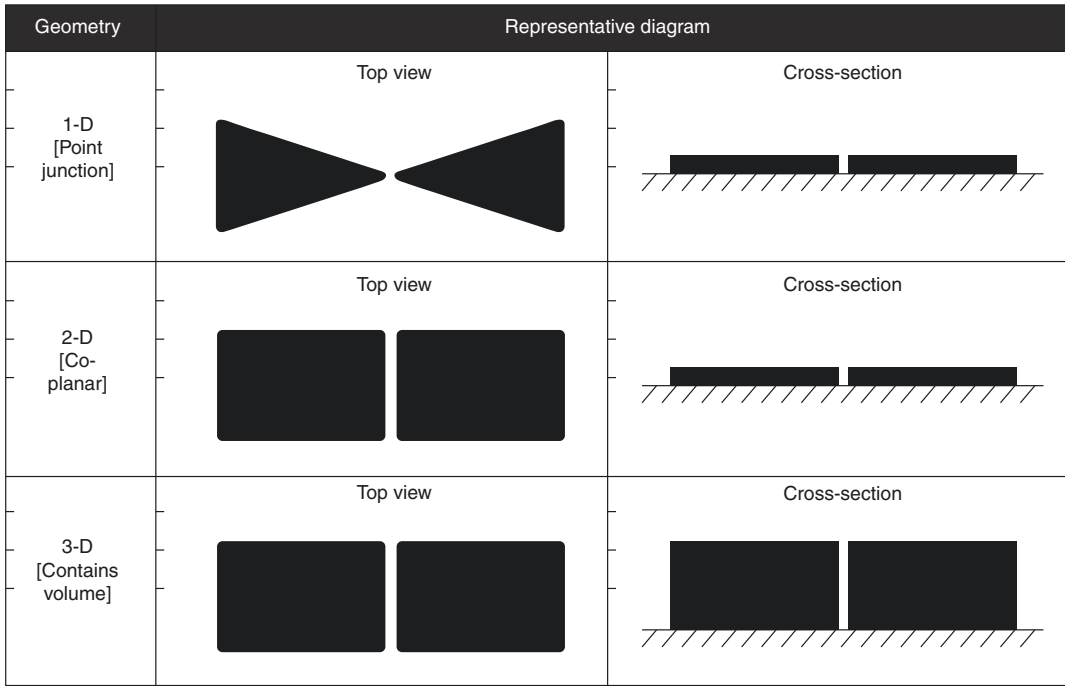
Overview

Nanogap biosensors are made using various micro- and nano-fabrication techniques to create a nanometer-scale detection region. This region is interrogated using electrical techniques to sense and measure the presence or activity of a biomolecule. All-electrical measurements offer the promise of low cost, rapid, and label-free detection. Many arguments are made for using nanogap biosensors, including higher sensitivity, reduction of parasitic effects, overlapping double layers, and the use of molecular-sized cavities. Liang and Chou use a nanogap electrode arrangement inside of a nanofluidic channel like a pore for detecting (and eventually sequencing) single strands of DNA [1]. Im et al. exploit the fact that a molecule can occupy a significant portion of the nanogap, thereby making it very sensitive to low numbers of molecules: By functionalizing the surface of the nanogap, analyte binding significantly changes the electrical characteristic of the sensing electrodes [2].

The electrical double layer, a cloud of counterions that balances out the charge present on any surface in solution, is often seen as a parasitic component of electrical measurements: This layer shields the bulk solution from the induced electric field thus decreasing the sensitivity of alternating current detection techniques. Because nanogaps have dimensions similar or smaller than the double layer thickness, the electric potential in a nanogap distributes differently than in a macroscale gap. In fact, nanogap devices typically create environs where the volume of interest consists exclusively of double layer regions, actually eliminating the bulk solution from the measurement. Elimination of the bulk response is desirable in many situations, where measurement and quantification of very few or even single molecule events is of interest, making the concept of overlapping double layers in nanogaps very compelling.

The sensors developed thus far can be classified by the geometry of the detection region. According to the number of dimensions along which the sensing cavity exists, there are three categories as depicted in Fig. 1: 1D nanogaps refer to point gap junctions, 2D devices consist of coplanar electrodes or "fractured planes," and 3D nanogaps are "nanocavities," where the electrode surfaces forming the cavity have a significant area relative to the gap length.

As form follows function, the measurement techniques and applications can be correlated with the geometry. 1D and 2D nanogaps are typically interrogated with DC voltages to produce a resistive measurement, while 3D nanogaps are mostly interrogated using AC measurement techniques, to measure a complex impedance response. Consequently, the discussion of nanogap biosensors is divided below into two sections.



One- and Two-Dimensional Nanogap Biosensors

Advantages and Disadvantages

The key advantage of one- and two-dimensional nanogaps as biosensors is the opportunity for surface-bound molecules to occupy a significant portion of the interelectrode spacing, thereby increasing sensitivity, even enabling single molecule detection [3].

The main drawback of these sensors is the difficulty in ensuring specificity in the measurements. For this reason, the electrodes in the device need to have been functionalized appropriately before sample introduction, to enable the determination of presence or absence of specific molecules quickly and with off-the-shelf electrical meters: IV (current–voltage) meters, electrochemical measurement stations, or patch clamp amplifiers.

From a fabrication point of view, while it is in principle very easy to fabricate one-dimensional nanogap electrodes by electromigration, repeatability of this process can be an issue; conversely, fabrication via electron beam lithography allows for extreme control and repeatability but has slower throughput and higher cost.

Nanogap Biosensors, Fig. 1 Definition of the three categories of nanogap geometry. Form follows function and each geometry is typically tuned for a different function

Methods of Fabrication

One-dimensional nanogap structures are most commonly realized using electromigration, electron-beam lithography, or a combination of the two techniques. In some cases to shrink gaps to nanometer dimensions, methods such as surface-catalyzed metal deposition or dielectrophoretic transport of metal nanoparticles are used. The latter methods are advantageous as they enable fabrication of many nanogap electrodes at once. On the other hand, electron beam lithography offers the elegant advantage of directly writing nanoscale features in photoresist, which, incorporated with ion milling, lift-off, or unique metal deposition techniques, allows for the creation of nanogap electrodes. Electromigration is an intriguing technique, because it was an originally undesirable effect often encountered in the electronics industry. As metal lines got smaller and smaller, the relatively higher current densities would cause breaks to occur. These breaks were a result of a momentum transfer between the electrons comprising current and the atoms in the metal lattice [4]. Breaks tended to happen at grain boundaries or along defects in the lattice, and were highly dependent on temperature. Researchers interested in molectronics (a field of study whereby individual molecules are used to perform electronic functions) recognized that this technique could be used to create nanogap electrode junctions. This method offers the ability to get very small point gaps in an inexpensive manner, but there is a notable lack of control. Numerous groups have made strides in creating feedback control for electromigrated nanogap devices in order to reliably control the gap sizes in addition to offering parallel fabrication methods [5]. Another method is the chemical deposition of metal or electroplating which allows for the creation of nanogap devices using traditional fabrication methods that would not normally be capable of nanoscale dimensions. Lastly, a few groups have used either mechanical manipulation of electrodes to create nanogap devices or have mechanically broken wires to create nanoscale gaps [6].

Two-dimensional nanogap devices are similarly realized using metal deposition over a sacrificial linear feature to create a linear nanogap. Oblique metal deposition is a simple way to create a metal overhang in order to form a nanogap [7]. Similar to one-dimensional nanogap sensors, electron beam lithography is a suitable alternative for 2D nanogap fabrication as well as the use of sacrificial layers [8].

Measurement Methods

Direct Current Measurements

The most elementary way of acquiring data from a nanogap biosensor is to apply a DC (direct current) potential, while measuring current flow through the sensor electrodes: When the gap is "open," no current flows through except for a small tunneling current. When a biomolecule, or other sample, is attached to both the electrodes or otherwise closes the circuit, a larger direct current starts to flow. Specificity in the measurement can be attained by appropriate functionalization of the electrodes' surface.

In the case of measurements carried out in solution a background current is continuously measured due to ion transport in the solution. Sample attachment to the electrodes is not necessary, and just proximity of charged species (such as DNA molecules) can be detected by measuring increases in current.

Ohm's law, $I = \frac{V}{R}$, is in most cases sufficient to interpret the data acquired.

The tunneling current by itself can be used to characterize the device and estimate the distance between two electrodes, if the gap is too small to be detected by optical or electron microscopy.

The equation describing the tunneling current between two electrodes is:

$$I = \frac{K_1 A}{S^2}\left[X^2 \exp(-k_2 X) - Y^2 \exp(-k_2 s Y)\right] \quad (1)$$

where $\sqrt{\phi - \frac{V}{2}}$, $Y = \sqrt{\phi + \frac{V}{2}}$, $k_1 = 6.32 \times 10^{10} V s^{-1}$, $k_2 = 1.025 J^{-\frac{1}{2}}$, A is the emission area in cm^2, s is the electrode separation or distance in Å, ϕ is the barrier height, and V is the voltage in Volts [9].

Current–Voltage (IV) Measurements

To determine the behavior and characteristics of the molecule under study, or the sensor itself, DC potential can be swept in incremental steps from a negative to a positive potential and the resultant current traces drawn: Asymmetries and/or nonlinearities in the measured IV traces can be used to extrapolate characteristics of the sample under study.

Three-Dimensional Nanogap Biosensors

Advantages and Disadvantages

Three-dimensional nanogap devices are significantly different from one- and two-dimensional nanogaps in fabrication methods, measurement techniques, and in many cases, applications. 3D nanogaps contain a significant volume relative to the nanogap width. This nanocavity allows for both surface bound and free molecules to be monitored. Alternating current measurement techniques are typically used (e.g., dielectric or impedance spectroscopy), which provide data from which meaningful biological parameters can be extrapolated (e.g., binding efficiency of biomolecules, hydrodynamic radius of proteins).

The key advantages of nanogap biosensors using impedance detection techniques (e.g., impedance spectroscopy) are a homogeneous interrogation electric field and the opportunity for surface-bound molecules to occupy a significant portion of the detection volume, thereby increasing sensitivity.

The disadvantages of these devices include complex fabrication, difficulty in coupling to external equipment without introducing parasitic components, and the need for on-sensor reference electrodes and controls.

Methods of Fabrication

Three-dimensional nanogap devices are almost exclusively fabricated by provisionally incorporating a sacrificial layer of nanoscale dimensions, which is used to separate two conducting (metal or semiconductor) electrodes. When this sacrificial layer is removed or etched away, in the final steps of the fabrication protocol, a nanocavity is created.

A common technique is to use a thermally grown oxide layer, which creates a precise thickness by tightly controlling growth conditions. This layer can then later be fully or partially removed with a wet etch.

The materials used to form the electrodes vary, but the significant majority of nanogap devices use either gold or semiconductor electrodes. Gold has numerous advantages over semiconductors for many of these devices, including biocompatibility, ease of surface modification (through thiol-based chemistries), stability (resistance to oxidation), and off-the-shelf availability. One disadvantage of gold is the lack of compatibility with some fabrication processes. In such cases semiconductor electrodes have been used, despite their inherent shortcomings: mediocre conductivity and susceptibility to spontaneous surface oxidation [10].

Overlapping Electrical Double Layers

In order to understand why 3D nanogap devices are so interesting as biosensors, the topic of overlapping electrical double layers must be covered. The electrical double layer at a single electrode surface is discussed in depth by Lyklema [11]. At a charged surface, electromigration of charged species balances with diffusion to create a diffuse layer of counterions that shields the bulk solution from the electrode's potential. Inside a nanogap, the situation is much different: The double layers can occupy the entire volume. The presence of the bulk solution, which can be measured in terms of parasitic capacitance and resistance, is virtually nonexistent. Depending on the solution's properties, the double layers can actually "overlap." This term has been used to describe the situation where the Debye length is greater than the distance between the electrodes. The Debye length (λD) is the characteristic length scale of the double layer thickness, and is defined for a symmetric electrolyte:

$$\lambda_D = \sqrt{\frac{\varepsilon_0 \varepsilon RT}{2z^2F^2c_0}} \tag{2}$$

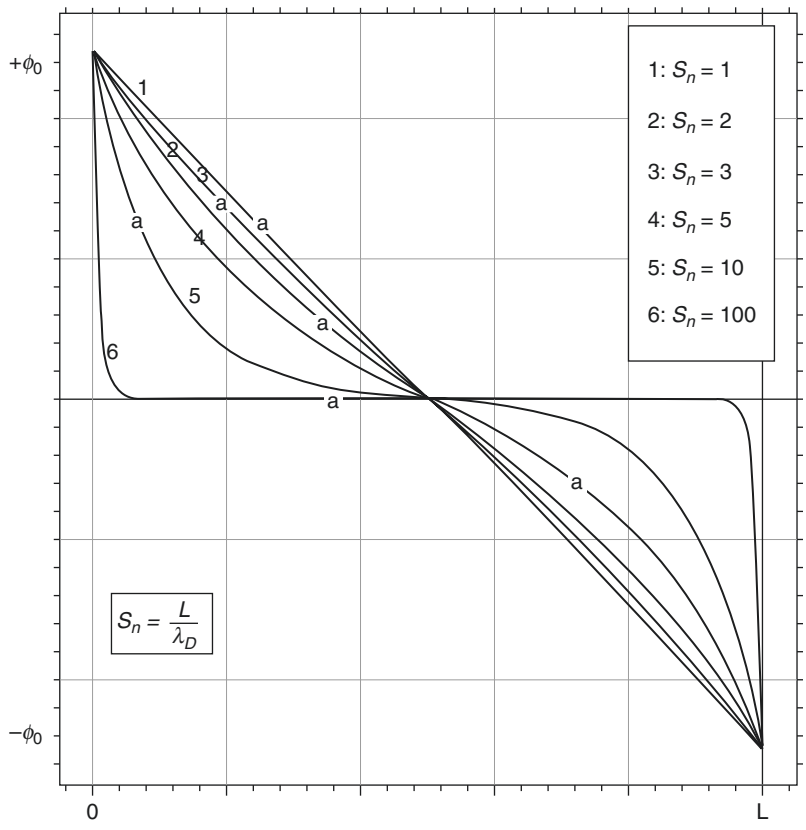
where ε_0 is the permittivity of free space, ε is the relative permittivity of the solution, R is the gas constant, T is the temperature in Kelvin, z is the chemical valence of the electrolyte, F is the Faraday constant, and c_0 is the molar concentration of the electrolyte. Table 1 shows theoretical Debye lengths for a symmetric monovalent electrolyte at room temperature. These lengths can range from less than a nanometer to hundreds of nanometers, so for many of the nanogap devices in use and under development, overlapping double layers are a commonality.

Nanogap Biosensors, Table 1 Debye lengths (λD) as a function of electrolyte concentration expressed as molarity (M)

Debye lengths	
c_0 (M)	λD (nm)
10^0	0.30
$10-^1$	0.96
$10-^2$	3.04
$10-^3$	9.62
$10-^4$	30.4
$10-^5$	96.2
$10-^6$	304

To investigate the electric potential that results from the distribution of ions or charges inside of a nanogap, Poisson's equation is used:

$$\nabla^2\phi = \frac{-\rho E}{\varepsilon} \tag{3}$$



where ϕ is the electric potential and ρE is the charge density:

$$\rho_E = F\sum_i z_i c_i \tag{4}$$

where i represents the ion species. If the nanogap is to be considered a closed system, mass must be conserved, so the following equation is also required:

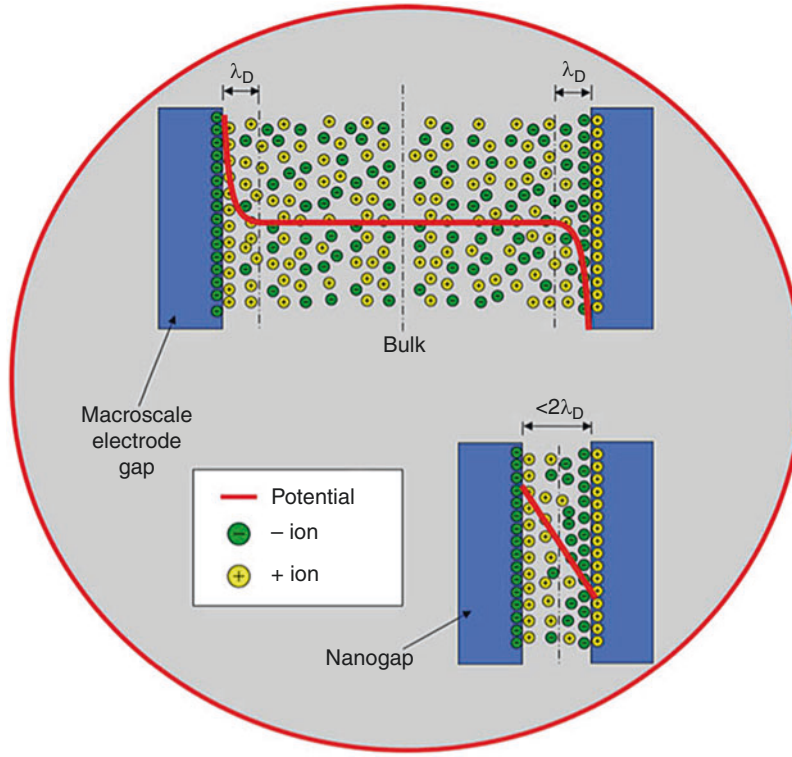
$$\frac{\partial c_i}{\partial t} = -\nabla \cdot J_i + R_i \tag{5}$$

where J_i is the flux density in mol/cm^2/s and R_i is the production of species i, which is assumed to be zero at the voltages common for impedance spectroscopy. The flux density can be shown as:

Nanogap Biosensors, Fig. 2 Numerical solution of overlapping double layers. The electrode surfaces are represented by the *left* and *right* plot borders. The *y*-axis is the potential, and the *x*-axis is the distance between the electrodes. The potential distribution is plotted as the dimensionless number, S_n

$$J_i = -D_i \nabla c_i - z_i F c_i u_i \nabla \phi \tag{6}$$

where D_i is the diffusion coefficient and u_i is the ion mobility. This represents diffusive flux and electric flux, as represented by the two terms in this equation, respectively. Flux across the boundaries is assumed to be zero, and the potential on the two electrode surfaces are:



$$\phi(x = 0) = -\phi(x = L) = \phi_0 \tag{7}$$

The distance between the electrodes, L, is varied. A dimensionless ratio of the distance between the electrodes and the Debye length is defined to be S_n:

$$S_n \frac{L}{\lambda_D} \tag{8}$$

The results from this solution are shown in Fig. 2. Although this analysis is based on steady-state assumptions, it is a good approximation for most impedance spectroscopy systems, since the relaxation frequency of the electrical double layer is typically faster than the frequency of the current injected by the analyzer.

It is clear from the numerical solution shown in Fig. 2 that when the double layers overlap, the potential drop across the electrodes approaches a linear regime. This is significantly different from a macroscopic gap, where virtually all of the potential drops across the double layers and the bulk solution in a macro-gap typically exhibits a null electric field. This is an important point for biosensors, since the entire solution should ideally be subjected to the same conditions. For macroscale electrode sensors, molecules in the middle of the gap will behave much differently from molecules found on or near the electrode surfaces. The uniform field inside a nanogap is a significant advantage for these devices, since all molecules inside of the gap will see the same electrical conditions. The bulk solution is essentially removed, thereby providing, at least in theory, a more homogenous

Nanogap Biosensors, Fig. 3 Electrical double layers and overlapping electrical double layers. Schematic of ion distribution inside macroscale gaps and nanogap devices, and resultant potential distribution. λ_D represents the Debye length

response. Figure 3 depicts a simple illustration of the electrical double layers in a macroscale gap and a nanogap with overlapping double layers.

Measurement Methods

The detection method is typically achieved by measuring the complex impedance response to either a single excitation frequency or a full range of frequencies, or spectrum: The impedance spectrum of a system is measured by applying a frequency-dependent excitation voltage and measuring the resulting current. From the impedance spectrum and the geometrical parameters of the system, the complex permittivity or dielectric spectrum is derived.

Kaatze and Feldman have comprehensively reviewed the basic principles of dielectric spectroscopy and the methods in use to measure the dielectric properties of liquid samples over the frequency range from about 10^{-6}–10^{12} Hz [12].

Conventionally, a small AC (alternating current) potential, $V^*(j\omega)$, swept over a range of frequencies is applied. The electrical current response, $I^*(j\omega)$, is measured and the complex impedance $Z^*(j\omega)$, of the system is:

$$|Z^*(j\omega)| = \frac{V^*(j\omega)}{I^*(j\omega)} = Z_{\mathrm{RE}}(j\omega) + jZ_{\mathrm{IM}}(j\omega) \quad (9)$$

Here $Z^*_{\mathrm{RE}}(j\omega)$ and $Z^*_{\mathrm{IM}}(j\omega)$ are the real and imaginary parts of the complex impedance, respectively. The magnitude and phase angle of the complex impedance are

$$|Z^*(j\omega)| = \sqrt{[Z_{\mathrm{RE}}(j\omega)]^2 + [Z_{\mathrm{IM}}(j\omega)]^2} \quad (10)$$

and

$$\angle Z^*(j\omega) = \arctan\frac{Z_{\mathrm{RE}}(j\omega)}{Z_{\mathrm{IM}}(j\omega)} \quad (11)$$

respectively.

Knowing the geometrical and physical parameters of the biosensor, it is possible to model the physical mechanisms of conductivity and

polarizability with equivalent circuit analysis. Using networks of resistors and capacitors, the response of the system under controlled conditions can be predicted, and consequently the detection of biological events that cause deviations from the predicted response.

Determination of an appropriate equivalent model requires some a priori knowledge of the chemistry and physics of the system. Because multiple models can be found to fit any acquired set of impedance data, the choice of the "most appropriate" model is often the result of a complex balance between complexity, in terms of raw number of circuit elements employed, and efficiency, in terms of which chemical and physical phenomena of the system need to be characterized and with what level of sensitivity.

In general, it is of the utmost importance to design a nanogap sensor system where the number of parasitic circuit elements (which tend to increase the complexity of the resultant equivalent circuit model) is minimized, while the impedance response of the system is maximally affected by specific biological events taking place in the nanogap. This is usually achieved by a combination of clever design, appropriate choice of materials, and a reasoned choice of range of frequencies to be measured.

To maximize sensitivity, it is advantageous to have large active areas and small interelectrode distances, maximizing device capacitance. In the particular case where biomolecules are sensed as they bind to the surface and modify the double layer, it is also convenient to minimize the contribution of the bulk solution to the overall impedance, which leads to a sensitivity response that is inversely proportional to the interelectrode distance. Defining ξ as the *quality factor*, the two dependencies can be formulated as follows:

For a generic parallel-plate capacitive sensor, the measured quantity is capacitance, while the sensed parameter is the permittivity ε. The two are related by the well-known expression:

$$C = \varepsilon \frac{A}{d} \tag{12}$$

where A is the area of the electrodes, d the distance separating them, and ε the permittivity of the dielectric between the two plates. To maximize the measured capacitance given a fixed permittivity it is necessary to maximize the area-to-interelectrode distance ratio. Therefore, the first quality factor can be defined as

$$\xi_1 = \frac{C}{\varepsilon} = \frac{A}{d} \tag{13}$$

For the specific case of sensors sensitive to surface binding events where bulk contributions (due to the total volume enclosed by two parallel electrodes) are to be minimized, a second quality factor can be defined as the area-to-volume ratio, i.e.,

$$\xi_2 = \frac{A}{V} = \frac{A}{A \cdot d} \tag{14}$$

The combination of these two factors yields:

$$\xi = \xi_1 \xi_2 = \frac{A}{d^2} \tag{15}$$

This dimensionless parameter can be used to quantitatively compare the efficiency of different nanogap sensors, as well as to optimize the design of new sensors.

Although alternating current methods are the most common methods used with 3D nanogap biosensors, changes in direct currents (and similarly, shifts in IV curves) have been used [13].

Key Research Findings

Some key pieces of literature are briefly listed below. This list is not meant to be exhaustive, but rather illustrative of the most significant research findings achieved using nanogap sensors, and a starting point for further exploration.

One- and Two-Dimensional Nanogap Biosensors

One- and two-dimensional nanogap devices have been used mostly in proof-of-concept studies, to determine the ability to detect and to a limited extent, characterize nucleic acids (DNA, RNA)

binding events, and presence of other biologically relevant biomolecules such as proteins and antibodies. Chen et al. detected specific target DNA concentrations of as low as 10 picomolar identifying single-base-pair mismatches [14]. Liang et al. observed electrical signals caused by 1.1 kilobase-pair (kbp) double-stranded (ds)-DNA passing through the gap in the nanogap detectors with a gap equal to or less than 13 nm [1]. More recently, Cingolani et al. demonstrated that hybridization events are detected by the discrete increase in conductivity when the target AuNC–DNA conjugates bridge the electrode gap [15].

The electrical detection of other biomolecular interactions has also been demonstrated. For example, Haguet et al. have detected the capture of antibodies as well as the specific interaction between the biotin and the streptavidin molecules [16]. Subsequently, the same group has shown that the same method can be extended to the detection of immunoglobulin G (IgGs) in serum using protein probes [17].

Three-Dimensional Nanogap Biosensors

Three-dimensional nanogap resistive sensors with gaps of 5, 10, and 15 nm have been used to detect biotin–streptavidin binding events by measuring peak increases in direct current [13].

Single-frequency AC impedance measurements have been used successfully with three-dimensional nanogap sensors adopting metal electrodes and integrated reference sensing on-chip, for the detection of thrombin, a blood clotting factor, and to investigate its binding properties to a specific antibody and RNA-aptamer. A similar device was used to study the interaction of the Rev peptide with a corresponding RNA anti-Rev aptamer in concentration spanning the range of 100 nM–2 μ-M. The parasitic effect of the double layer was significantly reduced by using measurement frequencies of 800–1,280 MHz [18].

AC impedance spectroscopy has also been used to specifically detect the presence of thrombin in solution by looking at impedance spectra recorded using an 20 mV AC signal swept over a frequency range of 10 Hz–100 kHz [19].

Similarly, hybridization of poly-A nucleotides to immobilized poly-T between nanogap electrodes has been shown to result in a measurable change in capacitance over a frequency range of 100 Hz–10 kHz [20].

Future Directions

At this point in time, the development of nanogap biosensors is still in the research phase, i.e., there are no commercially available nanogap biosensors. However, the promise of sensitive, label-free devices with small footprints is alluring. Great strides have been made in terms of nanogap manufacturing and detection. Future work is needed in scale up of manufacturing, as few groups have achieved repeatable large-scale fabrication. This will be essential in developing sensors in quantities at low cost.

For applications relating to nucleic acid determination and sequencing, increases in sensitivity and specificity are necessary for these biosensors to compete with existing industry standard sensors which offer fluorescence-based readouts.

Specific label-free, all-electrical nucleic acid detection can still be valuable for diagnostic point of care devices, although additional work is needed to enable multiplexed detection which will allow the analysis of a panel of biomarker sequences, rather than a single short target sequence.

Similarly useful will be nanogap devices that enable the detection of specific proteins in serum or blood, forfeiting the cost and complexity associated with traditional antigen–antibody assays such as ELISAs. Devices aimed at point-of-care testing are particularly exciting because this application capitalizes on the inherent advantages of a nanogap: small volumes, small footprint, low power consumption, and label-free, all-electrical detection. The future will likely see many point-of-care biosensors using electrical-based detection, and perhaps nanogap technology can play an important role.

Nanogrippers

Peter Bøggild
DTU Nanotech – Department of micro- and Nanotechnology, Technical University of Denmark, Lyngby, Denmark

Synonyms

Nanotweezers

Definition

Nanogrippers are micro- or nanoactuators equipped with high-precision multiple end effectors, capable of applying controllable, opposing forces on nanoscale objects and thereby allowing these to be lifted free from a surface, held in a well-defined position, moved to another position, and/or placed in a controlled way.

Overview

Nanogrippers allow structures with at least one dimension being of order 100 nm or smaller to be manipulated in a predictable manner. Such grippers consist of one or more mechanically connected actuators, which determine the gap between two or more end effectors. Arrangements where independent macroscopic motors or actuators control multiple end effector individually are not considered to constitute nanotweezers or nanogrippers. The actuators are operated through variations of a physical quantity, which is typically an electrical current or voltage, but might also be the temperature, a magnetic field, or even light. While there is a wide selection of actuators

available for conventional microelectromechanical systems (MEMSs), nearly all nanogrippers which have been demonstrated in practical manipulation of nanostructures so far have either used electrostatic or electrothermal actuation. These actuation principles combine simplicity and compactness of design with predictable actuation behavior and are well suited for downscaling. The nanogripper itself could in principle have any size, as long as this does not prevent it from accessing and manipulating nanostructures in a controlled manner. There are, however, several reasons why grippers shown to be effective in manipulation of nanostructures tend to have an overall size significantly smaller than microgrippers; large grippers tend to block the line of sight of the microscope which is necessary to align the gripper to the object. By using conventional contact photolithography, the lateral resolution with which the end effectors – the parts of the gripper touching the sample – can be shaped is limited to around 1 μm. While high-precision fabrication techniques such as electron beam lithography and focused ion beam lithography can be used to achieve more well-defined end effectors, nanogrippers have been realized with multiwalled carbon nanotubes acting as both electrostatic actuators and end effectors. Nanogrippers can be used to manipulate objects which are difficult or time-consuming to approach, touch, and move or to place them in special positions. While manipulation is inherently slow compared to conventional parallel fabrication techniques in terms of mass fabrication, gripper-based nanoassembly has shown to be a flexible, rapid prototyping technique with a short turnaround time for small-scale production of nanodevices. Robotic manipulation using microgrippers has, for instance, been used to break off individual carbon nanotubes from their initial positions and mount these onto cantilever probes for high-aspect ratio atomic force microscopy. Other applications for nanogrippers include using the multiple tips as probes for fast electrical characterization, for assembly of nanostructures using dielectrophoresis, or to arrange nanoscale objects for subsequent structural analysis with a transmission electron microscope.

Design Considerations

The choice of actuator principle has considerable influence on the size, shape, generated force, and thereby the applicability of a gripper tool, and for nanoscale gripping the options are in practice much fewer as compared to microgrippers. Piezoelectric actuators made from ceramic materials can generate very precise motion with a high force but are notoriously difficult to integrate in a small tool. A large number of actuation principles have been proposed for nanogrippers and nanotweezers; however, nearly all attempts so far resulted in working devices having been made with either electrostatic or electrothermal actuation. Both of these principles provide a reasonable compromise between ease of fabrication and device integration, high reliability, high resolution, a large generated force, and a small overall footprint. The discussion will mainly focus on these two, as a treatment of the numerous other potential actuation principles and their role in hypothetical nanogrippers is beyond the scope of this entry. Emerging actuator concepts that may become important for more complex gripping/grasping schemes are briefly mentioned.

With a very few exceptions, all nanogrippers perform their motion in a single plane. Conventional bulk micro- and nanofabrication is highly suited for making in-plane actuators for electrostatic and electrothermal actuation, which is very convenient for miniaturization. Where electrostatic actuation uses Coulomb attraction between oppositely charged capacitor plates to generate a force, electrothermal actuation arises from exploiting the thermal expansion of materials, when heated up by an electrical current. In a review article, Sahu [22] discusses the most relevant actuator options for micro- and nanomanipulation and lists the key design characteristics, which are adopted for nanogrippers in the following:

Size – small size to allow interaction with nanoscale components. An important trade-off for all types of grippers is to make the actuators, or at least the end effectors, small and precise enough for delicate manipulation with a good

line of sight between the microscope and the manipulated object while at the same time providing a sufficiently solid structure to overcome surface forces between the object and the substrate or in some cases to break off the object from its initially fixed position. Many designs fail to be ever used in practice either because they make it extremely difficult to observe the manipulation process due to their bulkiness or because the force they provide is way too small to detach the objects of interest from a surface in a controlled way. Finally, larger actuators often suffer from out-of-plane bending of up to tens of micrometers, requiring constant realignment and can lead to damage of the samples. This is not necessarily a problem for manipulation of microscale objects but can make nanomanipulation extremely difficult and cumbersome.

Range of motion and applied force – depending on the size of the objects, as well as how much force is required to release them from their initial position, a proper balance between range of motion (actuation range) and gripping force must be chosen – generally, this is a trade-off given by the choice of actuation principle and design.

Actuation resolution – the deflection per input voltage /current should be small enough to accurately administer the force, e.g., in the range 0.1 nm/mV for a voltage source. Since the deflection is basically quadratic in drive signal, both for electrothermal and electrostatic nanogrippers, the resolution depends on the deflection.

Contact and force sensing – to avoid damage to samples and to allow detection of the nanogripper, contact and force sensing are very attractive. This is best done with either capacitive or piezoresistive readout, which unfortunately both add to the complexity of the devices and therefore make design of nanogrippers even more challenging. In practice, analysis of microscope images often serves as a convenient way to both detect contact and infer the applied forces. Knowing the spring constant of a gripper, the gripping force can be estimated from the observed deviation from its known mechanical equilibrium position. It is still very challenging to detect forces in a range that is relevant for manipulation of nanoscale objects (Yamahata et al. 2008a), in particular if such sensitive force-sensing components have to be integrated with a minute nanogripper device. For biological nano- and microscale objects, the relevant force range is pN to nN. Nanonewton force resolution for microgrippers can be achieved by capacitive readout [15]. Manipulation of hard, rigid objects like silicon nanowires or multiwalled carbon nanotubes may involve forces in nN, while for picking up (detachment or breaking) of such structures, forces in the μN range are relevant [3].

Power – a low power dissipation is beneficial for avoiding damage to the samples and in the case of electrothermal grippers also to protect the grippers themselves. High peak temperatures in such grippers may cause deformation or failure not just in polymer but also metallic or silicon actuator structures. Careful topological design of the layout [23] or proper choice or combinations of materials [12] can significantly reduce the peak temperature at the end effector and the overall heat dissipation to the environment.

Fabrication and material selection – both for electrostatic and electrothermal actuators, the choice of material and fabrication strategy can have a great impact. While silicon is often chosen as a default material due to the availability of proven fabrication methods and its excellent mechanical properties, there are sometimes more suited alternatives. For instance, the much larger thermal expansion coefficient of the polymer SU-8 in combination with a metallic heating layer can provide large actuation stroke at far lower temperatures than pure metallic or silicon actuators [12]. With photolithography, it is possible to fabricate end effectors capable of manipulating nanoscale objects with dimensions down to around 100 nm [9, 20, 21]. For entering the sub-100 nm range, electron beam lithography (EBL) is an obvious choice due to its order-of-magnitude improvement of the resolution

compared to photolithography. Alternatively, focused ion beam milling can be used to fine-tune end effectors [8, 10].

Micro- and nanoscale surface interaction – while van der Waals interactions comprise the most consistent and ubiquitous type of surface force, several other types of interactions interfere with nanogripper operation depending on the environment and the involved surfaces. Such effects are mostly but not always unwanted. In humid conditions capillary forces are the most prominent among a wide range of surface/contact interactive effects [6], while electrostatic forces due to charging by the electron beam can lead to strong stiction and unpredictable motion and behavior of nanostructures, for instance, inside a scanning electron or ion microscopes where the constant bombardment with charged particles can lead to strong charging effects. In both focused electron and ion microscopy, the intense beam can also directly lead to "gluing" or fusing of objects, by deposition of material.

Scaling, Surface Forces, and Pick and Place

The concept of nanogrippers is based on the presumption that manipulation using opposing forces is somehow useful similar to human hands, tweezers, and grippers in interacting with the environment. While robotic grippers comprise one cornerstone in the industrial civilization with more than a million industrial robots in operation worldwide, many of which are using gripper-like end effectors, it is not at all obvious that manipulation can ever be as important on a scale that is six orders of magnitude smaller. In the macroscale world, mechanical forces and gravity play a large role, simply due to the volumetric size and mass of the objects compared to the surface area. A stone is picked up using a hand, while sand or dust is far easier to wipe up with a wet cloth. The dominant role of surface forces in nanomanipulation can be illustrated by considering a sphere of radius R in close contact with a flat surface, assuming these to be separated by a few Ångstrøm. Both the van der Waals force [6]

$$F_{vdW} = \frac{A_H R}{6D^2} \tag{1}$$

and the capillary force

$$F_{\text{cap}} = 4\pi\gamma_L R\cos\theta \tag{2}$$

for this system are linearly dependent on R. The Hamaker constant $A_H \approx 10^{-19}J$ represents the combined van der Waals interactions acting between the atoms in the sphere and the surface, $\gamma_L = 0.072\ \text{J/m}^2$ is the surface tension of water, and θ is the contact angle. Comparing the magnitude of these forces to the gravitational force, $F_g = 4\pi R^3\rho g/3$, where ρ is the density and g is the gravitational constant, the surface forces exceed the gravitational force for objects smaller than roughly 10^{-3} m. While for macroscopic objects surface roughness generally decreases the effective contact area and thus the magnitude of the surface forces by orders of magnitude, surfaces and nanostructures encountered in nanomanipulation are ever so often in much more intimate contact – either because the nanostructures are small compared to the scale of the surface features or because the surfaces involved are atomically smooth, such as the surface of a carbon nanotube. Even in the extreme case of the effective contact area being reduced by three orders of magnitude due to surface roughness effects, the surface forces still dominate over the gravitational forces for objects in the submicron scale.

If the object can be picked up by adhesion forces using just a single end effector, it appears that there is not much use of dual end effectors; it is frequently observed in practice that the object remains attached to one of the end effectors after the gap has been opened. The macroscale analogue is picking up sand or salt using a pair of tweezers as compared to using a moist cloth. In this case, the capillary forces are clearly more effective than a mechanical force. However, since the surface forces can keep nanoscale objects strongly fixed to a surface, the possibility

of applying *a larger* mechanical force is required to pick up the objects [21]. For nanowires or carbon nanotubes grown directly on a substrate, the dual end effector is highly suited; epitaxial nanowires and carbon nanotubes typically have a maximal strength of order 10 GPa, with defect-free single-walled carbon nanotubes closer to 60 GPa, significantly larger than, for instance, hardened steel (1–2 GPa). A dual end effector can apply the mechanical force necessary to break off the object, maintain it in a fixed position between the jaws [21], and finally deliver it with the correct orientation at the target device or position. Dual end effectors are also convenient for electrical measurements of an object held between the jaws [14].

Environment and Microscopy

As seen from the above discussion, the performance characteristics of a nanogripper depend on a complex interplay between the material properties, actuation principle, size, and design of the gripper but also the application scenario in which the gripper are to be used. A key aspect of a nanogripper's usability is indeed the manipulation environment. This is determined by the environmental tolerances of the samples to be manipulated, the requirements and limitations of the microscopy technique needed for monitoring the process, and finally the physical space required to host the nanogripper, samples as well as the often quite bulky positioning manipulators. Issues related to environment and microscopy are discussed in the following.

Nanomanipulation may be performed in vacuum, ambient, or liquid conditions. A liquid environment is often chosen for manipulation of biological samples, and in this case the solution is typically a saline solution, which is electrically conducting. The biological objects are typically damaged at elevated temperatures, which nearly rules out electrothermal actuators as these invariably dissipate heat into the surrounding liquid when immersed. Similarly, most electrostatic actuators reported on today require application of voltages larger than a few volts, which leads to hydrolysis and consequently bubble formation in the liquid, which prevents any form of nanomanipulation. Finally, the liquid environment makes optical microscopy the only viable option, which even at the very best conditions makes alignment or even visualization of immersed sub-100 nm structures extremely difficult. The three-dimensional nature of nanogrippers excludes ultrahigh-resolution monitoring possible with scanning probe microscopy, as such techniques can only image and manipulate 2D and quasi-2D surfaces. Although atomic force microscope probes with integrated carbon nanotube tweezers have been fabricated by Akita and coworkers [2], a combination of scanning electron microscopy and a separate scanning probe was used to in a later demonstration [1]. There has thus been little progress in gripper-based manipulation of nanostructures in a liquid environment so far; here, optical tweezers are is a more powerful method along far-field manipulation strategies such as dielectrophoresis (Yamahata et al. 2008).

Ambient or atmospheric conditions allow both electrostatic and electrothermal grippers to operate in a useful way. Just as for a liquid environment, optical microscopy is the only practical option, providing imaging of wire-like structure (such as carbon nanotubes) with sizes down to roughly 100 nm and in some cases tens of nanometers. In ambient conditions, and in particular in very humid conditions [6], water films will reside on most surfaces and lead to strong capillary forces as discussed above. These surface forces can be very powerful and can make picking and placing of objects difficult.

Vacuum conditions allow electron microscopes to be used, and this is a key advantage. The scanning electron microscope allows imaging of nanostructures with lateral dimensions down to 1 nm (such as single-walled carbon nanotubes) while providing sufficient space inside the specimen chamber for the manipulation stages required to move the nanogripper. Capillary forces are largely eliminated, and the absence of air and water makes the behavior of the gripper more predictable. However, the constant and concentrated irradiation with electrons may damage the

samples, just as particularly biological samples cannot stay alive in vacuum. Scanning electron microscopes also tend to deposit thin layers of carbonaceous contamination, which can influence the sample, change the morphology, or even bind the samples in unwanted position. A consequence of this is sometimes that the manipulation has to be conducted with a strict control of the imaging, to avoid excessive contamination. This electron beam-induced deposition (EBiD) can be used to an advantage, providing a handy "glue," which can be applied simply by focusing the electron beam at a junction until a sufficient amount of carbon material has mechanically connected the two objects [9, 13, 23].

In terms of electron microscopes, other types of microscopes are relevant to mention. The transmission electron microscope provides atomic resolution in ultrahigh vacuum conditions, but allows far less than a cubic centimeter of sample space. It is possible to manipulate a single sharp tip inside a TEM using highly specialized nanomanipulators, but so far, nanogrippers as such have not been used in in situ TEM.

The environmental scanning electron microscope (ESEM) allows up to about 10 mbar gas to be inside the sample chamber, with a moderate degradation of the imaging resolution. The ESEM is a very flexible system for nanogripper operation, providing high-resolution monitoring, a certain degree of control of the environment, and sufficient space to operate one or more nanogrippers in situ. The dual-beam FIB/SEM combines a scanning electron microscope with a focused ion beam system, which is highly convenient for combination of nanogripper manipulation with in situ shaping of nanostructures and nanotools, deposition of metal electrodes, or fastening glue by EBiD. To date, most gripper-based manipulation of nanoscale objects has been done inside some type of scanning electron microscope.

Finally, the nanomanipulation or nanorobotic system used to perform the manipulation is a key factor in the success of a nanogripper. A deep discussion of nanomanipulation systems is beyond the scope of this entry; however, a few, highly successful examples of platforms for complex manipulative operations include, for instance, the semiautomatic nanomanipulation system by Eichhorn, Fatikow, and coworkers [13] with integrated depth detection using advanced three-dimensional scanning electron microscopy and image recognition technology and commercial, high-resolution multi-manipulator workstations from the US company Zyvex Corporation and German companies Klocke Nanotechnik GmbH, Kleindiek Nanotechnik GmbH, and SmarAct GmbH.

Electrostatic Nanogrippers

The electrostatic actuator is very widespread in MEMS, due to its convenient simplicity and ease of integration with standard silicon fabrication processes. It has a fast response time, provides nanometer-precision motion, consumes very little power, and thus dissipates virtually no heat to the surroundings. High-precision capacitive position sensors can be made with the same fabrication process and a similar capacitor layout, which means that integration of capacitive position sensors is natural and straightforward using bulk microfabrication. Nevertheless, some of the simplest, smallest, most well-known electrostatic nanogrippers are constructed through manually nanoassembly, rather than using bulk microfabrication.

Electrostatic Actuation

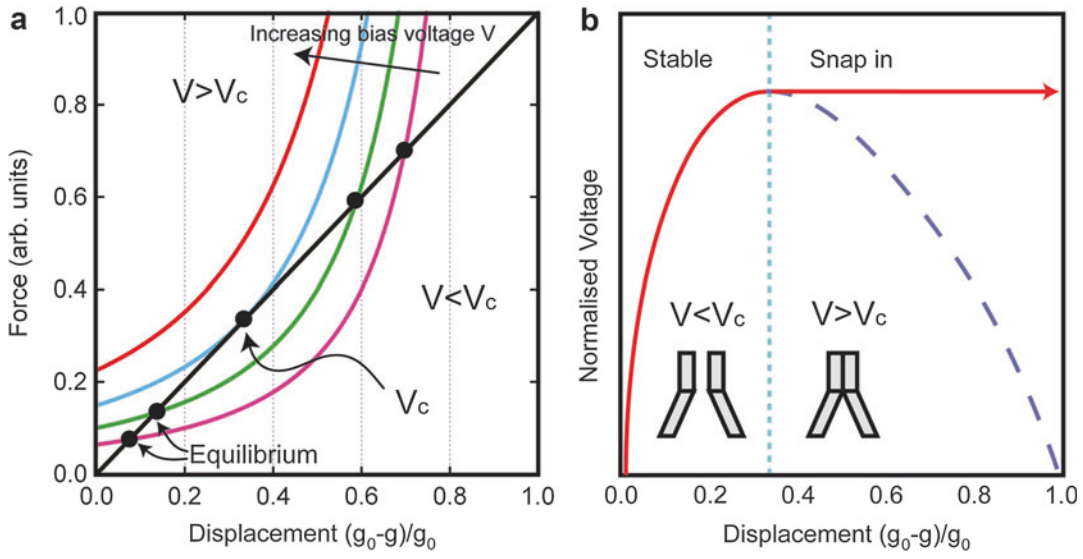
Electrostatic actuators are variable capacitors with air, liquid, or vacuum as a dielectric. A voltage difference V applied to two plates leads to a net electrostatic force acting between these. Depending on the design, the force F_{el} is translated into motion of two or more end effectors which can close around an object and hold it, thus constituting an electrostatic gripper. The electrostatic gripper comes in two varieties, the plate-type or the comb-type actuator. In the generic plate-type actuator, the capacitor gap is variable, while in the generic comb-type actuator, the effective (overlap) area is varied.

For a plate capacitor with area A and gap size g and dielectric absolute permittivity ε, the capacitance is $C = \varepsilon A/g$. The capacitor plates are

assumed to be kept in position by a spring with the spring constant k. With an applied voltage V across the capacitor plates, the change in potential energy ΔU for the spring-capacitor-voltage source system [24] is

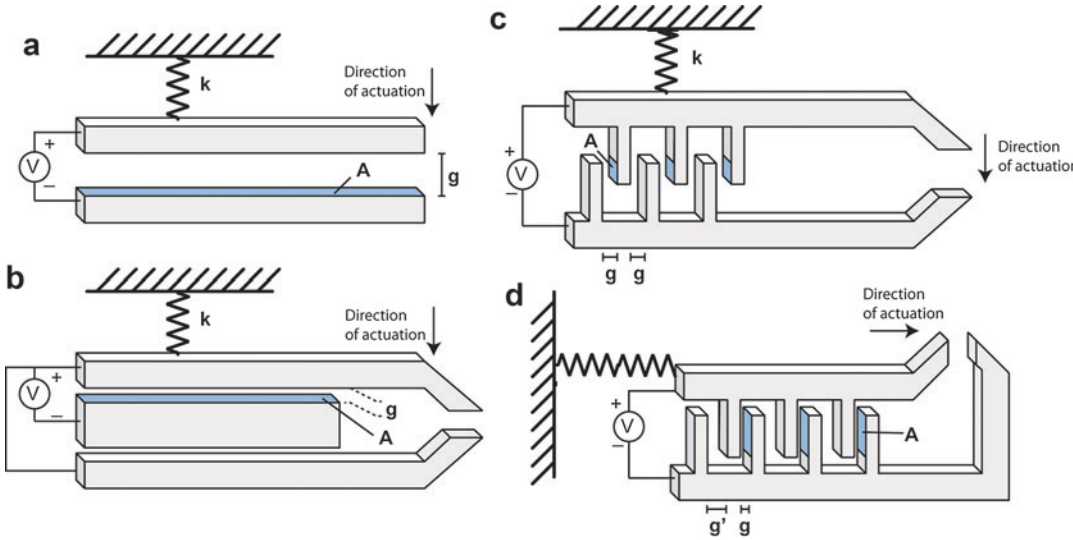
$$\Delta U = \frac{1}{2}k(g - g_0)^2 - \frac{1}{2}CV^2, \tag{3}$$

where g_0 is the initial gap size. In equilibrium the total potential energy is minimum, $\nabla(\Delta U) = \mathbf{0}$, and thus for actuation with one degree of freedom actuation, the balance equation becomes



$$g - g_0 = \frac{1}{2}\frac{V^2}{K}\frac{\partial C}{\partial g} = -\frac{\varepsilon A V^2}{2kg^2}. \tag{4}$$

This corresponds to a spring force $F_m = -k(g - g_0)$ balancing the electrostatic force $F_e = \varepsilon A V^2/2g^2$, which is quadratic in V. As the gap is decreased, the magnitude of the capacitance gradient increases. At a critical voltage V_c corresponding to the gap size $g = 2g_0/3$, the spring force can no longer balance the electrostatic force, and the system becomes unstable, which is illustrated in Fig. 1. The actuator will experience a "pull-in," where the gap size is reduced to zero, possibly leaving the system in this state, even after the voltage has been reduced to below V_c (see Fig. 1b).



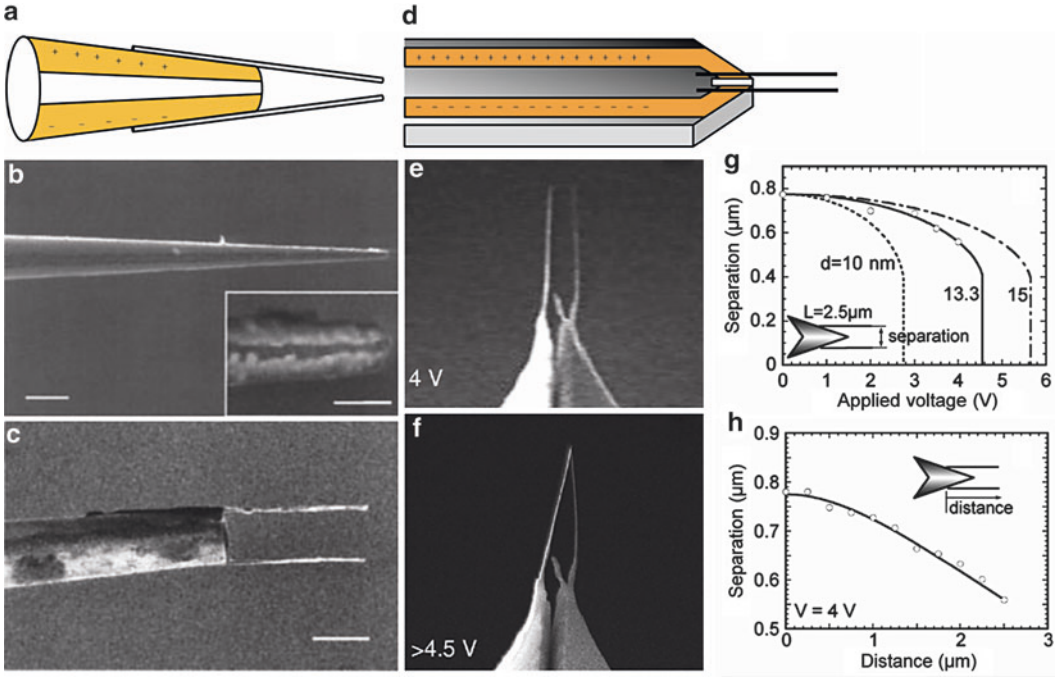
The instability can be avoided with the comb-type design, where the capacitors are equipped with interleaved, sliding pins. With this type of actuator, the capacitance is changed through the area rather than the gap size, as shown in Fig. 2. The force generated by comb-type actuators scales with the number of gaps, so higher forces can be achieved by increasing the area of the actuators. The displacement is thus [22]

$$\Delta x = N\frac{\varepsilon h V^2}{kg^2}, \tag{5}$$

where N is the number of gaps, h is their height, and the area between each capacitor pair is $A = h\Delta x$ (see Fig. 2). Comb-drives are generally larger and more bulky than plate capacitor drives and have only been used in a few instances for nanoscale manipulation. The operating voltage for electrostatic nano- and microgrippers ranges from about 5 V [2] to several hundred volts,

Nanogrippers, Fig. 1 (**a**) Force against displacement showing the mechanical equilibrium points where the linear elastic restoration force is balanced by the electrostatic force. At the critical voltage V_c, there is a singular equilibrium point, beyond which there are no stable solutions; the actuator thus experiences "pull-in." (**b**) The normalized bias voltage versus displacement illustrates the sudden snap-in event at Vc

Nanogrippers, Fig. 2 Different types of electrostatic actuators for nanogrippers. (**a**) Basic plate capacitor, where the gap size is changed upon increasing the bias voltage V, while the area A is constant. The movable part is thought to be connected to the device via an elastic support, here represented by a spring with a spring constant k. (**b**) A fixed center electrode for the two end effectors to remain at the same potential, thus preventing current from running through the gripped object. (**c**) A comb-drive used to close two end effectors. In this configuration the overlap area A between the two arrays of capacitors is varied rather than the gap size g, which avoids the pull-in instability. (**d**) Comb-like drive where the direction of motion of the movable part is lateral rather than vertical, with capacitor gaps g' and g. This configuration suffers from the pull-in instability, since it is essentially of the parallel plate type



depending on the design, the size, and the requirements, with a resolution of order 1 nm.

Nanotube Nanotweezers

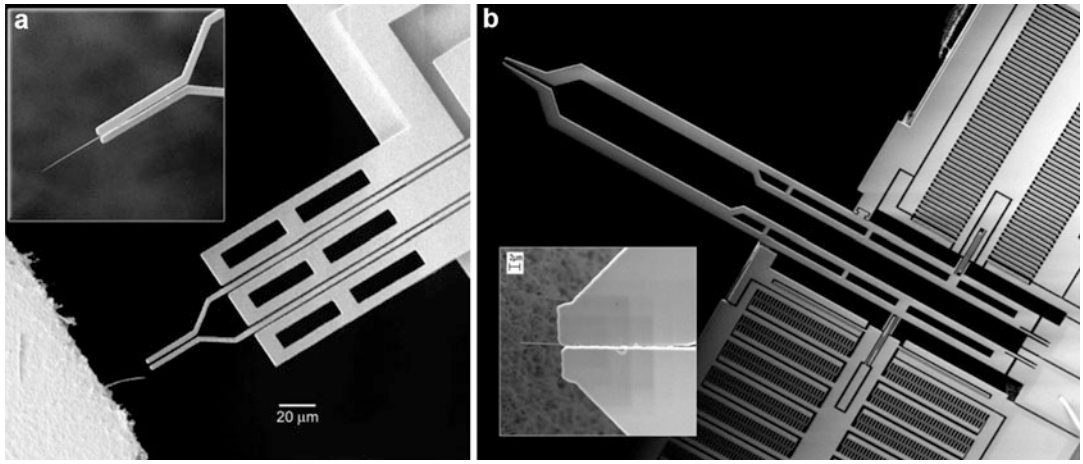
Although microgrippers of different types were developed already in the 1990, the first and most spectacular type of gripper tool capable of manipulating nanostructures is the nanotube nanotweezers [14]. This gripper is comprised of multiwalled carbon nanotubes glued to the sides of a glass microcapillary under an optical microscope. On each side of the glass capillary, a metal electrode was evaporated to provide electrical contact to the carbon nanotubes. By applying a moderate voltage, the nanotubes were attracted toward each other, until pull-in at 8.5 V where the gap g was roughly equal to $2g_0/3$. The authors demonstrated picking up of 500 nm diameter fluorescent nanobeads. As an added feature, the high conductance of the carbon nanotubes allowed electrical characterization of the held object. Following this approach, Akita et al. [2] integrated carbon nanotubes with an atomic force microscope probe, which was split in two electrically separated parts using focused ion beam milling (see Fig. 3).

Batch-Fabricated Grippers

While an impressive range of electrostatic microgrippers has been fabricated using bulk microfabrication, the majority is not designed to engage in manipulation of nanoscale objects, as this require very precisely manufactured end effectors as well as high resolution and precision of motion. Nelsons and coworkers [5] developed a range of advanced, highly integrated, and very well-characterized electrostatic grippers, which have since been commercialized by the Swiss company FemtoTools (see Fig. 4b). These grippers have a well-functioning force feedback sensing; have been tested thoroughly in air, liquid, and SEM; and are fully integrated with measurement and control electronics and computer interfaces. Although primarily designed for microscale manipulation, these are capable of nanoscale manipulation, as shown in the inset in Fig. 4b. Yamahata and coworkers reported a precision-

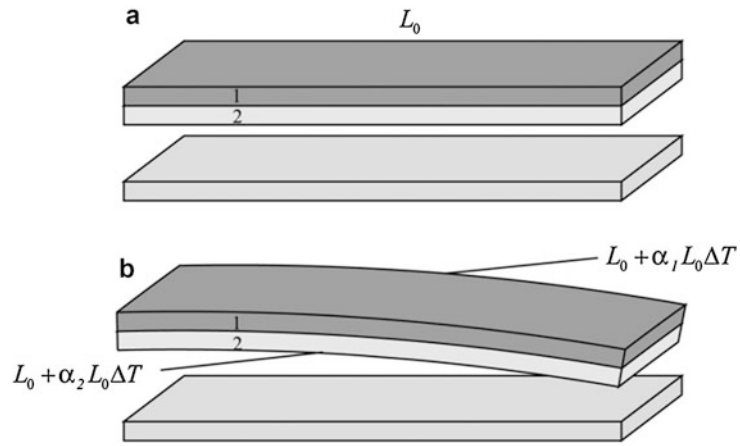
Nanogrippers, Fig. 3 (**a**) Kim and Lieber's nanotube nanotweezers [14] with multiwalled carbon nanotubes glued to the sides of a glass capillary, where an electrode layer has been deposited on each side. (**b**) Magnified view of the capillary after metal deposition. (**c**) The nanotweezers after mounting of the nanotubes. (**d**) Nanotweezers made by focused ion beam milling a metallized cantilever to separate the electrode into two [2]. (**e**) Two nanotubes attached to the tips at 4 V. (**f**) At a bias voltage of 4.5 V, the nanotubes pull in. (**g**) The separation versus applied voltage, showing pull-in occurring at different voltages depending on the initial separation. (**h**) Variation of gap separation for different initial lengths of the nanotubes, all at a bias voltage of 4V

manufactured electrostatic nanogripper with an integrated displacement sensor intended for biomolecules and demonstrated trapping of bundles of DNA molecules using dielectrophoresis rather than mechanical gripping (Yamahata et al. 2008). Mølhave [21] reported manipulation of silicon nanowires inside a scanning electron microscope using a plate capacitor gripper with five legs, of which two served as thin flexible actuator arms and three as rigid electrodes, allowing the gripper to both open and close compared to its neutral position (see Fig. 4).



Thermal Grippers

The volume of most solids will increase with temperature, and this effect can be exploited in several ways to provide accurate, yet forceful motion. The thermal expansion of, for instance, a rod with length L as the temperature is changed from T_s to T_h can be written as



$$L(T_h) = L(T_s)\,(1 + \alpha\Delta T), \Delta T = T_h - T_s \quad (6)$$

where $\propto$ can be regarded as a constant, nearly independent of temperature. The thermal expansion coefficient varies between about 1–5 for Si, Ge, and C, 5–30 ppm/K for clean room relevant metals, and 52 ppm/K for a polymer material such as SU-8. A temperature increase of 100 K thus only leads to a 0.5 % expansion of silicon; hence, a key design feature is amplification of this expansion to a useful actuation range. A basic strategy is to obtain a different thermal expansion for two objects, which are connected mechanically in a way that amplifies the deformation.

In a bimorph actuator this can be done by coupling two layers of material with different thermal expansion coefficients α_1 and α_2 to each

Nanogrippers, Fig. 4 Two examples of electrostatic actuators: (**a**) a plate capacitor-driven microgripper with both open and close capability [21]. The *inset* shows the gripper holding a silicon nanowire with a diameter of 200 nm. (**b**) Gripper with lateral comb-drives and integrated capacitive position readout. The inset shows a similar gripper manipulating a silicon nanowire (Courtesy of V. Eichhorn and FemtoTools)

Nanogrippers, Fig. 5 Bimorph actuator used as a gripper. Two-layered beams with different thermal expansion coefficients α_1 and α_2 and initial length L_0 will deflect sideways upon a uniform temperature change ΔT. This could be used to form a compact nanogripper

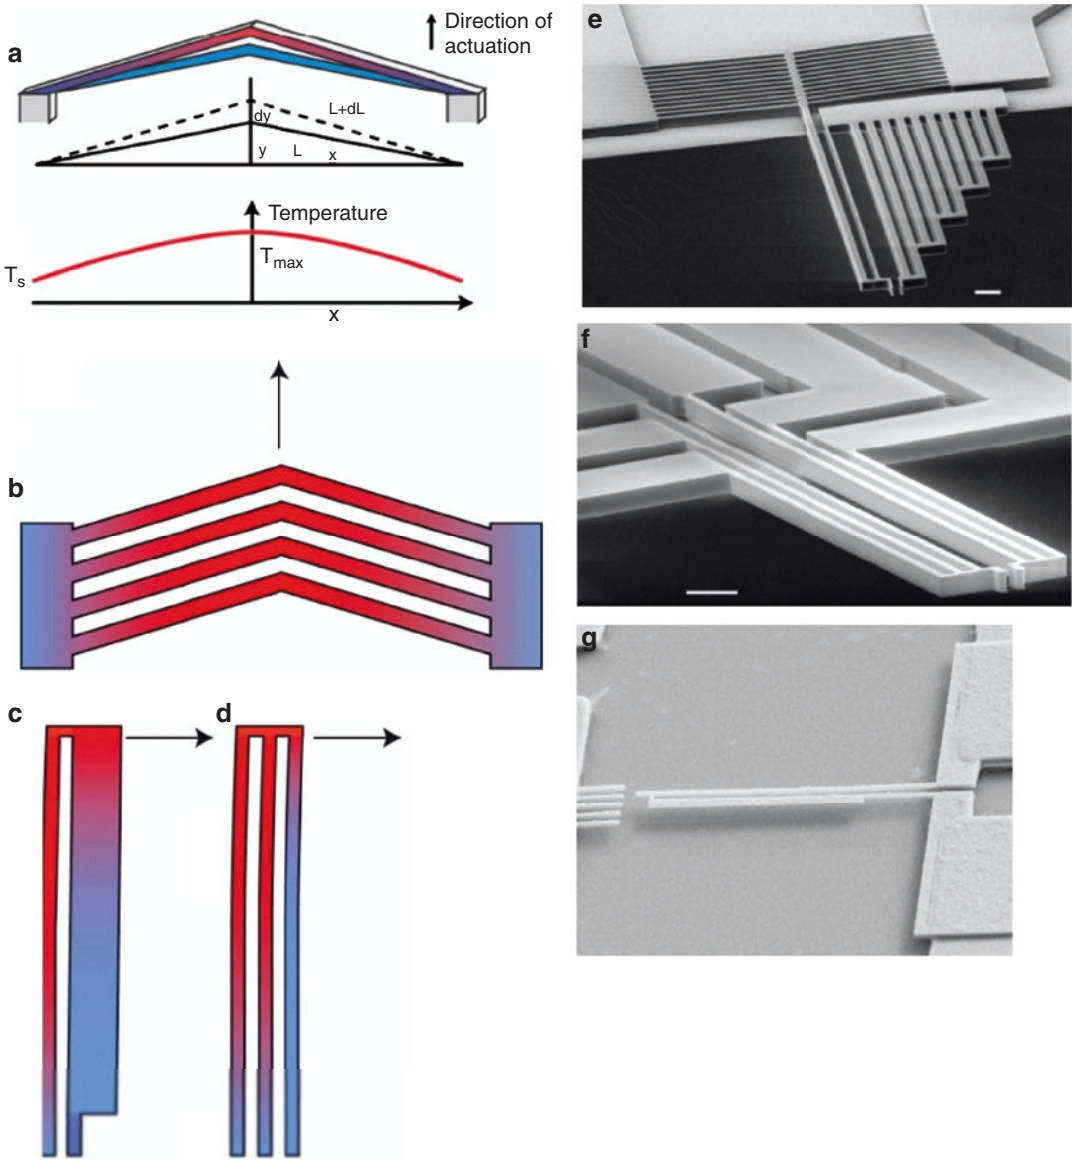
other in a single beam as illustrated in Fig. 5. A homogeneous heating of the structure will then cause the beam to deflect toward the side with the smallest expansion. The bimorph actuation principle is well suited for downscaling, as demonstrated in the work by Sul and coworkers [26], which was capable of delivering 1 μN at a temperature of 430 K. The actuator was realized by depositing aluminum on multiwalled carbon nanotubes. Yet, there are no examples in literature of nanomanipulation carried out with a bimorph gripper.

Electrothermal Actuation

Correspondingly, a current I passing through two rods with different cross sections will be led to different temperature increases through Joule heating, as the dissipated power in a volume element of length Δx and cross section A is given by $RI^2 = \rho(dx/A)A^2J^2 = \rho AJ^2dx$, where the current density is $J = I/A$ and the $\rho = RA/dx$ is electrical resistivity. The temperature distribution can be found by solving the heat conduction continuity equation, which in its simplest form reads

$$\frac{d^2T}{dx^2} = -\frac{\rho J^2}{\kappa}, \tag{7}$$

where κ is the thermal conductivity. The heat exchange with the surrounding air/liquid is ignored, which corresponds to an electrothermal device in vacuum. Moreover, energy loss by radiation is omitted. While this can be solved analytically for temperature distribution and actuation response with many basic actuator designs, finite element method is often used for its greater applicability to nontrivial designs [23]. Two often used designs are the Guckel actuator (also called thin-beam thick-beam) and the ribcage actuator, also called the Chevron actuator [22]. The Guckel actuator is a loop where the two conducting arms have different cross sections and the thick beam has a hinge to allow flexible sideways motion. The ribcage actuator consists of opposing rods, which are angled slightly, so that the longitudinal expansion of the rods forces the actuator to move perpendicular to the beam direction, as indicated in Fig. 6, which also amplifies the motion.

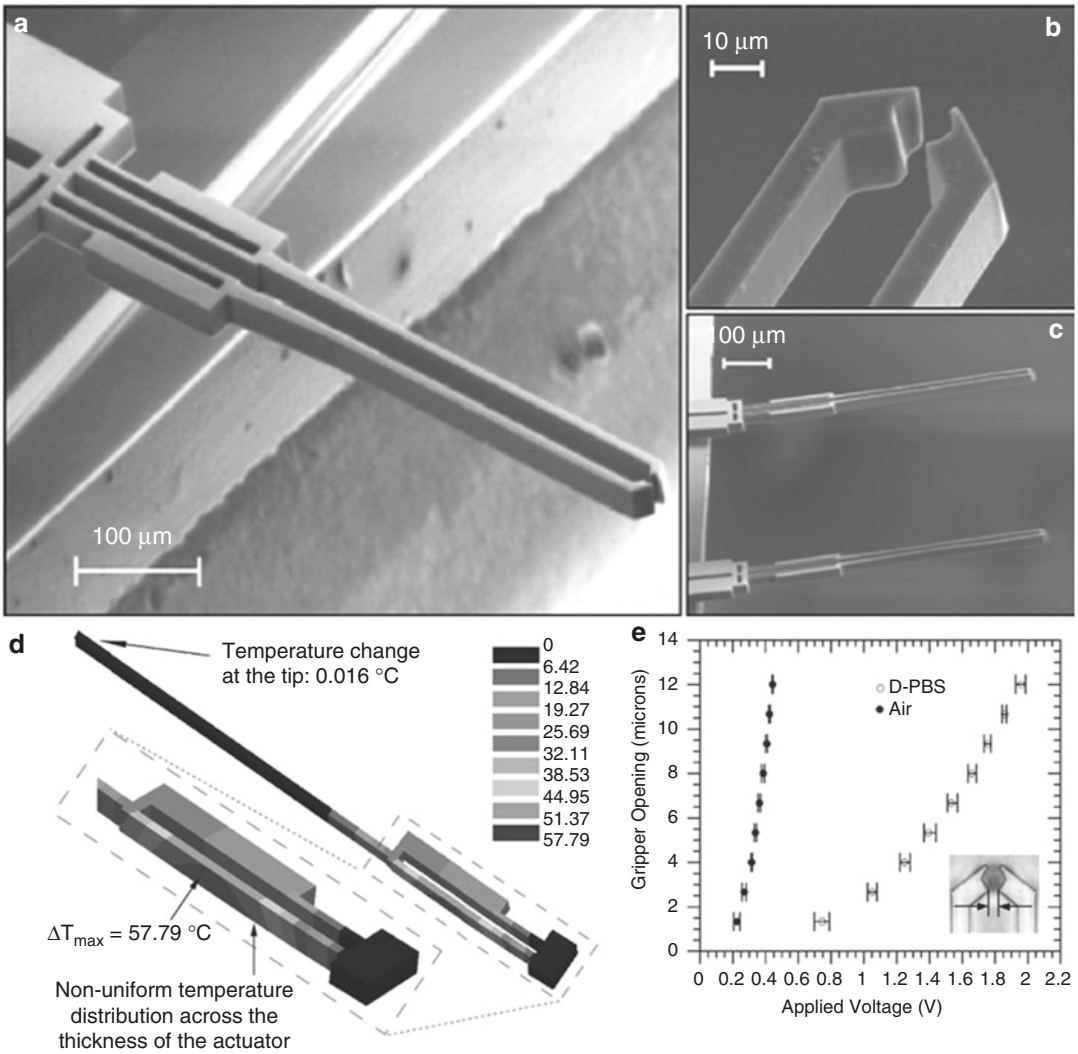


Carlson and Eichhorn [9] used an advanced nanorobotic manipulation system equipped with an electrothermal ribcage gripper to break off a multiwalled carbon nanotube from a substrate, mount it as a tip of an atomic force microscope probe, and finally fasten the nanotube to the probe by electron beam-induced deposition. The US company Zyvex manufactures a line of advanced electrothermal microgrippers. The conversion from electrothermal actuation to a mechanical motion of the end effectors is done through a highly optimized design where a capacitive comb structure provides force readout. While these grippers were clearly designed for micron-sized or larger objects, the precision and overall size of the end effectors should allow manipulation of submicron objects.

Chronis [12] employed a hybrid material approach to achieve a large actuation range at a much lower temperature than what can be achieved in bulk silicon or metal. Thin metallic structures for conducting the electrical current was combined with the high thermal expansion coefficient material SU-8 (52 ppm/K). The gripper has submicron features, can open almost 10 μm at a bias voltage of around 1 V, and most notably imposes a very small heat load onto the surroundings. Finite element calculations showed the temperature increase at the end effector of a fraction of a degree, while the overall temperature increase was around 60 K for the gripper opening of 12 μm. When using such a hybrid with different expansion coefficients, there is a risk of out-of-plane bending due to the bimorph effect. In this case, however, the thickness of the SU-8 layer was larger than the metal film that out-of-plane bending could be avoided.

Topology Optimization

Compared to electrostatic nanotweezers where the basic capacitor structures have proven their worth in millions of commercial MEMS devices, there is more room for improvement for electrothermal actuators. Electrostatic actuation is governed by large thermal gradients and involves the detailed shape of the actuator as well as the material properties in the mechanical, electric, and thermal domain. While the formalism outlined above (Eq. 7) is capable of predicting the behavior of any design, electrothermal actuators are often based on rather simple variations of either the thin-beam thick-beam actuator or the ribcage/V-shaped actuator.

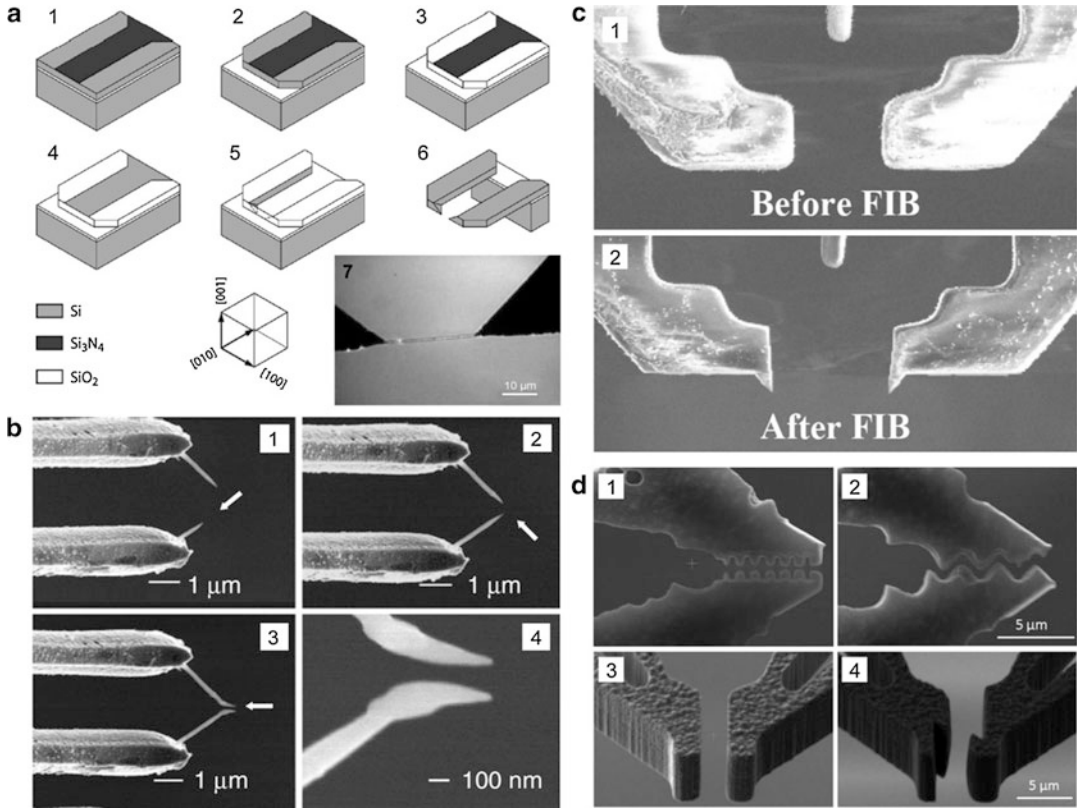


For nanogrippers, however, there are good reasons to push beyond the standard solutions. When downsizing the actuators to make overall smaller and more precise grippers, the available force typically also is decreased. To avoid strong out-of-plane bending, a high aspect ratio of the gripper arms is necessary, making it difficult at the same time to reduce the size and maintain a high lateral spring constant. Just as for macroscopical tweezers, the optimal shape of a gripper in terms of accessibility and actuation stroke is long and slender, while for strength and force, it should be short and wide. Sardan et al. [23] replaced the three-beam actuator with a topology-optimized actuator and achieved two orders of magnitude higher spring constant at the same actuation stroke (1 μm), while the peak temperatures were conveniently moved toward the base rather than

Nanogrippers, Fig. 6 Electrothermal actuators. (**a**) A V-actuator is pushed in the upward direction, as the opposing beams expand upon heating. By passing a current through the structure, it will attain a parabolic temperature distribution with the peak temperature Tmax in the center. (**b**) Ribcage or "Chevron" actuator consisting of many V-actuators in parallel. (**c**) Thin-beam thick-beam or "Guckel" actuator. As current is passed through the loop, the larger heat generated in the narrowest beam will lead to a skewed expansion, i.e., to the wide beam. (**d**) The three-beam actuator operates by passing a current through either the left or right two legs, consequently allowing for actuation in two directions, or open as well as close capability of the gripper. (**e**) Silicon ribcage actuator [9]. (**f**) Silicon three-beam actuator [3]. (**g**) Thin-beam thick-beam actuator with submicron dimensions [17]

end effectors (see Fig. 7). This strategy leads to grippers capable of successful, repetitive mounting of carbon nanotubes onto AFM probes, TEM grids, and fixed electrodes [23].

Cagliani and coworkers [8] used electron beam lithography to batch-fabricate topology-optimized nanogrippers with a length of 35–50 and a gap size of 300 nm, reducing the overall



Nanogrippers, Fig. 7 (**a**) Micro-/nanogripper with electrothermal actuators defined in SU-8 with thin chromium-gold electrodes heating the Guckel-type actuators at the base. (**b**) Zoomed in and (**c**) overview micrographs of the gripper. (**d**) Finite element calculations showing negligible temperature increase at the tip. (**e**) Actuation curves for the gripper in both liquid (D-PBS) and air. Due to a different thermal resistance in liquid as compared to air, opening the gripper in liquid requires far higher applied voltage [12]

size by a factor of 2–6 times compared to Ref. [23]. The reduced size and thickness of the end effectors in combination with the enhanced rigidity given by the topology-optimized layout made it possible to break off as-grown gallium phosphide nanowires from the substrate inside a scanning electron microscope. By coating the grippers with a thin layer of gold, bundles of single-walled carbon nanotubes could be lifted up and mounted inside a transmission electron microscope for subsequent electrical and structural characterization. This device is so far the smallest batch-fabricated nanogripper in operation.

Nanoengineering of End Effectors

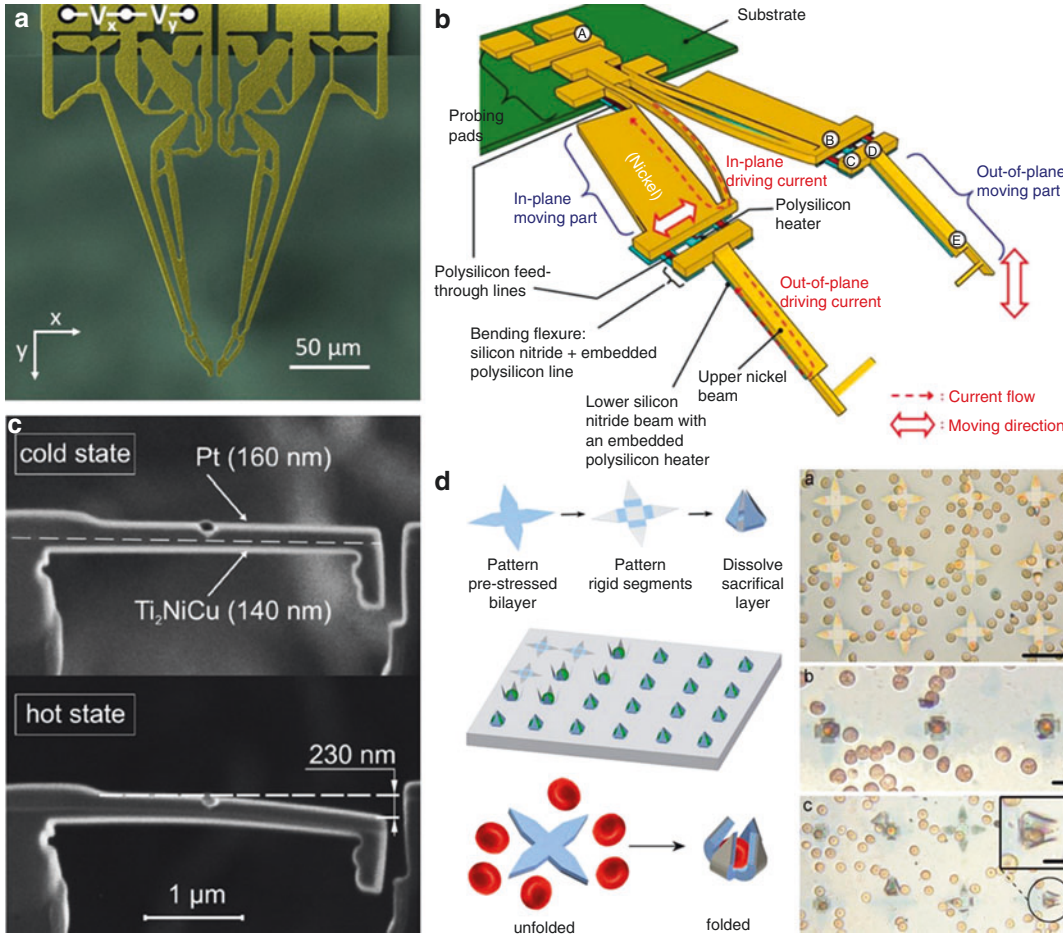
Just as for macroscale grippers, the size and shape of the end effectors – the critical interfacial part of the gripper where the contact is made to the nanostructures – are vitally important for successful application of the tool. While

Nanogrippers, Fig. 8 Customization of end effectors. (**a**) Anisotropic wet etch with potassium hydroxide (KOH) etch can be used to create sharp edges and tips in silicon. A narrow gap with ultrasharp opposing tips was created in a batch process using KOH etch by Yamahata (Yamahata et al. 2008). (**b**) Electron beam-induced deposition performed in the direction of the white arrow shows gradual build-up of dual supertips on silicon dioxide end effectors with a gap of 100 nm. The method was used to create gaps down to 25 nm. [7]. (**c**) Focused ion beam milling used to reshape end effectors (Chen, Zhang et al.). (**d**.1) Silicon microgripper fabricated with an initial closed gap, which is subsequently opened and further shaped by the focused ion beam milling for reduced contact area. (**d**.2) FIB milling is done so that the gripper will apply a finite force even in the neutral position, i.e., with no applied voltage. (**d**.3–4) show end effectors equipped with a self-locking mechanism, so the gripper when pushed together will lock in this position similar to some macroscopic tweezers (Courtesy of Özlem Sardan and Mikkel Klarskov)

conventional nanofabrication techniques such as electron beam lithography are sometimes used [8], this critical part of the gripper is often engineered using creative and unusual solutions. Elegant use of photolithography combined with an anisotropic potassium hydroxide wet etch allowed Yamahata (Yamahata et al. 2008) to create sharp opposing tips on the end effectors in a batch process (see Fig. 8a). Boggild et al. [7] used angled electron beam-induced deposition (EBiD) to define needle-shaped end effectors with a gap size of just 100 nm inside a scanning electron microscope, as shown in Fig. 8b. A gap size of just 25 nm could be achieved by gradually allowing the deposited material on the two tips to grow until the desired gap size was achieved. Focused ion beam milling is highly convenient for in situ reshaping of nanodevices, since it can both perform milling of material and deposition using precursor gases. FIB milling has been used to define end effectors with a more well-defined or smooth contact plane (Fig. 8c), to achieve a smaller contact area for reduced surface force interactions (Fig. 8d.1), or to engineer the end

effector so that it applies a force in its *neutral* position and has to be opened rather than closed during the actuation phase (Fig. 8d.2). Finally, FIB can be used for more exotic mechanism such as self-locking grippers which can keep a nanostructure mechanically fixed even when "released" (Fig. 8d.4). As an example, Bartenwerfer et al. ([4], #19567) demonstrated that careful FIB milling of the end effectors to become slightly tilted with respect to the vertical direction allowed picking up an object with one angle and mounting it with another, which is otherwise very difficult using linear actuated end effectors. Micrometer-sized flakes were picked up and turned 90° while being held within the gripper, before being stored in a cartridge.

Emerging Concepts for Advanced Gripping



Within the general field of micro- and macroactuation, several emerging approaches have the potential to become relevant for nanogrippers; in some cases proof-of-concept prototypes have already been realized with dimensions, functionality, and actuation precision in the relevant range. A general restriction of nanogripper-based nanomanipulation in comparison with macroscopic robotic manipulation is the lack of non-translational degrees of freedom (DOF), such as rotation, as previously mentioned in section "Design Considerations." While a typical manipulation system features a stage with three linear DOF, as well as in-plane motion of one or two end effectors, the three-dimensional grasping capability of a human hand with multiple joints does not exist in any nanogripper reported in literature. Gripping or grasping is likely to be more flexible and object tolerant if not just the shape of the end effector but also the angle can be changed dynamically. In the following a few promising technologies for enhancing nanogripper functionality are discussed.

Multiple-Axis Grippers

For electrothermal as well as electrostatic actuators, it is relatively straightforward to add an extra in-plane degree of freedom, turning a single arm into a two-axis actuators. This will in many situations be possible without changing materials or fabrication process. The complexity of the gripper will increase, which will typically lead to a less compact design and possibly increase of out-of-plane bending and cross talk between the axes. For electrothermal actuators, cross talk is hard to avoid, as heat may easily dissipate from one actuator part to another in an uncontrollable way. Here, topology optimization could be helpful in achieving multiple-DOF designs with a small footprint and manageable cross talk, as such features can be incorporated explicitly as optimization goals. The review paper [25] describes the general topology optimization design procedure and examples of multiple-DOF electrothermal actuators. Figure 9a shows a two-axis topology-optimized gripper fabricated with the same process as in Ref. [23]. Chen and coworkers [10] included hinges in an actuator fabricated by metal MUMP (multiuser MEMS process), allowing the actuator arms of a prototype gripper to bend controllably in plane as well as out of plane (see Fig. 9b). While this particular design is not easily scaled toward nanoscale manipulation, the use of a standard planar MEMS process to integrate hinges into actuator structures and thereby achieve out-of-plane actuation is relevant. Angular alignment of end effectors for optimal interaction with nonspherical objects is a tedious and difficult task. By placing the hinges closer to the end effectors, the angle of the end effector could be changed without large translational shifts, thus increasing the versatility of the gripper.

Shape Memory Alloys (SMAs)

SMAs are alloys that upon heating recovers the original shape given by annealing at a high temperature, even after severe deformation at low temperature. While SMAs can produce a very high energy density (up to 10 MJ/m^{-3}) compared to other materials ([29], #19552), the memory effect is a one-way actuation process; an actuator needs external forces to deform with respect to the memory state. Also, SMAs are difficult to fabricate with small dimensions. Zakharov

Nanogrippers, Fig. 9 (**a**) Two-axis topology-optimized electrothermal gripper, with Vx and Vy indicating the terminals for actuation in the x and y direction, respectively. The length of the microgripper is 200 µm (Courtesy of Özlem Sardan and Mikkel Klarskov. (**b**) Two-axis microgripper with out-of-plane bending of the individual arms, incorporated by bending flexures (electrothermally actuated) [11]. (**c**) Shape memory alloy actuator demonstration showing significant actuation range compared to the length of the actuator [30]. (**d**) Built-in stress during fabrication allows small gripper structures equipped with hinges to fold and capture living blood cells upon release from surface [19]

et al. constructed a composite bimorph actuator with a $Ti_{50}Ni_{25}Cu_{25}$ SMA for generating closing motion of a dual end effector and a Pt layer for generating the stress that recovers the "open" state, as shown in Fig. 9c. The structure was milled out by focused ion beam milling. Provided the issues concerning machining and shaping SMAs with high precision are addressed, such materials could be used to generate high forces in compact end effectors.

Origami/Folding Grippers

The philosophy of producing independent end effectors with a built-in compact actuation mechanism is taken a step further in nano-origami. Nano- and microgrippers were fabricated by layering metals, silicon, and polymers, where a combination of built-in, temperature-dependent stresses and well-placed hinges allows the structure to fold and capture a target object in a handlike motion [18]. These structures are nearly

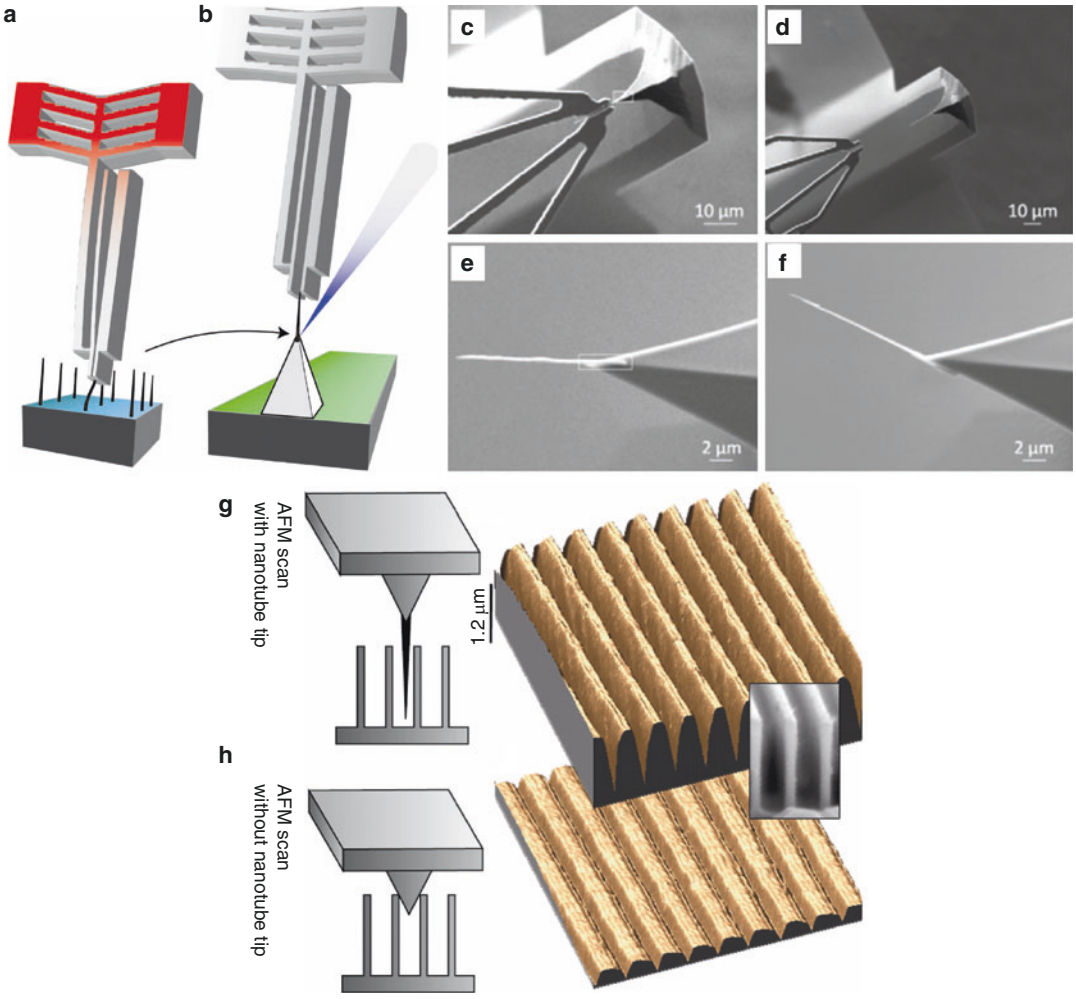
mm sized but provide predictable closing of the jaws from thermal or biochemical stimuli. As a nickel layer is integrated in the structure, they could even be manipulated with a magnetic field, allowing tetherless object retrieval and transport. A similar but simpler and much smaller design with 10–70 μm gripper arm [19] could catch individual living blood cells (see Fig. 9d). With this design the built-in stress during deposition causes the grippers to close once released from the substrate, which was done with a timed chemical process.

While these studies are clearly far from high-precision nanomanipulation, the intriguing prospect of a compact, reversible three-dimensional gripping suggests that this may be developed in the future. Applications have so far been within liquid-phase environment (life science); however, it is quite possible that similar principles could become feasible in a nanogripper operating in dry or vacuum environment, provided an approach to reversible open and close operations is developed.

Applications

In terms of nanomanipulation, the objects of interest may be small in either one, two, or three directions, i.e., plates, wires, or particles, and this makes quite a difference in terms of how they can be handled and with which tools. In the following the feasibility and optimal strategy of manipulating such objects will be discussed in the light of possible applications.

Quasi-0D Structures: Particles



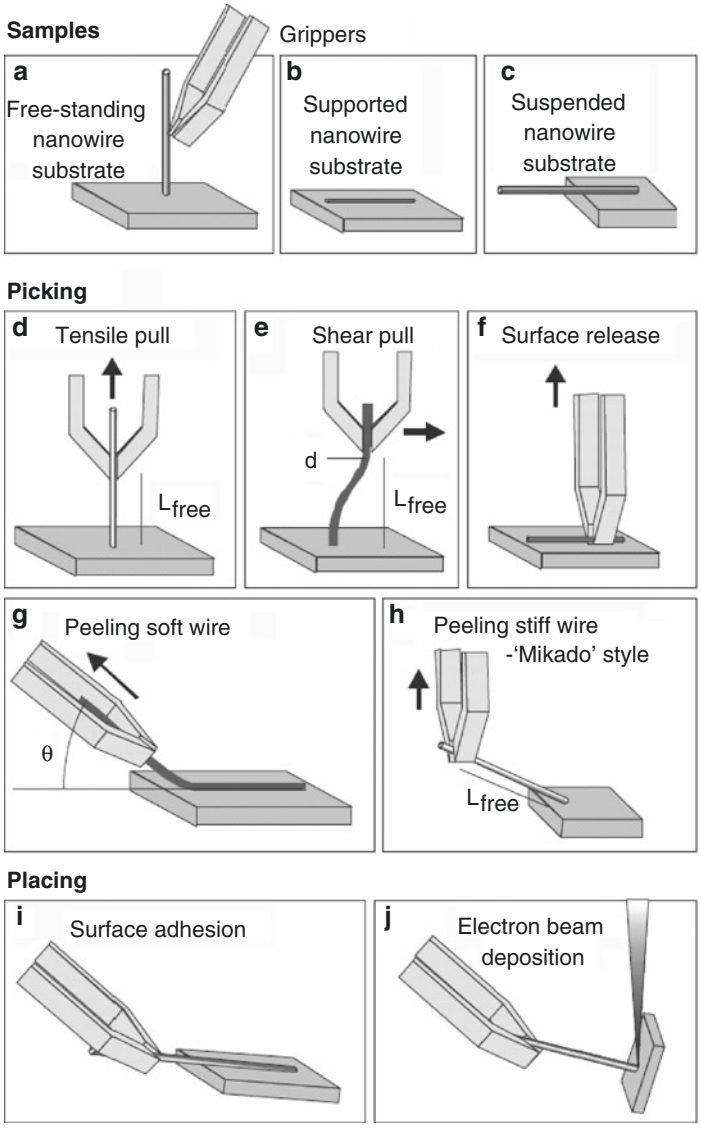
There are a few example pickups of submicron particles to demonstrate the capability of a nanogripper [1, 14]. Such manipulation can also be combined with electrical characterization of an object if the end effectors are conducting, such as carbon nanotubes [14]. For the manipulation process itself, a simple tip will in most cases be effective for particles as numerous pick-and-place experiments using scanning probe tips have. Submicron and nanoscale particles will in the majority of practical scenarios be notoriously difficult to pick up using a gripper, either because the gripper force is too weak to overcome the surface forces or too bulky to access the particle in a predictable way. This situation is comparable to lifting up grains of sand using fingers, which is possible but hardly convenient. While microgrippers [19] and other types of micromanipulators [27] have shown clear potential for handling and analyzing of biological particles down to the size of red blood cells, it is doubtful that mechanical nanogrippers will play an important role in applications involving manipulation of nanoparticles in the foreseeable future.

Quasi-1D Structures: Fibers, Wires, and Tubes

Just as for the macroscale, the most obvious and convenient object to handle with a gripper or a pair of tweezers is a quasi-one-dimensional object, such as a carbon nanotube. The oblong shape of the object makes access far easier than for nanoparticles, with excellent visibility as the nanowires/nanotube does not block the vision. Moreover, the fact that the free end of the nanowires or nanotube can easily be positioned and even by electron beam-induced deposition (EBiD) of focused ion beam deposition provides a straightforward and reliable pick-and-place process, which can even be automatized [13]. Manipulation of nanowires/nanotubes falls in two categories:

(i) Investigation of the mechanical, electrical, or structural properties of individual nanowires/nanotubes. The mechanical properties of nanostructures can be measured by inferring the gripping force from the visible deformation of the nanogripper upon contact, given that the spring constant is known, or by using sensors integrated in the gripping device [15]. The electrical properties can be measured if the end effectors are conducting [8, 14] or if the nanostructure is placed onto electrodes [23]. The structural properties can be measured by transporting the nanostructure to a transmission electron microscope [8] or onto a TEM grid [23].

(ii) Direct application of the nanostructure to perform a function in a device. Microfabricated electrothermal grippers were used in a



Nanogrippers, Fig. 10 (**a**–**b**) Illustration of pick and place of vertically aligned multiwalled carbon nanotubes from their as-grown position to the tip of a scanning probe tip, where the *blue triangle* illustrates the electron beam-induced deposition used to fasten the nanotube to the probe. semiautomated assembly procedure [23] to first break off multiwalled carbon nanotubes from their as-grown position on a substrate, transport and align them to an atomic force probe, and finally hold them in place, while electron beam-induced deposition was used to fasten the nanotube to the probe.

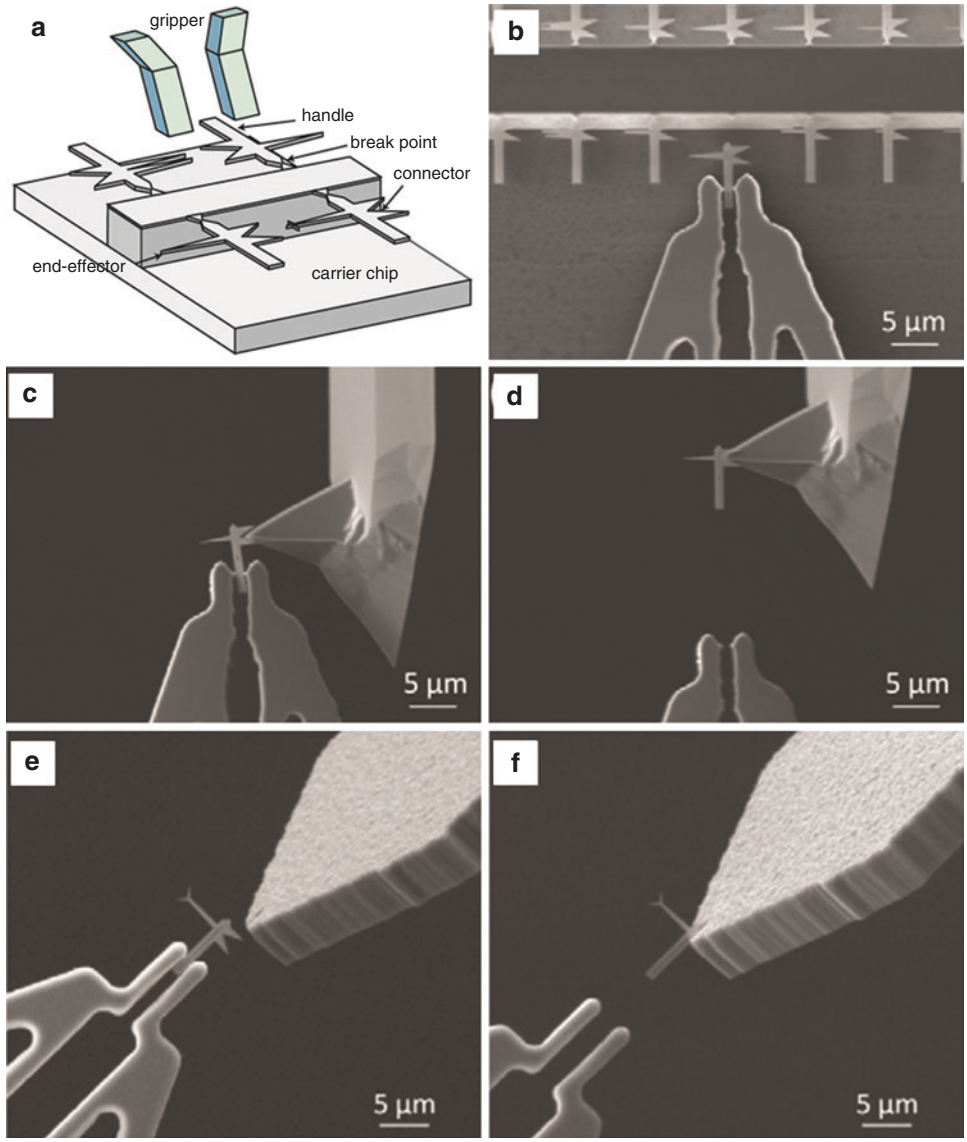
Figure 10a, b illustrates the basic procedure and the device during (11c) and after (11d) mounting of carbon nanotube is shown as scanning electron images. (11e) and (11f) show two configurations with different angles of the carbon nanotube tip, and (g) and (h) shows AFM scans of 2.5 µm-deep microfabricated trenches with and without the carbon nanotube supertip attached to the AFM probe. The trenches are well resolved by the supertip-enhanced AFM probe.



Detaching nanorods from a fixed position using a nanogripper is a nontrivial problem. Mølhave [21] divided the possible arrangements of nanorods on a surface into freestanding,

Nanogrippers, Fig. 11 (**a**–**c**) Initial configurations of rodlike nanostructures. Picking strategies: (**d**) tensile pull, (**e**) shear pull, and (**f**) surface release and (**g**) peeling of soft wire and (**h**) peeling of rigid wire. Strategies for placing using either (**i**) surface adhesion or (**j**) electron beam-induced deposition (EBiD) [21]

supported and (partly) suspended initial states, and compared different pick-and-place strategies for such structures. Cartridges of carbon nanotubes suspended from a razor sharp knife edge were used by [1] to assemble the nanotubes on scanning probe tips to be used as nanotweezers.

Freestanding nanowires and nanotubes are very convenient objects for manipulation: they can be catalytically grown with great uniformity and in large numbers using physical or chemical vapor deposition techniques, with positions and diameter determined by pre-positioned catalytic particles. Thus, it is straightforward to produce large arrays of accessible nanostructures, with well-controlled dimensions, position, and physical properties. The deterministic nature of such a periodic arrangement directly facilitates automation. Detachment of as-grown structures, however, requires a considerably larger force as the often very high maximal strength must be overcome. Mølhave considered mainly two approaches to detach freestanding 1D nanostructures: tensile pull along the longitudinal

Nanogrippers, Fig. 12 (**a**) Illustration of the "nanobit" concept (**b**) arrays of premade scanning probe tips fabricated with electron beam lithography, with a single "nanobit" being detached using a nanogripper. (**c**) Mounting of nanobits onto AFM scanning probe tip. (**d**) The nanobit-enhanced scanning probe ready to scan. (**e**) A sidetip-equipped nanobit tip mounted in a focused ion beam slit in an AFM scanning probe. (**f**) [16]

axis of the nanorod and shear pull in the perpendicular direction with respect to the substrate (sideways). In practical experiments as well as finite element calculations by Andersen et al. [3], it turned out that shear pulling is far the most effective strategy for multiwalled carbon nanotubes. A range of principal sample configurations and gripper operations are shown in Fig. 11.

Quasi-2D Structures: Flakes, Membranes, and Slices

Microgrippers can be used to manipulate thin slices of material, which has been cut out by

focused ion beam milling, onto a transmission electron grid for inspection of the cross-sectional structure. Although the thickness of such slices is often just of order of hundred nanometers to allow transmission of electrons through the slice, the grippers do not have to be particularly small for this task; in fact, a considerable force may be required to detach the TEM samples from their support. Nanogrippers might be envisioned for manipulation of very small flakes of material onto TEM grids or for other plate- or flake-like nanostructures. Kumar and coworkers [16] demonstrated predictable pick and place of nanoscale flake-like scanning probe supertips as shown in Fig. 12. These detachable, 130 nm-thin silicon nitride membrane tips, termed "nanobits," were defined by electron beam lithography and arranged in large reservoirs for convenient access. The most successful strategy for picking up these objects turned out to be grasping at the edges of the flakes with the gripper and breaking the tips off with a sideways motion (see Fig. 12), similar to the strategy used to detach as-grown carbon nanotubes [9]. In these experiments, several nanobits were mounted on AFM tips and used for scanning of deep trenches and sidewalls, showing considerable improvement over conventional AFM probes.

Non-manipulative Applications

Even when not actuated mechanically, nanogrippers provide two individual fingers with a narrow spacing, which can easily be made conductive. This has shown to be convenient for a number of tasks that are not themselves mechanical manipulation including "grasping" nanostructures through dielectrophoresis (Yamahata et al. 2008), electrical characterization ([8, 14, 23]; Yamahata et al. 2008), transporting nanostructures into a TEM for structural analysis, and in situ experiments [8] as well as alternatively placing nanostructures on a TEM grid for analysis. Nanostructures with diameters in the 10 nm range are exceedingly difficult to manipulate through mechanically actuation of dual end effectors.

Conclusion

Despite recent progress in gripper technology as well as robotic manipulation systems, reliable operation of nanogrippers still remains a challenge. The necessity of real-time observation of the mechanical interactions on the nanoscale and surface forces, as well as the difficulty in creating gripper devices small enough to handle sub-100 nm structures, is limiting the transition from literature's numerous proposed nanogripper concepts to devices that sustain practical applications. All in all, state-of-the-art nanogrippers are highly useful tools for basic nanomaterial research, in addition to providing a shortened turnaround time for single device prototyping and perhaps even small-scale production of specialized nanodevices, which involves nanostructures in the 10–1000 nm range.

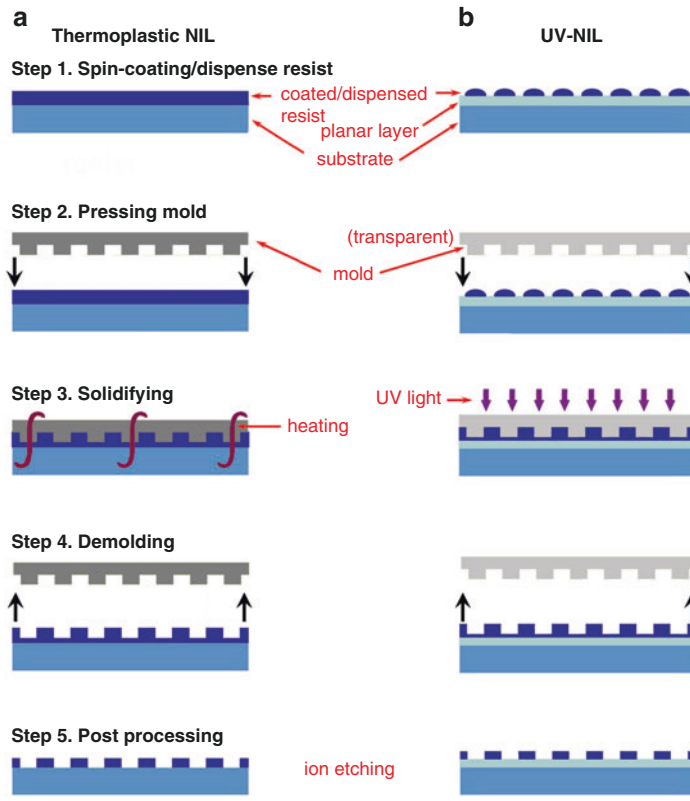
Nanoimprint lithography

Definition

Nanoimprinting is a type of lithographic technology that provides a simple and efficient approach of patterning various nanostructures with sub-10-nm resolution.

Overview

Nanoimprinting can promise state-of-the-art smaller electronics. Although nanoimprint lithography (NIL) is not yet an industrial process with well-established standard, extensive interests in NIL processes come from a large community of sensor, biochip, and nano-optics manufactures and institutes [1]. Nanoimprinting has received increased research motivation due to its ability to create smaller functional device structures such as nanoscale transistors, single-electron memory, nanofluidic channels, etc., via an accurate and efficient nanolithography process [2].



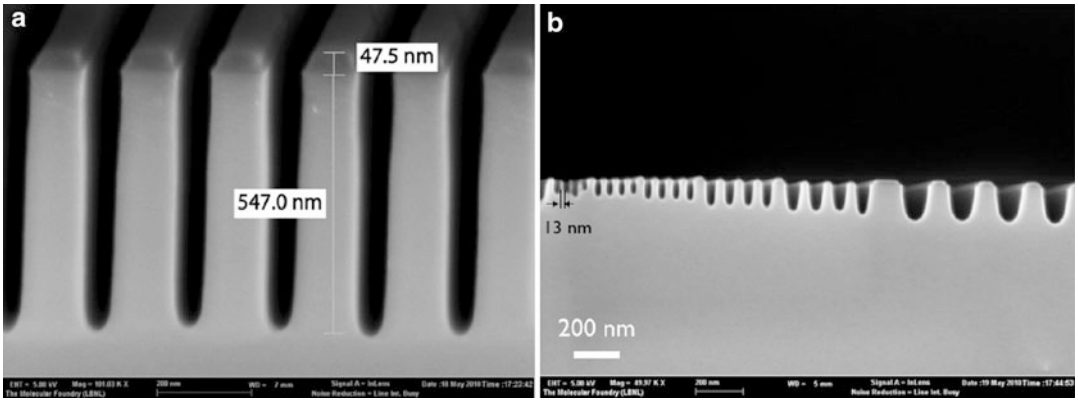
NIL is very similar to conventional hot embossing, which is based on stamping of a pattern into a polymer softened by raising the temperature of the polymer just above its glass transition temperature. The hot embossing stamp can be made in a variety of ways including micromachining from silicon, LIGA (a German acronym for Lithographie (lithography), Galvanoformung (electroplating), Abformung (molding)), and machining using a CNC (computer numerical control) tool (for making large features). A wide variety of polymers have been successfully hot embossed with submicron size features, including PC (polycarbonate) and PMMA (polymethylmethacrylate).

In the current encyclopedia, a general introduction about NIL process, the involved materials such as resist and mold (template), as well as NIL manufacturers are presented. The detailed and intensive discussions about NIL are lucubrated in the related review papers [3, 4].

Key Concepts

Nanoimprinting Process

NIL, i.e., thermal NIL process, was first reported by Chou S. et al. from the University of Minnesota in 1995 [5, 6]. Subsequently, Haisma J. et al. from Philips Research laboratories developed photo-NIL, i.e., UV-NIL process [7]. The processes of NIL mainly involves the following steps: spin-coating or dispensing resist (polymer or monomer) on the substrate, pressing resist layer with



Nanoimprinting, Fig. 1 Schematic of typical (**a**) thermal NIL and (**b**) UV-NIL process

patterned mold, solidifying patterned resist by heating or UV exposure, separating mold (demolding), and post-processing. The schematic drawing of the NIL fabrication process is shown in Fig. 1. Briefly, a resist with thermoplastic or photosensitive characteristic is first spin-coated or dispensed on a wafer substrate. As for photo-NIL process, there is a predeposited planar layer on the substrate. Then, a hard mold containing nanometer-scale surface-relief features is pressed into the above thin resist cast. Note that a transparent mold is requested in the UV-NIL. As shown in Fig. 1 (Step 2 and 3), the mold protrusions are squeezed into the soft resist layer. After the treatment of heating or UV exposure, the patterns of mold are solidified inside the resist. The mold is then removed from the imprinted resist layer, i.e., demolding process. The desired nanostructured patterns in the residual layer are obtained after the appropriate pattern definition process using ion etching posttreatment.

The NIL process is suitable for fabricating various nanodevices, whose basic components can be prepared through traditional UV-NIL process. Figure 2 shows examples of patterns transferred into silicon [8]. The residual nanostructure layer with an aspect ratio greater than six is obtained after reactive ion etching (as depicted in Fig. 2a). Maintaining the fidelity of the resist mask by controlling the residual layer thickness allows transfer features down to 13 nm as shown in Fig. 2b. These various nanostructures offer basic units to fabricate photonics or other functional nanodevices at low cost and high throughput.

Nanoimprinting Resist

The resist materials used in imprinting should be able to deform easily under an applied pressure and have sufficient mechanical strength. The resist should also have good mold-releasing properties to maintain their structural integrity during

Nanoimprinting, Fig. 2 SEM pictures of imprinted gratings after transfer into silicon wafers. (**a**) 90-nm-linewidth gratings with 547-nm-depth into silicon and 47.5-nm-thick UV-NIL resist remaining after the etching steps. (**b**) Grating with variable pitch/linewidth. The minimum feature size is 13 nm with an etching depth of around 50 nm [8]

the demolding process since imprint lithography makes a conformal replica of the surface-relief patterns by mechanical embossing.

Thermoplastic Resist Materials

The thermoplastic polymers such as PMMA and PS (polystyrene) can be easily deposited on the substrate with desired thicknesses by spin-coating process. These polymers are usually used as imprint resists in thermal NIL. The glass transition temperature (T_g) of the polymer is a key parameter for the determination of the solidifying treatment temperature in thermal molding processes. Typically a suitable imprint temperature is chosen 70–90 °C above the resist's T_g, so that the polymer materials reach a viscous flow state. In order to preserve the imprinted pattern, the mold and the imprinted resist must be cooled down to below T_g. In addition, there is a trade-off between the imprinting temperature and the thermal stability, which indicates that although a low-T_g material can be used in NIL for the sake of reducing the processing temperature, the imprinted patterns are also unstable and tend to deform at temperatures close to the imprinting temperature.

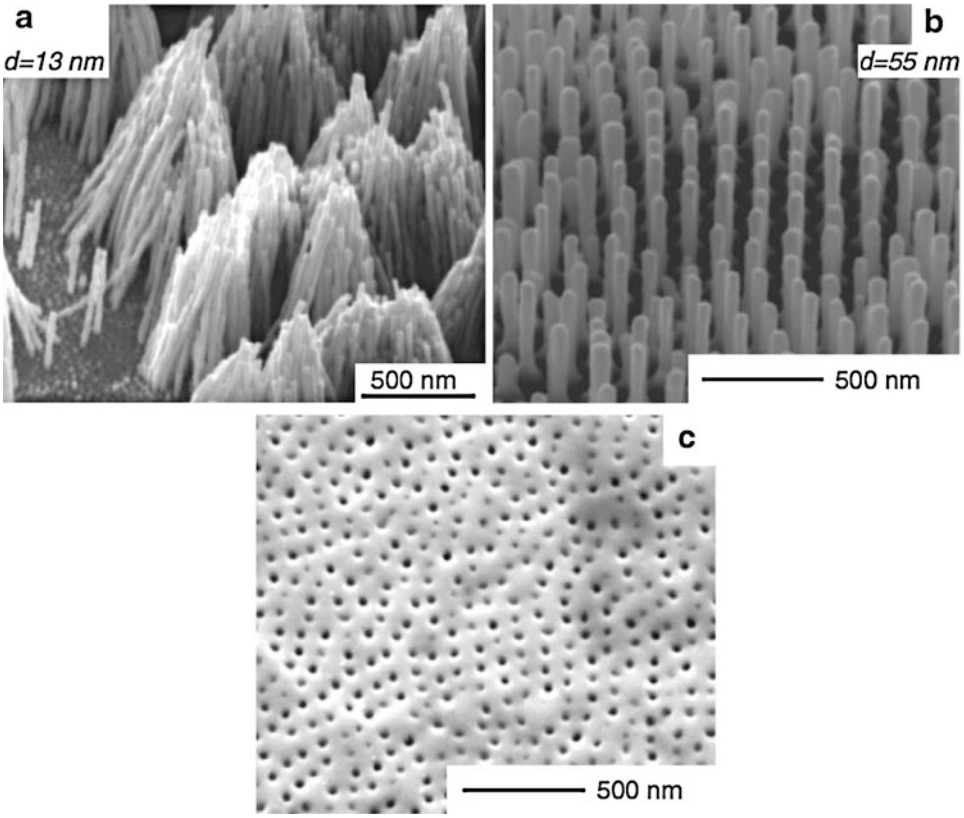
In a NIL process, the polymers also need to have a sufficiently low viscosity for efficient squeeze to complete the imprinting process within a practical time frame [9]. The viscosity of a polymer material not only depends on the temperature, but also depends strongly on the polymer's molecular weight (M_w) relative to the so-called critical molecular weight (M_c) of a given polymer. The M_c can be interpreted as the molecular weight at which a temporary network of entanglements spans over macroscopic dimensions. In practice, low-molecular-weight polymers with $M_w < M_c$ can be imprinted at lower temperatures, lower pressures, or within shorter times. Therefore, the choices of T_g and M_w are both important in maintaining the structural stability of the imprinted patterns.

Various alternatives have been exploited to lower the viscosity of thermoplastic materials. These include dissolving the polymer in its monomer [10] or another solvent and using a PDMS (polydimethylsiloxane) stamp for solvent evaporation [11]. It is inferred that thermally curable or thermosetting polymers are excellent resist for NIL because of the possibility of low-pressure imprinting and good mechanical integrity after cross-linking by thermal treatment.

UV-NIL Resist Materials

Different from thermoplastic materials requiring high temperature and pressures, photo-NIL (UV-NIL) materials can be handled at ambient temperatures. UV-curable NIL materials are composed of a mixture of monomers or prepolymers and a suitable photoinitiator, and often chemicals are added which decrease the effect of radical scavengers on photopolymerization [12].

The monomer fluid with low Young's modulus and low viscosity is less sensitive to the effects of pattern density in imprinting process, which allows the use of a small-area mold and the patterning of large-area substrate by a step-and-repeat process. Immediately during contact of the stamp with the liquid mixture, filling of the mold starts by capillary forces, which pulls the stamp toward the substrate. Therefore, the general strategy is as follows: Low viscosities are needed both for rapid dispensing and filling of mold cavities. Thin resin layers on top of a thicker transfer layer are used to achieve a homogeneous film thickness. Cross-linking and photopolymer conversion are adapted to achieve high curing speed and high etch resistance in the following breakthrough plasma etching process. Shrinkage and etching rate need to be controlled for optimum pattern transfer. Often trade-offs are needed to achieve a good balance between good physicochemical properties wetting and curing kinetics and the suitability for the NIL process [13]. For specific applications such as the dual damascene process for the structuring of interconnects on microchips, resists with adapted dielectric properties have been developed [14].



It should be recognized that NIL cannot only be used to form patterns in a polymer resist but can also be extended to create desired structures in many other polymer systems, especially those that have special functionalities, or can be used to form functional polymer device structures directly.

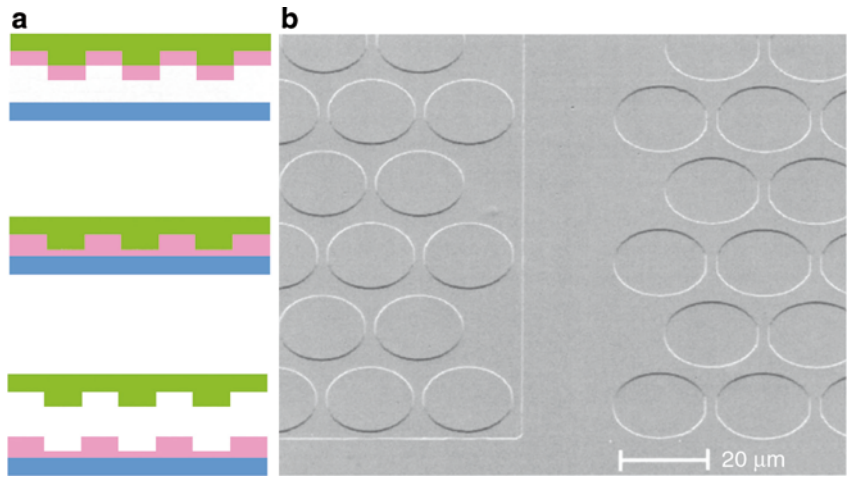
Nanoimprinting Mold

The mold in the nanoimprint technique plays the same role as the photomask in photolithography. The mold used in NIL can essentially be any type of solid material that has a high strength and durability, which can be made of metals, dielectrics, or semiconductors. Various hard materials such as Si, SiO_2, SiC, silicon nitride, and sapphire are suitable for imprinting molds [15]. Diamond is also investigated as a potential mold material for NIL [16]. These studies showed that Si and SiO_2 have sufficient hardness and durability for the nanoimprint application, which make themselves a very good pair for the NIL process. In addition, the UV transparent properties are essential for mold materials of UV-NIL, which render UV light pass through mold itself and irradiate the resist layer.

After spin-coated with a resist, the mold materials are patterned with various features using UV lithography, interference lithography, and electron beam lithography depending on the size requirements. A minimum lateral feature size can be obtained using electron beam lithography; interference lithography is fitted for large-area periodic features while UV lithography for microscale and larger features. Then, a hard masking layer, such as a metal, can be deposited over the patterned resist template, followed by a lift-off process that removes the resist template and the material on top, leaving a patterned mask layer on the substrate. Lastly reactive ion etching process is used to selectively etch away the mold materials in the unmasked area and produce surface-relief features required for NIL.

Silicon-based molds are expensive to make and are not very durable. Schroers J. et al. at Yale University developed the nanopatterning of amorphous metals which can be used as inexpensive templates for nanoimprinting [17]. These bulk metallic glasses (BMGs) could be ideal materials for small-scale applications due to their superior mechanical and homogenous properties. There molds with features as small as 13 nm can be used to imprint onto polymers and other materials. Figure 3 shows SEM images of Pt-BMG nanorods with 13-nm (Fig. 3a) and 55-nm (Fig. 3b) diameters fabricated by embossing on porous alumina. The Pt-BMG substrate with nanorods was pressed into a PMMA sheet at 160 °C. Figure 3c shows an SEM image of 55-nm-diameter holes imprinted in Pt-BMG using the crystallized Pt-BMG mold. The results demonstrate the ability of metallic glasses to precisely replicate mold features ranging from 250 to 13 nm. The two attractive features of metallic glass molding – the ability to replicate features from tens of micrometers down to 13 nm and the possibility of using BMGs as nanotemplates – stem directly from the unique softening behavior and homogeneous structure of metallic glasses.

Nanoimprinting, Fig. 3 SEM images of (**a**) Pt-BMG mold with 13-nm-diameter rods fabricated by embossing on porous alumina; (**b**) Pt-BMG mold with 55-nm-diameter rods; (**c**) The Pt-BMG mold, after crystallization, imprints holes into the same Pt-BMG [17]



Variation of Nanoimprinting

Some innovative processes such as roller-type NIL, combined thermal/UV-NIL, and reverse tone NIL are developed to meet various requirement, which make conventional NIL more flexible and practicable.

Conventional NIL process cannot significantly improve the throughput in the patterning of large-area product with low cost because it is not a continuous process. To overcome this problem, a continuous roller-type NIL is proposed and developed. In roller-type NIL process, only the adjacency area of contact line is pressed for a given time, significantly reducing the printing force and providing better uniformity [18]. Jacob J. et al. demonstrated that large-area high-speed continuous roll-to-roll nanoimprinting of 1D and 2D micron to sub-100 nm features on flexible substrate using perfluoropolyether composite molds on a custom designed roll-to-roll nanoimprinter [19].

Combined thermal/UV-NIL can address the issue of replicating patterns with various sizes and complexity by the separate lithography steps [20]. Sole NIL process experiences difficulties in replicating larger features or resulting in incomplete pattern.

In order to obtain nanosized patterns on the flexible substrate, such as polymer membrane, a reversal imprinting technique was developed [21]. Different from conventional NIL process, a resist layer is first spin-coated on a patterned hard mold and then transferred to a substrate under an elevated temperature and pressure (as shown in Fig. 4a). The reverse NIL process can be accomplished under different pattern transfer modes by controlling imprinting temperature and degree of surface planarization of the spin-coated mold.

Nanoimprinting, Fig. 4 (**a**) Schematic illustrations of the pattern transfer processes in reversal nanoimprinting at temperatures well above the glass transition temperature; (**b**) patterns in PMMA created by reversal imprinting at 175 °C on a 50-mm-thick Kapton film: 190-nm-deep micrometer-sized mold coated with a 7 % solution [21]

Figure 4b shows PMMA patterns created by reversal imprinting at 175 °C after spin-coating the mold with 190-nm-deep micrometer-sized features.

In addition, recently a die nanoimprinting technique has been developed, which can effectively enhance the stress uniformity within the supercooled liquid of glassy alloys [22]. By employing the technique, large-area amorphous metallic nanowire arrays with nanowire diameter of about 55 nm and uniform length around 650 nm have been prepared.

Main Manufacturers for Nanoimprinting

The NIL machines are very important for the development and applications of NIL technology. In this review, the most famous manufactures in the world are listed. The general information about these enterprises are excerpted from their homepage, and more details can be referred to corresponding website, which are attached in the last sentence of every paragraph.

AMO

AMO, i.e., Gesellschaft für Angewandte Mikro- und Optoelektronik mbH, is an important enterprise in the area of nanofabrication. AMO supports customers with focused research and development, prototyping, and contract manufacturing. AMO offers the entire infrastructure required for nanofabrication for semiconductor-based applications and related technologies. Nanofabrication, nanoelectronics, nanophotonics, and biotechnology are AMO's competences. AMO is a research service provider for nanofabrication, a pathfinder for your exceptional demands. For more information, readers can visit the website of AMO: http://www.amo.de.

EV

EV Group (EVG) is a leading supplier of wafer bonding and lithography equipment for the MEMS, nanotechnology, and semiconductor markets. EVG devotes to be the first in exploring new techniques and serving next-generation applications of micro- and nanofabrication technologies. The basis for EVG's success is their products: lithography, bonding, and imprint systems. EVG holds the dominant share of the market for all types of wafer bonding equipment and is the market and technology leader in lithography and nanoimprinting. The official website of EV is http://www.evgroup.com.

NLS

Nanolithosolutions (NLS) Inc. empowers researchers and technology developers through their easy-to-use nanolithography platform to develop next generation of nanotechnology applications. NLS provides complete turnkey solution for nanolithography applications. The product offering includes nanofabrication equipments, all the necessary chemicals and materials, imprinting mold preparation process and imprint fabrication process, and custom process development services. The website of NLS Inc. is http://www.nanolithosolution.com.

MII

Molecular Imprints Inc. (MII) is the market and technology leader for nanopatterning systems and solutions and uses its innovative Jet and Flash™ Imprint Lithography (J-FIL™) technology to provide high-resolution, low-cost-of-ownership nanopatterning capability for flat panel display, hard disk drive industries, light-emitting diodes, life science, and other high tech industries. J-FIL™ has further application in emerging light-emitting diodes (LED), solar energy, and biotechnology markets. Http://www.molecularimprints.com is the website of MII.

Nanonex

Nanonex was founded in 1999 by Stephen Y. Chou, a Professor of Princeton University and a renowned pioneer in nanotechnology. The mission of Nanonex is to deliver, today, user-friendly NIL tools and solutions to a broad spectrum of markets and to both experts and nonexperts of microfabrication. Nanonex products include NIL tools, resists, masks, and processes for a variety of NIL including thermal and photo-curable NIL, as well as direct imprinting of materials. Nanonex's current team consists of seasoned business and technical members from industry as well as the experts in nanoimprint technology and applications. The Nanonex solution makes a turnkey nanoimprint operation today a reality. The website of Nanonex is http://www.nanonex.com.

OAI

OAI is a Silicon Valley-based manufacturer of advanced precision equipment for the solar, photovoltaic, semiconductor, MEMS, and microfluidics industries. The company offers a broad portfolio of field-proven products that include mask aligners, UV exposure systems, UV light sources, solar simulators, I-V testers, and reference cells. The website of OAI is http://www.oainet.com.

Obducat

Obducat is the world-leading supplier of lithography solutions for manufacturing and replication of advanced micro- and nanoscale structures. Obducat provides viable and cost-effective lithography solutions that will give a competitive edge to the customers, enabling them to deliver breakthrough applications and achieve improved profitability and success. Obducat is the first company to commercialize NIL. Today it is the market leader with the largest installed base worldwide of NIL. The details about Obducat are shown in the website http://www.obducat.com.

SUSS MicroTec

SUSS MicroTec is a supplier of equipment and process solutions for microstructuring applications with more than 60 years of engineering experience. The solution portfolio covers a comprehensive range of products and solutions for backend lithography, wafer bonding, and photomask processing, complemented by micro-optical components. The website of SUSS MicroTec is http://www.suss.com.

Martini Tech

Martini Tech is a company specialized in micro- and nanofabrication based in Japan. Martini Tech offers the following services: NIL sample master mold and custom nanoimprint mold design and manufacturing, UV nanoimprint and hot embossing replica on polymer, MEMS design and development, MEMS foundry, patterned sapphire substrate manufacturing, MOCVD deposition of gallium nitride on sapphire substrates for LED applications, sputtering deposition, and other micro- and nano-manufacturing services.

The official website of Martini Tech is http://www.martini-tech.com.

Future Directions for Nanoimprinting

Nanoimprinting technique offers overwhelming advantages for nanoscale device fabrications, including low cost, resolution scalability, and pattern repeatability. The simplicity of NIL has made it appealing to researchers in various fields, such as next-generation HDD storage and future semiconductor devices. However, standard processes or criterions about NIL are not establish, which affect the NIL industrial application and development. In addition, the fabrications of high-quality templates with high-resolution periodic features are still key issues limiting the popularization of NIL. Despite all difficulties, a large community of researchers and enterprises, such as Molecular Imprints Inc. (MII) and AMO, are trying to establish standard NIL processes and develop significantly advanced materials and molds. Toshiba's most advanced production process for NAND flash memory available is 19 nm and will work with fab-tool maker Canon to develop 15-nm NAND chips with volume production slated for 2015. IBM also focused on understanding the basic physics and chemistry of the nanoimprint process, from initial resist dispense to removal of the template after cure, and use that knowledge to design optimum resist materials and interfacial surface treatments. In the near future, NIL will become a preferred and universal process in nanofabrication technology.

Definition

Nanoindentation refers to the experiment conducted using a depth-sensing indenter at the nanometer or sub-micrometer scale. The nanoindentation apparatus continuously monitors the load and the position of the indenter relative to the surface of the specimen (depth of an indent) during the indentation process. Sharp indenters can be used to measure hardness, elastic modulus, continuous stiffness, scratch resistance, film-substrate adhesion, residual stresses, time-dependent creep and relaxation properties, fracture toughness, and fatigue.

Overview

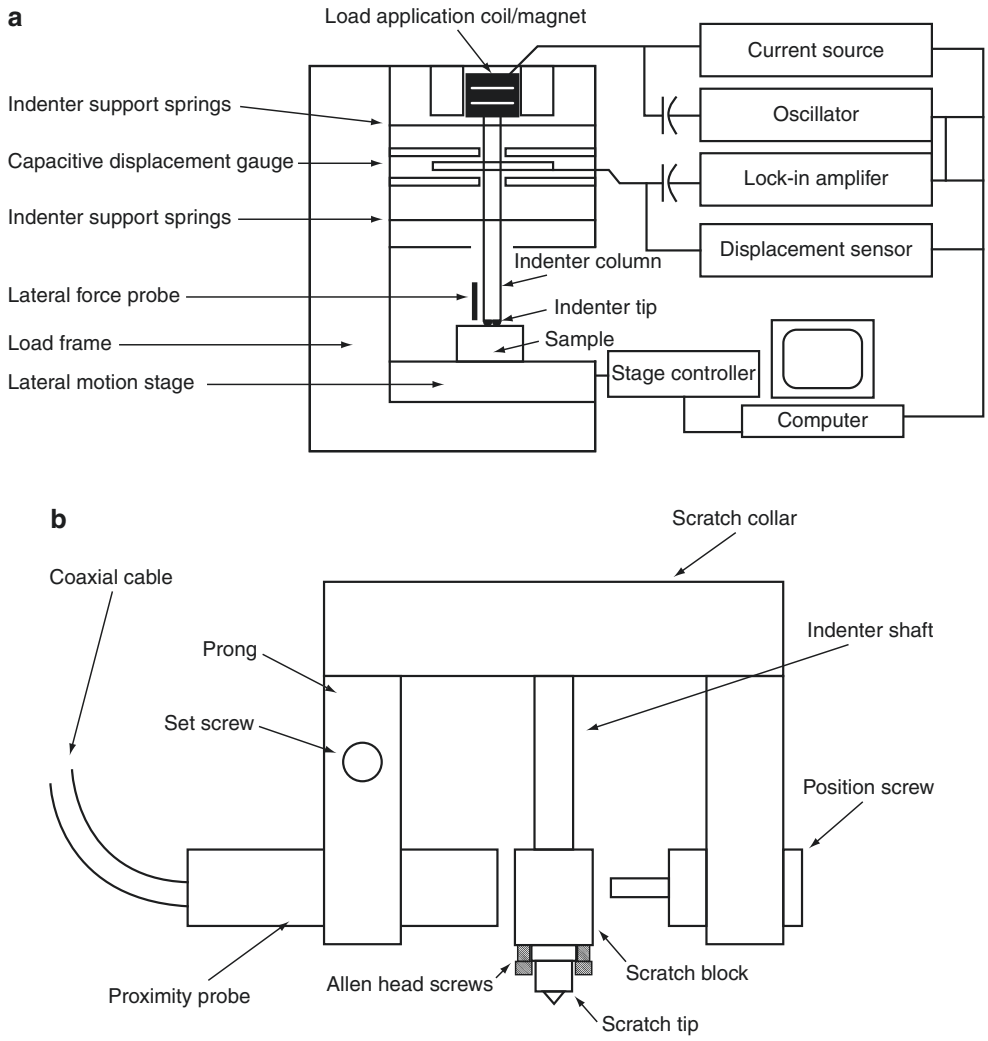
Mechanical properties of solid surfaces and thin films are of interest as the mechanical properties affect the tribological performance of surfaces [1–5]. Among the mechanical properties of interest, one or more of which can be obtained using commercial and specialized indentation testers, are elastic–plastic deformation behavior, hardness, Young's modulus of elasticity, scratch resistance, film-substrate adhesion, residual stresses, time-dependent creep and relaxation properties, fracture toughness, and fatigue. Indentation measurements can assess structural heterogeneities on and underneath the surface, such as diffusion gradients, precipitates, presence of buried layers, grain boundaries, and modification of surface composition. Physical contacts at sliding interfaces in magnetic storage devices and micro/nanoelectromechanical systems (MEMS/NEMS) occur at very low loads; thus, friction and wear of sliding surfaces is primarily controlled by the physical and chemical properties of a few surface atomic layers. In this entry, the applications of nanoindentation to nanotechnology will be illustrated for the digital micromirror device (DMD), probe-based ferroelectric information storage, and biological MEMS sensor devices.

Nanoindentation Apparatus

In the depth-sensing indentation instruments, the load-indentation depth is continuously monitored during the loading and unloading processes. Commercially available nanoindenters are made by various manufacturers, some of which include Agilent, Oak Ridge, TN; Hysitron, Minneapolis, MN; CSIRO, Lindfield, Australia; CSM Instruments SA, Neuchatel, Switzerland, and Micro Materials, Wrexham, UK.

An example of a common nanoindentation apparatus is the Nanoindenter XP, manufactured by Agilent. The apparatus continuously monitors the load and the position of the indenter relative to the surface of the specimen (depth of an indent) during the indentation process. The area of the indent is then calculated from knowledge of the geometry of the tip of the diamond indenter. Mechanical properties measurements can be made at a minimum penetration depth of about 20 nm (or a plastic depth of about 15 nm) [6]. Specifications and commonly used operating parameters for commercial nanoindenters are given in Table 1.

Nanoindentation, Table 1 Specification and commonly used operating parameters for a commercial NanoIndenter



Load range	
Standard heads	0–500 mN
High load head	0–10 N
Load resolution	
Standard head	±50 nN
High load head	±50 nN
Vertical displacement range	0–500 mm
Vertical displacement resolution	±0.05 nm
Typical approach rate	10 nm/s
Typical indentation load rate	10 % of peak load/s
Typical indentation displacement rate	10 % peak displacement/s
Optical microscope magnification	Up to 1,500 *x*
AFM objective magnification	Up to one million *x*
Spatial resolution of the X-Y-Z table	±400 nm in the *X* and *Y* directions
Area examined in a single series of indentations	150 × 150 mm
Minimum penetration depth	~20 nm
Continuous stiffness option	
Frequency range	10–150 Hz
Time constant	0.33 s
Smallest measurable distance	0.1 nm
Scratch and tangential force option	
Scratch velocity	Max. 100 mm/s with 20 points/mm
Tangential displacement range	2 mm
Tangential displacement resolution	100 nm
Tangential load resolution	10 mN
Minimum measurable tangential load	10 mN

The NanoIndenter XP consists of three major components: the indenter head, an optical/atomic force microscope, and an *x*-*y*-*z* motorized precision table for positioning and transporting the sample between the optical microscope and indenter, Fig. 1a. The load on the indenter is generated using a voice coil in permanent magnet assembly, attached to the top of the indenter (loading) column. The generated load is the vector product of the current through the coil and the magnetic field strength of the permanent magnet. (Other methods of load application are found in other instruments, e.g., electrostatic.) Two interchangeable indenter heads are available with a load range of 50–840 mN. The displacement of the indenter is measured using a three-plate capacitive displacement sensor. The indenter column is attached to the moving plate. Two outer plates are maintained at equal and opposite drive voltages. The output voltage of the center-pickup plate is uniquely related to the position of that plate in the capacitive gap. The displacement system is calibrated using a laser-interferometric calibration system. This plate-and-indenter assembly is supported by two leaf springs cut in such a fashion to have very low stiffness. The motion is damped by airflow around the central plate of the capacitor, which is attached to the loading column.

A diamond tip is attached at the bottom of the indenter rod. The indenter head assembly is rigidly attached to the "U" beam below which the *x*-*y*-*z* table rides, Fig. 1a. The optical microscope is also attached to the beam. The position of an indent on a specimen is selected using the optical microscope. The specimens are held on an *x*-*y*-*z* table whose position relative to the microscope or the indenter is controlled with a joystick. The spatial resolution of the position of the table in the *x*-*y* plane is ±250 nm and its position is observed on the computer screen. The nanoindenter is placed on a vibration-isolation table, and the entire apparatus is enclosed in a heavy wooden cabinet to ensure the thermal stability of the samples.

The Indenters

The main requirements for the indenter are high elastic modulus, no plastic deformation, low friction, smooth surface, and a well-defined geometry that is capable of making a well-defined indentation impression. The first four requirements are satisfied by choosing the diamond material for the tip. A well-defined perfect tip shape is difficult to achieve. Berkovich is a three-sided pyramid and provides a sharply pointed tip compared with the Vickers or Knoop indenters, which are four-sided pyramids and have a slight offset (0.5–1 mm) [6]. Because any three nonparallel planes intersect at a single point, it is relatively easy to grind a

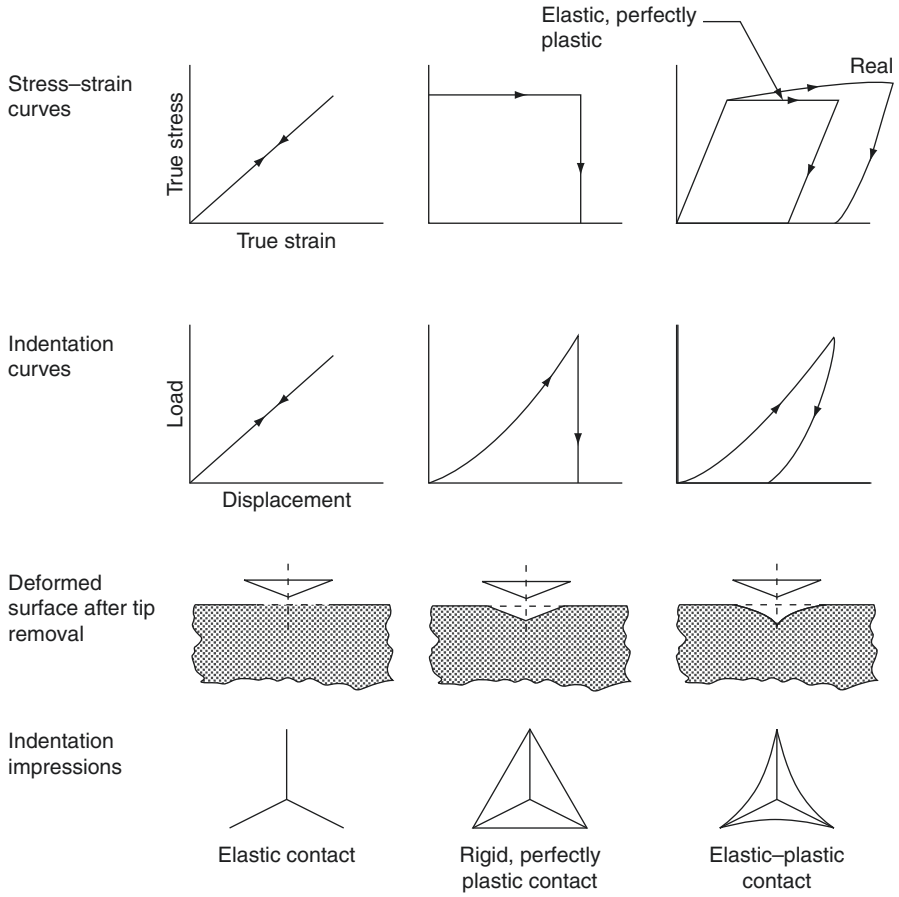
Nanoindentation, Fig. 1 Schematics of the nanoindenter XP (**a**) showing the major components – the indenter head, a *X-Y-Z* motorized precision table, and tangential force option, and (**b**) detailed schematic of the tangential force option hardware (not to scale and the front and rear prongs not shown)

sharp tip on an indenter if Berkovich geometry is used. However, an indenter with a sharp tip suffers from a finite but an exceptionally difficult-to-measure tip bluntness. In addition, pointed indenters produce a virtually constant plastic strain impression and there is the additional problem of assessing the elastic modulus from the continuously varying unloading slope. Spherical indentation overcomes many of the problems associated with pointed indenters. With a spherical indenter, one is able to follow the transition from elastic to plastic behavior and thereby define the yield stress [6]. However, a sharper tip is desirable, especially for extremely thin films requiring shallow indentation. Therefore, the Berkovich indenter is most commonly used for measurements of nanomechanical properties.

The Berkovich indenter, directly brazed to a 304 stainless steel holder, is a three-sided (triangular-based) pyramidal diamond, with a nominal angle of 65.3° between the (side) face and the normal to the base at apex, an angle of 76.9° between edge and normal, and with a radius of the tip less than 0.1 μm.

Another three-sided pyramidal indenter, the cube corner indenter, can displace more than three times the volume of the Berkovich indenter at the same load, thereby producing much higher stresses and strains in the vicinity of the contact and reducing the cracking threshold. This makes this indenter ideal for the estimation of fracture toughness at relatively small scales. The spherical indenter initiates elastic contact and then causes elastic–plastic contact at higher loads, and is well suited for the examination of yielding and work hardening.

Nanoscratch and Lateral Force Measurements



The nanoscratch and lateral force option which allows making of the scratches of various lengths at programmable loads is described here. Lateral (friction) forces can also be measured simultaneously. The additional hardware for the lateral force option includes a set of proximity (capacitance) probes for measurement of lateral displacement or force in the two lateral directions along x and y, and a special "scratch collar" which mounts around the indenter shaft with hardness indenter, Fig. 1b. A scratch block is mounted on the end of the indenter shaft, in line with the proximity probes and the positioning screws. The scratch tip is attached to the scratch block with two Allen head screws. The scratch tip can be a Berkovich indenter or a conventional conical diamond tip with a tip radius of about 1–5 mm and an included angle of 60–90° (typically 1 μm of tip radius with 60° of included angle). A larger included angle of 90° may be desirable for a more durable tip. The tip radius should not be very small because it will get blunt readily [7].

During scratching, a load is applied up to a specified indentation load or up to a specified indentation depth, and the lateral motion of the sample is measured. In addition, of course, load and indentation depth are monitored. Scratches can be made either at the constant load or at ramp-up load. Measurement of lateral force allows the calculations of the coefficient of friction during scratching. As an example, for the Nanoindenter XP, the resolution of the proximity probe provides resolution of lateral force of about 2 mN; therefore, a minimum load of about 20 mN can be measured. Consequently, a minimum normal load of about 0.2 mN should be used for a sample with coefficient of friction of about 0.1 using the Nanoindenter XP. Microscopy of the scratch produced at ramp-up load allows the measurement of critical load required to break up of the film (if any) and scratch width and general observations of scratch morphology. Typically, draw acceleration (mm/s^2), and draw velocity (mm/s) are 10 mm/s^2 and 5 mm/s, respectively.

Analysis of Indentation Data

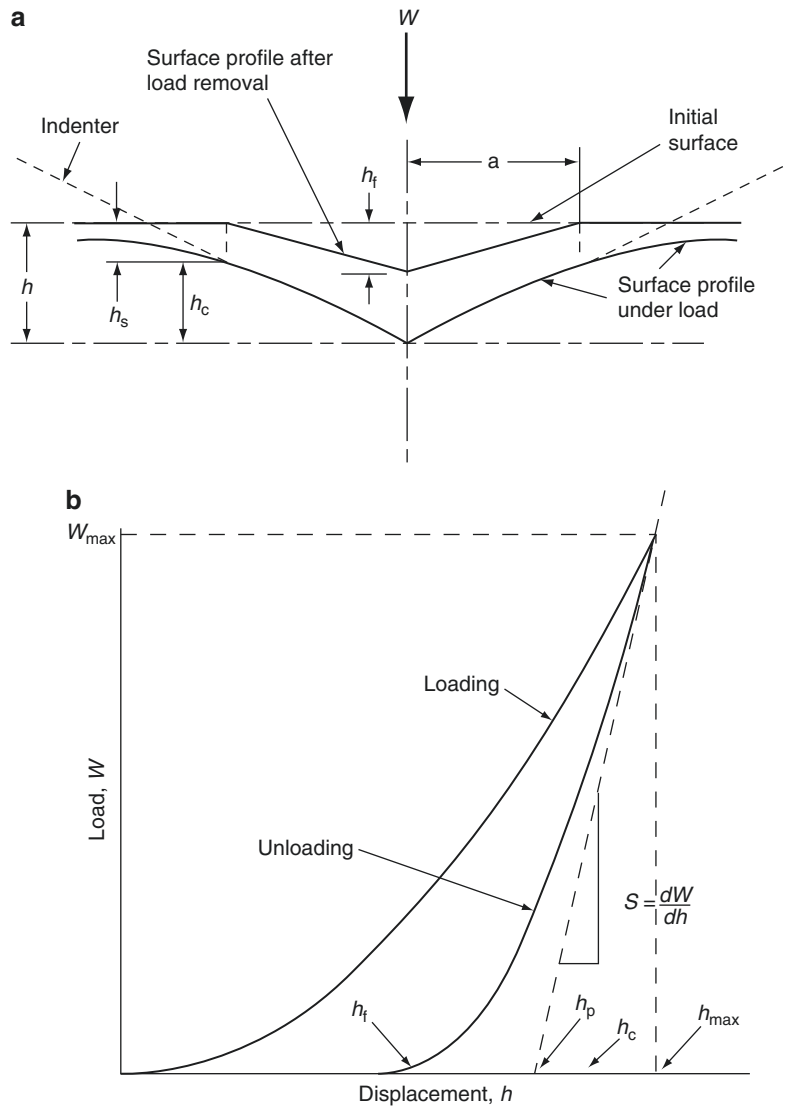
An indentation curve is the relationship between the load W and the displacement (or indentation depth or penetration depth) h, which is continuously monitored and recorded during indentation. Stress–strain curves, typical indentation curves, the deformed surfaces after tip removal, and residual impressions of indentation for ideal elastic, rigid-perfectly plastic and elastic-perfectly plastic, and real elastic–plastic solids are shown in Fig. 2. For an elastic solid, the sample deforms elastically according to Young's modulus, and the deformation is recovered during unloading. As a result, there is no impression of the indentation after unloading. For a rigid-perfectly plastic solid, no deformation occurs until yield stress is reached, when plastic flow takes place. There is no recovery during unloading and the impression remains unchanged. In the case of elastic–plastic solid, it deforms elastically according to Young's modulus and then it deforms plastically. The elastic deformation is recovered during unloading. In the case of an elastic-perfectly plastic solid, there is no work hardening.

All engineering surfaces follow real elastic–plastic deformation behavior with work hardening [1, 3, 5, 8, 9]. The deformation pattern of a real elastic–plastic sample during and after indentation is shown schematically in Fig. 3a [10]. The contact depth (h_c) is defined as the depth of indenter in contact with the sample under load. The depth measured during the indentation (h) includes the depression of the sample around the indentation in addition to the contact depth. The depression of the sample around the indentation ($h_s = h - h_c$) is caused by elastic displacements and must be subtracted from the data to obtain the actual depth of indentation or actual hardness. At peak load, the load and

Nanoindentation, Fig. 2 Schematics of stress–strain curves, typical indentation curves, deformed surfaces after tip removal, and residual impressions of indentation, for ideal elastic, rigid-perfectly plastic, elastic-perfectly plastic (ideal), and real elastic–plastic solids

displacement are W_{max} and h_{max}, respectively, and the radius of the contact circle is a. Upon unloading, the elastic displacements in the contact region are recovered and when the indenter is fully withdrawn, the final depth of the residual hardness impression is h_f. A load–displacement curve schematic is shown in Fig. 3b.

Oliver and Pharr [10] developed an expression for h_c at the maximum load (required for hardness calculation) from h_{max},



$$h_c = h_{max} - \varepsilon W_{max} = S_{max} \quad (1)$$

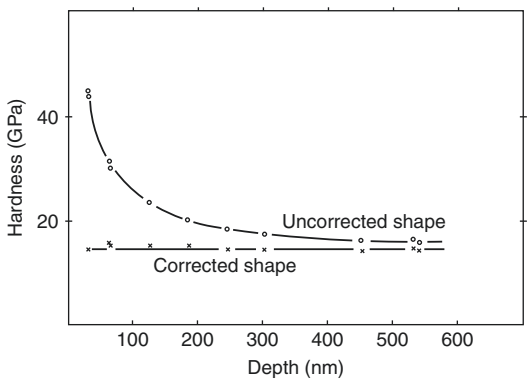
where $\varepsilon = 0.72$ for the conical indenter, $\varepsilon = 0.75$ for the paraboloid of revolution, and $\varepsilon = 1$ for the flat punch; and S_{max} is the stiffness (=1/compliance) equal to the slope of unloading curve (dW/dh) at the maximum load. Oliver and Pharr [10] assumed that behavior of the Berkovich indenter is similar to that of the conical indenter, since cross-sectional areas of both types of indenters varies as the square of the contact depth and their geometries are singular at the tip. Therefore, for Berkovich indenter, $\varepsilon \sim 0.72$. Thus, h_c is slightly larger than plastic indentation depth (h_p), given by

$$h_p = h_{max} - W_{max} = S_{max} \quad (2)$$

For a Vickers indenter with ideal pyramidal geometry (ideally sharp tip), projected contact area-to-depth relationship is given as [6, 11]

N

Nanoindentation, Fig. 3 (**a**) Schematic representation of the indentation process illustrating the depression of the sample around the indentation and the decrease in indentation depth upon unloading [10], and (**b**) schematic of load–displacement curve



$$A = 24.5h_c^2 \tag{3}$$

Since the area-to-depth relationship is equivalent for both typical Berkovich and Vickers pyramids, Eq. 3 holds for the ideal Berkovich indenter as well. However, the indenter tip is generally rounded so that ideal geometry is not maintained near the tip. The actual indentation depth, h_c, produces a larger contact area than would be expected for an indenter with an ideal shape. For the real indenter used in actual measurements, the nominal shape is characterized by an area function $F(h_c)$, which relates projected contact area of the indenter to the contact depth

$$A^{1/2} = F(h_c) \tag{4}$$

The functional form must be established experimentally prior to the analysis.

Hardness Berkovich hardness *HB* (or H_B) is defined as the load divided by the projected contact area of the indentation. It is the mean pressure that a material will support under load. From the indentation curve, the hardness at maximum load can be obtained as

Nanoindentation, Fig. 4 Hardness as a function of indentation depth for polished single-crystal silicon (111) calculated from the area function with and without tip shape calibration [11]

$$HB = W_{\max} = A \tag{5}$$

where $W_{\max}$ is the maximum indentation load and A is the projected contact area at the peak load. The contact area at the peak load is determined by the geometry of the indenter and the corresponding contact depth h_c using Eq. 1 and 4. A plot of hardness as a function of indentation depth for polished single-crystal silicon (111), with and without tip shape calibration, is shown in Fig. 4. It should be noted that for this example, tip shape calibration is necessary and the hardness is independent of the corrected depth.

It should be pointed out that hardness measured using this definition may be different from that obtained from the more conventional definition in which the area is determined by direct measurement of the size of the residual hardness impression. The reason for the difference is that, in some materials, a small portion of the contact area under load is not plastically deformed, and, as a result, the contact area measured by observation of the residual hardness impression may be less than that at peak load. However, for most materials, measurements using two techniques give similar results.

Stresses during the indentation process can induce phase transformation in some ceramic materials, such as yttria-stabilized ZrO_2. Stress-induced-phase transformation can cause a change in volume of indented material that will in turn affect the load–displacement data. A relationship between indentation pressure and phase transformation and resulting change in volume of indental material during the indentation would need to be studied.

Modulus of Elasticity Even though during loading a sample undergoes elastic–plastic deformation, the initial unloading is an elastic event. Therefore, the Young's modulus of elasticity or, simply, the elastic modulus of the specimen can be inferred from the initial slope of the unloading curve (dW/dh) called stiffness (1/compliance) (at the maximum load). It should be noted that the contact stiffness is measured only at the maximum load, and no restrictions are placed on the unloading data being linear during any portion of the unloading.

It has been found that the compliance for the indenter is approximately *independent of the shape* (with a variation of at most 3 %) if the projected area is fixed [6]. The relationship for the compliance C (inverse of stiffness S) for an (Vickers, Knoop, and Berkovich) indenter is given as

$$C = \frac{1}{S} = \frac{dh}{dW} \approx \frac{1}{2E_r}\left(\frac{\pi}{A}\right)^{1/2} \tag{6}$$

where $\frac{1}{E_r} = \frac{1-\nu_s^2}{E_s} + \frac{1-\nu_i^2}{E_i}$, dW/dh is the slope of the unloading curve at the maximum load, E_r, E_s, and E_i are the reduced modulus and elastic moduli of the specimen and the indenter, and ν_s and ν_i are the Poisson's ratios of the specimen and indenter. C (or S) is the experimentally measured compliance (or stiffness) at the maximum load during unloading, and A is the projected contact area at the maximum load.

The contact depth h_c is related to the projected area of the indentation A for a real indenter by Eq. 4. A plot of the measured compliance (dh/dW) the reciprocal of the corrected indentation depth obtained from various indentation curves (one data point at maximum load for each curve) should yield a straight line with slope proportional to $1/E_r$ [11]. E_s can then be calculated, provided Poisson's ratio with great precision is known to obtain a good value of the modulus. For a diamond indenter, $E_i = 1{,}140$ GPa and $n_i = 0.07$ are taken.

The most frequently used method to measure initial unloading stiffness (S) is by Doerner and Nix [11], who measured S by fitting a straight line to the upper about one third portion of the unloading curve. The problem with this is that for nonlinear loading data, the measured stiffness depends on how much of the data is used in the fit. Oliver and Pharr [10] proposed a new procedure. They found that the entire unloading data are well-described by a simple power law relation:

$$W = B(h - h_f)^m, \tag{7}$$

where the constants B and m are determined by a least-square fit. The initial unloading slope is then found analytically, differentiating this expression and evaluating the derivative at the maximum load and maximum depth.

This analysis is based on an elastic solution that only accounts for sink-in (the indented material around the indenter below its original surface). However, in the more realistic case of elastic–plastic contact, sink-in or pile-up (the indented material around the indenter above its original surface) can occur depending on the specific mechanical properties of the material. For pile-up situations, the just-described method would underestimate the true contact area by as much as 50 %. This in turn leads to overestimation of the hardness and elastic modulus. Based on some modeling, pile-up is significant only when $h_f/h_{max} > 0.7$ and the material does not appreciably work harden. Note that h_f/h_{max} equal to zero corresponds to fully elastic deformation and a value of 1 corresponds to rigid-plastic behavior. Compressive residual stresses result in pile-up whereas tensile stresses result in sink-in. Although some correction procedures have been proposed [12], the real contact area measurement requires imaging of indentation impressions.

Determination of Load Frame Compliance and Indenter Area Function The measured displacements are the sum of the indentation depths in the specimen and the displacements of suspending springs and the displacements associated with the measuring instruments, referred to as load frame compliance. Therefore, to determine accurately the specimen depth, load frame compliance must be known. This is especially important for large indentations made with high modulus for which the load frame displacement can be a significant fraction of the total displacement. The exact shape of the diamond indenter tip needs to be measured because hardness and elastic modulus depend on the contact areas derived from measured depths. The tip gets blunt and its shape significantly affects the prediction of mechanical properties (Fig. 4).

Oliver and Pharr [10] proposed a method for determining area functions. Their method is based only on one assumption that Young's modulus is independent of indentation depth. They modeled the load frame and the specimen as two springs in series; thus,

$$C = C_s + C_f \tag{8}$$

where C, C_s, and C_f are the total measured compliance, specimen compliance, and load frame compliance, respectively. Combining Eqs. 6 and 8 yields

$$C = C_f + \frac{1}{2E_r}\left(\frac{\pi}{A}\right)^{1/2} \tag{9}$$

From Eq. 9, it should be noted that if the modulus of elasticity is constant, a plot of C as a function of $A^{1/2}$ is linear and the vertical intercept gives C_f. Accurate values of C_f are obtained when the specimen compliance is small, i.e., for large indentations.

To determine the area function and the load frame compliance, Oliver and Pharr made relatively large indentations in aluminum because of its low hardness. In addition, for the larger aluminum indentations (typically 700–4,000 nm deep), the area function for a perfect Berkovich indenter (Eq. 3) can be used to provide a first estimate of the contact.

Using the measured C_f value, they calculated contact areas for indentations made at shallow depths on the aluminum with measured E_r and/or on a harder fused silica surface with published values of E_r, by rewriting Eq. 9 as

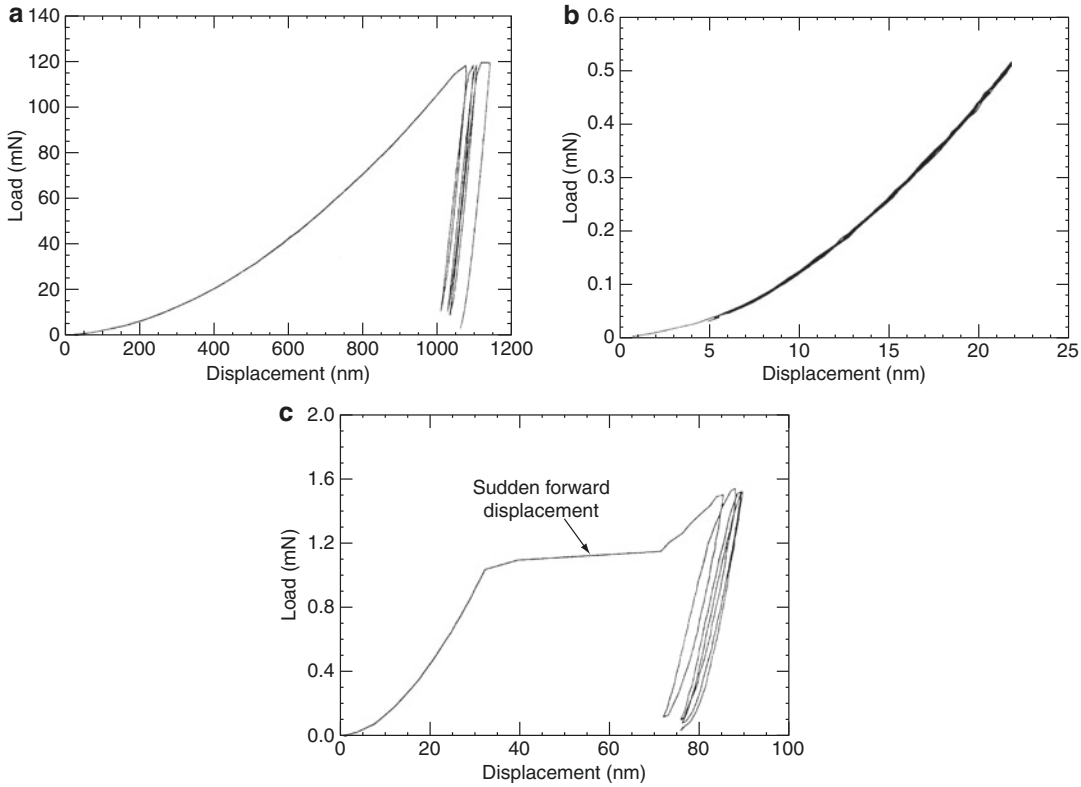
$$A = \frac{\pi}{4}\frac{1}{E_r^2}\frac{1}{(C - C_f)^2} \tag{10}$$

from which an initial guess at the area function was made by fitting A as a function h_c data to an eighth-order polynomial

$$A = 24.5h_c^2 + C_1h_c + C_2h_c^{1/2} + C_3h_c^{1/4} + \ldots + C_8h_c^{1/128} \tag{11}$$

where C_1 through C_8 are constants. The first term describes the perfect shape of the indenter; the others describe deviations from the Berkovich geometry due to blunting of the tip.

Key Research Findings

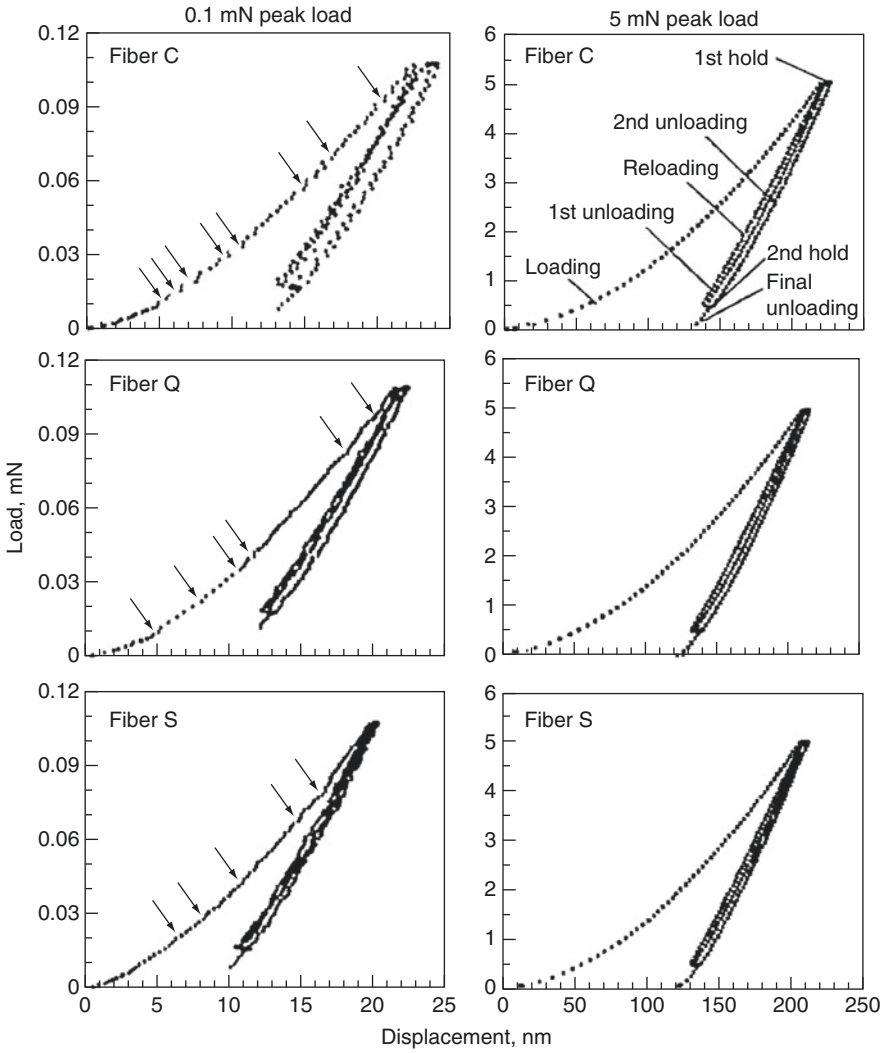


Examples of Measured Mechanical Properties

To illustrate the usage of nanoindentation techniques, typical data obtained on various bulk materials, coatings, and microstructures is presented below.

Load–Displacement Curves A variety of mechanical phenomena, such as the transition from elastic to plastic deformation, creep deformation, formation of subsurface cracks, and crystallographic phase transition, can be studied by the load–displacement curves obtained at different loading conditions [6]. The load-time sequence used by Oliver and Pharr [10] for study of various materials included three loading–unloading cycles, hold for 100 s at 10 % of the peak load, reload, hold for 100 s, and unload. Load–displacement curves for electropolished single-crystal tungsten are shown in Fig. 5. The tungsten data are typical of materials in which the hardness is relatively small compared to the modulus, as is observed in most metals; most of the indenter displacement in these metals is accommodated plastically and only a small portion is recovered on unloading. Figure 5 shows that the peak load displacements shift to higher values in successive loading/unloading cycles. In addition, the relatively large displacement just prior to final unloading is due to creep during the 100-s hold period at peak load. Indentation at a very low load of 0.5 mN caused only elastic displacements (Fig. 5b). At higher peak loads, the indentation is not just elastic (Fig. 5c). When a threshold load of about 1 mN is reached, a sudden jump in displacement corresponding to the onset of plasticity is observed, and a permanent hardness impression is formed. Tungsten at low loads (Fig. 5c) exhibit distinct hysteresis loops, as might be expected if there were a small amount of reverse plasticity upon loading. However, the looping degenerates with cycling after three or four cycles, the load–displacement behavior is largely elastic.

Another set of load–displacement curves is shown in Fig. 6 for glass fibers, which are used as reinforcements in numerous materials including plastic, rubber, cement as well as heat insulation materials [13]. The indents were made on polished cross sections of the fibers. Fibers C, Q, and S are all 16 μm diameter fibers, each with different formulations. The load–displacement plots of indentations made at 0.1 mN peak loads on all fibers exhibit several displacement discontinuities of pop-in marks during the first and second loading steps of the indentation, as denoted by the arrows in Fig. 6. Pop-in marks in the loading curves result from sudden penetrations of the tip into the sample. Fiber S exhibits the smallest pop-in marks, followed by fibers Q and C, which suggests that Fiber S has the highest resistance to plastic deformation as well as crack formation and crack propagation.

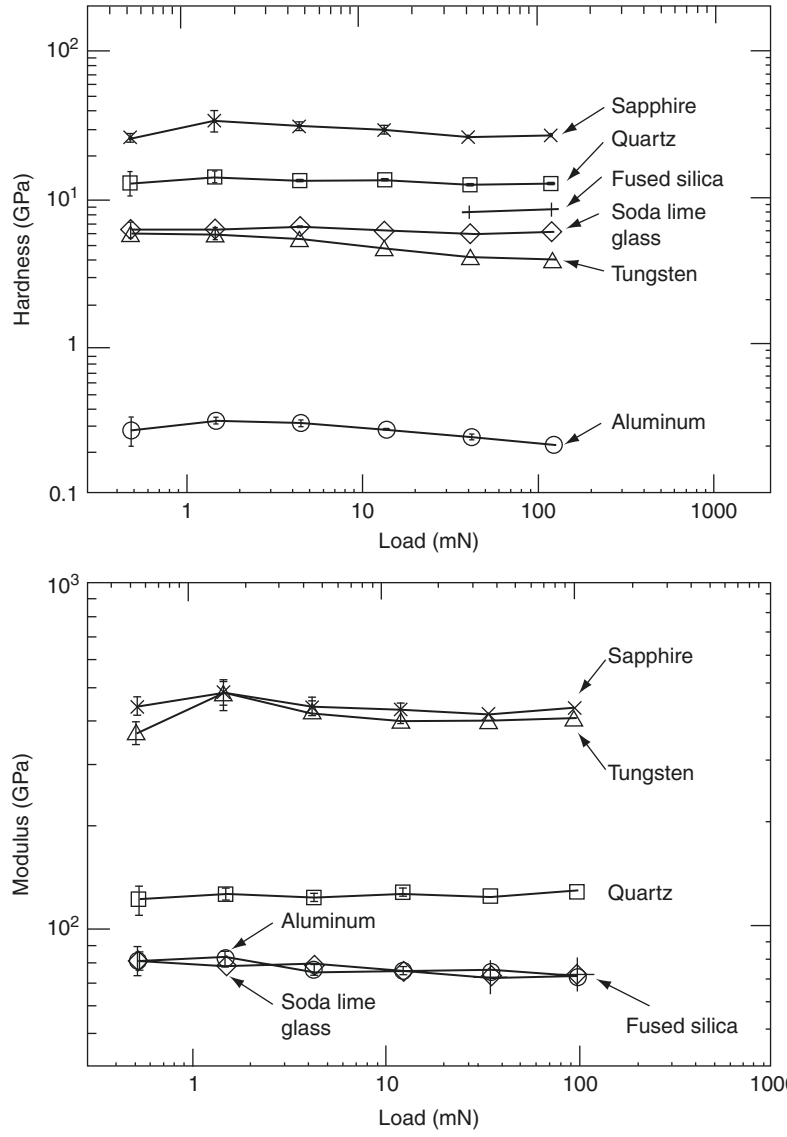


Hardness and Elastic Modulus Measurements The nanoindenter is commonly used to measure surface mechanical properties of bulk materials [6, 10]. Hardness and elastic moduli for six bulk materials and three materials used as a substrate for the construction of magnetic rigid disks and single-crystal silicon are presented in Fig. 7. The data show that there is a very little indentation size effect in several materials on the hardness values. In the case of aluminum and tungsten in Fig. 7, there is a modest increase in hardness at low loads, which could be due to surface-localized cold work resulting from polishing [10]. The modulus data also show that there is very little evidence for an indentation size effect; i.e., the moduli remain more or less constant over the entire range of load.

Nanoindentation, Fig. 5 Load versus displacement plot for an electro-polished single-crystal tungsten (**a**) at a peak load of 120 mN, (**b**) at a peak load of 0.5 mN (elastic contact), and (**c**) at a peak load of 1.5 mN showing the yield point [10]

The nanoindenter is ideal for the measurement of mechanical properties of thin films and composite structures. A number of investigators have reported hardness of composite structures with thin films on a substrate. It is widely accepted that to measure true hardness of the films, the indentation depth should not exceed 10 % of the film thickness [14]. However, based on a finite element analysis of the indentation of thin films of various thicknesses it was found that the true hardness of the films could be obtained if the indentation depth does not exceed about 30 % of the film thickness. At higher indentation depths, the composite hardness changes with the indentation depth [6].

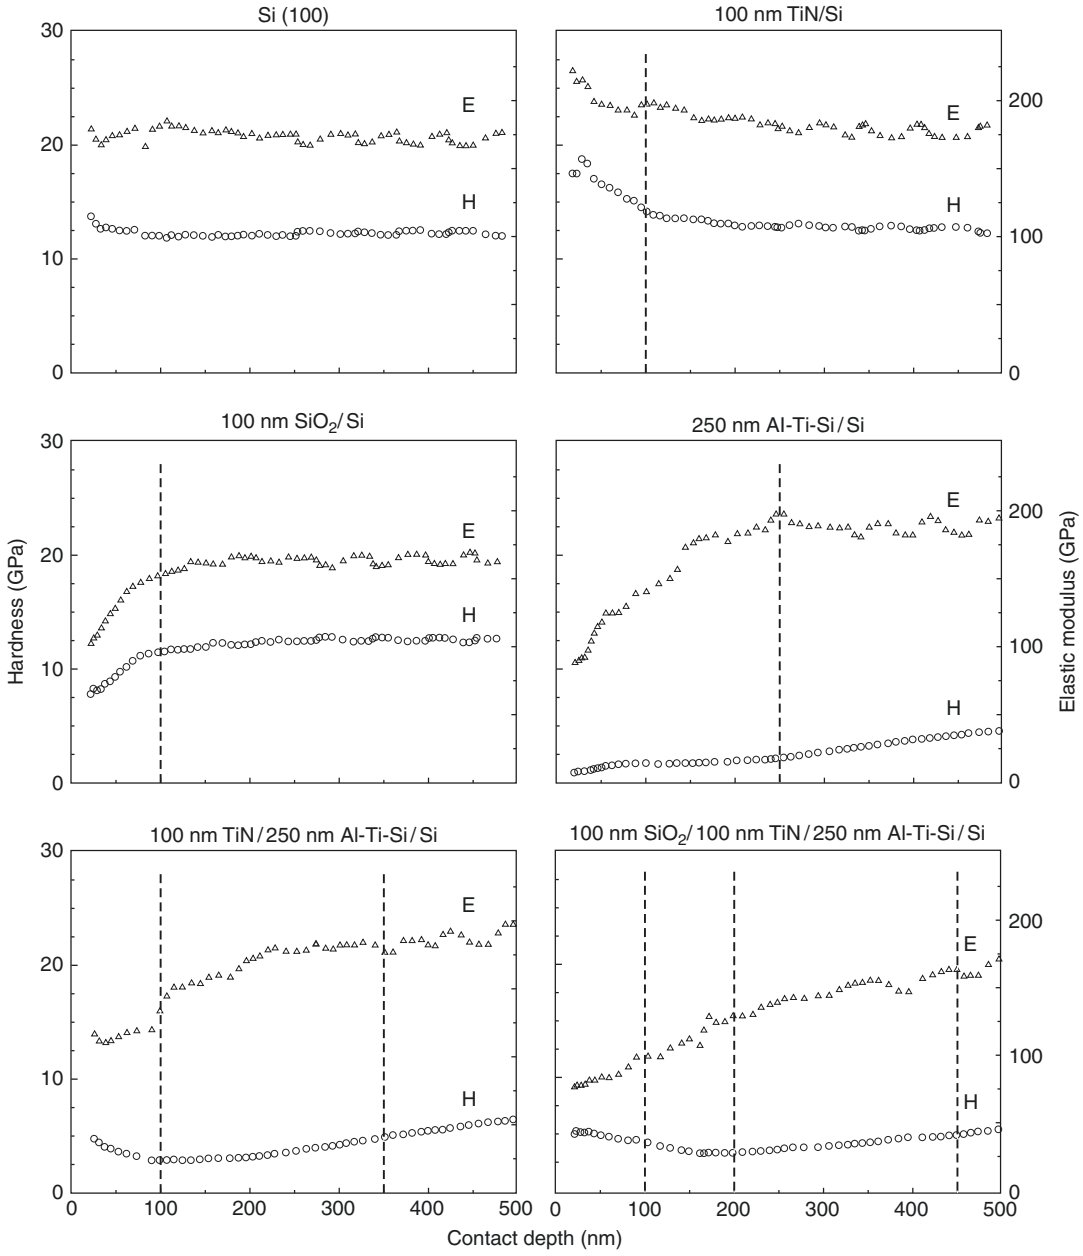
The significance of the composite hardness and modulus on multilayered thin films is illustrated for the components of the digital micromirror device (DMD). The DMD is the main component of commercial DLP^{TM} projectors, invented at Texas Instruments (TI) in 1987. The DMD chip is composed of an array of micromirrors, along with a yoke and hinge array underneath. The contact between the tips at the end of the yoke and the underlying landing site is required for operation. Since the DMD chip is composed of various thin film structures, the mechanical properties of the component materials are important to the DMD performance. Figure 8 shows the hardness and elastic modulus as a function of contact depth for the DMD materials measured using the continuous stiffness method, with data for Si (1 0 0) included for reference. The samples belong to three categories: bulk material, single-layer, and multilayered materials. For bulk material, Si (1 0 0), the hardness and elastic modulus does not change with contact depth, as expected. For a hard film on soft substrate, TiN/Si, the hardness and



Nanoindentation, Fig. 6 Representative load versus displacement plots of indentations made at 0.1 and 5 mN peak indentation loads on various glass fibers [13]

elastic modulus values decrease with contact depth. For soft films on hard substrates, SiO_2/Si and Al alloy/Si, their hardness and elastic modulus values increase with contact depth. The hardness and elastic modulus of TiN/Si and SiO_2/Si gradually approach the hardness and elastic modulus values of Si (1 0 0) after the contact depths exceed 100 nm, due to the substrate effect [15].

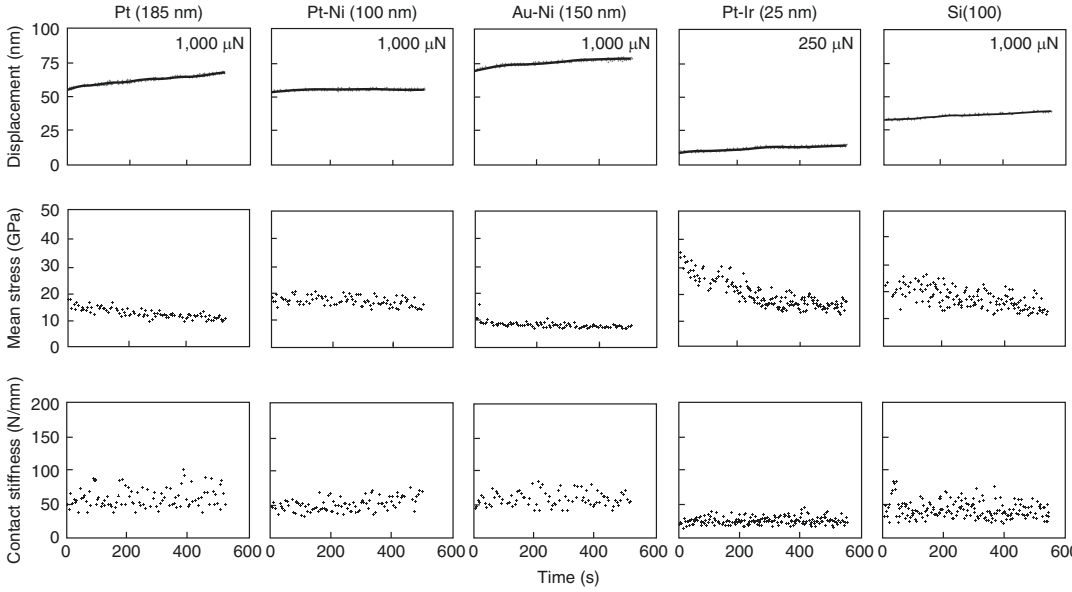
For multilayered materials, TiN/Al alloy/Si and SiO_2/TiN/Al alloy/Si, there are two common observations. For both samples, the lowest hardness values were obtained near the TiN/Al alloy interfaces, which are approached at the contact depth of about 100 and 200 nm, respectively. It is observed that both samples show much lower hardness values (~5 GPa) at the contact depth of about 30 nm as compared to the corresponding single-layer materials. The substrate effect contributions are expected to be small at this contact depth.



It is known that for a metallic thin film, the measured hardness is sensitive to grain size, film texture, film thickness, level of adhesion of the film to the substrate, and presence of residual

Nanoindentation, Fig. 7 Hardness and elastic modulus as a function of load for six bulk materials – mechanically – polished single-crystal aluminum, electro-polished single-crystal tungsten, soda-lime glass, fused silica, (001) single-crystal sapphire, and (001) single-crystal quartz [10]

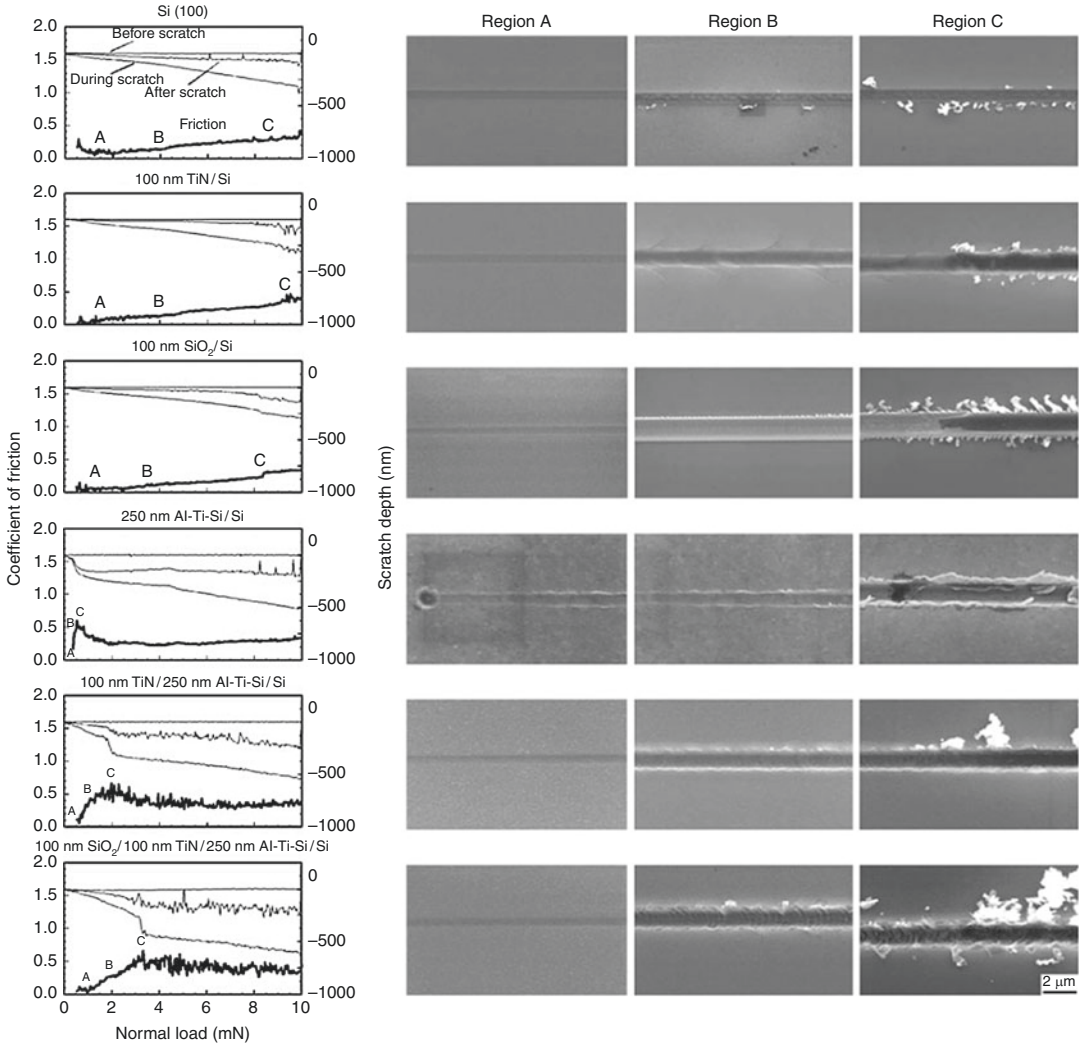
stress. When TiN was reactively sputtered onto Al alloy, the stress state and microstructure (grain size, texture) of TiN might be changed as compared to TiN/Si, since the film growth substrate is changed. According to the Hall–Petch relationship, in metal and alloy films, if the grain size of the TiN/Al alloy/Si was greater than that of the TiN/Si, then the hardness would decrease. It is believed that films grown by physical and chemical vapor deposition techniques usually display a preferred orientation, which is dependent upon deposition process variables. Hardness reductions by as much as two orders have been observed in cubic coatings (e.g., TiC, TiN, ZrC) as a function of the preferred orientation plane [e.g., (1 1 1), (1 0 0) and (1 1 0)]. For SiO_2/TiN/Al alloy/Si, since SiO_2 is usually amorphous when deposited as films, the grain size and texture may not be the parameters responsible for the hardness decrease of SiO_2/TiN/Al alloy/Si [15].



Creep Resistance Most materials, including ceramics (and even diamond) are found to creep at temperatures well below half their melting points, even at room temperature. Indentation

Nanoindentation, Fig. 8 Hardness and elastic modulus as a function of contact depth for the thin films used in the digital micromirror device (*DMD*) [15]

creep and indentation load relaxation (ILR) tests are commonly used to measure the time-dependent flow of materials. These techniques offer an advantage of being able to probe the deformation properties of a thin film as a function of indentation depth and location [6].



An example of nanoscale creep is shown in Fig. 9 for the noble metal thin films used for probe-based ferroelectric data recording. In this technology, a conductive atomic force microscope (AFM) probe with a noble metal coating is placed in contact with lead zirconate titanate (PZT) film,

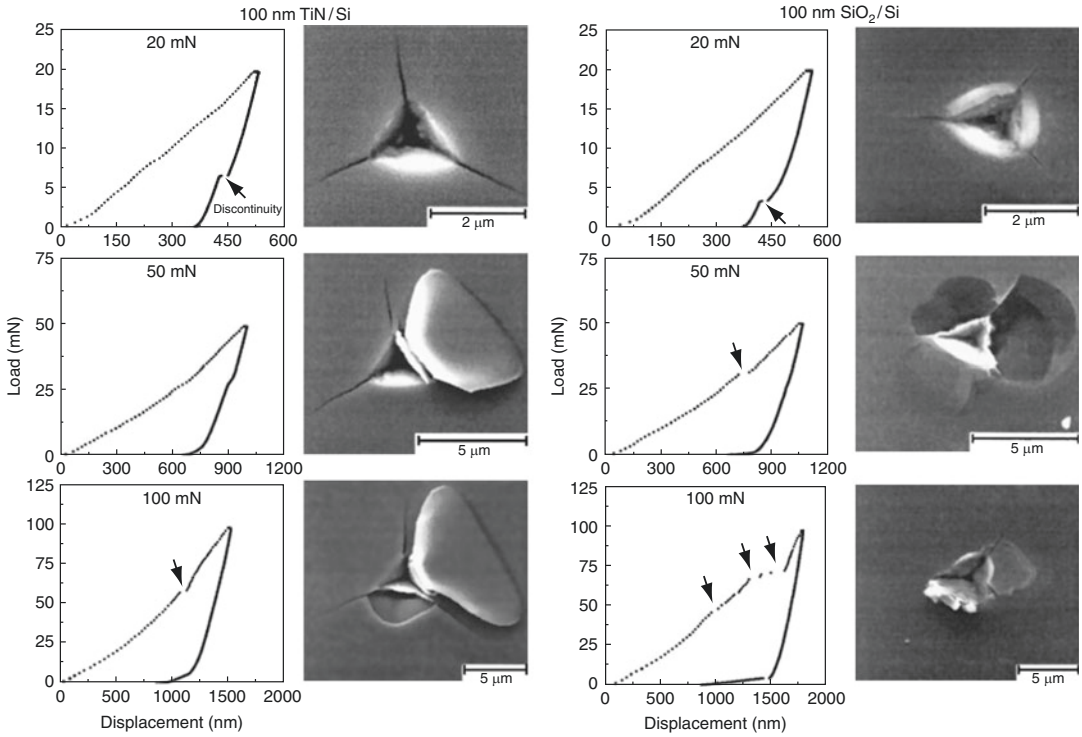
Nanoindentation, Fig. 9 Creep displacement, mean stress and contact stiffness as a function of time of the various metal-coated AFM probes used in ferroelectric data recording and Si(100) as reference [16]

which serves as the ferroelectric material. The long-term device performance will be compromised if the metal films exhibit excessive creep [16]. Figure 9 shows creep data for the various metal-coated probes and Si, where the change in displacement, mean stress, and contact stiffness was monitored while holding the tip at the maximum imposed load (P_{max}). A lower P_{max} was applied on Pt–Ir as it is a very thin coating; the selected load of 250 mN ensures that the tip is measuring the creep resistance of the coating and did not penetrate the substrate during the creep experiment. From the displacement plots, it is observed that the three alloyed coatings (Pt–Ni, Pt–Ir, and Au–Ni) exhibited less creep compared to Pt. The Si surface also shows significant creep, which is consistent with previous reports. This creep on silicon is a combination of two factors: initial creep can occur as the tip penetrates the native oxide surface, which is then followed by a dislocation glide plasticity mechanism [16, 17].

Microscratch Resistance of Various Materials Using Micro/Nanoscratch Technique The microscratch technique is commonly used for screening of bulk materials for wear resistance. As stated earlier, normal load applied to the scratch tip is gradually increased during scratching until the material is damaged. Friction force can be measured during the scratch test [7]. After the scratch test, the morphology of the scratch region including debris is observed in an SEM. Based on the combination of the changes in the friction force as a function of normal load and SEM observations, the critical load is determined and the deformation mode is identified. Any damage to the material surface as a result of scratching at a critical ramp-up load results in an abrupt or gradual increase in friction. The material may deform either by plastic deformation or fracture. Ductile materials (all metals) deform primarily by plastic deformation, resulting in significant plowing during scratching. Tracks are produced whose width and depth increase with an increase in the normal load. Plowing results in a continuous increase in the coefficient of friction with an increase in the normal load during scratching. Debris is generally ribbon-like or curly, whereas brittle materials deform primarily by brittle fracture with some plastic deformation. In the brittle fracture mode, the coefficient of friction increases very little until a critical load is reached at which the material fails catastrophically and produces

Nanoindentation, Fig. 10 Coefficient of friction and scratch depth profiles as a function of normal load for DMD thin films and SEM images of three regions over scratches: at the beginning of the scratch (indicated by "A" on the friction profile), at the point of damage initiation (indicated by "B" on the friction profile), and at the point of film delamination (indicated by "C" on the friction profile). For Si substrate, region C is where severe damage began) [15]

fine debris, which is rounded, and the coefficient of friction increases rapidly above the critical load.



In the example for the digital micromirror device (DMD) mentioned above, the repeated contact between the yoke and landing site components eventually leads to wear over time. The wear resistance of these materials can be evaluated through a nanoscratch experiment. For the components of the DMD, Fig. 10 shows the coefficient of friction and scratch depth profiles as a function of increasing normal load, along with SEM images of three regions over scratches [15]. SEM images were taken at the beginning of the scratch (indicated by "A" on the friction profile), at the point of initiation of damage at which the coefficient of friction increases by a factor of two (indicated by "B" on the friction profile), and at the point of the initiation of the delamination of the films (for Si substrate, this region represents

the position where severe damage began) (indicated by "C" on the friction profile). The normal load corresponding to region B is defined as the "critical load." Before the critical load (from regions A to B), the coefficient of friction of the Si (1 0 0), TiN and SiO_2 films increased at a slower rate, and at the critical load (region B), these three samples exhibit a small increase in the coefficient of friction. However, for the remaining samples, i.e., Al alloy, TiN/Al alloy, and SiO_2/TiN/Al alloy, the coefficient of friction increased sharply from regions A to B. The slopes of the increase of the coefficient of friction in these three samples from regions A to B are inversely proportional to the hardness of the samples. For instance, the Al alloy shows the lowest hardness, but highest slope of the increase of the coefficient of friction. The increase of the coefficient of friction during scratching was attributed to the increasing plowing of the sample by the tip with increasing normal load, and the softer material led to deeper plowing of the tip and faster increase of the coefficient of friction. At region C, all films were delaminated and experienced an abrupt increase in the coefficient of friction, which was associated with catastrophic failure as well as significant plowing of the tip into the sample.

The SEM images show that all the samples experienced plastic deformation at the beginning of the scratch (region A). For Al alloy, because it is very soft, region A is very close to region B. The indent of the conical tip, the plastic deformation associated with the pile-up was observed at the beginning of the scratch for Al alloy. At region C, for Si (1 0 0) substrate, only some debris particles were found without any cracks on the side of the scratch, which is responsible for the small increase in the coefficient of friction. For TiN, SiO_2 and Al alloy films, it is clear that at region C, the scratch tip reached the Si substrate and delaminated the film. The irregular cracks found on the side of the scratch in TiN indicate that TiN is brittle. However, it is interesting to observe that the SiO_2 film shows high ductility according to the SEM images at region C, where regular film pieces were found to attach to the sample surface even after the film was delaminated. As expected, severe plowing and high pile-up were found for Al alloy. For TiN/Al alloy and SiO_2/TiN/Al alloy, a lot of debris were found at region C, indicating that more materials were torn away from the films. By investigating the corresponding scratch depths, it can be seen that at region C, the in situ scratch depth of TiN/Al alloy and SiO_2/TiN/Al alloy are about 350 and 450 nm, respectively, indicating that for both multilayer films, the tip reached the Si substrates. This may explain why more material was torn away from the multilayered films at region C. For the thin film materials used in DMD, the damage initiated at the "critical load" should be prevented in order to make the DMD operate properly. Therefore, the film topography and mechanical property changes due to scratch in the region from A to B, especially the film failure mechanism at region B, are of great interest for DMD [15].

Nanofracture Toughness Nanoindentation can be used to determine fracture toughness [6]. The indentation cracking method is especially useful for measurement of fracture toughness of thin films or small volumes. For fracture toughness measurement of ultrathin films ranging from 100 nm to few micrometers, traditional indentation or four-point flexure techniques cannot be used. Because of shallow indentation depths required in the indentation technique, it is difficult to measure a radial crack length under even SEM. Li et al. [18] developed a novel technique based on nanoindentation in which through-thickness cracking in the coating is detected from a discontinuity in the load–displacement curve and energy released during cracking is obtained from the curve. Based on the energy released, fracture mechanics analysis is used to calculate fracture toughness. A cube corner is preferred because the through-thickness cracking of hard films can be accomplished at lower loads.

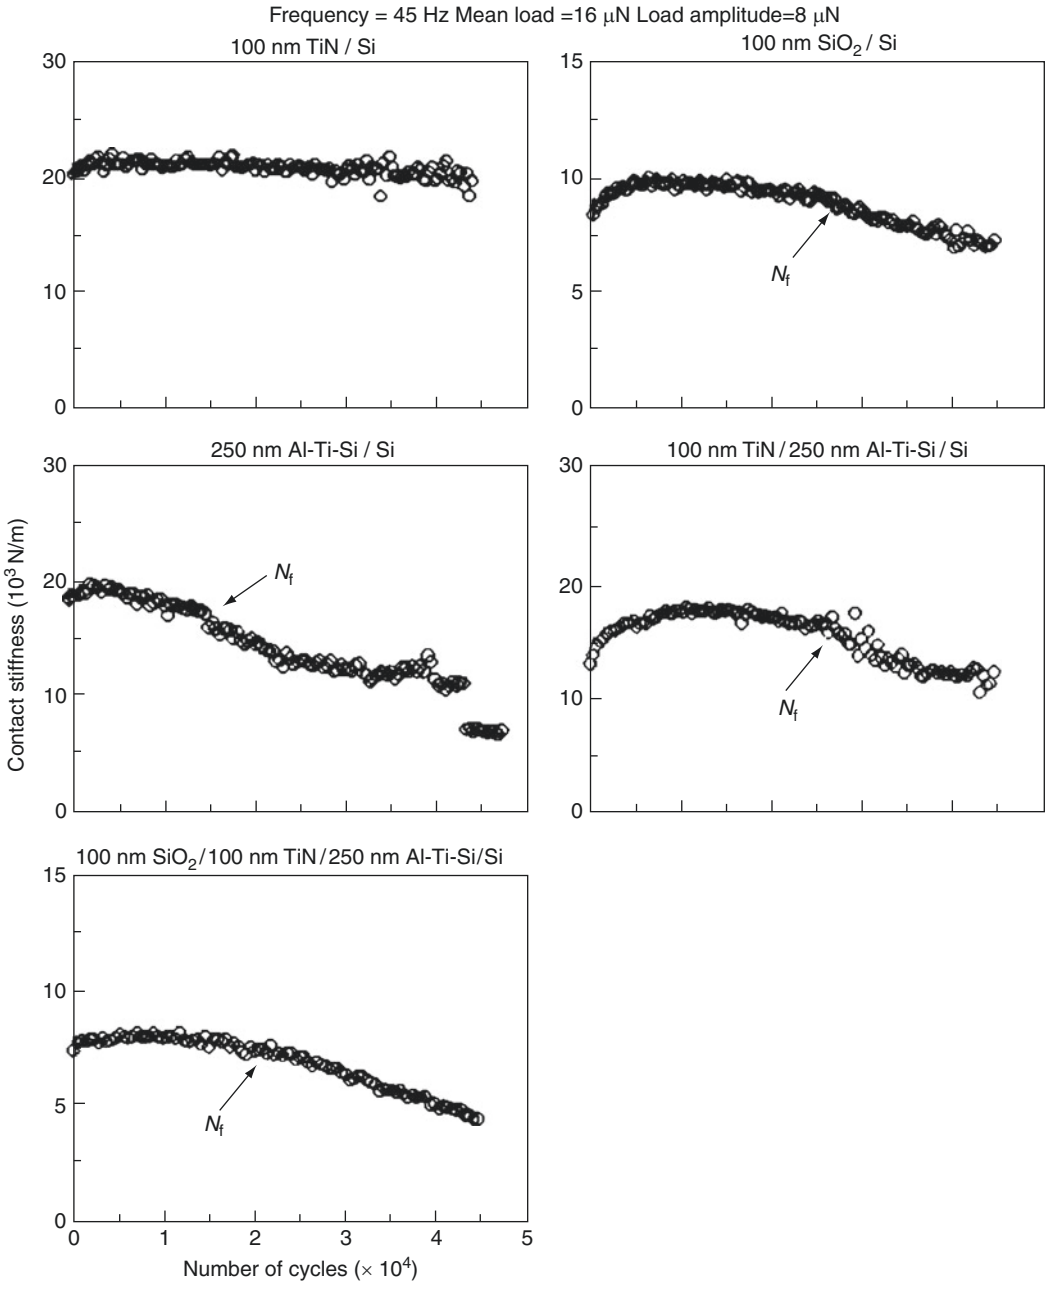
An example of the fracture toughness determination for the thin films used in DMD is shown in Fig. 11, which contains load–displacement curves of indentations made at 20, 50, and 100 mN peak indentation loads together with the scanning electron microscopy (SEM) micrographs of indentations on the TiN/Si and SiO_2/Si. Steps are found in the loading curves obtained at 100 mN for TiN/Si, and at 50 mN (and 100 mN) for SiO_2 as shown by

Nanoindentation, Fig. 11 Load–displacement curves of indentations made at 20, 50, and 100 mN peak loads and corresponding SEM micrographs of the indents on two of the films used in the DMD. *Solid arrows* indicate discontinuity during the unloading portion of the curve and the *hollow arrows* indicates a step during the loading portion of the load–displacement curve [19]

N

arrows in Fig. 11. The steps in the loading curves of indentations result from the ring-like through-thickness cracking as shown in the SEM images. These ring-like through-thickness cracking were used to calculate the fracture toughness together with the strain energy release obtained from the steps in the loading curves, which will be described later. At 20 mN, the radial cracks were found in both TiN/Si and SiO_2/Si. The discontinuity in the displacement observed during unloading is believed to be due to the formation of lateral cracks at the base of the median crack which results in the surface of the specimen being thrust upward [19].

Li et al. [18] suggest that the steps in the loading curve on the films result from the film cracking, and that the fracture process progresses in three stages: (1) first ring-like through-thickness cracks form around the indenter by high stresses in the contact area; (2) delamination and buckling occur around the contact area at the film/substrate interface by high lateral pressure; and (3) second ring-like through-thickness cracks and spalling are generated by high bending stresses at the edges of the buckled film. The fracture toughness was calculated from the second ring-like through-thickness cracking generated in the third stage. In this stage, the stress concentration at the end of the interfacial crack cannot be relaxed by the propagation of the interfacial crack. With an increase in indentation depth, the height of the bulged film increases. When the height reaches a critical value, the bending stresses caused by the bulged film around the indenter will result in the second ring-like through-thickness crack formation and spalling at the edge of the buckled film, which leads to a step in the loading curve. The step in the loading curve is totally from the film cracking and not from the interfacial cracking or the substrate cracking [19].



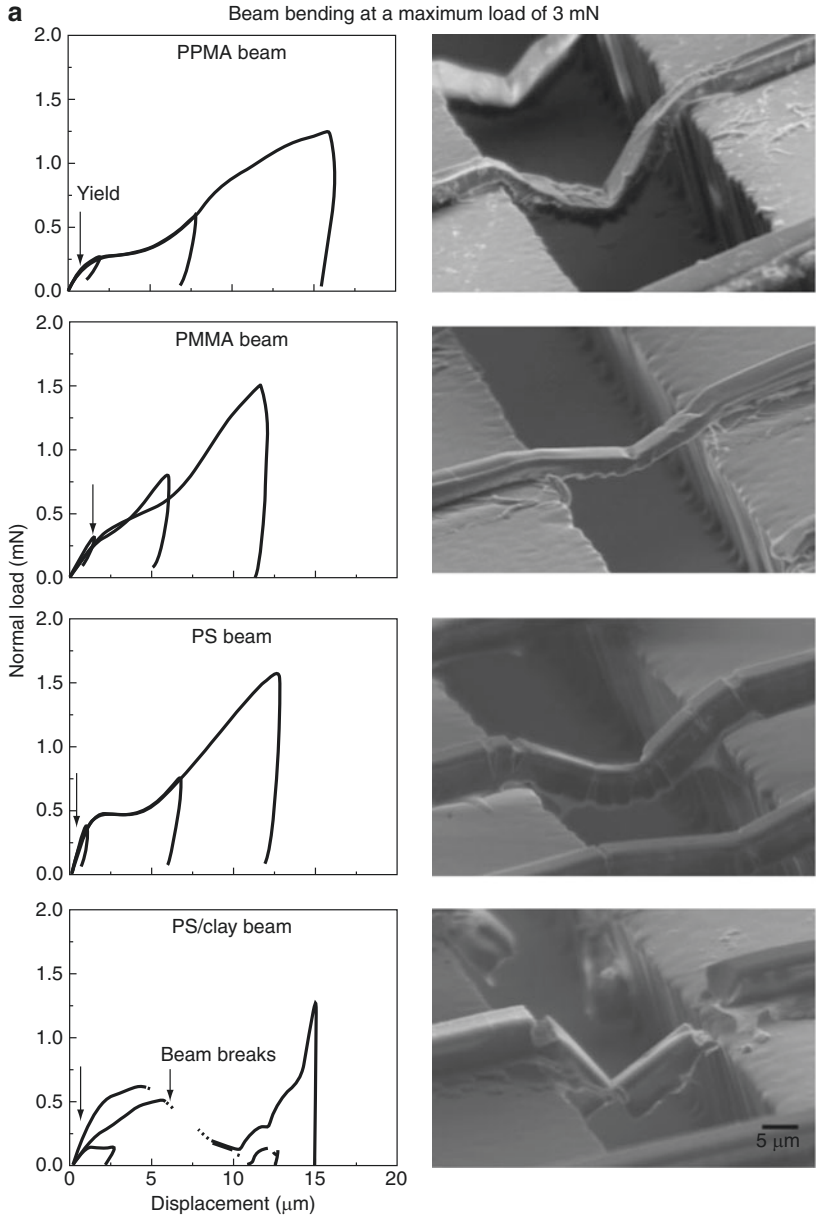
Nanofatigue Fatigue fracturing progresses through a material via changes within the material at the tip of a crack, where there is high stress intensity. There are several situations: cyclic fatigue, stress corrosion, and static fatigue. In this discussion, the focus is on cyclic fatigue, which results from the cyclic loading of machine components; e.g., the stresses cycle from tension and compression occurs in a loaded rotating shaft.

To compare the fatigue lives of the thin film structures used in the DMD, the contact stiffness data as a function of the number of cycles for TiN/Si, SiO_2/Si, Al alloy/Si, TiN/Al alloy/Si, and SiO_2/TiN/Al alloy/Si cyclically deformed at an oscillating load amplitude of 8 mN with a mean load of 16 mN at a frequency of 45 Hz are shown in Fig. 12. For all the samples, the contact stiffness increased to varying degrees at the beginning of the fatigue test as a result of strain hardening. TiN/Si and Al alloy/Si films have the longest and shortest N_f, respectively. By comparing the N_f of multilayered thin film structures with the corresponding single top layer films ∼ TiN and SiO_2), it can be seen that the multilayered thin film structures exhibited shorter N_f. Ranking of the nanoscale fatigue data is similar to results from hardness studies, i.e., the hardness of multilayered thin film structures is lower than that of the corresponding single top layer films [19].

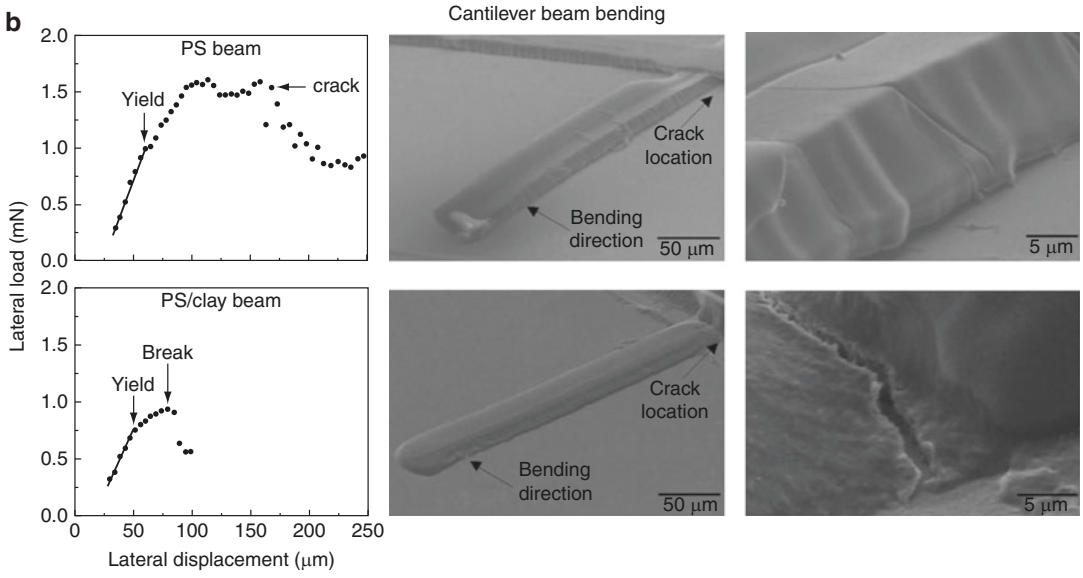
The relationship between fatigue life and hardness is as follows. At the beginning of the fatigue test, the tip penetrates into the sample a certain displacement, depending on the hardness of the sample. Then the tip is held and a cyclic load is applied. As the number of cycles increases, the tip penetrates deeper. It is known that during the indentation fatigue test, even though there may be no cracks, the tip of the sharp indenter can sink deeper into the material and extend the plastic zone. At this stage, the compressive stress and the deformation volume may not be high enough to cause cracks. In this case, the contact stiffness would not decrease abruptly. It is known that voids and impurities act as original cracks. As the number of cycles reaches a critical value N_f, the original cracks beneath and around the tip would propagate due to the accumulated deformation, as well as new cracks that may develop at high deformation volume. This would cause the contact stiffness to drop suddenly. Since TiN/Si is the hardest sample, it resisted the tip to sink and consequently results in lower accumulated deformation volume. So it took a longer time for TiN/Si to fail due to the fatigue-induced crack. For softer materials, SiO_2/Si and Al alloy/Si, the tip sank easily and caused larger deformation volume and earlier fatigue failure. This explanation can also be used to understand the data that multilayered thin film structures with soft interlayer showed shorter fatigue life than the corresponding top hard films. The hardness of multilayered structures is lower than the top hard films responsible for shorter fatigue life [19].

Deformation of Microbeams Microscale structures, such as beams, are common in MEMS/NEMS devices. In this example, the focus is on polymer microbeams designed for the BioMEMS device known as a cell force sensor. In the work by Palacio et al. [20], the materials considered were poly(propyl methacrylate), poly(methyl methacrylate), poly(styrene), and a poly(styrene)-nanoclay composite (abbreviated as PPMA, PMMA, PS and PS/clay, respectively). For this application, nanoindentation can be used for conducting bending experiments in the normal and lateral directions. These experiments provide information on the elastic modulus, yield strength, and breaking strength of these materials. This example illustrates how nanoindentation can be used beyond the more traditional experiments carried out on bulk materials and thin films.

Bending experiments were performed by Palacio et al. [20] with applied loads in the millinewton range in order to investigate the behavior of polymer beams beyond the elastic deformation regime. Figure 13a shows normal load–displacement profiles at maximum imposed loads of 0.5, 1.5 and 3.0 mN applied on three different beams in one wafer sample. For PPMA, PMMA and PS, the loading portion overlaps, indicating uniform beam quality. Slight variability in the loading profile is observed in the PS/clay composite, which is attributed to variable interfacial adhesion between the filler and the matrix and inhomogeneities in the dispersion of the clay particles.



Nanoindentation, Fig. 12 Contact stiffness as a function of the number of cycles for various thin films used in the DMD [19]



The first inflection in the load–displacement profiles implies the onset of yield and its location is indicated by arrows. The three unfilled polymers (PPMA, PMMA and PS) exhibit ductility, as seen in the SEM images for the beams tested with an applied load of 3 mN. The beams stretch at the ends and underneath the center of the beam. These correspond to regions subjected to maximum tensile stress. The beams deformed symmetrically, indicating that the load was applied equidistant

from the clamping points. The PS/clay nanocomposite beam exhibited slight yielding, followed by breaking, as indicated by an arrow in the load–displacement profile. After breaking, the load continued to increase because a predefined load is imposed by the nanoindenter. The corresponding SEM image for PS/clay shows a flat fracture surface, indicating that the crack propagated perpendicular to the direction of the applied stress [20].

From the load–displacement curves, the yield strength can be evaluated by using [20, 21]:

Nanoindentation, Fig. 13 (continued)

Nanoindentation, Fig. 13 (**a**) Load–displacement curves for the normal beam bending of the PPMA, PMMA, PS and PS/clay polymer beams for use in the cell force BioMEMS sensor device. SEM images correspond to the beams subjected to 3 mN load. (**b**) Lateral bending of PS and PS/clay cantilever beams. The lateral force is plotted as a function of the lateral displacement, and the *arrows* indicate the onset of yield for both PS and PS/clay, cracking for PS and breaking for PS/clay. SEM images indicate the bending direction and the crack locations [20]

$$\sigma = \frac{3}{4}\frac{Fl}{bh^2} \tag{12}$$

where F is the load corresponding to yield of the beam (as indicated by arrows in the load–displacement profile), l, b, and h are the beam's length, width and height, respectively. It is assumed that the beam ends are clamped.

Figure 13b presents the results of the lateral bending experiments on PS and PS/clay cantilever beams. On the left column are the plots for the lateral force recorded as a function of the lateral displacement. From the linear elastic regime (as indicated by the straight line drawn over the data points), the modulus can be evaluated. For a cantilever beam with one end clamped, it is expressed as [20, 21]:

$$E = \frac{l^3}{3I}m \tag{13}$$

where l is the beam length, I is the area moment of inertia for the beam cross section, and m is the slope of the linear region of the force–displacement curve.

From the load–displacement curves, the yield strength can be evaluated by using [20, 21]:

$$\sigma = \frac{6Fl}{bh^2} \tag{14}$$

where F, l, b, and h are defined similarly as in Eq. 12. The force used for calculating the yield strength is taken at the point where a change in slope was observed (as indicated by the arrows on the left in Fig. 13b).

For PS, a steady decrease in the lateral load was observed at 160 mm, while for the PS/clay beam, the drop at 80 mm was abrupt (as indicated by the arrows on the right). SEM images reveal that for PS, this corresponds to crack formation at the base of the beam that did not run throughout the entire thickness of the beam. However for PS/clay, the beam broke, which implies that the addition of the nanoclay filler induces embrittlement of the beam.

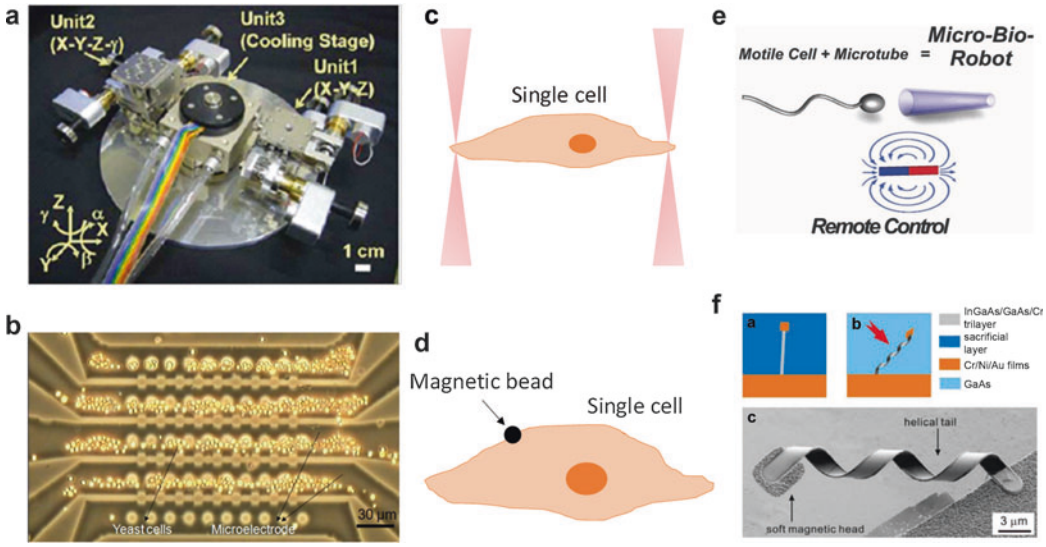
Definition

Nanomanipulation for biocells is the usage of precise manipulation techniques to tackle the fundamental and practical problems in biological cells at small scale, including, but not limited to, cell positioning, cell characterization, cell assembly, and so on.

Overview



Biological cell is the basic unit of life. This small organizational system maintains a highly complex and hierarchical architecture of interconnected molecular networks. The analysis on biological cell greatly benefits the basic research in life science and also clinical applications. Nanomanipulation enables to control the cell's position precisely; thereby, it provides the possibility to study the cell's properties at very small scale. Nowadays, nanomanipulation has been successfully used in cell positioning, cell characterization, cell assembly, and other biological cell analysis fields.

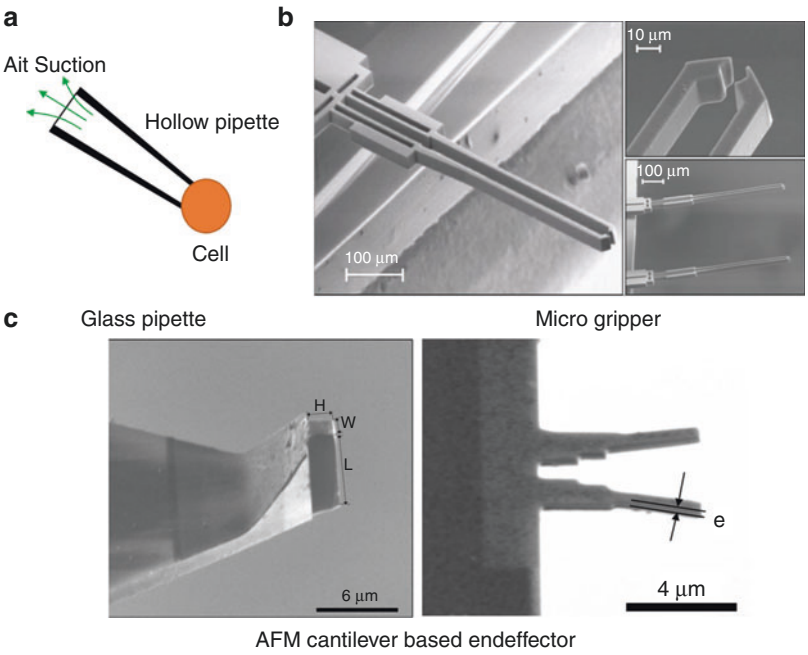
Key Techniques in Nanomanipulation

Nanomanipulator

A main type of nanomanipulator is based on the piezo effect, which is able to convert the electrical power input to the mechanical movement output. Piezo actuator can provide long movement distance up to several centimeters and high positioning resolution up to a few nanometers. Because of these advantages, this type of actuator has been widely used as the basic units to develop the nanomanipulation system. Figure 1a illustrates an example of this kind of nanomanipulation system. It has seven degrees of freedom in total and can provide positioning resolution at nanometer scale, which has been successfully used to study the single cell's property [1]. One potential drawback for this type of nanomanipulator is the existence of wires, which makes it not applicable for the cell manipulation in narrow closed environments, such as inside a microfluidic chip.

Wireless manipulators, including dielectrophoresis (DEP), optical tweezers, magnetic twisting cytometry, and others, avoid the usage of electrical wires (Fig. 1b–d). Thus, they are able to manipulate the sample remotely without physical contact, which provides the possibility for the biological cell analysis in a closed environment. Nowadays, these manipulation systems have been widely used for the cell analysis in the microchip, including for cell array, cell characterization, and so on [2]. One potential problem of the wireless manipulation is that they have special requirements on the manipulation environment, such as light transmission solution, magnetic objects, and so on. Another problem is force-producing ability of this kind of system is relative low, i.e., usually less than micro-Newton. Thus, the application area of the wireless manipulators is not as wide as the piezo actuator.

Nanomanipulation of Biocells, Fig. 1 Examples of the manipulators at small scale. (**a**) Piezo-based nanomanipulator [1]. (**b**) Dielectrophoresis [5]. (**c**) Optical tweezers. (**d**) Magnetic twisting cytometry. (**e**) Sperm-flagella-driven micro-bio-robot [3]. (**f**) Artificial bacterial flagella [4] (Reproduced with permission from Refs. [1, 3–5])



In addition to the above methods, the bio-inspired manipulator also has fast-rising growth these days. Creatures or the actuation part of creatures have been taken as the manipulator directly, such as sperm, bacteria, flagella, protein, DNA, and so on (Fig. 1e) [3]. These bionanomanipulators have many advantages, such as tiny size, simple structure, self-assembly, and biocompatibility. Inspired by the actuation mechanism of bacteria, an artificial flagella is developed (Fig. 1f) [4]. Although the research in this field is still at the preliminary stage, it is thought that the biochemical-inspired nanomanipulator would play more and more important roles in the future.

End Effector

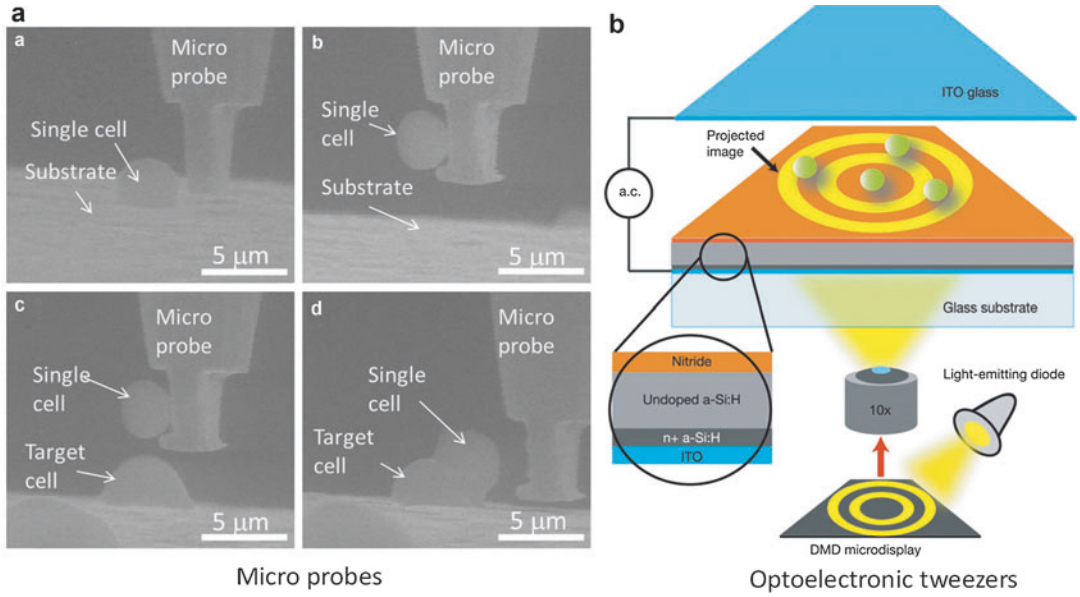
End effector is the "hand" to manipulate the biological cells. The nanomanipulation system, especially for the manipulator with wire, is hard to manipulate the biological cell directly. Thus, the design of the end effector regulates the working efficiency of the nanomanipulation system directly. Generally, the end effector should be of a small tip to fit the size of the cell. The simple endeffectors include tungsten probe, glass needle, micropipette, and so on (Fig. 2a). To enhance the manipulation ability, many functional end effectors are also developed based on micro–nano-fabricated techniques, such as MEMS (Micro-electromechanical Systems)-based and AFM (atomic force microscopy) cantilever-based end effectors, which are illustrated in Fig. 2b, c respectively.

MEMS device is one type of successfully applicable end effector for the manipulation of cells at small scale. It is usually designed based on the electrostatic mechanism. Controlling by the input voltage, the different parts of the MEMS device can move relatively. Therefore, the MEMS device enables to do the open and close motion if well designed with two probes, such as microgripper [6]. In addition, some unique materials, such as shape memory alloy and thermal expansion polymer, are also used to improve the movement ability of the MEMS device.

AFM cantilever is another type of widely used end effector for cell manipulation. AFM cantilever can be integrated with the nanomanipulation system easily owing to its small size. More important, AFM cantilever can provide force information during the manipulation process based on the

Nanomanipulation of Biocells, Fig. 2 Examples for the end effectors. (**a**) Micropipette. (**b**) Microgripper [6]. (**c**) AFM cantilever–based end effector [7, 8] (Reproduced with permission from Refs. [6–8])

deflection of the cantilever beam. Regarding these advantages, AFM cantilever provides a great opportunity for the cell characterization, including the mechanical, electrical, and other properties. To improve the function of AFM cantilever further, various shapes of end effectors are developed based on AFM cantilever. These end effectors not only keep the force measurement ability but also have specific function according to the design. For instance, by modifying the tip of AFM cantilever via focused ion beam (FIB) etching, different functional end effectors are developed to study the properties of single cell, such as the nanopicker for cell-cell adhesion study, dual probe for cell electricity study, microprobe for cell adhesion strength study, and so on [7–9].



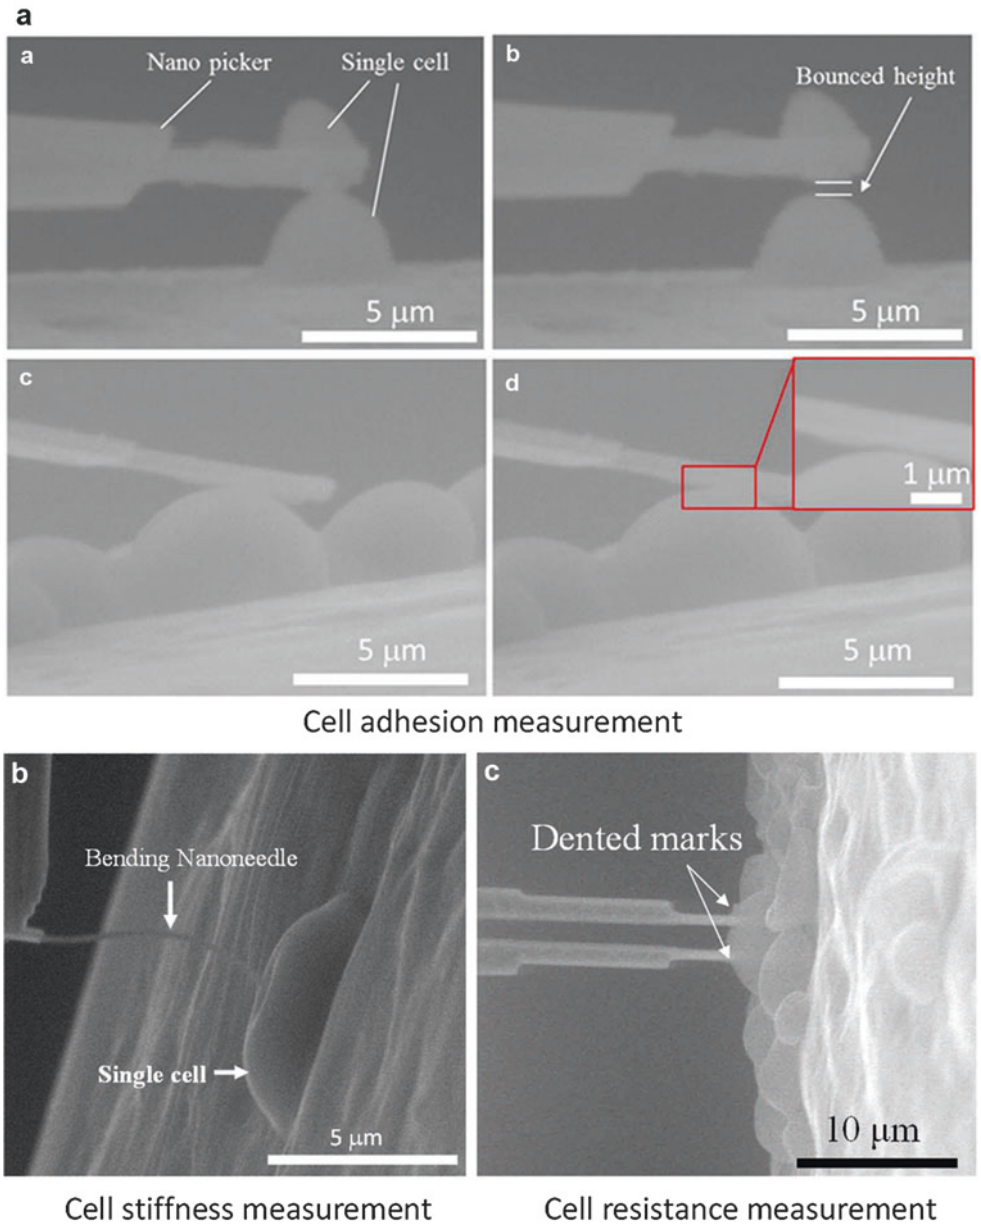
Examples of Applications

Cell Positioning

Cell positioning is the basic technique for cell array and single-cell analysis, in which nanomanipulation techniques provide a great support. The techniques for cell positioning can be classified into direct and indirect cell positioning according to the physical contact and noncontact manipulation, as illustrated in Fig. 3.

In the direct cell positioning, the end effector, such as micropipette and microgripper, are assembled on the nanomanipulator firstly. Driven by the nanomanipulator, the position of the end effector is able to be precisely controlled. Since the end effector is able to handle and release the cell, this integrated system enables the pick-transport-place of a specific biological cell precisely and effectively. The issue for the direct manipulation is that the end effector has to contact with the cell during the manipulation process. Thus, it is difficult to implement this platform in the closed environment, like inside the microfluidic channel.

Indirect cell positioning method is based on the wireless actuation techniques, which can manipulate the sample remotely without physical contact. Optical tweezers are instruments that use a highly focused laser beam to hold and manipulate small objects. In the late 1980s, Arthur and Joseph demonstrated the first application of optical tweezers to the biological sciences, using it to trap an individual tobacco mosaic virus and Escherichia coli bacterium [10]. Today, optical tweezer has been a



Nanomanipulation of Biocells, Fig. 3 Application examples of the nanomanipulation for cell positioning. (**a**) Manipulation with physical contact: cell transfer by microprobe [8]. (**b**) Manipulation without physical contact: cell array by optoelectronic tweezers [11] (Reproduced with permission from Refs. [8, 11])

common scientific instrument in trapping cells to study a variety of biological problems. Because optical tweezers can manipulate the object precisely without physical contact, it is very useful for the cell positioning inside the microchip. The main issue of the optical tweezers is that the generated force by laser is usually limited to nano-Newton, which is not large enough to drive the nonsuspending cells some time. Dielectrophoresis (DEP) is the phenomenon in which a force is exerted on a dielectric particle when it is subjected to a nonuniform electric field. DEP has the advantages of noncontact manipulation, good controllability, and high integration ability with the microchip. Therefore, it is another powerful technique for the cell trapping and sorting, especially for the cell analysis in the microfluidic chip. The drawback of DEP is that the strength of the force depends strongly on the medium and particles' electrical properties, on the particles' shape and size, as well as on the frequency of the electric field. Another problem is that it is difficult to make the size of the electrode to nanoscale, which affects the manipulation accuracy. To overcome these drawbacks, a new concept called optoelectronic tweezers (OETs) is proposed [11]. OETs use projected optical images to grab and corral tiny particles with sizes ranging from hundreds of micrometers to tens of nanometers. In this method, light first creates "virtual electrodes" on the substrate. Then, the image in conjunction with an externally applied electrical bias creates the localized DEP traps in the illuminated areas. This method combines the advantages of optical tweezers and electrode-based DEP, which is expected to have a bright future in the cell positioning.

Cell Characterization

Cell characterization provides a quantitative method to study cell behavior, which greatly benefits the basic research and the clinical application. In the characterization process, the cell has to be handled and manipulated flexibly to allow the measurement of different properties, such as strength, stiffness, electrical conductivities, and so on. As the key technique to provide precise positioning, nanomanipulation involves deeply in cell characterization. Figure 4 demonstrates three application examples of cell characterization, i.e., cell adhesion, stiffness, and electrical resistance.

Nanomanipulation of Biocells, Fig. 4 Application examples of the nanomanipulation for cell characterization. (**a**) Adhesion study [8]. (**b**) Stiffness characterization [21]. (**c**) Electrical properties study [9] (Reproduced with permission from Refs. [8, 9, 21])

Cell adhesion is a very important research topic in biological field, since many cell activities depend on the attachment of cells to the extracellular matrix or neighboring cells. One traditional nanomanipulation technique for cell adhesion study is micropipette aspiration [12]. In this method, two aspiration pipette end effectors are assembled on two micromanipulators, respectively. The negative pressure from the pipette allows the cell to be grasped on the tip.

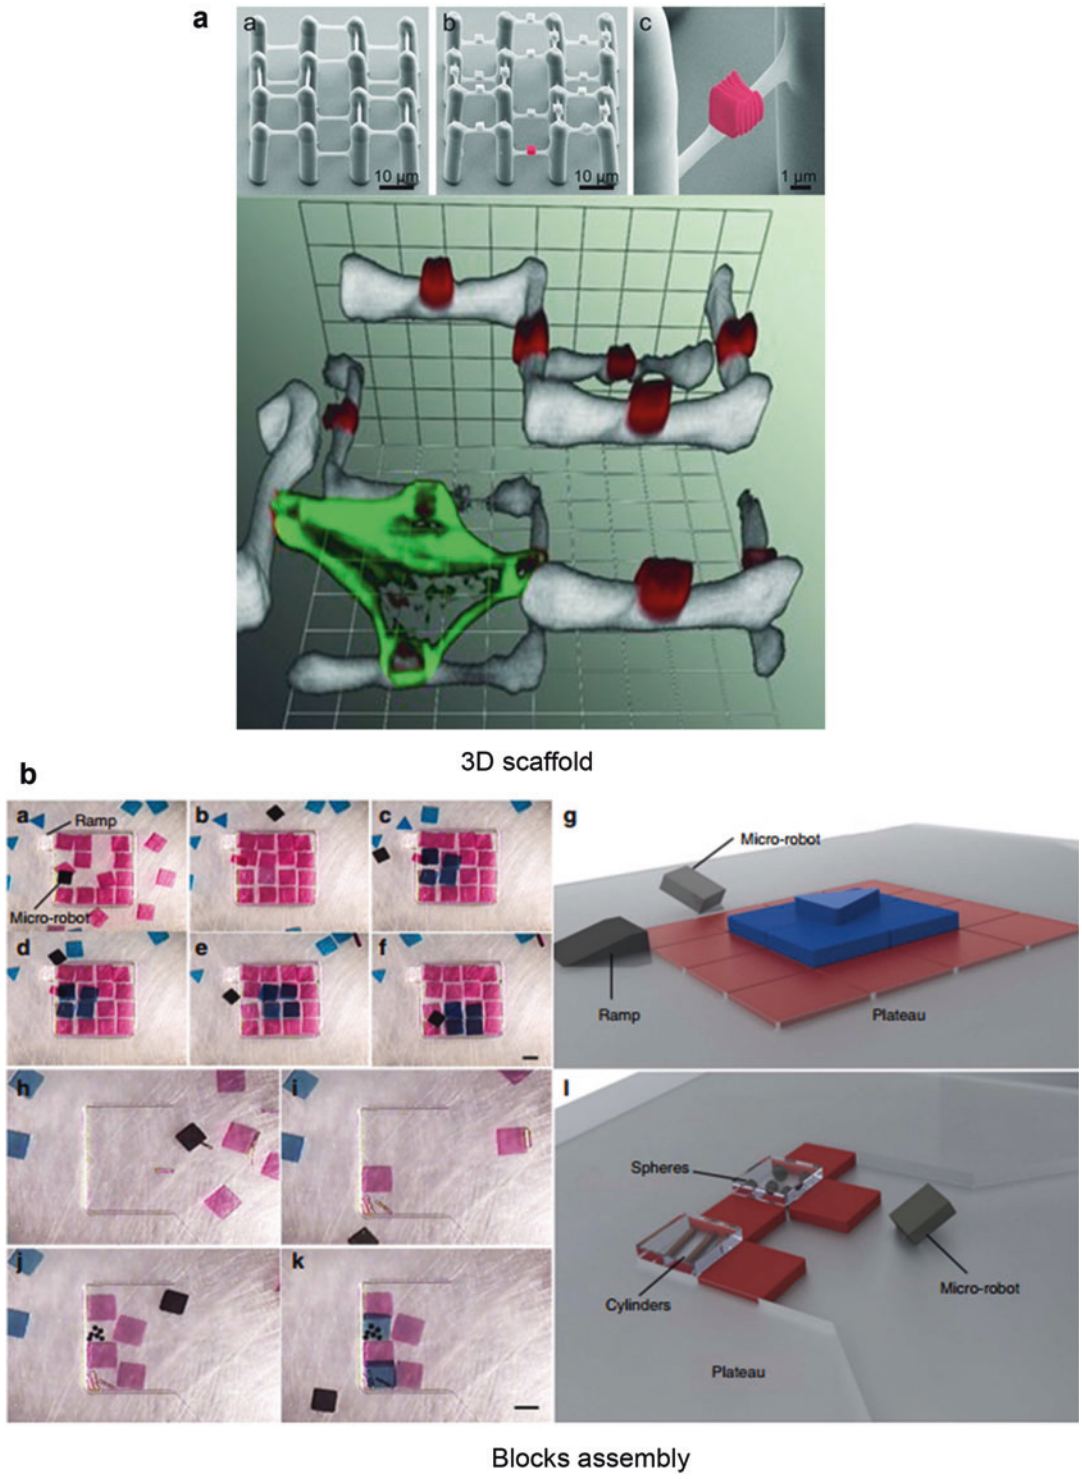
Driven by the nanomanipulator, the two pipettes pull the cells from opposite direction to separate them. With the increasing of the suction force gradually, the cell would be separated finally. In this process, the cell-cell adhesion strength is able to be calculated based on the suction pressure. AFM system is another powerful nanomanipulation system to study the cell's adhesion properties, including both the cell-substrate and the cell-cell adhesion [13, 14]. Here, AFM cantilever is not only the end effector to manipulate the cell but also the sensor to measure the adhesion force. One common setup is to use the AFM cantilever to detach the cell on the sample stage, in which the adhesion strength is measured based on the deflection of the AFM cantilever. If one cell is immobilized on a modified AFM cantilever tip, the adhesion cell-cell force can be measured, in which process the specific tip is used to press on and leave from another cell. The adhesion between these two cells can be calculated based on the deflection of the AFM cantilever. In addition, AFM nanomanipulation system also allows the adhesion strength measurement between the cell and the proteins. In this process, the AFM cantilever tip is modified with protein first. Then, this cantilever is used to study the cell-protein adhesion following the same process of cell-cell adhesion measurement. AFM system has the advantages of higher positioning accuracy and higher force resolution. One main issue is that the AFM system cannot scan the sample to get high-resolution image during the adhesion characterization process. Environmental scanning electron microscope (ESEM) is one unique type of SEM. It can not only keep the real-time observation ability of SEM but also allow the nonconductive and aqueous sample observation. Integrating with the nanomanipulation technique, ESEM provides a novel approach for single-cell analysis [1, 15]. AFM cantilever–based end effector is usually used in this characterization system. By modifying the AFM cantilever with nanofabrication technique, various end effectors can be developed for different characterization tasks, such as the microputter and nanopicker for the cell-substrate and cell-cell adhesion measurement respectively [7, 8]. This system allows the real-time imaging at nanometer resolution during the manipulation, which provides more information to benefit the single-cell characterization.

Cell stiffness and elastic characterization is another application example of the nanomanipulation system. Recently, various nanomanipulation methods have been reported to study single cell stiffness, including MEMS tool, optical tweezers, magnetic beads, AFM system, ESEM nanotool, and so on. MEMS tool is an effective end effector for cell characterization owing to its force measurement ability. For example, an integrated manipulator and MEMS probe system is developed to measure the stiffness of the pollen tube cell [16]. This characterization system allows measuring the local region of the cell, but the probe size of the MEMS tool is difficult to be at nanoscale. Optical tweezers enable high positioning accuracy and high force resolution for the stiffness characterization. It has been successfully used to study the mechanics of the human red blood cell [17]. The relative low force output ability ($\sim$pN) and light-induced damage are thought as the challenges for optical tweezer manipulation. Magnetic manipulation drive small beads to deform the cell based on the controlling of the magnetic field, which avoids potential light-induced damage as in laser trapping. The local viscoelastic value of the cell can be measured based on the applied magnetic strength on the beads. In this method, the modeling and controlling of the nonhomogeneous magnetic field are considered as the challenge. The high force sensitivity of the AFM system makes it particularly suitable for cell stiffness study [18]. Here, the AFM cantilever is used as the nanoindentor to deform the cell. Then, the stiffness value is calculated based on the cell deformation and the applied force. One potential problem in this method is the pyramid structure of AFM tip, which causes difficulty to the mechanical modeling when the cell has a large deformation. To overcome this drawback, a nanoneedle with a long slim probe is designed based on FIB etching technique [19]. Driven by the nanomanipulator, the nanoneedle allows a large deformation on the cell surface, thereby to provide more accurate mechanical models for the cell.

Nowadays, the characterization of a cell's electrical property has attracted increasing interest, because it reflects the physiological state of the cell and has wide application in medical field. To study the electrical properties of the cell accurately, a precise nanomanipulation system and a tiny conductive probe are required. An integrated system, consisting of robot-assisted AFM nanomanipulation system and the traditional patch-clamp system, is able to measure the electrical response of the human cell corresponding to external mechanical stimulation [20]. This system expects to benefit the drug test in the future. More than the single probe, an end effector with dual probes is also developed to study the electrical resistance of the cell [9]. Driven by the nanomanipulation system, the dual probes penetrate the cell wall first. Then, the current between the two probes is measured by applying a low voltage. This experiment setup can detect the resistance difference of living and dead cells, which expects to have wide applications in cell biology study.

Cell Assembly

As the basic unit, a cell is always considered as the "block" of life. How these blocks build life is one of the biggest questions in the world. Therefore, increasing interests have been focused on the assembly of 3D biostructure from single cells.



Generally, a cell requires a relative strong "scaffold" to support its growth in 3D space. Thus, the preparation of 3D scaffold is one key step in cell assembly. 3D printing is a novel technique that combines robotic manipulation and material science together. It is able to print the scaffold or components with single cells to 3D structure directly. With the support of nanomanipulation, 3D printing can also work at small scale. For instance, a scaffold with structure at nanoscale is fabricated based on nanoscribe technique, which is successfully used to study the growth of single cells in 3D space [22]. In addition to 3D printing, other fabrication techniques are also applicable for 3D cell assembly, such as the controllable optical induced method. Because some gels are sensitive to light, the formation of the gel can be controlled by light. On the basis of this principle, 3D gel has been generated successfully with different shape and height by controlling the light illumination area and the exposure time [23].

Another assembly method is to directly build the blocks with cells to 3D structure, as house building. First, the biological cells are capsulated in series gel blocks by biochemical process. Then, small robots actuated by magnetic fields are used to manipulate these blocks to build complex 3D structures [24]. To improve the manipulation ability, the biocompatible magnetic nanoparticles can also be mixed in the gel, so the position of the gel can be manipulated by magnetic fields more flexibly.

Nanomanipulation shows its high applicability in 3D cell assembly owing to its controllability and flexibility. One main goal of 3D cell assembly is to construct artificial functional units that can take place in our natural organ one day. Thus, there are still many challenges for the manipulation technique, such as the precise position control of the cell in 3D space, the assembly of different types of cells, and so on (Fig. 5).

Future Research

Nanomanipulation technique has greatly benefited the biological cell research from many aspects. However, there are still lots of challenges for the manipulation system. The first one is the actuation technique for the nanomanipulator, which covers power supply, energy transmission, driven approach, and so on. To address the problems in practice, the actuation system for the nanomanipulator should be much smaller, higher output capability, and higher efficiency. Biological creature is the "nanorobot" in nature, which has high working efficiency and exactly compatible for bioapplication. "Learn from nature" will drive new inspiration to the nanomanipulation, which is expected to benefit the biomedical field in the future. Secondly, the data with high spatial and time resolution would help us to understand the cell activities better. Nowadays, people have shown increasing interest to cell research at the subcellular or molecule level. Thus, the nanomanipulation system should be much more accurate and intelligent to meet the above

Nanomanipulation of Biocells, Fig. 5 Application examples of the nanomanipulation for cell assembly. (**a**) Fabrication of 3D scaffold for cell growth in space [22]. (**b**) Assembly of blocks containing cells [24] (Reproduced with permission from Refs. [22, 24])

requirement. Last, the commercialization of the nanomanipulation system should be considered. Although many exciting nanomanipulation techniques have been reported, most of them are still in the laboratory. How to bring these techniques to market to benefit our society will be a significant task in the future.

Self-assembly; nanofabrication; bottom-up processing

Definition

Nanomanufacturing originally refers to alternative approaches to achieving nanoscale resolution in manufactured devices by means other than integrated circuit fabrication (i.e., photolithography performed in a large-scale cleanroom on large area silicon wafers). One example of so-called bottom-up processing includes the concept of self-assembly [1], where nanoscale material components interact with each other or with external forces to build themselves into complex structures at larger length scales. Examples of external forces include thermal, electrical, magnetic, etc. Here, a magnetic field-driven nanomanufacturing technology is discussed that uses the disk from a commercial disk drive as a programmable template to direct self-assembly and nanomanufacture at cm length scales with nanometer resolution.

Commercial magnetic recording uses a nanometer-scale electromagnet to magnetically align <5 nm diameter Co grains that are embedded in a Cr matrix along one of two directions to create a binary pattern of 1s and 0s for the storage of information [2]. These patterns are then arrayed over a two-dimensional circular disk into concentric rings, known as tracks, with individual bits oriented along the circumference of the tracks. The electromagnet is fabricated as a part of a recording head that is on a movable arm that reaches individual tracks, while the spinning of the disk allows the head to reach the entire circumference of a given track. Typical patterns recorded onto a disk are as small as 12 nm by 30 nm, with transitions between regions a mere 1 nm in size. This size continues to decrease as the recording industry scales the component materials and technologies to increase the number of bits that can be stored on a single disk. To recover the stored 1s and 0s, a separate sensor fabricated on the same recording head uses a magnetically induced change in electrical resistance (magnetoresistance) to sense the spatially varying magnetic fields emitted from the patterned magnetic regions, which change sign depending on whether the recorded bit is a 1 or a 0.

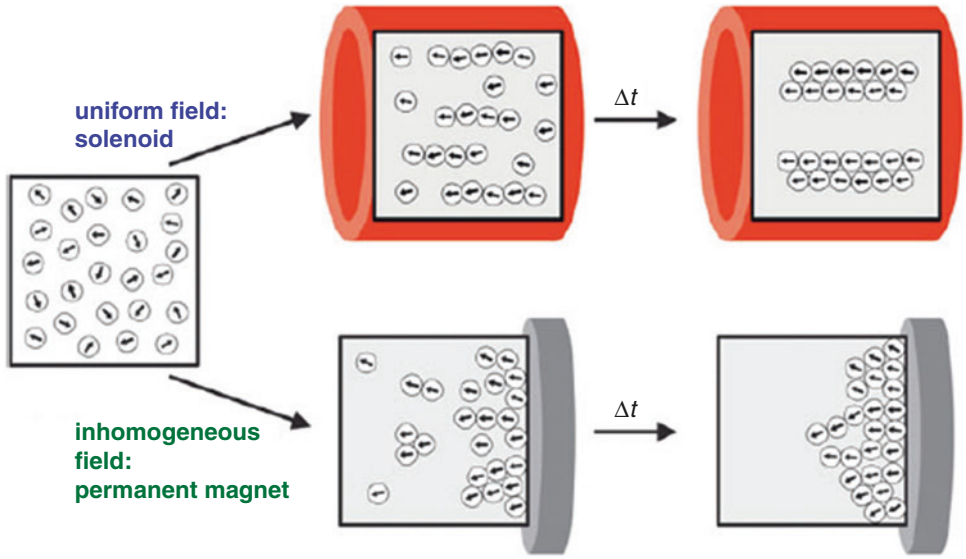
Because the magnetic fields change sign over a spatial region that is only a few nm across, the spatial gradient in magnetic field located at these transitions can exceed 10 MT/m. In addition to enabling magnetic information storage, these field gradients can be used to nucleate and direct the self-assembly of nano-sized magnetic particles into complex patterns over the entire disk surface (approaching 50 cm^2). Nanoparticles as small as 5 nm in diameter can thus be assembled into cm-sized patterns with single nm resolution, spanning seven orders of magnitude in size with a single assembly step that is effectively passive.

The particles to be assembled are colloidally stabilized in a dilute fluid (ferrofluid). This fluid is

then introduced in the space above the disk medium, and the magnetic field gradients attract the particles to the surface through a combination of Newtonian mechanics and diffusion. As they arrive at the surface, they cluster around the recorded transitions, replicating the pattern that has been recorded into the medium. Once the pattern has been assembled on the template surface, the fluid and remaining particles are removed, and the surface is rinsed. Next, an air-curable, water-based polymer is spin coated onto the nanoparticle/template surface. After curing, the polymer is peeled from the template surface, transferring the patterned nanoparticle assembly to a free-standing polymer film, yielding an engineered polymer nanocomposite material. The recorded template can then be reexposed to new nanoparticle solution and the manufacturing process is repeated. Templates can be reused over and over to manufacture large quantities of material. The number and size of templates can be scaled to increase manufacturing output while maintaining single nanometer resolution. Once the template is recorded, the assembly process is passive. The fluid is placed on the surface, and the nanomanufacturing proceeds via the magnetic and other forces present at the disk surface.

Overview: Magnetic Field-Directed Self-Assembly

This entry will describe a method for nanomanufacturing using the patterned, nanoscale magnetic field gradients found at the surface of a standard, commercial, hard disk drive. The disk in the disk drive is coated with a thin film containing billions of tiny nanomagnets that can be magnetized by an external field. Once magnetized, these grains create their own magnetic field, and, at nanoscale transitions where these grains switch their magnetic direction, extremely large magnetic field gradients arise due to the degree of spatial confinement. This highly engineered nanotechnology can be adapted to enable manufacturing of macroscopic composites containing patterned nanomaterials, or hierarchical nanomanufacturing.



Francis Bitter first detailed his work observing magnetic inhomogeneities, i.e., magnetic domains, using a fluid suspension of maghemite γ-(Fe_2O_3) particles in 1931 [3]. Known thereafter as the "Bitter technique," the use of iron filings, micro- and nanoparticle ferrofluids, and other materials have long been staples of physical science demonstrations from elementary school through college. Broadly, the reason magnetic particles are attracted to these inhomogeneities is because a spatially changing magnetic field is present, i.e., a magnetic field gradient (Fig. 1). One can picture the process as follows. A local magnetic field magnetizes a particle that can be paramagnetic, ferromagnetic, superparamagnetic, etc., and then the magnetized particle is attracted toward the direction of increasing gradient, which is opposite to the direction of the aligned moment.

This magnetic force, which is why magnets stick to refrigerators, why giant electromagnets can pick up entire automobiles, and why entire trains can be levitated, allows assembly of magnetized objects into structures. In addition to these macroscopic manifestations of this force, it also works at the nanoscale, i.e., nine orders of magnitude smaller. While the concept of self-assembly is well established, as discussed in recent review articles [1, 4], magnetic field-directed self-assembly is now arguably a separate subfield within self-assembly [5]. Combined with recent interest in magnetic nanoparticles [6, 7], magnetic field gradient-driven assembly has seen strong interest over the past decade across multiple fields.

The motion of magnetized objects caused by magnetic fields is known as magnetophoresis. The force on a magnetized object can be calculated as the gradient of a potential energy; here the energy of a magnetized object in a magnetic field is as follows [8]:

$$\vec{F}_{\mathrm{mag}} = \mu_0 \vec{\nabla} \left(\vec{m} \cdot \vec{H} \right)$$

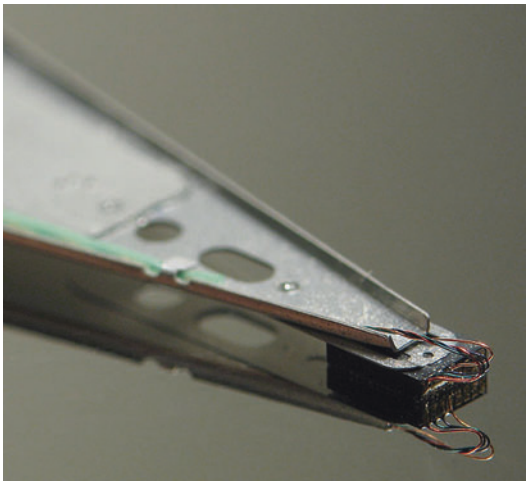
where in SI units, μ_0 is the permeability of free space, **m** is the magnetic moment of the magnetized objects in Am^2, and **H** is the magnetic field in A/m. By applying standard vector identities and

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 1 Schematic comparing magnetic field-directed self-assembly in uniform magnetic fields, i.e., produced by a solenoid, and in field gradients (i.e., spatially varying fields), which can be generated by permanent magnets. The uniform field aligns the nanoparticle moments, and it is the nonuniform field emitted by the particles themselves that self-assembles them into chains. For the permanent magnets, its inhomogeneous field generates attractive forces that pull the nanoparticles toward the region of the strongest field. *Arrows* indicate the magnetization directions of single-domain magnetic nanoparticles, and Δt indicates the passage of time in the applied field. Used with permission and reprinted from Ref. [5]

the definition of the vector product, this expression can also be written as

$$\vec{F}_{\text{mag}} = \mu_0 \left(\vec{m} \cdot \vec{\nabla} \vec{H} \right)$$

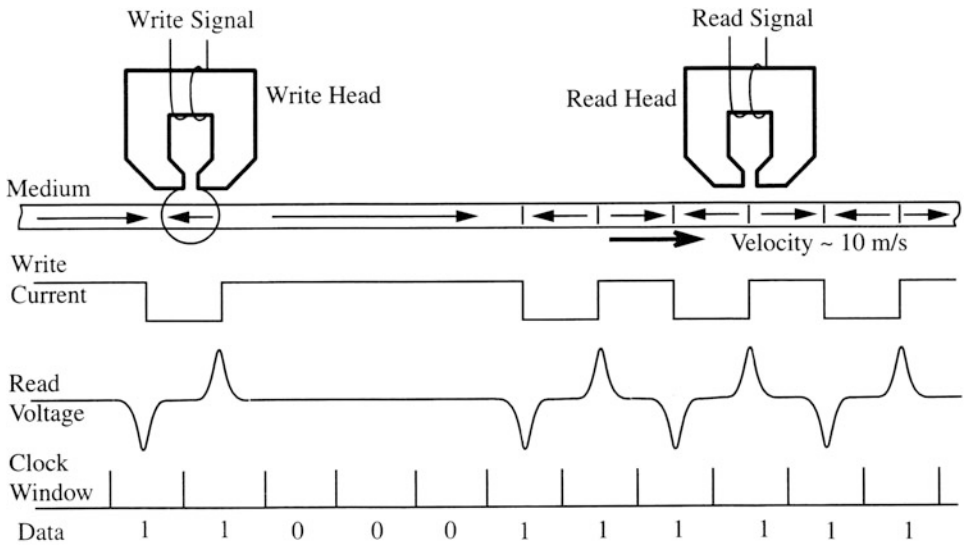
In the rewritten expression, the force is more easily seen as arising from the component of the magnetic moment along the magnetic field gradient scaled by the size of the gradient itself. Importantly, for this force to be maximized, the magnetic field must be sufficiently strong to magnetize the object, i.e., align its moment, in the direction of the local field. Thus, the magnitude of the force depends on both the size of the object's moment and the size of the gradient, as well as the degree to which that moment is aligned with the local direction of the field gradient. This force is the basic driver of magnetic self-assembly. In the next section, magnetic recording, i.e., the disk drive, is described with the goal to identify why it makes a potentially transformative template for nano assembly.



A Primer on Magnetic Recording

Figure 2 shows a cutaway view of the dominant magnetic recording technology, the disk drive. In addition to motors for spinning the disks and actuating the heads to sweep radially across the data tracks, the thin films that coat the disks, called the recording medium, together with the layers used to create the write electromagnet and the readback sensor, are the magnetic subsystems. Figure 3 shows a close-up of a recording head, while Fig. 4 shows a schematic of the recording process [2].

The medium is deposited onto an aluminum or glass disk and consists of multiple underlayers to establish the correct crystal texture for growing the recording layer itself, which typically is a thin

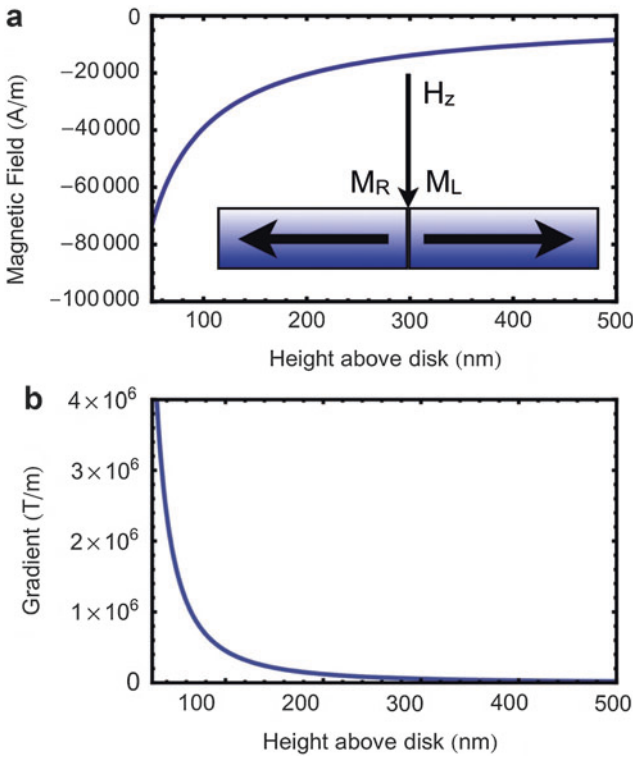


Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 2 The inside of a disk drive. The circular reflective surface is the recording medium, which is where the nanoscale magnetic field patterns are created by a magnet in the recording head, which is located at the end of the armature to the upper right of the platter. The heads pivot using a voice coil (far right corner) to access circumferential rings at different radii from the disk center

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 3 Close-up of recording head (and its mirror image in the reflective surface of the recording medium). The wires bring current to a >1 T electromagnet that writes, i.e., magnetizes the nanometer-scale Co grains that comprise the thin-film media. It also contains a magnetoresistive sensor that can detect the spatially changing magnetic fields that indicate the state of a data bit

film that contains Co, Cr, and Pt. The Pt acts as a catalyst to enable nanometer-sized Co grains to be separated by Cr at the grain boundaries, allowing for the proper magnetic anisotropy to control the grain-to-grain coupling. On top of the recording media layer is a diamond-like carbon layer followed by a monolayer hydrocarbon lubricant. The diamond-like carbon serves as wear protector, while the lubricant helps prevent the head from sticking to the media.

The recording head is fabricated using cleanroom-based nanoelectronic processing to build the nanometer-scale electromagnet on a highly wear-resistant ceramic of Al, Ti, and C. First, the magnetoresistive readback sensor is fabricated using high-resolution lithography. This sensor consists of several magnetic films together with biasing magnets to help orient the magnetic moments in the sensor to yield a linear resistance variation in response to an applied magnetic field. This readback sensor is deposited between two thicker, magnetically soft films that shield the sensor layer from stray magnetic fields, i.e., from adjacent magnetic bits. Often the top shield is connected with the bottom pole of the write electromagnet. After this first pole, a coil is deposited to energize the electromagnet. Finally, a top pole is deposited and high-resolution lithography is used to ensure that the field of the electromagnet is confined to the ~30 nm wide region of a single track.



Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 4 Schematic of magnetic recording process (longitudinal recording). The write head magnetizes the medium. Where the current energizes the electromagnetic in the write head, a transition between directions (shown as opposing arrows in the medium) is created. At these locations a spatially confined magnetic field is emitted from the medium (here labeled as "read voltage"). In magnetic recording, these spatially confined magnetic fields indicate a "1" in a bit sequence; they create enormous magnetic field gradients that can be used to direct assembly of magnetic nanoparticles for nanomanufacturing. Used with permission and reprinted from Ref. [2]

The recording head is mounted on a suspension that includes a gimbal to allow the head to fly over the surface of the disk that spins beneath it. This gimbal allows the AlTiC substrate, called a slider, to both pitch and roll. The part of the head that is exposed to the disk, called the air bearing surface, is in reality the thickness of the substrate, while the layers that comprise the read and write head are oriented 90° to the plane of the disk. This surface is further textured with lithography and etching to provide a negative pressure cavity that counteracts the lift generated by the air dragged under the head by the spinning disk, in order to keep the head ~3–5 nm away from the disk surface during recording.

To illustrate the enormity of the field gradients present at the recorded "bits" in disk drive media, Fig. 5 plots the perpendicular magnetic field (Fig. 5a) and the perpendicular component of the magnetic field gradient (Fig. 5b) as a function of height above the disk medium surface (centered on the transition shown in the inset) [2].

As discussed above, the field gradient near the surface is three orders of magnitude larger than the gradients traditionally used for magnetophoretic nanoparticle transport. The magnetic force on a nanoparticle can be integrated over different heights to obtain the work done by the magnetic field [2, 9]. In moving a 10 nm particle from 50 to 40 nm, the magnetic force in Fig. 5 does $\sim k_B T$ of work on the nanoparticle at 295 K. Thus, at five nanoparticle diameters above the surface or closer, the work done by the magnetic field rapidly grows beyond the thermal energy that drives Brownian motion. Even though the work done by the field is less than $k_B T$ for $z > 50$ nm, it is always directed toward the surface, while Brownian forces are randomly oriented. This force anisotropy assists the recorded transitions to capture nanoparticles and assemble them on the medium surface.

Regardless of whether one considers 1.5 T electromagnets that produce 30 nm confined fields, recorded bit areas that are 10×30 nm^2, or a 3 nm separation between the disk and a head flying at 30 m/s, the disk drive is a nanotechnology in almost every facet of its operation. Before discussing how to nanomanufacture composites

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 5 (**a**) Magnetic field in the z-direction (z = height above the disk) of a longitudinally recorded transition as a function of height. (**b**) Z-component of the gradient of the z-magnetic field as a function of height above the disk. Note that the gradient changes rapidly with height, falling from a maximum of 10–20 MT/m at 10–20 nm above the disk to kT/m in a mere 500 nm. Used with permission and reprinted from Ref. [9]

and devices using magnetic field-directed self-assembly with a disk drive, it is important to consider the raw material that is used in the manufacturing process, a material that comes with its own set of built in complexities, the chemically-synthesized magnetic nanoparticle.

Synthesis of Magnetic Nanoparticles

The production of magnetic nanomaterials can be accomplished either through top-down or bottom-up techniques. Regardless of production technique, the vast majority of these colloidal suspensions consist of magnetic particles suspended in some sort of carrier media. The composition of the magnetic particles is typically magnetite (Fe_3O_4) or maghemite ($\gamma-Fe_2O_3$) because they are biocompatible and have relative oxidative stability. To maintain stable suspensions of these colloids, attractive forces including van der Waals and magnetic interactions need to be overcome through electrostatic, osmotic, and/or repulsive forces [10, 11]. Typically the surface of the inorganic particle is modified with an organic material to alter the surface charge or provide a steric layer to reduce interparticle interactions. Concentration of these materials is also important as rates of aggregation have been tied to the average interparticle distance, which is derived from concentration [12, 13].

To produce the magnetic nanoparticles, several different methods have been developed. A brief overview of topics is described here. Nonetheless, the reader is encouraged to seek more detailed reviews available in the literature [10, 14–17].

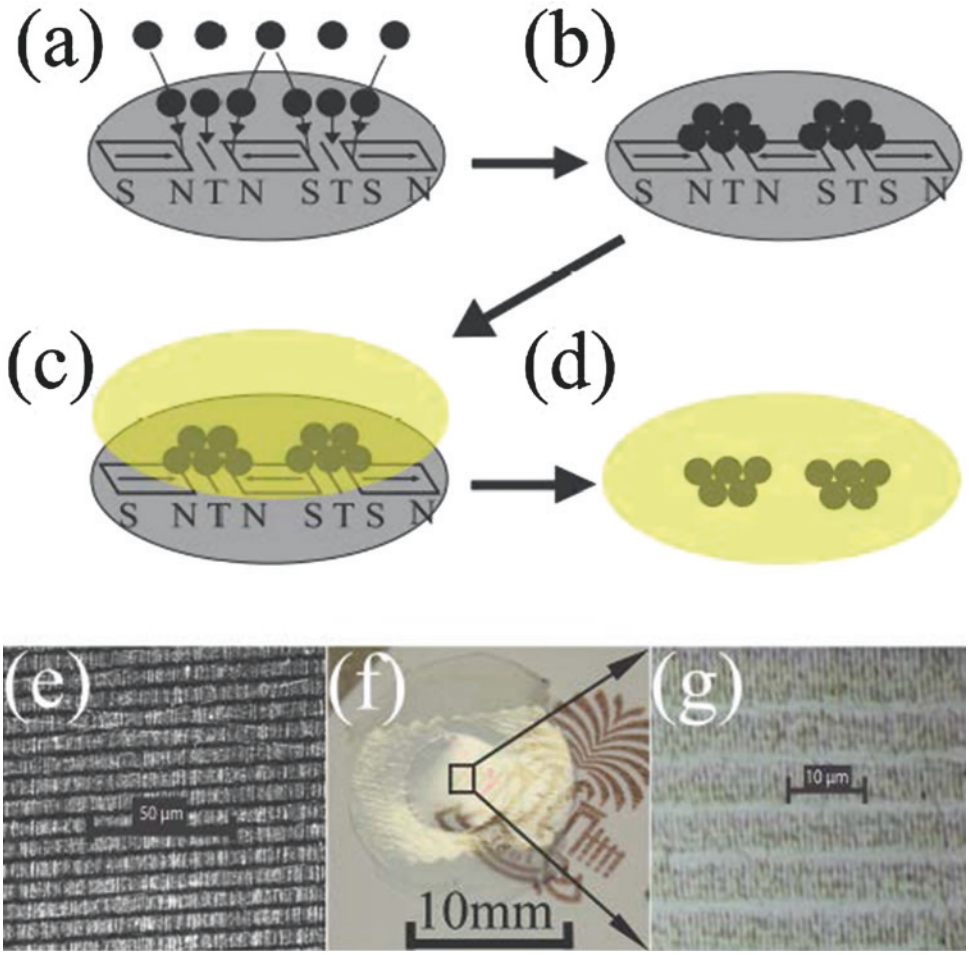
One of the earliest methods to produce these materials was the top-down technique of grinding these materials to sizes suitable for a colloidal suspension. For example, Papell first described the preparation of oleic acid-stabilized magnetite particles in heptane following grinding for 19 days [18]. Later, Rosensweig and Kaiser demonstrated that ferrofluids could be prepared by grinding for a variety of media beyond hydrocarbons, including fluorocarbons, water, and

esters [19]. While this method has some advantages, including low cost, versatility, and the ability to create large batches of materials, there are distinct limitations in size control of the particles produced.

One of the simplest bottom-up technique is the coprecipitation of metal salts to form particles. This technique was pioneered by Khalafalla and Reimers [20]. Within the nanoparticle community, this is sometimes referred to as the "Massart technique" as this methodology is the one most commonly used for the formation of aqueous-based fluids [21]. To date, this is an extremely popular method for those new to the field. In addition, it makes a great demonstration for students of any age [22]. Typical sizes of magnetite nanoparticles produced by coprecipitation are around 10 nm in diameter. Unfortunately broad polydispersities and aggregation are concerns with this process.

In an effort to control particle size, reverse micelles have been used. For example, Pileni demonstrated the production of cobalt ferrite nanoparticles with relatively uniform size using dodecyl sulfate inverse micelles as templates [23]. Alternatively, by using dioctyl sodium sulfosuccinate (AOT) to form micelles, chemistries similar to coprecipitation can yield improved size control [24]. While there are some improvements, this technique has yet to provide the versatility promised. Also, the presence of the charged surfactants used to create these materials may present challenges for additional modification.

In a similar vein, hydrothermal reactions can be employed with aqueous-based reactants in high-pressure autoclaves, where typical reaction temperatures are 200-250 °C and pressures are ~ thousands of psi. An example synthesis includes the production of iron oxide nanorods via the reaction of iron sulfate, iron (III) chloride, and ethylenediamine in water at 120 °C for 20 h in a sealed reactor [25]. Similar methods include use of iron (II) and iron (III) chlorides and ammonium hydroxide and heating at 250 °C for 24 h [26]. Again, this method does help with size distributions, but the resulting particles are typically heavily aggregated. Benefits do include the use of aqueous methods that are more environmentally benign than organic routes.



Thermal decomposition of chelates of metal precursors provides the best route to date of creating magnetic particles with uniform particle size distributions. With careful selection of stabilizing ligands, these materials can be further modified by removal and replacement of the sacrificial ligand, which is often oleic acid and oleylamine. The seminal papers in this area include the thermal decomposition of iron (III) acetylacetonate [27, 28], iron pentacarbonyl [29], and iron oleate [30, 31]. Typical procedures involve controlled reaction temperatures typically in the range of 300–350 °C, where the organic metal chelate is decomposed and off gassed.

More recently alternatives to traditional chemical processes are being explored. For example, flame spray pyrolysis is another method to produce particles but has limitations associated with addition modification. The composition and oxidative state can be controlled through the gas input of the flame [32]. Another alternative method of note is electrochemical or electrodedeposition, where a sacrificial metal anode(s) is charged in solution media containing surfactant. The size of the resulting particles can be controlled through the current applied to the system [33].

Nanomanufacturing 2D Structures

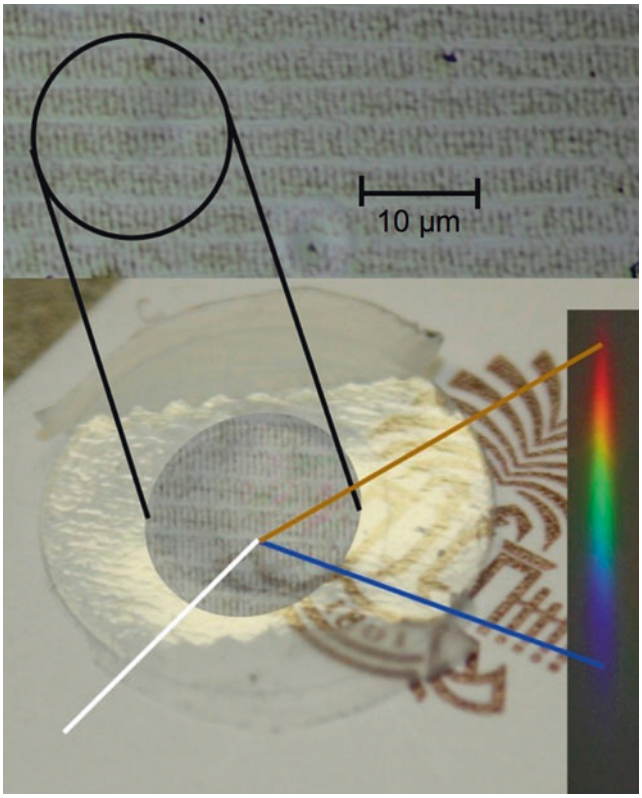
To use the spatially confined fields at the surface of the disk drive to direct self-assembly of magnetic nanoparticles, the magnetic recording medium must be programmed (encoded) with a desired pattern to be manufactured. After the template is programmed, the recording medium is coated with dilute colloidal fluid containing the magnetic nanoparticles discussed in the previous section. These nanoparticles can be thought of as raw materials or feedstocks for the manufacturing process. Figure 6 graphically illustrates the process schematically and with images [34].

The original studies of self-assembly for nanomanufacturing with recording media templates were performed on prerecorded, 1 cm diameter pieces of longitudinal magnetic recording media. These media have magnetization ~450 kA/m as determined using a vibrating sample

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 6 Schematic of nanomanufacturing with magnetically recorded nanotemplates. (**a**) Magnetic nanoparticles are attracted to the magnetic field gradients that are emitted from longitudinally recorded transitions on the surface of recorded magnetic media. (**b**) The nanoparticles self-assemble onto the medium surface at the recorded template locations. (**c**) A liquid polymer film is spin coated onto the disk surface. (**d**) After curing, the film is peeled from the disk medium. (**e**–**g**) Images of the assembled nanoparticles on the medium, the peeled film, and the nanoparticles in the film after transfer, respectively. Used with permission and reprinted from Ref. [34]

magnetometer (VSM). They are patterned into sectors along the circumference of the disk prior to distribution, through a process called servo writing, which creates regions known as servo sectors between the data sectors [2]. These regions contain complex magnetic field patterns which are used with a servo algorithm to keep the recording heads accurately positioned over the data tracks during read and write operations. It is these regions which are easiest to use for nanoparticle self-assembly [9, 35].

To create custom magnetic field templates to assemble user-customized patterns, it is critical to be able to record an arbitrary pattern into the medium. Fortunately, magnetic recording has been performed by raster scanning the head in contact with the disk for a number of years, using an instrument called a contact recording tester [36, 37]. The contact tester is similar to a scanning probe microscope, only it uses a recording head instead of a sharp tip. Either the head or the media is mounted on a precision XY scanning



stage, and electrical connections are made to the recording head to allow for both programmable magnetic recording and pattern imaging using the readback sensor.

A variety of nanoparticle species can be assembled; however, they have to contain sufficient magnetizable matter so that the magnetic field gradient can exert a force on the particle sufficient to cause it to move through the fluid. The original experiments employed both commercial ferrofluid and in-house colloidal nanoparticles synthesized using standard coprecipitation recipes. Monodisperse thermal decomposition particles (as discussed above) can also be used, and assembly can be done in water or a nonpolar organic solvent such as hexane. The ferrofluid is diluted significantly so the nanoparticles are well separated and is then pipetted onto the surface of the medium. Alternatively, the media coupon can be dipped into a beaker filled with the dilute ferrofluid. The superparamagnetic nanoparticles then assemble on the patterned magnetic transitions in a passive process that can take anywhere from 1 min to an hour, depending on the properties of the ferrofluid. After assembly, the ferrofluid is removed from the coupon surface. This removal can be done with a pipet, with a pump, or by simply tilting the coupon on its side and allowing the fluid to drain off. The coupon surface can be dried with nitrogen, or it can be rinsed with freshwater or hexane and then dried. After assembly and fluid removal, the coupon surface contains a patterned array of self-assembled nanoparticles that are stable and easily imaged with an optical microscope or a scanning electron microscope (for nanometer-scale features). Typically dark-field optical microscopy is used together with a CCD camera and imaging software to acquire images of the patterns for analysis. The diamond-like carbon (DLC) coating on the surface of the medium is sufficiently conductive, so charging in the SEM is not an issue, and high-quality images of the assembled nanoparticles can be obtained with nanometer resolution. To obtain quantitative information about the height of the assembled nanoparticles, atomic force microscopy (AFM) can be used. However, care must be taken to ensure that the AFM tip does not become contaminated with nanoparticles that can reduce the lateral resolution or corrupt the height measurement.

Transferring the Assembled Nanoparticles to a Standalone Film

After metrology, to confirm that the nanoparticles are assembled on the disk drive surface using optical, electron, or atomic force microscopy and to verify that the pattern is visible and properly defined, the next step in the nanomanufacturing process is to remove these nanoparticles from the template surface and embed them in a separate film for application. Once the nanoparticle assembly is transferred, the disk template can be cleaned and the assembly process repeated. Because of its wear-resistant diamond-like carbon coating, the media template can be used repeatedly to manufacture many standalone assembled nanoparticle films. Obviously, many templates could be coated simultaneously to achieve manufacturing scale, and in principle, each template could have a different pattern.

To transfer the nanoparticle array, a liquid polymer is spin coated onto the medium surface. One example of an air-curable water-based polymer is Diskcoat 4220 from General Chemical Co., Brighton, MI, which is designed to be cured and then peeled from a surface. After spin coating, the polymer films are cured in an airstream for $\sim$20 min at room temperature. After curing, the polymer–nanoparticle assembly is peeled from the medium with adhesive tape. Using circular tape with a central hole yields a suspended film with a 5 mm diameter circular window. The Diskcoat can be diluted in DI water, and by varying dilution, spin speed, and spin time, a variety of polymer thicknesses can be obtained, ranging from 100 nm to several micrometers. Typically it is difficult to peel films thicker than 200 nm and still yield an intact film, and peeled film thicknesses range from 200 to 500 nm. With peeling, these polymer films remove the nanoparticle assembly from the medium surface, i.e., the peeling causes pattern transfer, leaving the medium clean and the nanoparticle array embedded at the

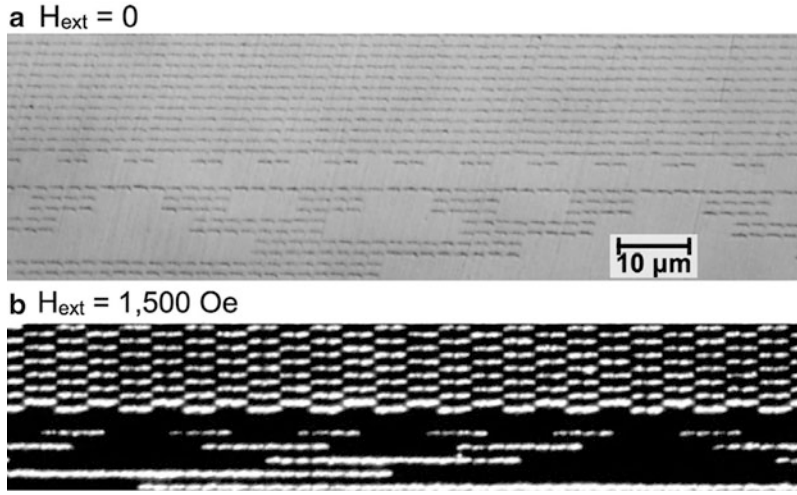
Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 7 Upper panel: Optical microscope image of a diffraction grating embedded in polymer film nanomanufactured using pattern transfer nanomanufacturing. The grating period was 750 nm as shown with the 10 μm scale bar. The lower panel shows the adhesive tape (with a cartoon of the grating) showing white light diffraction from the grating. The rainbow spectrum at right was obtained from an all-nanoparticle diffraction grating nanomanufactured PTNM™

surface of the cured polymer. These nanomanufactured materials are flexible, transparent, and contain the programmed arrays of nanoparticles [9, 34].

Figure 7 shows a reflection optical diffraction spectrum created by sending collimated white light through the assembled nanoparticle layer in the central 5 mm region in the lower panel. The peeled films are mechanically stable but are relaxed, meaning they can have wrinkles. These wrinkles can be made to repeatedly change shape in response to a temporary increase in humidity, temperature, or magnetic field. For example, breathing on the polymer film, induces a shape distortion sufficient to cause the diffracted spot to vanish. However, the diffraction returns as soon as the humidity is reduced to ambient.

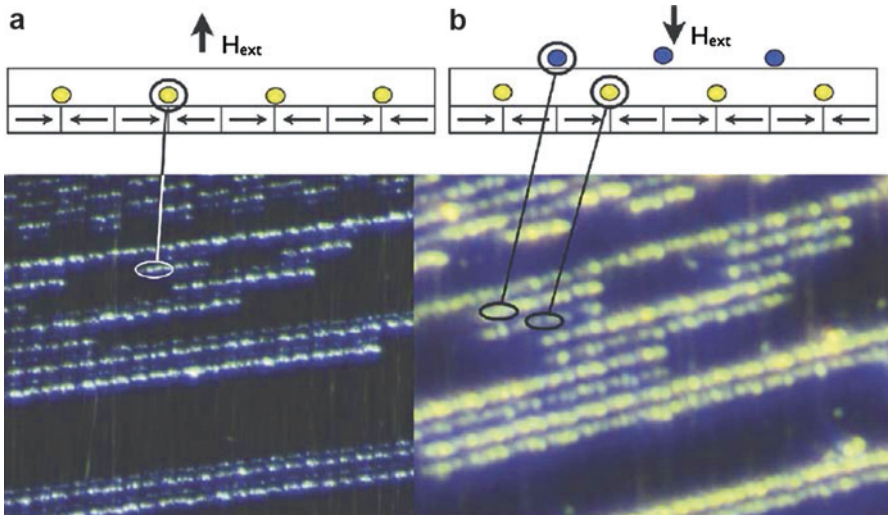
These polymer/nanoparticle diffraction gratings have been used in a spectrograph to demonstrate the viability of these nanomanufactured materials. Using standard diffraction grating analysis, the angle of diffraction was measured for different optical wavelengths, verifying that the line spacing was close to what was measured with the optical microscope. Importantly, the analysis of the diffracted signal from the nanomanufactured grating was based on a 1–2 mm diameter region of the film, whereas the optical microscope measurement was done on a limited sample size, say 50–75 lines. The optical microscope and diffraction measurements yielded 742 $\pm$ 12 nm and 770 $\pm$ 10 nm, respectively [34]. Thus, while the agreement was not perfect, the diffraction measurement was over a much larger sample of nanoparticle patterns than could be counted from a single (or even multiple) microscope images. Given the quality of the diffracted spectra (which were limited by the optical components of the spectrometer and not by the grating), these nanomanufactured materials could find application for building wavelength-sized structures for photonics applications.

To prove that the pattern transfer process completely transfers the nanoparticles to the polymer film, magnetometry is performed on the first



peeled film, yielding a magnetic moment versus field curve that would be expected for superparamagnetic nanoparticles. After the first transfer, second and third polymer coat, cure, and peels were performed on the same template without cleaning the surface. The second and third peeled films were measured with the VSM, and the resulting measurements are indistinguishable from measurements made on films without any nanoparticles. Based on the VSM's rms sensitivity of 1×10^{-6} emu, which is 2 % of the total moment measured from first peeled films that contain the patterned, transferred nanoparticles, at minimum, 98 % of the nanoparticles are transferred to the film during the initial peeling step. Optical microscopy images obtained of the coupon surface after peeling show no remaining nanoparticles, and AFM measurements of coupons after peeling likewise show no particles in several locally imaged regions.

Manufacturing Process Extensions



With the pattern creation, assembly and spin/cure/peel polymer processes established, there are several extensions that can be made to gain further control over the assembly process. For example, we extend the nanoparticle assembly process by applying a uniform external field over the fluid cell during the nanoparticle self-assembly step [9].

Figure 8a, b shows optical images of the same region of media coated in zero external-field (Fig. 8a) and with an external field, $H_{ext} = 1.5$ kOe, directed toward the medium surface (Fig. 8b). In contrast to the zero-field assembly process, here the external field superposes with the field emitted from the patterned transitions and changes the assembly process. Superposition of a 1.5 kOe field with the transition field means H_{net} goes to 0 at a height of $z = 20$ nm above the surface. Therefore, the external field will exceed the medium field for $z > 20$ nm. The larger external field will cause nanoparticles further than 20 nm from the surface to be magnetized along the external field direction.

These pre-magnetized nanoparticles will now be repelled from transitions with oppositely directed local fields (with $H = 0$ at $z = 20$ nm) while still being attracted to transitions whose local field constructively superposes with the external field. Thus, in Fig. 8a every transition is coated, while in Fig. 8b only every other transition is coated. Close inspection of Fig. 8 shows

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 8 (**a**) Optical image of servo patterns assembled in zero external field. (**b**) Same pattern showing nanoparticles assembled in a 1.5 kOe magnetic field. Note that every feature is no longer coated, with gaps opening up in the structures that are closed in panel (**a**). Used with permission and reprinted from Ref. [9]

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 9 A bilayer, interleaved composite. (**a**) Image of first layer assembled in an external field. Note that the double features are visible, but one is much weaker. (**b**) Image after a second round of coating was performed only this time in an oppositely directed magnetic field. The features that were dim in panel (**a**) are now bright. The schematic above the images represents which layers and which locations correspond to particular features in the images (Used with permission and reprinted from Ref. [9])

similarities between the two images, with spatially modulated features in the upper half of Fig. 8b replacing horizontal lines in the upper half of Fig. 8a, and gaps opening in the lower half of Fig. 8b compared with the lower half of Fig. 8a. Generally, there are half as many coated features in Fig. 8b as in Fig. 8a. These changes from Fig. 8a to b are all caused by the repulsion of pre-magnetized particles from opposing, spatially alternating transitions.

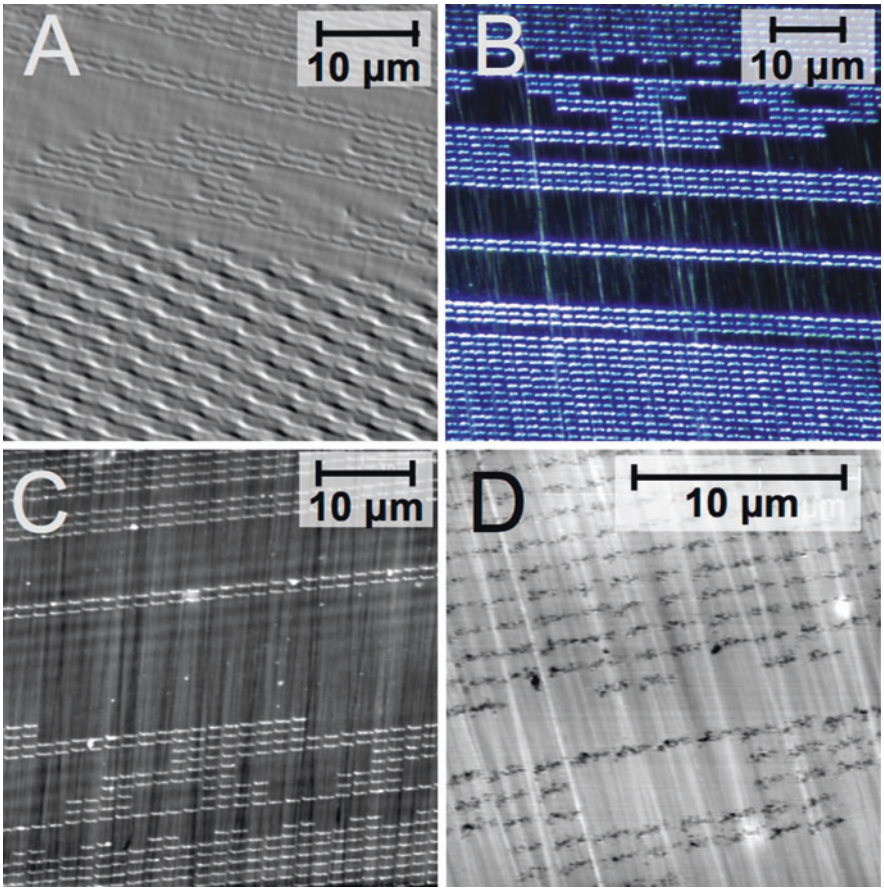
While $H_{ext} = 1.5$ kOe is sufficient to prevent nanoparticle coating on opposing transitions, in weaker external fields, for example, $H_{ext} = 900$ Oe, the opposing transitions can be partially coated with nanoparticles. Since the external field magnitude controls the height where $H_{net} = 0$ above opposing transitions, as well as enhances the magnetization of nanoparticles above aligned transitions, transitions with constructive field superposition can yield thicker nanoparticle layers than the zero external field case, while transitions which oppose the external field produce a thinner layer than the zero-field case. Thus, manufacturing process control over topography within the assembly can be achieved, or to create assemblies with varying nanoparticle layer thicknesses within the assembly simply by applying a varying external magnetic field.

The direction of the external field can be used to control the pattern across multiple layers to form a vertically separated, horizontally interleaved nanoparticle composite, with the layers assembled in oppositely directed fields and separated by a polymer layer. Figure 9a, b shows this process, with the left panel (Fig. 9a) demonstrating external field assembly at "positive" field transitions. After removing the nanoparticle fluid, the layer is spin coated with the polymer. Here instead of peeling the polymer, the polymer surface is exposed to fresh magnetic fluid, now with a "negative" magnetic field (right panel (Fig. 9b)), and thus the particles assemble on "negative" field transitions. After this second nanoparticle assembly step, the film is coated with a second layer of polymer, which is cured and peeled from the medium. The dark-field images show alternating bright and dim features. The dimmer interleaved features are the "negative" field transitions, which are still slightly coated at the intermediate external field used

here, $H_{ext} = 900$ Oe. The dark-field image in panel (Fig. 9b) (two layers of nanoparticles) shows bright nanoparticle lines at the locations in panel A that were dim and weakly coated. Thus, Fig. 9a, b demonstrates the potential for nanomanufacturing 3D composites with both inter-layer and intra-layer control over the assembled topography and feature spacing.

Metrology for Pattern Transfer Nanomanufacturing™

Measuring the assembled nanoparticles to determine pattern quality and repeatability, is a critical step in establishing whether this approach can lead to manufacturable materials. As discussed above, a variety of microscopy techniques have been employed to image these patterns. One difficulty with large area patterns is not having the ability to measure the same region repeatedly. To determine repeatability of the assembly process over multiple assembly steps, we employed optical photolithography to place a series of numbered frames on top of the disk coupon [35]. These 30 nm thick Cu frames were deposited onto patterned photoresist using sputtering, and the photoresist was then lifted off to permanently label particular regions of the disk media surface. These frames enable one to find the exact same region of the disk with AFM or SEM so that the assembled pattern can be (re)imaged as a function of coating process, nanoparticle species, colloidal stability, etc., to determine process repeatability and optimize the assembly process. Figure 10a–d shows a series of images of disk drive servo patterns: Coupon images obtained with (Fig. 10a) MFM, (Fig. 10b) dark-field microscopy, and (Fig. 10c) AFM of the coupon surface after assembly. Figure 10d shows an AFM of the peeled film itself. While Fig. 10a–c demonstrate that the nanoparticle assembly (imaged both optically and with AFM) closely matches the magnetic force gradients imaged with MFM, Fig. 10d shows that the nanoparticles maintain their pattern after transfer to the polymer film [9].

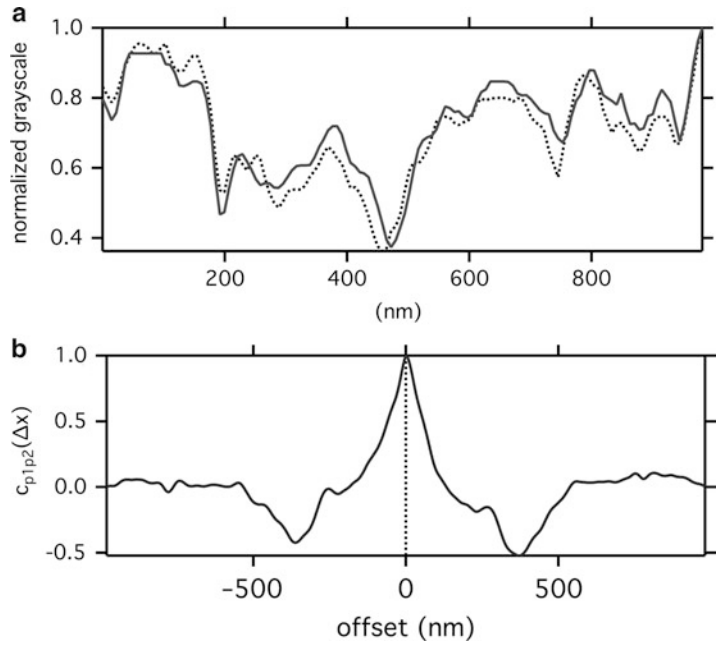


Note the striations observed in Fig. 10c, d. These marks are ~10 nm high and are likely polishing marks left from the disk manufacturing process. These surface features do not change from coating to coating and therefore make an excellent reference that can be used for image correlation to determine the repeatability of our assembly process. Cross-correlation of these marks obtained by aligning multiple images and correlating the same line scan from two images (Fig. 11) suggests that the spatial precision of the nanoparticle assembly on a particular region of the disk surface is $\sim 25 \pm 11$ nm [35].

Real-Time Diffraction Metrology

Early experiments showed that the longer the colloidal fluid remains on the media coupon, the more nanoparticles are assembled. Smaller concentrations and shorter times gave fainter patterns, while larger concentration and longer times gave darker patterns. A key need, therefore, is to understand the dynamics of the nanoparticle assembly process, as well what happens over a large patterned area beyond simply imaging it. A difference of a few seconds is hard to observe from an image.

Similarly, it takes a significant quantity of time to obtain AFM images from multiple repeated coatings, and thus a technique to monitor the assembly process as a function of time and assess quality over large areas was needed. Since diffraction grating patterns had been assembled and used in a spectrometer as discussed above [9, 34], a real-time dynamic measurement of optical diffraction was attempted [38]. Note that without the nanoparticles, the medium surface is not topographically patterned, merely magnetically patterned. Thus, without imaging the disk using a magnetically sensitive probe, an unpatterned disk appears visually flat. However, as soon as nanoparticles begin to assemble onto the medium, they are directed by the recorded template. At the earliest stage of assembly, these patterns appear to the eye, in an electron or optical microscope image, to be random. However, the diffracted signal exists almost immediately because the scattered light from these patterned nanoparticles is in phase on the diffraction detector.



To perform this real-time study of nanoparticle self-assembly, the disk media coupon is placed in

[9])

a transparent fluid cell that has a glass lid. Figure 12 shows a schematic of the apparatus used for real-time monitoring of diffraction during assembly. The medium coupon is located at the bottom of the cell, 0.5 mm vertical distance (h) from a glass window held onto the cell by a vacuum pump. The nanoparticle suspension is injected into the fluid cell by a syringe pump, and the fluid flow is stopped immediately after the fluid is pumped into the cell. A HeNe laser (wavelength 632.8 nm) is incident onto the coupon with a 5° angle to avoid multiple light reflections between the glass window and the coupon surface. The diffraction angle is related to the grating spacing and the laser wavelength by the standard diffraction grating equation [39]. A photodetector (DD) is used to measure first-order diffraction, while a second photodetector (SD) is used to measure the laser scattering from the nanoparticles in the fluid as well as on the surface.

Both light scattering and diffraction efficiency (SE and DE) are measured and are given by the ratio of the scattered and diffracted intensity divided by incident power, respectively. Of course the diffraction detector includes intensity both from the grating as well as background scattering. The diffraction plus scattered signal changes

linearly with the scattered intensity, and the diffraction intensity is obtained by subtracting the scattered intensity from the diffracted intensity.

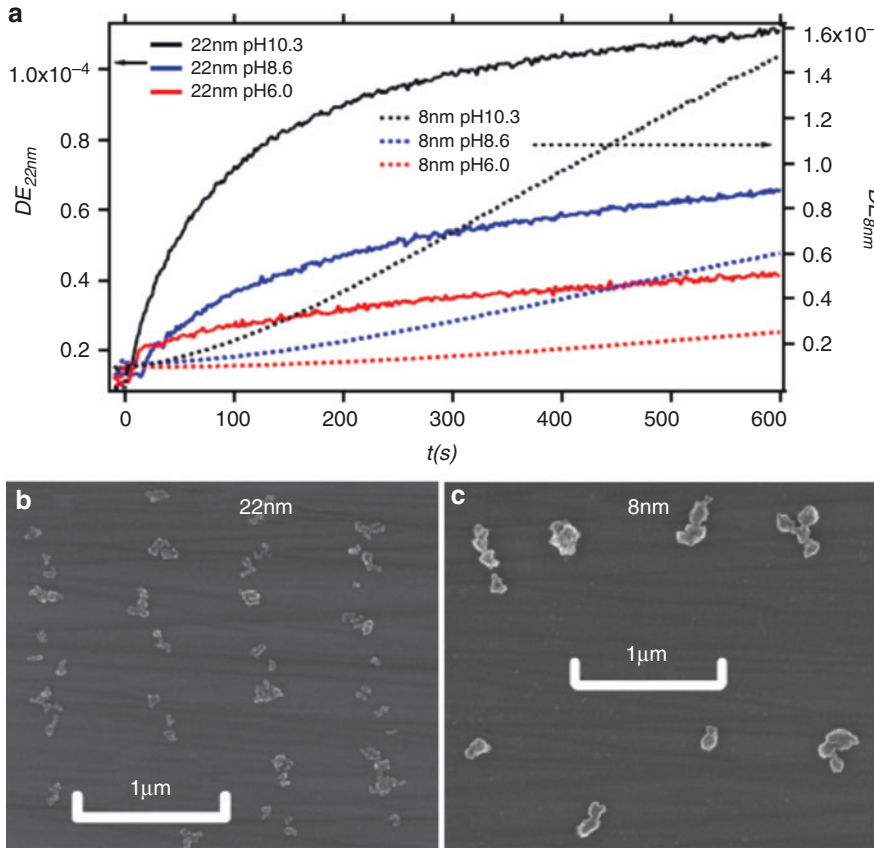

Figure 13 shows the measured first-order diffraction as a function of time from zero to 10 min for four particle suspensions with different concentrations 1, 0.5, 0.25, and 0.125, respectively (curves C1, C0.5, C0.25, C0.125 in Fig. 13a). Here, C1 has a 0.002 % volume concentration of nanoparticles. Both signals show spikes that

(**b**) Diffraction efficiency versus time for different solution pH values. (Inset shows dependence of diffraction efficiency on pH.) Used with permission and reprinted from Ref. [38]

remain for 3–5 s, caused by light scattering from the wavefront of flowing fluid. After the spike, the SE remains constant as a function of time [inset in Fig. 13a], and the average SE is a linear function of the suspension concentration. However, the diffracted intensity is not linear, but increases rapidly at a rate that slows as time increases. For the same instant of time, larger concentrations produce larger diffraction (doubling concentration produces almost doubles the DE for $t > 100$ s). Figure 13b shows first-order DE as a function of t for C0.5 as a function of pH, for values of 7, 8, 9, 10, and 11. The DE decreases as the pH value increases but then begins to increase again [inset in Fig. 13b]. At $t = 600$ s, the pH7 suspension produces a DE three times larger than the pH9 suspension. Interestingly, the average hydrodynamic diameter obtained using dynamic light scattering does not change with pH for these nanoparticles. This result is in strong contrast to how the diffraction intensity changes with suspension pH.

The DE also varies for nanoparticle suspensions with different core particle sizes and colloidal stabilities. Figure 14a shows first-order diffraction efficiencies (DE22nm and DE8nm) versus time for equal concentration suspensions with pH 6.0, 8.6, and 10.3 that were made from nanoparticle colloids with 8 nm and 22 nm diameter nanoparticle species. DLS measurements show that the 8 nm nanoparticles have significantly weaker colloidal stability than the 22 nm nanoparticles, but both types of particles remained colloidally suspended over the measurement timescale. Interestingly, for the same pH and times greater than 100 s, the 8 nm particles produce diffraction efficiencies that are ten times larger than the 22 nm particles. Further, the smaller

Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly, Fig. 14 Demonstration of the ability to distinguish between aggregated and non-aggregated nanoparticle species. (**a**) Non-aggregated 22 nm Fe_3O_4 nanoparticles and aggregated 8 nm Fe_3O_4 nanoparticles assembling versus time for 3 different pH values. Note that the aggregated particles have intensities nearly 12 times larger than the non-aggregated particles. (**c**–**d**) SEM images of assembled 22 and 8 nm gratings after 15 min. For the higher diffraction efficiency 8 nm particles, the SEM image hardly appears to suggest a diffraction grating (Used with permission and reproduced from Ref. [38])

particles display dramatically different time dependence than the other curve shapes. These 8 nm particles show "inverted" curve shapes, i.e., the rate of DE increase accelerates with time as opposed to slowing.

The 8 nm suspension appears to contain large aggregates of particles with significantly weaker colloidal stabilities. Figure 14b, c shows representative scanning electron microscopy (SEM) images of the 8 nm and 22 nm particles that are coated on the medium surface, respectively. A statistical analysis of SEM images shows that the nanoparticle aggregates attracted from the 8 nm particle suspensions are more periodically distributed than those from the 22 nm particles. In addition, the 8 nm particles show significantly larger aggregates than the 22 nm particles. This further suggests the aggregation of particles causes the inverted shape. While larger aggregates explain the large difference in DE between the two particle species, since particles scatter light with the intensity proportional to the sixth power of diameter, it is still not clear how the aggregation changes the curve shape.

While development of this real-time measurement is ongoing, it appears to have significantly

greater sensitivity to subtle changes in colloidal properties relative to what can be measured with light scattering alone. The scattered signal correlates well with what is observed with DLS, suggesting that the assembly process is very sensitive to the colloidal stability

Conclusions and Outlook

This entry has provided an overview of how to combine magnetic field-directed self-assembly, magnetic recording, and magnetic nanoparticles to manufacture patterned composite materials with 25 nm repeatability over length scales as large as 10 cm using a standard 3.5 in. hard disk drive platter. A number of measurement techniques necessary to verify the quality and repeatability of nanomanufactured structures were discussed, including a novel metrology that uses a diffraction grating template to monitor self-assembly of nanoparticles in real time. This metrology appears to be more sensitive to colloidal stability, likely because the large field gradients at the media surface aggregate the nanoparticles on the surface in a manner that depends strongly on the surface stabilization of the nanoparticles.

While not yet able to make patterns with single nanometer feature control, this approach to nanomanufacturing appears to have repeatability and precision sufficient to build materials for manipulating light at wavelengths from 400 nm to several micrometers. Importantly, since the assembly process requires primarily a disk drive and magnetic nanoparticles, there is potential for patterning photonic structures at lower cost than wafer-based processing.

It also has strong future potential. To date, the only media and heads studied are those that are commercially available. Such media and heads are highly engineered for storing, reproducing, and maintaining the fidelity of digital data. If a purpose-designed media/head combination can be engineered specifically for nanoparticle self-assembly, the potential exists to improve pattern quality such that it is limited only by the diameter of the nanoparticle feedstocks used as raw materials. Such purpose-designed recording components could allow further improvements in manufacturing repeatability and user customizability. Given the low cost and ability to rapidly reprogram the template, this nanomanufacturing technology could find application in rapid prototyping or rapid on-site assembly of custom optical patterns for fiber optics, custom diffractive optics, and spectrometers/optical sensors.

Definition

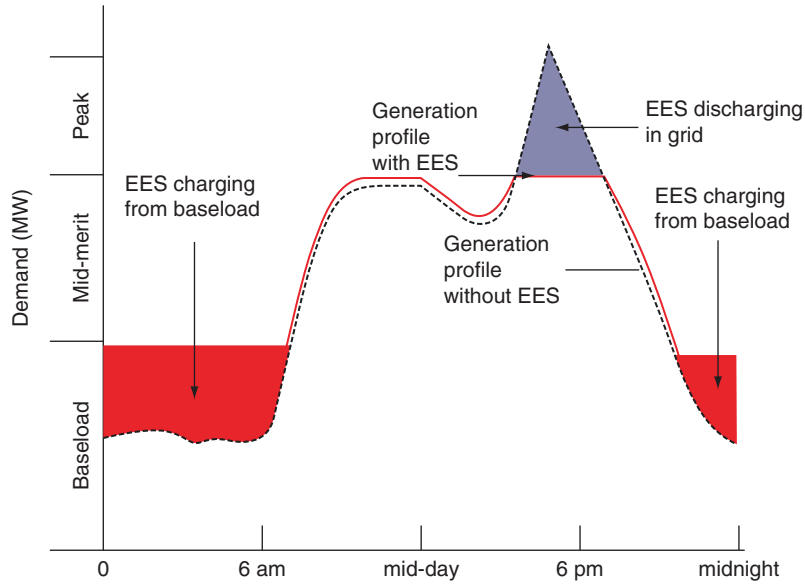
An electrical energy storage device stores the input energy and delivers it in the form of electrical energy when needed.

A material that is engineered with morphological features on the order of less than 100 nm and exhibits different characteristics compared to its bulk counterpart is defined as a nanomaterial.

Overview

Need for Energy Storage Devices

Storage of electrical energy is one of the major research focuses of this century. Energy storage devices have already helped revolutionize the electronic gadget industry, but apart from this, energy storage devices of higher capacity and power rating can prove to be very beneficial in other stationary applications such as load-leveling in existing power plants and nonstationary applications such as electric vehicles.



The demand for electric power from an electric grid varies based on the season, day of the week, hour, and also due to transients. Figure 1 shows a typical electrical power supply and demand curve over a 24-h period [53]. The power plants are always designed to meet the peak power demand. However, in a 24-h cycle, there are instances when the demand for the power supply is less than the peak power available. Thus, at times, power plants are forced to operate at lower output levels which prove to be uneconomical as the power plants are most efficient at their rated capacity. Energy storage devices can help balance this demand by shifting the load from peak to off-peak hours. During the off-peak hours the electrical energy can be stored in an energy storage device, and then this stored energy would be used during the peak hours. This load-leveling would help in designing power plants with lower rated capacity, thus reducing the cost of installation. The operating cost of a power plant can be reduced by operating the plants at the rated capacity for most of the time during its life. Another advantage is that the utility company can manage the demand with the existing power plants and defer the installation of the higher capacity power plants and thus reduce the overheads.

Electrical energy storage devices also play a vital role in the design and development of power plants based on other unconventional renewable energy sources, such as solar or wind energy [53]. The energy harvested in such power plants varies largely due to operating conditions such as weather, wind speed, and temperature. In this case, electrical energy storage devices can be used to store the energy during the smooth operation of the plant and overcome the intermittent nature of it. Thus, harvesting energy from unconventional sources would be more feasible.

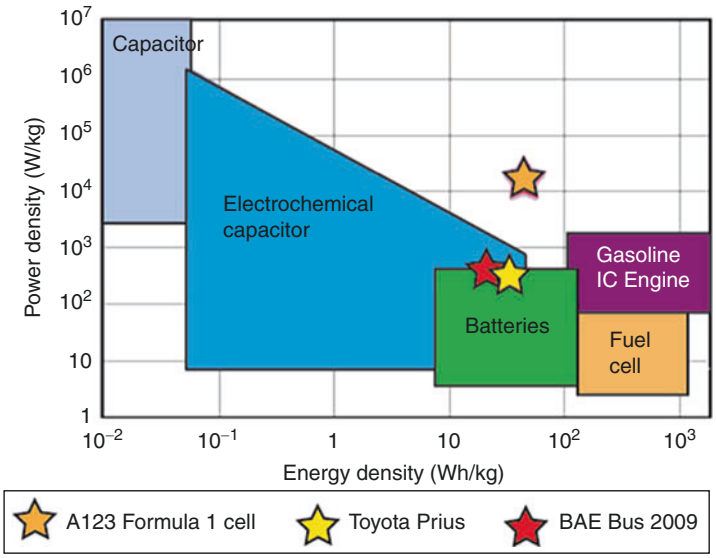
Apart from these stationary applications energy storage devices are also necessary for certain nonstationary applications. Since about 2000, batteries have been seriously considered in the development of electric vehicles. The automotive industry has developed hybrid electric vehicles, plug-in hybrid electric vehicles, and electric vehicles, which would reduce dependence on oil and reduce greenhouse gas emissions.

Need for Nanomaterials in Energy Storage

Nanomaterials, due to their unique characteristics, are very instrumental in developing energy storage devices with high energy and power density. Energy conversion in energy storage devices takes place with a chemical reaction at the surface, charge transfer, etc. These processes occur at the nanoscale. Nanomaterials provide a large surface

Nanomaterials for Electrical Energy Storage Devices, Fig. 1 A typical electrical power demand profile for a 24-h period. During early morning hours the demand is below the capacity of the power plant while the demand is at peak in the evening around 6 PM. During off-peak hours an electrical energy storage (*EES*) device would store the energy and during the peak hours the EES will be discharged. Thus EES would level the load and the actual demand cycle will be as shown by the solid line (Adapted from Ref. [53])

area to volume ratio for such processes to occur. A high surface area permits a high contact area with the electrolyte and a larger number of reaction sites. In certain cases they enable electrode reactions to occur that cannot take place for materials composed of micrometer-sized particles.



The kinetics of the energy storage device are governed by the kinetics of the diffusion process within the device elements. Nanomaterials help in reducing the diffusion length and hence improve the kinetics of the operation of an energy storage device. Thus, nanomaterials can improve the charge–discharge rates. The electron transport within the electrode is also improved by nanometer-sized particles.

Since the charge transfer reactions occur mostly at the surface of the nanometer-sized particles, the induced stress and crystal lattice breakdown is less during the repeated charge–discharge cycles. This helps in improving the cycle life of the device.

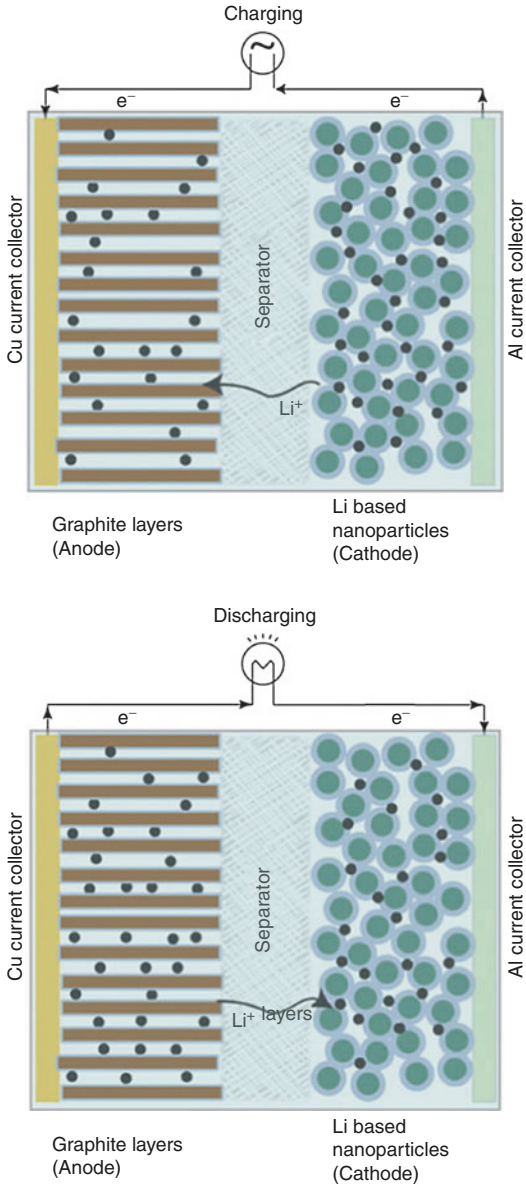
Recent Trends in Electrical Energy Storage Devices

A Ragone plot, shown in Fig. 2, is used to compare the energy density and power density of various electrical energy storage (EES) devices [53, 54]. Energy is defined as the capacity to do work, so energy density represents the capacity of the EES, i.e., the amount of energy stored in the device. Power is defined as the rate of doing work, so power density represents the rate at which the EES is charged or discharged.

As seen in the Ragone plot (Fig. 2), a fuel cell has the highest energy density but poor power density, so fuel cells are suitable for applications where high energy storage is necessary. They also tend to operate at optimum efficiency only at a constant output. They have a certain warm-up time necessary to bring them to operating conditions, and as such they are often coupled with other EES. As opposed to fuel cells, an electrochemical capacitor has high power density but low energy density, so they are suitable for applications where rapid charge/discharge in necessary. However the output of the electrochemical capacitor depends largely on its state of charge, and thus it fails to deliver energy at constant voltage [53]. Batteries lie in between the fuel cell and the electrochemical capacitor on the Ragone plot. They have higher power density than fuel cells and do not require any warm-up time. They also have higher energy density than an electrochemical capacitor and have a flat voltage curve during discharge. Thus, batteries have been actively pursued as the EES for immediate future applications.

Nanomaterials for Electrical Energy Storage Devices, Fig. 2 Ragone chart showing the comparison of the power density and energy density for batteries, capacitors, and fuel cells and internal combustion engine. Energy density represents the capacity while power density represents the rate of the charging/discharging of EES device (Adapted from Ref. [54])

Li-Ion Batteries

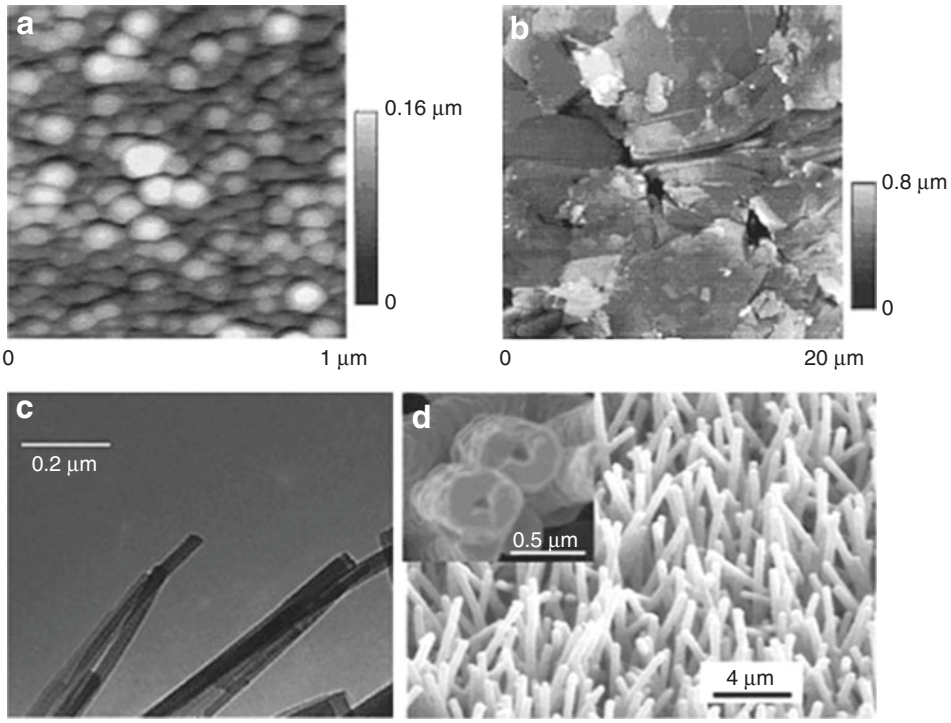


In 1912, G. N. Lewis started developing lithium batteries. Lithium (atomic number 3, group 1, period 2) metal was used as an anode in these batteries. Lithium is an alkali metal, and being the lightest of the metals with the greatest electrochemical potential, it has the largest energy density for its weight. However, lithium is very unstable and highly reactive, as it has only one valence electron, which makes it unsafe as the electrode material. As such, research shifted from a lithium battery to a lithium-ion battery, which is a much safer option. In 1991, Sony commercialized Li-ion batteries and started using them in its electronic products. Since then the importance and market for Li-ion batteries has been ever increasing.

Figure 3 shows a schematic of a typical lithium-ion battery. In a typical cylindrical lithium-ion battery separator, anode, cathode and separator are stacked alternately then rolled and packed in a cylindrical can filled with electrolyte. The anode is the electropositive electrode which holds the lithium in the charged state. The cathode is the electronegative electrode which serves as the source for the lithium [3]. The electrodes are immersed in an electrolyte solution which is mostly a lithium hexafluorophosphate ($LiPF_6$) salt dissolved in organic solvent. A separator is used in between the anode and the cathode to avoid short-circuiting between the electrodes. The electrochemical reaction in the case of the lithium-ion battery is based on the intercalation of Li^+ ions in the electrodes. During charging the Li^+ ions are transferred from the cathode and intercalated into the anode. During discharging, a deintercalation reaction occurs, and Li^+ ions are transferred from the anode to the cathode while the electrons flow through the external circuit. The cell voltage is determined by the energy of the chemical reaction, such as given by Eq. 1, occurring in the cell [37].

$$Li_{1-x}FePO_4 + Li_xC_6 \rightleftarrows Li_{1-x}C_6 + Li_xF_ePO_4 \quad (1)$$

The anode and cathode electrodes used in Li-ion batteries are complex composites with active material bonded to the current collector with polymeric binders. The anode material is bonded to the copper current collector and the cathode material is bonded onto an aluminum current collector. The cathode material is also coated with carbon black to improve the electronic conductivity.



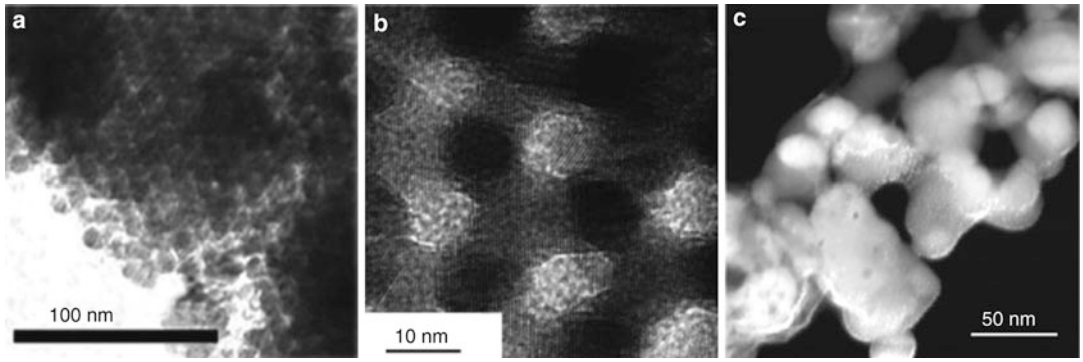
Anode Lithium is an ideal anode material for Li-ion batteries, but because of the plating out of lithium during the charge/discharge cycle and subsequent formation of dendrites, there is a risk of the cell being short-circuited. Instead,

Nanomaterials for Electrical Energy Storage Devices, Fig. 3 Schematic showing operation of a Li-ion battery. In a cylindrical battery separator, anode, cathode and separator are stacked alternately then rolled and packed in a cylindrical can filled with electrolyte solvent containing Li salt. During charging Li^+ ions are inserted in the anode structure by virtue of intercalation and during discharging, these Li^+ ions are removed from the anode structure by virtue of deintercalation and transferred to the cathode

carbonaceous materials are preferred for anodes in most commercially available Li-ion batteries [22]. Studies have been conducted on graphite [6], C-C composite, mesocarbon microbeads (MCMB) [18], carbon nanotubes [13, 52], and carbon films. Evaporated carbon film and a natural graphite anode is shown in Fig. 4a, b respectively [22]. These anodes have a very good rate of lithium insertion/removal and thus improve the charge/discharge rate (power rating) of the battery, but in any Li-ion cell with a carbonaceous anode a solid electrolyte interphase (SEI) is formed during the cycling of the cell [21, 22, 43]. The SEI is formed from the electrolyte decomposition products [50]. This SEI layer prevents the graphite surface from further exfoliation and also prevents further reduction of the electrolyte and consumption of active lithium. In the case of nanoparticulate graphite, the consumption of active lithium would be still higher, and the excessive charge developed between the graphite surface and the SEI would result in a loss of overall cell voltage. Also, it is important to note that the lithium is intercalated into graphite at potentials less than 100 mV versus Li^+/Li. There is always a risk of lithium depositing on the graphite surface resulting in dendrite formation and fatal short-circuiting of the cell [6]. Carbon nanotubes exhibit twice the lithium storage compared with graphite but have similar problems of surface-layer formation and safety [6]. To overcome some disadvantages of graphite, the research has been focused on the titanium oxide.

The nanoparticles of non-toxic $Li_4Ti_5O_{12}$ ($Li[Li_{1/3}Ti_{5/3}]O_4$) with spinel structure have high diffusion rates due to short diffusion distance. In this spinel structured oxide, lithium can be intercalated to give a composition range of $Li_{4+x}Ti_5O_{12}$, $0 < x < 3$ [14, 20], but the capacity of the $Li_4Ti_5O_{12}$ is only 150 mAh/g compared to 300 mAh/g capacity of graphite. Instead nanotubes/nanowires composed of TiO_2-(B), as shown in Fig. 4c, are actively studied [6]. This fifth polymorph of titanium dioxide has all the advantages of $Li_4Ti_5O_{12}$ but also has a capacity of 300 mAh/g. TiO_2-(B) is also safer as it eliminates the risk of lithium plating on the electrode and can be cycled with higher rates as in $Li_4Ti_5O_{12}$. The TiO_2-(B) nanowires exhibit better performance than TiO_2-(B) nanoparticles as they have higher reversibility of intercalation

The *inset* shows the open tips of the nanowire [28]



N

(>99.9 % per cycle, after the first cycle). Other similar oxide nanowire electrode materials of interest include Sn, Co, and V oxides [6]. Lithium metal alloys such as $Li_{4.4}Sn$ (993 mAh/g) and $Li_{4.4}Si$ (4,200 mAh/g) with high specific capacity are also being considered as anode materials in Li-ion batteries. The major drawback of these materials is the large volume change during the cycling of the cell to accommodate the large amounts of lithium [6].

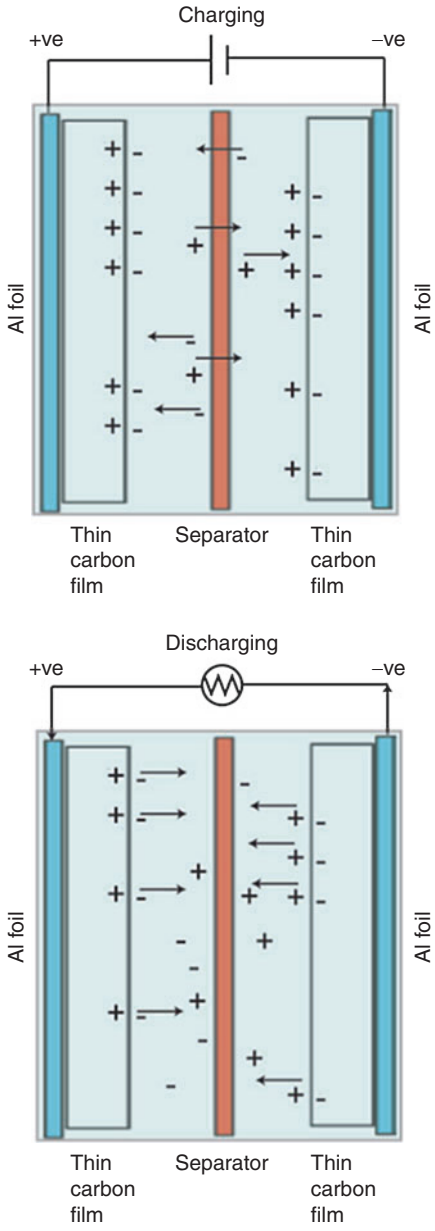
Lithium's ability to react reversibly with the binary transition metal oxides is exploited in developing anode materials such as mesoporous Co_3O_4, shown in Fig. 4d [28]. This reaction is not limited by the one or two lithium atoms per host as in intercalation, and so such materials can have a higher capacity than conventional anode materials. The poor kinetics of these types of materials can be improved by using nanowires or nanoparticulates as the anode material.

Cathode The potential area of greatest opportunity for nanomaterials is the cathode of the Li-ion battery [53]. The most common cathode materials are layered oxides $LiMO_2$, the spinels $Li[M_2]O_4$ and olivines $LiMPO_4$ where M is a transition metal atom [16]. The nanoparticulates of these materials reduce the diffusion length, provide a higher electrolyte/electrode contact area, and thus improve the charge/discharge kinetics of the Li-ion batteries. The nanoparticles of these lithium compounds are made by grinding, synthesis from solution, or by solgel approaches [6].

Initially a $LiCoO_2$, as shown in Fig. 5a, was developed as the cathode material for Li-ion batteries [6, 16], but due to expensive and toxic cobalt they were later replaced by oxides such as $LiNi_{0.8}Co_{0.15}Al_{0.05}O_2$ $LiNi_{0.8}Co_{0.2}O_2$, $Li_1-xNi_1-yCoyO_2$, and $LiMn_{0.5}Ni_{0.5}O_2$ in commercial batteries [16, 23, 24]. These oxides have a

Nanomaterials for Electrical Energy Storage Devices, Fig. 5 Different types of cathode materials used in the Li-ion battery. (**a**) TEM image of mesoporous $LiCoO_2$ transition metal oxide [6], (**b**) TEM image of nanostructured $LiMn_2O_4$ spinel [6], and (**c**) TEM image of olivine structured $LiFePO_4$ nanoparticles embedded in carbon matrix [38]

high operating voltage, in the range of 2.75–4.3 V [16]. They have very high energy density and power density but they lack the necessary structural stability for deep discharge cycles, during which the host oxide structure collapses upon removal of more than 50 % of the Li. Li spinel compounds, such as $LiMn_2O_4$ shown in Fig. 5b, has good structural stability [6]. They also have higher operating voltage and high charge/discharge rate but low energy density. The most recent among these lithium compounds has been the olivine structured $LiFePO_4$ shown in Fig. 5c [38]. It has a lower operating voltage of ~3.3 V but demonstrates higher power and energy density along with a good structural stability.



Electrochemical Capacitors

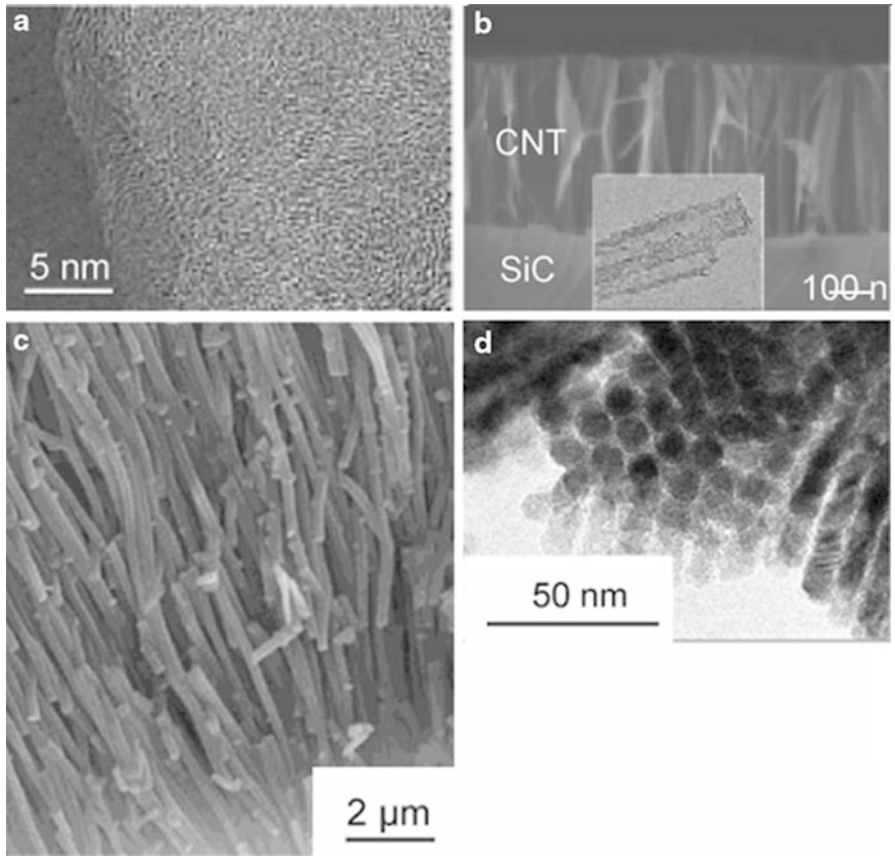
Capacitors are commonly used in power and consumer electronic circuits. However they have very low capacitance in the range of few millifarads which make them unsuitable for large storage devices. In 1957, Becker filed the first patent describing the concept of electrochemical capacitors (EC) which have capacitance in the range of a few hundred farads [4, 46]. It was then commercialized by Nippon Electric Company (NEC), Japan, under a license from Standard Oil of Ohio (SOHIO) [46]. EC are also called supercapacitors or ultracapacitors. The two different types of EC are the electric double layer capacitor (EDLC) and the pseudocapacitor.

A schematic showing the operation of an EDLC is shown in Fig. 6. EDLC consists of two electrodes with a thin coating of active material having very high surface area. These electrodes are immersed in an electrolyte, mostly sulfuric acid or acetonitrile, containing both positive and negative ions. When the capacitor is connected to the external power source, the electric field attracts the opposite charged ions toward the surface of the electrode. The charge separation occurs near the surface of the electrode, and energy is stored in the EDLC. During discharging, as the electrons flow through the load the ions disperse in the electrolyte solution and the electrode-electrolyte interface fades [25, 35]. A separator is used to prevent the tunneling of the electrons between the electrodes through the electrolyte. The other type of EC capacitor, the pseudocapacitor, has essentially the properties of the EDLC as well as a battery. Thus a charge is stored by the surface as well as subsurface activities. In EDLC there is no physical or chemical change in the electrode, and the ion adsorption process is highly reversible. Thus, theoretically EDLC can be charged/discharged without any damage to its components [34].

The charge separation at the electrode-electrolyte interface is given by Helmholtz's double layer capacitance C:

$$C = \frac{\varepsilon_r \varepsilon_o A}{d} \tag{2}$$

Nanomaterials for Electrical Energy Storage Devices, Fig. 6 Schematic showing operation of an electrochemical capacitor (*EC*). During charging the ions in the electrolyte are attracted to the nanoporous electrodes with opposite charge. This creates the charge separation at the electrode-electrolyte interface and the energy is stored in EC. During discharging, as the electrons flow through the load the ions disperse in the electrolyte solution and the electrode-electrolyte interface fades



where ε_r is the electrolyte dielectric constant, ε_o is the dielectric constant of the vacuum, d is the effective thickness of the double layer (charge separation distance), and A is the electrode surface area [46].

Many materials used as an anode in Li-ion batteries are generally considered suitable for EC. In general, to achieve high capacitance between the charged double layer it is necessary to have a high specific surface area (SSA) of the double layer material and electrodes with high electronic conductivity. Carbonaceous material has high SSA, high electronic conductivity, electrochemical stability, and structural stability and is suitable for the EC. The various carbon-based materials such as carbon fabrics, carbide-derived carbons, carbon nanotubes, onion-like carbon, and nanohorns are studied as potential EC electrode materials. Disordered microporous carbon (SiC-derived carbon), shown in Fig. 7a, and carbon nanotubes, shown in Fig. 7c, are among the various carbonaceous ideal EC electrode materials due to their high SSA [46].

Several other materials, such as V_2O_5 nanowires shown in Fig. 7b, and ruthenium oxides are actively being studied as EC electrode materials due to their broad range of morphologies [12, 49]. Hydrated ruthenium oxide has the highest capacity, 200 Wh/kg [53]. The other promising EC material is nickel oxide due to its high specific capacitance value compared to carbon materials [1, 10, 27, 33]. Thin films of nickel oxide can be easily synthesized through electrochemical route or solgel method. The nanostructured NiO thin films shown in Fig. 7d can be produced with specific microstructure, high surface area, and reduced crystallite size [39, 51].

Fuel Cell

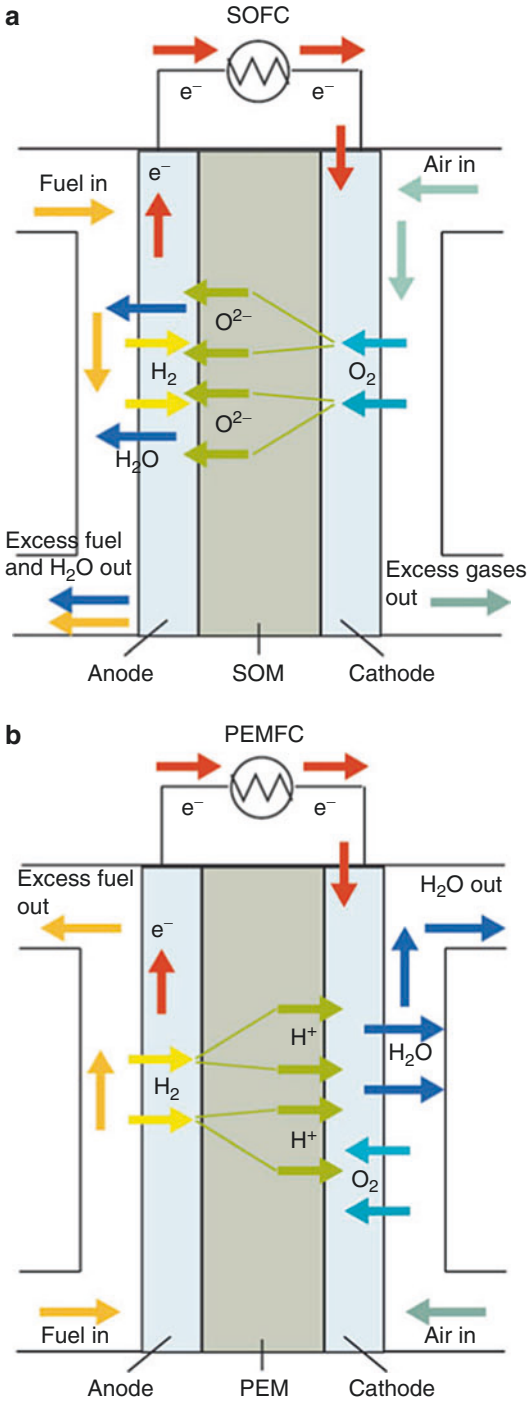
A fuel cell converts the energy stored in the source fuel to usable electrical energy. It is different from other EES in that the reactants flow through the cell rather than being sealed within the cell. There are several types of fuel cells, but the most common are the solid oxide fuel cell (SOFC) and the proton exchange membrane fuel cell (PEMFC) [7]. A schematic of SOFC is shown in Fig. 8a

Nanomaterials for Electrical Energy Storage Devices, Fig. 7 Different types of electrode materials used in EC. (**a**) TEM image of a disordered microporous carbon (SiC-derived carbon) [46], (**b**) SEM image of an array of carbon nanotubes (CNT) on Si-C (*inset* shows the TEM image of the same CNT) [46], (**c**) TEM image of V_20_5 nanowires [49], and (**d**) TEM image of ordered mesoporous NiO [51]

and schematic of PEMFC is shown in Fig. 8b. SOFC is the most fuel flexible among all fuel cells. Other than pure hydrogen, it can run on hydrocarbon, methanol, or even gasoline, but in the case of PEMFC pure hydrogen is the only choice of fuel. Essentially both fuel cells have similar principles of operation except that in SOFC, O^{2-} ions are conducted through the solid oxide membrane (SOM) while in PEMFC H^+ ions are conducted through the proton exchange membrane (PEM) [17, 19].

In SOFC, the oxygen is oxidized to O^{2-} as per the following half-cell reaction at the cathode:

$$\frac{1}{2}O_2 + 2e^- \rightarrow O^{2-} \tag{3}$$



These O^{2-} ions are conducted through the solid oxide membrane to the anode where they are reduced by hydrogen with water as a by-product. The anode half-cell reaction is:

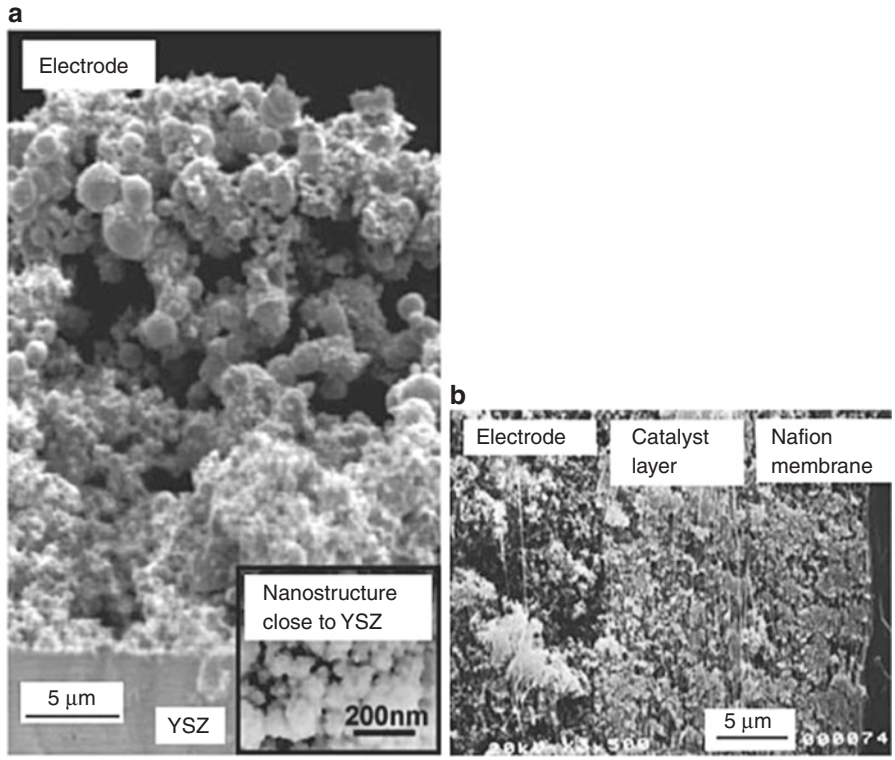
$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \tag{4}$$

In the case of PEMFC, hydrogen is reduced at the anode, and the H^+ ions are formed as per the following half-cell reaction:

$$H_2 + 2H^+ + 2e^- \tag{5}$$

These H^+ ions are conducted through the proton exchange membrane, and they are combined with oxygen at the cathode to form water as the

Nanomaterials for Electrical Energy Storage Devices, Fig. 8 (**a**) Schematic showing operation of a solid oxide fuel cell (*SOFC*). Oxygen is reduced at cathode and the resulting O^{2-} ions are conducted through the solid oxide electrolyte membrane (*SOM*) to the anode where they are oxidized with the hydrogen to form water. (**b**) Schematic showing operation of a proton exchange membrane fuel cell (*PEMFC*). Hydrogen is oxidized at the anode and the resulting H^{+} ions are conducted through the proton exchange membrane (*PEM*) to the cathode where they are reduced with O to form water

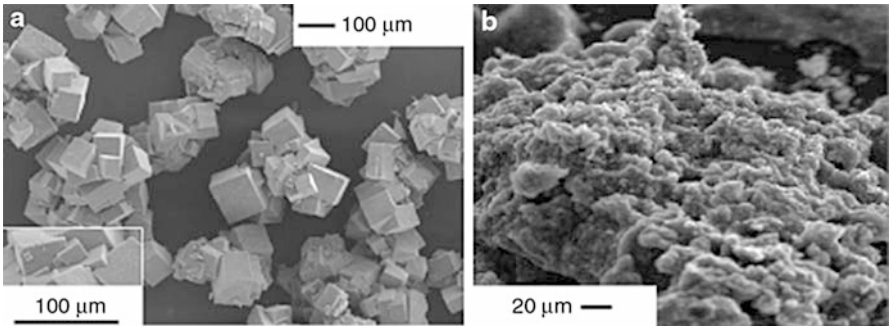


by-product of the reactions. The half-cell reaction at the cathode is:

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O \qquad (6)$$

Due to the high operating temperatures, in the range of 500–1,000 °C, SOFC is more cost effective as it does not need an expensive catalyst such as Pt, used in PEMFC, but the disadvantage of high operating temperatures is that the components of SOFC should demonstrate higher thermal and thermomechanical stability. In the case of the PEMFC the operating temperature is lower (70–100 °C), but the proton exchange membrane needs to be hydrated to optimum levels to maintain the proton conductivity [17]. Too much wetting of the membrane causes flooding of the cell. If the membrane is dry then it can also lead to cracking of the membrane and overheating of the cell [17].

A good electrolyte membrane for a fuel cell should have high ionic conductivity, low electronic conductivity, should be stable in both oxidizing and reducing environments, good mechanical properties, and good thermal stability. The electrodes should have high electronic conductivity and high (electro)catalytic activity. The anode catalyzes the oxidation of the fuel components by the ions transported through the electrolyte membrane and the cathode catalyzes the reduction of oxygen [19].



SOFC An extensive review of SOFC has been presented by Minh [36], Singhal [47], and Ormerod [41]. The most widely accepted electrolyte for SOFC is yttria-stabilized zirconia (YSZ) [39]. Figure 9a shows a complex structure of the composite cathode supported by a 240 μm thick dense YSZ electrolyte. The cathode fabricated by combustion chemical vapor deposition (CVD) consists of three porous layer structures, with about 5 μm thick 60 wt% lanthanum strontium

Nanomaterials for Electrical Energy Storage Devices, Fig. 9 Different types of electrode-electrolyte materials used in SOFC and PEMFC. (**a**) SEM image of strontium doped lanthanum manganite (*LSM*)–strontium doped lanthanum cobaltite (*LSC*)–gadolinia doped ceria (*GDC*) composite cathode electrode fabricated on yttria-stabilized zirconia (*YSZ*) electrolyte membrane used in SOFC. The *inset* shows the high resolution imaged of two nanostructured bottom layers close to the YSZ (Adapted from Ref. [30]). (**b**) PEM membrane-electrode assembly used in PEMFC. SEM image of the cross-section of the Nafion® 117 membrane and electrode impregnated with the Nafion® 5 % solution [5]

manganite (LSM)-40 wt% gadolinia doped ceria (GDC) fine agglomerates (0.5 µm diameter) at the bottom (close to YSZ electrolyte), followed by 5 µm thick 30 wt% LSM-30 wt% lanthanum strontium cobaltite (LSC)-40 wt% GDC fine agglomerates (0.5 µm diameter), and 15 µm thick 60 wt% LSC- 40 wt% GDC coarse agglomerates (2–3 µm diameter) on the top (air side) [30]. The inset shows the nanostructure present in the bottom two layers. This nanostructure offers extremely high surface area for oxygen reduction. The anode is mostly a ceramic metal composite (cermet) comprised of Ni + YSZ [17]. The other electrolyte systems investigated for SOFC are strontium, magnesium-doped lanthanum gallate (LSGM), and gadolinium- or samarium-doped ceria (CGO or CSO).

PEMFC Operation of PEMFC and its materials has been covered extensively in Costamagna and Srinivas [8, 9]. In the case of PEMFC the most commonly used electrolyte is Nafion® (sulfonated polymer), manufactured by DuPont. Nafion is comprised of perfluorinated backbones, which provide chemical stability, and of sulfonated side-groups which aggregate and facilitate hydration, which is necessary for proton conductivity. Figure 9b shows a typical membrane-electrode assembly of PEMFC [5]. In this assembly, the Nafion® membrane is hot-pressed onto the electrode impregnated with Nafion® 5 % solution by

Nanomaterials for Electrical Energy Storage Devices, Fig. 10 Different types of materials used to store hydrogen. (**a**) SEM image of metal-organic framework – 5 (*MOF-5*) which stores hydrogen by physisorption on its surface [42], and (**b**) SEM image of the complex borohydride ($LiBH_4$ + 1/2 $ZnCl_2$) doped with nano-Ni which stores hydrogen by chemisorptions

brushing technique. Other sulfonated polymers have been discussed by Kreuer [26]. For hydrogen/air fuel cells, Pt nanoparticles supported on carbon are utilized for both the anode and cathode.

Hydrogen storage Hydrogen is the optimal fuel for all types of fuel cells. Storage of hydrogen on-board a transportation vehicle continues to be one of the most challenging topics for the commercialization of hydrogen-fueled vehicles. Hydrogen has very high energy density by mass but very poor volumetric energy density. The higher volumetric energy density can be achieved for smaller but not lighter containers by compressing pure hydrogen to higher pressures, but compressing the pure hydrogen requires a high-powered compressor. Similarly, higher volumetric density can be achieved by liquid hydrogen, but it requires cryogenic storage systems as liquid hydrogen boils at 20.268°K, increasing the cost of insulation. To overcome these difficulties, storage of hydrogen by adsorption (physisorption) on materials with high specific surface area or chemical bonding (chemisorption) in covalent and ionic compounds is becoming more attractive [55]. Nanostructured materials improve the thermodynamics and kinetics of hydrogen adsorption and dissociation by decreasing the required diffusion length and increasing the diffusion rate [40]. Carbonaceous nanomaterials such as activated carbon, graphene nanofibers, carbon nanotubes, or a group of synthetic materials called as metal oxide frameworks (MOF) are considered for storage by physisorption [29]. The hydrogen is adsorbed onto the surface by weak van der Walls interaction between the hydrogen molecules and the surface of the adsorbent material [15, 39]. MOF-5, shown in Fig. 10a, with a formula unit of $Zn_4O(C_{24}H_{12})_{12}$ or Zn_4O (benzene decarboxylate)$_3$, is one such extensively studied MOF material [42]. A hydrogen storage capacity of 4 wt% at 78 K (−195 °C) and 1 wt% at room temperature has been reported for different MOFs [40]. However, due to the highly porous nature of these materials, volumetric capacity may still be a significant issue [40]. The other frequently studied physisorption-based materials include zeolites [11], clathrate hydrates [45, 48], and hollow glass microspheres (HGM) [2]. Usually hydrogen storage by physisorption-based materials, such as MOF, HGM, CNT, etc., has poor capacity at normal operating conditions [29]. Figure 10b shows another class of materials – a complex hydride, borohydride ($LiBH_4$ + 1/2 $ZnCl_2$) doped with nano-Ni which stores hydrogen by chemisorptions – used in storage of hydrogen [40]. These hydrides along with other chemisorption materials, e.g., magnesium-based hydride, metal nitrides, and amides imides, are very expensive, and in some cases the hydrogen absorption/desorption process is irreversible [29, 31, 32, 44]. The huge capacity values of various materials published in respected technical and

scientific reports should be accepted with caution as many values were wrongfully reported due to gross experimental measurement errors [29].

Challenges

There is a profound effect of spatial boundaries and contribution of surfaces due to small particle size on many of the properties of materials; this challenges researchers to develop new theories or at least adapt and develop theories that have been established for bulk materials [46]. Understanding how materials store and transport charges at electrode-electrolyte interfaces is critically important and will require a fundamental understanding of charge transfer and transport mechanisms. High electrolyte/electrode surface areas may lead to more significant side reactions with the electrolyte, and more difficulty maintaining interparticle contact. There is also a challenge to synthesize nanoparticles having controlled dimensions with a cost effective process. The characterization of functional and structural properties of these nanomaterials also challenges the scientific community in modifying the existing tools and/or developing the new tools.

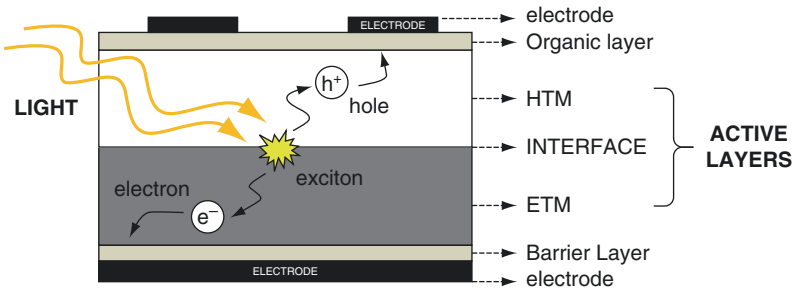
Definition



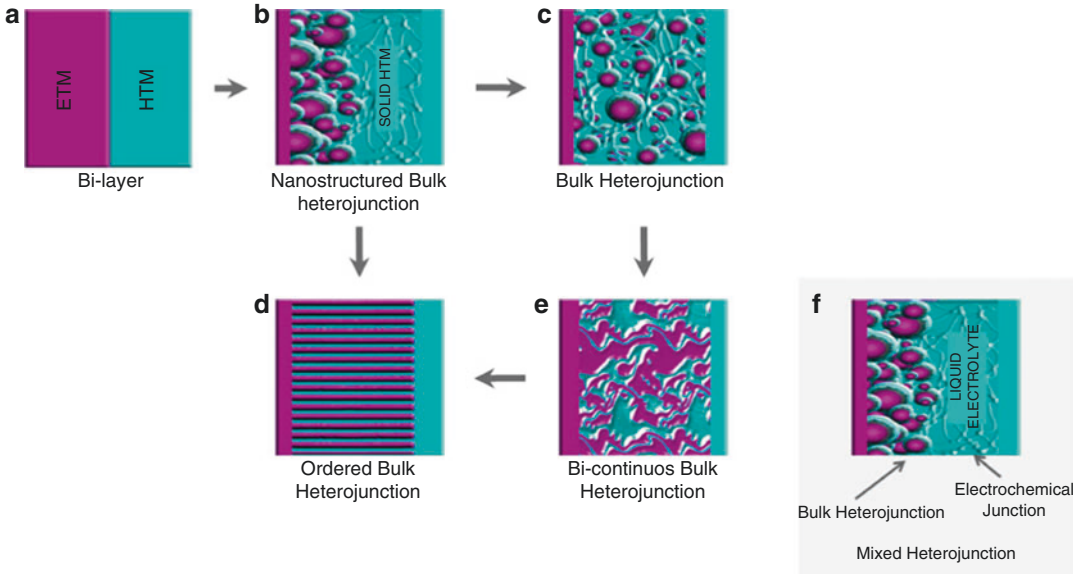
An excitonic solar cell (XSC) is characterized by the formation of an *exciton* that is produced from the absorbed photons from sunlight. An exciton is a tightly bound electron–hole pair which must be split for charge generation. The exciton dissociation takes place at the interface between the constituent semiconductors. Nanostructuration of interfaces is a crucial approach toward highly efficient devices.

Overview

Among the many energy resources, the conversion of sunlight into electricity has emerged as one of the most promising alternatives. The evolution of photovoltaic systems initiated several years ago with the silicon-based solar cells (SiSCs). The need to lower energy cost and to improve device versatility (e.g., flexible, lightweight devices) has resulted on the maturity of the technology toward inorganic thin film photovoltaics (TFSCs) and, more recently, into a new generation called excitonic solar cells (XSCs) [1–3]. The most representative examples of XSCs are dye-sensitized solar cells [1, 4], hybrid solar cells [3, 5–9], and organic polymer solar cells [2, 3, 10–13]. The main difference between inorganic solar cells (SiSCs and TFSCs) and XSCs is their photoconversion mechanism. In an inorganic solar cell, the absorption of light leads to the direct formation of free electron–hole pairs and the direct production of charge carriers. In XSCs, the absorption of photons from sunlight produces an exciton, a tightly electron–hole pair which must be separated for charge generation. The exciton dissociation takes place at the interface of the constituent semiconductors. While inorganic solar cells relay only on inorganic semiconductors, XSCs apply organic semiconductor materials as part of the device active layer. The presence of organic semiconductors (e.g., dyes, small molecules, organic polymers) implies weak intermolecular interactions and low dielectric constants which leads to greater localization of the photoexcited states. The dissociation of the exciton can only be possible if the band offset energy at the junction is greater than the exciton binding energy in the material from which it was generated. In comparison, excitons in SiSCs have binding energies of about 20 meV, and, as a consequence, the absorption of photons generates free charge carriers in the bulk. The electron and hole formed segregates to the electrodes due to the build-up potential generated at the p-n junction. These different mechanisms indicate that each type of solar cell shows a high level of dependence on the crystallinity of the materials applied. Therefore, inorganic solar cells require highly pure and highly crystalline inorganic semiconductors (e.g., Silicon), while XSCs can utilize less crystalline and less pure compounds (e.g., TiO_2). The application of less crystalline materials together with organic semiconductors indicates that the interface between constituents must be carefully controlled, but also permits the fabrication of XSCs by low-cost and scalable printing techniques. The key for highly efficient XSCs is the control of the interfaces through materials nanostructuration.

Classification of Excitonic Solar Cells (XSCs)

XSCs can be classified by the type of semiconductor material applied or by the type of p-n junction used in the final device [7]. Both types of classification are strongly interconnected and



Nanomaterials for Excitonic Solar Cells, Fig. 1 A general schematic representation of an excitonic solar cell (*XSC*) showing the active layers made of the hole transport material (*HTM*) and the electron transport material (*ETM*). The possible extra layers that can be found in XSCs are also indicated. The interface plays a crucial role in exciton dissociation

sometimes generate confusion. A good example is given by the terms *bulk heterojunction solar cell* and *organic solar cell*, which are usually employed when a blend between a polymer and an electron transport material (e.g., P3HT and PCBM) is used as the active layer. In this case, the term *organic solar cell* indicates that the device is being labeled depending on the materials employed (two organic semiconductors). In the case of the term *bulk heterojunction*, the solar cell is defined by the type of p-n junction, since the organic semiconductors employed for the fabrication of the device (donor and acceptor) are mixed heterogeneously in the bulk.

Before a general classification can be defined, the identification of the basic components of XSCs must be made. The main parts of these systems are the electron transport material (ETM) and the hole transport material (HTM) that are in contact through an *interface* (Fig. 1). In some cases, the ETM and the HTM are separated by a thin layer of a light-harvesting molecule (LHM), like the dye in a dye-sensitized solar cell, or inorganic quantum dots (QD) in some hybrid solar cells. In other cases, the light-harvesting material has a dual purpose acting also as the HTM, for example, in an oxide/polymer hybrid solar cell, where the polymer is the responsible for light harvesting and hole transport at the same time. The ETM, LHM, and HTM are "sandwiched" between two electrically conductive electrodes, accountable for charge collection. Thus, in a working device, the LHM is the responsible for photon absorption, the exciton that is formed is then dissociated at the *interface* between the HTM and ETM. Both the ETM and the HTM are responsible for charge transport (electrons and holes, respectively) through the current collectors. *Thus, the LHM, the ETM, and the HTM are the main components of XSCs* for which the device is being classified. Other components of the solar cell offer benefits to the whole device, for example, oxide buffer layers in DSCs or PEDOT and oxide layers in OSCs, among others. These extra layers are used for multiple purposes, especially to facilitate electron or hole transport or to improve interface connection, but are not the main active layer of the solar cell. Thus, in order to identify the type of XSCs under study, a clear differentiation of these extra layers from the main active layer of the XSCs should be made. An easy rule of tomb is that the XSCs will never function without the main active layers, but they can still show photovoltaic response (perhaps not optimal) when the "extra" layers are not present. Figure 1 shows a schematic representation of a XSCs indicating each layer within the device.

Classification by the Type of p-n Junction

XSCs can be classified by the type of junction used [3]. However, it has to be clear that the p-n junction is composed by the ETM and the HTM. Examples of ETM are semiconductor oxides like TiO_2 or ZnO, inorganic semiconductors like Sb_2S_3 or CdS, or C_{60} or C_{70} derivatives. Conducting organic polymers usually act as HTM, but some of them can also act as

Nanomaterials for Excitonic Solar Cells, Fig. 2 Schematic representation of p-n junctions found in XSCs: (**a**) bilayer, (**b**) nanostructured bilayer, (**c**) nanostructured bulk heterojunction, (**d**) ordered bulk heterojunction, (**e**) bicontinous bulk heterojunction, and (**f**) mixed bulk heterojunction and electrochemical junction

the light-harvesting material (LHM) like polythiophenes. There are also HTMs made of small molecules like the *spiro*-OMeTAD. In the case of LHM, a dye molecule is an excellent example. These dyes are usually applied in DSC, but some conducting polymers and inorganic quantum dots can also act as the LHM.

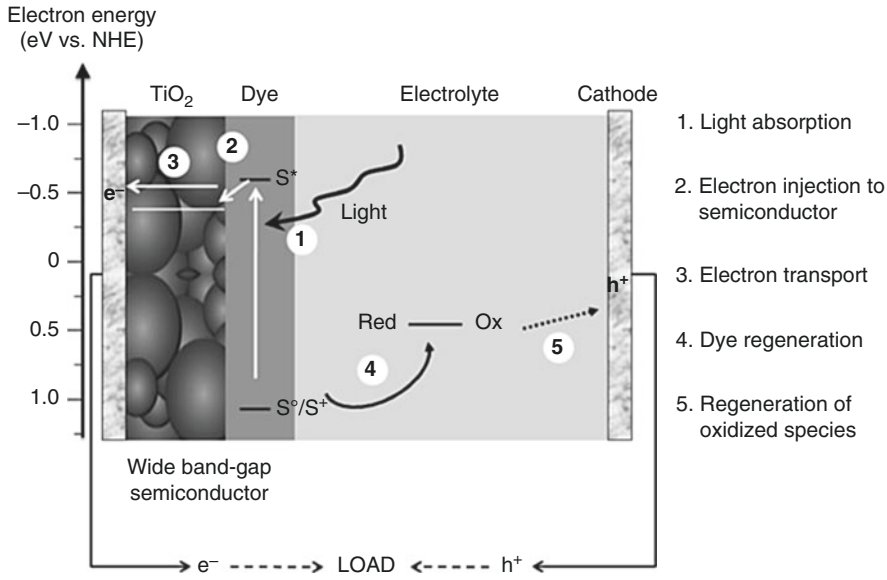
In an XSC, the p-n junction is a critical parameter, since the exciton diffusion length is limited to 10–20 nm in polymers and up to 1 μm in high-quality small molecule films. Thus, in the device structure, the p-n junction must maximize the volume of the light-harvesting material at the interface of the constituent semiconductors, contributing in this way to an optimum charge generation and providing mobility pathways to enhance charge collection. A schematic representation of some of the possible p-n junctions is illustrated in Fig. 2. The most basic p-n junction is the bilayer (Fig. 2a) where a smooth and flat interface is made between the HTM and the ETM. The example in Fig. 2b represents a nanostructured bulk heterojunction where the surface area of the p-n junction has been enhanced by the application of nanoparticles increasing the amount of LHM present at the interface, if compared to bilayer flat devices represented in Fig. 2a. This type of heterojunction can be well ordered, as represented in Fig. 2d, by the application of vertically aligned nanowires, nanorods, nanotubes, or similar. If the nanoparticles in the electrode shown in Fig. 2b, are distributed heterogeneously within a polymer matrix, the final electrode will look like as in Fig. 2c. The latter configuration is now called a "bulk heterojunction." In this junction, the electrons and holes must be transported through the bulk and reach the current collector; thus an interconnection between materials constituents (especially between molecules, nanoparticles, or similar) must be made. The latter is achievable usually by the application of thermal treatments (or similar), and the resulting p-n junction is a bicontinuous network represented in Fig. 2e. A bicontinuous bulk heterojunction is usually observed in organic solar cells (OSC) where the ETM, a C_{60} derivative like the PCBM, is well dispersed within a polymer matrix, like the P3HT. The same heterojunction can also be found in, for example, an HSC of the type polymer/oxide where different nanoforms of ZnO, can dispersed on a polymer matrix like P3HT polymers. The bicontinuous bulk heterojunction is

characterized by the randomly dispersion of the active constituents. A drawback is observed if some of the materials used stay isolated after thermal treatment, forming islands that cannot account for exciton dissociation, and an unoptimized charge generation is observable form the solar cell. Thus, optimization of the bulk heterojunction to enhance charge separation at the interface is possible if these interfaces can be arranged, for example, by the application of well-ordered nanostructured electrodes. Nanostructuration provides order, and order means control over the electron transport and charge collection. Figure 2d represents an example of such electrode: a well-ordered nanostructured bulk heterojunction made of vertically aligned nanorods, nanowires, or similar (other different nanoforms are also possible).

Two or more heterojunctions can be part of a single device. For example, Fig. 2f represents a device where a bulk heterojunction and an electrochemical junction are used. This example is representative of a DSC where the bulk heterojunction is made between the interaction of the TiO_2 electrode and the light-harvesting dye, and the electrochemical junction is made by the TiO_2/dye electrode and the liquid electrolyte. In a solid-state dye-sensitized solar cell (ss-DSC), where a solid organic semiconductor replaces the liquid electrolyte, both junctions are bulk heterojunctions [3].

Classification by the Type of Material

Classification of XSCs can be made by the type of semiconductor applied: organic (polymers, dyes, small organic molecules, etc.) or inorganic (e.g., ZnO, TiO_2, CdSe, etc.). The outcome is three basic solar cell types: organic solar cells (OSCs), hybrid solar cells (HSCs), and dye-sensitized solar cells (DSCs). In OSCs, both materials are purely organic semiconductors, for example, the blend between two conducting organic polymers or a mixture between a C_{60} derivative and a conjugated polymer. In the case of HSC, the device is characterized for the presence of, at least, one phase of an inorganic semiconductor (e.g., Sb_2S_3, TiO_2) and a second phase of an organic semiconductor, like a conducting organic polymer. Although DSC can be classified also as HSC (due to the application of organic and inorganic materials), it is considered a different type of XSC, due to the presence of an electrolyte (semiliquid, gel, solid, etc.).



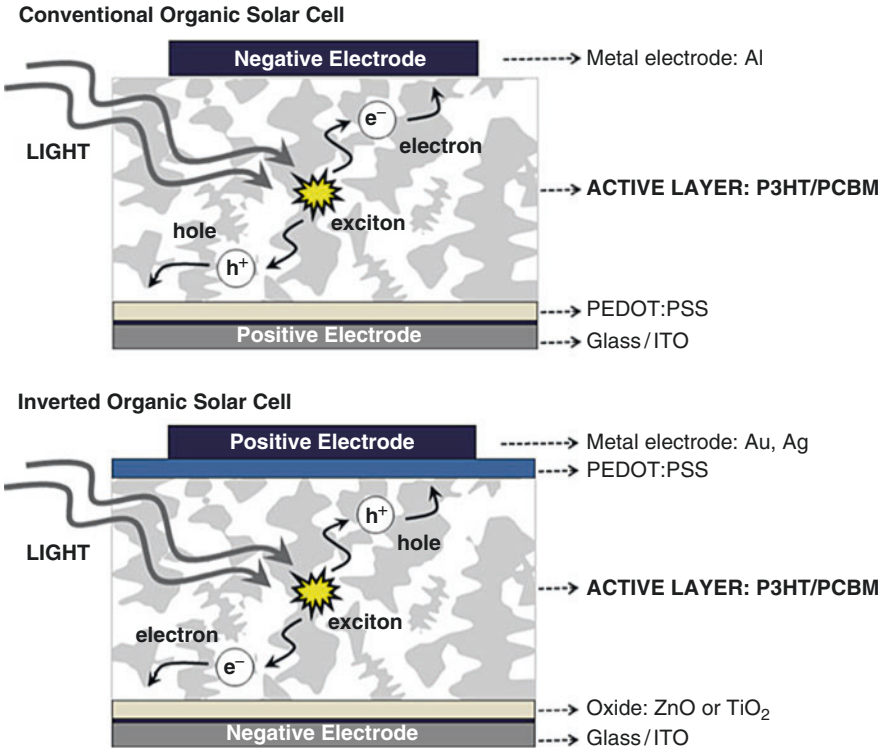
Dye-Sensitized Solar Cell (DSC)

A DSC is characterized by an electrode made of a semiconductor oxide, usually TiO_2 but others like ZnO can also be employed. A charge transfer dye is anchored to the surface of the semiconductor oxide, and finally, a liquid electrolyte containing a redox couple, usually iodide/triiodide in a solvent, completes the device (Fig. 3). The photovoltaic process initiates when photons from sunlight are absorbed by the dye. The exciton is formed and dissociated at the interface between the dye molecule and the semiconductor oxide. The corresponding electron travels through the semiconductor oxide until reaching the current collector (a transparent electrode), and the hole travels through the liquid electrolyte. The regeneration of the dye is possible when it accepts an electron from the electrolyte. The iodine is regenerated by the reduction of the triiodide at the counter electrode (Pt), and the circuit is complete by the migration of the electron through an external load. The voltage generated from the DSC under illumination corresponds to the difference between the Fermi level of the electron in the oxide and the redox potential of the electrolyte [1, 4].

A variation of the DSC is the solid-state dye-sensitized solar cell (ss-DSC) that rose in order to overcome the problems observed in DSC due to the application of liquid electrolyte (solvent evaporation, electrode corrosion, among others). Thus solid, semisolid, gel-type, or nanoclay-based hole conductors have been employed to replace it.

Organic Solar Cells (OSC)

Organic solar cells are characterized for the presence of organic semiconductors in a bulk heterojunction configuration as the main active



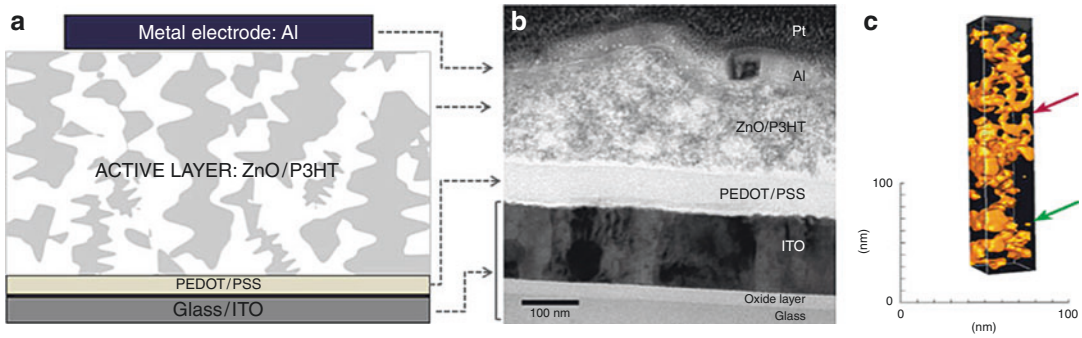
Nanomaterials for Excitonic Solar Cells, Fig. 3 Schematic representation of a DSC. The photovoltaic process initiates with the absorption of photons from sunlight on the light-harvesting dye (S). The different processes taking place are light absorption (*1*), electron injection into the TiO_2 (*2*), electron transport through the TiO_2 (*3*), dye regeneration (*4*), and electrolyte regeneration (*5*) (Adapted from Ref. [1])

layer [2, 10–13]. The best combination is the blend between a C60 derivative, PCBM, acting as the ETM and a conducting organic polymer as the HTM, yet other combinations of organic semiconductors are possible (e.g., the blend between two polymers) [14, 15]. In general, the photovoltaic energy conversion in OSCs is shown schematically in Fig. 4. Photons from sunlight are absorbed by the light-harvesting component, usually a polymer. An exciton is formed at the interface between the HTM and the ETM (or donor/acceptor interface) and dissociates in electron and hole. The electron travels through the ETM and the hole through the HTM until reaching the electrodes and generate charge. Since the active materials that form the bulk heterojunction are distributed on the whole active layer, thin films used, made of organic PEDOT:PSS or inorganic semiconductor oxides, determine the direction at which the electrons and holes migrate, as shown in Fig. 4. Thus, two types of configurations can be found in OSC: the conventional and the inverted. In a conventional OSC, a thin film of PEDOT:PSS is placed between the transparent conducting oxide (TOC) and the active material. Thus, the holes generated at the interface will be transported toward the PEDOT:PSS electrode and the electrons toward the opposite direction. In an inverted device, a thin-film layer of a semiconductor oxide is placed between the TOC and the active layer, while in the opposite side of the solar cell, a layer of the PEDOT:PSS polymer is used. This configuration allows for the electrons to travel toward the side of the oxide thin film, while holes are transported in the opposite direction toward the PEDOT:PSS layer. Although lower photovoltaic properties have been found for the inverted solar cell configuration, the lifetime of the device is being enhanced.

Hybrid Solar Cells (HSC)

Hybrid solar cells present very similar characteristics and mechanisms with OSC; the main difference is that at one of the main components is an inorganic semiconductor [5–9, 16, 17]. The ETMs in an HSC are, for example, semiconductor oxides like TiO_2, ZnO, etc., or inorganic semiconductors like CdS, CdSe, and Sb_2S_3. In both cases, the

Nanomaterials for Excitonic Solar Cells, Fig. 4 Schematic representation of organic solar cells (*OSC*) showing the two configurations: conventional and inverted. Charge generation is possible though three general steps: photon absorption, charge separation, and charge extraction



N

inorganic semiconductor can be used in any form: as a dense layers, nanoparticles, nanorods, nanowires, etc. Except for the case of dense layers, all other nanoforms can be mixed within a conducting organic polymer to form a bulk heterojunction configuration. Figure 5 shows an example of an HSC. The active layer is composed of nanoparticles of ZnO (the ETM) in direct contact with a conducting organic polymer like P3HT (as the HTM) acting as the main active layer. The presence of a PEDOT:PSS layer on the ITO side is used as the hole collector, and the Al metal electrode as the electron collector. The position of these electrodes indicates that the device is in its conventional configuration.

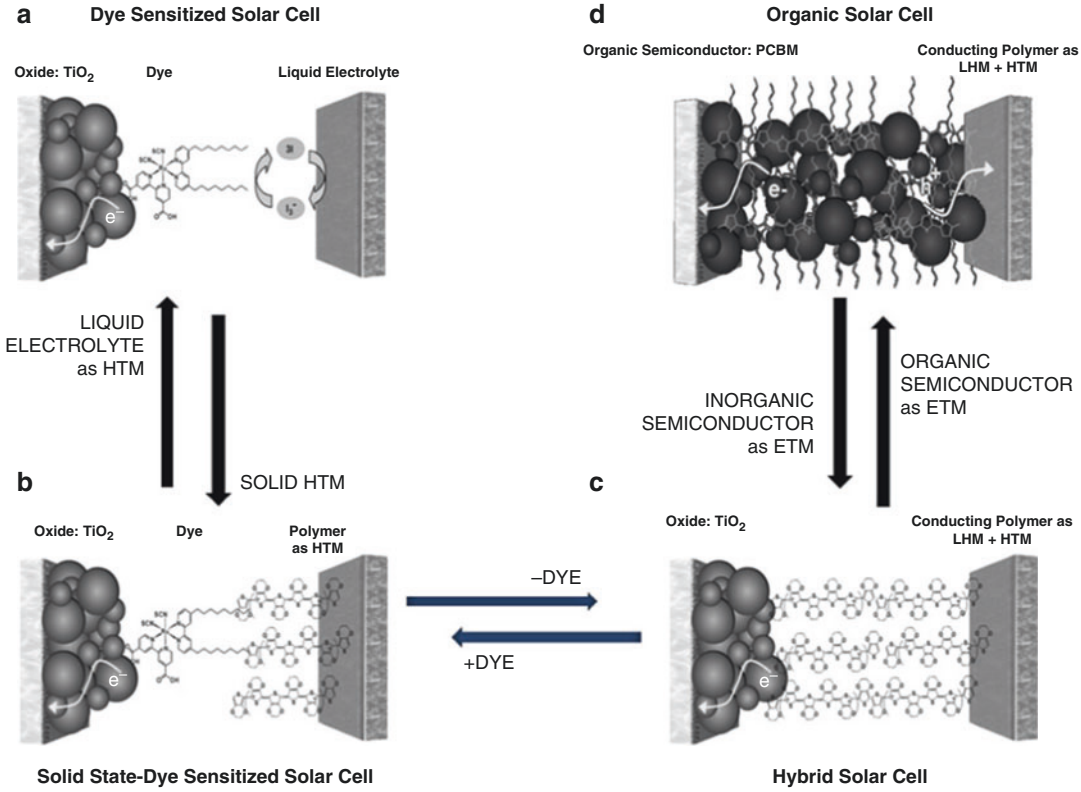


Figure 5c shows a SEM-3D tomography of a section of the active layer of an HSC made of nanoparticles of ZnO and a conducting polymer, P3HT. In the image, the polymer P3HT is represented as transparent and the ZnO nanoparticles in gray. The arrows show two of the main problems observed in bulk heterojunctions: the presence of islands or isolated material (useless as charge carriers) and the connection of some ZnO domains connected only by the top but not through a correct path for charge transport. The latter reduces the efficient electron transport lowering overall device efficiency.

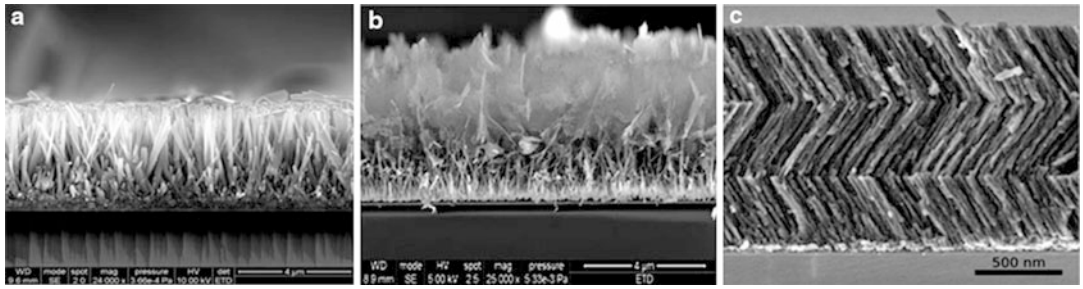
Device Configuration

All XSCs share similar device configuration, active materials, and p-n junctions. To illustrate the latter, in Fig. 6 representation of different XSCs is shown, where the same device configuration is maintained though all the examples and only the materials employed have been changed depending on the type of XSC. Figure 6a represents the DSC device made with a nanoparticulated electrode (usually TiO_2) with a Ru-based dye anchored to it. A redox liquid

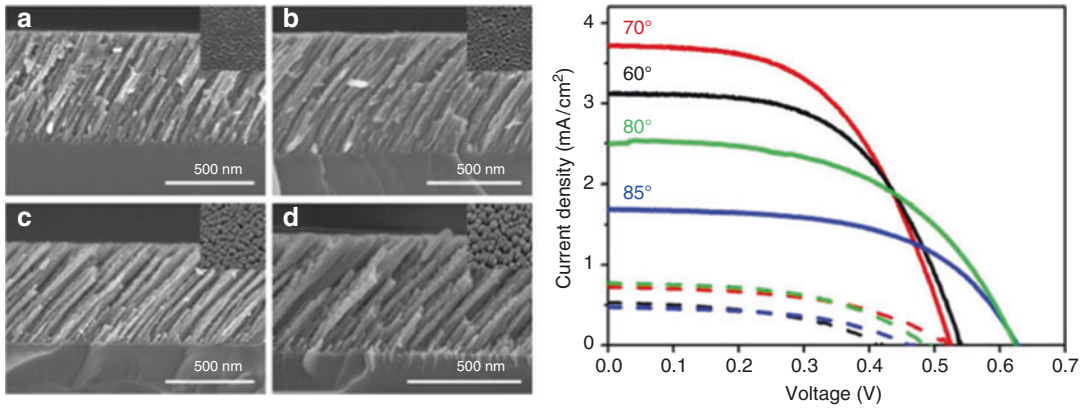
The *upper arrow* indicates a ZnO domain that is connected to the top, but not through a strictly rising path (Copyright Nature Publishing Group for images (**b**) and (**c**) [16])

Nanomaterials for Excitonic Solar Cells, Fig. 6 Schematic representation of XSCs by the type of material applied and the relation between solar cell types: (**a**) dye-sensitized solar cell (*DSC*), (**b**) solid-state dye-sensitized solar cell (*ss-DSC*), (**c**) hybrid solar cell (*HSC*), and (**d**) organic polymer solar cell (*OSC*)



electrolyte completes the device. All the components are "sandwiched" between two electrically conductive electrodes, FTO and Pt respectively, where one of these electrodes must be transparent for light irradiation. A modification of the DSC has been made by the replacement of the liquid electrolyte, with the purpose of minimizing its disadvantages like solvent evaporation, electrode corrosion, etc. Thus, the replacement of the liquid electrolyte in a DSC by a solid HTM, like a conducting organic polymer or organic molecule like *spiro*-OMeTAD, results in what is called a solid-state dye-sensitized solar cell, ss-DSC (Fig. 6b). The light-harvesting dye and the solid hole conductor can be replaced by a single material, for example, a polymer like P3HT which is characterized by a dual function: to collect photons from sunlight and to work as a hole transport. In this simplified version of the ss-DSC, where the ETM is an inorganic semiconductor (e.g., TiO_2, CdS, or similar) and the HTM is an organic polymer (P3HT, MEH-PPV, etc.), the solar cell is known as a hybrid solar cell, HSC (Fig. 6c). The term hybrid is used since the device is made of both organic and inorganic compounds. In this HSC, replacing the *inorganic* ETM semiconductor (e.g., TiO_2, CdS, or similar) by an *organic* ETM semiconductor (e.g., C_{60}, C_{70}, or similar) without modifying the HTM (same organic semiconductor) would result in an organic solar cell (Fig. 6d).

The Benefit of Nanostructuration in XSCs



The development of new materials tailored at the nanoscale has become a major research area due to the unique and novel properties that can be obtained. Nanostructured excitonic solar cells have shown the advantages of controlling the interfaces at the nanoscale level. For example, in a bulk heterojunction made of inorganic nanoparticles and a conducting organic polymer, the inorganic semiconductor oxide nanoparticle is dispersed within the conjugated polymer matrix. The resulting oxide nanoparticle/polymer blend must be annealed to improve nanoparticle connection and to favor electron pathway through the electrode. Nevertheless, these devices are still limited by incomplete exciton dissociation due to the isolation of some nanoparticles from each other after thermal treatment.

A nanostructured thin film, for example, well-crystalline and vertically aligned nanowires can provide higher interfacial area between the donor and the acceptor material (polymer/oxide, respectively) with highly efficient electron transport pathways. In the case of DSCs, the replacement of the nanoparticles electrode by vertically aligned nanostructures emerged also as a possibility to obtain faster electron transport thus improving solar cell efficiency [7]. Moreover, the need to replace problematic liquid electrolytes in DSC by solid hole conductors with slower kinetics impels the application of faster electron transport materials like in vertically aligned nanostructures. Figure 7 shows SEM images of different oxide nanostructures, from nanorods (a), nanotrees (b), nanocolumns (c). The electron transport in an electrode made of nanoparticles is limited by the grain boundaries encountered between each nanoparticle. The application of nanorods, especially if well ordered, paves the way for an efficient electron transport through the crystalline structure. The nanostructure can also be tailored to enhance light absorption without eliminating the advantage of the nanorods. The nanotrees (Fig. 7b) were synthesized with a dual purpose: to enhance the light-harvesting properties of the nanorods by increasing the surface area and by maintaining the good electron transport properties that characterize nanorods.

A practical approach of electrode nanostructuration where high transparency is needed has been recently reported. In this case, increasing the NR length will increase light scattering and decrease the transparency of the DSSC device. A singular example to overcome these problems is the application of nanostructured thin films [7, 18]. Transparent TiO_2 thin films were grown by the physical vapor deposition method at glancing incidences (PVD-GLAD). This method of synthesis furnishes aligned nanocolumnar layers at well-controlled oblique angles. This nanostructure is advantageous for solar collection, as it has already been proved that tilting the nanocolumns improves light entrapment efficiency. Zig-zag and

other complex morphologies can be also prepared by this method. The resulting thin-film electrodes present very open and porous microstructure where nanometer size columns with a high internal porosity are separated by wide pores that extend from the electrode substrate up to the film surface. Many are the factors to be considered when synthesizing these nanostructures: the effect of electrode thickness, TiO_2 crystallinity, topology when arranged into multilayers, the pore structure, or the distribution and concentration of dye molecules within the film thickness. Figure 8 shows SEM images (left) of ordered nanocolumns of TiO_2 deposited by the GLAD technique at different angles. Each sample is 500 nm thick and the angles at which were deposited vary between 60° and 85°. Analyses of the samples as electrode in DSC demonstrated that an optimal deposition angle exists at 70°.

The enhancement observed has been attributed to the increase in the dye-loading capacity of the thin films. Setting the deposition angle at around 70°, at which a 500-nm-thick electrode solar cell presents a maximum efficiency of 1.04 %. A zig-zag nanostructure of the TiO_2 thin films made of stacks of 500-nm layers deposited at the optimum 70° angles, was applied to grow thicker films. This configuration ensured good mechanical stability and high transparency for the films. Power conversion efficiency was observed to increase with electrode thickness, reaching a conversion efficiency of 2.78 % for 3-μm

electrodes of quite good transparency [18]. The high transparency of the obtained cells supports its implementation onto colored glass and other related applications.

There are many possible methods to fabricate nanomaterials, and the observed properties depend a great extent on the preparation conditions. Nanostructure synthesis can be found as simple nanoparticles or as nanorods, nanobelts, branched nanorods, nanowires, ultranarrow nanobelts, hierarchical nanostructures, nanocombs, nanosprings, nanospirals, searnless nanorings, core-shell nanostructures, nanocages, nanoflowers, among many others. It is, however, also difficult to establish the optimal synthesis methodology for solar cell applications because the efficiency of an XSC depends on many aspects and not only on the material nanostructure, like thin film thickness, nanostructure dimension or surface area, but also on overall device preparation like polymer or dye applied, back contacts, active area, etc. However, for XSCs, the most attractive syntheses techniques due to the ease of its process, the low temperature employed, and the possibility to obtain the oxide nanostructures on a large area by continuous methods and in different nanostructures are the hydrothermal methods, among them the chemical bath deposition. The SILAR method is also an alternative which interest is growing due to the ease of its application. These methods permit the synthesis of materials not only as nanoparticles but also as well-aligned nanostructures or core-shell nanostructures. These synthesis methods have been applied for the synthesis of many different inorganic semiconductors like TiO_2, ZnO, CdSe, etc. The synthesis involves precursor baths with the ions of the materials to be synthesized and the technique can be applied for the synthesis of isolated materials (e.g., nanoparticles), the fabrication of nanostructured electrodes, or the sensitization of molecules on different substrates. One of the most attractive examples applying the hydrothermal method is the synthesis of vertically aligned nanostructures. The reason behind the interest in these materials is due to the excellent transport properties if compared to nanoparticles. An example is the synthesis of ZnO nanorods that can be made at low temperature, on almost any substrate, and in a continuous mode [19]. The latter are attractive conditions for large scale production. In general, the method to obtain vertically aligned ZnO nanorods is based on a two-step technique involving the coating of a substrate with ZnO seeds of less than 10 nm in diameter. Every ZnO seed works as a nucleation site for the formation of ZnO nanowires under mid-wet conditions. The synthesis conditions, like zinc concentration in solution, growth time, or growth temperature, determine the final nanorod dimensions and quality. Also the stability of the precursor ZnO seeds (nanoparticles) or the substrates to be applied are important factors affecting the final ZnO nanostructures with reproducible results. As an example, the variation of ZnO nanorod length and diameter can be adjusted depending on the additives added during synthesis. Polyethylenimine (PEI) has been used for large surface area electrodes, so higher amount of dye absorption can be obtained when applied in a DSC. Nanorods as long as 30 μm were observed when PEI additive was used; without additive the length of the nanorods was not more than 5 μm, and their diameters increased also with time. Yet, the longest nanorods, 20–25 μm, show only one fifth of the surface area of an electrode made of nanoparticles [7]. Vertically aligned nanostructures of ZnO have been extensively applied in XSCs. Nevertheless, in terms of upstanding and well-ordered alignment, the current synthesis methodologies applied for their fabrication produce irreproducible nanostructures with dimensions that are too far away from the ideal electrode characteristics. Synthesis condition must be controlled carefully; the minimal change in synthesis condition or even the roughness of the underlying substrate can affect nanorod dimension. Thus, a careful design of the nanostructured electrode made of vertically aligned nanorods should be made in order to fulfill the best requirements for the type of solar cell where it will be applied. For example, one of the most problematic issues observed in XSCs is dye or polymer infiltration (wettability); a solvent-soluble dye could reach the whole surface area of the nanostructured electrode more easily than a

Nanomaterials for Excitonic Solar Cells, Fig. 9 A roll of the printed modules showing how two parallel sets of modules were prepared simultaneously. The zoom-in shows the layer stack which is PET-ITO-ZnO-P3HT: PCBM-PEDOT:PSS-printed silver. The device stack was encapsulated using roll-to-roll lamination post production (From Ref. [20], copyright 2011 Royal Society of Chemistry)

viscous polymer solution which has to penetrate into dense packed nanowire network.

Vertically aligned nanocolumns (nanorods, nanowires, nanotips, etc.) made of semiconductor oxides have been proved to enhance electron transport and reduce the recombination probability in different excitonic solar cells (organic, dye sensitized, or hybrid). Nevertheless, the power conversion efficiencies of these modified solar cells are still far below that obtained with nanoparticle-based electrodes. Their lower efficiency has been attributed to the relatively low surface area of nanocolumnar electrodes and some inefficiency of light absorption since some photons fall on the gap between adjacent vertical nanorods. Moreover, the possibility to obtain highly porous ZnO nanomaterials with good crystalline structure is possible and it suggests that there is room for improvement on solar cell efficiency. In principle, the efficiency of these type of solar cells could be enhanced by increasing the thickness of the aligned nanocolumnar thin films. The solar cells can be nanostructured to get higher surface areas and longer nanocolumns. Nevertheless, recent results show that even NR lengths as large as 40 μm result in low power conversion efficiency. Most recent results show that the modification of the synthesis methodology by the application of additives or the tuning of the synthesis conditions (temperature, time, etc.) reduces traps found on the semiconductor surface. The challenge nowadays resides in the interplay between large-area printing technology and high-quality nanostructuration. The control of both parameters will balance final device cost and functionality.

Future Trends: From Nanomaterials to Large-Scale Printed Devices

XSCs are promising devices due to the possibility to be fabricated by scalable and low-cost printing techniques (as example see Fig. 9), unachievable nowadays for photovoltaic systems based on crystalline silicon. Application of printing methods, like screen printing, roll-to-roll, gravure, offset, lithography, inject, etc., will also permit the integration of other printing electronic devices (lighting, batteries, etc.) to constitute a complete system [10, 12, 20–22]. A challenge in printing

technology is to achieve well-ordered nanostructuration to the main active layer. For the latter, friendly and low-temperature processes (synthesis, pre-/post treatments, etc.) are required.

The development of liquid precursors or "inks," is the key for the scale-up of laboratory devices to commercialization of large-scale printed photovoltaics. Inks can be made from solutions or suspensions. Solution-based inks present advantages like uniform composition and phase, and the possibility of modification of the material (e.g., doping). Nevertheless, the ink solubility may depend on factors such as additives, solvents, humidity, and temperature, among others. All these parameters must be carefully controlled in order to obtain a final useful ink. The preparation of suspensions is another alternative which allows the application of nanostructured solids designed and synthesized at the nanoscale level, with good results [20–22]. Moreover, some recent synthesis methods allow for certain degree of control of the final nanoforms [22]. In the suspension, the problem of the elimination of organic precursors or additives after treatments is a challenge, but the benefits range from tunable electrical and optical properties to the enhancement of mechanical characteristics.

Definition

Structural integrity is of paramount importance in all devices. Load applied during the use of devices can result in component failure. Cracks can develop and propagate under tensile stresses, leading to failure. Knowledge of the mechanical properties of nanostructures is necessary for designing realistic micro-/nanoelectromechanical systems (MEMS/NEMS) and biological micro-/nanoelectromechanical systems (BioMEMS/BioNEMS) devices. Elastic and inelastic properties are needed to predict deformation from an applied load in the elastic and inelastic regimes, respectively. The strength property is needed to predict the allowable operating limit. Some of the properties of interest are hardness, elastic modulus, bending strength, fracture toughness, and fatigue strength. Many of the mechanical properties are scale dependent; therefore, these should be measured at relevant scales. Atomic force microscopy and nanoindenters can be used satisfactorily to evaluate the mechanical properties of micro/nanoscale structures.

Overview

A wide variety of MEMS, including Si-based devices, chemical and biological sensors and actuators, and miniature non-silicon structures (e.g., devices made from plastics or ceramics) have been fabricated with dimensions in the range of a couple to a few thousand microns (see e.g., [4, 5, 9, 10, 15–17, 21–23, 29, 32, 40]). A variety of NEMS have also been produced (see e.g., [13, 14, 18, 33, 38, 43]). MEMS/NEMS technology and fabrication processes have found a variety of applications in biology and biomedicine, leading to the establishment of an entirely new field known as BioMEMS/BioNEMS [2, 3, 9, 12, 19, 24, 30, 31, 37, 44]. The ability to use micro/nanofabrication processes to develop precision devices that can interface with biological environments at the cellular and molecular level has led to advances in the fields of biosensor technology [42, 44], drug delivery [34, 36], and tissue engineering [25]. The miniaturization of fluidic

systems using micro/nanofabrication techniques has led to new and more efficient devices for medical diagnostics and biochemical analysis [39]. The largest "killer" industrial applications of MEMS include accelerometers (over a billion US dollars a year in 2004), pressure sensors for manifold absolute pressure sensing for engines (more than 30 million units in 2004), and tire pressure measurements, inkjet printer heads (more than 500 million units in 2004), and digital micromirror devices (about US $700 million revenues in 2004). BioMEMS and BioNEMS are increasingly used in commercial applications. Largest applications of BioMEMS include silicon-based disposable blood pressure sensor chips for blood pressure monitoring (more than 25 million units in 2004), and a variety of biosensors.

Structural integrity is of paramount importance in all devices. Load applied during the use of devices can result in component failure. Cracks can develop and propagate under tensile stresses leading to failure [6, 8]. Friction/stiction and wear limit the lifetimes and compromise the performance and reliability of devices involving relative motion [4, 5, 7, 9, 10]. Most MEMS/NEMS applications demand extreme reliability. Stress and deformation analyses are carried out for an optimal design. MEMS/NEMS designers require mechanical properties on the nanoscale. Elastic and inelastic properties are needed to predict deformation from an applied load in the elastic and inelastic regimes, respectively. The strength property is needed to predict the allowable operating limit. Some of the properties of interest are hardness, elastic modulus, creep, bending strength (fracture stress), fracture toughness, and fatigue strength. Micro/nanostructures have some surface topography and local scratches dependent upon the manufacturing process. Surface roughness and local scratches may compromise the reliability of the devices, and their effect needs to be studied.

Most mechanical properties are scale dependent [5, 6, 8–10]. Several researchers have measured the mechanical properties of silicon and silicon-based milli- to microscale structures including tensile tests and bending tests, resonant structure tests for the measurement of elastic properties, fracture toughness tests, and fatigue tests. A few researchers have measured the mechanical properties of nanoscale structures using atomic force microscopy (AFM) and nanoindentation. For stress and deformation analyses of simple geometries and boundary conditions, analytical models can be used. For analysis of complex geometries, numerical models are needed. Conventional finite element method (FEM) can be used down to a few tens of nanometer scale, although its applicability is questionable at nanoscale. FEM has been used for simulation and prediction of residual stresses and strains induced in MEMS devices during fabrication, to perform fault analysis in order to study MEMS faulty behavior, to compute mechanical strain resulting from doping of silicon, analyze micromechanical experimental data, and nanomechanical experimental data. FEM analysis of nanostructures has been performed to analyze the effect of types of surface roughness and scratches on stresses in nanostructures.

Commonly used materials for MEMS/NEMS are single-crystal silicon and silicon-based materials (e.g., SiO_2 and polysilicon films deposited by low pressure chemical vapor deposition (LPCVD) process) [9, 10]. An early study showed silicon to be a mechanically resilient material in addition to its favorable electronic properties. Single-crystal 3C-SiC (cubic or β-SiC) films, deposited by atmospheric pressure chemical vapor deposition (APCVD) process on large-area silicon substrates, are produced for high-temperature micro/nanosensor and actuator applications. Amorphous alloys can be formed on both metal and silicon substrates by sputtering and plating techniques, providing more flexibilities in surface-integration. Electroless deposited Ni-P amorphous thin films have been used to construct microdevices, especially using the so-called LIGA techniques. Micro/nanodevices need conductors to provide power as well as electrical/magnetic signals to make them functional. Electroplated gold films have found wide applications in electronic devices because of their ability to make thin films and process simplicity.

As the field of MEMS/NEMS has progressed, alternative materials, especially polymers, have

established an important role in their construction [9, 10]. This trend has been driven by the reduced cost associated with polymer materials. Polymer microfabrication processes, including micromolding and hot embossing techniques, can be orders of magnitude less expensive than traditional silicon photolithography processes. Many polymers are biocompatible, so these can be integrated into biomedical devices with minimal detrimental effects to the host or on the biofluids. An improvement in device functionality (relative to silicon) is also possible due to the mechanical properties of the polymer used, which have properties much closer to biological tissues. Polymer BioMEMS structures involving microbeams have been designed to measure cellular forces. Polymer materials most commonly used for biomedical applications include poly (methyl methacrylate) (PMMA), poly(dimethylsiloxane) (PDMS), and polystyrene. Another material of interest due to ease of fabrication is poly(propyl methacrylate) (PPMA), which has lower glass transition temperature (Tg) (35–43 °C) than PMMA (104–106 °C), which permits low temperature thermal processing.

Experimental Techniques for Measurement of Mechanical Properties of Nanostructures

Indentation and Scratch Tests Using Micro/Nanoindenters

A nanoindenter is commonly used to measure hardness, elastic modulus, and fracture toughness, and to perform micro/nanoscratch studies to get a measure of scratch/wear resistance of materials [5, 9–11].

Hardness and Elastic Modulus

The nanoindenter monitors and records the dynamic load and displacement of the three-sided pyramidal diamond (Berkovich) indenter during indentation with a force resolution of about 75 nN and displacement resolution of about 0.1 nm. Hardness and elastic modulus are calculated from the load–displacement data [5, 10, 11]. The peak indentation load depends on the mechanical properties of the specimen; a harder material requires a higher load for reasonable indentation depth.

Fracture Toughness

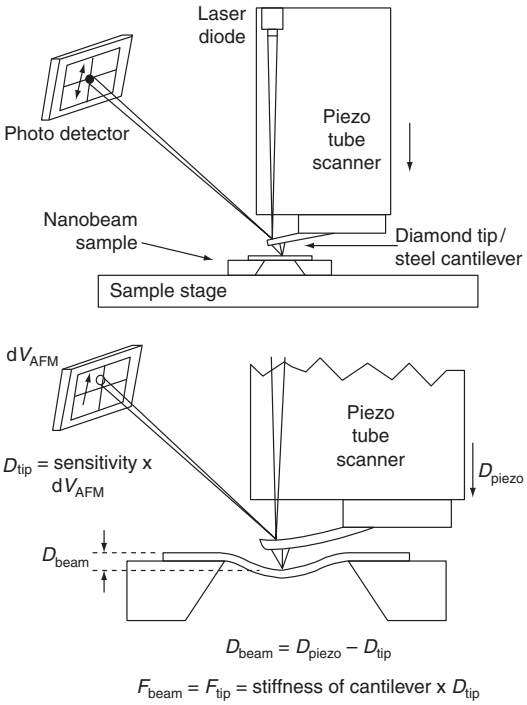
The indentation technique for fracture toughness measurement of brittle samples on the microscale is based on the measurement of the lengths of median-radial cracks produced by indentation. A Vickers indenter (a four-sided diamond pyramid) is used in a microhardness tester. A load on the order of 0.5 N is typically used in making the Vickers indentations. The indentation impressions are examined using an optical microscope with Nomarski interference contrast to measure the length of median-radial cracks, c. The fracture toughness (K_{IC}) is calculated by the following relation [26]:

$$K_{IC} = \alpha \left(\frac{E}{H}\right)^{1/2} \left(\frac{P}{c^{3/2}}\right) \quad (1)$$

where α is an empirical constant depending on the geometry of the indenter, H and E are hardness and elastic moduli, and P is the peak indentation load. For Vickers indenters, α has been empirically found based on experimental data and is equal to 0.016 [5]. Both E and H values are obtained from the nanoindentation data. The crack length is measured from the center of the indent to the end of crack using an optical microscope. For one indent, all crack lengths are measured. The crack length c is obtained from the average value of several indents.

Indentation Creep

For indentation creep test of polymer samples, the test is performed using a continuous stiffness measurements (CSM) technique [11]. In a study by Wei et al. [45], the indentation load was typically 30 μN, and the loading rate was 3 μN/s. The tip was held typically for 600 s after the indentation load reached 30 μN. To measure the mean stress and contact stiffness, during the hold segment the indenter was oscillated at a peak-to-peak load amplitude of 1.2 μN and a frequency of 45 Hz.



Scratch Resistance

In micro/nanoscratch studies, in a nanoindenter, a conical diamond indenter having a tip radius of about 1 μm and an included angle of 60° is drawn over the sample surface, and the load is ramped up until substantial damage occurs [9–11]. The coefficient of friction is monitored during scratching. In order to obtain scratch depths during scratching, the surface profile of the sample surface is first obtained by translating the sample at a low load of about 0.2 mN, which is insufficient to damage a hard sample surface. The 500 μm long scratches are made by translating the sample while ramping the loads on the conical tip over different loads dependent upon the material hardness. The actual depth during scratching is obtained by subtracting the initial profile from the scratch depth measured during scratching. In order to measure the scratch depth after the scratch, the scratched surface is profiled at a low load of 0.2 mN and is subtracted from the actual surface profile before scratching.

Bending Tests of Nanostructures Using an AFM

Quasi-static bending tests of fixed nanobeam arrays in the normal direction are carried out using an AFM [41]. A three-sided pyramidal diamond tip (with a radius of about 200 nm) mounted on a rectangular stainless steel cantilever is used for the bending tests. The beam stiffness is selected based on the desired load range. The stiffness of the cantilever beams for application of a normal load up to 100 μN is about 150–200 N/m.

For the bending test, the tip is brought over the nanobeam array with the help of the sample stage of the AFM and a built-in high magnification optical microscope (Fig. 1) [41]. For the fine positioning of the tip over a chosen beam, the array is scanned in contact mode at a contact load of about 2–4 μN, which results in negligible damage to the sample. After scanning, the tip is located at one end of a chosen beam. To position the tip at the center of the beam span, the tip is moved to the other end of the beam by giving the *X*-piezo an offset voltage. The value of this offset is determined after several such attempts have been made

Nanomechanical Properties of Nanostructures, Fig. 1 Schematic showing the details of a nanoscale bending test using an AFM. The AFM tip is brought to the center of the nanobeam and the piezo is extended over a known distance. By measuring the tip displacement, a load–displacement curve of the nanobeam can be obtained [41]

in order to minimize the effects of piezo drift. Half of this offset is then applied to the *X*-piezo after the tip is positioned at one end of the beam, which usually results in the tip being moved to the center of the span. Once the tip is positioned over the center of the beam span, the tip is held stationary without scanning, and the *Z*-piezo is extended by a known distance, typically about 2.5 μm, at a rate of 10 nm/s, as shown in Fig. 1. During this time, the vertical deflection signal (dV_{AFM}), which is proportional to the deflection of the cantilever (D_{tip}), is monitored. The displacement of the piezo is equal to the sum of the displacements of the cantilever and the nanobeam. Hence the displacement of the nanobeam (D_{beam}) under the point of load can be determined as

$$D_{beam} - D_{piezo} - D_{tip} \quad (2)$$

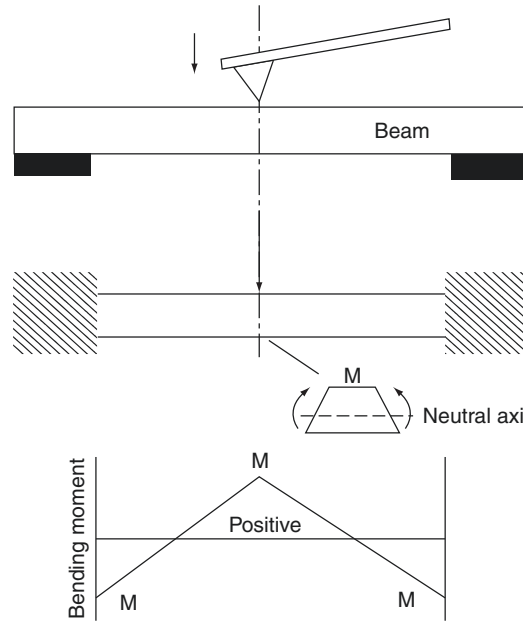
The load (F_{beam}) on the nanobeam is the same as the load on the tip/cantilever (F_{tip}) and is given by

$$F_{\text{beam}} = F_{\text{tip}} = D_{\text{tip}} \times k \tag{3}$$

where k is the stiffness of the tip/cantilever. In this manner, a load–displacement curve for each nanobeam can be obtained.

The photodetector sensitivity of the cantilever needs to be calibrated to obtain D_{tip} in nm. For this calibration, the tip is pushed against a smooth diamond sample by moving the Z-piezo over a known distance. For the hard diamond material, the actual deflection of the tip can be assumed to be the same as the Z-piezo travel (D_{piezo}), and the photodetector sensitivity (S) for the cantilever setup is determined as

$$S = D_{\text{piezo}}/\mathrm{d}V_{\text{AFM}}\text{nm}/V \tag{4}$$



In the measurements, D_{tip} is given as $\mathrm{d}V_{\text{AFM}} \times S$.

Since a sharp tip would result in an undesirable large local indentation, Sundararajan and Bhushan [41] used a diamond tip which was worn (blunt). Indentation experiments using this tip on a silicon substrate yielded a residual depth of less than 8 nm at a maximum load of 120 μN, which is negligible compared to displacements of the beams (several hundred nanometers). Hence one can assume that negligible local indentation or damage is created during the bending process of the beams and that the displacement calculated from Eq. 2 is from the beam structure.

Elastic Modulus and Bending Strength

Elastic modulus and bending strength (fracture stress) of the beams can be estimated by equations based on the assumption that the beams follow the linear elastic theory of an isotropic material. This is probably valid since the beams have high length-to-width ℓ/w and length-to-thickness ℓ/t ratios and also since the length direction is along the principal stress direction during the test. For a fixed elastic beam loaded at the center of the span, the elastic modulus is expressed as

$$E = \frac{\ell^3}{192I}\text{m} \tag{5}$$

Nanomechanical Properties of Nanostructures, Fig. 2 A schematic of the bending moments generated in the beam during a quasi-static bending experiment, with the load at the center of the span. The maximum moments occur under the load and at the fixed ends. Due to the trapezoidal cross section, the maximum tensile bending stresses occur at the top surfaces at the fixed ends

where ℓ is the beam length, I is the area moment of inertia for the beam cross section, and m is the slope of the linear region of the load–displacement curve during bending [46]. The area moment of inertia for a beam with a trapezoidal cross section is calculated from the following equation:

$$I = \frac{4w_1^2 w_1 w_2 + w_2^2}{36(w_1 + w_2)} t^3 \tag{6}$$

where w_1 and w_2 are the upper and lower widths, respectively, and t is the thickness of the beam. According to linear elastic theory, for a centrally loaded beam, the moment diagram is shown in Fig. 2. The maximum moments are generated at the ends (negative moment) and under the loading point (positive moment) as shown in Fig. 2. The bending stresses generated in the beam are proportional to the moments and are compressive or tensile about the neutral axis (line of zero stress).

The maximum tensile stress (σ_b, which is the bending strength or fracture stress) is produced on the top surface at both the ends and is given by [46]

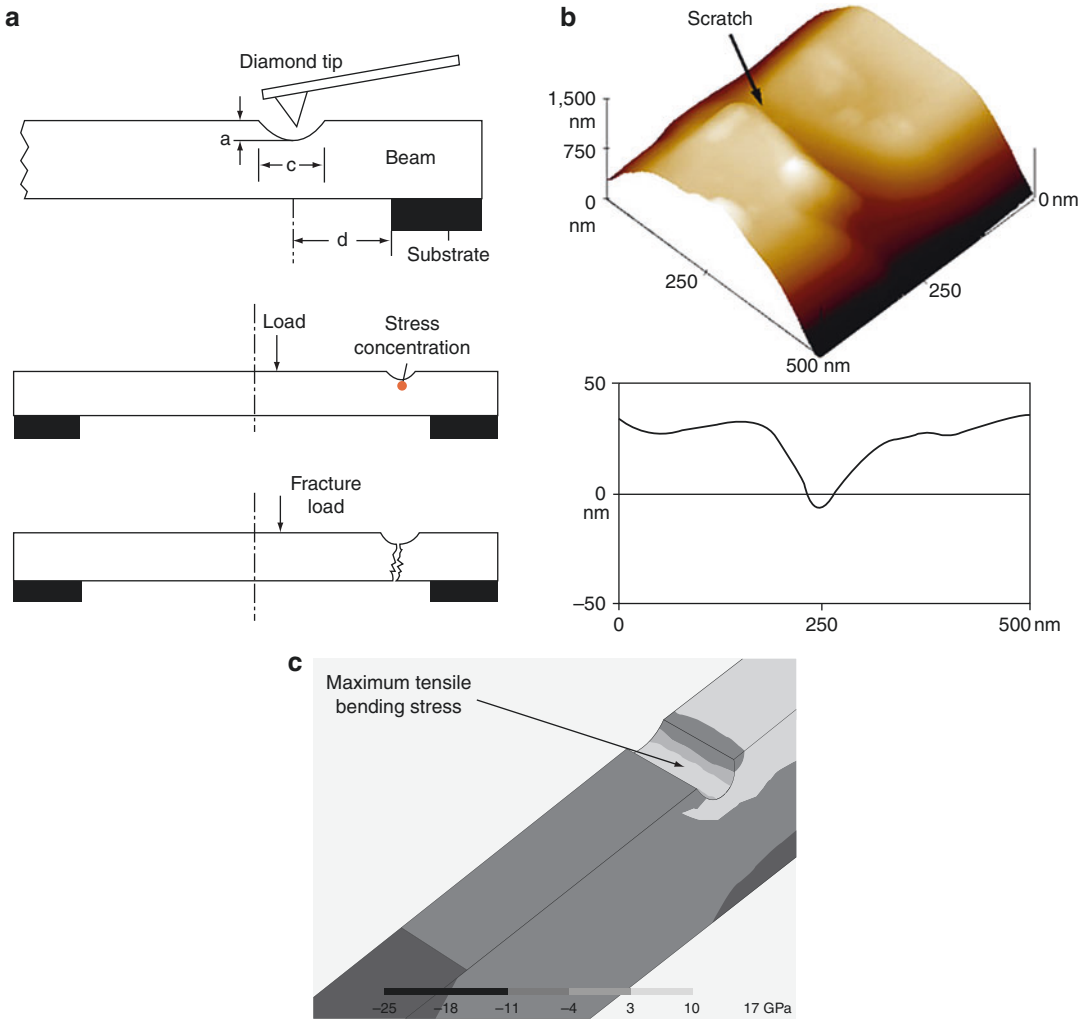
$$\sigma_b = \frac{F_{\max} \ell e_1}{8I} \tag{7}$$

where $F_{\max}$ is the applied load at failure, and e_1 is the distance of the top surface from the neutral plane of the beam cross section and is given by [46]

$$e_1 = \frac{t(w_1 + 2w_2)}{3(w_1 + w_2)} \tag{8}$$

Although the moment value at the center of the beam is the same as at the ends, the tensile stresses at the center (generated on the bottom surface) are less than those generated at the ends (per Eq. 7) because the distance from the neutral axis to the bottom surface is less than e_1. This is because of the trapezoidal cross section of the beam, which results in the neutral axis being closer to the bottom surface than the top (Fig. 2).

In the preceding analysis, the beams were assumed to have fixed ends. However, in the nanobeams used by Sundararajan and Bhushan [41], the underside of the beams was pinned over some distance on either side of the span. Hence a finite element model of the beams was created to see if the difference in the boundary conditions affected the stresses and displacements of the beams. It was found that the difference in the stresses was less than 1 %. This indicates that the boundary conditions near the ends of the actual beams are not that different from that of fixed ends. Therefore the bending strength values can be calculated from Eq. 7.



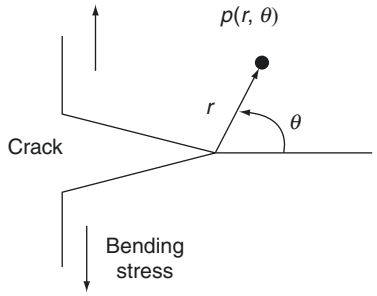
Fracture Toughness

Fracture toughness is another important parameter for brittle materials such as silicon. In the case of the nanobeam arrays, these are not best suited for fracture toughness measurements because they do not possess regions of uniform stress during bending. Sundararajan and Bhushan [41] developed a methodology, and its steps are outlined schematically in Fig. 3a. First, a crack of known geometry is introduced in the region of maximum tensile bending stress, i.e., on the top surface near the ends of the beam. This is achieved by generating a scratch at high normal load across the width (w_1) of the beam using a sharp diamond tip (radius < 100 nm). A typical scratch thus generated is shown in Fig. 3b. By bending the beam as shown, a stress concentration will be formed under the scratch. This will lead to failure of the beam under the scratch once a critical load (fracture load) is attained. The fracture load and relevant dimensions of the scratch are input into the FEM model, which is used to generate the fracture stress plots. Figure 3c shows an FEM simulation of one such experiment, which reveals that the maximum stress does occur under the scratch.

If one assumes that the scratch tip acts as a crack tip, a bending stress will tend to open the crack in Mode *I*. In this case, the stress field around the crack tip can be described by the stress intensity parameter K_I (for Mode *I*) for linear elastic materials [20]. In particular the stresses corresponding to the bending stresses are described by

$$\sigma = \frac{K_1}{\sqrt{2\pi r}} \cos\left(\frac{\theta}{2}\right)\left[1 + \sin\left(\frac{\theta}{2}\right)\sin\frac{3\theta}{2}\right] \tag{9}$$

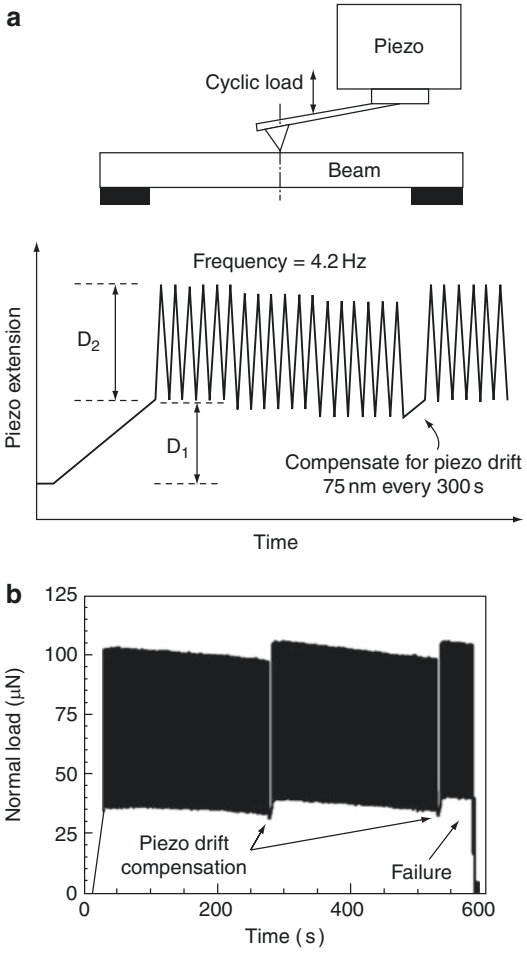
for every point $p(r,\theta)$ around the crack tip as shown in Fig. 4. If the fracture stress (σ_f) is substituted into the left hand side of Eq. 9, then the K_I value can be substituted by its critical value, which is the fracture toughness K_{IC}. Now, the fracture stress can be determined for the point ($r = 0$, $\theta = 0$), i.e., right under the crack tip as explained above. However, $r = 0$ cannot be substituted in Eq. 9. The alternative is to substitute a value for r which is as close to zero as possible. For silicon, a reasonable number is the distance between neighboring atoms in the (111) plane, the plane along which silicon exhibits the lowest fracture energy. This value was calculated from silicon unit cell dimensions of 0.5431 nm [1] to be 0.4 nm (half of the face diagonal). This assumes that Si displays no plastic zone around the crack tip, which is reasonable since in tension, silicon is not known to display much plastic deformation at room temperature. Sundararajan and Bhushan [41] used values $r = 0.4$–1.6 nm (i.e., distances up to four times the distance between the nearest neighboring



Nanomechanical Properties of Nanostructures, Fig. 3 (**a**) Schematic of technique to generate a defect (crack) of known dimensions in order to estimate fracture toughness. A diamond tip is used to generate a scratch across the width of the beam. When the beam is loaded as shown, a stress concentration is formed at the bottom of the scratch. The fracture load is then used to evaluate the stresses using FEM. (**b**) AFM 3-D image and 2-D profile of a typical scratch. (**c**) Finite element model results verifying that the maximum bending stress occurs at the bottom of the scratch [41]

atoms) to estimate the fracture toughness for both Si and SiO_2 according to the following equation:

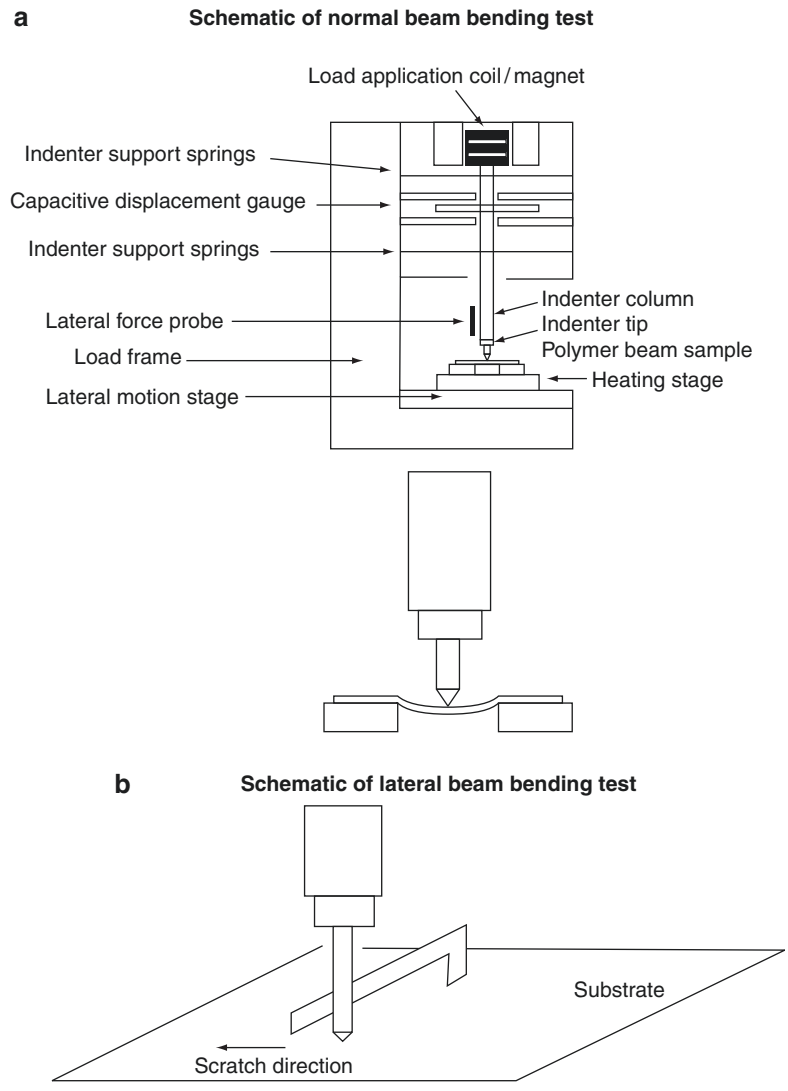
$$K_{IC} = \sigma_f \sqrt{2\pi r} \quad r = 0.4 \text{ to } 1.6\,\text{nm} \qquad (10)$$



Fatigue Strength

In addition to the properties mentioned so far that can be evaluated from quasi-static bending tests, the fatigue properties of nanostructures are also of interest. This is especially true for MEMS/NEMS involving vibrating structures such as oscillators and comb drives and hinges in digital micromirror devices. To study the fatigue properties of the nanobeams, Sundararajan and Bhushan [41] applied monotonic cyclic stresses using an AFM, Fig. 5a. Similar to the bending test, the diamond tip is first positioned at the center of the beam span. In order to ensure that the tip is always in contact with the beam (as opposed to impacting it), the piezo is first extended by a distance D_1,

Nanomechanical Properties of Nanostructures, Fig. 4 Schematic of crack tip and coordinate systems used in Eq. 9 to describe a stress field around the crack tip in terms of the stress intensity parameter, K_I [41]



which ensures a minimum stress on the beam. After this extension, a cyclic displacement of amplitude D_2 is applied continuously until failure of the beam occurs. This results in the application of a cyclic load to the beam. The maximum frequency of the cyclic load that could be attained using the AFM by Sundararajan and Bhushan [41] was 4.2 Hz. The vertical deflection signal of the tip is monitored throughout the experiment. The signal follows the pattern of the piezo input up to failure, which is indicated by a sudden drop in the signal. During initial runs, piezo drift was observed that caused the piezo to gradually move away from the beam (i.e., to retract), resulting in a continuous decrease in the applied normal load. In order to compensate for this, the piezo is given a finite extension of 75 nm every 300 s as shown in Fig. 5a. This results in keeping the applied loads fairly constant. The normal load variation (calculated from the vertical deflection signal) from a fatigue test is shown in Fig. 5b. The cyclic stress amplitudes (corresponding to D_2) and fatigue lives are recorded for every sample tested. Values for D_1 are set such that minimum stress levels are about 20 % of the bending strengths.

Nanomechanical Properties of Nanostructures, Fig. 5 (**a**) Schematic showing the details of the technique to study fatigue behavior of the nanobeams. The diamond tip is located at the middle of the span and a cyclic load at 4.2 Hz is applied to the beam by forcing the piezo to move in the pattern shown. An extension is made every 300 s to compensate for the piezo drift to ensure that the load on the beam is kept fairly constant. (**b**) Data from a fatigue experiment on a nanobeam until failure. The normal load is computed from the raw vertical deflection signal. The compensations for piezo drift keep the load fairly constant [41]

Bending Tests of Micro/Nanostructures Using a Nanoindenter

Quasi-static bending tests of micro/nanostructures in both normal and lateral directions are carried out using a nanoindenter (Fig. 6) [27, 28, 35, 45]. The advantage of a nanoindenter is that loads up to about 400 mN, higher than that in AFM (up to about 100 μN), can be used for structures requiring high loads for experiments. Bending experiments in the normal direction have been carried out on the suspended beams using the nanoindenter fitted with a conical tip that has a 1 μm radius of curvature and a 60° included angle. Figure 6a shows the schematic of the beam bending experimental setup. To avoid the indenter tip

Nanomechanical Properties of Nanostructures, Fig. 6 Schematic of micro/nanoscale bending experimental setup using a nanoindenter (**a**) in the normal direction, and (**b**) in the lateral direction

pushing into the specimen, a blunt tip is used in the bending and fatigue tests. For ceramic and metallic beam samples, Li et al. [28] used a diamond conical indenter with a radius of 1 μm and an included angle of 60°. For polymer beam samples, Wei et al. [45] and Palacio et al. [35] reported that the diamond tip penetrated the polymer beams easily and caused considerable plastic deformation during the bending test, which led to significant errors in the measurements. To avoid this issue, the diamond tip was dip-coated with PMMA (about 1–2 μm thick) by dipping the tip in the 2 % PMMA (wt/wt) solution for about 5 s. Load position used was at the center of the span for the bridge beams and at 10 μm off from the free end of cantilever beams. An optical microscope with a magnification of 1500× or an in situ AFM is used to locate the loading position. Then the specimen is moved under the indenter location with a resolution of about 200 nm in the longitudinal direction and less than 100 nm in the lateral direction. Using the analysis presented earlier, elastic modulus and bending strength of the beams can be obtained from the load–displacement curves [28, 35, 45]. For fatigue tests, an oscillating load is applied and contact stiffness is measured during the tests. A significant drop in the contact stiffness during

the test is a measure of the number of cycles to failure [27].

A schematic of the lateral bending experimental setup in shown in Fig. 6b. The nanoindenter was fitted with a conical tip which has a 1 μm radius of curvature and a 60° included angle. The tip was positioned at 200–300 μm away from the beam anchor and 20 μm from the edge of the beam length. The indenter was programmed to perform a scratch at a constant load of 400 μN, and the stage was moved at a rate of 10 μm/s. Since the lateral force contribution of the substrate surface is constant, any additional force recorded comes from the cantilever beam response. From the linear elastic regime in the measured lateral force as a function of lateral displacement, the elastic modulus can be evaluated. For a cantilever beam with one end clamped, it is expressed as [46]

$$E = \frac{\ell^3}{3I}\mathrm{m} \tag{11}$$

where, as described earlier, ℓ is the beam length, I the area moment of inertia for the beam cross section, and m is the slope of the linear region of the force–displacement curve.

Closure

Mechanical properties of nanostructures are necessary in designing realistic MEMS/NEMS and BioMEMS/BioNEMS devices. These can be measured using an AFM or nanoindenter. Most mechanical properties are scale dependent.

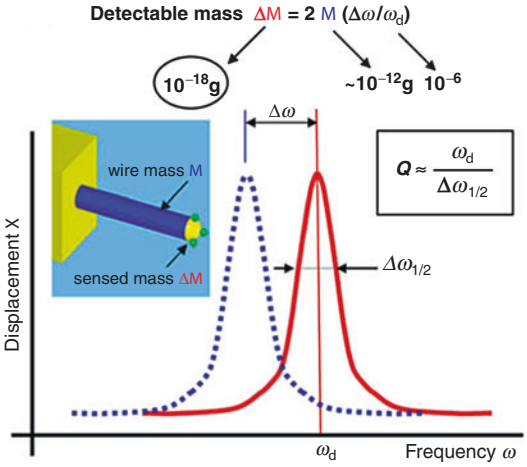
Nanomechanical Resonant Sensors and Fluid Interactions

Rustom B. Bhiladvala
Department of Mechanical Engineering,
University of Victoria, Victoria, BC, Canada

Definition



Nanomechanical resonators (or nanoresonators, for this entry) are typically simple nanoscale objects such as rods, beams of rectangular cross-section, grids, or hollow tubes, set into mechanical vibration around a resonance frequency. This entry focuses on ambient fluid (gas or liquid) interaction with nanoresonator-based sensors.

Introduction

Nanoresonators, often referred to as examples of NEMS (Nano Electro Mechanical Systems) devices, are of technological interest because of their potential for extraordinary sensitivity as mass and force measurement devices. To convey this sensitivity to the nonspecialist, a relevant unit for measurable added mass is a zeptogram ($1\ \text{zg} = 10^{-21}$ g), the mass of about 33 water molecules, or a billionth part of one trillionth of a typical 0.1 ml water droplet seen in a household faucet; a relevant unit for measurable force is an attonewton ($1\ \text{aN} = 10^{-18}$ N), equivalent to the weight of one millionth part of one billionth of such a droplet. In the last half-decade, published reports of zeptogram mass resolution [1] and attonewton force resolution [2], using nanomechanical structures of submicron dimensions, now allow us to anticipate new roles for nanoresonators in healthcare, biological research, surface science, and several interdisciplinary areas across physics, chemistry, and engineering.

How has the scientific community moved to use the extraordinary capabilities of nanomechanical resonators to measure such small forces and mass? Perhaps the most widespread interest expressed has

been in molecular diagnosis – screening for, or quantifying, small concentrations of biomarker molecules of devastating disease states such as cancer and neurodegeneration, with the goal of early intervention to improve prognosis – well before disease symptoms appear. Cantilevered tips of less than 100 nm width have been batch fabricated for metrology of biomolecules and Magnetic Resonance Force Microscopy (MRFM) with 4 nm resolution for imaging single viruses [2]. The role of mechanics in the intriguing and complex world of living cells and tissues is being investigated by cell stiffness and tissue elasticity measurements using small-scale resonators for force microscopy in liquids [3, 4]. In the physical sciences, the quest to correlate the structure and behavior of matter at small scales, occupies a significant fraction of research with nanoresonators. Examples are the quantum behavior of mesoscopic mechanical systems, the understanding of elastic and dissipative processes in solids with a large surface to volume ratio, the description of fluid–solid interaction at small scales, high frequencies and in particular, in gases at moderate rarefaction.

Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 1 Schematic of a cylindrical nanoresonator made by nanowire assembly. The left-shift $\Delta\omega$ of the damped resonance peak frequency ω_d, upon binding of mass, allows attogram-level mass resolution. The quality factor, Q, as defined, may be obtained from the spectrum by measuring the full width at half-peak power, $\Delta\omega_{1/2}$

Two measured quantities of interest in nanoresonator-fluid interaction are the resonance peak frequency ω_d, and the quality factor or Q-factor, (symbol Q), as shown in Fig. 1. Nanowire (NW) resonators, tenths of a micron in diameter and a few microns long, typically have resonance frequencies in the MHz-range and small masses (pg), which allow attogram-level resolution of added mass. Measurement of damping force uses the quality factor, Q, as defined in Fig. 1. The Q-factor is the most relevant quantity for fluid-nanoresonator interaction studies. Why is nanoresonator interaction with fluids – liquids or gases – of interest? There are two points of view. The first view to emerge was that interaction with fluids is a nuisance in many nanoresonator applications and it is necessary to learn enough about it to reduce or correct for its effects. Resonance experiments showing great promise for sensor performance in a high-vacuum environment, quickly encountered the sobering reality of high fluid damping in air and water. Measurement attempts showed that high fluid damping could reduce accuracy of frequency peak location, decrease signal-to-noise ratio, and, in liquids, make resonance spectra difficult or impossible to detect. Efforts aimed at addressing these problems constitute the bulk of published research in fluid-nanoresonator interaction. The second and more recent view to emerge is that fluid interaction with nanoresonators is worthy of study in its own right. Such studies aim to answer questions of broad applicability in fluid mechanics of external oscillatory flows, in which viscous forces dominate over inertial forces (i.e., flows at low Reynolds numbers, Re). Examples are the material behavior of fluids at very high forcing frequencies, where the timescales can be small compared to relaxation time of the fluid, and flow in moderately rarefied gases, where the derivation of governing equations and boundary conditions to describe the flow are a subject of active research. The fluid mechanics of internal (channel) flows of liquids at micro and nanoscale is acquiring some maturity, with several books now available in microfluidics and nanofluidics. The study of oscillatory flows around nanostuctures is presently seeing a period of vigorous early growth in research publication.

This entry is organized in four sections. The section "Nanoresonator Applications Involving Fluid Interaction", divides nanoresonator-fluid interaction applications into those in which fluid interaction is primarily a performance concern to be reckoned with or is proposed as a sensor principle and those applications where research toward formulating and answering questions in fluid mechanics is the primary goal. As the scope and limitations for both sets of applications is coupled strongly to choices of materials and transduction methods, this coupling is first introduced in the section "Interdisciplinary Development of Nanoresonator Sensor Platforms", but plays a significant role throughout the article. The section "Measurement Relations" deals with the development of the simplest relations required to interpret measurements. The role of geometry, materials, and fabrication schemes in nanoresonator-fluid interaction measurement is discussed in detail in the section "Fabrication and Materials", and a summary and a few reviews with complementary material are presented in the section "Summary and Related Reviews".

Nanoresonator Applications Involving Fluid Interaction

While the potential field of nanoresonator applications is large, this entry is restricted to applications of nanomechanical resonators that involve fluid interaction. It is useful to divide these into two cases: (1) Nanoresonators for technological applications involving fluid interaction and (2) Nanoresonators as fluid damping sensors for research in fluid mechanics. In case (1), an accurate value of the Q-factor is not important, provided it is large enough ($Q >> 1$) and does not change significantly in the course of measurement. A significant decrease in Q-factor as a result of increasing ambient gas pressure can reduce accuracy and signal-to-noise ratio and constitutes a decrease in performance in this case. In case (2), an accurate value of the Q-factor is required, as it constitues the raw data for the measurement of fluid damping. In this case, a larger change in Q-factor for a given change in fluid damping is desirable, as this increases the dynamic range for fluid damping measurement.

Technological Applications Involving Fluid Interaction

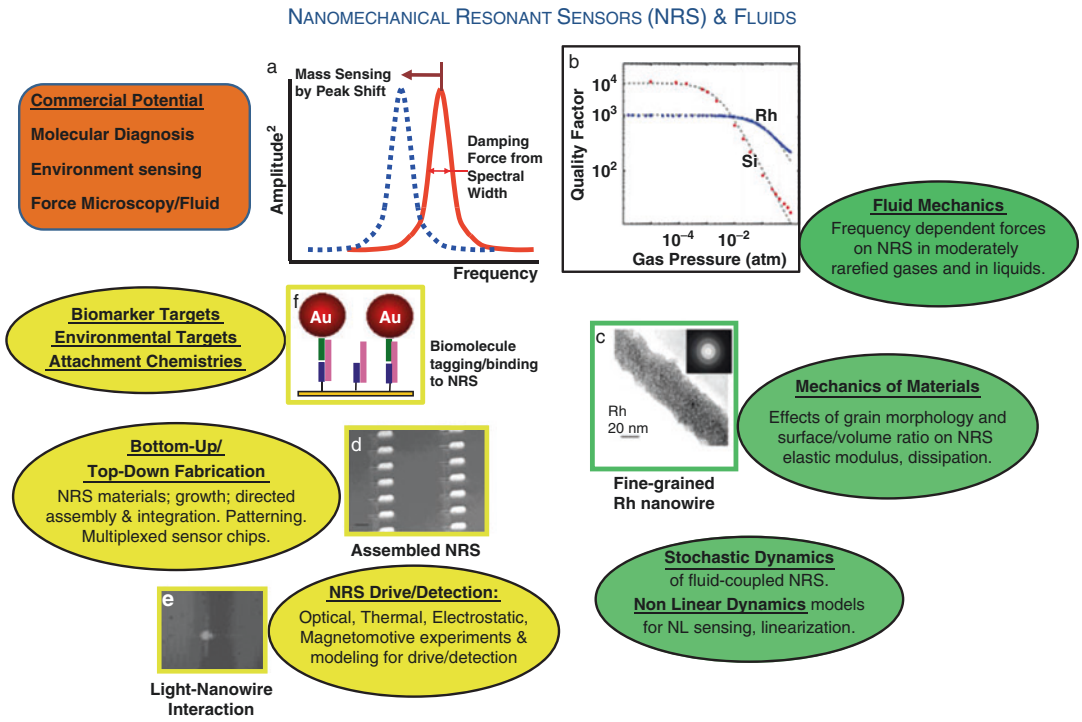
The extraordinary mass and force sensitivity of nanoresonators and their size, commensurate with length scales of large macromolecules in living cells, makes them well suited to cellular and molecular studies. For microcantilevers, Lavrik et al. [5] provide a comprehensive review of studies using resonance mode detection, static deflection, or a combination of both for gas and vapor phase analyte sensing. Molecular diagnosis/screening can be enabled by functionalizing nanoresonators for specific binding of target biomarker molecules and using the frequency shift following target binding. Accurate measurements of small mass require a resonant spectrum with adequate signal-to-noise ratio and a sharp resonant peak (high quality factor) for the resonance curve. Since the aqueous environment is native to most cells and biomolecules, this would be most preferred for operating nanoresonator biosensors – but it is also the environment with highest fluid damping, which degrades the overall performance of the resonators. Demonstration of ideas such as the use of higher harmonics of the fundamental resonance frequency [6] or high pretension in nanobeams [7] for viable resonance in fluids are an established stream of research literature focused mainly on reducing the deleterious effects of fluid damping on sensor performance in measurement schemes. Use of the change in damping of a single nanoresonator or the resonance properties of a group of fluid-coupled nanoresonators by the binding of biomolecular analytes have also been proposed [8]. The development of scanned probe microscopies for mapping and understanding the structure of biomolecules is an important research area. Q-control techniques have been developed to offset the deleterious effects of fluid damping in scanned force microscopies.

Sensing for Fluid Mechanics Research

Nanoresonator interaction with gases of varying density can span rarefaction regimes from

continuum flow to highly rarefied (free-molecular) flow. While both these limits and quantitative approaches to them are familiar, neither free-molecular nor standard continuum calculation methods are valid [9] in the intermediate transition regime of rarefied gas flow. NWs can serve as measuring instruments of gas damping forces from atmospheric pressure to a modest vacuum ~10^{-3} atm and spanning Knudsen numbers (gas molecule mean free path/wire diameter) in the range of $0.1 < \mathrm{Kn} < 100$ which includes the transition and free-molecular flow regimes of rarefied gas dynamics. Neither the continuum fluid approach nor simple models for molecular momentum transport can be trivially extended to work in the transition regime – the development of theoretical and computational models in this regime is currently a research area of significant interest [9–11]. Gas damping force measurements with nanowires can provide data for these models.

A theoretical quantitative description allowing accurate calculation in the transition regime must blend smoothly into known solutions for the free-molecular and continuum regimes. For fluid which may be regarded as a continuum, what is the effect of forcing at high frequencies, or times small compared to any relaxation (i.e., adjustment) time within the fluid? For a smooth blend at the continuum end, the large span in frequencies (and Reynolds numbers, Re) can require either steady or unsteady forms of the Stokes equation, and for a few exceptional high-frequency cases, the usually appropriate neglect of inertial effects represented by the nonlinear term in the Navier–Stokes equations is not valid (i.e., $\mathrm{Re} > 1$). How should the physics of unsteadiness and inertia be modeled in the transition regime of rarefaction? How should transition regime calculations for geometries more complex than beams be approached? What are the appropriate length scales to be used in determining the boundaries of rarefaction regimes? How do the results scale with Mach number (nanoresonator velocity/gas molecule velocity)? Fundamental insights into fluid mechanics at small scales and high frequencies can be gained by comparing results from proposed models with those from tabletop experiments using oscillatory nanoresonator flows.



While early experimental demonstrations of viable micro or nanoresonator operation in fluids [5, 6] have provided some data suitable for a study of resonator-fluid interaction, experimental studies focused solely on understanding fluid interaction are now beginning to emerge [12, 13]. Better answers to some of the questions above are being proposed, as members of computational, analytical, and experimental subcommunities undertake collaborative work [10, 14] to improve understanding of fluid mechanics at small scales, high frequencies, and in regimes of gas rarefaction that are not yet well described. These fundamental studies aim to create the analytical and computational framework, which in turn will enable a diverse range of useful applications. Such applications range from the very small – for example, sensitive nanoscale instruments for understanding biology and the physical sciences, building sensors for healthcare, engineering and technology – to the macroscale – for example, drag force and trajectory calculations of space vehicle or satellite fragments following atmospheric entry.

The potential to create extraordinarily sensitive instruments from nanoresonators is easy to see in principle, but the path to realization of such sensor platforms is paved with challenges. Some of these challenges are introduced and explained with an example in the following section.

Interdisciplinary Development of Nanoresonator Sensor Platforms

The challenge in measurements is that the high surface to volume ratio of nanostructures can cause an unusual and strong coupling of physical effects. Sensor platform development must typically reckon with such coupling between transduction (vibration detection and driving) schemes, intrinsic stresses from fabrication, and nonlinear geometric effects [15]. While the focus here is on nanoresonators and fluid mechanics, note that the actual conduct of work for technological applications requires making several choices in other areas that are strongly coupled and cannot be ignored.

A representative view of these areas is shown in Fig. 2. A few partially realized examples of

Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 2 One view of the scope of research for nanomechanical resonant sensors (*NRS*) involving fluid interaction. Commercial potential (*top left*) and experimental methods development (three ellipses at *left, yellow*) have served as drivers. Fields of engineering science which support and are enriched by such research, are shown on the *right* (three ellipses, *green*) ((**c**, **d**) reproduced with permission, from Refs. [16, 17])

commercial potential are listed at the top left of the figure. Experimental research areas for engineering and technological development are shown in the three ellipses on the left. What are the sensor targets – for example, which gases, biological macromolecules, or cell components? How can attachment chemistry be developed to help functionalize a nanomechanical resonator (NR) – that is, to give it surface properties that will enable specific capture of only the selected target(s)? The attachment chemistry is dependent on the choice of NR material. The material choice may be limited by the fabrication approach used. Choice of the fabrication approach, in turn, may alter the ability for creating multiplexed sensors (capable of sensing different targets on the same chip). What schemes are suitable for driving and detecting resonance for these small high-frequency devices? Each method listed in Fig. 2 is associated with advantages, and frequently, with measurement artifacts. Experiments and theoretical or computational analysis are often required to quantify the artifacts. Fundamental understanding in the disciplines of Fluid Mechanics, Mechanics of Materials, and Nonlinear Dynamical Systems (right half of figure) guides this engineering and technological work. Many aspects of this understanding need to be improved. A strong application for nanoresonators in fluids is thus to help improve the framework of areas of Fluid Mechanics that are not well understood. For example, what happens when a shear disturbance (vorticity) is introduced in a fluid at time scales far smaller than the time taken for viscosity to smoothen it out (viscous relaxation time)? Nanoresonator-fluid experiments are especially suitable for this question – they can provide very small forcing timescales (very high frequencies) and are typically associated with small fluid inertia (low

Reynolds number) so that the nonlinear inertial effects are associated negligible.

As an example of iterative work due to interdisciplinary coupling shown in Fig. 2, consider a long, thin, doubly-clamped resonant nanobeam made from a metal film, with high intrinsic stress from a top-down fabrication process. Suppose the metal was chosen because the attachment chemistry for molecules enabling specific capture of a desired detection target molecule is well understood. During optical measurement of the motion of the doubly-clamped nanobeam in a high damping gas environment, one may turn up the power of the measuring laser to improve signal strength at low vibration amplitude. Experiments and modeling (nonlinear dynamics, mechanics of materials) have shown this can cause periodic heating of the vibrating beam and a thermomechanical coupling which has been shown to introduce softening and hardening nonlinearity as a function of laser power [15]. To circumvent this problem arising from intrinsic axial stress in the metal film, a similar long, thin, cantilevered metal beam (no axial stress) will be a necessary replacement. Such beams are difficult to make with a top-down technique, spurring efforts in the use of alternate fabrication techniques to make such structures.

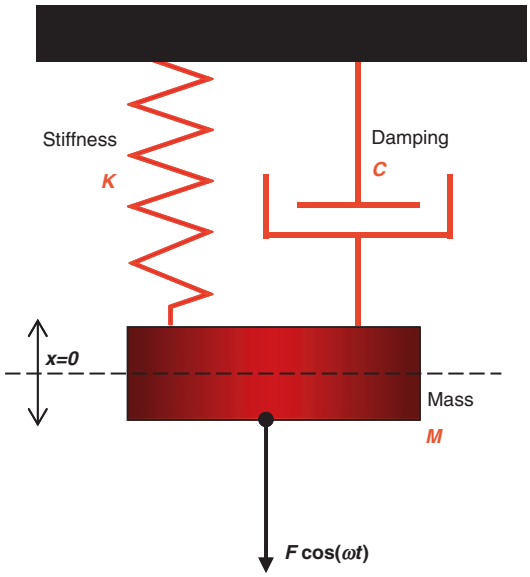
This example shows that the conduct of work as well as the correct interpretation of data needs continual interaction between different disciplines to sort out artifacts arising from the coupling of physical effects, materials, fabrication schemes, and transduction methods. It is important to be mindful of this coupling while approaching the following section of relations used in the design of experiments and the interpretation of data.

Measurement Relations

This section presents different definitions of the Q-factor (Fig. 1) based on material properties, energy, and on spectral or time-domain measurements of resonator amplitude. The distinctions between definitions are usually and justifiably ignored if the Q-factor is very large compared to unity, but can be significant for fluid-nanoresonator interaction with high damping. These relations and the relations for the resonance frequency also provide a scaling guide for geometry and material choice to tune the range of Q-factor for a given range of fluid damping.

When the modes of vibration are sufficiently separated, a single degree of freedom, harmonically driven, linear resonator model is reasonable for understanding key features of fluid-nanoresonator interaction. The damped resonance peak frequency ω_d and the dimensionless quality factor (Q-factor, or Q), which allows the measurement of dissipation through the sharpness of the resonance peak, are the most widely used quantities. Most instruments based on resonators avail of simplifications that are possible when the quality factor is large ($Q >> 1$). High fluid damping produces systems with low Q-factor, leading to errors from the use of these simplifications. It is helpful to gather the concepts and relations necessary to maintain the accuracy of calculations for resonators where Q may not be much larger than 1. A summary is included later in this section.

The displacement with time, $\{x(t)\}$, of a resonator with mass M, damping C, and stiffness K, driven harmonically with a forcing amplitude F_0 at a frequency ω, as seen in Fig. 3, is



$$M\ddot{x} + C\dot{x} + Kx = F_0 \cos(\omega t) \tag{1}$$

A surrogate form of the Q-factor, defined using material properties alone, is the dimensionless ratio Q_p, given by $Q_p = \sqrt{MK}/C = M\omega_0/C$ where $\omega_0 = \sqrt{K/M}$ is the undamped resonance frequency. Q_p is related to the commonly used damping ratio ζ through $\zeta = C/C_c = 1/(2Q_p)$, where $C_c = 2\sqrt{MK}$ is the critical value of damping. Damping decreases the resonance frequency ω_d, from the undamped resonance value ω_0, as given by the relation,

$$\omega_d = \omega_0\left[1 - 1/\left(2Q_p^2\right)\right]^{\frac{1}{2}} = \omega_0\left[1 - 2\zeta^2\right]^{\frac{1}{2}} \tag{2}$$

For steady-state resonance, the mean power supplied by the driving force balances the energy dissipation rate, and the total stored kinetic energy and spring potential energy, averaged over many

N

Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 3 Single degree of freedom model for resonator

cycles, does not change with time. With displacement amplitude x_0, the cycle-averaged value for the displacement-squared, $\langle x^2 \rangle = (x_0^2/2)$ and velocity-squared $\langle \dot{x}^2 \rangle = (\omega^2 x_0^2/2)$. The mean power dissipated, $<P>$, the average energy dissipated per cycle $< E_{dissip} >$ and the stored energy $< E_{stored} >$ are related [18] by

$$\langle E_{dissip} \rangle = \langle P \rangle (2\pi/\omega) = C < \dot{x}^2 > \left(\frac{2\pi}{\omega}\right) = \pi C \omega x_0^2 \tag{3a}$$

$$\langle E_{stored} \rangle = M(\omega^2 + \omega_0^2) x_0^2/4. \tag{3b}$$

If the average energy stored in the resonator is very large compared to the energy dissipated (= energy supplied, for steady-state) per cycle, one may anticipate lower noise operation when driven, and a slower decay of the oscillation amplitude envelope when the driving force is switched off, allowing for a time-domain measurement of damping. These are measures of the quality of a resonator, expressed by the magnitude of the quality factor, defined [18] as

$$Q = 2\pi \frac{\langle E_{stored} \rangle}{\langle E_{dissip} \rangle} \tag{4}$$

Using Eqs. 3a and 3b, this yields

$$Q = \frac{M(\omega_0^2 + \omega^2)}{2C\omega} = \frac{K + M\omega^2}{2C\omega}. \tag{5}$$

For forcing at the damped resonance frequency ω_d, using Eq. 5 with the definition for Q_p, $\omega = \omega_d$, with ω_d given by Eq. 2, the expression for the quality factor reduces to

$$Q = \frac{Q_p^2 - (1/4)}{\sqrt{Q_p^2 - (1/2)}}. \tag{6}$$

Most applications aim for quality factors $Q >> 1$, for which ω_d reduces to ω_0 and Q to Q_p, as seen from Eqs. 2 and 6. It is also easy to show [18] that for high Q-factors, the measured resonance spectrum, expressed as a plot of amplitude-squared against forcing frequency, has a full width at half maximum (FWHM) height, as seen in Fig. 1, equal to damping coefficient divided by mass, C/M, which allows for a simple measurement of damping.

The ringdown method is an alternative to the spectral technique above. It is a time-domain technique for measuring damping. In this method, the forcing for a driven nanoresonator is turned off, and the amplitude of the oscillation begins to decay with time t as $\exp(-t/\tau)$, where the time constant $\tau = C/M = \omega_0/Q_p$ [18]. Q_p can be obtained from τ, the time taken for the measured amplitude envelope to reduce to 1/e of the previous value.

Nanoresonator operation in a fluid environment is typically associated with high damping (C). Some consequences of low Q_p due to high damping may now be examined. Low Q-factor spectra, $Q \sim 1$, have been encountered in measurement attempts in liquids. For low Q-spectra, the spectral width (FWHM) may be hard to obtain and the spectra are noisier – the signal-to-noise ratio, SNR $\sim Q^{1/2}$. Using the best-fit Lorentzian curve solution of Eq. 1 to low-Q experimental spectra is preferable for the evaluation of the

Nanomechanical Resonant Sensors and Fluid Interactions, Table 1 Significant deviations at low Q_p

Q_p	ζ	$(Q - Q_p)/Q_p$	$(\omega_d - \omega_0)/\omega_0$
1,000	0.0005	3.12E-14	−2.50E-07
100	0.0050	3.13E-10	−2.50E-05
10	0.0500	3.14E-06	−2.50E-03
5	0.1000	5.10E-05	−1.01E-02
2	0.2500	2.22E-03	−6.46E-02
1	0.5000	6.07E-02	−2.93E-01

damping. As seen in Table 1, obtained using Eqs. 2 and 6, the deviations of Q from Q_p and ωd from ω_0, become significant and increase rapidly as Q_p approaches a value of 1. As an example, the fractional shift of the resonance peak frequency due to damping, changes from 0.25 ppm (parts per million) at Q_p of 1,000 to 65,000 ppm at Q_p of 2. Sensitive mass detection aims for resolution of frequency shifts of the order of 10 ppm or less, between mass-loaded and unloaded measurement states. For $Q_p \sim 1$, small variations in fluid damping between these states could themselves cause frequency shifts that will exceed the frequency shift from small added mass. The experimental evaluation of the Q-factor (sketch in Fig. 1) shows that the accuracy of any sensing scheme dependent on location of the peak frequency will also degrade significantly for broad peaks (low Q). In liquids and dense gases, there are cases where fluid damping can be high enough to prevent the detection of the resonance peak altogether. Ringdown measurements also become less accurate or impossible, if Q is low enough to reduce the displacement amplitude to zero in a time comparable to one oscillation time period. Finally, when an electrostatic or piezoelectric drive is used for exciting and driving the nanostructure through resonance, the large range of swept frequency required to capture low Q-factor spectra, has the potential to create nonconstant forcing F_0. This arises due to changes in the amplitude of the driving signal, due to significant frequency-dependent changes in the impedance of the driving circuit (parasitics).

Techniques for enhancing the Q-factor Q_p of nanoscale resonators in fluids could include the use of resonance at higher frequency harmonics (higher ω_0), and an increase of effective string-like stiffness (higher K, ω_0), by using tensioned beams [7]. These have demonstrated viable resonance with high quality factor in some fluid measurements, and should prove useful for many applications. However, their reduced sensitivity to fluid damping makes them less suitable as measurement devices for well-resolved and accurate measurement of the value of fluid damping, when that is the object of the study.

To complete this section, the experimental steps used for the evaluation of gas damping force on nanomechanical resonators are reviewed. A few results from mechanics of materials and vibration of continuous beams will be useful to see the interplay of geometry, material characteristics, and measurement artifacts related to nanoresonator fabrication and transduction schemes that are characteristic of nanoresonator measurements.

Consider fluid interactions with the nanoresonator that are linear – that is, they are not functions of products of the displacement x or its time derivatives. The nanoresonator motion may then be represented by the equation governing the displacement x,

$$\left(M_s + M_f\right)\ddot{x} + \left(C_s + C_f\right)\dot{x} + \left(K_s + K_f\right)x = F_0 \cos\left(\omega t\right)\cdot \tag{7}$$

In Eq. 7, subscripts s, f denote structural intrinsic (solid material) and fluid quantities respectively. The fluid force on the beam in phase with the velocity is represented using fluid damping Cf; the force on the beam due to the fluid in phase with the acceleration can be significant in liquids, and is represented by the fluid added mass term M_f; a restoring spring force component is represented by a fluid stiffness term K_f. A measurement at high vacuum, where fluid molecules have no appreciable effect, will involve only the intrinsic quantities. In nanoresonators, Eq. 2, with typical $Q_{p,s} >> 1$, based on intrinsic damping C_s, shows that C_s is not large enough to cause an appreciable shift of the resonance peak frequency from the undamped value.

The undamped resonance frequency for transverse flexural vibrations of a solid beam having l, M_s, K_s, ρ_s, E, and I as the length, mass, stiffness,

density, Young's modulus, and cross-sectional moment of inertia, is [19]

$$\omega_s \approx \omega_0 = \sqrt{K_s/M_s} = \beta_n^2\sqrt{EI/M_s l^3} \tag{8}$$

$$= \beta_n^2\sqrt{(1/12)^*(E/\rho_s)^*}\left(t/l^2\right) \tag{8a}$$

$$= \beta_n^2\sqrt{(1/16)^*(E/\rho_s)^*}\left(d/l^2\right) \tag{8b}$$

where Eq. 8a is for a rectangular beam of width w, and thickness t parallel to the direction of motion and Eq. 8b is for a circular section beam (nanowire) of diameter d.

For rigid clamping, β_0 is 1.88 for cantilever beams and 4.73 for doubly-clamped beams vibrating in the fundamental mode ($n = 0$). The surrogate Q-factor for the beam in vacuum is given by,

$$Q_{p,s} = \sqrt{M_s K_s/C_s} = M_s\omega_0/C_s$$
$$= (1/C_s)^*\sqrt{M_s EI/l^3} \tag{9}$$

$$= (1/C_s)^*\beta_n^2\sqrt{(E\rho_s/12^*}\left(wl^2/l\right) \tag{9a}$$

$$= (1/C_s)^*\beta_n^2\sqrt{(E\rho_s/16^*}\left(\pi d^3/4l\right) \tag{9b}$$

with Eq. 9a for the rectangular beam and (Eq. 9b) for the circular section nanowire. If squeeze-film damping is negligible, the effective stiffness in the fluid remains unchanged from its intrinsic value in vacuum, so that $K_{s+f} = K_s = M_s\,\omega_0{}^2$. Substituting for effective mass and damping, $M_{s+f} = M_s + M_f$ and $C_{s+f} = C_s + C_f$, yields the damped resonance frequency ω_{s+f} and quality factor $Q_{p,s+f}$ for the beam in fluid,

$$\omega_{s+f} = \omega_0\sqrt{\left(1 - 1/(2Q_{p,s+f}^2\right)} \tag{10}$$

$$Q_{p,s+f} = \sqrt{\left(M_{s+f}K_s\right)}/C_{s+f}$$
$$= \mathrm{Q}_{p,s}\left[\frac{\left\{1 + \left(M_f/M_s\right)\right\}^{0.5}}{1 + \left(C_f/C_s\right)}\right] \tag{11}$$

For rarefied gas damping experiments with nanoresonators, the situation is usually simplified with fluid added mass M_f being negligible. A first measurement may be made at high vacuum, with no gas damping ($C_f = 0$), for which the Q-factor value, Q_s, depends only on the structural properties of the solid nanowire, M_s, C_s, and K_s. Following this, the ambient gas pressure in the chamber is increased in steps, and the frequency ω_{s+f} and quality factor Q_{s+f} are measured at each step. In experiments, we assume the surrogate property-related Q-factor (Q_p) relations hold true for the measured Q-factor values. This yields

$$Q_s = \frac{M_s\omega_0}{C_s} \tag{12a}$$

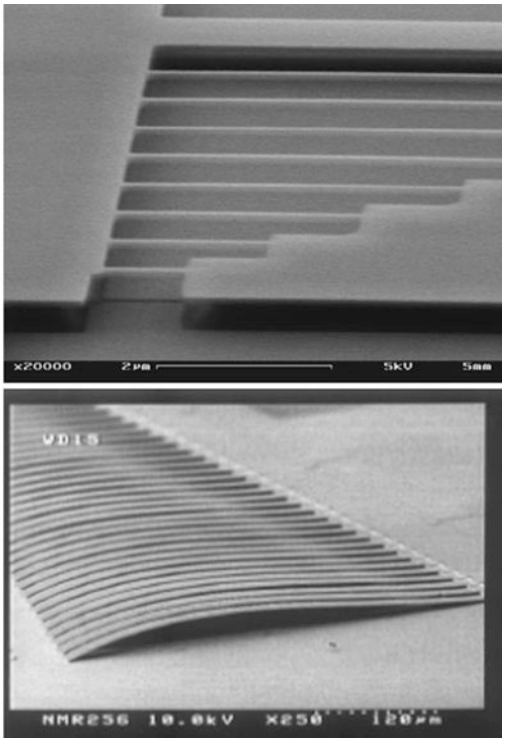
$$Q_{s+f} = \frac{M_s\omega_0}{C_s + C_f} \tag{12b}$$

Using Eq. 12a and mass M_s from known density and geometry of nanoresonator, the value of intrinsic damping C_s may be obtained from measurement at high vacuum. Subsequent measurements of the Q-factor Q_{s+f}, at each value of ambient gas pressure, are related using Eqs. 12a, b to obtain

$$Q_{s+f} = Q_s\left(1 + \frac{C_f}{C_s}\right)^{-1}, \tag{13}$$

from which the gas damping C_f can be calculated. For liquids or dense gases, the added fluid mass M_f is not negligible, and the full Eq. 11 must be considered (see [9]), in place of its subset Eq. 13.

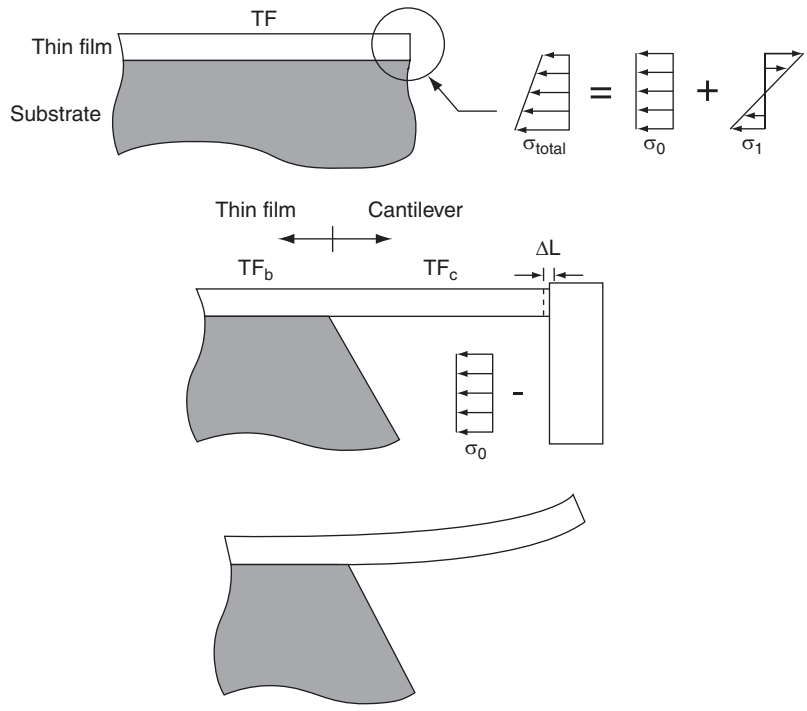
These relations provide a summary for the conduct of experimental work and are useful in a number of ways. For measurements in vacuum, they establish the expected scaling of frequency and Q-factor with parameters that depend on geometry, material, mode shape, and type of clamping. They allow evaluation of the rigidity and repeatability of the clamps (through the value of mode constant β_n in Eq. 9) if the geometric parameters and material properties are accurately known. Most importantly, they allow experimental testing of models for fluid damping C_f and fluid added mass M_f. These relations also show how nanoresonator materials may be chosen to



increase or decrease the Q-factor range for a given range of fluid damping. This is discussed in the following section detailing the coupling of fabrication, materials, and transduction choices.

Fabrication and Materials

Nanomechanical resonators are suspended structures – most often long and prismatic, clamped at one end (cantilevered) or both ends (doubly-clamped). How does the choice of geometry, material, fabrication, and transduction schemes influence the operation of nanomechanical resonant sensors in fluids? Earlier discussion of Fig. 2 showed the strong coupling between these choices and the necessity of using the framework of mechanics of fluids, mechanics of materials, and nonlinear/stochastic dynamics as guides to make sensor design choices. Fabrication choice plays a dominant role and it is worth briefly reviewing two fabrication paradigms – termed top-down and bottom-up fabrication and an example of the synergy that may be obtained by hybrid methods combining features of each.



Top-down Methods

Top-down methods are named for the processes of patterning and etching from larger planar sheets of material (top-level) to obtain smaller desired structures (bottom-level), typically as large arrays. No assembly is required as the structures are built in the desired locations. Typically, a sacrificial layer is sandwiched between the substrate and a film of the intended nanoresonator material (device layer). An etch mask, usually made from a photosensitive chemical that resists etching (photoresist) is used while etching through the device layer, leaving it in the shape of the desired resonator array. A second etch targeted at the sacrificial layer material is then used to remove material beneath the devices and create suspended resonators. Doubly-clamped resonators created by this method are shown in Fig. 4. Optical lithography allows transferring micrometer scale features on to large (upto centimeter-scale) areas of photoresist for patterning thousands of devices

Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 4 (**a**) Doubly-clamped nanoresonator beams of different lengths with the same undercut (Figure reprinted from Ref. [20], with permission). (**b**) Distortion of long thin metal cantilevers attempted using a top-down process (Figure reprinted from Ref. [21], with permission)

using a single exposure through a patterned mask. This well-established technique, long used in microelectronics to make integrated circuits (ICs), is easy to implement, and is almost always preferred at microscale. Minimum feature sizes for ICs, limited by the wavelength of light used, have been extended to submicron scale with deep-UV light sources and phase-shift masks. Nanoresonators, involving smaller features, from tens to hundreds of nanometers, typically have been made by electron-beam (e-beam) lithography. Here, no mask is used, but an electron beam is rastered across a film of e-beam resist to create the pattern for nanoscale structures. Time-consuming coverage of large areas required to make commercial sensor arrays, the cost of procuring and operating e-beam equipment, and the fabrication sensitivity to small perturbations do

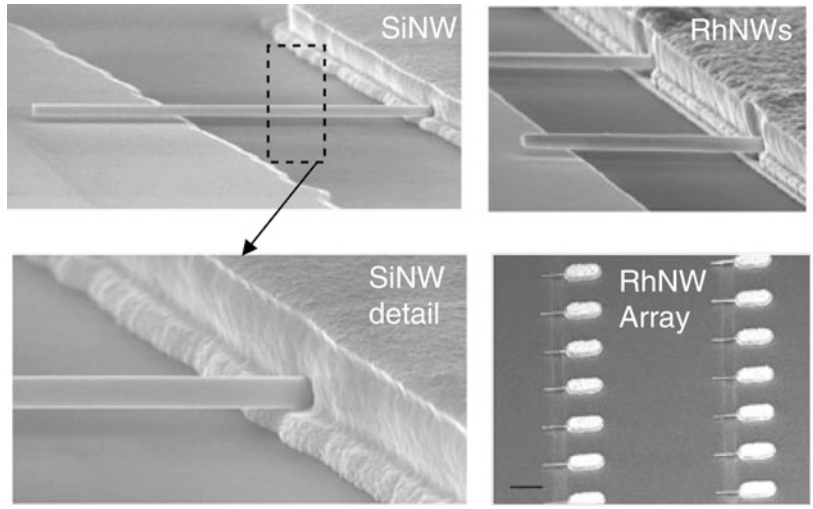
Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 5 Film stress and stress gradients create residual axial stresses in doubly-clamped beams and distort cantilevered beams, during their release from the substrate, by etching (Figure reprinted from Ref. [22], with permission)

not allow inexpensive production of large-area sensor arrays by e-beam lithography. An alternative pattern transfer technique of imprinting, molding, and stamping known as microcontact printing, or soft lithography, is similar to the use of an inked rubber stamp. This technique, somewhat surprisingly, has been used to demonstrate the ability to transfer pattern features below 100 nm in size. The master pattern in this case may be made by e-beam lithography and transferred to one or more soft "stamp pads," thus reducing the requirements for e-beam lithography, with the promise of lowered costs. Mature techniques, relatively well-controlled shape, size and position, the ability to make devices with well-ordered internal structure through the use of single-crystal layers, are important strengths of top-down fabrication [20].

There are limitations of top-down fabrication for nanoresonator sensor arrays. Besides the cost of large-area coverage, the limited choice of local material selection (e.g., difficult to have resonator material different from clamp material) can restrict functionality. Geometries such as smooth rods or hollow tubes, with a high cross-sectional moment of inertia allowing for a higher stiffness per unit mass, are prohibitively difficult to produce in large numbers by top-down techniques. Undercuts, or significant underetching of supports during the removal of the sacrificial layer [20] are seen as a lighter-gray region around the periphery of the harp-like structure of Fig. 4a. Undercuts depend on the sacrificial layer etch time and are of the same depth for all structures released on a chip. They can cause significant increase in the compliance, particularly for short, stiff, nanoresonators seen in Fig. 4a. Energy losses and cross talk between devices through undercuts can cause significant changes in frequencies and Q-factors. During release by etching of the sacrificial layer, shape distortion (see Fig. 4b) in the case of cantilevered structures [21] or residual axial stress in doubly-clamped nanoresonators (see Fig. 5) typically arises due to stress gradients in the device layer [22]. For long thin metal film structures, these effects are particularly difficult to control. Higher residual axial stress adds an increasing string-like component to the restoring force (normally flexural), changing the simple frequency scaling presented in Eq. 9 and makes the nanoresonator

more prone to geometric stiffness nonlinearities. High axial stress and string stiffness can, however, be used to increase the effective stiffness K and the peak frequency, to enable a higher Q-factor value for given damping, provided a sufficient linear range exists. Distorted cantilevers also cannot be described by Eq. 9 – furthermore, it may be difficult or impossible to drive and detect resonance in such structures. Film stress gradient effects can be controlled in device materials such as single-crystal silicon, silicon nitride or carbide, using silicon oxide as a sacrificial layer. These materials are frequently used for laboratory experiments. However, stress gradient effects (Fig. 5) are very pronounced for metal films. It is therefore difficult for top-down methods to yield long, thin metal cantilevers which are free of distortion – a "convex-up" example [21] of such distortion for titanium cantilevers is seen in Fig. 4b. Though long thin cantilevered resonators made of metals may have desirable surface functionalization attributes, they are difficult to achieve using top-down methods. Finally, for multiplexing, or the sensing of multiple analytes on the same chip, functionalization of different devices to capture different targets is tedious, and one may anticipate the value of nanostructures that can be made and functionalized off-chip, then directed to predetermined areas of a chip and integrated to form nanoresonators.

While top-down methods remain the primary choice for most microcantilever fabrication, in spite of their obvious strengths, many of the shortcomings of established top-down techniques discussed above have led to an interest in alternatives that bottom-up fabrication could provide. This is particularly true for nanoscale resonators, when long thin cantilevers made of metals are required for their attachment chemistries, or when undercut reduction or multiplexed sensor arrays are important.

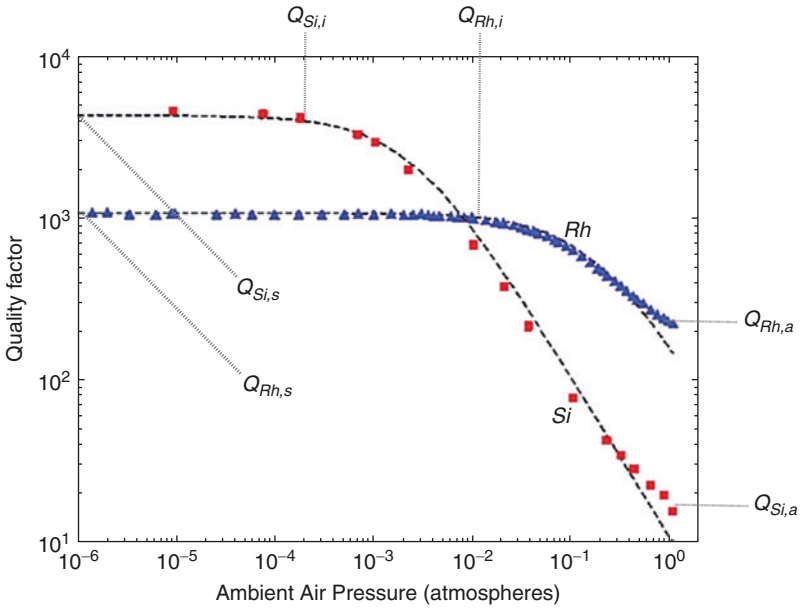


Bottom-Up Methods

Bottom-up methods are identified by their use of assembly of smaller units into larger structures, for example, single nanoresonator elements assembled and integrated into arrays for sensing. While the possibilities for improved control of individual element geometry and clamping are attractive, making arrays of a few tens of thousands of elements by an individual pick and place technique is unfeasible. Bottom-up methods are thus defined by the use of physical or chemical forces for self-assembly or directed assembly of nanostructures. A recent review of the directed assembly of nanowires [23] discusses assembly by molecular forces, electrostatic interactions, shear forces, magnetic fields, and dielectrophoresis. A significant advantage over top-down methods is that special vapor or solution phase synthetic chemistry can be used to tailor the shape, composition, and crystallinity of nanoscale elements, before their assembly and integration on a sensor chip. This greatly widens the scope of material properties (e.g., nanowires made of magnetic, piezoelectric, semiconductor, or multiple-metal segments) and available geometries (e.g., cylindrical or hexagonal section rods, hollow tubes, single and multi-walled carbon nanotubes) that can be put to use. The elements may also be functionalized off-chip to capture different sensing targets on the same chip (multiplexing), with each target-type assembled in a predetermined area on the chip. This requires the development of assembly and integration techniques that do not destroy the capability of molecules used for functionalization.

N

Results Using a Hybrid Fabrication Strategy for Nanoresonator Arrays



Hybrid strategies combine the ease of patterning simple planar structures, borrowed from top-down methods, with the flexibility of tailoring individual nanostructures provided by bottom-up methods, while partially overcoming the difficulties of each method. As an example of this synergy, consider the hybrid bottom-up method reported for nanoresonator array assembly and integration, and designed to accommodate a multiplexed biosensor chip [16]. In this study, both metallic rhodium and semiconducting silicon were synthesized off-chip. Polycrystalline rhodium nanowires were grown by electrodeposition in nanoporous aluminum oxide membranes, while predominately single-crystal silicon nanowires were grown by the Au-catalyzed vapor–liquid–solid (VLS) technique. Bottom-up directed assembly was used to position single nanowires at lithographically defined locations

Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 6 Silicon and rhodium nanowire resonators made by a hybrid scheme using top-down patterning of electrodes and a bottom-up directed assembly scheme. Scale bar is 10 μm, for picture at *lower right* (Figure reprinted from Ref. [16], with permission)

on a silicon chip for fabricating multiplexed arrays. To do so, patterned arrays of wells in a sacrificial insulating photoresist layer covering metal guiding electrodes were defined on the chip surface. Dielectrophoretic forces were used to align the nanowires within the wells. Thick metal clamps were then built over the guiding electrodes by electrodeposition. The photoresist was dissolved to leave arrays of freestanding single-NW cantilevers as shown in scanning electron micrograph images of Fig. 6. The figures show the electrodeposited metal in intimate contact with the nanowire at each nanowire clamp. The clamps were shown to be of repeatable rigidity, with no undercuts. Besides securing the nanowire to the chip, the choice of gold for the clamp material, irrespective of the nanowire material, enables a good electrical connection between the chip and conductive nanowire, which can be used for electrical drive and detection of single nanowires in the array. Figure 6 shows that the distortion found in metal cantilevered nanowires from thin film stress evolution in the top-down process is absent. The photoresist used as a sacrificial layer was removed without the need for etchants that could damage the surface functionalization for biosensing. The example hybrid method above eliminates expensive e-beam lithography (reduces cost), shows the viability of long cantilevered metal nanoresonators. It uses lithographic patterning to enable directed assembly and nanoresonator clamping, allows choice of different materials for clamps and nanoresonators, and shows the potential to use different nanoresonator cross-section shapes, materials, and sensor functionalization chemistries for multiplexing on a single chip.

As seen above, the choice of fabrication technique plays a strong role in determining the nanoresonator properties available for sensing. In particular, flexible methods such as the hybrid technique described above, allow a wider choice of nanoresonator materials and cross sections. The density, Young's modulus and intrinsic damping within the nanowire material (C_s) can serve to provide some measure of tuning of the Q-factor for a given fluid damping, depending on the application desired. Figure 7 provides an example of this. It shows the Q-factor change from moderate vacuum to atmospheric pressure for a rhodium and a silicon nanowire of roughly comparable dimensions and fluid damping C_f. Although fine-grained, polycrystalline Rh should be expected to have a much higher intrinsic damping Cs compared to the single-crystal silicon nanowire, its higher elastic modulus and density compared to silicon compensate (Eq. 9), giving it a vacuum Q-value ($Q_{Rh,s}$) as high as a fourth of that of the silicon nanoresonator ($Q_{Si,s}$). The experimental data [16] of Fig. 7 further agrees with a prediction that may be made from Eq. 13 – the Q-factor for the silicon nanowire, with smaller intrinsic

Nanomechanical Resonant Sensors and Fluid Interactions, Fig. 7 Measured quality factor variation with ambient gas pressure for silicon and rhodium nanowires of comparable size (Figure reprinted from Ref. [16], with permission)

damping C_s, should begin to deviate from its vacuum value at a lower pressure value (point $Q_{Si,i}$ vs. $Q_{Rh,i}$) and show a sharper fall-off with pressure, than the rhodium nanowire. The Q-factor of the rhodium nanowire at atmospheric pressure ($Q_{Rh,a}$) is seen to be higher than that of the silicon nanowire ($Q_{Si,a}$). Gas damping of the nanoresonator motion increases as ambient gas pressure is raised from high vacuum to atmospheric pressure. Equation 13 shows that the high intrinsic damping in the rhodium nanowire serves as a buffer to delay the onset of Q-factor reduction and to limit its rate of change. This makes it more suitable for applications such as small mass sensing where reduction in Q-factor would adversely affect performance. However, the value of the Q-factor for the silicon nanowire begins to decrease at a lower pressure and then shows a larger change in measured Q-factor over the same pressure range, compared to the rhodium nanowire. As an instrument for measuring gas damping force, the silicon wire begins to show response at lower pressure and has a greater dynamic range than the rhodium nanowire. Silicon nanowires would thus serve as better instruments for studying gas damping as a function of pressure than rhodium nanowires.

In this section, the link between fabrication technique and nanoresonator material choice has been reviewed. Well-established top-down methods remain a strong choice for most batch-fabricated resonant sensors at microscale. For nanoresonators with dimensions far smaller than the wavelength of UV light sources, the costs of patterning nanostructures by rastering an electron beam, increase with chip area. Bottom-up methods, which rely on assembly of nanostructures made off-chip, begin to look more favorable for such structures. A larger variety of materials and shapes may be synthesized and assembled by these techniques, but precise location and individual addressing of assembled structures can be a challenge. An example of a hybrid fabrication scheme that borrows simple top-down photolithography steps for patterning relatively large microscale structures to enable spatially directed assembly and clamping to create nanoresonator arrays was reviewed. Nanoresonators of two different materials –polycrystalline rhodium and single-crystal silicon, illustrated how this method may be used to match material with different performance requirements for two different nanoresonator applications. The data show rhodium to be a more favorable nanoresonator material for a sensitive mass detector operating in air at near atmospheric pressure. The material properties of

silicon make it a better choice for a nanoresonant sensor of gas damping force over a large range of pressure, spanning the transition and free molecular flow regimes of rarefied gas dynamics.

Summary and Related Reviews

This section provides a summary of the choice of topics presented in this entry and points to kindred reviews of complementary material, which could not be accommodated here. Nanoscale resonant sensors were chosen due to their potential for creating new instrument systems of unprecedented sensitivity – the promise of their application to biosensing has been included in a recent comprehensive review of mechanical biosensors [24]. Table 1 of Ref. [24] indicates detection limits of 300 fM (femto-molar) and 1.5 fM concentration have been achieved with mechanical microcantilever resonators with and without mass-amplifying labels, respectively, compared to ~1,000 fM for the nonmechanical standard test ELISA (enzyme-linked immunosorbent assay). Biomolecular target capture kinetics, target depletion upon capture from small analyte volumes, target sequestration of low-abundance molecules by abundant nontarget molecules are a few other areas where a research effort is focused on extending the current boundaries of knowledge for molecular diagnosis with resonant cantilevers. Related work may be found in the entries on "Cantilever Biosensors" and "Nanowire Biosensors" in this Encyclopedia.

Work in nanoresonators constitutes a large field and the focus in this entry has been restricted to nanoresonators interacting with fluids – either gases or liquids. The goal has been to establish notions and the simplest useful quantitative framework to interrogate fluid interaction with nanoresonators. Damping in fluid environments can be strong and lead to low Q-factor operation, associated with a divergence in values calculated from different definitions of the Q-factor. Low Q-factor operation demands large frequency sweeps, which can bring about nonconstant forcing due to frequency-dependent circuit parasitics. Figure 2 provides an example summary of the coupled interdisciplinary work required to deal with the interdependencies between material properties desired for an application, fabrication schemes available, and transduction artifacts. Such work both requires and can extend knowledge in mechanics of materials, and fluid mechanics of continuum and rarefied gas flows at small scales [9, 14]. Details of transduction artifacts in nanoresonator measurements are worthy of a separate review and have not been included here. Ekinci [25] provides a useful review of nanoresonator transduction schemes. While the field of micro/nanofluidics, dealing with small-scale internal flows has acquired some maturity, small-scale external flows at high frequencies realized with nanoresonators hold promise of both technological application and an improved understanding of fluid mechanics.

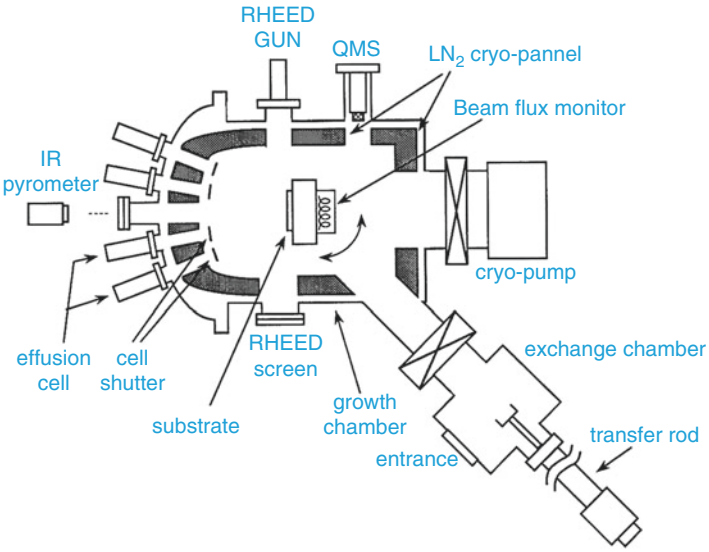
Definition

Mechanical resonators synthesized from III-V semiconductors are micro- to nanoscale mechanically compliable devices with a single degree of freedom, usually in the form of beams and cantilevers, whose mechanical motion is excited and detected via the electronic and optical properties inherent to the underlying compound semiconductor.

Overview

In early reports, nanomechanical resonators were invariably synthesized from silicon which was metalized to form electrical leads that enabled mechanical motion to be excited via electrostatic or magnetomotive techniques and detected by capacitive or electromotive force methods, respectively [1]. The role played by silicon was to form the mechanical resonator and to sustain the electrical circuitry, enabling the motion



transduction. The only relevant intrinsic material requirement related to the purity and crystallinity of the silicon which enabled the realization of high-quality mechanical resonators. The quest for mechanical performance initially lead to the substitution of silicon with tensile-strained silicon nitride which resulted in quality factors of millions at room temperature [2]. The ultimate evolution of this approach led to the abandonment of silicon all together, and instead the mechanical resonator was formed from an amorphous metal which could readily be coupled to the electrical transduction circuit and simultaneously be tensile strained via thermal annealing for unprecedented mechanical performance [3].

Although the approaches outlined above have been incredibly successful, they have utilized silicon purely for its mechanical performance, and the electrical and optical properties inherent to it have played little or no role in either transducing the mechanical motion or controlling its vibration dynamics (note the optical properties referred to here relate to the underlying semiconductor band structure rather than radiation pressure, gradient optical and photothermal forces, all of which have been demonstrated with silicon-based optomechanical resonators). This state of affairs has primarily arisen from the fact that silicon is an indirect bandgap semiconductor and consequently it has limited optical functionality. The low mobility of its carries arising from the large electron/hole effective masses has also resulted in the intrinsic electronic properties of silicon, proving challenging to exploit, for instance, the piezoresistance arising from sub-Angstrom level mechanical vibrations at high frequency is almost undetectable. In contrast, direct bandgap III–V semiconductors with highly mobile carriers are capable of hosting optical and electronic phenomenon which can be modulated by mechanical fields and be readily measured, thus bringing a range of functions unavailable to silicon mechanics to the fore.

As an illustrative example, the optical emission wavelength in III–V compound semiconductors can be tuned via strain which shifts the conduction and valence band edges, thus modifying the bandgap energy. Consequently, the strain field arising in a III–V semiconductor-based mechanical resonator naturally leads to the optical emission being modulated on resonance, thus enabling the realization of a unique motion transducer that is unavailable to silicon mechanics [4]. The electronic properties in III–V semiconductors can also be far superior to those in silicon, for example, their electron mobility can be orders of magnitude greater, particularly in a two-dimensional electron gas (2DEG), thus making III–V semiconductors highly amenable to transducing the high-frequency mechanical vibrations in nanoscale mechanical resonators [5, 6]. On the other hand, the compound nature of III–V semiconductors lends itself to hosting piezoelectric fields, thus enabling transducers to be engineered directly into the mechanically compliable element which not only permits highly efficient displacement transduction but also renders the mechanical properties to be controlled, for example, the resonance frequency [7, 8].

In spite of the potential offered by III–V semiconductor-based mechanics, silicon mechanics (including SiC and SiN) have been ubiquitously embraced primarily due to the widespread availability of silicon stemming from the microelectronics industry. However, as research avenues with silicon have become exhausted, compound III–V semiconductors have emerged as natural arena in which optoelectromechanics exploiting their intrinsic material properties can be developed offering physics, functions, and applications beyond silicon mechanics.

To that end, this entry is organized as follows: The first section details crystal growth where electronic and optical properties of choice can be selectively incorporated into the semiconductor. The second section examines the optomechanical properties of III–V resonators by exploiting their direct bandgaps without requiring cavities to mediate this coupling. The third section describes the transport properties of III–V semiconductors which can both be modulated by the mechanics, and their subsequent back action can even control the mechanical vibration characteristics. The fourth section deals with the piezoelectric properties of III–V semiconductors which can be exploited to dynamically engineer the mechanical

Nanomechanical Resonators Based on III–V Semiconductors, Fig. 1 A simplified schematic of an MBE system showing all the major components needed to synthesize high-quality III–V semiconductor crystals

resonator's harmonic potential. Finally, the last entry will briefly discuss future trends and prospects of III–V compound semiconductor-based mechanical resonators.

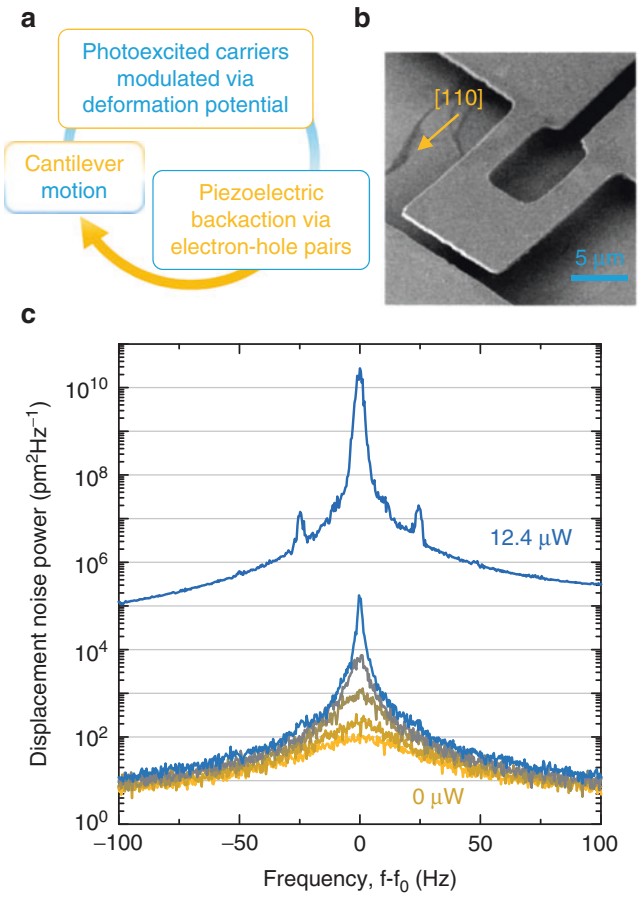
MBE Crystal Growth

III–V compound semiconductors have a key advantage for application to mechanical devices due to their high-quality and function-enabled single crystal heterostructures being readily available via state-of-the-art growth techniques, for example, molecular-beam epitaxy (MBE) and metalorganic vapor phase epitaxy (MOVPE). These crystal growth techniques were originally pioneered to synthesize perfect materials that could be applied to developing high-speed electronics and high-performance optoelectronic devices which required defect-free interfaces at their heterojunctions. These growth techniques enabled crystals to be grown layer by layer with different chemical compositions to form artificial heterostructures with atomically flat interfaces while preserving their crystallinity. One of the most successful material systems developed by these growth techniques are the GaAs/AlGaAs heterostructures which exhibit a lattice mismatch of less than 0.3 % resulting in dislocation-free crystals. Other material systems developed using the techniques pioneered for GaAs/AlGaAs include InGaAs/InAlAs/InP, GaN/InGaN/AlGaN, and InAs/GaSb/AlGsSb which are employed to access different parts of the electromagnetic spectrum in optoelectronic devices. For the purpose of this chapter, the MBE growth technique will be briefly reviewed as MBE-grown GaAs/AlGaAs crystals are used to develop nanomechanical resonators described below.

Fundamentally MBE is an advanced evaporation technique in which precisely controlled substrate and source temperatures in an ultrahigh vacuum environment enable extremely stable deposition which permits high-quality single crystal films to be grown. Figure 1 shows a two-chamber configuration which is the minimum requirement of a practical MBE system.

The larger chamber is used for crystal growth in which a stable standby vacuum pressure typically on the order of 10^{-10} Torr is maintained. The smaller chamber is for loading or unloading the substrate or sample from and to the atmospheric environment, respectively, and it is operated at pressures below 10^{-7} Torr after evacuation. In order to maintain the ultrahigh vacuum in the growth chamber, it is baked for several days to desorb all atmospheric contamination and is subsequently not directly exposed to the local atmospheric environment via the smaller load-lock chamber. The source materials for crystal growth

are stored in effusion cells from where they are evaporated. The evaporation rate can be controlled by the cell temperature and its duration by the shutter located in front of the effusion cell. The evaporated molecular beams are directed toward the substrate where a seed crystal with a defined crystal orientation is located which gestates synthesis of a crystalline film. Crucially the substrate temperature is precisely controlled during this process which facilitates equilibrium growth conditions yielding almost perfect crystals. To that end, MBE systems are usually equipped with in situ characterization systems, typically reflection high-energy electron diffraction (RHEED), which can monitor the growth rate and surface quality during the growth process.



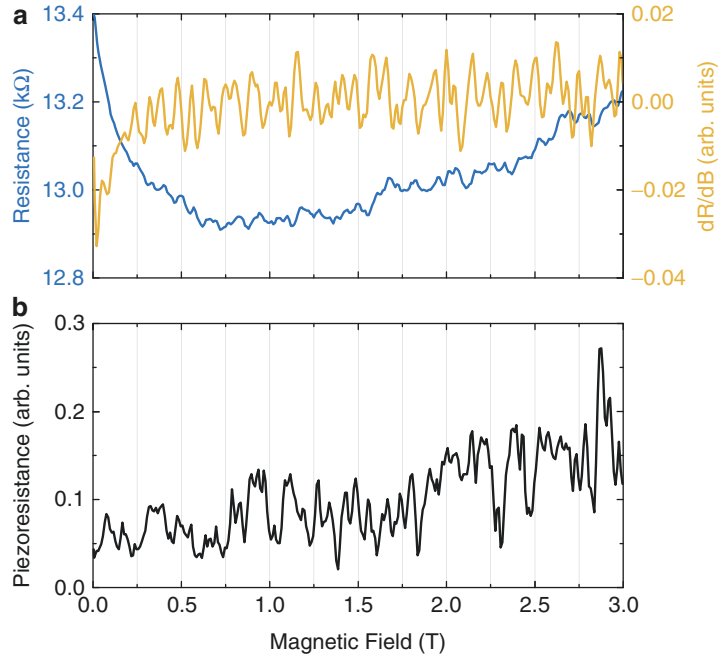
A major success of MBE is the growth of high-mobility modulation-doped heterostructures in which the carrier transport layer is isolated from the doping layer leading to the scattering of carriers by ionized donors being strongly suppressed. Indeed low-temperature electron mobilities of more than 10^6 $cmV^{-1}s^{-1}$ are now routinely accessed in such heterostructures. The use of such perfectly crystalline layers in the fabrication of mechanical devices not only yields high-quality factor resonators, but it also makes it possible to study the coupling between low-dimensional electronic systems and mechanical degrees of freedoms. Moreover, in optically active heterostructures in which high luminescence efficiencies are available allows for new flavors of optomechanical coupling to be explored, and ultimately these systems will pave the way toward a new class of optoelectromechanical platform.

Optomechanics with Direct Bandgap III–V Semiconductors

Invariably almost all optomechanical systems utilize a cavity to mediate the interaction between optics and mechanics, where the cavity's wavelength is modulated by the motion of the mechanical element, leading to parametric coupling which enables the mechanical oscillation dynamics to be optically controlled and engineered [9]. Remarkably a III–V semiconductor-based optomechanical system integrated with a laser actuator and a Fabry–Perot cavity-based displacement detector, where the cantilever formed one end of the cavity, was pioneered as long ago as 1993 [10].

On the other hand, the availability of direct bandgaps in III–V semiconductors, for example, in the GaAs/AlGaAs system, offers a different route to optomechanical coupling where crucially the optical cavity can be eliminated. Specifically, this can be realized via carriers excited at wavelengths selectively determined by the semiconductor bandgap which plays a similar role as an optical cavity. Particularly, the two major strain-stimulated phenomena in III–V semiconductors, namely, piezoelectricity and the deformation potential, can mediate this cavity-free optomechanical coupling. The former arises between the optically excited electron–hole pairs which generate stress in the resonator and leading to a bending moment which develops into a mechanical resonance. The latter induces a strain-dependent bandgap energy which results in the mechanical motion modulating the optical absorption wavelength. These processes in sequence lead to the establishment of a feedback loop (see Fig. 2a) which enables the mechanical resonance characteristics to be dynamically engineered via carrier-mediated optomechanical coupling.

The mechanical cantilever shown in Fig. 2b was the test bed system in which this cavity-free optomechanical coupling was explored, and it consists of a bilayer structure composed of Si-doped GaAs (100 nm) above undoped GaAs (200 nm) [11]. Excitation of this system with a TiSa laser, focused on one of the cantilever's clamping points, i.e., the position of maximal strain, with a wavelength around the GaAs bandgap (~840 nm at 50 K), resulted in the cantilever's thermal motion being amplified to the point where it self-oscillated above a threshold laser power of 10 μW as shown in Fig. 2c. In this configuration, the cantilever's motion modulates absorption of the laser light via the bandgap through the deformation potential which in turn transmits this modulation to the generated carriers

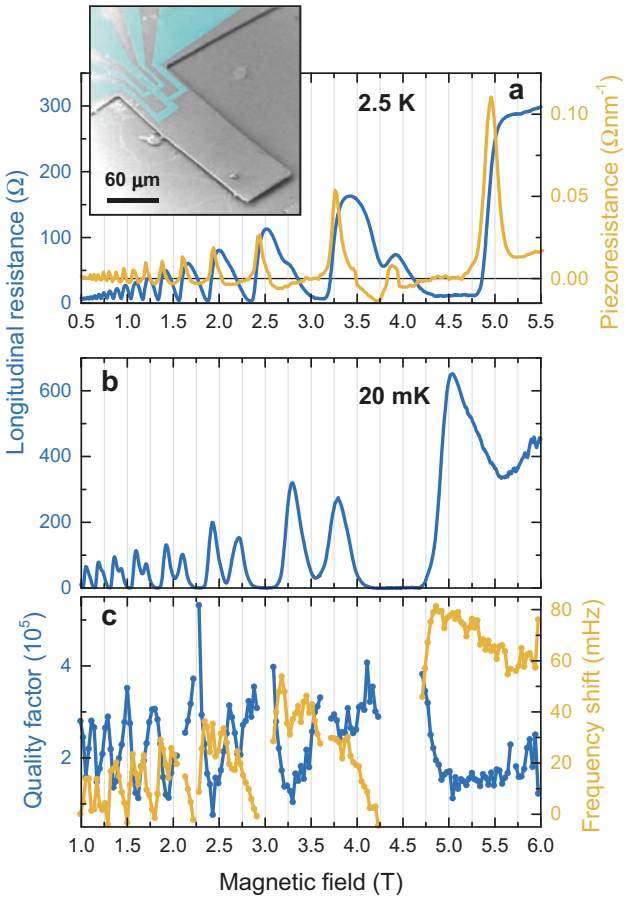


Nanomechanical Resonators Based on III–V Semiconductors, Fig. 2 (**a**) A schematic of the feedback loop at the heart of the carrier-mediated optomechanical coupling established by the deformation potential and the piezoelectric effect. (**b**) A scanning electron micrograph of the cantilever used to explore the cavity-free optomechanical coupling. (**c**) The noise power spectra from the cantilever's thermal motion acquired at 50 K in high vacuum via optical interferometry. As the laser's power, at 840 nm, is increased from 0 to 12.4 μW, the cantilever's motion is amplified to the point where it begins to self-oscillate, resulting in a dramatic increase in the corresponding displacement noise power (Figure 2c is adapted with permission from Okamoto et al. [11]. Copyrighted by the American Physical Society)

that underpin the resultant piezoelectric back action force, and it leads to a positive feedback loop that can amplify the mechanical motion. On the other hand, a negative feedback loop can also be activated with the inversion of the piezoelectric back action force's polarity by simply selecting a perpendicular crystal orientation for the cantilever, i.e., [$\bar{1}$10]. Indeed this polarity selection via the crystal orientation clearly demonstrates the central role played by the photoexcited carriers in this optomechanical coupling. Ultimately if the piezoelectric back action force can be made sufficiently strong in this configuration, it could even lead to mode cooling [11, 12].

Most tantalizingly this carrier-mediated optomechanical coupling opens up new directions for the use of III–V semiconductor-based optomechanical resonators, for example, it provides a unique probe for studying the optical and electrical properties of semiconductors such as carrier dynamics and strain effects [13].

Electromechanics with Quantum Transport



Nanomechanical resonators fabricated from III–V semiconductors can uniquely be integrated with low-dimensional electron systems which can sustain a range of quantum transport phenomena, for example, the quantum Hall effect. Since the resonance characteristics of the mechanics are fundamentally determined by their intrinsic system parameters, for example, the mass, any change in these critical parameters can be readily detected by the corresponding change in the resonance. Consequently, the dynamics of the integrated electron system can also be probed via the

Nanomechanical Resonators Based on III–V Semiconductors, Fig. 3 (**a**) The resistance across a cantilever, of a similar design to that shown in Fig. 2b, measured as a function of magnetic field at 2.5 K and the corresponding derivative. (**b**) The piezoresistance measured across the cantilever on resonance, with a frequency of 283.16 kHz and a quality factor of approximately 12,000, exhibits fluctuations that are reminiscent to *dR/dB* which indicates their similar origin, namely, from electron interference in the quasi-one-dimensional channels (Adapted with permission from Yamaguchi et al. [14]. Copyrighted by the American Physical Society)

mechanical resonator, and uniquely in equilibrium, which can enable the intrinsic properties of the electron system to be determined in contrast to transport measurements. Moreover, this platform can also be used to impart strain fields, akin to electric and magnetic fields, to the low-dimensional structures integrated into the mechanics in order to study their effect on and control of the underlying electron system.

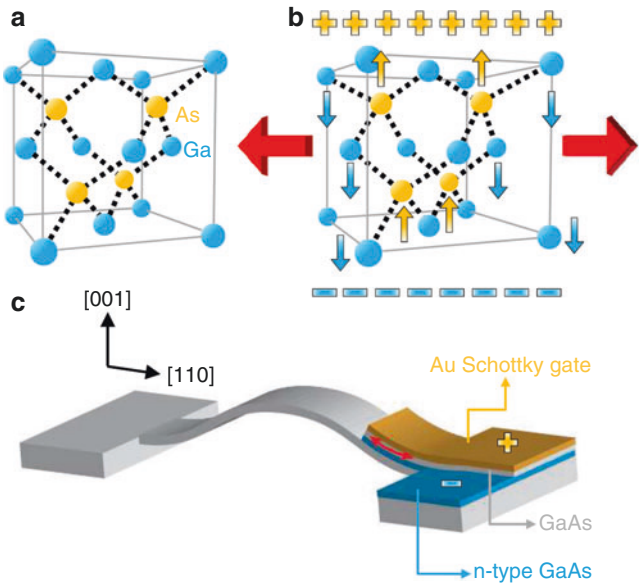
As an example of this approach, the coupling between mechanics and a quasi-one-dimensional electron system in a cantilever of similar design to the one shown in Fig. 2a is reviewed. In this case, the cantilever consisted of a bilayer composed of InAs (15 nm) above AlGaSb (285 nm) where the legs of the cantilever of 4 μm width sustained the quasi-one-dimensional channels in the InAs layer which confined the electrons two dimensionally in-plane [14]. Transport measurements across the cantilever, where the two legs acted as the source and drain, enabled the resistance (R) to be extracted as a function of magnetic field (B) in a high vacuum at 2.5 K. This measurement, shown in Fig. 3a, exhibits the well-known universal conductance fluctuations, which can more clearly be seen in the derivative *dR/dB*, and they arise from interference between the different electron trajectories confined in the quasi-one-dimensional channels. On the other hand, when the piezoresistance is measured with the cantilever excited on resonance, it also exhibits aperiodic oscillations, similar to *dR/dB*, as shown in Fig. 2b. These observations can be understood as follows: in the case of the former, the electron interference is driven by the magnetic field which modifies the phase of the different electron trajectories, resulting in the aperiodic conductance fluctuations. In the case of the latter, the mechanical motion of the cantilever directly modifies the wavelength of the electron trajectories in addition

Nanomechanical Resonators Based on III–V Semiconductors, Fig. 4 (**a**) The longitudinal resistance and the on-resonance piezoresistance as a function of magnetic field measured at 2.5 K in a 2DEG confined to a Hall bar that is integrated onto the cantilever, with a resonance frequency of 20.19 kHz and a quality factor of 108,000, which is shown in the scanning electron micrograph in the inset where the Hall bar is artificially colored. (**b**) The longitudinal resistance as a function of magnetic field measured in the same device at 20 mK. (**c**) The cantilever's resonance exhibits changes in quality factor and shifts in frequency, both of which correlate with the quantum Hall effect in the 2DEG integrated into the cantilever (Figures 4b and 4c have been reproduced with permission from Yamaguchi et al. [17]. Copyright 2012, AIP Publishing LLC)

to the magnetic field modifying their phase, resulting in interference that manifests itself in the aperiodic oscillations in the piezoresistance. Consequently, the mechanical motion in principle can be detected with high sensitivity by exploiting this electron interference where it is maximized from the constructive interference [15].

Another example of this approach is the integration of a high-mobility 2DEG, in the form of a Hall bar, into the clamping point of the cantilever shown in Fig. 4a which consists of the layer structure detailed in Fig. 6. The integrated 2DEG exhibits an extremely high mobility of 10^6 $cm^2V^{-1}s^{-1}$ at liquid helium temperatures which enables the quantum Hall effect to be accessed, as evidenced when the 2DEG's resistance is measured with the application of a magnetic field, and it reveals zero resistance minima corresponding to the localization of electrons as shown in Fig. 4a. Surprisingly, when the piezoresistance in the 2DEG is measured with the cantilever on resonance, it correlates with quantum Hall effect as shown in Fig. 4a. Indeed the piezoresistance exhibits a dramatic enhancement at magnetic fields corresponding to the transition

between localized and extended states, i.e., where *dR/dB* is maximized at which point it yields a piezoresistance gauge factor that is more than two orders of magnitude greater than silicon [16]. This enhancement arises from motional-induced strain at the position of the 2DEG which modulates the position of the Fermi level with respect to the conduction band minimum. The resultant change in the carrier density shifts the piezoresistance response with respect to the magnetic field. Consequently, if the magnetic field is critically biased between the localized and extended states, the motional strain can drive transitions between the zero and high resistance states, resulting in the piezoresistance being dramatically enhanced.



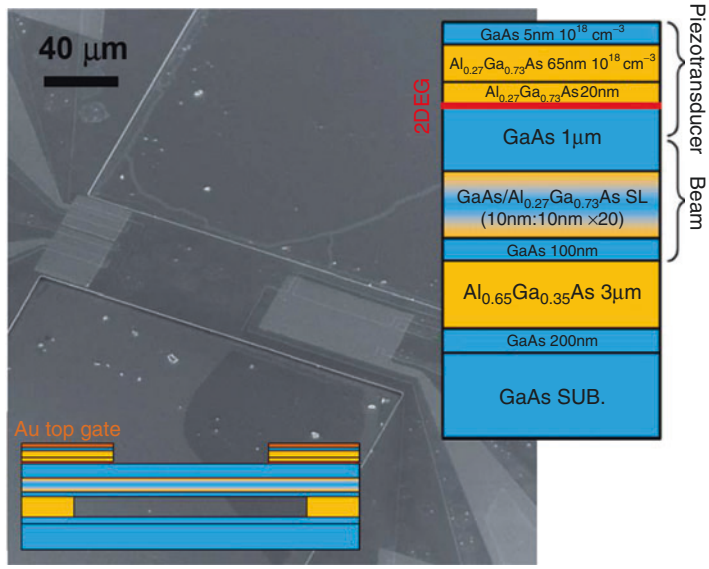
As the cantilever's motion can modify the electronic states of the 2DEG, analogously the 2DEG can also exert a back action onto the mechanics. Indeed if the cantilever's resonance frequency is monitored as a function of the magnetic field, it exhibits shifts which correlate with the magnetoresistance in the 2DEG as shown in Fig. 4b, c. The amplitude of the sawtooth-like frequency shifts at the edge of the localized/extended states in the 2DEG increases in proportion to the applied magnetic field. This behavior originates from the torque generated on the cantilever from the magnetic moment in the 2DEG which tries to align itself with the external magnetic field and is known as the de Haas-van Alphen effect [17]. Since the magnetic moment in the 2DEG oscillates between the extended and localized electron states, it results in the torque and hence the cantilever's resonance exhibiting frequency shifts with the same oscillatory period.

However, more surprisingly, this measurement also reveals that the cantilever's quality factor also correlates with the electron localization/delocalization observed in the magnetoresistance as shown in Fig. 4c. This effect arises from the strain-induced modulation of the Fermi level, resulting in current flow that undergoes ohmic losses, and the resultant energy dissipation manifests itself as a reduction in the cantilever's quality factor at magnetic fields corresponding to the extended electron states in the 2DEG. On the other hand, at magnetic fields where the localized electron states emerge, strain-induced current flow stimulated by the cantilever's motion is unavailable, and consequently ohmic losses and the corresponding energy dissipation are suppressed, resulting in an enhancement in the quality factor [17]. Consequently, the energy loss measured by the cantilever offers a unique probe to study the equilibrium electron dynamics in the 2DEG.

The above results vividly illustrate that III–V semiconductor-based low-dimensional electron systems can be readily incorporated into mechanical resonators which can be used to not only transduce the mechanical motion, but the mechanics can also provide a unique probe to study the electron dynamics of these systems.

Piezoelectric Mechanical Resonators

III–V semiconductors offer enormous potential for developing highly integrated electromechanical resonators due to the availability of the piezoelectric effect. The word piezoelectricity originates from the Greek word *piezien* which means to press and was discovered by the Curie brothers in 1880 who showed that certain crystals develop opposite charges on their surface with the application of pressure. Nowadays, the piezoelectric effect can be defined as the electric polarization produced with the application of mechanical strain in certain classes of crystal and can be expressed as $P_i = e_{ijk}S_{jk}$ where P is the polarization, S is the strain tensor, e is the piezoelectric coefficient, and i, j, and k are the Cartesian indices. This effect is reversible, namely, an electric field can also strain the crystal and the strength of the electromechanical coupling is determined by the piezoelectric coefficient which varies from crystal to crystal. At the microscopic level, this effect arises from a crystal lacking inversion symmetry along a particular crystal orientation, for example, in GaAs, the prototypical III–V semiconductor possesses a zinc blende crystal structure with a center of inversion along the [110] crystal orientation as shown in Fig. 5a. Application of an electric field along the [001] crystal orientation as shown in Fig. 5b results in the cation and anion sublattices from the gallium and arsenic atoms, respectively, being displaced due to their different electronegativity and thus being



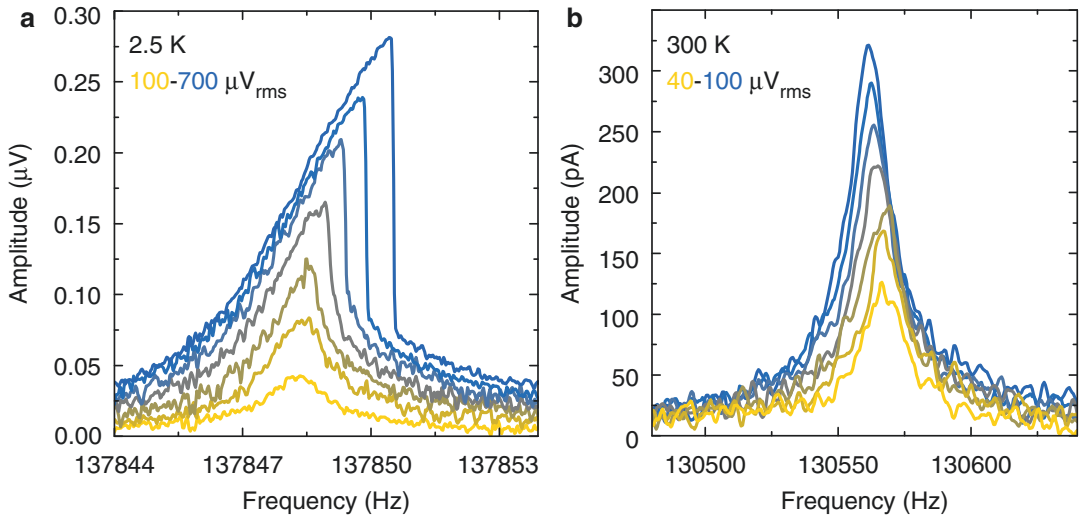
Nanomechanical Resonators Based on III–V Semiconductors, Fig. 5 (**a**) A schematic of the zinc blende arrangement of atoms in a GaAs unit cell. (**b**) Application of an electric field along the [001] crystal orientation causes the gallium and arsenic atoms to be displaced and polarized, resulting in strain being generated along the [110] crystal orientation via the piezoelectric effect. (**c**) Sandwiching GaAs between an n-doped GaAs layer and Au electrode enables a piezotransducer to be formed over a clamping point on the mechanical resonator which can activate mechanical vibrations via the piezoelectrically generated strain (*red arrow*). This transducer can also detect the mechanical vibration via the motional strain which induces a measureable voltage

polarized. The creation of dipoles in response to the electric field results in strain being generated along the [110] crystal axis and is at the heart of the piezoelectric effect in III–V semiconductors.

A scheme to exploit this elemental electromechanical effect as a motion transducer in a mechanical resonator is depicted in Fig. 5c. Here a hypothetical piezotransducer is created over one of the clamping points of a GaAs mechanical resonator, which is a bridge-like structure that is designed to only move up and down, and it consists of a Au Schottky gate and an n-type GaAs layer sandwiching a thin layer of undoped GaAs. As described in Fig. 5b, application of an electric field between the Au electrode and the n-type GaAs layer results in an elongation along the [110] crystal orientation, leading to a bending moment emerging in the mechanical element as a consequence of the doubly clamped geometry. If the electric field is modulated at the natural frequency of the mechanical element, this bending moment evolves into a mechanical resonance.

Although this concept had originally been developed for lead zirconate titanate piezoelectric transducers deposited onto Si-based micromechanical resonators [18], Roukes et al. extended this to GaAs nanomechanical cantilevers and beams integrated with p-type GaAs/intrinsic-GaAs/n-type (PIN-diode)-based piezotransducers which enabled large electric fields to be confined over nanometer length scales. Consequently, the application of even a single-electron charge could activate nanomechanical resonances with frequencies of 10s of MHz, demonstrating the efficiency of this highly integrated motion transducer [7]. However, detection of the corresponding mechanical resonance via the motion-induced voltage in the PIN-piezotransducer was unavailable.

To enable both mechanical resonances to be actuated and detected via the piezoelectric effect, the device shown in Fig. 6 was fabricated via conventional lithography, lift-off, and wet etching processes in a GaAs/AlGaAs modulation-doped

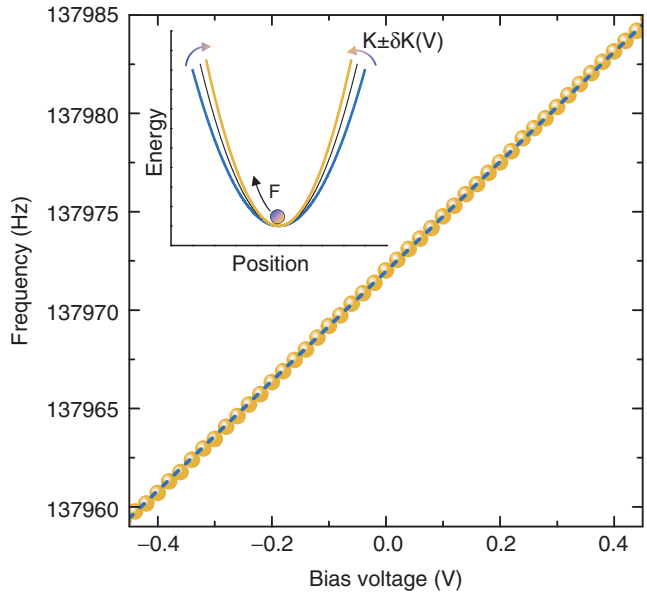


Nanomechanical Resonators Based on III–V Semiconductors, Fig. 6 A scanning electron micrograph of the electromechanical resonator formed from the GaAs/AlGaAs modulation-doped heterostructure, sustaining a 2DEG as detailed in the upper inset. The electromechanical resonator is integrated with piezoelectric transducers at both clamping points via the 2DEG and Au Schottky gates as detailed in the lower inset. The mechanically compliant element is a bridge-like structure which is suspended above the GaAs substrate, and when activated it vibrates with a sub-nanometer amplitude in the out-of-plane direction

heterostructure, sustaining a 2DEG located 90 nm below the surface. The 2DEG enabled the formation of a thin and highly integrated AlGaAs piezotransducer sandwiched between the Au Schottky gate and located at both clamping points of a micromechanical resonator as shown in Fig. 6. The corresponding device when measured in high vacuum and liquid helium temperatures enabled not only highly efficient activation of mechanical motion but also detection of that motion via the generated piezovoltage as shown in Fig. 7a [8]. Further, by incorporating a Si-transistor on-chip to amplify the motion-induced piezovoltage even enabled room temperature operation as shown in Fig. 7b [20]. Indeed operation frequencies of ~10 Mhz with displacement responsivities as high as 4 Am^{-1} yielding displacement sensitivities approaching 10^{-15} $mHz^{-1/2}$ have also been demonstrated in this system [21, 22].

A key feature of the piezoelectric transducers is their capacity to control the mechanical resonance frequency with the application of DC voltage. This results in the generation of strain via the piezoelectric effect which is converted into stress in the doubly clamped geometry shown in Fig. 6. This effect is analogous to tuning the frequency of a stringed instrument via the tension in the strings. For the device shown in Fig. 6 and measured at cryogenic temperatures (cf. Fig 7a), application of voltage to the largest gate electrode could tune the resonance frequency by ~30 HzV^{-1} which corresponds to more than 30 times the bandwidth of the resonance as shown in Fig. 8. For nanoscale resonators, this effect can be further enhanced, as consequence of their smaller masses and spring constants, which has yielded values as high as 80 $kHzV^{-1}$ [23].

At a more fundamental level, the ability to tune the tension and hence the frequency of the mechanical resonator with the application of voltage corresponds to controlling the harmonic potential underpinning the mechanical resonator. Specifically, the equation of motion of a mechanical resonator can be expressed as $m\ddot{x} + m\omega_0\dot{x}/Q + m\omega_0^2 x(t) = F(t)$ where m is the effective mass of the resonator with a natural frequency ω_0 and a spring constant $K = \omega_0^2 m$

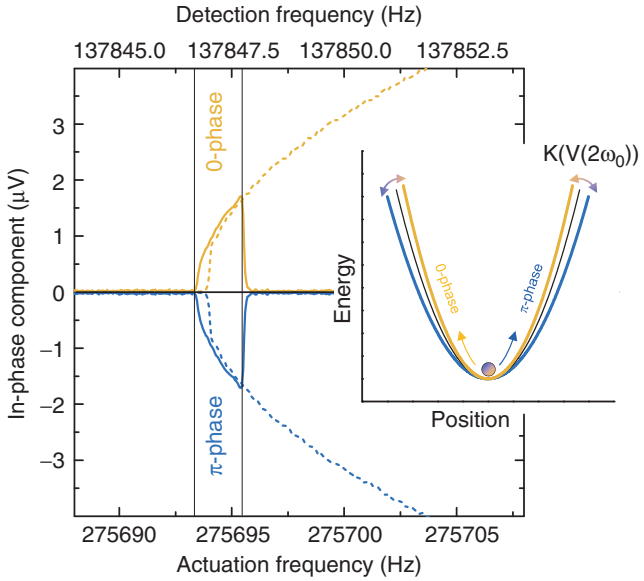


Nanomechanical Resonators Based on III–V Semiconductors, Fig. 7 (**a**) The frequency response of the mechanical oscillator shown in Fig. 6 measured at 10^{-7} mbar and 2.5 K when piezoelectrically excited via the largest piezotransducer in increments of 100 μV_{rms} reveals the fundamental mode at 137,848 Hz with $Q = 115{,}000$. By increasing the driving amplitude, the resonance develops the well-known Duffing nonlinearity [19]. (**b**) The frequency response of an identical device measured at room temperature and in a high vacuum with actuation amplitudes in increments of 10 μV_{rms}, where the motion-induced piezovoltage is amplified on-chip via a Si field-effect transistor, reveals the fundamental mode at 130,570 Hz with $Q = 10{,}000$. The piezotransducer can even activate the mechanical resonance with an amplitude as small as 10 μV_{rms} which corresponds to just 100 electrons being introduced onto the gate electrode. The high-quality factor resonance is also replicated at room temperature as a consequence of the excellent crystalline quality of the MBE-grown III–V semiconductor (Figure 7a is adapted from Mahboob and Yamaguchi [8]. Figure 7b has been reproduced with permission from Mahboob et al. [20]. Copyright 2009, AIP Publishing LLC)

N

that is driven by a force $F(t)$ yielding a displacement $x(t)$. This equation can be imagined as depicted in the inset to Fig. 8 where the mechanical motion corresponds to the ball moving in a harmonic potential in response to $F(t)$, and the energy loss rate during this motion is given by ω_{-0}/Q. Application of DC bias to the piezotransducer modifies the spring constant to $K \pm \delta K(V)$ which corresponds to the curvature of the harmonic potential changing where an increase in curvature with positive bias results in the ball oscillating more quickly, or in other words the resonance frequency increases and vice versa. Consequently, the piezotransducer not only enables a mechanical resonance to be activated and measured, but it also permits the harmonic potential which defines the dynamics of the mechanical resonator to be controlled.

The ability to control a fundamental parameter of the harmonic oscillator opens up the possibility of parametric resonance [24, 25]. Specifically modulating the spring constant of the mechanical resonator, or in other words its harmonic potential as depicted in the inset to Fig. 9, via application of voltage V to the piezotransducer at twice its natural frequency, namely, $\delta K = cV\cos(2\omega_0 t)$ where c is the coupling coefficient, can activate a parametric resonance. This effect is analogous to a child periodically standing and squatting on a swing during its arc to modulate its length in order to swing. Experimentally the mechanical resonator shown in Fig. 6 is parametrically excited by applying an AC bias to the largest piezotransducer at twice its natural frequency while simultaneously measuring its frequency response at half of the actuation frequency via another piezotransducer. The parametric resonance line shape shown in Fig. 9 is highly asymmetric, and it does not become damped as the actuation frequency is swept forward across the

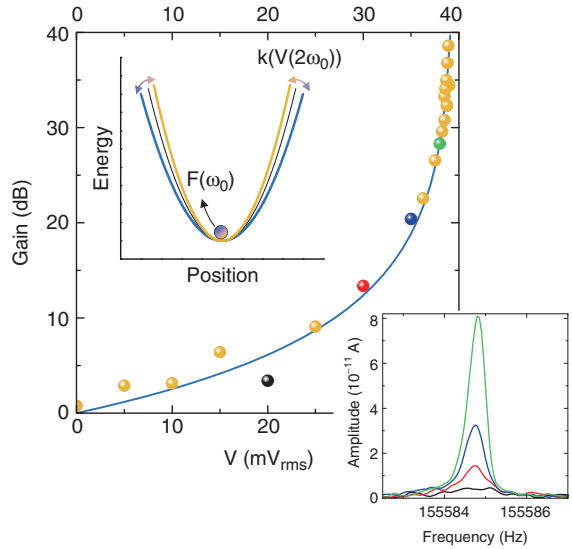


Nanomechanical Resonators Based on III–V Semiconductors, Fig. 8 The resonance shown in Fig. 7a is activated by one of the small piezotransducers shown in Fig. 6 and is measured in the adjacent piezotransducer, as a function of DC bias applied to the largest piezotransducer, and it reveals a linear frequency shift (points) corresponding to ~30 HzV^{-1} extracted from the fit shown in the dashed line. The shift in the resonance frequency via piezoelectric control of the spring constant can be envisaged as controlling the underlying harmonic potential of the mechanical resonator which determines its oscillation dynamics as depicted in the inset (Adapted from Mahboob and Yamaguchi [8])

resonance, but it does become damped if the actuation frequency is swept back across the resonance.

A unique feature of the parametric resonance is that it has only two stable oscillation phases which can be experimentally observed by decomposing the mechanical displacement into $x(t) = P\ \cos(\omega_0 t) + Q\sin(\omega_0 t)$ in a phase-sensitive detector where P and Q are slowly varying in-phase and quadrature components. In Fig. 9, the in-phase component of the parametric resonance is measured for increasing and decreasing frequencies multiple times. In the spectral region around the harmonic resonance, the parametric resonance can *only* oscillate with either a positive or a negative in-phase component of the same magnitude corresponding to a π radian phase difference between them. Physically this phase bistability can be understood by examining the dynamics of the ball in the harmonic potential as it is modulated at twice its natural frequency. In this regime, the ball has the option to move either toward the left or the right where the initial trajectory is selected by its random fluctuation driven by the thermal Langevin force. Consequently, if the initial movement of the ball is toward the left, this then corresponds to the 0 oscillation phase, for example, and by moving toward the right first corresponds to the π oscillation phase. By repeatedly parametrically exciting across the resonance, both oscillation phases can be accessed randomly which are identical in magnitude as shown in Fig. 9.

The availability of bistable oscillation phases to the parametric resonance provides a platform within which a mechanical memory can be executed [19, 26]. Indeed if a weak harmonic trigger is applied via $F(t)$ with a specific phase, the parametric resonance can be selectively switched between the 0 and π oscillation phases, enabling binary logicals 0 and 1 to be stored and switched between [8]. This concept can even be extended to build logic gates by utilizing multiple parametric

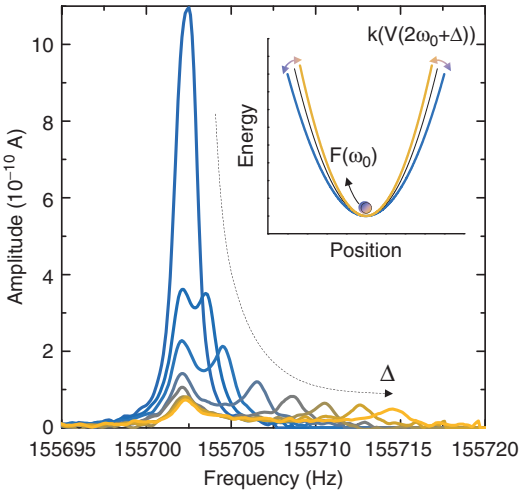


Nanomechanical Resonators Based on III–V Semiconductors, Fig. 9 A parametric resonance activated in the device shown in Fig. 6 at 10^{-7} mbar and 2.5 K via the largest piezotransducer with an amplitude of 80 mV_{rms} and measured in one of the smaller piezotransducers at half the actuation frequency. The parametric response is decomposed in phase space where the dashed and solid traces correspond to increasing and decreasing the actuation frequency across the resonance, respectively, and the two colors correspond to 0 and π oscillation phases. The two oscillation phases can be understood as the motion of the mechanical oscillator, as depicted by the ball in the harmonic potential in the inset, moving either first to the left or to the right in response to the parametric modulation of the harmonic potential (Adapted from Mahboob and Yamaguchi [8])

N

resonances [27], and it paves the way toward highly efficient mechanical computing [28]. Although parametric resonances in mechanical systems have previously been accessed via electrostatic transducers, they have invariably required 10s of volts [25]. In stark contrast, the highly integrated nature of the piezotransducers enables parametric resonances to be activated with amplitudes as small as 10 mV_{rms}, making this phenomenon more accessible for the development of technological applications [27].

The ability to modulate the spring constant of the mechanical resonator via the piezotransducer also opens up the possibility of degenerate parametric amplification. This effect is comparable to the child being *harmonically* pushed on the swing by an adult while the child alternatively raises and lowers their legs on the swing arc to *parametrically amplify* the swing's motion. Analogously this corresponds to the harmonic potential being modulated at twice the frequency of the harmonic force which is simultaneously driving the motion of the ball as depicted in the upper inset to Fig. 10. Clearly this effect is maximized when the harmonic actuation and the parametric modulation are in phase. In Fig. 10, the mechanical resonator is harmonically actuated with an amplitude of 1 μV_{rms}, and simultaneously it is parametrically pumped at exactly twice the harmonic actuation frequency. As the amplitude of the pump is increased, the harmonic motion is amplified as explicitly shown in the lower inset to Fig. 10, and gains of 40 dB could be achieved for pump amplitudes below 40 mV_{rms} beyond which parametric resonance occurred as shown earlier in Fig. 9 [29]. The degenerate parametric amplifier increases the mechanical resonator's vibration amplitude from a small harmonic driving force which in turn enhances its force responsivity, yielding an unprecedented force sensitivity of 200×10^{-18} $NHz^{-1/2}$ in a stiff system with $K > 100$ Nm^{-1} [30]. In contrast, earlier attempts to parametrically amplify the harmonic motion of the mechanical resonator utilized off-board electrostatic transducers which not



Nanomechanical Resonators Based on III–V Semiconductors, Fig. 10 A weak harmonic input can be amplified by parametrically modulating the harmonic potential at twice its frequency below the parametric resonance threshold as depicted in the upper inset. Experimentally, the resonator shown in Fig. 6 was harmonically activated with a 1 μV_{rms} input, while simultaneously it was parametrically pumped at exactly twice the frequency of the harmonic input, i.e., degenerately. As the pump amplitude is increased, the weak harmonic input can be amplified (points), as detailed in the lower inset where the color of the traces corresponds to the colored points, with a gain of 40 dB being possible before the onset of parametric resonance. The solid line corresponds to the theoretical response of a degenerate parametric amplifier indicating the almost perfect performance of the electromechanical variant [29] (Reproduced with permission from Mahboob et al. [29]. Copyright 2010, AIP Publishing LLC)

only required large voltages but also gave only modest gains of ~20 dB [31]. Again the integrated nature of the III–V semiconductor-based piezotransducer facilitates highly efficient degenerate parametric amplification.

A final example of the functionality accessed in the mechanical domain via the piezotransducers' ability to modulate the spring constant is nondegenerate parametric amplification [32]. In this configuration, the modulation of the harmonic potential is detuned by Δ from the degenerate case outlined above as depicted in the inset to Fig. 11. The nondegenerate parametric amplifier is routinely employed in optics to tune the frequency of a laser by exploiting the interaction of a high-frequency and high-intensity pump beam (ω_p) with a lower-frequency and lower-intensity signal beam (ω_s) in a crystal whose nonlinearity is activated by the pump, for example, the Kerr effect. This interaction amplifies the signal beam as well as generating an *idler* beam (ω_i) where this process conserves energy, i.e., $\hbar\omega_p = \hbar\omega_s + \hbar\omega_i$ and $\hbar$ is the reduced Planck constant.

This phenomenon can be replicated in a mechanical resonator with a periodic nonlinearity in its harmonic potential activated by the detuned piezoelectric pump. When the mechanical resonator is harmonically excited with a signal excitation at the fundamental mechanical mode ω_0 and simultaneously parametrically pumped at $2\omega_0 + \Delta$, an idler is created at their frequency difference $\omega_0 + \Delta$. By increasing the detuning Δ, the idler can be observed at the same time as the signal excitation within the bandwidth of the fundamental mode as shown in Fig. 11. Further if the mechanical resonator is excited with multiple detuned pumps, it results in the generation of multiple idlers which can further intermix via the periodic nonlinearity in the harmonic potential, and it results in a rich spectrum of idlers being generated. Indeed these idlers have even been exploited to construct

Nanomechanical Resonators Based on III–V Semiconductors, Fig. 11 The inset shows the interaction of a harmonic input and the parametric modulation of the harmonic potential at almost twice its frequency which can generate a new vibration, the idler, at their frequency difference. Experimentally the electromechanical oscillator shown in Fig. 6 is harmonically excited at 50 μV_{rms}, while simultaneously it is parametrically pumped with an amplitude of 40 mV_{rms} at frequency that is slightly detuned from twice the harmonic input. As the pump is detuned from $\Delta/2\pi = 0$ to 15 Hz, the idler emerges and becomes increasingly visible, whereas the harmonic input remains fixed. Note that when the detuning is zero, the idler and the signal input overlap, leading to degenerate parametric amplification (Adapted from Mahboob et al. [32])

all-mechanical logic gates and circuits that can be executed in parallel [32]. This concept can be further extended to multiple vibration modes, enabling the generation of combs and correlated mechanical states [33, 34]. Although nondegenerate parametric amplification has been widely exploited in optics, the extension of this concept to mechanics opens up the tantalizing prospect of phonons being utilized in the same vein as photons for range of applications.

III–V semiconductor-based mechanical resonators enable piezoelectric transducers to be synthesized directly within the mechanical element during crystal growth and subsequent fabrication. The piezotransducer can not only harmonically activate mechanical motion with unrivaled efficiency, but it can also detect motion with femtometer sensitivity. Moreover, it can also induce tension in the mechanical element to tune the resonance frequency which provides the key to dynamically engineer a range of nonlinear phenomenon into the mechanical domain, thus dramatically expanding the functionality portfolio of mechanical resonators.

Outlook and Prospects

Although the focus of this chapter has been on nanomechanical resonators fabricated from III–V compounds based on aluminum, gallium, indium, and antimony, arsenic atoms, respectively, many other compounds have remained largely unexplored. Of particular interest are the III-nitride semiconductors which sustain piezoelectric constants that are an order of magnitude larger than the more conventional III–V compounds detailed above as a consequence of the large size mismatch between the group III and nitrogen atoms [35]. Indeed given the promise of enhanced electro-to-mechanics coupling mediated via the piezoelectric effect has led to III-nitride semiconductors being explored for mechanical resonators [36, 37]. However, invariably the III-nitride films used to fabricate the mechanical resonators have been prepared via sputtering, resulting in poor crystalline quality which inevitably not only compromises the piezoelectric effect, but it also results in low-quality factor resonators. To that end, MOVPE-based crystalline III-nitride resonators offer the prospect of bypassing the above limitations, leading to new opportunities; for instance, the enhanced electric-to-mechanics coupling could give rise to mechanical single-electron detectors [38, 39]. In addition to offering access to more energetic parts of the electromagnetic spectrum to explore optomechanical coupling, III-nitride resonators also hold the promise of quality factor engineering as the nitrogen films can be readily grown with tensile strain [40]. Ultimately, and in contrast to the more conventional silicon-based mechanical resonators, the choice of atoms and the design of the layer structure can enable III–V semiconductor-based mechanical resonators to be readily functionalized for electrical, optical, or mechanical applications.

Definition

Nano- and micro-optomechanical systems (NOMS and MOMS) are nanoscale and microscale mechanical devices that are driven by optical forces and sensed with optical detection methods.

Chemical and Physical Principles

Light can generate forces on matter. The nature of these forces is electromagnetic force, or Lorentz force. Fundamentally they originate from the forces exerted on the charges (electrons and nuclei) that constitute the matter by the electric and magnetic fields in light. The optical forces are generally considered too weak to have any significance at macroscale. However, the emergence and rapid progress of nanotechnology provided an unprecedented platform where the very feeble optical forces can play significant roles and lead to various optomechanical phenomena. On the one hand, nanoscale structures can be engineered to tightly confine light near or below the diffraction limit, which greatly enhances the light field strength, hence the optical force. On the other hand, nanoscale objects possess small mass and are generally compliant, therefore can be easily moved or deformed by the optical forces. Conversely, the motion and deformation of these nanoscale objects can change the propagation and frequency of light. In NOMS devices, this new form of light-matter interactions can be rationally engineered and lead to many unprecedented physical phenomena in both classical and quantum regimes. Also, NOMS devices have enabled and opened up possibilities of novel functionalities for practical applications.

The electrical and comparably conventional counterpart of NOMS and MOMS devices are ▶ NEMS and ▶ MEMS devices, which employ the interactions between electricity (as the letter "E" in their acronyms implies) and mechanical structures via electrical forces and mechanical motions (and/or deformations).

Optical Force

Optical forces may manifest themselves in drastically different ways, including (but not limited to) pushing, pulling, squeezing or expanding, determined by the particular configuration of mechanical structure and light field confinement in the device. Consequently, in different contexts and situations, different terminologies for optical forces are used, including gradient force, optical dipole force, optical electrostriction force, and, perhaps the most commonly known, radiation pressure.

To calculate optical force, there are in general three methods – calculating the Lorentz force directly, calculating the time derivative of the momentum of the light wave, and calculating the space derivative of energy (or work) of the optical field. Within each method, light can be modeled quantum-mechanically as photons or classically as electromagnetic waves. In certain cases semiclassical approaches may also be used.

Before the methods of optical force calculations are briefly reviewed, it is worth emphasizing that, to obtain correct and meaningful results, caution must be exercised when using any of the following methods. The applicability and subtle implications of the methods must be carefully checked. Microscopic and macroscopic quantities such as charge, current, and fields sometimes need to be clearly differentiated. Any medium that is anisotropic, inhomogeneous, lossy, or dispersive may need special treatment. Calculations of the electromagnetic field momentum inside a medium, the optical force distribution inside a medium, or the total optical force exerted on a partial volume of a medium may lead to ambiguous results, sometimes involving the Abraham–Minkowski dilemma [1]. The readers will be referred to dedicated literature for more details.

When calculating optical forces directly, the expression for Lorentz force density [2] should be used, and light is modeled as electromagnetic waves.

$$\mathbf{f}^{\mathrm{L}} = \rho\mathbf{E} + \mathbf{J} \times \mathbf{B} \tag{1}$$

Oftentimes the charge density ρ and current density $\mathbf{J}$ are further expressed in terms of electric and magnetic fields according to Maxwell's equations, leading to the following two distinct expressions for the force density [2, 3]:

$$\mathbf{f}^{c} = -(\nabla \cdot \mathbf{P})\mathbf{E} + \dot{\mathbf{P}} \times \mathbf{B} \tag{2}$$

$$\mathbf{f}^{d} = (\mathbf{P} \cdot \nabla)\mathbf{E} + \dot{\mathbf{P}} \times \mathbf{B} \tag{3}$$

Generally, the electric and magnetic fields of the light inside the medium volume of interest should be calculated first before Eqs. 1, 2 or 3 is used to calculate the optical force density. The total optical force is the integration of the force density over the medium volume of interest. For more details and subtleties the readers are referred to the following literature [2–5].

When calculating optical forces as the time derivative of light momentum, light can be modeled as photons or electromagnetic waves. In either case, the total optical force should be calculated from the net momentum flow into a closed surface that surrounds the medium volume of interest. Generally, for simple cases concerning only monochromatic plane waves in vacuum, reflected or absorbed by a flat surface, it is very convenient and intuitive to model light as photons, the momentum carried by each of which is h/λ, according to the de Broglie relations. For more complicated cases, it is more convenient to model light as electromagnetic waves that carry momentum. In practice, Maxwell's stress tensor [6] $\mathbf{T}$ defined in Eq. 4 is often used to quantify the linear momentum flux (rate of flow of momentum per unit area) of electromagnetic waves.

$$T_{ij} = \varepsilon_0 \left[E_i E_j + c^2 B_i B_j - \frac{1}{2}\delta_{ij}\left(\mathbf{E} \cdot \mathbf{E} + c^2 \mathbf{B} \cdot \mathbf{B}\right) \right] \tag{4}$$

The total optical force can be found by the integration of the normal component of $\mathbf{T}$ over the closed surface that surrounds the medium volume of interest.

$$\mathbf{F} = \oint_S \mathbf{n} \cdot \mathbf{T} da \tag{5}$$

For more details and subtleties, especially about the momentum of light in medium, the readers are referred to the following literature [6–9].

When calculating optical forces as the space derivative of light energy (or the work done by the light), closed systems and open systems need to be treated differently. The simpler case is the closed systems, which in this context means a perfect cavity where light is forever trapped inside. Light is conveniently modeled as photons. Assume that the cavity, whose angular resonance frequency is ω_0, very slowly undergoes an infinitesimal mechanical displacement along a generalized coordinate q. Due to the optical force exerted on the cavity, photons inside the cavity do work and their energy (hence frequency) changes according to the shift of the cavity angular resonance frequency. Therefore the optical force along the same generalized coordinate q satisfies Eq. 6, where U is the total photon energy and N is the total photon number.

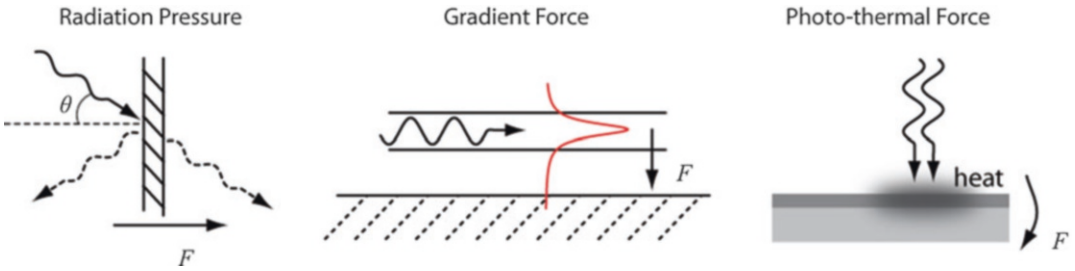
$$F_q(q) = -\frac{dU}{dq} = -N\hbar \frac{d\omega_0(q)}{dq} \tag{6}$$

This conclusion is generally a very good approximation for any real-world high-quality cavities excited on or near resonance. However, many real-world NOMS devices cannot be approximated as closed systems and have to be treated as open systems, which light can flow into and out of. In this case, the Response Theory of Optical Forces (RTOF) [10] should be used. RTOF is a semiclassical approach that relates the work done by the photons transiently stored in the system to the phase changes of the light waves, when the system very slowly undergoes an infinitesimal mechanical displacement along a generalized coordinate q. For a lossless one-port system driven at a single frequency, the optical force along the generalized coordinate q satisfies Eq. 7, where Φ is the photon flux (rate of flow of photon number) and ϕ is the phase of the output light wave. For more details and subtleties the readers are referred to the following literature [10, 11].

$$F_q(q) = \Phi\hbar \frac{d\phi(q)}{dq} \tag{7}$$

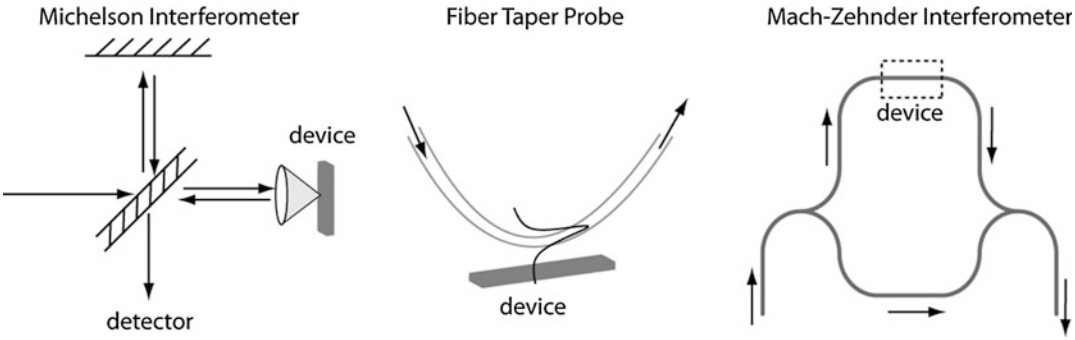
Finally, a completely different category of optical force is photothermal force [12]. Since optical

absorption and heat generation are inevitable in all realistic materials, thermal effects due to optical heating, i.e., photothermal effects, are always present. On devices with multilayers of different materials with differential thermal expansion coefficients, optical heating can induce mechanical motion which is equivalent to a thermal force applied on the device. A significant drawback of photothermal actuation, however, is that its effective bandwidth is inherently limited by the cutoff frequency determined by the device's thermal response time constant. Beyond this cutoff frequency, which is often much lower than the device's mechanical resonance frequency, the actuation efficiency rolls off at 20 dB per frequency decade. Therefore, due to its low efficiency as well as its dissipative nature, photothermal effects are less desirable in NOMS and often need to be minimized by reducing optical absorption.



Optical Transduction of Mechanical Motion and Deformation

Various optical transduction techniques have been applied to measure mechanical motion and deformation. These techniques can be divided into two general categories: those based on optical interference and those based on light deflection. The first category includes all kinds of laser interferometers such as Fabry-Perot, Michelson, Mach-Zehnder, and Sagnac interferometers. The laser Doppler vibrometer also belongs to this category. In a recent magnetic resonance force microscopy (MRFM) experiment, an optical fiber-based Fabry-Perot interferometer is used to read out a microcantilever's motion with attonewton force resolution [13]. The second category includes the optical lever technique, which is widely used in atomic force microscopy (▶ AFM) to detect the motion of microcantilever probes. The above methods are all implemented with free-space optics whereby a laser beam has to be focused on the mechanical device's surface and the reflected optical intensity or interference is measured. Therefore, these techniques are subject to the diffraction limit of conventional optics: when the device's dimensional scales are significantly smaller than the optical wavelength as in the situation of nanomechanical devices, these methods will have significantly reduced sensitivity if they are not completely inapplicable.



Recent development of near-field optics and integrated photonics can extend optical transduction beyond the diffraction limit. In near-field schemes, a tapered fiber or a microscale optical resonator, for example, are employed as optical probes when they are brought to the proximity of the mechanical devices [14, 15]. At a distance less than the wavelength, the optical field in the fiber or the resonator can evanescently couple with the mechanical devices. The motion of the mechanical devices will either cause additional scattering loss or shift the resonance frequency of the resonator so it can be measured in the transmitted optical signals with high precision. In integrated photonic schemes, optical interferometers can be implemented on a chip using dielectric waveguides. For example, a Mach-Zehnder interferometer built with silicon waveguides is demonstrated in reference [16] to measure the vibration of a nanomechanical beam that is embedded in the sensing "arm" of the interferometer. The motion of the beam induces a phase shift to the optical signal propagating through it. Interference between the optical signals from the sensing and the reference arms of the interferometer converts the phase shift to an intensity variation at its output where the signal is measured with a photodetector. Other than interferometers, various integrated optical resonators or cavities including microrings, microdisks, and photonic crystals have been utilized to measure nanomechanical devices with even better resolution [17, 18]. These devices of optical cavities with mechanical elements embedded inside are among the representative systems of the emerging field of "cavity optomechanics" [19, 20].

Key Research Findings

Although the first conception of radiation pressure dates back to as early as 1619, when Johannes Kepler attempted to explain the observation that a tail of a comet always points away from the sun, it was not until late 1980s that optical force

Nano-optomechanical Systems (NOMS), Fig. 1 Optical forces that are available for actuating mechanical devices

Nano-optomechanical Systems (NOMS), Fig. 2 Examples of free-space interferometer, near-field fiber taper probe, and integrated waveguide interferometer

N

found its first remarkable and widespread application – ▶ optical tweezers [21]. Experimentally demonstrated and reported by A. Ashkin et al. in 1986 for the first time [22], optical tweezers use optical forces to trap and manipulate biological cells or mesoscale particles micron- or nanometer-sized.

In 2005, the interactions between the light field inside a Fabry-Perot (F-P) cavity and a movable cavity mirror predicted in V. B. Braginsky et al.'s theoretical work [23, 24] were experimentally observed and reported for the first time by T. J. Kippenberg et al. [25, 26]. Instead of an F-P cavity, this experiment was conducted with a microtoroid ultrahigh-quality-factor (Q) optical cavity accessed by a fiber taper, which turned out to be an excellent experimental platform for cavity optomechanics [19, 20, 27]. The circulating light field inside the microtoroid cavity exerts distributed optical force that tends to expand the toroid. The resonance frequency of the microtoroid cavity red-shifts when the circumference of the toroid increases, leading to change of the intracavity light field. Due to the ultrahigh resonator Q, the change of the intracavity light field, hence that of the optical force, is delayed from the mechanical deformation. These dynamic interactions [19] modify the effective spring constant and damping coefficient of the mechanical mode, resulting in intriguing phenomena such as optical spring and optomechanical heating (also known as amplification) [26] and cooling [28, 29] of the Brownian motion.

The aforementioned breakthrough was followed immediately by almost a decade of active theoretical and experimental investigations up to now, which are still ongoing and constitute a whole new burgeoning branch of nanotechnology, nano-optomechanical systems (NOMS). Although the research scope of NOMS is now much wider than that of cavity optomechanics, the latter has always been the most important part of NOMS so far. The major experimental

milestones in the development of NOMS should include the following, sorted by the time of their publication in peer-reviewed journals.

In 2005 and 2006, cavity optomechanical heating (or amplification) and cooling were demonstrated, respectively, in silica microtoroid optical cavities [26, 28]. Also in 2006, the same phenomena were demonstrated in an F-P cavity with a microscale movable mirror [30, 31].

In 2008, two more NOMS experimental platforms were proposed and implemented. One is a high-finesse optical F-P cavity with a silicon nitride micromechanical membrane inside, which is parallel to the cavity mirrors and of nanoscale thickness [32]. The other is nanoscale suspended silicon photonic waveguides fabricated on silicon on insulator (SOI) wafers [16]. The former platform is implemented with high-quality free-space optics, while the latter is completely integrated on an SOI chip.

In 2009, three more NOMS experimental platforms were proposed and implemented. One is the "zipper" cavities, which consist of a pair of specially patterned nanoscale silicon beams to support colocalized photon and phonon modes that realize large per-photon optical forces [17]. Another is optomechanical crystals, which are suspended one-dimensional (1D) nanoscale periodic silicon structures, whose photonic and phononic bandgaps and defects are engineered to support colocalized photon and phonon modes that strongly interact [33]. The third is vertically stacked silicon nitride double disk resonators, whose optical response can be efficiently statically controlled using attractive and repulsive optical forces [34].

In 2009, tunable attractive and repulsive optical forces exerted on two coupled parallel nanoscale optical waveguides were demonstrated on an integrated silicon photonics platform [35].

In 2010, the tunable nonlinear optomechanical coupling in a low-loss system, which consists of an F-P cavity with a membrane of nanoscale thickness inside, was systematically explored [36].

In 2010 and 2011, optomechanically induced transparency (OMIT) was demonstrated with a microtoroid [37] and an optomechanical crystal [38], respectively.

In 2011, laser cooling of a nanomechanical oscillator into its quantum ground state was achieved in an optomechanical crystal device [29].

In 2011, a nonvolatile mechanical memory element fully integrated on an SOI chip was demonstrated, in which bits are written and reset by using optomechanical back-action [39]. The bistability (buckling up or buckling down) of a suspended silicon nanobeam with compressive stress is used to represent "0" or "1."

In 2012, optomechanical synchronization of two dissimilar vertically stacked silicon nitride double disk oscillators was demonstrated. The two oscillators are coupled through optical cavity field [40].

In 2012, quantum-coherent coupling of a mechanical oscillator to an optical cavity mode was achieved in a microtoroid cavity optomechanical system [41].

In 2013, squeezed light from a silicon micromechanical resonator was demonstrated with the "zipper" cavity [42].

In 2014, optically mediated hybridization between two mechanical modes was demonstrated in an F-P cavity with a membrane of nanoscale thickness inside [43].

In 2014, optomechanical photon shuttling between photonic cavities was demonstrated with a "photon see-saw" device fully integrated on an SOI chip [44].

Examples of Application

Nano-optomechanical systems have demonstrated both exceedingly high sensitivity and large dynamic range in measuring their mechanical motion. Therefore, when optimized for specific applications, they can be highly sensitive mechanical transducers that are capable of measuring weak forces in attonewton range, minuscule masses below a zeptogram and ultimately at the single molecule level, magnetic fields below a picotesla, and mechanical effects induced by single electrons or spins. The intrinsic high speed, efficiency, and sensitivity of optical actuation and sensing also enable the operation of mechanical resonators at very high frequencies, which

makes them very promising for applications in RF/microwave communication and signal processing.

The optomechanical effect also provides an all-optical approach to tune the functionalities of integrated photonic devices adaptively. Many reconfigurable photonic devices, including tunable optical filters, couplers, and switches, have been proposed and demonstrated. For example, in reference [45], the frequency of a microring optical filter is tuned by the application of optical force by more than 4 nm, a remarkably large spectral range that is hardly attainable with other methods.

Nanoparticle Cytotoxicity

Nastassja A. Lewinski
Department of Bioengineering, Rice University, Houston, TX, USA

Synonyms

Cellular toxicity; In vitro toxicity

Definition

Nanoparticle cytotoxicity is defined as the extent to which the interaction of nanoparticles with cells disrupts cellular structures and/or processes essential for cell survival and proliferation. Cytotoxicity assays are a quick and simple way to perform initial acute toxicity assessments. Coupling nanoparticle cytotoxicity data with other safety testing data can help predict the biocompatibility of nanoparticles.

Overview

When evaluating the biocompatibility of a chemical, often the first step is to screen for adverse effects in cultured cells before using animal models. Compared to animal studies, in vitro testing is less ethically ambiguous, easier to control and reproduce, and less expensive. Conducting preliminary evaluations in vitro also provides a basis for prioritizing chemical testing and reducing the number of animals used for in vivo toxicity testing. Generally, the first endpoint tested in chemical biocompatibility assessments is cell lethality. Cytotoxicity assays are used to measure the extent of cell death and inhibition of cell proliferation after exposure to a chemical. Since toxicity is often dose-dependent, a range of concentrations is tested to determine the LC_{50} or the concentration at which 50 % cell death occurs. The LC_{50} serves as a point of comparison of the toxicity of chemicals and is used to group chemicals into toxicity classes ranging from extremely toxic (e.g., botulinum toxin) to relatively harmless (e.g., water). Knowledge of dose is essential as many chemicals that are beneficial at low doses can be toxic at high doses.

When evaluating the toxicity of a new chemical, characterizing the composition, purity, stability, and solubility is necessary before testing. In the case of nanoparticles, more extensive characterization, including particle size and size distribution, shape, crystal structure, surface charge, and surface chemistry, is warranted since these factors may also contribute to the observed effects. Generally size, shape, and agglomeration state are thought to be governing properties; however, surface composition and structure also influence the way nanoparticles interact with biological environments. Careful attention should be paid to how the various physiochemical properties of nanoparticles modify their toxicity. Although a detailed assessment of the various particle characterization techniques is beyond the scope of this definition, the reader is referred to review articles on this topic [1, 2]. Given the combinatorial nature of nanoparticle testing, in vitro assays facilitate quick screening of nanoparticle formulations to identify which nanoparticles elicit adverse effects. Depending on their intended use, the results from initial in vitro tests can be used to prioritize them for further development and/or in vivo testing. The following sections will describe some of the most common cytotoxicity assays, the potential mechanisms of nanoparticle toxicity that have been determined to date, and some challenges for future nanoparticle cytotoxicity research.

Common Cytotoxicity Assays

Cytotoxicity assays can be categorized by the endpoints they evaluate. Markers of cell injury and death include changes in membrane integrity, mitochondrial function, and cell proliferation. While some of these endpoints can be identified by microscopy, visual inspection of cellular changes provides only qualitative information. Instead, a majority of published nanoparticle cytotoxicity studies present measurements of cell death using colorimetric methods. A compilation of the assays discussed is presented in Table 1 toward the end of section.

Membrane Integrity

The cell membrane serves as a physical barrier separating the cell from its surrounding environment, with traffic into and out of the cell regulated by transporters, receptors, and secretion pathways. Exposure to nanoparticles could compromise the cell membrane, making it "leaky" which is the basis for the following assays. Membrane integrity is typically assessed by measuring either (1) the uptake of a cell impermeable dye, (2) the retention of a cell permeable dye, or (3) the release of a cell biomolecule into the extracellular media.

Cell impermeable dyes can only enter cells with compromised membranes; therefore, injured or dead cells are stained while intact or live cells remain unstained. Examples of dyes normally excluded from intact cells that are utilized for cytotoxicity assays include trypan blue, ethidium bromide (EtBr), and propidium iodide (PI). Trypan blue is an absorbing dye, staining dead cells blue which can be manually counted using a hemocytometer. Although trypan blue assay

Nanoparticle Cytotoxicity, Table 1 Summary of common cytotoxicity assays

Assay	Mechanism of action	Indication	Limitations in testing NPs
Trypan blue	Dye exclusion	Dead cells stained blue	
Neutral red	Lysosomal retention	Live cells stained red, abs = 540 nm	Dye adsorption to NPs in the absence of cells results in absorbance readings
Calcein AM	Dye retention	Live cells fluoresce green, em = 520 nm	
Fluorecein diacetate	Dye retention	Live cells fluoresce green, em = 520 nm	
Ethidium homodimer	DNA marker	Dead cells fluoresce red, em = 620 nm	
Propidium iodide	DNA marker	Dead cells fluoresce red, em = 620 nm	Dye adsorption to NPs quenches fluorescence
LDH	LDH release	LDH presence converts dye, abs = 490 nm	
MTT	Mitochondrial reduction	Live cells stained purple, abs = 570 nm	Substrate adsorption to NPs reduces absorbance
Alamar blue	Mitochondrial reduction	Live cells fluoresce red, em = 590 nm	Substrate adsorption to NPs quenches fluorescence
Luciferin/luciferase	ATP-dependent oxidation	Live cells luminesce, em = 560 nm	
Annexin V-FITC	Phosphatidylserine binding	Apoptotic cells fluoresce green, em = 520 nm	

NPs nanoparticles, *abs* absorbance, *em* emission

results have been published by a few groups, it is generally considered a qualitative assay as it is less sensitive and less reliable than other assays. EtBr and PI are red fluorescent dyes, whose peak emission intensities at 620 nm are greatly enhanced upon binding to DNA and can be measured using a flow cytometer or spectrofluorometer. Since quantitative measurements can be derived from these fluorescent dye based assays, they are more widely used. In addition, EtBr and PI can be used to identify necrotic cells and when co-stained with annexin V-FITC differentiate them from apoptotic cells. Refer to the *Apoptosis* Versus *Necrosis* section for further discussion.

A complementary technique to dye exclusion uses cell permeable dyes, which tend to accumulate within cells, to assess membrane integrity. If the cell membrane is damaged, the dye can leak out of cells or its uptake is decreased, with fluorescence intensity differentiating live and dead cells. Examples of commonly used dyes include neutral red, calcein acetoxymethyl (calcein AM), and fluorescein diacetate (FDA). Neutral red absorbs at 540 nm and can be measured with a spectrophotometer. Calcein AM and FDA are nonfluorescent dyes, which are converted by intracellular esterases to their fluorescent counterpart once within the cell. Cytotoxicity can be quantified by measuring the fluorescence intensity at 520 nm using a flow cytometer or spectrofluorometer. While the fluorescent dyes can be used individually, they are more commonly used in a double "live/dead" assay. The cell sample is exposed to fluorescent dye pairs (e.g., calcein AM/EtBr, FDA/PI) where live cells fluoresce green and dead cells fluoresce red.

Another membrane integrity assay detects lactate dehydrogenase release. Lactate dehyrogenase (LDH) is an enzyme normally present in the cytosol and can only be detected outside the cell after cell damage has occurred. In this assay, LDH released from damaged cells oxidizes lactate to pyruvate which promotes the conversion of tetrazolium salt INT to formazan. The amount of LDH

released, determined by measuring the absorption of formazan at 490 nm, is proportional to the number of cells damaged or lysed. Significant LDH release from the cytosol is associated with necrosis.

Mitochondrial Function

Changes in cell function due to toxicity can occur before serious cell damage, such as compromised membrane integrity, are detected. Indicators of metabolic activity can be used to detect early cell injury. Considered the "gold standard" for cytotoxicity, the MTT assay is a colorimetric assay that measures the activity of mitochondrial enzymes. MTT, or 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide, is yellow in solution but is converted into an insoluble purple formazan product in living cells. Absorbance measurements at 570 nm can be made after solublizing the formazan with DMSO or isopropanol, and the absorbance intensities can be correlated to cell viability. In addition, the absorbance is also representative of cell number and can be used to measure cell proliferation. While MTT is less expensive and more common, other tetrazolium dyes (MTS, XTT, or WST) similarly produce a formazan that absorbs around 570 nm in live cells but have greater sensitivity with less reaction time. Similar to the MTT assay, the alamar blue assay is another colorimetric assay that measures metabolic enzyme activity. The assay is based on the reduction resazurin, a nonfluorescent dye, to resorufin, a pink fluorescent dye, mainly by acting as an electron acceptor for enzymes such as NADP and FADH during oxygen consumption. The converted dye fluoresces at 590 nm and can be detected using a fluorometer. In addition, alamar blue shows little to no cytotoxic effects in tested cells, and thus has been used to perform several tests or kinetic measurements on the same set of cells.

Measurement of ATP levels and oxygen consumption rate are less commonly used methods of assessing nanoparticle cytotoxicity. This could due to the assays being more expensive or requiring specialized equipment. Briefly, ATP bioluminescence assay measures the concentration of ATP, which is proportional to the number of metabolically functional cells, using a luciferin-luciferase system. Healthy cells maintain ATP concentrations through a balance of production and consumption pathways. Since the oxygen consumption rate is disrupted upon cell death, cells lose the ability to produce ATP, and since ATPases can continue to consume ATP after cell death, the concentration of ATP decreases. The decrease in ATP concentration corresponds to a loss of luciferin–luciferase luminescence. The oxygen consumption rate of cells can be measured using electron paramagnetic resonance oximetry, Clark-type polarographic oxygen electrode, and fluorescent oxygen sensors. However, to date, little or no nanoparticle cytotoxicity studies use these approaches.

Proliferation

If nanoparticle exposure induces cell senescence but not cell death, this could be considered a cytotoxic effect as cell proliferation has been disturbed. Comparing the number of cells present at different exposure time points can indicate effects on cell proliferation. Cell number can be measured by direct cell counting, nuclei counting, or by the measurement of total cell protein or DNA content, which are proportional to the number of cells. Fluorescence from dyes that label DNA, such as Hoechst or PI, is directly proportional to the sample DNA content. Compared to the control, higher fluorescence indicates proliferation and lower fluorescence signals cytotoxicity. This method is relatively cheap and fast. In comparison, markers such as ^{3}H-thymidine and 5-bromo-2′-deoxyruidine (BrdU) incorporation into DNA can also be used to measure cell proliferation; however, both methods require significant sample processing. As mentioned previously, MTT can also be used to measure cell proliferation since the dye absorbance is proportional to cell number.

Apoptosis Versus Necrosis

Differentiating the type of cell death can elucidate information about the mechanism of toxicity. For example, the plasma membrane of apoptotic cells remains largely intact, and therefore cell death via

may not be accounted for when using assays based on compromised membrane integrity, such as PI staining. Apoptosis involves a series of signaling cascades that are initiated by the cell after disruption of intracellular homeostasis. During apoptosis, phosphatidylserine is transported from the inner surface of the cell membrane to the outer surface. Annexin V binds specifically to phosphatidylserine and therefore can be used to label apoptotic cells. In contrast, necrosis is passive and results from irreversible cell damage, such as disruption of the plasma membrane. As mentioned previously, PI is a nuclear stain that only fluoresces in cells with compromised plasma membranes. Combined cell staining with annexin V–FITC (fluorescein isothiocyanate) and PI allows for the discrimination of intact cells (no staining), early apoptotic (FITC staining only), and late apoptotic or necrotic cells (both PI and FITC staining). Staining can be observed using fluorescence microscopy or quantified using flow cytometry.

Additional Study Design Considerations

Choice of Cell Type

Most nanoparticle cytotoxicity data is generated from monocultures of cells representative of specific organs of the body. Recently co-culture in vitro systems have been developed to better simulate the cellular environment in vivo [3]. Cell lines recommended in the ASTM E2526-08 and ISO 10993-5 cytotoxicity testing standard protocols include LLC-PK3 porcine kidney cells, HepG2 liver cancer cells, and 3 T3 mouse embryo fibroblasts. Other cell lines often used in nanoparticle cytotoxicity studies include A549 lung cancer cells, HEK293 human embryonic kidney cells, human epidermal keratinocytes, human dermal fibroblasts, and HeLa human epithelial cancer cells. Epithelial cells are often used because they form the outer barrier layer of organs and are usually the first cells to come into contact with nanoparticles during exposure. Regardless of which cell lines chosen, it is important to recognize that there may be differences in sensitivity between cell types [4]. In addition, if primary cells are chosen, these cells may have greater sensitivity than established cell lines.

Suitability for High-Throughput Screening

A considerable amount of time and money can be lost on nanoparticle development when they fail late in the process due to toxicity issues. The growing number of nanoparticles needing to be screened places new demands on cytotoxicity tests, with more attention being drawn to the use of high throughput methods. High-throughput screening (HTS) utilizes automated systems to rapidly conduct in vitro tests on microtiter plates. If multiple measurements are obtained from each well, then the process is referred to as high content screening. Several of the established cytotoxicity assays mentioned have been successfully adapted to 96-well and 384-well plates for use in high-throughput plate reader and flow cytometer setups [5]. Since the advantage of in vitro cytotoxicity screening is the ability to evaluate the toxicity of a large number of compounds, testing nanoparticle libraries with HTS is one strategy toward generating the volume of data needed to identify toxic nanoparticle formulations, elucidate nanoparticle structure-activity relationships, and better prioritize nanoparticles for further in vivo testing.

Potential Mechanisms of Nanoparticle Toxicity

Critical determinants of nanoparticle-induced cytotoxicity include exposed cell type, composition, and size of nanoparticles. In addition, through one-by-one evaluation of nanoparticles, structure-activity relationships specific to certain nanoparticle formulations have been observed. Several reviews provide detailed discussions on general and nanoparticle-type specific cytotoxicity, and recent examples are included in the References section. A summary of the current understanding on the mechanisms behind toxicity observed from six widely used nanoparticles with reference to recent reviews is presented in Table 2. The following section elaborates on some of the effects that are common across nanoparticle types.

Aggregation and Agglomeration

Nanoparticle stability can vary in different dispersion solutions, such as deionized water and cell

Nanoparticle Cytotoxicity, Table 2 Toxicological effects of some widely used NPs

NP	Toxicity observations	Reference
C_{60}	Unmodified C_{60} more toxic than functionalized (hydroxylated and carboxylated) C_{60}, residual THF solvent can contribute to toxicity observed from unmodified C_{60} cluster (nC_{60}) toxicity, photocatalytic behavior contributes to toxicity	[6]
CNTs	Unpurified as-prepared CNTs exhibit toxicity possibly due to presence of catalytic iron, single-walled CNTs elicit more toxic response than multiwalled CNTs	[7]
Au	Relatively "nontoxic," cationic AuNPs more toxic than anionic AuNPs, CTAB and citrate coatings contribute to toxicity but can be mitigated with PEG	[8]
Ag	Silver ion release contributes to toxicity, ROS generation and oxidative stress are two major mechanisms, different surface chemistries induce different DNA damage responses	[9]
QDs	Heavy-metal (e.g., Cd) leaching contributes to toxicity, shell and surface coating can reduce toxicity by containing core and modulating surface charge, toxicity also influenced by oxidative & photolytic stability	[10]
TiO_2	Anatase form ~10 times more cytotoxic than rutile form, photoactivity enhances toxicity, oxidant driven inflammation and protein nitration also associated with TiO_2 NP exposure	[11]

CNTs carbon nanotubes, *NPs* nanoparticles, *THF* tetrahydrofuran, *CTAB* cetyl trimethylammonium bromide, *PEG* polyethylene glycol

culture media. Aggregation, or the strong binding of nanoparticles together, and agglomeration, or the clustering of nanoparticles held together by relatively weak forces, can change the concentration and physicochemical properties of nanoparticles in solution. The properties affected are their size, size distribution, surface area, and therefore their surface reactivity. Since these parameters play a role in the toxicity of nanoparticles, it is important to keep in mind the potential contribution of aggregation and agglomeration during study design and analysis. Methods of reducing nanoparticle aggregation and agglomeration as well as homogeneously dispersing them in liquids include surface modifications and sonication before exposure. While surface modifications may improve nanoparticle stability, they may also influence their bioactivity. The durability of the surface coatings once inside biological environments is another issue, and release of the surface coatings may also contribute to the toxicity of nanoparticles.

Cellular Uptake

Uptake of nanoparticles into cells through endocytosis or phagocytosis processes is size-dependent and can vary greatly among cell types. The amount of nanoparticle internalization by cells can contribute to the observed toxicity as internalized nanoparticles may interact with cell organelles and disrupt cellular equilibrium or homeostasis. Transmission electron microscopy has been the preferred method of studying the cellular uptake of nanoparticles due to its high resolution, resolving the intracellular location of nanoparticles. Most studies have found internalized nanoparticles localize in endosomes or lysosomes. The low pH in endosomes and lysosomes has been suggested to dissolve or degrade nanoparticles releasing their core atoms. This can result in cytotoxicity, especially with metal nanoparticles, since metal ions can disrupt calcium homeostasis and/or generate reactive oxygen species.

Oxidative Stress and Inflammation

In vitro studies have shown that nanoparticles of various compositions generate free radicals and reactive oxygen species (ROS) more than larger particles, due to their higher surface area. ROS can damage cells by inducing oxidative stress, which involves a redox imbalance within cells often due to increased intracellular ROS and decreased antioxidants. The oxidative stress associated with nanoparticle exposure can result from:

- The presence of transition metals (e.g., iron, copper, nickel) catalyzing Fenton reactions.

- Generation of ROS at the particle surface.
- Phagocytosis of nanoparticles by inflammatory cells, such as alveolar macrophages and neutrophils.
- Physical damage due to nanoparticles interacting and/or entering mitochondria, altering mitochondrial function.

The cellular damage resulting from ROS generation and activation of inflammatory cells can also lead to inflammation. Markers of inflammation include the pro-inflammatory cytokines IL-1b, IL-6, and TNF-α plus the chemokine IL-8. Cytokines can be quantified using the enzyme-linked immunosorbant assay (ELISA), and ELISA results have been reported for metal oxides, carbon-based nanoparticle, silica, and quantum dots. However, carbon nanoparticles and metal oxides have also been reported to adsorb cytokines IL-8 and IL-6, interfering with the ELISA assay. These observations should be considered when interpreting results from nanoparticle inflammation testing.

DNA Damage

Of the cellular events that can occur in the absence of cell death, DNA damage is of critical concern as it can initiate disease development, such as cancer, and genetic abnormalities in reproductive cells. Both the nanoparticles themselves as well as nanoparticle-elicited events, such as overload and persistent inflammation, have been suggested to play a role in nanoparticle-induced genotoxicity. However, to date, limited genotoxicity testing of nanoparticles has been conducted. Genotoxicity may result from nanoparticle exposure due to their (a) small size which may facilitate their transport across cell and nuclear membranes where they may interact directly with DNA, (b) high surface area and/or chemical components (e.g., heavy metals) could generate ROS, which damage DNA. The comet assay has been used to detect DNA damage in individual cells using gel electrophoresis. Cells with damaged DNA appear as "comets" with intact DNA residing in the head portion and broken DNA pieces migrating away, forming the tail. A DNA-specific dye such as PI is used to read the gel, and the amount of DNA found in the tail is proportional to the amount of DNA damage. The comet assay is the most widely used genotoxicity test in published nanoparticle studies; however, it only nonspecifically indicates the presence of DNA strand breaks. The most investigated oxidative lesion caused by hydroxyl radical attack, 8-OHdG, has been shown to be induced in vitro by nanoparticles, including carbon nanotubes, CeO_2, gold, and TiO_2 nanoparticles [12]. Isotope-dilution gas chromatography–mass spectrometry (GC-MS) can be used to detect and quantify DNA damage mediated by ROS produced from nanoparticle interactions in cells. This method is more robust compared to the commonly used comet assay since it has been shown to differentiate among more than 20 DNA base lesions. Since oxidatively modified DNA lesions have different mutagenic potential, it is important to identify the types of DNA modifications that occur due to nanoparticle exposure.

Challenges for Future Nanoparticle Cytotoxicity Testing

It is important to consider that in vitro dose–response data serves as a starting point for evaluating the cytotoxicity of nanoparticles. Often in vitro data cannot be extrapolated to nor is representative of what would occur in vivo. For example, cells exposed to nanoparticles suspended in cell culture media poorly reflects inhalation exposure conditions, where lung cells at the air–liquid interface are exposed to aerosols of nanoparticles. In addition, in vitro cell culture systems are controlled environments, often containing a single cell line at low cell density, which may not accurately model normal cell–cell interactions or tissue injury signaling cascades. However, these shortcomings arise from the inherent differences between in vitro and in vivo systems. Cytotoxicity assays also presents unique challenges for nanoparticle testing since particulates differ from soluble chemicals. The following section describes areas for improvement in nanoparticle cytotoxicity testing.

Dose Metric

Compared to soluble chemicals, nanoparticles can agglomerate, aggregate and, as a consequence, settle out of solution depending on their size, concentration, and surface chemistry. These processes can affect the cellular dose, making quantification of the exposure concentration more complicated and less comparable across nanoparticle types. As a result, questions have been raised on the applicability of standard cytotoxicity assay protocols, developed to test soluble chemicals, for nanoparticles. Nanoparticle–cell interactions may be enhanced due to nanoparticles settling to the cell surface, leading to potential nanoparticle overloading of the cells. Resulting cytotoxicity may therefore be due to the higher exposure level from poor stability. It is important to account for this phenomenon when conducting nanoparticle in vitro dose–response assessment. In addition, the exposure dose is often inconsistently reported. There are several dose metrics that can be used, such as mass per volume, particles per volume, mass per surface area, or mass per cell number. To aid study interpretation, enough data should be reported so that the reported values can be converted to different dose metric units.

Most in vitro studies assess dosimetry by observing the dose–response relationship after external introduction of different concentrations of nanoparticles. Yet the internalized concentration of nanoparticles may better correlate to cytotoxicity [13]. A more informative representation of exposure dose would be to quantify the amount of nanoparticles externally attached or internalized by the cells (delivered dose) in addition to the concentration of nanoparticles added to the media (administered dose). Teeguarden et al. and more recently Wittmaack provide thoughtful discussions on how the particulate nature of nanoparticles introduces issues such as gravitational settling that impact dosimetry [14, 15]. Despite these examples, few studies make a distinction between administered and delivered dose. Knowing the external and internal fractions of the delivered dose could also give insights into the mechanisms of nanoparticle toxicity; however, experimental methods to resolve these concentrations need to be developed. Future research should work to correlate the deposited and internalized nanoparticle concentrations to observed cytotoxicity.

Nanoparticle Interference

Due to their high surface area, and in some cases optical properties, the presence of nanoparticles in the test solutions can interfere with cytotoxicity assay results. The increased adsorption capacity and increased catalytic activity resulting from their high surface area can either bind or interact with assay dyes leading to false readings. For example, carbon nanomaterials, especially single-walled carbon nanotubes (SWCNTs), have been reported to interact with cytotoxicity indicator dyes, including MTT, WST-1, Coomassie blue, alamar blue, and neutral red. Adsorption of the dyes to the carbon nanotubes results in either false negative data for the absorbing dyes or false positive data for the fluorescent dyes. Fluorescence quenching by carbon nanomaterials has also been reported with adsorption of the dye suggested as a reason for the quenching response. Other ways nanoparticles can contribute optical interference include physically blocking the emitted light, scattering the excitation light, and adding their own fluorescence signal (e.g., quantum dots or polystyrene beads). The reader is also referred to a review that describes in more detail these and other assay interferences derived from nanoparticles [16, 17]. Future developments could include designing label-free cytotoxicity assays, which would eliminate the issue of nanoparticle–dye interactions. As a safeguard, conducting multiple tests is advantageous to ensure valid conclusions are drawn.

Inter-Laboratory Consistency

While many studies using two or more different cytotoxicity assays have reported reasonable agreement in the results, large discrepancies have also been reported. Lanone et al. showed that for highly toxic or not toxic nanoparticles, inter-laboratory reproducibility was good, with LC_{50} values very similar for toxic nanoparticles [4].

However, their data also indicated that the reproducibility for nanoparticles with intermediate toxicity was lower in comparison. Since the cell lines and methodology were the same between labs, the variation between labs found suggests that there may be other factors unaccounted for in protocol development to ensure reliability in performance. These could include differences in nanoparticle storage methods, age of nanoparticle solution at testing, instrument calibration, and user performance may have contributed to the variability observed. Until data generated in different labs come within an accepted margin of error, inconsistencies in study findings and questions on methodology appropriateness during nanoparticle cytotoxicity assessment will remain.

Conclusion

Cytotoxicity testing constitutes just one of many steps required for nanoparticle biocompatibility and human health risk assessment. Traditionally, in vitro toxicity testing focuses on whether or not exposure to a potentially toxic agent results in cell death. However, changes in cellular function may serve as early signs of cytotoxicity when no cell damage or death may be apparent. As not all disruptive effects result in cell death, more extensive toxicity studies have attempted to determine the sublethal effects of nanoparticles. Given the variety of assays developed for cytotoxicity testing, it is important to verify that the endpoints of the assay used are appropriate for the hypothesis being tested. In addition, many of these assays were developed for testing soluble chemicals and may not be suitable for nanoparticle testing. Evidence of nanoparticle interferences with the indicator dyes has raised questions on the accuracy of currently available nanoparticle cytotoxicity data. Researchers should take care when interpreting the available literature as well as when conducting their own nanoparticle cytotoxicity testing. Ultimately, the goal of nanoparticle cytotoxicity assessments is to provide initial toxicity data to guide further risk assessment, which will inform decision making to protect human health.

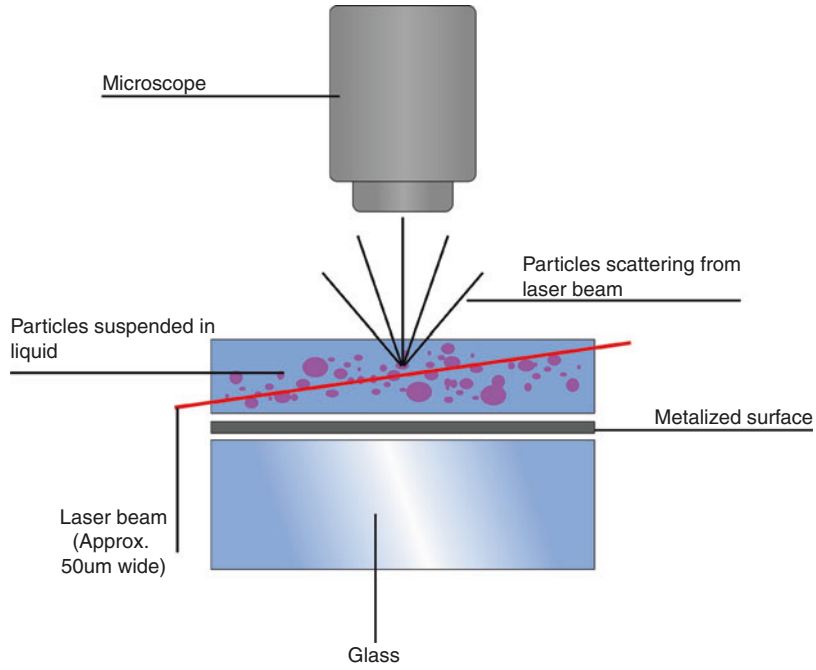
Definition

Nanoparticle Tracking Analysis (NTA) is an analytical methodology which facilitates the direct and real-time visualization and characterization of nanomaterials sized between 10 and 1,500 nm in liquid suspension.

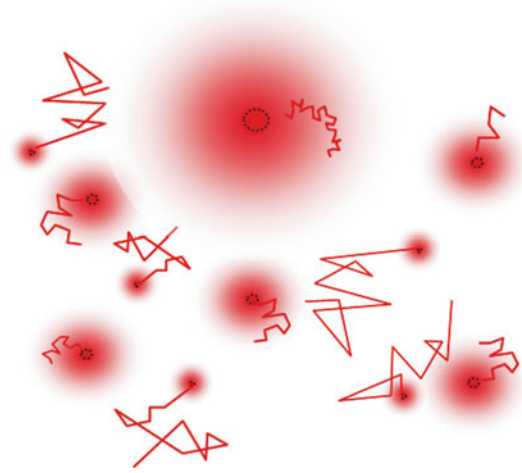


The aim of this entry is to address the need to characterize different properties of particles in the nanoscale, explain the principles of operation of Nanoparticle Tracking Analysis, explore the concentrations and size ranges measurable, look at other parameters characterized by Nanoparticle Tracking Analysis (NTA) as well as functions and applications of the technique.

The use of nanoscale materials is widespread throughout many different industries. Whether this is in pigments for the paint industry, or viruses used in the development and manufacture of vaccines, materials in this size range play a large part in the effectiveness and constancy of many products and processes. As differences in not only the size and concentration, but also shape and both magnetic and electrical charge of these materials can make a substantial difference to the end product, it is clear there is a need for processes and techniques that have the ability to characterize the different properties of these materials. There are numerous techniques that allow different aspects of this combination of properties to be determined, each with their own sets of benefits and limitations. These techniques include dynamic light scattering, also known as photon correlation spectroscopy, analytical disk centrifuge, flow cytometry, transmission electron microscopy, and scanning electron microscopy.

NTA is a multiparameter methodology that allows the direct and real-time visualization, sizing, and concentration determination of materials between 10 nm and 1.5 μm in liquid suspension. As populations of particles can be simultaneously analyzed on an individual basis, it is ideally suited for analysis of polydisperse systems ranging from 10–20 nm to 1–1.5 μm (depending on particle type). Concurrent measurements also allow users to acquire information on concentration, zeta potential, and relative intensity of light scattered and also to analyze fluorescently labeled particles as discussed by Carr et al. [1].

Principles of Operation and Analysis



NTA obtains particle size distributions of samples by utilizing properties of both light scattering and Brownian motion.

Nanoparticle Tracking Analysis, Fig. 1 Configuration of components used by NTA in order to visualize nanoparticles (Figure courtesy: NanoSight Ltd.)

A finely focused laser beam (usually from laser diodes operating at 642, 532, 488, or 405 nm) is passed through an optical flat with a beveled edge within a sample chamber. The angle that the laser is introduced to the flat is such that when the beam reaches the interface between the flat and the liquid layer of solvent containing the sample above it, it is refracted almost flat. This compression of the laser to such a low profile gives a very high power density. As such, a region of intense illumination is created within which particles can be visualized by utilizing the light scattered from them by Rayleigh scattering. Figure 1 shows a simplified version of the configuration of laser (running from left to right), glass flat, and objective lens used by systems using NTA. This allows particles to be visualized using light scattered.

A conventional microscope arrangement with a × 20 magnification objective fitted is used in order to visualize the particles in suspension. Coupled with this microscope arrangement, is a video camera (typically a CCD, emCCD, or CMOS). This camera, operating at 30 frames a second, is used to capture a video field of approximately 106 × 80 × 6 μm, within which particles in the sample can be seen moving under Brownian motion. Figure 2 shows the movement of a system of polydisperse nanoparticles under Brownian motion. On average, smaller particles move at a greater rate than larger particles, as can be seen by the relative step lengths of the trails following the particles (each change in direction or "step" indicating one video frame).

Nanoparticle Tracking Analysis, Fig. 2 Showing the movement of polydisperse nanoparticles under Brownian motion (Figure courtesy: NanoSight Ltd.)

Once a field of view containing particles in suspension moving under Brownian motion has been established, the NTA software is used to record a video file of the movement, typically 30–60 s in duration. This video file is then analyzed by the software which automatically finds the center of each scattering point using a proprietary version of a Centroid tracking algorithm to give x- and y-coordinates for each particle.

Equation 1: Centroid tracking algorithm

$$C_X = \sum_{i=1}^{n} \sum_{j=1}^{m} \frac{\left(x_i \cdot \mathbf{I}_{ij}\right)}{\sum_{i=1}^{n} \sum_{j=1}^{m} \mathbf{I}_{ij}}$$

where

- x_i = *Coordinate of pixel on the x-axis*
- $\boldsymbol{I}_{ij}$ = *Pixel intensity [2]* The center of the same scattering point is then found in the next frame, and the distance that the particle has moved in that time is calculated.

Equation 2: Finding displacement of particles between frames (r)

$$r^2 = \Delta x^2 + \Delta y^2$$

By tracking this movement over several consecutive frames, the software determines the mean displacement and hence the diffusion coefficient of each particle within the field of view. Provided that the temperature (T) and the viscosity (η) of the system are known, the Stokes-Einstein equation (Eq. 3) is then used to relate the diffusion coefficient to the hydrodynamic sphere equivalent particle diameter of the material. The Stokes-Einstein equation is as follows:

Equation 3: The Stokes-Einstein equation

$$Dt = \frac{K_B T}{3\pi\eta d_h}$$

where

- Dt = *Diffusion coefficient*
- K_B = *Boltzmann constant*
- T = *Temperature*
- η = Viscosity
- d_h = *Sphere equivalent hydrodynamic diameter particle size*

As Brownian motion occurs in three dimensions, a modified version of the Stokes-Einstein equation is needed for NTA as this technique only observes the motion in two dimensions. However, it is possible to determine Dt from the mean squared displacement of a particle in one, two, or three dimensions (Eq. 4a–c, respectively).

Equation 4: (a, b, and c): Tracking Brownian motion in different numbers of dimensions

$$\overline{(x)^2} = \frac{2TK_B T}{3\pi\eta d} \quad (a)$$

$$\overline{(x, y)^2} = \frac{4TK_B T}{3\pi\eta d} \quad (b)$$

$$\overline{(x, y, z)^2} = \frac{2TK_B T}{\pi\eta d} \quad (c)$$

So in the case of Nanoparticle Tracking Analysis where measurements are made in two dimensions:

Equation 5: Tracking Brownian motion in two dimensions to determine particle size

$$\frac{\overline{(x, y)^2}}{4} = Dt = \frac{K_B T}{3\pi\eta d_h}$$

Equation 5 is applied to the trajectories of each of the particles within the field of view allowing the user to obtain a reading of particle size (hydrodynamic diameter, in nm) against concentration (absolute in particles per ml).

Other Measurable Parameters

Concentration

The field of view interrogated by NTA systems is of known dimensions and therefore known

volume which means that determining the concentration of particles in terms of particles per ml can easily be achieved using the NTA software. As the software not only tracks and sizes every particle within the field of view but also counts the number of particles identified, a concentration can be achieved by extrapolation of this number.

The field of view measures 106 × 80 × 6 μm. This leads to a volume of 50,880 μm^3. Equation 6 shows how this is used in order to determine particle concentration.

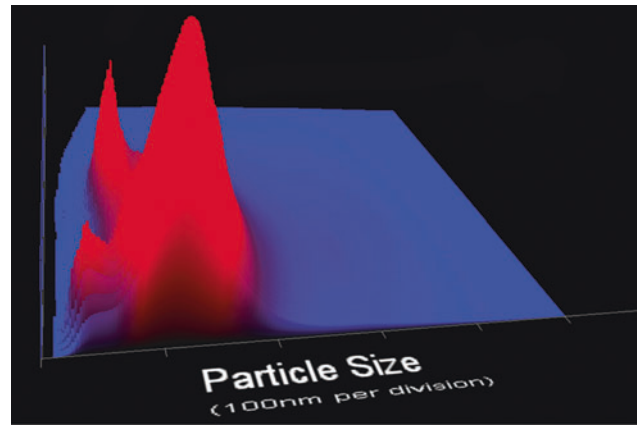
Equation 6: Extrapolation of particle count to concentration in particles per ml

$$\text{Concentration} = P_{count} \times \left(\frac{10^{12} \mu m^3}{50,880 \mu m^3} \right)$$

$$\text{Concentration} = P_{count} \times 1.97 \times 10^7$$

where P_{count} = Number of particles within the field of view.

In a 2010 study Filipe et al. investigated the ability for NTA to measure concentration and concluded that the capability of NTA to determine approximate concentration ranges for submicron particles offers an advantage over other techniques for particle sizing [3]. A study conducted by Du et al. found that concentrations obtained using NTA correlated very well with those they calculated using other methodologies [4].



Scatter Intensity

While the size of particles is determined by the NTA software using Brownian motion, the system also measures the relative amount of light scattered by each particle in the scattering volume. These two properties can be plotted as a function of one another allowing differentiation of particles not only by size, but also by composition. For a mixture of similar-sized particles with significantly different refractive indices (e.g., gold particles of 100 nm and polystyrene particles of 100 nm), both would appear in the same size distribution, but can be separated when size is plotted against relative refractive index. Figure 3 shows a distribution of 30-nm and 60-nm gold nanoparticles mixed with a population of 100-nm polystyrene particles, separated by both particle size and the relative amount of light scattered. Particle size is given on the x-axis, with relative intensity on the y-axis and number of particle on the z-axis.

These populations may have merged with one another on a simple particle size versus concentration graph. However, by employing the third dimension of relative intensity of light scattered, it is easy to define the three discrete populations of materials.

Fluorescence

Being a direct visualization and tracking method, NTA does not rely on interference from coherent light sources. This means that fluorescently labeled or inherently fluorescent materials can be

Nanoparticle Tracking Analysis, Fig. 3 Illustrating differentiation of particle material by comparing particle size (x-axis), relative intensity (y-axis), and number of particles (z-axis) (Figure courtesy: NanoSight Ltd.)

analyzed without affecting the results that are obtained. In order to do this, typically a green laser (532 nm), a blue laser (488 nm), or a violet laser (405 nm) is used in place of the usual red laser used within the system allowing the fluorescent excitation of particles with absorption spectra that span these wavelengths. By comparing profiles generated with and without a filter removing the excitation wavelength present in the optical path of the system, the user is able to determine the effectiveness of their labeling process, or the proportion of labeled to unlabelled material within their sample, and whether or not the presence or absence of fluorescence is in any way related to the hydrodynamic sphere equivalent particle size.

Suspension Viscosity

NTA can also be used to determine unknown viscosities of fluids. The system uses the Stokes-Einstein equation in order to relate the diffusion coefficient of the material to the sphere equivalent particle size. However, if the size of the particles in question is already well characterized, then it is possible to rearrange the Stokes-Einstein equation as shown in Eq. 7 and use the known parameters of diffusion coefficient, particle size, and temperature in order to use the collected data to determine the viscosity of the system. This will be briefly discussed in the section on drug delivery studies.

Equation 7: Stokes-Einstein equation to find viscosity

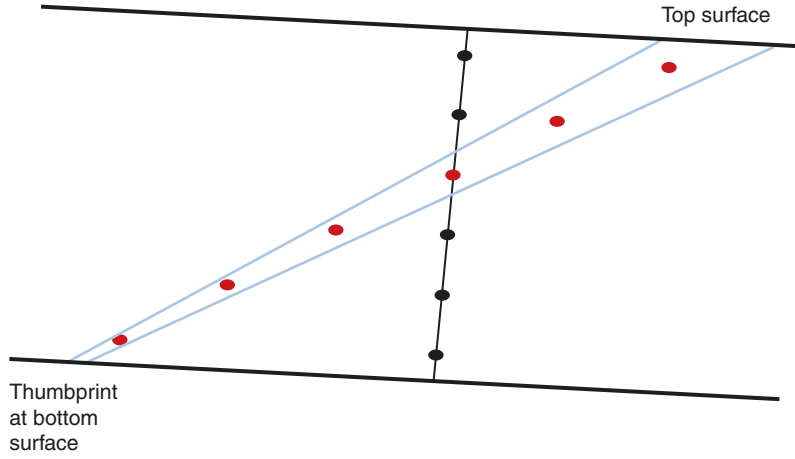
$$\eta = \frac{K_B T}{3\pi D_t d_h}$$

where

- D_t = *Diffusion coefficient*
- K_B = *Boltzmann constant*
- T = *Temperature*
- η = Viscosity
- d_h = *Sphere equivalent hydrodynamic diameter particle size*

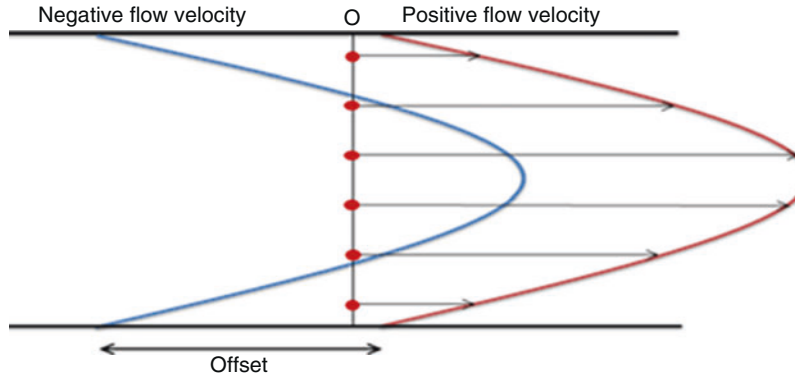
Zeta Potential

The zeta potential of a system is a measure of charge stability and has an effect on all particle-particle interactions within a system. Understanding zeta potential is of critical importance in controlling dispersion and determining the stability of a nanoparticle suspension. The zeta potential is the electric potential at the slip plane between the bound layer of solvent molecules surrounding the particle and the overall solution. This can be closely linked to the particle's surface charge in simple systems but is also heavily dependent on the properties of the solvent in which the particles are suspended. A higher level of zeta potential results in greater electrostatic repulsion between the particles, which results in less aggregation and flocculation.



In order to carry out investigations into the zeta potential of a system, the hardware used for NTA is adapted so that the sample chamber is fitted with platinum electrodes through which an electric field can be applied to the cell.

This field causes motion of both the sample particles (electrophoresis) and the diluent (electroosmosis). The NTA software records the apparent drift velocity for each tracked particle, which will be a superposition of both electrophoresis and electroosmosis. This total velocity is measured at different depths within the sample chamber (as shown in Fig. 4, each dot corresponding to a depth of measurement), making it possible to separate these components and obtain a measurement of the electrophoretic velocity (due to the force impinged directly on the particles), and hence the zeta potential of the particles.



By employing the assumption that the net electroosmotic flow summed over the chamber depth will be zero, as should be the case for a closed system, the electroosmotic profile can be inferred, as shown in Fig. 5.

Using the calculated flow profile, the velocity component caused by electroosmosis is removed from the tracked velocities for each particle. The corrected drift velocities then give a measure of the electrophoretic mobility of individual particles.

The electric field strength (E) within the flow cell is determined using the voltage (V) applied through the sample by the electrodes and the distance between the electrode surfaces (d) (Eq. 8).

Nanoparticle Tracking Analysis, Fig. 4 Diagram showing profile map positions where six standardized depth locations intersect the laser beam (Figure courtesy: NanoSight Ltd.)

Nanoparticle Tracking Analysis, Fig. 5 Total velocity profile measured using NTA (*red*) and electroosmotic velocity profile (*blue*) inferred by subtraction of a contact offset to obtain a velocity profile that sums to zero over the channel depth (Figure courtesy: NanoSight Ltd.)

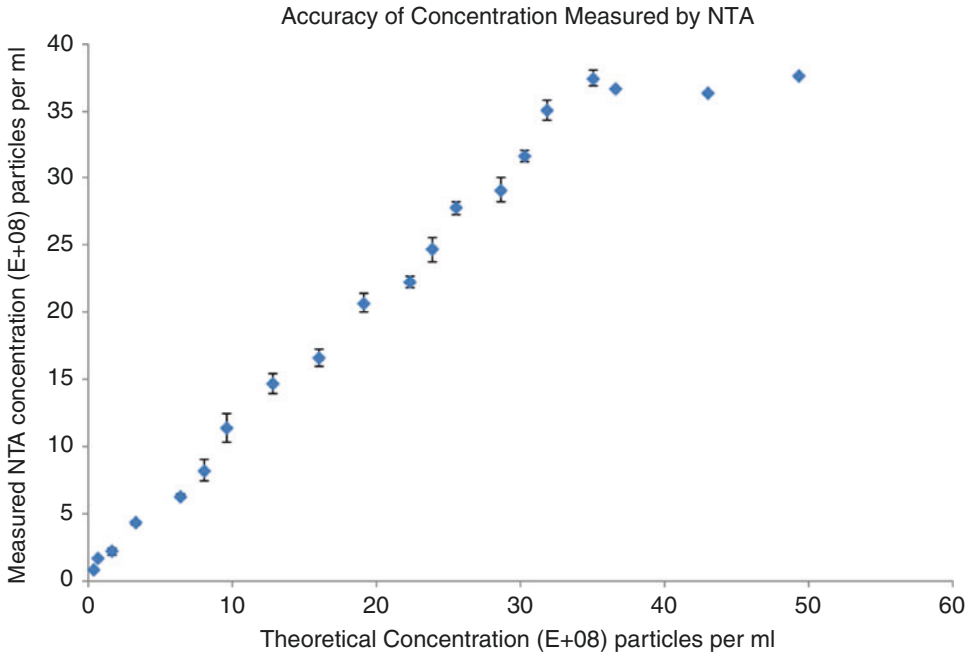
Equation 8: Determining electric field strength

$$\mathrm{E} = \frac{\mathrm{V}}{d}$$

The particle velocities can then be converted into electrophoretic mobilities (velocity divided by electric field strength).

By application of the Henry equation using the Smoluchowski approximation (appropriate for aqueous diluent media with moderate electrolyte concentration, seen in Eq. 9), the zeta potential (ZP) for each particle can be calculated:

Equation 9: Calculation of zeta potential



$$ZP = \frac{\mu\eta}{\epsilon_0\epsilon_r}$$

where μ is the electrophoretic mobility of the particle, ϵ_0 is the permittivity of free space, ϵ_r is the relative sample solution permittivity, and η is the sample solution viscosity.

This particle-by-particle approach allows different charge populations within a sample to be determined rather than being lost in the "noise" of an ensemble technique.

Concentration and Size Ranges Measurable

The ability of NTA to analyze polydisperse samples comes from the ability to track and analyze each particle in the system individually, irrespective of the others around it. It is therefore important that a sufficient number of particles are analyzed during analysis to ensure that the data produced is statistically viable. Repeatable and accurate results can be obtained when analyzing

Nanoparticle Tracking Analysis, Fig. 6 Relationship between absolute concentration (x) versus that measured by NTA(y) (Figure courtesy: NanoSight Ltd.)

particles in concentrations between 10^7 and 10^9 particles per ml. Below this concentration, the number of particles within the field of view is so low that the typical analysis time of 30–60 s will only allow a very small number of particles to be analyzed, leading to inaccuracies of a statistical nature. Above 10^9 particles per ml, the field of view becomes very crowded. As Brownian motion is a random process, when two particles cross over, the tracking software is unable to determine which particle is which and must therefore stop tracking both to avoid erroneous tracking. When the field of view is crowded, the rate at which crossover of particles occurs is so great that there is insufficient time to determine diffusion coefficient and therefore size.

A high concentration of particles also leads to erroneous results when trying to identify solution concentration. Figure 6 shows the relationship between the concentration of particles in a solution and the concentration as measured using NTA.

It is clear that the correlation between the actual and measured concentration remains stable until a concentration of around 3.5×10^9 particles per ml whereupon the accuracy of the NTA concentration reading begins to deteriorate.

The typical size range between which NTA operates is from 10 to 20 nm up to 1.5 μm. The lower limit of this figure is mainly dependent upon the amount of light scattered by the particles. This value in turn varies in relation to particle size, shape, refractive index (real and imaginary), illumination power, wavelength, power, and polarization as well as solvent refractive index. The amount of light falling on the detector also fluctuates according to many variables including efficiency of optics, sensitivity, and spectral response of the camera.

In their 1983 work, Bohren et al. comprehensively describe the theory of light scatter and the formula for Rayleigh scattering of small particles [5]:

Equation 10: Rayleigh scattering of light by small particles

$$\frac{\mathbf{I}}{\mathbf{I}_{in}} = \frac{16\pi^4 a^6}{r^2\lambda^4}\left(\frac{n^2-1}{n^2+2}\right)\sin^2\psi$$

where

- a = *Particle radius*
- n_1 = *Refractive index of particle*
- n_2 = *Refractive index of solvent*
- λ = Wavelength of light
- I_{in} = *Incident power per unit area*
- I = *The scattered power per unit area*
- r = *Distance from the scattering region and*
- ψ = Angle between input polarization and scattering direction

The total scattering (P_{scat}) into an aperture of collection angle θ (numerical aperture NA = sin θ) is then:

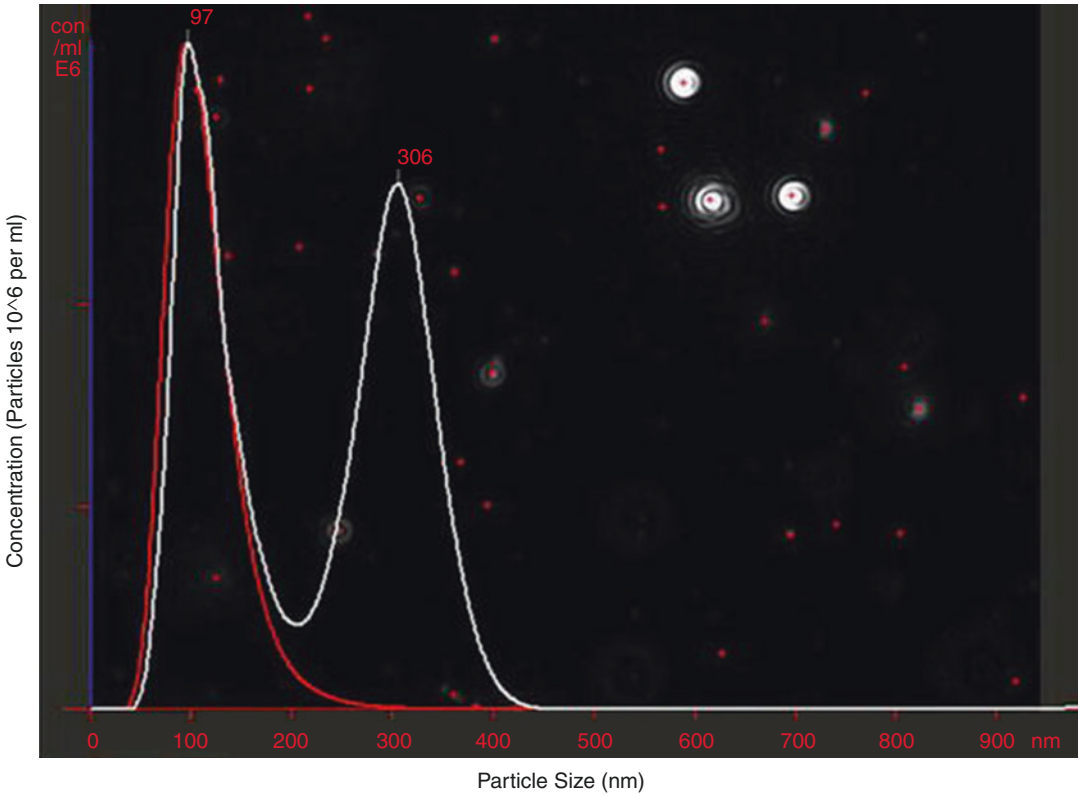
Equation 11: Total light scattered into an aperture

$$\mathbf{P}_{\text{scat}} = \frac{64\pi^4 a^6}{\lambda^4}\left(\frac{n^2-1}{n^2+2}\right)\eta_0 \mathbf{I}_{\text{in}}$$

where $\eta_0 = \frac{(1-\cos\theta)}{4} + \frac{1-\cos^3\theta}{12}$

As the system has fixed laser wavelength and power as well as a fixed aperture and detection angle, the variables that affect the lower limit of detection consist primarily of the particle size and the relative refractive index difference between the particles and the solvent in which they are suspended.

As light scattering at these scales varies as a function of radius [6], as particles reduce in size, they scatter considerably less light. The functionality of NTA relies on the ability to visualize the particles, and so if the amount of light scattered is not sufficient that the particles can be seen, then it is not possible to size them. For strongly scattering materials such as colloidal gold, the lower limit of detection is around 10 nm. For those materials with a weaker scattering potential, such as biological materials, the lower limit of detection is more likely to be 20–40 nm. The upper size limit of the system is determined by the rate of Brownian motion. When particles reach a certain size, the rate of Brownian motion becomes so low that inherent centering errors in the software start to negate the tracking of the movement leading to inaccuracies in sizing. For dense, high Ri particles such as gold, their rapid sedimentation rate and excessive scattering restrict the upper size at which they can be analyzed to approximately <500 nm. This limit is typically 1–2 μm.



Applications of Nanoparticle Tracking Analysis

Owing to the varied nature of work at the nanoscale, NTA has been found to be of use across a variety of different applications.

Virology and Vaccine Production. Due to the nature in which NTA tracks, sizes, and counts particles on an individual basis, the methodology allows users to obtain an immediate and direct estimation of product purity and concentration. This also allows researchers and manufacturers to monitor the degree and rate of formation of aggregates within a virus preparation, complementing the process of product optimization and purification. An example of the use of NTA for virus purification studies can be seen in Fig. 7. This shows the difference between a partially purified virus preparation (white line) and the same sample having undergone a successful purification protocol, removing all the aggregated material or contaminates (red line). In this figure, the x-axis represents the particle size and the y-axis represents the particle concentration in virus particles per ml.

Exosomes. Originally, it was thought that microvesicles (typically in the 100 nm to 1 μm range) and nanovesicles (also known as exosomes, with a size range of around 30–100 nm) were cellular debris. However, it is now appreciated that these cell-derived particles are of significant importance and play an important role in cell-to-cell communication and cell signaling.

Recent research suggests that exosomes are present in significantly elevated concentrations in samples taken from patients with a number of diseases including preeclampsia, diabetes, coronary artery disease, and cancer. NTA is not only able to visualize, size, and determine concentration of these materials in liquid suspension, but when used with specific fluorescent labels, for example, antibody-mediated fluorescent labeling,

Nanoparticle Tracking Analysis, Fig. 7 Illustrating the use of NTA in virus purification processes with purified (*red line*) against non-purified (*white line*) product shown (Figure courtesy: NanoSight Ltd.)

it can be used to selectively analyze specific populations within a complex sample.

In their evaluation of systems for the analysis of exosomes in liquid suspension, Harrison et al. concluded that NTA's single-particle tracking and sizing offers advantages over bulk scattering measurements found in other light scattering methodologies [6].

Nanoparticle Toxicology and Ecotoxicology. Current research suggests that the biological response to nanoparticles in living organisms, and thus any potential health implications, can be affected by particle size, composition, shape, aggregation state, and exposure route. Before any studies into these effects can be carried out, it is imperative that the particles used are as well characterized as possible, in particular their size distribution and concentration in appropriate test media. Researchers are also interested in what happens when engineered nanoparticles are released into the natural environment.

Protein Aggregation. Biological activity and immunogenicity of a biopharmaceutical product are both highly susceptible to the state of protein aggregation. These aggregates span a broad range of sizes, from the small oligomers (a few nanometers) to insoluble micron-sized aggregates that can contain millions of monomer units. Determining and understanding the state of aggregation in these systems can not only help in improving product stability, but can also lead to efficiency gains and aid in process optimization. Individual protein monomers are far smaller in size than the lower resolving limit of the Nanoparticle Tracking Analysis methodology. When a solution containing only protein monomers is viewed using this technique, a background "haze" is seen within which individual monomers cannot be resolved. However, when aggregates start to form within the system, and reach around 25–30 nm in size, it is possible to differentiate them from the background signal and count and

size them as the technique normally would. This, combined with the possibility of controlling the temperature within the sample cell, from 10° below ambient to 60 °C, can allow characterization of the parameters that cause aggregation within the product. A full critical evaluation of the NTA technique by Filipe et al. concluded that the technique was suitable for the analysis of protein aggregates; however, care should be taken that sample preparation does not affect the aggregate distribution.

Drug Delivery. By utilizing Nanotechnology, it is possible to deliver drugs to a specific area of the body. Localized drug delivery allows the required drug volume to be reduced, along with any associated negative health implications. Both poorly soluble and fragile drugs can be carried using drug delivery vectors such as degradable polymeric nanoparticles or liposomes. It is clear that both the particle size and concentration will affect the payload, and so Nanoparticle Tracking Analysis provides a unique way to monitor these properties in liquid suspension. The location of drug delivery can also have an impact on the effectiveness of the drug. If particles are unable to pass through biological barriers, then these can act as natural filters, preventing the drug from reaching the desired location. By using Nanoparticle Tracking Analysis to compare concentrations of particles before and after passing through membranes and barriers, researchers are able to study the ability for the drug delivery vector to reach the desired location.

Nanobubbles. Nanobubbles are stable pockets of gas in liquid suspension which can be applied to drug delivery, cleaning, and sterilization. As Nanoparticle Tracking Analysis allows direct visualization, sizing, and concentration determination of the nanobubbles in liquid suspension, users are able to characterize their product in the final liquid state. This could prove to be difficult when using other techniques such as electron microscopy, due to the preparation required in order for electron microscopy to function.

Inks and Pigments. In the field of inkjet applications, the particle size and concentrations of pigment particles are very important. The particle size has a great effect on the strength of the color generated, and aggregation of the particles could lead to the blockage of nozzles. The high-resolution size distribution that Nanoparticle Tracking Analysis can provide allows both studies into the relationship between size and color to be analyzed, as well as the conditions that lead to aggregation of pigment particles.

In conclusion, Nanoparticle Tracking Analysis is an analytical technique which allows the direct visualization, sizing, and concentration determination of materials between 10 and 1,500 nm in liquid suspension. The technique works by tracking the Brownian motion of each particle within the field of view, irrespective of the others, and relating this movement to the sphere equivalent hydrodynamic diameter of the particle. This parameter is calculated for each particle within the field of view, and a particle size distribution is produced. In addition, particle concentration, light scattering intensity, zeta potential, and fluorescent properties can also be measured. The technique is of use in a variety of different applications, both as a competing and complementary technique to other particle sizing methodologies.

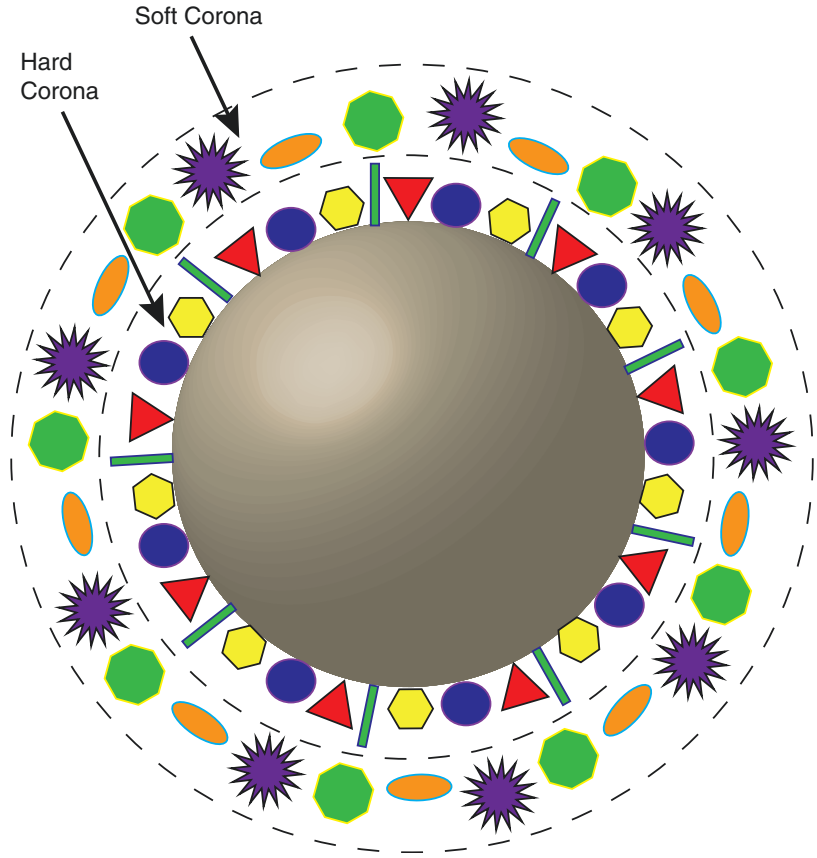
Definition



Nanoparticle–biocorona: a layer(s) of biomolecules that adsorbs to the surface of a nanoparticle in a biological environment.

Introduction

Following their introduction into a physiological environment, the surface of nanoparticles readily associates a variety of biomolecules including proteins, peptides, and lipids forming a nanoparticle–biocorona. This biocorona can be subdivided into two portions, the "hard" which consists of tightly bound biomolecules and "soft" that consists of loosely associated biomolecules (Fig. 1). The "soft" biocorona sits on top of the "hard" biocorona and is more dynamic in nature with biomolecules rapidly being exchanged. The composition of the biocorona is dependent on the physicochemical properties of the nanoparticle as well as the identity of the biological environment. The addition of the biocorona can modify numerous nanoparticle characteristics including hydrodynamic size, charge, and state of aggregation; and most importantly it modifies the nanoparticle biological interface. The addition of the biocorona, and the new interface it imparts, mediates subsequent physiological interactions with additional biomolecules and cellular membranes and receptors. Ultimately, the addition of the biocorona on the surface of nanoparticles can alter their activity, biodistribution, pharmacokinetics, cellular uptake, toxicity, and clearance. Understanding and controlling the biocorona is necessary to enhance the therapeutic efficacy of nanomedicines while also mitigating unintended toxicity.

Methods to Evaluate Coronal Structure and Composition

The evaluation of the nanoparticle–biocorona typically is performed by introducing a nanoparticle into a biological environment or by collecting samples such as serum, plasma, gastrointestinal fluid, or alveolar lavage fluid, which represent the in vivo environment. Following introduction into a biological environment, nanoparticles are often isolated for analysis through centrifugation or size exclusion chromatography. The structure and properties of the biocorona are evaluated by assessments of biocoronal thickness, charge,

Nanoparticle–Biocorona, Fig. 1 Graphical representation of the nanoparticle–biocorona. The "hard" biocorona is composed of tightly bound biomolecules, which do not readily dissociate from the nanoparticle. The "soft" biocorona is composed of loosely bound biomolecules and is dynamic in nature with biomolecules constantly being exchanged

strength of protein interactions, and protein conformational changes. The thickness of the biocorona on the surface of the nanoparticle can be studied through the use of dynamic light scattering, size exclusion chromatography, differential centrifugal sedimentation, and/or transmission electron microscopy. Alterations in surface charge or zeta potential can be evaluated by microelectrophoresis. The strength of protein interactions can be studied through the use of isothermal titration calorimetry and surface plasmon resonance, whereas circular dichroism and Fourier-transform spectroscopy and computational modeling are often used to determine changes in protein structure due to association with the nanoparticle. Evaluation of the compositional biomolecular content of the biocorona is performed by isolating biomolecules from the surface of the nanoparticle and utilizing SDS-PAGE and/or liquid chromatography–tandem mass spectrometry for the identification and quantification of individual components. Removal of the "hard" corona for biomolecule identification is difficult due to the strong association between the biomolecules and the nanoparticle, whereas the "soft" corona can easily be lost during processing due to its dynamic nature and weak interactions.

Directing Protein Adsorption for Nanomedicine Targeting

The field of nanomedicine is beginning to utilize the nanoparticle–biocorona to increase the targeting capability of nanoparticles for drug delivery. Typically, the formation of the biocorona has been associated with a decrease in cellular uptake; however, biocoronas formed of specific

ligands to direct nanoparticles to particular receptors have shown promise under in vitro experimentation. In contrast, the biocorona may have unintended consequences on nanoparticle delivery. For example, the enhanced targeting ability of nanoparticles with a transferrin biocorona was lost in vivo due to the addition of the endogenous biocorona [1]. The complexity of the biocorona as it pertains to nanoparticle cellular uptake will influence the targeting of nanomedicines. It has been demonstrated that the association of a specific protein with nanoparticles of differing size and surface coatings can have vastly different effects on cellular uptake, thereby modifying the capacity to effectively target nanotherapeutics. For example, the formulation of an IgG biocorona on 20 nm silica-coated silver nanoparticles increases cellular uptake in human epidermal keratinocytes. In contrast, an IgG biocorona on 110 nm silica-coated silver nanoparticles had no effect on uptake, whereas cellular uptake was reduced by changing the surface coating to citrate on the 110 nm silver nanoparticle with an IgG biocorona [2]. Instead of preloading the biocorona onto nanoparticles, it may be more feasible to synthesize nanoparticles with specific physicochemical characteristics, which allow for the enrichment of certain biomolecules, resulting in a biocorona that facilitates targeted uptake. For example, PEG-coated polyhexadecyl cyanoacrylate nanoparticles have been shown to translocate from the circulation into the brain, whereas non-PEG-coated polyhexadecyl cyanoacrylate did not readily cross the blood–brain barrier [3]. Upon investigation, this differential uptake was related to the identity of the biocorona, specifically the preferential abundance of apolipoproteins in the biocorona of PEG-coated nanoparticles.

Adverse Biological Implications of the Nanoparticle–Biocorona

The association of the biocorona with nanoparticles may result in unintended adverse biological consequences. Binding of biomolecules to the surface of nanoparticles can result in protein modifications and conformational changes, which may facilitate toxicity through activation of the immune system. Many nanoparticles have been shown to associate with biocoronas that are rich in immunoglobulins and complement proteins, which act as opsonins, facilitating uptake of nanoparticles by phagocytic cells (initiating an inflammatory response) as well as resulting in increased biodistribution to the liver and spleen. Albumin biocoronas however have been shown to increase retention time in the circulation, whereas apolipoprotein-rich biocoronas cause increased distribution into the brain. These effects demonstrate biocorona-dependent differences in the biodistribution of nanoparticles, which need to be taken into consideration for their effective utilization in biomedical applications to reduce off target effects. The addition of the biocorona can also have unintended consequences on the release of drugs from nanoparticles by not only interfering with biodistribution but also possibly causing premature or delayed release of drugs from the nanoparticle carrier [4].

Future Directions

Recent research efforts have begun evaluating how to regulate the nanoparticle–biocorona for applications in nanomedicine. However, most of the work has been done to identify the protein content of the biocorona, while less emphasis has been placed on other biomolecules such as lipids and other macromolecules. Many studies have also evaluated the influence of diverse nanoparticle physicochemical characteristics on the composition of the nanoparticle–biocorona; however, modifications in the physiological environment, which may influence the nanoparticle's pharmacokinetic profile, still require extensive study. Further, methods and investigation of the more dynamic "soft" corona need to be performed. Most studies also focus on an individual time point of biocorona formation; however, the kinetics of the biocorona lacks sufficient

analysis. Furthermore, since the "soft" corona is more dynamic with almost a constant exchange of biomolecules, studies need to be performed, addressing the impact of possible biomolecule conformational changes and oxidative modifications and the likely resulting biological consequences. Currently, the evaluation of the biocorona is limited to in vitro assessment; however, extensive in vivo analysis is needed, particularly in human populations of various underlying disease states. Ultimately, for the future development of effective nanomedicines, it will be necessary to predict the identity and the biological impact of the biocorona based on the physicochemical properties of the nanomaterial.

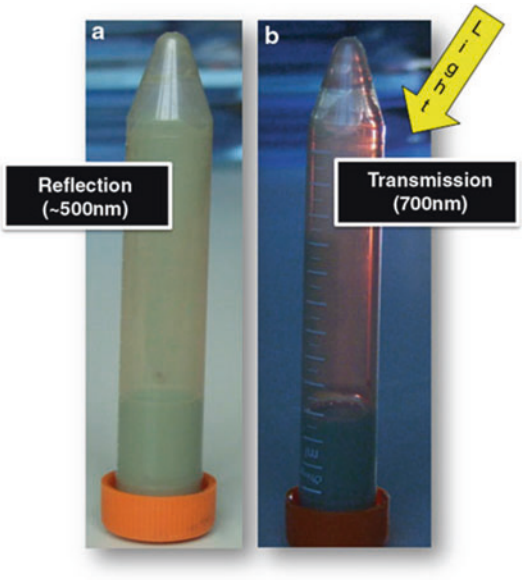
Definition



Ultrafine particles featuring a size distribution in the nanometer range.

Introduction

Studies of nanostructured materials have been steadily developing in recent years; in particular, metallic, magnetic, and oxide nanoparticles (NPs) have become a subject of increasing scientific interest. At the present time they hold a place of great importance that covers a wide range of potential applications including biomedical, optical, and electronics.

Although NPs are generally considered an invention of modern science, they actually have a very long history: centuries ago, NPs of silver, gold, and copper were used by artisans to decorate pottery; the first examples date from the ninth century A.D. and were found in Mesopotamia [1]. An important archeological finding is a Roman cup, currently at British Museum in London, called the Lycurgus cup (fourth century A.D.). It contains tiny amounts of colloidal gold and silver, which give it unusual optical properties: when illuminated from outside, it appears green; when retro-illuminated by an inner source, it glows red. An example of this property is well represented in Fig. 1a, b that shows a special silver colloidal NPs ink (by Politronica® Inkjet Printing Technologies S.r.l.) in emitted (green) and transmitted (red) light.

In addition, NPs exist widely in the natural world, for example, as photochemical by-products generated by plants and algae. They have also been created for thousands of years as by-products of combustion and cooking, and more recently from industrial and vehicle exhausts [2].

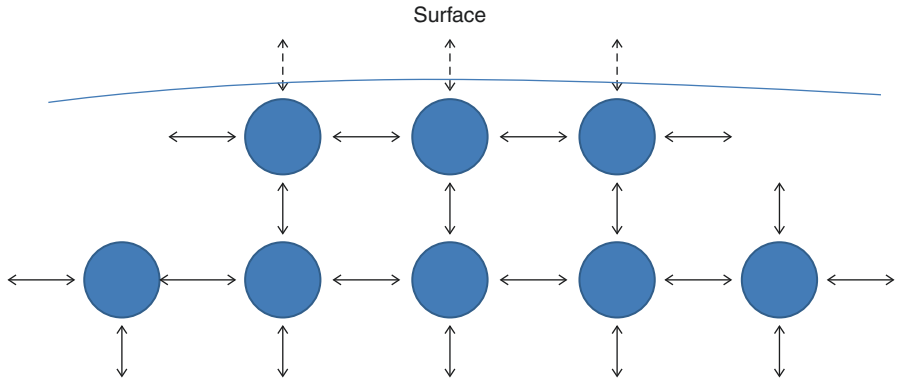
Definition of Nanoparticles

The term "nanoparticles" (NPs) is a very general one and mainly identifies ultrafine particles in the size of a nanometer. The definition of NPs differs depending upon the materials, fields, and application one refers to. In a narrow sense, they are regarded as the particles smaller than 10–20 nm but, generally speaking, all particles in the 1 nm–1 μm range may still be defined as NPs [3].

The principal parameters of NPs are their shape (including aspect ratios where appropriate), size, and the morphological substructure of the substance.



"Size Effect" and Size-Dependent Properties

NPs represent a bridge between bulk materials and atomic, ionic, or molecular structures. Bulk materials should have constant physical properties regardless of its size, whereas at the nanoscale, size-dependent properties are often observed.

The changes in the physical properties with particle size (from bulk to NPs) are called "size effects": by decreasing particle size, the solid particles generally tend to show different properties from the bulk material due to the increased importance of surface upon bulk. Even physical properties like melting point and dielectric constant may change. In addition, it is important to underline that the "size effect" not only allows one to discriminate between physical properties of the bulk when compared to NPs, but also to distinguish among NPs having different size distributions.

For bulk materials larger than one micrometer, the fraction of atoms, ions, or molecules at the surface is insignificant in relation to the fraction corresponding to its volume. In NPs the fraction of atoms, ions, molecules located at the surface becomes greater and, therefore, more active because it is subject to asymmetric interaction forces due to a different bonding state, the bonds at the interface between solid and vacuum (or liquid or atmosphere) are broken (Fig. 2). This affects either the properties of the particle itself or its interaction with other materials.

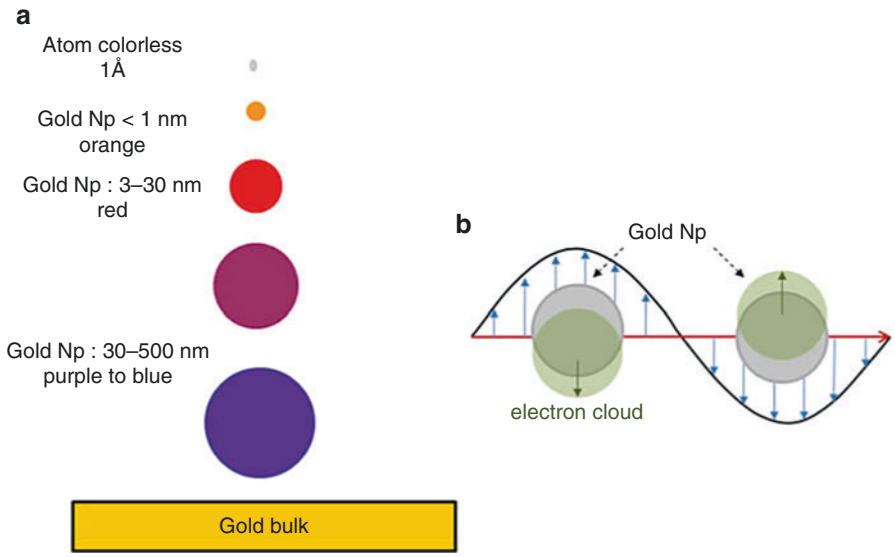
One of the most important size-dependent consequences of the "size effect" of NPs is the drastic reduction of the *melting point* of ultrafine particles

Nanoparticles, Fig. 2 Schematic representation of surface of a NP. The bonds on the solid surface are broken up

if compared to that of bulk material: the high surface area to volume ratio of NPs provides a big driving force for diffusion. NPs, in fact, tend to be able to move easier at lower temperatures. For example, the melting point of gold is 1,336 K, but if the size of material decreases to 2.5 nm, it becomes about 570 K [3].

A second size-dependent feature of NPs is the *dielectric constant*. The use of NPs embedded in electronic devices allows one to improve the product performance making smaller devices with high dielectric constants. $PbTiO_3$ represent a significant example of this feature because its dielectric constant tends to increase considerably as the particles become smaller than about 20 nm [3].

NPs often possess unexpected *optical properties* as they are small enough to absorb the light with a specific wavelength: a coherent oscillation of the conduction band electrons is induced by interaction with the optical electromagnetic field. Consequentially, a transmitted light with different color depending upon the kind of metal and particle size is obtained. This resonance is called Surface Plasmon Resonance (SPR) (Fig. 3) [4].



Another size-dependent feature of NPs are *mechanical properties*. Nanocomposites with nanoscale dispersed phases and nanocrystalline materials provide quite different mechanical properties when compared to conventional microstructures. The hardness of the crystalline materials generally increases with the decreasing of crystallite size and the mechanical strength of the metal and ceramic materials considerably increases by decreasing grain size down to the nanoscale or by making composites at the nanoscale [5].

The NPs are seldom used by themselves; they are dispersed instead in other materials or combined with them. The dispersion process is a crucial point for the NPs technology as well as their preparation methods, because the performance of final products is affected by their dispersion conditions. In this way, it is expected with great possibility to develop various new materials and applications by producing and processing the NPs, which have different properties from the bulk material due to size effects as mentioned above [3].

Synthesis Methods

Synthesis methods for NPs are typically grouped into two categories: *top-down* and *bottom-up* approaches (Fig. 4). The first approach involves the breaking down of the bulk material into nano-sized structures or particles. This approach may address milling or attrition, chemical methods, and volatilization of a solid followed by condensation of the volatilized components. Metal NPs so produced are usually large in size (close to 1 μm) and have wide size distribution. High-energy ball milling is shown below as an example of such a method.

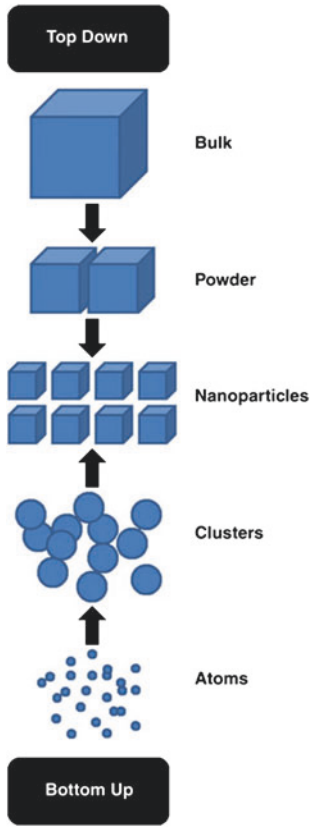
The alternative approach, *bottom-up*, refers to the buildup of a material from the bottom: atom-by-atom, molecule-by-molecule, or cluster-by-cluster in a gas phase or in solution. The latter approach is far more popular and less expensive in the synthesis of NPs and can be identified in two

Nanoparticles, Fig. 3 (**a**) Size-dependent changes in color of gold, from gold bulk to atomic size; (**b**) schematic drawing of plasmon oscillation for a gold NP, showing the displacement of the conduction electron charge cloud relative to the nuclei

sub-categories: (1) Vapor (Gas) Phase Methods (e.g., pyrolysis, inert gas condensation); (2) Liquid Phase Methods (e.g., solvothermal reaction, sol–gel, microemulsion method).

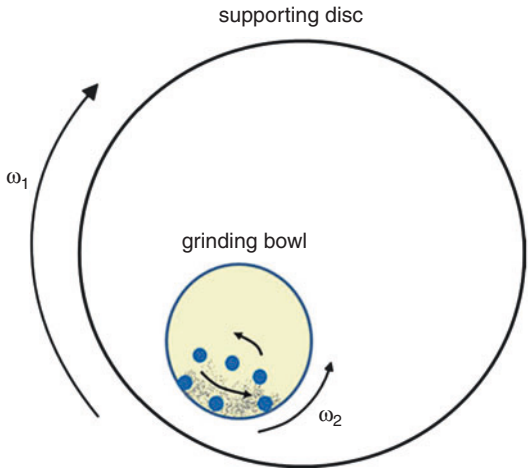
Top-Down: High-Energy Ball Milling

Within top-down technologies, one of the most representative techniques is High-Energy Ball Milling (HEBM). This technique is well known as a simple and inexpensive method for the production of nanostructured materials, in particular it allows the preparation of alloys and composites, which cannot be synthesized via conventional routes. Different types of milling devices have been developed for different purposes including tumbler mills, attrition mills, shaker mills, vibratory mills, planetary mills, etc. In HEBM, particles of the starting material are subject to heavy deformation, cold work hardening, and subsequent fragmentation [6].



In a HEBM system, the grinding balls and the material in the grinding bowl are thus acted upon by centrifugal forces, which constantly change in direction and intensity. The grinding bowl and the supporting disc rotate in opposite directions, so that the centrifugal forces alternatively act in the same and opposite directions (Fig. 5). The process requires a long milling time to activate and complete the structural changes and chemical reactions, as well as a control of milling atmosphere and temperature which are crucial to create the desired structural changes or chemical reactions [7].

Bottom-Up: Vapor (Gas) Phase Methods



Vapor (Gas) phase synthesis is a well-known chemical manufacturing technique for an extensive variety of nano-sized particles. The transformation of a gaseous precursor to the final particulate is a complex physical process involving nucleation of the particulate phase, condensation of gasses onto particles, and coagulation and coalescence between particles.

Vapor phase fabrication processes are typically conducted in vacuum under elevated temperatures. The mechanism for particle formation starts with the precursor vaporization (typically involves a catalyst) followed by the nucleation and growth stage.

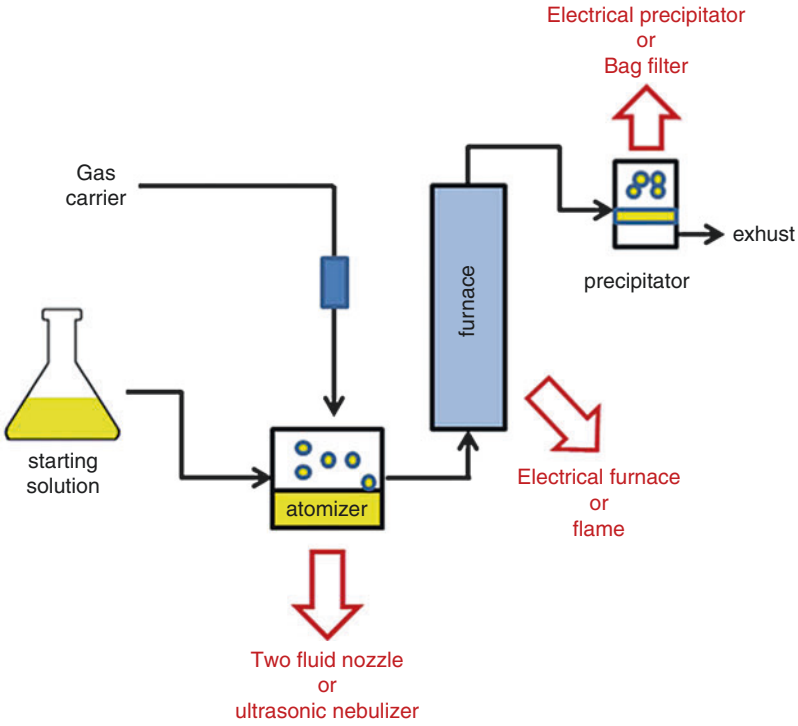
Synthesis of NPs via high-temperature processing is a promising technique that offers a good route to production of high-purity NPs with specifically tailored chemical and physical

Nanoparticles, Fig. 4 Schematic representation of the *bottom-up* and *top-down* synthesis processes of nanomaterials

Nanoparticles, Fig. 5 Schematic drawing of a high-energy ball mills

properties. However, NPs generated by gas phase processes are usually in the form of aggregates, due to their Brownian coagulation at high temperatures in the reactor: coagulation is an intrinsic mechanism which inevitably occurs at high particle concentrations and therefore in all industrial aerosol processes [8].

Bottom-Up: Spray Pyrolysis Methods



Spray methods, such as spray pyrolysis, spray drying, and the flame spray method, have the advantage of being continuous, low-cost, and single-step methods for the preparation of NPs and nanocomposites (which includes metals, metal oxides, non-oxide ceramics, superconducting materials, and nanophase materials) that are spherical, chemically homogeneous, and comprised of multiple materials. A representative spray system is shown schematically in Fig. 6.

In spray pyrolysis, the starting liquid solution is dispersed as droplets into a gas carrier and then sprayed into a drying chamber (furnace) that is heated above the solvent vaporization temperature. The remaining solutes undergo precipitation, thermal decomposition, and intraparticle reactions to form NPs. The solid particles are then collected by an electric field precipitator or a bag filter.

This technique is flexible as it allows the use of a wide range of precursors, solvents, and process conditions and thus provides control over particle size and composition [9].

Bottom-Up: Inert Gas Condensation

Inert Gas Condensation (IGC) process entails the evaporation of a source substance in an inert gas atmosphere to generate the nanopowder which is convectively transported and collected on a cold substrate. The NPs develop in a zone just above the evaporative source, due to interactions between the hot vapor species and the much colder inert gas atoms in the chamber. A feature of the process is the ability to generate non-agglomerated nanopowders, which are sinterable at relatively low temperatures. IGC process is generally classified as a Physical Vapor Deposition (PVD) method, but if a catalytic process is involved in addition, reference is made to it as *Chemical Vapor Deposition* (CVD) method.

Nanoparticles,
Fig. 6 Schematic drawing of a spray pyrolysis system

CVD is one of the most important synthesis processes for fabricating metal, semiconductor, and magnetic NPs. In the CVD process, the reaction or the thermal decomposition of gas phase takes place in a reaction chamber maintained under vacuum at high temperature (>1,173 K).

In common CVD reactors, source molecules react and produce both molecular and cluster intermediates in the gas phase. The intermediates become supersaturated and cause the nucleation in the gas phase due to the low vapor pressure. Nucleated NPs collide vigorously with each other and form agglomerated particles [10].

Growth and agglomeration of the particles are mitigated via rapid expansion of the two-phase gas stream at the outlet of the reaction chamber. Subsequent heat treatment of the synthesized nanopowders in various high-purity gas streams allows compositional and structural modifications, including particle purification and crystallization, as well as transformation to a desirable size, composition, and morphology. CVD is widely used to produce carbon nanotubes [11].

Bottom-Up: Liquid Phase Methods

Liquid phase methods include the set of processes that involve a wet chemistry route such as *Hydrothermal (solvothermal) synthesis, sol–gel synthesis*, and *microemulsion synthesis*. The particle formation mechanism is the same as in the vapor phase process. While in gas condensation it is not easy to control grain size and crystal shape, and furthermore its product yield is low, the wet chemistry route provides reasonable control over growth by utilizing organic ligands that act as growth confining agents.

Bottom-Up: Hydrothermal Synthesis

Hydrothermal synthesis of NPs provides precise control over particle size, shape distribution, and crystalline fraction.

This method takes advantage of the solubility of almost all inorganic substances in water at elevated temperatures and pressures and subsequent crystallization of the dissolved material from the fluid.

Water at high temperatures plays an essential role in the precursor material transformation

because the vapor pressure is much higher and the structure of water at elevated temperatures is different from that at room temperature. The properties of reactants, including their solubility and reactivity, also change at high temperatures. The solvent is not limited to water but includes also other polar or nonpolar solvents, such as benzene, and the process is more appropriately called *solvothermal synthesis* in different solvents [12].

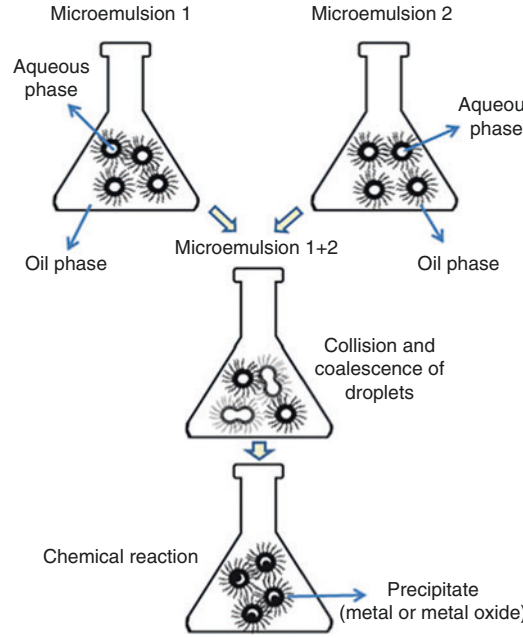
Bottom-Up: Sol–Gel Synthesis

The sol–gel process is a recent technique widely used in the field of material science and ceramic engineering for the generation of colloidal NPs from liquid phase. Sol–gel method is well adapted for oxide NPs and composite nanopowder synthesis starting from a chemical solution (*sol*) which is followed by the formation of a *gel*. It is based on inorganic polymerization reaction including hydrolysis, polycondensation, drying and thermal decomposition.

Typical starting materials are inorganic precursors: metal or nonmetal alkoxides (MOR) dispersed in an appropriate solvent. Precursors hydrolyze with water or alcohols, according to the reaction scheme:

$$-\mathrm{MOR} + \mathrm{H_2O} \rightarrow -\mathrm{MOH} + \mathrm{ROH}\,(\mathrm{Hydrolysis})$$

$$-\mathrm{MOR} + \mathrm{MOR} \rightarrow -\mathrm{MOR} + \mathrm{MOR}$$



or

$$-\mathrm{MOR} + \mathrm{MOR} \rightarrow -\mathrm{MOM} + \mathrm{H_2O}(\mathrm{Condensation})$$

The rates of hydrolysis and condensation are important parameters that affect the properties of final products. Slower and more controlled hydrolysis typically leads to smaller particle size and more unique properties. After solution condensation to gel, the solvent should be removed. This requires a drying process, which is typically accompanied by a significant amount of shrinkage and densification. Generally, higher calcination temperatures are needed to decompose the organic precursors [11].

Bottom-Up: Microemulsion Method

A microemulsion is a thermodynamically stable dispersion of at least three components: two immiscible fluids and a surfactant with amphiphilic properties (stabilizer).

Nanoparticles, Fig. 7 Proposed mechanism for the formation of metal particles within micelle "nanochamber"

A surfactant is a molecule that possesses both polar and nonpolar moieties. In very diluted water (or oil) solutions, it dissolves and exists as monomer, but when its concentration exceeds a certain minimum critical micelle concentration (CMC), the stabilizer molecules associate spontaneously to form aggregates-micelles [13]. The formation of microdroplets can be in the form of oil-swollen micelles dispersed in the aqueous phase as the oil/water (O/W) microemulsion or water-swollen micelles dispersed in oil as the water/oil (W/O) microemulsion (reverse microemulsion) [12]. The formation of O/W or W/O micelles is driven by strong hydrophobic interactions of the hydrophobic tail of the surfactant molecule (O/W micelle) or by hydrophilic interactions of the polar head of the surfactant molecule (W/O micelle).

Micelles in these systems can be described as "nanoreactors" providing a suitable environment for controlled nucleation and growth. Figure 7 illustrates the mixing of two microemulsions containing the appropriate reactants (metal salt and reducing agent) during the collision of the

Nanoparticles, Table 1 Parameters versus principal characterization methods for Nps

Parameters	Characterization methods
Particle size, size distribution, morphology	Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), Atomic Force Microscopy (AFM), X-ray Diffraction (XRD), Laser diffractometry
Charge determination	Zeta potentiometer
Surface hydrophobicity	Water contact angle measurements, hydrophobic interaction chromatography
Magnetic features	Vibrating Sample Magnetometry (VSM), Alternating gradient force magnetometry (AGFM), Magnetic Force Microscopy (MFM)
Electronic properties	Percolation threshold measure (both current–voltage DC and AC), dielectric characterization

water droplets. This intermicellar interchange process is very fast (from 10 μs to 1 ms) and it is the rate-limiting step for particle growth, but it is slow when compared to diffusion of reagents inside the nanoconfinement ("nanoreactor"). The attractive interaction between the droplets, which is responsible for the percolation process, is of great importance for the kinetics [13].

Characterization of Nanoparticles

NPs are generally characterized in particle size distribution, morphology, charge determination, and surface hydrophobicity. More specific characterizations depend on the properties of NPs synthesized such as magnetic characterizations for NPs featuring magnetic properties (e.g., Fe, Fe_3O_4) and electric characterizations for conductive or dielectric NPs (e.g., Ag, Cu, Au, SiO_2, $BaTiO_3$, etc.). Different parameters versus principal characterization methods used for NPs are given in Table 1.

Magnetic Nanoparticles

Magnetic NPs containing pure 3D transition metals – or some mixture of their oxides – are one of the most studied nanomaterials in view of the prospective, ubiquitous applications in quite different areas, the most notable being biomedicine, sensor technology, and magnetic recording [14]. According to their usage, magnetic NPs are often either embedded in a (typically diamagnetic) solid [15], or dispersed in a fluid; in some cases they are surrounded by an outer shell of a diamagnetic material.

This entry deals with particles having sizes not exceeding a few tens of nanometers. The lower limit is taken to be a few (>2) nanometers. As a result, the number of magnetic atoms per NP typically ranges between hundreds and a few millions. Smaller aggregates should be more properly termed magnetic clusters; their magnetic properties are closer to those of magnetic surfaces and are described in a quite different way. On an even smaller scale, magnetic molecules (mainly organic molecules containing a small number, about 10, of transition metal ions) are the subject of much study even if their applicability is still controversial.

Nowadays, magnetic NPs are routinely prepared by a variety of techniques which can be termed as physical (e.g., laser-assisted deposition, sputtering, etc.) or chemical (e.g., wet chemical routes) [14, 16].

The main feature of bona fide NPs made of a particular element or compound is that their magnetic properties are quite different from those of the corresponding bulk material. In a simplified picture, an ideal magnetic NP can be figured out as provided of a highly symmetrical body (e.g., spherical, ellipsoid, acicular, etc.) and characterized by a homogeneous magnetization provided by the ferro- (or ferri-) magnetic alignment of elementary magnetic moments, giving rise to a mesoscopic permanent magnetic moment associated to the particle. Of course this picture can be improved to account for the role played by the NP surface, whose chemical and magnetic properties can be quite different from those at the particle core. Strictly speaking, the locution "core-shell nanoparticle" [17] means a particle whose chemical or stoichiometric properties are substantially different when moving from the center to the surface (e.g., a metallic core surrounded by an

oxide shell). In a sense, however, all magnetic NPs fall in this category at least when their magnetic properties are considered, even when surface and core do not substantially differ in their chemistry.

The simplified approach is instrumental in understanding the reason why magnetic properties of NPs change with respect to bulk counterparts. Any macroscopic magnetic material is usually divided into magnetic domains in order to minimize the magnetostatic energy; the number of domains, as well as their shape, is dictated by the interplay and balance between magnetic energies, such as exchange, anisotropy, and domain-wall energy. When the size of a piece of magnetic material is ideally shrunk down to the sub-micrometer range without changing its aspect ratio, all the associated magnetic energies decrease accordingly; however, they decrease following different laws. Both magnetostatic energy and anisotropy energy are volume energies; however, domain wall energy being a surface energy, it has a slower reduction rate with reducing particle size. This makes the nucleation of magnetic domains unfavorable when the size of a particle becomes smaller. Below a critical size which strongly depends on the material's magnetic properties and morphology, the total energy at remanence is no longer decreased by magnetic domains, and the NP remains in the single-domain state. The magnetic moment points along one of the magnetically "easy" directions corresponding to the minima of the anisotropy energy. In order to have it switched away from the easy direction, one must apply a magnetic field; on removing it, the magnetic moment will be again aligned along any one of the easy directions. This is the so-called single-domain (magnetically) blocked state [18]. However, on further decreasing the particle size, the anisotropy energy keeps decreasing as the particle volume, and eventually becomes so small that it falls below k_BT, where k_B is the Boltzmann's constant and T the absolute temperature, that is, the typical thermal energy steadily exchanged at equilibrium by the NP with the thermal bath. As a consequence, the magnetization is no longer "blocked" along an easy direction, being continuously affected by thermal (random) torques of thermal origin, and the magnetic moment vector behaves in a sense as a free rotator which can be aligned by an external magnetic field, very much as paramagnetic substances do. However, the NP's magnetic moment is usually much larger than that of a single atom or ion, so that it can be termed as a "supermoment," and the particular magnetic behavior of such a NP is known as "superparamagnetism" [19]. The size below which a NP ceases to be in the magnetically blocked state at a given temperature to enter the superparamagnetic (SP) region, and the temperature above which a NP of given size begins to follow the SP behavior are termed critical size (temperature) for the onset of superparamagnetism, respectively. Both depend on NP size, shape, and the leading anisotropy term.

The transition from blocked to SP state is not a thermodynamic phase transition, because the SP behavior emerges only when the magnetic moment's direction randomly fluctuates at a rate high enough that during the time needed to perform a single measurement it virtually takes all directions in space, so that its time average is zero at zero applied field. The observation time plays a crucial role in determining whether a NP at a given temperature is in the SP state or not. From this viewpoint, the blocked-SP transition resembles, in a sense, that between an undercooled liquid and a glass.

SP particles exhibit a reversible magnetization versus field behavior, as paramagnetic substances do. Therefore, no hysteresis loop appears when an alternating magnetic field is applied to a system of genuine SP particles. The material's coercivity and remanence disappear. On the other hand, blocked single-domain NPs usually exhibit coercivity and remanence values which can be much higher than the ones measured in a macroscopic specimen of the same material. This means that a system containing blocked NPs made of a magnetically soft material acts as a magnetically hard material [18]. Therefore, two quite opposite magnetic behaviors are expected at the same temperature, strictly depending on NP size (and shape) alone.

Magnetic NPs in the SP phase are attractive for biomedical applications, because they can be

easily driven by a magnetic field (an oscillating field makes them their "free" moments to oscillate; an inhomogeneous field exerts a force on them, displacing them toward a target point). Oscillating magnetic moments dissipate energy as heat, and may effectively contribute in the local heating of organic tissue, for example, malignant tissue. Magnetic NPs may be properly functionalized with diamagnetic, organic shells in order to act as the portable inner core of a larger, multi-layered particle aimed to a specific intra-body target where it can release specific drugs carried by the organic shell (drug delivery). Other applications of functionalized particles include cell separation and DNA reconnaissance.

Blocked NPs are interesting because they can be exploited as low-cost substitutes of more expensive high-coercivity materials in permanent magnet industry and in magnetic data storage [16]. Hard-disk magnetic memories are often based upon nanoparticulate media where the information can be safely stored owing to the high coercivity of the medium. In this case, superparamagnetism is detrimental because it causes a loss of information. The SP limit introduces a lower boundary to the size of the NPs which a magnetic memory can be composed of, and poses a major, still partially unsolved technological problem in the development of higher-density magnetic memories.

A major drawback of almost all techniques proposed so far to produce magnetic NPs (at least, all of the low-cost ones) is the lack of full control on their size, which results in a (more or less) broad size distribution. Considering how size matters in determining the magnetic properties of these magnetic nanomaterials, it is apparent why many efforts of both fundamental and applied research are now aimed to develop preparation techniques resulting in monodisperse nanoparticle systems.

Application of Nanoparticles

Here it is proposed a selection of the application fields of NPs, in addition to those of magnetic NPs which were summarized in the previous paragraph. As references, the same literature previously cited was kept.

Drinking water purification is a new and promising application, performed making use of Fe, Ni, Au, Ag, or Cu NPs, for example for pesticide removal and organic contaminant detection. The NPs feature an enhanced reactivity and selectivity toward some dangerous elements (such as heavy metals) and organic substances (pesticides); when combined with a MEMS structure, this property is used to detect the chemicals by monitoring certain physical properties of the system (resonance frequency, impedance, etc.).

The enhanced chemical activity of metal NPs is also well known in catalysis, where transition metal NPs are used in the synthesis of organic compounds. Catalytic NPs may be surrounded by a dendritic polymeric structure (dendrimer) in order to allow catalyst recovery at the end of the chemical reaction. A peculiar form of catalysis, called water splitting, is performed using semiconductor NPs (Cu_2O, Fe_3O_4), where sunlight is directly converted in a current (either electrons or holes, depending on the semiconductor properties) and used to split the water molecule into oxygen and hydrogen, to produce an environmentally friendly fuel.

Cellular imaging, intended as optical microscopy performed on cells using fluorescence, Raman spectroscopy and SERS, is normally enhanced by uptake of NPs into the cell body. For this purpose are often used Au and, TiO_2 NPs, and so-called quantum-dots, where this definition includes semiconductor NPs, as CdSe and ZnS.

Photoluminescence of semiconductor NPs (quantum dots) is well known and studied in CdTe, Au/CdTe NPs assemblies, PbS, CdS, etc.

Biomedical applications of noble metal NPs include targeted drug delivery and targeted heat release; similar applications are more commonly approached by using ferromagnetic NPs (e.g., hyperthermia treatment on malignant cells). Also polymeric NPs, which are not a matter of discussion here, are currently used as vectors for drug delivery.

Inhibition of microorganisms and antimicrobial effects are obtained using Ag and/or TiO_2 NPs.

For solar cells optimization noble metal (Au, Ag) NPs have been proposed as electromagnetic

field enhancement media due to their SPR, even though TiO_2 and SiO_2 NPs possess more interesting antireflection properties.

Flexible electronics: Metallic NP tracks (Au, Ag, Cu, Sn), deposited by means of inkjet printing technology, are sintered toward electrical percolation at very low temperatures, allowing the realization of conductive paths on flexible polymeric substrates [20]. Currently, research is going on, considering possible solutions to assemble NPs and realize functional devices.

Besides the direct application of NPs, they are currently added to either metallic or ceramic or polymeric matrices to realize nanocomposite materials featuring enhanced mechanical, electronic, thermal, magnetic, and optical properties, which are not a matter of discussion in this entry.

Synonyms

Core/shell nanostructures; Synthesis of nanoparticles; Wet chemical synthesis

Definition

Nanoparticulate materials are defined as the materials with particle sizes smaller than 100 nm and exhibit different characteristics compared to their bulk counterpart.

Core/shell structures are a class of engineered nanostructures which have core and shell layers with different properties, compositions, crystal structures, etc.

Wet chemistry methods is a term used to refer to chemical approaches generally done in the liquid phase.

Introduction

Nanoparticulate materials with particle sizes smaller than 100 nm have attracted enormous attention over the past three decades because of their unusual properties that cannot be derived from conventional micrometer-sized particles. Due to their unique properties, nanoparticles have found wide applications in energy, electronics, photonics, magnetics, biomedical engineering, catalysis, transportation, health care, communication, and medicine. This entry focuses on synthesis of nanoparticles. Generally speaking, synthesis methods of nanoparticles can be classified into two categories, one being wet chemistry methods and the other non-wet chemistry methods. The latter could include inert gas condensation, chemical vapor synthesis, laser ablation, high-energy ball milling, laser-assisted synthesis, and plasma-assisted synthesis among others. Wet chemistry methods may include sol–gel process, precipitation, hydrothermal synthesis, reduction, solvothermal synthesis, cryochemical synthesis, and spray pyrolysis. This entry will describe the key principles and major parameters of the first four wet chemistry methods, while the last three methods, requiring large deviation from the ambient temperature during synthesis, either significantly below room temperature (i.e., cryochemical synthesis) or significantly above room temperature (e.g., solvothermal synthesis and spray pyrolysis), will not be described in this entry. Nanoparticles with core/shell structures will also be addressed in this entry because they often offer special functionalities that cannot be obtained even from nanoparticles. The methods for synthesis of core/shell structures are typically derived from a combination of two different wet chemistry methods or from one wet chemistry method with two steps of different chemistries. Therefore, the basic principles of synthesis science for core/shell structures are in many cases the same as individual wet chemistry methods except the additional requirement of interface control without which core/shell structures are difficult to synthesize.

Sol–Gel Process

Key Principles of Sol–Gel Process

This process involves the hydrolysis and condensation of molecular precursors to form a sol which

can then precipitate out as nanoparticles or change to a gel, a semirigid network, by evaporation of the solvent or by continuous inorganic polymerization. Whether nanoparticles or gels are formed depends on the nature of the precursor(s) and the synthesis conditions. The precursors for the sol–gel process can be inorganic or organic salts (e.g., nitrates, chlorides, acetates, etc.) as well as alkoxide precursors [1, 2]. Metal alkoxides, $M(OR)_n$ where M is a metallic element (such as Si, Al, Fe, Cr, Mn, Ce, Y, W, etc.) and OR is an alkoxide ligand with R being an alkyl group, are most widely used precursors. The sol–gel reaction using metal alkoxides can be considered as a two-step inorganic polymerization [1–5]. The first step is the hydrolysis of alkoxide ligands to yield hydroxylated metal centers, M-OH:

$$M(OR)_n + H_2O = M(OR)_{n-1}(OH) + ROH \quad (1)$$

The second step is the condensation of the hydroxylated species to form oxypolymers, involving an oxylation reaction which creates oxygen bridges and expels XOH species as follows:

$$M - OH + M - OX = M - O - M + XOH(X = H \text{ or } R) \quad (2)$$

Transition metal alkoxides has a strong electrophilic character and their ability to increase the coordination number is high [1–3]. As a result, their hydrolysis and condensation rates are very fast, which leads to rapid growth of oxypolymers and thus precipitation of nanoparticles. To avoid fast precipitation and to form a gel, metal alkoxides need to be modified at the molecular level by chelating ligands such as acetylacetone which is nucleophilic. The chelated complex has a reduced electrophilic character of the transition metal and lowers hydrolysis and condensation rates substantially, and thus gels rather than nanoparticles can be formed [2].

In contrast, nontransition metal alkoxides such as tetraethyl orthosilicate ($Si(OC_2H_5)_4$, TEOS) have a weak electrophilic character because transition metal elements are more electropositive than silicon [1]. As a result, their hydrolysis and condensation rates are very slow, about five orders of magnitude slower than that of transition metal alkoxides [1, 3]. Therefore, the products of TEOS can be adjusted to be nanoparticles or gels relatively easier by controlling the pH value and hydrolysis ratio during sol–gel reactions [5].

There are multiple major parameters during the sol–gel process that can alter the reactions and final products. These major parameters and their effects are discussed below.

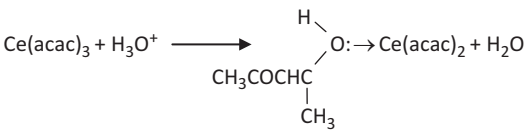
Major Parameters of Sol–Gel Process

Chemical Compositions of the Precursors

As pointed out above, the nature of the precursor can significantly affects the sol–gel reaction kinetics and final products. For example, cerium alkoxides, acetylacetone-modified cerium alkoxides, and cerium acetylacetonates can all be used as sol–gel precursors to synthesize CeO_2. However, cerium alkoxide precursors often lead to the formation of nanoparticles due to the strong electrophilic character of their cerium metal and thus rapid hydrolysis and condensation rates [3]. In contrast, acetylacetone-modified cerium alkoxides exhibit preferential hydrolysis of less electronegative alkoxide ligands, while strongly bonded complexing groups are difficult to be hydrolyzed [1]. Similarly, cerium acetylacetonates with the absence of alkoxide ligands have been found to be hydrolyzed very slowly [4]. Specifically, the detailed FTIR analysis reveals that the hydrolysis rate of cerium acetylacetonates in methanol is relatively fast at the early stage of hydrolysis (<6 h at room temperature), but becomes very slow beyond 6-h of hydrolysis, and hydrolysis cannot be completed even after 7 days of hydrolysis at room temperature [4]. The slow hydrolysis and condensation rates of both cerium acetylacetonates and acetylacetone-modified cerium alkoxides facilitate the formation of gels [1–3].

Hydrolysis Ratio

The hydrolysis ratio, as defined by Eq. 3, is the main external parameter and has been shown to be



important in controlling the hydrolysis and condensation of metal alkoxides [3]:

$$h = \frac{[H_2O]}{[M(OR)_z]} \quad (3)$$

where $[H_2O]$ and $[M(OR)_z]$ are the molar numbers for the water and metal alkoxide, respectively. When $h < 1$, water molecules are not sufficient for complete hydrolysis, and thus gelation or precipitation cannot occur. When $1 < h < z$ (where z is the valance charge of M metal as shown in Eq. 3), chain oxypolymers can form. When $h > z$, excess water is present and cross-linked oxypolymers can be obtained, leading to the formation of nanoparticles or gels. The hydrolysis ratio also has significant impact on the hydrolysis and condensation rates [5]. When h is small ($< \sim 1$), the hydrolysis rate is low, and thus the sol–gel reaction, which includes both hydrolysis and condensation, is slow. When h is high ($> \sim 7$), the hydrolysis rate is high, but the condensation ratio is low. As a result, the sol–gel reaction is slow. When h is intermediate ($1 < h < 7$), the sol–gel reaction is the fastest because both hydrolysis and condensation rates are high.

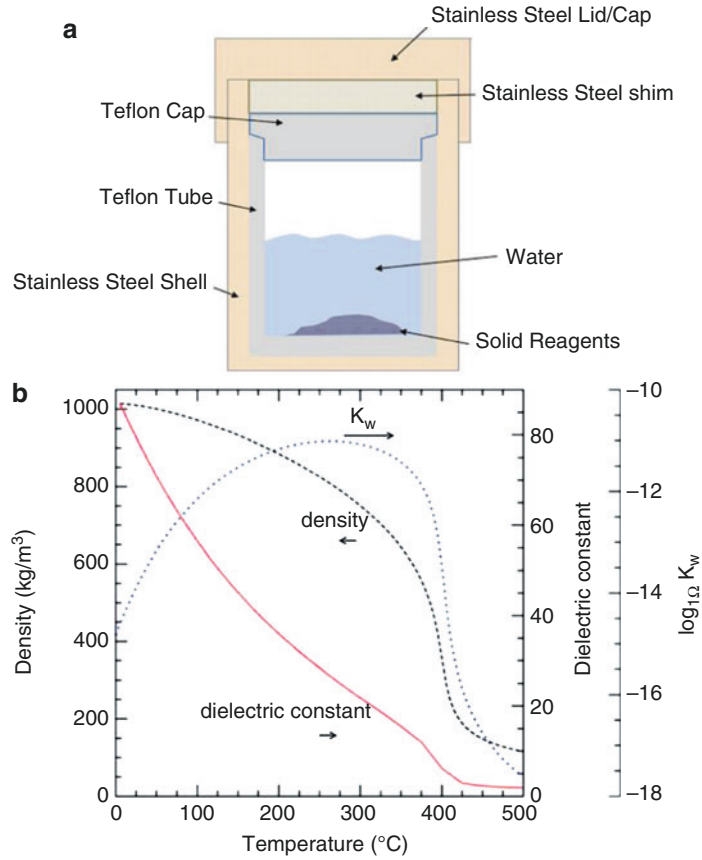
Catalysts

Both acids and bases can catalyze sol–gel reactions. For example, acids and bases have been used to catalyze the sol–gel formation of SiO_2 using TEOS as the precursor [5]. Acids can catalyze hydrolysis of metal alkoxides and acetylacetonates because negatively charged alkoxide groups and acetylacetonate (acac) anions can be protonated by H_3O^+ ions, as shown below [2].

(4)

Under such conditions, the prototropic transfer and the departure of the leaving group from the transition state can no longer be the rate-limiting step, and thus hydrolysis rates are increased substantially. As a result, nanoparticles can be formed from acetylacetonate precursors in spite of the nucleophilic nature of the acetylacetonate anions [2]. However, not all acids can catalyze hydrolysis. For example, carboxylic acids can serve as a complexing agent to react with metal alkoxides via a nucleophilic substitution to slow down hydrolysis and condensation of metal alkoxides [1, 3].

Bases catalyze hydrolysis of transition metal alkoxides by nucleophilic addition of OH^- ions, which decreases the positive charge of the transition metal atom [3]. Condensation is accelerated through the formation of highly nucleophilic species such as $M\text{-}O^-$, as shown below [3]:



$$M - OH + OH^- = M - O^- + H_2O \quad (5)$$

The reactive condensation intermediate shown above will attack the more positively charged metal atom to complete the condensation reaction and form oxypolymers.

Combination of the pH Value and Hydrolysis Ratio

The pH value of the sol–gel solution will change when acids or bases are added to catalyze the reactions. It has been shown that the pH value and hydrolysis ratio have a combined effect on the morphologies of the final products, particularly for the SiO_2 system [5]. Under base-catalyzed conditions ($pH > 9$) and high hydrolysis ratios (h = 7–25), the hydrolysis rate of silicon alkoxides is high and condensation is rate limiting. As a result, smooth, uniform nanoparticles are formed. Under these conditions, depolymerization of clusters to form monomers is facile. This leads to particle coarsening if the reaction time is long, a phenomenon called Ostwald ripening in which many smaller particles are depolymerized into monomers which then deposit on larger particles via repolymerization.

Under acid-catalyzed conditions ($pH < 3$) and high hydrolysis ratios, the hydrolysis rate of silicon alkoxides is high, but condensation and depolymerization rates are low. With these conditions, monomers are consumed by condensation but not produced by depolymerization, leaving only

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 1 (**a**) Schematic of a Teflon-lined stainless steel autoclave typically used for hydrothermal synthesis. (**b**) Density, dielectric constant and ionic product (K_w) of water at 30 MPa as a function of temperature (Reproduced from Einarsrud and Grande [6])

clusters which are unable to interpenetrate and condense to fill the entire space. As a result, randomly branched oxypolymer structures are formed [5].

Under low pH and low hydrolysis ratios, linear oxypolymer chains are formed. This is the condition used to produce gels for SiO_2 fiber production. However, the mechanism of forming linear oxypolymer chains under the low pH and low hydrolysis ratio condition is not fully understood yet [5].

Reaction Temperature

Increasing temperature typically results in increased hydrolysis and condensation rates. Thus, poorly reactive precursors, such as Si $(OR)_4$, often require relatively high temperature (40–80 °C) to activate the sol–gel reaction. In contrast, for highly reactive precursors, such as transition metal alkoxides, the reaction temperature must be lowered in order to slow down hydrolysis and condensation [3].

Hydrothermal Synthesis

Key Principles of Hydrothermal Synthesis

The hydrothermal synthetic process generally involves heterogeneous chemical reaction in aqueous media above room temperature ($T > 25$ °C, normally above 100 °C) and at a pressure greater than 1 atm. The chemical solutions are heated in a sealed vessel (autoclave, Fig. 1a); thereby the autogenous pressure increases inside the vessel beyond the atmospheric pressure, especially when temperature exceeds the boiling point of the solvent. This

will provide increased solubility and reactivity of the precursors used. The process is called hydrothermal when water is used as the solvent, while the term solvothermal is used in the case of nonaqueous solvent. During the hydrothermal synthesis, the density, ionic product, viscosity, and dielectric constant of water change with temperature and pressure.

The most accepted mechanism of hydrothermal synthetic process is dissolution–reaction–reprecipitation, which includes dissolution of precursors, diffusion of dissolved precursor species, and reaction/precipitation to give the target compound. Once a nucleus forms, the particle grows depending on the crystallite- and morphology-control experimental conditions. The dissolution and diffusivity of precursors are increased by the high pressure and reduced viscosity of the water under hydrothermal conditions.

Hydrothermal method has been so generally used to synthesize almost every kind of nanostructures, such as ceramics, metals, and semiconductors. All forms of nanostructures can be prepared with hydrothermal synthesis, namely, nanoparticles, nanowires, nanorods, core–shell nanostructures, porous nanostructures, etc. Hydrothermal synthesis offers many advantages over conventional and nonconventional synthetic methods, especially for ceramics. This process is simple, low cost, easy to scale up (continuous fabrication, etc.), and environmentally benign. The ability to precipitate already crystallized powders directly from solution regulates the rate and uniformity of nucleation, growth, and aging, which results in improved control of size distribution and morphology of crystallites and significantly reduced aggregation levels. Another important advantage of the hydrothermal synthesis is that the purity of hydrothermally synthesized nanostructures can exceed the purity of the starting materials. It is because the hydrothermal crystallization is a self-purifying process, during which the growing crystals/crystallites tend to reject impurities present in the growth environment. In other synthesis routes such as high temperature calcination, the self-purifying process is less likely to occur. The low reaction temperatures also avoid other problems encountered with high temperature processes, for example, poor stoichiometry control due to volatilization of components (e.g., Pb and Cd volatilization in Pb-/Cd-based ceramics).

Major Parameters of Hydrothermal Synthesis

Temperature and Pressure

The autoclave (Fig. 1a) is heated either by placing it in a water bath, oil bath, or oven or by using microwaves. During hydrothermal synthesis, the density, ionic product, viscosity, and dielectric constant of water change with temperature and pressure [6], as illustrated in Fig. 1b. At and above the critical point (374 °C, 218 atm), the densities of water gas and liquid phases are equal and the difference between liquid and gas disappears, becoming supercritical fluid. Most hydrothermal syntheses are conducted below the critical point, which is under mild hydrothermal conditions. The filling factor (or the percentage of free volume) of the autoclave and temperature determine the prevailing pressure in the vessel. On using a filling factor lower than 32 %, the liquid water–gas interface inside the autoclave will be lowered, and at a certain temperature, the autoclave will be completely filled with only the gas phase [6]. Typically, precursor aqueous solution or suspension fills the autoclave up to 70–80 % of its capacity. It should be noted that the precursors used will influence the composition of both the liquid and gas phase, hence change the pressure–temperature profile of the liquid–gas equilibrium in the autoclave during the hydrothermal synthesis. In addition, the pressure will be affected if gas product/side-product is generated during the process at the given temperature, e.g., nitrates and carbonates decomposing to nitrous gases or CO_2.

In general, an increase in temperature and/or decrease in pressure thermodynamically favors the less hydrated solid oxide phases. Temperature, pressure, and pH which are most important thermodynamic parameters determine which substance can be produced.

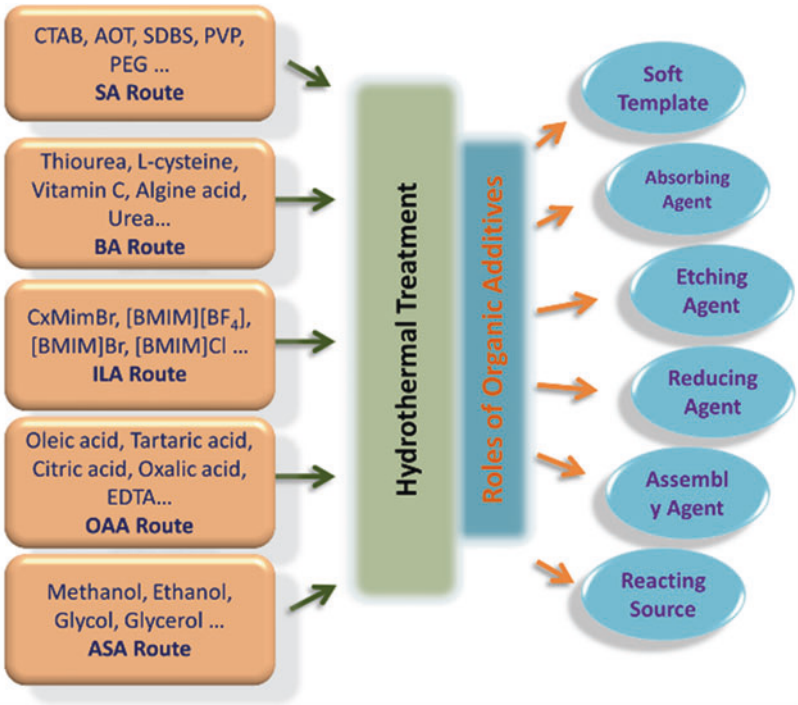
Precursors, Mineralizer, pH, and Pourbaix Diagrams

Precursors can be oxides, hydroxides, or salts of the elements to build up the material. The reaction formula can be described as follows:

$$MA + OH^-/\text{additives} \rightarrow M_xO_y \quad (6)$$

or

$$MA + M'B + OH^-/\text{additives} \rightarrow M_xM'_y\ O_z \text{ or } M_xM'_y \quad (7)$$



Small changes in the chemical parameters such as the type of precursors, concentration, and pH can dramatically affect the phase composition and morphology of the product. For achieving metal oxides or complex oxides, NaOH, KOH, or some other basic reagents are used as **mineralizer** to further increase the solubility of precursors by adjusting the pH value of the solution system. At progressively higher pH, the solubility of some metal oxide precursors is governed by stepwise hydrolysis species, such as GaOOH, as shown below.

$GaOOH\ (s) + 3H^+ + 4H_2O \rightarrow Ga(H_2O)_6^{3+}\ (aq)$	Acidic	(8)
$GaOOH\ (s) + 2H^+ + 4H_2O \rightarrow Ga(OH)(H_2O)_5^{2+}\ (aq)$		(9)
$GaOOH\ (s) + H^+ + 4H_2O \rightarrow Ga(OH)_2(H_2O)_4^{+}\ (aq)$		(10)
$GaOOH\ (s) + 4H_2O \rightarrow Ga(OH)_3(H_2O)_3\ (aq)$		(11)
$GaOOH\ (s) + 2H_2O \rightarrow Ga(OH)_4^-\ (aq) + H^+$	Very basic	(12)

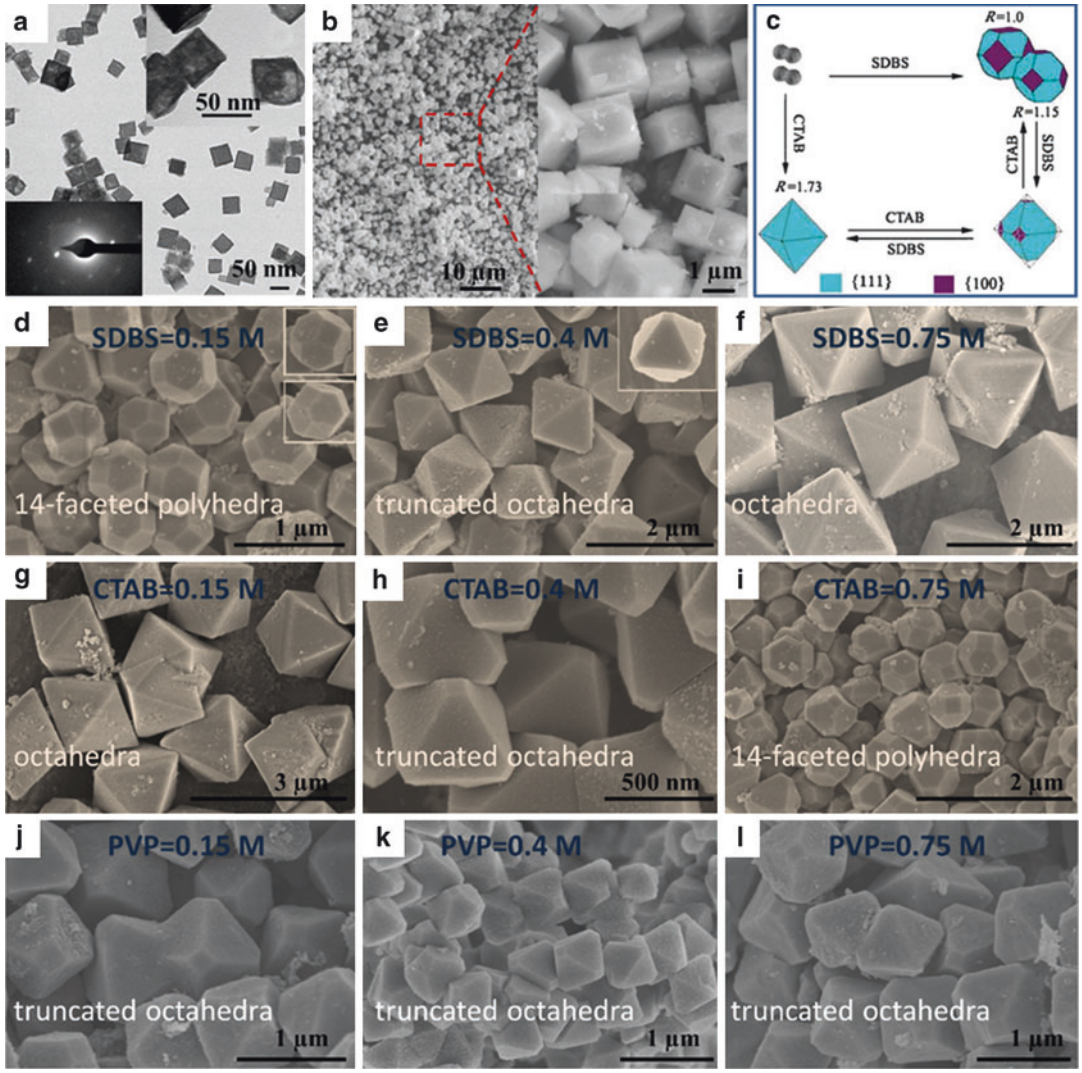
In addition, different salts and organic additives like complexing agents are commonly used as mineralizers, especially for larger metal cations to enhance solubility. For instance, EDTA and citric acid were used for the formation of Pb $[Zr_xTi_{1-x}]O_3$ ($0 \leq x \leq 1$) to overcome the problem of differing solubilities between different cations. The organic additive-assisted hydrothermal synthetic strategies could realize further control of the morphology, uniformity, and dispersibility of inorganic nanostructures via the introduction of various organic additives compared with the organic additive-free hydrothermal routes. According to the properties of organic additives, studies based on these strategies may be mainly classified into five kinds of basic routes: surfactant-assisted (SA) route, biomolecule-assisted (BA) route, ionic liquid-assisted (ILA) route, organic acid-assisted (OAA) route, and alcoholic solvent-assisted (ASA) route [7]. Figure 2 shows the basic states of these five routes and the effects of organic additives in them. These organic additive or organic mineralizers can function as soft template, assembly agent, etching agent, reducing agent, reacting source, or absorbing agent. The function of these organic additives will be further mentioned in the hereinafter morphology control and template-assisted hydrothermal synthesis.

These mineralizers not only facilitate the solubility and hydrolysis of precursors but also alter/adjust the pH value of the solution system which is critical factor in most case for the final product phase. The solution pH determines different hydrolysis species of a metal cation and their abundance. Reactions in which elements possess various oxidation states are also dependent on the pH value, as well as oxidation potential of the solution. The Pourbaix diagram (also known as potential/pH diagram, EH/pH diagram, or pE/pH diagram) maps out possible stable phases of metal species, or the reaction equilibria and dominant metal species in relation to the redox potential and pH of an aqueous system. It summarizes thermodynamic possibilities, redox properties, and chemical speciation for reactions in which metals capable of existing in different oxidation states participate. Therefore, it is very important to hydrothermal synthesis.

However, most Pourbaix diagrams and formed species are constructed from experimental

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 2 Five basic routes of the organic additive-assisted hydrothermal synthetic strategies, namely, SA route, BA route, ILA route, OAA route, and ASA route (Reproduced from Shi et al. [7])

information and collected under ambient conditions. Higher temperatures and pressures toward preparative hydrothermal chemistry are necessary. The constructions of elevated temperature Pourbaix diagrams, which are incomplete for many metal ion species, require experimental data (e.g., Gibbs free energy, standard molar entropy, and specific heat capacity) under hydrothermal conditions. To overcome this, numerous high-temperature metal ion-H_2O systems have been extrapolated from room temperature data although limited by the uncertainty of extrapolated data above 150 °C [6]. Calculated Pourbaix diagrams can aid experimental formulations by illustrating the trends in species forming as the temperature increases.



Morphology and Polymorph Control

Application-Driven Nanostructure Control

Crystalline products can be in a variety of forms, such as equiaxed (e.g., cubes, spherical), elongated (fibers, whiskers, nanorods, nanotubes), plates, nanoribbons, nanobelts, etc. Core–shell particles (semiconductor/semiconductor, semiconductor/metal, metal/metal, ceramic/semiconductor, ceramic/conductor, etc.) and composite nanostructures consisting of a mix of at least two different materials (SnO_2/CdS, Li_2CoSiO_4/C, TiO_2/SiO_2, Au/C) can be also prepared. Generally, the size and morphology can be engineered over a wide range and even adopt nonequilibrium morphologies. The size and morphology control are the key factors to many applications, such as nanostructures for catalysis, battery active material, optoelectronics, etc. This topic is one of the most exciting subfields in both nanoscience and catalysis and aims to allow the control of chemical reactions through changes in the size, shape, and interface of solid catalysts at the nanoscale.

Size Control

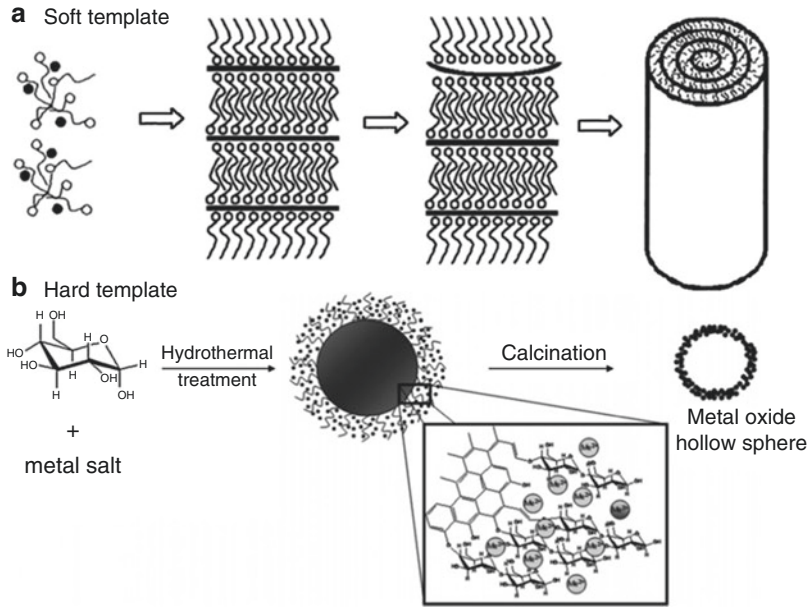
The particle size can be controlled by reaction time and temperature, precursor concentrations, and mineralizer species. If the outcome nanoparticles grow according to Ostwald-ripening process, the particle size will be

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 3 Microscopic structures of hydrothermally synthesized perovskite $ZnSnO_3 \cdot 3H_2O$ nanoparticles under surfactant-free condition with different temperatures: (**a**) room temperature (RT, ~25°C), (**b**) 60°C and/or anionic (SDBS), cationic (CTAB), and nonionic surfactants (PVP) with increased surfactant concentration. (**c**) schematically illustrated the transformation in crystal shapes as a function of the ratio between the growths rates along the <100> and <111> directions (R) (Figures (**a**–**b**) adopted from Liu et al. [8] and Fig. (**c**–**l**) reproduced from Geng et al. [9])

uniformed and increased with the increase of reaction time or temperature. Typical examples can be found in synthesizing many kinds of metal oxide or metal oxide complex nanostructures. Figure 3a, b showed $ZnSnO_3 \cdot 3H_2O$ (perovskite, ABO_3) nano-/micro-cubes fabricated under different temperatures and the particle size increased with temperature [8]. When the surfactants, such as sodium dodecylbenzenesulfonate (SDBS), cetyl trimethylammonium bromide (CTAB), and polyvinylpyrrolidone (PVP), are added in the solution, the particle size and morphology of perovskite $ZnSnO_3 \cdot 3H_2O$ can be further finely tuned (Fig. 3c–l) [9].

Morphology and Growth Direction Control (Additives and Anions)

As previously mentioned, controlling the shape of oxide particles on the nanometer scale enriches their active sites (i.e., their electronic structure and surface coordination environment) through the selective exposure of reactive facets on their surface, which improves the catalytic performance. In principle, the shape of an oxide nanoparticle is governed through thermodynamics and kinetics. Thermodynamic equilibrium states minimize particle surface energy and preferentially expose the less active or inactive crystal facets. Morphology control to expose a large fraction of reactive facets generally can only occur via kinetic mediation of the growth of different crystal facets. The shape of the particles is determined primarily by the intrinsic energy balance of the crystallographic features and growth regime between the thermodynamic and kinetic processes. The systematic manipulation of the synthesis parameters, such as the precursor composition, pH, temperature, and surfactant, can feasibly adjust the relative growth rates of the different crystal facets and thus control particle morphology. Mostly used strategies are involved with the use of surfactants such as CTAB and SDBS or adjusting anion species in metal salt as structure-directing agents to induce the anisotropic nanocrystal growth by selectively capping specific facets.



One example has been shown in Fig. 3. In the hydrothermal synthesis of perovskite $ZnSnO_3 \cdot 3H_2O$ nanostructures, anionic (SDBS), cationic (CTAB), and nonionic surfactants (PVP) with increased surfactant concentration were used. The effects of these surfactants on the specific facet growth have been summarized in Fig. 3c. It is found the CTAB facilitates the growth of {111} facets of $ZnSnO_3$, while SDBS favors the formation of {100} facets. No effect of PVP on facet selectivity was observed [9].

Except surfactants and other organic additives, the type of anion species in the metal salt affected the shape of the nanoparticles. For instance, the hydrothermal treatment of $Ce(NO_3)_3 \cdot 6H_2O$ in ammonia at 180 °C yielded spherical nanoparticles with 12 nm in size. The use of $CeCl_3 \cdot 7H_2O$ as the cerium source resulted in ceria nanowires of ~40 nm in diameter and 3–10 mm in length; replacement of the salt anions with HPO_4^{2-} obtained CeO_2 nanorods having diameters of 5–10 nm and lengths of 7.5–50 nm [10]. The chemical role of these anions was ascribed to their selective interaction with the specific CeO_2 facets. Chloride ions preferentially adsorbed onto the (111) facets and led to the growth of CeO_2 nanowires with polygonal cross-sections. This selectivity was further confirmed by the morphology evolution from nanoparticles to nanowires via the hydrothermal treatment of a mixture of $CeCl_3 \cdot 7H_2O$ and $Ce(NO_3)_3 \cdot 6H_2O$. An increase in the Cl^-/NO_3^- molar ratio from 1/3 to 3/1 changed the products from spheres to rods [10].

Hydrothermal Synthesis with Templates

Soft Template

Surfactants, biomolecules, and organic acids have been systematically studied as "soft templates" in the hydrothermal synthesis of hollow inorganic nanostructures. Numerous examples for each of the above can be found in literatures. Figure 4a gives a typical surfactant-templated hydrothermal synthesis. The cationic surfactant CTAB was used to aggregate VO_3^- nucleus to form lamellar structures. Under hydrothermal conditions, these lamellar sheets became loose at the edges and then roll into themselves to form the VO_x nanotubes [7]. Biomolecules used include macromolecules, e.g., proteins, polysaccharides, lipids, and nucleic acids, and small molecules, e.g., vitamins, glycolipids, glycerolipids, phospholipids, hormones, and so on. Due to their special structures, these biomolecules tend to self-assemble into certain patterns which can be used as template for the formation of inorganic nanostructures. The organic acids such as ethylenediaminetetraacetic acid (EDTA), oleic acid, tartaric acid, citric acid, oxalic acid, salicylic acid, and malic acid have been found to play four important roles in the growth process of nanostructures, namely, as a structure-directing agent, assembly agent, reducing agent, and gas bubble release agent. Due to strong chelating and capping capabilities, organic acids display well balancing the growth rate of

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 4 Schematic illustration of soft (**a**) and hard (**b**) template in hydrothermal synthesis. (**a**) mechanism for the formation of vanadium oxide nanotubes: the mixture of NH_4VO_3 and the template molecules; layered structures formed through the hydrothermal treatment; the beginning stage of the rolling process; and the formed nanotubes. (**b**) Synthesis of metal oxide hollow spheres from hydrothermally treated carbohydrate–metal salt mixtures with carbon nanosphere template (Figures reproduced from Shi et al. [7])

different facets. Interestingly, same organic acid in a different reaction environment often exhibits different or even opposite structure-directing effects.

Hard Template

Polystyrene (PS), silica (SiO_2), and carbon nano-/microspheres are widely used in hydrothermal synthesis as "hard templates" for hollow or porous nanostructures. After hydrothermal synthesis, these hard templates can be removed either by chemical etching or thermal annealing. Among them, PS and SiO_2 nanospheres are normally added with metal salt precursor. But carbon nanosphere template can be formed in the hydrothermal process. Hence, the template precursor and metal oxides precursors are mixed in one pot. Figure 4b shows the hydrothermal synthesis method for the formation of hollow metal oxide (Fe_2O_3, NiO, $7Co_3O_4$, CeO_2, MgO, and CuO) nanospheres [7]. In this process, various metal salts were dissolved together with glucose in water. During the hydrothermal treatment, carbon spheres are formed with metal ions incorporated into their hydrophilic shell. Under high-temperature calcination, hollow metal oxide spheres could be obtained. Changing the ratio between the metal salt and glucose can realize the control of the surface area and shell thickness of hollow oxides spheres.

Design of Hydrothermal Experiments

At the present stage of understanding the hydrothermal synthesis of nanostructures, it is difficult to predict the effect of the chosen reaction parameters. A majority of the hydrothermal synthesis work that has been done in the past has used trial-and-error methods for process development. This type of experimental approach suffers from the inability to clearly discern between processes that are controlled by either thermodynamics or kinetics. Thermodynamic processing variables, such as temperature, pH, and pressure, determine not only the processing space for a given material

but also influence both reaction and crystallization kinetics. Hence, to approach a rational materials design for hydrothermal synthesis (especially for new phases), thermodynamic calculations of phase equilibria to aid in the determination of the parameter space which will give the targeted phase need to be conducted. For a given precursor system, the effects of concentration, temperature, and pressure can be modeled to define the processing variable space over which the phase (s) of interest is stable. The application of in situ characterization techniques to study the reaction intermediates and reaction mechanisms also can significantly facilitate a rational design for hydrothermal synthesis for nanostructures with desired composition, crystal phase, size, and morphology.

Reduction

Key Principle of Reduction Synthesis

This process involves the reduction of an inorganic salt in liquid phase by reducers. This wet chemical reduction method is applied to synthesize metal nanoparticles as well as metal oxide nanostructures with decreased oxidation number. During metal nanoparticle synthesis, metal salt reduction can be expressed as

$$M^{n+} + ne^- \rightarrow M \quad (13)$$

Whether the redox reaction takes place or not relies on whether the standard electrode potential of the metals/ions is higher than that of the other redox pair.

The widely investigated metal nanomaterials include plasmonic Ag, Au, and Cu nanoparticles which can be used as biosensor imaging and optoelectronic devices; Pt, Pd, Ir, and Ru nanostructures as well as Ag and Au which have outstanding catalytic activity; and transition ferromagnetic metals, such as Fe, Co, and Ni nanoparticles which have been widely used in different magnetic and spintronic devices. A variety of bimetallic nanostructures have interested research communities because their performance often surpasses the enhancement of the properties associated with their single counterparts and exhibits many interesting and useful properties with broadened application fields often explained by synergistic effects of nanomaterials.

Metal salt reduction is well suited for metal and metal alloy nanoparticle synthesis. This facilitates pure, well-controlled nanoparticle formation with desired crystallinity. However, the reaction process can be complicated and the reaction by-products can be toxic. The discovery of various reducing agents and stabilizers has made possible the development of mild conditions that can be employed for the preparation of large amounts of nanoparticles of reproducible quality.

Major Parameters for Reduction Process

Same as other wet chemical synthetic methods, the solvent and temperature of the liquid system play important roles in reduction synthesis. It relates with the dissolution of precursor and stability of the target products/phases. High-temperature reduction in metal salts in the presence of stabilizing agents can be employed to produce transition metal nanoparticles (cobalt, nickel) that do not crystallize well at room temperature. Generally, the reaction temperature for reduction synthesis range from 60 °C or room temperature to 300 °C. And solvents can be water and/or organic compounds, such as polyol. Here, the effects on above two parameters won't be discussed in detail since pretty similar effects have been described in other wet chemical methods. Instead, the chemical factors, such as chemical composition of precursors, reducers, and stabilizers, will be focused in the following discussion.

Chemical Compositions of the Precursors

The species present in the solution have an impact on the resulting nanoparticles. Metal carbonyls are reported precursors for Fe, Co, and Ni nanosized colloids. To fabricate Au, Pt, Pd nanoparticles, metal halide salts (such as $AuCl_4^-$, $PtCl_6^{2-}$, $PdCl_2$) have been commonly used as precursors. Metal precursor choice has a major effect on the resulting nanoparticles and their behaviors. For example, the usual synthetic route to prepare Ag nanoparticles involves the

reduction of $AgNO_3$ or Ag organic compounds. Highly monodisperse myristate-capped silver nanoparticles can be obtained by suspending silver myristate (14 C in the alkyl chain) in triethylamine (reducer) followed by gentle heating at 80 °C for 2 h. This process gradually produces a solution of uniformly spherical silver nanoparticles that can be precipitated by addition of acetone. Thus, the nanoparticles can be isolated as solid materials and redispersed in nonpolar solvents where they are relatively stable. The particle size and size distribution are affected by the alkyl chain length of the carboxylate ligand in Ag organic compounds. With silver stearate (18 C in the alkyl chain) instead, the particles are highly monodispersed with sizes between 1.9 and 3.5 nm, whereas with silver octanoate (6 C in the main alkyl chain), the particle distribution is broad and the sizes are larger (between 5.5 nm and 31.5 nm) [11]. Here, the silver organic compounds played both as precursor and stabilizer or capping reagents. Many other metal organic compounds have also been developed based on that.

Reducers

As reported, the Ag particle size decreases, but the size distribution is also broader when octylamine is in the place of triethylamine as reducing agent [11]. *The size and morphology of the metal nanoparticles can be tuned by choosing a suitable reducing agent.* A weak reducing agent, such as citrate or tartrate, will favor a slow reaction allowing particle growth over a long period to yield faceted and small (<5 nm) nanoparticles, whereas with relatively strong reducing agents, such as $NaBH_4$, formamide, or o-anisidine, bigger and generally spherical nanoparticles will form. For achieving desired Au nanostructures, many variations of reduction method have been developed in the past decade. $NaBH_4$, sodium citrate, potassium bitartrate, dimethyl formamide, ascorbic acid, and alcohols are some of the reducing agents that have been successfully used. $NaBH_4$, potassium bitartrate, superhydrides, amines, and alcohols are widely reported as reducing agents for fabrication of Pd and Pt nanoparticles.

In some case, the solvent can be the reducing agent. One example is the synthesis of monodisperse silver nanocubes (100 nm) by reduction of silver nitrate with ethylene glycol. In this preparation, PVP stabilizer was used to form a monolayer on the surface of Ag nanoparticles to prevent fast nanoparticle growth and agglomeration. Ethylene glycol serves both as reducing agent and solvent. Moreover, polyol synthesis was a simple and versatile route to many other colloidal metals and/or alloys such as Au, Cu, Co, Ir, Ni, Pd, Pt, Ru, CoNi, and FeNi. Reasons for the popularity and versatility of this synthesis include the ability for polyols to dissolve many precursor salts and their highly temperature-dependent reducing power [12].

Stabilizers

Stabilizer, sometimes called protective agent or capping agent, can be used to form a monolayer on the surface of nanoparticles to prevent fast nanoparticle growth, Ostwald ripening, or agglomeration. Moreover, the concentration of stabilizer, or more effectively the ratio of (surface group of stabilizer)/(metal salt), is one of the critical factors to metal particle size and size distribution. And the ratio varies for different metal nanoparticles. Stabilizer can be polymer, aromatic amine, and alkanethiols, etc., depending on the weak bonding between metal and organic compounds.

Thiols are excellent stabilizers for capping gold nanoparticles owing to strong Au-S bonding, which enables the isolation of the particles as solid materials following solvent evaporation. The isolated particles can be readily redissolved in nonpolar solvents where they are indefinitely stable. Other good protective agents, such as phosphanes, phosphines, amines, chalcogenides, carboxylates, and polymers, have been successfully used. Long-chain n-alkanethiols are the most common protective agents employed to stabilize silver colloids, even though aromatic amines (such as aniline), carboxylic acids, and polymers have been also employed. The most common capping agents are n-alkanethiols and polymers, but a few examples of Pt and Pd nanoparticles capped with amines, alkyl isocyanides, and cyclodextrins have also

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Table 1 Precipitation diagram of aqueous solutions

been reported. Co, Ni, and Ni-Co highly monodispersed nanoparticles have been achieved in the presence of stabilizers including oleic acid, TOP, tributylamine, and hexadecylamine via reduction of metal acetates in solution by polyalcohols or $NaBH_4$.

Precipitation

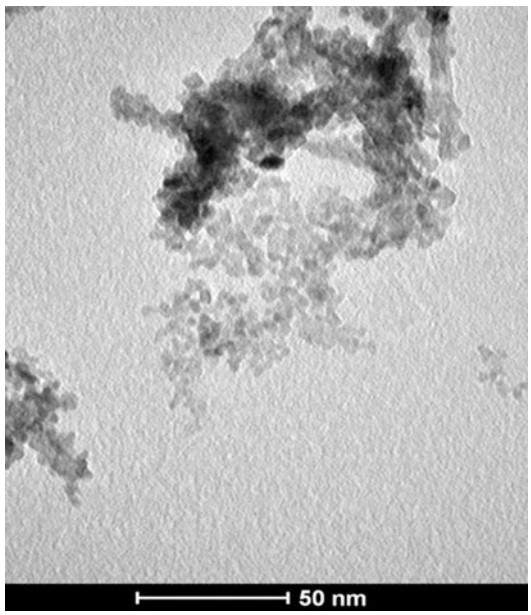
Key Principles of Precipitation Reaction

This is a process in which insoluble solid particles separate out of a solution. To obtain nanoparticles from this process in a controlled manner, it normally requires mixing of a cation-containing solution with an anion-containing solution. Insoluble nanoparticles are formed upon mixing of the two clear solutions. The following reaction illustrates how $Ni(OH)_2$ nanoparticles are synthesized via precipitation reactions:

$$\left(Ni^{2+} + 2Cl^-\right) + \left(2Na^+ + 2OH^-\right) = Ni(OH)_2 \downarrow + 2Na^+ + 2Cl^- \quad (14)$$

For the reaction above, one aqueous solution containing nickel chloride ($NiCl_2$) and the other with sodium hydroxide (NaOH) are mixed together to produce the $Ni(OH)_2$ precipitate. To predict this type of reaction, one needs to know whether the product is insoluble in the solvent (e.g., water) or not. Table 1 shows the precipitation diagram for aqueous solutions [13]. The compounds inside the hatched areas are not soluble, while the compounds inside the blank areas are soluble. For example, Na_2CO_3 is soluble in an aqueous solution, while $MnCO_3$ is not. Thus, when a $Ni(NO_3)_2$ solution is mixed with Na_2CO_3, $NiCO_3$ will precipitate out of the solution. Table 1 also reveals that AgCl, $BaSO_4$, and $Mg(OH)_2$ are insoluble, while all other chlorides and sulfates are soluble. Based on Table 1, many nanoparticles can be synthesized via precipitation reactions.

Major Parameters of Precipitation Reactions



Precipitants

Precipitation reactions are often induced by addition of a precipitant, without which precipitation will not occur. Ammonium hydroxide (NH_4OH) is often used as a precipitant to synthesize hydroxides and oxides [14]. For example, to synthesize gadolinium-doped ceria ($Ce_{0.8}Gd_{0.2}O_{1.9}$), particles of 10 nm in diameter (Fig. 5), cerium nitrate, $Ce(NO_3)_3$, and gadolinium nitrate, $Gd(NO_3)_3$, are dissolved in deionized water first in a right proportion. The nitrate solution is then added at room temperature dropwise to the NH_4OH precipitant, while stirred using a magnetic bar, and maintained at a pH of 10. The solution is then heated to 75 °C while being stirred continuously and homogenized at that temperature for 1 h [14].

Selection of a proper precipitant is essential for synthesizing nanoparticles with the desired composition. To synthesize nanoparticles of $Ce_{0.8}Gd_{0.2}O_{1.9}$ plus (Ni,Cu)O, one can start with an aqueous solution containing proper amounts of $Ce(NO_3)_3$, $Gd(NO_3)_3$, $Ni(NO_3)_2$, and $Cu(NO_3)_2$. However, using NH_4OH as the precipitant results in nanoparticles of $Ce_{0.8}Gd_{0.2}O_{1.9}$ + NiO. No CuO or (Ni,Cu)O is produced, indicating that Cu^{2+} ions do not precipitate out as hydroxides or oxides from the solution. In contrast, using NaOH as the precipitant leads to the formation of $Ce_{0.8}Gd_{0.2}O_{1.9}$ + (Ni,Cu)O nanoparticles because NaOH is a stronger precipitant than NH_4OH.

Oxygen Dissolved in Water

The presence of oxygen in aqueous solutions could oxidize the precipitate, leading to a product with the composition different from that predicted from Table 1. The effect of oxygen dissolved in water can be deduced based on electrochemical potential of the element, as illustrated below. Adding NH_4OH to each of the $Ni(NO_3)_2$, $Co(NO_3)_2$, $Fe(NO_3)_2$, and $Mn(NO_3)_2$ solutions can result in hydroxides and oxides with different oxidation states. As indicated by the reactions below, $Ni(OH)_2$ will be the final product of the precipitation reaction of Ni^{2+} ions even in the presence of oxygen dissolved in water. However, this is not the case for other metallic elements. For Fe^{2+} and Mn^{2+} ions, their precipitation products, $Fe(OH)_2$ and $Mn(OH)_2$, will be oxidized by the oxygen in the solution to form Fe_2O_3 and Mn_3O_4, respectively. For Co^{2+} ions, its precipitation product, $Co(OH)_2$, will also be oxidized by the oxygen in the solution, but not to form oxides. Instead, an oxyhydroxide, CoO(OH), is formed, suggesting the Co atoms have a better resistance to oxidation than Fe and Mn. By comparing the final products of these metallic ions with their standard electrochemical potentials in aqueous solution (Table 2), it can be seen that the propensity for each metallic hydroxide to be oxidized by the oxygen in the aqueous solution is inversely proportional to its standard electrochemical potential. The lower the potential is, the easier its hydroxide is to be oxidized by the oxygen in the aqueous solution to form its respective oxide. Ni has the highest resistance to oxidation among these elements, and thus its $Ni(OH)_2$ is stable even in the presence of oxygen in the aqueous solution. Co has an intermediate resistance to oxidation, and thus its $Co(OH)_2$ is oxidized to an oxyhydroxide, a compound between a hydroxide and an oxide. Fe and Mn have the lowest resistance to oxidation among these elements, and thus its hydroxides are oxidized all the way to form oxides.

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 5 Transmission electron microscopy (TEM) image of $Ce_{0.8}Gd_{0.2}O_{1.9}$ nanoparticles synthesized via precipitation. Note the uniform size of particles of ~10 nm in diameter

$$Ni^{2+} + 2\,OH^- = Ni(OH)_2 \quad (15)$$

$$Co^{2+} + 2\,OH^- = Co(OH)_2 \quad (16)$$

$$Co(OH)_2 + ¼\,O_2 = CoO(OH) + ½\,H_2O \quad (17)$$

$$Fe^{2+} + 2\,OH^- = Fe(OH)_2 \quad (18)$$

$$2\ Fe(OH)_2 + ½\,O_2 = Fe_2O_3 + 2\,H_2O \quad (19)$$

$$Mn^{2+} + 2\ OH^- = Mn(OH)_2 \quad (20)$$

$$3\ Mn(OH)_2 + ½\,O_2 = Mn_3O_4 + 3\,H_2O \quad (21)$$

Multicomponent Compounds via Coprecipitation

Multicomponent hydroxides and oxides can be formed via coprecipitation of insoluble solid

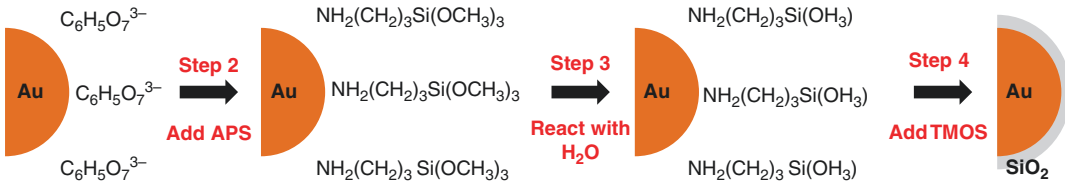
Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Table 2 Standard electrochemical potentials of various species in aqueous solution at 25 °C

Species	Mn^{2+}/Mn	Fe^{2+}/Fe	Co^{2+}/Co	Ni^{2+}/Ni
E^o	−1.182 V	−0.409 V	−0.282 V	−0.236 V

with multicomponents. The synthesis of $Ce_{0.8}Gd_{0.2}O_{1.9}$ discussed in section "Precipitants" is a good example of coprecipitation. In the case of $Ce_{0.8}Gd_{0.2}O_{1.9}$, the two cations have similar properties (e.g., similar propensity for oxidation), and thus the molar ratio of Ce to Gd in the precipitated $Ce_{0.8}Gd_{0.2}O_{1.9}$ nanoparticles is identical to that of the Ce ions to Gd ions in the solution. However, this may not be the case if the cations have dissimilar properties. A good example for this case is the synthesis of $Ni_{0.5}Mn_{0.5}(OH)_2$ via coprecipitation [15]. When the nitrate solution containing equal molar ratios of Ni and Mn cations is bubbled with N_2, the precipitate is $Ni_{0.5}Mn_{0.5}(OH)_2$. However, if the nitrate solution is not bubbled with N_2, the precipitate is composed of $Ni_{5/6}Mn_{1/6}(OH)_2(NO_3)_{1/6} + Mn_3O_4$. Such a dramatic change in the final products is due to the fact that Mn cations are easier to get oxidized than Ni cations (see Table 2). As a result, Mn cations are oxidized to become Mn_3O_4 by the oxygen in the solution if the oxygen is present in the solution.

Solvents for Precipitation

For precursors that are unstable in an aqueous solution, precipitation in a nonaqueous solvent is often utilized. Synthesis of semiconductor PdSe nanoparticles via precipitation is a good example of this kind [15]. In this process, lead-cyclohexanebutyrate (Pb-cHxBu) and selenium precursors are dissolved in a tri-butyl-phosphine (TBP) solution at room temperature. Another solution containing the tri-octyl-phosphine-oxide (TOPO) surfactant is prepared at 150 °C. The TBP solution is then injected rapidly into the TOPO solution, followed by immediate drop of the temperature to 118 °C. The reaction between Pb-cHxBu and Se at 150 °C leads to the formation of PdSe, and the rapid cooling to 118 °C results in precipitation, while TOPO serves as a capping agent to prevent the growth of PdSe nanoparticles [15]. Nonaqueous precipitation often offers excellent crystallinity, monodispersity, and high-purity nanoparticles. However, disadvantages may include use of expensive precursors, sensitivity to moisture, and complicated experimental setups.



Core/Shell Structures

Key Principles in Synthesizing Core/Shell Structures

As pointed out before, the methods for synthesis of core/shell structures are typically derived from a combination of two different wet chemistry methods or from one wet chemistry method with two steps of different chemistries. Therefore, the basic principles of synthesis science for core/shell structures are in many cases the same as individual wet chemistry methods except the additional requirement of interfacial control. The purpose of interface control is to create a preferential environment for the shell material to deposit on the surface of the core and prevent homogeneous nucleation of the shell material. If the latter occurs, one ends up with a mixture of two types of nanoparticles of different compositions instead of the desired core/shell structure. Thus, our discussion below will focus on interfacial control in synthesizing different core/shell systems, including metal–polymer, metal–ceramic, polymer–metal, polymer–ceramic, ceramic–polymer, ceramic–metal, and semiconductor–semiconductor core/shell structures. The principles that guide the interfacial control for each of these systems will be illustrated by examples below.

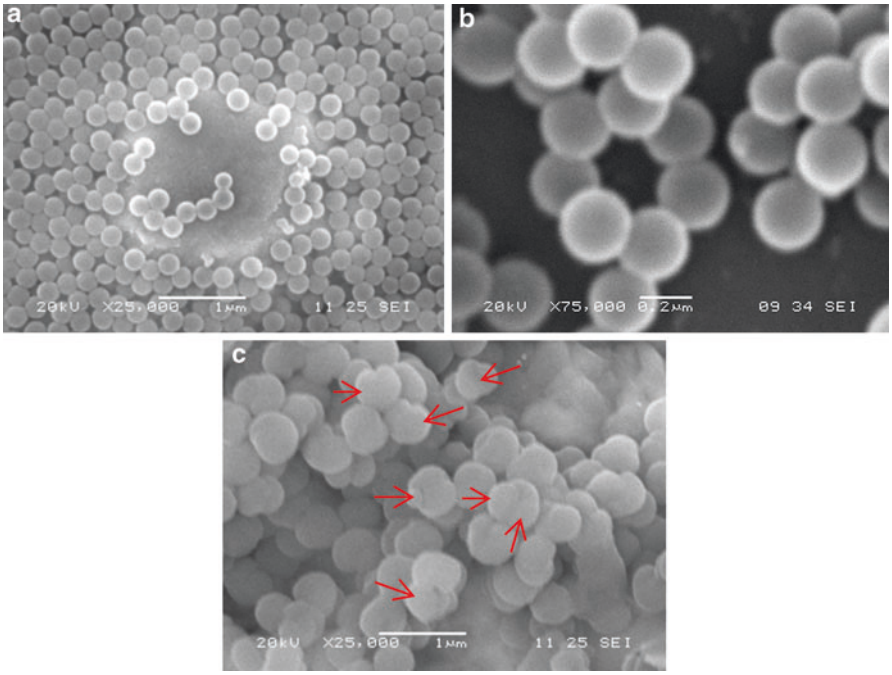
It should be noted that not all core/shell structures are produced through "two-step" methods mentioned above. Some core/shell structures are synthesized via "one-pot" methods. However, one-pot methods are chemistry specific and thus only work for certain systems. In contrast, two-step methods are very general and can be used to synthesize almost any core/shell structures. Since one-pot methods are system specific, the coverage of this topic would require the discussion of system by system. The space here does not permit such coverage, and thus this topic will not be addressed further.

To simplify the discussion below, core/shell structures will be expressed using a shorthand defined here. For instance, CdSe/ZnS will stand for a CdSe core with a ZnS shell. Ag/SiO_2 will represent an Ag core with a SiO_2 shell.

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 6 Schematic of the procedure in synthesizing the Au/SiO_2 core/shell structure. Step 1 – reduction reaction to synthesize Au nanoparticles (not shown); Step 2 – adding APS; Step 3 – hydrolysis of the silane group of APS; and Step 4 – hydrolysis and condensation of TMOS to form the SiO_2 shell. See the text for more description of the procedure and reactions

Semiconductor–Semiconductor Core/Shell Structures

Semiconductor core–shell structures, such as CdSe/ZnS, CdSe/CdS, and PdSe/CdSe, are normally synthesized by two-step precipitations. The first precipitation reaction leads to the formation of the core, and the second precipitation reaction forms the shell. For most of these core and shell structures, the lattice mismatch between the core and shell is very small (~4 %) and thus allow hetero-epitaxial growth of the shell directly on the surface of the core. Under these conditions, no surfactants are needed, and the core/shell formation is achieved by preventing homogeneous nucleation of the shell material in the solution. Only growth on the surface of the core is promoted. This can be done by controlling the concentration of the growth species so that the supersaturation is not high enough for nucleation, but high enough for growth. There are normally two approaches to control the supersaturation of growth species. One is by the dropwise addition of the growth precursor solution into the reaction mixture which contains the cores. Another approach is to vary the growth temperature because the supersaturation is a function of temperature. An example synthesizing the CdSe/ZnS core–shell structure using both approaches coupled with two-step precipitations can be found in Hines and Guyot-Sionnest [16].



Metal–Ceramic Core/Shell Structures

Such core/shell structures often require the use of coupling agents to allow the ceramic shell to interact with the metal core. An example of this kind is the Au/SiO_2 core/shell structure. Gold surface has very little electrostatic affinity for silica because gold does not form a passivation oxide layer. Thus, to ensure that SiO_2 can grow on the surface of Au, (3-aminopropyl) trimethoxysilane (APS) can be used which links to Au particle surface at one end and to SiO_2 at the other end [17]. Figure 6 shows schematically how the Au/SiO_2 core/shell structure is synthesized with the aid of APS.

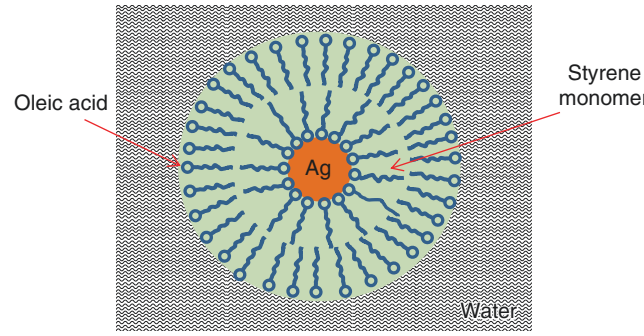
As shown in Fig. 6, the Au nanoparticles are first synthesized via reduction of chloroauric acid ($HAuCl_4$) by sodium citrate ($Na_3C_6H_5O_7$). At the as-synthesized condition, the surface of Au nanoparticles is negatively charged due to the absorption of negatively charged citrate groups. In Step 2, an APS aqueous solution is added to the Au sol to allow the complexation of the amine groups with the Au surface, leading to the replacement of the citrate group by the amine group, with the silane group of APS pointing into the solution. The silane group then undergoes hydrolysis to form silanol groups (Step 3), which can then participate in the condensation reaction with tetramethyl orthosilicate (TMOS), the SiO_2 precursor, to form the SiO_2 shell in Step 4.

Polymer–Ceramic Core/Shell Structures

Interfacial control is also necessary for polymer–ceramic core/shell formation because chemical properties of polymers and ceramics are dramatically different. A good example to illustrate the interfacial control in synthesizing polymer–ceramic core/shell structures is the polystyrene (PS)/SiO_2 core/shell structure. After formation of PS nanoparticles via emulsion polymerization, PS nanoparticles can be dispersed in water with the aid of sulfates or amines. Sulfates

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 7 SEM images of polystyrene nanoparticles before and after subjecting to the sol–gel reaction to form the SiO_2 shell under different conditions: (**a**) before subjecting to the sol–gel reaction, (**b**) after subjecting to the sol–gel reaction using the positively charged PS nanoparticles, and (**c**) after subjecting to the sol–gel reaction using the negatively charged PS nanoparticles. *Arrows* in (**c**) point out several nonspherical particles and particles with different sizes

result in PS nanoparticles with negatively charged surface, whereas amines give rise to PS nanoparticles with positively charged surface. In order to form the SiO_2 shell on the surface of PS nanoparticles via the sol–gel process, PS nanoparticles with proper surface charges are necessary. Using tetraethyl orthosilicate (TEOS) as the SiO_2 precursor and conducting sol–gel reactions at pH > 7, PS nanoparticles with positively charged surface (amine-stabilized) should be used to form the core/shell structure. This is because of the negative charge of the intermediate $\equiv Si-O^-$ formed during hydrolysis of the sol–gel reaction, as show in Eqs. 22 and 23.



$$\equiv Si - OH + OH^- \rightarrow \equiv Si - O^- + H_2O \quad (22)$$

$$\equiv Si - O^- + \equiv Si - OH \rightarrow \equiv Si - O - Si \equiv + OH^- \quad (23)$$

A positively charged PS surface allows the condensation reaction to take place at the surface of PS nanoparticles and thus the formation of the core/shell structure. If PS nanoparticles are negatively charged at their surface, the intermediate $\equiv Si-O^-$ cannot approach the PS surface due to charge repulsion. As a result, homogeneous nucleation of SiO_2 takes place in the solution and no core/shell structure is formed. Figure 7 compares the scanning electron microscopy (SEM) images of nanoparticles after sol–gel formation of SiO_2 in a PS nanoparticle sol. It can be seen that when PS is positively charged at the surface, the resulting particle sizes are very uniform, indicating the formation of a uniform SiO_2 shell on the PS surface. In contrast, when PS is negatively charged at the surface, different sizes of SiO_2 particles are present, and some particles have irregular shapes, indicating no formation of the core/shell structure.

Metal–Polymer Core/Shell Structures

Interfacial control is required for metal–polymer core/shell formation because chemical properties

Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods, Fig. 8 Schematic of formation of the Ag/PS core/shell structure in the presence of oleic acid

of metals and polymers are dramatically different. The importance of the interfacial control for this group of core/shell structures can be well illustrated by the Ag/PS core/shell structure. To synthesize the Ag/PS core/shell structure, one can start with reduction of $AgNO_3$ to form Ag sol, followed by polymerization of styrene in emulsion of oleic acid [18]. The thickness of the PS shell can be readily controlled by changing the concentration of monomers in emulsion. The presence of oleic acid ($C_{17}H_{33}COOH$) is required to form the polymer shell. Without oleic acid, only polymer particles are formed and Ag particles are not coated with the polymer. Figure 8 illustrates the principle of forming the PS shell on the surface of an Ag particle. Oleic acid has a high affinity for the oxide layer on the surface of Ag. Thus, it absorbs on the surface of Ag nanoparticles to form a micro-reactor within which styrene monomers are present, and polymerization of styrene can proceed when water-soluble initiator is added. Clearly, oleic acid is essential for the formation of the PS shell.

Ceramic–Polymer Core/Shell Structures

In general, this group of the core/shell structure also requires interfacial control. This can be illustrated well using the formation of the SiO_2/poly (divinylbenzene) (PDVB) core/shell structure. Monosized SiO_2 nanoparticles can be synthesized first via the sol–gel process. After generation of SiO_2 nanoparticles, they are pretreated with a coupling agent, e.g., 4-vinylpyridine, and then mixed with divinylbenzene monomers and a radical polymerization initiator [19]. The pretreatment with 4-vinylpyridine imparts the surface of SiO_2 particles with the vinyl functional group which can subsequently participate in polymerization with divinylbenzene monomers and thus promote the formation of the PDVB shell.

Metal–Metal Core/Shell Structures

Similar to semiconductor–semiconductor core/shell structures, metal–metal core/shell structures may not need surfactants because of the similar properties between the core and shell materials. The Pd/Ag core/shell structure synthesized via co-reduction can serve as a good example for this synthesis method. A $Pd(NO_3)_2$ and $AgNO_3$ mixture in an aqueous solution can be reduced by $NaBH_4$ readily to form the Pd/Ag core/shell structure. During the co-reduction process, Pd will be reduced first because it has a higher redox potential than Ag. Thus, Pd nanoparticles grow first, which is then followed by reduction of Ag ions and the direct growth of Ag on the surface of the Pd nanoparticles.

Concluding Remarks

In all, the wet chemical synthetic methods have been predominant in synthesis numerous nanostructures over decades. The synthetic methods discussed above all possess virtues over physical deposition methods or top-down methods, including that it is very simple, is less costly, can easily be scaled-up, and easily be tuned by varying

the synthesis parameters like temperature, precursors, and concentration of the solution, etc. Core–shell nanostructures are just one of the typical examples for the ability of these wet chemical methods toward hierarchical nanostructures [20]. By understanding the mechanism and effective factors, diversity of advanced nanostructures can be synthesized in large volume in a controlled manner. These nanomaterials and synthetic technologies have been applied in so many devices and appliances (from military to domestic) and affected our daily life deeper than we noticed. They are the foundation of our nanotechnologies and certainly will affect our life more in every aspect in the future.

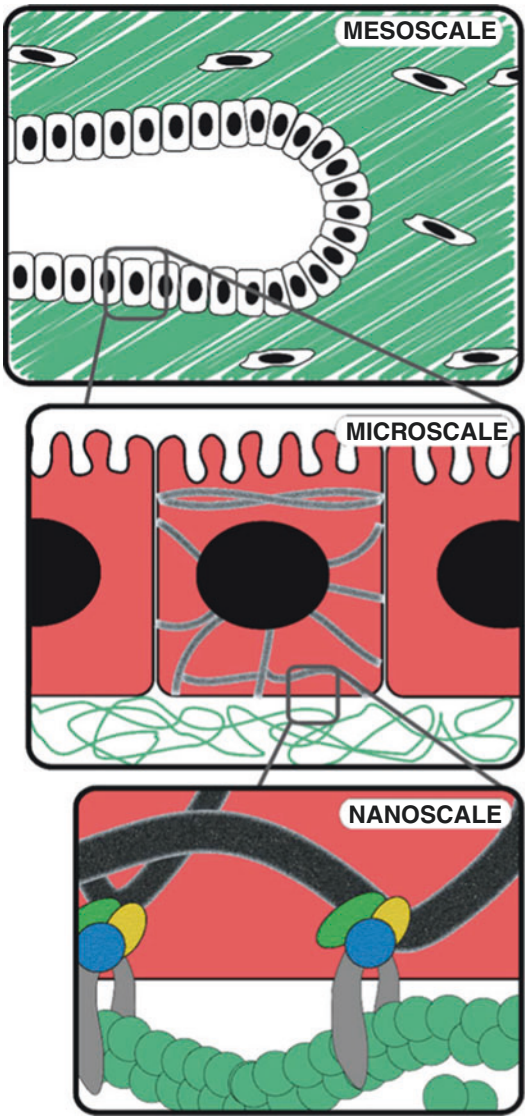
Nanopatterned substrata

Definition



Surfaces (substrata) that are fabricated to have chemically or topographically nanometer-sized features, which are used to investigate cell morphology, phenotype, and/or behavior.

Overview

Cells Sense and Respond to Their Environment

Cellular environments consist of complex mechanical, chemical, electrical, and topological gradients ranging in size from the nanoscale (1–100 nm) to the macroscale (>1 mm) (Fig. 1). Cell behavior is governed by these multiscale environmental properties, which, when disrupted, lead to aberrant tissue function and disease. At the mesoscale (100–1,000 μm), aggregate cell behavior resulting from cell-cell interactions, coupled with properties of the extracellular matrix (ECM), create the tissue architecture and sculpt the mechanical and chemical microenvironment. Heterogeneity of the tissue architecture at the mesoscale produces unique microenvironments. Cell-cell and integrin-dependent cell-ECM interactions at the microscale (1–100 μm) regulate cell shape and adhesion, and consequently affect cell survival, growth, differentiation, and migration. At the nanoscale, molecular and subcellular processes such as integrin activation, focal adhesion formation, actin polymerization, and cytoskeletal organization enable the cell to be physically coupled to its ECM. Additionally, membrane-bound receptors signal through intracellular pathways to modulate gene expression and protein synthesis in response to chemical signals such as morphogens.

Cells interact with and regulate their surroundings in a relationship referred to as dynamic reciprocity [1]. Through dynamic and reciprocal crosstalk, cell behavior is modulated by cell-cell and cell-ECM interactions, and that behavior sculpts and defines the microenvironment. One of the many ways in which the cell senses and reacts to its environment is through integrin-dependent signaling. Transmembrane integrins attach and mechanically couple to several ECM ligands, including the prototypic sequence arginine-glycine-aspartic acid (RGD). Integrin engagement leads to recruitment and clustering to form focal adhesions. Intracellularly, integrins within the focal adhesion associate with several proteins including vinculin, talin, tensin, α-actinin, paxillin, Src, and focal adhesion kinase. These proteins couple the focal adhesion to the actin cytoskeleton. This physical linkage enables the cell to adhere to, move along, and interact mechanically with the ECM. In addition, the focal adhesion activates several kinase cascades that biochemically transduce information about the microenvironment into the nucleus, which leads to changes in gene expression. These gene expression changes can result in the production and secretion of soluble signaling molecules, enzymes, and ECM components that

Nanopatterned Surfaces for Exploring and Regulating Cell Behavior, Fig. 1 Cell interaction and behavior are governed over multiple length scales. Cell-cell and cell-matrix interactions collectively form tissue architecture and function at the mesoscale. Microscale interactions guide cell shape and connectivity, whereas nanoscale interactions influence cell processes such as adhesion, motility, and gene expression

shape and maintain the extracellular environment. The formation, maturation, and disassembly of focal adhesions are not only key for cell spreading and migration, but also appear to be central modulators of many cellular functions including proliferation and differentiation.

Engineering Model Substrata

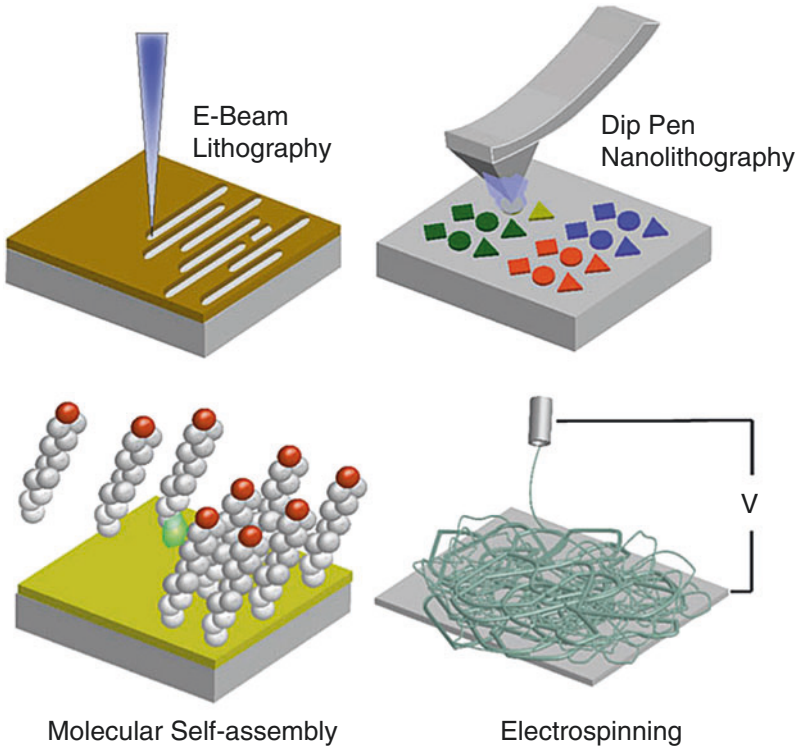
The tissue microenvironment is complex and the responses of cells to microenvironmental interactions can occur through individual and synergistic mechanisms. As a result, model substrata are often employed to decouple and isolate the effects of various microenvironmental factors. These model surfaces typically fit into one of two categories: chemically or topologically patterned. Chemically patterned surfaces contain regions of active and inactive (inert) biomolecules and thus present spatial patterns of chemical ligands to the cells of interest. ECM proteins such as fibronectin, vitronectin, laminin, and collagen or their active binding motifs are often used. In contrast, topologically patterned surfaces alter the surface topology that is presented to the cells. In these systems, etched pits, posts, grooves, and gratings are used to characterize cell behavior. Regardless of the type of model substratum used, advances in micro- and nanotechnology have enabled the creation of such tailored surfaces to investigate the interactions between cells and their microenvironment at multiple length scales.

Because of the existence of several simple, well-established techniques, micropatterned surfaces have become a popular tool to interrogate cell behavior. Micrometer-scale topology can be created using standard photolithography coupled with traditional etching processes; however, at the micrometer scale most studies have focused on chemically patterned substrata. For chemically patterned surfaces, photolithographic techniques can be used to spatially deposit or remove different materials and thus define regions for chemical functionalization. Microcontact printing is the most common method of microscale chemical functionalization. This technique employs the use of micropatterned elastomeric stamps that are "painted" with the ECM ligand of interest. The coated stamps are then pressed onto a treated surface, which deposits the cell-adhesive ECM ligands onto the surface in the same spatial pattern as that of the stamp.

Micrometer-sized features can be used to control cell position and connectivity; and thus micropatterning is often employed to investigate both mesoscale and microscale cell behavior.

Micropatterned surfaces have been used to coculture fibroblasts and hepatocytes to maintain normal hepatocyte phenotype [2]. Additional mesoscale behavior has been investigated with epithelial sheets grown on micropatterned islands of varying size and shape. Patterns of cell proliferation emerge that result from cell-cell and cell-ECM interactions within the epithelial sheet [3]. Chemical micropatterning has also been used with single cells to identify the role of cell shape in determining cell fate [4]. Geometric control of cell growth and viability was demonstrated by varying the size of chemically patterned islands of ECM.

Although micropatterning is a powerful tool to investigate cell behavior, particularly at the mesoscale, this approach has its limitations. Micropatterning techniques do not afford the ability to control the surface density of the patterned ligand. Additionally, the minimum feature sizes achieved with these techniques do not permit the exposure of multiple different ligands to a single cell. These drawbacks make it difficult to probe cell-ECM interactions at the scale of integrin engagement or focal adhesion formation. Additionally, cells in vivo are not exposed to flat two-dimensional (2D) surfaces but rather to a complex topological microenvironment. The ECM consists primarily of interwoven protein fibers ranging from 10 to 300 nm in diameter. Basement membranes consist of complex mixtures of nanoscale pits, pores, and fibers ranging in size from 5 to 200 nm with peaks and valleys of approximately 100 nm in height [5]. The investigation of cell behavior in response to these native nanotopologies cannot be explored using micropatterned surfaces.



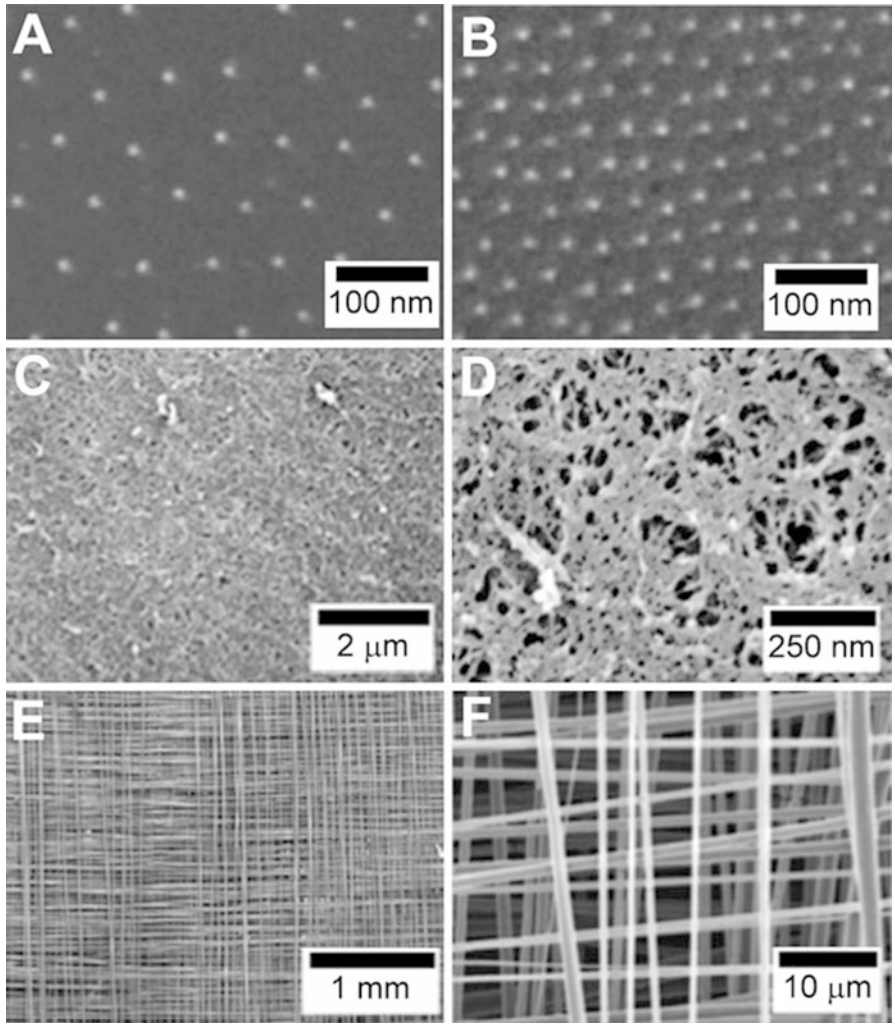
The advent of new tools and fabrication techniques has enabled the creation of spatial patterns in chemistry and topology that can vary greatly over the length scale of a cell. Nanoscale differences in surface roughness, fiber diameter, and ligand spacing can be produced using micropatterned substrata to more closely recapitulate the native tissue microenvironment. Thus, the goal of nanoscale patterning is to investigate molecular mechanisms and subcellular processes that determine fundamental cell behaviors including adhesion, proliferation, gene expression, and differentiation.

Fabricating Nanopatterned Substrata

Unlike micropatterned surfaces, fabrication of nanopatterned surfaces large enough for multicellular studies is technically challenging as well as time and labor intensive. As a result, studies to date have focused primarily on the behavior of single cells. The types of fabrication methodologies discussed herein are by no means comprehensive, but rather a sampling of commonly used techniques to create chemically and topologically defined nanopatterned surfaces. Fabrication technologies adapted from the semiconductor industry as well as novel nanobiotechnology methods are rapidly changing, enabling faster and simpler creation of nanopatterned features. For a more comprehensive review of fabrication techniques, the reader is directed to specialized reviews [6].

Topologically nanopatterned substrata are created using several techniques. These surfaces can be categorized as unordered or ordered topologies. Unordered topologies typically arise spontaneously as a result of processing methods including chemical etching and polymer demixing. Surfaces with unordered topologies have randomly patterned features and lack orientation and geometrical control, but the fabrication processes are relatively simple, fast, and inexpensive. Ordered topologies, on the other hand, are created with precise control of feature pattern, orientation, and geometry. Electron-beam (e-beam) lithography (Fig. 2) is the most commonly used approach to create nanoscale ordered topologies. E-beam lithography uses an electron beam to develop a layer of resist coated on the substratum. Following e-beam lithography, further processing of the substratum using standard etching techniques results in nanoscale topologies including nanoscale grooves, gratings, or pits.

Dip-pen nanolithography (Fig. 2) is a method to create chemically nanopatterned surfaces using an atomic force microscopy (AFM) tip [7]. The AFM tip is “dipped” into a reservoir, coating the tip with the ligand of interest, and is then used to repeatedly deposit small amounts of the ligand



Nanopatterned Surfaces for Exploring and Regulating Cell Behavior, Fig. 2 Cartoon representations of various fabrication modalities used to create nanopatterned surfaces

onto the substratum to form chemically patterned regions with an approximate spatial resolution of 5 nm. This technology enables the placement of different adhesive ligands in close proximity in defined shapes with nanoscale precision and dimensions. Additionally, this technology can be multiplexed to create a higher throughput chemical patterning system by combining multiple AFM tips in parallel.

In addition to the "top-down" fabrication strategies used to deposit or remove material from a surface as described above, newer "bottom-up" technologies of molecular self- or templated-assembly (Fig. 2) have been used to create larger chemically nanopatterned surfaces. Molecular self-assembly is a broad category of techniques wherein (supra)molecular building blocks or colloids are spontaneously self-organized as a result of their interactions to form nanoscale topology and/or spatial patterns of cell-adhesive ligands [8]. Similarly, templated-assembly creates the same types of surfaces with the use of a reusable template to define an organization for the molecular building blocks. These newer fabrication techniques (e.g., self-assembled monolayers (SAMs) and phase-separated block copolymers) have enabled the reliable creation of large patterned areas.

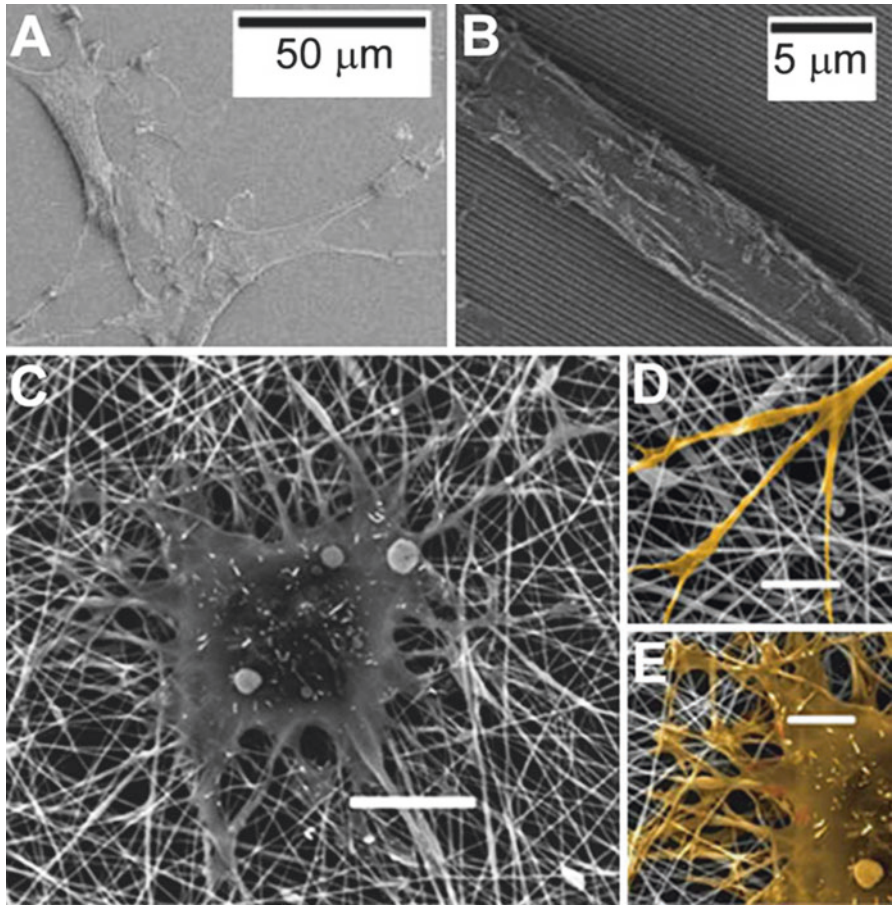
Whereas all of the fabrication techniques described above can be combined to create surfaces with heterogeneously patterned features that vary across length scales, other techniques such as electrospinning [9] do exist to create patterned surfaces that simultaneously expose cells to topologies with widely different dimensions. In electrospinning, an electric field is used to produce polymer fibers from a liquid solution. As the fiber orientation and diameter are easily controlled with simple experimental parameters, fibrous mats containing both nanoscale and microscale fibers can be created with aligned or randomly oriented topologies. Additionally, multiple fibers and complex fiber geometries can be spun simultaneously from different materials or conjugated with different cell-adhesive ligands. This produces substrata that more closely mimic the topology of tissues in vivo: complex fibrous meshes with nano- to micro-sized fibers and randomly

Nanopatterned Surfaces for Exploring and Regulating Cell Behavior, Fig. 3 Example substrata. (**a**, **b**) Ligand-coated gold nanodots can be spaced at varying distances to form chemically nanopatterned substrata (Reproduced with permission from Selhuber-Unkel et al. [12]). (**c**, **d**) The basement membrane of the cornea has topographical variations with both micrometer- and nanometer-sized features (Reproduced with permission from Abrams et al. [5]). Electrospun meshes can be formed to create both unordered and ordered topographies (**e**) and fiber diameters can vary within individual samples (**f**) (Reproduced with permission from Carnell et al. [13])

sized micropores/pits. Thus, electrospun substrata are widely used to determine how cell behavior is regulated by fiber alignment and multiscale distributions of fiber size and surface ligands.

Key Research Findings

Chemically nanopatterned substrata have been primarily used to investigate integrin engagement and focal adhesion formation in an effort to dissect out cell adhesion properties. The majority of these studies have been carried out on self-assembled surfaces containing RGD-functionalized gold nanoparticles [10] (Fig. 3). Integrin receptors are approximately 10 nm wide and these "nanodots" can be fabricated such that they bind to single integrins. As a result, spacing of bound integrins can be altered by changing the spacing of the nanodots on the substrata.



These nanopatterned surfaces have revealed that cell behavior is regulated by the spacing of adhesive ligands. Results from early studies showed that cell motility was affected on surfaces with RGD ligand spacings in the range of 6–300 nm and that spacings from 14 to 25 nm influenced cell-adhesion strength. Subsequent studies explored nanodot spacings between 28 and 85 nm [11] and found that RGD ligand spacings from 58 to 73 nm are optimal for integrin clustering and activation, whereas ligand separation greater than 73 nm causes significantly less cell adhesion, spreading, and integrin-mediated focal contact formation in osteoblasts. Additional studies have measured cell detachment forces from these substrata and demonstrated that spacings greater than 90 nm inhibited focal adhesion formation and decreased detachment forces compared to spacings less than 50 nm [12]. Overall, the data obtained using these chemically nanopatterned surfaces indicate that RGD ligand spacings should be less than approximately 70 nm to stimulate collective cell functions. Additionally, these stimulatory effects tend to increase as the ligand spacing decreases down to approximately 10 nm.

Studies using topologically nanopatterned substrata can be grouped into two categories, ordered or unordered, based on the layout of the surface features. Ordered surfaces consist of repeated features that are arranged with consistent height, spacing, and orientation. Such surfaces include those with uniform posts or pits and gratings formed by regularly spaced groves. Conversely, surfaces with randomly oriented, varying sized features, such as electrospun meshes, are classified as unordered. The mechanisms by which nanotopographic cues regulate cell behavior are not well understood. The emerging picture is that changes in cytoskeletal organization and structure may drive some of these cell behaviors, potentially in response to the underlying geometry or feature size of the surface. Regardless, it is clear that there is a range of different responses, or differing levels of response that vary by cell type.

Morphology and proliferation are altered when cells are cultured on surfaces with ordered nanotopography [14] (Fig. 4). Human mesenchymal stem cells (MSCs) grown on 350 nm-wide grooves have an aligned cytoskeleton along the direction of the features. Likewise, stem-cell-derived osteoblasts not only aligned and spread in response to nanogrooves of polystyrene, but also showed alignment in actin and mineralized matrix. Additional studies with human embryonic stem cells (ES) cultured on 600 nm polydimethylsiloxane (PDMS) ridges have demonstrated an altered organization of cytoskeletal components including F-actin, vimentin, γ-tubulin, and α-tubulin. The alterations to morphology and proliferation were eliminated when the ES cells were exposed to actin-disrupting drugs [15]. Generally, cells seem to be more sensitive to the depth of the groove as opposed to the groove pitch or spacing. Additionally, cell orientation increases with increasing groove depth on grated surfaces but decreases as the groove width or pitch increases.

Whereas the phenomenon of cell and cytoskeletal alignment is fairly conserved over a wide range of nanogratings of varying dimensions, cell behavior is more varied in response to ordered surfaces with pits and posts. The adhesion of osteoblasts was significantly increased when cultured on 11 nm-high posts compared to either 85 nm-high posts or flat polystyrene [16]. Similarly, fibroblasts also demonstrated increased adhesion and spreading on 13 nm posts compared with 95 nm-high posts. However, endothelial cells displayed less spreading and lower cytokine production when cultured on 100 nm-high posts as compared to flat control surfaces. In general, cells cultured on surfaces that are uniformly or randomly textured with nanometer-sized pits and pillars do not display aligned or preferential orientations.

Although comparing different unordered topologies is difficult due to differences in feature size, shape, uniformity, and chemistry, a trend does seem to emerge. In electrospun fiber meshes ranging from 283 to 1,425 nm in diameter, rat hippocampus-derived adult neural stem cells differentiate and proliferate in response to fiber diameter [17]. For fiber meshes smaller than 283 nm, cells did not demonstrate preferential patterns of spreading; however, as the fiber

Nanopatterned Surfaces for Exploring and Regulating Cell Behavior, Fig. 4 Examples of cell responses to nanotopography. Uniform cell spreading is observed on flat substrata (**a**), whereas cells spread and align along the direction of nanograted substrata (**b**) (Reproduced with permission from Yim et al. [14]). Cells spread, attaching to and around fibers on an unordered electrospun mesh (**c**–**e**). The cell is highlighted in *yellow* and scale bars are 10 μm (**c**) and 5 μm (**d**, **e**) (Reproduced with permission from Christopherson et al. [17])

diameter increased, cells extended along the length of the fiber. In contrast, proliferation increased as fiber diameter decreased. In another study investigating cell adhesion, fibroblasts demonstrated a higher level of adhesion to surfaces with unordered topology as compared to either flat surfaces or those with ordered topology [18]. In summary, the general trend is that cell behaviors such as proliferation, adhesion, and spreading are positively stimulated as the feature size decreases from ~100 to 10 nm.

While almost all of the studies to date have focused exclusively on either chemically or topologically patterned substrata, these parameters are difficult to decouple. Chemically nanopatterned surfaces inevitably have 5–10 nm variations in height across the substratum due to the islands of conjugated ligands. In topographically nanopatterned systems, differences in protein transport and adsorption due to structural features may result in differences in the presentation of adhesive areas and thereby alter cell behavior. Few studies have investigated the competitive or synergistic effects of both chemical and topographic cues [16]. When continuous chemically patterned strips of cell-adhesive ligand were orthogonally overlaid onto nanogrooves, fibroblasts preferentially oriented along the chemical

patterns. However, when fibronectin was orthogonally overlaid discontinuously along the top of a nanogroove pattern, osteoblasts preferentially aligned along the topographic pattern. From these limited data it is clear that a variety of systems involving both chemical and topological patterning over varying nanometer-sized scales need to be employed to fully understand interaction effects.

Applications

The basic science studies highlighted herein that seek to understand how nanoscale environmental cues influence cell behavior are fundamental to a range of applications. In particular, these data can be used to engineer biomaterial surface characteristics for improved performance. Materials that interact with the circulatory system, such as those used for stents or cardiac catheters, could be designed with a nanopatterned surface to prevent cell adhesion and clotting. Conversely, orthopedic implants, which need to integrate strongly with the surrounding tissue, could be designed with a nanopatterned bioactive surface to encourage cell adhesion, proliferation, and motility into the surface. Thus, understanding the nano-environmental cues will enable engineers to recreate physiologically desirable microenvironments for various biomaterial-tissue applications.

Nanopatterning also has applications for diagnostics and cell biology studies such as cell-based biosensors and cell sorting and culture systems. Integration of micro- and nanotechnologies with cell biology has yielded many new and exciting approaches. Use of microfluidics has created cells-on-a-chip or lab-on-a-chip designs where differential cell adhesion based on cell type is critical. Introduction of nanopatterned surfaces can enable a passive physical modification to these systems that would save fabrication time and complexity. Nanopatterned surfaces can be used as passive cell sorting systems that leverage the fact that different cell types respond differently to the same nanotopology. Thus a heterogeneous mixture of cells could be exposed to a nanopatterned surface and only the desired cell population would adhere. Additionally, as understanding of stem cell behavior on nanopatterned substrata grows, one could envision designing substrata that control stem cell adhesion, proliferation, and differentiation – cell behaviors that are difficult to control and that are currently modulated using complex media formulations and cell handling procedures.

Finally, studies with nanopatterned substrata can be integrated into the fields of tissue engineering and regenerative medicine. It is clear that the native in vivo environments and the chemical and physical cues to which cells are exposed are vastly different from those presented by traditional in vitro surfaces such as tissue culture plastic. Examination of signaling cascades within cells on nanopatterned surfaces can reveal how cells detect and respond to chemical and topographic signals in terms of short- and long-term cell functions, such as changes in gene expression and protein synthesis. These details of scaffold architecture and ligand presentation can improve tissue engineering technologies, and provide insight on disease processes where microenvironmental regulation is disrupted, such as in cancer. While some examples of nanopatterned tissue scaffolds exist, particularly with nanoporous materials for bone tissue engineering, the link between cell behavior in 2D and 3D is not straightforward. Cells in 3D environments adhere differently than those in 2D environments and contain different cell-ECM adhesions [19]. A recent study has even demonstrated that cells cultured on 1D patterns (lines) of adhesive ligands behave more similarly to cells in 3D matrices than to those on 2D chemically patterned islands [20]. Thus, while the link between cell behaviors in 2D and 3D is not certain, it is clear that further understanding gained using well-controlled nanopatterned surfaces can contribute to improved 3D tissue models and translational tissue engineering technologies.

Nanophotonic Fabrication

Takashi Yatsui
Department of Electrical Engineering and Information Systems School of Engineering, University of Tokyo, Tokyo, Japan

Definition

The word nanophotonic means the use of an optical near field. By using the optical near field, the spatial resolution of the fabricated structure is not limited by the diffraction limit of the light. In

addition, the optical near field can couple with material excitations including electron, hole, and phonon in the nanometer-scale range and result in the energy up-conversion with respect to the incident light energy. The coupled state of photon and material excitations is a quasiparticle and called a dressed photon. The true meaning of the nanophotonic fabrication requires the use of the dressed photon. Therefore, the unique fabrication process can be realized in the nanometer scale using the dressed photon, such as sub-nanometer-scale surface flattening [1], visible water splitting, and light-emitting diode with an indirect bandgap semiconductor [2].

Nano-optical biosensors; Nano-optics biosensing

Definition

One-dimensional, two-dimensional, or three-dimensional structures made of suitable materials, having dimensions ranging from few nanometers to few hundreds of nanometers in size, and said structures showing a well-defined interaction with light providing an optical transduction mechanism for detecting/revealing specific biomolecules in close proximity to the structure itself.

Overview

Optical biosensors [1] constitute powerful detection and analysis tools with wide applications in the biomedical domain. They can provide parallel detection within a single device. Generally speaking, there are two detection methods that are implemented in optical biosensing: fluorescence-based detection and label-free detection. Thanks to the recent advances of technological capabilities for the fabrication of nanometer-sized structures, most of the conventional techniques can be improved, and new original techniques have become feasible.

In fluorescence-based detection, target molecules are labeled with fluorescent tags, typically organic dyes and/or chemically functionalized/decorated quantum dots; the overall intensity of fluorescence indicates the presence of the target molecules. Some quantification can also be inferred, but in general quantitative analysis is challenging due to the fluorescence signal bias, as the number of fluorophores on each molecule cannot be precisely controlled. While fluorescence-based detection is extremely sensitive, with the detection limit down to a single molecule, it suffers from laborious labeling processes that may also interfere with the biological/chemical function of the biomolecule and/or its interaction with the environment.

In label-free techniques, target molecules are not labeled or altered and are detected in their natural forms. This type of detection is relatively easy and cheap to perform and allows for kinetic measurement of molecular interaction.

Despite all these differences between fluorescence-based and label-free detection, both protocols can benefit from the use of proper nanostructures and provide complementary information regarding interactions among biomolecules. In this framework, the use of dielectric,

metallic, and metallo-dielectric structures obtained by means of a number of methods, e.g., optical, electronic, or ionic lithographic processes, physical/chemical deposition/sputtering, chemical synthesis, or self-assembling, can improve both fluorescence-based and label-free biosensing. In the following, a broad variety of structures are described with particular focus to their respective main applications, but additional original combinations are still under investigation.

Label-Free Detection

Label-free techniques include refractive index (RI) detection, optical absorption detection, and Raman spectroscopic detection. In a typical label-free biosensing application, a means should be provided in order to uniquely identify the desired target biomolecules. There are basically two strategies that are implemented: a chemical functionalization of the optically sensitive area of the photonic nanostructure and a spectroscopic measurement. In the first case, the specificity of the photonic biosensor is demanded to the chemical functionalization, therefore allowing the specific detection of desired target molecules on the unique molecular recognition mechanism embodied by the chemical functionalization. In the second case, the recognition of the target molecules is performed by detecting the corresponding spectroscopic fingerprint (either the IR absorption or the Raman emission spectra). Unfortunately, the low Raman activity of the majority of biomolecules makes them little suitable for Raman analysis. Furthermore, a detectable Raman spectrum cannot be attained by simply increasing the power of the laser excitation radiation, because irreversible damages to the biological matter can be induced. Photonic metallic nanostructures producing strong field enhancements by means of localized surface plasmons (LSPs) can overcome this limitation, thus allowing a surface-enhanced Raman scattering (SERS) or a tip-enhanced Raman scattering spectroscopic detection. Nanostructures sustaining LSP can also provide for surface-enhanced infrared absorption (SEIRA) spectroscopic detection.

Surface-enhanced Raman spectroscopy (SERS) was originally discovered in the 1970s where it was found that submonolayers of small organic molecules, when adsorbed onto the surface of silver nanoparticles (and a few other metals such as copper and gold), would exhibit greatly enhanced Raman intensities (enhancements of 10^6) [2]. These results have always held the promise for using this technique to observe very low concentrations of molecules on nanoparticles and nanostructured surfaces, but only recently has this promise started to be fulfilled in a predictable way.

Thanks to exciting advances in techniques for making nanoparticles (such as nanosphere e-beam lithography and focused ion beam), to characterizing the surfaces using electron and scanning probe microscopies, to functionalizing the surfaces of the particles using self-assembled monolayers with attached chemical receptors, and to the laser and optics technology associated with measuring the Raman spectra, a number of important applications have been reported recently. SERS has almost exclusively been associated with three metals, silver (by far the most important), gold, and copper. The generalization to other metals and other materials has been explored since the discovery of SERS, but only in the last few years have the tools been available to generate well-characterized experiments where the reported enhancements are reliable.

Light incident on the nanoparticles induces the conduction electrons in them to oscillate collectively with a resonant frequency that depends on the nanoparticles' size, shape, and composition. As a result of these LSPR modes, the nanoparticles absorb and scatter light so intensely that single nanoparticles are easily observed by the eye using dark-field (optical scattering) microscopy. The shape of the nanoparticle extinction and scattering spectra, and in particular the peak wavelength λ_{max}, depends on nanoparticle composition, size, shape, orientation, and local dielectric environment [3]. The LSPR can be tuned during fabrication by controlling these parameters with a variety of chemical syntheses and lithographic techniques. Although silver and gold are the most commonly used materials, LSPR is theoretically possible in any metal, alloy, or semiconductor with a large negative

real dielectric constant and small imaginary dielectric constant.

When molecules adsorb onto a plasmonic nanoparticle or move to within a few nanometers of its surface, the local electromagnetic fields around the nanoparticle can enhance the Raman scattering by a factor of 10^6–10^8 for an ensemble of molecules and by as much as 10^{14}–10^{15} for single molecules. Two principal enhancement mechanisms are generally thought to explain the large SERS signals. First, an electromagnetic enhancement factor arises because LSPR modes in the metal nanoparticles focus the incident light energy at the nanoparticle surface and also increase the density of states at Stokes-shifted wavelengths. The electromagnetic enhancement factor is typically 10^5–10^8 for nanoprisms, but simulations indicate that it can be as large as 10^{13} for structures such as arrays of nanoprism dimers. Second, chemical enhancement factors arise from changes in the molecular electronic state or resonant enhancements from either existing molecular excitations or newly formed charge transfer states.

Wet chemical synthesis methods have now made it possible to fabricate plasmonic nanoparticles having a variety of shapes (e.g., spheres, triangles, prisms, rods, and cubes) with controllable sizes and narrow size distributions. Furthermore, metallic–dielectric and metallic–metallic core–shell nanoparticles and mixed metallic–alloy nanoparticles with different shapes (e.g.,, nanoshells and nanoprism) have been prepared. Fabrication of this large variety of different structures makes a variety of applications possible, as the spectral position of the surface plasmon resonance depends on both the shape and the size of the nanoparticle [4].

An alternative possibility of exploiting the localized near field generated in close proximity to metallic nanostructures is to employ a metallic nano-probe or tip where LSPs are coupled. Such a structure allows a well-localized source of highly confined electromagnetic field to be raster scanned on the surface of a given sample, in such a way that a high spatial resolution Raman mapping of the surface can be performed [5]. Tip-enhanced Raman scattering (TERS) has been observed for a number of molecules adsorbed at various substrates, including single-crystalline metal surfaces, showing thereby more than a millionfold enhancement of the Raman scattering [6].

In order to excite LSPs at the apex of a metallic nano-probe, a further structuring can be performed. For example, gratings can be lithographed on the side surface of a gold cantilevered tip to ease the excitation of plasmon polaritons upon external lateral illumination of the tip. Alternatively, resonant nano-antennas can be fabricated directly on the top of the tip.

An effect quite similar to SERS occurs in the mid-infrared region: molecules on metal surfaces show infrared absorption 10–1000 times more intense than would be expected from conventional measurements without the metal. This effect is referred to as surface-enhanced infrared absorption (SEIRA) to emphasize the analogy to SERS [7, 8]. Vacuum-evaporated thin metal films are used most frequently for SEIRA experiments. Thin metal films that show strong SEIRA are not continuous but consist of metal islands smaller than the wavelength of the incident light. The average dimension of the islands is few tens of nanometers. The density, shape, and size of the islands depend on the mass thickness, the evaporation conditions, and the chemical nature of the substrate. As the mass thickness increases, the islands grow in size, contact each other, and eventually form a continuous film. Connection of the islands significantly reduces the enhancement, suggesting that the small metal islands play an important role in the enhancement. The metal islands are polarized by the incident photon field through the excitation of collective electron resonance, or localized plasmon, modes, and the dipole p induced in an island generate a local electromagnetic field stronger than the incident photon field around the island. Experimental results suggest that the collective electron resonance is excited even in the mid-infrared region and that the enhanced electromagnetic field enhances the infrared absorption of adsorbed molecules.

Unfortunately, SERS-based biosensing shows low reliable quantifiable signals, because it

usually suffers from a wide distribution of enhancement factors. Recently, metamaterials have emerged as an excellent sensing technology that complements traditional plasmonic biosensors based on metallic colloidal nanoparticles or nanostructures [9].

Metamaterials are materials engineered to show properties that you cannot find in nature. They are conventional materials as metals or polymers densely packed in a periodic way. Their engineered structure (shape, geometry, size, orientation) and arrangement give them their peculiar properties. Those that exhibit a negative index of refraction for particular wavelengths have attracted significant research. Especially, the plasmonic responses of metamaterials can be tuned to the visible near-infrared region of the electromagnetic spectrum, which is in resonance with available laser frequencies widely used in spectroscopy, enabling a strong signal enhancement for both quantitative measurement and molecular identification [10].

As previously stated beside those label-free techniques based on spectroscopic measurements, there are quantitative methods based on the measurements of refractive index changes close to the nanostructured surface of the photonic biosensor. Among these, the surface plasmon resonance (SPR) technique and the waveguide-based (or optical fiber-based) technique play a major role.

SPR is based on the coupling of propagating or stationary plasmons on silver/gold/copper thin films. The potential of surface plasmon resonance (SPR) for characterization of thin films and monitoring processes at metal interfaces was recognized in the late 1970s. Generally, an SPR optical sensor comprises an optical system, a transducing medium which interrelates the optical and (bio) chemical domains, and an electronic system supporting the optoelectronic components of the sensor and allowing data processing. The transducing medium transforms changes in the quantity of interest into changes in the refractive index, which may be determined by optically interrogating the SPR. The sensor sensitivity, stability, and resolution depend upon properties of both the optical system and the transducing medium [11].

SPR can be used in a prism coupler configuration or with a grating coupler configuration. If a metallic–dielectric interface is periodically distorted, the incident optical wave is diffracted forming a series of beams directed away from the surface at a variety of angles. If the total component of momentum along the interface of a diffracted order is equal to that of the plasmon, the optical wave may couple to the plasmon. Grating-based optical SPR sensors have been demonstrated which use the measurement of the light intensity variations at SPR and the wavelength interrogation. A high-sensitivity SPR grating-based gas sensor using silver as an SPR active metal has attained sensitivity of 1000 nm RIU^{-1} in wavelength interrogation mode; in angular interrogation mode, the system's sensitivity would be about 100 deg RIU^{-1}. Gold-based SPR grating sensors have been used for monitoring biomolecular interactions in aqueous environments, with estimated refractive index sensitivity of 30 deg RIU^{-1} and 900 % RIU^{-1} in the angular interrogation and intensity measurement modes, respectively. The grating coupler has been also used for the excitation of an SPW in an optoelectronic SPR-sensing device based on a Schottky barrier semiconductor structure. Periodic and quasiperiodic structuring of smooth metal films sustaining plasmons can be used to create Bragg mirrors (stationary plasmons) and Fabry–Pérot cavities.

Electromagnetic modes propagating at the interface between a homogeneous medium and a truncated periodic structure like a dielectric monodimensional photonic crystal (1DPC), also referred to as Bloch surface waves (BSWs), have been proposed as an alternative to surface plasmon polaritons (SPP). The possibility to excite simultaneously several different BSW modes in the same 1DPC allows for self-referencing sensing [12]. In analogy to surface plasmons on smooth thin films, a surface periodic patterning of 1DPC sustaining BSWs has been performed in order to fold BSW dispersion curves, open photonic band gaps in the dispersions, and further enhance the sensitivity of BSW upon surface perturbations.

Dielectric micro- and nanostructures can be used for biosensing based on either refractometric or absorption measurements. Such sub-wavelength structures include Bragg mirrors, gratings, microcavities, micro-rings, and optical fibers and waveguides based on photonic crystals (PCs). Provided that some of the photonic structures mentioned above produce strong field localization that can be exploited for field enhancement effects, a large portion of their application consists in measuring shifts of the resonance conditions (light incident angle and/or wavelength) upon a perturbation of the refractive index of the external medium, containing the target biomolecules [13, 14].

Bragg mirrors consist of a periodic stack of dielectric materials acting like a lossless mirror for a given wavelength band. Periodic multilayers can be fabricated, e.g., by sputtering, thermal evaporation, and chemical vapor deposition (CVD) techniques. When one or more defect layers (spacers) are introduced therein, a defect (cavity) mode is obtained. In such a simple case, the cavity is a one-dimensional Fabry–Pérot cavity that has been widely used for refractometric measurements. If the material is porous in nature, such as electrochemically etched porous silicon, target molecules can penetrate inside the porous photonic structure (pore sizes are from few nanometers to tens of nanometers), thus providing a much stronger perturbation and lowering the detection threshold. If fluorescent labels are used, one-dimensional microcavities can also be used to improve the detection of fluorescence radiation, as described in the following.

Photonic crystal surfaces can be designed to provide a wide range of functions that are used to perform biochemical and cell-based assays. Detection of the optical resonant reflections from photonic crystal surfaces enables high-sensitivity label-free biosensing, while the enhanced electromagnetic fields that occur at resonant wavelengths can be used to enhance the detection sensitivity of any surface-based fluorescence assay. Fabrication of photonic crystals from inexpensive plastic materials over large surface areas enables them to be incorporated into standard formats that include microplates, microarrays, and microfluidic channels. The periodic modulation of the refractive index within a PC, along with incorporation of intentional line or point "defects" in the PC, can be used to concentrate and direct the electromagnetic fields associated with light to produce efficient wavelength-selective reflectors, waveguides, optical circuits, beam-steering devices, and optical multiplexors. PCs can be designed to interact strongly with particular optical wavelengths through selection of their materials and the period of their modulation. At the wavelengths of "optical resonance" (also known as "guided-mode resonance"), light will couple strongly to the PC structure for a particular incident angle, resulting in electric fields inside the PC that can be many times higher than the electric field of incident radiation. These optical resonances can be observed by an external observer simply by illuminating the PC at normal incidence with a broadband of and observing a narrowband of wavelengths that are reflected back with nearly 100 % efficiency.

Two-dimensional photonic crystals used for sensing applications are typically microfabricated periodic nanostructures on a two-dimensional planar silicon on insulator (SOI) chip. Such structures can be designed to exhibit a two-dimensional photonic band gap (PBG) that can be tuned by varying the structural parameters. Photonic cavity states within this PBG are formed by systematically introducing defects into the perfect hexagonal lattice during the fabrication process. In the case of nanocavities, the modal volumes are very small, of the order of $V < 1\ \mu m^3$, and, furthermore, the strongly localized electric field in the cavity is highly sensitive to local changes of the refractive index of the environment.

The photonic crystal concept is fruitfully applied to optical fibers, in which the transverse cross section of the fiber is patterned with channels specifically arranged, wherein the refractive index contrast provided by the nanostructuration results in multiple effects such as optical field localization, multimodal guiding, etc.

By combining the technology available for waveguide fabrication and the working principle of Fourier transform-based spectrometers, a suitable micro-device based on a high-density sample of the standing-wave interferogram produced inside a single waveguide has been obtained [15].

All the abovementioned techniques can be combined for obtaining devices and structures aimed at biosensing based on one or more of the described principles. For example, optical fibers presenting metal coatings or hosting metallic nanostructures can combine guiding and plasmonic effects, and fiber grating can ease light coupling/decoupling, resonance conditions, etc.

Fluorescence-Based Detection

As already mentioned, dielectric micro- and nanostructures can provide a means to improve the detection of labeled target molecules in close contact or impregnated within the photonic nanostructure. An example of such a structure is represented by one-dimensional porous silicon microcavities [16], in which the fluorescence emitted by labeled molecules (e.g., proteins) is enhanced upon diffusion of said molecules inside the porous structures of the cavity. Additional one-dimensional, two-dimensional, and three-dimensional (e.g., artificial opals) dielectric structures can be exploited for such enhancement effects, reaching very high Q factor of the order of 10^3 or more [17–19].

In recent years there has been a growing interest in the interactions of fluorophores with metallic surfaces or particles. Near-field interactions are those occurring within a wavelength distance of an excited fluorophore. The spectral properties of fluorophores can be dramatically altered by near-field interactions with the electron clouds present in metals. These interactions modify the emission in ways not seen in classical fluorescence experiments and can be controlled by properly structuring the surface of plasmonic substrates [20, 21].

While all metal–fluorophore interactions are based on the same physics [22], the effects can be different based on the geometry of the metal structure. Three possibilities are considered, in which a fluorophore is interacting with silver particles, a smooth metal surface, and a metal surface with a regular pattern. Metal particles can be typically used to increase the fluorescence intensities. This increase occurs by a combination of enhanced fields around the metal and rapid and efficient plasmophore emission. These effects are usually called metal-enhanced fluorescence (MEF) and typically result in increased intensities and decreased lifetimes.

In the case of a fluorophore interacting with a smooth metal film, it is typically about 40 nm-thick silver or gold. In this case the fluorophore creates plasmons which radiate at a defined angle into the substrate. Typically the intensities and lifetimes are not dramatically changed. This phenomenon is called surface plasmon-coupled emission (SPCE). Here the emission spectrum is the same as the fluorophore but the polarization properties indicate that the plasmon is radiating. Finally, an exemplary fluorophore can be placed over regular patterns (nano-rings, grooves, gratings, etc.). In this case the emission at certain wavelengths is expected to show well-defined beaming into the substrate (or air), while other wavelengths are deflected from the normal. These effects are due to a combination of interactions with a smooth surface and with the sub-wavelength features (according to a diffraction phenomenon). This more general effect is called plasmon-controlled fluorescence (PCF). Plasmon-controlled fluorescence provides an opportunity to create ultra-bright probes based on complexes of metal particles with fluorophores. The basic idea is to create metal–fluorophore complexes in which the metal particle increases the brightness of the bound fluorophores. This can be accomplished by trapping the fluorophores in metal shells or by coating metal particles with fluorophores [23]. Theory has predicted that fluorophores in metal shells can be 100-fold brighter than the isolated fluorophore, even after consideration of the transfer efficiency of incident light into the shell and radiation out of the shell. Such probes may have the advantage over quantum dots because of the low toxicity of silver particles, even if the silver surface is completely exposed.

Instead of organic fluorophores such as dyes, solid-state semiconductor nanoparticles (quantum dots) can be used. The luminescent nanostructures are becoming more and more popular in labeling bioassay [24].

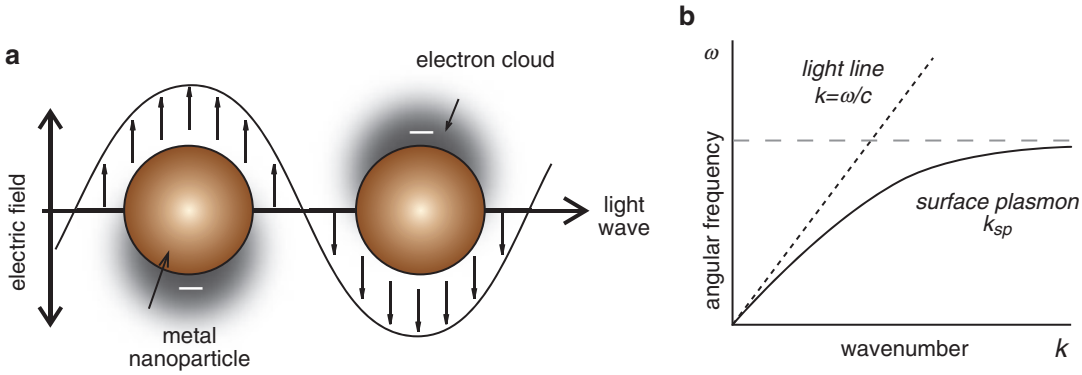
Plasmon-Assisted Two-Photon Polymerization; Photopolymerization Induced by Localized Surface Plasmon Resonance



Definition

Nanoplasmonics is an optical phenomenon occurring at the nanoscale vicinity confined to the surface of metal nanoparticles, and the electromagnetic field is generated only at their surface by the interaction with incident light. This effect induces a localized photopolymerization only at the restricted field near the nanostructures.

Nanoplasmonics on Metal Nanoparticles

Localized surface plasmon resonance (LSPR) is an interaction between free electrons of metal nanoparticles and incident light confined with three dimensions [1–5]. When light is incident to a metal nanoparticle with wavelength matched with the electron frequency, the collective oscillations of free electrons occur, and a localized electromagnetic field is formed at the surface. The intensity of the local electromagnetic field around the surface of nanoparticles is strongly enhanced, compared with the field of the incident light. Figure 1a shows a schematic image of LSPR excitation that forms an electron dipole on the metal nanoparticles.

The peak of the LSPR mode depends on material, size, shape, and aspect ratio (the ratio of long-to-short length) of nanoparticles, as well as dielectric properties of their surrounding environment. Spherical nanoparticles have only one LSPR mode. For example, gold spherical particles with diameter of less than 100 nm in aqueous solution show a strong extinction peak at 500–600 nm. On the other hand, nonspherical nanoparticles exhibit anisotropic optical and electronic responses. In the case of rodlike particles, namely, nanorods, two distinct peaks appear. One is the transverse LSPR mode excited by the light polarized along the short axis of nanorods. The other is the longitudinal LSPR mode excited along the long axis. The resonant wavelength of the longitudinal mode shifts to shorter/longer wavelength decreasing/increasing the aspect ratio of the nanorod. The resonant wavelength of the longitudinal mode is tuned across a broad spectral range, covering the

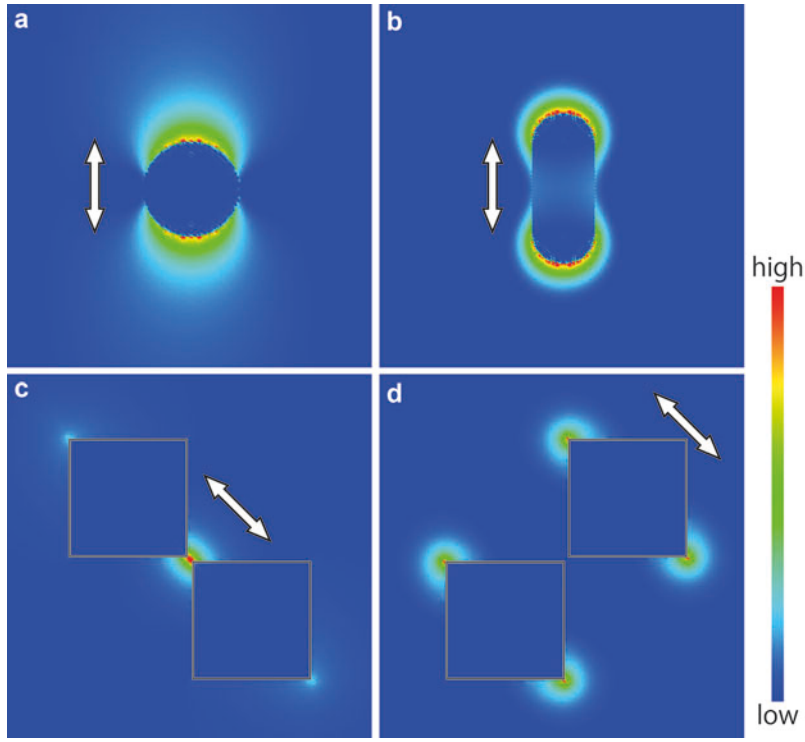
visible and near-infrared regions according to their aspect ratio.

Metal colloidal nanoparticles have been traditionally utilized as coloring materials, such as stained glass. Michael Faraday found that the color of ruby stained glass was caused by colloidal gold nanoparticles. In 1857, he had a Bakerian Lecture of the Royal Society entitled "Experimental Relations of Gold (and other Metals) to Light" [6]. He showed a ruby aqueous solution synthesized with gold salt and reducing agent. In his day, it was impossible to observe such small particles. In the twentieth century, by development of the electron microscope, it was revealed that the ruby red solution made by Faraday's method contained particles with average diameters of $3 \sim 30$ nm.

Dispersion Relation of LSPR

LSPR is three-dimensionally confined surface plasmon polariton (SPP), which propagates at the interface between metal and dielectric surface. The propagation mode of SPP can be explained with Maxwell's equation. Figure 1b shows the dispersion relation of SPP at the interface between a metal and a dielectric medium represented by the following equation:



$$K_{sp} = \frac{\omega}{c}\sqrt{\frac{\varepsilon_m \cdot \varepsilon_d}{\varepsilon_m \cdot \varepsilon_d}}$$

where K_{sp} is the wave vector of surface plasmon, ω is the angular frequency, c is speed of light in vacuum, and ε_m and ε_d are the dielectric constants of the metal and the surrounding dielectric medium, respectively.

When wave vector of light at frequency ω propagates through the dielectric medium ε_d, its dispersion curve is straight. The wavelength of SPP is shorter than the wavelength of light line in vacuum. The curve of the dispersion relation of SPP does not interact with the straight light line. However, the evanescent light with transverse magnetic polarization can react with the electric field on the metal surface. Coupling with evanescent wave, the dispersion relation of light inclines to the new line and makes a cross point with the dispersion curve of SPP. Therefore, the electromagnetic field on the metal surface is enhanced, whose intensity is larger than the incident light.

Theoretical Calculation of LSPR

The intensity distribution of enhanced field has been theoretically investigated with calculation methods, such as the finite difference time domain method (FDTD) and discrete dipole approximation. Extension of Mie scattering theory is utilized to analyze the mode of plasmon resonance. FDTD is a calculation method based on Maxwell's equation. Figure 2 shows the field intensity patterns by using calculation software of Poynting for Optics (Fujitsu Limited). Gold nanoparticle (Fig. 2a), nanorod (Fig. 2b), and nanoblocks with a nanogap (Fig. 2c, d) were set as model structures. A nanoparticle had a diameter of 50 nm. A gold nanorod

Nanoplasmonics Involved in Localized Photopolymerization, Fig. 2 FDTD calculation result of the intensity distribution of local enhanced field on (**a**) gold nanoparticle, (**b**) gold nanorod, (**c**, **d**) gold nanoblocks with nano gap

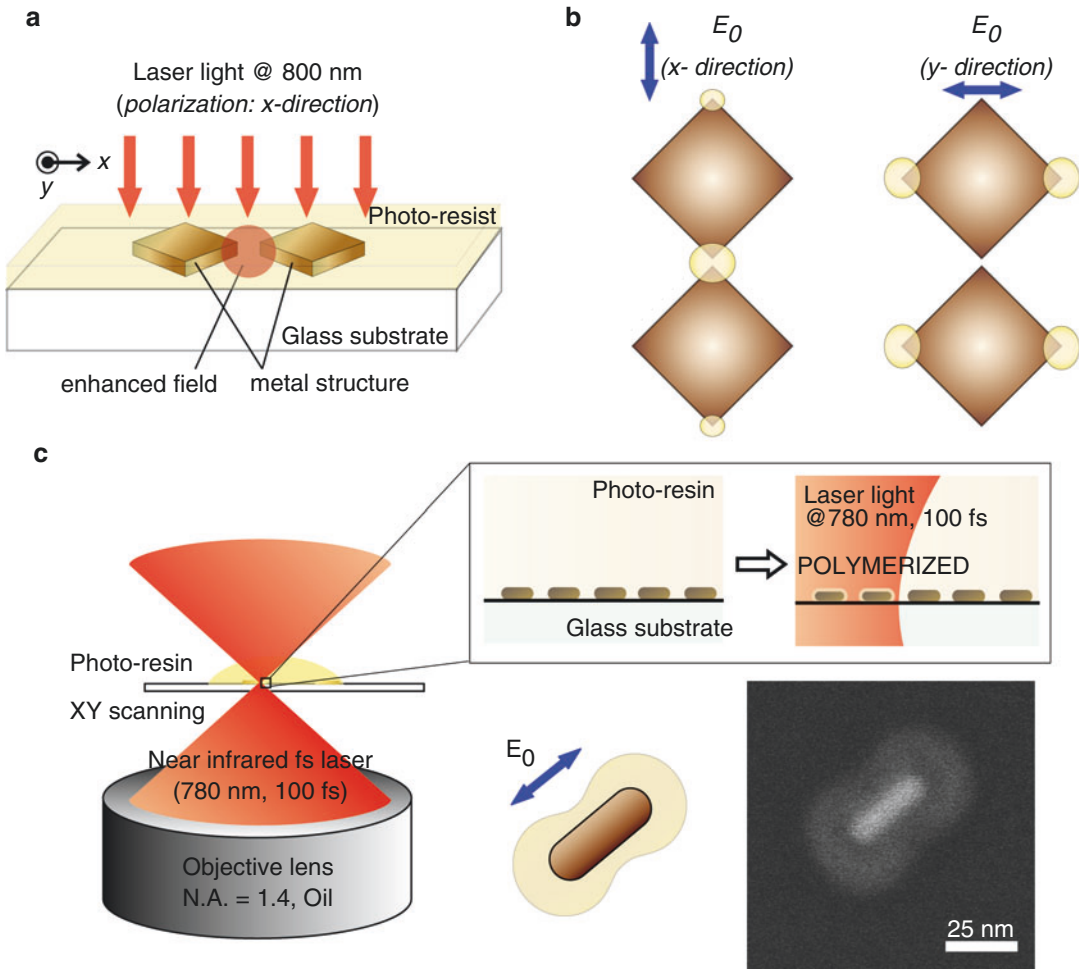
was designed as a cylinder capped with a half sphere at both ends. The total length of the nanorod was 60 nm, and the diameter was 25 nm. Each size of gold nanoblocks was X = Y = 80 nm and Z = 40 nm and was set with a gap distance of 4 nm. All components were set in vacuum. The dielectric function of gold was represented with a combination of the Drude and Lorentz model. Each incident light was set to the resonant wavelength of each structure polarized in the arrow direction. For example, in the case of nanorod, the polarization direction was set parallel to the long axis. The entire field was discretized with a spatial mesh with variable size, which reached down to 0.5 nm in the vicinity of the structure. Far-field and near-field intensity patterns were monitored on a range of x-y planes cutting through the structures. As a result, the enhanced field was localized at both corners of nanoparticles along the incident polarization direction. At the gap between nanoblocks, a strong electromagnetic field was excited as a near-field enhancement on their surface. The strong enhancement was up to 3 orders larger than the incident light. When the incident light was polarized perpendicular to the axis of the pair, the enhanced field is concentrated on the left and right tips of the nanoblocks.

Visualization of Local Enhanced Field

Experimental observation of the intensity distribution caused by LSPR on the nanostructures as mentioned above gives us valuable information to utilize the optical field enhancement in optical applications. There are roughly two types of direct observation methods to visualize the optical field and to understand the basic features. One is to use a microscopic technique [1, 7] and the other to induce a photochemical reaction at the local enhanced field.

Local Enhanced Field Observation by Microscopic Technique

When the diameter of nanoparticles is much smaller than the wavelength of incident light, observation methods beyond the diffraction limit

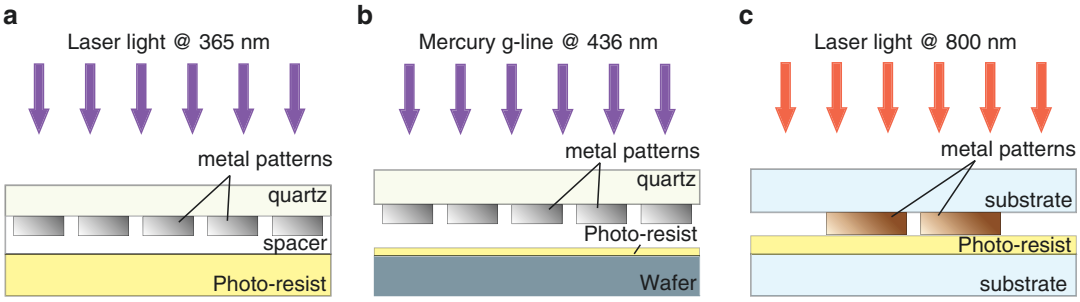


of light are needed to visualize the optically enhanced field on the small nanostructures. The spatial resolution of a conventional optical microscope is restricted to the wavelength of incident light, because of the diffraction limit of light. For observation with high spatial resolution, several types of optical microscopic techniques have been studied, that is classified with super-resolution far-field optical microscopy with nonlinear optical responses, and aperture-type and scattering-type near-field optical microscopy. Electron microscopy with cathodoluminescent detection and with electron energy loss spectroscopy has also been used for observation of LSPR modes [1, 7]. The spatial resolution is similar to that of optical microscopy.

These microscopic techniques show the result of localized electromagnetic density on metal nanostructures. The resulting images correspond to the wave functions of the excited state on the nanostructures. The wave functions are indicated as amplitude of the collective oscillation of plasmon as a function of the position.

Photochemical Reaction Induced by Local Enhanced Field

Photochemical reaction is utilized for visualization of the intensity distribution of local enhanced field. For example, photopolymerization induced by a local enhanced field has been demonstrated with several types of nanostructures, such as spherical nanoparticles, nanorods, nanobowties, and nanoblocks with a nanogap. These kinds of metallic nanostructures are produced by lithography technique. Various types of lithography techniques have been proposed to produce arbitrary nanostructures with the size, shape, configuration, and gap size between nanostructures, not only the polymeric structures but also the metallic structures [8]. The nanostructures are fabricated on a substrate and are covered with negative or positive photoresist. The absorption peak appears in the ultraviolet (UV) region, because of the photoinitiator contained in the photoresist. The wavelength of incident light is selected as a resonant wavelength of nanostructures in the visible or near-infrared regions for generating one-photon or multiphoton absorption of photoresist. The intensity of light is set weaker than that for usual two-photon polymerization. When the light is incident on the nanostructures, LSPR occurs on their surface. Only at the enhanced field with high intensity, cross-linking reaction of photoresist is induced via absorption of photoinitiator in photoresist and photopolymerization occurs. Figure 3a shows the schematics of predictive photopolymerization patterns on nanoblocks with a nanogap. The nanoblocks are set on a substrate and covered with photoresist, and then, polarized light at a wavelength of 800 nm is incident to them. When the light is polarized along x-direction and the absorption peak of photo resist exists around 400 nm, the enhanced field is generated and is localized at the nanogap between nanoblocks. Therefore, photopolymerization occurs at the local position. The enhanced field corresponds to the FDTD calculation result shown in Fig. 2c. Depending on the polarization direction of light, the position of the enhanced field changes. The arrows shown in Fig. 3b indicate the polarization direction of incident light. If the light is incident to the pair of nanoblocks parallel to the long axis of the pair, photopolymerization occurs at the gap. When the incident polarization is perpendicular to the gap, the enhanced field is excited at each corner of nanoblocks, not at the nanogap.



Not only the lithography techniques but also the chemical synthesis methods are useful for producing nanoparticles, which have been established as a simple mass production method of uniform metal nanoparticles [9]. A number of methods are reported to synthesize nanoparticles with various sizes and shapes. Figure 3c shows the schematic image and experimental result of photopolymerization at the local enhanced field at a single gold nanoparticle [10]. Controlled by additive chemicals during synthesis, the resonant wavelength of nanorod was tuned to fit the incident laser light. Synthesized nanoparticles in aqueous solution are dried on a substrate and then are covered with UV photosensitive resin composed of methyl methacrylate (MMA) monomer. A femtosecond laser with a wavelength of 780 nm was irradiated onto the nanorod, which was polarized parallel to the long axis, and then

Nanoplasmonics Involved in Localized Photopolymerization, Fig. 3 Schematic images of (**a**) Schematic image of setup for photo polymerization by local enhanced field at the nanogap induced by LSPR of metal nanoblocks, (**b**) predictive photopolymerization part, (**c**) experimental condition and the experimental result of LSPR-induced photopolymerization at the gold nanorods

the uncured resin was washed away. By scanning electron microscope (SEM) observation, photopolymerization was obtained only at both edges of the nanorod. The thickness of the polymerized layer covered the nanorod with length of 62 nm and diameter of 22 nm were characterized as 21 and 14 nm at the end and the middle of the gold nanorod, respectively. The shape and thickness of the polymerized part was in proportion to the intensity of laser light. The shape was changed from the "dumbbell" to the "ellipsoid" with increasing laser intensity. The thickness of obtained photo-polymerized layer was less than 30 nm from the surface. This result indicates that the effective intensity distribution of enhanced field of plasmonic resonance is less than 30 nm. It is clear that the shape of the polymerized area provides a snapshot of the near-field intensity distribution with high spatial resolution.

Furthermore, the local enhanced field induces a local movement of the polymer film caused by a photochromic reaction via two-photon absorption [11]. Polymer film mixed with photochromic dye molecule, such as azo-benzene and diarylethene, is put on the metal nanostructures. Since the dye molecules give rise to trans-cis isomerization after

Nanoplasmonics Involved in Localized Photopolymerization, Fig. 4 Schematic images of (**a**) plasmonic nanolithography with metal photomask, (**b**) surface plasmon resonant interference lithography (SPRINT), (**c**) nanogap-assisted surface plasmon nanolithography

photo-excitation, the dye along the local enhanced field changes its orientation in the polymer matrix, resulting in forming the surface relief of polymer film. In the case of nanoparticles, the local enhanced field is generated at their corner or edge. Two holes are observed on the polymer film close to the particles along the direction of the polarization of incident light.

Plasmonic Nanolithography

Three-dimensional (3D) micro/nanofabrication techniques have been established to produce micro/nanoscale devices. By reducing the wavelength of incident light and utilizing a nonlinear response of photo resists, the fabrication resolution has been improved beyond the diffraction limit of light. Two-photo polymerization technique is also well known as a fabrication method of 3D arbitrary micro/nanostructures [8, 12–14]. When a femto second near infrared laser light with high intensity is focused in UV-photosensitive resin, the intensity of photons becomes high only at the focus position and the opportunity of two-photon absorption of the resin becomes high. Then, two-photon polymerization occurs. Scanning the focus spot of laser light can produce arbitrary micro/nano structures. The finest structure by using this technique is reported as less than 20 nm.

On the other hand, plasmonic nanolithography is one high-resolution lithography technique with SPP, for achieving fabrication resolution beyond the diffraction limit of light. SPP generates a strong enhancement of electromagnetic field at the surface of metal nanostructures.

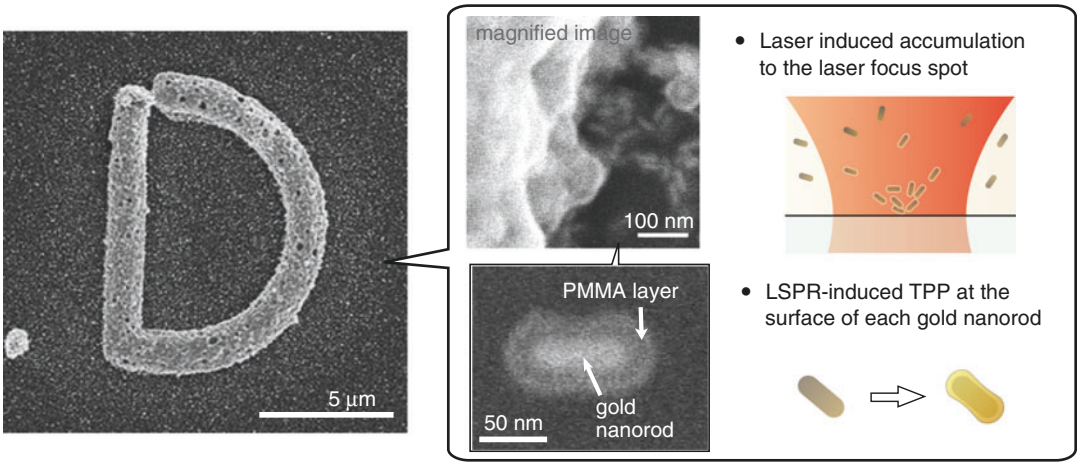
Several methods have been reported, such as plasmonic nanolithography with photomask [11, 15], surface plasmon interference nanolithography [11, 15], and nanogap-assisted surface plasmon nanolithography [11, 16, 17]. Furthermore, there is a method that a local photopolymerization excited at a surface of metal nanoparticles by enhanced field is used as a glue to fabricate 3D structure of metal/polymer composite. [18]

Plasmonic Nanolithography with Photomask

Experimental possibility of plasmonic nanolithography has been studied with a photomask that has metal patterns on quartz substrate, as shown in Fig. 4a [11, 15]. Aluminum or titanium exhibits strong plasmon resonances in UV region. The light at a wavelength of 365 nm is blocked at the aluminum or titanium patterns and transmitted through the photomask. 2D periodic structures on aluminum or titanium film are fabricated by using Focused Ion Beam lithography and Electron Beam Lithography. Then, the film was sandwiched by quartz substrate and PMMA spacer to work as a photomask. UV light was irradiated through an array of 40 nm holes with 170 nm periods on the mask and the pattern was transferred to a negative photo resist of SU-8. The size of the resulting structure was 90 nm with the same period. However, small holes on the aluminum mask led to a strong attenuation of light

transmission. Silver exhibits plasmon resonance with UV light, so serves as a material for photomask As a result, 60 nm resolution patterns were obtained. The size was less than 1/6 of the wavelength of incident light. The features of the obtained patterns were not perfect, but almost equal to those of the photomask.

Surface Plasmon Resonant Interference Lithography



Surface plasmon resonant interference lithography (SPRINT) is a method to fabricate the periodic grating patterns with sub-100 nm lines with high efficiency using photo-resin and UV or visible light [11, 15]. The point of SPRINT is to use interference of SPP for producing nanoscale spatial resolution and to suppress the exposure time by using the enhancement of SPP. Figure 4b shows the schematic setup. When the light (Mercury g-line at the wavelength of 436 nm) is illuminated from the top, the light transmits through the mask via SPP. The SPP propagates and interferes with each other and then, induces the strong field with spatial distribution in nanoscale on the metal surface. The resulting enhanced field is irradiated to the photo resist directly below the mask. As an experiment, a silver mask was fabricated on a 2-mm thick quartz plate with a periodicity of 300 nm and the opening of 1/5 of the periodicity. The resulting structure was 50 nm line width of grating pattern with a period of 300 nm. The other experiment using silver and magnesium fluoride multilayer achieved a feature size of 20 nm of periodic patterns under the wavelength of 193 nm. Changing the pattern of photomask with various size, shape and layout easily controls the fabricated patterns.

Nanogap-Assisted Surface Plasmon Nanolithography

The hot spot of metal nanostructures with nanogap is useful to fabricate a nanometer-size polymer structure by transferring it to photo resist [11, 16, 17]. This technique is similar with the method to visualize the local enhanced field on nanoparticles or structures. Figure 4c indicates the geometry of a pair of gold nanoblocks separated by a nano gap and the setup for nanogap-assisted surface plasmon nanolithography with positive photo resist. An array of gold nanoblocks (80, 80, 35 nm) with a gap width of 4 nm was prepared on a glass substrate as a photomask. A pair of nanoblocks resonated to the light of wavelength around 800 nm, which polarization direction was set parallel to the long axis of the pair. The photomask was put on a thin layer of positive photo resist coated on substrate. This photo resist has absorption around 500 nm. A femto second laser light with a wavelength of 800 nm is illuminated through the photomask to the photo resist. Through the two-photon absorption process, the photo resist was polymerized only at the nano gap position of the photomask. The calculated result of the enhanced field was 5 orders larger than the incident light. As an experimental result, a polymerized spot with 5 nm in a diameter was obtained with a periodicity of 400 nm. This corresponded to the hot spot of the nano gap between nanostructures. This method can be utilized as a lithography technique to produce small nano patterns with the diameter in sub-nanometer scale.

3D Micro/Nanofabrication of Metal Nanoparticle Aggregated Structures Based on LSPR-Induced Photo Polymerization

LSPR at the metal nanoparticles has potential to produce local photopolymerization at its surface. Not only to the nanoparticles fixed on a substrate, LSPR on the nanoparticles floating in photosensitive resin is also excited by light irradiation of their resonant wavelength [18]. By means of LSPR at meal nanoparticles, 3D micro/nanofabrication technique was proposed to fabricate metal nanoparticles/polymer composite with arbitrary structures. The key of this technique is LSPR induced two-photon polymerization on metal nanoparticles and optical gradient force to the nanoparticles into the focus position. The resulting composite structures are formed with aggregation of metal nanoparticles glued by polymer. Figure 5 shows the experimental result and the schematic image of experiment. Gold nanorods was chemically synthesized, which absorption peak was around 520 nm and 780 nm corresponding to their anisotropic shape.

Nanoplasmonics Involved in Localized Photopolymerization, Fig. 5 Schematic image and the resulting SEM image of 3D micro/nanofabrication technique for making metal nanoparticles aggregated structures base on LSPR-induced photopolymerization

The nanorods were mono-dispersed in UV photosensitive resin composed of MMA monomer. Illuminated by femto second laser light at a wavelength of 780 nm, LSPR on the nanorods was excited and photo-polymerization was observed locally at both their edges. Because the absorption peak of photosensitive resin appears at the wavelength shorter than 400 nm, this polymerization is caused by two-photon absorption of photosensitive resin and two-photon polymerization was induced only at the enhanced field. Simultaneously, the floating nanorods accumulated at the focus spot by optical gradient force generated by tightly focusing the laser light. Gold nanorods and the polymerized layer at their surface worked as building blocks and glue, respectively, to make aggregation of nanorods. SEM image shows the resulting structure by scanning the laser spot. Each nanorods were covered by polymer layer and stacked together. This method can create metal nanorod aggregates with desired micro/nanostructures.

Summary

Nanoplasmonics is an optical phenomenon on metal nanostructures. LSPR is an interaction with metal nanoparticles and incident light, which causes a collective oscillation of free electrons at the surface of metal nanoparticles. It is known that the intensity of LSPR enhanced field is very high only at the interface between metal and dielectric materials and localized at the edge of nanoparticles or nanostructures. The visualization of the enhanced field is an important role for development of plasmonic nanolithography. Not only the observation by using optical microscopy but also the photochemical reactions induced by the enhanced field on metal nanostructures have been used for visualization, such as the local photopolymerization at the surface of metal nanoparticles, and the movement of polymer films. Furthermore, this restricted enhanced field can produce nanostructures with a size beyond the diffraction limit of light. Nanopatterns of metal nanostructures can be reflected to the photoresist with photo-polymerization induced by local enhanced field of LSPR. The local photopolymerization occurs not only at the surface of nanostructures fixed on substrates, but also that of floating nanoparticles in photosensitive resin. A fabrication technique with floating meral nanoparticles with LSPR induced photo polymerization was proposed for fabrication of 3D metal nanoparticle aggregated structures in micro/nano scale. By the illumination of incident light, floating nanoparticles are coated by photo-polymerized layer induced by

LSPR of nanoparticles. Occurring simultaneously with their accumulation by optical gradient force, the polymer layer works as a glue to fix them together. These techniques would pave the way for novel micro/nanofabrication methods for plasmonic materials and devices.

Definition

Molecular nanopolaritonics is the study of nanoscale control of near-field energy transport via combined plasmon–molecule excitations.

Introduction

Absorption and emission of light (from near-IR to UV) on the nanoscale is qualitatively associated with one of two types of entities: excitons and plasmons. Excitons are associated with transition of electrons between occupied and unoccupied orbitals, i.e., a particle-hole excitation. Plasmons, on the other hand, are classical-like collective excitation of electrons in metals that are analogous to tidal waves. Specifically, when an electric field excites a plasmon, all the valence electrons in the metal shift, in tandem, creating a surface dipole; the remaining background exerts a restoring force and the resulting oscillation is in the IR to UV range, depending on geometry.

The coupling of an exciton and a plasmon is known as a polariton. Polaritons are usually associated with surface excitons. They have been applied in various fields, and at low temperatures even exhibit Bose–Einstein condensates [1]. Here, the combination of excitons and plasmons on the nanoscale is discussed, where the plasmon is part of a relatively small metal structure and even more importantly, the exciton is associated with a molecule or a cluster. Such a combination is labeled as nanopolariton [2], and its properties and approaches for simulation are discussed here. The greatest emphasis here is on the manipulation of transport of nanopolaritons by varying the molecular properties, as detailed below.

Broadly speaking plasmon–molecule interactions come in two forms: the influence of plasmonic fields on molecules, and the influence of molecules on plasmonic fields. The first, which is the typical focus of plasmon–molecule studies, is where plasmons focus light into molecules driving them into highly excited states, such as in surface-enhanced Raman spectroscopy (see ▶ Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy). SERS relies on the fact that classically, an electric field near a metal surface is very strong, especially near the plasmon resonance. In SERS, the massive electric fields due to plasmons on a metal lead to huge enhancements in Raman scattering, allowing for the detection of single molecules [3]. Other examples of plasmons acting on molecules include plasmon-enhanced fluorescence, near-field optical microscopy, and enhancements in FRET [4].

The second direction, where single molecules have a significant effect on plasmons, is more subtle and less understood. Molecules have a much smaller transition dipole moment than metal nanostructures (as they have few electrons, versus hundreds to million and more electrons in metal structures) and therefore molecules will generally have a negligible effect on overall light absorption of a polaritonic system, except possibly at very low temperatures. However there is one place where plasmonic interactions are weak: in the transport of plasmons from one structure to another. As this transport involves comparatively weaker coupling between plasmon modes, under certain circumstances it can be influenced by nearby molecules. While this article focuses primarily on molecule-mediated plasmon transport, linked DNA molecules have been shown to alter the dielectric properties of arrays of metal nanoparticles [5].

The length scales relevant for nanopolaritonics are significantly smaller than even UV wavelengths. At such scales, the electromagnetic fields are essentially "near fields," i.e., the field due to a dipole is closer to its electrostatic form, so it is strong and decays rapidly with distance; the far-field-radiated part, proportional to the acceleration of the dipole, is much weaker over these scales (the ratio between the far and near fields for a distance scale R is approximately R^2/λ^2, where λ is the wavelength). The simulation of the near-field combined plasmon–molecule excitations (polaritons) involve a complicated interplay of distinct mechanisms, including quantum excitations, classical electrodynamics, and charge transfer, which involve a range of length and energy scales. This makes concise treatment of these systems very difficult: molecules on the order of a nanometer must be treated quantum mechanically, whereas plasmonic materials with sizes of up to hundreds of nanometers are usually too large to treat quantum mechanically in a computationally efficient way, and thus must be

treated classically in most cases. Therefore, a primary thrust of theoretical molecular nanopolaritonics is and will be the development of methods which can effectively treat and provide an interface between these classical (metal) and quantum (molecular) regions.

Nanopolaritonics: Methodology

Overview

There are several techniques used to model behavior in nanopolaritonic systems, but in general they involve coupling classical fields to a quantum mechanical molecule. Some examples are described in greater detail below. Briefly, the simplest method evolves the spatial charge density of the metal in time and couples plasmons to a molecular density matrix via dipole interactions. A more sophisticated treatment models classical regions with the finite-difference time-domain (FDTD) method (see the entry in this volume on ▶ Finite-Difference Time-Domain Technique), and couples the classical electric field to the molecular density matrix again via dipole interactions. This particular technique has the advantage that the classical description can easily be interfaced with essentially any type of quantum mechanical treatment of a molecule, including time-dependent density functional theory (TDDFT), time-dependent Hartree–Fock (TDHF), or semiempirical methods, as described later.

Plasmon Surface Modes Coupled to Electronic Density Matrices

In the simplest treatment, appropriate for molecules near metallic structures, a set of modes is first used to represent the plasmons via surface modes on the metals [6]. The charge density on the metals is written as

$$\sigma(\mathbf{r},t) = \sum_J C_J(t) S_J(\mathbf{r}) \tag{1}$$

where $S_J(\mathbf{r})$ is a surface-localized charge mode on a metal particle (e.g., dipole, quadrupole, etc., for a spherical metal particle, or a more general function in other cases), and the time-dependent coefficients which determine the evolution of the surface modes were introduced. The dynamics of these surface modes is associated with plasmons; the collective oscillation of the charges causes a time-dependent surface charge.

The surface charges are then coupled via dipole interaction to specific molecules; the resulting equation for the motion of the modes, including interaction with other modes and with specific molecules is then [2]:

$$\sum_K M_{JK}\ddot{C}_K(t) = -\sum_K V_{JK}C_K(t) - \sum_K M_{JK}\frac{\dot{C}_K(t)}{\tau_K} - \sum_{ij}\rho_{ij}(t)q_{ij,J} - v_J(t). \tag{2}$$

The first three terms are purely plasmon related, including mass terms (M_{JK}) associated with the kinetic energy of the surface modes, potential terms (V_{JK}) associated with coulomb interactions between the surface modes, and Drude damping terms ($1/\tau_K$) responsible for the dephasing and damping of the surface modes. The next term contains a dipole integral $q_{ij,J}$ coupling the plasmon modes to the molecule; the molecular density is represented as a density matrix with a constant (pre-interaction) part, ρ^0_{ij}, and a time-dependent part induced by interaction with the plasmons, $\rho_{ij}(t)$. Finally, the last term is the interaction with the external field, $V_J(t)$.

The other relevant equation is the time-dependence of the density matrix for the molecules. For each molecule, schematically, apply the Liouville equation:

$$i\frac{d\rho_{ij}(t)}{dt} = [F(\rho),\rho]_{ij} - i\gamma_{ij}\left(\rho_{ij}(t) - \rho^0_{ij}\right) + \left[\sum_J C_J(t)q_J,\rho\right]_{ij}, \tag{3}$$

where the following variables are introduced: the Fock matrix ($F(\rho)$), which depends itself on the density matrix; the damping coefficients (γ_{ij}) which determine the return of ρ to the equilibrium density matrix, ρ_0; and the coupling to the

classical fields of the plasmons via the dipole coefficients $q_{ij,J}$. Details of the different possibilities for a Fock operator are presented later.

The simplest way to view Eqs. 2 and 3 is when the excitation is not very large, as then they can be linearized in the density matrix. Then, the linearized equations have a simple form:

$$i\frac{d\mathbf{f}}{dt} = \mathbf{L}\mathbf{f}, \tag{4}$$

where $\mathbf{f}$ is the nanopolariton, i.e., the combined vector describing both the plasmon modes and the density matrix. Schematically, $\mathbf{f}$ is made from four parts: the surface charge coefficients and their time derivatives, as well as the real and imaginary part of the excitation of the density matrix away from the ground state:

$$\mathbf{f}^T = \left(C_J, \frac{dC}{dt}, \mathrm{Re}\left(\rho - \rho^0\right), \mathrm{Im}\left(\rho - \rho^0\right)\right). \tag{5}$$

In the generalized Liouville coupling matrix, L is straightforwardly shown to be

$$L = \begin{pmatrix} 0 & -\mathbf{M}^{-1} & 0 & 0 \\ -\mathbf{V} & -\tau^{-1} & -q & 0 \\ 0 & 0 & -\gamma & \Delta \\ -q & 0 & -\Delta - Z^{2B} & -\gamma \end{pmatrix}$$

The specific terms in the Liouville matrix result from a linear-response analysis of Eqs. 2 and 3.

Maxwell–Schrödinger Simulations

The plasmonic-mode model is appropriate for qualitative studies, especially because of its very modest computational requirements. However, a quantitative investigation requires a more realistic treatment of the electric field distribution. The best-known approach for simulating the electromagnetic fields is FDTD, where one propagates the Maxwell equations [7]. Assuming for simplicity no magnetic susceptibility effects, these read:

$$\begin{aligned} \frac{\partial \mathbf{E}(\mathbf{r},t)}{\partial} &= \frac{1}{\varepsilon_{\mathrm{eff}}(\mathbf{r})}\left(\nabla \times \mathbf{H}(\mathbf{r},t) - \mathbf{J}\,(\mathbf{r},t)\right) \\ \frac{\partial \mathbf{H}(\mathbf{r},t)}{\partial t} &= -\frac{1}{\mu_0}\nabla \times \mathbf{E}(\mathbf{r},t), \end{aligned} \tag{6}$$

where the electric and magnetic fields and the frequency-independent part of the susceptibility are introduced.

The current, J, is made from two parts, $\mathbf{J} = \mathbf{J}_p + \mathbf{J}_m$; the first term is the usual plasmonic contribution, which in FDTD is simulated as a sum of terms,

$$\mathbf{J}_p(\mathbf{r},t) = \sum_n \mathbf{J}_{p,n}(\mathbf{r},t), \tag{7}$$

where the individual terms fulfill

$$\frac{d\mathbf{J}_{p,n}(\mathbf{r},t)}{dt} = \alpha_n(\mathbf{r})\mathbf{J}_{p,n}(\mathbf{r},t) + \beta_n(\mathbf{r})\mathbf{E}(\mathbf{r},t). \tag{8}$$

The sum typically includes 1–5 terms, and the individual terms ($\alpha_n(\mathbf{r})$ and $\beta_n(\mathbf{r})$) in the sum are usually fitted to give the correct dielectric function in the frequency range of interest. Other, somewhat more sophisticated time evolution techniques for Eq. 8 have also been suggested.

The second part of the current is the molecular contribution, which for a single molecule will be

$$\begin{aligned} \mathbf{J}_M(\mathbf{r},t) &= \delta\left((\mathbf{r} - \mathbf{r}_M)\frac{d}{dt}\mathrm{Tr}(\rho\mathbf{x})\right) \\ &= -i\delta(\mathbf{r} - \mathbf{r}_M)\mathrm{Tr}([F,\rho]\mathbf{x}) \end{aligned} \tag{9}$$

where $\mathbf{x}$ is the electronic 3-D coordinate, and the delta function in the position of the molecule is represented numerically on the FDTD grid. The molecular current is obtained from a time-dependent study of the density matrix (or alternatively from propagating the molecular orbitals). In the simplest version, where only a dipole electric field is assumed, these take a form similar to Eq. 3 but now the coupling is directly due to the electric field:

$$i\frac{d\rho_{ij}(t)}{dt} = \left[F_{\mathrm{tot}}(\rho),\rho\right]_{ij} - i\gamma_{ij}\left(\rho_{ij}(t) - \rho_{ij}^0\right), \tag{10}$$

where

$$F_{\text{tot}}(\rho) = F(\rho) - \mu \cdot \mathbf{E}. \tag{11}$$

Molecular Simulation Methodologies

Throughout, the molecules are simulated in real time. For the present purposes, the molecules will be treated by a Liouville equation or a time-dependent orbital equation, where the initially occupied orbitals are propagated as:

$$i\frac{\partial \psi_n}{\partial t} = F(\rho)\psi_n. \tag{12}$$

There are different possible Fock operators; the most established are TDDFT and TDHF. Both methods, however, could be numerically expensive, so a simple alternate approach is to propagate in time a semiempirical approach; an example is TD-PM3 (time-dependent Parameter-Method 3) where the Fock operator has the generic TDHF form:

$$F_{ij}H_{0,ij} + \sum_{kl} V_{ijkl\rho kl}, \tag{13}$$

but with a very sparse set of matrix elements, V_{ijkl}. TDPM3 generally gives excitation energies with a $\sim$ 15 % accuracy [8], so is very suitable for the qualitative questions which arise in the study of nanopolaritonics. As the method uses a minimal basis set and scales well with system size, it is ideal for simulating large dye molecules.

Splitting Fields

It turns out that when there is one molecule, the delta function associated with having a localized charge is problematic and leads to numerical singularities. The reason is that this strong delta function source due to the molecule acts back on the molecule, creating an artificial self-energy problem. More precisely, for a single electron this is a self-energy problem as the electron interacts with itself; for a general molecule, the interaction with the molecule-induced current induces a double-counting problem, since the Fock operator already includes the electron–electron interaction and the interaction with the molecular current has essentially the same role.

This difficulty was alleviated through the development of a new formalism, in which the electric field is divided into two parts, a molecular and a plasmonic part [9]. The molecule is only affected by the external part, while the total field acts on the plasmon. Specifically, for the electric field the resulting equations are:

$$\frac{\partial \mathbf{E}_p}{\partial t} = \frac{1}{\varepsilon_{\text{eff}}}\nabla \times \mathbf{H} + \left(\frac{1}{\varepsilon_{\text{eff}}} - \frac{1}{\varepsilon_0}\right)\nabla \times \mathbf{H}_m - \frac{\mathbf{J}_p}{\varepsilon_{\text{eff}}}, \tag{14}$$

$$\frac{\partial \mathbf{E}_m}{\partial t} = \frac{1}{\varepsilon_0}(\nabla \times \mathbf{H}_m - \mathbf{J}_m) \tag{15}$$

while the magnetic fields equations are simpler

$$\frac{\partial \mathbf{H}_p}{\partial t} = \frac{1}{\mu_0}\nabla \times \mathbf{E}_p, \tag{16}$$

$$\frac{\partial \mathbf{H}_m}{\partial t} = \frac{1}{\mu_0}\nabla \times \mathbf{E}_m. \tag{17}$$

As mentioned, only the electric field that acts on the molecule enters into the evolution equation for the density matrix. Only the plasmonic field affects now the molecule, so that the Fock operator for the evolution of the density matrix is now:

$$F_{\text{tot}}(\rho) = F(\rho) - \mu \cdot \mathbf{E}_p. \tag{18}$$

The advantage in this approach is that the decoupling prevents numerical singularities. The disadvantage is that a separate electric field is required for each molecule. Therefore, future approaches will mix the FDTD treatment of the plasmonic field with a dipole and quadrupole treatment of the molecules, i.e., write the total electric field as

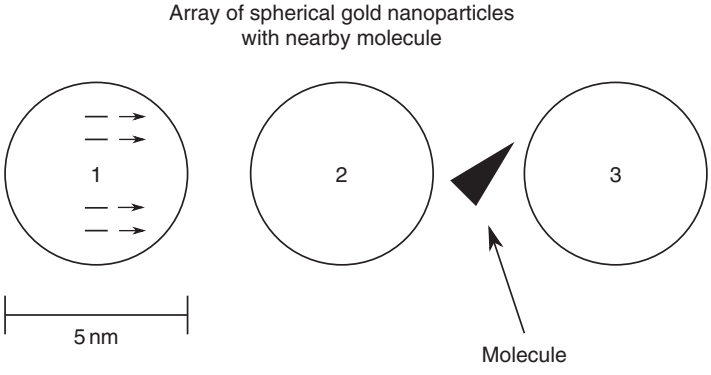
$$\mathbf{E}(\mathbf{r},t) = \mathbf{E}_p(\mathbf{r},t) + \sum_j \mu(\mathbf{r},t')\nabla\frac{1}{|\mathbf{r}-\mathbf{r}_j|} + \text{Quad.}, \tag{19}$$

where "Quad." refers to quadrupolar interaction with nearest neighbors, and the molecular dipole is introduced. The magnetic field is written

similarly in terms of the molecular current and the plasmonic field, and the equation of evolution of the total field can be derived directly from Eq. 14. This mixed field-dipole approach will allow the treatment of a host of molecules interacting with an external field.

In the extreme limit that a continuum of molecules are required, the FDTD equations will be solved directly; then, the effect of each molecule will be relatively small so that the separation between plasmonic and molecular fields will not be needed, and the resulting, single electric field equations are the familiar Maxwell–Bloch equations, i.e., there will be no need to split the electric fields.

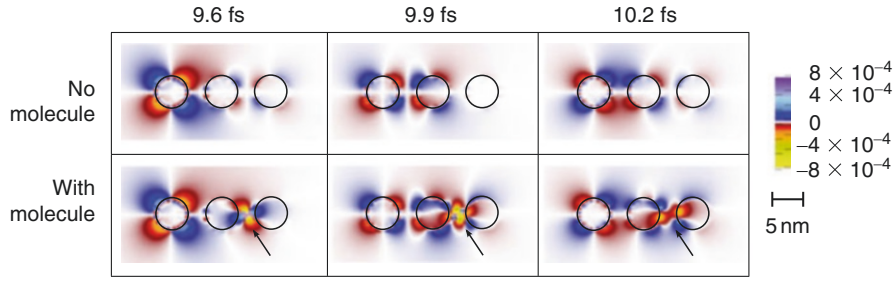
Key Findings



The fundamental conclusion from plasmon mode and Maxwell–Schrödinger (section Nanopolaritonics: Methodology) simulations is that under certain circumstances single molecules have a marked effect on the near-field transport of plasmons, as detailed below.

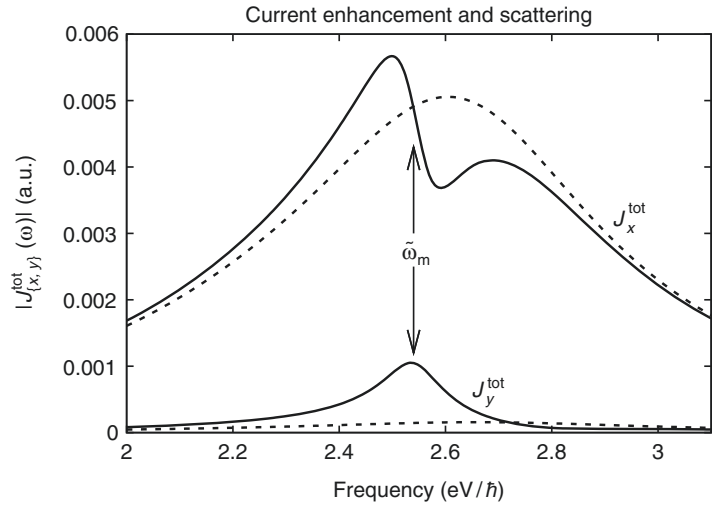
Molecule-Mediated Plasmon Transfer in Waveguides

An illustrative example of the type of system studied is shown in Fig. 1, where a single two-level dipolar molecule is located near a linear array of gold nanoparticles. In the absence of a molecule, an initial *x*-polarized plasmon excitation on the leftmost (input) nanoparticle will propagate down the array, which after a few femtoseconds results in an *x*-polarized plasmon on the rightmost (output) nanoparticle. Since the *x*, *y*, and *z* plasmon modes are decoupled in this linear configuration, no *y* or *z* excitation is induced on the output nanoparticle. Noble metal plasmonic waveguides of this type have been extensively studied both theoretically and experimentally [10].



Perhaps surprisingly, the addition of a single molecule to the waveguide can have a drastic effect. Take, as a simple example, an *xy*-oriented two-level molecule with a strong resonance at $\omega_m = 2.55$ eV, which is close to the plasmon frequency of the array (2.60 eV). Figures 2 and 3 show results of a FDTD/linear-response TDDFT simulation. Figure 2 shows the clear transmission effect of a molecule in a time-domain simulation; the presence of the molecule causes significant enhancement in the amount of transmitted light in the nonnative initial polarization.

The frequency-domain picture is even more revealing. Figure 3 shows that the Fourier transform of the total current on the output nanoparticle displays a Fano-like resonance. As a reminder, Fano resonance are generally the result of coupling of single (or a few, in the generalized case) "dark" quantum level(s) to a continuum of states.

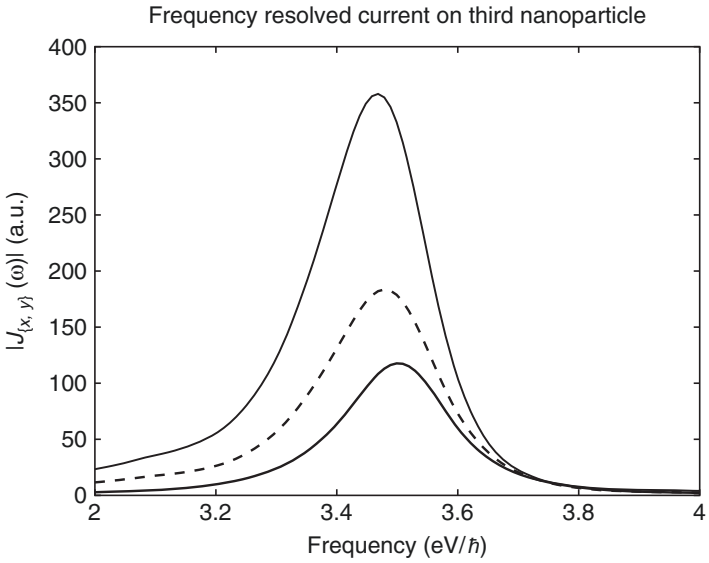


Nanopolaritonics, Fig. 1 Schematic of the computed setup. Three small metal spheres are placed close to each other. The *leftmost* sphere is excited; the *middle* sphere mediates this transfer. The molecule is placed between the middle and the final, *rightmost* sphere, and mediates this transport. The direction of the molecule influences the final polarization of the molecule

N

Nanopolaritonics, Fig. 2 Three snapshots in time of the *y*-component of the electric field with (*bottom*) and without (*top*) a molecule, for an excitation starting on the left sphere. The dipolar molecular field serves to scatter *x*-oriented energy (not shown) into *y*-oriented energy (From Ref. [9])

Nanopolaritonics, Fig. 3 Fourier transform of the currents on the output nanoparticle of a linear waveguide, showing that a single two-level *xy*-oriented molecule rotates incident plasmon polarization from $x \rightarrow y$ (From Ref. [9])



Their most obvious mark is a sine-like modification of the observable (spectrum or transmission profile) which in the original Fano resonance case will actually lead to a dip of zero absorption due to destructive interference caused by the presence of the quantum level.

In the present simulation case, a clear Fano-like transmission profile results due to the presence of the molecule; the excitation of the *x*-polarization is drastically modified. Specifically, the molecule enhances the *x*-polarized plasmon transmission over a range of frequencies below ω_m and decreases the transport for a range above. Further, the molecule rotates the excitation from the *x*-polarization to the *y*-polarization, resulting in a significant *y*-current (approximately 20 % of the *x*-current). Physically, the molecule, which has a transition dipole moment aligned along the *xy* axis, scatters *x*-polarized near-field light and reemits *y*-polarized light.

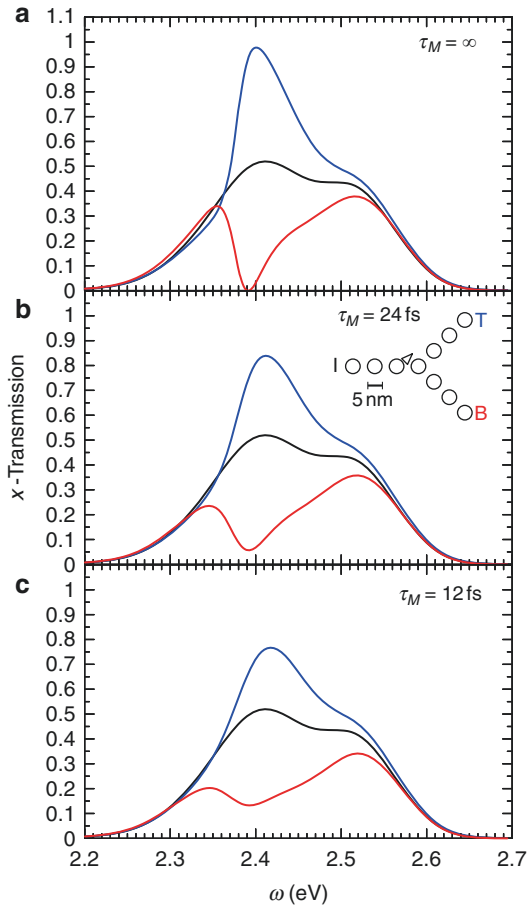
Despite the fact that the molecule does not affect the overall absorption of the array, the intense molecule–plasmon resonance in the gap between nanoparticles strongly influences plasmon transport, to the point of significantly scattering plasmons between otherwise orthogonal modes of excitation.

Realistic Simulations

To study this problem in a more rigorous manner, i.e., by using a more realistic quantum-chemistry treatment, the FDTD approach has also been combined with a time-dependent semiempirical method, TDPM3, mentioned above, to show rotation of current for large molecules with a significant number of possible excitations [11].

Nanopolaritonics, Fig. 4 Frequency-resolved current on the third silver nanoparticle of the system shown in Fig. 1 with 2-nm nanoparticles with (*bold lines*) and without (*thin line*) a molecule in the *x*-direction (*solid*) and *y*-direction (*dashed*) (From Ref. [11])

The system examined used silver nanoparticles, and thus tartrazine, a yellow dye molecule having a strong transition dipole moment near the plasmon resonance of silver, was chosen. The realistic simulations verify that molecules with an excitation energy near the plasmon resonance of the metal scatter the *x*-oriented current into the *y*-direction, as observed with the two-level molecule. The results are shown in Fig. 4. These results are encouraging as they confirm that even a molecule with a broad range of excitations can influence the transport of plasmons.



These studies offer insight into near-field light transport in heterogeneous nanosystems. Single molecules, although too weak to play a role in overall light absorption, can have drastic effects on transport if strategically placed in "hot spots," where they can modulate the comparatively lower energy coupling between nearby metal structures.

Since this is a resonance effect, it is highly dependent on the materials involved. The molecule, in order to scatter current, must have a strong optical transition at or near the coupling (i.e., plasmon resonance) of the waveguide. On one hand, this limits the diversity of the systems that can be used; however, this specificity is actually advantageous for sensing applications and tunable frequency-dependent wave guiding.

Controlling Plasmon Transport with Single Molecules

The strong effect of a single molecule on nanopolariton transport can be exploited to selectively control plasmon transport on the nanoscale. This has implications in the field of plasmonics, where molecule–plasmon interactions have promise as device components such as switches or higher harmonic generators. A molecule placed near a fork-like arrangement of gold nanoparticles, e.g., can selectively divert incoming plasmon waves into either the top or bottom paths, as demonstrated in Fig. 5, which shows transmission through the fork calculated using the plasmon mode approach. Beyond being sensitive to the molecule's location, this effect is also highly dependent on its orientation: When the molecule points upward, the plasmons are directed into the upper branch of the fork (*blue curve* in Fig. 5) much more than to the lower branch (*red curve*). In the absence of a molecule (*black curve*), the transition probabilities of the two branches are equal.

The controllability can be extended to use in molecular switches: Molecules can potentially be used to gate the transfer of near-fields in a specific and deliberate manner. Likewise, a similar configuration can act as a type of highly specific

Nanopolaritonics, Fig. 5 Simplified-model study of control of radiation transfer through a fork by placing a molecule aligned parallel to the top branch of the fork. *Blue top* branch, *red bottom*, *black* either branch without a molecule. The frames differ by the amount of dephasing on the excited state of the molecule. The gold dots have the experimentally fitted dephasing time, ~6 fs (From Ref. [2])

molecular sensor, sensitive to a molecule's identity, orientation, and position.

Limitations

There are several important caveats to these findings. First, compared to metals, molecules have a much smaller capacity to absorb and radiate light, as they are unable to further absorb light (of a given frequency) once already in their excited state. FDTD/TDDFT simulations of nanopolaritonic systems which treat the molecule beyond linear response have shown that under increasing field intensities the polarization rotation effects saturate rapidly; this transition region is especially interesting, since it can be used as a nonlinear gating mechanism.

Future Directions

Nanopolaritonics is still in its infancy. Although a variety of simulations have demonstrated proof of concept for controlling near-field light with molecules, there is much untapped potential for novel plasmon–molecule applications, as well as many outstanding theoretical and experimental questions. This last section briefly overviews future directions for both experiments and theory.

Transport-Based Sensing

Among the most promising potential applications is transport-based sensing, where extremely dilute concentrations of molecules are detected and uniquely identified based on how they alter the plasmon transport properties of a nanostructure system. In contrast to a SERS-like device, which is used to enhance and probe the response of a molecule, here the plasmon transport is measured, which is predicted to be extremely sensitive to the presence of select molecules. A pair of nanoscale metal tips, e.g., can act as a sensor for molecules which drift between them. Alternatively, one can build a parallel detector using a chip containing a series of different plasmonic junctions, each with a slightly different plasmon resonance, which are tuned to different target analyte molecules and excited by different frequencies of light.

Plasmonic Metamaterials

Another potential application of nanopolaritonics is in the development of more sophisticated metamaterials. Beyond simply mediating wave guiding, molecules could also mediate coupling between elements of a plasmonic metamaterial. This could lead to, e.g., tunable metamaterials where the presence of different molecules shifts the resonant frequency of the device.

Need for Experimental Studies

There is a pressing need for high-quality experimental measurements of plasmon transport in the

presence of strongly interacting molecules. Whereas there have been a wealth of experiments concerning the effects of intense fields on single molecules, studies on the effects of molecules on plasmons are lagging.

Improved Multiscale Simulation Methodologies

From a theoretical standpoint, progress needs to be made on efficiently and accurately capturing plasmon–molecule interactions, especially in the "chemical" regime where molecules are bound to the surface of a metal and share electrons. In reality both charge and energy are shared on a surface, and developing real-time embedding approaches capable of describing this is necessary to drive the field forward. This is a daunting task as it necessitates treating the quantum mechanical and classical regions as open systems. Moreover, seamless integration of the two regions requires careful choice of either boundary conditions or embedding potentials.

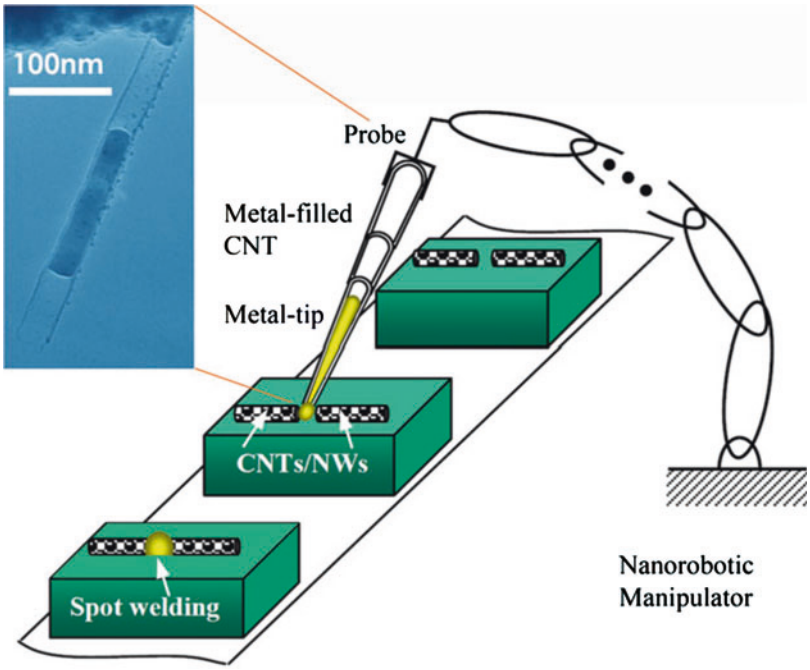
Definition



Spot welding, a widely used resistance welding process, was originally developed by Elihu Thompson in the early 1900s [1]. The most common application of spot welding is in the automobile industry, where it is widely used and most often performed automatically by preprogrammed industrial robots on assembly lines. With the continuing development of bottom-up nanotechnology fabrication processes, the nanoscale version of robotic spot welding, or nanorobotic spot welding [2], may likewise play an important role in interconnecting carbon nanotubes (CNTs), nanowires, nanobelts, nanohelixes, and other nanomaterials and structures for the assembly of nanocircuits and nanoelectromechanical systems (NEMS).

Overview

Van der Waals forces [3], electron-beam-induced deposition (EBID) [4], focused-ion-beam chemical vapor deposition (FIB-CVD), high-intensity electron-beam welding [5], Joule-heating-induced joining [6], and nanomechanochemical bonding [7] are experimentally demonstrated interconnection strategies, although all have limitations. Van der Waals forces are generally very weak, Joule-heating-induced joining and nanomechanochemical bonding are promising but not yet mature, and the other methods involve high-energy electron or ion beams, which significantly limits their applications. Another interconnection approach is to use CNTs, with their hollow cores and large aspect ratios, as possible conduits for nanoscale amounts of various materials that can be used to fuse CNTs together.

The concept of nanorobotic spot welding is schematically shown in Fig. 1. A metal-filled carbon nanotube is positioned with a nanorobotic manipulator to the interconnection site and the metal is then deposited to solder the nano-building blocks, such as CNTs and nanowires, together, or to weld them onto electrodes.

To facilitate the deposition, the encapsulated metallic materials may need to be melted or

Nanorobotic Spot Welding, Fig. 1 Concept of nanorobotic spot welding

evaporated, which means only materials with a lower melting point than that of CNTs can be applied. Fortunately, most pure metals have a lower melting point than that of CNTs in vacuum and a large portion of them have a lower melting point than that of CNTs in air (Table 1). Alloy solders routinely used in the larger scale for electronics and silversmithing may also serve as excellent candidates of nanosolders and they typically have lower melting points than the pure metals. These include soft solders (melting range: 90–450 °C, typically tin-lead (Sn-Pb) alloys), lead-free solders (melting point 5–20 °C higher than soft solders, alloys contain tin, copper (Cu), silver (Ag), bismuth (Bi), indium (In), zinc (Zn), antimony (Sb), and traces of other metals), and hard solders (melting point >450 °C, alloys of copper with either zinc or silver).

Figure 2 shows CNT samples synthesized using an alkali-doped Cu catalyst by a thermal CVD method [11]. Figure 2a–d show their structures imaged by field emission scanning electron microscopy (FESEM, Sirion, FEI), transmission electron microscope (TEM, JEM-2010, 200 kV), selected area electron diffraction (SAED), and high-resolution TEM (HRTEM). It can be seen from these observations that the yield of the Cu-filled CNTs was high. The CNTs were up to 5 μm long with outer diameters in a range of 40–80 nm. The single-crystalline Cu nanoneedles were encapsulated in graphite walls approximately 4–6 nm thick in the first sections of the bamboo-structured CNTs. The graphite layers were not parallel to the tube axis.

Key Research Findings

An experimental investigation of controlled melting and flowing of single crystalline copper from CNTs has been performed using nanorobotic manipulation [3], and its application in spot welding of nanotubes has been demonstrated using this copper. Because copper is a good conductor of heat and electricity and has a very low binding energy (0.1–0.144 eV/atom) when bound to carbon, copper-filled CNTs were used in the investigation.

The experiments were performed in a CM30 TEM equipped with a scanning tunneling microscope (STM) built in a TEM holder (Nanofactory Instruments AB, ST-1000) serving as a

manipulator, as shown in Fig. 3a or schematically in Fig. 3b. The material consisting of a CNT bundle was attached to a 0.35 mm thick Au wire using silver paint, and the wire was held in the specimen holder. The probe was an etched 10 μm thick tungsten wire with a tip radius of approximately 100 nm (Picoprobe, T-4-10-1 mm). The probe can be positioned in a millimeter-scale workspace with subnanometer resolution with the STM unit actuated by a three-degree-of-freedom piezo-tube, making it possible to select a specific CNT. Physical contact can be made between the probe and the tip of a nanotube. Applying a voltage between the probe and the sample holder establishes an electrical circuit through a CNT and injects thermal energy into the system via Joule heating. By increasing the applied voltage, the local temperature can be increased past the melting point of the copper encapsulated in a tube. The process was recorded by TEM images and real-time video.

In the experiment, the tip of a Cu-filled CNT was first brought into contact with the tungsten probe. Then a bias voltage was applied on the two ends of the CNT with the tungsten probe serving as the anode. The voltage was slowly increased from 0 mV with 100 mV steps. When the voltage reached 1500 mV, a vacant section inside the carbon shells appeared, indicating that the copper has begun melting. Transportation of the copper to the probe-tip contact moved the vacant section to the root of the first bamboo section of the Cu-filled CNT. After the vacant section reached the root, the copper core started to flow to the tip of the CNT when bias was increased to 2500 mV.

Figure 4a is a series of time-resolved TEM images taken from video frames showing the flowing process. The copper core started to flow inside the carbon shell from the bottom to the tip of the first bamboo section as the bias voltage reached 2.5 V. The entire process continued for about 70 s. The flow rate was found to be 11.6 nm/s according to the change of apparent length of the copper core (Fig. 4b). Accordingly, the mass change was calculated as shown in Fig. 4c, and the mass flow rate can then be determined by fitting the data to the curve, yielding approximately 120 ag/s, which is strikingly slow and well controllable, allowing precise delivery of mass at the attogram scale for time-based control that can readily reach sub-second precision.

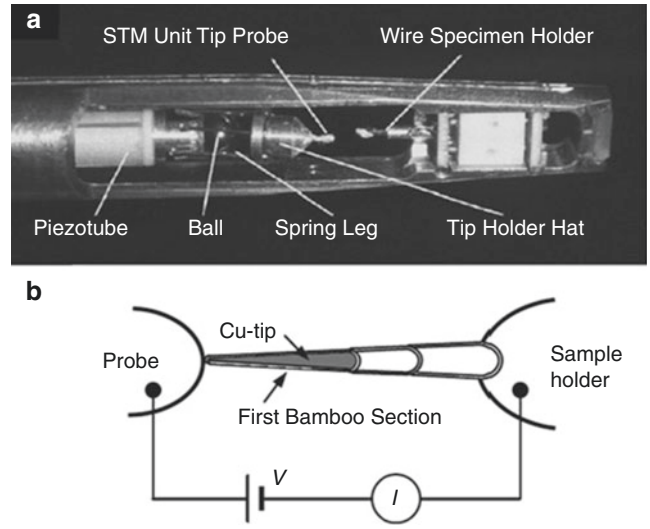

Figure 4d shows time-resolved current versus voltage characteristics under a constant positive bias of 2.5 V. The current density under 2.5 V when flowing occurred was then calculated according to the cross-sectional area as $2.60–3.07 \times 10^6$ A/cm^2. This is comparable to the observed value for electromigration of iron in CNTs (ca. 7×10^6 A/cm^2) [9]. The difference can be a result of the lower binding energy of copper to the carbon shells (0.1–0.144 eV/atom) than that of irons to carbon shells (0.3 eV/atom). The high current

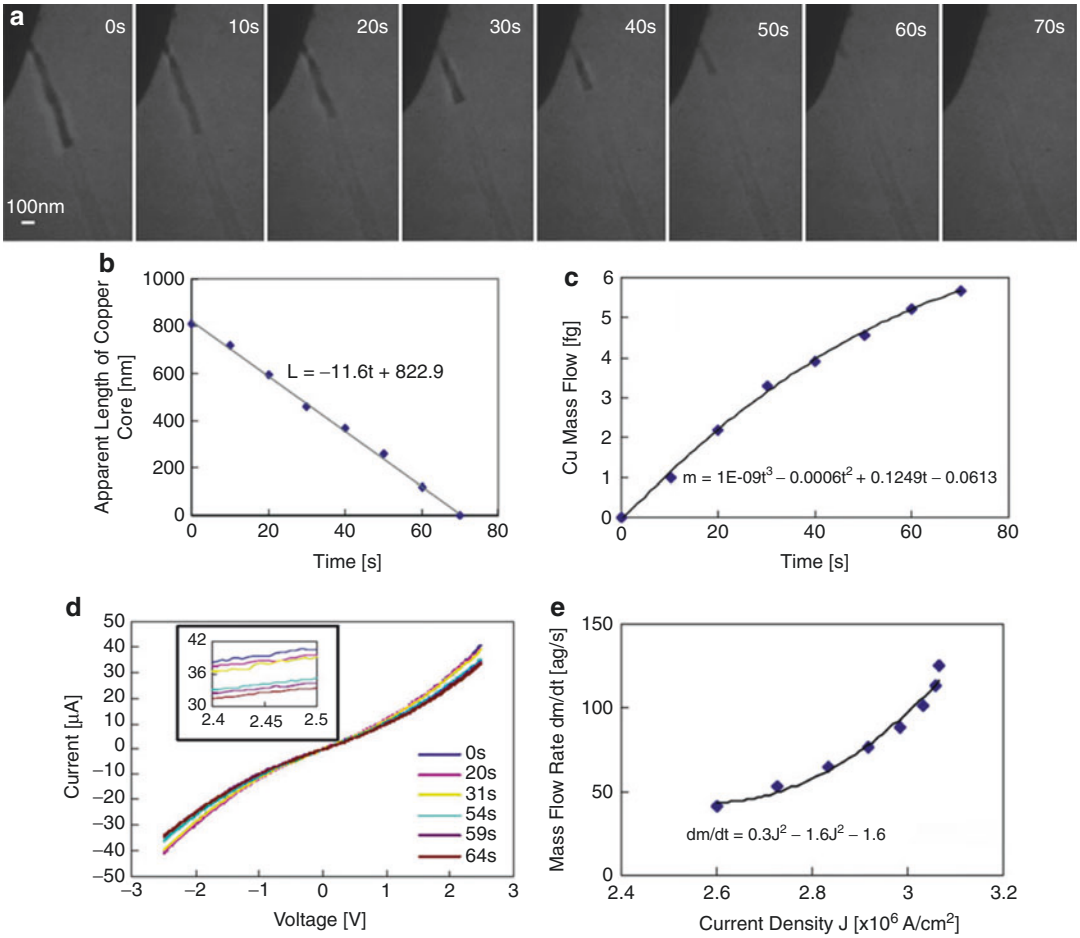
Nanorobotic Spot Welding, Fig. 2 (**a**–**d**) Copper-filled CNTs. (**a**) FESEM images of Cu-filled CNTs. Observation shows that all the CNTs have sharp tips filled with metal nanoneedles. These CNTs are up to 5 μm long with outer diameters in a range of 40–80 nm. (**b**) A typical copper-filled CNT synthesized for 30 min. (**c**) HRTEM image reveals that the Cu nanoneedles are encapsulated in graphite walls approximately 4–6 nm thick. The inset is the corresponding SAED pattern of the Cu nanoneedle along the zone axis, showing that the Cu nanoneedle is single crystalline. The appearance of a pair of arcs in the SAED pattern indicates some orientation of the (002) planes in the carbon tubes. (**d**) The magnified image of the rectangular region in (**c**). The *large arrows* indicate the growth direction of the CNTs. The interlayer spacing of carbon nanotube is about 0.34 nm, consistent with the (002) plane lattice parameter of graphite. It can also be seen that the graphite layers are not parallel to the tube axis

densities employed here will lead to resistive heating. Temperatures as high as 2000–3000 °C have been estimated according to the lattice spacing change in electric breakdown experiments on non-filled multiwalled nanotubes (MWNTs) [16] at a slightly higher bias (3 V) than those used here. The current density J and the mass flow rate $\dot{m}$ were then correlated as shownine. The relation $\dot{m} = 0.3135J^2 - 1.6206J + 2.1373$ suggests that a real positive value of $\dot{m}$ ($\geq$42.9 ag/s) can only be given when the current density J surpasses 2.5847×10^6 A/cm^2. The existence of this threshold also implies that the mechanism of the observed flowing is most possibly electromigration [9]. Under a negative bias, that is, when the tungsten probe served as a cathode, the flow was observed in the opposite direction.

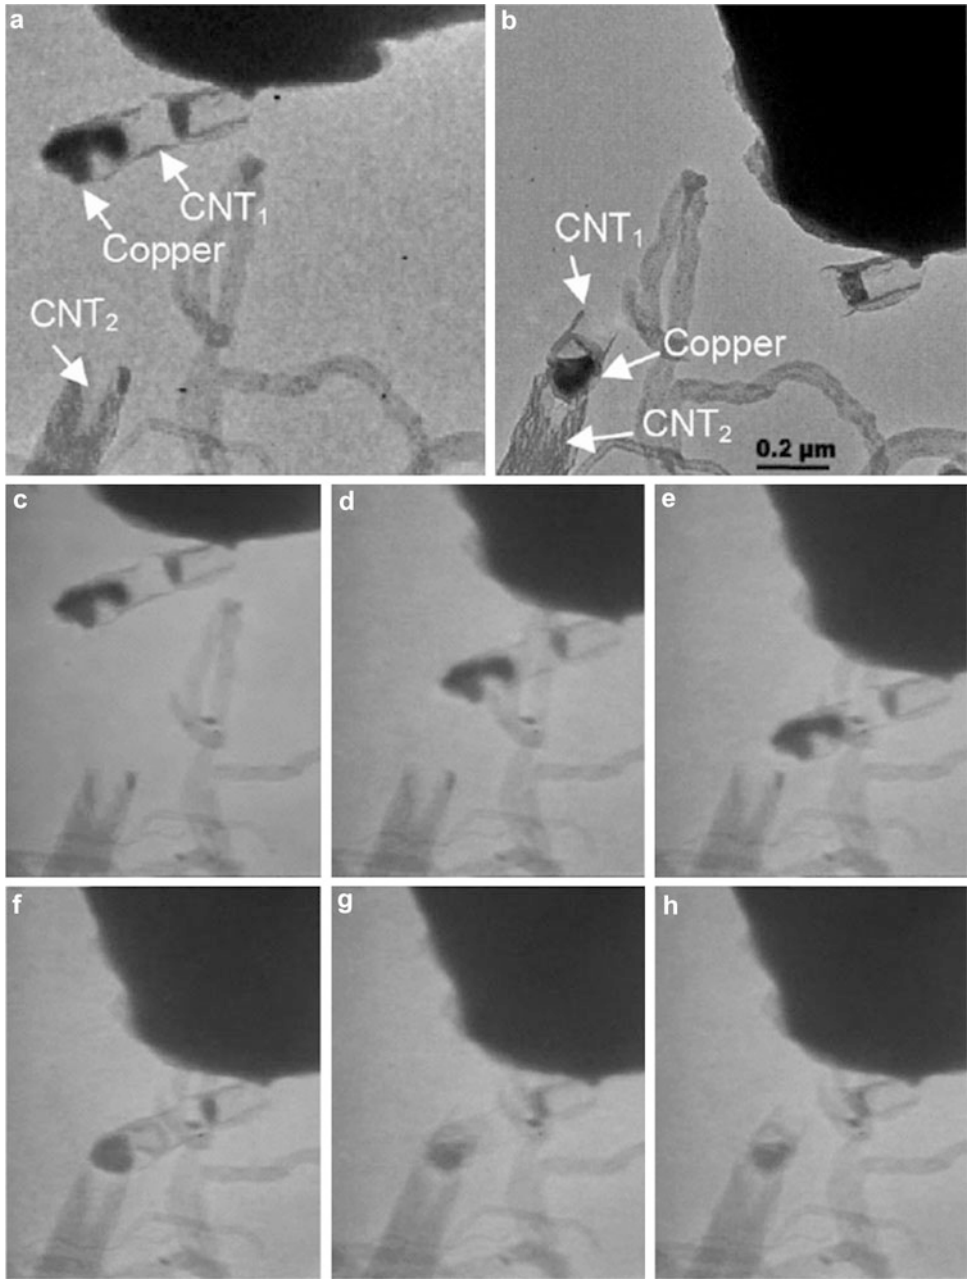
Other possible mechanisms for flow can be excluded. Capillary force can induce filling/flowing, but the direction should be opposite to the observed flow, that is, from the tip to the bottom of the carbon shells. Thermal expansion can enable flow, but the flow should be isotropic, heading toward both the tip and the bottom. A recent investigation showed that the irradiation of MWNTs can cause a large pressure buildup within the nanotube core that can plastically deform, extrude, and break encapsulated solid



Nanorobotic Spot Welding, Fig. 3 (**a**, **b**) Nanorobotic manipulation system in a TEM

material [17]. In the experiments, however, no contraction of the carbon shells was observed.

Although there is no way of measuring the actual temperature of the nanotubes or the copper core, this process provides the possibility for estimating the temperature according to the resistivity change if Matthissen's rule is applied on temperature dependence of resistivity, provided that the resistivity was known at a certain temperature. Unfortunately, the latter is unknown. However, it has been noted that the temperature for CNT growth from 100-nm scale Cu particles in the synthesis (700 °C) is far lower than the melting point of bulk Cu (1083 °C) [11]. It is well known that the surface-to-volume ratio with respect to a nanosized particle can affect the melting point. Although the exact reason for melting at such a low temperature is not yet known, a rough estimation of the melting point of the copper core can be made, that is, around 700 °C. This is comparable to the in situ electron microscope observations of the melting point of the encapsulated 20–60 nm diameter Cu nanocrystals in multilayer graphitic carbon spheres, which was reported at 802 °C [18]. It is also known according to the experiment that the melting point of the carbon shells is much higher than that of the copper core. This provides further evidence of molten copper inside carbon shells.



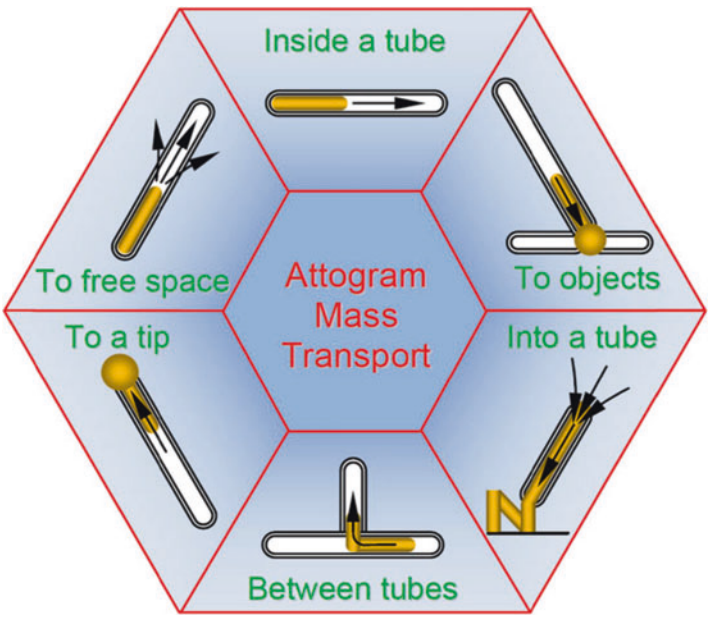
Examples of Application

The application of such controlled transportation of the copper core was then investigated. Self-soldering of CNTs with copper encapsulated in a CNT is shown in Fig. 5. A copper-filled tube, CNT_1, was first attached to a tungsten probe (Fig. 5a). A section of CNT_1 was then attached to and soldered onto CNT_2 by the melted copper (Fig. 5b). Figure 5c–h are video frames showing the soldering process. A copper-filled tube, CNT_1, was attached to a probe, and brought into contact with another tube, CNT_2. The probe has a −10 V bias. Parts c–e of Fig. 5 show three different positions as the probe was approaching CNT_2, and Fig. 5f shows how the contact has been made. The shape change of the copper suggests a melting process has occurred. It has been found from the video frames (25 fps) that the melting of the copper happened in a very short interval (<70 ms). With a higher bias (−15 V), CNT_1 was broken (Fig. 5g) and its end section remained soldered to the tip of CNT_2 (Fig. 5h).

Nanorobotic Spot Welding, Fig. 4 (**a**) Time-resolved TEM images from video frames showing the flowing process. The copper core started to flow inside the carbon shells from the root to the tip as the bias voltage reached up to 2.5 V. The whole process was continued for about 70 s. (**b**) The flow rate has been found to be 11.6 nm/s according to the change of apparent length of the copper core. The tungsten probe has been positively biased. (**c**) The mass changes along the time. The mass flow rate can be then drawn out from the fitting curve as approximately 0.12 fg/s. (**d**) Time-resolved current versus voltage characteristics under a constant bias of 2.5 V. The current density under 2.5 V as flowing occurred is about 2.60–3.07 × 106 A/cm^2. (**e**) Correlation of the current density J and the mass flow rate dm/dt

Compared with the other interconnection processes previously investigated, electrically driven spot welding has several interesting aspects: (1) A very low current can induce the melting and drive the flow; which is much more efficient that irradiation-based techniques involving high-energy electron beams [4, 5, 17, 19, 20], FIB, or lasers. Combined with dielectrophoretic assembly, it is possible to solder the tubes onto electrodes for batch fabrication of NEMS. (2) The welding site can be readily selected using nanorobotic manipulation, which enables 3D position and orientation control for continuous mass delivery and will potentially enable 3D prototyping and assembly. (3) The melting occurs rapidly (at least at the millisecond level), several orders of magnitude faster than that using high-intensity electron-beam or FIB, which is generally

Nanorobotic Spot Welding, Fig. 5 Self-soldering of CNTs with copper encapsulated in a CNT. (**a**) A copper-filled tube, CNT_1, was attached to a tungsten probe. (**b**) A section of CNT_1 was soldered onto CNT_2 by the melted copper. (**c**–**h**) Video frames showing the soldering process. A copper-filled tube, CNT1, was first attached to a probe, and brought into contact with another tube, CNT_2. The probe (cathode) has a −10 V bias. (**c**–**e**) Three different positions as the probe is approaching CNT_2. (**f**) Showing how contact has been made. The shape change of the copper suggested a melting process has occurred. With a higher bias (−15 V), CNT_1 was broken (**g**) and its end section remains soldered to the tip of CNT_2 (**h**)



on the order of a minute [4, 5, 17, 20, 21]. (4) Because both the rate and direction of mass transport depends on the external electrical drive, precise control of an ultrasmall mass delivery is possible. Time-based control will allow the delivery of attograms of mass. (5) Copper has good compatibility in the conventional semiconductor industry. The experiments show that it will likewise play an important role for scaled-down systems. Carbon shells provide an effective barrier against oxidation and consequently ensure a long-term stability of the copper core, which also facilitates the conservation of the material than conveying mass on the external surface of nanotubes.

Future Directions for Research

The investigation on nanorobotic spot welding has so far shown that controlled melting and flowing of copper inside nanotube shells can be realized by applying a low bias voltage (~1.5–2.5 V). The melting can facilitate the flowing and it is a result of Joule heating, whereas the flowing is caused by electromigration. The mass flow rate can be controlled to the scale of attogram per second based on time: a typical value is around 1 atom/μs.

As an emerging technique, there are still a lot of unsolved problems with nanorobotic spot welding. (1) The materials investigated are limited to copper and tin. More efforts need to be put into the filling of conventional alloy solders and silver-based solders to broaden the adaptability of this technique. Universal and high yield filling techniques need to be developed. (2) The controllability of melting and flowing is related to the bias profile, which is determined mainly by the diversity of the resistivity of CNTs. Uniform CNTs in a batch are strongly required. (3) TEM provided an ideal environment for the in situ investigations. To lower the cost for practical applications, it would be a better solution to combine the spot welder with an AFM. The impact of the change of the environment from a high-vacuum chamber to the air needs to be evaluated. Obviously, solders with lower melting points will be required. (4) For automatic batch soldering, continuous feeding, arrays of solders (can be individually filled with heteromaterials), automatic detection of the soldering sites, and path planning are some examples of critical techniques.

Nanorobotic spot welding is a fundamental technology related to the mass transport inside, between, and into nanochannels (Fig. 6). Mass transport systems at this scale provide a platform

Nanorobotic Spot Welding, Fig. 6 Related investigations and applications

for the investigation of nanofluidics and can serve as components for prototyping nanostructures. Mass flowing out from a nanotube can generate a variety of results based on the targets. Evaporation to a free space is a result of discharging, ionization, or heating. Deposition on a surface can be obtained if placing the nanotube tip against such a target. Nanorobotic spot welding is based on mass transport to the interface between two objects. Free-standing nanostructure can be formed on the tip of the injector nanotube if moving it back from the target. As an emerging additive nanolithography technique, electromigration-based deposition (EMBD) is a more general term representing the mass transport of metallic materials against a surface. The investigations of all these systems are correlated and can benefit from the development of each other.

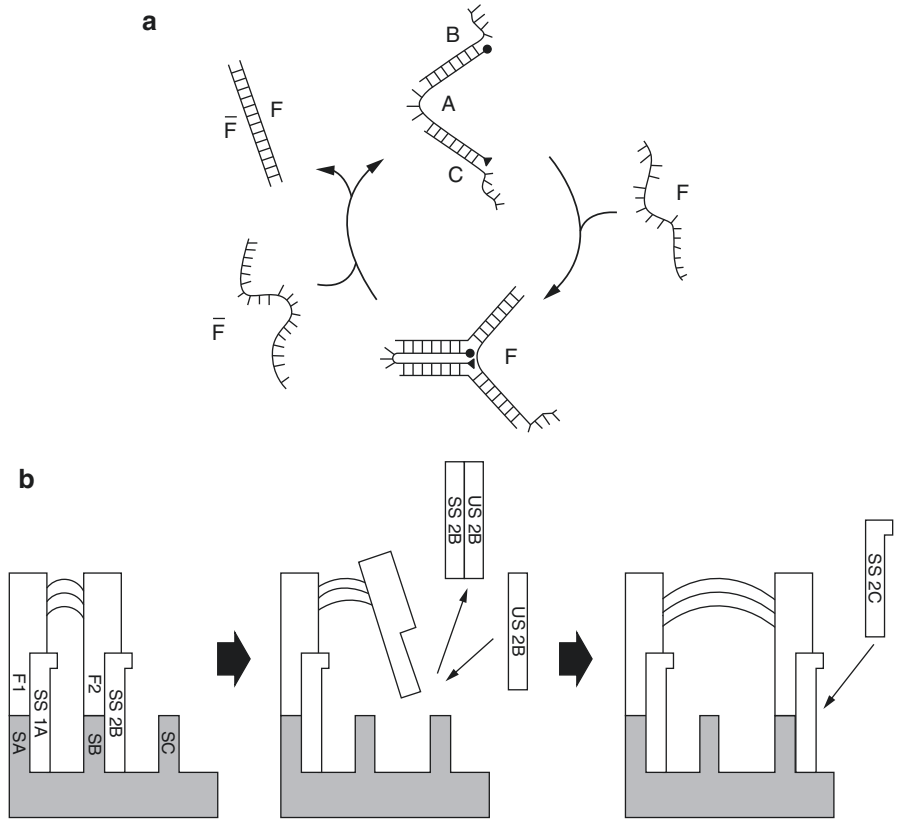
Microrobotics

Definition

Nanorobots are robotic devices operating at micro- and nanoscale.

Overview

Nanorobotics is an emerging subfield of nanotechnology that aims to build robotic devices operating at micro- and nanoscale. The envisioned applications of nanorobotics are quite wide, ranging from medical and environmental sensing to space and military applications [1, 2]. Devices at micron scale that handle micron objects (e.g., bacterial robots), which are sometimes termed as "microrobots," are also referred to as nanorobots here. Nano manipulators that control nanoscale objects using microscope devices are also referred to as nanorobots, but it is not covered in this article.



While nanotechnology developed so far is concerned with the construction of static nanoscale structures and manipulation of nanoscale objects, the field of nanorobotics studies more dynamic and active structures. It includes the design and development of nanoscale machines that are capable of actuation, sensing, signaling, information processing, and intelligent behavior at nanoscale [1]. Being extremely small (potentially at atomic scale), nanorobots are unlikely to be equipped with many functions as in their macroscopic counterparts. A possible solution to implement more complex functionality would be to use swarm intelligence and cooperative behavior, in which a swarm of nanorobots communicate each other and accomplish tasks collectively. Another issue in regard to nanorobotics is the basic law that governs the dynamics of nanorobots. Conventional robots at macroscopic scale are governed by Newtonian mechanics, whereas nanorobots are governed mostly by quantum mechanics. The design principle of nanorobots is thus bound to be different from macroscale robots. For example, Brownian motion would need to be taken into serious consideration at such scale. Molecules constituting nanoscale devices are constantly exposed to collisions with other smaller molecules (e.g., water molecules) and not in a rigid, static structure [3]. Therefore, novel schemes of design, manufacturing, programming, and control for nanorobots are needed because schemes for macroscale robots cannot be applied.

Although nanorobots in practical use are yet to be developed, several prototypes of nanorobots have been built in recent years. In particular, they have been explored in the context of biomolecular machines inspired by "nature's way of doing things" [1, 2]. Biomolecules are of particular interest in the field of nanorobotics because they operate at extraordinarily high efficiencies and readily available in nature [4]. In addition, they have several functions which are difficult to achieve with artificial molecular machines, for example, self-assembly and self-replication. As it is impossible to precisely fabricate nanomachines atom by atom, nature employs self-organization to build natural molecular machines. Proteins, the most widely used nature's nanomachines, are constructed using DNA as blueprint. A DNA sequence is translated into a chain of amino acids via messenger RNA, and the amino acid chain will self-assemble into a three-dimensional structure through free-energy minimization. By separating replication process from the system itself (i.e., protein), self-replication becomes easier, and over one billion possible types of proteins are possible out of 20 amino acids and four nucleic acids. Potentially, nanorobots could be fabricated in a similar way that biological devices are assembled. In fact, several prototypes of nanorobots, such as

DNA-based robots, rely on self-assembling nature of biomolecules for their operation. The following section gives a brief overview of nanorobotic devices implemented on various materials.

DNA-Based Nanorobots

Yurke and coworkers developed a molecular machine that takes DNA strands as fuels, called DNA tweezers [5]. The machine itself is also consists of three single-strands of DNA (Fig. 1a). Two of these stands (Strand B and C) have complementary sequence with another strand (Strand A). In particular, half of Strand B is complementary to half of Strand A and half of Strand C is to another half of Strand A. Thus, when they are bound together, the DNA tweezers has a single-stranded DNA sequence on each end, which are parts of Strand B and C. Strand A is labeled with fluorescent dye TET (5′ tetrachloro-fluorescein phosphoramidite) and TAMRA (carboxy-tetramethylrhodamine) on each end. Fluorescence emission from TET reports the positions of DNA tweezers. When TET is excited with a 514.5 nm argon ion laser, it emits fluorescent light with a peak wavelength of 536 nm. TAMRA works as a quencher of TET due to resonant intramolecular energy transfer when they come close together. When no fuel DNA (Strand F) is present, the DNA tweezers is "open" and TET fluoresces. If Strand F is added, it binds to the

Nanorobotics, Fig. 1 (**a**) A schematic diagram of DNA tweezers. Open-close operations are controlled by additional fuel strands F and $\overline{F}$. *Black circle* and *triangle* indicate TET (fluorescent dye) and TAMRA (quencher), respectively. After Yurke et al. [5]. (**b**) DNA walker walks on the steps constructed with single-stranded DNA. F1 and F2 indicate feet of the DNA walker, SA, SB, and SC are steps for DNA walker. Gaits of the walker are precisely controlled by external DNA strands, SS (Set Strand) and US (Unset Strand). See text for details. After Sherman and Seeman [6]

sticky ends of DNA tweezers because it has complementary sequences to single-stranded ends of the tweezers (parts of Strand B and C). As a result, they take a Y shape and the DNA tweezers are in "closed" position. This brings together TET and TAMRA attached to Strand A, and the light emission from TET is quenched. The tweezers can be reopened by adding Strand $\overline{F}$, a complementary DNA to Strand F. It cleaves the hybridization between the DNA tweezers and Strand F and forms a double-stranded DNA with Strand F. This open-close cycle can be repeated several times by removing fuel DNA added in the previous cycle. They have estimated the force exerted by the closing as 15 pN, which is at the upper range of measured forces exerted by biomolecular motors, such as kinesin and myosin.

Sherman and Seeman developed a simple mobile robot based on DNA strands, called DNA walker [6]. The walker has two feet (Foot 1 and 2 in Fig. 1b), each of which is comprised of double-stranded and single-stranded DNA sequences. Two DNA feet are connected with three single-stranded DNA. The DNA walker walks on a line of "stepping stones" that are also made of single-stranded DNA sequences. The DNA walker is set to "stand" on stepping stones by another DNA strands (Set Strand) that are complementary to a Foot and a Step. For example, to set Foot 1 on Step A, a Set Strand 1A, which is complementary to the sequences of Foot 1 and Step A, is added to a solution, and it hybridizes with the foot and step to connect them together. The molecular machine walks on the stepping stones by addition and removal of Set Strands: If feet are set on neighboring stones Step A and B - (linked by Set Strand 1A and 2B), the DNA walker lifts up one of legs by adding a complementary DNA strand to Set Strand 2B (called Unset Strand 2B). The strand cleaves the binding of Set Strand 2B with the foot and step to form a double-stranded DNA, and thus the Foot 2 is released from Step B. Foot 2 can be set on Step C by adding new strand Set Strand 2C. The same process can be applied to Foot 1 in order to step forward from Step A to B. Hence, the DNA walker can walk on the steps by repeating the process.

Based on the DNA walker, Lund and colleagues developed a DNA-based molecular robot that walks on two-dimensional prescribed landscapes [7]. The robot, called molecular spider, consists of a head and three legs, all of which are made of DNA. The way the molecular spider walks is basically similar to the DNA walker: It proceeds on a "track" because each leg (a single-stranded DNA) hybridizes and dehybridizes with another single-stranded DNA with complementary sequences to the leg. A big difference with the spider is autonomous behavior. It carries out sequences of actions, such as "start," "follow," "turn," and "stop," without any external controls. This autonomous action relies on catalytic activity of the spider legs. A DNA sequence with catalytic action, called DNA enzyme, constitutes each leg, and a track on the 2D DNA origami landscape [8] is constructed with three lines of oligodeoxynucleotide substrates (i.e., stepping stones). The locomotion of DNA spider is carried out as follows: First, a leg binds to a substrate by hybridization. DNA enzyme cleaves the single ribonucleotide linkage in the substrate strand into two shorter products. Due to a lower affinity of the products for the DNA enzyme, the leg will be dissociated from the site. It will quickly find a nearby substrate to reattach because multiple legs binding to substrates prevent the molecular spider from being completely dissociated from the track. Although the leg could attach to a site visited before (i.e., stepping back), it is likely to stay longer on new sites because the substrate has higher affinity for the enzyme than the products. Once a molecular spider is set on the starting point of a track, three legs bind and cleave the substrates in parallel, and the robot moves forward as a result. It has been shown that the spider can not only walk on a straight track, but also turns the direction (30° and 90°). After it reaches the end of the track, it would perform random Brownian walks because all the substrates are converted to the product and, therefore, any sites on the track have same affinity for the legs. To prevent this, "stop" sites, which are non-chimeric and uncleavable analogues of the substrate, can be introduced at the end of a track. When a leg steps on the site, cleavage of DNA strand does

not occur, and, therefore, the robot stays in the stop sites and never goes back.

Cell-Based Nanorobots

Another approach towards nanorobots is to employ whole living cells as machines. As mentioned above, natural biomolecular machines are quite efficient in many aspects, and it is hard to fabricate competing artificial robotic elements from scratch. Cell-based nanorobotics aims at making use of biological functionality of living organisms for man-made tasks, such as cargo transportation.

Behkam and Sitti developed a bacterial actuator for propulsion of polystyrene microbeads [9]. The cell-based actuator employs flagella motors of *Serratia marcescens*. Using a plasma-based bacteria patterning technique, the flagellated chemotactic bacteria have been randomly attached to half of a 10 μm microbead. This configuration of bacteria attachment propels the microbead, although the direction of motion is stochastic. It has been shown that the more bacteria are attached, the faster the bead is propelled. The on-off motion of the flagella motors can be controlled by introducing copper ions (Cu^{2+}) and ethylenediaminetetraacetic acid (EDTA). Steager and colleagues [10] showed the bacteria can thrust SU-8 microfabricated structures (larger than the microbeads) and the movement of the structures can be halted and resumed by UV exposure.

Martel and colleagues has been taking a different approach to the development of bacterial microrobots [11]. They point out several drawbacks of bacteria actuators using *Serratia marcescens*: First, the directional control is difficult. Second, the chemical control of bacterial motion is not appropriate for applications in many environments, especially when applications for operations in the human body are in focus. Third, chemical control is not compatible with electronic circuits, i.e., digital computers. To tackle these problems, they use magnetotactic bacteria (MTB). The bacteria, marine magnetotactic coccus strain MC-1, incorporate a chain of nanoparticles called magnetosomes which are used to orient the bacteria in geomagnetic fields. On the other hand, the direction of magnetotactic bacteria can be controlled by external magnetic field by inducing a torque on a magnetosome. A bacterium can produce a thrust force exceeding 4 pN, and a collective of MC-1 cells assembled by computer-controlled magnetic field can generate larger force. It has been shown that the collective of approximately 5,000 flagellated magnetotactic bacteria can not only propel microstructures, but also complex microassembly tasks, such as building a pyramid-like structure [12].

Other Types of Nanorobots

There are several approaches toward nanorobots apart from the DNA and cell-based implementations. Another example is protein-based nanorobotic system. Protein is the most common natural molecular robotic devices and abundant in living cells. Central to the protein-based nanorobotics is the conformational change of three-dimensional structure because proteins are quite sensitive to the environmental changes. It has been proposed to use viral proteins as motors (viral protein linear (VPL) motor). This has been inspired by the fact that the families of retroviruses, such as influenza virus and HIV-1, are able to sensitively detect a drop in pH as a signal that its future host is close. The drop of pH is detected by a protein on the viral membrane, which changes the conformation from loosely connected structure to a distinctive α-helical structure. Artificially synthesized protein-like viral proteins could potentially used to produce forces of the order of μN.

Inorganic nanorobots are also pursued (cf. [13]). What has been proposed is controllable nanomotor devices using catalytic reaction of bimetal. When cylindrical asymmetrical alloys (e.g., gold and platinum) are suspended in a solution with hydrogen peroxide as fuel, the platinum segments catalyze the oxidation of hydrogen peroxide (i.e., $H_2O_2 \rightarrow O_2 + 2H^+ + 2e^-$) whereas the gold segments enhance the opposite reaction. As a result, electrons in the nanomotor flows from the

platinum to gold side along with migration protons in the double layer on the motor, and the nanomotor shows random but non-Brownian movements. Precise directional control for performing complex tasks is also possible by applying magnetic field. Ferromagnetic nickel incorporated in the nanomotors allows the aligning of the motor and modulation of magnetic field strength enables start and stop control of the motion.

Definition

Nanorobotics for bioengineering is the use of robotic platforms capable of nanometer resolution, nanoscale robots, or microscale robots relying on nanoscale components and phenomena being applied to living systems.

Overview

Robotics

The field of nanorobotics bridges nanotechnology with robotics. As such, to understand the fundamentals of nanorobotics, one must first know the basic elements being associated with robotics and nanotechnology.

While robotics would be defined as the science or study of the technology associated with the design, fabrication, theory, and application of robots, a robot would typically be referred to as a machine or device that operates automatically or by remote control. As such, a robot must have an appropriate structure suitable for its working environment while being able to hold all embedded components and will include a power source (embedded, wired, or wireless), actuation (e.g., for displacement, grasping, etc.), sensing (vision, pressure, temperature, etc.), and control or computation (embedded or remote). Depending on the tasks and requirements, communication may also be involved.

Nanotechnology

Nanotechnology on the other hand is often defined as the understanding and control of matter at dimensions of roughly 1–100 nanometers (nm), where unique phenomena enable novel applications. Nanotechnology involves imaging, measuring, modeling, and manipulating matter at this length scale. It is important to note that at the nanoscale, the physical, chemical, and biological properties of materials differ from the properties of matter at the macroscale, and this fact has motivated research and development in nanotechnology to be directed toward understanding and creating improved materials, devices, and systems that exploit these new properties.

Nanorobotics

So far, researches in nanorobotics are being done within a range delimitated by two extremes. The bottom one is devoted to the design of robots with overall dimensions in the nanometer scale, while the other involves interactions with nanoscale objects using macroscopic instruments such as scanning probe microscopes (SPMs) used for automated nanomanipulation. Indeed, nanotechnology and nanoscience began in the early 1980s in great part due to the invention of the scanning tunneling microscope (STM) [1] that allowed scientists to observe atomic structures. Later, other forms of SPMs such as the well-known atomic force microscope (AFM) [2] appeared allowing more tasks to be performed at the atomic and molecular scales. Soon, engineers put efforts at making SPM-based tasks remotely [3] and later automatically [4] with more precision by integrating robotic principles, and, hence, these efforts have led among the first known applications of nanorobotics.

Although intensive research efforts were done in the various disciplines required to enhance the functionality and performance of these macroscale nanorobotic platforms, other efforts aimed at designing robots with overall dimensions in the nanometer scale. But although some experimental principles in the form of primitive molecular machines have been shown, the field of creating real practical machines or robots with overall dimensions in the nanometer range (e.g., 1–100 nm) is still beyond present technological limits.

As such, in an attempt to design the smallest practical robots, some research efforts concentrated on nanorobots with overall dimensions in the micrometer (μm) scale. These microscale nanorobots typically differ from the more classic microrobots by the fact that unlike the latter, the formers exploit the unique properties of nanotechnology by embedding the appropriate nanoscale components to integrate within the robots, the required functionalities to allow them to accomplish their assigned tasks.

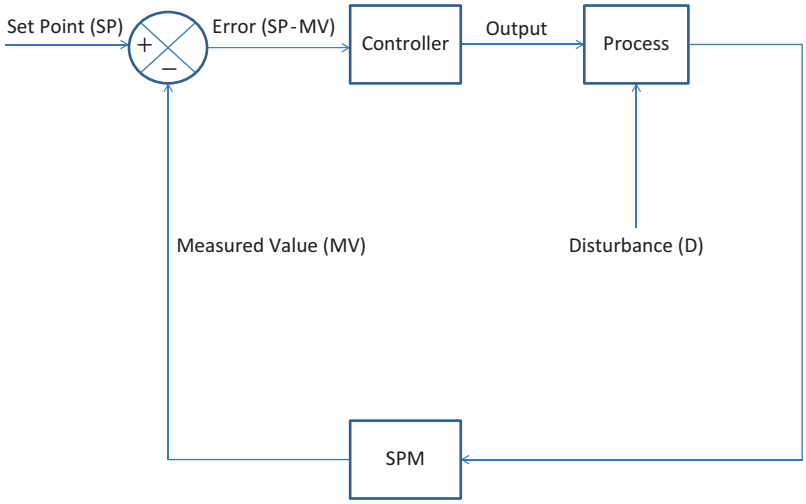
Previous experimental results have also shown that the implementation of these so-called microscale nanorobots can be entirely artificial

(synthetic) including biologically inspired nanorobots, natural including bacterial nanorobots (e.g., bacteria controlled by the computer to perform the same tasks as futuristic artificial microscale nanorobots), or hybrid (also sometimes referred to as bio-nanorobots), i.e., built with a mix of artificial or synthetic and biological components.

Bioengineering

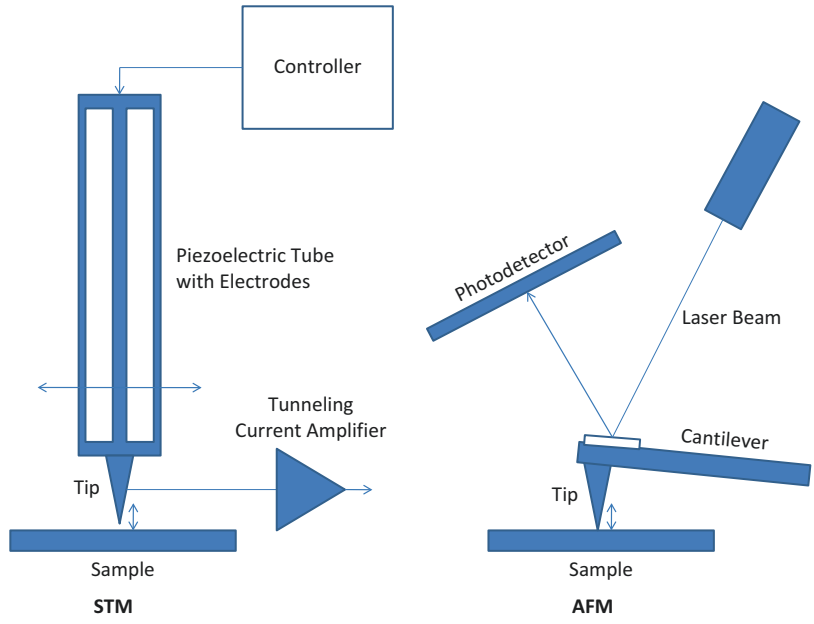
Although several applications for nanorobotics have been envisioned including but not limited to nano-assembly tasks within nanofactories, by observing the more recent experimental results it becomes obvious that the field of nanorobotics has great potential in providing significant contributions for instrumentation in bioengineering.

Bioengineering [5] can be defined as the application of engineering design and technology to living systems. As such, bioengineers are concerned with the application of engineering sciences, methods, and techniques to problems mainly encountered in medicine and biology. Although macroscale nanorobotics as defined earlier can play a great role for biology, microscale nanorobots due to their overall dimensions could be particularly suited for in vivo applications in medicine. These two main approaches in nanorobotics applied to bioengineering are described in more detail in the following sections.



Macroscale Nanorobotics in Bioengineering

Macroscale nanorobotic platforms can be generally categorized as contact-mode nanomanipulation systems using SPM and non-contact-mode systems such as the ones using techniques such as optical trapping.



SPM-Based Macroscale Nanorobotics

In recent years, SPMs were used to image and manipulate biological samples, and as such, it had a tremendous impact on the field of biology. Indeed, SPMs can be used to gather intrinsic properties of individual molecules as opposed to just bulk properties of larger samples. Therefore, since SPM technology has become an invaluable tool for the understanding of biological structures and processes at the nanoscale, it was adopted by the nanorobotics community for providing nanoscale sensing and manipulation in their platforms. The basic principle of these macroscale nanorobotic platforms is depicted in Fig. 1.

Figure 1 shows a closed-loop control system based on negative feedback. Here, the controller implementing a given control algorithm computes an output signal that will typically be used to actuate or move a SPM tip (i.e., the interfacing point between the SPM and the sample) at a desired location or set point (SP). As such, the controller corrects for any drifts resulting from the

Nanorobotics for Bioengineering and Medical Interventions, Fig. 1 Block diagram showing the basic principle of SPM-based macroscale nanorobotic platforms

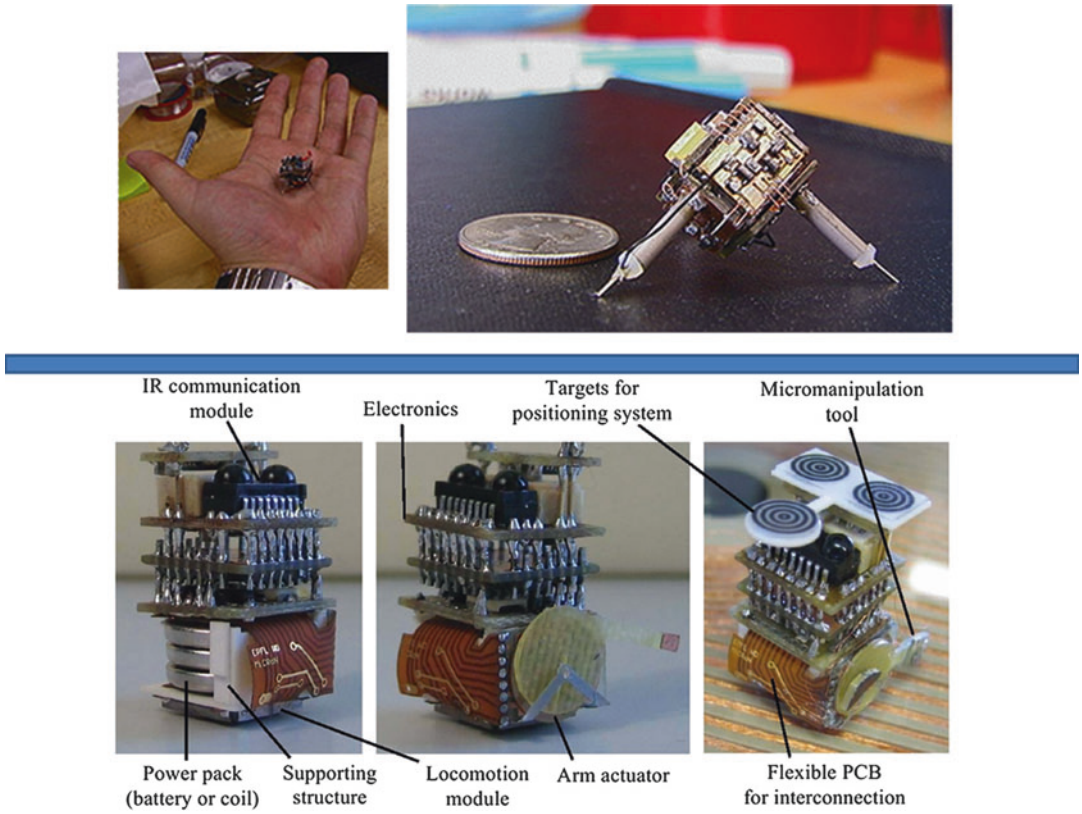
Nanorobotics for Bioengineering and Medical Interventions, Fig. 2 Basic functional principles of STM and AFM

difference between the measured value (MV) from the SPM and the set point (SP). These drifts or errors may be caused by the SPM itself (e.g., hysteresis and nonlinear characteristics of the piezoelectric (PZT) actuators used to move the SPM tip) and by various disturbances in the process. Such closed-loop control process is repeated at a rate sufficiently high to avoid excessive drifts beyond an acceptable error margin. The output computed by the digital controller is converted to an analog form using a digital-to-analog converter (DAC) and amplified to drive the actuator acting on the SPM which in most cases will be piezoelectric (PZT) actuators which are capable of atomic-scale resolution.

Although there is a huge variety of SPMs, so far most development projects of macroscale SPM-based nanorobotic systems used STM or AFM, and as such, they will be emphasized here. The type of SPM and the mode used for biological samples are of critical importance. For instance, AFM has been particularly popular in biology since it has the unique capability of imaging biological samples with molecular resolution in buffer solution. Not only topographical images of surfaces with nanometer- to angstrom-scale resolution can be achieved, but the forces between single molecules and mechanical properties of biological samples can be investigated as well. Since the measurements can be made in buffer solutions, it allows researchers to maintain biological samples alive within a physiological-like environment. This allows temporal changes in nanostructures to be measured such as comparing structural changes before and after the addition of chemical reagents. These advantages distinguish AFM from conventional imaging techniques of comparable resolution, including electron microscopy (EM) which will be discussed later. Thus, the attractive potential of SPMs and particularly AFM for biologists is the ability to visualize molecular processes under natural or physiological conditions. As such, AFM offers the resolution of most commercial electron microscopes but under the experimental conditions familiar with the much lower resolution of optical microscopes. For these reasons, AFM has been the most popular SPM in nanorobotics for bioengineering applications. The basic principle of AFM compared to STM is depicted in Fig. 2.

As shown in Fig. 2, the method used for AFM differs from STM. For STM, a controller generates voltage outputs to electrodes on a piezo-tube in order to deflect the tip in any directions. When

the tip is positioned close enough to a sufficiently conductive sample, electrons from the atoms on the surface of the sample are attracted to the positively charged tip resulting into a tunneling current which is then amplified to create an output analog signal that will be converted to digital form by an analog-to-digital converter (ADC). This digital signal is then fed back to the digital controller that will compute the voltage outputs to move the tip in order to perform a scan of the surface of the sample using closed-loop control as depicted in Fig. 1. The changes in the magnitude of the tunneling current can be used to create an image of the atomic structure, or the tip can be positioned to maintain the tunneling current constant. In the latter case, the position of the tip or nanorobotics is controlled as depicted in Fig. 1 and is used to create the image of the atomic structure.



For AFM, a cantilever with a tip is used instead. When the cantilever is deflected due to the interaction between the tip and the sample, a laser beam is also deflected along a photodetector. The position of the laser beam on the photodetector provides information about the interaction between the tip and the sample that can be used by a controller to perform closed-loop control in a macroscale nanorobotic platform. Such information can not only be used for generating an image point by point, but it also provides information such as the force involved, etc. The latter would prove to be useful to characterize the mechanical properties of biological samples and in performing nanomanipulation tasks under robotic closed-loop control such as the nanomanipulation of single DNA molecules [6].

Research and development of macroscale nanorobotic systems has taken two main approaches that could be referred to as desktop SPM-based platforms and platforms based on miniature robots carrying a SPM. Instead of bringing the samples to the instrument as the former suggests, the latter proposes to bring the instruments to the samples, allowing the potential for higher throughput through parallelism and enhanced scheduling or dispatching of each instrumented miniature robots. The concept of a nanorobotic platform relying on the dispatching of SPM-based miniature robots to the samples was first proposed and introduced with a robot known as the NanoWalker [7, 8]. Photographs of the first prototypes of the NanoWalker are being shown in the top section of Fig. 3.

The NanoWalker project began in the late 1990s. Equipped with three piezo-legs mounted in a pyramidal fashion with the apex pointing upward, the miniature robot could move with nanometer precision using approximately 4000 steps per second (being equivalent to the resonant frequency of the robot). The maximum recording displacement speed was approximately 200 mm per second. The final design of the NanoWalker robot was equipped with an onboard computer with infrared (IR) wireless communication. It was powered through the legs when in contact with a special power floor. Although it was designed to have several types of SPMs, the initial design included only an embedded STM. With an STM, the NanoWalker robot, although it could later be upgraded with an AFM, was not initially suited for bioengineering applications.

This issue was corrected later with the MiCRoN robot [9] (see bottom of Fig. 3) capable of maximum displacement speed of 0.4 mm per second while being powered with batteries or wirelessly using inductive coupling. The goal of this project was to make automated manipulation with nanometer precision of micrometer-scale objects possible by these robots. Bioengineering applications included closed-loop force control for an embedded AFM tool in cell manipulation [10].

But to date, demonstrations of bioengineering applications for both types of macroscale nanorobotic platforms are still relatively few. On the other hand, efficient automatic micrometer-scale manipulations in bioengineering have been demonstrated for desktop versions especially in autonomous cell injection [10] where micromanipulation strategies required for manipulating individual biological cells with a microrobotic system capable of conducting automatic embryo pronuclear DNA injection (cell injection) were described. One of the main reasons explaining that micromanipulation instead of nanomanipulation has generally been applied more

Nanorobotics for Bioengineering and Medical Interventions, Fig. 3 *Top*: Photographs showing two different prototypes of the NanoWalker robot. *Bottom*: Photographs of the MiCRoN robot

successfully in robotics is the fact that autonomous nanoscale operations is much more challenging due in great part to the accuracy required for successful operations coped with the difficulty in gathering real-time visual feedback information for the essential closed-loop control used in robotics.

To improve performance in gathering real-time visual feedback information, SPM-based microscale mobile nanorobots were placed in the vacuum chamber of a scanning electron microscope (SEM) [11]. The SEM electron beam was used to provide real-time 3D positional information about the tool used for nanomanipulation. Applications in bioengineering were limited since the samples needed to be electrically conductive and placed in a vacuum environment. Living cells, tissues, and soft-bodied organisms usually required chemical fixation to preserve and stabilize their structure.

Non-contact-Mode Macroscale Nanorobotics

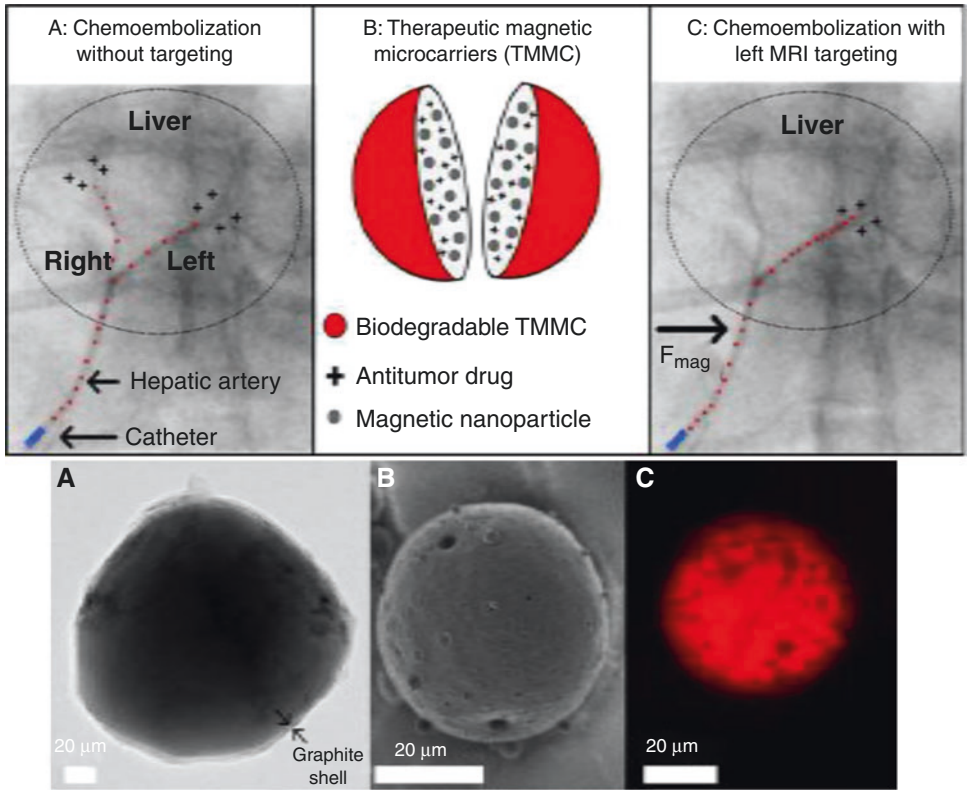
Non-contact nanomanipulation is presently dominated by optical trapping using optical tweezers. Optical tweezers use the forces exerted by a strongly focused beam of light to trap and move objects ranging in size from tens of nanometers to tens of micrometers [12]. Since its introduction in 1986, the optical tweezer has become an important tool for research in the fields of physical chemistry, soft condensed matter physics, and biology. Since optical tweezers apply loads in the order of piconewtons (pN) in a non-contact mode, it is widely used in bio-nanomanipulation and mechanical studies of very fragile biological samples. For instance, single molecule manipulation combined with interaction study of double-stranded DNA [13] is only one example. Nanorobotic platforms relying on optical tweezers generally operate in a manner to assist a human

operator. Furthermore, unlike SPMs, optical tweezers are generally more difficult to integrate in miniature robots, and, hence, they are typically more appropriate for desktop macroscale nanorobotic platforms.

Microscale Nanorobotics in Medical Interventions

Because of their overall dimensions, research and development efforts for microscale nanorobotics applied to medical interventions have been focused primarily toward in vivo target therapeutic interventions and diagnostics. Nanorobotic R&D efforts for in vivo applications were initiated in great part following the first demonstration of the MR-Sub (Magnetic Resonance Submarine) project where an untethered object was successfully navigated automatically for the first time in the blood vessels of a living animal [14] with the experimental data published in 2007. Although this field is relatively new, substantial advanced experimental results have been recently published, providing important insights about the future possibilities for medical interventions in the human body. But as shown in the following sections, several types of microscale nanorobots have been and still been investigated for such bioengineering applications.

Artificial and Synthetic Microscale Nanorobotics: An Introduction



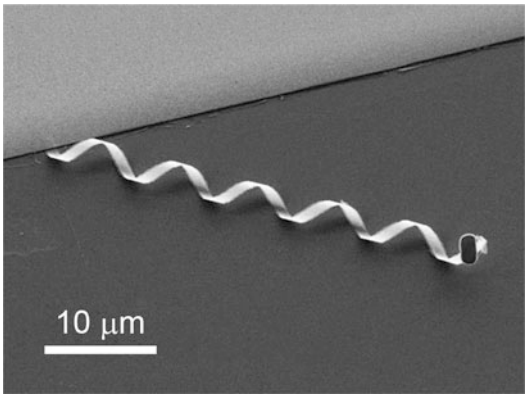
Although both artificial and synthetic robots refer to man-made robots, synthetic robots, although artificial, often imply unlike non-synthetic artificial robots the use of a chemical process to produce such robots. Hence, synthetic microscale nanorobots can typically be produced in large quantities at a relatively lower cost compared to the production of non-synthetic artificial (later simply referred to as artificial) microscale nanorobots.

The concept of integrating processes based on self-assembly for the synthesis of synthetic microscale nanorobots is an important yet critical aspect since for many targeted nano-medical interventions, large quantities of the so-called synthetic microscale nanorobots produced at a relatively low cost would typically be required, e.g., in targeted drug delivery through the vasculature in cancer therapy. On the other hand, one or a relatively small number of artificial microscale nanorobots could be useful in other particular medical interventions such as in surgical tasks.

But at these scales, one of the primary challenges shared by both artificial and synthetic microscale nanorobotics is power. Traditional onboard power supplies such as batteries cannot be scaled at these levels, and, therefore, two main approaches have been considered, namely, relying on an external source of energy or harvesting energy from the environment. For artificial and synthetic microscale robots, the former has been preferred where in most cases a magnetic field gradient generated by electric coils and induced on the microscale robots was used to create motion.

Synthetic Microscale Nanorobotics: Therapeutic Magnetic Micro-carriers (TMMCs)

The first untethered examples based on nanometer-scale components and depicted in Fig. 4 that were navigated through the blood vessels toward a predefined target in a living animal using the same method previously reported in Ref. [14] with a larger untethered device being propelled by magnetic gradients have been recently described in Ref. [15]. Referred to as therapeutic magnetic micro-carriers (TMMCs), these untethered microscale agents were synthesized to act like synthetic microscale nanorobots as defined previously. Indeed, each TMMC had an appropriate structure with a diameter of approximately 50 micrometers which was the most suitable dimensions for targeted liver chemoembolization in live rabbits in these particular experiments. For humans, the diameter would typically be expanded between 100 and 300 micrometers. The structure was built with a biocompatible and biodegradable polymer that was able to hold all embedded components, namely, the magnetic nanoparticles (MNPs) and the therapeutic agent. The embedded MNPs allowed propulsion and navigation of the TMMCs in the blood vessels by inducing



Nanorobotics for Bioengineering and Medical Interventions, Fig. 4 Unlike simple passive micro-entities that would be injected in the bloodstreams without control, TMMCs (B-upper) are synthesized to be compatible and integrated within a robotic environment allowing them to be controlled precisely as required to perform a given task such as the precise controlled navigation and delivery of therapeutic agent to a specific targeted location (C-upper vs. A-upper). In the lower section, photographs of the TMMC (B), with image of the loaded drug (C), are shown with one of the MNPs (A) allowing closed-loop MRN to be performed by inducing the correct directional propelling force on the embedded MNPs from MR-tracking information gathered from distortions in the MRI homogeneous magnetic field caused by the same MNPs (Reprinted from Pouponneau et al. [15] with permission)

propelling force using magnetic gradients generated by an upgraded clinical magnetic resonance imaging (MRI) system, a method referred to as magnetic resonance navigation (MRN). The same MNPs were also acting as MRI contrast agents, and as such, they enabled the TMMCs to be tracked by MRI, providing the possibility for feedback information required to execute closed-loop navigation control. Like other forms of robotic systems such as the ones relying on a central computer to remotely control a robotic arm or manipulator, this approach also relies on computation to remotely control special agents designed to perform a particular task. While the larger and more familiar robots often use mechanical means to embed functionalities (e.g., mechanical grippers), microscale nanorobots for bioengineering would not typically use mechanical parts, and as such, they would not appear as conventional robots as we know since they rely more on less familiar fields such as nanotechnology and biochemistry to implement embedded functionalities (e.g., with the use of antibodies instead of mechanical grippers).

But with MRN, the propelling force induced decreases with the quantity of magnetic material embedded in the microscale nanorobots, and, hence, larger magnetic gradients must be generated to navigate smaller nanorobots efficiently in tinier blood vessels. In an upgraded clinical MRI

platform, an approximate tenfold increase in magnetic gradients is technologically feasible from conventional scanners, increasing the typical 40 milli-teslas (mT) per meter (m) 3D gradients of many conventional MRI systems up to approximately 400 $mT \cdot m^{-1}$ in upgraded MRI scanners (referred to as MRN systems, i.e., upgraded MRI scanners by software only or a combination of software and hardware for MRN operations). Despite the increase in magnetic gradients, miniaturization of the microscale nanorobots conceived for MRN-based interventions is still limited to a few tens of micrometers in diameters. To navigate in the microvasculature and in the tiniest blood vessels found in humans and required to target deeper inside tumors, microscale nanorobots with an overall diameter of approximately 2 micrometers are required. Therefore, in order to compensate for the limitation of generating larger magnetic gradients for interventions in humans, other approaches have been investigated.

Nanorobotics for Bioengineering and Medical Interventions, Fig. 5 Photograph of an artificial bacterial flagellum about half as long as the thickness of a human hair. This one can swim at a speed of up to one body length per second (Image: Institute of Robotics and Intelligent Systems/ETH Zurich. Image reprinted with permission)

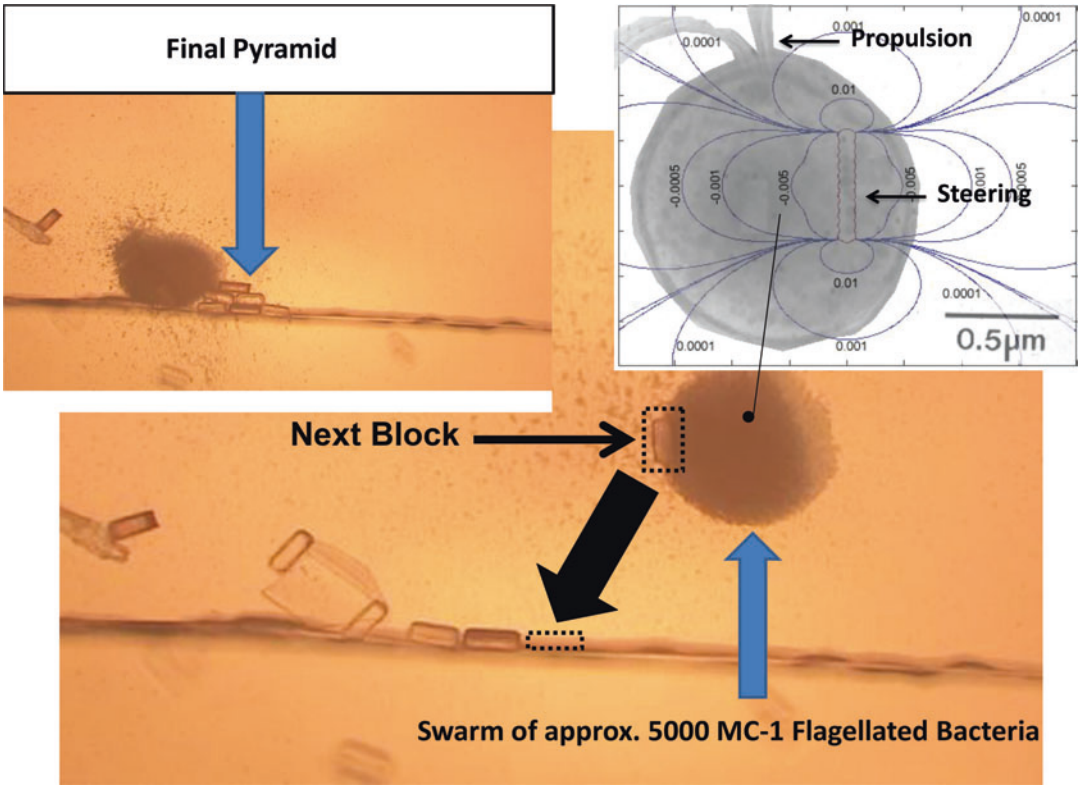
Biologically Inspired Artificial Microscale Nanorobotics: Artificial Bacterial Flagella (ABF)

One of the best known approaches to compensate for the limitation in generating larger magnetic gradients is referred to as artificial bacterial flagella (ABF) where a good up-to-date review is given in Ref. [16]. ABF (one example is depicted in Fig. 5) are good examples of biologically inspired artificial devices that can act under computer closed-loop control. Indeed, in nature, microorganisms swim in a low Reynolds number regime using a variety of techniques that differ from macroscale swimmers. The most studied experimental technique in micro- and nanorobotics due in great part to the possibility in micro- and nanofabrication technologies has been flagellated propulsion systems.

ABF typically rely on a rotating magnetic field creating a torque instead of a pulling force as for MRN to move the robot forward. Since creating a torque requires much lower magnitudes of magnetic gradients compared to pulling as done during MRN operations, the gradients required could be decreased to a few $mT \cdot m^{-1}$ instead of a few hundred $mT \cdot m^{-1}$. But to date, no known experiments have been done yet in the blood vessels using ABF. Although the approach has advantages, several issues would have to be addressed before being adopted for targeted interventions through the human's vasculature. Two critical aspects are the biodegradation and response to the immune system since once located deep in the human's body, possibility for recovery will be unlikely. For the TMMCs described earlier, these issues have already been resolved by using materials that are biodegradable and biocompatible and MNPs with dimensions that already prove to be compatible with the human's immune system.

Another consideration for robotic operations is the possibility of gathering positional feedback data for closed-loop navigational control. The spatial resolution of all medical imaging modalities is too low for detecting a robot or an aggregation of robots with overall diameters of only a few micrometers or a few tens of micrometers, respectively, due to the space available in the microvasculature. X-ray systems have among the best spatial resolution to image inside humans (approximately 200–300 micrometers), but they will fail to detect and hence track microscale nanorobots operating in the microvasculature such as in capillaries. Although MRI has typically

a slightly lower spatial resolution than X-ray, the microscale nanorobots can be made such that the embedded magnetic particles would create a magnetic field distortion much larger than the robot itself and large enough to be visible with MRI. Past studies have shown that a single magnetic object as small as 10 micrometers could be detected inside the human's body using MRI. But because MRI scanners have a high homogeneous magnetic field referred to as the B_0 field (1.5 T or 3 T in most clinical MRI scanners) along a given direction, the shape of the robots must ideally be isotropic such as the spherical shapes of the TMMCs depicted in Fig. 4. For instance, the B_0 field would induce a directional torque on ABF if operated inside a MRI scanner such that they will always point to the same direction during the entire intervention and, hence, making directional control or steering for targeting purpose impossible. On the other hand, because of the spherical shape of each TMMC, steering in all directions is not an issue. But one fact remains true that up to now, TMMCs are still too large to be navigated in the microvasculature and, as such, the idea of using a propulsion method suited for low Reynolds hydrodynamic conditions such as flagella-based propulsion allowing for the implementation of smaller untethered devices is still a valid and promising approach.



Natural Microscale Nanorobotics: Bacterial Nanorobots

One strategy that was recently considered in nanorobotics was to harness what nature provides instead of mimicking it using modern technologies. An example that showed its potential through experimentations conducted in the blood vessels of living mice is the use of MC-1 flagellated magnetotactic bacteria (MTB) acting as bacterial nanorobots or natural microscale nanorobots [17]. Although most people would see this bacterium as a simple living microorganism, in an engineering point of view, this microorganism can be considered as a sophisticated robot with a very effective embedded propulsion system and control interface. The possibilities of computer closed-loop control of these MTB compared to potential far-futuristic artificial nanorobots can be appreciated by observing the example of a tiny pyramid being built one component at a time by a swarm of approximately 5000 MC-1 flagellated bacteria (see Fig. 6).

As depicted in the upper right corner of Fig. 6, the cell of the MC-1 bacterium is spherical in shape and measures between 1 and 2 micrometers in diameter, making it ideal for navigation in the tiniest blood vessels found in humans. Each cell has two bundles of flagella providing a thrust force exceeding 4pN, making it a serious candidate for operations in the human's microvasculature. This value is also relatively high compared to other known species of flagellated bacteria characterized with a typical thrust force in the range of 0.3–0.5pN. This allows the MC-1 bacteria to swim in water and human's blood at speeds often exceeding 200 μm/s. This is a very high speed when we know that the swimming speeds of other well-known species of flagellated bacteria in the same conditions are ~30 μm/s. Maximum displacement speeds of ~300 μm/s and corresponding to ~150 times its cell's length for a relatively large proportion of the MC-1 bacterium samples have also been recorded experimentally.

Unlike most bacteria that are based on chemotaxis to detect nutrient gradients and hence influence their motility, the direction of displacement of MTB with their chain of magnetosomes which are membrane-based MNPs that acts like an embedded nano-compass can be influenced by a directional magnetic field, hence allowing for magnetotaxis-based control by inducing a directional torque on the same chain acting as a nano-steering system. Since this magnetic nano-compass is extremely sensitive, an extremely low-magnitude magnetic field is required to influence their directional motions.

Since the same MNPs used for directional control also act as MRI contrast agents, it was shown that a sufficiently large aggregate of MTB can be detected using a clinical MRI scanner. But as for the ABF, MTB cannot change direction while operating in the MRI scanner. But unlike artificial or synthetic microscale nanorobots, these microorganisms do not need real-time closed-loop navigation control but rather computer guidance for determining their positions using MRI at relatively

Nanorobotics for Bioengineering and Medical Interventions, Fig. 6 Computer control of a swarm of approximately 5000 magnetotactic bacteria is demonstrated by the coordinated construction of a tiny pyramidal structure using blocks with length approximately equivalent to a human's hair thickness

long time intervals in order to guide them toward the targeted site. Indeed, MTB when encountering an obstacle will not require real-time closed-loop navigation control to direct them around the obstacle as an artificial robot would, but they will typically swim without any external control around obstacles and toward the direction indicated through magnetotaxis using a special platform named a magnetotaxis system, a platform located outside and sufficiently far from the MRI scanner. This self-contact avoidance capability is a significant advantage compared to artificial versions since real-time closed-loop navigation control is not possible in these regions considering that the microvasculature cannot be imaged due to a lack of spatial resolution in existing medical imaging modalities. Nonetheless, although these bacteria can swim efficiently in the microvasculature, they are ineffective in larger blood vessels such as the arteries and the arterioles where blood flow velocities are too high. Hence, a means of transport is needed to bring such bacterial nanorobots from the injection location in an artery to the entrance of the microvascular network.

Hybrid Microscale Nanorobotics: Bio-nanorobots

One solution that is under study for the transport of bacterial nanorobots toward the microvasculature is the use of microscale liposomal transporters. Already, such transporters with diameters of a few tens of micrometers have been synthesized with free swimming MC-1 bacteria inside. Although not tested yet in a living animal, these liposomal microscale transporters can be synthesized with MNPs acting as propulsion engines and for MRI-based tracking for MRN operations. This is a perfect example of

hybrid microscale nanorobots where biochemistry and biology are used in their implementations. Since biological components are also used, they could also be referred to as bio-nanorobots. Bio-nanorobots could also refer to artificial or synthetic robots relying on nanostructures such as MNPs being functionalized with biomolecules. Indeed, often in targeted therapeutic or diagnostic applications, microscale nanorobots would be functionalized, i.e., that they will be coated with molecular components, e.g., antibodies that have specificity for the targeted cells such as specific cancerous cells. Functionalized hybrid or bio-nanorobots could not only help in achieving more retention when coming in contact with the targeted cells for targeted therapies, but functionalized microscale nanorobots could also be potentially useful in targeted diagnostics as well.

Magnetic Field Actuation Approaches in Medical Nanorobotics

Magnetism is presently the most popular and suitable means of actuation for medical nanorobotics. With magnetic actuation, it is important to understand that both the magnetic field strength which is the amplitude of the magnetic field at the location of the nanorobots being actuated and the magnetic gradient which is the variation of the magnetic field at the location of the nanorobots that must be moved are important parameters to consider. Increasing the field strength results in an increase in the magnetization level of the nanorobots up to a maximum level known as the saturation magnetization. The magnetic gradient is used to move the nanorobots in a given direction. The higher is the magnetization of the nanorobots, the higher is the force induced on the nanorobots from the magnetic gradient. Therefore, ideally both the magnetic field strength and the magnetic gradient must be increased. But there are technological limitations that lead to compromises in the form of various magnetic field actuation approaches where each one would be better suited for particular physiological conditions and/or types of medical interventions.

When using one or several permanent or electromagnets around the patient, the magnetic field strength decays rapidly as the distance for the magnetic source increases. For whole-body interventions where nanorobots must operate in deep tissues and especially in constrained physiological environments where the size of the nanorobots becomes very small, the magnetic field strength becomes very small and insufficient to induce sufficient directional actuation forces from the magnetic field gradient. As such, increase in the magnetic field strength has been provided with MRN as specified earlier by exploiting the high uniform magnetic field of a clinical MRI scanner. In modern MRI scanners such as the 3 T-platforms, the magnetic field strength is sufficient to bring the best magnetic nanorobots at saturation magnetization at any depth in the body of a patient. But the main drawback is that clinical MRI scanners offer limited magnetic directional gradients. Such gradients have been increased in MRI scanners by inserting a gradient coil assembly inside the tunnel of the scanner, but by doing so, the reduced inner diameter prevents whole-body interventions when using conventional clinical scanners and becomes more appropriate for parts of the body that can fit in such restricted space such as the head.

To maintain the advantage of a high magnetic field strength while providing much higher magnetic gradients, another approach known as dipole field navigation (DFN) is presently under investigation [18]. The basic principle is that when a magnetic object such as a sphere is placed in the tunnel of a clinical MRI scanner, it creates a dipole field that distorts the high uniform magnetic field inside the tunnel of the scanner. Such distortion results in a variation of the magnetic field that can be used as directional magnetic gradients. With DFN, nanorobots are submitted to both high magnetic gradients and high magnetic field strength. The drawback of this approach is that because the uniform field is distorted, real-time navigation control based on feedback positional data during travel is not presently possible as for MRN. There are two main approaches in DFN, namely, static and dynamic DFN. For static DFN, one or more magnetic spheres are positioned prior to the navigation phase and remain statically positioned at specific locations necessary to create the required set of directional gradients based on previous

acquired images of the vascular network. For dynamic DFN, the set of magnetic gradients is achieved by dynamically moving a magnetic sphere along a specific path outside the patient typically by inducing a pulling force using the scanner's imaging gradient coils. A hybrid version is also possible where a magnetic sphere is moved in the neighborhood of statically positioned magnetic spheres.

Another approach provides a compromise in magnetic field strength between the use of permanent or electromagnets alone and MRN or DFN, but with much higher magnetic gradients. To achieve such higher magnetic gradients, superconducting magnets as opposed to permanent or electromagnets must be considered. In a clinical setting, such superconducting magnet is in the form of a clinical MR scanner where superconductivity is used to generate the high uniform field inside the tunnel of the scanner. But such magnetic field cannot be modulated and must be maintained constant. This is the reason that imaging gradients in a MRI scanner are generated by coils that are not superconducting. In proximity of the scanner, the high magnetic field generated by the superconducting magnet decays rapidly which results in a very high magnetic gradient and a relatively high field strength when placed in proximity of the scanner. But since such high magnet cannot be moved and the field cannot be varied for navigation purpose, the patient is robotically moved instead outside and in proximity of the scanner based on the computed directional gradients required. This is the fundamental idea behind an approach that has been referred to as fringe field navigation (FFN) [19]. The actual main drawbacks of this approach are the relatively slow directional changes of the gradients and a lack of an effective real-time tracking modality.

Medical Nanorobots with Additional Functionalities

Embedding more functionalities in each nanorobotic agent would lead to higher impacts on a wider range of medical interventions. But embedding additional functions in such small entities becomes a real challenge due to the fact that adding more components is often not an option. One strategy has been to integrate components with characteristics suitable for the implementation of several functions. Magnetic nanoparticles, for instance, synthesized adequately can not only be used for inducing displacement forces and acting as a contrast agent for tracking the position or location of the nanorobots by MRI but can also create a localized elevation of the temperature (known as hyperthermia) to enhance treatment [20] or for other functions such as temporarily opening the blood-brain barrier (BBB) [21] or computer-triggered drug releases by changing the shape of the nanorobotic agents [22]. These are just some examples of several functions that can be implemented in such nanorobotic agents.

Conclusions

The two main forms of nanorobotic platforms for practical applications in bioengineering are the macroscale nanorobotic platforms and the microscale nanorobotic platforms which are mainly dedicated to biology and in vivo medical interventions, respectively. Macroscale nanorobotic systems rely mainly on AFM for contact-mode nanomanipulation and studies of biological samples, while optical tweezers are mostly used for non-contact applications. Microscale nanorobots can be artificial, synthetic, or natural. Synthetic versions called TMMCs based on biodegradable polymer and MNPs and capable of releasing therapeutic agents have already been navigated to target sites in live animals using an upgraded clinical MRI scanner, but the miniaturization of these synthetic carriers is limited to a few tens of micrometers in diameter due to limitation in increasing magnetic gradients beyond approximately half a tesla for human subjects. To compensate for such limitation, artificial versions called ABF using a rotary magnetic field to induce a torque to mimic the flagellum of bacteria have been proposed. Although the magnitude of the magnetic gradients could be reduced significantly, several issues would need to be resolved before ABF can be used for in vivo interventions in the blood vessels. Instead of a biomimetic artificial version, another strategy relies on harnessing

natural bacteria and, more specifically, the MC-1 flagellated magnetotactic bacteria. But the latter would need to be encapsulated in special microscale carriers for many target medical interventions. As such, hybrid microscale nanorobots are likely to play an important role in medical interventions conducted deeply in the vasculature, especially hybrid functionalized nanorobots.

This entry only provided a quick overview of the present state of the art for nanorobotics in bioengineering, and for more details, the readers should consult the adequate literature. Research and development in the field of nanorobotics is progressing at a very fast pace where significant progresses have been observed particularly in medical applications where efforts have been oriented toward the developments of medical nanorobots with enhanced capabilities.

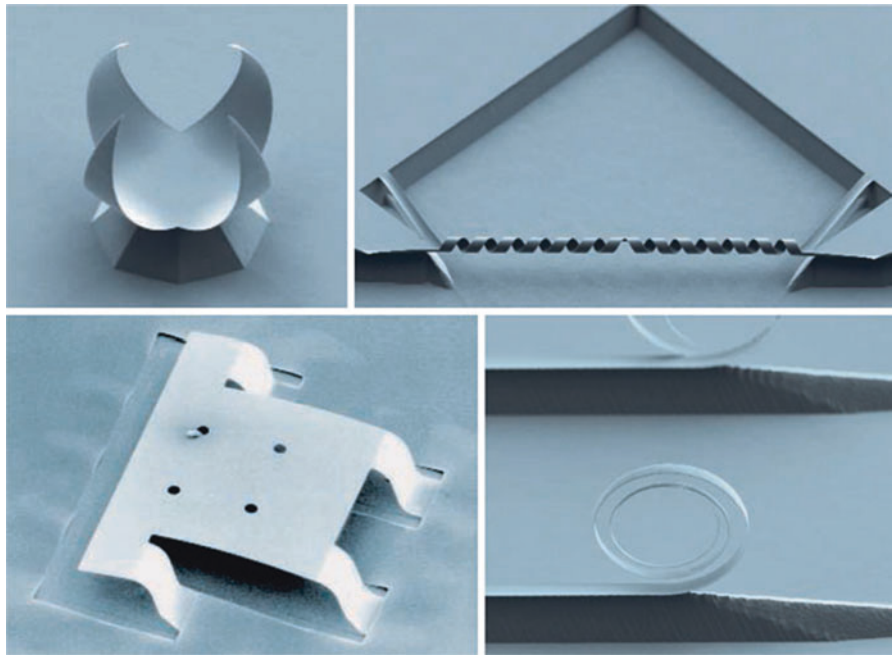
Definition

Three-dimensional helical nanostructures, such as carbon nanotube coils (CNTs) [1], zinc oxide helical nanobelts [2], and rolled-up helical nanostructures [3–7] (Fig. 1 [5, 8–10]) have attracted intensive research interest because of their potential applications in nanoelectromechanical systems (NEMS) as springs, electromagnets, inductors, resonators, sensors, and actuators [11–14]. These NEMS will serve as the tools for fabricating future nanorobots, and in the meantime basic components constructing those nanorobots. Three-dimensional helical nanostructures could be manipulated and characterized by the nanorobotic tools, which could be a good candidate for fascinating applications, such as, mass sensors in femtogram ranges, force sensors at pico-Newton scales, and resonators at GHz ranges.



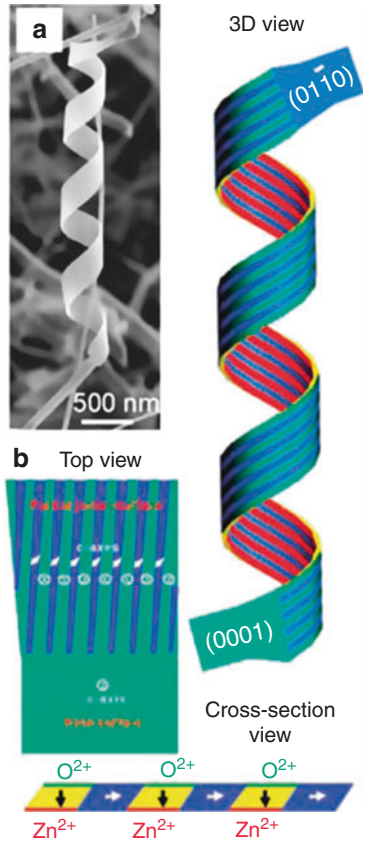
Physical and Chemical Properties

Bottom-up Fabrication of Helical Nanostructures

Top-down and bottom-up nanofabrication strategies are being independently investigated by various researchers to realize helical nanostructures. Bottom-up strategies are assembly-based techniques, resulting in controllable nanopatterns at large scales, such as carbon nanotube coils [1], silica nanosprings [15], and SiC nanohelices [16]. For example, helical nanostructures of semiconducting zinc oxide (ZnO) were grown using a vapor-solid process. A rigid structural alteration, as a result of superlattice formation [17], gives rise to the formation of a helical structure, either left-handed or right-handed, as shown in Fig. 2. The diameters, widths, and pitch distances of the nanohelix range between 300 and 700, 100–500, and 500–2,500 nm, respectively. The length of the as-fabricated ZnO nanohelix can be as long as 100 μm and the thickness of the helical ribbon is less than 20 nm [17].

Top-down Fabrication of Helical Nanostructures

Top-down approaches are based on conventional fabrication process, including nanolithography,



Nanorobotics for NEMS Using Helical Nanostructures, Fig. 1 Various helical nanostructures. *Bottom left* is reproduced with permission from Ref. [8], (Copyright 2003 APEX/JJAP. The others are in courtesy of L. Zhang and D. Grützmacher)

nanoimprinting, and chemical etching. Nanocoils are created through a top-down fabrication process in which a strained nanometer-thick heteroepitaxial layer of semiconductor compounds curls up to form 3-D structures [4]. Using GaAs-InAs bilayer as an example, when the basic bilayer film is released from an InP substrate by selective etching, the elastic forces of two layers are oppositely directed, generating a nonzero moment of forces, therefore its top layer contracts and its bottom layer expands, causing the film to curl and roll up [4]. The preferential direction for the film to roll up depending on the orientation of a mesa stripe on the substrate, either tube-like or helical nanobelts, can be formed [5]. A helical geometry based on the bilayer SiGe/Si can be achieved through this process (Fig. 3) [9]. The gray arrows indicate the <100> directions, that is, the smallest Young modulus direction on a <001> substrate, in which the bilayer will start to roll up when it has been freed from the substrate. Several techniques have been proposed to improve the control over the fabrication process in terms of the resulting length, shape, and orientation of structures. It has been demonstrated that the misaligned angle between the stripe and etching direction and the edge effect of the helical-shaped ribbon are crucial to determine the chirality and pitch of a helical nanobelt [5, 9]. Moreover, various materials, such as metal, dielectrics, and polymers, can be integrated into the helical nanobelt by thin film deposition and lithographic patterning [9]. It is worthy of note that nanohelices with a minimum diameter of 7 nm were obtained using 6-monolayer-thick InGaAs/GaAs bilayers [4].

Key Research Findings

Nanorobotic manipulation [18] enables property characterization to be performed after intermediate processes, and in situ characterization can be performed using manipulation rather than conventional static observations. Nanorobotic approach extends the lower limit of robotic manipulation to the dimension of nanometers, and it paves the way for the design and fabrication

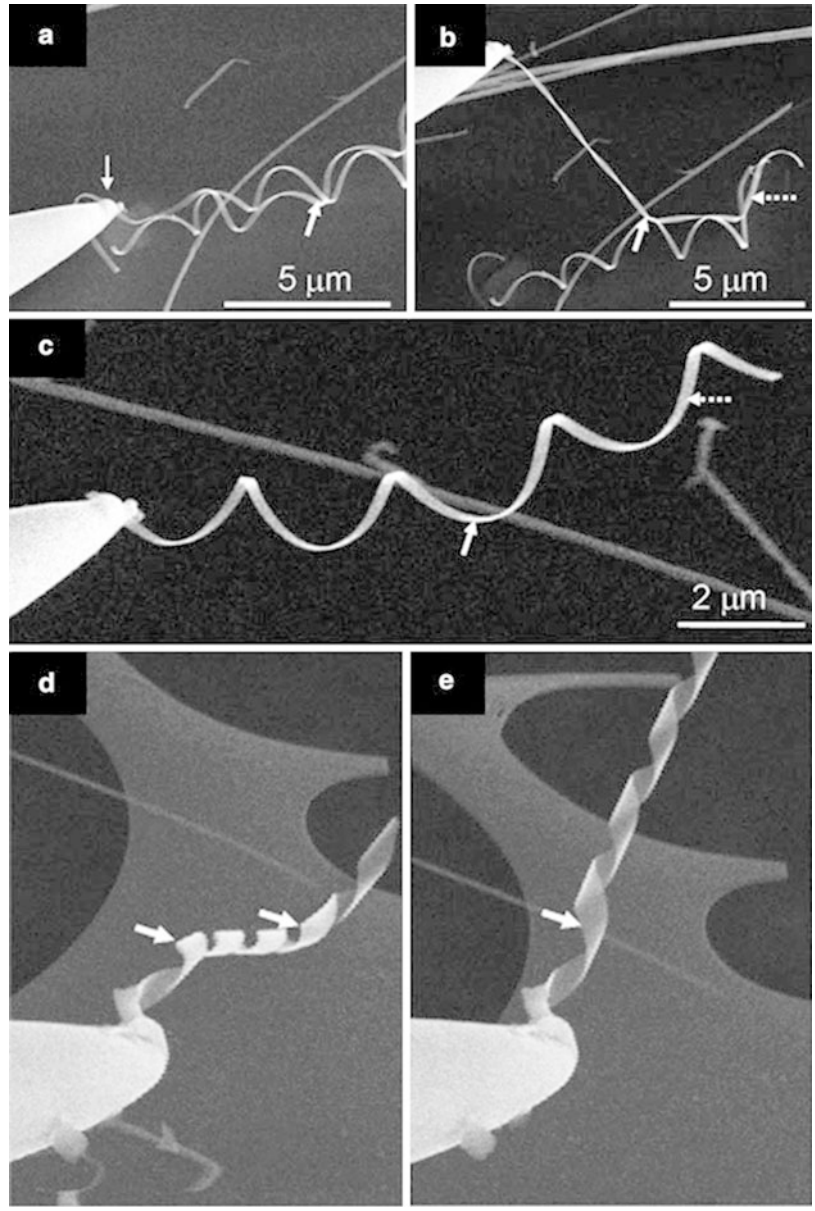
of nanocomponents having applications in NEMS.

Mechanical Properties of Helical Structures



By in situ manipulation using a nanoprobe, mechanical properties of various helical structures have been investigated, such as superlattice-structured ZnO nanohelices, carbon nanocoils, and rolled-up nanosprings [11, 12, 14]. It is found that the superelasticity (shape memory) of superlattice-structured ZnO nanohelices enables the nanohelix to recover its shape after an extremely large axial stretching and compressing,

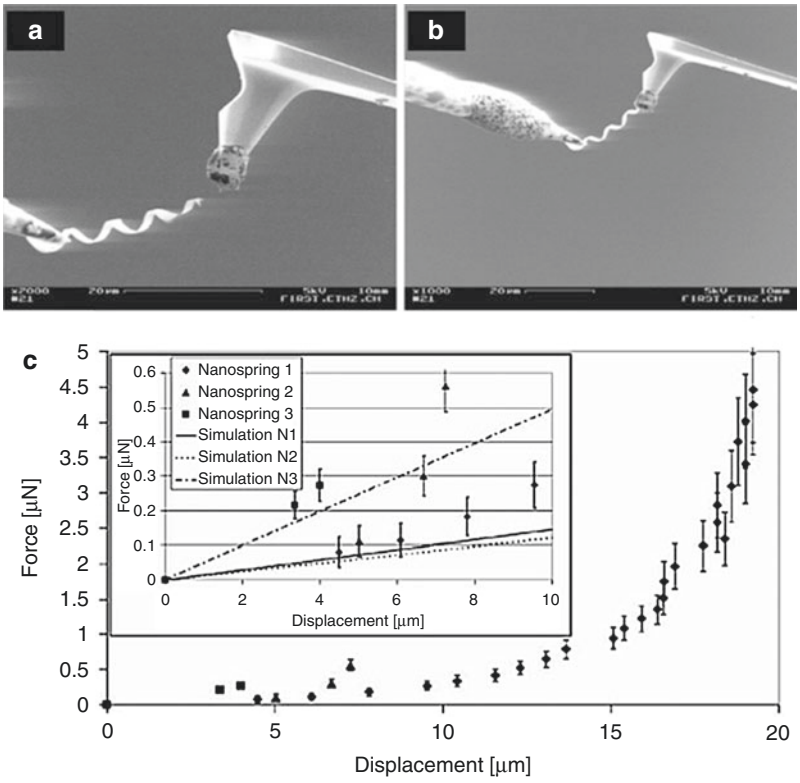
which could be of great interest for fabricating nanoscale elastic energy storage in microelectromechanical systems (MEMS) and NEMS. The manipulation experiments of rolled up helical nanostructures can be performed by a nanomanipulator and an atomic force microscope (AFM) cantilever inside a scanning electron microscope (SEM). The nanohelix was picked up by welding its one end using platinum (Pt) deposition onto the tip of a tungsten nanoprobe, and the mechanical deformation was recorded via extending or compressing the nanohelix using the nanoprobe. As a result, its spring constant can be increased continuously for up to 300–800 %.



In Fig. 4a, b, it is evident that the welded nanohelix can be pulled to an almost straightened shape, with its twist cycles preserved. Next, the welded nanohelix is released and started to restore its original shape, as shown in Fig. 4c. With comparison to the initial nanohelix dimensions in Fig. 4a, it indicates that the nanohelix has an almost identical dimensionality including pitch and radius, suggesting a complete elastic recovery

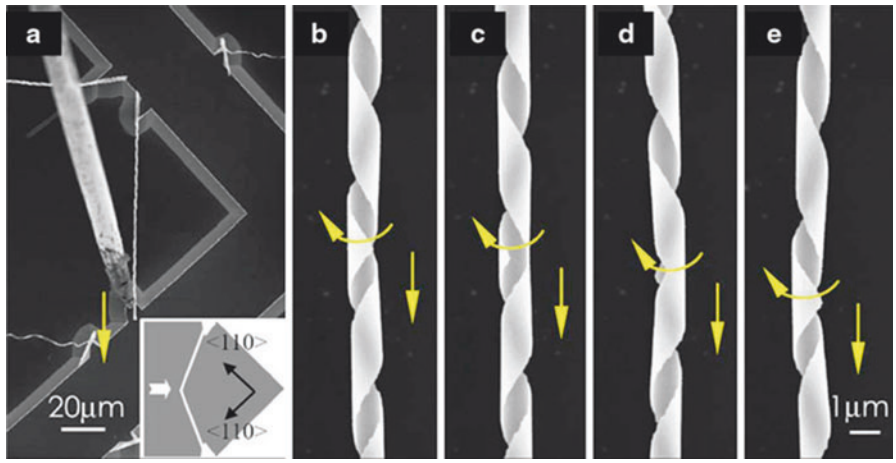
from stretching. Similar mechanical behavior, that is, the superelasticity (shape memory) behavior, has also been observed when applying a compression load on the welded nanohelix (Fig. 4d, e). The spring constant of ZnO nanohelices is in a range of 0.07–4.2 N/m, and the transverse fracture force is in the micro-Newton range [12, 17].

Nanomanipulators can also be used to carry out the mechanical characterization of rolled-up helical structure. A probe picked up an InGaAs/GaAs nanospring and attached it to the AFM tip (Fig. 5a, b). Then, a tensile force was applied to the nanospring, while continuous SEM images were taken to detect the AFM tip displacement and the nanospring deformation. When the tensile force was increased dramatically, the attachment between the nanospring and the AFM cantilever broke, and the nanosprings returned to their initial shape at the zero-displacement position. From the displacement data and the known stiffness of the

(**c**) Simulation and experimental results of axial force versus nanospring displacement (Reproduced with permission from Ref. [14], Copyright 2006 ACS)

AFM cantilever, the tensile force acting on the nanosprings versus the nanospring displacement was plotted (Fig. 5c). For the nanospring, an overall elastic strain of 48 % was measured when the attachment to the AFM tip broke. Ultra-flexible rolled-up Si-based nanospring with a spring constant of 0.003 N/m was also reported which exhibits long-range linear elasticity (with ca. 189 % relative elongation) and excellent mechanical stability [19]. The rolled-up structure is promising for use in electromechanical sensors, such as force or pressure sensors, because of intrinsic piezoresistive and piezoelectric properties of these materials.



Linear-to-Rotary Motion Converter

The conversion between various forms of motions will play an important role in future NEMS applications. Among various nano building blocks, 3-D helical nanostructures, for example, dual-chirality helical nanobelts (DCHNBs), could realize conversion between linear and rotary motion [20]. As schematically shown in Fig. 6a, the motion converter consists of a DCHNB with a left-handed and a right-handed part. By linearly stretching both ends of the DCHNB, the central part was mobilized in rotary motion; allowing for linear-to-rotary motion conversion, which has not been previously demonstrated in other nanostructures. With an extended arm, the output can be linear (small displacement) or rotary (large displacement) motion, as seen in Fig. 6b. When a tensile force F is applied to the DCHNB, it elongates and rotates about the unwinding direction.

To implement and characterize motion converters, experimental investigations have been performed in the SEM using a nanomanipulator equipped with a tungsten probe and an AFM cantilever. Manipulation of an as-fabricated DCHNB was performed by cutting the lower end of the DCHNB shown in Fig. 7a. A "sticky" probe was then prepared by dipping a tungsten probe (Picoprobe, T-4-10-1 mm) into a silver tape and attached on the lower end of the DCHNB. Rotation was then generated in the central part by moving the probe downward (Fig. 7b–e).

[20], Copyright 2009 IEEE)

Examples of Application

A fundamental application of the rolled up nanohelix is the 3-D microscopy based on the linear-to-rotary motion conversion [20], in which samples are rotated so that different views are exposed to light, electron beams, or focused-ion beams (FIBs). Due to their extremely compact size, the dual-chirality helical nanobelts are well suited to serve as rotary scanners for creating 3-D scanning probe microscope (SPMs), rotary stages for a microgoniometer for observing an object from different crystal surfaces, and components of nanomachines.

Figure 8 shows 3-D imaging of a pollen grain. The pollen grain is picked up by a Picoprobe and attached to the DCHNB. The motion converter has been characterized before loading the sample. Figure 8a–d shows that the sample rotates counterclockwise (top view) for approximately 180° when releasing the extended DCHNB. Figure 8e–h shows further stretching of the DCHNB, and the sample rotates clockwise (top view) for another 180°. It can be seen that the

different aspects of the sample can be exposed to the electron beam simply by extending or releasing the DCHNB with a small displacement. Further possibilities for this converter include goniometry for a transmission electron microscope (TEM), tomography for a SEM or a TEM, and 3-D SPM. By integrating in the fabrication processes of DCHNBs, rolled-up spirals can serve as claws for holding relatively large samples [6].

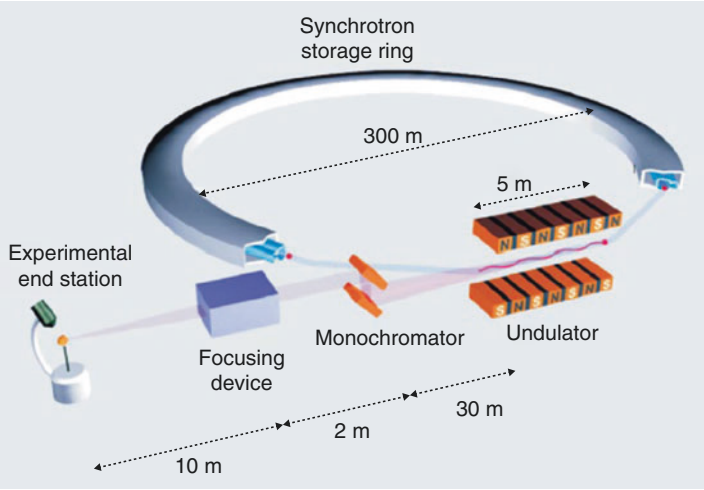
Nanorobotics for Synchrotron Radiation Applications

Nabil Amari, David Folio and Antoine Ferreira
INSA Centre Val de Loire, Université d'Orléans, Bourges, France



Definition

By nanorobotic manipulation, it is meant that nano-objects are localized, positioned, and placed by controlling external forces under the X-ray beam of a synchrotron.

Introduction

Nanorobotics for Synchrotron Radiation Facilities

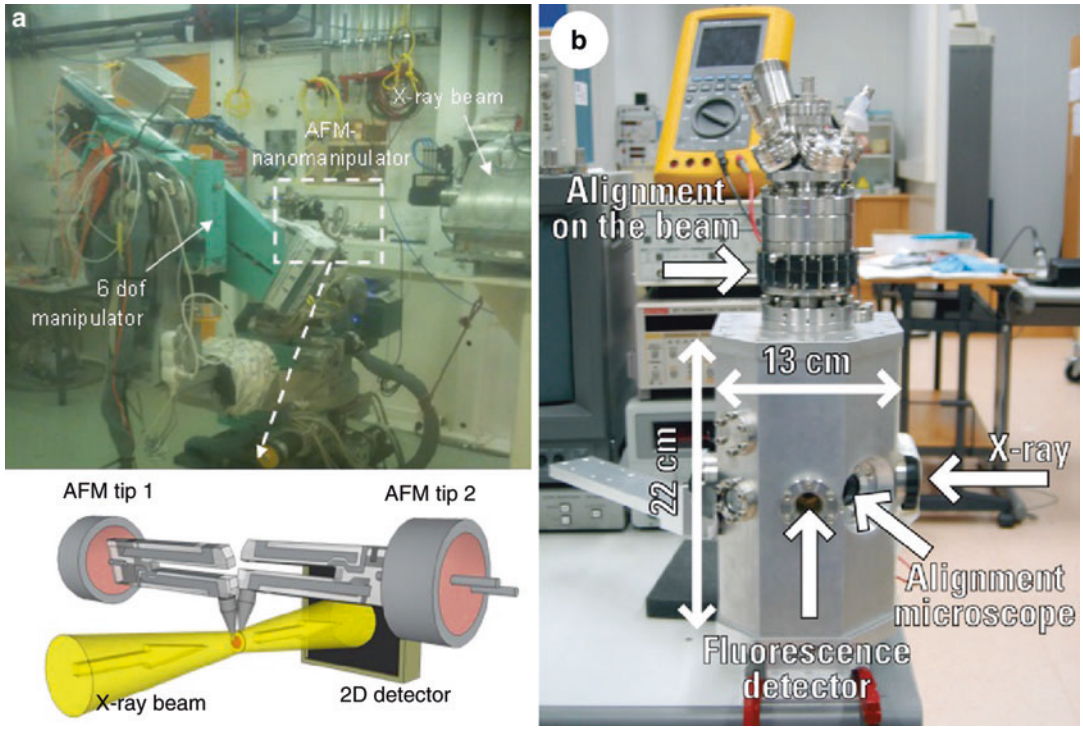
In nanosciences and nanotechnology, the frontiers between chemistry, physics, biology, and engineering become blurred, and more and more an integrated, multimodal approach to the characterization of the intrinsic properties of individual nano-objects becomes essential. The goal is to distinguish the properties of the object itself free from object–surface or object–environment interactions. Indeed in the continuous reduction of the device size where smaller and smaller material quantity is involved, the individual properties of each nano-object will tend to modify the collective properties. In this frame, the development of reliable applications, often based on auto-organization process, required the knowledge of the effects that are coming from the intrinsic properties of the nano-object compared to the ones that are coming from its interaction with the environment as well as what is due to a collective behavior of several nano-objects in interaction. The key point is to study these differences on objects ranging from few nanometers to 1 μm, where specific and size-dependent properties find their expression. Since long, several spectroscopic techniques as X-ray (for inorganic sample) or laser radiation (for inorganic and biological sample) have been used to characterize structural and electronic properties of materials and objects. Laser spectroscopies as fluorescence or Raman have improved their efficiency and can also be used to analyze very small quantity of materials down to a single nano-object [1]. In parallel, the development of synchrotron radiation has increased the energy span of radiation available for characterizing materials. As the focalization of X-ray beam improves regularly (presently less than 100×100 nm^2), it becomes possible to analyze smaller and smaller sample [2] (10^8 atoms which corresponds to a 100 nm radius object). Based on this X-ray optical progress and to address the needs of the nano-community, specific beamlines dedicated to nanosciences are currently developed or will be developed in the frame of the ESRF (European Synchrotron Radiation Facility located in Grenoble, France) Upgrade Programme, for example, UPBL1, UPBL4, and UPBL5 [3]. This work is carried out within the PIANHO project n°ANR-NANO-042 funded by the French National Agency (ANR) in the frame of its 2009 Program in Nanosciences, Nanotechnologies, and Nanosystems (P3N2009). As illustration, Fig. 1 shows the general scheme of the robotic platform handling the nano-sample directly installed on synchrotron radiation end station for nano-object characterization experiments.

Nanorobotics for Synchrotron Radiation Applications, Fig. 1 Scheme of the synchrotron radiation facility with AFM-based robotic system (NanoWorker) directly installed on synchrotron radiation end station for nano-object characterization experiments

Usually, the robotic platform is composed of a multidegree-of-freedom robotic manipulator (Fig. 2a) handling a vacuum chamber with inert gas (Fig. 2b) that holds the nanomanipulation system inside. Different optical access are possible for X-ray radiation, fluorescence detector, alignment on the beam, and alignment microscope.

Application Fields of the X-Ray NanoWorker

Nanorobotics systems have the possibility to measure and characterize intrinsic properties of an individual nano-object by picking up and holding a free nano-object in the probe beam (synchrotron or laser beam) for several minutes and releasing it without damage. To reach these goals, we propose in this entry to develop an advanced nanomanipulation platform composed of a dual scanning probe system called X-ray NanoWorker (see Fig. 2). It is composed of two atomic force microscope probes and associated electronics for morphological characterization of objects in the nanoregime under synchrotron radiation X-ray beams (XAFM or X-Ray AFM). The potential impacts of this X-ray NanoWorker will touch all the scientific areas that already use the synchrotron radiation. Indeed, it will provide a unique way to access the intrinsic properties of inorganic, organic, and biological nano-objects as modified carbon nanotube, proteins, or macromolecules [4]. In the middle term, with few modifications, the nanorobotic platform could be used in different environments that could be liquid or in controlled atmosphere and with all sources of excitation (lasers, protons, electrons, etc.). It appears highly promising the possibility of mechanically modifying in situ both inorganic and biological materials. In solid-state physics, it would offer the unique opportunity of submitting to stress single nanocrystals and observe the formation in situ of dislocations [5]. In biology it would offer literally a hand in modifying the structure of molecules the same way scanning probe microscopes (SPMs) do with atoms in 2D systems.



Actual Limitations in X-Ray Nanomanipulation

In this section, we analyze the different scientific and technological limitations associated with the nanomanipulation under an X-ray or laser beamline.

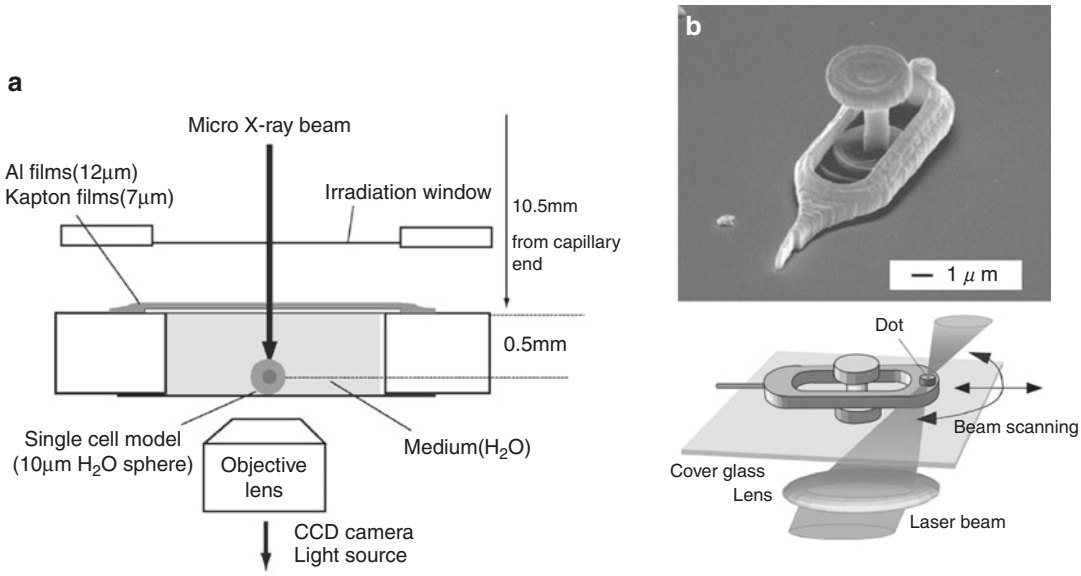
Physical Aspects of the Existing Techniques of Nanomanipulation

At the nanometer scale the physical effects that dominate the interactions between the objects are completely different from the micrometric or larger scale.

Indeed, friction as well as adhesive, magnetic, or electric forces largely overcomes gravity. This

Nanorobotics for Synchrotron Radiation Applications, Fig. 2 The experimental setup for the combined planning and tracking experiments at the European Synchrotron Radiation Facility located in Grenoble, France. (**a**) Experimental end-station setup composed of a 6-DoF serial PUMA manipulator as a beamline sample holder (NanoWorker). (**b**) General view of the vacuum chamber that holds the nanomanipulation system X-ray NanoWorker (courtesy of Prof. Joël Chevrier, ESRF Grenoble, France).

is due to the very low mass of the nano-object on one side as well as to the strongly increased surface–volume ratio. In addition, as the distances are small, quantum phenomena as tunneling effects or Casimir forces become not negligible. These quantum effects increase the complexity of the interrelation between the objects and their environment. For all of these reasons, object manipulation at nanometer scale is very different from micromanipulation, and new strategies far from our classical human perception and habits have to be elaborated. Nevertheless, the need of nanomanipulation is not new, and specific tools have been developed to interact and manipulate at nanoscale. Three main techniques are currently employed: optical tweezers, scanning probes, and mechanical nano-grippers:



– Optical tweezers: Optical tweezers have been developed 20 years ago [6] and are currently used to manipulate microspheres or biological entities in liquid environment. Optical tweezers trap objects near the waist of strongly focused laser beams and position them in 3D with nanometer resolution. Nevertheless, optical trapping in air or in vacuum remains difficult, because van der Waals or capillary forces are several orders of magnitude larger than the optical ones, even if lately they succeeded in trapping droplets in air [7].
– Scanning probe technique: Scanning probe microscopy (SPM) techniques are well known in surface science to study surface morphology and properties from micron down to atomic scale. In addition to scanning probe, local probes have demonstrated their capability to manipulate single nano-objects, molecules, and atoms on surfaces in different environments (from ultrahigh vacuum to liquids, see, e.g., http://www.almaden.ibm.com/vis/stm/

corral.html). However, this manipulation stays mainly in 2D; it confines this technique to support object on a surface: until now, this technique has not been successful to pick up and place a nano-object from a given support to another one. More recently, a SPM developed for operating on an X-ray beamline has demonstrated the compatibility of the local probe technique with the noisy X-ray working environment of the experimental end stations [8]. This beamline AFM can image with a nanometer resolution, and the tip has been used as a nano-indenter on a germanium pyramidal dot or metal surfaces in order to characterize in situ with the X-ray the induced crystal.

– Mechanical nano-gripper: In the past year, mechanical nano-grippers have been fabricated through MEMS/NEMS (micro-/nano-electromechanical system) technology process or by the use of carbon nanotubes [9]. These devices, when coupled to a SEM [10] (scanning electron microscope), a fluorescent microscope [11], or an AFM [12], are capable of manipulating individual inorganic or biological sub-micro-/nano-objects in different environments. However, all these prototypes present several common weak points. Firstly, an additional online technique is required to control in real time the object manipulation (SEM, optical fluorescent microscope, AFM), which limits the type of nanomanipulation and work environments. Secondly, the determination of the more reliable and effective manipulation strategy is based on trial–error method that is time consuming and not fully efficient because the gripping and holding methods are based on short-range interactions (strong contact). These methods can induce modifications of geometrical, electrical, or mechanical object properties; thus, inherent information about individual and intrinsic properties of nano-object are hardly obtained.

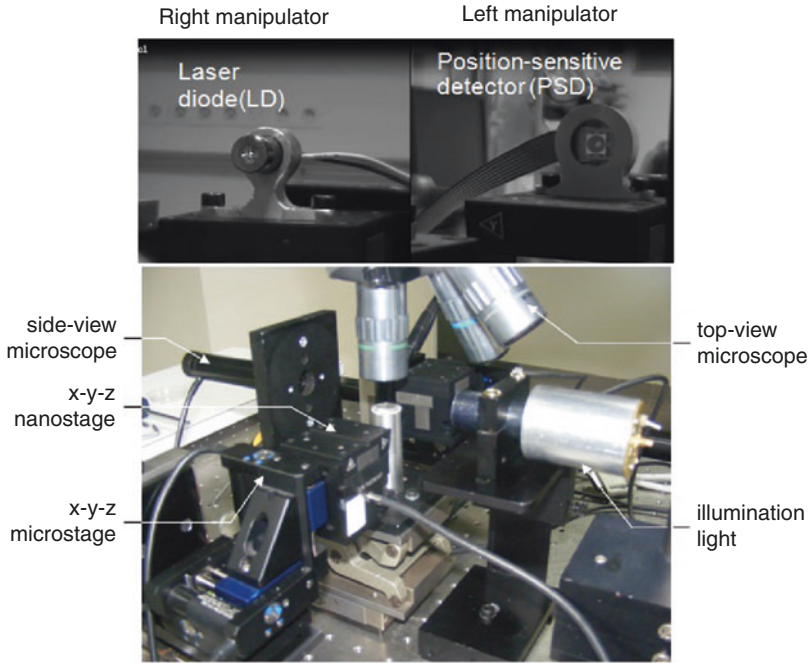
Limitations on Nanomanipulation Under a Beamline

Actually, manipulation at nanoscale still presents some significant weakness, such as low accuracy or low repeatability. Our goal is to combine the high-lateral resolution imaging capability of atomic force microscopy (AFM) with the high penetration power and high element sensitivity of X-rays. We will show the ability of our home-built microscope to perform AFM imaging on a beamline sample holder, align the AFM tip with the X-ray beam, and perform total electron yield (TEY) detection with the AFM tip. The present entry addresses the possibility to measure and characterize intrinsic properties of an individual biological cell by picking up and holding a "free" micro-/nano-object in the probe beam (synchrotron or laser beam) for several minutes and releasing it without damage. To reach these goals, we propose to develop an advanced nanomanipulation platform: a dual scanning probe's coupling with a haptic system through specific and novel control feedback loops. The whole system is called an X-ray NanoWorker. High-precision position measurement systems based on laser beam reflection and/or transmission are commonly used in nanorobotics applications. In particular, laser beam nanomanipulation is a useful tool to either characterize material properties of organic cells [13], to study biological radiation effects on single cellular [13], or to interact with cells even in liquid environment [2, 27]. Classically, a laser beam nanomanipulation platform is composed of the optical device, including the laser beam and sensor (e.g., a camera or position-sensitive detector (PSD)), and alignment mechanisms. The frame structure for maintaining the optical configuration allows precise control positioning of the cells or microrobots. For instance, Fig. 3 illustrates the general microbeam system for radiation and transport tasks. The main problem is then to focus the beam in a few micrometer-size spots and to control actively the beam direction to stabilize the beam at a desired location with a nanometer resolution. Such issues must be addressed when focusing a near-infrared laser beam at a nerve cell's leading edge [14, 15], when the laser beam perfectly tracks the moving AFM probes [16] during manipulation tasks, or when the laser beam illuminates a micro-object handled by a nano-gripper for material characterization [17]. In the abovementioned cases, precise laser

Nanorobotics for Synchrotron Radiation Applications, Fig. 3 The microbeam system for radiation and transport: (**a**) model of single cell irradiation with micro X-ray beam [13] and (**b**) optically driven micro tools in liquid for cellular manipulation [2] (Courtesy from the author of [2])

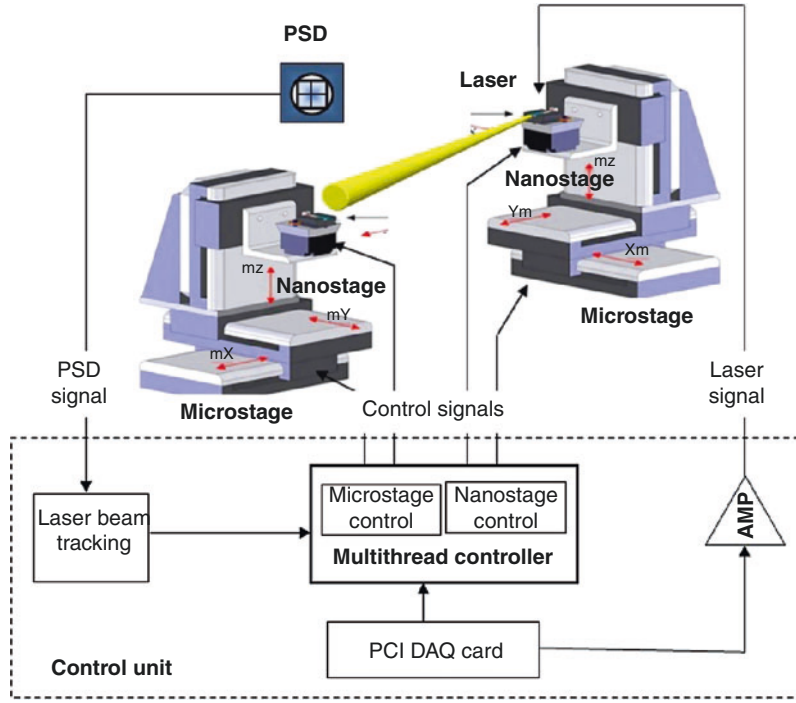
beam tracking of dynamic position with high-bandwidth rejection of disturbances produced by nanomanipulator platform vibration, piezoelectric actuator thermal drifts, photodetector noises, Brownian motion of laser beam, and atmospheric turbulence is critical for the success of micro- and nanomanipulation radiation tasks.

The single photodiode sensor is currently being introduced in the nanomanipulation tasks and used only for position measurement. Especially, the PSD is advantageous in terms of high-speed response compared to the camera processing. In this entry, we propose to use the PSD at the same time as indicator and feedback control in order to increase the overall performance and reliability of microbeam irradiation systems. The literature provides mainly two laser beam tracking configurations, that is, steering (i) the laser beam or (ii) the photodetector. In the first case, some works propose to use fast tilt two-axis steering mirrors based on electrostatic MEMS actuators [18] or piezoelectric actuators with a fixed four-quadrant PSD. In the second case, the PSD is driven by a dual actuation system with robot micro-/nanomanipulators [19] or x-y linear positioning stages [20]. Whatever the technology involved, robust control of the laser beam tracking system is needed.



Control Systems Dedicated to Nanoscale Instrument

Classically, most mechanical micro- or nano-grippers used piezoelectric actuators to move in 2D or 3D in the nano-space. Indeed, piezoelectric components allow continuous motion with high resolution (about 1 nm). Moreover, they are easy to implement against other positioning systems as capacitive or inductive one. Nevertheless, piezoelectric devices present several drawbacks: (i) hysteresis behavior, (ii) creep, and (iii) thermal drift. These weaknesses lead to nonlinear effects of piezo-actuation which are difficult to model and to correct. As nanopositioning is a strong prerequisite for nanomanipulation, the design of reliable and precise nanopositioning control systems is a serious bottleneck in terms of speed and accuracy for nano-investigation. In addition, many applications impose some important



constraint on the tracking bandwidth and reliability in term of repeatability of experiments. Since a few decades, there are further and further scientific studies on the design of new control scheme dedicated to nanopositioning. Hence, the main difficulty to overcome is to synthesize control strategies robust to piezoelectric nonlinearities. The different control approaches are broadly classified into feedback, feedforward, iterative, and sensorless control [21]. One most considerate approach relies on feedforward control scheme. Indeed, the use of feedforward where energy-based model of the piezoelectric behavior (for instance, by integrating the dependence of hysteresis loops) is applied can lead to improved output tracking performance. More recently, some control law which combines feedforward and feedback strategies has been reported [22]. Another solution to design fine control law with high-repeatability movement is to use, for instance, a Kalman estimator to compensate the nonlinear effect and the piezoelectric hysteresis behavior [23]. Nevertheless, all of these new nanopositioning approaches are mainly dedicated to scanning application and not yet to manipulation aim. The following sections are based on previous works published by the authors in [28].

Experimental Setup

The experimental setup of the beam pointing and tracking is shown in Fig. 4. Two controllable micro-/nanomanipulators face each other, composed of 3-DoF high-precision dual stages, i.e., magnetic *X-Y-Z* closed-loop microstage (MCL Nano-Bio2M, from Physics Instruments) and piezoelectric *x-y-z* closed-loop nanostage (P-611.3S NanoCube, from Physics Instruments), respectively. Each pair of micro-/nanomanipulators constitutes a compact computer-controllable system for *X-Y-Z* alignment (scanning) and positioning. In particular, the travel range of the microstage in the *X-Y-Z* directions is about few centimeters, while the fine motion of the nanostage is about 100 μm. Thus, this dual-stage manipulator combines the advantages of ultrahigh resolution of the piezo-stage together with the long travel range of the

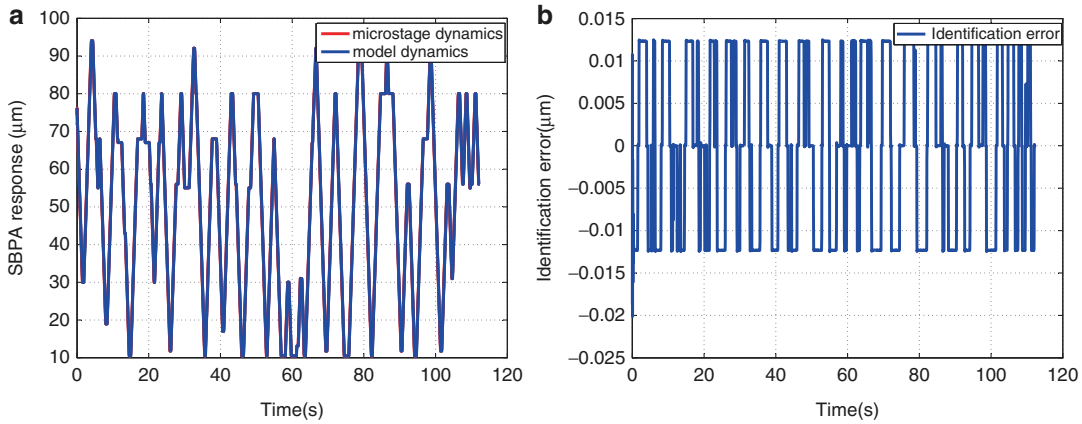
Nanorobotics for Synchrotron Radiation Applications, Fig. 4 Experimental setup

Nanorobotics for Synchrotron Radiation Applications, Fig. 5 Schematic diagram of the architecture of the laser beam tracking control system

micropositioning stages. The laser source is mounted on top of the nanostage (right manipulator) producing the laser beam. The main components of the beam steering experiment are a 635 nm laser. A four-quadrant position-sensitive detector (PSD) is mounted on top of the nanostage (left manipulator). The PSD measures the position of the image that the laser beam forms on a fixed plane. On the side view, a white light illuminates the workspace for top-view (optical microscope: Mitutoyo × 50) imaging for observing the laser beam when subjected to the micrometer variation and side-view (digital microscope: TIMM × 150) imaging used to observe the image of the laser beam in the operating region of the PSD. The sample platform is fixed on the system base.

Figure 5 shows the overall control scheme for power, laser beam tracking, and micro-/nanomanipulator control. The laser beam motion control (Brownian or stochastic trajectory) and measurement sequences are processed in real time using MATLAB™ xPC software with a stand-alone target machine operating at a sample and hold rate of 2 kHz. A data acquisition (DAQ) (NI 6289) card is used for high-speed capturing of photodiode voltage output from a lock-in to detect maximum laser beam intensity and beam tracking. A multi-thread planning and control system is developed to independently manage the coordination during parallel laser beam motion and tracking, respectively.

Dynamics Modeling



This section reviews the different model dynamics of the different system components.

Dynamics of Piezoelectric and Magnetic Actuators

The first step for controller synthesis is to identify the model dynamics of the actuation platform. As no parametric information on drivers are available, an identification phase is needed to set up dynamics modeling of dual micro-/nanostages. The piezoelectric 3-DoF nanostage and the magnetic 3-DoF microstage are deemed as three-input and two-output (MIMO) system.

Nanorobotics for Synchrotron Radiation Applications, Table 1 Identified parameters of the dynamic models of the micro (G_m)- and nano (G_n)-stages for each x-, y-, and z-axis

Parameters	G_{mx}	G_{my}	G_{mz}	G_{nx}	G_{ny}	G_{nz}

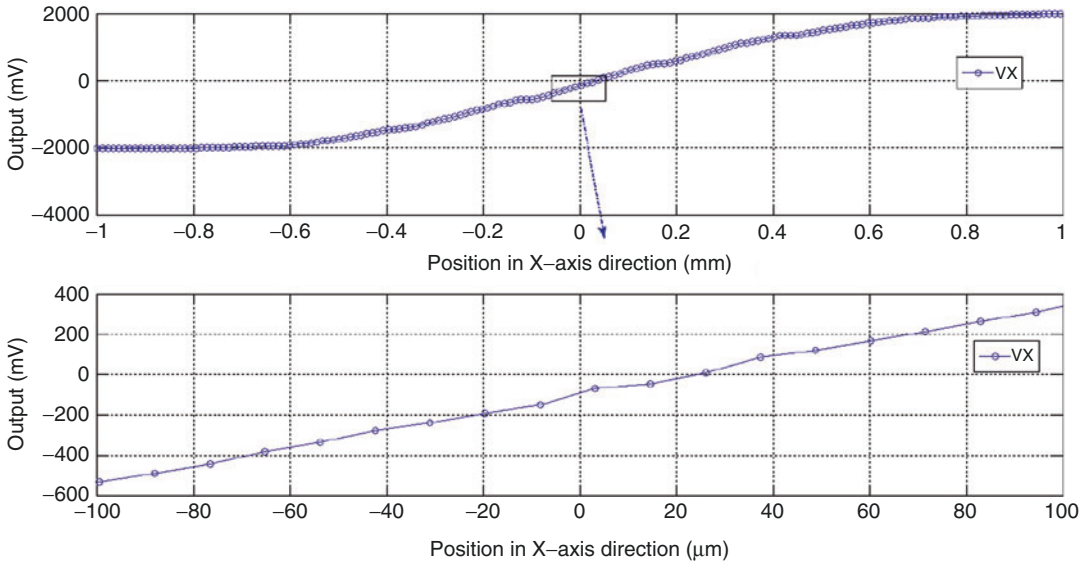
b_3	−0.168	−0.201	−0.156	0.0507	0.0117	0.00761

Nanorobotics for Synchrotron Radiation Applications, Fig. 6 Identification results along the x-axis (**a**) microstage dynamics when excited by a PRBS signal and (**b**) the identification error

Thus, the modeling approach is based on system identification by experimental responses of micro-/nanostages using a pseudo-random binary sequence (PRBS) input signal. This input signal is implemented as a set of digital step signals with several operating points ranging from 0 to 100 µm with an elementary step of about 10 µm. The driving frequencies are lower than the first resonant mode of the nanostage system. The identification procedure is then realized using a closed-loop response in order to protect the system submitted to large domain frequency and subtract the model dynamic in open loop. To reduce the system order, the dynamic models of the micro (G_m)- and nano (G_n)-stages are chosen as a third-order approximation for each x-, y-, and z-axis, respectively:

$$G_{m(x,y,z)}(\mathsf{z}) = \frac{b_0 + b_1\mathsf{z}^{-1} + b_2\mathsf{z}^{-2} + b_3\mathsf{z}^{-3}}{1 + a_1\mathsf{z}^{-1} + a_2\mathsf{z}^{-2} + a_3\mathsf{z}^{-3}} \quad (1)$$



$$G_{n(x,y,z)}(\mathsf{z}) = \frac{b_1\mathsf{z}^{-1} + b_2\mathsf{z}^{-2} + b_3\mathsf{z}^{-3}}{1 + a_1\mathsf{z}^{-1} + a_2\mathsf{z}^{-2} + a_3\mathsf{z}^{-3}} \quad (2)$$

This choice was based on the correlation factor rate between the response of the model dynamics and the manipulators. The proposed optimized structure gives very high correlation factor values close to 99.5 %. The obtained parameters values are listed in the Table 1.

Figure 6 depicts the identification results of the dynamic responses and the identified model to the PRBS excitation signal along the x-axis of the microstage. Let us notice that a same behavior could be reported for the other axes. As one can see the identified model approximates suitably the system dynamics with an error close to 0.01 µm.

Dynamics of Four-Quadrant Detector

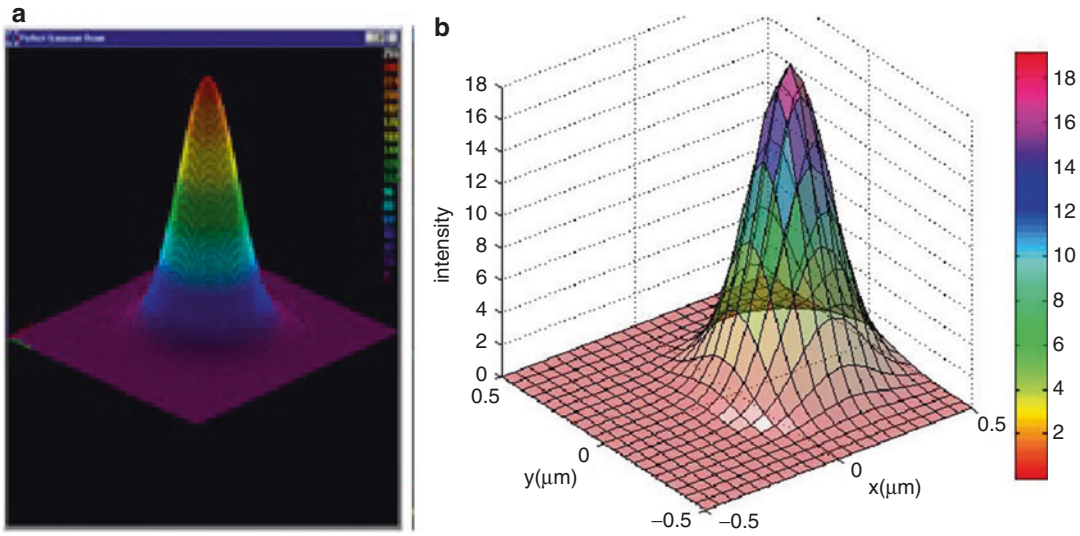
A four-quadrant position-sensitive detector (PSD) has four photosensing parts arranged in four

Nanorobotics for Synchrotron Radiation Applications, Fig. 7 Output voltage curve V_x with a zoom in the block area near zero on a four-quadrant PSD

quadrants, respectively. When the elements are lighted by a beam of laser, they will generate currents according to the light intensity and then amplified into voltage signals. The combinations of voltages V_1 to V_4 can be used to indicate the offsets of the spot in relation to the center of the PSD as follows:

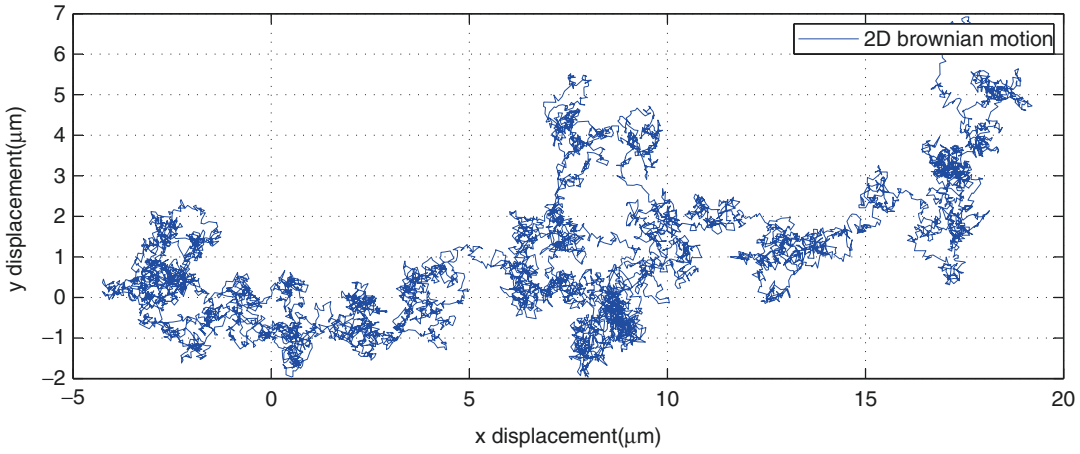
$$\begin{aligned} V_x &= (V_1 + V_4) - (V_2 + V_3) \\ V_y &= (V_1 + V_2) - (V_3 + V_4) \\ V_s &= V_1 + V_2 + V_3 + V_4. \end{aligned} \tag{3}$$

The V_x and V_y channel outputs are directly related to the energy of the laser beam that falls in each quadrant, while V_s is the sum voltage. It is assumed that the light intensity on the laser beam's cross section obeys Gaussian distribution. The current generated by each sensing element can be described as given in:



$$I = k_1 \iint \frac{2E_l}{\pi^2 r} \cdot \mathrm{e}^{\frac{2\left(x_1^2 + y_1^2\right)}{r^2}} \cdot dx_1 dy_1 \tag{4}$$

where I is the current, r is the radius of the laser light spot, E_t is the energy of the laser beam, (x_1, y_1) is the coordinate of a point on the light spot in a coordinate system located at the center of the light spot, and k_1 is a coefficient. The calibration of the PSD is performed by moving the laser beam in the operating region of the fixed PSD. Figure 7 presents an output voltage V_x measured by the PSD when the laser beam moves in the x-axis direction, with respect to the manipulator measured position. As one can see, in the operation region (small neighborhood of the aligned location), the photodiode voltage output V_x is approximately linearly related to light intensity units, with a negative slope. As the curve V_y is similar to that, it is omitted here. Obviously, when the spot is located in the sensing surface $V_x \neq 0$, $V_y \neq 0$ while if the spot is located in the center $V_x = 0$, $V_y = 0$. Moreover, we notice that there is a nonzero output at $x = 0$ due to the amplification of the noisy signals provided by the PSD sensor, which will be processed by the Kalman filter (KF).



Furthermore, as one can see in Fig. 8, the experimental intensity sensed by the PSD can be fitted with a Gaussian distribution as calculated by the theoretical Eq. 4.

Dynamics of Laser Beam Position

In this study, a dynamic disturbance is considered where the laser beam motion variation is assumed similar to the Brownian motion (represented in

Nanorobotics for Synchrotron Radiation Applications, Fig. 8 Light intensity on the laser beam's cross section: (**a**) theoretical and (**b**) experimental intensity obeying to Gaussian distribution

Nanorobotics for Synchrotron Radiation Applications, Fig. 9 Particle Brownian motion

Fig. 9) of a particle subjected to excitation and frictional forces. The Brownian motion is applied as an input disturbance to the position of the laser beam carrier and to the expected displacement measured by the PSD sensor. The Brownian motion is given by the following generalized differential equation:

$$\frac{d^2x(t)}{dt^2} + \beta_x \frac{dx(t)}{dt} = W_x \qquad (5)$$

where β_x is the coefficient of friction and $W_x \sim \dot{N}\left(0, \delta_x^2\right)$. To estimate with a discrete filter the laser beam positions at each sampling time t_k, a discrete model of the continuous dynamics (Eq. 5) is necessary. In the x-axis the discretized equations of motion using a zero-order hold (ZOH) are given by:

$$\dot{x}_k = \frac{x_k - x_{k-1}}{\Delta T}; \quad \ddot{x}_k = \frac{\dot{x}_k - \dot{x}_{k-1}}{\Delta T} \qquad (6)$$

From Eqs. 5 and 6, we obtain:

$$\dot{x}_k = \frac{\dot{x}_{k-1} + \Delta T W_{x_k}}{1 + \beta_x \Delta T} = a_x \dot{x}_{k-1} + b_x W_{x_k} \quad (7)$$

where ΔT is the discretization time step and the statistic properties of the excitation W_{x_k} force are assumed to be a zero-mean Gaussian random variable with variance δ_x^2. The y-axis can be modeled in the same manner as the x-axis, though with different dynamics. For 2D representation, the source state at discrete time k is defined as:

$$X_k = [\, x_k \quad y_k \quad \dot{x}_k \quad \dot{y}_k \,]^T \quad (8)$$

where (x_k, y_k) and $(\dot{x}_k, \dot{y}_k)$ are the source potion in the plane x-y and velocity, respectively. The discrete state space of the Brownian laser beam is then represented by:

$$X_k = AX_{k-1} + BW_k \quad (9)$$

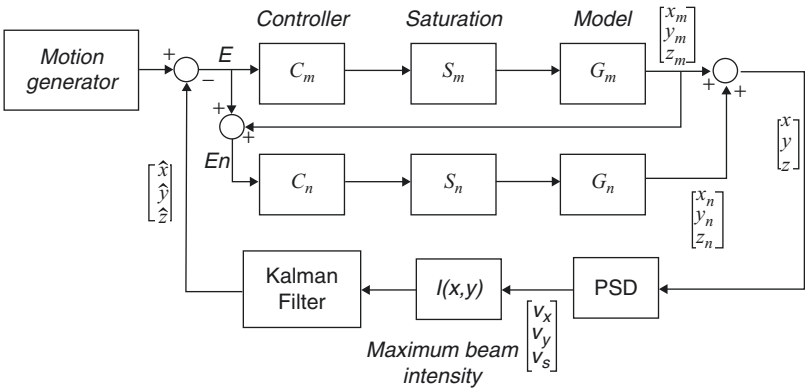
$$Y_k = CX_{k-1} \quad (10)$$

The state representation matrices (A, B) are derived from the particle dynamics defined in Eqs. 6 and 7, and $W_k \sim N(0, Q)$ is a zero-mean Gaussian random variable with matrix variance Q. It comes from Eq. 9 that:

$$X_k = \sum_{i=1}^{k} A^{k-i} B W_i + A^k X_0 \quad (11)$$

Because successive random variables W_i form a priori discrete zero-mean white Gaussian process, X_k from Eq. 11 is Gaussian if the knowledge on X_0 is assumed Gaussian or equal to some fixed value. Its a priori variance at each step k can be calculated, thanks to:

$$\sigma^2(X_k) = \sum_{i=1}^{k} A^{k-i} B \sigma^2(W_i) + A^k \sigma^2(X_0) \quad (12)$$



Eq. 12 shows that the bigger is the variance of W_k to set, the bigger is the a priori uncertainty variance on the possible values of the modeled unknown position of the beam laser at t_k. Finally, the measurement Y_k of position takes into account the discrete-time zero-mean white Gaussian noise V_k and variance R added by the four-quadrant position-sensitive detector, that is:

$$Y_k = CX_{k-1} + V_k \quad (13)$$

Control Scheme of Beam Pointing and Tracking

Dual Micro-/Nanomanipulator Controller

The problem considered here is to track the position variation of the laser beam into the x-y plane of the PSD by robust control commands sent to the dual micro-/nanomanipulator's motions. The localization of the current laser beam position depends on the maximum beam intensity detection. Hence, a monitoring of the maximum intensity of the laser beam is needed [24]. It implies to integrate a prediction model that anticipates the a priori laser beam motion, taking into account both dynamics, i.e., the laser beam and manipulator models. However, the different dynamics of the manipulators should be considered. The first actuator stage (microstage) has a large moving range but a low bandwidth while the second actuator stage (nanostage) has a high bandwidth but small moving range. The dual problem considered here is to know how to coordinate both micro- and nanostages in order to track the laser beam motions using only signal position feedback delivered by the PSD. We adopted the master–slave control design to transform the dual-stage control design problem into decoupled or sequential multiple independent controller designed separately. Figure 10 presents the master–slave control scheme to control two independent outputs of the micromanipulator G_m (1) and nanomanipulator G_n (2) systems by only one position feedback signal. This approach allows to combine the optical device with the micro-alignment mechanisms for an autonomous procedure especially when it comes to illuminating a micro-object under the focus of the laser beam for several minutes where the laser beam position is required or limiting the gripper deflection in interaction with a micro-object to not damage a flexible micro-object and the gripper tool.

Nanorobotics for Synchrotron Radiation Applications, Fig. 10 Master–slave controller with decoupling structure for maximum light tracking

Thanks to the master–slave controller based on the mixed sensitivity, it is possible to fix the adapted dynamic performances of microstage using a simple proportional–integral–derivative (PID) controller in the C_m controller. To ensure robustness of the piezoelectric nanopositioning stages, a H_∞ control scheme is implemented.

Kalman Filter Estimator

In robotics, the Kalman filter (KF) is most suited to problems in tracking, localization, and navigation and less so to problems in mapping [25, 26]. This is because the algorithm works best with well-defined state descriptions (e.g., positions, velocities) and for states where observation and time-propagation models are also well understood. The prediction–estimation stages of the Kalman filter are derived from Eqs. 9 and 13:

Prediction. A prediction $\hat{X}_{k|k-1}$ of the state at time k and its covariance $P_{k|k-1}$ is computed according to:

$$\hat{X}_{k|k-1} = A\hat{X}_{k-1|k-1} + BU_k \tag{14}$$

$$P_{k|k-1} = AP_{k-1|k-1}A^T + Q(k) \tag{15}$$

Update. At time k an observation $y(k)$ is made, and the updated estimate $\hat{X}_{k|k-1}$ of the state X_k, together with the updated estimate covariance $P_{k|k}$, is computed from the state prediction and observation according to:

$$\hat{X}_{k|k} = \hat{X}_{k|k-1} + K_k\left(Y_k - C_k\hat{X}_{k|k-1}\right) \tag{16}$$

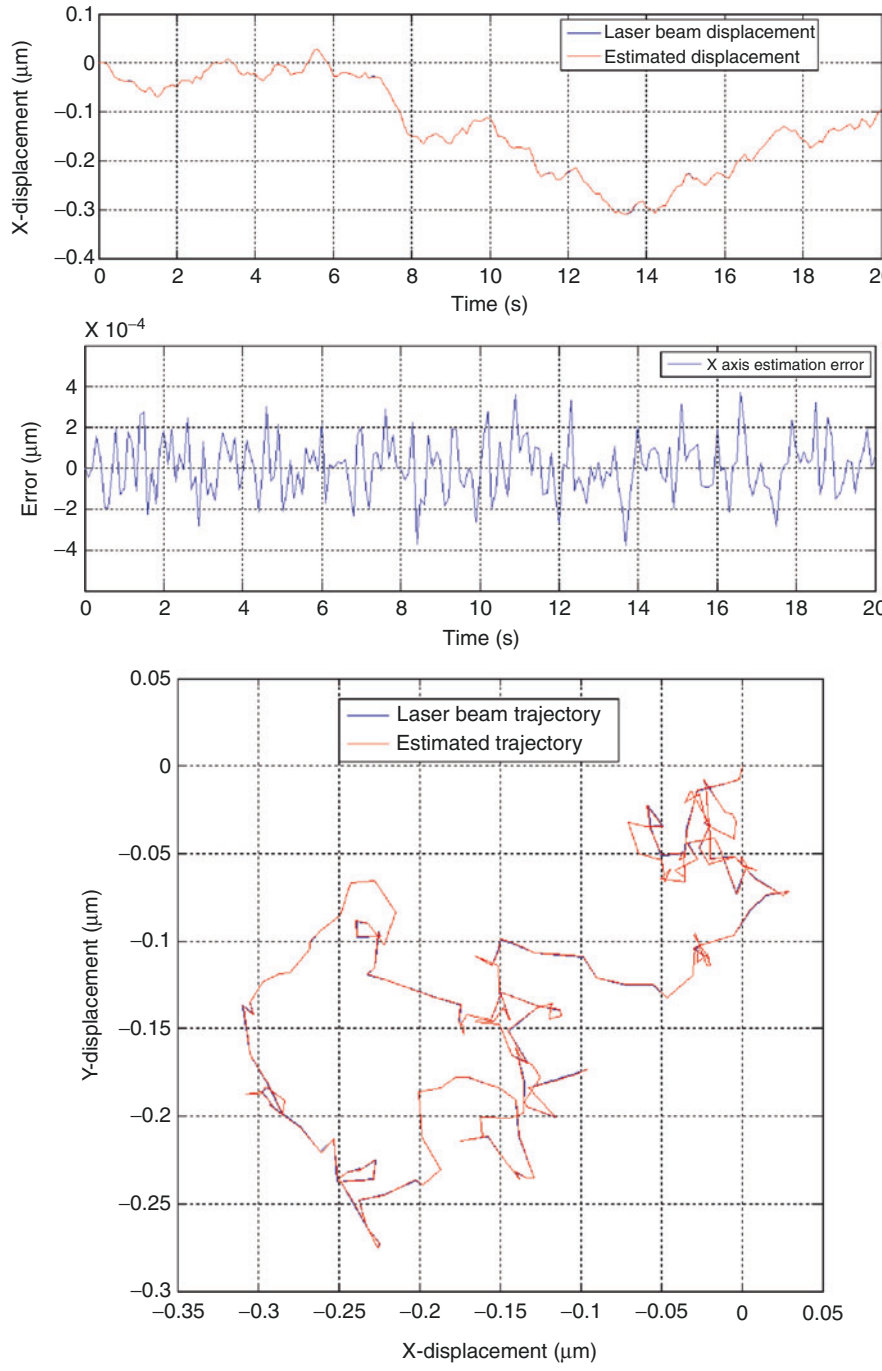
$$P_{k|k} = P_{k|k-1} - K_kS_kK_k^T \tag{17}$$

where the gain matrix K_k is given by:

$$K_k = P_{k|k-1}C_kS_k^{-1} \tag{18}$$

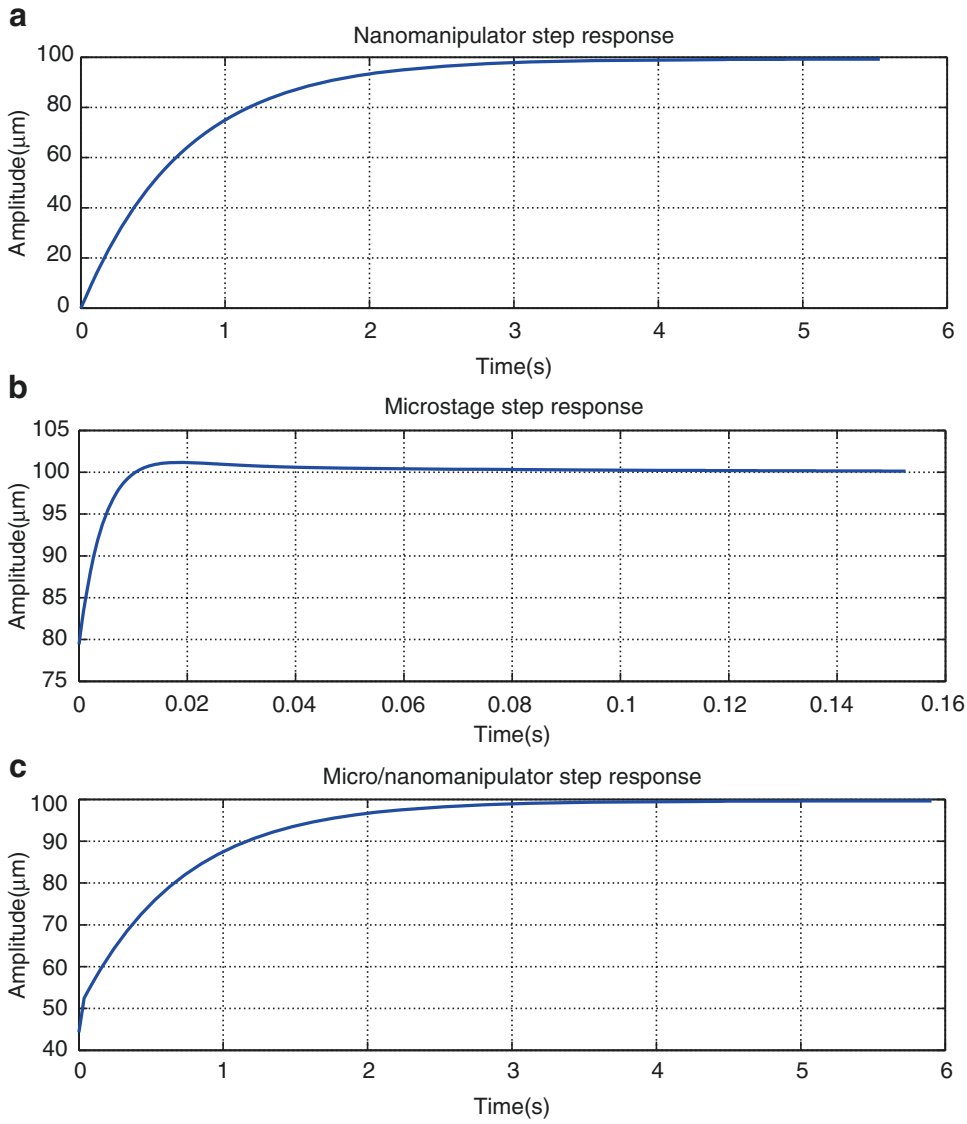
where:

$$S_k = C_kP_{k|k-1}C_k + R_k \tag{19}$$



is the innovation covariance. The difference between the observation Y_k and the prediction observation $C_k\hat{X}_{k|k-1}$ is termed the innovation or residual $r(k)$. Thus, the input of the KF is the noisy measurement of the laser beam displacement in the x-y direction delivered by the photodiode detector and $\hat{X}_k$ is the output of the filter representing the estimation of the displacement at time t_k.

Figure 11 illustrates a simulation result of the laser beam tracking using a Kalman filter. Here, the laser beam is animated with a synthetic Brownian motion. As one can see, the KF allows to estimate efficiently the laser beam motion.



Experiments

Dual Micro-/Nanomanipulator Control Evaluation

First, the performance of the dual micro-/nanomanipulator is evaluated using step response experiments with a reference set to 100 µm. Figure 12 illustrates the obtained step response

Nanorobotics for Synchrotron Radiation Applications, Fig. 11 Simulation of the laser beam tracking with the Kalman filter: motion estimation along the *x*-axis with its corresponding errors and the 2D displacement

Nanorobotics for Synchrotron Radiation Applications, Fig. 12 Step responses of the (**a**) nanomanipulator stage, (**b**) the micromanipulator stage, and (**c**) the dual micro-/nanomanipulator system

of the x-axis of the (a) nanostage with the H_∞ controller, (b) microstage with the proportional–integral–derivative (PID) controller, and (c) master–slave controller where the decision of switching between the microstage and the nanostage depends on the error resolution. At first glance, the dual micro-/nanomanipulator controller converges with no error to the reference, with no overshoot, and with a settling time of about 4 s leading to a velocity of 25 μm/s.

The closed-loop sensitivity function S_T defines the performance of the dual micro-/nanomanipulator controller. Classically, in the frequency domain, sensitivity S_T is equal to the sum of the closed-loop sensitivity of the micromanipulator S_M and the nanomanipulator S_N (Fig. 10), that is:

$$S_T = \frac{1}{1 + G_T} = S_N S_M \tag{20}$$

with

$$S_N = \frac{1}{1 + C_N G_N}, \quad S_M = \frac{1}{1 + C_M G_M} \tag{21}$$

The sensitivity of the dual micro-/nanomanipulator demonstrates the possibility to design and combine the performances of each stage defined by their sensitivity function for control synthesis. Firstly, the microstage is governed by a serial proportional–integral–derivative (PID) controller formulated for each axis as:

$$C_M = K_p \frac{\tau_I s + 1}{\tau_I s} (\tau_D s + 1) \tag{22}$$

For the step response of the x-axis, the PID parameters are set to $K_{Px} = 140$, $\tau_{Ix} = 180$, and $\tau_{Dx} = 120$. Secondly, the nanostage uses a H_∞ robust controller. Classically, the H_∞ synthesis problem is expressed as a matrix optimization problem, that is:

$$\min_k \|N(k)\|, \quad N = [W_1 KS \;\; W_2 T \;\; W_3 S]^T \tag{23}$$

For a displacement in the x-direction of the nanomanipulator, the H_∞ synthesis allows to obtain a robust controller by using the following weighting functions:

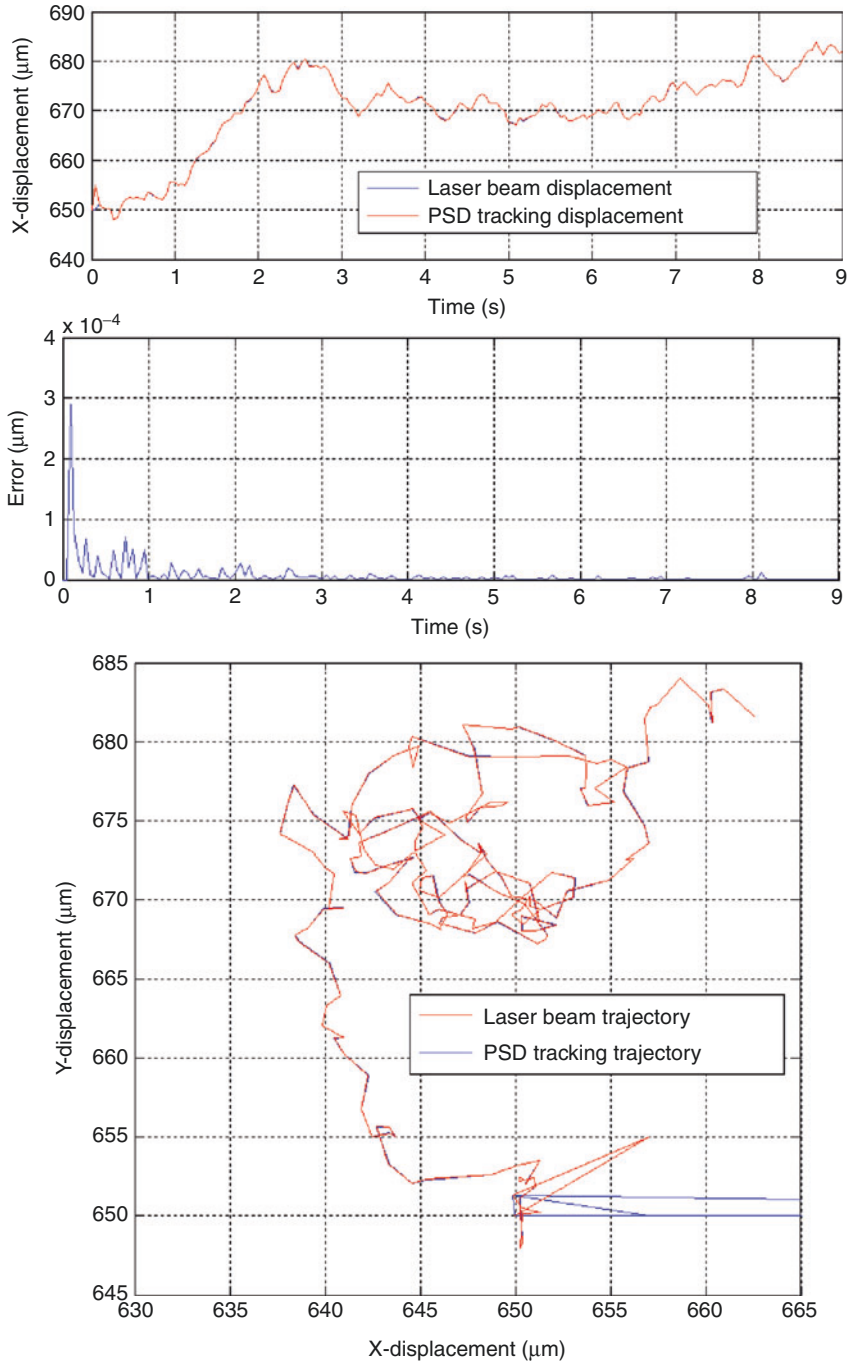
$$\begin{aligned} \mathbf{W}_{1x} &= \frac{s+1}{s+0.9258}, \quad \mathbf{W}_{2x} = 0.7097, \\ \mathbf{W}_{3x} &= \frac{s+0.005935}{0.9613s+0.9032} \end{aligned} \tag{24}$$

The optimized discrete transfer function of the x-axis nanomanipulator controller is then given by:

$$\mathbf{C}_{Nx}(z) = \frac{1.186z^4 - 4.01z^3 + 5.623z^2 - 3.953z + 1.154}{z^4 - 3.25z^3 + 4.405z^2 - 3.06z + 0.9044} \tag{25}$$

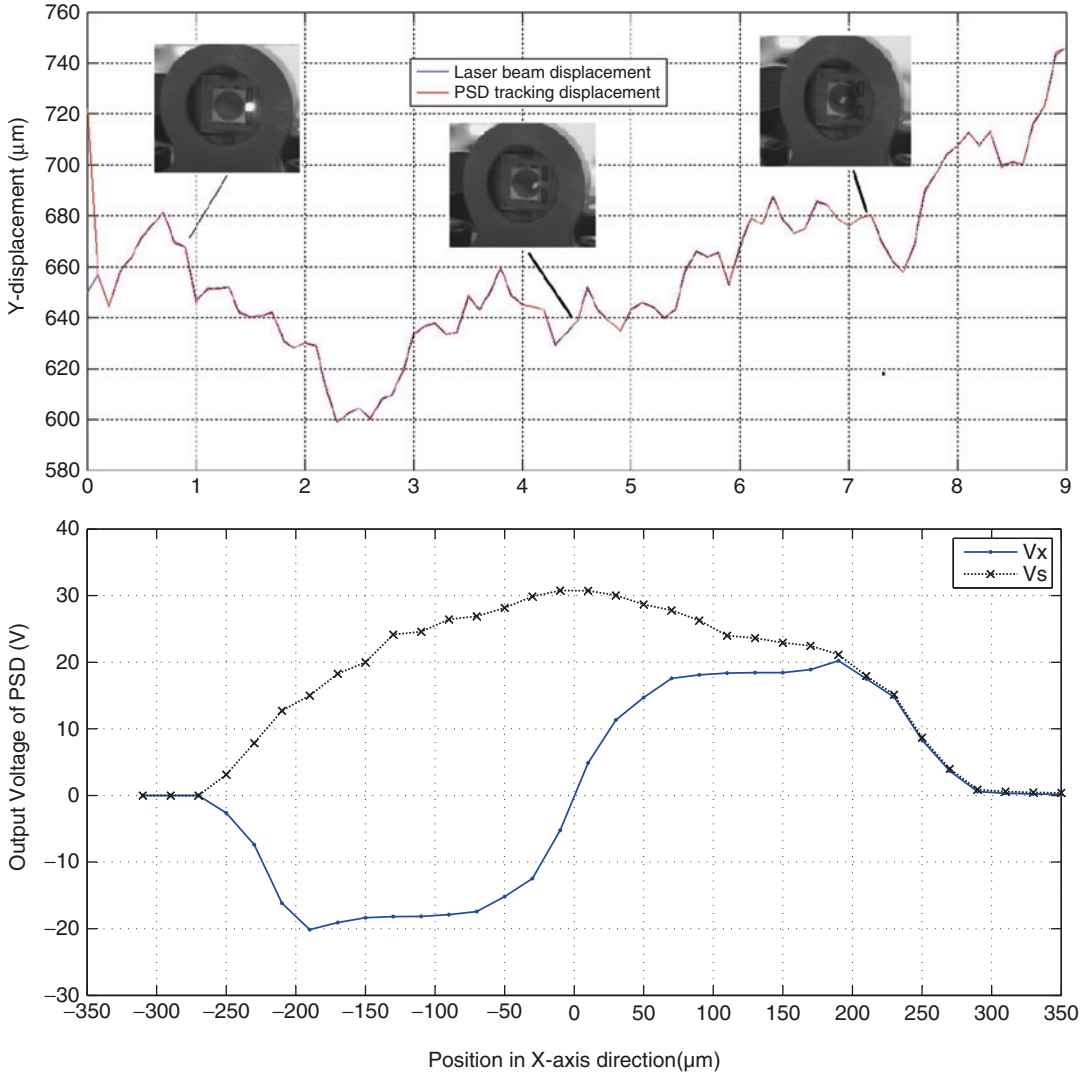
Laser Beam Motion Prediction

Secondly, the laser beam motion is estimated using the presented Kalman filter (KF) based on the identified Brownian model. To evaluate the performance of the KF, the laser beam is mounted on the right manipulator, while the PSD sensor is mounted on the left manipulator, as depicted in Fig. 4. Then, a random trajectory is generated to the laser beam before to initiate the laser beam tracking by the PSD sensor. The data rate of the sensor is $\Delta T = 2$. The KF parameters, i.e., measurement noise matrix R, process noise matrix Q, and initial state error matrix P_0, are defined as:



$$\begin{aligned} \mathrm{Q} &= 10^{-2}\mathbb{I}_{4\times4} \\ &\quad + \begin{bmatrix} 0 & 2b_x^2 & b_x & b_x \\ 2b_x^2 & 0 & b_x^2 & b_x^2 \\ b_x & b_x & 0 & 2b^3 \\ b_x & b_x^2 & 2b_x^3 & 0 \end{bmatrix}, \quad \text{and } R \\ &= 10^{-4}\mathbb{I}_{2\times2}. \end{aligned} \tag{26}$$

where $\mathbb{I}_{n\times n}$ is the $n \times n$ identity matrix. These noise matrices were chosen empirically in order to achieve the best performance of the filter.



To evaluate the performance of Kalman filter, we settled the maximum intensity of the laser beam in the PSD center. The resulting estimation of laser beam motion prediction using KF is presented in Fig. 13. The blue color represents the PSD trajectory resulting from the KF and red color the given variation in the position of the laser beam. At first glance, the KF succeeds to reach quickly the real position and to follow the laser beam motion variation very closely. As one can see in Fig. 11c, the PSD trajectory presents a convergence phase (bottom right part of the plot). This convergence step is due to the KF that has to reach its optimum prediction along with tracking the laser beam motions. As illustrated, the performances of the KF, in terms of precision, converge to the real position of the laser beam with a minimal estimation error around 0.01 nm. These results demonstrate clearly the sensitivity performances of the KF algorithm to detect and to estimate small variations of the laser beam motions.

Laser Beam Maximum Intensity Tracking

In this scenario, the PSD has to track the laser beam motion and find its maximum intensity.

Nanorobotics for Synchrotron Radiation Applications, Fig. 13 Experimental tracking with Kalman filter: motion estimation along *x*-*y* axis with corresponding errors and 2D displacement

Nanorobotics for Synchrotron Radiation Applications, Fig. 14 Laser beam detection of maximum intensity

In addition here, the right manipulator moves the laser beam with a composite motion defined by a constant displacement together with a Brownian motion. The resulting motion of the PSD along the *y*-axis is shown in Fig. 14. These results illustrate a typical tracking task of a composite motion with a fast convergence time of the dual micro-/nanomanipulator controller despite the constant bias displacement. Furthermore, the dual controller is able to find and to maintain the maximum beam light intensity in the center of the PSD against external perturbations. Let us also notice that this approach assumes variations of laser light intensity during motion, measurement noise, and high motion dynamics. Moreover, these experiments demonstrate the robust estimation of the laser beam motion in real time. As expected, the filtered estimate exhibits smaller variations. Finally, the master–slave controller with decoupled sensitivity is optimized in terms of tracking error.

Summary

In this entry, the authors discussed the major applications of nanorobotics systems in synchrotron radiation facility centers for the characterization of nanomaterials. As the focalization of X-ray beam improves regularly (presently less than 100×100 nm^2), it becomes possible to analyze smaller and smaller sample [2] (10^8 atoms which corresponds to a 100 nm radius object). Based on this X-ray optical progress and to address the needs of the nano-community, specific beamlines dedicated to nanosciences are currently developed or will be developed in the frame of the ESRF (European Synchrotron Radiation Facility located in Grenoble, France) Upgrade Programme, for example, UPBL1, UPBL4, and UPBL5 [3]. This entry has presented a study on the control problem of a laser beam illuminating a target when subjected to dynamic disturbances using light intensity feedback. The main idea is to guide and track the beam with a hybrid micro-/nanomanipulator which is driven by a control signal generated by processing the beam intensity sensed by a four-quadrant photodiode. The simulations and experiments demonstrated the efficiency of the approach when submitted to external disturbances, such as platform vibration, piezoelectric actuator thermal drifts, photodetector noises, Brownian motion of laser beam, and atmospheric turbulence. The use of a Kalman filter algorithm to estimate the laser beam motion has proven to be efficient despite the encountered high dynamics at such nanometer scale. Different experiments of single biological cell irradiation with a micro X-ray beam subjected to environmental perturbations are actually investigated with the proposed beam tracking system.

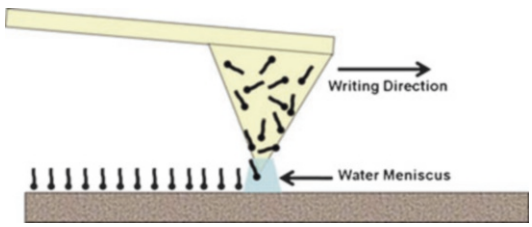
Definition

Nanoscale printing refers to the patterning of surfaces in two or three dimensions with at least one feature on the submicron length scale. The printing techniques may resemble macroscopic printing, in which a material, or ink, is transferred to a substrate by a stamp or a stylus. However, nanoscale printing may also refer to embossing or molding processes, in which topographical features are transferred from a three-dimensional mold to a surface by either elevating or depressing areas or by the addition of material. For the case of patterning features in three dimensions, two distinct outcomes are possible: the features generated can remain connected by an underlying layer of material, yielding an embossed film or, alternately, the molded features can be free of the connecting layer, yielding discrete particles. Arrays of features have been used to direct the assembly of materials for applications in molecular electronics, genetic analysis, and disease detection. Particles generated by these methods have found a myriad of uses, including those in drug delivery and biomedical imaging.

Overview

Methods used to generate nanoscale structures are generally divided into "top-down" and "bottom-up" approaches. In bottom-up approaches, features are generated from the atomic or molecular level to the supermolecular or macroscopic level and utilize interactions between molecules or particles to achieve two- or three-dimensional structures [1]. For top-down methods, materials are processed at the desired size scale, with external forces directing the material to form the desired architecture. The development of nanoscale printing methods for drug delivery and imaging applications have been enabled by the remarkable developments in the semiconductor industry over the last 50 years to reduce feature sizes in order to increase the number of transistors in a microchip [2]. Now these top-down technologies are poised to be exploited for benefit in a variety of new industries, especially in the life sciences and energy sciences fields.



Patterning Surfaces

Two complementary nanoscale printing techniques have emerged for the transfer of reagents, both chemical and biological to a surface: techniques based on scanning probe microscope-based lithography (SPL) and soft lithography-based

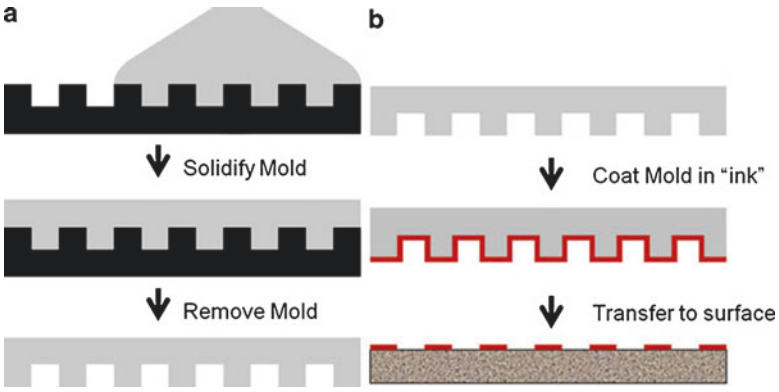
techniques. Based on the development of scanning probe microscopy in the 1980s, SPL nanofabrication techniques have emerged that exploit the use of the tip of the scanning probe to manipulate matter on a surface. These methods offer the advantage of extremely high resolution as these probes are capable of manipulating individual atoms or molecules. However, this typically requires high vacuum and temperatures which approach absolute zero, and is not readily scalable for patterning of large areas [2]. While these methods represent powerful tools for high-resolution patterning over a small area, probe tips were not used in a printing method until the advent of dip-pen nanolithography (DPN) in 1999 [3].

Patterning with Dip-Pen Nanolithography

Using an "ink"-coated atomic force microscope (AFM) tip as a stylus, DPN is a direct-write method in which soft or hard materials can be deposited to a surface with sub 50 nm resolution [3]. Developed in the Mirkin laboratory at Northwestern University in 1999, DPN relies on humidity to cause the spontaneous formation of a meniscus between the AFM tip and the surface (Fig. 1). The ink is deposited along this meniscus, with the deposition rate dependent upon factors such as the nature of the ink, the contact time between the tip and the substrate, and the coverage of the ink on the AFM tip. The first example of DPN deposited an alkanethiol onto a gold substrate, with the strong interactions between the gold substrate and the thiol overcoming the weaker interaction between the tip and the thiol to drive the formation of patterns on the surface. A variety of metallic, semiconducting and insulating substrates have been used with DPN [3]. The technique has proven to be quite versatile with respect to the composition of the ink; structures have been formed from organometallics, polymers, colloidal nanoparticles, metal ions, and a range of biologicals including DNA, proteins, peptides, and affinity templates which allowed for the subsequent immobilization of viruses [2].

Nanoscale Printing, Fig. 1 A schematic showing the dip-pen nanolithography (*DPN*) technique. In DPN, ink molecules are transferred from the tip of an atomic force microscope stylus to a surface through a water meniscus

A primary application of DPN techniques is the generation of biological nanoarrays for the study of cellular genetics and rapid screening of diseases. DPN-generated nanoarrays of an antibody have been used to screen for the human immunodeficiency HIV-1 virus antigen in serum samples. This study demonstrated an increase in detection limits of orders of magnitude over conventional enzyme-linked immunosorbent assays [3]. Nanoarrays generated in this way have advantages of holding 10^4–10^5 more features than conventional microarrays, offering the opportunity for either decreased sample volume or for the screening of a larger number of targets per experiment.



While printing with a single AFM tip over large areas would be impractically slow, massively parallel arrays of cantilevers have been fabricated to increase the throughput of the technique. Arrays with as many as 1.3 million cantilevers have been microfabricated toward this end, increasing the throughput by four orders of magnitude. A number of variations to DPN have emerged to broaden the applicability of the technique, with modification of the tips a common theme. Coating the AFM tip with a silicone polymer increases the amount of ink that can be loaded to the tip, allowing for printing of larger areas. The inclusion of microfluidic channels to deliver ink to the tips, termed nanofountain pen (NFP) probes, ensures a constant supply of ink to the surface. Features with greater than 50 nm resolution have been printed with NFP probes. The technique also serves to keep the ink molecules solvated, an aspect which can be critical for biological applications. Heating of the AFM tip (thermal DPN) can allow for deposition of insoluble ink molecules that are solids at room temperatures.

Patterning with Soft Lithography Techniques

Pioneered in the 1990s in the Whitesides laboratory at Harvard University, soft lithography begins with the generation of a rigid template which is used to generate an elastomeric mold or stamp which replicates the three-dimensional shape of the original template. Master templates are typically prepared by photolithographic techniques, which were pioneered in the electronics industry. The molds of these master templates are typically generated from poly (dimethyl siloxane) (PDMS), although polyurethanes, polyamides, perfluoropolyethers, and natural polymers such as agarose have been used for this purpose. To fabricate the mold, the desired polymer is poured onto the master template and cured, generating a relief structure with the raised portions of the stamp defining the pattern to be transferred.

Microcontact printing (μCP) is the process by which the mold is used as a stamp after it is coated with an ink, and subsequently brought into contact with a substrate to transfer the ink (Fig. 2). The ink transfers from the stamp by chemisorption or physisorption to the surface. While alkanethiol inks transferred to a gold substrate are, perhaps, the most common usage of μCP, the technique has also been used to pattern proteins, DNA, cells, colloids, and polymers [4] onto a variety of surfaces. The flexibility of the elastomeric stamp allows for conformal atomic level contact to be achieved on flat and curved surfaces, and over large stamp areas. The μCP technique has advantages as it is low-cost, is high-throughput and is easy to use which has earned it popularity as a tool among researchers. While the low cost of the elastomeric molds has rendered μCP accessible to researchers in many fields, there are some limitations to the technique. Patterns are determined by the original master template, so that each stamp can only produce one pattern. The mechanical properties of the stamp can limit the flexibility of the design; features spaced too widely (>20 times the feature height for typical PDMS) or with aspect ratios outside of the 0.2–2 range can cause defects from deformation of the stamp [2]. Stamping of features smaller than 150 nm is a challenge using conventional methods, though features as small as 80 nm have been prepared by using DPN to modify the surface of a flat stamp to passivate surrounding areas with a perfluorinated monolayer.

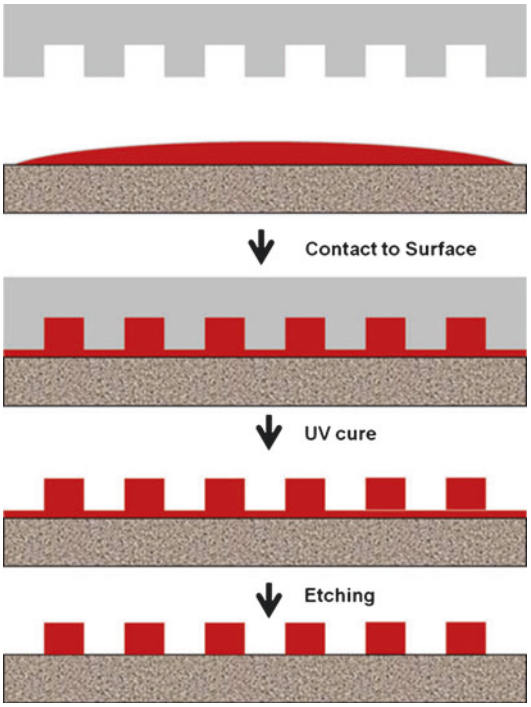
Nanotransfer printing (nTP) is the process of transferring a thin solid film from a nanoscale-featured stamp to a substrate. In this case, the stamp can be either rigid or flexible and the material transferred is typically a metal. In a typical process, the stamp is coated with a thin film (e.g., 20 nm of gold) and brought into contact with the desired surface. The film can transfer from the stamp by a number of methods, including binding

Nanoscale Printing, Fig. 2 A schematic for microcontact printing (*μCP*). (**a**) The fabrication of a mold (*top* to *bottom*). The mold material (*gray*) is poured onto a master template with topographical features (*black*). The liquid mold materials solidifies and is removed from the master template, producing a mold with the inverse of the features found on the master template. (**b**) The μCP process (*top* to *bottom*). The elastomeric mold is coated with a chemical ink (*red*). Ink is transferred to the surface by contact to the raised features of the mold

to reactive self-assembled monolayers (SAMs) like alkanethiols, cold welding between two metal layers, or condensation between silanol or titanol groups [5]. Applications for nTP-derived structures are typically electronic in nature, including organic thin film transistors, capacitors, and electrostatic lenses. Features as small as 70 nm have been fabricated with nTP.

The recent innovation of polymer pen lithography (PPL) in 2008 combines many of the advantages of μCP and DPN by using an elastomeric array of tips to print a pattern. With PPL, a PDMS stamp consisting of an array of tips is affixed to a piezo scanner and delivers an ink with spot sizes from 65 nm to over 10 μm determined by varying the force and time over which the ink is delivered [6]. The elastomeric arrays of PPM pens, which can contain as many as 10 [8] pyramid-shaped tips, are made from a master prepared by traditional photolithographic techniques. The cost of preparing new arrays of tips is greatly reduced for PPL compared to DPN, with the cost of a new PPL array estimated at less than $1 after the fabrication of the initial master template [2]. The resulting arrays are transparent, allowing for registration of the cantilevers with previously printed features. The master template used to generate the arrays can be filled by injet printing, allowing it to be used as an array of inkwells with which the array of tips is perfectly aligned. The entire elastomeric array absorbs ink, acting as a reservoir and allowing for printing over large areas without reinking.

Molding and Embossing Methods



The molding process involves pouring a liquid precursor onto a nanopatterned template and curing or solidifying it into a solid which replicates the original features. Molding features on the nanoscale can be performed with both hard and soft molds. This is the basis for techniques such as step-and-flash imprint lithography (SFIL), replica molding (RM), and pattern replication in non-wetting templates (PRINT). Embossing or imprinting methods use a mold to transfer features to an initially flat polymer film. Embossing methods include nanoimprint lithography (NIL), solvent-assisted micromolding (SAMIM), and PRINT.

Hard molds have been fabricated out of quartz, silicon, and metals, though quartz and silicon are the most commonly used. Features as small as 10 nm have been transferred into silicon, while quartz molds have a minimum size of 20 nm [4]. Though soft molds are less costly and easier to fabricate, rigid molds offer several advantages over softer molds. Rigid molds will show little deformation over large areas with the pressures required for embossing. Hard molds are stable at the temperatures required for cross-linking polymer precursors and are chemically inert to them. Release of the mold from the patterned substrate can be difficult, depending on the surface properties of the mold and the molded polymer, and release coatings of fluoroalkyl silanes are typically linked to the mold surface to facilitate release. Quartz substrates are transparent to UV light and visible light, while silicon is not, allowing for photochemical cross-linking of prepolymer with quartz molds.

Step-and-Flash Imprint Lithography

Step-and-flash imprint lithography replicates the topography of a quartz mold using a photocurable prepolymer solution as the molded material at room temperature using low applied pressure. The prepolymer solution consists of a monomer and a photoinitiator with hardening of the material proceeding by free-radical polymerization upon exposure to UV light. An important consideration for complete filling of the mold is the viscosity of the prepolymer, or monomer, solution; low molecular weight monomers are used due to their low viscosity ($<$5cPs) which allows for complete filling of the mold features. The quartz mold is pressed down onto a substrate which is coated with a liquid prepolymer and cured with UV light. While the mold features fill completely, they remain connected by a thin residual layer of cured monomer. This layer can be removed by an etching process (such as reactive ion etching), yielding discrete features on the substrate (Fig. 3).

The quartz molds used in SFIL are typically coated with a release layer to facilitate release of the mold from the cured polymer and to increase the lifetime of the mold. Failure of the mold to release cleanly can result in broken mold features,

Nanoscale Printing, Fig. 3 A schematic for step-and-flash imprint lithography (*SFIL*). From *top* to *bottom*: A UV transparent quartz mold (*gray*) is brought into contact with a thin coating of a prepolymer solution (*red*) on a surface. The prepolymer is exposed to UV light through the quartz mold, leaving a patterned polymer surface after removal of the mold. An etching step removes the thin layer of polymer which connected the raised features

which adds to the cost of this technique. The first reported coatings were fluorinated silanes, which provided a mold lifetime of less than 100 uses. Newer coatings have extended this lifetime to the patterning of over 1,500 substrates [4].

In addition to the generation of patterned surfaces, SFIL can be used to generate polymeric particles. In this case, after the etching step removes the connecting layer from between the particles, a subsequent step provides release of the cured polymer from the substrate. Particles can be removed by physical agitation or by dissolution of a sacrificial surface coating (i.e., poly vinyl alcohol) on the initial substrate. While the etching process, which involves exposure to an oxygen plasma, could be considered quite harsh, the biological activity of a protein encapsulated in SFIL particles was maintained after 20 s of exposure to plasma [7]. SFIL particles have potential for use in drug delivery, as particles containing an enzymatically degradable peptide sequence and carrying a DNA plasmid cargo were fabricated and demonstrated successful cargo release in an in vitro experiment [8].

Nanoimprint Lithography

Nanoimprint lithography (NIL) involves the transfer of a pattern from a rigid stamp to a polymer film via application of pressure at temperatures above the glass transition temperature of the polymer. The typical mold material is silicon with features as small as 5 nm patterned. While NIL is typically used to pattern polymers, biomolecules have also been successfully patterned. High pressures and temperatures are required with NIL, putting stress on the molds and limiting their lifetime to $\sim$ 50 imprints. The high viscosity of many of the polymers selected for patterning is another issue with this technique. Low molecular weight polymers may be desirable due to their lower viscosities and relative ease of processing [9].

Imprint Lithography

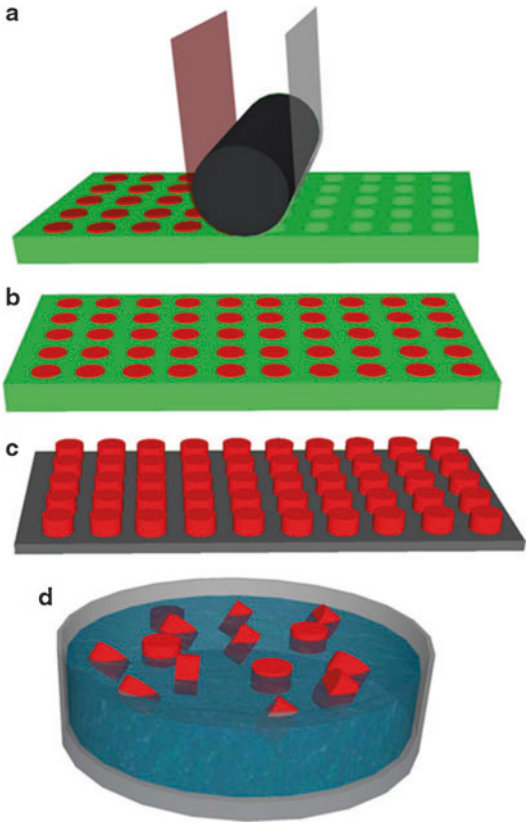
Soft, or imprint, lithography generates elastomeric molds from rigid substrates and uses the molds to replicate the original topographical features. Imprint lithography methods were first seen as a low-cost, high-resolution alternative to photolithographic techniques for the replication of patterns in the micro- and nanoscales. The typical mold materials have included cross-linked poly (dimethyl siloxane) (PDMS or silicone) or perfluorinated polyethers which have low toxicity, are extremely flexible, and have low surface energies, all of which make them excellent materials for molding applications.

Replica Molding

The replica molding (RM) process consists of transferring the topographical pattern of a master template to an elastomeric mold (typically made from poly (dimethyl siloxane) (PDMS)) which is in turn used to transfer the pattern to a liquid which is cured, or solidified, in contact with the mold. Molded materials can be photo or thermally curable, though there are limitations. Many low

molecular weight monomers display some solubility in PDMS, causing the mold to swell and limiting the molding process. Molded materials include polymers, gels, precursors to ceramics and carbons, luminescent phosphors, salts, and colloids [5]. The use of the soft PDMS mold allows for molding of non-flat surfaces, an advantage over hard template molding techniques. While molds may only remain viable for approximately 20 replications, the mold material is inexpensive and many molds can be prepared from a single master template. Replication of the high-cost master templates in a low-cost material makes this technique accessible to a broad range of researchers.

Replica molding in PDMS has transferred features as small as 3 nm wide structures with 0.5 nm vertical deflections. Based on the physics of van der Waals interactions, the theoretical ultimate size limit for molding with PDMS is less than 0.5 nm. Another advantage of PDMS is the low surface energy of the material, which promotes facile release from the master template as well as the patterned surface. The PDMS mold surface can be modified to tailor the hydrophilicity; treatment with oxygen plasma and with fluorosilane have been explored to increase or decrease hydrophilicity, respectively. Changing the surface properties of the mold has implications in wetting and filling of the mold as well as mold release [8].



One limitation of RM techniques is difficulty in eliminating the thin layer of material which connects the patterned features, called a flash layer. While this layer can be etched away generating isolated structures or free particles, as in the case of SFIL, exposure of biological or otherwise sensitive materials to this harsh condition is thought to be undesirable due to the risk of degradation. However, there are many examples of particle replication using PDMS molds. Particles were generated from thermoplastics, thermosets, and hyperbranched polymers, though these were all on the micron size range and the generation of nanoparticles remains a challenge.

PRINT

The particle (or pattern) replication in non-wetting templates (PRINT®, Liquidia Technologies) technique, developed in the DeSimone laboratory at the University of North Carolina at Chapel Hill and commercialized by Liquidia Technologies, has extensively focused on the use of a perfluoro polyether (PFPE) elastomer as the mold material to replicate the features of a rigid master template. Though similar to other soft lithography techniques, the use of PFPE offers several advantages over PDMS. First, the PFPE is not as responsive to solvents as PDMS, which tends to swell when exposed to organics. This allows for the patterning of a wide variety of substrates with varied properties. Second, PFPE has a lower surface energy than PDMS which is advantageous for particle making applications. Due to the non-wetting nature of the PFPE mold, the depressions in the mold can be filled without wetting the landmass in between, yielding distinct particles without the troublesome flash layer. Thirdly, the properties of the PFPE allow for facile release of the particles from the mold without the modification of the mold surface as is required with PDMS molds. Lastly, PFPE forms a less flexible mold than PDMS, which is advantageous for high fidelity molding since the PFPE molds are less prone to unwanted deformation than their PDMS counterparts [10].

A drawback of the PRINT technique is the cost associated with PFPE when compared to the relatively inexpensive PDMS. The amount of PFPE can be minimized with the use of an inexpensive backing material coated with a very thin film of the PFPE molding material. Molds produced in this way have facilitated scale-up and commercialization of the PRINT technique, with a rate of 1,000 ft of mold per day [7]. Scalability is crucial to the application of PRINT, and other particle fabrication techniques, in nanomedicine due to the high material demands of clinical trials.

PFPE has been used to replicate the topography of a variety of nanoscale objects, including carbon nanotubes with diameters of 2 nm and soft objects such as block copolymer micelles and viruses [8], which were then replicated on a substrate by an embossing process. To generate particles, the PRINT mold is filled with a liquid preparticle solution, with the excess solution removed with a high surface-energy polymer

Nanoscale Printing, Fig. 4 A schematic for particle replication in non-wetting templates (*PRINT*). (**a**) A preparticle solution (*red*) is distributed evenly into an elastomeric mold made from perfluoro polyether (*green*) by a roller (*black*) covered by a high-surface-energy sheet (*gray*) which removes excess solution. (**b**) The particle solution is solidified in the mold. (**c**) Particles are removed from the mold with a harvesting film (*gray*). (**d**) The film is dissolved, freeing the particles

sheet via a wicking process. The preparticle solution is solidified and particles removed from the mold by physical agitation or by transfer to a surface through use of an adhesive which is subsequently dissolved, yielding free particles (Fig. 4). Particles have been generated from a variety of materials, including cross-linked PEG hydrogels, linear biocompatible polyesters, proteins, therapeutics, and block copolymer micelles. A variety of cargos have been encapsulated in PRINT particles, including proteins, anticancer drugs, nucleic acids, as well as a variety of imaging agents such as iron oxides, gadolinium chelates, and ^{64}Cu chelates [10]. PRINT has evolved to a roll-to-roll process and includes the use of a very important film splitting technique that allows the flash-free filling of the cavities in the mold to generate the individual particles. Such a roll-to-roll process is amenable to a wide range of materials to be processed using PRINT including the use of an increasing variety of mold materials that are being employed which are tailored to the chemistries being used to fill the mold [7].

Particles generated by nanoscale printing methods like PRINT and SFIL are of growing interest to researchers in the areas of drug delivery and medical imaging. These processes offer precise control over the size, shape, and composition of the particle, with broad capabilities with respect to the loading of imaging agents and/or therapeutics. PRINT particles of various shapes and sizes were used to probe cellular uptake kinetics and mechanisms with respect to particle size and shape.

Statement of disclosure: Joseph DeSimone is a founder, member of the board of directors, and maintains a financial interest in Liquidia Technologies. Liquidia was founded in 2004 to commercialize PRINT technology and other discoveries of Professor Joseph DeSimone and colleagues at the University of North Carolina at Chapel Hill.

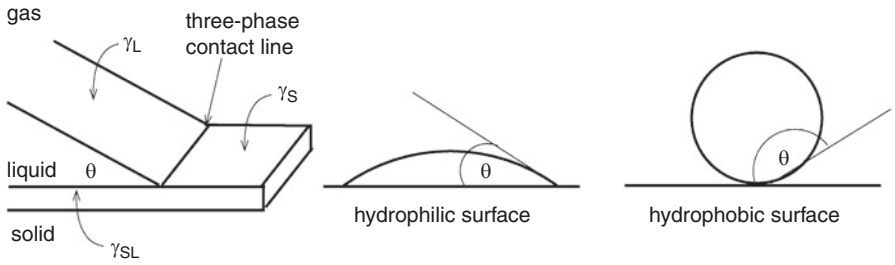
Solid–liquid interfaces

Definition

A solid–liquid interface is the boundary region separating a solid phase from a liquid phase. While its extension is strongly dependent on the particular phases, for poorly soluble solids and small-molecule liquids such as water, it spreads over a thickness of the order of a few nm. The properties of solid–liquid interfaces can be described at a macroscopic, continuum level, but are ultimately governed by atomistic details. These are the subject of the present entry, which is written with a particular emphasis on results stemming from molecular dynamics simulations and focuses especially on interfaces between inorganic solids and water.

Macroscopic Description of Solid–Liquid Interfaces

The macroscopic interaction between a liquid phase (l) in contact with a solid surface (s) is described by the *interface energy* γ_{sl}, defined as the (positive) change in free energy associated with a unitary change of the interface area. The spreading of a liquid droplet over a solid surface can be quantified by the equilibrium *contact angle* θ at the droplet's edge, which is related to γ_{sl} and the surface energies of the two separated phases, γ_s and γ_l, via the Young equation

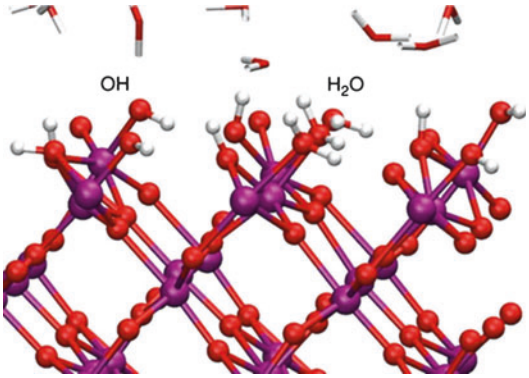


$$\gamma_{s1} + \gamma_1 \cos\theta = \gamma_s \tag{1}$$

Small values of the contact angle indicate easy spreading of the liquid phase and thus wetting of the solid surface, while large values indicate only partial spreading, up to the limit of complete dewetting for $\theta = 180°$. In the case of water, the solid is considered *hydrophilic* or *hydrophobic* depending on whether θ is smaller or larger than 90° (Fig. 1).

Chemical Details of Solid–Water Interfaces

The interface energy and the contact angle defined above capture effects at the macroscopic level that are ultimately driven by the microscopic interactions of liquid molecules with the superficial atomic layers of the underlying solid substrate.



Water molecules interact with hydrophobic surfaces via weak *van der Waals forces*. These include a repulsive contribution at very small distances arising from the non-allowed mixing of molecular orbitals with electronic surface states,

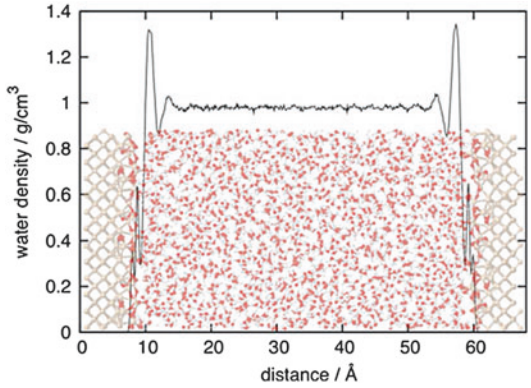
Nanoscale Properties of Solid–Liquid Interfaces, Fig. 1 Scheme of the three-phase contact of a liquid droplet with a contact angle θ on a solid surface and typical water droplet shapes on a hydrophilic and a hydrophobic surface

and attractive contributions due to *London dispersion* and *induced polarization* effects. Polarization is especially important in the case of polar liquids with a high dielectric constant, such as water, close to non-reactive metallic surfaces, such as gold or defect-free graphene sheets. It is important to note that all other metal surfaces are reactive in a water environment and spontaneously form ultrathin *native oxide* layers (with a thickness of the order of 1 nm), which confer them a hydrophilic character. Border-line cases are noble metals such as platinum, to which water is able to chemisorb through relatively weak chemical bonds, but not to trigger the formation of superficial oxides under normal conditions. Non-metallic hydrophobic surfaces of technological relevance include for instance hydrogen-terminated silicon or carbon (typically produced via etching of the natively oxidized surfaces with fluoridic acid), hydrocarbon or fluorocarbon polymers such as polyethylene and Teflon, and, to a lesser extent, silicones.

The surfaces of ceramic oxides, natively oxidized metals, and polar polymers such as polyethylene oxide are hydrophilic. Water molecules bind to them strongly via hydrogen bonds, with typical bond distances in the range 1.5–2.0 Å, which are smaller than typical van der Waals distances by about 1.5 Å. Covalent bonds are readily formed upon reaction between water molecules and anhydrous inorganic solid surfaces. Depending on the bulk composition and the surface crystallographic direction, the reaction can lead either to molecularly chemisorbed water, or to dissociative chemisorption with formation of terminal OH groups (Fig. 2). Mixed molecular and dissociative

Nanoscale Properties of Solid–Liquid Interfaces, Fig. 2 Chemisorbed water layer on a rutile $TiO_2(100)$ surface, as obtained in first-principles molecular dynamics simulations. Note the mixed dissociative adsorption mode with both terminal OH and H_2O groups

adsorption is common and the resulting hydroxylation equilibrium on the surface can be determined with the help of the so-called *Multi Site Complexation Model* [1]. In analogy with the standard nomenclature of organic alcohols, terminal hydroxyl groups can be classified as: *geminal* (two groups bound to the same site), *vicinal* (two groups bound to nearest-neighbor sites), or *isolated* (otherwise).



After chemisorption, the terminal groups may either donate or accept protons to or from the water solution, depending on their equilibrium dissociation constants and the solution pH. This results in the formation of charged surface sites, such as $O-$, $OH-$, H_2O^+, and an average surface charge density σ. At the macroscopic level, charged surfaces in contact with electrolyte solutions can be described by well-known theories

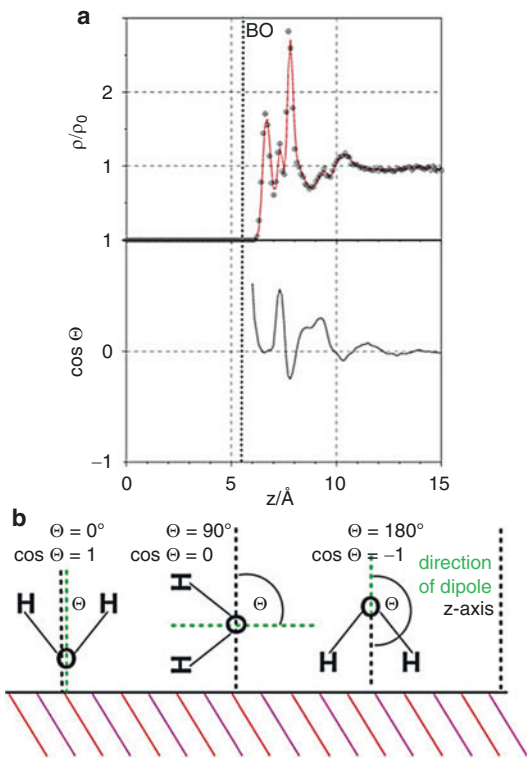
such as the *Gouy-Chapman electrical double layer model* [2]. The protonation/deprotonation equilibrium at the interface can be shifted by varying the pH of the solution. The pH value at which the surface is neutral is defined as the *point of zero charge* (pzc), an intrinsic property of the solid surface. This is conceptually different, but technically often difficult to distinguish, from the *isoelectric point* (IEP), defined as the pH for which the electrokinetic *ζ-potential* is zero. The latter is defined as the electrostatic potential at the edge of the layer of fluid molecules that remain immobile (either chemisorbed or otherwise strongly adsorbed) over the surface when subjected to a hydrodynamic flow. The ζ-potential at a given pH, and thus the IEP upon continuous pH variation, can be determined, e.g., from electrophoretic measurements of solid particle suspensions.

Molecular Ordering in Surface Proximity

Liquid molecules close to a solid–liquid interface experience a substantial reordering with respect to their arrangement in bulk, induced by the interaction with the surface atoms. This manifests itself with a typical increase of the liquid density in proximity of the surface, followed by density oscillations with amplitude of the order of the molecular diameter, which may reach up to several nm within the liquid phase. The density profile of water at a natively oxidized Si(100) surface, as obtained in molecular dynamics (MD) simulations [3], is reported in Fig. 3, clearly showing the oscillatory behavior described above. Noteworthy is the presence of water molecules deep inside the crevices of the atomic-scale roughness intrinsic of the native oxide layer, as indicated by the small features preceding the first main density peak. These features are characteristic of amorphous oxide phases such as glasses or superficial native oxides.

In contrast, hydrophobic surfaces are separated from the liquid phase by a vacuum gap with thickness of the order of a van der Waals distance, known as *depletion layer*. Knowing the density profiles $\rho_s(z)$ and $\rho_l(z)$ and the corresponding bulk

Nanoscale Properties of Solid–Liquid Interfaces, Fig. 3 Density profile of water in contact with a natively oxidized Si(100) surface, schematically shown in the background, as obtained in molecular dynamics simulation [3]



values ρ_s^B and ρ_l^B of the solid and liquid phases, the thickness δ of the depletion layer can be calculated as

$$\delta = \int_{-\infty}^{+\infty} \left(1 - \rho_s(z)/\rho_s^B\right) - \left(\rho_l(z)/\rho_l^B\right) \mathrm{d}z \quad (2)$$

Note that this definition is general for any interface between two phases, in particular also for hydrophilic, rough, or porous surfaces in contact with water, where negative values of δ can be expected. For ideally flat surfaces (where δ cannot be negative), MD simulations have shown that the degree of hydrophobicity, as measured by the contact angle θ, is related to the thickness of the depletion layer according to [4]

$$\delta^{-2} \propto (1 + \cos\theta) \quad (3)$$

In the water layers closer to the interface, water molecules assume, on average, a preferential orientation that strongly depends on the surface charge, the available terminal groups, the presence of adsorbed counterions, and the surface polarizability. This effect can be quantified by an analysis of the average angle between the water molecular axis (i.e., the molecular dipole) and the surface plane, as obtained in MD simulations. An example is shown in Fig. 4 for the case of a TiO_2 surface in contact with a saline water solution.

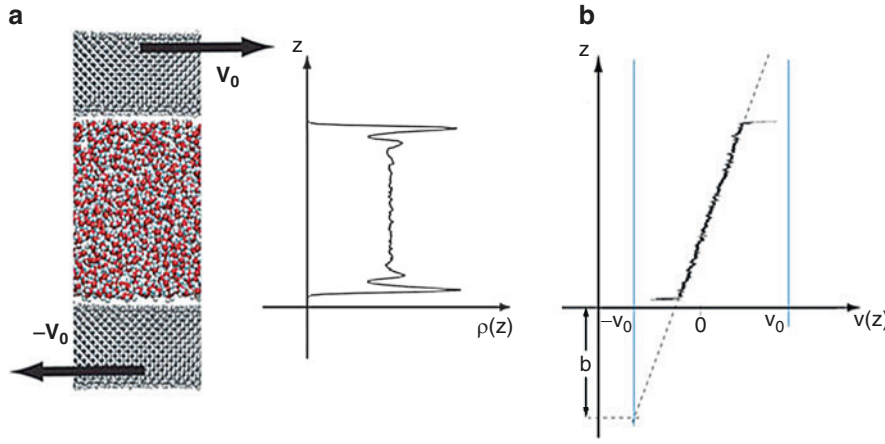
Nanoscale Properties of Solid–Liquid Interfaces, Fig. 4 Profiles of the density and molecular dipole orientation of liquid water at a rutile TiO_2(100) surface in contact with a 0.15 M NaCl solution at pH 9. Note the non-trivial structuring induced both by negatively charged surface sites and by adsorbed positive counterions. The angle Θ is defined as in the scheme here above [5]. The label BO indicates the position of the outermost O atoms (bridging oxygen) of the surface

Consistently with the variation of preferential water orientation, also the profile of the electrostatic potential in the liquid phase shows a characteristic oscillatory behavior [5]. Moreover, the higher molecular density, preferential orientation, and reduced mobility (see section "Self-Diffusion at Solid–Liquid Interfaces" below) of the water layers in surface proximity are at the origin of a considerably reduced *relative dielectric constant* with respect to bulk liquid water. While the latter is about 80, values around 10 describe correctly the dielectric properties of the water (and ion) layers in the interface region [6].

Slip Length at Solid–Liquid Interfaces

The presence of a depletion layer between hydrophobic surfaces and liquid water is connected with the existence of a positive *slip length* characterizing the flow of liquid at the interface. The slip length b is defined as the ratio between the relative velocity of liquid molecules at the interface with respect to the surface and the *shear rate* at the surface, or

$$v(0) - v_{surf} = b\dot{\gamma}(0) \tag{4}$$



The slip length can be computed theoretically in MD simulations under shear boundary conditions, in which a bulk liquid is confined between two surfaces moving at equal and opposite velocities v_0 (Fig. 5). At the solid–liquid interface, the molecules slip over the depletion layer and move with a velocity different from v_0. The slip length is obtained by extrapolation of the linear velocity profile (see Fig. 5b).

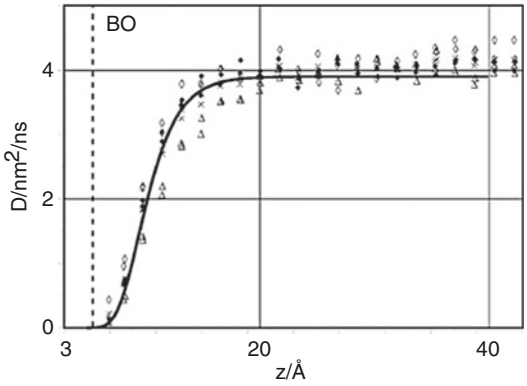
By varying the strength of the molecule-surface interactions (i.e., the degree of hydrophobicity), Netz and collaborators have demonstrated that the slip length is related to the contact angle θ and the depletion layer thickness δ by the following relationships:

$$b \propto (1 + \cos\theta)^{-2}; \quad b \propto \delta^4 \tag{5}$$

These, combined, lead to the relationship between δ and the contact angle described in the previous section.

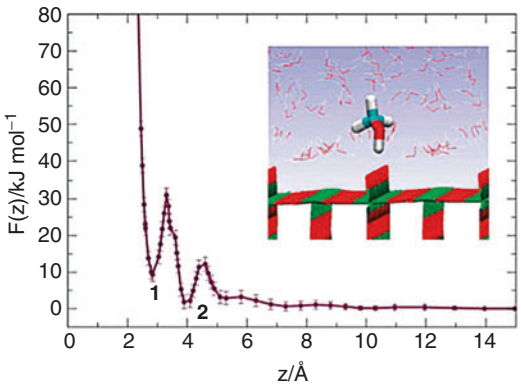
In the case of hydrophilic surfaces, the water-surface hydrogen bonds effectively anchor the interfacial molecules to the surfaces, and no-slip conditions are attained. Simulations under shear boundary conditions have revealed that in this case, the shear rate at the interface is smaller close to the surface than in the bulk, in a region defined roughly by the first main density peak of the layered water structure. This smaller shear rate corresponds to an increase of water viscosity, the extent of which is about half an order of magnitude and is strongly dependent on the degree of surface hydrophilicity. The increased velocity gradient in the bulk region leads, by extrapolation, to negative slip lengths for hydrophilic surfaces.

Nanoscale Properties of Solid–Liquid Interfaces, Fig. 5 Water confined between two H-terminated C (100) surfaces under shear boundary conditions, the surfaces moving at equal and opposite velocities v_0. Density profile of the water molecules (cf. Fig. 3) between the surfaces (**a**). Profile of the average molecular velocity between the surfaces (**b**). Note the non-zero relative velocity at the solid–liquid interface, defining a slip length b (Reproduced with permission from Ref. [4])



Self-Diffusion at Solid–Liquid Interfaces

The layering of the molecular structure of liquids in proximity of a solid surface and the corresponding increase of viscosity are at the origin of a reduced mobility of the molecules close to the interface. In particular, in the case of anhydrous oxide surfaces in contact with water, the first water layer is chemisorbed to reactive surface sites and thus almost completely immobile, except for the intrinsic equilibrium exchange between adsorbed and desorbed molecules. Correspondingly, the self-diffusion coefficient of water is vanishingly small at hydrophilic surfaces and increases at increasing distances from the surface. (Note that in this discussion the chemisorbed water is considered to be part of the liquid phase, but it could be considered equally well as belonging to the solid.) Quantitative investigations of the self-diffusion coefficient in MD simulations are difficult due to a number of reasons (see e.g., Ref. [7] and references therein). In particular, the long residence time of water molecules close to the interface makes difficult the convergence of the velocity autocorrelation function from which the diffusion coefficient is typically calculated.



Nevertheless, the available literature results show that the diffusion coefficient of water at polar surfaces qualitatively follows a sigmoidal function, indicative of strong water trapping in the near-surface region. Simulations of a 0.15 M saline water solution in contact with the TiO_2(100) surface (Fig. 6) reveal that the bulk diffusive behavior of the water solvent is reached for distances of about 1.5 nm from the solid–liquid interface.

Molecular Adsorption at Solid–Liquid Interfaces

The adsorption of molecules, in particular organic residues and peptides, at solid–liquid interfaces has gained large attention in the past few years, due to its importance in a variety of applications such as biomedical implants, biosensors, pharmaceutical packaging, and many others. Atomistic details of the adsorption can be successfully investigated in MD simulations, provided that the force fields employed in the simulations realistically capture the chemical details of the interface. It is now well established that the water layering at the interface has an important influence both on the structural and energetic details of the adsorption. This holds for small molecules as well as for larger peptides such as collagen fragments

Nanoscale Properties of Solid–Liquid Interfaces, Fig. 6 Variation of the self-diffusion coefficient of water near a hydrophilic surface, calculated in an MD simulation for a 0.15 M NaCl solution in contact with a TiO_2(100) surface terminated according to the hydroxylation equilibrium at pH 7.4. The different symbols correspond to different directions used to compute the velocity autocorrelation function, indicating a roughly isotropic diffusive behavior [5]. The label BO is defined as in Fig. 4

Nanoscale Properties of Solid–Liquid Interfaces, Fig. 7 Free energy profile of a methanol molecule interacting with a rutile TiO_2(110)–water interface. The oscillatory behavior reflects the water layering in surface proximity (cf. Fig. 3). Note the lack of a net driving force for adsorption but the presence of relatively deep local minima that can kinetically trap the molecule close to the surface (Adapted and reproduced with permission from Ref. [9])

[8]. In the latter case, for instance, a helical molecular configuration has been observed to be stabilized at hydrophobic surfaces in part by a striking matching between the water density oscillations in surface proximity and the ordered hydrophilicity/hydrophobicity pattern of the adsorbed peptide.

Correspondingly, the free energy profile relative to the approach or retraction of a molecule from solid–liquid interfaces often presents a complex structure as a direct consequence of the oscillatory behavior of the solvent layers. This can be observed in MD simulations that sample the molecular *potential of mean force* near the interface by means of constrained methods such as *umbrella sampling* (Fig. 7).

It is interesting to note that an influence of the interfacial water structuring on free energy adsorption profiles has been observed both for hydrophilic surfaces such as TiO_2 [9] and for rather hydrophobic surfaces such as gold [10]. As mentioned above, in the latter case, an important contribution of the interaction across the solid–liquid interface is the electronic charge redistribution in the metal surface when polar molecules approach it (induced polarization).

Nanoscale Water Phase Diagram

Michael Nosonovsky
Department of Mechanical Engineering, University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Definition

The phase diagram of water shows conditions (temperature and pressure) at which thermodynamically distinct phases can occur at equilibrium at the nanoscale.

Theoretical Background

Physical properties of many materials at the nanoscale are different from their properties at the macroscale due to the so-called scale effect. The causes of the scale effect include geometrical reasons (such as high surface-to-volume ratios at the nanoscale) and physical reasons (different physical mechanisms acting at the nanoscale compared to those at the macroscale).

Capillary Bridges and the Kelvin Equation

Besides high surface-to-volume ratios, an important feature of a small mechanical system is that capillary forces are often present. When contact of two solid bodies occurs in air, water tends to condense near the contact spots. This is because a certain amount of vapor is always present in air. Even under low relative humidity (*RH*), it is not possible to completely eliminate condensation in the form of water capillary bridges forming menisci near the contact spots, such as the tips of the asperities of rough solid surfaces. The menisci are usually concave and, therefore, the pressure inside them is reduced compared with the pressure outside in accordance with the Laplace theory. This leads to the attractive capillary force between the contacting bodies that is proportional to the foundation area of the meniscus. For small systems, this capillary force may become very significant, dominating over other forces such as the van der Waals adhesion or electrostatic forces. Therefore, understanding the properties of water in capillary bridges (menisci) is very important.

A flat water–air interface is in thermodynamic equilibrium with a certain amount of vapor in air, the partial pressure of which is referred to as "the saturated vapor pressure," P_{sat}, so that evaporation and condensation between the flat interface and vapor occurs at the same rate. If the partial pressure of vapor in air, P_V, is lower than P_{sat}, evaporation prevails over condensation, whereas in the opposite case ($P_V > P_{sat}$) condensation prevails over the evaporation. The ratio of the two values is the relative humidity, $RH = P_V/P_{sat}$. For a concave interface, the equilibrium occurs at $P_V/P_{sat} < 1$, whereas for a convex interface is occurs at $P_V/P_{sat} > 1$. The exact value of P_V/P_{sat}

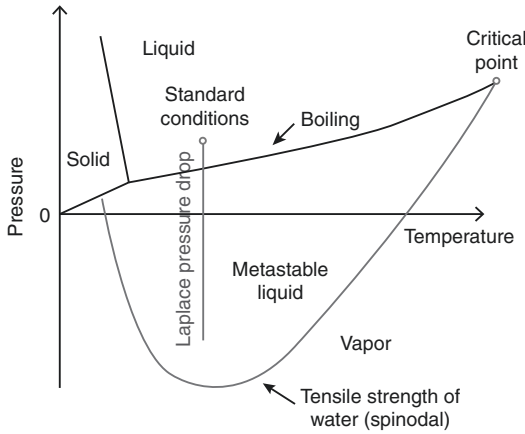
for a meniscus of a given curvature is given by the Kelvin equation. The pressure drop of water with density ρ risen for the height h in a capillary tube is $\Delta P = \rho g h$. Using the Laplace equation and the hydrostatic formula for vapor pressure $P = P_0 \exp(-gh/RT)$ – where R is the gas constant, P_0 is the pressure at the surface ($h = 0$), and T is the temperature – yields the Kelvin equation:

$$\gamma_{LV}\left(\frac{1}{R_1}+\frac{1}{R_2}\right) = \rho RT \ln\frac{P_V}{P_{sat}} \qquad (1)$$

where R_1 and R_2 are the principle radii of curvature of the meniscus ($R_k = (1/R_1 + 1/R_2)^{-1}$ is referred to as the Kelvin radius). Equation 1 relates the interface curvature at the thermodynamic equilibrium with the ratio of actual and saturated vapor pressure, P_V/P_{sat} (relative humidity). According to the Kelvin theory, a concave meniscus with a negative curvature given by Eq. 3 may form at any relative humidity [1].

Water at the Nanoscale

Normally, the phase state of water is uniquely characterized by its pressure and temperature. The phase diagram of water shows whether water is in its solid, liquid, or vapor state at a given temperature and pressure. However, at the nanoscale, the situation may be different. Both molecular dynamics (MD) simulations and experimental studies with the atomic force microscope (AFM) and the surface force apparatus (SFA) show that the state of nanoscale volumes of water at a given pressure and temperature is not always the same as prescribed by the macroscale water phase diagram. In particular, confined small water volumes demonstrate quite unusual properties, such as the melting point depression. Several effects that can be detected by AFM are related to this unusual phase behavior of the nanoscale capillary bridges.



First is the metastability of small volumes of water. When pressure is below the liquid–vapor transition line of the water phase diagram, vapor is the most stable state. However, the liquid–vapor transition involves energy barriers, and thus a metastable liquid state is possible [1]. At the macroscale, random fluctuations are normally large enough to overcome the barriers. The metastable states are very fragile, and thus they are not normally observed, except for special circumstances (e.g., superheated water). However, at the nanoscale, the barriers are large compared with the scale of the system, and metastable states can exist for long intervals of time [1].

Second, it was argued that ice could form at room temperature inside the capillary bridges. The water in such a bridge can be neither liquid, nor solid, but form a liquid–ice condensate. This explains the slow rearrangement of the bridges between tungsten AFM tips and graphite surfaces reported in recent experiments [2]. The presence of ice-like structured water adsorbed at the silicon oxide surface was suggested to be responsible for the large RH dependence of the adhesion force in the single-asperity contact between silicon oxide surfaces in AFM experiments.

Third, pressure inside the capillary bridge is lower than the pressure outside. At the reduced pressure, the water boiling point is lower than 100 °C. There is experimental evidence that boiling in the capillary bridges indeed happens in concave water menisci. Investigating nanoscale water phase transitions using AFM data can lead to modifications of the conventional water phase diagram by introducing a scale dependence. Such a diagram should depend on the characteristic size of the system, in addition to the pressure and temperature dependencies [3].

Stretched Water

When a phase transition line in the phase diagram is crossed, it is normally expected that the substance would change its phase state. However, such a change would require additional energy input for nucleation of seeds of the new phase. For example, the liquid–vapor transition requires nucleation of vapor bubbles (this process is called cavitation), while the liquid–solid transition requires nucleation of ice crystals. If special measures are taken to prevent nucleation of the seeds of the new phase, it is possible to postpone the transition to the equilibrium state phase leading to supercooled, superheated, or stretched water (Fig. 1).

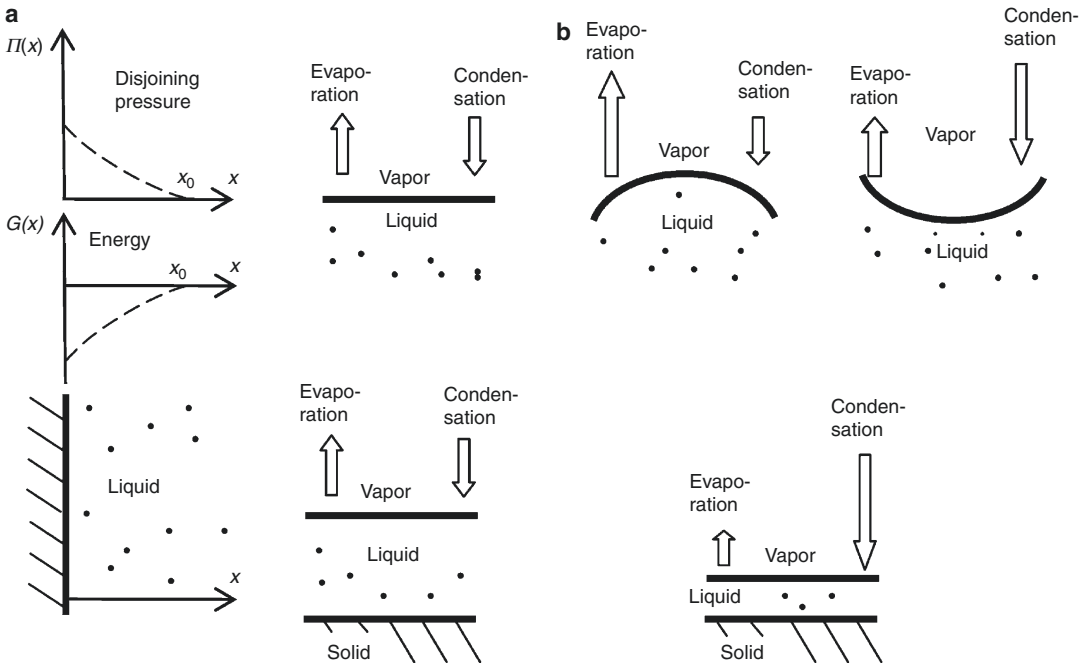
Nanoscale Water Phase Diagram, Fig. 1 Schematic of a phase diagram of water showing solid, liquid, vapor, and metastable liquid phases. While the energy barriers separating the metastable states are small, at the nanoscale these barriers are very significant

Two factors affect a vapor bubble inside liquid, needed as a nucleation center for vapor in superheated or stretched water: the pressure and the interfacial tension. While the negative pressure (tensile stress) is acting to expand the size of the bubble, the interfacial tension is acting to collapse it. For a small bubble, the interfacial stress dominates; however, for a large bubble, the pressure dominates. Therefore, there is a critical radius of the bubble, and a bubble with a radius larger than the critical radius would grow, whereas one with a smaller radius would collapse. The value of the critical radius is given by:

$$R_C = \frac{2\gamma_{LV}}{P_{sat} - P} \tag{2}$$

where γ_{LV} is the liquid–vapor surface tension, P_{sat} is the saturated vapor pressure, and P is the actual liquid pressure [1].

With the further decrease of pressure in the negative region, the so-called spinodal limit can be reached. At that pressure, the critical cavitation radius becomes of the same order as the thickness of the liquid–vapor interface. In this case, there is a lower energy path of nucleation connecting the liquid to the gas phase by expansion of a smoothly varying density profile. In the phase diagram, the line that corresponds to the spinodal limit is expected to go all the way to the critical point. This critical spinodal pressure at a given temperature effectively constitutes the tensile strength of liquid water. Various theoretical considerations, experimental observations, and MD simulation results have been used to determine the value of the spinodal limit. At room temperature, the spinodal pressure is between −150 and −250 MPa [1].

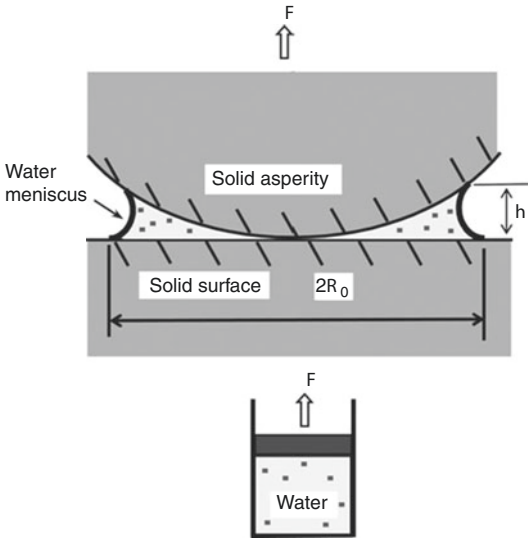


Disjoining Pressure

Another important effect is the so-called disjoining pressure. The adhesion force between the solid and water has a certain range x_0 and decreases with the distance x from the interface. As a result, water in the layer next to the interface is subjected to higher pressure $P = P_0 + \Pi_d(x)$ than the bulk pressure, where $\Pi_d(x)$ is the so-called disjoining pressure. For a thin liquid layer of thickness $H < x_0$, the evaporation/condensation equilibrium will be shifted toward condensation, since an additional attractive force acts upon water molecules from the solid surface. As a result, a thin water layer can be in equilibrium with undersaturated vapor, $P_V/P_{sat} < 1$, so the effect of the disjoining pressure on the thermodynamic equilibrium is similar to the effect of concave meniscus [4]. The influence of the disjoining pressure and the related wetting films in narrow confinement have to be considered as they may significantly change the meniscus curvature (Fig. 2). A typical effect of nanoscale confinement is the appearance of capillarity-induced negative pressure [3].

Key Findings

Negative Pressure in Water Capillary Bridges



It is very difficult to obtain deeply negative pressure at the macroscale because of bubble nucleation. The pressure values that have been reported constitute −19 MPa with the isochoric cooling method, −17.6 MPa with the modified centrifugal method, and −25 MPa with the acoustic method. The situation is different at the micro- and nanoscale. The pressure of −140 MPa in the microscopic aqueous inclusions in quartz crystals

Nanoscale Water Phase Diagram, Fig. 2 (**a**) Disjoining pressure near a solid surface (**b**) The effect of meniscus curvature (*flat*, *concave*, and *convex*) and liquid layer thickness on the evaporation–condensation equilibrium

was reported. Water plugs in hydrophilic nanochannels can be at a significant absolute negative pressure due to tensile capillary forces [1].

Negative pressure of −160 MPa was reported in nanoscale liquid capillary bridges. The capillary component of the adhesion force was determined by the comparison of the adhesion force in air (at different *RH* levels) and in ultra-high vacuum (UHV), where capillary bridges are absent. Very small values of the Atomic force microscope (AFM) tip radius (on the order of 10 nm) correspond to a small size of meniscus (meniscus foundation area on the order of 10^{-16} m^2) and thus even a small force of 10 nN corresponds to huge pressure differences inside and outside the meniscus on the order of 100 MPa or 1,000 atm (Fig. 3). The reason for the existence of such large tension limits lies in the strength of the hydrogen bonds which must be broken in order to form a cavity that is large enough to act as a stable nucleus for cavitation. The metastable state of the capillary bridges is observed because the size of the bridges

Nanoscale Water Phase Diagram, Fig. 3 A water capillary bridge between an AFM tip and a flat sample. The Laplace pressure inside the bridge is reduced because the bridge is concave. The bridge is under tension, similarly to water in a sealed tube with a piston with the applied tensile force *F*

is smaller than the critical cavitation radius given by Eq. 2 and, therefore, no cavitation occurs [1].

Room Temperature Ice in Capillary Bridges

Most AFM results show that the capillary force has a strong dependence on *RH*: first it increases with increasing relative humidity up to approximately 30 % and then decreases with a further increase of the relative humidity. For low humidity, the pressure difference inside and outside the bridge is large; however, the size of the bridge is small due to high curvature of the meniscus. For very low humidity, the size of the bridge may be insufficient to generate a capillary force. On the other hand, for high humidity, the pressure difference is small; however, the meniscus is large (but, of course, its size is limited by the radius of the tip). Thus, it is expected that in the limiting cases of $RH = 0$ % and $RH = 100$ % the capillary force would vanish, since at $RH = 0$ % there is no capillary bridge and at $RH = 100$ % the Laplace pressure drop is zero. The capillary force achieves its maximum at a certain value of *RH* [3].

It has been argued that the capillary force alone cannot explain the observed magnitude of the humidity dependence. The origin of the large *RH* dependence is due to the presence of ice-like structured water adsorbed at the silicon oxide surface at room temperature. Thus, the force is due to the rupture of an ice–ice bridge at the center of the contact region with the structure, thickness, and viscoelastic behavior of the adsorbed water layer influencing the adhesion force [2].

Water often forms adsorbed layers at the surface of many materials, and these layers may have an ice-like structure and be connected to the capillary bridge, as indicated by the study of the molecular configuration of adsorbed water as a function of relative humidity using attenuated total reflection (ATR) infrared spectroscopy [4]. A completely hydrogen-bonded ice-like network of water grows up to three layers as the relative humidity increases from 0 % to 30 %. In the relative humidity range of 30–60 %, the liquid water structure starts appearing, while the ice-like structure continues growing to saturation. Above 60 % relative humidity, the liquid water configuration grows on top of the ice-like layer.

During the contact between a tungsten tip and a graphite surface it was found that water in the nanoscale capillary bridges may include ice or be a mixture of liquid water with ice [2]. Such a mixture would have high viscosity and may act like glue, demonstrating elastic response.

Low-Temperature Water Boiling

Another important consequence of the water pressure reduction in the capillary bridges is the possibility of boiling at temperatures lower than 100 °C. If a capillary bridge is large enough, so that cavitation occurs, the pressure inside the bridge is reduced compared with the ambient, and the boiling point is depressed by the amount ΔT. The Clausius–Clapeyron equation provides the change of pressure $\Delta P = P_2 - P_1$ as related to the change of the boiling temperature $\Delta T = T_2 - T_1$ as

$$\ln(P_2/P_1) = \Delta h/R(1/T_1 - 1/T_2) \qquad (3)$$

where Δh is the change of specific enthalpy [54]. Note that ΔP is given by Eq. 1.

For example, for a meniscus between an AFM cantilever and a flat surface with a gap between them of 3 μm and the principal radii of curvature of the meniscus $R_1 = R_2 = -2$ μm, the Kelvin radius is $R_k = (1/R_1 + 1/R_2)^{-1} = -1$ μm and the pressure drop, based on (6) is $\Delta P = 72.9$ kPa (or 0.72 atm). Thus, the pressure inside the meniscus is $P = 28.1$ kPa (or 0.28 atm), which corresponds to the boiling point of about 333 K [3].

Nanobubbles

There is no adequate theoretical explanation why ice can be present in the capillary bridges at room temperature; however, it is clear that this effect is related to the adsorption of water to solid surfaces. The ability of water to form thin layers on hydrophobic surfaces is associated with the disjoining pressure caused by the spatial dependence of the van der Waals adhesion force. Due to the dependence of the adhesion force of the distance (on the scale of nanometers), the energy of the water

molecules in the vicinity of the solid surface is lower than the energy of those far away. Thus, it is often not only energetically profitable for water to cover the solid, but also to create a thin layer.

It is noted that not only the solid phase can be adsorbed at a surface. Very thin (5–80 nm) gas films could exist for a long time at the interface between a hydrophobic solid and water. Despite certain thermodynamic objections for nanobubble existence (such as expected high pressures in bubbles leading to their dissolution), some experimental studies with the AFM and other equipment have demonstrated the existence of nanobubbles at the solid/water interface [5, 6]. Nanobubbles can play a significant role in a number of processes, such as the long-range hydrophobic attractive force.

Water in Confinement

A number of studies are devoted to water phase behavior in confinement. MD simulations show that water confined to carbon nanotubes of a critical size under ambient conditions (1 bar, 300 K) can undergo a transition into a state having ice-like mobility with an amount of hydrogen bonding similar to that in liquid water. Maeda [7] investigated experimentally phase transitions of capillary-held liquids in a slit-like pore. When the surfaces were placed at a separation very close to the Kelvin length, it was possible to detect a stage in which the system was in an apparent kinetic equilibrium between two physical states – with and without the liquid connecting the two surfaces. Giovambattista et al. [8] used MD simulation to investigate the phase behavior of water confined between two nanoscale hydrophobic or hydrophilic plates at room temperature, varying the pressure ($-0.15\,\text{GPa} \leq P \leq 0.2\,\text{GPa}$) and plate separation ($0.4\,\text{nm} \leq d \leq 1.6\,\text{nm}$). With hydrophobic plates, capillary evaporation occurred between the plates at low P. The threshold value of d at which this transition occurs decreases with P (e.g., 1.6 nm at $P = 0.05$ GPa, 0.5 nm at $P = 0.1$ GPa), until, at high P, no capillary evaporation occurred. For $d = 0.6$ nm and $P > 0.1$ GPa, the system crystallizes into a bilayer ice. They developed a P–d phase diagram showing the vapor, liquid, and bilayer ice. With hydrophilic plates, water always remained liquid even at the P at which bulk water cavitates. This indicates that size is important for a phase diagram due to the finite range of the adhesion force in addition to the critical cavitation radius and curvature of the meniscus, which were discussed in the preceding sections.

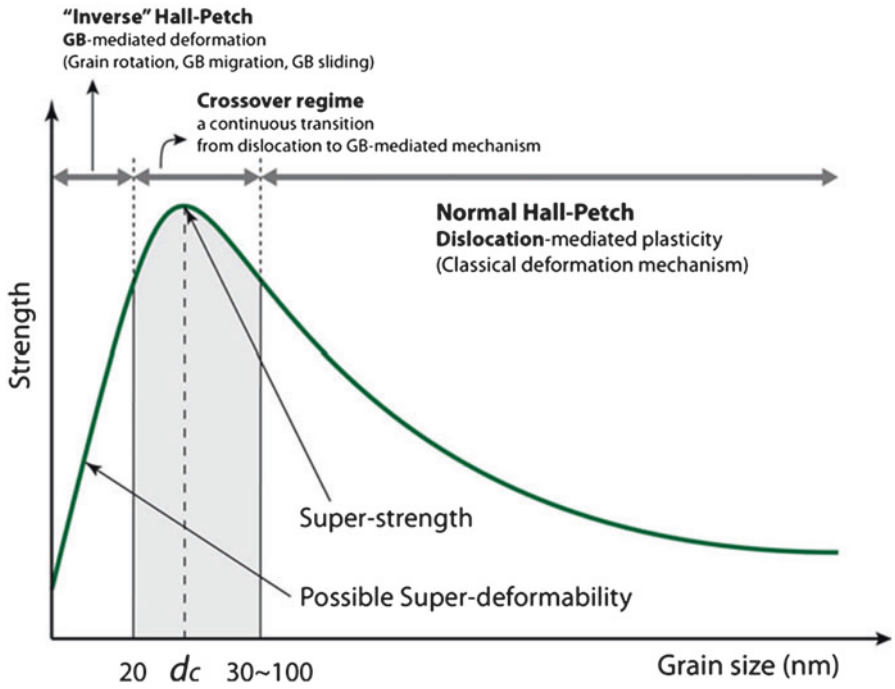
Electroplating; Nanocrystalline materials; Nano-pillars; Nano-twinned materials

Definition

- Nano-pillars are pillar-shaped specimens at the nanoscale, whose aspect ratio (height/diameter) is generally within $3 \sim 7$.
- Nanocrystalline material refers to a class of polycrystalline materials whose grain size is smaller than $\sim$100 nm.
- Nano-twin refers to a class of crystalline materials that contain a number of parallel coherent twin boundaries with the inter-boundary distance at the nanoscale.

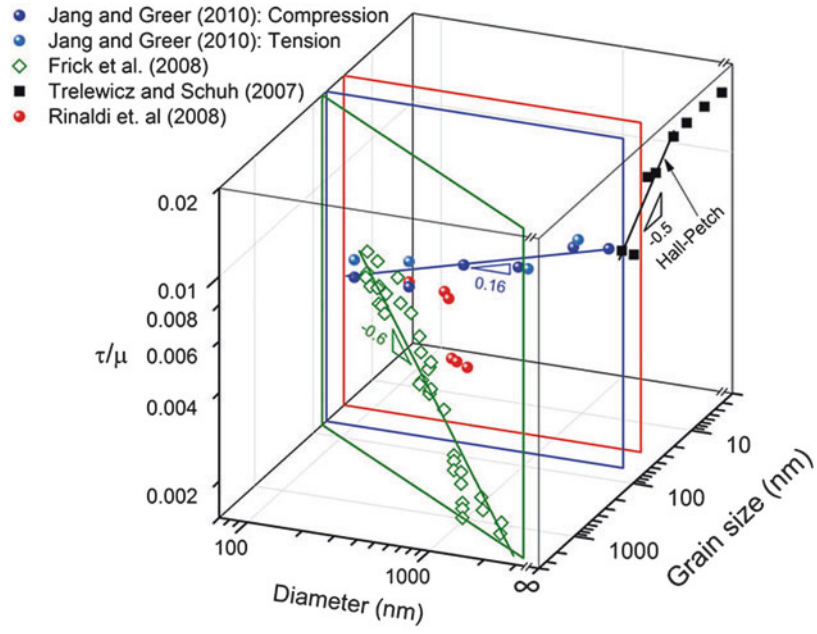


Overview

Traditionally, the most fundamental principle in materials science is that the properties of materials are strongly influenced by their internal microstructure [1]. During the plastic deformation of many metallic systems, dislocations carry most of the plasticity and hence their interactions with the internal microstructure, such as grain boundaries, solute atoms, precipitation or even other dislocations, are the most influential in determining mechanical responses of those materials [2]. However, recent studies found that the microstructure is not the only factor that affects the mechanical properties, but the external dimension of the specimen also significantly changes the mechanical behavior when it is reduced to the submicron and nanometer scale [3]. Therefore, when the effects from those two factors, microstructure and specimen size at the nanoscale, are combined, the materials often exhibit very unique properties distinguished from both of the bulk samples containing same kind of microstructure and nano-samples not containing the corresponding microstructure [3]. Especially, the homogeneous internal interfaces, such as ordinary grain boundary (GB) and coherent twin boundary (TB), are one of the most interesting microstructures as their interaction to dislocations is a key parameter in understanding plasticity of metallic materials. In this entry, the review of the recent studies investigating the mechanical properties of nano-sized metallic samples containing ordinary GBs and coherent TBs is presented. The main focus is placed on the results from uniaxial tension/compression experiments on the nanometer-sized pillar-shaped specimen (nano-pillars). Fabrication techniques to produce the nano-pillars with various internal interfaces are also introduced.

Mechanical Properties

Nanocrystalline Nano-pillars



GB is the interface between differently oriented grains in the polycrystalline materials. Generally, there is atomic mismatch across the GB as the crystallographic orientation of one grain abruptly changes to that of the adjacent one [1]. In conventional bulk polycrystalline materials, GBs usually act as a barrier to the dislocation motion across the boundary because of the discontinuity of atomic planes at the GB [1]. As a result, the strength of the bulk polycrystalline materials is inversely correlated with the grain size because total GB area increases with decreasing grain size, so dislocations are impeded more often with smaller grain size. For many conventional polycrystalline

Nanosized Nanocrystalline and Nanotwinned Metals, Fig. 1 Strength of polycrystalline materials as a function of grain size: Hall–Petch relation and transition to inverse Hall–Petch (Reprint with permission from [3])

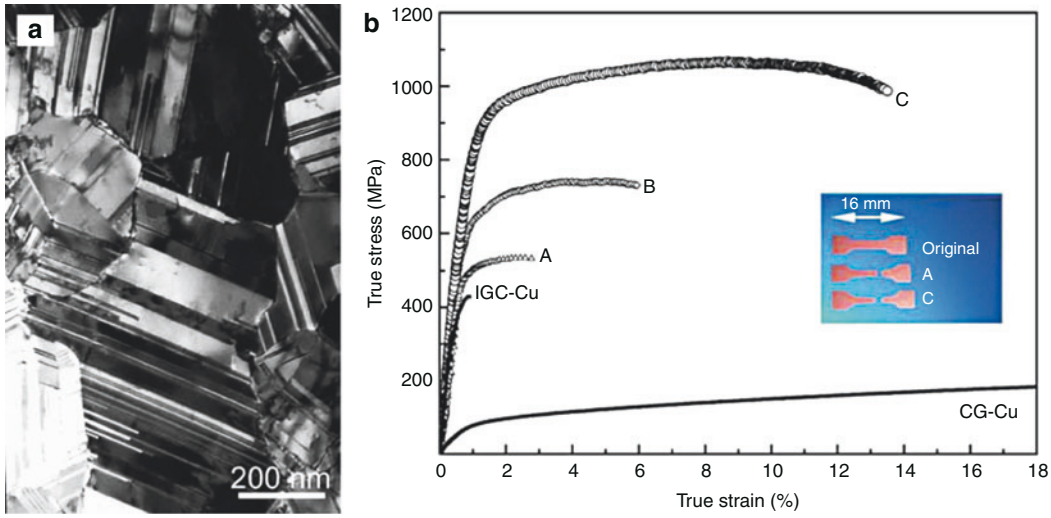
metals, the strength is inversely proportional to the square root of grain size, i.e., $\sigma_y = \sigma_o + k_y d^{-1/2}$, where σ_y and d are the yield strength and grain size, respectively, and σ_o and k_y are constants for a particular material. This expression is called Hall–Petch relation [1, 4, 5]. However, this Hall–Petch relation cannot be extrapolated down to infinitesimally small grain sizes. Instead, it is reported to break down when grain size is reduced below a critical value (usually $10 \sim 20$ nm). Below this critical size, the strength is often saturated or decreases with further reduction of grain size. This reversed relation between the strength and grain size is called inverse Hall–Petch equation. The deviation from the Hall–Petch relation is likely due to the transition in plastic deformation mechanism from dislocation-driven in Hall–Petch to GB-mediated in inverse Hall–Petch. The dependence of strength on the grain size and the corresponding deformation mechanism change are schematically summarized in Fig. 1. Further details of bulk nanocrystalline materials are available in the entry "▶ Mechanical Properties of Nanocrystalline Metals."

As briefly stated in the Overview section, the specimen with external dimensions at the nanoscale shows different mechanical responses from those of their bulk counterpart. For example, the strengths of single-crystalline nano-pillars drastically increase when their diameters decrease below submicron scale, showing the well-known "Smaller is stronger" trend (See the entry "▶ Size-Dependent Plasticity of Single Crystalline Metallic Nanostructures" for further details). In nanocrystalline nano-pillars, where both of the external specimen and internal grain sizes are in the nanometer range, the mechanical properties are clearly distinguishable from those of bulk nanocrystalline materials and single-crystalline nano-pillars. Figure 2 shows the 3D plot, where the strengths for nearly the same materials, Ni, are plotted as functions of nano-pillar diameter (D) and grain size (d). Quantities τ and μ in this plot are the shear strength and shear modulus, respectively. When $D \gg d$, the sample dimension approaches

Nanosized Nanocrystalline and Nanotwinned Metals, Fig. 2 3D representation of strength of Ni as functions of nano-pillar diameter (D) and grain size (d). The quantities τ and μ are the shear strength and shear modulus, respectively (Reprint with permission from [3])

to the bulk poly-/nanocrystalline materials, and the strength becomes independent of the sample size, D. Therefore, the strength is the function of grain size, d, only and follows the ordinary Hall–Petch and inverse Hall–Petch relations of the bulk nanocrystalline Ni. In Fig. 2, the data points (solid squares) on the vertical plane perpendicular to the D axis at $D \sim \infty$ show these relations. When $D = d$, there is only one grain across the diameter, and the resultant microstructure is single crystal (another possibility is bamboo structure, where the GBs are orthogonal to the pillar axis, but this structure is not discussed in this entry). The single-crystalline nano-pillars display "Smaller is stronger" trend, where the strength increases as decreasing the pillar diameter, D. In Fig. 2, the green plane satisfies the condition of $D = d$, and the data points on that plane (open diamonds) represent the strength of single-crystalline Ni nano-pillars as a function of pillar diameter, D (or equivalently as a function of d). The linear regression line in this log-log scale plot shows the power-law slope of ~0.6. Further details on the single-crystalline nano-pillars are available in Refs. [3, 6]. While both of bulk nanocrystalline Ni and single-crystalline Ni nano-pillars exhibit "Smaller is stronger" trend, where the strength increases as decreasing either d or D (in bulk nanocrystalline samples, this statement is valid only down to the critical grain size of ~20 nm), the strength of nanocrystalline nano-pillars shows different aspects from both of them. In Fig. 2, the vertical plane perpendicular to the d axis at $d = 60$ nm displays the strength of nanocrystalline Ni nano-pillars with fixed grain size of 60 nm as a function of D ranged from 1,600 to 100 nm. Unlike bulk nanocrystalline Ni or single-crystalline Ni nano-pillars, this nanocrystalline Ni nano-pillars show "Smaller is weaker" trend, where the strength decreases with decreasing D. Possible explanation to this trend can be due to the contribution of the free surface, whose relative fraction increases with decreasing the pillar diameter. In general, the strength of an individual grain embedded within the surrounding ones (i.e., a grain in bulk polycrystalline materials) is higher than that of the same but completely freed grain. It is because for plastic deformation in bulk polycrystalline materials, all grains must deform cooperatively by matching the displacement across the GB, and it applies additional constraints to the plastic deformation. However, when the adjacent grains are removed, those constraints are released, and the grain can deform

more easily. In nanocrystalline nano-pillars, the grains located at the free surface (surface grains) have less constraint than those in the pillar (inner grains) since the surface grains face the empty space at least to one direction. Therefore, the strength of the surfaces grains is lower than that of the inner grains, dividing the whole nano-pillars into hard inner core and soft outer shell. The thickness of the outer shell is approximately same with the average grain size of the nano-pillar. Therefore, when they have a fixed average grain size, the relative fraction of the soft outer shell increases as the diameter of the nanocrystalline nano-pillars decreases. As a result, the strength of the nanocrystalline nano-pillar lowers [3].

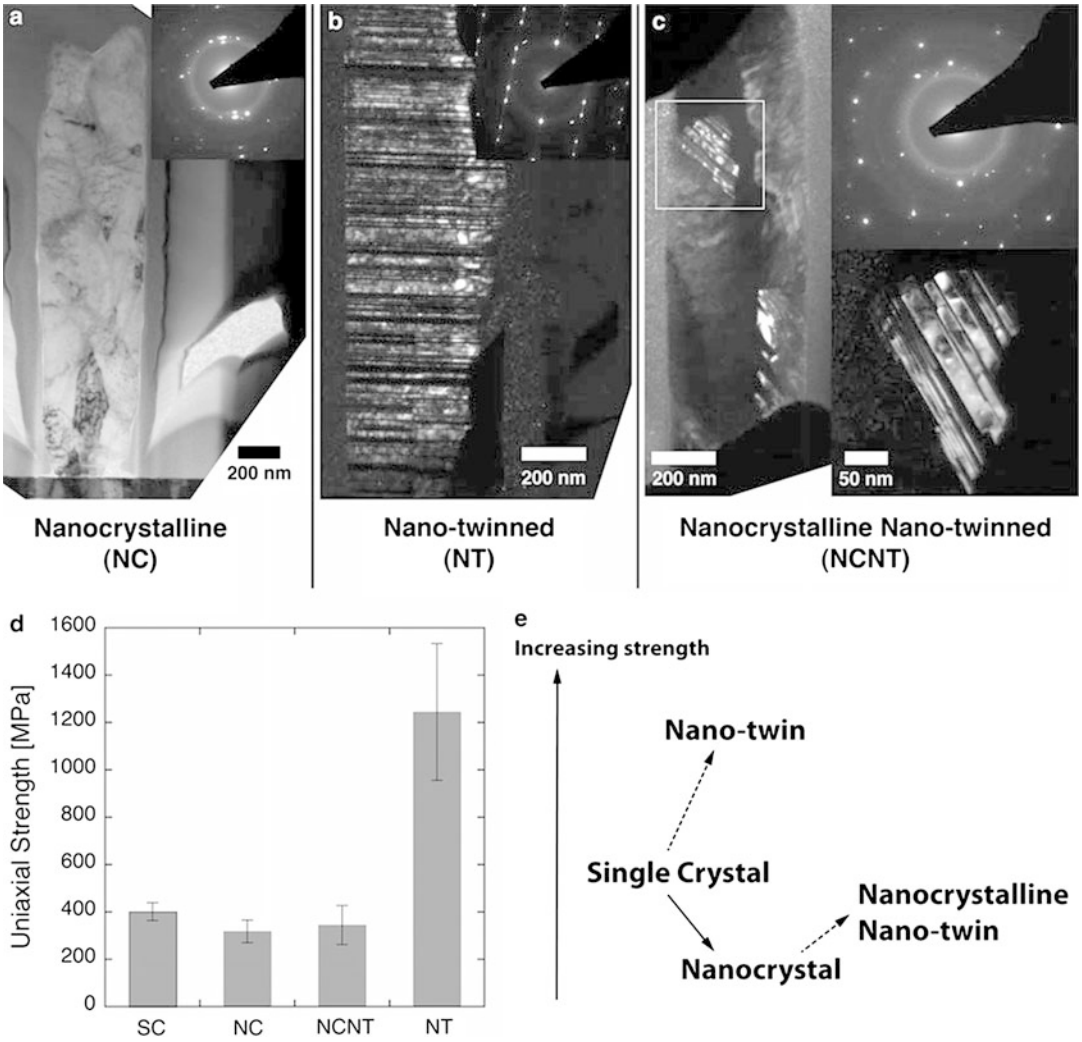


Another important observation on the nanocrystalline nano-pillars is the onset of GB-mediated plasticity at larger grain size than that of bulk nanocrystalline samples. In bulk nanocrystalline metals, activation of GB-mediated plasticity is usually correlated with transition from the Hall–Petch to inverse Hall–Petch relation, and this transition grain size for Ni is around 20 nm, as can be seen in Fig. 2. However, recent study reveals that reduction of the nano-pillar diameter to ~100 nm facilitates the activation of GB-mediated process, such as grain boundary sliding and grain rotation, at 60-nm grain size, which is significantly larger than the transition size of bulk samples, 20 nm [3].

Nano-twinned Nano-pillars

In general, the misorientation angles between the crystallographic planes across the ordinary GBs described in the previous section are randomly distributed, and atomic structure of those GBs is incoherent in that the lattice planes lose the crystallographic registry across the interface. However, there is a different type of internal coherent and homogeneous interface, called twin boundary (TB). Twinned microstructure usually refers to a special type of relative adjacent grain orientations, where one of the grains has the mirror-symmetric crystallographic structure of the other, and the mirror plane is called a twin boundary [1]. In this structure, one of the grains is called matrix and the other twin. Particularly, when the lattice planes do not lose the crystallographic registry across the boundary, the TB is called coherent. Because the TBs are also a special type of the GB, their strengthening mechanism shares many common factors with the ordinary GBs, i.e., TBs also interfere with the glide of dislocations. However, their influence on strengthening is known to be less pronounced because they are less effective at resisting the penetration of the moving dislocations, especially when the distance between the neighboring TBs is in micron range [7].

Over the last decade, the so-called nano-twinned materials (usually metals) have attracted a lot of scientific and industrial interest as promising candidates for the next generation structural and/or electrical material because of their simultaneous attainment of high strength, ductility, and electrical conductivity. In these nano-twinned metals, the nano-twinned area consists of alternative pileup of nanometer-thick planar matrix and twin grains (nano-twin lamellas). The transmission electron microscope (TEM) image of a typical nano-twinned Cu and the corresponding stress–strain curve is presented in Fig. 3 [8].



An important difference between ordinary GB and coherent TB in their roles during plastic deformation is that while the dislocation can hardly move along or across the ordinary GBs because of their disordered or discontinued atomic structure, the coherent TBs relatively easily allow dislocations to glide along and across the boundary [7]. The consequence of this difference is that dislocation mobility is highly limited in the presence of GBs, resulting in increased strength with sacrificing the ductility in regular nanocrystalline metals. On the other hand, because of its coherent nature, the TBs are capable of accommodating more various interactions with moving dislocations other than simply blocking their glide. For example, a moving dislocation can be absorbed to the TB, leaving a sessile dislocation on the interface plane, or can be dissociated into two gliding partial dislocations on the TB plane, leaving the stacking fault, or can transmit across the TB, leaving a step at the TB [7]. All of these interactions gradually degrade coherency of the TBs, hinder subsequent dislocations in interacting in the similar manners, and hence change the

Nanosized Nanocrystalline and Nanotwinned Metals, Fig. 3 (**a**) TEM observations of typical microstructure in nano-twinned Cu sample. (**b**) Typical tensile stress–strain curves for the as-deposited Cu samples with average nano-twin thickness of 93, 30, and 15 nm for samples A, B, and C, respectively. For comparison, the stress–strain curves for coarse-grained polycrystalline Cu sample (CG-Cu) and nanocrystalline Cu (IGC-Cu) are also displayed (Reprint with permission from [8])

characteristic of coherent TB close to that of ordinary incoherent GBs. As a result, it gradually requires higher applied stress to keep the dislocations moving, and the material is work-hardened [7]. Usually, the increase of work-hardening coefficient correlates with higher resistance to instability, such as necking [4, 9], so it can contribute to the effective increase of ductility.

Most of nano-twinned samples fabricated to date are polycrystalline in the sense that the nano-twin lamellas are embedded within polycrystalline grains as sub-grain structures as can be seen in Fig. 3. Properties measured in the polycrystalline nano-twinned samples are convoluted by the effects from many different microstructures like GBs, and differently orientated TBs, etc. Therefore, the specific role of TBs and nano-twinned lamellae in the enhanced mechanical properties is far from being understood. However, recent studies on the nano-twinned nano-pillars, where the specimen contains well-aligned TBs only, offered an insight into understanding the specific role of TB during plastic deformation. The TEM images in Fig. 4a–c show the Cu nano-pillars with 500-nm diameters, whose microstructures are nanocrystalline (NC), purely nano-twinned (NT), and nanocrystalline nano-twinned (NCNT), respectively [10]. NC nano-pillars only contain the randomly distributed ordinary GB with average grain size of ~160 nm, while NT nano-pillars have only coherent TBs orthogonal to the pillar axis. Average twin thickness of NT nano-pillars is ~8.8 nm. NCNT nano-pillars contain both of GBs and TBs, where nano-twin lamellae are embedded within the regular grains. Average grain size and twin thickness of NCNT nano-pillars are 250 and 6.7 nm, respectively. The strengths of those Cu nano-pillars measured by uniaxial nano-compression experiments are shown in Fig. 4d, where SC stands for single-crystalline Cu nano-pillars. These results suggest that in Cu nano-pillars with 500-nm diameter, the two different interfaces, ordinary GB and coherent TB, appear to affect the strengths differently. Given that strength of NC is lower than that of SC by ~20 %, the ordinary GBs seem to lower the strength of the nano-pillars. On the other hand, strength of NT is higher than that of SC by a factor of ~3, implying that orthogonally aligned TBs drastically increase the strength of nano-pillars. Comparing the strengths of NC and NCNT, TBs also increase the strength even in the

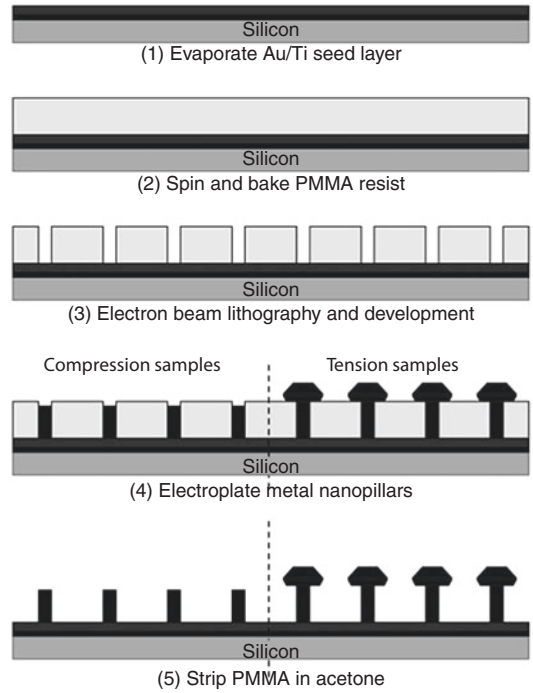
polycrystalline case. The influence of GBs and TBs on the strength of 500-nm Cu nano-pillars is summarized in the diagram in Fig. 4.

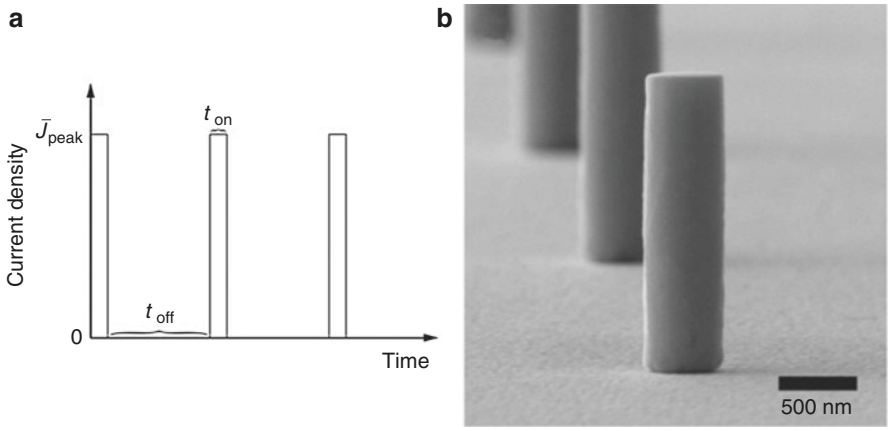


Fabrication of Nano-pillars via Electroplating

Traditionally, electroplating is a widely used metallic surface coating technique on a conductive surface. During electroplating, the metallic ions in the electrolyte migrate to the surface of the cathode under externally applied electrical voltage between the cathode and anode, and deposit a thin metallic layer on the cathode. Basically, the fabrication of nano-pillars shares the same physics and chemistry with this traditional electroplating technique. However, rather than forming a metallic layer of uniform thickness, it requires the ions to deposit only onto

prescribed locations. This can be achieved by using the pre-patterned template as the cathode. The template consists of the chemically etchable (e.g., polymethylmethacrylate (PMMA)) patterned nonconductive sacrificial layer on top of a conductive metallic thin film deposited on an insulating substrate (Si, SiO_2 or sapphire). A pattern of desired shapes can be written via e-beam lithography, and the resist is subsequently developed to generate arrays of through-holes to the underlying conductive metallic film. The underlying thin metallic layer provides an electric-conducting path for the electroplating, and the ions deposit onto the metallic layer through the open spaces in the patterned template. After electroplating, the PMMA sacrificial layer can be stripped off in acetone. Therefore, the resulting electroplated structure becomes a negative of the pattern. The nonconductivity of the substrate prevents the ions from depositing to the backside of the template. The schematic illustration of this process is presented in Fig. 5.

The specific details of the template fabrication are available in [11]. For example, a 100-nm thick Au seed layer on top of the 20-nm thick Ti adhesion layer is deposited on the Si wafer by electron beam evaporation. The Au layer provides the electric-conducting path for the electroplating and Ti layer enhances the adhesion of the Au layer to the Si substrate. The PMMA resist diluted in anisole is spin-coated on top of the Au seed layer. The thickness of the PMMA resist determines the maximum height of the nano-pillars, as illustrated in Fig. 5. Table 1 shows the list of some examples of the resist parameters and corresponding layer thicknesses [11].



The fabricated template can be used as the part of the cathode during the electroplating. The cathode is split into two parts: the template and a Cu-coated dummy chip. The purpose of the dummy chip is to precisely control the current density at the cathode ($\overline{J}$), which is defined as the total current divided by the cross-sectional area of the cathode. With the template alone, the cross-sectional area, which is the sum of the area of the patterns on the template, is extremely small (on the order of nm^2 or μm^2) so that the current density can sharply change by a small error in the

Nanosized Nanocrystalline and Nanotwinned Metals, Table 2 The electroplating condition for the fabrication of 500-nm Cu nano-pillars for each microstructure (Reprint with permission from [10])

Microstructure	Electrolyte composition	J_{on} (A/cm^2)	t_{on} (ms)	t_{off}(ms)	Feature sizes	
					Grain size (nm)	Twin thickness (nm)
Nano-twinned (NT)	125 g/L of $CuSO_4{}^{\circ}5H_2O$ + 50 g/L of H_2SO_4	0.4	1	100	N/A	8.8
Nanocrystalline (NC)	100 g/L of $C_6H_8O_7{\cdot}H_2O$ + 28 g/L of $CuSO_4{}^{\circ}5H_2O$ + 50 g/L of $(NH_4)_2SO_4$	1.2	1	100	160	N/A
Nanocrystalline Nano-twinned (NCNT)	50 g/L of $C_6H_8O_7{\cdot}H_2O$ + 28 g/L of $CuSO_4{}^{\circ}5H_2O$ + 50 g/L of $(NH_4)_2SO_4$	0.72	1	100	250	6.7

area measurement. By adding the dummy chip whose cross-sectional area is a few orders of magnitude larger than the patterns, the total cross-sectional area of the anode becomes insensitive to the small error in the area measurement, so that the current density at the cathode can be reliably controlled. As the anode material, either insoluble platinized titanium mesh or soluble metallic plate can be used, depending on the material to be plated. Microstructure of the electroplated nano-pillars is highly dependent on the plating condition, including composition of electrolyte, waveform of the applied current, and current density at the cathode. For example, in order to fabricate the Cu nano-pillars, the platinized titanium mesh was used as the anode material, and rectangular pulsed current was applied between the cathode and anode, as shown in Fig. 6a, where the current density is maintained at $\bar{J}_{peak}$ during on time, t_{on} and becomes zero during off time, t_{off} [10]. Electrolyte composition is also an important factor to control the microstructure of the Cu nano-pillars. In Table 2, the electroplating parameters to create the NT, NC, and NCNT Cu nano-pillars are summarized, including the electrolyte composition, $\bar{J}_{peak}$, t_{on}, and t_{off} [10]. The Scanning Electron Microscope (SEM) image of a typical as-fabricated pillar is shown in Fig. 6b.

Fundamentally, all conventional electroplatable metals can be also fabricated into the nano-pillar forms utilizing the method in the previous paragraph. However, determining electroplating parameters for specific microstructure,

especially the waveform of the applied current, can be challenging. While specific details have to be developed for each material, the general guideline is that (1) the grain size inversely scales with the plating overpotential, and hence reducing forward current density often yields the larger grain size. (2) Sometimes, using pulsed current is efficient in producing larger grain size as it periodically reduces the depletion region near the cathode, and consequently lowers the overpotential. The recipes to create single crystalline Cu [11], polycrystalline Au [11], and polycrystalline In [12] nano-pillars are available elsewhere.

Definition

Nanostructure field effect transistor (nano-FET) biosensors are nanoscale electronic devices used to detect and measure the presence and concentration of specific biological molecules within a given sample solution. These sensors utilize a quasi-one-dimensional semiconducting nanostructure as the active sensing element to detect the presence of local electric fields produced by charged biological molecules.

Overview

Biomolecular Detection Technologies

Methods for detecting and measuring the presence, abundance, and activity of biological molecules, such as proteins, DNA, and RNA, enable the investigation of basic biological function, molecular diagnosis of diseases, and development of therapeutic treatments. The combination of polyacrylamide gel–based electrophoresis separation (and related blotting techniques) and absorption-based chromogenic dye staining (e.g., Coomassie brilliant blue or silver staining) has traditionally formed the core technologies for protein and nucleic acid detection. Subsequent development of fluorescence- and luminescence-based labeling stains offered the opportunity for multicolor labeling, making multiplexed analysis possible. However, these methods were limited to the detection of biological molecules on gels and blots. Immuno-labeling of fluorescent and luminescent probes allowed specific protein detection and facilitated the emergence of immunoassays able to detect and quantify the abundance of a target protein molecule in solution. These optical detection methods suffer from large sample volume consumption, high reagent costs, and long assay times which, when combined with the drawback of using labeling molecules, preclude the application of these technologies to many laboratory and clinical applications (e.g., real-time protein quantification and point-of-care clinical diagnostics).

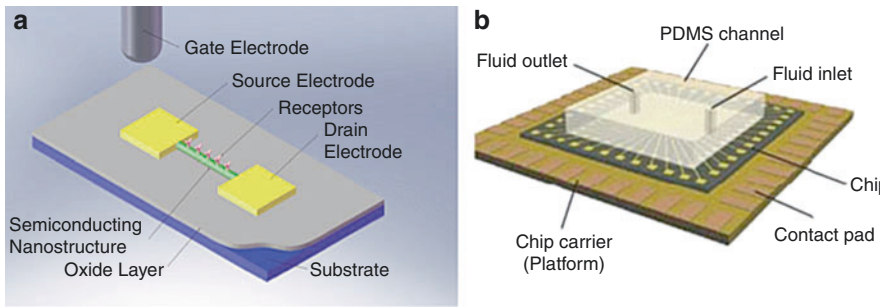
A number of novel label-free protein-detection strategies have since been developed in an effort to overcome some of the aforementioned limitations. Many of these strategies leverage nonoptical transduction modalities to circumvent the limitations imposed by optical probes. Examples include micro-/nano-surface plasmon resonance sensors [1], micro- and nano-cantilevers that translate biomolecular interactions into mechanical deformations [2], nanostructured field effect transistors (FETs) that measure intrinsic biomolecular charge [3], and electrochemical sensors that translate biomolecular adsorption to changes in redox current [4]. Of these technologies, nano-FET biosensors offer unique device characteristics including ultrasensitive, real-time, and label-free measurement capability, compact physical form, CMOS-compatible and simple on-chip integration with circuitry and microfluidic systems, direct electrical readout, and multiplexed detection capability.

Structure

Nano-FET biosensors are composed of a semiconducting quasi-one-dimensional nanostructure (e.g., nanowire or nanotube) bridging the source and drain electrodes (Fig. 1). The nanostructure serves as the transistor's channel and functions as the sensing element of the device. The biosensor structure deviates slightly from that of the transistor in the placement and structure of the gating electrode. While the gate electrode in a nano-FET is typically located directly above the channel, separated by a thin dielectric layer, the nano-FET biosensor uses a solution gate electrode that is typically composed of platinum or Ag/AgCl and is immersed within the aqueous solution being measured. Furthermore, the nanostructure surface is functionalized with a layer of analyte-specific receptors to impart a degree of specificity to the sensor. This may be accomplished via chemical bonding using bifunctional linker molecules, or through physical interaction due to adsorption, van der Waals forces, and weak electrostatic forces.

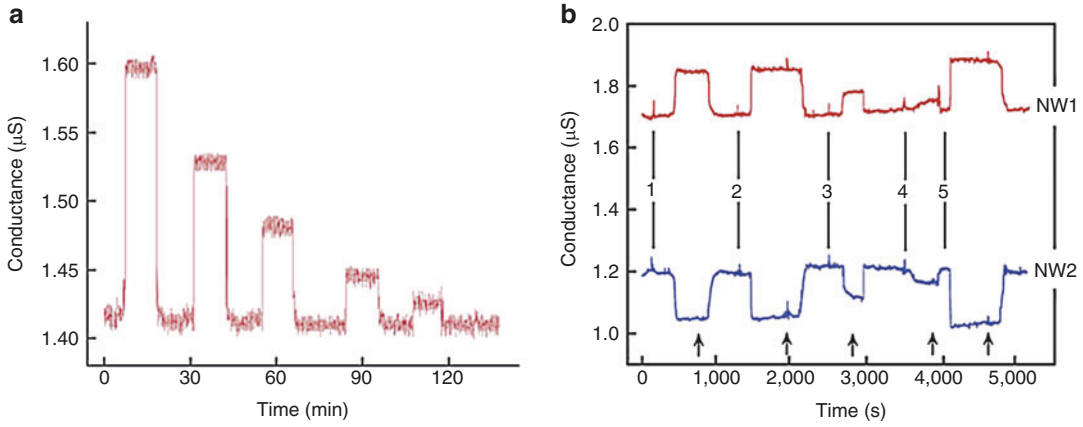
While the specific nanostructure employed may vary in shape, size, and composition, it is important that these structures be quasi-one-dimensional and exhibit semiconductive material properties. Typical nanostructures used in the construction of nano-FETs include single and multi-walled carbon nanotubes, graphene, and silicon nanowires. Devices constructed from other semiconductive materials such as metal-oxides and nanostructures of various shapes including nanotubes, nanobelts, nanorods, nanoribbons, and nanobars have also been reported.

Physics



Nano-FET biosensors utilize semiconductive nanostructures to detect the presence of charged molecules in the immediate vicinity around the nanostructure surface. The sensing mechanism is based on the observation that an externally applied electric potential is capable of modulating the number of free charge carriers within a semiconductive material, thus leading to a measurable change in electrical conductance. For a cylindrical semiconducting nanostructure with radius R and length L, the charge carrier concentration may be described as a function of the applied potential:

$$n_0 = \frac{C(V_G - V_t)}{q\pi R^2 L} \tag{1}$$



where C is the gate capacitance, q is the elementary charge, V_G is the gate voltage, and V_t is the threshold voltage [6]. As the conductance of the semiconducting nanowire is described by:

$$G = nq\mu\left(\frac{\pi R^2}{L}\right) \tag{2}$$

the current passing through the nanowire (I_D) for a given source-drain voltage (V_{DS}) is therefore:

[5], copyright 2006)

$$I_D = \frac{\pi R^2}{L} n_0 q \mu V_{DS} \tag{3}$$

where μ is the carrier mobility. Charged functional groups present on the surface of bound biological molecules such as proteins and nucleic acids provide the necessary electric potential required to induce a conductance change in the semiconductive nanostructure, thus enabling the direct electrical detection of such molecules using nano-FET devices (Fig. 2). The strength of a molecule's surface charge is a function of electrolyte pH and is characterized by the molecule's isoelectric point.

The simplified analysis qualitatively illustrates the physical sensing mechanism behind nano-FET biosensors. However, this treatment does not accurately describe the complexities of the nano-FET biosensor system. Equations 1, 2, and 3 describe the electrical behavior of a cylindrical semiconducting crystal subjected to a uniform charge density over the entire nanostructure surface. This assumption fails to take into consideration the nonuniform nanostructure surface charge distribution resulting from discrete biomolecular binding events. The discrete gating mechanism by individual molecules in solution introduces several additional phenomena that significantly influence the sensor's response including depletion of analyte from solution, analyte transport mechanisms to the nanostructure surface, and analyte-receptor binding and unbinding kinetics. These effects become particularly important in the detection of rare analytes.

Equation 3 also neglects the influence of electrostatic screening – the spatial arrangement of mobile ions around a charged molecule to effectively neutralize that charge. Importantly, target analytes must be sufficiently close to the sensor surface in order to elicit a conductance change due to electrostatic screening by mobile charges around the analyte molecule (e.g., ions in solution and charge carriers in the semiconducting crystal). The Debye screening length, the distance away from a charged molecule at which the electrostatic potential is diminished to zero due to screening, defines the required proximity.

Debye length (aqueous electrolyte):

$$k^{-1} = \frac{1}{\sqrt{8\pi\lambda_B N_A I}} \tag{4}$$

where I is the ionic strength of the electrolyte (mole/m^3), N_A is the Avogadro number, and λ_B is

the Bjerrum length of the medium (0.7 nm for water).

Debye length (silicon):

$$L_D = \sqrt{\frac{\varepsilon_0 \varepsilon_r k_B T}{q^2 N_D}} \quad (5)$$

where ε_r is the dielectric constant of the semiconducting material, k_B is the Boltzmann's constant, T is the absolute temperature in Kelvin, q is the elementary charge, and N_d is the density of donors in a substrate. The implications of charge screening and a finite Debye length make several important predictions on nano-FET biosensing performance. Namely, these relations suggest a conductance dependence on charge carrier concentrations (ionic strength of an electrolyte solution and doping density of a semiconductor), size of the semiconducting crystal, strength of the molecule's net surface charge, and the nanostructure-analyte separation distance. Inclusion of these phenomena into a unified analytical model that accurately describes experimental nano-FET biosensor response is an active area of research.

Performance Parameters

Nano-FET Sensitivity

Nano-FET sensitivity is the induced change in device conductance (ΔG_{sd}), upon exposure to a certain biomolecular stimulus for a constant source-drain voltage (V_{ds}). Sensitivity is defined as:

$$\text{Sensitivity} = \frac{\Delta G_{sd}}{G_0} \quad (6)$$

where ΔG_{sd} is the direct conductance change observed in sensing experiments and G_0 is the initial device conductance [7]. Because ΔG_{sd} depends on the specific nanowire parameters (e.g., diameter, mobility, etc.) this value does not reflect the intrinsic sensitivity. Instead, it is more meaningful to characterize the sensitivity using a dimensionless parameter (6). Normalization enables comparison across devices with different physical dimensions.

Sensitivity is closely related to three additional parameters: *detection limit* (the smallest analyte concentration that can be measured, which is dictated by the system signal-to-noise ratio); *measurement resolution* (the smallest detectable change in analyte concentration, which is dictated by noise levels); and *measurement range* (the measurable analyte concentrations, with the upper and lower bounds defined by nanostructure saturation and the detection limit, respectively). A higher sensitivity directly translates into lower detection limit, finer measurement resolution, and a broader measurement range. Typical protein and DNA detection limits reported in literature are in the pM (picomolar) to fM (femtomolar) range [8, 9]. Single virus detection has also been achieved [10].

Specificity

Specificity is a measure of a biosensors relative responsiveness to the target analyte as compared to all other molecules present within the sample solution. Very specific sensors should possess high sensitivity toward the target analyte and low sensitivity toward all other biomolecules. This attribute is imparted onto a nano-FET biosensor by functionalizing the nanowire surface (either covalently or noncovalently) with a confluent monolayer of analyte-specific receptors/ligands that bind specifically to the molecule of interest.

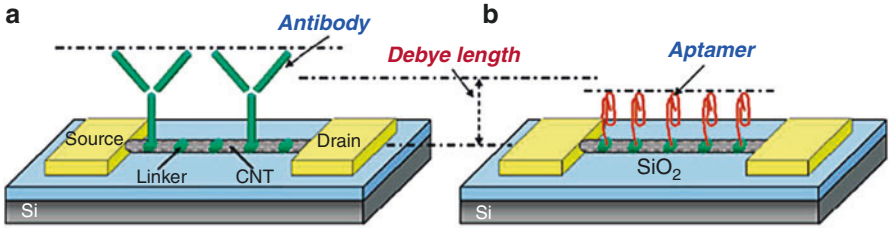
Response Time

Response time is the time it takes for the biosensor system to obtain a stable biomolecular concentration measurement upon introduction of the sample solution to the sensor surface. As with any dynamic system, this characteristic is captured in the step response of the system by the *settling time*. For a nano-FET biosensor, this parameter is influenced by the analyte-receptor binding and unbinding kinetics, transport of analyte molecules to the sensor surface, concentration and degree of mixing of the analyte solution, and the electrical response behavior of the measurement system. The typical response time of nano-FET biosensors is on the order of minutes.

Key Research Findings

Active areas of research in the field of nano-FET biosensing include: (1) optimization of biosensor performance based on the systematic examination of how fundamental device parameters affect sensitivity, specificity, and response time; (2) development of robust large-scale fabrication strategies for the manufacturing of biosensor arrays; and (3) development of an analytical model capable of accurately describing and predicting nano-FET biosensor performance.

Performance Optimization



Minimizing the Effects of Charge Screening

As the effect of charge screening acts to minimize the total nanostructure volume gated by surface charges, thus reducing device sensitivity, strategies that increase screening length are expected to improve device sensitivity. The maximum device sensitivity may be obtained in a situation where the effective screening length is much larger than the radius of the nanowire. Improved device sensitivity can thus be obtained through careful design and optimization of several device parameters that influence the effective screening length:

Diameter Reduction of the nanostructure diameter will dramatically increase the surface-to-volume ratio, thus improving device sensitivity. This is the primary advantage of decreasing the channel size and explains why nanostructure FET sensors exhibit significantly higher performance as compared to traditional planar FET devices.

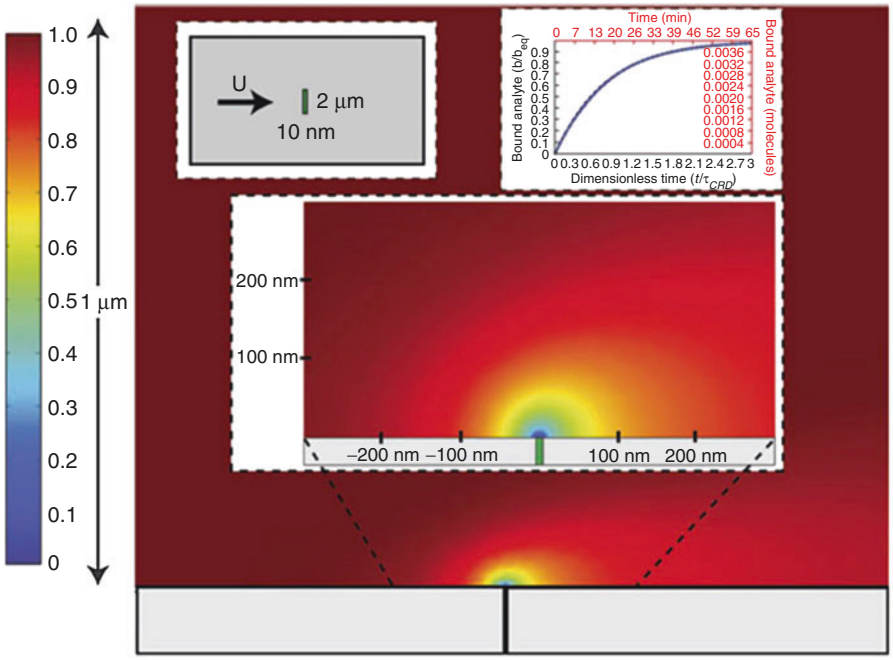
Dielectric Thickness Silicon nanowires form a native oxide layer (~1–2 nm) on their surface that serves as a dielectric layer reducing the electric field strength acting on the nanowire itself. This layer also increases the separation distance between surface-bound molecules and the semiconductive core of the nanowire. Thus, a thinner oxide layer is expected to improve sensitivity. Complete removal of the native oxide layer surrounding silicon nanowires has been shown to increase device sensitivity [11, 12].

Functionalization Scheme and Receptor Size Decreasing the separation distance between the receptor-bound analyte molecule and the nanostructure surface minimizes the effect of electrolyte screening. While antibodies are commonly used to selectively bind analyte molecules to the biosensor surface, the use of smaller capture probes such as antibody fragments or aptamers in place of antibodies can increase device sensitivity without the loss of selectivity (Fig. 3) [13, 14]. Similarly, utilizing shorter bifunctional linker molecules to attach the capture probes to the nanostructure surface may also increase device sensitivity. The choice of functionalization strategy may also dictate the capture probe density and coverage on the nanostructure surface. A poor capture probe density can result in the nonspecific adsorption of molecules onto unmodified areas of the nanowire surface and may also limit the upper

Nanostructure Field Effect Transistor Biosensors, Fig. 3 Schematic representation of nano-FET biosensors functionalized with (**a**) antibodies and (**b**) aptamers. Aptamers (and antibody fragments) are smaller than whole antibodies. The use of these capture probes thus results in increased nano-FET sensitivity. For certain experimental conditions, aptamers may serve as the ideal probe candidate as they are shorter than the system Debye length while antibodies are not (Reprinted with permission from [13]. Copyright 2007 American Chemical Society)

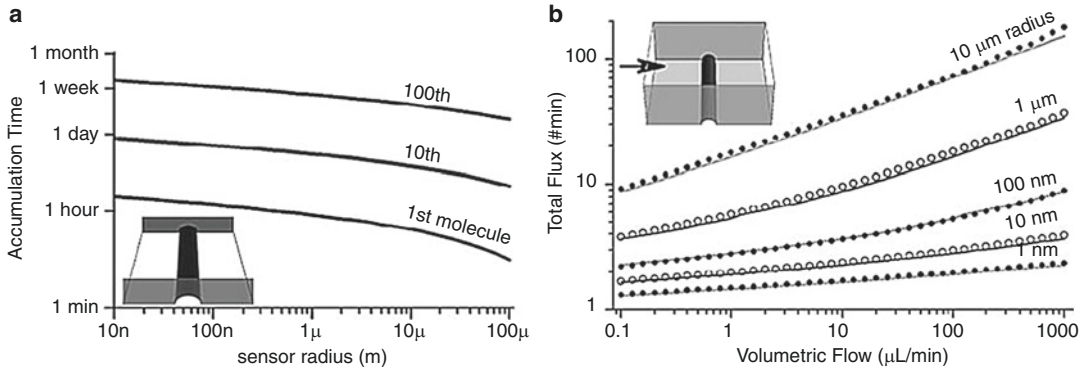
detection limit of the sensor due to capture probe saturation.

Electrolyte Ion Concentration and pH The ionic strength of the electrolyte solution influences the efficiency of charge screening as the density of free ions is directly related to size of the electric double layer formed around a charged molecule. Higher ionic strength electrolytes are thus able to screen a charged molecule over a shorter distance. It is therefore advantageous to perform biosensing experiments in low-ion conditions to maximize sensitivity [15]. However, this is not always feasible as many sensing applications are performed with physiological samples (e.g., serum, whole blood, etc.).



The pH of a solution also influences device sensitivity by changing the effective electrical charge on a biological molecule. Biological molecules such as proteins and nucleic acids contain both acidic and basic functional groups that may be positively or negatively charged depending on the availability of protons (H^+) present in solution. The pH for which the negative and positive charges on the molecule are balanced, resulting in zero net charge, is defined as the isoelectric point (*pI*). The net charge on a molecule is therefore a function of the electrolyte pH and can become increasingly more positively or negatively charged as the term |pI - pH| increases. While tuning this parameter may be useful in specific applications, the pH of a sample is usually fixed at physiological levels (pH = 7.4).

Carrier Concentration The screening length within a semiconductive nanowire dictates the depth of penetration into the nanostructure for which surface-bound charged molecules are able to gate. For example, the screening length in a silicon nanowire operating with a typical carrier concentration of 10^{18}–10^{19} cm^{-3} is $\sim$ 1–2 nm, suggesting that only a small portion of the total nanowire volume (a $\sim$ 1–2-nm thick layer at the nanowire surface) is affected by surface charges. Decreasing the charge carrier concentration will therefore increase device sensitivity by increasing the screening length and the total gated volume. This can be achieved by varying either of two device parameters: the nanostructure doping density or the bias voltage applied through a gate electrode on the nano-FET biosensor. In terms of semiconductors, lower doping densities result in longer screening lengths and therefore produce higher sensitivity devices [16]. It is instructive to note that the optimum biosensor sensitivity is obtained when the device is operating in the subthreshold regime, as under these conditions, the transconductance is at a maximum [7, 17, 18].



Optimization of Analyte Delivery Efficiency

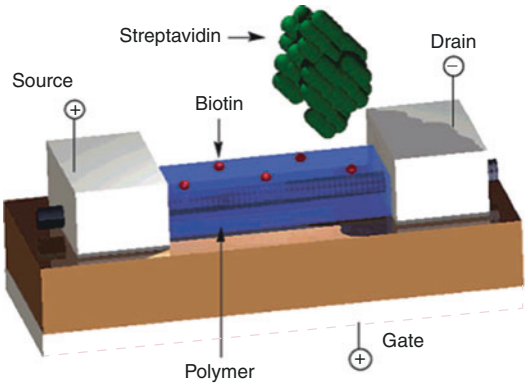
Biomolecular detection using nano-FET sensors requires the delivery of analyte to the sensor surface. The efficiency of this process can therefore limit the performance of nano-FET biosensors. Several phenomena that influence this process include diffusive and convective molecular transport mechanisms of analyte to the biosensor surface, depletion of free analyte from solution, and nonspecific analyte adsorption and binding.

Molecular Transport As with many surface-based biosensor systems, the transport of analyte in solution to the sensor surface plays a crucial role in governing binding kinetics and ultimately sensor performance. This is especially true when analyzing samples with dilute concentrations of target molecules and/or employing microfluidic systems for efficient and automated handling of small sample solution volumes. A number of competing physical processes influence target transport to the sensor surface. Analyte molecules suspended in solution may diffuse randomly within the solution, be convected along with flowing fluid, bind to adjacent surface-bound receptors, or subsequently unbind to reenter solution. The binding (or collection) of biomolecules onto the sensor surface simultaneously depletes the surrounding solution to form a so-called depletion region around the sensor (Fig. 4). As the depletion region grows in size, the analyte diffusive flux decreases and thus the collection rate becomes slower. Through finite element analysis, Sheehan and Whitman determined that the size and shape of the sensor profoundly affects the total analyte flux to the sensor surface (Fig. 5a)

Nanostructure Field Effect Transistor Biosensors, Fig. 4 The steady-state depletion zone around a nanowire sensor from a pure mass-transport problem. The depletion zone is thick compared to the nanowire, but is substantially thinner than the channel itself ($\delta_s \sim L\mathrm{Pe}_s^{-1/2} = 100$ nm). Reaction-limited binding onto the nanowire follows the Langmuir binding curve (inset *top right*) (Adapted with permission from Macmillan Publishers Ltd. Nature Biotechnology [19], copyright 2006)

Nanostructure Field Effect Transistor Biosensors, Fig. 5 (**a**) Theoretical calculation of the time required for a 10-μm-long hemicylindrical sensor to accumulate 1, 10, and 100 molecules due to diffusive molecular transport. The sensor lies at the *bottom* of a channel whose width is equal to the sensor's length and which is filled with a 1 fM analyte solution. (**b**) Finite element analysis (*points*) and theoretical calculation (*lines*) of the total flux of molecules to a hemicylindrical sensor in a microchannel (800 μm wide, 100 μm high). The total flux plotted is the steady-state value at the given volumetric flow rate for a 1 fM analyte concentration (Adapted with permission from [20]. Copyright 2005 American Chemical Society)

and further argues that without directed transport of biomolecules, individual nanoscale sensors would be limited to picomolar order sensitivity for practical time scales (hours to days) [20].



While the diffusive depletion zone grows indefinitely, albeit at an ever-decreasing rate, introduction of convective flow (assumed to be laminar) halts this growth resulting in a steady-state depletion zone with a length scale defined by the balance between the convective analyte flux delivered to the depletion zone boundary and the diffusive flux out of the depletion zone. By adjusting the convective flow rate through the channel, it is possible to tune the size of the depletion layer and thus control the rate at which molecules are delivered to the sensor surface (Fig. 5b). However, Squires et al. argue that the total mass transport varies only weakly with the flow rate as flow rates must be increased 1,000-fold to enhance flux by a factor of 10 [19]. The treatment thus far has assumed instantaneous analyte-receptor coupling upon transport of target molecules to the sensor surface. This represents one of two sensing regimes that can be described as being "transport-limited" as the availability of analyte adjacent to the sensor surface limits sensor response.

A second biosensing regime arises when considering the kinetics of analyte-receptor association and dissociation (assumed to be first-order Langmuir kinetics) [19]. If delivery of target molecules to the sensor surface occurs at a faster rate than the net analyte-receptor association rate, then the transport is said to be "reaction limited." In general, the reaction kinetics is determined by the fidelity of the immobilized reagents. While each of the two regimes imposes an independent maximum target collection rate, the "reaction-limited" condition is most desirable for nano-FET operation as, for a given device, biomolecular sensing is purely a function of analyte concentration. The sensor size and flow rate should thus be adjusted to ensure nano-FET operation within this regime. Alternatively, introduction of turbulent flow or fluid mixing through innovative microfluidic design may also be employed to overcome the limitations imposed by convective and diffusive molecular transport [8].

Depletion of Free Analyte As silicon and metal-oxide nanostructures share similar surface chemistries with several popular microfabrication substrates (e.g., silicon wafers, glass, quartz), surface modification techniques used to attach receptor molecules to the nanostructure surface can also functionalize the device substrate. In this situation, the total device surface area exposed to the sample solution during biomolecular detection experiments is proportional to the number of receptors available for reaction. Analyte binding events with substrate-bound receptors do not induce a change in nanostructure conductance. Rather, these reactions serve only to deplete free analyte molecules from solution, thus reducing the number of analyte molecules available for reaction with nanostructure-bound receptors. Minimizing the total surface area exposed to sample solutions is, therefore, important for maximizing device sensitivity. This effect may be circumvented using nanostructure-specific surface modification chemistries.

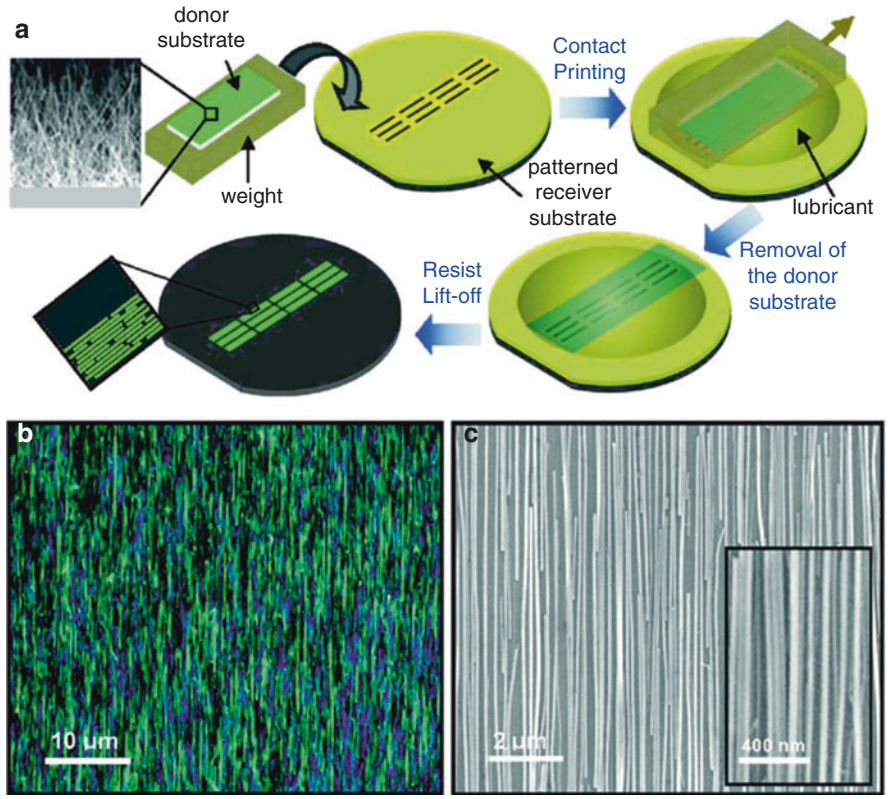
Nonspecific Adsorption Random adsorption of biological molecules onto the nano-FET sensor produces a false-positive measurement signal. This effect may be minimized by grafting a dense layer of long nonreactive polymer chains (e.g., polyethylene glycol) onto the nanostructure surface alongside receptor molecules (Fig. 6). The polymer chains prevent molecular adsorption directly onto the nanostructure surface by acting as a spacer while the co-functionalized receptors are able to bring analyte molecules into intimate contact with the nanostructure through molecular binding. The length of the polymer chains used for this application should exceed the screening length of the system.

Nonspecific adsorption of random molecules is especially problematic when working with samples containing numerous types of biological molecules such as whole blood. One strategy that enables detection of a specific analyte within a whole blood sample involves the use of a sample pre-purification procedure before nano-FET measurement [22]. In this method, the whole blood is introduced into a chamber in which analyte-specific receptors have been immobilized on to

Nanostructure Field Effect Transistor Biosensors, Fig. 6 Schematic of a nanotube field effect transistor coated with a polymeric functional layer. Co-functionalization with a molecular receptor (biotin) and a nonreactive polymer (e.g., polyethylene glycol or polyethylene oxide) prevents nonspecific adsorption of molecules onto the nanotube surface (Adapted with permission from [21]. Copyright 2003 American Chemical Society)

the chamber walls. Upon binding of free analytes to the surface-bound receptors, the whole blood solution is flushed out of the chamber and discarded. The receptors are then detached from the chamber surfaces and transported to the nano-FET biosensor for analysis.

Large-Scale Methods of Fabrication

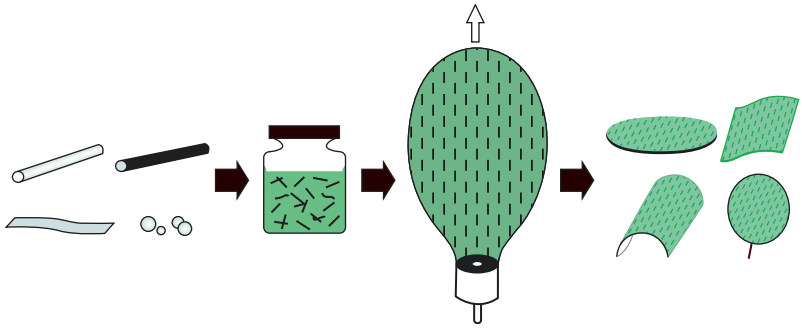


Reliable large-scale fabrication of nano-FET biosensors remains to be a significant technological challenge, impeding the adoption of this technology in medical diagnostic and biomolecular detection applications. Unlike traditional microfabrication methods for producing micrometer-level structures, the difficulties encountered in nano-FET biosensor fabrication arise from the process of establishing electrical contact with nano-sized structures in a high-throughput and reproducible manner.

Early methods for manufacturing nano-FETs involve (1) the growth of individual nanostructures using a chemical vapor deposition process, (2) transfer of as-grown nanostructures from the growth substrate onto a device substrate (a process which results in the random placement and orientation of the deposited nanostructures), and (3) identification of a suitable nanostructure on the device substrate followed by the patterning of metallic electrodes onto the ends of that nanostructure using a mask-less nano-lithographic tool (e.g., electron beam lithography or focused ion beam lithography), which has a low throughput and is only suitable for proof-of-principle use. Recently devised batch-fabrication strategies for the wafer-scale production of nano-FET arrays can be broadly categorized into "bottom-up" or "top-down" fabrication methods.

Bottom-Up Fabrication Methods

One strategy for bottom-up fabrication is to make use of pre-synthesized freestanding nanostructures using epitaxial growth methods such as chemical vapor deposition. This strategy affords several advantages over top-down and other bottom-up approaches including (1) strict control over nanostructure dimensions and electrical properties, (2) the ability to assemble nano-FET devices onto flexible and transparent substrates, and (3) the ability to incorporate nanostructures with unique chemical compositions and architecture into nano-FET devices. Successful incorporation of these nanostructures into nano-FET devices relies primarily on the ability to transfer, align, and position the as-grown nanostructures onto a device substrate. Contacting electrodes may then be patterned using conventional photolithography to form individual sensors or sensor arrays.



Flow Alignment Flow alignment is a method that makes use of flowing fluid to align suspended nanostructures along a single orientation in the direction of flow [23]. By passing a nanostructure suspension through a microfluidic structure formed between a poly(dimethylsiloxane) mold and the device substrate, free-flowing nanostructures assemble onto the device substrate due to surface forces and remain relatively aligned parallel to the direction of flow. The resulting degree of alignment is a function of the flow rate as increased flow velocities result in a narrower angular distribution among deposited nanostructures. Furthermore, varying the total flow duration dictates the nanostructure deposition density, with longer flow durations favoring

Nanostructure Field Effect Transistor Biosensors, Fig. 7 Contact printing of nanowires. (**a**) Schematic of the contact printing process for producing well-aligned nanowire arrays. (**b**) Dark-field optical and (**c**) SEM images of 30-nm nanowires printed on a Si/SiO2 substrate showing highly dense and aligned monolayer of nanowires. higher nanostructure densities. This method is useful in controlling the degree of nanostructure alignment and the deposition density, thus allowing subsequent electrode formation. Nano-FET fabrication can therefore be achieved by patterning a pair of electrodes parallel to the flow direction using conventional microfabrication processes. For this physical arrangement, minimizing the electrode pair separation distance increases the likelihood of a bridging nanostructure between the electrode pair; however, the exact number of bridging nanostructures resulting from this process is probabilistic.

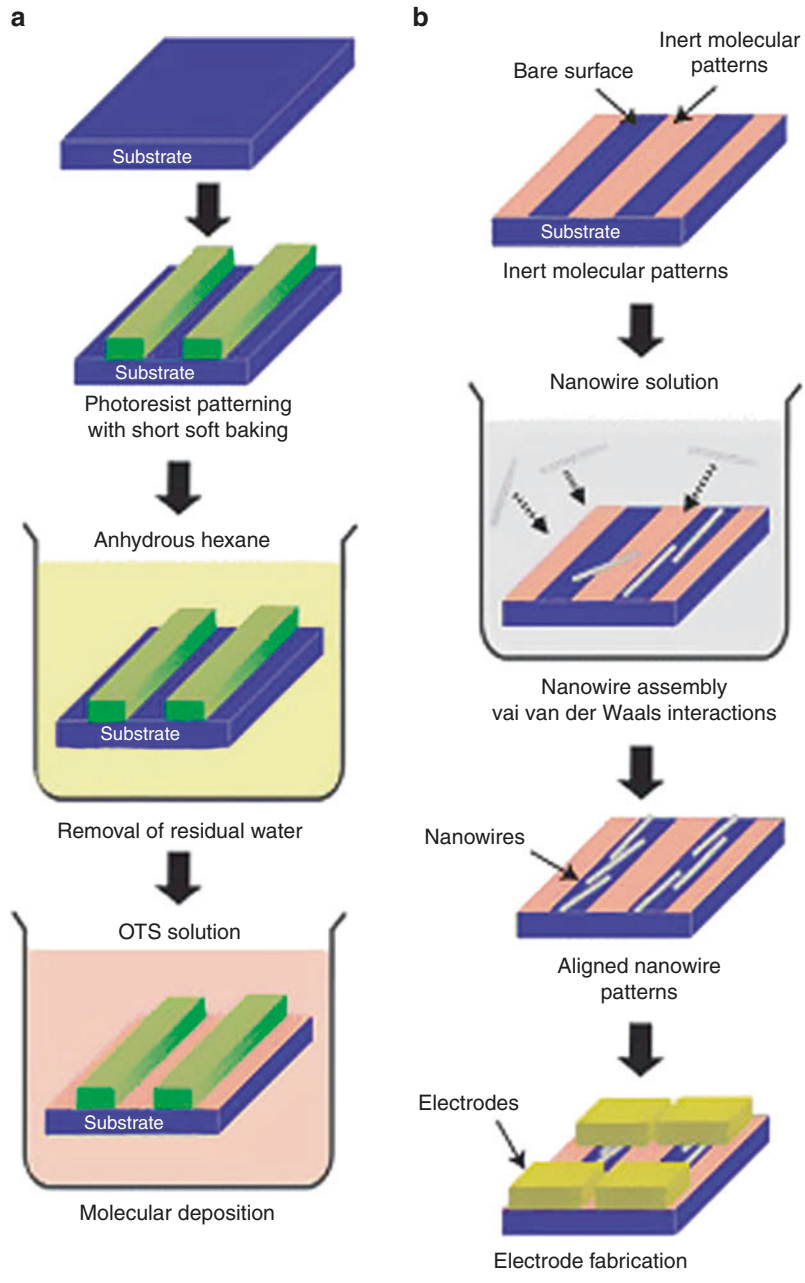
Nanostructure Contact Printing Nanostructure contact printing is a method that provides similar results to the flow alignment strategy. This method, however, relies on mechanical shear forces to detach freestanding nanostructures from the growth substrate, and friction to align the deposited the nanowires onto the device substrate [24]. In this method, the growth substrate is inverted and placed on top of the device substrate such that the nanostructures are sandwiched in between (Fig. 7). Weights are added on top of the growth substrate to control the applied pressure between the two substrates in order to optimize the deposited nanostructure density. The growth substrate is then pulled over the device substrate at a continuous velocity in order to deposit and align the nanostructures onto the device substrate. The shear velocity and the amount of friction between the two substrates influence the resulting degree of nanostructure alignment. The latter may be adjusted with the use of a lubricant.



Nanostructure Field Effect Transistor Biosensors, Fig. 8 Blown bubble film approach. Nanostructures are dispersed in a polymer solution. A volume of solution is expanded as a bubble using a die to produce well-aligned nanostructures suspended within a thin film. The film is then contacted with a substrate to deposit well-aligned nanostructures onto the substrate ([25] Reproduced with permission of The Royal Society of Chemistry)

Thin-Film Nanowire Suspension Thin-film nanowire suspension is a method that makes use of the observation that nanostructures suspended within a liquid thin film will align along a single direction when that film is elongated. Therefore, this method involves the formation of a large balloon from a nanostructure suspension (Fig. 8) [25]. The aligned nanostructures within the thin film can then be transferred to a substrate by placing the substrate in contact with the balloon. Nano-FET fabrication would subsequently proceed as in the case of flow alignment.

Directed Self-Assembly Directed self-assembly relies on the minimization of surface energy to assemble suspended nanostructures into predefined locations on a substrate [26]. In this method, surface modification strategies are used to render certain portions of the device substrate either hydrophobic or hydrophilic (Fig. 9). Upon immersion of the substrate into a nanostructure suspension, individual nanostructures will self-assemble onto the hydrophobic portions of the substrate. This strategy can be used to deposit individual nanostructures at specific locations over a large area on a substrate. A similar strategy using analyte-ligand interactions has also been employed in which suspended nanostructures are functionalized with biotin molecules. Upon immersion of a substrate with bound streptavidin molecules at predefined locations, biotin-streptavidin conjugation forces the nanostructures to assemble onto the device substrate at predefined locations.

Dielectrophoresis Dielectrophoresis (DEP) utilizes electrical fields to manipulate nanostructures. In this method, metallic contact electrodes are patterned on the device substrate prior to the assembly of nanostructures onto the device. By applying a biased alternating voltage across the electrodes, a local nonuniform electric field is produced, exerting a force on suspended semiconducting nanostructures. This force causes the nanostructures to assemble across the two electrodes. This process is easily amenable to the large-scale production of nano-FET arrays and can be used to fabricate single nanostructure FET devices; however, typical DEP trapping processes yield networked multi-nanostructure FET devices [27]. This process is highly susceptible to the experimental conditions including the size, shape, and properties of the nanostructure to be manipulated, and parameters of the electrical signals, as well as the electrical properties of the surrounding medium.

In Situ Growth of Nanostructures In situ growth of nanostructures is a method that utilizes patterned catalysts to selectively synthesize nanostructures at certain regions on the device substrate. These catalysts (e.g., iron or gold particles) are required to initiate and/or propagate nanostructure growth. In some cases, the direction

(**a**) The patterning process of octadecyltrichlorosilane self-assembled monolayer on a solid substrate via photolithography. (**b**) Self-assembly suspended nanostructures onto the bare surface regions on the substrate. Subsequent photolithography and metallization can be used to pattern electrodes onto the ends of the deposited nanostructures (Adapted with permission from Macmillan Publishers Ltd. Nature Nanotechnology [26]: copyright 2006)

of nanostructure growth can be influenced with the application of an electric field, therefore enabling control of the resulting nanostructure orientation. This method usually produces numerous nanostructures and is, therefore, useful in fabricating nano-FET sensors that utilize a network of nanostructures.

Top-Down Fabrication Method

Anisotropic Lateral Wet Etching Top-down methods are typically based on the anisotropic lateral wet etching of nanometer-thin SOI (silicon-on-insulator) wafers to produce well-defined nanostructures from the device layer

Nanostructure Field Effect Transistor Biosensors, Fig. 10 (**a**) Schematic of nano-FET device after anisotropic etching. (**b**) Scanning electron micrograph of a complete device (Adapted with permission from Macmillan Publishers Ltd: Nature [26], copyright 2007)

(Fig. 10) [8]. Micro- or nano-sized etch masks are patterned via conventional or e-beam photolithography and anisotropically time-etched to produce nanometer-wide nanostructures. Source and drain electrodes are degenerately doped, rendering them conductive and unaffected by the etchant. This approach enables wafer-scale formation of semiconducting nanostructures at precise locations on a wafer-scale, making subsequent electrode fabrication relatively straightforward using conventional photolithography. As this method relies on time-controlled anisotropic etching for the removal of material, it is highly susceptible to small changes in processing conditions such as etch time, processing temperature and mixing, and device-layer doping density and crystal orientation.

Future Directions

At this point in time, the development of nano-FET biosensors is still in the proof-of-concept phase. The promise of highly sensitive, label-free electrical sensors with real-time measurement capability remains attractive for numerous medical and basic science research applications. While great progress has been made in nano-FET fabrication and detection, continued research into large-scale fabrication methods for batch-manufacturing nano-FET sensors will be essential for the ultimate commercial success of this technology and its application to clinical and research applications. In addition to low cost and high yield, these fabrication methods must produce devices with consistent sensing performance across the nano-FET sensors such that measurements made with these devices can be standardized. Another critical hurdle that must be overcome is the issue of poor analyte specificity and nonspecific binding. While some strategies have been put forth to remedy these issues, these solutions must be further improved upon before nano-FET biosensors are able to reliably analyze whole blood, serum, and other specimens. Lastly, efforts in the area of nano-FET biosensor integration with microfluidic and lab-on-chip devices will facilitate point-of-care diagnostic applications and real-time closed-loop drug delivery systems. Successful lab-on-chip integration will also enable the creation of multiplexed nano-FET biosensor arrays, which could hold great promise in the areas of basic chemical and biological research, high-throughput screening systems for drug development, and novel in vitro biology experimentation. The future will likely see many point-of-care biosensors using electrical-based detection, and nano-FET biosensing technologies can possibly play an important role.

Functionalized nanomaterials

Definition

Nanostructured functionalized surfaces are materials that contain microscale and nanoscale features produced in a well-controlled manner with nanocoating, film deposition, or in situ surface modifications at nanoscale level, with the aim to improve the material performances. The potential applications of nanostructured functionalized surfaces are wide; some examples are in vivo imaging and diagnostics (nanosized contrast agents for medical imaging, miniaturized devices); in vitro miniaturized diagnostics (lab-on-a-chip, point-of-care measurements); drug development, delivery, and therapy (nanoparticles, nanobody, affibodies); tissue engineering; and implants of drug dispenser/factory.

Overview

Nanostructures or nanomaterials have peculiar physical and/or chemical properties, different from their bulk material. Main differences rely on topography or chemistry or on both aspects of the outer layer of the material which becomes "nanostructured" when these topographical and/or chemical modifications are made at a nanometric level. Nanostructured surfaces can be produced by surface modification of materials conventionally interacting with biological systems such as human body (biomaterials). Nanofunctionalization techniques can be divided in two main categories: (a) nanocoating and film deposition and (b) in situ surface nanofunctionalization. These two types of techniques are often combined to produce surfaces with hybrid nanostructures such as a coating/film and a nanostructured zone. Typical techniques belonging to the first category are, for example, plasma spraying, plasma immersion ion implantation and deposition, chemical or physical vapor deposition, cold spraying, and self-assembly, whereas the second category is represented by methods like laser etching, shot blasting, acid and alkali treatments, anodic oxidation, micro-arc oxidation, ion implantation, and similar [1].

The nanofunctionalization of the surface can improve the performances of biomaterials, helping their use in clinical applications. In fact, cells life in complex tissues is controlled through modulation of cell binding to the extracellular matrix, which is composed by nanostructures. Cells respond to micro- and nanofeatures with different chemistries and topographies, resulting in changes in cell alignment, polarization, elongation, migration, proliferation, and gene expression. Through micro- and nanopatterning techniques it is possible to precisely position selected biomolecules on a substrate for driving cell growth and, possibly, regulating cell functions [2].

While flat nanostructured surfaces are mainly suitable for cells growing in different conditions depending on chemical and topographical patterning of substrates, other nanostructures are also deeply studied for various applications. Nanostructures such as metal or metal oxide nanoparticles, quantum dots, silica, carbon nanotubes, C_{60}, hydrogel, block copolymer, and dendrimer are reported [3]. Main applications of these different types of nanostructures are imaging (both biolabeling and biosensing, comprising diagnostics purposes) and drug or gene delivery (for instance nanobodies or affibodies against cancer cells). Nanostructured surfaces, such as possibly functionalized nanoparticles or even nanotubes, are also included in micro- and

nanodevices aimed at diagnostics and/or medical treatments.

Various methods for the fabrication of nanostructured functionalized surfaces are available, either adapted from macro-scale technologies or ad hoc developed, while fewer are the techniques suitable for the production of nanoarrays containing multiple features such as a range of different proteins or small ligands. Topographical and chemical nanopatterning of surfaces by methodologies substantially developed for fabrication in the microelectronic field are not reported in this entry, whereas scanning probe–based techniques utilized to obtain functional structures at nanoscale (such as nanoarray) with different features are described in the following paragraphs. They are based on, for example, dip pen nanolithography, SNOM lithography, and nanografting.

Flat Nanostructured Surfaces

Flat nanostructured functionalized surfaces are surfaces with defined regions of different chemical functionality to achieve site-specific attachment of one species in some areas while minimizing unwanted surface interactions in other areas. Two surface patterning types can be distinguished, a structural topography and a chemical patterning, but at nanometric scale these features can be mixed. Moreover, a topographical pattern can be performed maintaining the surface chemistry, but the majority of chemical techniques induce a change in topography. Different strategies to achieve such patterned surfaces have been proposed, mainly using techniques developed in the microelectronics field to chemically modify some parts of the surface, for example, via electron irradiation or extreme UV interference lithography or via microcontact printing. Alternatively, the combination of different substrate materials for the creation of patterned surfaces, commonly via photolithography, is also reported [4]. The production of patterns of low cost and high complexity (three or more addressable chemistries) over large areas was recently described [5]. The method proposes the creation of a long-range-ordered array of microscale "cups" with multiple material regions by a combination of colloidal lithography and the bottom-up deposition techniques of plasma polymerization and evaporation as well as sputtering via physical vapor deposition. Plasma polymerization possesses indeed the unique practical advantages that offer single-step coating with nanometer-scale control over thickness and a wide range of functional groups can be presented with control over density.

Patterned surfaces gained great attention since cells respond to micro- and nanofeatures with different chemistries and topographies. The influence of various topographic features such as grooves, ridges, stops, pores, wells, and nodes in microscale or nanoscale has been analyzed by culturing a wide variety of cells in the presence of such patterned nanosurfaces. Fibroblasts are greatly studied with nanotopography, showing as a general behavior that the adhesion increases with decreasing feature size or height. Morphology and cytoskeleton arrangement also change. The details of the nanotopography, and hence randomness and pattern, play an important role in eliciting different cell responses [6]. Muscle cells, endothelial cells, blood cells, hepatocytes, and many other cell lines were also studied, as revised by Yim et al. [6], concluding that cells vary their adhesion, proliferation, migration, and gene expression properties if grown on nanostructured substrates. This behavior could be ascribed to the fact that cells in their natural environment interact with extracellular matrix components which are in the nanometer scale. For example, the basement membrane of many tissues displays features of pores, fibers, and ridges in the nanometer range.

Moreover, surface nanofunctionalization was demonstrated to significantly affect cellular and subcellular functions, as reviewed by Liu et al. [1], stating that clinical applications of biomaterials can be improved by producing a nanostructured surface. Apart from physical or chemical treatments aimed at the creation of nanostructures on a material surface, the modification of a substrate with specific ligand which improves cell attachment and differentiation is also well documented.

Bell et al. [7], for example, reported the use of oligopeptides to coat titanium surfaces for osteointegration of orthopedic implants by favoring attachment of osteoprogenitor cells and promoting osteoblastic differentiation. Stem cell differentiation to desired phenotypes was also deeply studied in response to nanostructured growing substrates [2]. In particular, it was demonstrated that it is possible to drive cell adhesion, migration, proliferation, and even differentiation of stem cells, by the design and fabrication of growing surfaces or scaffolds with controlled topography and chemistry at the micro- and nanoscale. Topography acts on cell shape and alignment through mechanical interaction of the plasma membrane and the specific ligands present on it with the nanostructures on the substrate surface. However, the most important parameter at micro- and nanometer level seems the order or randomness characteristic of the surface. Chemical patterning regulates cell functions by mechanical interaction (e.g., adhesive micro-islets) or by direct receptor-ligand interaction with cell-membrane proteins. Topography and chemistry can also be combined to have synergistic effects and mimic the natural cell micro-environment.

Apart from eukaryotic cells, bacteria can also colonize surfaces possibly responding to nanotopography. Main difference is however the fact that bacteria live on surfaces as a community within a species- and strain-specific extracellular polymer, forming the so-called biofilm. Little is known about the response of bacteria toward nanostructures and only indirect experimental results support the idea that bacteria are able to use molecular features of their cell membrane as sensors and implement intracellular signaling pathways to sense the surface and to react to the stimuli created by the surface [8].

Functionalized Nanostructures

Various nanostructures or nanomaterials sensitive to environmental or biological parameters have been reported. Usually they are made of metals, metal oxides, semiconductors, silica, carbon nanotubes, C_{60}, hydrogel, block copolymer, and dendrimer [3]. Nanometer-sized metallic structures, such as platinum, gold, and silver nanoparticles, exhibit unique optical properties. In fact, the characteristics of the plasmons excited by the light on their surface are depending on the dielectric constant of the media that constitute the interface. The adsorption of molecules to the nanoparticle changes this parameter, leading to detectable optical changes of the plasmon resonance. Moreover, these nanostructures can be functionalized to specifically interact, for example, with cells for site-specific drug delivery or imaging purposes. It was clearly demonstrated that differently decorated nanoparticles interact in different extent with cell membranes and cell uptake is indeed greatly influenced [9]. Iron oxide magnetic nanoparticles have been used widely in biological detection because of their good biocompatibility and ability to be manipulated under an external magnetic field. Quantum dots are also extensively used for biolabeling and biosensing, since they exhibit advantages in signal brightness, photostability, multicolor-light emission, and size-tunable properties.

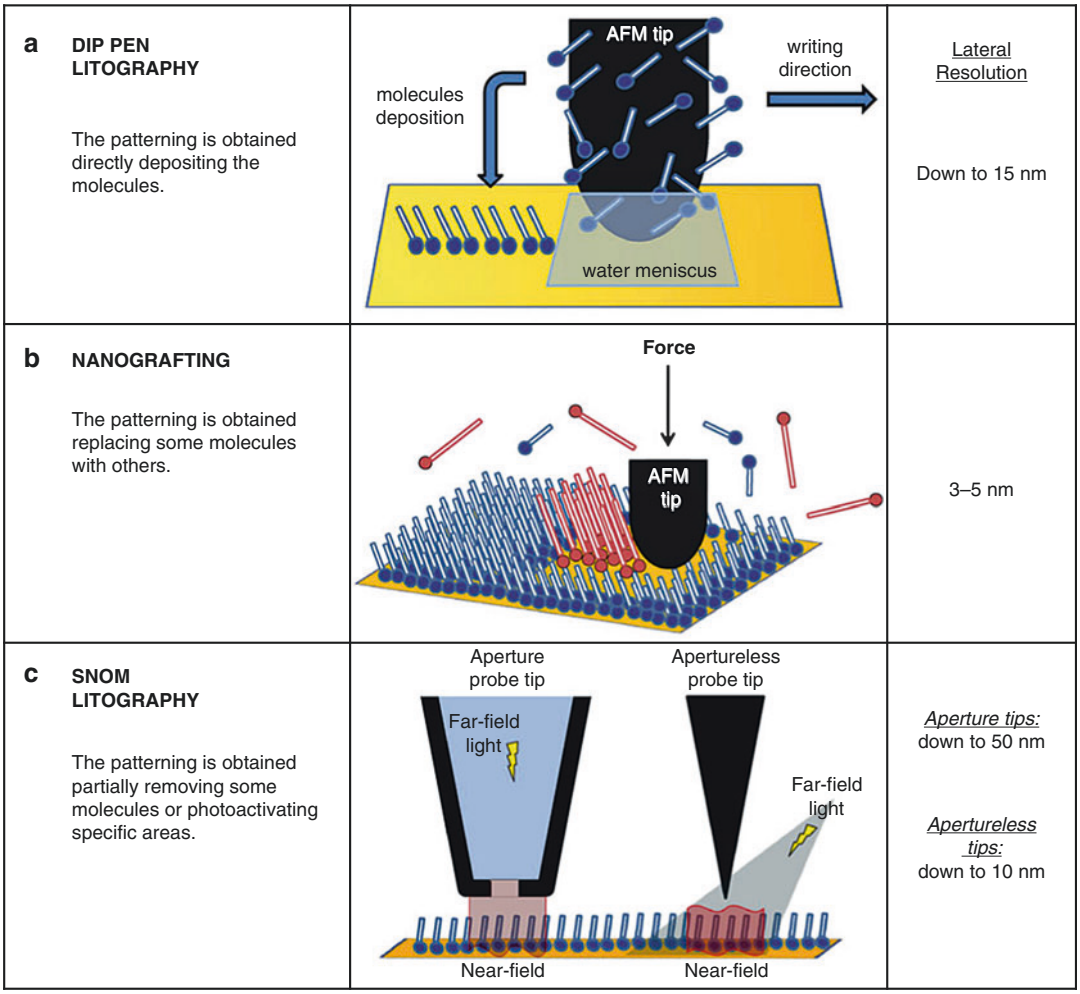
Carbon-based nanomaterials are recently gaining interest for biomedical applications. Carbon nanotubes have been used as drug or gene carriers and for biosensing, whereas certain fullerene C_{60} derivatives and fluorescent carbon dots have been developed as nontoxic alternatives to semiconductor quantum dots for biomedical imaging [10].

Self-assembly has been also extensively explored to functionalize the material surface and build nanostructures or nanomaterials, including ordered mono- and multilayers, liposomes or vesicles, nanoparticles, nanotubes, and nanofibers. Moreover, self-assembled nanostructures from block copolymers have also frequently been reported. They consist of two or more covalently bounded blocks with different physical and chemical properties, resulting in a supramolecular assembly that can respond to changes in temperature, pH, and redox potential. In fact, they can generate various microdomain morphologies by means of intramolecular forces.

Since active selectivity is often desirable, targeted drug delivery carriers are functionalized

with antibodies or antibody fragments to provide such active localization. The conjugation of multiple antibodies to each nanocarrier enhances their specificity and ability to detect their targets; nanocarriers can thus be surface-functionalized with multiple distinct antibodies to overcome tumor heterogeneity. Functional, single-domain heavy-chain antibodies, referred to as nanobodies, have been raised against cancer targets with the purpose to either antagonize receptor function or deliver an enzyme for prodrug activation. Affibodies against a variety of cancer-related targets have been developed and are now commercially available, including: EGFR, HER2, and transferrin [11]. Nanoparticles have also been capped with various biocompatible polymers such as PVA, dextran, silica, and inorganic capping agents like biotin, citric acid, avidin, carbodiimide, SiO_2, and chitosan-PEG. These molecules then act as linkers for the coupling of cytotoxic drugs or target antibodies. A step forward is, for example, the design of luminomagnetic nanocarriers functionalized with the ligand folic acid [12]. This approach combines the luminescent and magnetic properties of the luminomagnets with the specificity of folic acid making them feasible for folate receptor-mediated molecular imaging and targeted drug delivery. Besides these, the small size of these luminomagnetic particles (about 8 nm) can be exploited for their easy elimination from the body after delivery of the drugs.

Furthermore, micro- and nanostructures are included in the development of smaller medical devices or systems aimed to drug and gene delivery, tissue engineering, biosensors, and diagnostic systems. The final goal relies in developing implantable sensing and/or treatment devices to collect information for diagnosing disease and administrating treatment in vivo [3].



Finally, another class of nanostructured materials is often mentioned as potentially suitable for bio-applications. Hydrogels and molecular imprinted polymers can be considered either as flat nanofunctionalized surfaces or nanosystems similar to those described in this paragraph. Hydrogels are 3D high-molecular-weight networks composed of a polymer backbone, water, and a cross-linking agent. They can be stimuli sensitive, thus being of great interest in drug delivery, cell encapsulation, and tissue engineering [3]. Molecular imprinted polymers are also described as powerful nanotools for specific applications. They are tailor-made biomimetic receptors often used for functionalizing the surface of nanomaterials with sensing or separation purposes. Molecular imprinted polymers are produced by polymerization in the presence of molecular templates that are removed afterward, thus creating complementary nanostructured surfaces. These new surfaces can bind selectively the target (or template) used to prepare them [3].

Nanoscale Patterns Fabrication

Nanoscale patterns are generally quite difficult to work with, both in terms of preparation and characterization. Besides downscaling the fabrication methods originally developed for microconditions to nanoscale (such as photolithography, nanoimprint lithography), dedicated fabrication methods have been proposed for these applications. The following paragraphs describe the scanning probe–based techniques most commonly utilized to obtain functional structures at nanoscale such as nanoarrays containing different features.

Dip Pen Nanolithography

A scanning probe technique that has been developed for the production of nanoarrays is the ▶ Dip-Pen Nanolithography (DPN), first reported by Mirkin's group in 1999 [13]. DPN makes use of one or several AFM tips that are dipped into an ink and subsequently used to write a nanoscale pattern on a surface. The method was presented as a powerful technique to deposit molecules on a substrate from AFM tips at resolutions comparable to those achieved with much more expensive lithographic methods. The principle takes advantage of the water meniscus that naturally forms between the ink-coated probe tip and the substrate when the scanning was done in contact mode under ambient laboratory conditions. The ink moves on the substrate by capillary transport through the meniscus, as shown in Fig. 1, Panel A. A key point is the correct choice of the ink and the

Nanostructured Functionalized Surfaces, Fig. 1 Summary of scanning probe–based techniques for functional surface nanopatterning. A brief description of the principle, an illustrative cartoon, and the lateral resolution of each technique are reported

substrate, which have to possess reciprocal chemical affinities, thus favoring the chemical adsorption of the ink molecules onto the substrate. An useful application of this technique is related to the precise functionalization of nanoscale devices previously prepared by more conventional lithographic methods. The resolution of DPN depends on several parameters such as the grain size of the substrate, the molecule diffusion rate, the tip-substrate contact time and the scan speed, and finally on the environmental conditions such as humidity. The minimum feature sizes producible by DPN are in the range of 15 nm [8].

Nanografting

An effective way to introduce chemical and functional features with nanoscale lateral resolution down to few nanometers has been developed by Liu and coworkers starting from 1997 [14, 15] using an AFM (▶ AFM) tip. This method is based on the local modification of a self-assembled monolayer (▶ Self-Assembled Monolayers) surface, previously deposited starting from an alkanethiol solution, on a flat gold substrate. The surface is then mounted in a liquid environment AFM cell, allowing its observation and nanomanipulation with the AFM tip.

While scanning the surface in a low load regime (<1 nN) results in the three-dimensional imaging of the surface, increasing the load over a threshold value one obtains the removal of the previously deposited thiolated molecules under the tip, locally disrupting the monolayer and exposing the gold surface. If thiolated molecules (usually different from that used in the initial SAM deposition) are present in solution, a newly deposited SAM is obtained in areas where the tip is removing the old one, locally changing morphology and chemistry of the surface. Patches with different height with respect to the surrounding surface can be deposited and detected in topography AFM images. Nanografted structures can also introduce characteristic groups in specific areas that show a chemical contrast in AFM friction images. The principle is illustrated in Fig. 1, Panel B.

Nanografting can be applied even with a solution of the same molecule previously used for the initial SAM formation (homogeneous nanografting), obtaining in this case the removal of defects that were possibly present in the SAM [15]. Having obtained a nanopatterned surface endowed with specific chemical groups in well-defined patches, one can then exploit this method to create nanoarrays of biomolecules. Liu and coworkers [16] showed how to take advantage of both non-covalent and covalent attachments to form such protein nanoarrays, down to a lateral scale of tens of nanometers. This method generally leads to non-oriented protein patches, as demonstrated by the AFM analysis, that shows the presence of proteins with different heights with respect to the surface, corresponding to the different protein orientation. The nanografting technology can be also successfully applied to the realization of DNA nanoarrays, when thiolated single-stranded DNAs are used in the solution during the nanografting process. DNA lines as narrow as 10 nm can be indeed fabricated. Moreover, nanografting allows a controlled density deposition of DNA strands, depending on the number of tip passages over the same area [17]. Successful DNA hybridization has been demonstrated on such nanoarrays.

It is also possible to extend such a technique to realize protein nanoarrays: Patches of single-stranded DNAs of different sequences are deposited using nanografting in specific places of a surface previously covered with a SAM able to discourage aspecific protein adhesion. Then, proteins linked with DNA sequences that are complementary to that of the patch where the protein deposition is desired are incubated over the surface. Thanks to the DNA complementarity, a specific protein localization is then obtained. The effectiveness of this methodology for the realization of nanoscale protein sensors has been demonstrated using human serum enriched with antibodies against specific proteins that were previously immobilized on nanografted patches, showing that antibodies bind to the patches where their targets are present [18].

A method that in similar fashion takes advantage of the DNA hybridization properties to direct the localization of nanosized objects with the help of an AFM probe (although not based on nanografting) has been demonstrated by Kufer and coworkers in 2008 [19]. Their method is based on the fabrication of specific areas on a glass surface, namely, depot areas – where DNA-coupled nanoobjects are picked up by a single-stranded functionalized AFM tip, and target areas – where the nanoobjects are delivered with a precision of some nm to form the desired pattern. More than 5,000 object transfers with the same tip have been demonstrated.

SNOM Lithography

In 1983, it was proved the Scanning Near-field Optical Microscopy (SNOM), shortly after the invention of the first proximal probe technology, the Scanning Tunneling Microscope (STM). These two techniques are based on a similar principle, but in the case of STM the detection is performed on the electron tunneling currents, while in the case of SNOM the detection is performed on the tunneling of photons. This characteristic makes the SNOM suitable for the analysis of nonconductive samples [20].

By illuminating the sample with near-field light, the probe tip is held very close to the sample without touching. An evanescent light field is created in very close proximity of surface. The evanescent light through the aperture is incident on the sample, exciting the atoms in the surface to reradiate propagating waves. The same probe can

then collect the propagating light and transmit it to an appropriate detector. The probe tip can be designed in two different ways, an aperture-based tip and an apertureless-based tip (as illustrated in Fig. 1, Panel C). In an aperture-based SNOM, however, the nanometer-scale aperture limits the light throughput and the resolution. To overcome these limitations an apertureless SNOM was developed that uses an apertureless probe, similar to an STM or AFM tip, to scan within the near field of the sample. In this case the sample is first irradiated from above by far-field light in order to produce the evanescent field on the surface of the sample. The evanescent photons then excite the atoms in the probe tip, which reradiate the propagating photons.

An interesting application of this technique is related to the lithography-like process. The SNOM probe is used as an energy source for modifying a variety of materials at the nanoscale level, including conventional photoresists and non-conventional electro-magneto-optical materials as well as ferroelectric and SAM. The photoresists layer deposited on a substrate may be changed for instance by laser pulses emitted from the SNOM probe, offering resolutions unachievable by conventional optical and laser systems (well beyond the diffraction limit). Patterns are generated by scanning the probe over these target surfaces and both aperture and apertureless probe tips are used, obtaining different resolution limits (50 nm for aperture probe and down to 10 nm for the apertureless probe).

Nanomaterials for sensors

Definition

Materials having nanometric dimensions are able to improve their functional properties, which allow their exploitation in highly performing sensors.

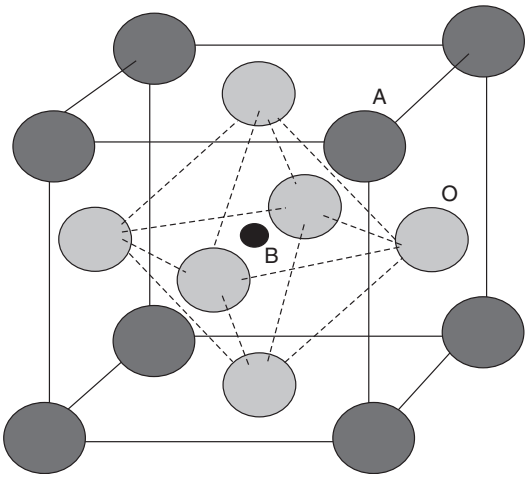
Overview

Materials with at least one dimension smaller than 100 nm are classified as nanostructured. Compared to micro-sized ones, nanomaterials are characterized by a higher surface to bulk ratio, usually leading to an enhancement of optical, mechanical, electrical, structural, and magnetic properties [1].

In the last few years, research focused its efforts on the development of multifunctional composite materials, able to perform multiple non-structural functions, sometimes combined with a suitable mechanical response. If nanostructured, they can also imply additional functional properties with respect to conventional composites. Multifunctional materials can be used for developing highly performing sensors, particularly in the case of single-phased and composite materials containing carbon nanotubes and piezoelectric phases [2].

Piezoelectric Materials

Piezoelectric materials are able to directly convert a mechanical signal into an electrical one and vice versa. For this reason piezoelectric materials produce a charge when subjected to a stress (direct effect) or a strain when an electric field is applied (converse effect). These materials can then be used as actuators or sensors, by exploiting their converse or direct piezoelectric effect, respectively. Generally piezoelectric sensors are used for measuring several parameters, like acceleration, angular rate, pressure, force, temperature, mass, magnetic field, and amount of several chemical substances [3].



Piezoelectricity can be expressed by several materials, such as single crystals, ceramics, polymers, and composites [4, 5]. Even if they naturally

present this behavior, piezoelectric single crystals, as quartz and Rochelle salt, cannot be easily used being isotropic, e.g., they have different properties depending on the cut and the orientation directions. Most piezoelectric ceramics applied in commercial sensing devices are made of polycrystalline ferroelectric ceramics [6], which present a higher strength and an easier fabrication with respect to single crystals [4]. Ferroelectrics are characterized by a spontaneous polarization which can be orientated under a realizable electric field. In fact, they initially contain randomly oriented, polarized regions, named domains. These polarized regions form upon cooling at a temperature called the Curie temperature to minimize the total elastic energy of the ceramic structure. In this state, they do not present piezoelectric properties. When an electric field is applied, the domains align; this process is known as poling. When the electric field is removed, most domains remain aligned and piezoelectricity is induced.

Generally the piezoelectric ceramics present a composition that implies a structural instability such as polymorphic phase transition (PPT) or morphotropic phase boundary (MBP) [7]. PPT-based systems are characterized by a large temperature dependence of piezoelectric properties and a rapid depoling, due to temperature changes close to PPT temperature. In the case of MBP-based materials, piezoelectric features are slightly influenced by temperature, but their working temperatures approach a half of Curie temperature.

Among polycrystalline ferroelectric ceramics, the first system studied for its piezoelectric properties was barium titanate ($BaTiO_3$) in 1943 and it remained the primary electroceramic material until the discovery of the lead zirconate titanate or PZT ($PbZr_xTi_{1-x}O_3$) in 1954 [4]. The former is a PPT-based, high-performance piezoelectric ceramic, the latter presents a MBP from tetragonal to rhombohedral phase at about 48 mol% $PbTiO_3$ content.

For a long time PZT was the most used piezoceramic for its very attractive behavior in sensor applications [5, 7]. Notwithstanding this, in 2003 the European Union claimed PZT as a hazardous substance and research efforts were

Nanostructured Materials for Sensing, Fig. 1 The perovskite structure common in most ceramic piezoelectric materials (With permission from Ref. [5])

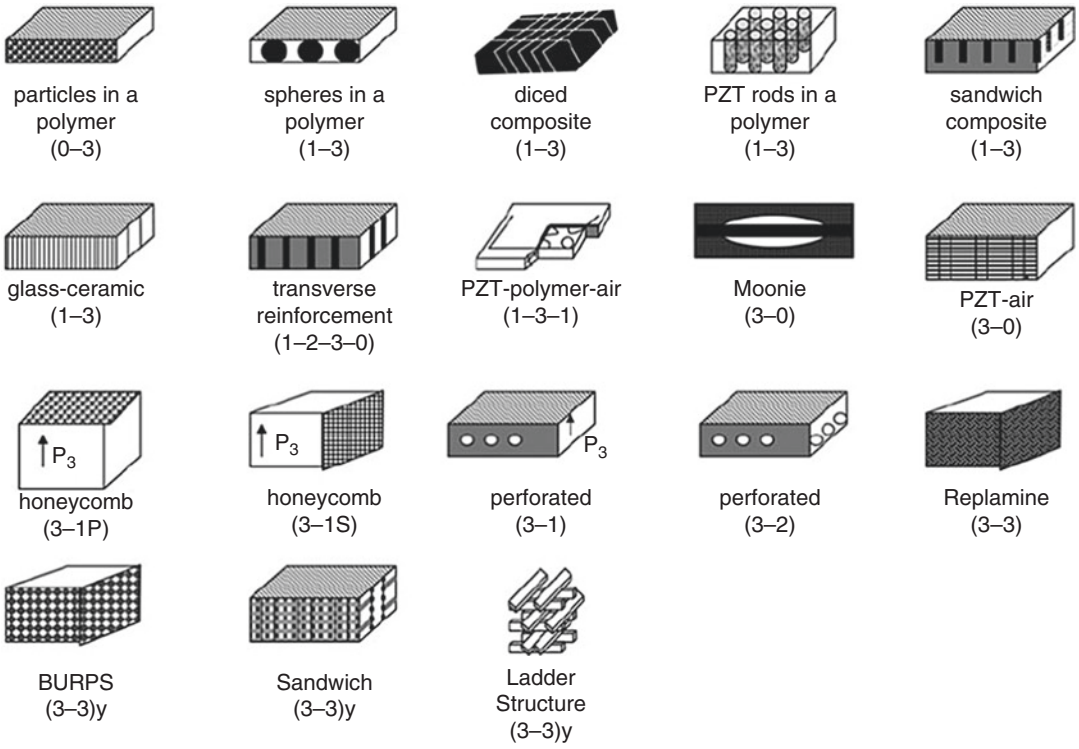
then focused on lead-free piezoceramics having high performances. For this reason, in the last decade, alternative systems were deeply studied modifying the composition of the traditional ferroelectric ceramics. In particular, this *compositional engineering approach* involved perovskite-based materials, exploiting their solid solutions with other ferroelectric systems or their doping, e.g., the introduction of different types of cations within their structure. The perovskite structure ABO_3 consists in a face-centered cubic array, in which the large cations A are placed at the corners of the unit cell, the smaller cations B in the body center, and the oxygen atoms in the center of each face, as illustrated in Fig. 1 [5–7].

Even if the high symmetry of the perovskite structure could lead to improved poling and consequently higher piezoelectric performances, currently no innovative lead-free ceramics are able to compare the piezoelectric and thermal behavior of PZT-based materials.

On the other hand, a *structural engineering approach*, based on template grain growth, grain size optimization, and domain engineering, is able to enhance the electromechanical performances of existing piezoelectric materials. For instance, in the case of $BaTiO_3$, a microstructural refinement can double the piezoelectric coefficient. In this case, the finer grain size implies a decrease of

the domain size and an increase in density of domain walls, which are able to influence the piezoelectric properties [5, 8]. Moreover, a fourfold increase of the piezoelectric coefficient can be reached synergically combining the effect of submicrometric domain sizes and grain orientation obtained by template grain growth technique. The positive effect of the grain orientation was also demonstrated in the binary system $(Bi_{1/2}K_{1/2})TiO_3$–$BaTiO_3$ (BKT–BT) [5].

Generally piezoelectric ceramics can be applied in sensors as bulk components or thin films, by using micromachining techniques [2, 3]. Thin films from one tenth to several tens of microns in thickness can present different properties with respect to the corresponding bulk material. This is due to the dependence of the piezoelectric features to the morphology and density of the film, as well as to the compositional aspects related to the stoichiometry and presence of impurities. Moreover, the piezoelectric behavior can also be influenced by the orientation and nature of the substrate material. All the deposition methods are based on three fundamental steps; firstly, the atomic or molecular species are yielded by chemical or physical processes. In the former case chemical vapor deposition or sol–gel techniques can be used; in the latter one, sputtering or pulsed laser deposition can be employed. After this step, deposition on the substrate is achieved through transport and condensation mechanisms and finally, the film is obtained by crystallization and annealing [3].



In order to achieve a long-term stability of piezoelectricity at room temperature and to develop flexible devices, piezoelectric polymers can be employed [9]. Generally ferroelectric materials based on polyvinylidene fluoride (PVDF), odd nylon, vinylidene cyanide (VDCN), and aromatic and aliphatic polyurea families are exploited [9, 10]. In the case of PVDF-based polymers, the residual polarization after poling is due to the alignment of CF_2 dipoles present in their structure $(CH_2–CF_2)_n$ and trapped charges. Dipoles are oriented in the crystalline phases inside lamellae and in the interfaces between crystalline and noncrystalline phases, while the charge traps are present at the surface of crystallites [10]. The electromechanical performances of these polymeric materials can be improved by the polymerization of PVDF with other fluorinated polymers, which implies an increase of the crystallinity [9]. In the case of odd-nylon and polyurea families the field-induced orientation of N–H and C–O dipoles is stabilized by the hydrogen bonding present between adjacent polymer chains. On the other hand, in the case of amorphous polymers such as VDCN-based materials, an easier orientation of the C–CN dipoles is obtained by poling at temperatures near to the glass transition temperature and freezing the residual polarization, through the cooling down of the system under the electric field [9, 10].

Among piezoelectric polymers, PVDF presents the best electromechanical behavior at room temperature, but its performances decrease at higher temperature [9]. This drawback can be partially limited through the copolymerization of PVDF [11]. Other ferroelectric polymers can be used, but they are characterized by less piezoelectric properties [9, 11].

Compared to the pure polymer performances, piezoelectric composites offer significantly higher functional properties. It is in fact possible to synergically couple the best features of the ceramic and polymeric phases while minimizing the poorest properties [4, 11]. Composites can be classified on the basis of the connectivity between the constituent phases according to Newnham notation [4]. This notation describes the number of dimensions each phase is physically in contact with itself. When just two components are considered, ten configurations are possible: 0-0, 1-0, 2-0, 3-0, 1-1, 2-1, 3-1, 2-2, 3-2, or 3-3, illustrated in Fig. 2 [5].

Among them, 0-3, 1-3, and 2-2 connectivity have been recently developed, in order to tailor the piezoelectric response through the exploitation of anisotropic composites having different ceramic phase contents [11].

In the last few years, miniaturization of devices based on piezoelectric behavior involves the exploitation of carbon nanotubes as functional materials [12].

N

Carbon Nanomaterials

Multidimensional carbon nanomaterials include graphite, graphene, and carbon nanotubes. They are made of carbon atoms in an exagonal configuration, bonded each other with sp^2 bonds [13]. Graphene is a two-dimensional sheet of carbon atoms and represents the repetitive unit of the graphite. Carbon nanotubes (CNT) consist in graphene sheets rolled to form cilynders, as shown in Fig. 3. In particular, carbon nanotubes can be classified as single-walled (SWCNT) or multi-walled (MWCNT); the former, consisting in a single graphene cylinder, the latter, being made of concentric cylinders with an interlayer spacing of 0.34 nm. CNT nanostructure, atomic arrangement, diameter, and length strongly affect their mechanical, electric, and thermal properties [12].

Carbon nanotubes show an electromechanical behavior that, unlike to piezoelectric ceramics, is due to the phonon frequency shifts as a consequence of a charge injection [12]. This feature is mainly exploited in carbon nanotubes composites, which are characterized by a change in resistance when subjected to a chemical, thermal, or mechanical loading. Among them, the most promising sensing devices based on carbon nanotubes are the chemiresistive-type ones. In fact, their high sensitivity, small size, high surface area, and high aspect ratio imply the ability to detect smaller concentrations of analyte than traditional sensors.

In comparison to carbon nanotubes, the homogenous distribution of electrochemically active sites at a nanometer scale and the higher purity could make graphene an ideal material for sensing and detection. Notwithstanding this, no consolidated studies have been carried out about its application in sensing devices to date [14].

Definition

Nanostructured thermoelectric materials are materials that contain nanoscale constituents and exhibit enhanced thermoelectric performance due to nanoscale phenomena.

Introduction

Electricity and heat are two important forms of energy; electricity remains the most convenient form of energy, while heat is an abundant but low-grade form of energy. As the simplest technology applicable to direct heat–electricity energy conversion, *thermoelectricity* is secured a position in the solution package of sustainable and alternative energy for mankind in the twenty-first century [1]. The study of thermoelectrics is an application-driven material-oriented fundamental research; the ultimate goal is to develop higher performance thermoelectric material for applications in power generation and heat management. The thermoelectric performance of a material is gauged by its figure of merit, ZT with $ZT = \frac{\sigma\alpha^2 T}{\kappa} = \frac{PF}{\kappa} = \frac{PF}{(\kappa_{ph}+\kappa_e)}$, σ is the electrical conductivity, α is the thermopower (i.e., Seebeck coefficient), κ is the total thermal conductivity, PF is the power factor, and T is the temperature in Kelvin. The κ is often expressed as the sum of the lattice thermal conductivity, κ_{ph}, and the carrier thermal conductivity, κ_e. ZT is the material parameter of prime importance in thermoelectrics research. A high ZT requires a high PF and a low κ_{ph}, succinctly phrased as "electron-crystal phonon-glass" (ECPG).

To date, degenerate semiconductors such as BiSb, Bi_2Te_3, SiGe, PbTe, $CoSb_3$-based skutterudites, and half-Heusler (HH) compounds remain the cornerstone for the state-of-the-art thermoelectric materials. These materials possess several common features [2]: (i) the bandgap size *on the order of* $10\,k_B T_o$, where k_B is the Boltzmann constant and T_o is the operation temperature; (ii) the carrier concentration *on the order of* 10^{18}–10^{20} cm^{-3}; (iii) high-symmetry crystal structure, either cubic or hexagonal (rhombohedral); (iv) small electronegativity difference among constituent elements; (v) low Debye temperature and/or strong anharmonicity. The first three features aim at a subtle balance among the carrier concentration, mobility, effective mass, and the bipolar effect, in line with "electron crystal." The last feature aims at a low κ_{ph}, in line with "phonon glass." Though initially developed for bulk thermoelectric materials, these criteria, *in principle*, hold for nanostructured thermoelectric materials.

In the past decade, the synergy of nanotechnology and traditional bulk thermoelectric material has culminated into a new paradigm, "nanostructured thermoelectric material" [3]. The major rationale behind this new paradigm lies in that *thermoelectricity* arises from *two* fundamental flows, namely, the charge flow and the entropy flow. The characteristic length scales of these two flows, namely, the mean free path and the wavelength of electrons and phonons, are on the order of *nanometers*. Hence, the nanostructuring process provides an extra layer of control of the charge and entropy flows beyond the atomic scale; one can resort to the classical size effects to optimize the mean free path of electrons and phonons while utilizing the quantum size effects

to optimize the electron band structure and phonon dispersion relations.

Recent Advances in Nanostructured Thermoelectric Materials

The main theme of this entry is on the latest advances in nanostructured thermoelectric material research. In general, advance can be achieved via (i) suppressing the lattice thermal conductivity in line with the "phonon-glass" approach and/or (ii) enhancing the *PF* in line with the "electron-crystal" approach. To date, most advances are achieved in line with the "phonon-glass" approach; *ZT* is almost doubled in several nanostructured thermoelectric materials due to significantly reduced κ_{ph} [3]. In contrast, less progress was made in enhancing the *PF*. We are now at a *crossroad*: the room for further reduction of κ_{ph} is getting marginal. Though it was proved that the κ_{ph} could be reduced below the *alloying limit* in specific materials [4], the procedure is hard to scale up. As such, the future of nanostructured thermoelectric material research hinges upon the successful focus shift from "phonon glass" to "electron crystal."

Next, we will briefly discuss two promising mechanisms that enhance the *PF* in nanostructured thermoelectric material, namely, (i) the electron energy-filtering mechanism and (ii) the "invisible dopants" mechanism. Despite different nomenclatures, these mechanisms are inherently related: the electron energy-filtering mechanism encompasses both *resonant* scattering and *nonresonant* scattering; the *invisible dopants* mechanism is a unique type of *resonant* scattering (namely, *antiresonant scattering*). In practice, the electron energy-filtering scheme is often implemented at interfaces; this is how "filtering" initially got its name.

Electron Energy-Filtering Mechanism

In this section, we use the Drude model and the Mott relation to help illustrate the rationales behind the electron energy-filtering scheme. Despite the assumptions and oversimplifications used, the conclusion drawn is general. The electron energy-filtering scheme was initially proposed for thermionics, the other direct heat–electricity conversion technology. The major difference between thermionics and thermoelectrics is that the electron transport in a thermionic process is ballistic across the energy barrier, while the electron transport in a thermoelectric process is quasi-equilibrium and diffusive [5].

In a quasi-equilibrium and diffusive electron transport process, it is instructive to relate the energy-specific electrical conductivity $\sigma(E)$ and the thermopower α in the Drude model (Eq. 1) and also in the differential form of the Mott relation (Eq. 2) [6]:

$$\sigma(E) = n(E)e\mu(E) = n(E)e^2\frac{\tau(E)}{m^*}\ , \qquad (1)$$

where the energy-specific carrier concentration $n(E)$ is defined as the number of carriers between energy E *and* $E + \Delta E$, $\mu(E)$ is the energy-specific mobility, $\tau(E)$ is the relaxation time, and m^* is the effective mass.

$$\alpha = \frac{k_B}{q}\int_0^\infty \sigma(E)\left(\frac{E-E_F}{k_BT}\right)\left(\frac{\partial f_0(E)}{\partial E}\right)dE \Big/ \int_0^\infty \sigma(E)\left(-\frac{\partial f_0(E)}{\partial E}\right)dE, \qquad (2)$$

where q is the elementary charge, k_B is the Boltzmann constant, E_F is the Fermi energy, and $f_0(E)$ is the Fermi–Dirac distribution function. The "Fermi window factor" $\left(\frac{\partial f_0(E)}{\partial E}\right)$ is, *to the first order*, a bell curve centered at $E = E_F$ and with a narrow width on the order of k_BT. Therefore, α is, *to the first order*, proportional to the mean excess energy $<E-E_F>$. At a given carrier concentration, the higher the $<E-E_F>$, the higher the α. In total, a high *PF*, thus, necessitates a *large* and *energy-asymmetric* $\sigma(E)$ within the Fermi window (i.e., a large and asymmetric electron density of states $g(E)$ near E_F).

Furthermore, one may rewrite Eq. 2 for a degenerate single-band electron system [7]:

$$\alpha = \frac{\pi^2}{3}\frac{k_B}{q}(k_B T)\left[\frac{g(E)}{n(E)} + \frac{1}{\mu(E)}\frac{d\mu(E)}{dE}\right] \quad (3)$$

Note that each of the *two* terms in the square bracket of Eq. 3 corresponds to a mechanism that governs α, the central component of the *PF*. While the electron band structure governs the $g(E)/n(E)$ term, the $\mu(E)$-containing term embodies the detailed form of energy-dependent scattering. The electron energy-filtering scheme aims at the $\mu(E)$-containing term.

The electron energy-filtering scheme ensures a higher α via filtering out those electrons with lower mean excess energy $<E-E_F>$; moreover, the reduction in σ is compensated by the increase in α, leading to a higher *PF*. More importantly, the stronger the energy dependence of scattering, the higher the *PF*, provided the mobility degradation is not large. With the relaxation time approximation [8], one may invoke the Matthiessen's rule to take into account the contribution from various energy-dependent scattering mechanisms:

$$\frac{1}{\tau} = \sum \frac{1}{\tau_i} \quad (4)$$

where τ_i is the relaxation time for the *ith* scattering channels and τ is the total relaxation time.

For *nonresonant* scattering mechanisms, it is customary to assume a power law $\tau(E) \sim E^r$; r is called the scattering parameter or the scattering exponent [8]. Specifically, $r = -1/2$ for electrons scattered by acoustic phonons, $r = 3/2$ for charged impurities, and $r = 0$ for charge neutral imperfections. These characteristic *nonresonant* scattering exponents are widely used in analyzing the mobility data to extract the dominant scattering mechanism. In view of Eq. 3, a larger magnitude of r, i.e., a stronger energy dependence, is thermoelectrically beneficial as long as μ is not degraded too much. In Pb or Ag nanoparticles embedded in a PbTe bulk host matrix, Nernst coefficient measurements showed that the scattering parameter r changed from $0.2 < r < 0.7$ to $r > 3$ upon nanocompositing, indicating an electron energy-filtering effect, though $r > 3$ doesn't correspond to any known scattering mechanism [9].

The scattering mechanism can be *resonant*. By *resonant* we mean the scattering is so strongly energy dependent and even diverging at specific energies that the aforementioned power law expression doesn't hold any longer. Though *resonant* scattering has several key advantages over *nonresonant* scattering, there are more restrictions and challenges in material chemistry to implement the *resonant scattering* mechanism than the *nonresonant* scattering mechanism. More discussion on the *resonant scattering* mechanism will be provided in section "Invisible Dopants" Mechanism.

The electron energy-filtering mechanism is often implemented on the interfaces. Nanostructured thermoelectric material is featured by a multitude of interfaces (grain boundaries); the interfacial effects will be more pronounced than conventional polycrystalline materials. To enhance the *PF*, interfaces must undertake multi-tier preferential scattering:

(i) Tier I: Interfaces should scatter phonons more effectively *than* electrons.
(ii) Tier II: Interfaces should scatter those carriers with lower mean excess energy more effectively *than* those with higher mean energy.
(iii) Tier III: Interfacial charged defects should scatter minority carriers more effectively *than* majority carriers.

"Invisible Dopants" Mechanism

The above discussion on the electron-filtering mechanism highlights the significance of energy-dependent scattering in thermoelectricity. In general, a stronger energy dependence tends to give rise to a higher α (cf. Eq. 3) and often a higher *PF*, provided the μ is not much degraded. Among the *nonresonant* scattering mechanisms, charged impurity scattering provides the strongest energy dependence $r = 3/2$; therefore, hetero-electron doping has been a prominent approach in thermoelectric material research for decades. However, one should note the *dual* role of such a hetero-electron dopant: it is an effective charge carrier donor and also a strong carrier scatterer. To mitigate this dilemma, people have developed

"modulation-doping" or "zonal-doping" method [10], in which the charge carriers are "separated" from the donors via, say, embedding heavily doped nanoparticles in a high-mobility host matrix and properly adjusting their band offset.

In this vein, attaining a high *PF* is thus broken down into specific tasks as (i) to introduce charge carriers, (ii) to maintain a strong energy dependence of scattering, and (iii) to minimize the mobility degradation. To this end, the resonance energy levels mechanism [11] has proved very effective in several bulk thermoelectric materials. The resonance energy levels induce narrow peak in $g(E)$ that centers at the resonant energy E_D and often adopts a Lorentzian line shape:

$$\tau_r(E) = \tau_0\left(1 + \left(\frac{E - E_D}{\Gamma/2}\right)^2\right) \qquad (5)$$

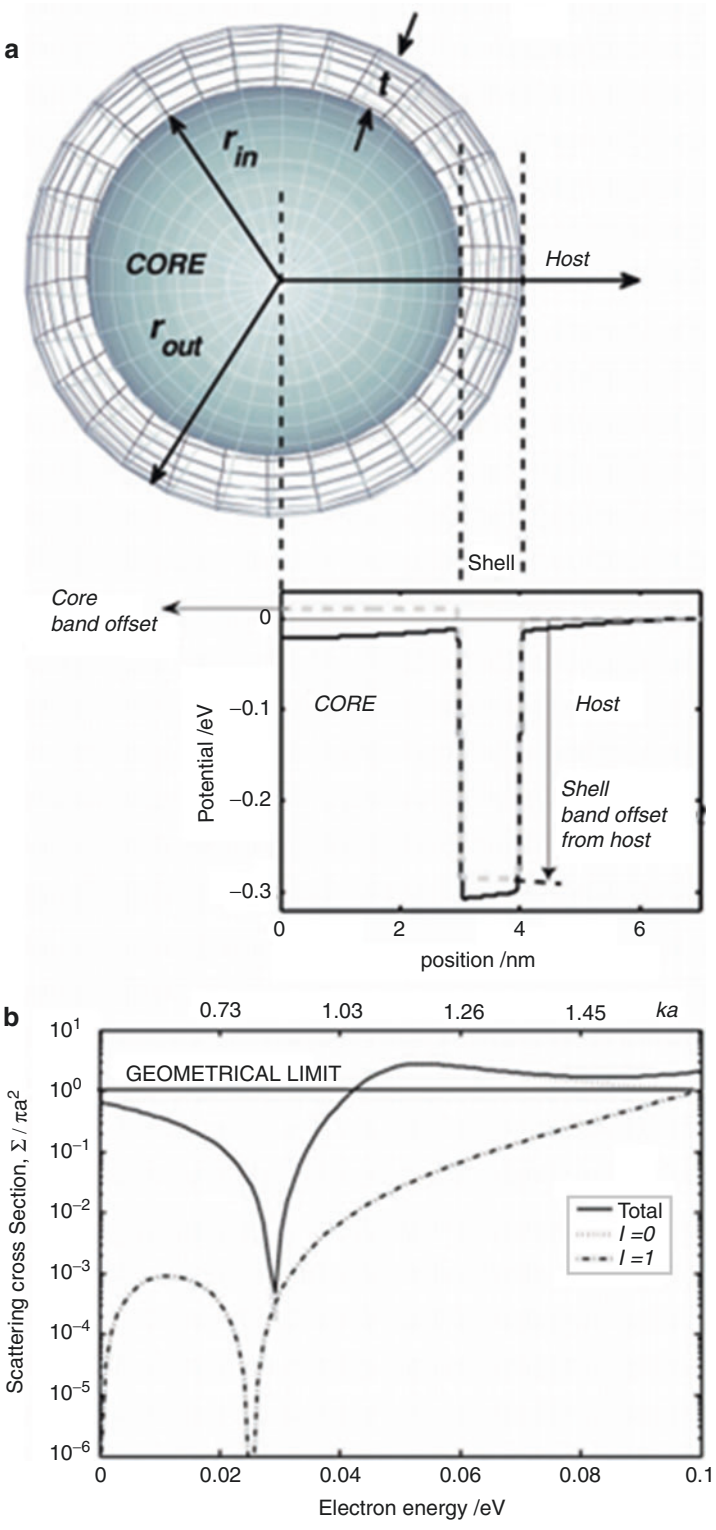
where τ_0 is the minimum value of $\tau_r(E)$ reached at E_D. Equation 5 can be incorporated into Eqs. 1 and 4 for in-depth data analysis.

Importantly, the resonant energy levels *not only* scatter charge carriers *but also* conduct current. This unique feature arises from the wave nature of electron. In quantum mechanical partial-wave analysis, the resonant scattering mechanism is described in terms of the phase angle shift δ_l of lth partial wave caused by a potential, where l is the orbital angular momentum quantum number [12]. Hence, *resonant scattering* mechanism is a "dephasing process."

The "invisible dopants" mechanism is also known as *antiresonant scattering* [13]. In an *antiresonant scattering* process, the phase angle shift is minimized by properly designing the potential profile. This interesting proposition by Zabarjadi et al. combines the *resonant scattering* mechanism and the modulation-doping method [10], thus easing the interdependence of the carrier concentration, the energy dependence of scattering. and the mobility.

The *invisible dopant* scheme is viable to be implemented in host matrix–nanoparticle composites. Specifically, the carrier-nanoparticle scattering cross section may exhibit a sharp dip (minimum) versus energy near E_F, making the nanoparticle *invisible* to conduction electrons. The most prominent consequence is that the mobility is retained, despite the numerous grain boundaries in nanostructured thermoelectric material. Second, the fast-varying scattering cross section with energy in the vicinity of E_F is favorable for a high α. One example of implementing the "invisible dopants" mechanism is to embed spherically symmetric core–shell particles of appropriate size, effective mass, and band offset inside a semiconductor host matrix (Fig. 1).

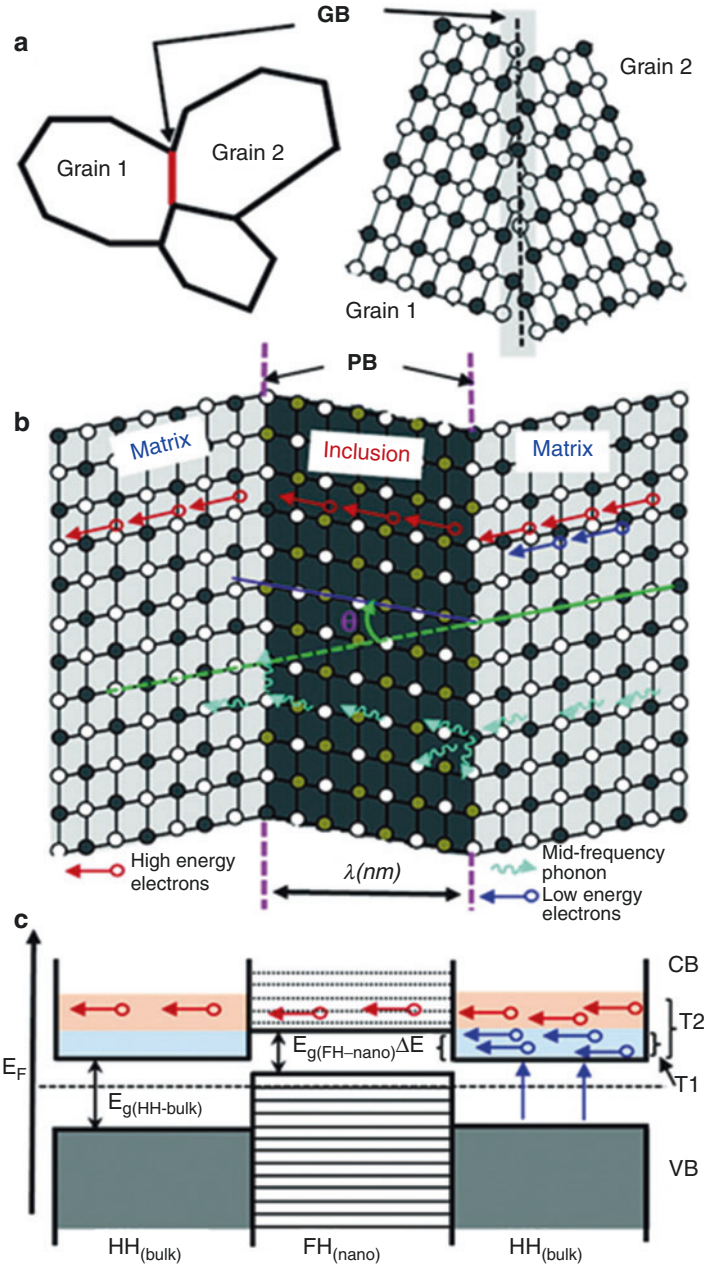
Several Examples



In this section, we will briefly introduce several state-of-the-art nanostructured thermoelectric materials, in which the *PF* is enhanced upon nanostructuring.

Half-Heusler-Based Nanostructured Thermoelectric Materials

Makongo et al. observed the simultaneous increases in the Seebeck coefficient and electrical conductivity of (Zr,Hf)NiSn half-Heusler compounds upon (Zr,Hf)Ni_2Sn full-Heusler nanoinclusions [14]. The 120 % enhancement of *PF* has been attributed to electron energy-filtering effect (Fig. 2). Xie et al. attributed an observed simultaneous improvement of *all* three thermoelectric properties of *p*-type Ti(Co,Fe)Sb-inSb nanocomposites to the combined interfacial effects [15].



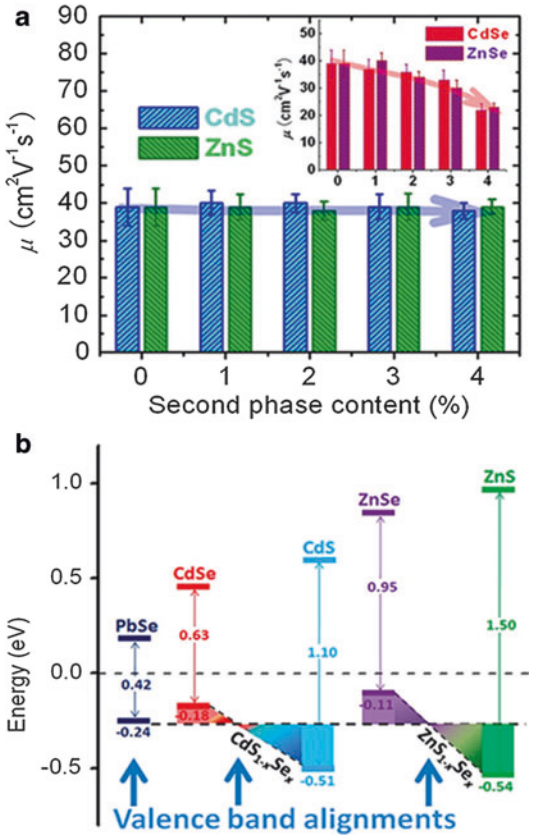
$CoSb_3$-Based Nanostructured Thermoelectric Materials

Tan et al. reported an improved *PF* and *ZT* in $CeFe_{4-x}Zn_xSb_{12}$-ZnSb nanocomposites [16]. Interestingly, the presence of ZnSb nanophase affects the crystal chemistry of the host matrix; Zn substitutionally dopes the Fe site, thus increasing the effective mass and the Seebeck coefficient. These results revealed an important aspect of those in situ formed nanostructured thermoelectric materials in which the crystal chemistry of the constituent phase is interdependent. While this constitutes a challenge in phase component control in sample synthesis, it provides a new layer of tunability in thermoelectric research.

Nanostructured Thermoelectric Materials, Fig. 1 (**a**) A core–shell structured spherical nanoparticle. The radial potential profile of the nanoparticle is plotted. The band offset profile across the core–shell nanoparticle is plotted with the dashed line and the screened bent potential with the *solid line*. (**b**) The total conduction electron–nanoparticle scattering cross section versus energy (*bottom scale*) or ka (*top scale*) is depicted with a *solid line. k* is the wave vector; a is the particle radius. The contribution of the zeroth order (*dashed line*) and the first order (*dotted line*) partial waves are displayed. The volume fraction of the nanoparticles is 1 %; the doping level is 5×10^{16} cm^{-3}, and this doping level corresponds to about 1 electron per nanoparticle (Taken from Ref. [13])

N

Nanostructured Thermoelectric Materials,
Fig. 2 Schematic illustration of atomic scale structural engineering that improves the thermoelectric performance of bulk HH matrices. (**a**) Incoherent grain boundaries (*GB*); (**b**) coherent phase boundaries (*PB*) between matrix and inclusion phases with similar structure, which allow close crystallographic registry between both regions; (**c**) heterojunction between bulk HH matrix and nm FH inclusion highlighting the electron energy-filtering mechanism. The conduction band offset, ΔE, is a critical parameter for simultaneous large increase in both Seebeck coefficient and electrical conductivity through filtering of low energy electrons. *Cyan* and *orange* color represents the distribution of low and high energy electrons at temperatures T1 and T2 (T2 > T1), respectively (Modified from Ref. [14])



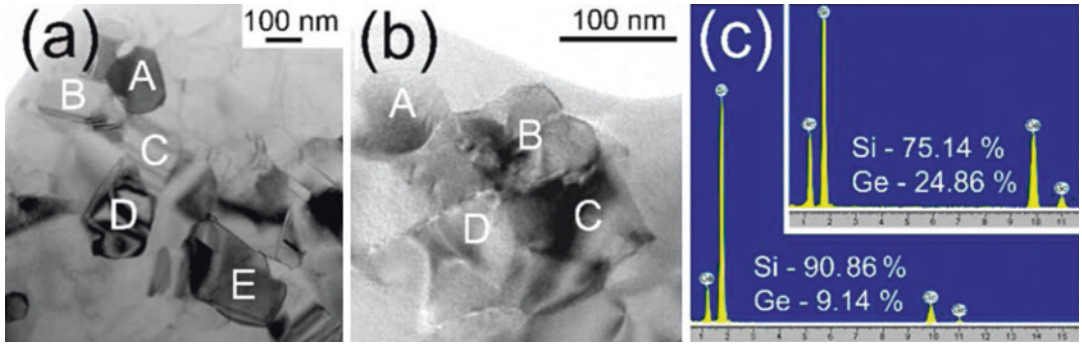
Bi_2Te_3-Based Nanostructured Thermoelectric Materials

Recent studies suggested that the interfacial charged defects *not only* tune the carrier concentration within the grain (and thus suppress the detrimental *bipolar* effect) *but also* act as potential barriers that scatter minority carriers more effectively than majority carriers. This was *inferred* from the observations in the ball-milled hot-pressed *p*-type Bi_2Te [17] and the chemically exfoliated spark-plasma-sintered *n*-type Bi_2Te_3 [18]. Concerning the effect on the electrical transport, interfacial charge defects are *not* a simple superposition of a charged point ("zero-

dimensional") defect and a charge neutral ("two-dimensional") grain boundary.

PbTe/PbSe-Based Nanostructured Thermoelectric Materials

Zhao et al. reported that the valence band alignment between PbSe and compositionally alloyed nanostructures of $CdS_{1-x}Se_x/ZnS_{1-x}Se_x$ plays an important role in the enhancement of *PF* (Fig. 3) [19]. A coherent or semi-coherent (epitaxial like, cf. Fig. 2) grain boundary is preferred to retain electrical properties, especially the mobility, while the total interfacial area per volume governs the lattice thermal conductivity [20].



Nanostructured Thermoelectric Materials, Fig. 3 Carrier mobility and valence band alignments of $Pb_{0.98}Na_{0.02}Se$ nanocomposites. (**a**) Carrier mobility as a function of nanophase content with a similar carrier concentration of $\sim 3 \times 10^{20}$ cm^{-3}, the impact of CdS and ZnS on the carrier mobility is negligible. (**b**) The density functional theory calculations show the band alignments of the conduction band (*CB*) and valence band (*VB*) energy levels for PbSe, CdS, CdSe, ZnS, and ZnSe. Notably, CdS_{1-x} Se_x and $ZnS_{1-x}Se_x$ solid solutions show an energy level "bridging" (Modified from Ref. [19])

SiGe-Based Nanostructured Thermoelectric Materials

Yu et al. implemented modulation doping to balance the carrier concentration and the mobility in SiGe-based nanocomposites; the resulting *PF* and *ZT* are significantly improved [10]. Figure 4 shows the TEM images and EDS spectra of modulation-doped sample with a 35 % nanoparticle molar fraction. Proper band alignment between the bulk matrix and the nanoparticles is crucial in implementing the modulation-doping scheme in a three-dimensional thermoelectric material as it ensures the carriers irreversibly flow from the nanoparticles into the bulk matrix. Importantly, the interfacial effects, say, dangling bonds, impurities, and trapped charges may lead to undesired effects on proper band alignment. The charge transfer between the bulk matrix and the nanophase makes them not the same phase as they stay separate.

Perspective Remarks

The recent progress in nanostructured thermoelectric materials has significantly increased the figure of merit. In a broader view and in the long run, the synergy of nanotechnology and traditional bulk thermoelectric materials will lead to more novel ideas and new material preparation/fabrication methods regarding the power factor enhancement. In the mean time, the progress in characterization techniques will allow for a better understanding of the charge and entropy flow and their interplay on the nanometer scale. In conjunction with the arsenal, we have accumulated over the past decade for suppressing the lattice thermal conductivity, this new knowledge will put thermoelectrics research in an unprecedented position to bring the performance of thermoelectric material and the range of thermoelectric application to the next level.

Introduction

Research on nanocarbons has been at the forefront over the past several decades and has unarguably contributed tremendously to the birth of the field of nanotechnology. These efforts include providing insights into the novel properties of carbon nanomaterials, development of large-area, wafer-scale synthesis techniques, design of new characterization tools for understanding the role of imperfections in these materials, and the development of processing methods to integrate these materials into novel device architectures. In particular, in the context of applications of interest to the electronics industry, carbon nanomaterials have been proposed as viable alternatives to traditional materials used in Si integrated-circuits (ICs), which includes their exploration in nanoscale transistors [1–6], interconnects [7, 8], field-emission displays [9], biosensors [10], heat-transporting assemblies [11], thermo-electric [12], photo-voltaic [13], and optical materials [14] platforms, as well as nano-electro-mechanical-systems (NEMS) [15–17] given their remarkable mechanical properties [18].

The origin of the extraordinary materials properties [19] prevalent in carbon-based nanomaterials arises from the structural arrangement of carbon atoms in the crystalline lattice. A diverse spectrum of allotropes is possible with these materials, which display a rich variety of physical properties. Even for the commonly known three-dimensional (3D) form of carbon, namely diamond and graphite, properties differ from the sp^3-bonded diamond to the sp^2-bonded graphene from which graphite is derived. A single layer of these carbon atoms in graphite results in the two-dimensional (2D) form of carbon, namely graphene, which is a honeycomb arrangement of carbon atoms. The lowest dimensional form of carbon, namely zero-dimensional (0D) buckyballs or buckminsterfullerene C_{60} spheres were discovered in 1985 by Smalley and coworkers [20], for which they received a Nobel Prize in chemistry in 1997.

When a 2D graphene sheet is rolled into a cylinder, a one-dimensional (1D) or quasi-1D form of carbon results, namely carbon nanotubes (CNTs). This 1D form of carbon has captured the interest of scientists and engineers for nearly two decades since its discovery in 1991 [21]. This first form of CNTs synthesized using an arc-discharge process was for multi-walled carbon nanotubes (MWCNTs). Two years later, another form of CNTs, namely single-walled carbon nanotubes (SWCNTs) [22], was discovered which is a single

rolled-up sheet of graphene having a typical diameter of 1–2 nm. MWCNTs consist of concentric cylinders that have an interlayer spacing of 0.3–0.4 nm and diameters that are at least an order of magnitude larger than SWCNTs, between 10 nm and 30 nm. When a 2D graphene sheet is patterned into strips, another 1D or quasi-1D form of carbon results, namely graphene nanoribbons (GNRs) [23]. An additional quasi-1D structure, carbon nanofibers (CNFs), comprise of graphene layers inclined to the central axis, commonly referred to as the fishbone or herringbone crystal structure.

Graphitic carbon nanomaterials, such as 0D fullerenes, 1D SWCNTs, quasi-1D MWCNTs and CNFs, and 3D graphite, are thus all derivatives of graphene's 2D honeycomb lattice. The sp^2-bonding of carbon atoms in graphitic carbon nanomaterials generally affords them exceptional materials properties, such as a high-charge-carrier mobility, high-thermal conductivity, and excellent mechanical flexibility, which make them attractive for a range of applications [24–27]. It is interesting to note that fullerenes – the lowest dimensional form of carbon nanomaterials – were the first to be discovered amongst the graphitic carbon nanomaterial family by Kroto et al. [20] in 1985, followed by carbon nanotubes in 1991 by Iijima [21], while graphene remained elusive until recently despite being the basis for the other forms of carbon nanomaterials.

Since the mechanical exfoliation of graphene in 2004 [28], there has been a surge in research for unveiling the remarkable properties of this single sheet of carbon atoms and applying these properties to a wide range of devices and technological applications. As early as 1962, Boehm et al. [29] reported on the synthesis of single and multilayer graphene through the reduction of graphene oxide, and this technique has gained renewed interest recently. In addition, graphene was also suggested to form on transition metals such as Pt (100) and Ni (111) by hydrocarbon dissociation [30–32] and by other techniques such as metal intercalation [33]. While these surface science investigations of graphene on metals [34] occurred several decades ago, the exploration of fundamental properties, such as the quantum hall effect and other interesting phenomena [35–37], as well as the ensuing applications of graphene, did not occur until after 2004, following the seminal experiments of Novoselov and Geim on mechanically exfoliated graphene that earned them the 2010 Nobel Prize in Physics.

Up until recently, two-dimensional (2D) atomic monolayers were presumed to generally exist only as parts of larger three-dimensional (3D) structures, such as epitaxially grown crystals on lattice-matched substrates [38]. The existence of free-standing graphene was dismissed for some time as not being thermodynamically stable by Landau [39] and then several decades later by Mermin [40]. At the same time, the electronic structure and properties of graphene were analyzed theoretically by Wallace as early as 1947 [41] who showed that a single sheet of sp^2-hybridized carbon would have a linear energy dispersion relation at the *K-point* of the Brillouin zone.

Due to its flexibility, strength, high conductivity, transparency, and low cost, graphene has been proposed for a number of applications reviewed recently [42], such as a replacement for indium tin oxide (ITO) [43]. It also appears attractive for organic light-emitting diodes (OLEDs) as well as displays, touch screens [44], and solar cells [45]. The large surface-area-to-volume ratio of graphene suggests it also has promise in ultracapacitor applications [46] or chemical sensors [47, 48], and coupled with its remarkable electronic properties it is a strong contender for next-generation electronic devices in nanoelectronics [49, 50]. Graphene and graphene-like materials have also been applied to composite materials applications [15, 51, 52].

In this entry, we present an overview of nanocarbon materials, focusing specifically on 1D CNTs, CNFs, and 2D graphene. In section "Nanocarbons for Optical Absorbers" of this entry, we will discuss the application of 1D CNTs for optical absorbers, and in section "Nanocarbons for NEMS,", the use of 1D CNFs and 2D graphene for NEMS is highlighted, specifically for resonator applications for mass and strain sensing.

Nanocarbons for Optical Absorbers

Nanomaterials for Optical Absorbers

The ability of nanomaterials to trap light effectively has important implications for their use in energy harnessing, optical blacks for radiometry, as well as detectors. A survey of a host of nanomaterials, such as CdSe nanocrystals [53], graphene [54], surface plasmon modes in metallic nanoparticles [55], reveals the promise such materials have in a wide range of optical applications. In this section, we describe another type of nanomaterial which is exceptional at trapping incoming light as a result of its unique physical structure. Such a structure is comprised of porous arrays of thin (10–15 nm diameter), vertically oriented MWCNTs. Interestingly, porosity in ordered nanostructures has been theoretically [56] shown to enhance optical absorption properties, which has also been verified experimentally in Si-based nanomaterials [57, 58], and similar conclusions have also been drawn from theoretical calculations made on low-density arrays of CNTs [59].

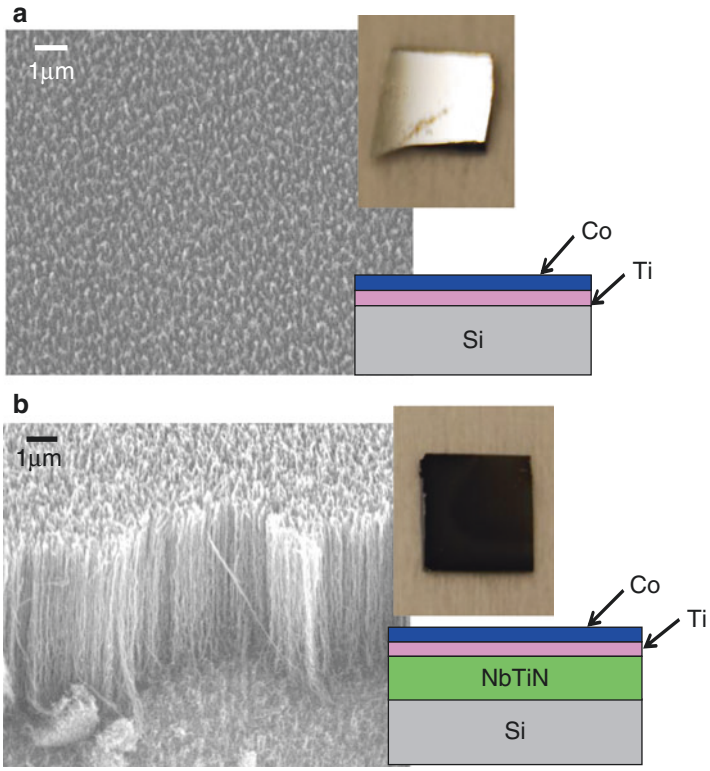
The CNTs synthesized here for the optical absorber applications suggest that the mechanism of transducing optical energy into thermal energy may be an attractive platform for using such absorbers in energy harnessing, high sensitivity thermal detectors, radiative cooling, thermography, antireflection coatings, and optical baffles to reduce scattering. In section "Synthesis and Optical Characterization," the synthesis and optical characterization of the absorbers are discussed, followed in section "High-Temperature Optical Performance" by the ruggedness of these absorbers when they are exposed to high temperatures.

Synthesis and Optical Characterization

Previously synthesized MWCNTs [60] and SWCNTs [61] for optical absorber applications used water-assisted thermal CVD [62], which yields exceptionally high growth rates with CNT lengths >100 μm; here alignment occurs primarily via the crowding effect [63, 64]. While thermal CVD is generally considered ineffective in aligning short CNTs (<10 μm), here we show that a glow discharge leads to vertically aligned CNTs with lengths more than an order of magnitude lower, which nonetheless still yield broadband, high-efficiency optical absorption characteristics in the ultraviolet (UV)-to-IR range. This vastly extends the previously reported measurements on MWCNTs that were conducted in the visible regime [61] to well into the IR regime where it is increasingly difficult to find suitable black and opaque coatings. A thin and yet highly absorbing coating with absorptance A is valuable for thermal detector applications in the IR, for radiometry in order to enhance sensitivity, since the detectivity $D^* \propto A$ [65], and there is also a concomitant reduction in the response time.

Besides the importance of vertical alignment in yielding highly absorbing materials, the other structural trait for enhancing optical absorption efficiency is a high site density. Unlike earlier reports where the CNTs were synthesized directly on Si or SiO_2 [60, 61], we demonstrate growth of high-efficiency MWCNT absorbers directly on metallic substrates with site densities as high as $\sim 4 \times 10^{11}/cm^2$. In many other applications, it is desirable to grow CNTs directly on metals for lowering contact resistance, but the challenges in stabilizing catalyst particles on metallic surfaces at high temperatures have generally reduced site densities of CNTs to manyfold (up to 100 X). In addition, prior attempts at growing MWCNTs for optical absorber applications on substrates other than Si, such as $LiNbO_3$, yielded an absorption efficiency of ~85 % from $\lambda \sim 600$ nm to 1800 nm [66], whereas the CNT absorbers synthesized here on metallic substrates are shown to have an absorption efficiency of >99.98 % from $\lambda \sim$ 350 nm to 2500 nm [67]. Even cermet-based materials, currently used for solar selective coatings on metallic substrates such as Cu and Al [68], have absorption efficiencies that are several orders of magnitude (up to 10^4X) lower than that reported in this entry. A plasma-based process increases the potential of forming these absorbers at lower synthesis temperatures compared to thermal CVD, increasing future prospects of integrating such absorbers with a wider range of materials such as low-cost flexible substrates for solar cells or with thermoelectrics, as well as fragile,

temperature-sensitive micro-machined structures for IR sensing.

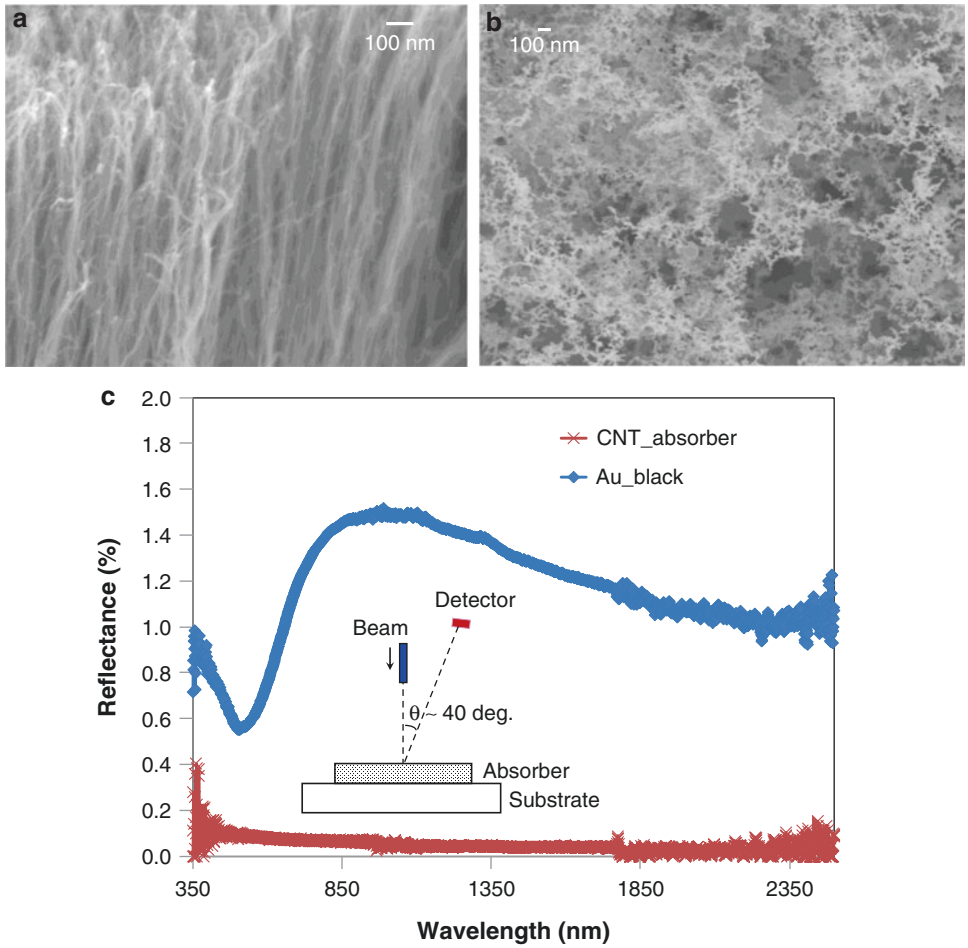


The initial substrate for the synthesis of the MWCNTs was a <100> oriented Si wafer on which a layer of 100–200 nm thick NbTiN – a refractory, high temperature conducting nitride – was deposited reactively in a N_2 and Ar ambient using dc magnetron sputtering at a power of ∼220 W and 5 mTorr. Bi-metallic layers of Co (thickness range, 0.6–6 nm) and 2.5 nm thick Ti were e-beam evaporated and served as the catalyst. Beside the Co/Ti/NbTiN/Si templates, control samples of Co/Ti/Si, Co/NbTiN/Si, and Co/Si were also prepared. Multiple samples (area ∼4 cm^2) were placed on a wafer during PECVD growth so that comparative analysis could be performed for different combinations of templates under similar synthesis conditions. At temperatures in the range of 550–750 °C, H_2 was flowed into the chamber for several minutes, and the growth gases acetylene (C_2H_2) and ammonia (NH_3) were then introduced to a typical pressure of ∼5 Torr, and the discharge was then ignited.

The choice of the template for PECVD synthesis of our MWCNTs was vital in synthesizing a high-density array of CNTs and directly impacts the optical absorption characteristics. For example, the scanning electron microscope (SEM) image in Fig. 1a shows amorphous carbon deposits when Co/Ti was placed directly on Si at 750 °C, exhibiting a largely reflective surface (inset of Fig. 1a). On the other hand, using a Co/Ti/NbTiN template yielded a visually black sample to the naked eye (inset of Fig. 1b), and the SEM image (Fig. 1b) depicts a high-density array of MWCNTs which traps incoming light and suppresses reflection. The lack of growth of MWCNTs on Co/Ti/Si templates (Fig. 1a) suggests that the presence of a refractory metallic nitride, such as NbTiN, is important in stabilizing the catalyst nanoparticle to prevent diffusion and alloying of the catalyst with the underlying Si at high temperatures. In addition, the density of MWCNTs in the absence of the Ti layer on the Co/NbTiN templates was low. It is speculated that the Ti may enable the Co to fragment into nanoparticles, similar to the role of Mo in the Co-Mo bi-metallic catalyst system [69]. The Ti-Co system also appears to incorporate a larger fraction of C compared to Co alone, enhancing CNT growth [70]. Besides being of interest as absorbers in solar photo-thermal applications, the high areal density of MWCNTs on reflective, low resistivity (∼110 μΩ-cm) metallic substrates may substantially reduce the CNT-to-substrate contact resistance.

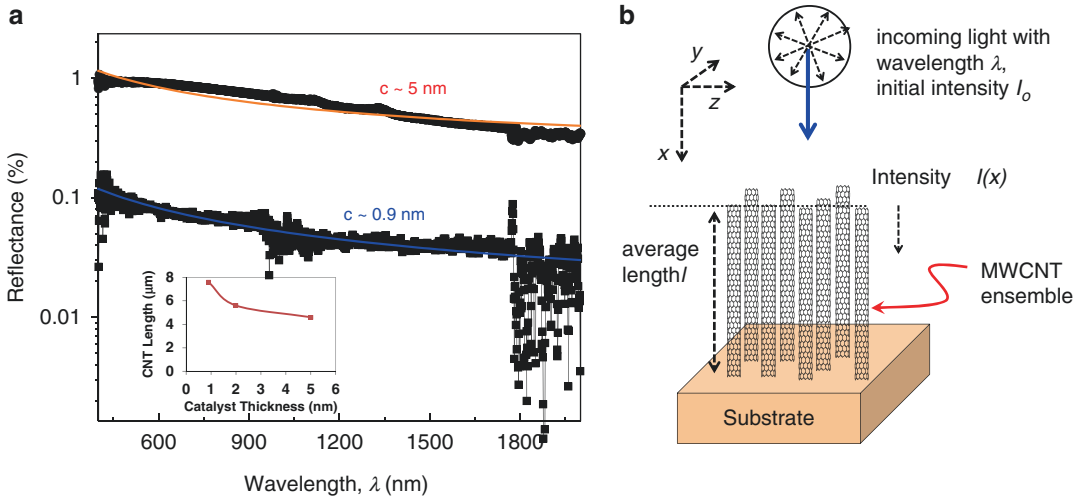
The high magnification image in Fig. 2a shows that the surface of the MWCNT arrays is rough, a factor which also contributes to scattering the incoming light diffusively. Shown in Fig. 2b is the SEM image of our benchmark, a Au-black absorber, which was synthesized using approaches similar to prior reports [71], where the percolated random network of such a diffuse metal-black should be apparent.

The optical measurements on the samples were conducted from $\lambda \sim 350$ nm to 2500 nm using a high resolution, fiber coupled, spectroradiometer (ASD inc, Fieldspec Pro) where a standard white light beam was focused at normal incidence to the sample, as shown by the schematic in the inset of Fig. 2c. The bare fiber connector of the spectroradiometer was oriented at ∼40° from the normal. Relative reflectance spectra were obtained by first white referencing the spectroradiometer to a 99.99 % reflective spectralon panel. The reflected light intensity from the sample was then measured, and the spectra compared for samples synthesized under different growth conditions.



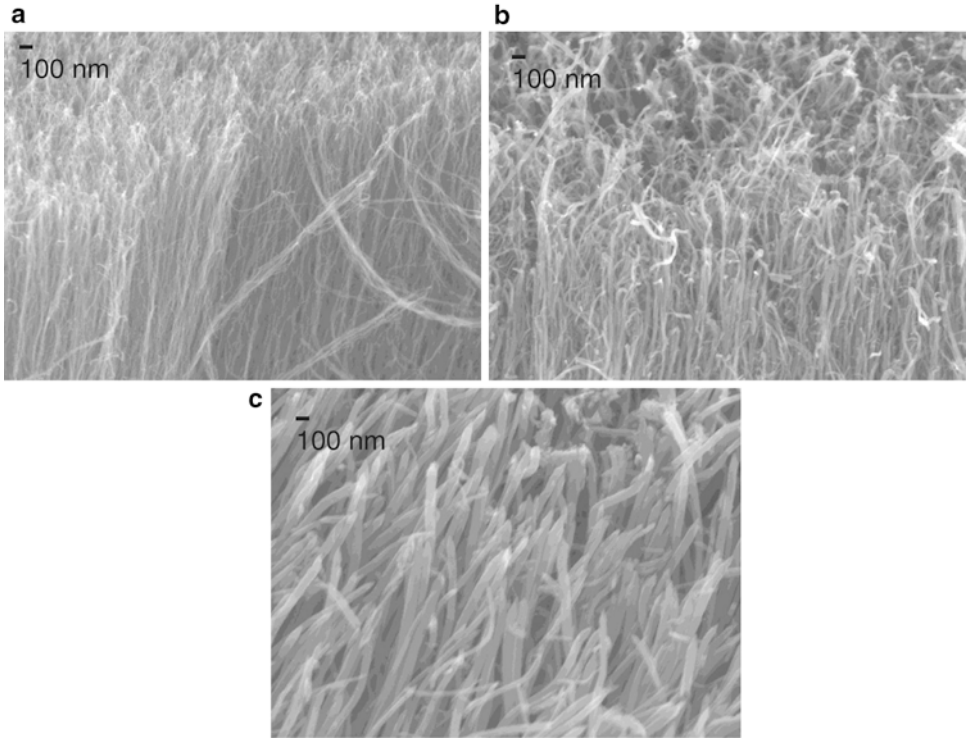
The optical reflectance response of the CNT absorber is shown in Fig. 2c, where the spectra are compared to the reference Au-black absorber. The reflectance R of the CNT absorber is nearly two orders of magnitude lower than that of the Au-black, e.g., ∼0.02 % at $\lambda \sim 2000$ nm compared to 1.1 % for Au-black. Other commonly used absorbers, such as NiP, have higher $R \sim 0.5$–1 % for $\lambda \sim 320$–2140 nm [72] while ultra-black NiP alloy has $R \sim 0.16$–0.18 % from $\lambda \sim 488$–1500 nm [73] and black paint has $R > 2.5$ % from $\lambda \sim 600$–1600 nm. Top-down synthesized Si nanotips exhibit $R \sim 0.09$ % at $\lambda \sim 1000$ nm [74], while bottom-up synthesized nanocone arrays have been reported to have an absorption efficiency of ∼ 93 % between $\lambda \sim 400$–650 nm [75].

Nanostructures and Characteristics of Carbon Nanofibers, Fig. 1 (**a**) SEM micrograph of a Co/Ti/Si sample after dc PECVD growth. *Top right inset* shows an optical image of the sample depicting a reflective surface. (**b**) SEM micrograph of a Co/Ti/NbTiN sample after growth, depicting a high density carpet of MWCNTs. *Top right inset* shows an optical image of the sample depicting a visually black sample to the naked eye. The spatial uniformity of the MWCNT ensembles is high over large length scales

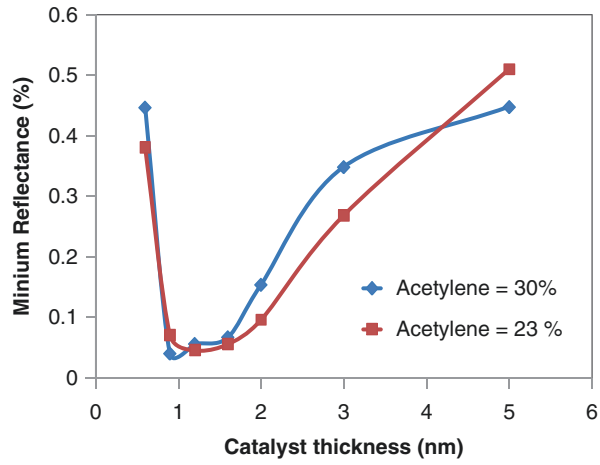


The catalyst thickness appears to be an important synthesis parameter that impacted the optical absorption efficiency in these carbon-based nanoabsorbers. Shown in Fig. 3a are reflectance spectra taken for two samples synthesized at Co catalyst thicknesses $c \sim 5$ nm and 0.9 nm (Ti thickness fixed at 2.5 nm). The sample with $c \sim 0.9$ nm has a wavelength independent response from $\lambda \sim 350$ nm – 2500 nm with R in the 0.02–0.03 % range. The sample with $c \sim 5$ nm, synthesized at identical conditions, has a wavelength dependent R which decreased from 0.94 % at $\lambda \sim 400$ nm to ~ 0.33 % at $\lambda \sim 2000$ nm.

Tentatively, the decreased reflectance/increased absorption may be expressed through an exponential decrease of the transmitted intensity $I(x)$ following a simple Lambert–Beer law formulation, i.e., $I(x) = I_o \, exp\,(-\alpha x)$, where I_o is the initial intensity of the incoming light and α is the absorption coefficient. The schematic in Fig. 3b shows the geometry of the optical interrogation, as the incoming light traverses through the sparse aerogel-like structure of CNTs with intensity $I(x)$ at any vertical location inside the CNT array. The typical absorption coefficient with $\alpha \sim 10^4$ cm^{-1} for $I(x = 8\ \mu m)$ is ~ 30 times the $I(x = 4.5\ \mu m)$. Now, the reflectance seems to decrease to the same order, i.e., on the average R drops from ~0.94 to ~0.03, ~30 times as well. The SEM images of the samples with $c \sim 0.9$ nm, 2 nm, and 5 nm are shown in Fig. 4a, b, and c, respectively. This yielded a MWCNT site density of $\sim 4 \times 10^{11}$/cm^2 with MWCNT diameters $d \sim 10$–15 nm for $c \sim 0.9$, and a site density of $\sim 6 \times 10^9$/cm^2 with $d \sim 80$-100 nm for $c \sim 5$ nm. Although the length l of the MWCNTs decreased as c increased (inset of Fig. 3a), with $c \sim 5$ nm, l was still >5 μm, well above λ in these measurements, suggesting that the reduced absorption from the thicker catalyst is likely a result of changes in the fill fraction. The ability to engineer optical absorption efficiency by controlling the catalyst thickness is an attractive feature in tuning the optical absorption properties of the MWCNT ensembles.



Nanostructures and Characteristics of Carbon Nanofibers, Fig. 2 (**a**) High magnification SEM image shows the porous, vertically aligned morphology of the CNT absorbers, in contrast to the reference benchmark Au-black absorber sample in (**b**) which depicts a percolated, randomly aligned network of fibers. SEMs taken at 30° viewing angle. (**c**) Reflectance measurement from $\lambda \sim$ 350–2500 nm for the MWCNT absorber and a Au-black absorber sample. The measurement setup is illustrated in the *bottom inset*. The Au-black reference sample has $R \sim$100 X larger where $R \sim 0.02$ % at $\lambda \sim 2000$ nm for the CNT sample compared to 1.1 % for the Au-black



A mechanism by which porous objects suppress reflection is through a reduction in the effective refractive index, n. However, porosity alone may not necessarily be the primary factor involved since the Au-black absorber samples, a largely porous structure (SEM in Fig. 2b), had higher reflectance compared to the MWCNT samples. This enhanced absorption may arise from the weak coupling of electrons in the vertically oriented CNTs to the incoming normally incident radiation, with minimal back scattering and enables light to propagate into the long pores within the arrays until it is finally absorbed. A phenomenological model for absorption was developed using a formulation where the ensembles are treated as a composite medium consisting of nanostructures and air. The intensity at any given point x in Fig. 2b is given by $I(x) = I_o \exp(-\alpha x)$, where $\alpha = \frac{4\pi\kappa}{\lambda}$ and κ is the extinction coefficient. Assuming that there is no effective transmission through the substrate, $R(x) \sim (I_o - I(x))$. The corresponding variation of R with λ was then fit to $\sim a_1 e^{a_2/\lambda} + a_3$ where a_1 is related to the incident intensity I_o, a_2 is a

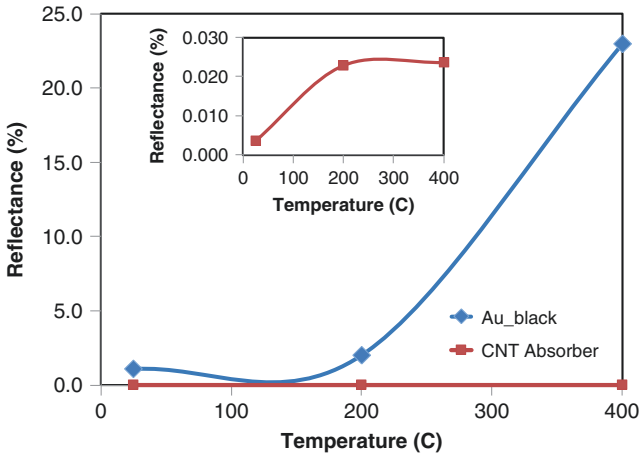
Nanostructures and Characteristics of Carbon Nanofibers, Fig. 3 (**a**) Optical reflectance spectra taken for two samples with $c \sim 0.9$ nm and 5 nm. The sample with $c \sim 5$ nm shows a wavelength dependent R. Inset shows the variation of l with c; superimposed in the reflectance versus wavelength data are theoretical fits from which the ratio of κ at $c \sim 0.9$ nm and 0.5 nm was determined. (**b**) The geometry used for the modeling analysis

Nanostructures and Characteristics of Carbon Nanofibers, Fig. 4 The morphology of the MWCNTs is depicted in (**a**), (**b**), and (**c**) for $c \sim 0.9$ nm, 2 nm, and 5 nm, respectively. In (**a**), thin, vertically aligned tubes are depicted that have a high fill fraction, with a site density of $\sim 4 \times 10^{11}/\text{cm}^2$ and MWCNT diameters ~10–15 nm, whereas in (**c**) the site density decreases to $\sim 6 \times 10^{9}/\text{cm}^2$ with MWCNT diameters ~80–100 nm

Nanostructures and Characteristics of Carbon Nanofibers, Fig. 5 The reflectance measurement as a function of c (taken at $\lambda \sim 1.5$ μm) for two acetylene gas ratios (30 % and 23 %). Growth conditions were: 750 ºC, 172 W of plasma power, 30 % C_2H_2, 5 Torr

measure of the optical absorption length ($=\kappa \cdot l$), and a_3 is a constant. The fit to the data is shown in Fig. 3a for $c \sim 0.9$ nm and 5 nm. From the fits, the value of a_2 was determined to be $\sim$ 0.025 and $\sim$0.026 for $c \sim 0.9$ nm and 5 nm, respectively, and given that the ratio, $\frac{(a_2)_{0.9}}{(a_2)_5} = \frac{(\kappa \cdot l)_{0.9}}{(\kappa \cdot l)_5}$ and that l is 8 μm and 5 μm, respectively, we obtain a ratio of the extinction coefficients, $\frac{\kappa_{0.9}}{\kappa_5}$ of $\sim$0.6.

It is interesting that the extinction ratio is smaller for the MWCNTs grown with $c \sim 0.9$ nm compared to the CNTs grown with $c \sim 5$ nm. This observation can be rationalized on the basis of a smaller area fraction in the former case, i.e., 0.31 versus 0.47. While such a rationalization does not explicitly consider the volume absorption due to a larger l in the former case (i.e., 8 μm vs. 5 μm), it is justified since it has previously been shown that for the case of absorption in Si nanowires [56], the absorption in a thin film over a wide energy range, comparable to the one used in the present work, is on the average equivalent to the absorption in the nanowires. The larger absolute magnitude of R for the sample with $c \sim 5$ nm compared to the sample with $c \sim 0.9$ nm may indicate an influence of the substrate in the latter, the effect of which is more pronounced due to a shorter l for $c \sim 5$ nm.



A more detailed analysis of the impact of catalyst thickness on the optical reflectance properties of the MWCNT absorbers was conducted for a wide range of catalyst thicknesses (Fig. 5). This data (at $\lambda \sim 1500$ nm) shows a minimum of R at $c \sim 1$ nm. However, R increases when $c \sim 0.6$ nm due to the inability to nucleate a high enough areal density of MWCNTs; such behavior was consistent for two different acetylene gas concentrations, as indicated in Fig. 5.

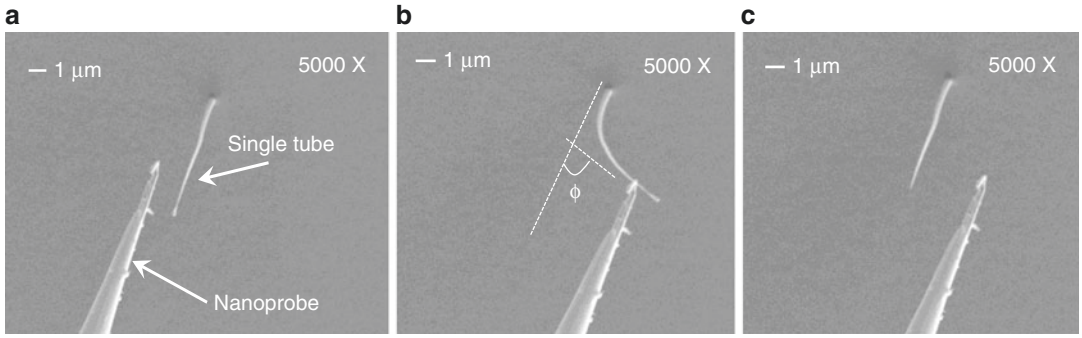
High-Temperature Optical Performance

We now present data which demonstrates the exceptionally low R of the MWCNT absorbers even after they were exposed to temperatures as high as 400 °C in air under an oxidizing environment, as might be expected with incident solar radiation. In comparison, the structural characteristics of the Au-black absorber reference gradually deteriorate with increasing temperature. However, the structural characteristics of the MWCNT absorber samples are largely unchanged when heated from 25 °C to 400 °C, as can be inferred from the data in Fig. 6.

From the optical spectra (Fig. 6), it is apparent that R of the Au-black absorber sample increases as it is heated from 25 °C to 200 °C (2 %) and is $\sim$23 % at 400 °C (at $\lambda \sim 2000$ nm). On the other hand, the R of the CNT absorbers is still very low ($\sim$0.022 %) after heating to 200 °C (inset Fig. 6) and remains unchanged after exposure to temperatures as high as 400 °C which can be correlated to the structural integrity of the CNT absorbers to temperatures as high as 400 °C.

In conclusion, we have successfully shown that, through catalyst engineering, PECVD synthesized MWCNTs yield a high site density on

Nanostructures and Characteristics of Carbon Nanofibers, Fig. 6 Optical reflectance measurements were made in the λ ∼ 350 nm–2500 nm range for the Au-black and CNT absorber samples at 25 ºC and after subjecting them to temperatures up to 400 ºC. Shown is *R* of the Au-black and CNT absorber samples as a function of temperature. The Au-black absorber shows *R* increases up to 23 % after heating to 400 ºC. The inset shows *R* of the CNT sample increases slightly after exposure to 200 ºC but it is still very low, ∼ 0.022 % at λ ∼ 2000 nm and remains unchanged after exposure to temperatures as high as ∼400 ºC



metallic substrates which exhibit ultra-low reflectance (∼0.02 %) over a wide spectral range from UV-to-IR for relatively thin (< 10 μm) absorber ensembles. Their highly efficient optical absorption properties and exceptional ruggedness at high temperatures suggest their promise in solar photothermal applications and IR thermal detectors for radiometry applications. In addition, the use of a plasma-based process increases the potential for synthesizing the absorbers at lower temperatures in the future, increasing the likelihood of integrating the absorbers with low-cost flexible substrates, potentially for solar-cell applications, as well as thermoelectrics and micro-machined structures for enabling new classes of IR sensors, particularly for rugged environments.

Besides the use of nanocarbons for optical absorbers, we now turn to their use as mechanical resonators for NEMS applications, as described in section "Nanocarbons for NEMS."

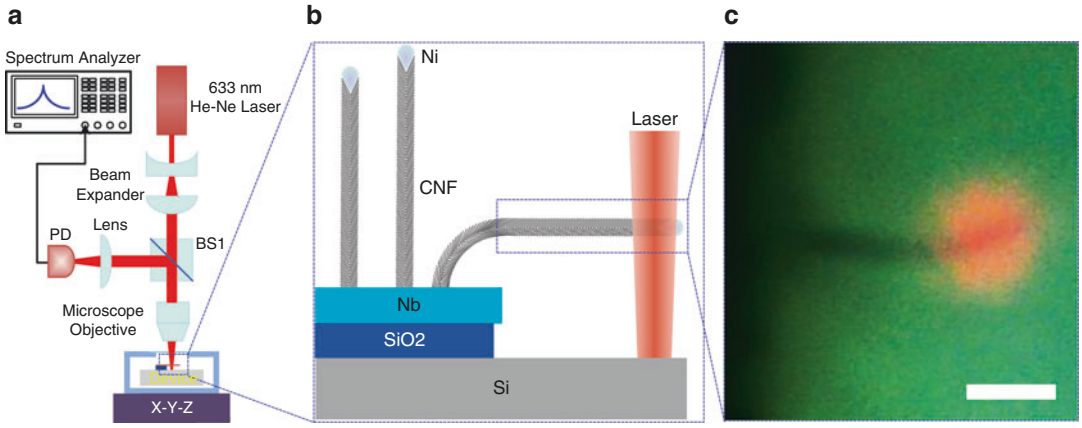
Nanocarbons for NEMS

Nano-electro-mechanical-systems (NEMS) are gaining increasing attention as viable alternatives for beyond-CMOS architectures, for enabling zero-leakage, ultralow-power, abrupt switching devices due to their inherently mechanical construction [76]. Such nanomechanical structures also offer advantages as electronic components operational in harsh environments, such as high radiation and high temperatures, in contrast to conventional solid-state devices which are more vulnerable to failure in hostile environments. In addition to their utility as potential beyond-CMOS switches, dynamical and resonant properties of NEMS have allowed these characteristics to be exploited for various sensing applications, such as mass sensing [77], force detection [78], and measurements in the quantum-mechanical regime [79].

While many materials have been explored for NEMS devices including conventional materials such as Si [80] and SiC [81], carbon-based materials have also been noted as another promising candidate for NEMS. Nanocarbons, such as graphene [82], CNTs [15, 83, 84], and CNFs [17, 85], exhibit ultralow density and an exceptionally high Young's modulus. Coupled with their high elasticity and mechanical resilience, nanocarbon materials appear to be ideally suited for enabling high-performance, high-longevity NEMS resonators. In section "Carbon Nanofiber

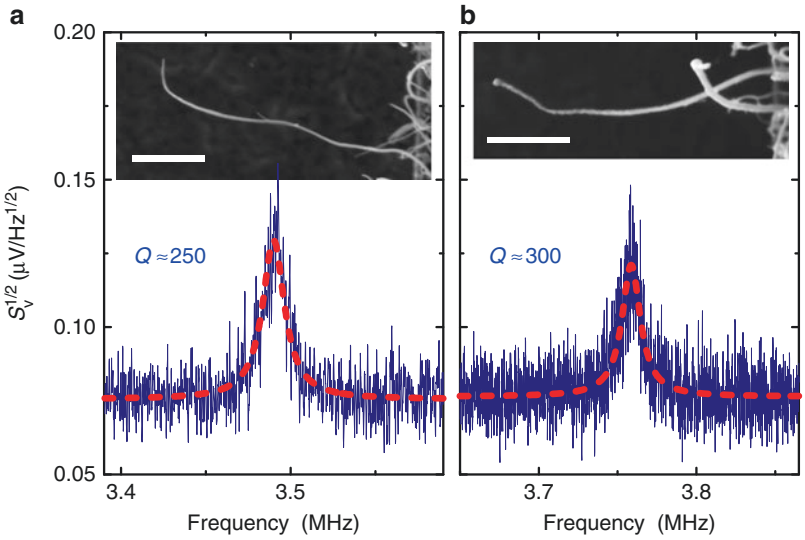
Nanostructures and Characteristics of Carbon Nanofibers, Fig. 7 (**a**) Bending test on a single CNF with a nanoprobe reveals that the CNF is extremely resilient and able to tolerate bending angles ϕ as large as 70° as shown in (**b**). The CNF returns elastically to its initial position as shown in (**c**)

(CNF)-Based NEMS Resonators," we discuss the application of quasi-1D CNFs for NEMS resonator applications, followed in section "Graphene-Based NEMS Resonators" with a discussion on the use in 2D graphene for NEMS.



Carbon Nanofiber (CNF)-Based NEMS Resonators

Our carbon nanofibers were synthesized using electric field assisted growth. Electric fields applied during CVD growth of nanotubes serve to preferentially orient them in the direction of the field [86] which has also been observed in the PECVD synthesis of MWCNTs and fibers [87, 88]. We have also applied the inherent E-fields present in plasma growth to develop processes for forming vertically aligned MWCNTs using dc PECVD, where a gas mixture of NH_3 and C_2H_2 were used at ~ 700 °C. A stable and uniform dc glow discharge results over an area as large as ~ 75 mm. The plasma is more intensely concentrated toward the base electrode as pressure is increased, and the self-charging voltage also saturates after the first few minutes of growth under constant current control.



The vertically oriented CNFs were synthesized with pre-patterned Ni catalyst islands. Catalyst islands in the 300 nm range were formed in between the electrodes using top-down wafer scale approaches. After the liftoff process of the e-beam evaporated catalyst islands, high purity acetylene (C_2H_2) and ammonia (NH_3) were introduced at 700 °C, which served as the carbon feedstock and diluent gas, respectively, for the bottom-up synthesis of the CNFs using dc PECVD. When the desired growth pressure had been attained (~ 5 Torr), the dc discharge was ignited at a power of ~200 W, and growth was carried out for a fixed duration to the desired length of the CNFs. The CNFs ranged in length from 1 μm to 10 μm.

Given that the CNFs synthesized here using PECVD are targeted for NEMS applications, it is important to gain some insights into their mechanical properties. In this regard, bending tests were conducted on individual CNFs using a nanoprobe inside an SEM. The nanoprobe was mechanically manipulated so that it physically deflected the CNF to the right, as shown in Fig. 7a. The CNF sustained bending angles ϕ as large as ϕ ~ 70° (Fig. 7b), and it then returned elastically to its initial position (Fig. 7c). The CNFs were able to tolerate such severe strains over tens of cycles without detachment from the substrate or fracture within the tube body, suggesting their mechanical resilience and elasticity are extremely attractive for NEMS applications.

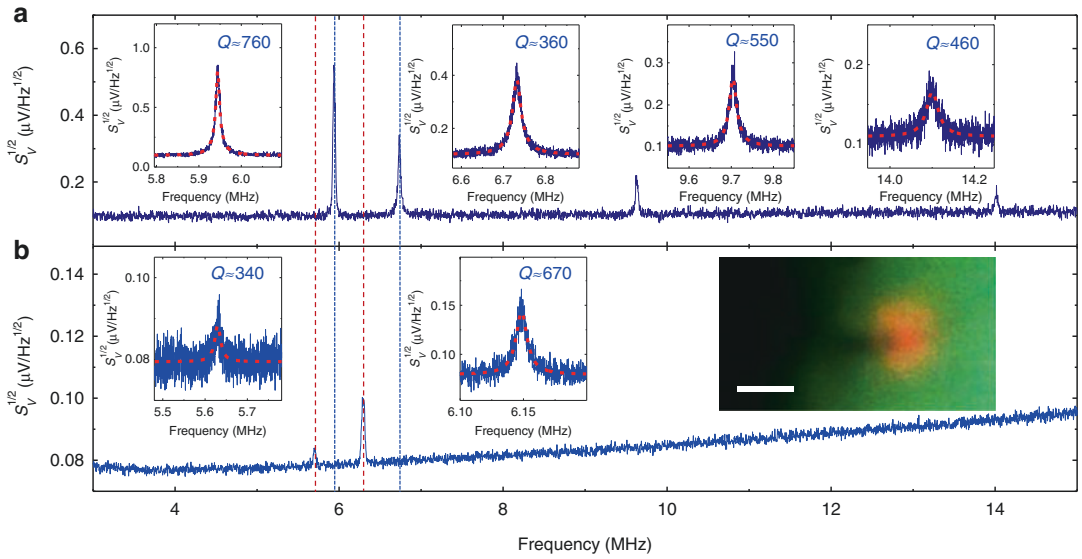
The resonance measurements are conducted using an optical interferometry setup as shown in Fig. 8, where a 633 nm He-Ne laser with a spot size of ~1 μm is focused on a single CNF inside a vacuum chamber equipped with an X-Y-Z stage. The X-Y-Z stage is manipulated so that the laser spot is placed precisely on the tip of the CNF, as shown by the schematic in Fig. 8b.

(**b**) A schematic illustration of a focused laser beam interrogating a single CNF. (**c**) An optical micrograph of a CNF under a laser spot focused near the tip of the CNF. Scale bar is 1 μm

Nanostructures and Characteristics of Carbon Nanofibers, Fig. 9 Resonances measured from two individual CNFs. Red dashed line shows fitting results for determining Q factors of the resonances. Insets are SEM images of the CNFs. Scale bars are 1 μm

Figure 8c depicts the optical microscope image of a single CNF captured within the focused laser spot. In prior measurements, high laser power was shown to melt and oxidize the Ni catalyst, leading to structural deformations in the CNFs [89]. It appears that at 500 μW, the laser power is low enough to prevent damage to the Ni catalyst and yet high enough to enable resonance measurements with high precision. As the reflected light from the CNF and the substrate interferes, the Brownian motion arising from fundamental thermal fluctuations in the CNF is detected by a photo detector, and the readout is captured by a spectrum analyzer that displays the fundamental thermo mechanical noise spectrum.

The undriven Brownian motion of a number of CNFs is recorded, with representative examples shown in Figs. 9a, b, where the top insets depict the corresponding scanning SEM images of the CNFs under consideration. The Q is extracted by fitting the measured thermo mechanical noise spectrum to a damped harmonic resonator model. Figure 9a exhibits a measured resonance at 3.490 MHz with Q of 250, while Fig. 9b shows



Nanostructures and Characteristics of Carbon Nanofibers, Fig. 10 SEM images of a CNF cantilever resonator showing the effects of electron beam induced carbon deposition on surface. (**a**) *Top view* SEM image before electron beam shower. (**b**) After ~15 min of 3 kV, 1.9 nA electron beam irradiation. Scale bar: 1 μm

a resonance frequency of 3.789 MHz with Q of 300. Most of the devices tested had CNF lengths and diameters in the range of $L \approx 2 - 6$ μm and $d \approx 40 - 100$ nm, respectively, and the corresponding fundamental mode of the resonance frequency was within $\sim 3 - 7$ MHz.

The resonance characteristics of the CNFs is examined before and after exposing the CNFs to electron radiation inside an SEM operated at relatively low acceleration voltage (3 kV), high current (1.9 nA), and long irradiation time. The electron beam inside an SEM can easily react with residual organic material in the SEM chamber and deposit amorphous carbon on the surface of the CNFs. This is clearly visible from the SEM images in Fig. 10, which shows the CNF to be apparently thicker after electron beam exposure (Fig. 10b) compared to before exposure (Fig. 10a).

Figure 11 shows the measured multimode resonance response from this single CNF before any electron beam treatment in the SEM, with four distinct resonance modes detected in the $5 - 15$ MHz range, with Qs of $360 - 760$. After irradiation of the CNF with the electron beam, the resonance response is immediately measured again. As shown in Fig. 11b, the first 2 major resonance peaks, originally at 5.94 MHz and 6.73 MHz, shift down to lower frequencies at 5.63 MHz and 6.15 MHz, respectively, with noticeable changes in Q factors. In addition, the signal amplitudes are lowered, and the two initially higher frequency resonances at 9.70 MHz and 14.10 MHz are no longer present after the electron beam shower. The disappearance of the 3rd and 4th modes can also be explained on the basis of carbon deposition which makes those peaks less responsive to optical detection.

The above results indicate that our 1D CNF NEMS devices encounter a reduction in resonance frequency due to electron beam irradiation induced amorphous carbon deposition on the surface. Based on measured frequency shift of the lowest resonance mode, the added mass can be calculated by using $\delta M/M \approx 2\delta f_0/f_0$, where, δM, M, δf_0, and f_0 are the added mass, total mass of resonator, added mass induced frequency shift, and initial resonance frequency of the device, respectively. Given the measured resonance frequency shift of the fundamental mode in Fig. 11b, we estimate the deposited mass on the CNF surface to be $\delta M \approx 4.4$ fg, while the CNF's own mass is $M \approx 41.5$ fg. Being able to have response to this ~5.2 % frequency shift due to ~10.6 % loaded mass suggests that the CNFs have exciting prospects for enabling robust adsorption-based mass sensors with very wide dynamic range.

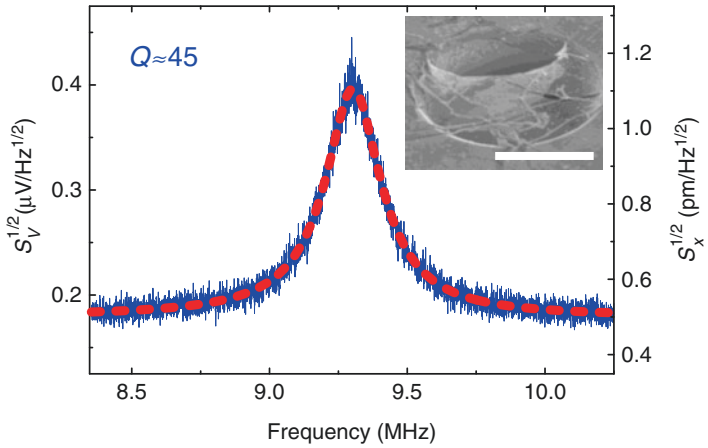
Graphene-Based NEMS Resonators

Just like carbon's other low dimensionality – 0D and 1D structures – 2D graphene exhibits very interesting properties. Electrons in graphene interact with the honeycomb lattice in a remarkable way which leads to unique electron transport properties. Graphene's charge carriers are referred to as massless Dirac fermions, where the electrons move relativistically at speeds of $\sim 10^6$ ms^{-1} instead of 3×10^8 ms^{-1}. These unique physical attributes make graphene a remarkable platform in which to also examine relativistic and interesting low-dimensional physics effects, besides the obvious potential it has for technological applications. The massless carriers and minimal scattering over micron size crystallites result in quantum mechanical effects that can survive even at room temperature. Graphene also exhibits ballistic room-temperature electron mobility of 2.5×10^5 $cm^2/V\text{-}s$ [90], the ability to carry ultra-high current densities $\sim 10^9$ A/cm^2 [91], an ultra-high Young's modulus of 1 TPa with a breaking strength of ~40 N/m [92] and excellent elasticity for accommodating strains of up to 20 % without breaking, a very high thermal conductivity of ~5000 W/m-K [93, 94], and optical absorption of 2.3 % [54]. Graphene also appears to be an excellent barrier for gases [95].

In work conducted here, we have explored the potential of graphene for enabling 2D NEMS resonators. The 2D graphene resonators were fabricated by transferring monolayer CVD grown graphene to lithographically pre-patterned microtrenches. While the transfer of graphene from metal growth substrates has become common practice for laboratory device fabrication, more work is necessary to achieve reproducibility and address issues of defect introduction. As an example, when clean interfaces are achieved between two transferred graphene layers, hybridized properties emerge that open new scientific and technological opportunities. It is also critical to grow graphene directly on high-quality dielectrics such as hexagonal boron nitride (h-BN), which is free of dangling bonds and charge in homogeneities, unlike SiO_2. This is crucial in order to maintain graphene's high charge carrier mobility and, in this regard, all future heterostructure architectures with active graphene elements.



Nanostructures and Characteristics of Carbon Nanofibers, Fig. 12 CVD graphene on different substrates. (**a**) An optical microscope image of CVD graphene on Cu foil. Different sizes of Cu grains exhibit different surface morphologies. (**b**) Transferred CVD graphene on 290 nm-thick SiO_2 on Si substrate. Graphene is continuous over entire optical images. (**c**) A prospective view SEM image of suspended graphene on circular microtrenches, demonstrating drumhead graphene resonators

Nonetheless, although polycrystalline CVD graphene consists of various defects such as grains boundaries arising from initial growth and through transfer to other substrates, the mechanical properties of CVD grown graphene are comparable to that of mechanically exfoliated monocrystalline graphene [96]. In addition to the excellent mechanical properties, polycrystalline CVD graphene can be grown over large areas on copper (Cu) foil, facilitating the fabrication of large suspended structures through transfer techniques to pre-patterned microtrenches. In contrast, achieving such large suspended structures with mechanically exfoliated, monocrystalline graphene has been a significant challenge. CVD growth of graphene is performed by using a one-inch (1″-diameter) quartz tube furnace. Before growth, Cu foil is carefully cleaned with acetic acid to remove the native Cu oxide and the foil is then annealed at 1000 °C for 3 h in hydrogen (H_2) to remove any residual oxide; this anneal also allows for the small Cu grains to merge to form larger grains that serve as growth templates for graphene. Figure 12a shows an optical microscope image of graphene on Cu foil, showing the smooth surface of merged large Cu grains during the annealing process. Graphene is then synthesized using H_2 and methane (CH_4) gases at 1000 °C for 5 min. During the growth, we flow 100 sccm of CH_4 with 20 sccm of H_2 and at a pressure of 10 Torr. After growth, we perform Raman spectroscopy to characterize the CVD grown graphene. From Raman results, our CVD graphene has very high uniformity and high quality [97]. CVD graphene is then transferred to pre-patterned microtrenches to fabricate graphene resonators by using conventional wet transfer processes. Figure 12 demonstrates examples of transferred graphene onto (b) SiO2 substrates and (b) suspended over an array of microtrenches to yield drumhead resonators.

The resonance characteristics of circular drumhead CVD graphene resonators are measured by using an optical interferometry system, similar to the schematic shown in Fig. 8a. Figure 13 shows an example of the measured thermo mechanical noise spectrum from a drumhead graphene resonator. Thermo mechanical noise at resonance is given by $S_{x,th}{}^{1/2}(\omega_m) = (4k_BTQ/\omega_m{}^3M_{eff})^{1/2}$, where T, ω_m, k_B, Q, and M_{eff} are temperature, angular resonance frequency, the Boltzmann's constant, Q factor, and the device effective mass, respectively. From this equation, the calculated Brownian motion of the device at room temperature is $S_{x,th}{}^{1/2}(\omega_m) = 0.98$ pm/Hz$^{1/2}$ and responsivity and sensitivity of interferometry system with the graphene resonator are $\Re = S_{v,th}{}^{1/2}/S_{x,th}{}^{1/2} = 0.358$ μV/pm and $S_{x,sys}{}^{1/2} = 0.49$ pm/Hz$^{1/2}$, respectively.

The measured resonance characteristics provide precise mechanical properties of graphene. By using the drumhead membrane resonator model, $f_0 = 2.4048(\gamma/\rho t)^{1/2}/\pi d$, where, d, γ, ρ, and t are diameter, tension (N/m), density, and

Nanostructures and Characteristics of Carbon Nanofibers, Fig. 13 Measured thermo mechanical resonance response of a monolayer CVD graphene resonator. *Inset* shows an SEM image. Scale bar is 5 μm

thickness of the resonators, respectively, and the estimated tension in the resonator is $\gamma \sim 0.01$ N/m (strain of 3×10^{-5}), demonstrating the unique capability of measuring ultra small strain levels in a 2D NEMS platform.

Conclusions

In summary, we have successfully shown that dc PECVD synthesized MWCNTs exhibit ultra-low reflectance properties over a wide spectral range from UV-to-IR for relatively thin (<10 μm) absorber ensembles. The structural characteristics of the MWCNT absorbers were engineered by controlling the bottom-up synthesis parameters during PECVD which enabled optimization of the optical properties of the nanoabsorbers. Such vertically oriented nanocarbon aero-gel structures were also found to be extremely rugged, withstanding temperatures of up to 400C, without showing signs of any significant degradation in optical properties.

We also demonstrate 1D CNFs and 2D resonant NEMS derived from nanocarbon materials, where the resonance frequency and the quality (Q) factor of the devices are measured experimentally using ultrasensitive optical interferometry. The 1D nanocarbon resonators are formed using CNFs which are prototyped into few-μm-long cantilever-shaped 1D resonators, where the resonance frequency and Qs are extracted from measurements of the undriven thermo mechanical noise spectrum. The thermo mechanical noise measurements yield resonances in the $\sim 3 - 15$ MHz range, with Q of $\sim 200 - 800$. Significant changes in resonance characteristics were observed as a result of electron beam induced amorphous carbon deposition on the CNFs, which suggests that 1D CNF resonators have strong prospects for ultrasensitive mass detection. We also presented results on NEMS resonators based on 2D graphene nanomembranes, which exhibit robust undriven thermo mechanical resonances for the extraction of ultra small strain levels.

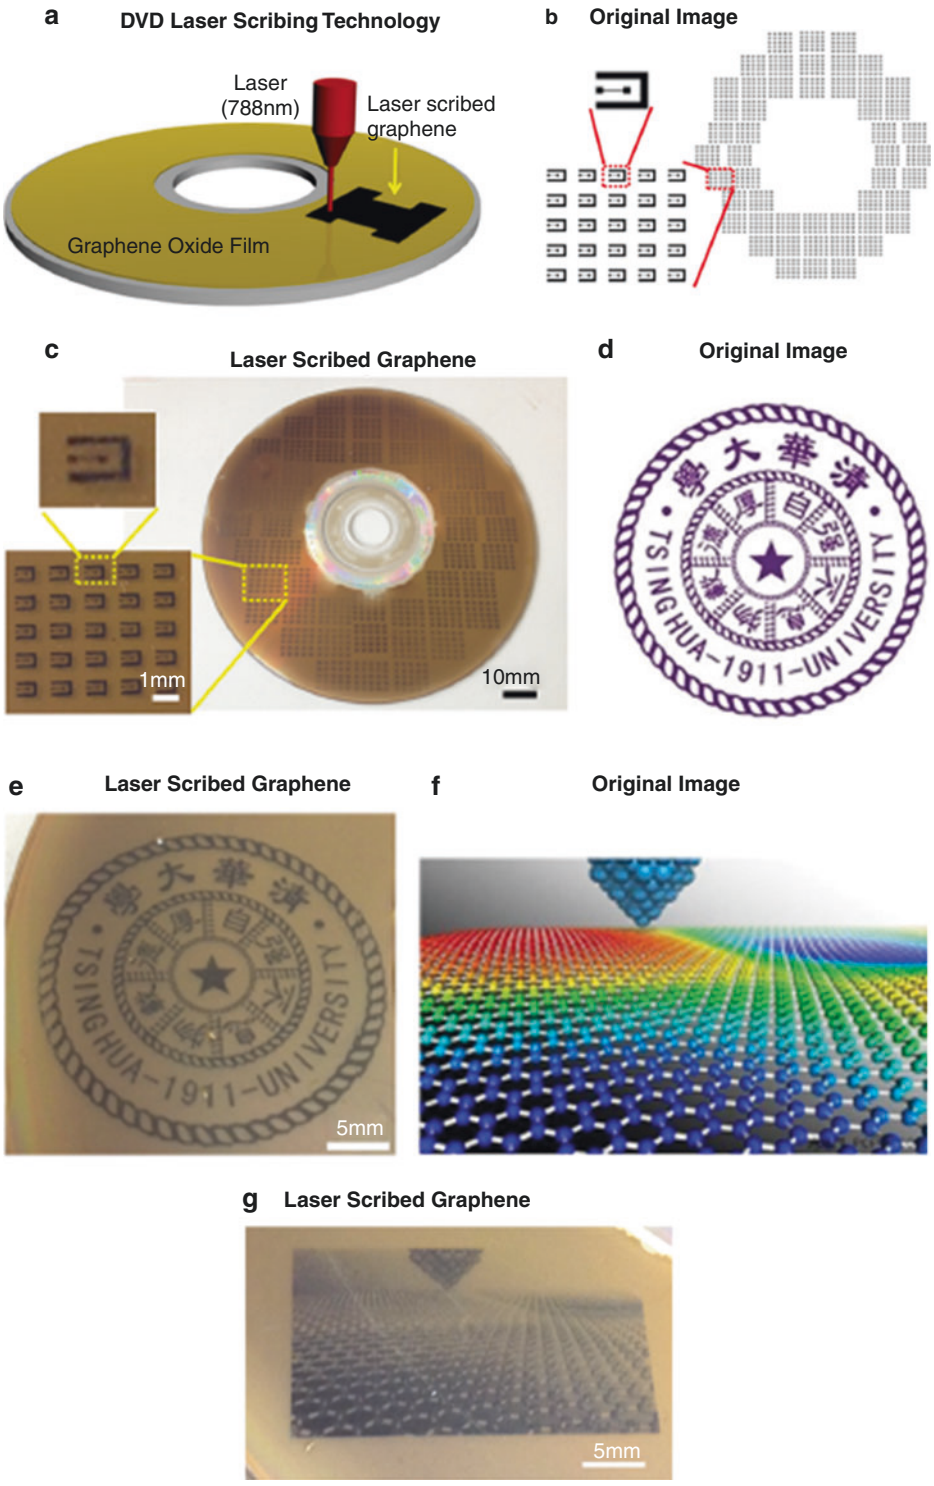
Definition

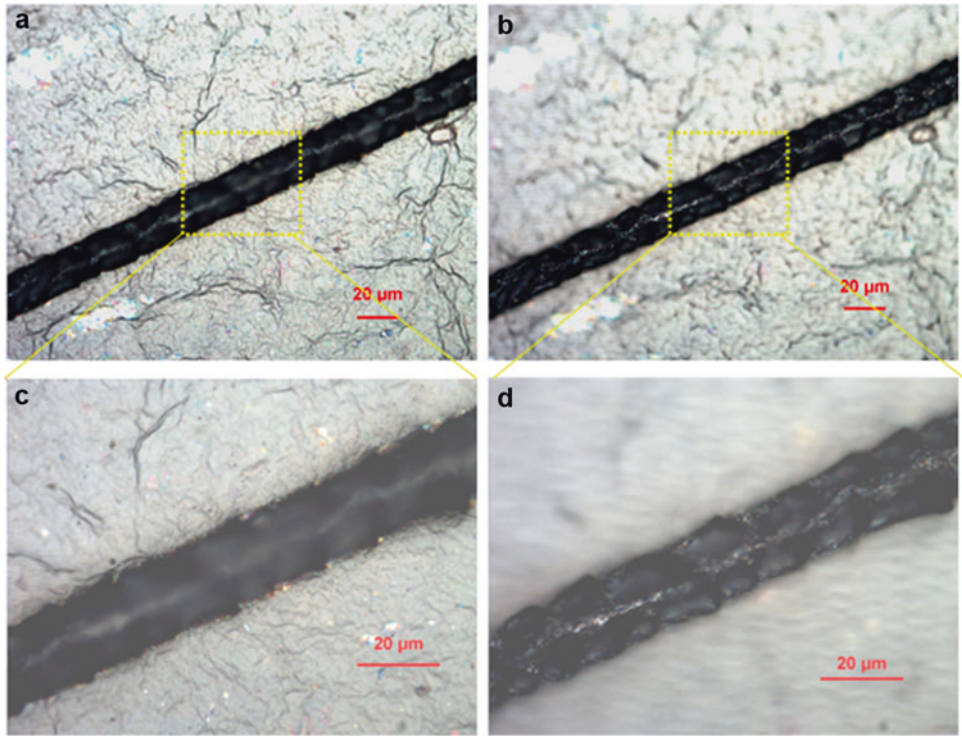
The laser scribing technology is the method via which the graphene oxide could be converted into reduced graphene oxide by the laser from the LightScribe DVD driver on specific pattern precisely.

Background



Large-scale graphene film has been prepared by chemical method at low cost. The graphene oxide (GO) dispersion could be obtained by the Hummers method [1], and it could be used to prepare the graphene oxide film via various ways [2] such as spin coating, spray coating, and vacuum filtration. Ultimately, the graphene film could be obtained by reduction. Since there would be some oxygen functional groups left in the film after reduction, it is also called the reduced graphene oxide (rGO) film. The large-scale GO film prepared via vacuum filtration method was firstly reported by Eda, G., et al. (Fig. 1), which revealed the application potential of rGO in transparent electrodes and transistors [3].

Though large-scale graphene film could be obtained by various methods, the laser scribe method [4, 5] was raised to achieve the precise pattern of graphene, which had never been realized before. The graphene pattern could be obtained by single-step laser scribing simply and cost-effectively, even on flexible substrates.



The laser (wavelength 788 nm, power 5 mW) in the LightScribe DVD driver could reduce the GO to rGO (Fig. 2a). And the laser could be controlled by software and transfer the input

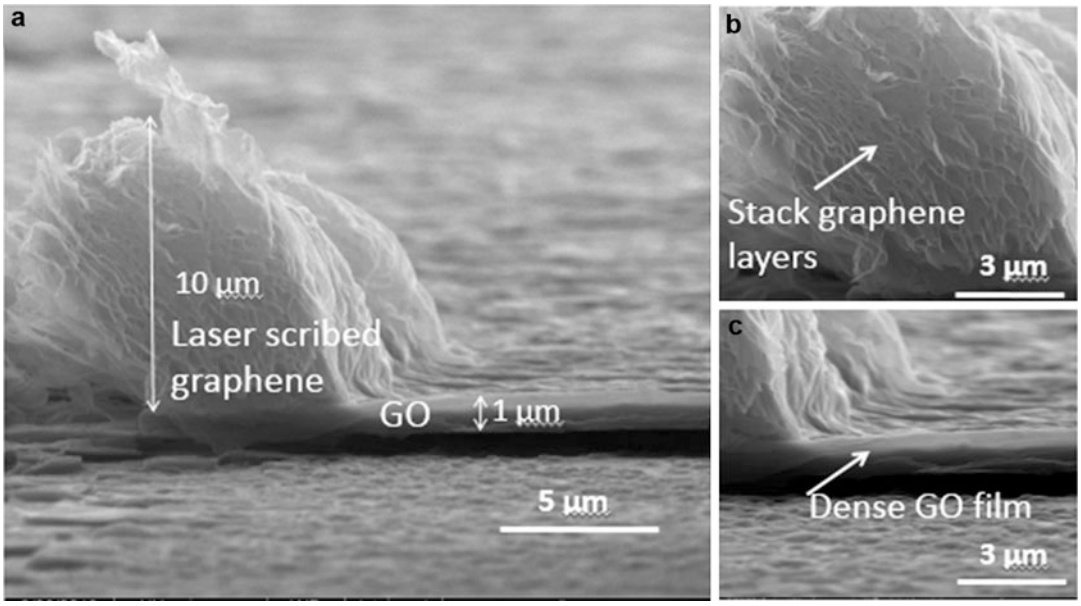
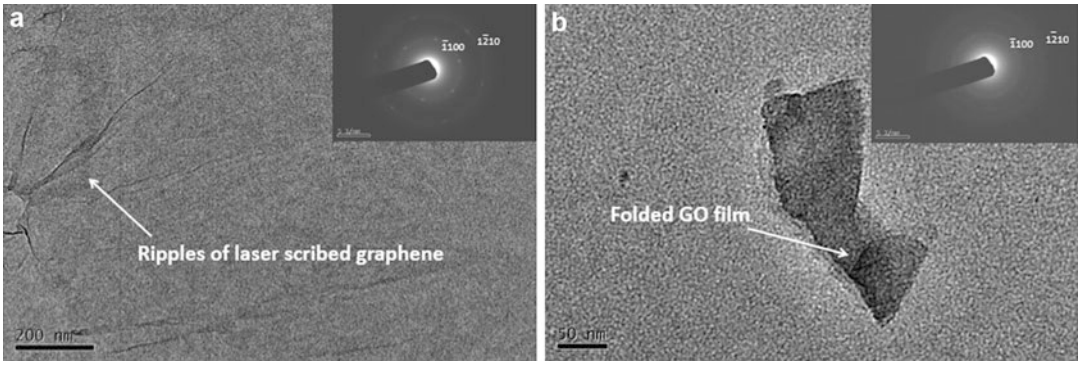
image to graphene pattern. The in-plane transistor design is shown in Fig. 2b, and it could be revealed on the graphene film in ~25 min by laser scribing. The golden film in Fig. 2c is graphene oxide and the black part is multilayer graphene. Complicated graphs could be also converted into graphene patterns, such as the Tsinghua logo shown in Fig. 2d–e. And a colored picture could be converted into grayscale graphene pattern (Fig. 2f–g), in which the grayscale corresponds with the degree of reduction.



Characterization of Laser-Scribed Graphene

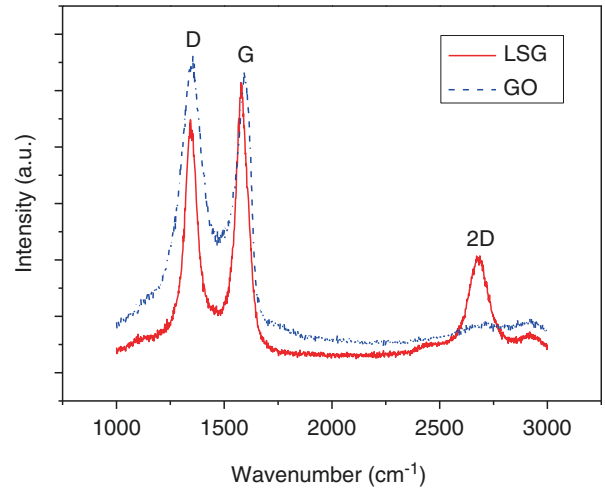
The spot size of the laser, which we used here is 20 μm, determines the precision of the laser-scribed graphene. And it could be observed under a microscope that the laser-scribed graphene consists of long micro-ribbon (Fig. 3). Figure 3a–b is the optical image of laser-scribed



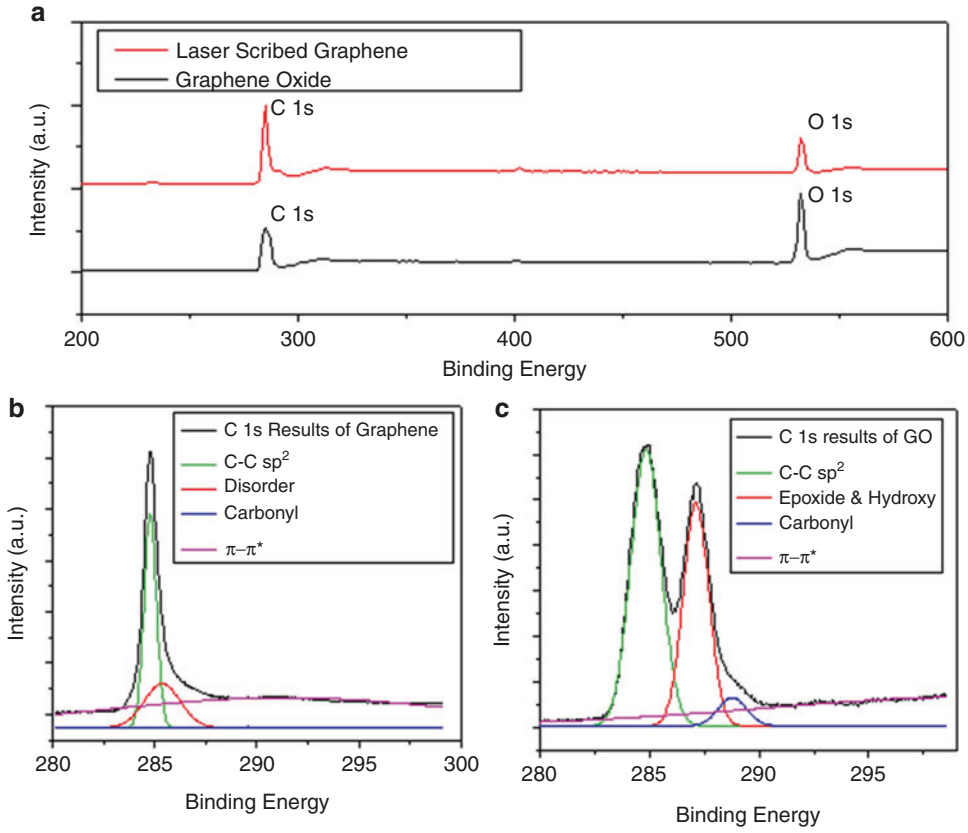
Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 4 The colored SEM image of laser-scribed graphene micro-ribbon (Figure reproduced with permission from Ref. [7], Nature Publishing Group)

graphene micro-ribbon under low magnification. In high-light conditions, the GO is white and the rGO is black. Increasing the magnification, a white line in the center of rGO micro-ribbon

Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 5 The lateral view of the laser-scribed graphene 3D structure (Figure reproduced with permission from Ref. [6], Nature Publishing Group)

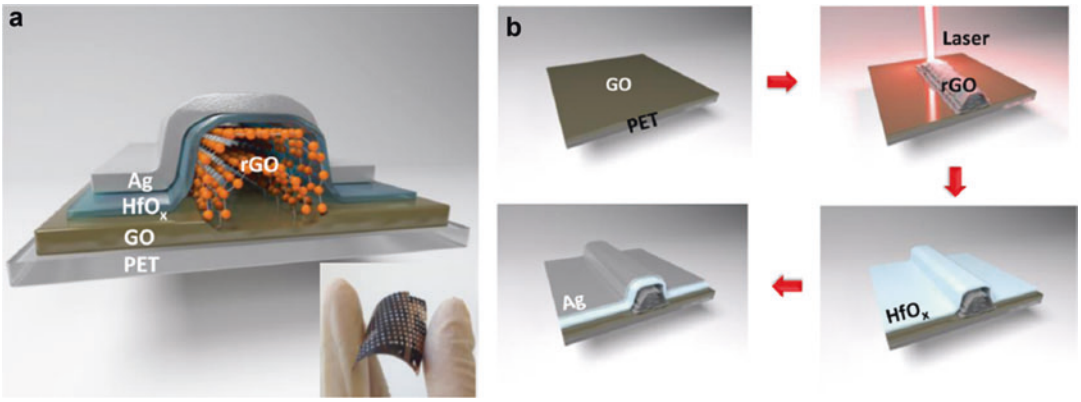


Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 6 The TEM image of (**a**) the laser-scribed graphene and (**b**) GO (Figure reproduced with permission from Ref. [6], Nature Publishing Group)



could be observed. Remarkably, different focus planes of GO and rGO, which are clearly shown in Fig. 3c–d, suggest the 3D structure of laser-scribed graphene micro-ribbon.

The colored SEM image of laser-scribed graphene reveals the 3D structure more clearly. The red part in the image is GO and the yellow one is rGO. The contrast of light and shade in the image of rGO ribbon indicates the valley in the center and the elevation on the two sides, which resemble the foam structure (Fig. 4).



The structural change of graphene before and after the laser scribing is shown in Fig. 5. The thickness of the laser-scribed graphene is 10 μm, which is 10 times bigger than that of the original GO film. It could be observed in the magnified image that the rGO is comprised of loose stacked graphene layers and the GO film is made of dense

layers. On the contrary, the thickness of the graphene film would decrease after traditional thermal reduction, which results from the loss of oxygen functional groups. However, the high-energy laser beam would convert the oxygen functional groups into the gas containing oxygen, which finally leads to the loose structure of rGO.

The diffraction pattern of the laser-scribed graphene (Fig. 6a) vindicates the hexagonal cellular lattice of graphene. On the contrary, the absence of crystal lattice in the diffraction pattern of the stacked GO film (Fig. 6b) indicates the broken lattice structure of GO, which results from the lattice defects due to the existence of oxygen functional groups.

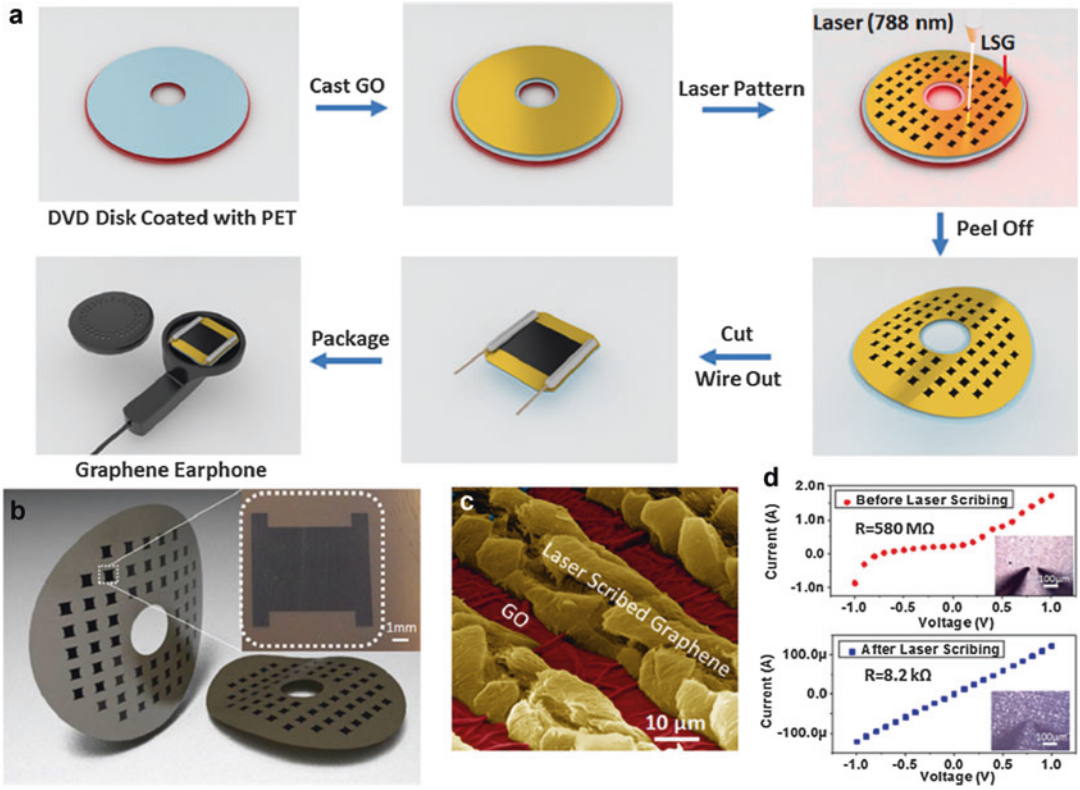
The change of the lattice structure could be also revealed in the Raman spectrum (Fig. 7). The decrease of the D peak intensity suggests that part of the C-C bonds were repaired after the laser

Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 11 The working principle of the graphene RRAM (Figure reproduced with permission from Ref. [8], American Chemical Society)

scribing. However, since there are still some defects left in the laser-scribed graphene, the D peak remains obvious. Besides, the left shift of the G peak indicates that the doping level of graphene decreased after the reduction, resulting from the removal of oxygen. And the appearance of obvious 2D peak after the laser scribing indicates the stacked multilayer graphene generated after reduction.

The component of the laser-scribed graphene is shown in the XPS spectrum (Fig. 8). The oxygen peak decreased obviously after the reduction. And the peaks of C-C sp^2 bond and π bond are enhanced.

Application



Graphene Resistive Random Access Memory

Using the laser scribing technology, the flexible graphene RRAM [8] with the structure like FinFET (Fig. 9a) could increase the robustness of the device.

As shown in Fig. 9b, the GO dispersion was firstly spin coated on the flexible PET substrates, and the GO could be converted into rGO in the specific location. Then, the HfO_x and the top electrode are deposited consequently.

The excellent performance of the flexible graphene RRAM is clearly shown in Fig. 10, including the forming-free feature (Fig. 10a), repeatability (Fig. 10b), multivalued feature (Fig. 10c), uniformity (Fig. 10d), feasible resistance window (Fig. 10e), and stability (Fig. 10f).

The working principle of the graphene RRAM could be revealed by the temperature characteristic analysis. When temperature rises, the increase of the resistance indicates that the conductive filaments are made of silver. Keeping an increasing temperature, some silver filament would

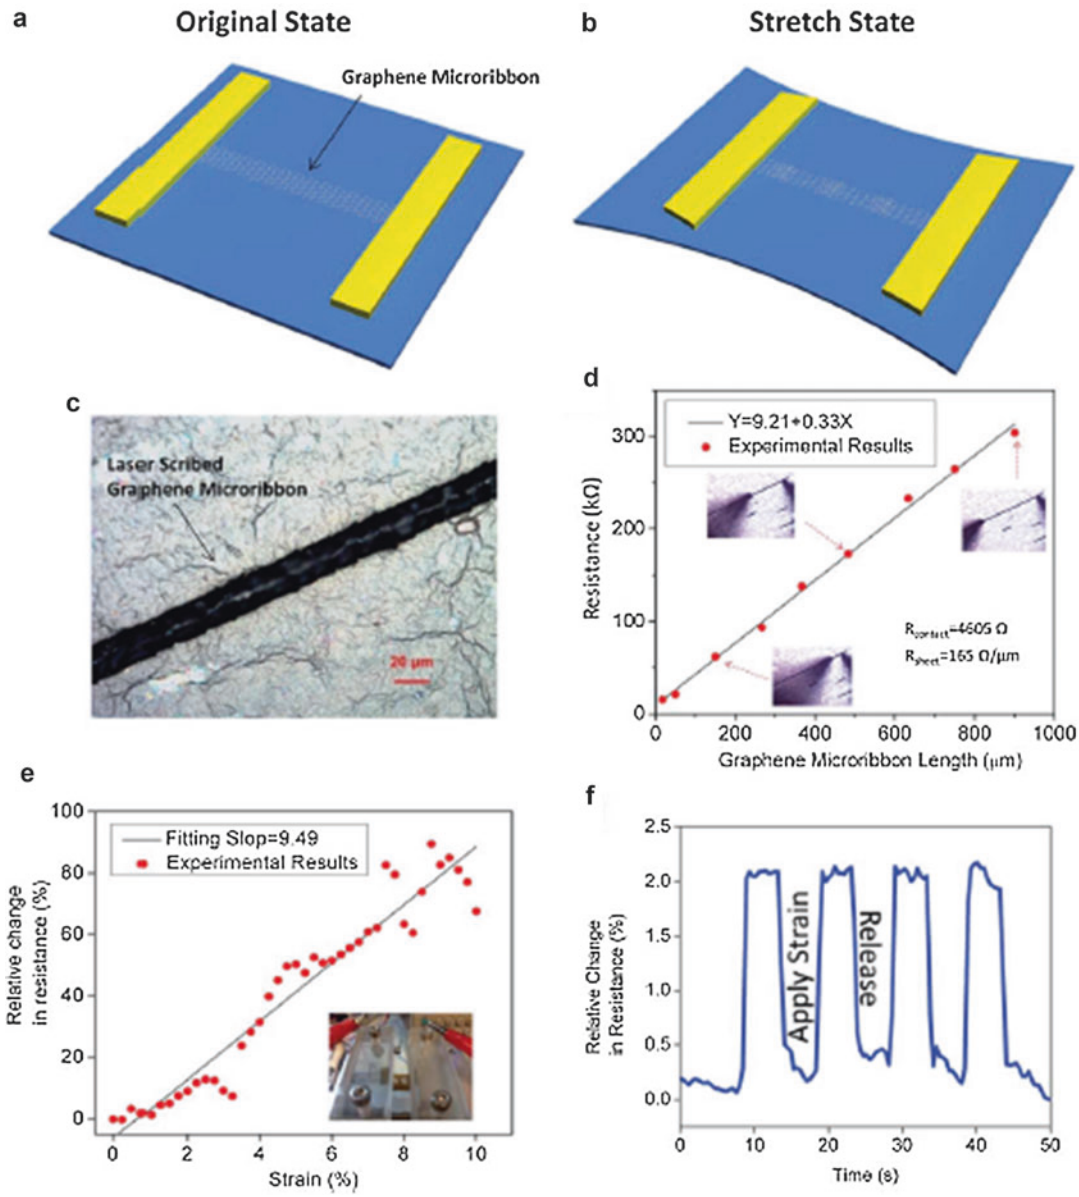
transfer to silver ions, leading to the increase of the resistance. As the silver ions increase, which are also conductive, the resistance would fall again (Fig. 11).

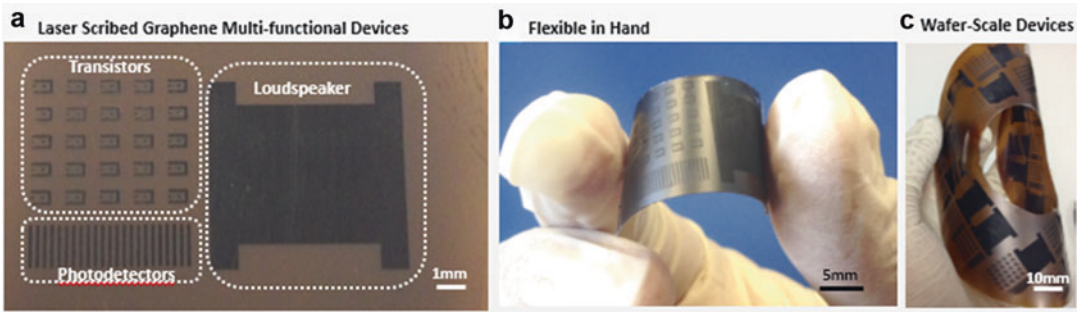
The working principle could be confirmed by the electrical measurement. The threshold voltage is only 0.5 V when the top electrode is silver. But for the device with Pt top



Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 16 Graphene strain sensor (Figure reproduced with permission from Ref. [10], The Royal Society of Chemistry)

electrodes, the threshold voltage is 2 V, which suggests that the breakdown voltage of the HfO_x is 2 V. Therefore, the HfO_x could not be broken through under 0.5 V to form the oxygen filament, which vindicates that the filament consists of silver.

Graphene Earphone



The flexible graphene earphone [9] could be fabricated based on the laser scribing technology. Compared to traditional earphones, the graphene earphone has the characteristics of flexibility and ultralow thickness.

Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 17 Test results of the graphene strain sensor (Figure reproduced with permission from Ref. [10], The Royal Society of Chemistry)

With the laser scribing technology, the graphene sound source array could be fabricated on the PET substrate (Fig. 12a–b). The sound source was wired out and packaged into commercial earphone case (Fig. 13). The I-V curve indicates the good conductivity of the graphene device.

The acoustic properties of the graphene earphone are tested on the measurement system shown in Fig. 14a. And the test result, the sound press level frequency spectrum, indicates that the response of the graphene earphone is flatter than that of commercial earphones, especially in the ultrasonic band. Moreover, the frequency

Nanostructures and Characteristics of Graphene and Graphene Oxides, Fig. 18 Wafer-scale graphene device integration (Figure reproduced with permission from Ref. [6], Nature Publishing Group)

spectrum of the graphene earphone could cover not only the audibility band (from 20 Hz to 20 kHz for human being) but also the ultrasonic band (from 20 kHz to 50 kHz), which is the audibility zone for some animals. It means that the graphene earphone could be the tool for inter-species communication, of which the example is shown in Fig. 14. The 35 kHz acoustic signal is conveyed to the dog via graphene earphones, and the dog stood up as soon as the signal is delivered (Fig. 15).

Graphene Strain Sensor

Strain sensors are widely used in various areas, but most of them are based on the rigid substrates, which limit the sensitivity of the sensor. Based on the laser scribing technology, the flexible graphene strain sensor [10] is achieved with the greatly enhanced sensitivity.

The pattern of the graphene strain sensor array could be fabricated on the GO film via the laser scribing technology on the flexible PET substrates with low cost and high speed (Fig. 16). The laser-scribed graphene is made of loose stacked graphene layers, which could greatly enhance the sensitivity of the graphene strain sensor.

The test results of the graphene strain sensor are shown in Fig. 17. The sheet resistance was observed while stretching the sensor. The sensitivity calculated from the data is 9.49, and Fig. 17f indicated the rapid response of the graphene strain sensor.

Wafer-Scale Graphene Devices Integration

Since a variety of graphene devices could be easily patterned on the GO film via the laser scribing technology, it is possible to integrate multifunctional graphene devices [6] on a whole wafer (Fig. 18). As shown in Fig. 18a, the graphene transistor, photodetector, and loudspeaker were fabricated on the same chip. And the substrates could be even flexible (Fig. 18b). The fabrication process of a whole wafer could be finished in 25 min.

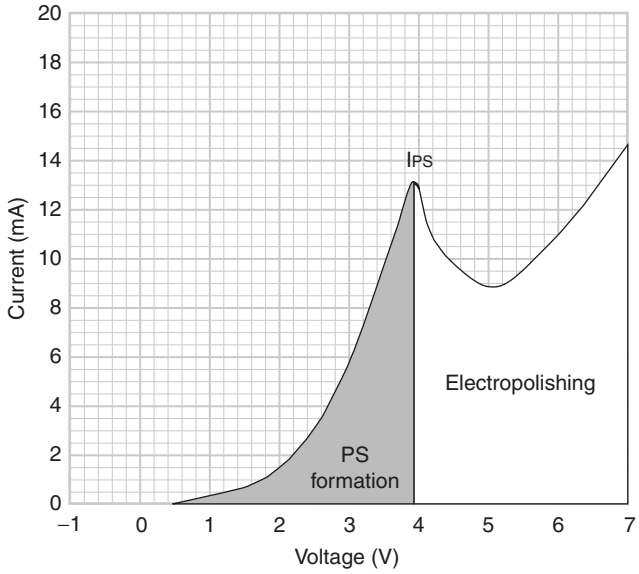
Definition

The term porous silicon (or, the more general, porous semiconductor) has been and is largely used to define a class of semiconducting material in which pores are opened, basically by means of electrochemical or chemical processes. According to the present definition (and to IUPAC), three different material types are identified, say, nanoporous, mesoporous, or macroporous. The important point is that these types are defined according to the dimension of the pores, instead of the residual structures.

In practice, a correlation between pore diameters and structure sizes is found, e.g., ensembles of macropores and nanostructures are found very seldom, and are the product of more complicated technological steps, not the simple (electro)chemical etching.



The term porous silicon has been extended in the past to define some kinds of disordered arrays of silicon nanowires. This extended definition does not keep into account for some regular macroporous structures obtained by means of electrochemical etching coupled with photolithography. Moreover, disorder is a typical consequence for the (electro) chemical processes employed, and cannot be considered as distinctive for the material. In other words, nanostructured arrays can be produced in many different ways, not only (electro) chemical ones, and ordered (electro) chemical etching is in principle possible.

Overview

Historical Notes

Porous silicon (PS) was accidentally discovered by Arthur and Ingenborg Uhlir at the Bell Labs, in 1956, in the framework of a research work on silicon and germanium electropolishing. If the electropolishing current was not reached for the electrochemical etching of the silicon wafer, instead of a clean and polished surface, a brown or black layer appeared, due to a nonuniform dissolution of silicon atom (see Fig. 1). The material is porous, full of fine holes, and the electropolishing regime is reached only at the pore tips in these conditions. This former evidence of PS was published in the Bell Lab's technical notes [1] and the study of this system abandoned until the 1970s–1980s, when the huge specific surface of the material, of the order of hundreds of square meters per square centimeter, gave origin to spectroscopic studies, as a precursor for thick oxide growth on silicon, and to the first applications to gas sensing. In 1977, the first patent of a humidity sensor based on porous silicon was deposited [2]. PS was also applied to silicon on insulator (SOI) technology [3].

At the end of the 80s, Leigh T. Canham working at the British Defense Research Agency obtained the experimental confirmation of his intuition that the nanofilaments of porous nature could exhibit good luminescence properties, due to quantum confinement effects. Although other authors were investigating on the phenomenon,

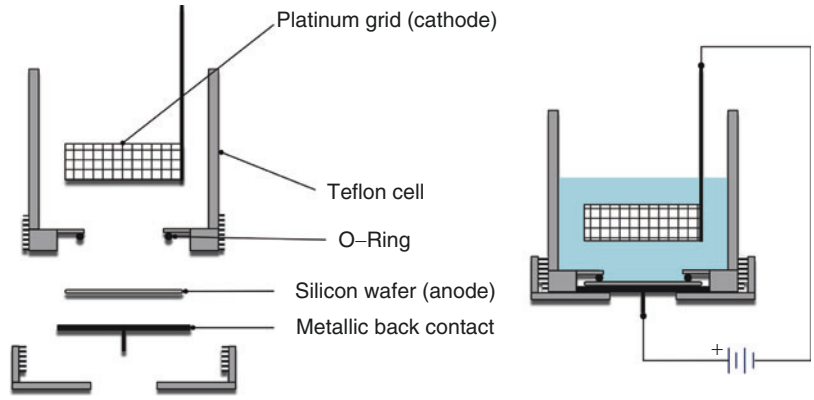
Nanostructures Based on Porous Silicon, Fig. 1 Porous silicon formation voltammogram. Over the I_{PS}, electropolishing regime occurs. At lower currents, porous silicon is formed

like V. Lehmann and U. Gösele, Canham was the first to publish, in 1990, the experimental evidence of PS room temperature photoluminescence [4, 5]. This experiment stimulated the work of many research groups all over the world in the nonlinear optical and electrical properties, and the number of published papers arose exponentially from 1991 to 1995. The premises of a brilliant future for silicon-based lasers were not maintained, due to the low efficiency of electroluminescence of this material, slow decay times, and to the chemical and mechanical stability.

In the mid-1990s, the main applications of porous silicon were micromachining, gas sensing, and with 1995 the medical and biological applications received a big boost, due to the demonstration of hydroxyapatite growth on porous silicon end to the proven biocompatibility and hemocompatibility of nanostructure silicon, again by L. T. Canham [6].

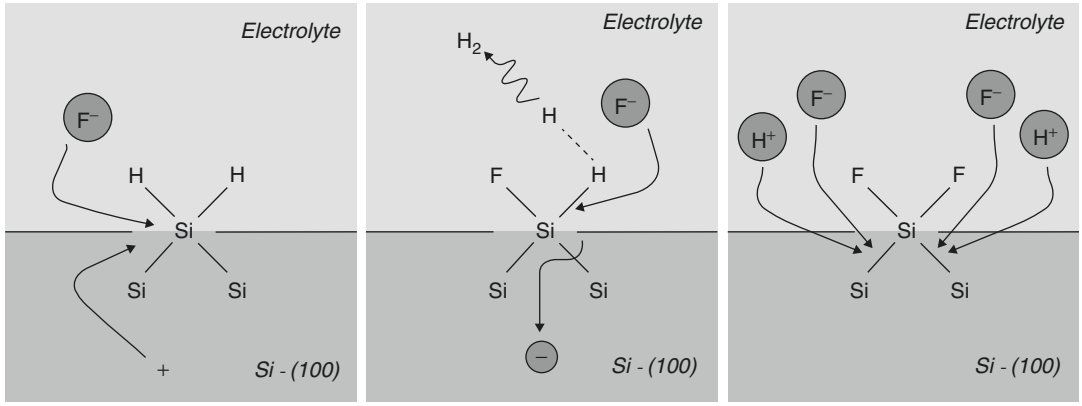
Other studies showed that B50 rat hippocampal cells have a better adhesion onto porous silicon with respect to untreated surfaces, so indicating suitability of porous silicon for cell-culturing purposes.

In 2001, a group of researchers at the Technical University of Munich [7] announced that hydrogenated porous silicon, in contact with liquid oxygen, reacts explosively, releasing more energy than an equivalent amount of TNT with higher speed, and with no necessity of a detonating material also for small quantities. The application of this discovery, substituting the liquid oxygen requiring very low temperatures with salts rich in oxygen, is in the air bag igniters in the automotive field, in the satellite propulsion, and in atomic emission spectroscopy [8].



Fabrication of Porous Silicon

Anodization



Porous silicon is realized by electrochemical anodization of a silicon substrate, in a solution of hydrofluoric acid (HF) and ethanol in different ratio, depending on the silicon wafer resistivity on the desired etch rate and thickness and characteristics of the porous layer. The cathode is a platinum wire or a grid; the beaker can be Teflon or PVC (Fig. 2). To obtain homogeneous and thick layers, a pulsed bias is preferable, so giving time to the solution at the pore tips to recover its title by fluorine ions diffusion from the bath.

The ethanol is added to the hydrofluoric acid to favor the hydrogen bubbles removal from the porous silicon layer during formation.

Formation Mechanisms The selective removal of the silicon atoms (local electropolishing at the

Nanostructures Based on Porous Silicon, Fig. 2 Electrochemical cell scheme for porous silicon fabrication, (exploded, *left*, and assembled, *right*)

Nanostructures Based on Porous Silicon, Fig. 3 Dissolution sequence of silicon in presence of HF and holes

pore tips) or complete electropolishing is performed by the fluorine ions in presence of two or four holes in the bulk of the semiconductor, allowing the breaking of the Si-Si backbonding (Fig. 3). After the initial work of Turner, Memming, and Schwandt proposed the overall dissolution reaction:

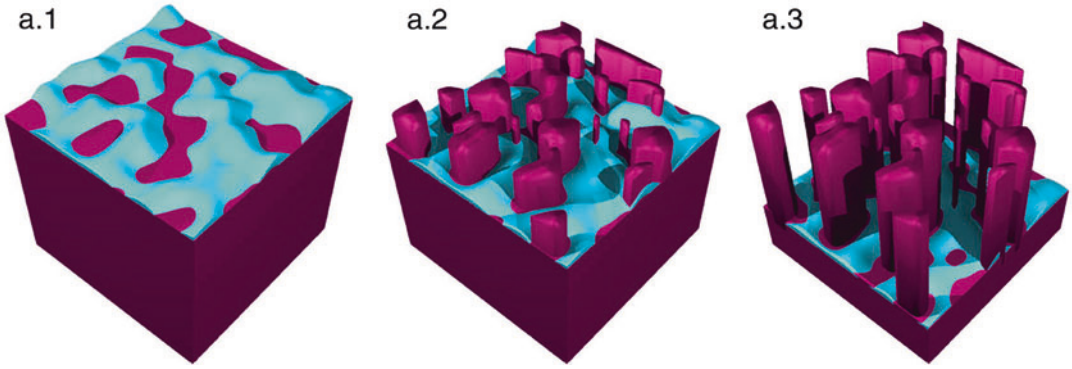
$$\mathrm{Si} + 2\mathrm{HF} + \lambda h^{+} \rightarrow \mathrm{SiF_2} + 2\mathrm{H}^{+} + (2-\lambda)\mathrm{e}^{-} \quad (1)$$

$$\mathrm{SiF_2} + 2\mathrm{HF} \rightarrow \mathrm{SiF_4} + \mathrm{H_2} \quad (2)$$

$$\mathrm{SiF_4} + 2\,\mathrm{HF} \rightarrow \mathrm{H_2SiF_6} \quad (3)$$

Where h^{+} is the hole, e^{-} the electron, and λ is the number of charges exchanged.

Similar mechanisms have been proposed in literature, including silicon oxide formation in presence of H_2O and dissolution in presence of HF, like in the case of the electropolishing regime:



$$\mathrm{Si} + 2\mathrm{H_2O} \rightarrow \mathrm{SiO_2} + 4\mathrm{H}^{+} + 4\mathrm{e}^{-}$$
$$\mathrm{E} = -0.84\mathrm{V/NHE(Normal\ Hydrogen\ Electrode)} \quad (4)$$

$$\mathrm{SiO_2} + 2\mathrm{HF_2}^{-} + 2\mathrm{HF} \rightarrow \mathrm{SiF_6}^{2-} + 2\mathrm{H_2O} \quad (5)$$

Stain Etching

Porous silicon formation occurs also in the absence of an external biasing, by stain etching with hydrofluoric acid, nitric acid, and water.

The vacancies necessary to silicon dissolution in this case are provided by HNO_3, the etchant

Nanostructures Based on Porous Silicon, Fig. 4 Dissolution sequence of silicon metal-assisted etching. In *light blue* the silver clusters are depicted, for different etching times (from a.1 to a.3)

concentrations are generally higher, and the etch rates are lower than in the electrochemical process. The first studies were carried on during the 1960s to probe P-N junction, then the discovery of room temperature photoluminescence of porous silicon obtained electrochemically renewed the interest for stain etching, and a systematic study regarding the structural and optical properties of porous films have been exploited [9].

The reactions are the following:

- Anode:

$$\mathrm{Si} + 2\mathrm{H_2O} + \mathrm{m\,h^+} \rightarrow \mathrm{SiO_2} + 4\mathrm{H^+} + (4 - \mathrm{m})\mathrm{e^-} \tag{6}$$

$$\mathrm{SiO_2} + 6\mathrm{HF} \rightarrow \mathrm{H_2SiF_6} + 2\mathrm{H_2O} \tag{7}$$

- Cathode:

$$\mathrm{HNO_3} + 3\mathrm{H^+} \rightarrow \mathrm{NO} + 2\mathrm{H_2O} + 3\mathrm{h^+} \tag{8}$$

- Overall:

$$3\mathrm{Si} + 4\mathrm{HNO_3} + 18\mathrm{HF} \rightarrow 3\mathrm{H_2SiF_6} + 4\mathrm{NO} + 8\mathrm{H_2O} + 3(4 - \mathrm{m})\mathrm{h^+} + 3(4 - \mathrm{m})\mathrm{e^-} \tag{9}$$

Recently, K. Kolasinsky [10] developed a new type of PS stain etching oxidants like, Fe(III), Mn (VII), and Cr(VI) drastically reducing hydrogen bubbling so obtaining very homogeneous and highly luminescent materials.

Metal-Assisted Etching

Metal-assisted etching (MAE) has been recently reported by Li, Bohn, and coworkers [11]; it is a sort of self-catalytic etching of silicon, with no need of polarization, since the formation mechanism is ruled by local redox potential of the metal with respect to silicon. This drives the holes necessary to dissolution at the metal–semiconductor interface. Noble metals like gold, silver, or platinum can be used and obtained by precipitation starting from liquid metallic salts like $AgNO_3$ and others but also deposited in form of thin solid films by sputtering or evaporation.

The metal clusters at the surface of the silicon wafer, rapidly sink following the crystallographic directions and, define silicon walls or wires (Fig. 4), depending on the metal particle distribution at surface, on the temperature, and concentration of the etchants. When the metal is patterned on the surface, MAE leads to regular morphologies.

The dissolution of silicon in HF and an oxidizing agent is a combination of chemical and electroless process, having strong similarities with porous silicon formation or electropolishing by stain etching in HF-HNO_3 [12].

In electroless metal-assisted etching, holes are injected in silicon by H_2O_2, independently from the original substrate doping. In this case, the oxidizing agent concentration can be considered

equivalent to current density in electrochemical process. HF concentration rules dissolution and surface chemistry at the same way for both the processes. The ratio between oxidizing agent and HF deeply affects the etching regimes and the morphologies.

The reaction mechanisms involved in the electroless dissolution of silicon in presence of metal particles are rather complex and will be given in summary following the work of Chartier and coworkers [13] for the case of Ag on Si.

The Ag metallic nuclei at the silicon surface are charged of electrons, and for charge compensation, localize holes at silicon–silver interface, in majority coming from H_2O_2 dissociation at cathode in presence of catalyzing Ag, as shown in Eq. 10 and forming SiO_2 or removing Si at anode, as in Eq. 11.

- Cathodic reaction

  The Ag particles at cathode catalyze the reduction of H_2O_2 as in Eq. 3, taking advantage from a favorable redox potential, and enhancing the etch rates by supplying free holes in proximity of Si-Ag interface.

$$H_2O_2 + 2H^+ \rightarrow 2H_2O + 2h^+$$
$$E_0 = +1.76\ \text{V/NHE(Normal Hydrogen Electrode)} \quad (10)$$

- Anodic reaction

  In analogy with the well-known chemical dissolution of Si in HF-HNO_3 [14], summarizing the different mechanisms proposed in literature and following the work of Chartier, the following anodic reaction is proposed:

$$Si + 6HF + nh^+ \rightarrow H_2SiF_6 + nH^+ + [(4-n)/2]H_2 \quad (11)$$

The general form is valid for the two already cited electrochemical regimes, porous silicon formation and electropolishing, where n, ranging from 2 to 4, is the number of holes per dissolved Si atom.

In the case of $n = 2$, porous silicon formation occurs, with the following overall dissolution anodic reaction:

$$Si + 4HF_2^- \rightarrow SiF_6^{2-} + 2HF + H_2 + 2e^- E_0 = -1.2\ \text{V/NHE} \quad (12)$$

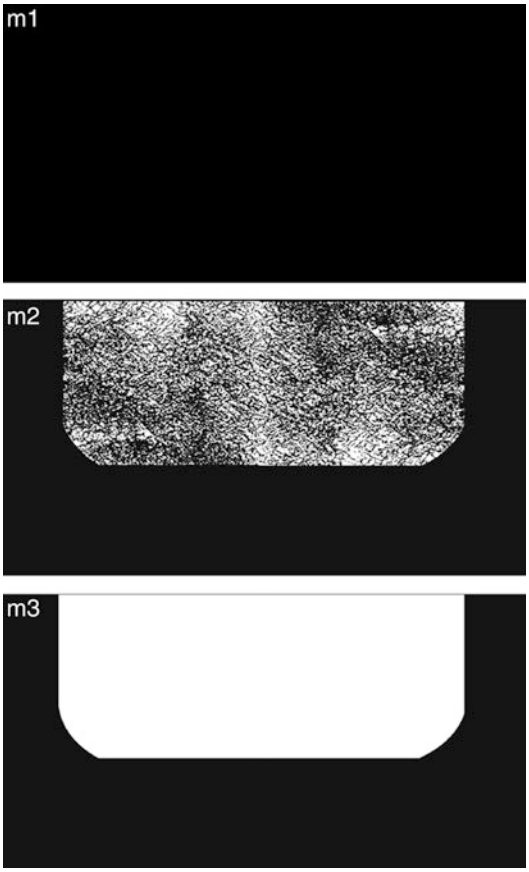
also valid for HF/HNO_3 stain etching well below the critical current density of electropolishing (J_{PS}).

In the case of $n = 3$, ½ H_2 per dissolved silicon atom, as in the case of 6 M HF – 6 M HNO_3 solutions or in stable electrochemical dissolution at J_{PS} [15].

When $n = 4$, the electropolishing regime occurs, as in the case of low HF/HNO_3 ratio or for current densities higher than J_{PS}, with a different mechanism involving the formation and dissolution of intermediate species like SiO_2 and without H_2 formation (Eqs. 13a and 13b).

$$Si + 2H_2O \rightarrow SiO_2 + 4H^+ + 4e^- \quad E_0 = -0.84\ \text{V/NHE} \quad (13a)$$

$$SiO_2 + 2HF_2^- + 2HF \rightarrow SiF_6^{2-} + 2H_2O \quad (13b)$$



The local mechanism of silicon dissolution in proximity of Ag particle is still unclear, but the pore morphology indicates hole consumption close to the silicon/metal clusters interface, also thanks to the catalytic reduction of H_2O_2.

This phenomenon can be ascribed to a faster surface reaction with respect to holes diffusion due to coupling between silicon valence bonds and energy levels of silver or a depletion layer around Ag nanoparticles allowing an easier access of holes in proximity of Ag/Si interface with respect to HF/Si interface to be produced.

Classification of Porous Silicon

Porosity

Porosity is defined as the volume fraction between silicon structures and voids in the porous layer, and it is determined by gravimetry by weighting the silicon wafer before the etching (m1), after the etching and drying (m2), and after PS removal by alkaline solution (m3) as in Fig. 5. Porosity is a number between 0 and 1 and is obtained by the formula:

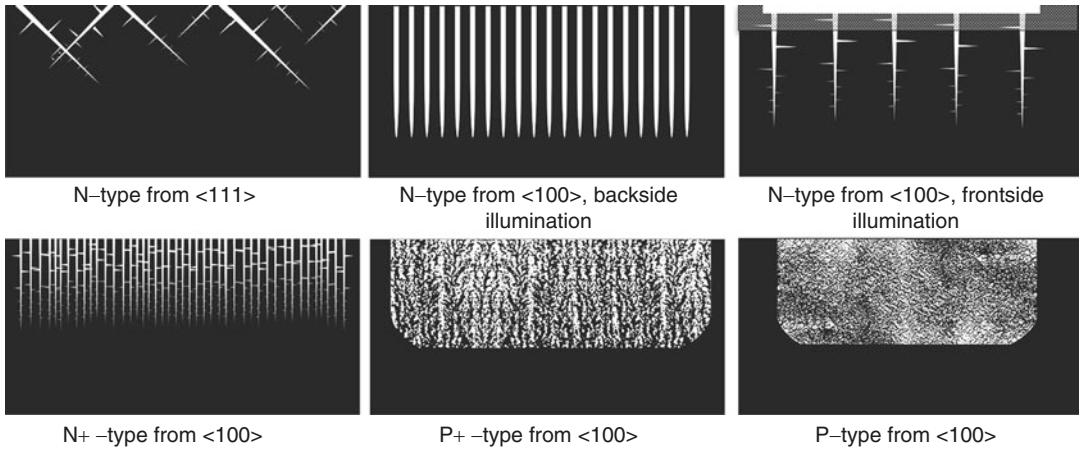
Nanostructures Based on Porous Silicon, Fig. 5 The three weights used in gravimetry for porosity evaluation. The first, m1, is the weight of the silicon sample before anodization;; the second, m2, is the weight of the sample after PS formation and at least 20 min of drying;; the third, m3, is the weight of the sample after alkaline removal of the PS layer

$$P(\%) = (m1 - m2)/(m1 - m3)$$

The most critical parameters affecting PS structure and porosity are current density and HF concentration. Porosity can range from 4 % for macroporous silicon to 95 % for mesoporous layers. Porosity is only an indicative parameter, and it does not yield information regarding the microstructure of the PS layer, structure size, and relative size distributions that are much more significative for the prediction and interpretation of physical phenomena like optical, thermal, and electrical responses of the system.

From gravimetry measurements, the thickness of the porous layer can also be determined using the following formula:

$$W = (m1 - m3)/S \times d$$



Where, d is the silicon density and S is the silicon surface exposed during etching. Other destructive methods to evaluate thickness are SEM sections, profiling after the porous layer removal, and among the nondestructive methods is ellipsometry, even if the final result is dependent on the adopted model.

Pore Size, Morphology, and Orientation

According to an IUPAC convention [16], porous silicon has been divided into three categories based on the size of its pores: macroporous, mesoporous, and microporous.

Type	Microporous	Mesoporous	Macroporous
Pore width (nm)	Less than 2	Between 2 and 50	Larger than 50

The pores are strongly dependent on the substrate characteristics like crystalline orientation and impurity concentration. In general, pores initiate at the wafer surface and tend to follow the crystalline directions, an example for different orientations is shown in Fig. 6. Since the electrochemical etching is dependent on the number of holes available in the substrate, PS morphology is deeply affected by the original impurity content of the donors or acceptors in the substrate. In low resistivity N-type silicon, no etching occurs in the absence of light or high bias. In the presence of light, if the energy hν of the radiation is greater or equal to the silicon band gap, 1.12 eV at room temperature, the energy excess is transferred to the crystal lattice by rapid thermal processes on the timescale of picoseconds, and the amount equal to the silicon band gap creates an electron–hole couple in conduction band and valence band, respectively. The holes can thus contribute to silicon dissolution, in presence of fluoride ions of the solution, removing the silicon–silicon bonding. If the illumination comes from the top of the silicon surface, from the same side of the etching

Nanostructures Based on Porous Silicon, Fig. 6 Some PS morphologies: from *left* to *right*, first row: N-type PS silicon from (111) substrate orientation, N-type PS silicon from (100) substrate orientation and *backside* illumination, N-type PS silicon from (100) substrate orientation and *front* illumination;; second row: N + type PS silicon from (100), P + type PS silicon from (100), P-type PS silicon from (100)

solution, the pores will initiate from the top and will follow the 100 direction, forming regular or branched macropores, depending on parameters like electric field and free carrier concentration available, but also a microporous phase, due to the quantity of holes generated by light. The depth of this layer depends on the spectral component of the lamp. If the light reaches the substrate from the bottom, the holes will drift through the silicon substrates, reaching the pore pits at the upper interface with HF and ethanol. There is a high probability that the holes will reach the pore tips, so contributing to maintain a stable and regular pore growth.

In N-type macroporous silicon pore etching, there are several critical parameters to be monitored for a regular and sufficiently fast etching: temperature, current density, electrode potential, and illumination intensity.

For the current density, galvanostatic or potentiostatic conditions can be used. Typically constant current conditions (i.e., galvanostatic) are adopted, so allowing the formation of pores under constant dissolution regime.

So, regular macropores on N-type silicon with backside illumination can be controlled in two ways: (1) by using galvanostatic/potentiostatic control maintaining the illumination intensity constant, (2) fixing current and potential and adjusting the illumination intensity via feedback loop.

The highly doped N-type and P-type silicon give origin to mesoporous structures. In the case of P-type, the great availability of free holes due to doping and the low resistivity of the material gives origin to high etch rates, of the order of hundreds of nanometers per second, depending on the current density. A typical value can be 300 nm/s with 300 mA/cm^2 in HF:Eth 1:1 starting from HF 49 %. Mesoporous silicon has an intrinsic anisotropy. The material shows an interconnected columnar structure, with structure size distribution extending from 1.5 to 15 nm [17]. This material is scarcely luminescent;; it is mechanically robust and its morphology is determined by the presence of impurities, since the etching does not remove them selectively (e.g., Boron), but the anodization deactivates the trivalent atoms leaving them in subsurface position [18].

For the highly doped N-type silicon, the mechanism is rather different. The right branch of the curve is determined by the applied current density, and the regime is electrochemical;; the left branch of the curve is more a chemical dissolution, with slow etch rates, and so reaching high porosities.

Low resistivity P-type silicon gives origin to a tiny coral structure, with typical sizes around

1–2 nm. These PS layers are fragile and show room temperature photoluminescence.

Optical Properties and Photoluminescence

Generally, nano-PS emits bright visible light at room temperature in spite of the fact that the pristine c-Si is a well-known indirect-gap semiconductor, with a fair emission in the near-IR, at cryogenic T.

The application of photoluminescence (PL) technique in PS involves several different physical processes, which make the final product (the PL spectrum) difficult to interpret. Absorption of the incident photon creates an electron–hole pair. If nanocrystallites are somehow interconnected, or imbedded in a medium, these particles can escape through different mechanisms. If not, they can decay to lower states *in the same nanocrystal*, or could recombine radiatively, directly from the excited state. If localized states are present, trapping into these shallow states can occur. On the contrary, deep states, e.g., unpassivated dangling bonds, can enable the competing nonradiative recombination of electron–hole pairs.

After several years of investigation, there is a general consensus about the origin of such strong light emission. Resonant PL technique proves that emission arises in the crystalline core of the material (instead of other Si-O, Si-H, or siloxene compounds) [19] where the energy gap is broadened, thanks to quantum confinement (QC) effects. On the other hand, the efficient passivation of the nonradiative pathways (due to H-, or O- termination of the Si nanostructures) plays an important role.

PL decay times are in the order from μs to ms, which makes practical application of PS in integrated optoelectronics unlikely. In particular, the red PL shows nonexponential decay, with typical times ranging in the μs and ms range at room T and at low T, respectively. The competition between radiative and nonradiative recombination processes depends on T. Generally, the PL intensity reaches a maximum around 50–200 K (depending upon the sample), the simple meaning being that one of the competing processes, say, the radiative one, prevails at those T values. The T dependence of the PL lifetime is the consequence of exchange splitting of excitons. Indeed, the electron and hole, with spin 1/2, can be combined into a singlet ($S = 0$) and a triplet ($S = 1$) state, the exchange interaction stabilizing the triplet. While at high T both of them are populated, the PL arising from the "fast" decay of the singlet state, at low T the PL becomes much slower because the triplet state is virtually stable. In the T range at which the PL emission is maximum, the radiative process is still related to population of singlet states, whereas the nonradiative one in quenched. When T is further decreased, radiative processes are now related to the slow decay of triplet states, and nonradiative ones become competing again.

PS Structures

PS has been fruitfully employed as a sacrificial layer since it is a strongly reactive material and easy to etch [20].

Generally, a wide class of materials, from metals to semiconductors and insulators, can be deposited onto PS. Due to the intrinsic reactivity of PS, it can be easily etched, giving rise to large undercutting of the layers deposited on it. This method is proved to be very efficient for realizing suspended membranes, bridges, or cantilevers.

PS has been also employed for the epitaxial deposition of c-Si because it conserves the lattice of the pristine material and can be used as a seed for further growth. Thanks to its reactivity and fragility, it allows transfer of the epitaxial film onto foreign substrates.

Macroporous Silicon

The former studies of N-type silicon anodization in the dark started in the early 1970s. Etch pits and silicon dissolution in dark is due to and breakdown between surface states tunneling in conduction band. From these studies, some evidences were clear: the channels formation is not due to crystal defects, the pores direction follows the orientation of the substrate, the growth rate is in general constant with anodization time, so the diffusion within the pores is not a rate-limiting process, and the pores' walls are passivated.

Beale proposed a depletion of porous layer, explaining the high resistivity of the material

after anodization, and localizing carriers at the pore tips. Several concepts introduced by this physical model were then adopted in successive works, but no chemical mechanisms were included, so providing poor comprehension of pore size variations and morphologies. Smith and coworkers, at the end of 1908s, postulated that the rate of pore growth is limited by the diffusion of the holes randomly walking in the bulk of silicon. This model was mainly ruled by the diffusion length L, a quantity that is function of dopant concentration and potential. A sticking factor varying from point to point of the partially oxidized pore tip was necessary to explain different morphologies and pore diameter variations. This model was too general to explain the conduction mechanisms and morphologies in different types of substrates and like the previous was not taking into account the electrochemical reactions at the interface. Zhang and coworkers [21] in the same period, thanks to a systematic study of the i-V characteristics, clarified that the PS formation or electropolishing is not dependent on the electronic properties of the substrate, but on the result of the two competing reactions occurring at the pore tips: direct dissolution by fluoride species and indirect removal of silicon through silicon dioxide formation and dissolution in HF. In the following years, Zhang also proposed that surface curvature of the pore tips could reduce the effective width of the space charge layer greatly increasing the interface tunneling current and the dissolution rates of silicon dissolution and oxide formation and removal. This model is also applicable to other substrates and PS morphologies.

Lehmann and Föll in 1990 described the formation of macropores from low-doped N-type silicon in aqueous HF-electrolyte, backside illumination, and pore nucleation predefined lithographically. They experimentally verified the hypothesis that the space charge region (SCR) around the pores can focus the holes diffusing in the silicon bulk on the pore tips, so enabling the growth of regular macropores. In further studies, Lehmann demonstrated that the equilibrium of the carrier transport in the semiconductor and the mass transfer in the electrolyte determines the etch rates and the morphologies in N-type silicon. At low current densities, there is no accumulation of holes and dissolution takes place only at the pore tips, leaving the walls unaffected thanks to carrier depletion. At high current densities, the reaction is mass transport limited and holes accumulate at the pore tips, dissolving walls and enlarging the pores.

Lehmann tried to unify the models describing the formation mechanisms of all types of PS, using the assumption that all the porous structures except the pore tips are passivated by carrier depletion. Depletion is due to quantum confinement for microporous silicon and to space charge layer for porous structures larger than few nanometers.

Föll et al. developed the current burst theory, one of the most recent and comprehensive models of PS formation;; it is so far the only model considering the electrochemical reactions under formation conditions in the different PS morphologies. The main assumptions are that the electrochemical reaction of silicon dissolution operates in microscopic units with a definite spatial and temporal distribution. Other important points are the following:

Current flow is inhomogeneous in space and time, from here the local current burst.
Current flow induces direct silicon dissolution and oxidation and removal following current burst.

As a result of hydrogen termination and desorption, the position of Fermi level and so of the space charge layer oscillates with the time.

The rate of hydrogen termination is fastest on the (111) surface, determining the probability of current burst on surfaces of different orientations.

This model is rather powerful in explaining many aspects involved in the PS formation, but it is extremely difficult to be expressed in mathematical form. [21].

Porous Silicon-Based Photonics

In nano- and mesoporous cases, application in 1D photonic structures deserves a mention. From an optical point of view, PS is seen from visible light

as a homogeneous material. In fact, the sizes of the pores and the Si nanocrystals are well below the light wavelength. When porosity is varied, the macroscopic dielectric constant (and the refractive index) is varied, too. In principle, it is possible to "choose" the refractive index of the layer between the limits of $n = 3.4$ (porosity $= 0$) to $n = 1$ (porosity $= 1$). The range of variation for n is smaller, but n can be varied in a continuous way in this wide range. Being the dependence of n from porosity relatively simple and considering that porosity monotonically increases with the anodization current, by changing the current during anodization in the right way, one is able to obtain optical devices like Bragg reflectors or Fabry-Perot microcavities done by PS. The advantage of this technology is evident: it allows obtaining optical devices directly integrated on Si [22].

A Bragg reflector is a periodical structure of layers with high and low refractive index. The optical thickness of both is chosen to be $\lambda/4$, λ being the light wavelength at which maximum rejection is wanted. The Bragg reflector is then a sort of 1D photonic crystal, there the rejection band stands for photons like energy gap stands for electrons in semiconductors. Correspondingly, one can choose to insert defect states within such gap: this can be accomplished by means of a Fabry-Perot microcavity, where a layer with optical thickness equal to $\lambda/2$ is sandwiched between two Bragg reflectors. The PS anodization technology allows for realizing Bragg reflectors with >98 % reflectivity at the rejection band and Fabry-Perot microcavities with peak FWHM <10 nm. This method could in principle be used to confine light arising from PL emission, but, unfortunately, the best optical 1D structures are obtained in highly doped material, in which the PL is generally poor. The roughness between layers of different porosity is dramatic in lightly doped PS and greatly affects the optical performances of the 1D devices. A possible solution has been found in freezing the anodization etchant;; roughness is greatly reduced in this way, but the quality is still far from devices realized by standard vacuum deposition methods.

Porous Silicon-Based Gas Sensors

The first patent related to porous silicon regards the anodization of silicon for the fabrication of a humidity sensor, US patent no. US4057823, by P. J. Burkhardt and M. R. Poponiak from IBM, in 1976 [2]. The high specific surface of oxidized mesoporous silicon was used here to detect moisture by capacitance variations in a capacitor in which oxidized porous silicon was the dielectric.

From then, a number of works investigated different readout approaches regarding the sensing properties of porous silicon in simple architectures and surface chemistry mechanisms. More recently, advanced architectures (rugate filters, FET transistors) and complex surface chemistry (metallization, silanization, carbonization, and other surface derivatizations) have been proposed trying to increase sensitivity, selectivity and reliability.

From this early application to 1996, several works were published on the sensitivity of porous silicon to different vapors and polar gases in saturation conditions, (i.e., parts per thousands level) [23–27]. In this year, Harper and Sailor observed PL quenching of N-type nanoporous silicon in contact with NO_2. The sensitivity was at ppb (parts per billion) level, but the effect appeared to be irreversible [28].

In 1998 and in the following years, Boarino et al. [29] reported a reversible effect of conductivity variation of p+ type mesoporous silicon in presence of NO_2 and successively with NH_3. The response in presence of these probe gases (the first attracting and the second donating an electron) was also confirmed by insitu FTIR spectroscopy. After investigations of the phenomenon by Electron Spin resonance and NMR, the interaction mechanisms were clarified as a chemisorption mechanism of the gases onto porous silicon surface, reactivating the boron impurities deactivated by surface dangling bond after electrochemical etching. The NO_2 has the higher electron affinity (2.2 eV), and the NH_3 easily tends to donate its outer electron. The material, apparently depleted from free carriers after etching, is reactivating its impurities in interaction with these gases restoring the original conductivity in presence of these

gases [18]. Since those years, a number of applications and investigations regarding NO_2 and gas sensing devices based on porous silicon have been exploited [30–34].

Good sensitivity to other gases and compounds has been obtained by porous silicon derivatization and functionalization,[35–37], a number of processes in which different chemistries are built on the porous silicon surface by proper immobilization of molecules and biomolecules, reducing aging, increasing sensitivity, selectivity, and reliability.

The methods of detection are several, mainly optical, electrical, and electrochemical, based on variations of refractive index, radiative recombination processes, dielectric constant, conductivity, and others in interaction with gas species (chemisorption, physisorption, or condensation processes). Thanks to the high specific surface of porous silicon, around 10^7 times greater than the bulk materials, the variation of a number of physical–chemical parameters have been demonstrated as a function of gas and vapor concentrations, like photoluminescence spectrum, optical reflection, transmission, diffracted optical power, capacitance, current, and resistance [38]. Several readout architectures have been proposed for the electrical parameters capacitors, resistors, diodes, and CMOS transistors [34]]; for the optical monolayers, waveguides, multilayers [39], Bragg mirrors [40], Fabry-Perot resonant cavities [41], rugate filters [42]; but also spectrometry, interferometry [43], ellipsometry, birifringence, conductometry, impedance spectroscopy, and others.

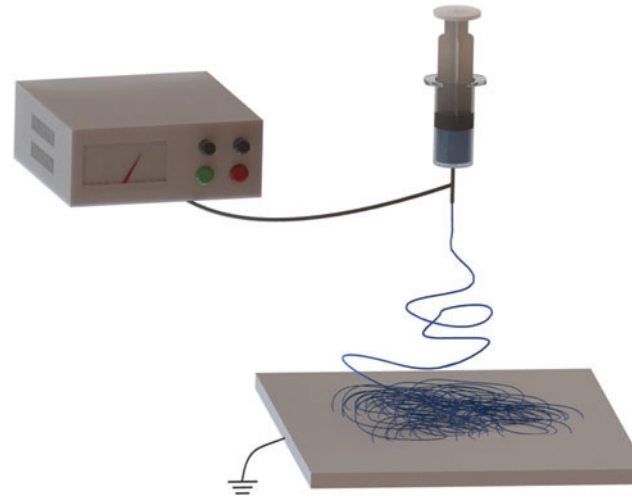
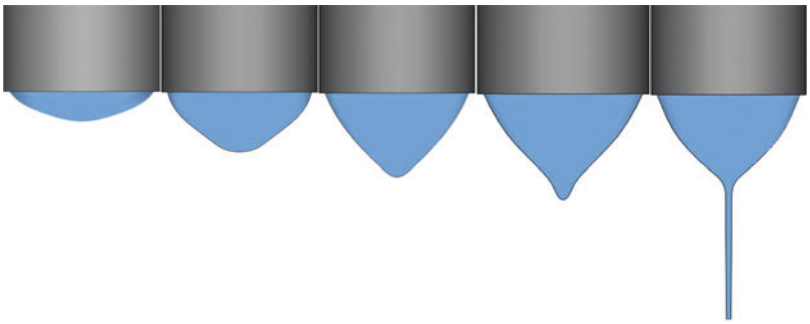
Definition



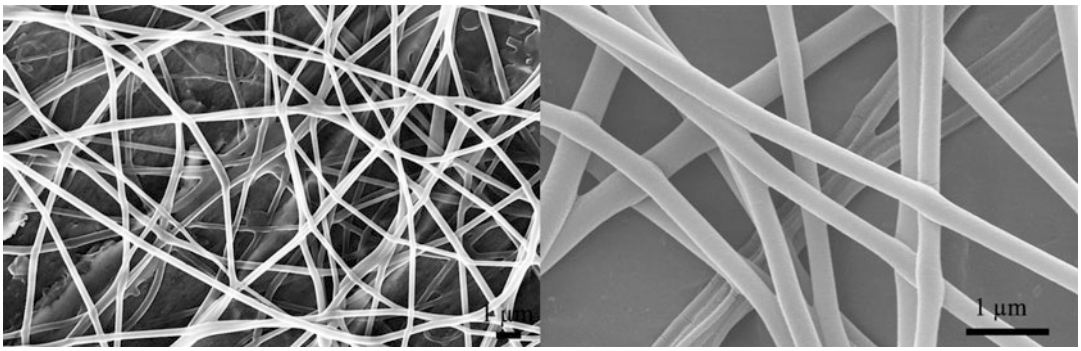
Electrospinning is a method to fabricate nanofibers via coupled effects of electric field on viscous fluids, e.g., polymeric, ceramic, or metallic solutions/dispersions/melts. In electrospinning process, fine charged jet/jets issue from liquid surface, following elongation, evaporation, and solidification. Then solidified nanofibers can be collected.

Introduction



In the electrospinning, a micro/nano jet is generated from the solutions/dispersions/melts under electrostatic field force (EF). As shown in Fig. 1, a typical electrospinning setup consists of a high voltage source, a spinneret, a grounded collector, and a pump. The pendant droplet at the nozzle tip is deformed into a Taylor cone under the EF. As the EF overcomes the surface tension, a fine jet can be ejected from the tip of Taylor cone as illustrated in Fig. 2. After solvent volatilization, solidification, and bending instability, the charged jet can be turned into a solid nanofiber on the grounded collector in Fig. 3.

The base diameter of Taylor cone is smaller than the inner diameter of the nozzle; therefore, electrospinning provides a simple way to decrease the size of spun-structure. Till now, hundreds of materials, such as polymer, ceramic, metallic, and bio materials, have been fabricated into nano/micro fibrous structure by using electrospinning.



Due to the unique features of low cost, easy process, small line width, and good material compatibility, nanostructures by electrospinning have showed potential applications in filtration, biomedical, energy materials, catalysis, etc. Since 1995, and more than 10,000 scientific papers

concerning electrospinning have been published (source: Web of Science). The statistical data chart of published papers is shown in Fig. 4 (The keyword for the researching is "electrospinning" in the topic.).

Concepts

As EF overcomes the surface tension, a charged fluid jet emanates from the apex of Taylor cone according to the Rayleigh instability [1].

G. I. Taylor [2] demonstrated the theoretical formula to calculate the critical voltage V_c for forming the charged jet, which can be expressed as:

$$V_c^2 = \frac{4H^2}{L^2}\left[\ln\frac{2L}{R_0} - \frac{3}{2}\right](0.117\pi\gamma R_0)$$

Where, H is the distance between spinneret and collector, L and R_0 represent the length and the radius of the spinneret, respectively. According to the experiment data and theoretical analysis, electric field strength higher than $1 \sim 10$ kV/m is required to generate a jet.

The charged jet that is ejected from spinneret is accelerated by FE and moves toward the collector directly. During the electrospinning process, the Coulomb Repulsion Force (CRF) and EF are the dominant factors that determine the ejection and motion behaviors of charged jet. There are two identified charge transfer mechanisms of free electron flow: Ohmic conduction and convective flow in the jet ejection process. The charged jet is elongated by EF and the stretching ratio from Taylor cone to solid nanofiber is about $1000 \sim 2000$. On the other hand, the solvent evaporation also decreases the diameter of charged jet further. The interaction between solvent and polymer determines the surface morphologies of electrospun nanofiber.

The motion behaviors of the as-spun nanofiber can be divided into two stages. In the first stage, the charged jet moves in a straight track. The competition between surface tension and EF leads to symmetrical instability, which affects the uniformity of electrospun nanofibers. In the second stage, CRF, nonuniform electric field, fluctuation instability makes the charged jet step into whipping and splitting, resulting in the random deposition of electrospun nanofiber.

Electrospinning jet displays viscous and elastic characteristics under stress. Viscoelasticity is used to describe the behaviors of electrospinning jet, which comprises the properties of solid and liquid phase. The axial stress inside the jet blocks the asymmetric instability and decreases the area of deposited zone of electrospun nanofiber.

The ejection behavior depends on process parameters of solution properties, applied voltage, polymer molecular weight, spinneret to collector distance, and ambient conditions. The solution properties of viscosity, surface tension, solution concentration, viscoelasticity, electric conductivity, and dielectric constant are the main factors that determine the ejection phenomena of electrospinning.

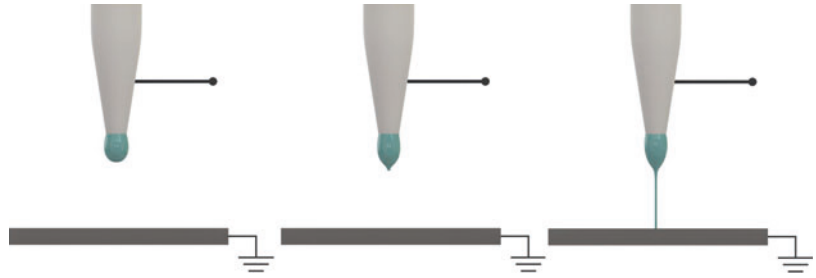
High viscosity solution produces continuous charged jet. Nanofiber is fabricated through the continuous jet ejection mode. Smooth, porous, beaded, or ribbon nanofiber can be generated by adjusting the experiment conditions. Due to its high surface tension, the jet of low viscosity solution is broken into nanoparticles. Electrospray and drop on demand (DoD) are two typical modes of discrete jet ejection. The jet is broken into nanoparticles with diameter ranging from nanometers to microns by the CRF. After that, electrosprayed particles are deposited on the substrate to form micro/nano membrane. On the other discrete ejection mode, jet is shrunk into micro droplets along the motion track. The droplets can be printed according to the requirements, called drop on demand (DoD). Orderly droplet with diameter ranging from 100 nm to 100 μm can be printed on the substrate to construct micro/nano patterns.

Direct current (DC) high voltage is often used to extend the solution and produce electrospun jet with positive charges. The jet and nanofiber carries positive charges from the spinneret under DC electric field. Currently, alternating current (AC) high voltage and pulse high voltage are also used to improve the controlling performance on the morphologies and deposition behaviors of electrospun nanofiber.

Historical Developments

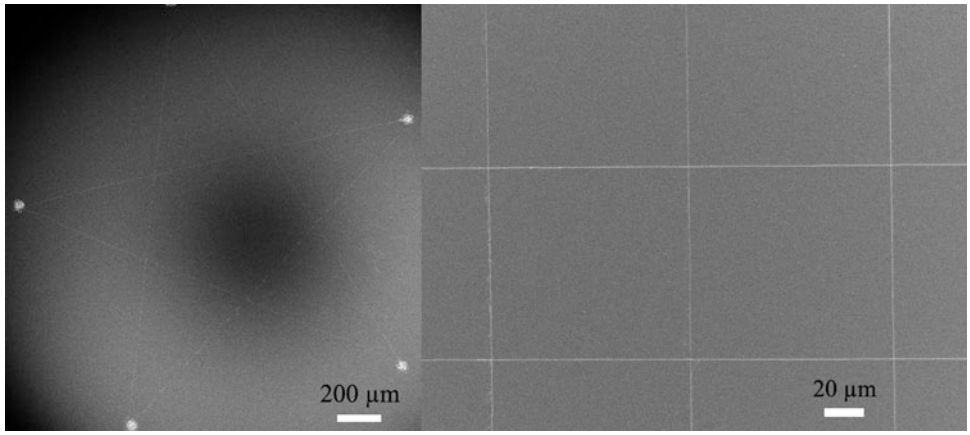
The theory of electrospinning can be dated back to 1600s. At that time William Gilbert firstly discussed the deformation of liquid droplets in an electric field. In 1882, Lord Rayleigh studied the instability of a charged droplet. Fine charged jet can be ejected from the solution surface when

the charge CRF is larger than the surface tension. In 1900, Cooley J. F. [3] published the first patent on the formation and ejection process of charged droplet in the electric field. Then, Anton Formals [4] described a patent for the generation of textile yarns in 1934 and Norton C. L. [5] invented the technique of melt electrospinning ejection in 1936. In 1964, Geoffrey Taylor [2] discussed in detail the deformation process of liquid in electric field. As voltage is increased to destroy the equilibrium between the EF and the surface tension, a liquid drop under the nozzle of spinneret would be deformed into conical shape (with a half angle of 49.3°) called Taylor cone. And then, a theoretical shape of liquid drop is also discussed by Geoffrey Taylor in his work. The word "electrospinning" first appeared in the published literature in 1995.



From 1990s, a lot of scientists focused on the different aspects of electrospinning. Firstly, the bending instability and electrically forced jet-stability theories have been studied further to understand the mechanism of electrospinning process better, which provide good ways to improve the deposition and morphology control. Secondly, more than 200 types of materials can be electrospun into nanofibers, including polymer, ceramic, metal, carbon, composite materials, and inorganic materials. Multifunctional nanostructure of piezoelectric, degradable, fluorescent, catalysis, photovoltaic, magnetic sensing, and optical nanofiber have been electrospun for the specific applications. At present, wide applications of electrospun nanostructures have been displayed in the fields of tissue engineering, drug delivery, filters, fiber reinforcement, sensor, optoelectronics, field-effect transistor (FET), nanogenerator, microelectromechanical systems (MEMS) device, etc. Diverse electrospinning setups have been built up to realize high efficiency and orderly deposition of electrospun nanofibers.

Charged Jet Ejection

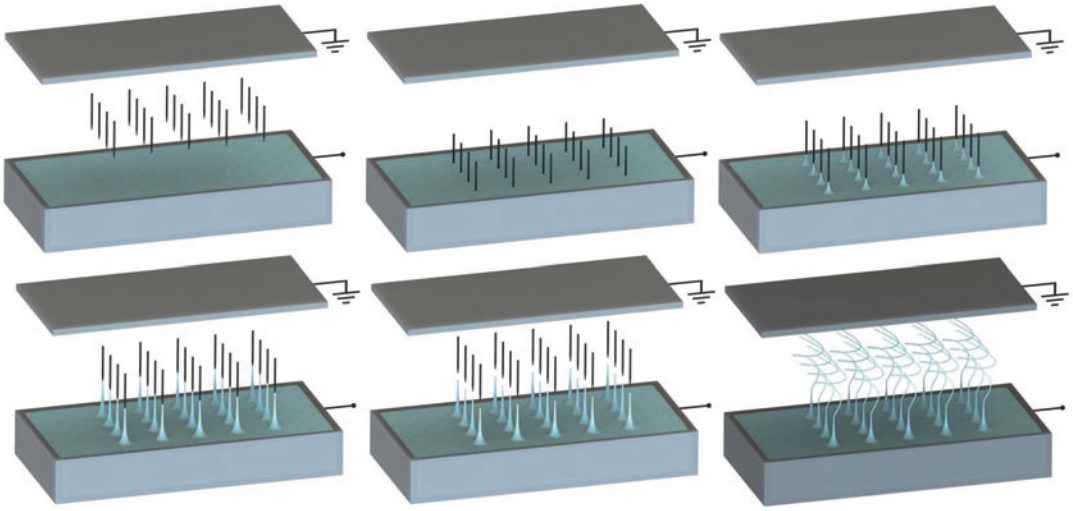


Hollow Spinneret. Most conventional electrospinning processes use a hollow nozzle as the spinneret. During the electrospinning process, the solution is transferred to the nozzle of the hollow spinneret by a pump. Then, a high voltage (typically 5–20 kV) is applied on the spinneret; the distance between spinneret and collector is usually 50 ∼ 150 mm. As applied voltage increases to critical value, the electrostatic force overcomes the surface tension of the solution and a jet is ejected from the tip of the Taylor cone. Undergoing the instability process of whipping and splitting instability, nanofibers can be gained on the collector as nonwoven. As there is only one jet ejected from one hollow spinneret. The throughput of electrospun nanofiber via single hollow spinneret is only ranging from 0.01 to 0.05 g/h. The low throughput of nanofiber is a great obstacle for the hollow spinneret. Multi spinneret array is utilized to increase the throughput of electrospun nanofiber.

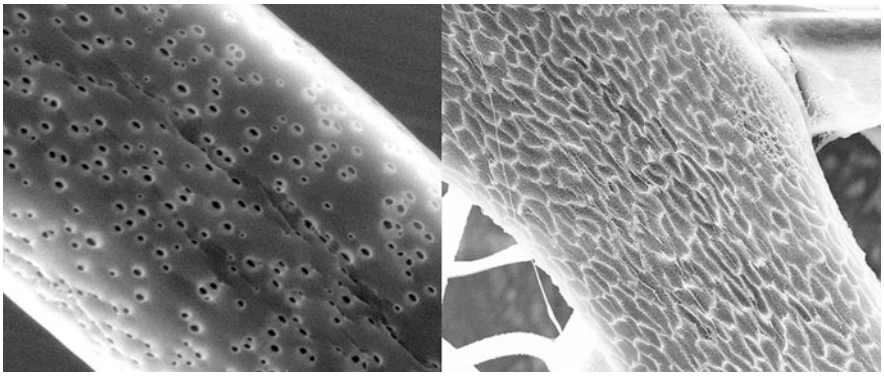
Core-Shell Spinneret. There are two liquid supply passages coaxially assembled in a spinneret, and two materials can be ejected synchronously into a charged jet. Thus, different types of nanofibers can be fabricated through such spinneret. For example, oil material and polymer material can be used in the core-shell spinneret synchronously to construct hollow fibers. When the oil material and polymer are transferred through inner and outer passages respectively, double-layer nanofibers with oil material and polymer can be generated through the spinneret. The oil material is removed further and hollow fibers are gained. The assisted gas is also introduced into the outer passages and acted as the focused sheath gas that can increase the stretching force on the jet. The focused sheath gas would decrease the threshold voltage for the ejection of jet and the diameter of electrospun nanofiber. Assisted sheath gas provides a novel way to promote the control of the jet.

Solid Tip Spinneret. A solid tip is also utilized as spinneret, which is immersed into and pulled out of solution during electrospinning. Sun D. H. and coworkers invented a novel electrospinning method called "near-field electrospinning (NFES)," in which a solid tungsten spinneret with tip diameter of 25 μm is used as spinneret [6], as shown in Fig. 5. Then, a liquid droplet with diameter of 50 μm is adhered to the

Nanostructures by Electrospinning, Fig. 5 Near-Field Electrospinning process



Nanostructures by Electrospinning, Fig. 6 Direct-written orderly nanofibrous pattern through near-field electrospinning



tip of the solid spinneret and straight jet under the tip of solid spinneret can be used to direct-write orderly nanofiber. The distance between spinneret and collector is shortened to 0.5 ~ 3 mm, and the jet deposits on the collector before the bending instability stage appears. Such method decreases the voltage required for the jet ejection from 10 kV to 0.6 kV. The oriental nanofibrous pattern can be direct-written as shown in Fig. 6.

Free Surface Spinneret. Electrohydrodynamic fluctuation instability induced by the electric field is used to generate multi-charged jets from the solution surface. The production efficiency of electrospun nanofibers can be increased greatly. There are several methods to realize the multi-jet ejection. For example, magnetic powder was added into the solution to enhance the fluctuation instability on the solution surface and increase the production efficiency of electrospun nanofibers [7]. Another good method is that cylinder and wire electrode are used as the spinneret and the multi-jet can be ejected from the solution surface that stems from the fluctuation instability on the surface of electrode [8, 9].

Inducing Spinneret. An outward drawing force is introduced to promote the easiness of ejection. Lin L. W. and coworkers [10] used a tungsten probe with tip diameter of 1 μm to draw fine jet from the droplet under the nozzle of spinneret, which decreases the voltage required for the ejection of charged jet and the diameter of electrospun nanofiber. The number and ejection position of charged jets can be controlled and adjusted by the inducing tip. Besides the single inducing tip, the probe array can be used to induce multi-jet from solution surface. The multi-jet induced by the probe array can sustain long and stable ejection. Moreover, the ejection efficiency of electrospun nanofiber is significantly improved, as shown in Fig. 7.

Nanostructures by Electrospinning, Fig. 7 Multi-jet induced by the probe array

Nanostructures by Electrospinning, Fig. 8 Porous morphologies

Morphology and Nanofiber Controlling of Electrospun Nanofiber

By adjusting the electrospinning parameters, electrospun nanofiber with different morphologies and diameter can be fabricated to meet the requirements of different applications.

Smooth Morphology. With the abundant elongation and low evaporation rate, charged jet can be transformed into smooth and uniform nanofiber. Smooth nanofiber is the usual type gained from electrospinning, which can be used as the connection in micro/nano electronic device.

Porous Morphology. High evaporation rate is the main factor that produces the porous structure in the nanofiber. The porous structure increases the specific surface area in the nanostructure by electrospinning. Porous nanostructure improves the performance of sensing and adsorption.

Beaded Structure. The competition between surface tension and EF is the most important role that defines the morphology of electrospun nanostructure. The fluid jet shrinks into beaded structure under the surface tension (Fig. 8).

Diameter Controlling. The effects of process parameters on the diameter of nanofiber have been studied deeply. Attributed to the random

disturbances in the ejection process, electrospun nanofibers have large diameter distribution range. Decreasing the diameter and the diameter distribution range is one of the great difficulties for the industrial application of electrospinning technology. Several works have been done to predict and control the diameter of electrospun nanofiber [11, 12]. Constant diameter electrospinning system has become the research focus for the application of nanostructure by electrospinning.

Deposition Controlling of Electrospun Nanofiber

Cylinder Collector. Rotating mandrel applies excess stretching force on the charged jet. As the rotation speed of the cylinder collector is higher than the travel speed of jet, the electrospun nanofibers can be taken up on the surface of the mandrel and wounded around the cylinder collector. Then, the oriented nanofibers can be deposited on the surface of the collector along rotation direction of the cylinder. As more nanofibers deposit on the cylinder collector, the CRF stemming from the accumulated charges causes subsequent nanofibers to be randomly deposited on the surface of collector. A modified cylinder collector of rotating wire drum was used to gain aligned nanofibers with slower rotation speed.

Knife-Edge Disk Collector. The electric field vector is guided directly to the knife-edge of the disk [13]. Coupled with the rotation of disk, oriented nanofibers are deposited along the edge of disk collector. The rotation speed of disk required to gain aligned nanofibers is about 1000 rpm. The angle of knife-edge can be changed to adjust the deposition pattern of nanofibers.

Parallel Electrode Collector. A collector composed of parallel electrodes can change the electric field distribution above the collector compared with that of traditional collector. With the guidance of uniform electric field perpendicular to the edge of electrode, the jet and nanofiber would be deposited orderly across the gap between parallel electrodes. The accumulated charges on the surface of deposited nanofiber would increase the mutual repulsion among charged nanofibers, and they also promote the parallel distribution of nanofibers. The aligned nanofiber deposited across the gap between parallel electrodes can be removed easily from the collector.

Inducing Tip Collector. Electric field distribution is an important role in determining the motion and deposition behaviors of the jet or nanofibers. The centralized and restriction electric field induced by the tip guides the nanofiber deposition on the predesigned point and decreases the deposition zone of charged nanofibers. The restriction electric field of inducing tip can also guide nanofiber deposited construct 3D structure layer by layer [14].

Near-Field Electrospinning. A solid tungsten electrode is utilized as spinneret, and the solution is supplied by immersing mode. During electrospinning process, the solid spinneret is inserted into the solution and carries out a droplet on the tip. The diameter of droplet adsorbed to the tip of spinneret is about 50 μm, which turns into Taylor cone and a jet. The tip restricts the position of the charged jet, and then the positioning accuracy of electrospun nanofiber is improved. Thanks to the $0.5 \sim 3$ mm distance between spinneret and collector, the straight stable jet is used to direct-write orderly nanofibers. The solid spinneret increases the electric field strength nearby, and the minimal voltage required for the jet ejection is decreased to only 0.6 kV in near-field electrospinning.

Applications of Electrospun Nanofiber

Reinforcement. Reinforcement material in composite system is the most important application for electrospun nanofiber. The modulus and strength to weight ratio of composite system can be increased by the addition of electrospun nanofiber. The Young's modulus of composite system is twice larger than that of bulk materials. Nanofiber with finer diameter plays better role to increase the mechanical properties of composite system, which can be applied in tissue engineering and structural elements, etc [15].

Filtration. Thanks to the good characteristics of high filtration efficiencies and low flow resistance, filtration is an important engineering field

for the application of electrospun nanofiber. During the filtration process, the size and morphology characteristics of electrospun nanofiber should match the scale of particles or droplets to increase the filtration performance. With the advantages of good porous interconnectivity, larger surface area, controllable pore sizes, high permeability, and low basis weight, nanofibers have demonstrated greater potential in the application of filtration. At present, many high-efficiency nanofibrous filters made of electrospun nanofibers have been manufactured and put into market.

Catalysis. With the advantages of larger surface area, electrospun nanofiber also provides an excellent way to promote the catalytic process. The catalytic actions occur on the surface of catalysis. Then, the active sites after catalytic actions prevent catalytic actions further. Nanofibers used as catalysts or catalyst supports can be beneficial to enhance the catalytic actions. Taking the advantages of high porosities and large surface area, electrospun nanofibers have been widely applied in the catalytic fields of chemical catalysts, electrochemical catalysts and photocatalysts, etc.

Micro/Nano Electronic System. The reduction of dimensionality of semiconductor or conductive electrospun nanostructures favors promoting the electrical and thermal transport properties. Electrospun nanostructures have displayed unique advantages in fabrication fields of micro/nano electronic, sensing devices. Continuous nanostructure, which is used as interconnects and functional units for the integration fabrication of electronic, optoelectronic, electrochemical, and electromechanical devices, can be electrospun orderly on the collector directly without photolithography and mask. The controllable deposition position of single nanofiber can be used in the fabrication process of micro/nano devices. Conductive, semiconductor, and sensing nanostructure can be fabricated through the electrospinning process, which have been used in the various electronic fields, such as field-effect transistor, chemical sensors, etc. The specific surface characteristics make electrospun nanofibers good candidates for sensing applications, such as humidity sensors and gas sensors.

Biomedical. Drug delivery system and tissue engineering are the main applications of electrospun nanofiber in the field of biomedical engineering. With the help of electrospun nanofiber, drugs can be delivered to the site of action at a controllable rate by adjusting the morphology, porosity, and composition of electrospun nanofiber. And then, the therapeutic safety and efficacy can be improved by the drug delivery system of antibiotic drug, anticancer drug, gene, and biomolecule, etc. For example, the postsurgical adhesions and infections can be prevented by the drug delivery system of electrospun nanofibers. The electrospun nanofibrous scaffolds can promote the growth of cell and improve the biocompatibility of material by decreasing the diameter of nanofiber. The porosity on the surface of electrospun nanofiber increases the surface area of nanostructure and plays a favorable influence on the cell growth. The nanofibrous scaffolds with large surface area provide good support for the growth of cell. The damages of cells or tissue occurred by the injury or disease can be repaired or regenerated well by the nanofibrous scaffolds. The three-dimensional nanofibrous structure is a new and good candidate for the human cell systems.

Energy Materials. Electrospun nanofibers can be used in high-efficiency energy conservation of lithium-ion battery and fuel cell [16]. With the advantages of short diffusion path, fast intercalation kinetics, large specific surface areas, thermal stability, wettability, and large porosity, nanofibrous membrane can be used as separator in lithium-ion battery with high energy density. Due to the large surface to volume rate and controlled diversity in compositions, proton exchange membranes based on electrospun nanofiber provide a good opportunity for the high efficient fuel cells. Lin L. W. and coworkers [17] utilized near-field electrospinning to direct-write piezoelectric nanofiber from poly(vinylidene fluoride) (PVDF) solution directly, which has high conversion efficiency and displays great advantages in the fields of sensing and actuation.

Micro/Nano Integration System. Electrospun nanostructures are also used as sacrificial layer to fabrication micro/nano integration

system [18, 19]. Firstly, orderly pattern nanofiber is printed on the substrate through the electrospinning process. Secondly, the structural material is deposited over the pattern nanofiber. Thirdly, the structural material layer is solidified and the sacrificial layer of nanofiber is removed. And then, the 3D micro/nano channel can be fabricated, which displays application potential in the fields of micro/nano fluidic chip, sensor, or biological diagnosis.

Outlook and Trend

Electrospinning is a versatile method to fabricate various nanomaterials through a simple and cost-effective process. Various materials can be used to produce nanofiber through electrospinning process. The multifunctional nanofibers have been applied in many fields of membrane reinforcement, biomedical, optoelectronics, flexible electronics, wound healing, micro/nano sensor, etc. The highly efficient production, direct three-dimensional structures forming, and precise integration deposition of functional nanofibers are the main development trends for the nanostructure by electrospinning. The ejection, motion, rheology, and deposition behaviors of the charged jet would be studied further in the future, which can improve the controlling level of electrospinning technology to meet the requirements of various applications.

Synonyms

Iridescent colors (organisms other than animals); Physical colors; Structural colors

Definition

Structural colors refer to colors generated by minuscule structures, with the characteristic dimension of the structures on the order of the wavelength of the visible light (i.e., some tens up to hundreds of nanometers). Examples for structural colors are the colors of CDs and DVDs, the colors of soap bubbles or oil films on water (thin films), or the colors of certain butterfly wings (e.g., photonic crystals) and even plants. Tiny wax crystals in the blue spruce scatter the light (Tyndall scattering), resulting in the blue hue. Thin films in tropical understory plants and diffraction gratings in hibiscus and tulip flowers are just some more examples of the amazing variety of natural nanostructures that are the basis for coloration in some plants. This entry reviews the physics behind structural colors; lists plants, microorganisms, and virus species with nanostructures responsible for their coloration; and also touches upon the multifunctionality of materials in organisms, nanobioconvergence as an emergent science, and biomimetics as a promising field for knowledge transfer from biology to engineering and the arts.

Introduction

Iridescent, metallic, or grayish coloration in some plants is not caused by pigments but rather by physical structures with characteristic sizes on the order of some tens up to several hundreds of nanometers [1]. The name-giver for the term iridescent, that is, color change with the viewing angle, is Iris (ιρισ), the Greek goddess and personification of the rainbow.

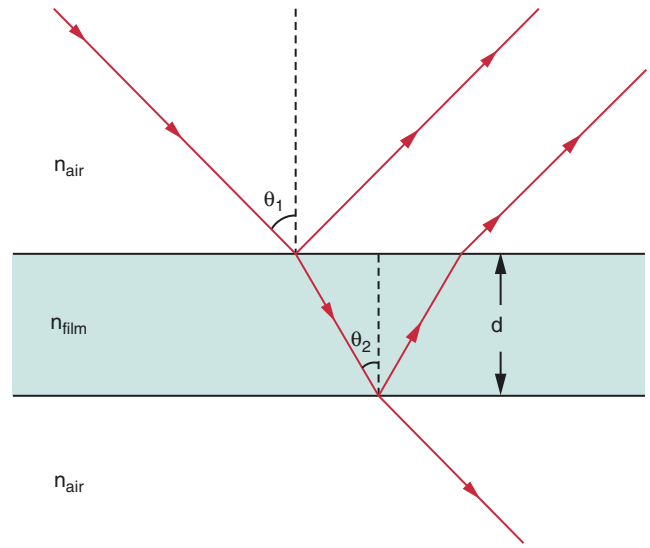
According to previous studies about various kinds of colors and their origins, colors are divided into two different categories: chemical colors and structural colors. Chemical colors are caused by pigments, whereas structural colors are caused by structures. The interaction of visible light with structures causes shiny, bright colors that might also show iridescence and/or metallic appearance. Vertical spatial structuring may limit the change in color bandwidth with angle – in this way, structural colors of specific hues such as the brilliant blue of the Morpho butterfly can be generated [2, 3]. In some of these structural colors with small bandwidth at ambient conditions, viewing at small angles and high light intensities reveals a wide spectrum of colors (e.g., in the national Malaysian butterfly Raja Brooke's Birdwing, *Trogonoptera brookiana*).

In chemical colors, light is selectively reflected, absorbed, and transmitted. Pigments reflect the wavelengths of light that produce a color and absorb the other wavelengths. Ultramarine blue, for example, reflects blue light and absorbs other colors. Light absorbed by the

pigment yields altered chemical bonds of conjugated systems and other components of the pigment and is finally released as heat, as reemission of light via fluorescence or by passing the energy on to another molecule. Plant pigments are largely soluble in aqueous solutions or lipids, and they actually work more like dyes in the sense that they do not actually directly reflect but allow the passage of wavelengths that are then reflected by structures with different refractive indices, such as cell walls. Plant pigments are therefore more like watercolors on white paper than the colors used in an oil painting.

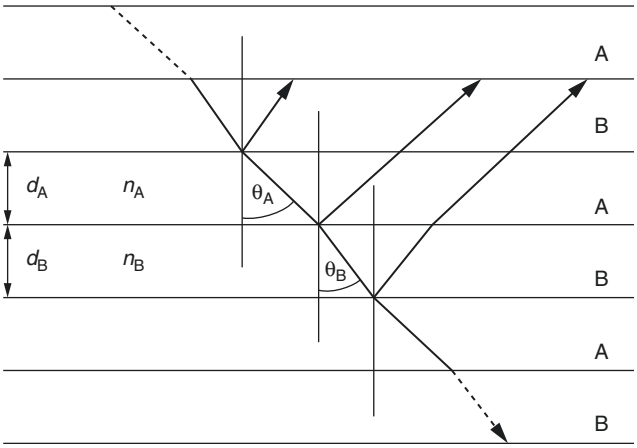
In structural colors, on the other hand, the incident light is reflected, scattered, and deflected on structures, with negligible energy exchange between the material and the light, resulting in strong, shiny coloration.

The objective of this entry is to give a review of the physical mechanisms leading to structural colors, introduce plant species as well as microorganisms and viruses with the respective nanostructures thought to be responsible for or contribute to the coloration, give some examples for structural colors in current technology, and introduce nanobioconvergence as an emergent science and biomimetics as a promising field for knowledge transfer from biology to engineering and the arts.



The Physics of Structural Colors

Five physical phenomena lead to structural coloration: thin-film interference, multilayer interference, scattering, diffraction, and photonic crystals.



Thin-Film Interference

Thin-film interference occurs when an incident light wave is partly reflected by the upper and lower boundaries of a thin film (Fig. 1). It is one of the simplest phenomena in structural coloration and can be found in various instances in nature, for example, in the wings of houseflies, in oil films on water, or in soap bubbles.

Light that strikes a thin film surface can be either transmitted or reflected from upper or lower boundary, respectively. This can be described by the Fresnel equation. Interference between two reflected light waves can be constructive or destructive, depending on their phase difference. Of relevance are the thickness of the film layer (d), the refractive index of the film (n), and the angle of incidence of the original wave on the film (Θ_1). In addition, if the refractive index n_2 of the thin film is larger than the refractive index of the outside medium n_1, there is a 180° phase shift in the reflected wave. This is, for example, the case in a soap bubble, with $n_1 = n_{\text{air}} = 1$ and $n_2 = n_{\text{film}}$, with $n_{\text{air}} < n_{\text{film}}$.

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 1 Thin-film interference in the case of, for example, soap bubbles

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 2 Multilayer interference. $n_B > n_A$. A change in viewing angle corresponds to a change in the perceived color, due to changes in the apparent film thickness

The reflection on the upper boundary of the film (the air-film boundary) causes a 180° phase shift in the reflected wave (since $n_{air} < n_{film}$). Light that is transmitted at this first boundary continues to the lower film-air interface, where it is either reflected or transmitted. The reflection at this boundary has no phase change because $n_{film} > n_{air}$.

The condition for constructive interference for a soap bubble in air is given in Eq. 1; the condition for destructive interference is given in Eq. 2:

$$2n_{film}d\cos(\theta_2) = (m - 1/2)\lambda \quad (1)$$

$$2n_{film}d\cos(\theta_2) = m\lambda \quad (2)$$

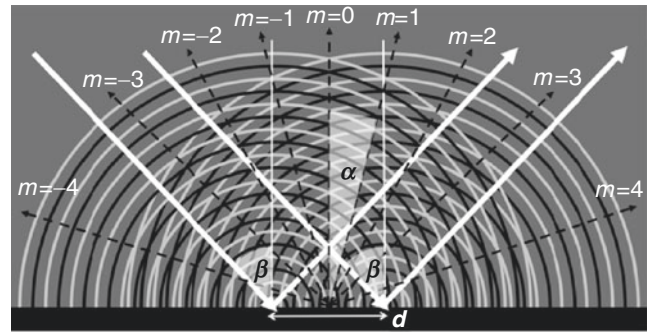
where d equals the film thickness, n_{film} equals the refractive index of the film, θ_2 equals the angle of incidence of the wave on the lower film-air boundary, m is an integer, and λ is the wavelength of the light.

Summing up, there are two conditions that should be satisfied for constructive interference: firstly, the thin film should be thin enough to crest the reflected waves, and secondly, the two reflected waves should be in one phase. The color seen depends also upon the viewing angle, which changes the apparent film thickness.

Multilayer Interference

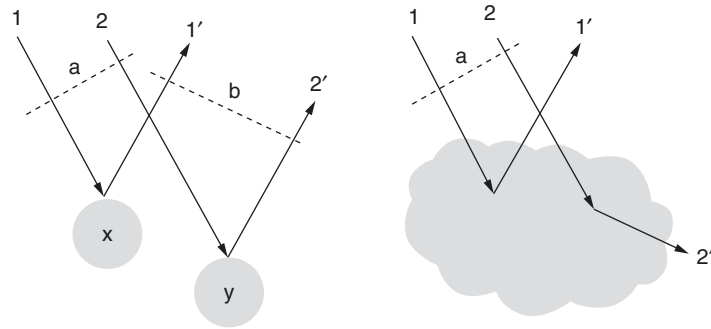
As described above, a light wave can be reflected from both boundaries of a thin film layer and dependent on the phase of the two reflected light waves either destructive or constructive interference occurs. The same phenomenon occurs in a series of thin films, a multilayer. A schematic of a multilayer is given in Fig. 2. With $n_B > n_A$, between each A-B interface, a 180° change in phase takes place, while at the B-A interface, there is no phase change. Reflection or refraction at the surface of a medium with a lower refractive index causes no phase shift. Reflection at the surface of a medium with a higher refractive index causes a phase shift of half a wavelength.

The condition for constructive interference for a multilayer is given in Eq. 3; the condition for maximum reflection is given in Eq. 4:



$$2(n_A d_A \cos\theta_A + n_B d_B \cos\theta_B) = m\lambda \quad (3)$$

$$2n_A d_A \cos\theta_A = (m - 1/2)\lambda \quad (4)$$



In ideal multilayers, all waves interfere constructively, resulting in colorful reflections, whereas in nonideal multilayers, some waves interfere destructively and the reflection is less colorful [4].

Diffraction Gratings

The grating equation (Eq. 5) correlates the spacing of the grating (d) with the angles of the diffracted and incident beams (α, β) and the wavelength of illumining light (λ) (Fig. 3). The coloration in a particular direction (viewing angle) is generated by the interfering components from each slit of the grating. The diffracted light has maxima at angles

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 3 Schematic of the color generating mechanism by the diffraction of light by a diffraction grating (*black bar* on *bottom*)

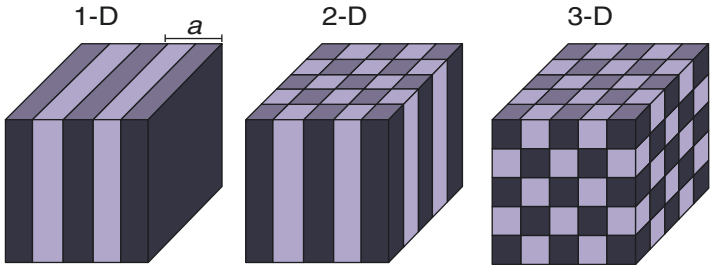
Nanostructures for Coloration (Organisms Other Than Animals), Fig. 4 Coherent (*left*) and incoherent scattering (*right*)

where there is no phase difference between the waves. The 0th order reflection corresponds to direct transmission and is denoted $m = 0$. Other maxima occur at angles with $m = \pm 1, \pm 2, \pm 3, \ldots$.

$$d(\sin\alpha - \sin\beta) = m\lambda \qquad (5)$$

CDs and DVDs are examples for this phenomenon. Recently, diffraction gratings that produce colors have been described in flowers [5].

Scattering



The term scattering is a more general denomination for the interference of light waves with different wavelengths reflected from scattering objects either in a constructive or destructive way (Fig. 4). In terms of coloration, scattering can yield either strong or weak colors. Examples of scattering, and more precisely coherent scattering, are the thin-film interference and the multilayer film interference described above.

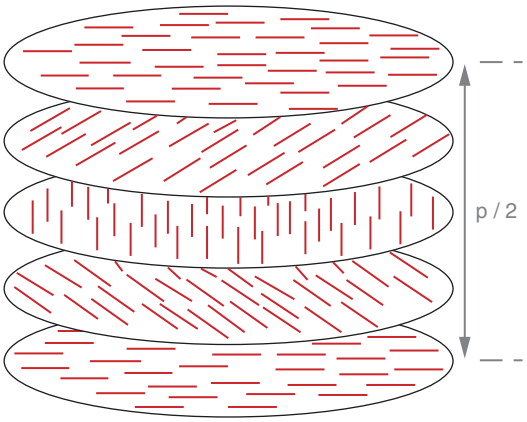
In coherent scattering, there is a definite phase relationship between incoming and scattered waves, whereas in incoherent scattering, this is not the case.

The two main types of scattering are termed Rayleigh scattering and Tyndall scattering. In both types of scattering, the intensity of the scattered light depends on the fourth power of the frequency. In Rayleigh scattering, the responsible particles are much smaller than the wavelength of the incident light, whereas in Tyndall scattering, the particles are macroscopic (e.g., dust particles in air or small fat particles in water, as in milk). Since blue light (i.e., shorter wavelengths) is scattered more than red light (i.e., long wavelengths), milk, tobacco smoke, and the sky are blue or have a blue hue. In plants, for example, the blue of the blue spruce can be explained by scattering [6]. Multiple scattering within regular structures produces highly reflective bands in the reflection spectrum and leads to the brilliant colors observed in, for example, iridescent fruits ([1] and references therein).

Photonic Crystals

Photonic crystals exhibit a periodicity a in the refractive index (Fig. 5). There are one-, two-,

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 5 Schematics of one-, two-, and three-dimensional photonic crystals (1-D, 2-D, 3-D). The colors represent materials with different refractive indices. The spatial period of the material is called the lattice constant, *a*



and three-dimensional photonic crystals. Depending on their wavelength, photons either can be transmitted through the crystal or not (allowed and forbidden energy bands). For effects in the visible range, the periodicity of the photonic crystal has to be between about 200 nm (blue) and 350 nm (red).

Vegetable opal is an example for a photonic crystal produced by plants. Opal is the only gemstone that is known to be formed also as a plant-produced product. There are three different types of opal produced by photosynthetic organisms: minuscule iridescent diatoms, phytoliths, and tabasheer. Tabasheer (bamboo opal, plant opal) is a hard, translucent to opaque whitish substance extracted from the joints of bamboo [7]. It can have a beautiful blue hue and was – cut as cabochons – used in China for fashion jewelry.

Cholesteric Liquid Crystals

Cholesteric liquid crystals are layered helicoidal structures, also known as chiral nematic liquid crystals, within which molecules take a preferred direction that gradually changes from layer to layer (Fig. 6). The variation of the director axis tends to be periodic in nature. The period of this variation (the distance over which a full rotation of 360° is completed) is known as the pitch, *p*.

Certain iridescent tropical understory ferns contain a helicoidal layering of cellulose microfibrils that produces multiple interference layers ([1] and references therein), similar to the helicoidal microstructure in a cholesteric liquid crystal and the characteristic liquid crystals in beetles [2].

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 6 The chiral nematic phase in a cholesteric liquid crystal. *p* refers to the chiral pitch (Image reproduced with permission under the terms of the GNU Free Documentation License)

The peak wavelength of the reflected light, λ, is determined by the helicoidal pitch, *p*, where

$$\lambda = pn \tag{6}$$

and *n* is the average refractive index of the anisotropic material [8].

Plants (and Other Nonanimals) with Structural Colors

Structural colors in nature are found in various animals, plants, microorganisms, and even viruses [1–3, 9]. Studies of structural colors date back to

the seventeenth century when the earliest scientific description of structural colors appeared in *Micrographia*, written by Robert Hooke in 1665. In his book *Opticks*, Sir Isaac Newton already in 1704 related iridescence to optical interference:

> The finely colour'd feathers of some birds, and particularly those of the peacocks' tail, do in the very same part of the feather appear of several colours in several positions of the eye, after the very same manner that thin plates were found to do.

Since then, various organisms with structural colors (almost all in animals) have been reported. This chapter focuses on organisms outside of the animal kingdom, primarily plants, but also macroalgae, slime molds, diatoms, and viral particles. For plants, the discussion is organized along the physical phenomena as well as the various organs where such color is found, that is, leaves, flowers, fruits, and seeds. Other organisms with simpler organization are classified by the major groups, for example, the red algae (Rhodophyta).

Gentner (1909) [10] performed various experiments on the origin of the structural colors generating the blue hue on leaves and fruits. He acknowledges Mohl (1870) [11] as the first one to describe this phenomenon (that time wrongly attributed to fluorescence), in the evergreen shrub Laurestine (*Viburnum tinus*).

The first English report on structural colors in plants was by Lee and Lowry [12], who described the physical basis and ecological significance of iridescence in blue plants. The most common mechanisms in plants leading to structural coloration are multilayer interference and diffraction gratings. Multilayer interference is found predominantly in shade-plant leaves, suggesting a role either in photoprotection or in optimizing capture of photosynthetically active light ([1] and references therein). Surprisingly, diffraction gratings may be a common feature of petals, and recent work has shown that bees use them as cues to identify rewarding flowers. Structural colors may be surprisingly frequent in the plant kingdom and still much remains to be discovered about their distribution, development, and function [13].

Nonanimals with Coloration Caused by Thin-Film Interference

True Slime Molds

Slime molds are organisms that normally live as single cells and that can aggregate to a multicelled organism and form fruiting bodies that produce spores. They have the characteristics of single-celled microorganisms as well as of fungi and occur worldwide on decaying plant material. Inchaussandague and coworkers [14] described structural colors produced by a single thin layer in the slime mold *Diachea leucopoda*. Interference within the peridium, a 200 nm transparent layer invariant along the different cells of the organism, is the basis for this color.

Plants with Coloration Caused by Multilayer Interference

Tropical Understory Ferns

The iridescent blue peacock fern Willdenow's Spikemoss, *Selaginella willdenowii* (actually a lycophyte or fern ally), is a common plant in the Malaysian rain forests [15]. It exhibits blue iridescence; investigation with TEM reveals various layers (with less than 100 nm thickness each) on the surface. The photo shown in Fig. 7 was taken in the Bukit Wang Recreational Forest in Malaysia, with very long exposure time as to better reveal the blue coloration of the leaves. Seen with the naked eye, the fern is bluish green and seems to glow in semidarkness. The blue coloration is iridescent and changes with the viewing angle. Holding and tilting the leaves results in color change from green to nearly total blue, although not as strong as seen in the long exposure time photograph shown in Fig. 7.

Also another species of *Selaginella* shows iridescence: *Selaginella uncinata*. As in *S. willdenowii*, a multilayer system where each layer is thinner than 100 nm is responsible for the structural coloration. When the leaves of these two *Selaginella* species are dried, the coloration disappears but comes back again when the plants are hydrated again. When a droplet of water is put on a *Selaginella* leaf, the blue coloration

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 7 The iridescent blue peacock fern *Selaginella willdenowii*, a common plant in the Malaysian rainforest. © Mr. Foozi Saad, IPGM, Malaysia (Image reproduced with permission)

disappears. Other tropical understory ferns where coloration is caused by multilayer interference are *Diplazium crenatoserratum*, *Lindsaea lucida*, *Danaea nodosa*, and *Trichomanes elegans* (the neotropical Bristle Fern, also called the dime store plant because it looks like it is made from plastic and is shade tolerant, is native to the American tropics) ([1] and references therein).

Tropical Understory Begonias

Gould and Lee (1996) reported structurally modified chloroplasts (termed "iridoplasts") in the Malaysian tropical understory plant *Begonia pavonina* (the Peacock Begonia) [16]. The structural coloration is generated by many layers, each less than 100 nm thick. In addition to *B. pavonina*, the authors have observed several other iridescent blue species on the Malaysian peninsula. Modified plastids produce blue colors in *Begonia*, *Phyllagathis* (see section "Other Tropical Understory Plants"), and *Trichomanes* (see section "Tropical Understory Ferns").

Other Tropical Understory Plants

A traditional Malaysian medicinal plant, the melastome *Phyllagathis rotundifolia* (in Malay known as *tapak sulaiman*) and also the Malaysian understory species *P. griffithii* exhibit iridoplasts, similar to the ones in *Begonia pavonina* described above.

Iridescent Macroalgae

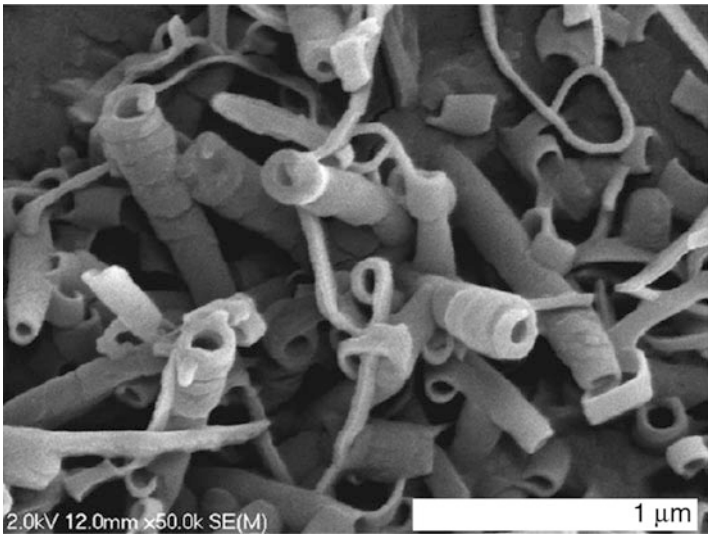
Among the red algae (Rhodophyta), several species of *Mazzaella* (=*Iridaea*) are strikingly iridescent [17]. Green and brown algae have been recorded as iridescent, but the phenomenon is most commonly found in red algae, where blue and green colors appear on the surface at certain stages of the life cycle. Iridescent red algae (e.g., *Mazzaella flaccida*, *Mazzaella cordata*) exhibit shiny blue, emerald-green, and deep red colors. The blades are relatively thin and vary in shape and size (up to 3 ft long and 10 in. wide) depending on the habitat and the amount of wave exposure. *Mazzaella flaccida* is iridescent yellow green with purple or brown near the base of the blade, and the iridescent blade of *Mazzaella splendens* is dark purple with a blue iridescent sheen. It is also known as the rainbow-leaf seaweed. The coloration disappears when the algae are dried and is restored when the algae become wet again. Wet *Iridaea* look like they have been coated with oil (Fig. 8), because of their rainbow sheen; iridescent spots, shaped like a teardrop, with a multilayer system of 17 electron opaque and translucent layers, some tens to a few hundred of nanometers thick, are responsible for the coloration. The iridescence might be a by-product of a wear protection mechanism of the algae.

The edible seaweed *Chondrus crispus* (carragheen, Irish moss) is a red algal species

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 8 *Mazzaella* sp., a highly iridescent red alga. © 2003 by J. Harvey, http://www.JohnHarveyPhoto.com (Image reproduced with permission)

that shows blue iridescence due to multilayer interference effects on the tips [18].

The function of algal iridescence is still unclear. Suggestions include a role in camouflage or a role in optimizing photosynthesis by enhancing the absorption of useful wavelengths of light at the expense of increased reflection of other wavelengths.



Plants with Coloration Caused by Diffraction Gratings

Glover and Whitney [13] reviewed the original research on iridescence in plants and presented very recent results on floral iridescence produced by diffractive optics. They identified iridescence in flowers of *Hibiscus trionum* (the inner part of its petals has an oily iridescence overlying red pigmentation) and tulip species (e.g., *Tulipa kolpakowskiana*) and demonstrated that iridescence was generated through diffraction gratings. The iridescence in the hibiscus is obvious to human eyes (appearing blue, green, and yellow depending on the angle from which it is viewed), whereas the iridescence in the tulip is in the ultraviolet spectrum, which bees can see, but people cannot. The surface striations in the diffraction gratings observed in the tulips are about 1 μm apart. Whitney and her coworkers investigated 22 tulip species from around the world and found ordered striations in 18 of them. They report iridescence generated by diffraction gratings in 10 families of angiosperms, tulips and hibiscus being just two of them: from the mallow family, the species example they give is *Hibiscus trionum*; from the lily family, *Tulipa* sp.; from the aster, daisy, or sunflower family, *Gazania klebsiana*; from the pea family, *Ulex europaeus*; from the Loasaceae family (of bristly hairy and often climbing plants), *Mentzelia lindleyi*; from the buttercup or crowfoot family, *Adonis aestivalis*; from the willow herb or evening-primrose family, *Oenothera biennis*; from the nightshades, *Nolana paradoxa*; from the iris family, *Ixia viridiflora*; and from the peony family, *Paeonia lactiflora*. According to this extensive list, it might well be that many more flowers are iridescent than previously thought – since they are iridescent in parts of the spectrum that people cannot see. The principal reason why not more species with diffraction-based coloration are known might simply be that until now nobody has looked.

Plants with Coloration Caused by Scattering

Some green leaves look white or silvery because microscopic air spaces in surface hairs reflect the light. Other leaves (such as the wax palm) and some fruits (such as plums and grapes) have a white "bloom" which is a surface deposit of wax.

Whitish, silvery, and other metallic finishes of leaves are generally produced by reflection of the light off microstructures, nonliving plant hairs called trichomes. In deserts, this increased reflection, especially of infrared radiation, off the

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 9 Monohelical tubular epicuticular wax structures in *Wollemia nobilis*. Scale bar 1 µm (From Ref. [19], reproduced with permission)

microstructures is important since it reduces heating of the leaf. However, a reflecting leaf has a much lower photosynthetic capacity than would an equal leaf without the reflectant trichomes. The Desert Brittlebush *Encelia farinosa* produces nonreflectant green leaves during the cooler springtime, when it is beneficial to have warmer leaves.

Silvery, gray, white, or blue coloration in plants might arise due to light scattering on three-dimensional epicuticular wax structures (structural wax). Leaves with a bluish gray waxy surface are called glaucous.

Generally, radiation is scattered across the spectrum, with increased reflectance in the ultraviolet, visible, and infrared windows. The size, distribution, and orientation of wax crystals and other surface features determine the extent to which light is scattered at the plant surface. In some plant species such as the Blue Spruce (*Picea pungens*), preferential scattering of shorter wavelengths and enhanced reflectance of UV radiation occur.

Epicuticular wax is a complex mixture of long-chain aliphatic and cyclic compounds. The bluish leaf hues of the evergreen Desert Mahonia *Berberis trifoliolata*, for example, arise from wax structures on nipple-like projections from the epidermal cells, called epidermal papillae. In some cases, for example, in the Blue Finger, *Kleinia mandraliscae*, and in cabbage, *Brassica oleracea*, powdery wax can be rubbed from the surface, causing the gray or bluish hue to disappear and revealing the green leaf color beneath. The Wollemia Pine *Wollemia nobilis*, an evergreen tree with bluish green mature foliage, has monohelical tubular epicuticular wax structures with a diameter of about 100 nm (Fig. 9) [19]. Depending on the wax compound present, epicuticular wax crystals can have various shapes [20]: The glaucous eucalyptus tree (*Eucalyptus gunnii*) has nanoscale β-diketone epicuticular wax tubules; the blue-gray foliage of the Dusty Meadow Rue (*Thalictrum flavum glaucum*) has nanoscale nonacosanol tubules. The Black Locust Tree (*Robinia pseudoacacia*) has dark, dull, blue-green summer foliage with nanoscale epicuticular wax platelets that are arranged in rosettes. The leaves of Wild Cabbage (*Brassica oleracea*) show simple nanoscale rodlets, whereas the nanoscale rodlets on the Silky Sassafras (*Sassafras albidum*) leaves are transversely ridged.

The epicuticular wax in the skin of plums (*Prunus domestica* L.) consists of an underlying amorphous layer adjacent to the cuticle proper together with crystalline granules of wax protruding from the surface. The epicuticular waxes in olive leaves serve as radiation inceptors.

Coloration Caused by Photonic Crystals: Plants, Diatoms, and Viruses

Iridescent Blue Fruits

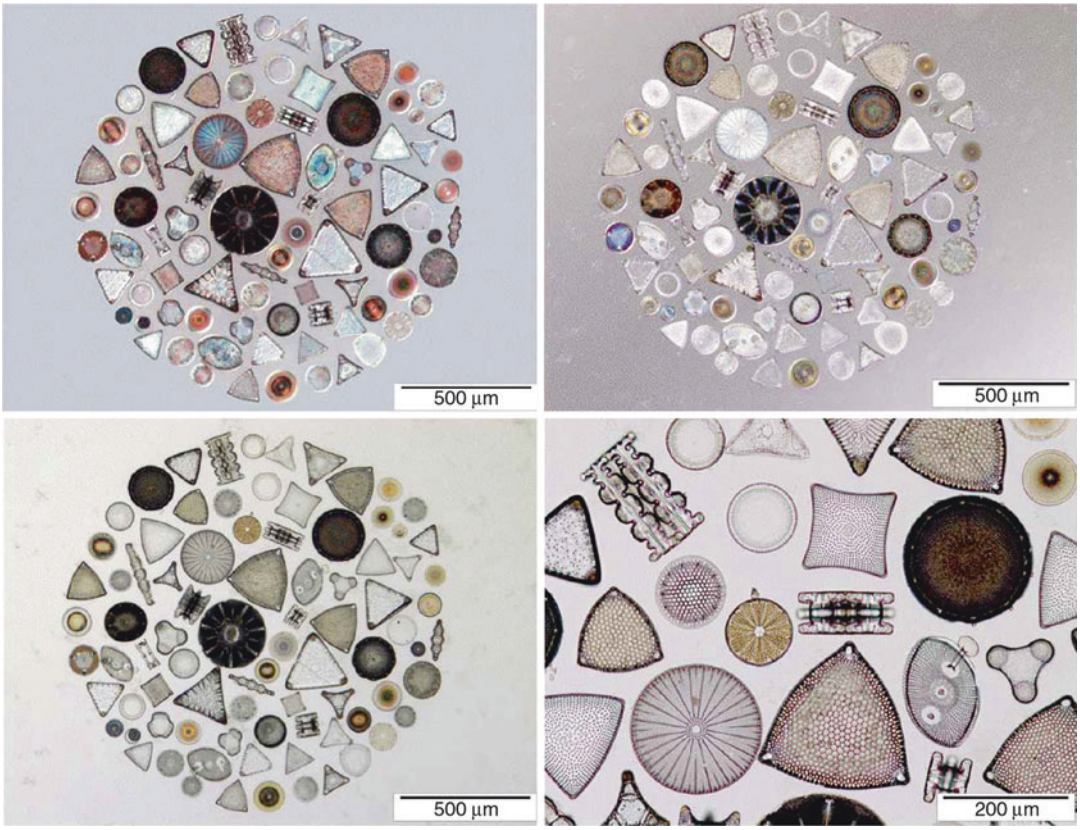
The fruits of the Blue Quandong (*Elaeocarpus angustifolius*, syn. *E. grandis*) and the Blue Nun (*Delarbrea michiana*) have brilliant blue coloration ([1] and references therein). The iridescent blue color of the quandong fruit is actually enhanced by wetting, not like in *Selaginella*, mentioned above, where it disappears when wet. Iridosomes, multilayered systems arranged in 3-D structures, similar to the structure yielding coloration in Morpho butterflies, are responsible for the coloration of these fruits. Iridosomes are different from the iridoplasts described above for leaves: They are secreted by the epidermal cells of the fruit and are located outside the cell membrane but inside the cell wall. The structures of the iridosomes are at least partly cellulosic. The stone of the silver quandong fruit is termed *rudraksha*. It is hard and highly ornamented and is used throughout India and Southeast Asia in religious jewelry.

Edelweiss

Edelweiss (*Leontopodium nivale* subsp. *alpinum*) is a European alpine flower that grows at high elevations up to 3400 m. Its body is covered with white hairs. Vigneron and coworkers showed in 2005 [21] that the internal structure of these hairs acts as a two-dimensional phonic crystal. The hairs are hollow tubes, about 10 μm in diameter, with an array of parallel striations with a lateral diameter of 176 nm around the external surface. Through diffraction effects determined by the optical fiber with photonic crystal cladding, the hairs absorb the majority of the UV light, thereby acting as an efficient sun block for the structures beneath.

Spores

Some ferns produce two types of spores: microspores and megaspores (size: some hundreds of micrometers). Hemsley et al. [22] reported iridescent megaspores in *Selaginella* (fossil and modern). They report that spore iridescence is not generally visible until the outer layers of the spore wall (with different organizations to the iridescent layer) are removed. The three-dimensional pattern yielding the iridescence, for example, in megaspores of *Selaginella exaltata*, is still unresolved. According to SEM images, an ordered structure of 240 nm diameter particles, perhaps an opal-like colloidal crystal that is generated via self-assembly, is the reason for the coloration.



Tabasheer

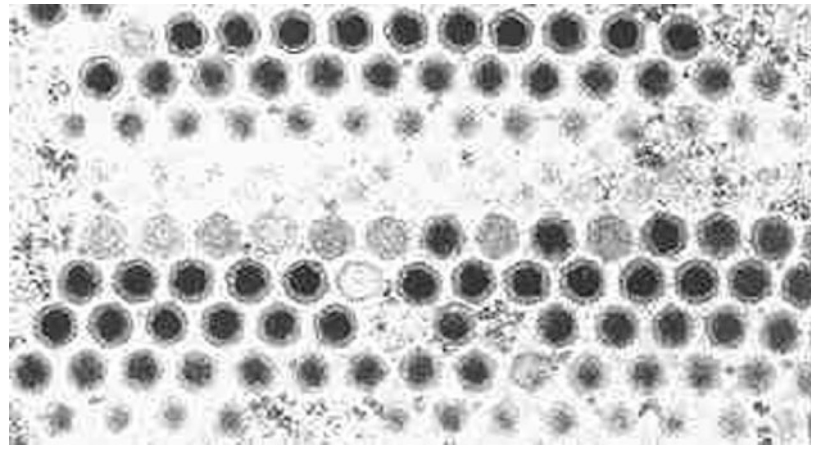
Opal is the only gemstone that can be produced in biotic and abiotic ways. Tabasheer (vegetable opal, pearl opal) consists of hydrated silica and is produced when bamboo is hurt; the plant sap comes to the surface and dries in small nodules. These little nodules are opaque or translucent white, sometimes with a faint hint of blue. They can be polished as cabochons and are often used in the orient as jewelry. Tabasheer is highly porous and hygroscopic and has been used in ancient times to remove snake poison from the body – therefore, it is also known as snake stone [7].

Diatoms

Diatoms (Bacillariophyta) are found in both freshwater and marine environments, as well as in damp soils and on moist surfaces. They are unicellular microalgae with a cell wall consisting of a siliceous skeleton enveloped by a thin organic case. The cell walls of each diatom form a pillbox-like shell consisting of two parts that fit within each other.

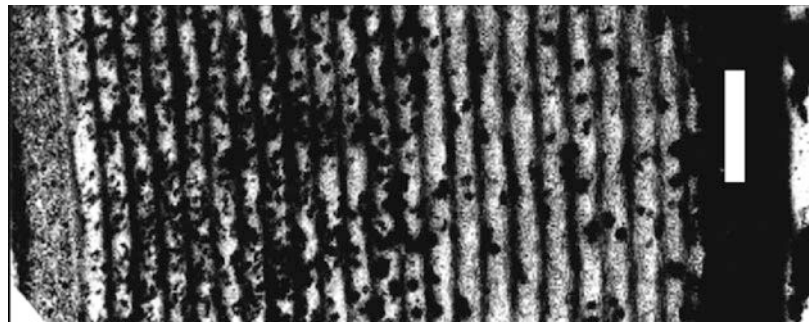
Diatoms exhibit an amazing diversity of nanostructured frameworks (Fig. 10), including two-dimensional inverse photonic crystals. The cell wall exhibits periodic arrangement of pores in the micrometer to nanometer range – each diatom species has its own specific morphology. Individual diatoms range in size from few micrometers up to several millimeters, although only a few species are larger than 200 μm. A patch of diatoms can look like iridescent scum to the naked eye. Under the microscope, beautiful iridescence can be seen on the single-cell level, and a microscope slide covered with a monolayer of diatoms also exhibits iridescence to the naked eye (with

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 10 Sample with various diatoms from New Zealand, laid by hand by Elger in 1925. The slide was photographed by Friedel Hinz under the optical microscope with slightly varying angles of view, revealing color change in some of the diatoms (*top* images and *bottom left*). *Bottom right*: Zoom. Marine fossil diatoms from Gave Valley, New Zealand, Sample T1/21 prepared by Elger, 1925. Image (c) 2011, F. Hinz, AWI Bremerhaven, Germany (Image reproduced with permission)



good illumination or in sunlight). Iridescent effects are used widely in color cosmetic products and personal care packaging, and there is great potential for using diatoms in this industry.

Viruses



Iridescent viruses (Iridoviridae) are between 120 and 140 nm in diameter and infect insects, fishes, and frogs. Iridescent viruses produce systemic infections, with the highest concentrations in the outer layer of the skin (the epidermis) and the fat bodies. Insect larvae infected with this virus develop iridescent lavender-blue, blue, and blue-green coloration. In older infections, the iridescent color is generally more vivid, and frequently, there are also small, extremely brilliant islands. Electron microscope examination reveals numerous viruses in paracrystalline arrays (see Fig. 11) [23].

Plants with Coloration Caused by Cholesteric Liquid Crystals

In three iridescent tropical understory fern species, structurally modified chloroplasts with helicoidal structures, similar to the characteristic liquid crystals in beetles [2], might be the reason for the blue coloration. These ferns are *Danaea nodosa* (with many multilayers, each less than 100 nm thin), the necklace fern *Lindsea lucida* (17 layers, 192 nm spacing), and *Diplazium tomentosum* (20–23 layers, 141 nm spacing; see Fig. 12) [1].

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 11 Paracrystalline array of virus particles within an infected cell. This array gives rise to the iridescent phenomenon (Image Source: http://www.microbiologybytes.com/virology/kalmakoff/Iridoviruses.html. Permission pending)

Structural Coloration Caused by Not Yet Described or Not Yet Identified Mechanisms

Macroalgae

Various red algae (Rhodophyta) and brown algae (Phaeophyta) exhibit iridescence and are completely unstudied. For example, of yet unknown origin is the bright blue, purple, or red iridescence in the red alga *Ochtodes secundiramea*.

Dictyota are widespread brown algae (Phaeophyta) along the Atlantic coast and very well known. *Dictyota mertensii* has blue/green iridescence; *Dictyota dichotoma* is also known as the purple peacock algae; *Dictyota barayresii* shows a translucent, iridescent blue; *Dictyota sandvicensis* exhibits a yellow-green iridescence; and *Dictyota humifusa* is light brown, often with brilliant blue iridescence. Iridescent bodies in the brown algae *Cystoseira stricta* are specialized vacuoles (vesicles) that contain numerous dense globules inside. The physics of their iridescence has not yet been clarified. The Hawaiian brown alga *Stypopodium hawaiiensis* has a beautiful blue or green color, and *Dictyopteris zonarioides* sometimes is iridescent blue [17].

Additional to the iridescence in red algae with multilayers responsible for the coloration (see section "Iridescent Macroalgae" above), the following red algae exhibit structural coloration: The Blue Branching Seaweed *Fauchea laciniata* shows deep red with iridescent blue; thin layer interference (whether from one layer or a multilayer system still needs to be clarified) is the reason for its coloration. *Fryeella gardneri* exhibits iridescent purple; *Cryptopleura ruprechtiana* is mildly iridescent. In *Chondracanthus corymbiferus*, the younger

Nanostructures for Coloration (Organisms Other Than Animals), Fig. 13 The iridescent Blue Strap Fern *Elaphoglossum herminieri*, at Sarapiqui, Heredia, near Puerto Viejo, La Selva Biological Station, Costa Rica. © 2008 R.C. Moran, The New York Botanical Garden (rmoran@nybg.org) [ref. DOL23374] (Image reproduced with permission)

blades are smooth and iridescent. Other iridescent red algae are *Chondria coerulescens* and *Drachiella spectabilis*. Also *Maripelta rotata* and *Botryoglossum farlowianum* are iridescent.

Slime Molds

As described above in section "True Slime Molds," the physical reason for the iridescent color in at least one type of slime mold is a single transparent thin layer. Slime mold iridescence is also described for some other species; however, its physical basis still needs to be determined. Spores of *Diachea subsessilis* exhibit dull greenish gray varying to blue iridescence; the peridium in *Diachea deviata* is iridescent and persistent. Beautiful bronze iridescent colors, sometimes tinged with blue, can be observed in the peridium of *D. subsessilis* (with the membranous peridium being colorless in water mounts, suggesting that pigments are not involved in the color production).

Plants

Bryophytes Bryophytes include the mosses, liverworts, and hornworts. The moss *Schistostega pennata* exhibits golden-green iridescence when it grows in caves where the light always comes from only one direction. This moss (also known as Dragon's Gold) shines like emerald jewels from the darkness of a rock crevice or cave. This unusual property is the result of lens-shaped cells with curved upper surface that focus the light on one point in the interior of the cell, where the chloroplasts aggregate. It remains to be determined if nanostructures are responsible for the coloration of this moss (Lee [1] and references therein).

Ferns *Elaphoglossum herminieri*, a strap fern that is native to tropical rain forests of the neotropics, shows iridescent blue color (Fig. 13) that is not removed by wetting. The reason of the coloration is unknown, as it is in *Elaphoglossum wurdackii* and *E. metallicum*. The oil fern *Microsorum thailandicum* (*Microsorum steerei*) from Southeast Asia has blue-green iridescent leaves. Also ferns of the family Vittariaceae can have iridescent scales. In this family, especially ferns of the genus *Antrophyum* (e.g., *Antrophyum formosanum*) and *Haplopteris* can be densely covered with iridescent scales. *Antrophyum mannianum*, a mountain fern liking full shade, has more or less iridescent leaves. There are also reports on an *Antrophyum* species found in Borneo (Mt. Mulu or Gunung Mulu) with an

iridescence that makes the plant look like it is covered with metallic eye shadow. *Haplopteris* ferns live in tropical and subtropical Asia. Obscure iridescence is exhibited by *Haplopteris amboinensis. H. doniana*, *H. taeniophylla*, *H. himalayensis*, *H. mediosora*, *H. fudzinoi*, *H. linearifolia*, *H. hainanensis*, *H. sikkimensis*, *H. elongata*, and *H. anguste-elongata* show bright iridescence. Also, *H. flexuosa* is iridescent, but not as bright. Malaysian individuals of the fern *Didymochlaena truncatula* are reported to be iridescent. The Venus Hairfern *Adiantum capillus-veneris* has iridescent stems, and the Aleutian Maidenhair *Adiantum aleuticum* has iridescent blackish foliage.

Grasses (Poaceae) Iridescence can be observed in the rosy inflorescences of the ornamental grass *Miscanthus sinensis*. Further grasses with startling iridescent inflorescences are the small grass *Pennisetum alopecuroides*, 'Little Bunny', and the even smaller variety 'Little Honey'. In late summer, these grasses are covered with blooms that look like hairy caterpillars.

Sedges (Cyperaceae) A sedge is a grass-like or rush-like plant growing in wet places having solid stems, narrow grass-like leaves, and spikelets of inconspicuous flowers. Leaves and seedlings of sedges can exhibit iridescence. The understory sedge *Mapania caudata* from Malaysia and also *M. graminea* exhibit iridescence in their leaves. The Smooth Black Sedge, *Carex nigra*, shows whitish iridescence, and the Autumn Sedge *Carex dipsacea* has iridescent olive green leaves. *Carex flagellifera* 'Toffee Twist' has iridescent, slender leaves.

The seedlings of the Pond Flatsedge *Cyperus ochraceus* are dark iridescent gray because of an outer one-cell thick covering of translucent cells, whereas the seedlings of the Marsh Flatsedge *Cyperus pseudovegetus* are brown with a very thin translucent-iridescent layer of cells. Also *Carex squarrosa* has blackish seedlings with iridescent superficial cells (when fully mature). In *Fimbristylis annua* and *F. vahlii*, the seedlings are often iridescent. Harper's Fimbry *F. perpusilla* has pale brown seedlings with iridescent tints, and the Southern Fimbry *F. decipiens* has seeds of whitened iridescent to brown.

Hypoxidaceae: Hypoxis The Star Grass *Hypoxis sessilis* has seedlings that are black but with iridescent membranous coats.

Orchids (Orchidaceae) Iridescent foliage in orchids occurs, for example, in *Macodes petola*, *Masdevallia* (*Byrsella*) *caesia*, and *Aulosepalum pyramidale*, where it is bright green with an iridescent shine. Flowers of many species of orchid (such as *Ophrys apifera* and the Mirror of Venus *Ophrys speculum*) have been reported to have an iridescent patch, the speculum. The shape and iridescence of this iridescent patch are thought to mimic the closed wings of female wasps or bees and sexually deceive the respective males, thereby pollinating the orchid (see [13] and references therein).

Others There are various further plant species that exhibit iridescence. Some of them are mentioned below. The main point is that there is a lot to study, and potentially several novel mechanisms of color production in organisms are yet to be identified.

- Purslanes (Portulacaceae): *Portulaca*. Seeds mostly glossy black or iridescent gray have been reported for various species of *Portulaca*. The reason of their iridescence is still unknown. In the Moss-rose Purslane *Portulaca grandiflora* Hooker, the mature seeds are steely gray and often iridescent; in the Pink Purslane *Portulaca pilosa*, the seeds are black, with very slight purplish iridescence when mature; in *Portulaca psammotropha*, the seeds are black, turning iridescent gray when fully mature; and in the Shrubby Purslane (Copper Purslane) *Portulaca suffrutescens* Engelmann and *P. halimoides*, the seeds are leaden and slightly iridescent.
- Grapes (Vitaceae): *Ampelopsis*. The Porcelainberry, *Ampelopsis brevipedunculata*,

has slightly iridescent fruits showing white, green, turquoise, blue, brown, and violet coloration.
- Lardizabalaceae (no common name): *Decaisnia*. The blue beans from the Blue Bean Shrub (*Decaisnea fargesii*) from Bhutan have iridescent, 4 in. large blue fruits.
- Pinks (Caryophyllaceae): *Spergularia*. Other plants with iridescent seeds are the Blackseed Sandspurry, *Spergularia atrosperma*, whose black seeds are often iridescent.
- Ice plants (Aizoaceae): *Sesuvium*. Another plant with iridescent seeds is the Slender Seapurslane, *Sesuvium maritimum*, with brownish-black, smooth, and somewhat iridescent seeds.
- Plantaginaceae (no common name): *Bacopa*. The Blue Waterhyssop, *Bacopa caroliniana*, has iridescent seeds.
- Goosefoot (Chenopodiaceae): *Chenopodium*. The White Goosefoot, *Chenopodium giganteum*, is an annual plant in which the young shoots are covered with a fine iridescent magenta powder.
- Rapataceae: *Stegolepis*. The leaves of *Stegolepis ligulata* have blue-green iridescence; even more impressive is the larger *S. hitchcockii*.
- Mallows (Malvaceae): *Hibiscus*. The African Rosemallow (*H. acetosella*) produces iridescent lobed maroon leaves on woody stalks.
- Palms (Arecaceae): *Chamaedorea*. Very impressive are the leaves of the Metallic Palm *Chamaedorea metallica*.
- Hydrangea (Hydrangeaceae): The United States patent PP18294 refers to the invention of a *Hydrangea macrophylla* plant named "HYMMAD I" whose inflorescences mature to an iridescent lime green.
- Starflowers (Hypoxidaceae): The flowering plant *Spiloxene capensis* can have white, cream yellow, or pink flowers with a dark center. In the pink form, the center is iridescent blue green, whereas in the white form, the center is iridescent bronze green.
- Ice plants (Aizoaceae): The inflorescences of the Hardy Pink Ice Plant *Delosperma cooperi* 'Mesa Verde™' have iridescent hues of salmon-pink.
- Gesneriads (Gesneriaceae): *Rhynchoglossum obliquum* is a highly shade-resistant flowering plant with deep blue iridescent inflorescences.
- Sea hollies (Apiaceae): *Eryngium maritimum*, Seaside Eryngo, and *E.* x *tripartitum*, Sea Holly 'Big Blue', have surprisingly iridescent blue flowers.
- Spikemoss (Selaginellaceae): *Selaginella kraussiana* 'Gold Tips', with the common names Golden Clubmoss and Krauss's Spikemoss, is a spikemoss found naturally in the Canary Islands, the Azores, and parts of mainland Africa. It has dark green foliage with golden tips.
- Begoniaceae: *Begonia*. Many begonia species have iridescent leaves; however, the coloration of the leaves is strongly dependent on the environment the plants are grown in. In *Begonia Rex*, the leaves can be of shiny metallic red. A begonia plant named 'Lady Rose' with iridescent foliage, flower bud, petals, and tepals was patented by Mr. Terry McCullough in December 1998 (patent number plant 10,736). There are no reproductive organs formed in this invention. Other iridescent begonias are *B. burkillii*, *B. limprichtii*, *B. congesta*, *B. hahiepiana*, and *B. sizemoreae* and the hybrids *Begonia* bandit, Bethlehem star begonia, *B*. comedian, *B*. Palomar prince, *B*. wild pony, *B*. his majesty, *B*. merry Christmas, *B*. little darling, *B*. max gold, *B*. stained glass, *B*. regal minuet, *B*. shirtsleeves, *B*. Venetian red, and *B*. hocking tutu terror. The authors have observed several iridescent members of this genus in Malaysia, besides the *B. pavonina* described previously.

Conclusion and Outlook

In this entry, the authors give a review of the physical mechanisms leading to structural colors, introduce plant species as well as microorganisms and viruses with the respective nanostructures

thought to be responsible for or contribute to the coloration, and present quite a number or organisms where the physical reason for the structural coloration has not yet been determined. Many animals have senses that either work in different bandwidths compared to the ones in humans, or they sense completely different properties (such as with echolocation or the magnetic sense). Since plants and animals interact on various levels and for various reasons, plants have evolved various properties tuned to animals.

Structural colors are increasingly being used in current and emerging technology as well as in the arts. Some examples: The Austrian company Attophotonics develops structural colors as sensors for lab-on-a-chip applications. The Japanese company Teijin Fibers Limited produced one blue dress made from Morphotex® structurally colored fiber, a flattened polyester fiber mimicking Morpho butterfly structures. Qualcomm's Mirasol™ display technology was inspired by butterfly wings. ChromaFlair® and SpectraFlair® color-shifting paints from the company JDSU create color-shifting effects in cars. The emerging contemporary design practice Biornametics explores a new methodology to interconnect scientific evidence with creative design in the field of architecture, with role models from nature (e.g., structural colors in organisms) being investigated and the findings applied to design strategies.

More often than not, natural structural colors are the inspiration for such technical products and applications. The field of biomimetics is dealing with the identification of deep principles in living nature and their transfer to humankind [24]. General biological principles identified by the German biologist Werner Nachtigall that can be applied by engineers who are not at all involved in biology are, for example, integration instead of additive construction, optimization of the whole instead of maximization of a single component feature, multifunctionality instead of mono-functionality, energy efficiency, and development via trial-and-error processes. We are hopeful that biomimetic colors will not only be tailored to show the bright and shiny properties as the natural examples do but will also exhibit one of the most important properties ensuring continuity of the biosphere: sustainability. Currently, with nanotechnology as booming new promising field, the sciences have started to converge, with nanobioconvergence as one of the most promising examples. New materials, structures, and processes can arise from this novel approach, perhaps exhibiting some of the multifunctional properties of the inspiring organisms, where various levels of hierarchy (with functionality on each and every level) are so refined. The convergence of the ways of thinking and novel approaches promises an interesting future.

Definition

Objects whose dimensions range between 100 and few nanometers can be classified as nanostructures. Since the physical-chemical properties of matter change dramatically at the nanometer scale, the introduction of this classification results in opening a particularly important new field of investigation for next-generation materials and devices.

Introduction

The worldwide need for power is mainly satisfied by the use of well-known energy resources such as oil, coal, hydropower, natural gas, and nuclear power. The environmental impact of most of those energy sources is tremendous, mainly

because of the emission of greenhouse gases that causes the increase in the globally averaged temperature. In the next decades, a rise of the global energy demand is expected, mainly because of the growth of world population especially in the developing countries. It is interesting to notice how the preindustrial world's energy consumption grew about 0.3 terawatts (TW) – year per year – and this value dramatically increased to 14 TW in years 2000s, and it is expected to double to 28 TW to year 2050. In the same period, the world population increased only five times, clearly showing how the energy consumption is not uniformly distributed. An improvement in life quality in developing countries will cause a further tremendous increase in energy demand in the next future [1, 2]. A fast-growing country needs far more energy than a developed country, essentially because a mature industrialized economy has learned how to produce and use energy more efficiently [2].

In this scenario, exploring renewable, efficient, and green energy sources is the greatest challenge to be won for sustainable human progress. Innovation is one of the key strategies to address this challenge, and some of the most promising solutions are related to nanotechnologies. Materials at the nanometer scale are able to show completely different properties than those we are used to in our everyday lives. Understanding the huge potentialities of materials at the nanoscale and learning how to drive them in real devices open new extraordinary opportunities. The field of alternative energy is certainly the most challenging platform for some of nanotechnology's most exciting contributions [3]. New nanomaterials and nanostructures showed recently their potentiality in the development of devices for both energy production and storage like third-generation photovoltaic, fuel cells, and lithium-based batteries.

Solar energy conversion systems are limited mainly by the poor properties of current materials, showing limited charge-carrier mobility and significantly high charge recombination rates for materials with sustainable costs. Moreover, theoretical limitations (Shockley/Queisser limit) are well established and fix a superior insurmountable efficiency threshold. Nanotechnology could help in the design of innovative architectures for new-generation solar cells, actually opening to a possible real alternative to traditional silicon solar cells. Significant examples are dye-sensitized solar cells (DSCs). In the last few years, significant efforts were spent in designing new dye molecules with an improved optical absorption coefficient as well as optimized mesoporous semiconducting layers with lower charge recombination rates. Devices based on photosensitized nanostructured TiO_2 films and on liquid electrolytes have demonstrated light-to-current conversion efficiency greater than 12 % [4]. Other approaches, like hybrid organic solar cells based on conjugated polymers or quantum dot solar cells with a light harvesting performed by semiconductor nanocrystals, are showing promising laboratory results, even if the reaching of satisfactory efficiency values still remains a challenge, mainly because of consistent losses during photoinduced charge separation and charge transport across the nanoassemblies.

Fuel cells represent another technological field in which new concepts from nanotechnology can be beneficial. The development of this kind of devices for large-scale use is still limited by the lack of adequate systems for hydrogen storage. At the same time, nanotechnologies offer new interesting opportunities, directly storing hydrogen into the fuel cells by nanostructures of carbon, zeolites, stacked clays, or light metals hydrides [5]. The introduction of nanoengineering also opens to the design of new electrodes. Nanotechnologies can lead a more reduced use of precious metals (e.g., platinum nanoparticles for high surface area and low volume) along with improved membrane function and durability [6].

Used batteries and accumulators represent a tremendous environmental problem in current days. Nanomaterials could help not only in developing batteries showing higher energy densities but also devices that will reduce the use of disposal energy storage systems [7]. For example, it was demonstrated that silicon-based nanowires could significantly improve the specific capacity of Li-ion accumulators, currently powering up electronic devices such as laptops, video cameras, cell phones, and many others [8]. In fact, such a

new technology can grant a ten times increase of the capacity of traditional Li-ion batteries. Also, nanotechnology can reduce the possibility of batteries catching fire by providing less flammable electrode materials.

New applications of nanotechnology are underway in the energy field. Their use will undoubtedly impact our society, hopefully changing and improving the way we are currently thinking to energy production and storage, leading to a more sustainable human growth.

Energy Supply Systems

The traditional approach to energy supply is based on the production of huge amounts (from MW to GW) of energy in localized production sites and its following delivery for minute use, causing significant losses across the distribution net. Petroleum and coal industry, nuclear power stations, hydroelectric dams, wind installations, and geothermal power installations are common examples of this approach (concerning both nonrenewable and renewable energy sources).

Nanotechnologies are expected to dramatically increase the efficiency of alternative energy devices in all the different fields [3], creating the starting point for a new approach to a more sustainable energy management. In fact, it is reasonable to believe that the current scenario will be slightly modified in the next future. The centralized production of high quantities of energy will be more intensively joined by a distributed system of energetic hot spots, able to produce very low amounts of energy, with high spatial density. By this way, the production of energy occurs in direct connection or in close proximity with its use in devices (often miniaturized or microdevices), thus avoiding losses. In this framework, the efficiency of the single energy harvester could be no more a crucial point, while other aspects (like flexibility, integration in complex systems, and even aesthetics) gain importance.

This kind of approaches covers a broad interest in different fields, starting from new-generation buildings to new smart portable devices. The firsts are designed and fabricated according to a sustainable construction approach and are able not only to reduce the total energy consumption but also to produce a large part of the energy required inside the building [9]. The next future devices (as household electrical appliances, cellular phones, computers, and biomedical devices) will be able to manage energy more efficiently, thanks to the introduction of new power supply systems. These systems will present an energy source, hopefully a renewable one as solar, harvesting, or thermoelectric, connected to a storage system as lithium-ion batteries, both managed by proper electronic power management circuits [10]. In this new futuristic scenario, the role of nanomaterials and nanostructures in devices for energy production and storage will be more and more crucial.

Two complementary strategies can be considered to manage energy in energy supply systems. A first class of devices, such as batteries, fuel cells, and supercapacitors, needs a finite quantity or a continuous supply of an active material or fuel to properly work. Devices of this kind can be classified as non-regenerative power supplies. A second class of tools, such as photovoltaic cells, harvesters, and thermoelectric devices, do not need any material or fuel to work and can be classified as regenerative devices. In the next sections, some valuable examples of both categories will be briefly introduced.

Nanostructures for Energy Production

Dye-Sensitized Solar Cells (DSSCs)

Dye-sensitized solar cells (DSSCs) were invented in the early 1990s by Michael Grätzel and Brian O'Regan at the École Polytechnique Fédérale de Lausanne (CH) [11], following extensive research in semiconductor photoelectrochemistry that started in the 1970s. These cells have immediately drawn a huge interest in the scientific community, because of their potentiality for the fabrication of cells with relatively high efficiency and potential low cost. In fact, these kinds of solar devices can be produced with abundantly available organic materials and widely diffused inexpensive semiconductors, using simple and scalable

technologies and avoiding costly and energy-intensive high-vacuum treatments and material purification steps.

The working principle of the cell [4] is based on the presence of a molecular light absorber, which is able to harvest photons from sunlight and convert them to electrons, pumped up from a lower to a higher energetic level creating an electric potential that can be used to produce electric work. The light-absorbing dye is attached as a monolayer to the surface of a nanocrystalline film of wide band gap semiconductor (TiO_2 in a pure anatase form in the most common DSSC architecture). The semiconductor works as electron collector, since the photogenerated charges are fast injected in the conduction band of the nanostructured solid. A careful design of the molecular energy levels of the dye makes the charge transfer toward the oxide strongly favored from an energetic point of view, thus drastically reducing the electron-hole recombination process. The dye is electrically regenerated by charge donations from an electrolyte, which penetrates the pores of the nanofilm to have a close proximity with the molecules of the sensitizer, creating a 3D interpenetrating network junction. The electrolyte is an ionic conductor able to accept hole from (or donate electrons to) the oxidized dye, and the best performance is noticed for liquid electrolytes containing a I^-/I_3^- redox system with a ruthenium-based sensitizer or a cobalt redox mediator with a donor-pi-acceptor porphyrin dye. The electrons percolate through the nanoparticles, which are interconnected because of a short sintering process, and are collected in an external circuit, thus generating electric power without causing any permanent chemical transformation inside the cell.

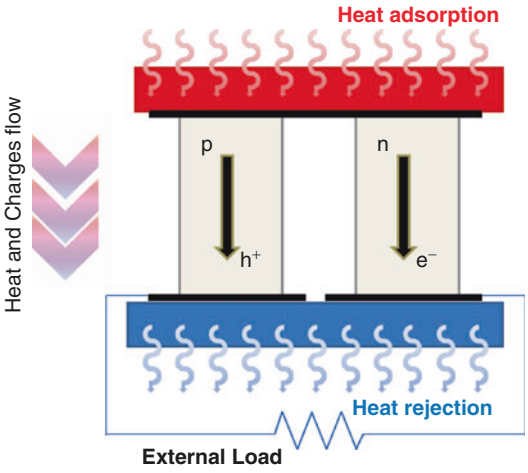
The role of the nanostructures in designing suitable photoelectrodes for high-performance cells is crucial. In fact, as reported from the first experiments of Grätzel, it emerges that it is possible to move from a sunlight-to-current conversion efficiency of 1.2 % using a polycrystalline anatase film [12] to the 7.9 % using a nanostructured mesoporous TiO_2 layer [11], just varying the active exposed surface area of the electrode. In fact, on a flat surface a monolayer of dye is able to absorb only a little percentage of the impinging photons, since its optical cross section is sensibly smaller with respect to the geometrical area it occupies. Thus, for good collection efficiency, it is mandatory that a great amount of area is exposed to the incident flux of photons, and this is possible only with a nanostructuring of the photoanode. By carefully controlling the porosity of the film, it is possible to find the optimal equilibrium between the thickness of the film and the path that photogenerated charges are able to cover (e.g., the diffusion length) before recombination.

Harvesting

Energy harvesting is the direct extraction of background energy from the environment and its conversion in electrical power [13]. Harvestable ambient energies can be classified in three main classes, namely, radiations (see paragraph 3.1), kinetic/vibration energy, and thermal energy. Energy recovery is possible through properly designed devices. The heart of energy harvesting devices is an active material that is actually able to change/modify at least one of its properties as a response to the stimulus of ambient energy. The change of the material behavior, induced by environmental energy, is usually turned into electrical power. The diffusion of harvesting devices has been very limited till now by their low efficiency in electrical energy production if compared to traditional energy sources, mainly due to the lack of well-performing materials. The development of new nanostructures and nanomaterials is promising to fasten up the development of a new generation of highly efficient devices for energy harvesting [3].

Energy from Vibrations

Several sources of environmental vibrations can be observed and used to harvest energy, such as vibrations from household appliances, moving equipment, trains, helicopters flying overhead, or human movement. Micro-generators based on microelectromechanical system (MEMS) technology have a leading role to extract and recover that energy from the ambient.



In piezoelectric-based energy harvesting, a piezoelectric material is needed as the active

material. Piezoelectric materials are able to directly convert the mechanical strain induced by vibrations into an electrical energy. The conversion is possible through the structural deformation of the material that induces a local spatial charge separation through an electric dipole. Piezoelectricity can occur in polycrystalline ferroelectric ceramic materials such as barium titanate ($BaTiO_3$) and lead zirconate titanate (PZT) and polymeric materials as poly(vinylidene fluoride) PVDF.

Traditional piezoelectric ceramics are very brittle, needing to be handled carefully to avoid breakage, and complicate bonding procedures. Their usability is also affected by their hard and fragile behavior since they have limited ability in following complex curved surfaces. This aspect is particularly limiting when sensors and harvesters are considered, since the ability of devices as harvesters to capture and extract energy is also related to the ability of the material (and so of the device) to well couple to the surface of the object generating the vibrations. Traditional polymeric piezoelectric materials can overcome this limitations being flexible and compliant, but unfortunately their electromechanical coupling coefficient is not comparable to traditional ceramics. These limitations have increased the attention to other approaches, and hybrid nanocomposite materials are one of the most promising alternatives. The final properties of nanocomposite materials are related to the connectivity between phases [10]. Nanocomposite materials are so promising for energy harvesting device because of high coupling factors, to which they add low acoustic impedance, mechanical flexibility, and broad bandwidth coupled with low mechanical quality factor that make them interesting candidates also for transducer and acoustic applications.

Energy from Temperature Gradients

A thermoelectric material is able to generate a voltage when a temperature gradient is applied to it (Seebeck effect) and vice versa (Peltier effect). The thermoelectric effect is related to the ability of charge carriers to move freely in metals and semiconductors (like molecules in a gas), and

Nanostructures for Energy, Fig. 1 Schematic of a thermoelectric device based on a p-n junction between semiconducting thermoelectric materials

while moving, they can conduct charge and heat. If a temperature gradient is applied to the material, charge carriers tend to move from the hot part to the cold region of the material through a diffusion process. While moving to the cold side, charges are accumulated, creating a voltage that can be externally exploited [14]. The conversion of thermal energy in electrical energy is possible through p-n junctions made of thermoelectric materials as described in Fig. 1.

Thermoelectric generators are characterized by no moving parts that make them silent, they are reliable and scalable, and so they are considered quite interesting as power generators. Efficiency for thermoelectric materials and devices can be described by a nondimensional figure of merit that can be evaluated as $ZT = \sigma S^2 T/\kappa$, where S is the Seebeck coefficient, σ is the electrical conductivity, k is the thermal conductivity, and T is the absolute temperature.

For a long time, thermoelectric materials have been considered too inefficient to be cost-effective for applications. The current state-of-the-art material in this field is a Bi_2T_3-based alloy showing a ZT close to one. New interest in thermoelectrics began in the mid of the 1990s, since theory suggested that thermoelectric efficiency could be significantly enhanced by the use of nanostructures. A well-performing thermoelectric

material needs a variety of conflicting properties to be well optimized to work properly. It needs a large thermopower, which means a large value of the Seebeck coefficient; it must be a good electrical conductor but showing at the same time a very low thermal conductivity. In traditional materials, these transport characteristics are dependent from one to the other, being deeply linked to interrelated material properties.

Based on both theoretical and experimental predictions, the current approach to increase ZT is to use nanostructured materials, both in form of films and for quasi-1D structures, like nanowires, nanobelts, and nanotubes. Nanostructured films are quite interesting because they can use the same fabrication routes of traditional materials, while showing improved thermal behavior, thanks to phonon scattering at the interfaces among nanograins. The main issue in nanostructured films is to control electron scattering at grain boundaries between randomly oriented grains that could decrease also electrical conductivity [14]. In one-dimensional (1D) materials as nanowires, the thermoelectric parameters (S, σ, and k) can be optimized independently. A high value of ZT is predicted for 1D nanostructures, as a result of an increase of charge mobility due to the quantum confinement of the density of the states, together with a reduction in thermal diffusivity because of scattering at the boundaries [3].

Fuel Cells

A fuel cell (FC) is an electrochemical cell that converts directly a chemical energy into electricity. This characteristic makes it an appealing system to provide a relatively cheap power source, by using hydrogen and ethanol as fuels and by producing water as waste.

Over the past few years, fuel cells have demonstrated increased reliability and lower costs because of the use of nanomaterials. Use of nanotechnology in the manufacturing process results in increased surface area and high aspect ratio, which originates large power and energy densities, a long shelf life, and ease of miniaturization; these features, combined with MEMS technology [10], are important for the development of a more powerful fuel cell for portable electronic devices. Nanomaterials are also increasingly used in the production, purification, and storage of hydrogen. In fact, at present, the ability to store hydrogen at high volumetric and gravimetric densities, as well as the ability to extract/insert it at sufficiently rapid rates, is still a hot topic that could condition the further improvements of the fuel cell technology. In particular, a big effort has been done by the research community in the past decades to identify candidates that could fit such strict characteristics. As an example of investigated nanostructures, there are CNTs, considered a promising solution, even if recently they were partially abandoned, light metal hydrides [5], graphene.

A fuel cell is mainly constituted by an anode, a cathode, and an electrolyte. At the anode, a catalyst oxidizes the fuel, usually hydrogen, turning it into a positively charged ion and a negatively charged electron. The electrons travel through a wire creating the electric current, while the ions travel through the electrolyte to the cathode. Once reaching the cathode, the ions recombine with the electrons and with another chemical, usually oxygen, to form water or carbon dioxide. The need to increase the performance of the fuel cells has nowadays motivated the researches to develop new materials and new synthesis approaches in order to gain the mentioned increased surface area and high aspect ratio of the different catalysts used for the different reactions at the anode and at the cathode.

There are many types of fuel cells, depending on the type of electrolyte used and on their working temperature.

In the low-temperature range, there are the proton exchange membrane fuel cells (PEMFCs), which use a polymer electrolyte membrane as electrolyte and work with above ambient temperatures up to 100 °C; phosphoric acid fuel cells (PAFCs), with phosphoric acid used as the electrolyte and working in the range 150–200 °C; and alkaline fuel cells (AFCs) that use a solution of potassium hydroxide in water as their electrolyte and operate in the range 150–200 °C.

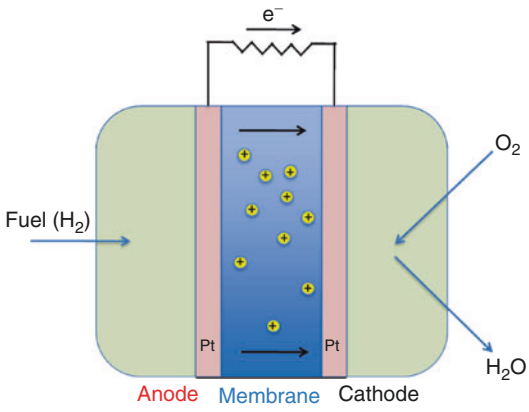
In the high-temperature range, there are the solid oxide fuel cells (SOFCs) that use a hard ceramic compound of metal (like calcium or

zirconium) oxides as electrolyte and work in the range 800–1000 °C and molten carbonate fuel cells (MCFCs) that use high-temperature compounds of salt (like sodium or magnesium) carbonates as the electrolyte and work at 650 °C. SOFCs can run on hydrogen, butane, methanol, and other petroleum products.

Among the various types of fuel cells, PEMFC technology has become the dominant choice for the portable electronics market, a market that is rapidly increasing. Nowadays, nanotechnology is deeply embedded in the design of fuel cell components, and therefore, the development of nanostructured catalysts at the electrodes or optimized proton exchange membranes (PEMs) has become an active area of research for fuel cell applications. The challenging possibility to tailor the properties of new materials to dedicated designs had speed up the development of portable and more efficient devices.

At present, many efforts were devoted to obtain an optimization of the PEM characteristics, but despite great advancement in the development of nanostructured membranes, some restrictions and limitations remain. One of the challenges in current PEM fuel cell development is the lack of appropriate membrane materials to be used as proton-conductive membranes for improving the performance of the fuel cell.

The high cost of the commercially available Nafion® membrane, the most diffused polymeric electrolyte in FC, has induced the development of new proton-conducting membrane materials, including polybenzimidazoles, polyamides, polyether imides, polysulfones, polyphenylene sulfides, polyetheretherketones, and polyphenyquinoxalines. However, the Nafion® membranes show superior performance because of their high ionic conductivity compared to other non-fluorinated membranes. Proton conductivity is the most important property of membrane efficiency in fuel cells.



Membranes with acceptable conductivity at high temperatures are desirable for fuel cell applications, but there is always the issue of decreased performance at high temperatures due to dehydration of the membrane and a resulting reduction in ionic conductivity. To overcome the problems faced by proton exchange membranes, numerous studies were conducted to develop alternative materials for membrane preparation. One of the approaches to improve water retention in the membrane is to incorporate hydrophilic, inorganic materials [6]. With this method, it is difficult to avoid nanoparticle self-agglomeration in the polymeric matrix, and the method therefore induces nonhomogeneous dispersions and poor electrochemical performance. Because good inorganic nanoparticle-doped membranes require the dopants to be distributed evenly in the membrane and able to fill hydrophilic clusters in the Nafion® membrane, addition of nanosized inorganic particles is carried out by various methods, such as the sol-gel method, the solution casting method, and PECVD to obtain high-performance nanocomposite membranes. The use of surfactants can assist in creating a uniform distribution of nanoparticles as well.

A second challenge for the ultimate commercialization of fuel cells is the preparation of active, robust, and low-cost catalysts. Emphasis is placed on nanoengineering-based fabrication, processing, and characterization of multimetallic nanoparticles (transition metals) with controllable size (1–10 nm), shape, composition, and morphology (Fig. 2).

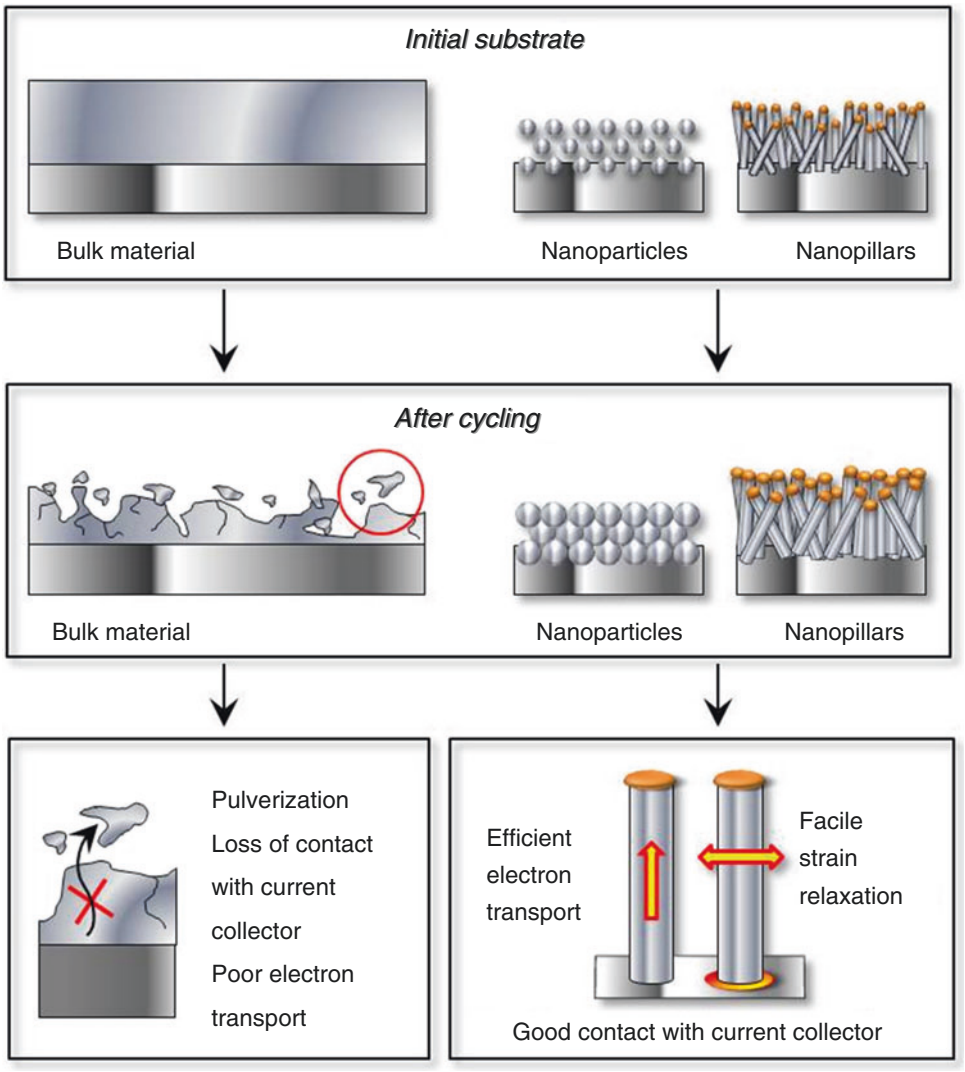
Another type of fuel cell that is drumming up an increasing interest as a potential candidate as portable device, and that differentiates it from the previously discussed fuel cells because it uses living organisms, is the microbial fuel cell (MFC).

MFCs are bioelectrochemical systems that can generate electricity by directly bioconverting the chemical energy of organic substrates into electrical energy through catalytic reactions of microorganisms under anaerobic conditions. In general, MFCs are able to oxidize biodegradable fuels, such as organic waste, to generate electrical power. The typical electrolyte is generally an aqueous solution or wastewater, acting as a feed source.

Some advantages of MFC over other types of fuel cells are that the reactions proceed at ambient temperature and ambient pressure, that they exploit waste rather than producing it, and that water is the only solvent used.

Nanostructures for Energy, Fig. 2 Basic operation of a PEM fuel cell. Hydrogen enters at the anode, where it is catalytically dissociated and ionized. The protons migrate by ionic conduction to the cathode through the polymer electrolyte membrane. Electrons travel through the external circuit where they do electrical work before arriving at the cathode. At the cathode, electrons, protons, and oxygen molecules form water molecules

Since MFCs satisfy at least 7 of the 12 principles needed to identify a chemical process as green, they belong to the class of "green chemistry."



Nanostructures for Energy Storage Systems

Many of the sustainable energy alternatives described produce or require electricity. Therefore, novel more efficient ways to store electricity are very much needed in the way to a more sustainable production, transformation, and use of energy. In this respect, electrochemical systems, such as batteries and supercapacitors, which can efficiently store and deliver energy on demand in stand-alone power plants, as well as provide power quality and load leveling of the electrical grid in integrated systems, are playing a crucial role in the present energy economy. In addition, they are also envisaged as the power sources of choice for the progressive diffusion of sustainable hybrid/electric vehicles at high levels.

Lithium-Ion Secondary Batteries

Lithium-ion batteries (LiB) are one of the greatest successes of modern electrochemistry of materials. Their science and technology have been extensively reported in reviews [7] and dedicated books [8] to which the reader is referred for more details. A commercial LiB does not contain lithium metal; it comprises a negative electrode (generally, graphitic carbon) and a positive electrode (generally, layered lithium metal oxides such as $LiCoO_2$), both capable of reversibly intercalate Li^+ ions, these being separated by a nonaqueous lithium-ion conducting electrolyte (generally, a separator diaphragm soaked in a mixed ethylene-diethyl carbonate solution of $LiPF_6$). During discharge, Li^+ ions carry the current from the negative to the positive electrode, through the nonaqueous electrolyte [8]. During charge, an external electrical power source (the charging circuit) applies a higher voltage (but of the same polarity) than that produced by the battery, forcing the current to pass in the reverse direction. Lithium ions then migrate from the positive to the negative electrode, where they become embedded in the porous electrode material in a process known as "intercalation."

The current generation LiBs are increasingly being used by virtue of their high (volumetric and gravimetric) energy density, but although commercially successful, some disadvantages arise, related to relatively low power density and large volume change on reaction, safety, and costs. In fact, we are reaching the limits in performance using the current electrodes/electrolytes, and further breakthroughs in material chemistry are essential, especially modifying and improving already known materials. The aforesaid shortcomings can be reduced by the application of nanotechnology. It is important to design and fabricate nanostructured electrode materials that provide high surface area and short diffusion paths for ionic transport and electronic conduction. This gives rise to a larger electrode/electrolyte surface and enables Li-ion diffusion through the electrode material to be limited as much as possible. Moreover, the volume changes and structural evolution that occur as the electrodes accept and release ions

Nanostructures for Energy, Fig. 3 Example of how nanostructuring can help in improving the performances of Li-ion battery electrodes by reducing the strain associated with lithium ion insertion/removal. Readapted from Chan et al. [15]

can be quite different for nanoscale materials, thus greatly affecting the cycle/service life.

The potential advantages and disadvantages associated with the development of nanomaterials applied to LiBs can be summarized as follows [7]. The advantages include: (a) The strain associated with lithium-ion insertion/removal is better accommodated (along with a wider solid-solution region), thus improving service life as shown in Fig. 3. (b) New electrode reactions occur, which are not possible for materials composed of micrometer-sized particles. (c) A high surface area permits a more extensive electrode/electrolyte contact area, leading to higher charge/discharge rates. (d) The reduced dimensions significantly reduce the path lengths for electronic and Li^+ transport, thus permitting operation with low electronic conductivity and/or at higher power. As for disadvantages, the following have been identified: (a) An increase in undesirable

(side) reactions with the electrolyte due to the high electrode/electrolyte contact area, possibly leading to self-discharge, poor cycling, and calendar life. (b) The volume of the electrode increases because of poor particle packing, leading to lower volumetric energy densities unless special compaction methods are developed. (c) Potentially, nanoparticles may be more complex to synthesize especially that their dimensions may be difficult to control.

There are numerous examples in which nanostructured materials as both electrodes and electrolytes have been used in Li-ion batteries. In meso- and/or nanoporous architectures, for instance, the nanoscale domains of the material are accessible to molecular reactants because of rapid mass transport via diffusion through the continuous volume of mesopores. Very recently, B. Scrosati, Y.-K. Sun, and colleagues developed a high-capacity, nanostructured tin-carbon anode and a high-voltage, high-rate Li $[Ni_{0.45}Co_{0.1}Mn_{1.45}]O_4$ spinel cathode. When the two parts are put together, the result is a high-performance battery with a high energy density and rate capacity, highly suitable for powering low or zero emission HEV or EV vehicles [16]. The ultimate expression of the nanoscale in rechargeable lithium batteries is the formation of 3D nanoarchitectured cells, in which pillared anodes and cathodes are interdigitated [17]. The prospect of having active and passive multifunctional components interconnected within a 3D architecture is envisioned to lead to superior energy storage capacity, high-volume synthesis, and improved safety. A nanowire battery has been invented by a team led by Dr. Y. Cui at Stanford University in 2007 [15], which produces ten times the amount of electricity of existing LiBs. The team's invention consisted of a stainless steel anode covered with silicon nanowires, to replace the traditional graphite anode. Silicon, which stores ten times more lithium than graphite, allows a far greater energy density on the anode, thus reducing the mass of the battery. The large surface area further allows for fast charging and discharging and efficient electron transport down the length of each nanowire.

Lithium-Sulfur Secondary Batteries

The high energy density battery system development is highly lucrative to fulfill the mounting demand from personal devices and electric vehicles. LiBs have dominated the rechargeable high energy battery market until now, in fast-moving electronics and to an extent in HEV and EV, but future enhancements in energy density require a different approach that can overrun the existing battery chemistries and mechanisms [18].

The 1960s saw an initial step in the development of lithium-sulfur (LiS) batteries, which in recent years gain an absolute momentum due to the high theoretical capacity (1672 mAh g^{-1}) they may offer. LiS have a theoretical energy density of 2600 Wh kg^{-1}, originating from the electrochemical reactions between lithium metal and elemental sulfur [19]:

$$S_8 + Li^+ + e^- \rightarrow Li_2S_x \quad (1)$$

$$Li_2S_x + Li^+ + e^- \rightarrow Li_2S_2 \text{and/or } Li_2S \quad (2)$$

The reaction (Eq. 1) produces soluble lithium polysulfides, and the reaction (Eq. 2) leads to the formation of insoluble lithium sulfide (Li_2S_2 and/or Li_2S).

The overall electrochemical reactions comprise of solid-liquid-solid transformations that cause great complexity in LiS systems upon charge/discharge. Plenty of problems persist, restricting further development. Smartly designed sulfur-carbon nanomaterials (e.g., core-shell-structured composites) may overcome the obstacles; moreover, efficient trapping configurations for polysulfides will improve the utilization of sulfur during cycling. Recently, research efforts are focused on the cathode side of the cell where nanomaterials have been widely applied as conducting frameworks. In this respect, carbon nanotubes (CNTs), mesoporous carbons, yolk-shell TiO_2 spheres, carbon fibers, carbon spheres, graphene, carbide-derived carbon, graphene oxides, CNT/graphene hybrids, etc. have been implemented that demonstrated to greatly improve the electrode capacity. Several important strategies were evaluated including the

confinement of the sulfur and related reaction products within the micropores, hollow sphere structures, conducting polymer coatings, polysulfide reservoirs, carbon interlayers, and even the bags created by folding the graphene sheets to limit the diffusion of polysulfides to the electrolyte and subsequent decay of the cell performance.

Lithium-Air Secondary Batteries

One of the most vibrating upcoming terms in the energy sector is the report on the development of new energy storage system: the lithium-air battery, for short Li-air, the so-called breathing battery. The concept is attracting great attention due to the possibility of achieving high energy density comparable to internal combustion engine; it possesses the potential to one day replace the LiB technology of today's EVs.

The main difference between LiB and Li-air is the absence of the physical existence of an insertion cathode material (e.g., transition metal oxide), a key component active in the electric current flow, which is replaced by air [20]. Thus, the rechargeable Li-air battery is lighter with the potential to stack more energy than its commercial counterparts do. Li-air batteries can be architectured either in aqueous or nonaqueous configurations. The basics of nonaqueous rechargeable Li-air cell lie in the reversible formation and decomposition of lithium peroxide (Li_2O_2) at the cathodic side during the discharge and the recharge processes, respectively. The aprotic version was first investigated by Abraham et al. [21]. The reaction product Li_2O_2 deposits at the surface of the air electrode (cathode, positive). On the contrary, in an aqueous-based Li-air system, the reaction product ($LiOH•H_2O$) is soluble into the electrolyte solution.

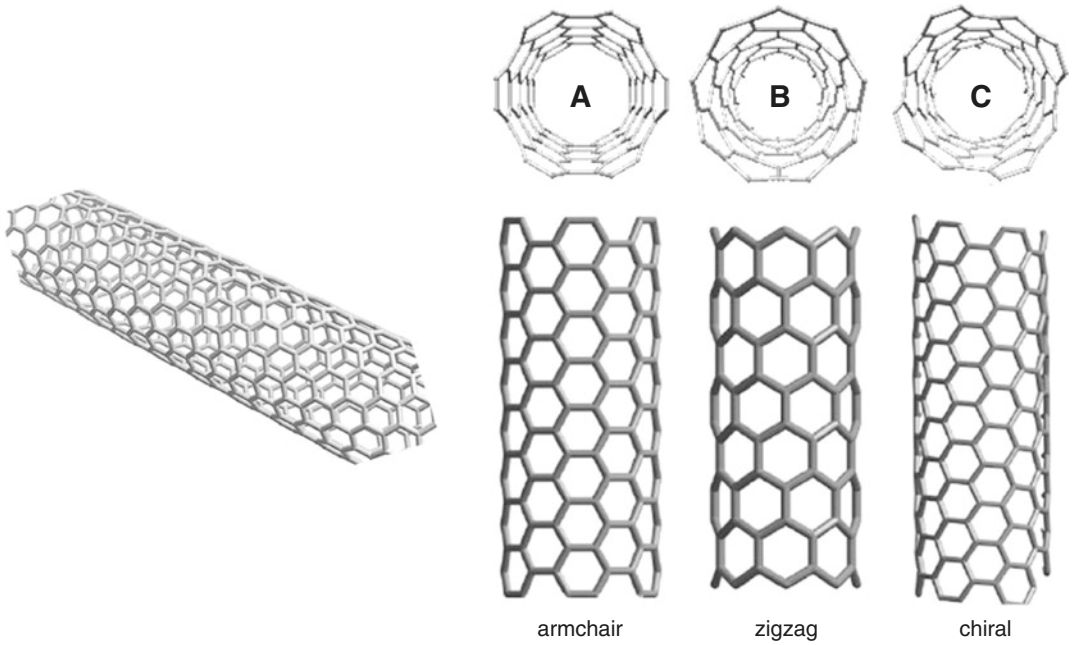
One of the key challenges of the aqueous system is the low output power of the protected lithium electrode. In this case, protection of the anode is necessary, and it is achieved by laminating the lithium metal using NASICON-type lithium conducting solid electrolyte (LATP); such thin layers can isolate the lithium metal from directly encountering the water molecules. Such mixed metallic oxides are also proposed as electrolyte systems as well, and they can be developed and deposited using technologies familiar to nanomaterial preparation.

In the case of aprotic Li-air systems, one of the key points is the lowering of the Li_2O_2 oxidation overpotential at the cathode. It is widely accepted that electrocatalysts can play a vital role in improving the cycling ability of such cells; they can be placed in the cathodic part of the cell in very less quantity, and serious efforts are focused on their development. Thus, the electrocatalyst in the cathode of the Li-air cell can significantly influence the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER). Nanostructured MnO_2 with different structures, along with noble metals, supported on various allotropes of carbon, is widely pursued due to its low cost, low toxicity, and good structural stability. There are other metals and metal oxides including Pd, Pt, Ru, PdO, and RuO_2 being studied in various shapes and forms that may influence the overall reaction kinetics. There are other areas where nanomaterials have been widely used in Li-air systems such as membrane to improve the ionic conductivity and, moreover, to prepare oxygen permeable membranes so that unpurified atmospheric air can be used as the source of O_2 for the formation of Li_2O_2. Thus, in every aspect of the lithium-based energy storage systems, nanomaterials are fundamental.

Electrochemical Capacitors

Electrochemical capacitors (ECs), also named "supercapacitors," are capacitors with relatively high energy density (typically on the order of thousands of times greater with respect to conventional electrolytic capacitors) [22]. The term supercapacitor is usually used to describe an energy storage device based on the charge storage in the electrical double layer (EDL) of a high surface area carbon in aqueous electrolytes. In fact, they store electrical energy, like batteries, but using a different mechanism: while batteries do it chemically, supercapacitors store electricity physically, by separating the positive and negative charges. Their lifetime is in principle infinite, as they operate solely on electrostatic surface charge accumulation. In comparison with conventional batteries or fuel cells, ECs also have a much

higher power density. They can be charged or discharged at a rate that is typically limited by current heating of the electrodes. So while existing ECs have energy densities that are perhaps 1/10 that of a conventional battery, their power density is generally 10–100 times greater. Supercapacitors can be used as uninterruptable power sources (UPSs), can be coupled with batteries to provide peak power, and can replace batteries for memory backup. The supercapacitor is ideal for energy storage that undergoes frequent charge and discharge cycles at high current and short duration. They have applications such as energy storage devices used in vehicles and for smaller applications like home solar energy systems where extremely fast charging is a valuable feature.



Since their discovery, these devices have attracted considerably less attention with respect to batteries as energy storage devices. Nevertheless, thanks to both the contribution of nanotechnology and the better understanding of charge storage mechanisms (ion behavior in small pores) the interest on ECs has noticeably increased very recently [22]. Nanotechnology is important because it enables large surface areas to be obtained to optimize performance in terms of capacitance and ionic and electronic resistance. There are numerous examples in the literature that show that nanosized crystallites and/or mesoporous materials exhibit significantly higher specific capacitance as compared to nonporous materials or micron-sized materials. The assembly of nanoscale materials is also important.

Recent trends in supercapacitors involve the development of high-surface-area-activated carbon electrodes to optimize the performance in terms of capacitance and overall conductivity. Attention has been focused on nanostructured carbons, such as aerogels, nanotubes, and nanotemplates [23]. One structure envisioned to be of interest is an array of vertically aligned carbon nanotubes where the spacing between the tubes is matched to the diameters of the solvated electrolyte ions. The main focus has been the optimization of interparticle contact resistance and electrolyte wettability of the pores. The capacitance increase is almost 50 % compared with the best performing commercially available activated carbons. Nanostructured metal oxide materials have also been investigated for supercapacitor applications, especially RuO_2 and $RuO_2 \cdot xH_2O$ nanotube composites [24].

The Impact of Nanostructures on Traditional Energy Sources: An Overview

As the worldwide demand for energy rises at an ever-increasing rate, there is a new urgency to improve the efficiency and sustainability of actual power generation technologies. One of the keys to addressing this challenge is innovation, and some of the most promising solutions are occurring at the nanoscale. Perhaps the most mainstream acceptance within renewable technology has come in the form of wind energy, which is approaching cost competitiveness with traditional energy sources. Countries such as Germany, Spain, and Denmark are already beginning to utilize substantial amounts of wind energy to meet their growing electricity needs. Nanotechnology impacts the wind industry by improving turbine performance and reliability to allow for longer lifetime, less fatigue failure, and lower costs of generation. New lubricants containing nanoparticles act like mini ball bearings, thus reducing the friction generated from turbine rotation, consequently improving its life cycle. Advancements in nanocoatings, such as de-icing and self-cleaning technologies, also help improving efficiencies, thus rendering ice and dirt buildup on the turbines virtually nonexistent.

In spite of the optimistic predictions of its proponents, alternative energy sources such as wind, hydro, and biomass are unlikely to seriously challenge coal, oil, natural gas, or nuclear power for a meaningful share of the worldwide energy needs in the near future. However, how these traditional energy sources are produced will rapidly change. In fact, nanotechnology is already at work

Nanostructures for Energy, Fig. 4 Structure of single-walled carbon nanotubes (SWCNTs). Carbon nanotubes can be metallic or semiconducting, depending on how their chicken wire-like lattice rolls into a tube

modifying how coal, oil, and gas are being produced. One of the more prominent examples can be found in the application of new nanoscale catalysts to the production and refining processes of our fossil fuel resources. Moreover, modern fossil fuel power plants, including coal-fired systems, require components that are able to withstand higher temperatures and pressures to improve efficiency, lower maintenance costs, and decrease emissions levels. In this field, nanotechnology-based innovation is being credited with improvements in efficiencies and life-spans of existing technologies, as well as the introduction of novel and disruptive power-generating components.

Nanotechnology has the potential to revolutionize the electric utility industry as well. Many of the components used in the electric utility industry can be modified to yield incremental improvements in the overall product performance. The end benefit is that electric utility providers can improve their operating margins by making existing equipment both last longer and more efficient. Nanotechnology can provide immediate improvements to the electrical utility system of moving power by efficiently improving the transmission of electrons, as well as creating newer and even better superconducting materials. The real payoff may be carbon nanotubes (CNTs), which are unbelievably thin, possess 100 times the strength of steel, have only 1/6 the density of aluminum, and efficiently conduct electricity. The most promising are the single-walled carbon nanotubes (SWCNTs). The broad range of uses for SWNTs is connected to the different nanotube properties according to how the hexagonal lattice is oriented (see Fig. 4), which together with the nanotube diameter determines the chirality. This combination of strength and conductivity suggests that in the future, energy providers should not have to dig up city streets to lay new wires. The existing lines could be simply replaced with super strong, highly conductive carbon nanotube wires.

Reduction of energy consumption is another active area in nanotechnology, targets being the

development of more efficient lighting, better combustion systems, and/or use of lighter and stronger materials in the transportation sector. Light-emitting diodes (LEDs) are interesting examples of how energy consumption can be reduced or "smart" windows, which can change reflective properties to attract or deflect sunlight depending on the customer's needs. Similarly, improved insulation materials could have a noticeable impact on overall energy demand. All of these products are made possible by advancements in nanotechnology. Nevertheless, the greatest long-term cost savings will probably come from the creation of "intelligent energy networks," that is, integrated systems of more energy-efficient computers and sensors that gauge and regulate customer energy use. Such networks already exist today, but as nanotechnology enables computers and sensors to become smaller, but correspondingly more powerful, the cost effectiveness of deploying such devices will increase, along with the number of possible applications.

Conclusions

New materials hold the key to fundamental advances in energy production and storage, both of which are vital in order to meet the challenge of global warming and the finite nature of fossil fuels. Nanomaterials in particular offer unique properties or combinations of properties as electrodes and electrolytes in a range of energy devices. Through innovation, we can improve the efficiencies of the technologies we have and discover new ways by which we can prosper. Nanotechnology provides us with the opportunity to attain sustainable development, thus overcoming one of the greatest challenges of our time, by using some of the simplest and smallest means at our disposal.

In conclusion, nanotechnology, known as paying attention to structures less than 100 nm and technology of twentieth century, had better be preferred owing to benefits such as being potentially inexpensive, effective, and promising for time to come. Hence, many companies and researchers are getting curious day by day in order to explore nanotechnology especially its energy application. Indeed, to minimize energy waste, it should become common and applicable as soon as possible in spite of the fact that it is a quite new technology.

Definition

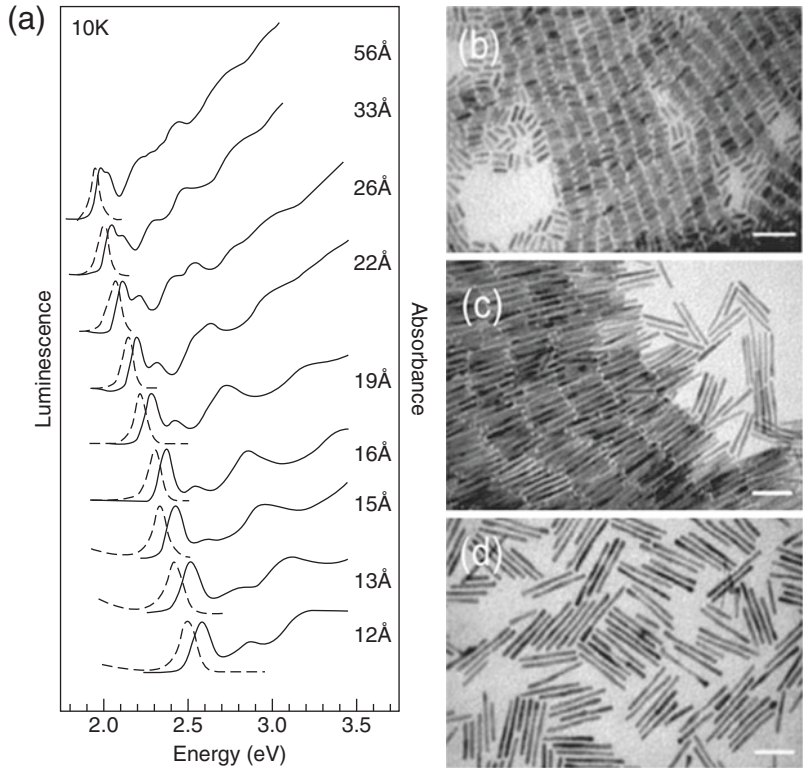
"Nanostructures for Photonics" represents a collection of devices whose working principles are based on photons at the nanoscale level.

Overview

In the last decade, new disciplines emerged where the terms *nano* and *photon* happen to play a fundamental descriptive role. Their origin dates back to the ancient Greece, with *nano* (=νανοζ) indicating something of small dimensions, and *photon* (=φϖΨψρζ) indicating the light. In Physics, but also in Chemistry, Biology, Material Science, and many more fields these terms have been used for indicating the studies of extremely small objects by means of light. This new technological frontier has already produced some amazing results: LCD based mobile phones, nanoparticles for optical tagging of biological molecules and hyperthermia, or devices for single-molecule detection are just few of many examples where nanophotonics plays a crucial role. In terms of optical devices,

Nanostructures for Photonics, Fig. 1 Schemes illustrating the core-shell architectures and the related band structure of spherical (**a**) and dot/rod nanocrystal structures (**b**)

their functionality can be divided in three general key parts: *light generation, light guiding* and *light harvesting*. Here will be introduced some approaches describing these aspects, starting from colloidal nanocrystals for photonics to end, through the introduction of photonic crystals and metamaterials, with plasmonic devices for Raman spectroscopy. The aim is to prove that photonics at nanoscale level is not just an exotic research field but a mature discipline capable of offering devices for a multitude of uses.



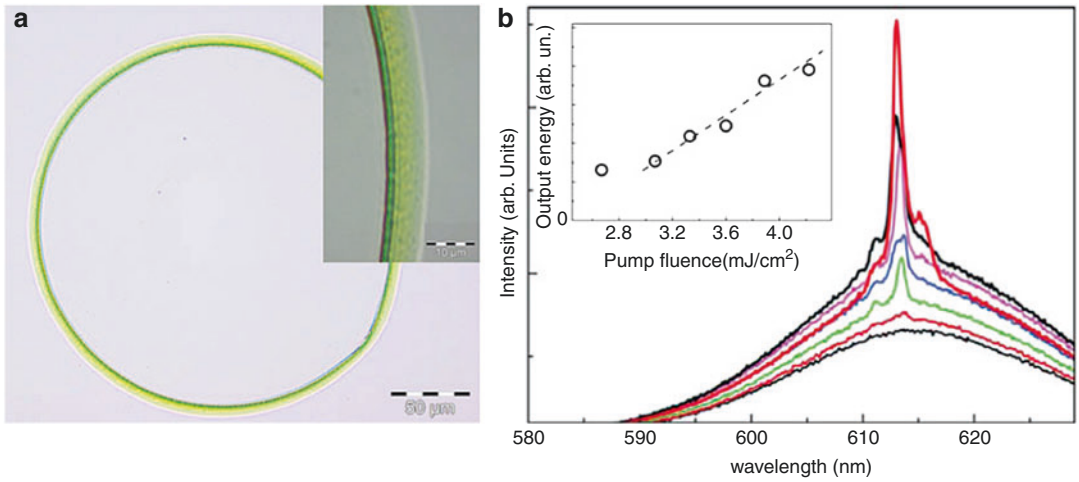
Light Generation: Semiconductor Nanocrystals for Lasing Applications

Colloidal semiconductor nanocrystals are a very attractive alternative as light emitting materials to more conventional nanostructures, because they can be fabricated in a cost-effective bottom-up approach by wet chemical synthesis. In the last decade, great progress has been achieved regarding the control on nanorcrystal shape and composition, leading to size dispersions of less than 5 % in spherical particle samples, and to rod- and multibranched shapes. One particular property of colloidal nanocrystals is their exposed surface that needs to be stabilized via surfactant molecules. The related obstacle that has to be overcome toward highly efficient light emission is the nonradiative recombination of the electrons and holes at surface states. The most promising solution to this problem are core-shell architectures, where a low band gap material nanocrystal is capped by a second material with higher band gap. In such structures, the photo-excited charges are confined by the nearly defect-free internal interface between the two materials (see band alignment illustration in Fig. 1).

Here, the emission wavelength is determined on one hand by the band gap of the core material, and on the other hand by the quantum confinement effects, since typical diameters of nanocrystals are in the range of 1–8 nm. The most popular systems for light emission in the visible consist of CdSe, CdS, ZnSe, and ZnS materials. For example, the emission of CdSe based systems can be tuned by the nanocrystal size in the range from 1.8 to 2.5 eV, as demonstrated in Fig. 2a.

Two very successful core-shell architectures are sketched in Fig. 1, the spherically symmetric core-shell structure, and the dot-in-a-rod (dot/rod) structure that can be fabricated by the seeded growth technique [1]. The dot/rod architecture in Fig. 1b combines the advantageous optical properties of rod-shaped nanocrystals, such as strongly linearly polarized emission and oriented assembly, with a high quantum yield (ratio photons in/photons out) comparable to that of spherical nanocrystals (Fig. 2).

For lasing devices two factors are important: the optical gain of the light emitting material and the quality of the resonant cavity that provides the optical feedback. The optical gain can be improved by the composition and architecture of the nanocrystals, and by the homogeneity and density of their assembly. The optical feedback can be obtained from semitransparent mirrors or distributed feedback resonators that consist of Bragg reflectors. The optical gain of the material is typically characterized by transient (time-resolved) optical absorption spectroscopy, which reveals the population dynamics of the energetic



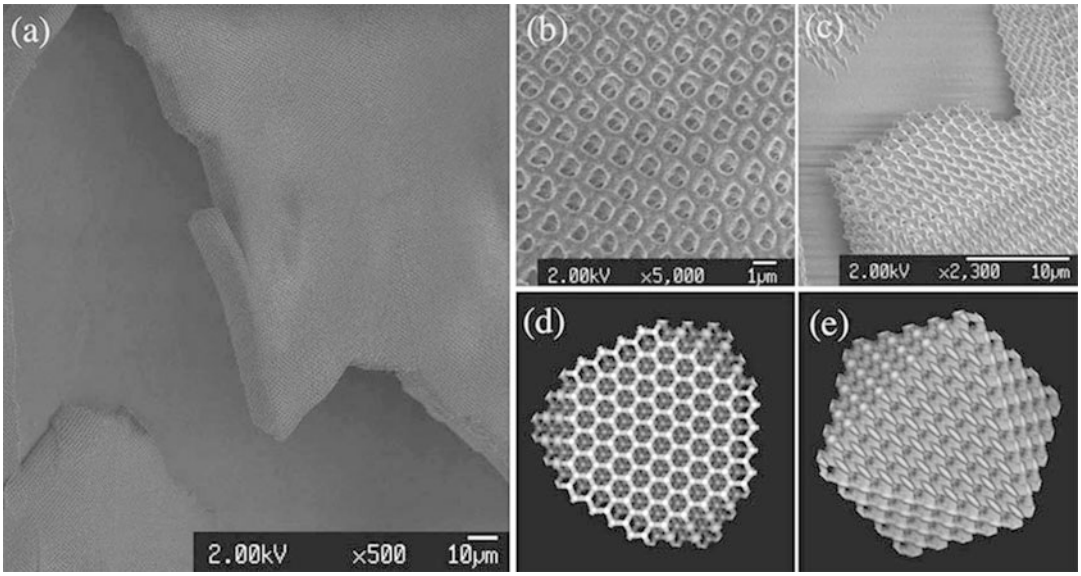
Nanostructures for Photonics, Fig. 2 (**a**) Emission and absorption spectra of spherical CdSe nanocrystals (With permission from Ref. [2]). (**b**) Transmission electron microscopy images of dot-in-a-rod core-shell nanorods with similar core size and different rod length. The scale bar corresponds to 50 nm (With permission from Ref. [1])

levels of the nanocrystals [3]. If the emitting ground state population maintains an occupation larger than unity, optical gain is achieved. One peculiar property of the dot/rod core-shell nanocrystals is that optical gain can be obtained from the optical transitions related to the core and from the transitions in the shell material. This effect extends the spectral range significantly, for example in the CdSe/CdS system from 570 to 650 nm (core emission) to 490 nm emission wavelength of the shell [4]. So far, the fabrication of efficient optical cavities for nanocrystal assemblies remain challenging since, for example, conventional sequential evaporation of Bragg reflectors does not work due to the incorporation of the inhomogeneous nanocrystal layer. Hence, novel approaches to obtain cavities have been sought, like the loading of cylindrical microcavities with nanocrystal solutions via the capillary effect [5], or the hot embossing of two pre-fabricated Bragg reflectors which embed the nanocrystal layer in a sandwich structure [6]. Another innovative approach consists in the laser emission from core-shell nanorod assemblies where the layer of nanorods itself formed the resonant cavity [3]. Here, circular rings with micron scale width and sharply defined lateral edges were formed via the coffee stain effect by simple deposition of nanocrystals dissolved in toluene (see Fig. 3a). The lateral edges of the rings themselves functioned as optical interfaces and were suitable for achieving feedback in a Fabry–Perot resonator scheme (Fig. 3b). Such microlasers could be very interesting for a new generation of photonic devices integrated onto substrates for lab-on-a-chip or for other compact, integrated applications.

Light Guiding: From Photonic Crystals to Metamaterials

Transportation of light to a detector is one of the fundamental aspects of any optical device. The light, during its path, might be affected by the surrounding world thus undergoing a

Nanostructures for Photonics, Fig. 3 (**a**) Optical microscope images of a self-assembled *circular* ring formed via coffee stain evaporation dynamics. The ring consists of densely packed core-shell nanorods and acts as a microcavity for laser feedback. (**b**) Emission spectra from a Fabry–Perot self-assembled microcavity made of nanorods with 25 nm length recorded at different pump fluences. Inset: emission intensity as a function of the pump fluence (With permission from Ref. [3])



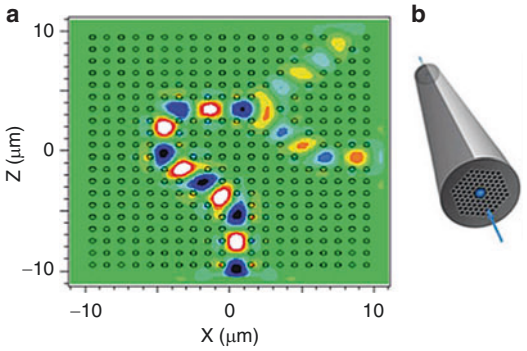
modification of its properties. This change can be temporary, namely existing only during the path toward the detector or even permanent. An example of the first kind is given by the effective wavelength of surface plasmon polaritons on a metallic interface whereas permanent modification can be well described by white light entering a fiber. In fact, in this case the light will loose most of its spectral components once the detector will be reached. A further example is given by metamaterials, usually defined as exotic devices capable of strongly modifying the standard properties of the light. These different situations indicate a strong relation between the intended application and the method of transportation of light which must be properly chosen.

Periodic and Quasiperiodic Fibers

A standard and well-established method for the transportation of light is by means of optical fibers. These devices are nowadays commonly used for applications such as Internet, allowing a high-speed data transfer (Fig. 4).

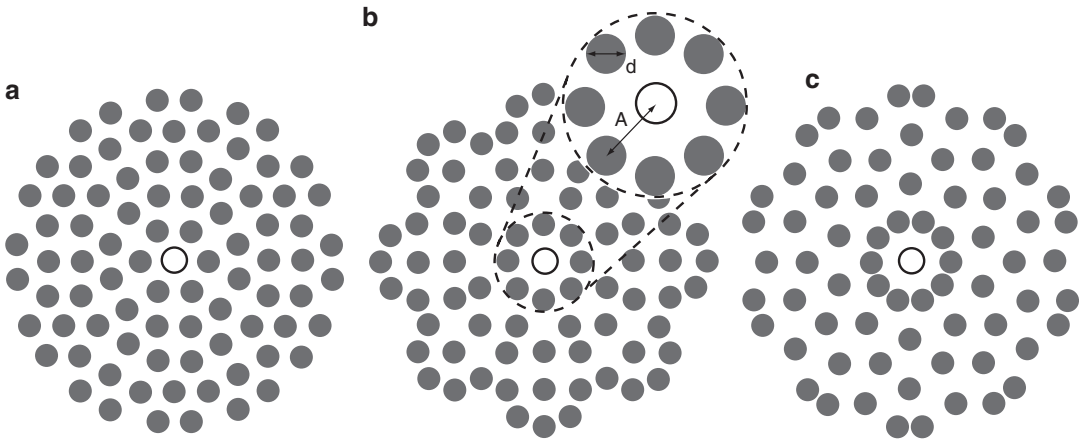
A different kind of fiber known as Photonic Crystal Fiber (PCF) was introduced in [8] with the idea of improving the classical fibers in many aspects, such as single-mode operation regime in a wide range of wavelengths, air-core guidance or reduced cross-sectional dimensions. In fact, while standard fibers have diameters of some hundreds of micrometers, PCFs can be reduced down to few microns [9–11].

The physics behind the working principle of PCFs fibers lies in their geometrical characteristics. Photonic crystals (PCs) are structures showing a *translational* periodicity of the medium permittivity [12, 13]. A three dimensional example of a face centered cubic PC is given in Fig. 4. The main characteristic of a PC is the capability of controlling the interaction between radiation and matter in order to obtain new physics. For example, they can induce a local modification of the field, which in turn will affect the optical characteristics of samples embedded in the crystal. For the present purposes, these devices will be seen either as filters or waveguides. In fact, according to their geometrical and material properties, PCs can realize optical gaps in specific spectral regions. Consequences are the impossibility of the light to propagate inside the crystal. Figure 5a is an example of a square-like photonic crystal waveguide where light at 2.85 μm is obliged in following the free path of the crystal. The structure is formed by Silicon cylinders of 200 nm



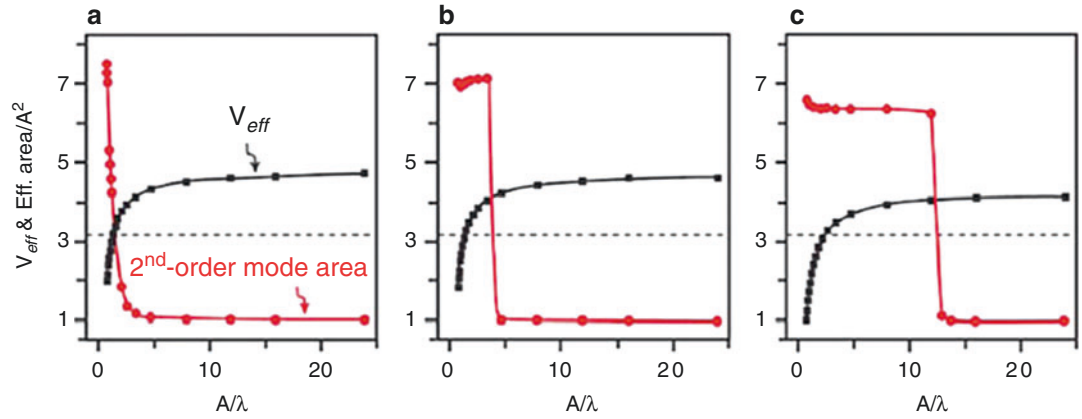
Nanostructures for Photonics, Fig. 4 The scanning electron microscope image of the scaffold type a fcc optical lattice. The lattice constant is about 1.5 μm. (**a**) A bird's eye view. (**b**, **c**) Magnified images of (**b**) *top* surface of the structure, and (**c**) cross section of a crack in the rim of the structure. (**d**, **e**) Simulated cross section of fcc lattice in (**a**) $< 1,1,1 >$ and (**b**) $< 1,1,-1 >$ (With permission from Ref. [7])

radius in air. The periodicity (lattice constant) of the crystal is 1 μm. When the optical gap concept is associated to the fiber world, Photonic Crystal Fibers are obtained. In this case, light propagates along the axis of the cylinders as in Fig. 5b.



Among the PCFs special attention deserves the Photonic Quasicrystal Fibers (PQFs). Their geometry is similar to photonic crystals with the fundamental characteristic of loosing the translational periodicity. Only rotational and mirror symmetry are proper of a quasicrystal [14, 15]. Figure 6 gives some examples of quasicrystal. One of the advantages of considering PQFs versus PCFs is in a wider single-mode operation regime than the PCFs, maintaining similar cross-sectional dimensions.

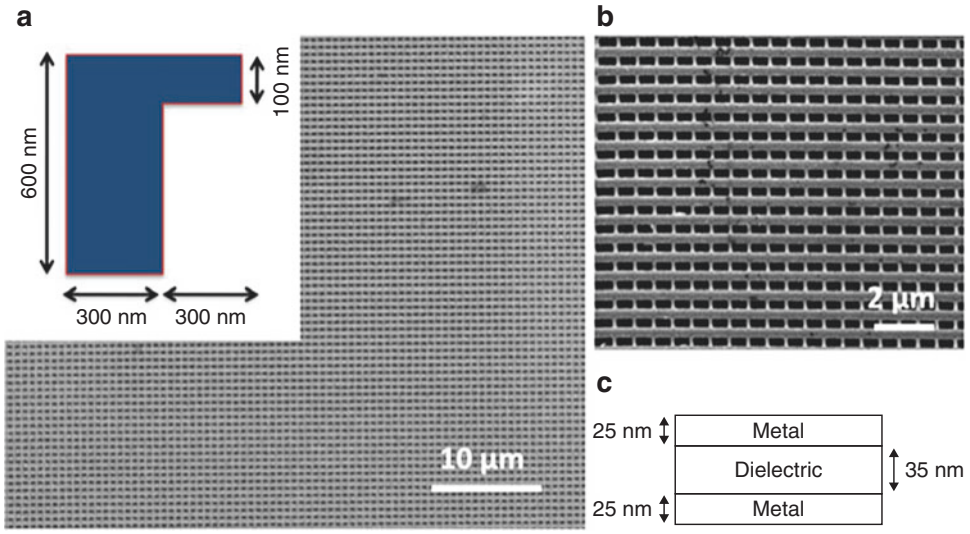
The typical approach for determining the optical characteristic of a fiber is the calculation of its V parameter. This value is usually considered as the quantity capable of identifying the single-mode operation regime of a fiber. In fact, in the case of single-mode fiber, for a given wavelength and polarization, only a particular mode can propagate. This avoids the problem of the destructive interference that occurs in a multimode fiber,



Nanostructures for Photonics, Fig. 5 (**a**) Two-dimensional photonic crystal waveguide. Transverse magnetic polarized light at 2.85 μm coming from the *bottom* of the figure travels along the free path. The period (distance between two Silicon cylinders) is 1 μm, the radius is 200 nm. (**b**) Photonic crystal fiber. The *blue arrow* indicates the direction of propagation of the light

which makes single-mode fibers the best choice for applications related to long distance communications. This explains why fibers working as single mode in a wide range of frequencies are very desirable for a number of applications. However, in case of PQFs the V parameter method has been demonstrated not to be working in many

Nanostructures for Photonics, Fig. 6 Cross section of three kinds of PQFs: (**a**) sixfold, (**b**) eightfold, and (**c**) tenfold. *Gray filled circles* denote air holes drilled in silica fiber. The central hole (empty *circle*) is absent in the fibers. The quantities *A* and *d* represent the lattice constant and the hole diameter, respectively (With permission from Ref. [15])



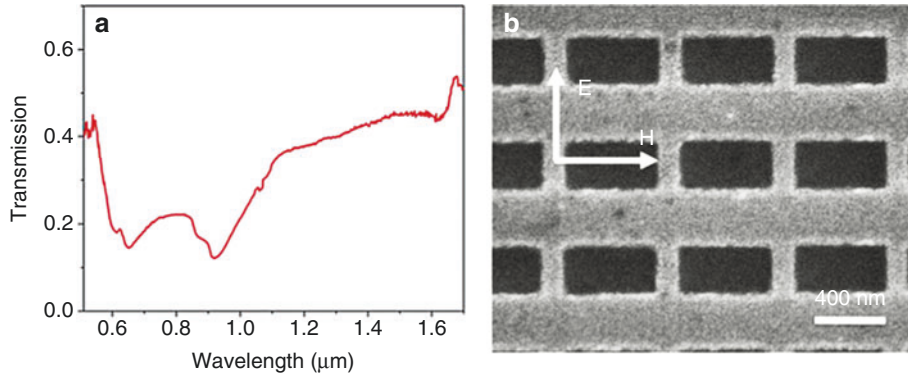
Nanostructures for Photonics, Fig. 7 Effective V parameter (*black squares and curves*) and the second-order mode normalized area (*red circles and curves*) as a function of A/λ for (**a**) sixfold, (**b**) eightfold, and (**c**) tenfold quasicrystal fibers. The dashed lines are drawn at π. A is the lattice constant (With permission from Ref. [15])

cases [15]. For this reason, a different approach consisting in the direct calculation of the effective area of the second-order mode is preferable. Figure 7 shows a comparison between these two approaches for three kinds of fibers.

Besides a disagreement between the V parameter and the effective area approach as in Fig. 7b, c, it is possible to notice that the single-mode operation regime for both the eightfold and tenfold fibers is much more extended than the sixfold one. This makes these kinds of fiber more robust for transporting signal at long distances.

Fishnet Structures: A First Step Toward Metamaterials

Metamaterials are artificial man-made materials exhibiting particular properties such as negative refraction [16–19], which can lead to several applications like the realization of superlenses or



Nanostructures for Photonics, Fig. 8 (**a**, **b**) SEM images of a fabricated fishnet structure. (**c**) Sketch of the *vertical* structure. The *inset* in (**a**) shows the cell unit of the fishnet structure

invisibility cloak. In order to reach a negative refractive index, simultaneously negative electric permittivity and magnetic permeability need to be reached as pointed out by Veselago in 1968 [16]. A negative permittivity is a relatively easy task to obtain, since all metals below their plasma frequency exhibit it. On the other hand, a negative permeability is more difficult to achieve; the lack of magnetic charges and the weak interaction between matter and the magnetic part of light, make scientists capable to attain it only in certain frequency regions. Combining thin metallic wires and rods in a three layers Metal/Dielectric/Metal structure (as shown in Fig. 8), constitutes the so called *fishnet structure* which has been proved to exhibit peculiar characteristics both in metamaterials and plasmonics fields.

Fishnet structures have been widely investigated in metamaterials research field both from an experimental and a theoretical point of view [20]. The reason is that their geometry is simple and its fabrication is relatively easy. However, the mechanism behind the negative refractive index behavior is nowadays not completely understood. The main idea is that properly polarized light passing through the structure can experience at the same time both negative permittivity and permeability. Considering, for instance, an impinging electromagnetic field polarized as shown in Fig. 9b: the electric field oscillates along thin wires allowing a negative electric permittivity and the magnetic field can induce a resonance through the aligned sets of rods, just like in a LC circuit. In fact, whereas the capacitor-like response is directly given by the vertical structure of the fishnet (two metallic plates separated by a dielectric, see Fig. 8c), the inductive response is expressed by the electric currents, generated by the oscillating magnetic field, that circularly flow in the plates (as regular currents) and across the dielectric (as displacement current). The resonant behavior can be observed, for example, in the transmission spectrum (Fig. 9a): if the magnetic resonance occurs, a dip in the transmission coefficient can be noticed.

Before performing the experiments, also according to previous studies where similar structure were investigated, a magnetic resonance between 1,300 and 1,500 nm was expected [20]. In Fig. 9b, this kind of resonance is not clearly visible, probably because of high losses in that spectral range which damp transmission or reflection features. Nevertheless, it is possible to notice a resonant behavior at shorter wavelengths.

Nanostructures for Photonics, Fig. 9 (**a**) Transmissivity spectrum for the presented fishnet structure. (**b**) SEM micrograph of measured fishnet structure and fields direction of the incident light

Indeed current loops, which are supposed to induce the magnetic resonances, are generated by internal gap surface plasmons polaritons (SPPs). This means that, more than one resonance exist, actually several of them may occur as far as the matching condition subsists:

$$k_{SPP} = k_{wave} + mG_x + nG_y \text{ with } : G_x = \frac{2\pi}{a_x} \text{ and } G_y = \frac{2\pi}{a_y}$$

In this relation, k_{SPP} and k_{wave} are, respectively, the wave vector of the excited SPP and the one of the incident light. a_x, a_y are the lattice periodicities along the x and y fishnets axis. Therefore, higher frequency resonances can be reached as far as the lattice provides the missing momentum through G_x and/or G_y. However, a negative refractive index is not guaranteed in the entire spectrum since the equivalent plasma frequency of the medium is dominated by the cutoff wavelength of the holes of the fishnet.

To conclude, fishnet structures represent a good example on the concept of metamaterials and how their fascinating properties are related to plasmonic effects. A deep study of these structures can be considered a first step to understand the underlying physics of negative refraction enabling, eventually, the realization of more complex devices exploiting the effects of negative index materials.

Light Harvesting: Supported Metal Nanoarrays for Plasmonic Devices

Light harvesting plays an important role for the operation of many kinds of devices, such as biosensors or photovoltaic cells. In fact, besides the generation and transportation of light, an efficient coupling mechanism between the guiding device and the investigated bio-sample in order to produce a readable signal is a fundamental step of a generic photonic device. For example, metallic nanostructures have the property of realizing a high localized electric field which can be efficiently coupled to a bio-sample. This, in turn, means high signal-to-noise ratio from the sample, namely a good signal for the detector can be produced.

Metallic nanoparticles exhibit specific optical properties in the visible/near-infrared range due to the collective excitation of the conduction electrons (Localized Surface Plasmon Resonances – LSPRs). The field enhancement provided by metallic nanostructures has been used to manipulate light-matter interactions and enhance nonlinear phenomena. The strong effects associated to the LSPR excitation on metal nanoparticles are the core of many interesting perspective applications such as single- molecule detection and photovoltaic conversion. Here two specific examples are introduced, that is, nanoaggragate and nanoantenna arrays where light harvesting and field enhancement will be

exploited with respect to high sensitivity Raman spectroscopy.

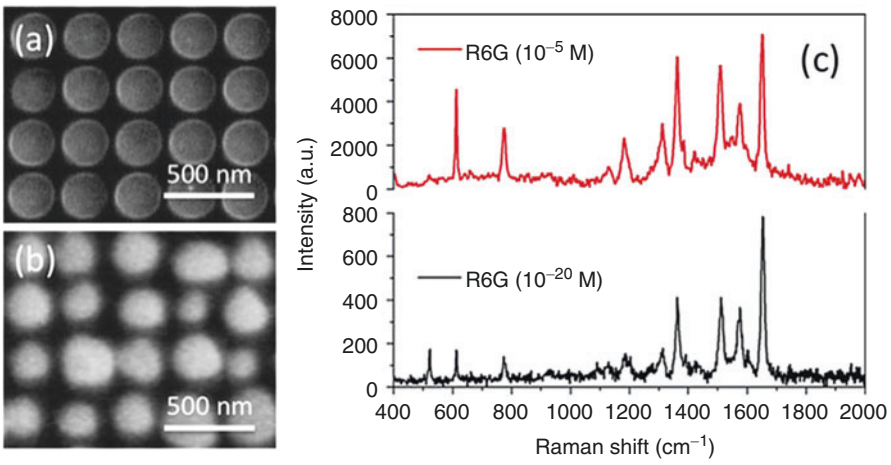
The use of advanced lithographic techniques allows precise control of particle shape and size, as well as interparticle separation [21, 22]. Electron beam lithography (EBL) has become the method of choice for fabricating single or periodic arrays of metal nanostructures endowed with the desired morphological features [23]. It is versatile and provides high resolution and precise control over the geometry and separation of nanostructures, guaranteeing a fabrication reproducibility, and precision down to the nanometer scale.

Nanoaggregate Array

The fabrication of an active SERS device was achieved by means of site selective deposition of Ag nanoparticles, exploiting electroless technique on Si pre-patterned substrates [23]. A large array of nanostructures with high degree of reproducibility at the nanometer scale was realized using electron beam lithography onto a Si substrate spin-coated with 50 nm thick ZEP layer.

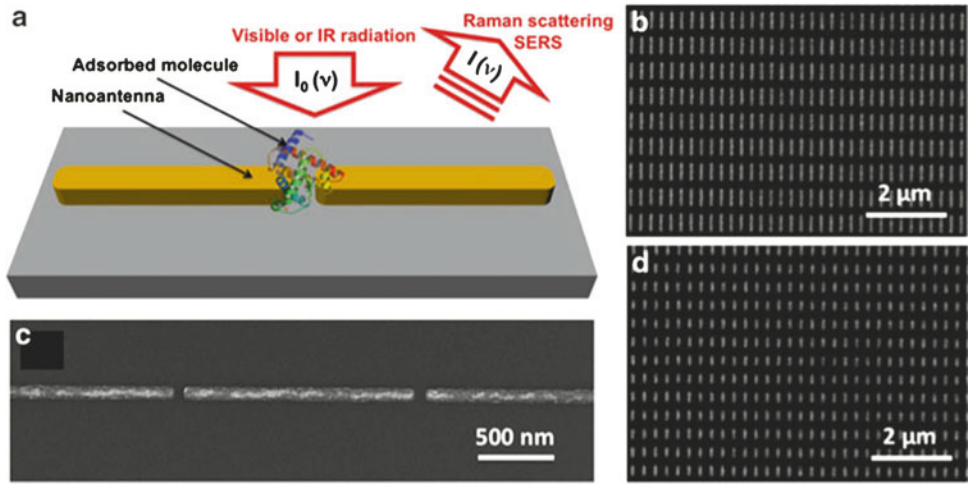
The Ag deposition was realized by means of a redox reaction between the metal and the Si surface remained uncovered after the lithographic process. The reaction occurs in a dilute (0.1–0.5 M) HF solution in which is dissolved a metal salt, that is, $AgNO_3$, at a concentration of about 1 mM. The global chemical reaction is:

$$4Ag^{+} + Si(s) + 6HF \rightarrow 4Ag^{0} + H_2SiF_6 + 4H^{+} \quad (1)$$



which in its turn can be separated into two half-cell reactions:

$$Si + 2H_2O \rightarrow SiO_2 + 4H^{+} + 4e^{-}(\text{Anode} - \text{Si oxidation}) \quad (2)$$



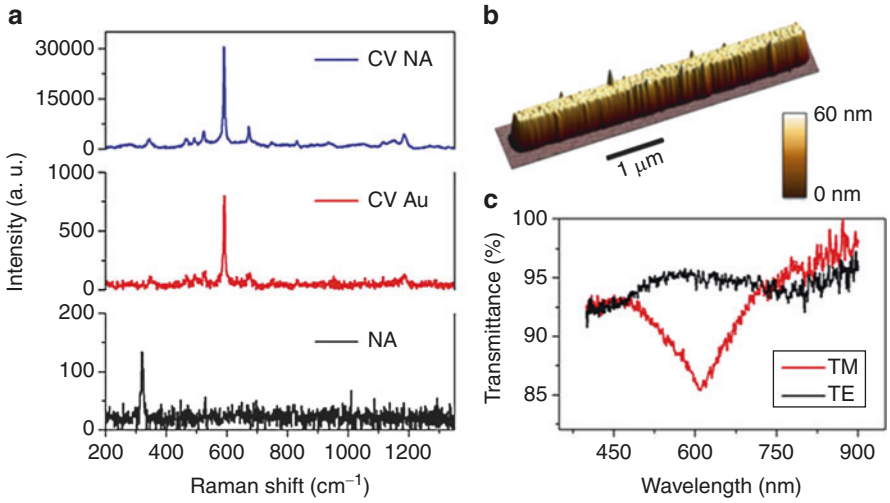
$$Ag^{+} + e^{-} \rightarrow Ag^{0}(\text{Catode} - \text{Ag reduction}) \quad (3)$$

The driving force of the whole process is coming from the potential difference in the two half-reactions, thus fostering the growth of Ag grains and the formation of well-organized metallic nanostructures (see Fig. 10a, b).

In order to probe the enhancement behavior in Raman spectroscopy related to the plasmon excitation, the sample was immersed in Rhodamine 6G (R6G) solutions with different concentration (10^{-5} M and 10^{-20} M in H_2O) for 30 min. The sample was gently rinsed in DI-water to remove molecules in excess not chemisorbed on the metal surface and then dried in N_2 flow.

Nanostructures for Photonics, Fig. 10 SEM micrographs of (**a**) array of empty holes fabricated by EBL technique and (**b**) Ag nanoaggregates selectively grown inside the nanohole pattern. (**c**) SERS spectra acquired from 10^{-5} to 10^{-20} M R6G, absorbed on the silver structures

Nanostructures for Photonics, Fig. 11 (**a**) The nanoantenna concept: fabrication of a highly sensitive and specific nanobiosensor based on extraordinary optical signal enhancement. (**b**, **d**) Representative SEM images of two different nanoantenna arrays fabricated by EBL technique. The dimensions of the NAs are of length 410 nm (**b**), 200 nm (**d**) while width and height both are 60 nm for all NA. (**c**) SEM of coupled nanoantenna array



In Fig. 10c, Raman spectra of R6G molecules, adsorbed on a Si substrate with a 60 s Ag deposition, are shown. There are various bands for R6G compound at around 1,650, 1,509, and 1,361 cm^{-1}, attributed to the xanthenes ring stretching of C–C vibrations, 1,575 cm^{-1} attributed to C–O stretching; while the band at 1,183 cm^{-1} is related to the C–H bending and N–H bending vibration of xanthenes ring. As can be clearly observed in Fig. 10c, the Raman intensity decreases with the decreasing concentration of R6G, as expected. Though, the concentration is very low, various bands are clearly visible even for R6G molecule with concentration of 10^{-20} M, keeping accumulation time 60 s and laser power 0.0018 mW.

Nanoantenna Array

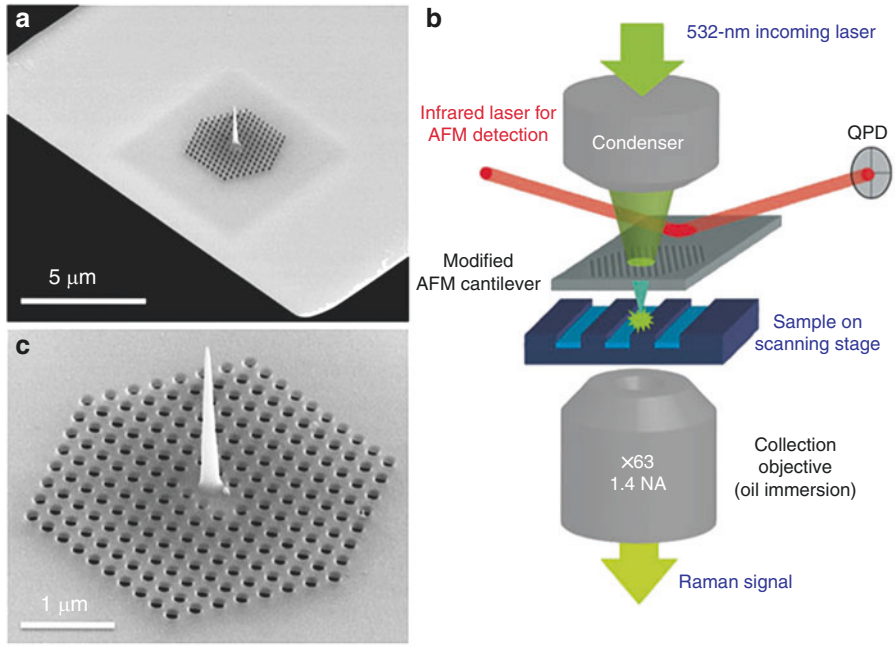
The ability to tailor the optical properties of structured plasmonic materials has proven to be crucial for a wide variety of applications, using them for surface-enhanced spectroscopy and biosensing. While a symmetrical geometry allows polarization independent plasmon excitation, a dichroic absorption is well expected for nanoantenna (NA) fabrication. Large scan overview of different nanoantenna patterns are reported in Fig. 11. The sample topography has been characterized recurring to scanning electron microscopy (SEM) and atomic force microscopy (AFM) operated in tapping mode.

The optical properties of the nanoantenna array, shown in Fig. 12c, were investigated by means of spectroscopic transmission of polarized light in the range between 400 and 900 nm. The polarization of the incident light was varied from transverse magnetic TM (electric field perpendicular to the short NA axis) to transverse electric TE (electric field parallel to the long NA axis). The optical transmittance spectra present evidence of a clear anisotropic behavior; for TM polarization a localized minimum around 620 nm is found. This is the typical behavior exhibited by subwavelength metal nanoparticles sustaining a localized surface plasmon resonance.

Evidence of plasmon-induced SERS effects is given in Fig. 12a in which the different Raman emission lines from cresyl violet (CV) molecules (with a concentration of 3.46 μM) deposited on the gold nanoantenna arrays are shown. The sample was excited by 633 nm laser wavelength (laser power = 0.14 mW and accumulation time = 50 s) through a 150X objective. The measurements were performed on bare nanoantenna arrays

Nanostructures for Photonics, Fig. 12 (**a**) SERS spectra of cresyl *violet* molecules deposited on NA sample (*blue line*) and flat Au film (*red line*). Background measurement performed on bare NA structure is also reported (*black line*). (**b**) AFM 3D image. (**c**) Transmission optical spectra of the NA array of Fig. 1.11b. *Red/black lines* are for TM/TE polarization respectively

(sample NA), on cresyl violet molecules chemisorbed on flat Au film (sample CV Au) and on CV deposited on the nanoantenna arrays (sample CV NA). To ensure the quality of the sample surface, the background measurements were performed at different positions of the nanoantenna SERS device. As shown in Fig. 12a (NA line) no characteristic Raman band, except at around 320 cm^{-1} related to the Ca-F vibration from the substrate, is observed. The characteristic vibrational bands of CV are observed in the SERS spectrum (CV NA trace). Intense Raman bands centered at around 591, 882, 927, and 1,189 cm^{-1} can be attributed to the N–H_2 rocking vibration, two benzene group bending, out-of phase N–H_2 rocking vibration, and combination of N–H_2 rocking and C–H_X rocking, respectively.



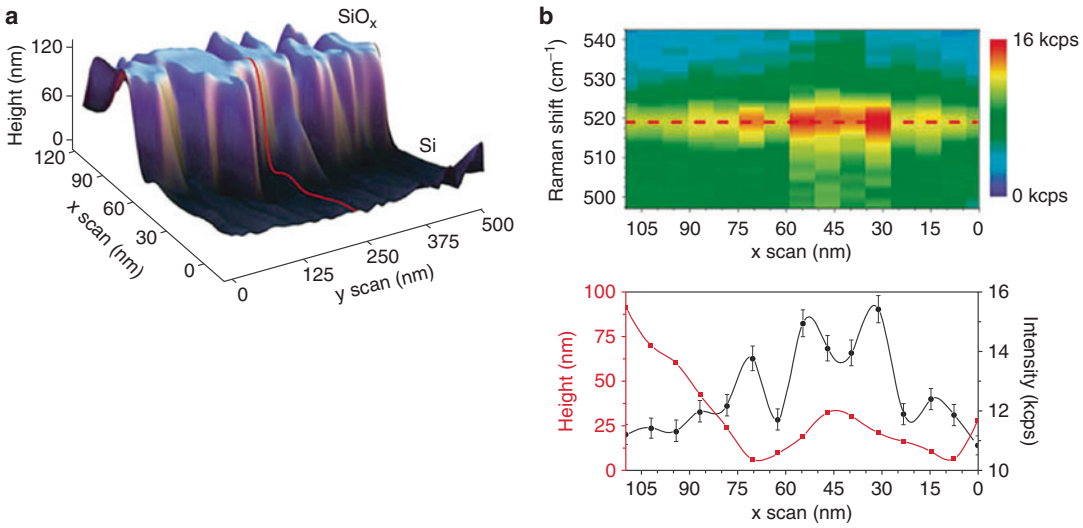
CV molecules chemisorbed over flat Au film are also shown in Fig. 12a. A giant enhancement in Raman signal for CV NA sample with respect to the CV Au one can be clearly observed. The maximum enhancement of the Raman emission is obtained when the excitation is polarized along to the nanoantenna short axis, in correspondence to the resonant excitation of the LSP resonance. The evaluated SERS enhancement for the fabricated nanoantenna device is 10^7.

Novel Nanophotonic Devices

The three standard aspects of a photonic device, namely light generation, guiding, and harvesting can be combined in a number of ways to obtain many kinds of functionalities. For example, metallic-nanorods can be used for shrinking the wavelength of the light to improve the coupling with detectors such as nanoantenna arrays, or optical fiber can be properly modified for three-dimensional optical trapping [24]. Here will be introduced two specific examples: photonic crystals combined to plasmonic devices for the realization of background-free Raman probes, and superhydrophobic devices for single-molecule detection.

Integration of Photonic Crystals and Plasmonic Devices for Label-Free Chemical and Structural Detection

A combination of different nanostructures for photonics give rise to a novel photonic-plasmonic device that allows label-free detection, through Raman spectroscopy, of single inorganic nanoparticles and of monolayers of organic compounds [25] and that allows, integrated on an atomic force microscope (AFM) cantilever, to



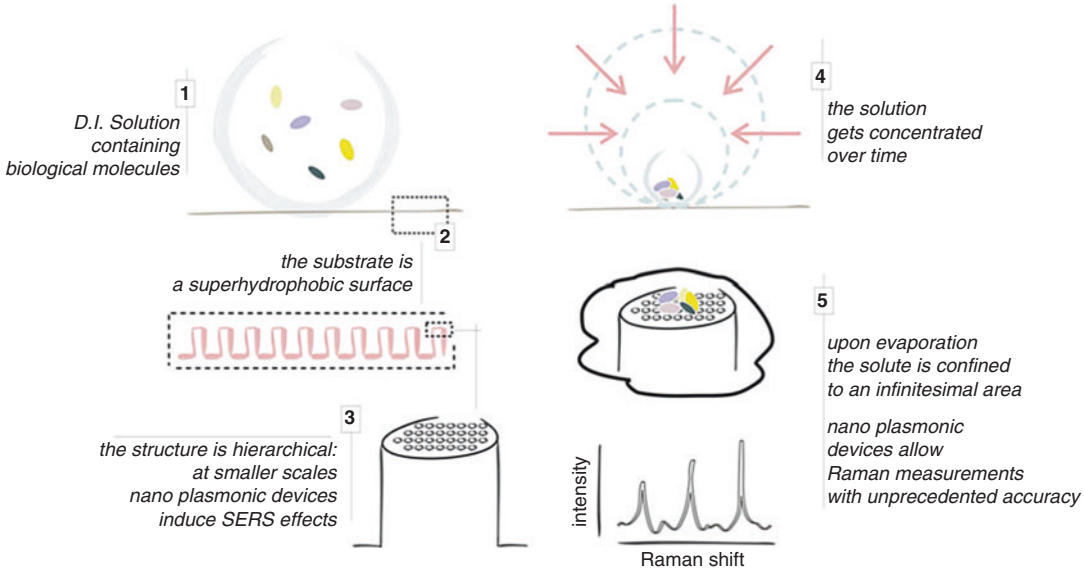
Nanostructures for Photonics, Fig. 13 (**a**) SEM image of the device fabricated on a silicon nitride AFM cantilever. (**c**) Zoom on the photonic crystal cavity and the tapered plasmonic waveguide with radius of curvature at the apex of 5 nm. (**b**) Sketch of the experimental setup, showing the integration of the photonic–plasmonic device into an AFM–Raman microscope

obtain topographic, chemical, and structural information at an unprecedently high spatial resolution (below 10 nm) [26].

The device consists of a two-dimensional dielectric photonic crystal cavity, which can be patterned on a Si_3N_4 AFM cantilever, together with a tapered silver plasmonic waveguide placed at the center of the cavity (Fig. 13a). The photonic crystal consisted of a triangular lattice of air holes (lattice constant = 250 nm, hole diameter = 160 nm) patterned on a 100-nm-thick Si_3N_4 membrane. Three missing holes in the center generated a photonic crystal cavity, termed L3, tuned at $\lambda = 532$ nm. The plasmonic waveguide is a 2.5-μm-tall metallic cone, with a base diameter of 300 nm, and the minimum radius of curvature at the apex is controllable in the range 2.5–5 nm (Fig. 1c). The entire device is fabricated by means of Focused Ion Beam milling and electron-beam induced deposition [27]. Ion beam milling was used to define the photonic crystal whereas the silver tapered waveguide was grown in the center of the cavity using electron-beam induced deposition from a gas precursor containing a platinum–carbon polymer $(CH_3)_3Pt(C_pCH_3)$.

The photonic crystal cavity enables an efficient coupling between the external laser source (used for Raman excitation) and the tapered waveguide, together with optimal sample illumination. In fact, the focal plane from which the SPPs are launched is 2.5 μm away from the cone apex where the Raman excitation is generated. This drastically lowers the background intensity at the sample plane. Thus, the spatial separation between SPP generation and Raman excitation efficiently increases the signal-to-noise ratio in the Raman spectrum, giving rise to a new optical configuration, namely Surface Plasmon Polariton Enhanced Spectroscopy (SPPERS). The focusing of SPPs follows an adiabatic compression mechanism, which causes a strong localization of the electrical field in a region with a size comparable to the apex radius of curvature [28]. This device can be fully integrated with an inverted Raman microscope combined with an AFM stage, as shown in Fig. 13b.

Nanostructures for Photonics, Fig. 14 (**a**) SEM image of the device fabricated on a silicon nitride AFM cantilever. (**c**) Zoom on the photonic crystal cavity and the tapered plasmonic waveguide with radius of curvature at the apex of 5 nm. (**b**) Sketch of the experimental setup, showing the integration of the photonic–plasmonic device into an AFM–Raman microscope (With permission from Ref. [26])



The SPP spatial confinement in the near field is comparable to the radius of curvature of the tapered waveguide apex, which lies between 2.5 and 5 nm. The expected electric field enhancement E due to adiabatic compression is defined as $E = E_{tip}/E_{base}$, where E_{tip} and E_{base} are the maximum electrical fields at the apex and bottom of the waveguide, respectively, and reaches values of practical interest in the range of 100 when the radius of curvature of the tip is below 5 nm. For successful spectroscopy applications, this necessitates state-of-the-art fabrication quality.

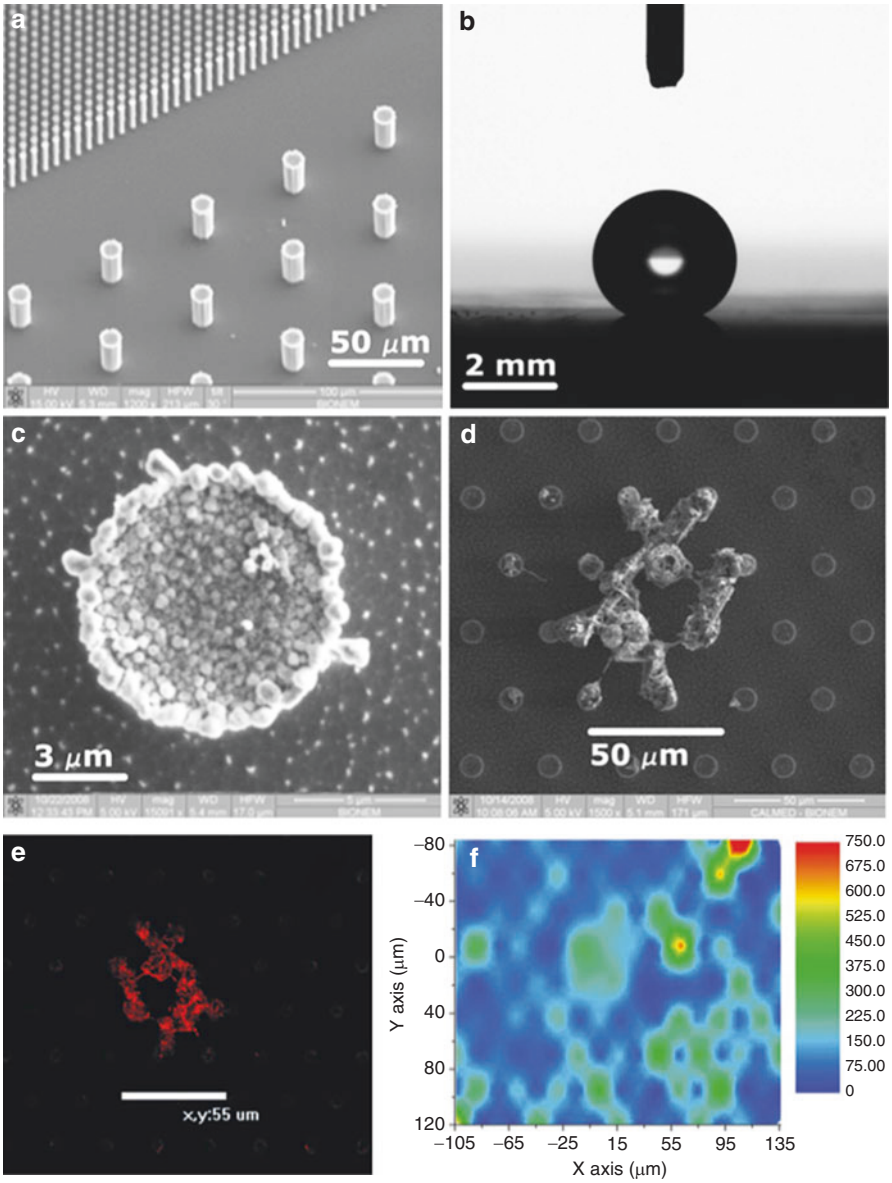
The architecture of the device and the mechanical stiffness of the tapered waveguide allow using it both as an AFM tip and as a nanometer light source for near-field Raman excitation. In other words, it is possible to obtain topographic and chemical mapping to yield structural and stress information with the same spatial resolution as is imposed by the geometry of the tip, that is, limited only by its radius of curvature.

Device performances have been assessed by measuring a test sample for which the chemical composition had periodic spatial variations in the range of few nanometers. The test sample consisted of patches and gratings of silicon nanocrystals having different pitches (from several micrometers to a submicrometer scale) obtained by laser melting of a silica substrate previously fabricated by plasma-enhanced chemical vapor deposition.

The AFM–Raman setup was operated in tapping mode and wet conditions (in distilled water) to measure simultaneously the topography and Raman intensity map by scanning the sample and acquiring Raman data across the lithographic structures, point by point.

A severe test on the described sample was performed by scanning the sample in a patterned region in which the crystalline and amorphous topography forms a grating with submicrometer pitch. From the AFM measurements, it could be seen that silicon, upon laser-induced crystallization, has its height reduced by 100 nm, which results in the formation of a trench on the sample surface, as shown in the three-dimensional AFM map in Fig. 14a. The AFM scan step size was 7 nm. The red line in Fig. 14a is a representative AFM line scan which provides simultaneously the Raman intensity map shown in Fig. 2b (upper panel), in which the Raman spectrum extends from 504 to 540 cm^{-1}. The acquisition time of each Raman map was 5 s. Figure 14b (lower panel) shows the topography and Raman intensity

Nanostructures for Photonics, Fig. 15 Biophotonic nanostructures integrated with superhydrophobic surfaces can lead to the fabrication of novel devices with advanced sensing capabilities



for the same line scan. The Raman intensity is taken at the maximum of the silicon phonon peak at 520 cm^{-1}. The Raman intensity and relative peak amplitudes change from point to point, indicating an optical resolution of better than 7 nm.

In conclusion, the development of a device based on the combination of photonic–plasmonic nanostructures that is fully compatible with AFM and Raman spectroscopy opens up a number of significant opportunities in the nanoscale chemical mapping of materials. The approach could be of particular benefit in the nanoscale analysis of biological matter, such as in the investigation of cell membrane protein spatial distributions, in which chemical/physical bond strengths and amino acid composition in vivo conditions could be revealed. Device architectures based on the adiabatic generation of SPPs have considerable potential for applications in which a reliable nanometer-sized light source is of utmost importance.

Integration of Biophotonic and Superhydrophobic Devices for the Detection of Low-Concentrated Biomolecules

Here, will be investigated how biophotonic nanostructures can be integrated to superhydrophobic surfaces (SHSs) to obtain devices with advanced sensing capabilities, thus offering new possibilities in the field of clinical medicine, especially toward the early diagnosis.

Superhydrophobicity is a phenomenon whereby a drop post upon a surface would preserve its original spherical shape rather than spreading or wetting indefinitely the plane of contact (Fig. 15). In the celebrated model of Cassie [29], a surface would be superhydrophobic on account of the pockets of air that remain trapped between the liquid and the substrate, and the smaller the fraction of solid in contact with the drop the larger the apparent contact angle. SHSs retain unique properties in terms of wettability that can be reviewed as follows: (a) SHSs have superior adhesive properties, in the sense that they exhibit vanishing friction coefficients; (b) a droplet, deposited upon these surfaces, would accordingly preserve a quasi-spherical shape while evaporates, and the contact area at the interface would thus progressively reduce; (c) SHSs can be artificially reproduced using micro and nanofabrication techniques. Using the properties above, micro textured surfaces may be successfully exploited to concentrate tiny amounts of moieties over micrometric areas, and

Nanostructures for Photonics, Fig. 16 (**a**) SEM micrograph of periodic hexagonal lattice of cylindrical Si micro pillars used as SHS. (**b**) The *spherical* shape of a drop positioned upon the SHS is preserved. (**c**) Arrays of Ag nanograin aggregates positioned upon the pillars. (**d**) SEM image of the residual solute of R6G at the end of process of evaporation. The intensity of fluorescence is shown in (**e**), while Micro-Raman mapping measurements are reported in (**f**)

consequently measure these moieties with unprecedented accuracy [30, 31].

SHSs typically comprise a periodic hexagonal lattice of cylindrical Si micro pillars with a certain diameter and pitch (Fig. 16a). The micro pillars are realized combining optical lithography, electroless growth, and Bosch Reactive Ion Etching (RIE) techniques. Nonconventional biophotonic nanostructures such as arrays of silver nanograin aggregates, conveniently positioned upon the pillars, would complete a hierarchical structure thus permitting the

identification of substances in the single-molecule regime. These "two-stages" micro and nanostructures act as superhydrophobic surfaces with an increased contact angle ranging from 155° to about 175°.

A particular kind of nanogeometry based plasmonic device is here reported as example, which is an electroless grown random assembly of silver nanograins [23]. Nevertheless, the method can be extended to a number of different plasmonic nanostructures, as those described in the sections above.

Imagine to deposit a drop of an extremely diluted solution upon a textured, superhydrophobic substrate. The drop would evaporate over time and thus the solution would get more and more concentrated (Fig. 15). At the end of the process, the residual solute would be confined within an exceptionally small region of the plane. With a suitable design, few molecules may be conveniently enforced to confine into the smallest area conceivable, at the limit upon a sole pillar. Nanogeometry based biophotonic devices, conveniently tiling these surfaces, would probe/detect the moieties with extremely small resolution limits. Here, the beneficial effects of superhydrophobicity and nanogeometry based spectroscopy are combined and conveyed into a unique platform, and from the combination of the two novel properties arise permitting the identification of proteins or analytes with unprecedented accuracy.

In order to clarify the concept, an experiment performed using R6G molecules, is reported. Evaporation processes of drops of D.I. water were followed over time. Few molecules were conveniently enforced to confine into a small area. A solution was investigated with initial concentration as small as 10^{-18} M. Figure 16d shows a SEM image of the residual solute of R6G at the end of process of evaporation. The intensity of fluorescence as in Fig. 16e is correctly proportional to the quantity of substance deposited upon the pillars, and thus the intensity signal of fluorescence follows the solute distribution upon the substrate. Micro-Raman mapping measurements were also performed (Fig. 16f). The mapping analysis was performed by referring the band centered at 1,650 cm^{-1}. The results demonstrate that the method is effective in measuring extremely small diluted solutions.

Definition

Modification and functionalization of substrates can lead to the presence at materials surfaces of molecular nanostructures. Their 2D packing and chemical functionalities may impart to surfaces particular properties that can be very different from the pristine ones.

Modification is a very general term concerning every kind of treatment leading to change the physical morphology or surface chemistry of a given material in order to obtain tailored properties with dependence on the material application field.

Functionalization is mainly related to the introduction at a surface of chemical groups with a variable surface density which are requested to subsequently react with other species.

When a process or a group of processes are applied to the surface of an inorganic or organic material, affecting both topography/morphology and surface chemistry at the micro- and/or nanoscale level, the material surface results physically and chemically patterned.

In the following the main modification, functionalization, and patterning surface techniques will be described according to process methods, substrate chemistry, and nanotechnological application fields.

Surface Modification and Functionalization

In general, some materials which have excellent bulk physical and chemical properties often do not possess suitable surface properties required for specific applications.

For this reason, surface-modification techniques, that can transform these materials into valuable finished products, become an important part of surface science and technology.

Processes, developed in the last decade, are able to simply modify surface morphology of materials or give rise to nanostructured coatings aimed to simply affect the adhesion or anti-adhesion properties, mainly hydrophilicity and hydrophobicity, or to promote specific bonding with other species. These features can be a crucial advantage in several applications in the fields of protective, anti-adhesion, adhesion coatings, friction and wear, composites, microelectronics and thin-film technology, molding and lithography, technical fabrics, biomaterials, sensing and in particular biosensing.

Generally, these surface-modification methods can be divided into two classes: physical modifications and chemical modifications [1].

In this entry will be reported the main topics regarding surface chemical modifications, both the surface derivatization or grafting method which depend on the chemistry of the substrate surface and the functional organic coating deposition which can be performed on the surface of very different materials without the need of a specific chemical binding with the surface (no-dependence on chemistry).

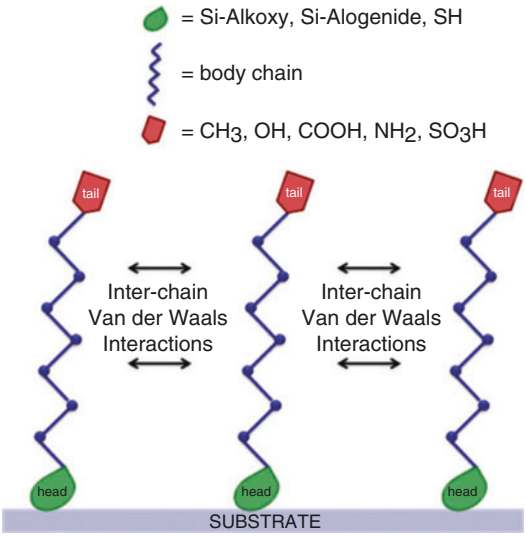
Finally, some surface patterning procedures devoted to get functional structures will be described as following process of the previously reported methods or based on other modification techniques including physical processes.

Chemical Derivatization or Grafting

The key advantage of these techniques is that the surface of the materials can be modified or tailored to acquire very distinctive properties through the choice of different grafting precursors, while maintaining the substrate properties.

The crucial point is to single out the suitable molecule to be grafted according to the chemistry of the material substrate, that is, the kind of atoms/groups with which the substrate is truncated with.

Before the grafting step, commonly a surface activation is needed in order to create reactive sites on the substrate surface or enhance the amount of the ones naturally already present.



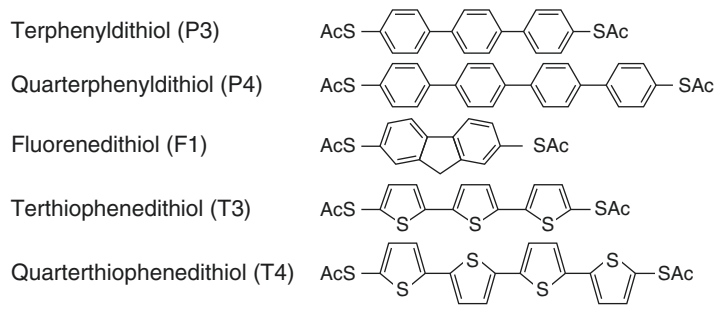
Practically, one can generate reactive groups through UV, high-energy electrons, γ irradiation, plasma treatment, ozone exposure [1] and chemical reactions performed in liquid and vapor phase. The kind of activation treatment heavily depends on materials.

For sake of simplicity, the different types of derivatizing treatments and the related materials activation procedures will be considered according to substrate chemistry.

Generally, among the surface-modification techniques, the formation of a Self-Assembled Monolayer (SAM) has been intensively studied. SAM is a kind of "bottom-up" technique which provides advantages regarding the surface modification. It leads to a structure which is at, or close to, thermodynamic equilibrium, and thus tends to self-healing/defect rejection and leads to a closely packed, well-ordered, and stable configuration on the surface [1]. SAMs offer unique opportunities to increase fundamental understanding of self-organization, structure–property relationships, and interfacial phenomena. The ability to tailor both head and tail groups of the constituent molecules makes SAMs excellent systems for a more fundamental understanding of phenomena (e.g., ordering and growth, wetting, adhesion, lubrication, corrosion, etc.) affected by competing intermolecular, molecule-substrate and molecule-solvent interactions.

SAMs provide the needed design flexibility, both at the individual molecular and at the material levels, and offer a vehicle for investigation of specific interactions at interfaces and of the effect of increasing molecular complexity on the structure and stability of two-dimensional assemblies.

The key factors characterizing the SAM precursor molecules consist in (a) the "head," (b) the "tail," and (c) the body chain length of the molecule (Fig. 1). The "head" is one of the terminal



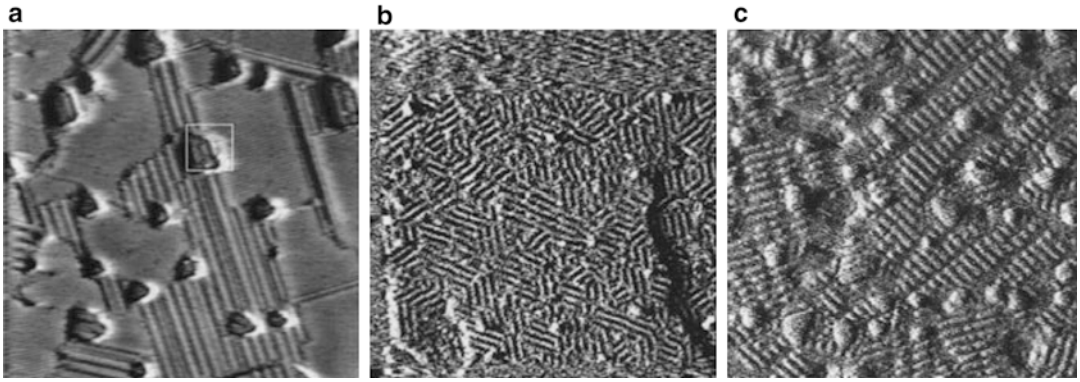
Nanostructures for Surface Functionalization and Surface Properties, Fig. 1 Scheme of a general SAM formed on the surface of a substrate

group of these normally linear species and has the role to anchor the surface by a favored and fast reaction producing the formation of a usually stable (covalent) bond linking the surface. The choice of this termination is driven by the chemistry of the material substrate.

The "tail" of the molecule, that is, the termination opposite to the "head," is deputed to perform the desired effect at the SAM surface. So as a rule of thumb, it can be a methyl termination ($–CH_3$), a perfluoroalkyl termination that generate at the most a hydrophobic or super-hydrophobic and repulsive behavior or a functional group such as –SH, –OH, $–NH_2$, –COOH able to carry out a subsequent reaction with other molecule (for example, biomolecules, polymers, suitable linker molecules) or simply express hydrophilic and adhesion properties.

The molecule length (the hydrocarbons chains can range, for instance, from C_3 to C_{24}) will strongly depend on the application for which SAM structures are needed.

Some reviews on the self-assembled monolayers have covered the SAM formation and structure their characterization by electrochemical and scanning tunneling microscopy [1], by PM-IRRAS vibrational spectroscopy techniques



Nanostructures for Surface Functionalization and Surface Properties, Fig. 2 Schematic structures of conjugated molecules studied in [7]

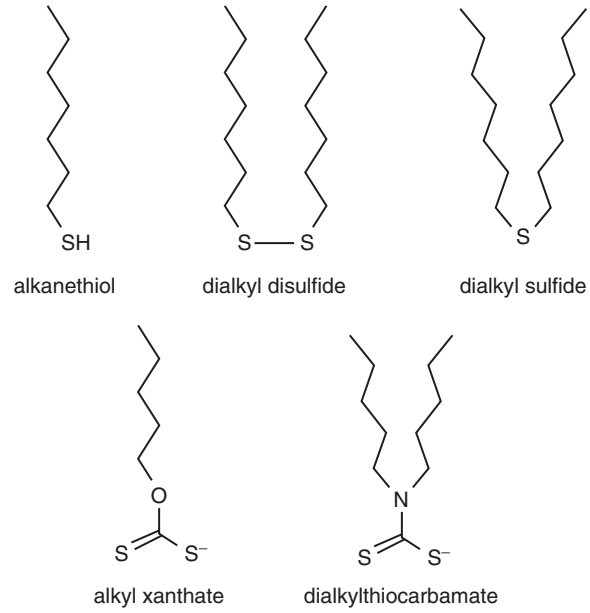
and XPS analysis [2], their application to biosensors [1], anti-stiction in MEMS devices and in nano-imprinting lithography techniques [3], and their advantages in providing controlled surface properties and unique reactions [1].

In particular, such monolayers have been generated mostly on metal surfaces, such as Au, Ag, and Cu, using the thiol chemistry [1]. Nuzzo and Allara, reported in 1983, [4] the procedure of bifunctional organic sulfides species self-assembly on the surface of Au (111) freshly evaporated substrates in the liquid phase by simply putting in contact the samples with a diluted (milliMolar range) solution of the reagent, for some hours. Successively many authors observed with other n-alkyl thiolates that in the first few seconds the species are able to bind the gold surface and in more than 1 h, they self-assemble into a compact, well-ordered flat intercrossed molecular monolayer. The –SH head is able to establish a strong Au–S bond and the chain-to-chain interaction performed by the adjacent grafted molecules is dominated by weak dispersion forces if nonfunctional interacting groups are present in the middle of the aliphatic chain. In this case, H-bond or other stronger van der Waals forces can be exerted. The interchain forces are able to produce, as calculated by Godin [5] an equilibrium separation between two alkyl chains of 0.44 nm. The alkanethiol SAM is formed as a densely packed structure showing $(\sqrt{3} \times \sqrt{3})R30^\circ$ overlayer on gold surface where the molecule is tilted about 30° from the surface normal with the sulfur atom chemically bonded to gold atoms. This implies that a compressive surface stress has to be generated during the self-assembly, and this stress will increase with increasing alkyl chain length.

Patel et al. [6] studied the effect of chain length on the reactivity of SAMs toward protein immobilization generating SAMs from short- and long-chain carboxylic acid terminating alkyl-thiols, 11-MercaptoUndecanoic Acid (11-MUA), 3-MercaptoPropanoic Acid (3-MPA) and from the mixture, 1:10, of the both. The accessibility of the carboxylic groups by the amino group of a lysine termination exposed by the protein, *catalase*, to be anchored, decreases in the order Mixed > 11-MUA > 3-MPA. The experiment was performed by previously activating the carboxylic groups by a water soluble 1-ethyl-3-[3-(dimethylamino) propyl]carbodiimide hydrochloride (EDC) and *N*-hydroxysuccinimide (NHS). Successful formation of the NHS ester intermediate is reliant on the accessibility of the terminal carboxylate groups. It was assessed that a steric packing of these acid groups can limit the rate of intermediate formation with full conversion of accessible acid groups only occurring after several repeated reaction cycles. The co-adsorption of different alkyl-thiols provides the system a degree of disorder which is strategic for an efficient protein immobilization.

SAMs of conjugate alkyl-dithiols are one of the more interesting solutions focused by research in molecular electronics which is open to the possibility of substituting inorganic materials with organic molecules in the core regions of devices. Jiang [7] reported STM characterization of the electronic transport properties of SAM of containing double bonds (insaturation) in the body chain such as the aromatic dithiols (Fig. 2).

Nanostructures for Surface Functionalization and Surface Properties, Fig. 3 (**a**) STM image (95 × 95 nm) of octanethiol SAMs on Au(111); (**b**) STM image (70 × 70 nm) of decanedithiol SAMs on Au(111); (**c**) STM image (75 × 75 nm) of the mixture SAMs on Au(111)



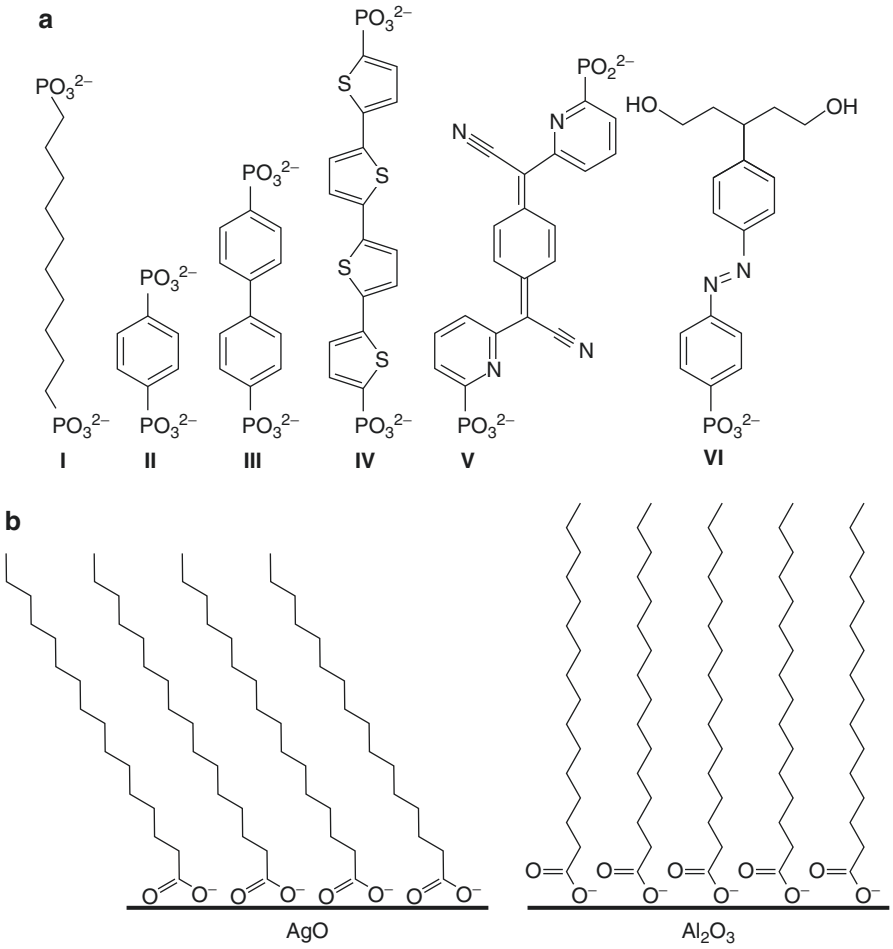
Co-assembly of conjugated dithiols and alkanemonothiols is suggested as a route to obtain dithiols that are denser packed and more vertical (with respect to what is obtained from pure dithiol routes). This surface condition is suitable to the evaporation on the top formed SAM of an Au layer and to the formation of other Au–S bonds with the free thiol end of the dithiol molecules.

Kobayashi [8] reported the study by Ultra High Vacuum Scanning Tunneling Microscopy (UHV-STM) of alkyl-thiol and alkyl dithiol SAMs on Au surfaces, characterizing the morphology of resulting nanostructures and the strength of molecules interaction with the surface. Figure 3 shows the different appearance of the surface according to the nature mono- or dithiolic of the molecule used to form the SAMs both by a liquid process in ethanolic solution (24 h) and by a vapor functionalization process (from a 10 mM ethanolic solution, for 2 h in a closed vessel). In (a) the 1,8-octanethiol SAM results in nanometric islands where molecules assume a surface-normal arrangements. In (b) the nanometric stripe structures are evident due to the molecules of dithiols (1,6-hexanedithiol, 1,10-decanedithiol) lying with their axes parallel to the surface (the bright spots are assigned as sulfur atoms). The different arrangement between (a) and (b) is probably ascribed to the stronger interaction between both thiol groups at the molecular ends with the gold atoms with respect to the case of alkanethiol SAMs. The parallel arrangement is more preferred than the normal arrangement in the case of alkanedithiol SAMs. In (c) the SAM is obtained by a mixture of the vapor of the ethanol solution which contained octanethiol and octanedithiol molecules at 1 mM each. The UHV-STM image shows stripe phase regions corresponding to the areas where alkanedithiol SAMs are formed. On the other hand, the island regions may be attributed to alkanethiol SAMs.

Ag (Silver) and other materials such as GaAs (Gallium Arsenide) can be functionalized by alkyl-thiols. Dubowski et al. [9] recently studied the formation mechanism of T-Alkanethiols (where T = NH_2, COOH, CH_3) SAMs on III–V semiconductors surfaces, in particular GaAs (001). They proposed the formation at the interface of a S–As or S–Ga bond according to which of the two elements is the richer in the exposed surface. They demonstrated the dependence of PhotoLuminescence signal on the terminal T group and the possibility to use these functionalized semiconducting materials in biosensing by PL technique.

In 1996 Ulman [10] reported other organosulfur molecules (Fig. 4) in addition to alkane thiols able to strongly graft and self-assemble on semiconductors surface, such as GaAs and InP, and other metals such as copper, platinum, mercury, iron, nanosize γ-Fe_2O_3 particles.

In Fig. 5a are displayed the diphosphates molecules used for Zirconium (Zr^{4+}) ions exploiting



Nanostructures for Surface Functionalization and Surface Properties, Fig. 4 Surface-active organosulfur compounds that form monolayers on metals and semiconductors [10]

their ability to form highly insoluble salts with tetravalent transition metal ions. At last, fatty acids, which are long-chain n-alkanoic acids ($C_nH_{2n+1}COOH$), are known, by an acid–base reaction, to form a surface ordered salt between the carboxylate anion and a surface metal cation, for example, with AgO and Al_2O_3 (Fig. 5b).

For inorganic oxides, the typical molecules used to form SAMs monolayers are organosilanes. They are characterized by a variability of possible structures and by the easiness of reaction performed both in the liquid and in the vapor phase.

In particular, Silicon/Silica (Si/SiO_2), glass and quartz surfaces, Aluminum/Alumina (Al/Al_2O_3), phyllosilicates such as mica, magnetic materials such as maghemite (γ-Fe_2O_3) nanoparticles, germanium oxide [1], and Zinc oxide (ZnO) [11] exposing naturally hydroxyl-terminated (–OH) surfaces or zinc selenide [1] and Gallium Nitride (GaN) Aluminum Nitride (AlN) and Silicon Nitride (SiN) [12–14], where the –OH species can be easily created by a pretreatment, react with alkylchlorosilanes and alkylalkoxysilanes. Stable siloxy linkages [2, 3] are formed between hydroxylated Silica and 3-aminopropyltriethoxysilane (3-APTES). The reaction proceeds through the hydrolysis of silane alkoxy terminations and the condensation with surface hydroxyls and elimination of an alcohol molecule. Further condensation between adjacent molecules already grafted to the surfaces take part stabilizing the SAM through the formation of siloxane bridges (Si–O–Si).

Glass and Si/SiO_2 are the most common inorganic materials used in many technological applications as optical and electrical materials and as MEMS (MicroElectroMechanical Systems). One major factor that limits the widespread use and reliability of MEMS is adhesion. Adhesion is a result of the dominance of surface forces, such as capillary, hydrogen bonding, electrostatic, and van der Waals forces, over body forces at the microscale. When internal restoring forces of microstructures cannot overcome surface adhesive forces, the devices are said to suffer from stiction. Many procedures based on organosilanes SAMs formation are reported to impart to MEMSanti-stiction properties. Comparing the SAM formation from dimethyldichlorosilane ($(CH_3)_2SiCl_2$, DDMS) and tridecafluoro-1,1,2,2-tetra-hydrooctyltrichlorosilane ($CF_3(CF_2)_5(CH_2)_2SiCl_3$, FOTS) [3], by a liquid (thermal annealing about 65 °C in anhydrous toluene solution) and a vapor procedure (dosage of organosilane vapor pressure

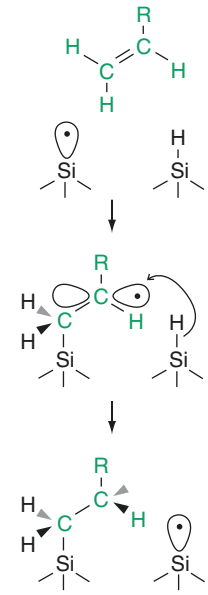
Nanostructures for Surface Functionalization and Surface Properties, Fig. 5 (**a**) Different diphosphonic acids used in self-assembled multilayer preparation. (**b**) A schematic description of fatty acid monolayers on AgO and on Al_2O_3

on an Oxygen plasma pre-activated surface in a low pressure CVD style reactor), it results that the vapor phase method avoid vertical polymerization of precursor molecule producing a flatter SAM with the same efficiency in anti-stiction properties.

3-APTES has been shown to be an efficient SAM precursor [2, 15] for biosensing of protein tumoral markers based on micro-cantilever devices.

Both the functionalization routes described above are efficient in reducing the mass effect of the functional coating which is detrimental for the device sensitivity and in providing a maximum coverage in the order of 10^{14} $-NH_2$ groups/cm^2 [2].

In the field of magneto-chemotherapeutics, where spatial control of conjugated active biomolecules under magnetic field and Magnetic Resonance Imaging (MRI) contrast can be achieved simultaneously are becoming always more relevant functionalized magnetic nanoparticles (NP) able to conjugate specific biomolecules, for instance, Matrix MetalloProteinase (MMP), zinc-containing endopeptidases, which are responsible for the regulated degradation and processing of extracellular matrices (ECM), with physiological functions such as wound healing, tissue remodeling, tumor



growth, and metastasis [16]. The silanization of the NP was conducted under anoxic (N_2 purging) suspension consisting of glycerol, aqueous methanol, and acetic acid. Mercaptopropyltrimethoxysilane (MPTMS) was added slowly to the suspension to ensure homogeneous hydrolysis of the silane agent, followed by reflux heating for 16 h. It is demonstrated that by this procedure it is possible not only to get at the NP surface a –SH terminated SAM able to react with MMP by the cross-linker Sulfosuccinimidyl-4--(*N*-maleimidomethyl)cyclohexane-1-carboxylate (Sulfo-SMCC), but also to reduce the iron oxide phase from γ-Fe_2O_3 to the higher magnetic moment phase of Fe_3O_4.

Other methods to functionalized Iron Oxide NP are reported by Wu et al. in [17]. For instance, alkyl phosphonates and phosphates are used which bind efficiently to iron oxide particle surfaces, and favor, due to their good biocompatibility, the utilization of encapsulated magnetic NPs in nanomedicines.

The no-oxide surfaces, such as nitrides, can be easily hydroxylated in order to exploit organosilanes chemistry in order to achieve surface functionalization. The well-assessed procedure consists in the substrate immersion in H_2SO_4:H_2O_2 (3:1) solution, also called Piranha solution, for 20 min, rinsed with deionized water and dried under Nitrogen flux prior to silanization. The highly oxidizing reagents produce, for GaN (deposited by MetalOrganic Chemical Vapor Deposition – MOCVD), an oxide layer exposing hydroxyl species. For AlN (also obtained by MOCVD) which is already covered by a native oxide layer, the only effect is surface hydroxylation [12].

The Piranha solution is used also on crystalline Silicon and on SiO_2 thermally grown from crystalline Silicon. On SiN (deposited by Plasma Enhanced Chemical Vapor Deposition, PECVD), a solution with 10 % nitric acid (HNO_3) at 80 °C for 20 min [13] or a mixture of CH_3COOH and H_2O_2 for 3 h [14] is used to activate the silanols (Si–OH); for the both water is used for rinsing and N_2 for drying.

Also polymers can be activated in order to react with organosilane "head" (trialkoxy- or trichloro-terminations) as suggested by Kühn et al. in [18]. The double procedure consists in an Oxygen plasma step in order to produce mixed oxygen containing species OH, C=O, C–O–C, CHO, COOH, C–O–OH, CO_3, C=C, etc., on a polyolefin polymer such as PolyEthylene (PE) or PolyPropylene (PP) and then a reduction step in diborane (gaseous procedure) or $LiAlH_4$ solution in order to obtain a monotype homofunctional surface exposing hydroxyls.

Nanostructures for Surface Functionalization and Surface Properties, Fig. 6 Proposed mechanism for surface hydrosilylation. Initial loss of silicon hydride generates a silicon dangling bond. Reaction between the silicon and an alkene molecule leads to an attached alkyl radical, which may abstract a hydrogen atom from a neighboring silicon

Since long time, Silicon surface reconstruction has been studied in order to understand the most suitable Silicon face (100) and (111) to get an organic functionalization avoiding detrimental side oxidation effects. Bent [19] reported some example of Silicon hydrosilylation by alkenes or alkines, molecules bearing C=C terminal groups that react with the Si–H of the Si surface under different activation methods.

A radical initiator, a species used to create free radicals in reactions, starts the reaction by abstracting H from a surface Si–H bond, producing a silicon dangling bond (which is also referred to as a silicon radical). The mechanism is illustrated in Fig. 6 on a (111) silicon surface.

The dangling bond is represented as an orbital with a dot, where the dot represents a single, unpaired electron. The silicon dangling bond

then reacts with the alkene molecule, forming a new Si–C bond at the surface and leading to the attachment of the organic molecule, which itself is left with a carbon radical. This surface bound organic radical is thought to abstract a hydrogen atom either from an unreacted alkene molecule or from a neighboring Si–H group on the surface. The net reaction sequence produces a stable, closed-shell organic group bound directly to the Si (111) surface. Hydrosilylation can be achieved also under UV irradiation in the range 200–400 nm, thermal activation at $T > 150$ °C (but a low quality of resulting organic monolayers has been noticed), introducing in the reactant mixture acidic molecules (called Lewis acids) to catalyze the reaction.

The main applications of organic layers on Silicon are related to protection of the underlying substrate from attack by etchants, attribution of chiral properties to the surface, addition of new optical properties to silicon and recently the substitution of organosilanes in sensing technology when the presence of oxide has to be avoided, also if the organic monolayers lacks in terms of order and cohesion, typical of SAMs.

Silicon/Silica and Diamond surface can be also directly derivatized through polymers grafting. On their own, polymers expose functionalities which are able to give further reactions.

Surface graft polymerization is a chemical modification method. In surface graft polymerization, the modification is achieved by grafting suitable macromolecular chains on the surface of materials through covalent bonding. The key advantage of these techniques is that the surface of the materials can be modified or tailored to acquire very distinctive properties through the choice of different grafting monomers, while maintaining the substrate properties. It also ensures an easy and controllable introduction of graft chains with a high density and exact localization onto the surface. Compared with the physically coated polymer chains, the covalent attachment of the grafted chains onto a material surface avoids their desorption and maintains a long-term chemical stability of the introduced chains.

Chiari et al. [20] used a *ter*-polymer of *N*,*N*-dimethylacrylamide, *N*-acryloyloxysuccinimide, and 3-(trimethoxysilyl)propyl methacrylate. The copolymer (DMA-NAS-MAPS) graft the SiO_2 surface of oxidized silicon or glass by a simple and robust procedure consisting in the dip coating in an aqueous solution, of substrates of different shapes in a short time span (less than 1 h) and in mild conditions without harmful treatments with harsh washing solutions. The film formed on the surface is thin, on the order of a few nanometers. For fluorescent microarray chips, this is a suitable coating as it does not affect the fluorescence intensification provided by the silicon/silicon oxide substrate. The trimethoxysilyl terminations react with surface silanols, as well as an organosilane, the acryloyloxysuccinimidyl ends give rise to covalent bonds with amino groups of biomolecules and the DMA units form the structural backbone of the polymer.

Recently, Oxidized Ultrananocrystalline diamond (UNCD) has been successfully coated with poly(styrene) (PS) using the self-initiated photografting and photopolymerization (SIPGP) approach with styrene as the monomer, within 16 h, under constant irradiation with UV light ($\lambda_{max} = 350$ nm) [21]. The obtained coating stable grafted to surface is then easily derivatized by sulphonation, nitration, and amido-alkylation carried out according to well-known liquid chemistry routes and so allowing the incorporation of additional functional molecules, such as fluorescent labels. This will open the way for designing more advanced biosensing schemes, incorporating multifunctional elements and with a higher loading capacity for biomolecules.

Ruckenstein et al. reported the graft polymerization reaction on already SAMs coated surfaces of glass and silicon wafers in order to introduce additional reactive sites. The method involves the aniline substitution at Br-terminated SAM through the aniline amino termination and further the surface oxidative graft polymerization of aniline on the modified glass surface via the covalently immobilized aniline sites. A PolyAniline (PANI) coating is so obtained, performing the reaction in the polymerization solution containing aniline, and due to its well-known conductivity

(conductive polymer) this can be a suitable substrate to be used as biosensor and biomaterial.

Another route to further derivatize an organosilane surface for biosensing purposes consists in the grafting, from a 8.5 pH solution, of homofunctional linkers such as Glutaraldehyde ($OHC–CH_2–CH_2–CH_2–CHO$) which is able through an aldehyde end to react with NH_2 exposed at amino-SAM modified surface and, then, through the second aldehyde termination to immobilize biomolecules exposing amino terminations.

This method has been successfully applied by Ricciardi et al. [15] for functionalization of cantilever based biosensors aimed to the detection of tumoral markers (Angiopoietin).

Surface Modification: No-Dependence on Materials Chemistry

Among the surface-modification techniques, deposition of coating obtained by plasma polymerization presents, respect to surface derivatization discussed in the previous paragraph, the advantage to allow the tailoring of properties of any kind of surface without involving the substrate surface chemistry in the functionalization mechanism.

Macromolecular plasma chemistry [22] has developed in the last two decades in the following directions: plasma-enhanced synthesis (deposition and/or grafting) of thin layer macromolecular structures; surface functionalization of polymeric materials; and etching of inorganic or polymeric substrate surfaces. Plasma-enhanced synthesis involves the dissociation of starting materials and reorganization of the resulting neutral and charged molecular fragments into macromolecular structures on the surfaces located inside or outside of the plasma zone. Outside the plasma zone, recombination mechanisms usually result in the incorporation of molecular fragments with lower degrees of dissociation into the nascent macromolecular structures. When the starting materials are common monomers the recombination processes are more complex due to the development of simultaneous conventional polymerization reactions along with the fragment-recombination mechanisms initiated by the plasma-created and surface-attached active species (e.g., ions, free radicals). In these cases, complex structures result and structural identification is difficult.

However, an advantage of conventional monomer-based processes is that specific functionalities can be retained in the polymer structures and consequently some characteristics can be more easily predicted and designed into the final product.

Macromolecular thin layers can also be synthesized by the plasma generation of active sites (e.g., ions, free radicals) or reactive functionalities (primary amine groups, etc.) on substrate surfaces, followed by the development of graft-polymerization reactions in the absence of the plasma in the presence of "true monomers." Remote (the recombination processes are developed outside the plasma zone) and pulsed (plasma sustained according to preselected duty cycles) plasma processes, allow recombination mechanisms in the absence of the plasma state in time or in space, and are characterized by significantly minimized dissociation processes. These approaches do not change dramatically the nature of molecular fragmentation processes (the nature and relative ratios of charged and neutral active species); however, they limit significantly the intensities of plasma-induced fragmentation mechanisms, and allow the development of recombination processes in the partial or total absence of plasma state. As a result, molecular precursors can be physically or through covalent bonding incorporated through surface-located charged and neutral (e.g., free radicals) active species, into the nascent macromolecular layers.

Owing to the high reactivity of plasma species, surface functionalization reactions of even the most inert polymeric substrates can be conveniently achieved. These mechanisms usually involve non-polymerizing gas plasmas, which generate active molecular fragments that covalently attach during the plasma reactions to the activated substrate surfaces. Recently, it has been demonstrated that even neutral molecules can be connected to active sites with covalent bonds on plasma-exposed substrates under in situ conditions [22]. At high particle energies, etching

processes dominate both the deposition and functionalization mechanisms.

Depending on the nature of the plasma gases, inert (sputtering) or reactive etching mechanisms can be developed. It should, however, be noted that these mechanisms can have practical importance; they allow the creation of specific surface morphologies by selective ablation, for instance, of amorphous and crystalline surface regions.

The nature of plasmas, the modalities of transferring electric or electromagnetic field intensities to the reaction systems, the geometry of reactor (shape and volumes of the reaction vessel, geometrical location of electrodes and substrates, etc.) and the selected experimental conditions (pressure, power, flow rates of gases, temperature of the substrates, etc.) crucially influence the gas-phase and surface-related plasma chemistry. Consequently, comparing experimental results from a large variety of plasma systems, even for identical starting components, is extremely difficult.

Cold-plasma-mediated processes involve both gas-phase and surface reaction mechanisms. The gas-phase reaction mechanisms involve the interaction of ab initio existing and nascent neutral and charged plasma-created species, including atoms, molecules, free radicals, ions of either polarity, excited species, electrons, and photons. Besides the recombination mechanisms developed on the surfaces which confine the plasma, the active species of the discharge interact and continuously tailor the artificially exposed (reactor walls, various substrates, etc.) and self-generated (e.g., plasma-synthesized macromolecular structures) surface layers. The competition between the recombination-deposition (deposition, grafting, functionalization) processes and "destructive interaction" of plasma species (etching) with the nascent macromolecular structures will control the intensities and the predominance of ablation, surface functionalization and macromolecular-film-formation reactions.

The mechanisms of surface functionalization of polymeric substrates are different from the gas-phase processes. While electrons play the most important role in the plasma state, positive ions also play a significant role in the surface chemistry during the interactions of plasma species with polymers. The resulting valence-ionized polymer chains undergo neutralization reactions leading to sufficiently intense localized internal energy concentrations (electronically excited states), which can induce homolytic bond cleavages. Free-radical and unsaturated-bond development can result in cross-linking of polymeric layers. Free radicals can further induce chemical reactions involving plasma species in situ and affect reactions controlled by specific chemical environments (gas-phase or condensed-phase compounds, including, oxygen, monomer molecules, etc.) in the absence of plasma.

Qualitative and quantitative evaluation of charged and neutral species of the gas phase and identification of charged and neutral surface functionalities on substrate surfaces is essential for understanding the plasma-induced reaction mechanisms and physical processes. Adaptation of in situ diagnostic techniques (including real time measurements) for relatively high and low pressure (100–1000 mTorr) plasma environments is a research area where many questions still remain unanswered. Continued research will promote the development of novel and/or improved processes for tailoring materials surface characteristics and the development of advanced laboratory plasma installations, required for scaling up plasma processes to industrial levels.

Recently, surface treatments and modification based on vapor phase plasma-assisted techniques have been widely applied to several biomedical fields. These processes are able to provide specific monotype chemical functionalities, exposed at materials surfaces. Respect to traditional liquid phase procedures, advantages such as the high process control and the use of small quantities of reagents, are crucial for the enhancement of efficiency of the interactions that materials must perform according to the application.

In particular, procedures for in situ plasma polymerization, starting from vapor released by liquid monomers, are presently used to synthesize innovative polymeric thin films applicable as substrates for cell culture [23], as adhesion promoter in prosthetic implants and for molecular recognition in sensors and biosensors.

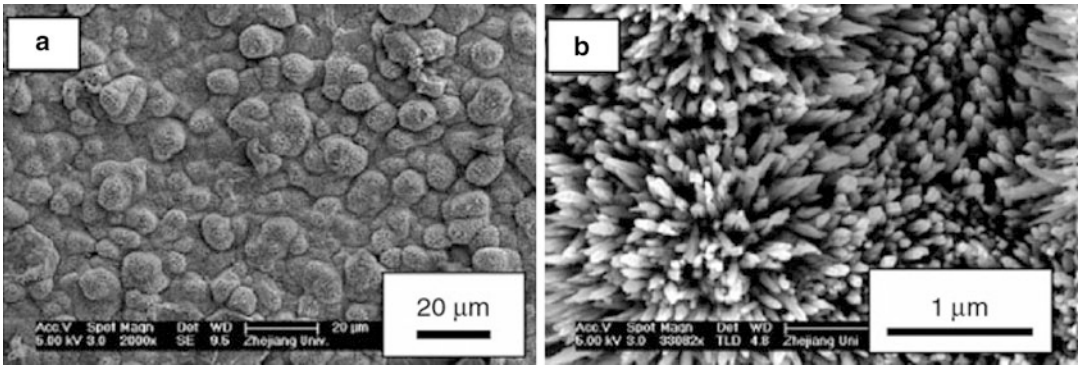
The low pressure plasma polymerization, starting from the same reagent and only varying the process parameters (modulation of the plasma discharge, monomer or mixture of monomers/process gas, reactant vapor partial pressure, etc.) leads to the deposition of polymeric materials with different features in terms of density of functional groups, wettability (hydrophilicity/hydrophobicity), and chemical stability [24].

The most studied polymers in biomedical and sensing fields, display as functional groups mainly carboxyls (–COOH) and amines ($–NH_2$), hydroxyls (–OH), and aldehydes (–CHO). Fewer reports exist on hydroxy and aldehyde surfaces prepared by plasma methods. Hydroxy surfaces can be prepared by water plasma treatment or the plasma polymerization of alkyl alcohol vapors. Water plasma treatment on many polymer substrates suffers from aging, with surface adaptation leading to the movement of surface-modification effects into the polymer. Both hydroxy and aldehyde surfaces have been used for the covalent immobilization of biologically active molecules. Aging effects are less well documented than for amine surfaces.

Aminated surfaces have been fabricated using various plasma vapors or mixtures (allylamines, ethylenediamine, diaminopropane, *n*-heptylamine [24]) and have found wide use for biointerface applications. However, in many cases the amine surfaces have a rather limited shelf life, with post-plasma oxidation reactions and surface adaptation leading to the disappearance of amine groups from the surface. Aging is a widespread phenomenon that often has not been recognized, particularly in some of the earlier studies on the use of plasma-fabricated surfaces for biointerfacial applications, and can markedly alter the surface chemistry [23].

Plasma-fabricated surfaces that contain carboxyl groups have also been well documented and are obtained, for example, by acrylic acid [23] and vinyl acetic acid or applying CO_2 plasma on olefin polymers [24].

In order to better tune the distribution and density of functional groups, are also widely known processes of plasma copolymerization, where the monomer containing functional groups of interest is mixed with a precursor which does not contain specific functionalities (e.g., styrene or octadiene [25]) and which has the function to dilute the reactive groups at the surface. For example, carboxylate copolymer surfaces have shown excellent ability to support the colonization of some human cell lines of clinical interest. Immobilization of proteins onto plasma-carboxylated surfaces is also well established. Generally, these surface chemistries show good ability to support cell colonization, though the effectiveness seems to depend on the process vapor and the plasma conditions.



An example in which process parameters affect the final properties of the plasma-polymer film is reported by Detomaso et al. [23]. Starting from Acrylic Acid vapor, processes obtained by Continuous Wave (CW) plasma discharge and by Modulated Wave (MW), that is pulsed, plasma discharge are compared respect to the efficiency of the final polymer coating toward cells growth. The –COOH terminated polymer obtained by MW, with a Duty Cycle (D.C. = $(T_{on}/T_{on} + T_{off})$ of 5, where $T_{on} = 5$ ms and $T_{off} = 95$ ms, is less useful to murine fibroblast growth than the CW plasma film, because more soluble in water due to the higher density of –COOH groups and the higher retention of the monomer (acrylic acid) structure (low cross-linking and backbone chain propagation).

Materials Surface Modification: Morphology Effects

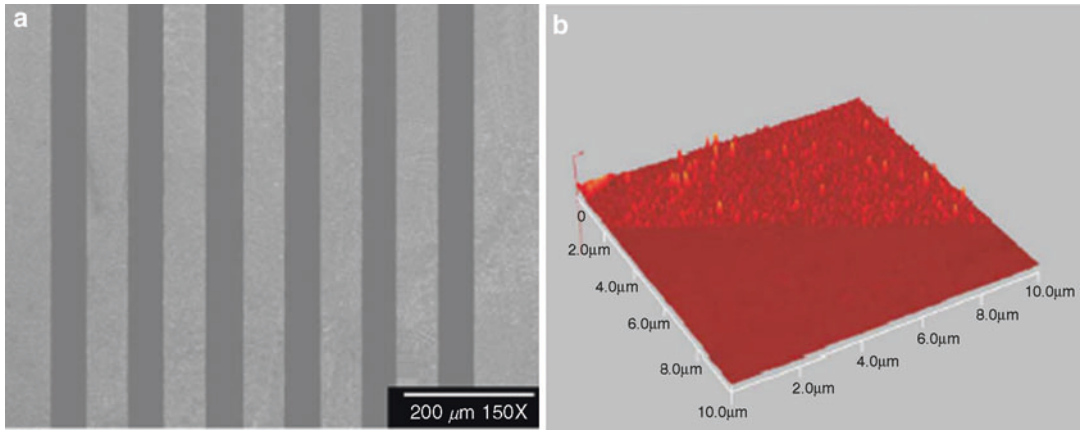
Fabrication of micro- and nano-patterned surfaces is a fundamental step for the development of engineered materials.

For biometerials, it is well known that a series of interactions occur between their surface and the biological environment after they have been implanted into the human body. Therefore, the biomaterials surface plays an extremely important role in the response of artificial medical devices to the biological environment.

The efficacy of artificial implants is determined mainly by their surface characteristics such as surface morphology, microstructure, composition, and properties. Liu et al. [26] reported many surface-modification methods mainly based on inorganic

Nanostructures for Surface Functionalization and Surface Properties, Fig. 7 SEM images of a titania nanorod formed on titanium substrate: (**a**) low magnification, (**b**) high magnification

nano-coatings deposition and functionalization at the nanoscale of obtained structures. Typical coating and film deposition techniques are plasma spraying, plasma immersion ion implantation and deposition (PIII&D), solgel, chemical vapor deposition (CVD), physical vapor deposition (PVD), cold spraying, self-assembly, and so on, whereas in situ surface-modification techniques include laser etching, shot blasting, acid and alkali treatments, anodic oxidation, micro-arc oxidation, ion implantation, etc.



In bioceramics field, for example, a critical grain size for osteoblast adhesion between 49 and 67 nm for alumina and 32 and 56 nm for titania, provides evidence about the ability of nanophase alumina and titania to simulate the desirable materials characteristics of bones in a physiological environment, particularly those associated with the enhancement of protein interactions such as adsorption, configuration, and bioactivity as well as subsequent osteoblast adhesion.

Metal surfaces with low micrometer to nanophase topography enhance adhesion of osteoblasts. A surface with various nanostructures can be obtained by chemically treating titanium and its alloys. Chemical treatments are suitable for the creation of micrometer-scale and nanometer-scale textures on large-area surfaces and multifaceted devices with complex 3D shape due to the non-line-of-sight nature. Titania nanorods can be produced at low temperature on a large scale via direct oxidation of titanium with hydrogen peroxide. The ordered nanorod layer with a thickness of approximately 1 mm is deposited on a 2 mm thick condensed anatase layer as illustrated by Fig. 7.

Concerning chemical patterning, microstructured surfaces containing opposite bio-properties such as cell and/or protein adhesive features in a non-bio-adhesive matrix provide valuable tools in the field of biotechnology and numerous methods have been successfully developed for the production of such surfaces. Besides, the development of chemical nanopatterning technology is great of interest due to its ability to provide powerful tools for studying fundamental aspects of cell adhesion at the level of single protein/receptor molecules or for the implementation of new generations of miniaturized biochips requiring smaller reagent quantities with lower detection limits [27].

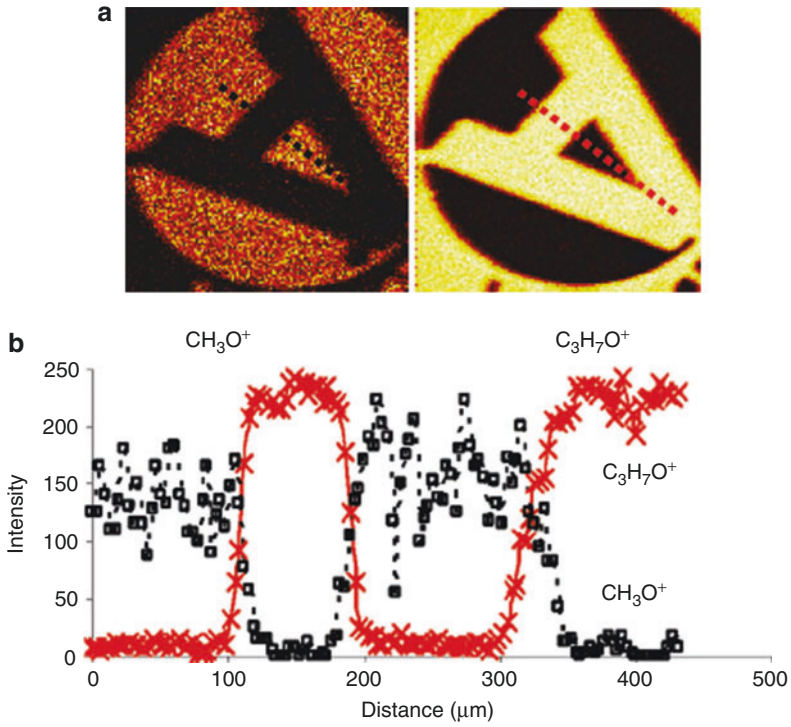
In general [28], the chemical patterning techniques commonly used in bioengineering can be divided into four categories: (a) lithographic patterning (photo-assisted and electron-beam assisted), (b) scanning probe microscopies (SPM); (c) transfer via polymeric stamps (soft lithography), and (d) physical patterning. The challenge with plasma polymerization lies in developing patterning techniques by which, reproducible spatial resolution and distribution of chemistries is achieved and the specific functional properties of the thin films are retained.

The simplest patterning approach reported by literature is the one based on the use of physical mask (solid materials deposited on defined areas

Nanostructures for Surface Functionalization and Surface Properties, Fig. 8 (**a**) SEM image of the patterned PANI film on a silicon substrate; and (**b**) selected edge area of (**a**) under AFM

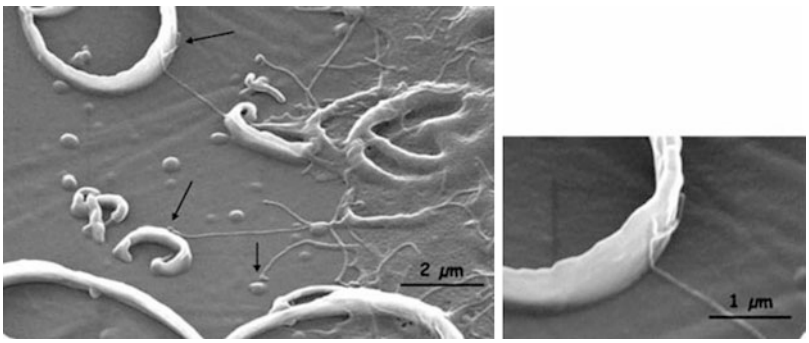
of the substrate), e.g., polymeric masks and TEM grids.

Sometimes, the substrates are previously coated with another plasma polymer obtained starting from a precursor which does not contain specific functionalities (e.g., styrene or octadiene [25]) with the role of non-bio-adhesive matrix.



Ruckenstein et al. [1] reported a method for graft polymerization patterning of polyaniline on Si surface previously coated by SAM monolayers from phenyltrichlorosilanes and further subjected to a laser photolithographic process. The subsequent treatment with trifluoromethanesulfonic acid (triflic acid; HOTf) results in the generation of reactive silyl cation sites on the backbones, which can react with suitable monomers to form functionalized polysilanes.

The aniline monomer undergoes to nucleophilic substitution reaction followed by the surface oxidative graft polymerization of aniline on the covalently immobilized aniline sites. The grafted PANI thus formed provided a negative of the lithographic mask. Figure 8a presents the scanning electron microscopy (SEM) image of the patterned PANI after the graft polymerization. The white strips represent the grafted PANI areas, whereas the black strips, the nongrafted ones. A relatively clear boundary between the patterned and nonpatterned areas could be observed in the SEM image. A closer look at the boundaries between the two can be achieved under a higher magnification by AFM (Fig. 8b), which demonstrated that this method provides a high line edge acuity of the patterned PANI.



Mishra et al. [28] studied, by using a TEM grid placed onto an already plasma polymer coated silicon wafer, a wide range of standard size patterns in order to vary the resultant pattern features from approximately 5–200 μm. After the plasma polymerization process starting from, for example, glycidyl methacrylate (ppGMA), maleic anhydride (ppMA), acrylic acid (ppAAc), allylamine (ppAAm), tetraglyme (ppTG), and grid remotion, AFM characterization highlighted the presence, at the physical boundaries, of a diffused interface rather than a sharp step (Fig. 9) and Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) analysis showed that there was diffusion of the plasma deposit below the physical mask during the second polymer layer deposition.

On the other side, ion beam etching and plasma etching through masks as well as electron beam lithography (EBL) [27], have been shown to be able to produce chemically resolved microscale and in some cases nanoscale plasma polymer patterns.

Bretagnol et al. [27] showed that chemically active features of polyacrylic acid (pAA),with lateral size down to 300 nm, exposing –COOH groups, obtained by EBL and the use of a photoresist mask, were able to graft a model protein

Nanostructures for Surface Functionalization and Surface Properties, Fig. 9 Positive single ion ToF-SSIMS images of ppMA patterned photolithographically on Si wafer precoated with ppTTg (500 × 500 μm^2). Unique secondary molecular fragments are presented in *inset* (**a**). The pixel intensity plot for secondary ions $C_3H_7O^+$ (ppTTg) and CH_3O^+ (ppMA) shown in *inset* (**b**). The image resolution was calculated to be ~10 μm, based on 80:20 definition

Nanostructures for Surface Functionalization and Surface Properties, Fig. 10 SEM images of MG 63 osteoblasts on hydrophobic structured samples showing in detail how filopodia could interact with nanostructures on the surface

(bovine serum albumin), even if a wet chemical step in acetone was performed.

Photolithographic patterning for plasma polymers is a particularly attractive approach for the fabrication of complex chemical arrays and the opportunity presented by plasma polymerization to produce thin films from a very wide range of different monomers with several properties such as surface charge, hydrophilicity, biospecificity, and adhesion properties alternated to the opposite such as hydrophobicity and, generally, non-fouling characteristics. Recently, it has been demonstrated that specific properties including protein resistance are maintained after performing the photolithographic patterning technique, with both spatial and chemical resolution down to 1 μm [27].

Finally, an exotic method for surface nanopatterning, based on plasma polymerization has been reported by Gristina et al. [29]. Teflon ribbon-like nanostructures (Fig. 10) have been obtained by C_2F_4 MW (low D.C.) plasma polymerization and it has been demonstrated that these structures promote fibroblast cell adhesion

through proteins interaction of cell filopodia with the nanostructures surface notwithstanding the well-known teflon super-hydrophobicity.

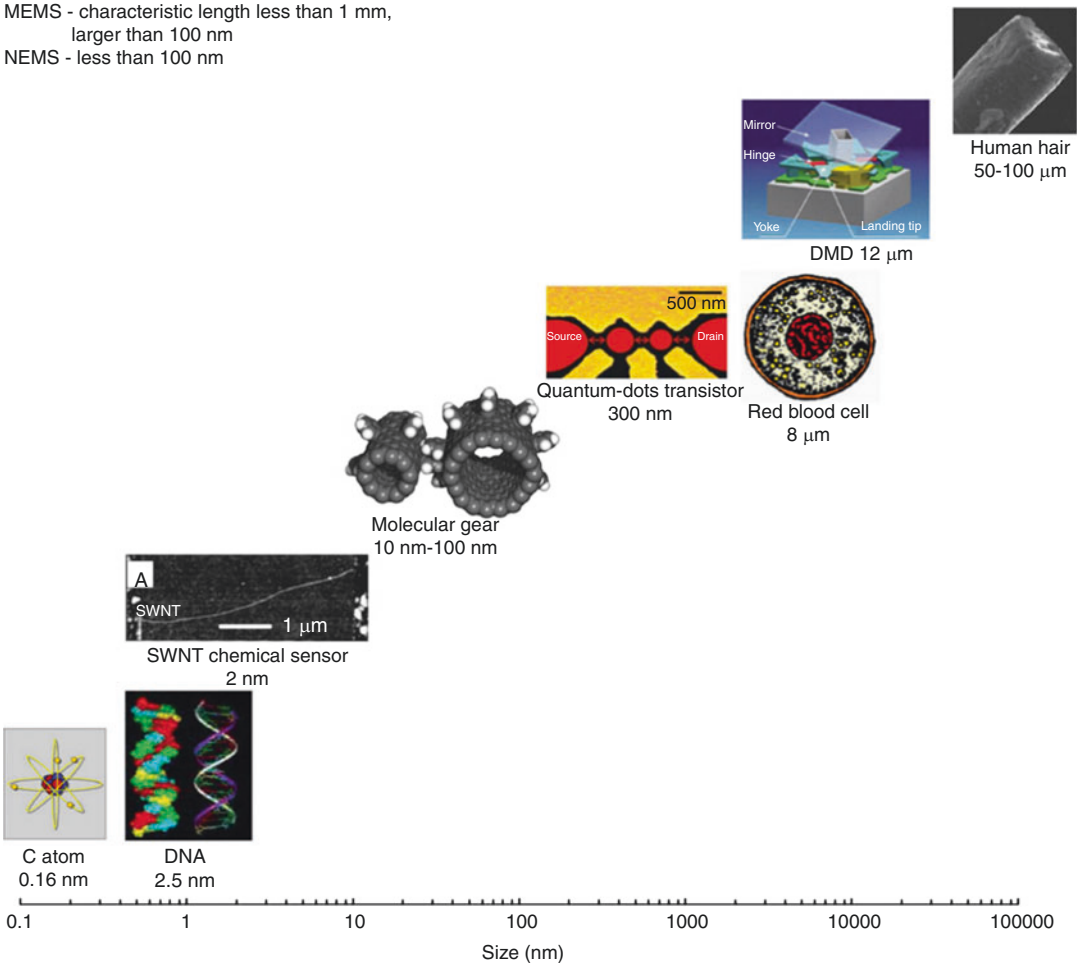
Definition

Nanotechnology literally means any technology done on a nanoscale that has applications in the real world. Nanotechnology encompasses the production and application of physical, chemical, and biological systems at scales ranging from individual atoms or molecules to submicron dimensions, as well as the integration of the resulting nanostructures into larger systems.

Overview

Nanotechnology is likely to have a profound impact on world economy and society in the early twenty-first century, comparable to that of semiconductor technology, information technology, or cellular and molecular biology. Science and technology research in nanotechnology promises breakthroughs in areas such as materials and manufacturing, nanoelectronics, medicine and healthcare, energy, biotechnology, information technology, and national security. It is widely felt that nanotechnology will be the next industrial revolution.

Nanometer-scale features are mainly built up from their elemental constituents. Examples include chemical synthesis, the spontaneous self-assembly of molecular clusters (molecular self-assembly) from simple reagents in solution, biological molecules (e.g., DNA) used as building blocks for the production of three-dimensional nanostructures, or quantum dots (nanocrystals) of an arbitrary diameter (about 10–105 atoms). The definition of a nanoparticle is an aggregate of atoms bonded together with a radius between 1 and 100 nm. It typically consists of 10–105 atoms. A variety of vacuum deposition and nonequilibrium plasma chemistry techniques are used to produce layered nanocomposites and nanotubes. Atomically controlled structures are produced using molecular beam epitaxy and organo-metallic vapor phase epitaxy. Micro- and nanosystem components are fabricated using top-down lithographic and nonlithographic fabrication techniques and range in size from micro- to nanometers. Continued improvements in



lithography for use in the production of nanocomponents have resulted in line widths as small as 10 nm in experimental prototypes. The nanotechnology field, in addition to the fabrication of nanosystems, provides impetus to the development of experimental and computational tools.

The discovery of novel materials, processes, and phenomena at the nanoscale and the development of new experimental and theoretical techniques for research provide fresh opportunities for the development of innovative nanosystems and nanostructured materials. The properties of materials at the nanoscale can be very different from those at a larger scale. When the dimension of a material is reduced from a large size, the properties remain the same at first; then small changes occur, until finally when the size drops below 100 nm, and dramatic changes in properties can occur. If only one length of a three-dimensional nanostructure is of the nanodimension, the structure is referred to as a quantum well; if two sides are of nanometer length, the structure is referred to as a quantum wire. A quantum dot has all three dimensions in the nanorange. The word quantum is associated with these three types of nanostructures because the changes in properties arise from the quantum-mechanical nature of physics in the domain of the ultra-small. Materials can be nanostructured for new properties and novel performance. This field is opening new venues in science and technology.

Micro- and nanosystems include Micro/NanoElectroMechanical Systems. MEMS refers to microscopic devices that have a characteristic length of less than 1 mm but more than 100 nm and combine electrical and mechanical components. NEMS refers to nanoscopic devices that have a characteristic length of less than 100 nm and combine electrical and mechanical components. In mesoscale devices, if the functional components are on the micro- or nanoscale, they may be referred to as MEMS or NEMS, respectively. These are referred to as an intelligent miniaturized system comprising of sensing, processing, and/or actuating functions and combine electrical and mechanical components. The acronym MEMS originated in the USA. The term commonly used in Europe is microsystem technology (MST), and in Japan it is micromachines. Another term generally used is micro/nanodevices. MEMS/NEMS terms are also now used in a broad sense and include electrical, mechanical, fluidic, optical, and/or biological function. MEMS/NEMS for optical applications are referred to as micro/nanooptoelectromechanical systems (MOEMS/NOEMS). MEMS/NEMS for electronic applications are referred to as radio-frequency-MEMS/NEMS or RF-MEMS/RF-NEMS. MEMS/NEMS for biological applications are referred to as BioMEMS/BioNEMS.

To put the dimensions of MEMS/NEMS and BioNEMS in perspective, see Fig. 1 and Table 1 [4]. Individual atoms are typically a fraction of a nanometer in diameter, DNA molecules are about 2.5 nm wide, biological cells are in the range of thousands of nm in diameter, and human hair is about 75 μm in diameter. Smaller length of BioNEMS shown in the figure is about 2 nm, NEMS ranges in size from 10 to 300 nm, and the size of MEMS is 12,000 nm. The mass of a micromachined silicon structure can be as low as 1 nN, and NEMS can be built with mass as low as 10–20 N with cross-sections of about 10 nm. In comparison, the mass of a drop of water is about 10 μN, and the mass of an eyelash is about 100 nN.

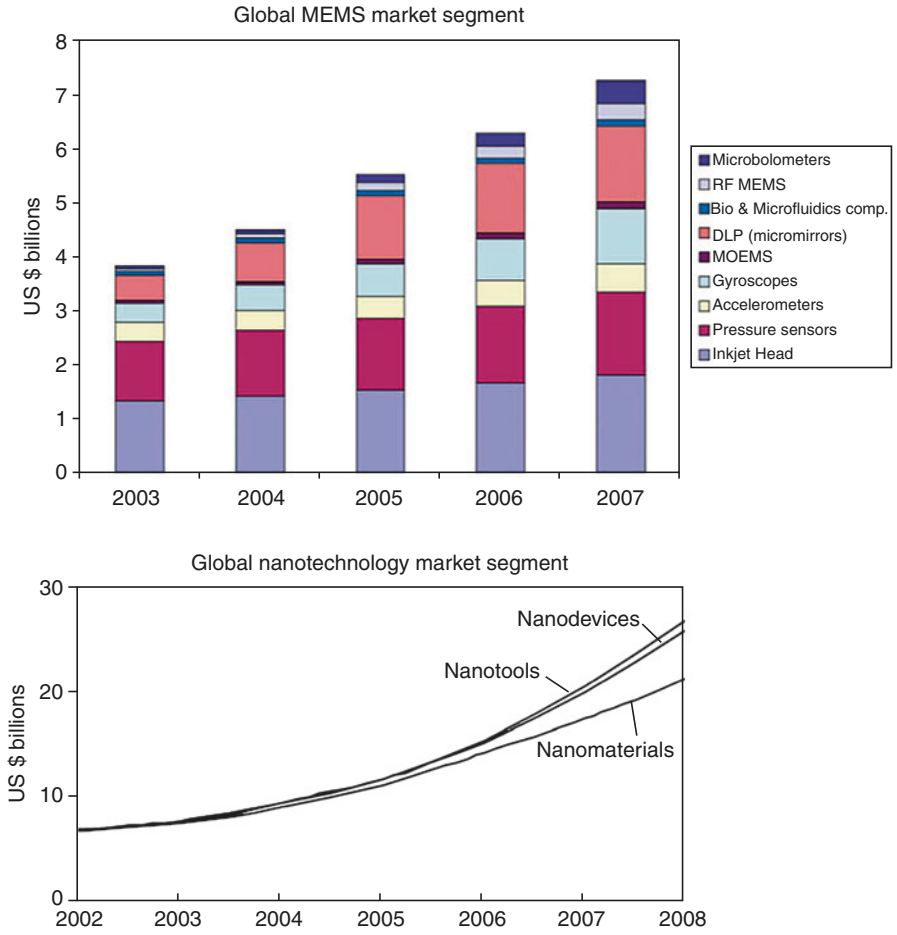
MEMS/NEMS and BioMEMS/BioNEMS are expected to have a major impact on people's lives, comparable to that of semiconductor technology, information technology, or cellular and molecular biology [5, 6]. MEMS/NEMS and BioMEMS/BioNEMS are used in electromechanical, electronics, information/communication, chemical, and biological applications. The MEMS industry in 2004 was worth about $4.5 billion with a projected annual growth rate of 17 %, Fig. 2 [7]. The NEMS industry was worth about $10 billion in 2004, mostly in nanomaterials, Fig. 2 [8]. Growth of Si-based MEMS/NEMS may slow down, and nonsilicon MEMS may pick up during the next decade. It is expected to expand in this decade, in nanomaterials and biomedical

Nanotechnology, Fig. 1 Dimensions of MEMS/NEMS and BioNEMS in perspective. Examples shown are of a single-walled carbon nanotube (SWNT) chemical sensor [1], of molecular dynamic simulations of carbon-nanotube–based gears [2], quantum-dot transistor obtained from van der Wiel et al. [3], and DMD obtained from www.dlp.com. For comparison, dimensions and weights of various biological objects found in nature are also presented

applications as well as in nanoelectronics or molecular electronics. For example, miniaturized diagnostics could be implanted for the early diagnosis of illness. Targeted drug delivery devices are under development. Due to the enabling nature of these systems and because of the significant impact they can have on both commercial and defense applications, industry as well as federal governments have taken special interest in seeing growth nurtured in this field. MEMS/NEMS and BioMEMS/BioNEMS are the next logical step in the "silicon revolution."

Background and Research Expenditures

On December 29, 1959 at the California Institute of Technology, Nobel Laureate Richard P. Feynman gave a talk at the Annual Meeting of the American Physical Society that has become one of the twentieth century classic science lectures, titled "There's Plenty of Room at the Bottom" [9]. He presented a technological vision of extreme miniaturization in 1959, several years before the word "chip" became part of the lexicon. He talked about the problem of manipulating and



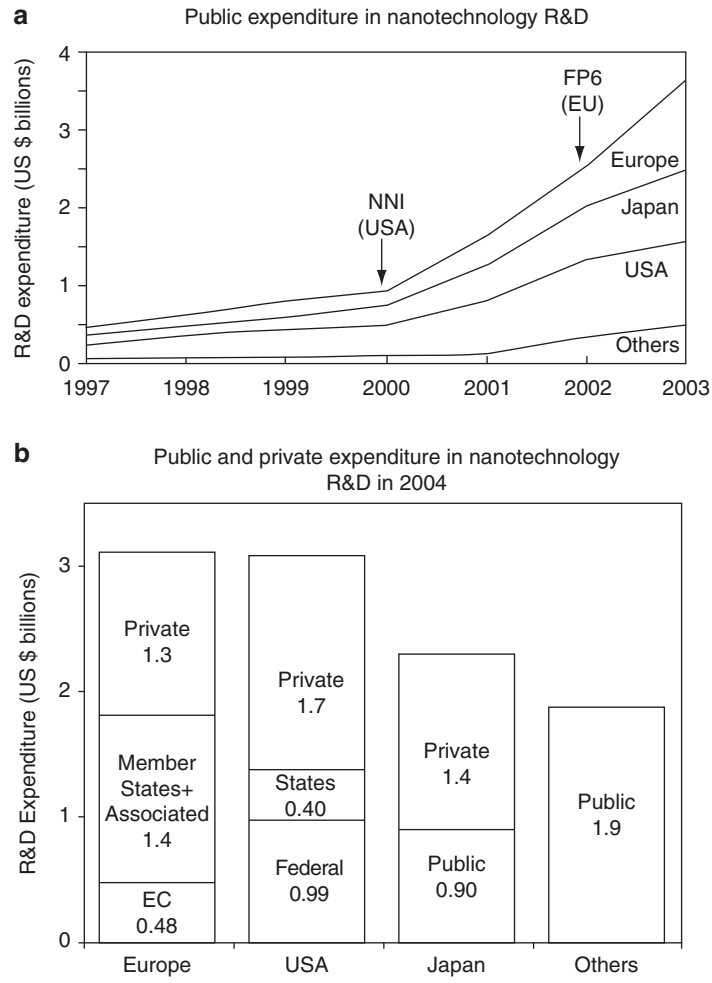
Nanotechnology, Table 1 Characteristic dimensions and weights in perspective

(a) Characteristic dimensions in perspective	
NEMS characteristic length	<100 nm
MEMS characteristic length	<1 mm and > 100 nm
SWCNT Chemical sensor	~2 nm
Molecular gear	~10 nm
Quantum-dots transistor	300 nm
Digital micromirror	12,000 nm
Individual atoms	Typically fraction of a nm in diameter
DNA molecules	~2.5 nm wide
Biological cells	In the range of thousands of nm in diameter
Human hair	~75,000 nm in diameter
(b) Weight in perspective	
NEMS built with cross-sections of about 10 nm	As low as 10–20 N
Micromachines silicon structure	As low as 1 nN
Eyelash	~100 nN
Water droplet	~10 μN

controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature, building nanoobjects atom by atom or molecule by molecule. Since the 1980s, many inventions and discoveries in the fabrication of nanoobjects have been testaments to his vision. In recognition of this reality, the National Science and Technology Council (NSTC) of the White House created the Interagency Working Group on Nanoscience, Engineering and Technology (IWGN) in 1998. In a January 2000 speech at the same institute, former President W. J. Clinton talked about the exciting promise of "nanotechnology" and the importance of expanding research in nanoscale science and technology more broadly. Later that month, he announced in his State of the Union Address an ambitious $497 million federal, multi-agency national nanotechnology initiative (NNI) in the fiscal year 2001 budget, and made the NNI a top science and technology priority [10, 11]. The objective of this initiative was to form a broad-based coalition in which the academe, the private sector, and local, state, and federal governments work together to push the envelope of nanoscience and nanoengineering to reap nanotechnology's potential social and economic benefits.

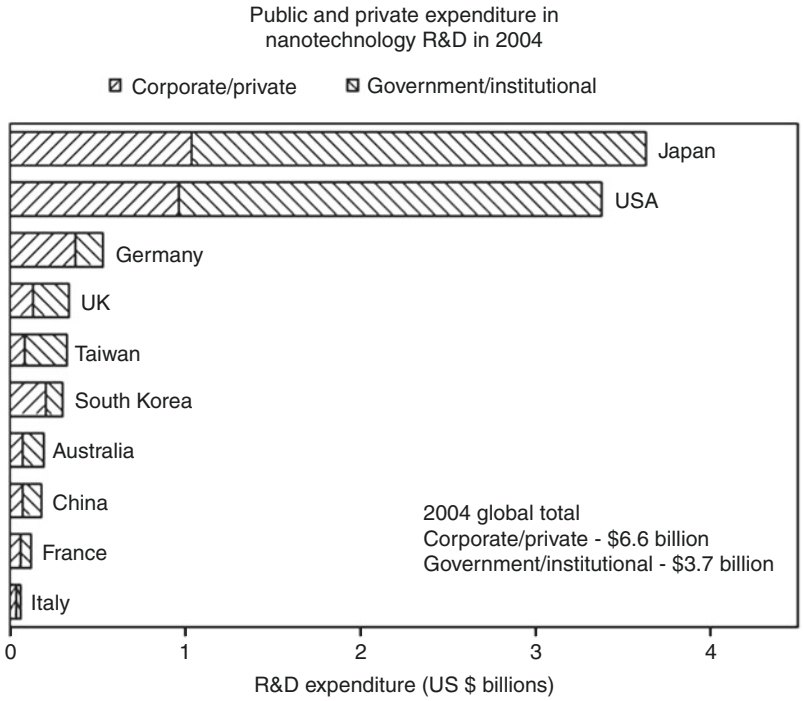
The funding in the USA has continued to increase. In January 2003, the US senate introduced a bill to establish a National Nanotechnology Program. On December 3, 2003, former President George W. Bush signed into law the twenty-first century Nanotechnology Research and Development Act. The legislation put into law programs and activities supported by the National Nanotechnology Initiative. The bill gave nanotechnology a permanent home in the federal government and authorized $3.7 billion to be spent in the 4-year period beginning in October 2005 for nanotechnology initiatives at five federal agencies. The funds would provide grants to researchers, coordinate R&D across five federal agencies (National Science Foundation (NSF), Department of Energy (DOE), NASA, National Institute of Standards and Technology (NIST), and Environmental Protection Agency (EPA)), establish interdisciplinary research centers, and accelerate technology transfer into the private sector. In addition, the Departments of Defense (DOD), Homeland Security, Agriculture, and Justice as well as the National Institutes of Health (NIH) also fund large R&D activities. They currently account for more than one-third of the federal budget for nanotechnology.

The European Union (EU) made nanosciences and nanotechnologies a priority in the Sixth Framework Program (FP6) in 2002 for a period of 2003–2006. They had dedicated small funds in FP4 and FP5 before. FP6 was tailored to help better structure European research and to cope with the strategic objectives set out in Lisbon in 2000. Japan identified nanotechnology as one of its main research priorities in 2001. The funding levels increased sharply from $400 million in 2001 to around $950 million in 2004. In 2003, South Korea embarked upon a 10-year program with around $2 billion of public funding, and Taiwan has committed around $600 million of public funding over 6 years. Singapore and China are also investing on a large scale. Russia is well funded as well.



Nanotechnology, Fig. 2 Global MEMS and nanotechnology market segments

Figure 3a shows the public expenditure breakdown in nanotechnology R&D around the world, with about $5 billion in 2004, being about equal by USA, Japan, and Europe. Next public expenditure on a per capita basis is compared. The average expenditures per capita for the USA, EU-25, and Japan are about $3.7 billion, $2.4 billion, and $6.2 billion, respectively [12]. Figure 3b shows the breakdown of expenditures in 2004 by public and private sources with more than $10 billion spent in nanotechnology research. Two thirds of this came from corporate and private funding. The private expenditure in USA and Japan was slightly larger than that of the public, whereas in Europe it was about one-third. Figure 4 shows the public and private expenditure breakdown in 2004 in various countries. Japan and USA had the largest expenditure, followed by Germany, Taiwan, South Korea, UK, Australia, China, France, and Italy. Figure 5 shows a breakdown of worldwide publications and patents. USA and Canada led, followed by Europe and Asia. Figure 6 shows the breakdown in start-up companies around the world (1997–2002). Entrepreneurship in USA is clearly evident followed by Europe.

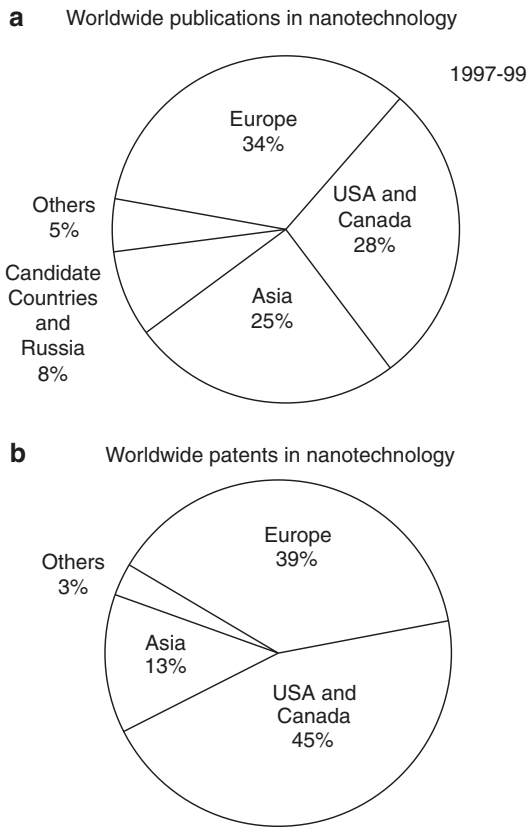


Applications in Different Fields

Science and technology continue to move forward in masking the fabrication of micro/nanodevices

Nanotechnology, Fig. 3 Breakdown of public expenditure in nanotechnology R&D (**a**) around the world (European Commission 2003), and (**b**) by public and private resources in 2004 (European Commission 2005; figures from private sources based upon Lux Research)

and systems possible for a variety of industrial, consumer, and biomedical applications (e.g., [4, 13, 14]). A variety of MEMS devices have been produced, and some are commercially used [4, 15–24]. A variety of sensors are used in industrial, consumer, defense, and biomedical applications. Various micro/nanostructures or micro/nanocomponents are used in micro-instruments and other industrial applications such as micromirror arrays. The largest "killer" MEMS applications include accelerometers (some 90 million units installed in vehicles in 2004), silicon-based piezoresistive pressure sensors for manifold absolute pressure sensing for engines and for disposable blood pressure sensors (about 30 million units and about 25 million units, respectively), capacitive pressure sensors for tire pressure measurements (about 37 million units in 2005), thermal inkjet printheads (about 500 million units in 2004), and digital micromirror arrays for digital projection display (about $700 million revenue in 2004), and optical cross-connections in telecommunications. Other applications of MEMS devices include chemical/biosensors and gas sensors, microresonators, infrared detectors and focal plane arrays for earth observations, space science and missile defense applications, pico-satellites for space applications, fuel cells, and many hydraulic, pneumatic, and other consumer products. MEMS devices are also being pursued in magnetic storage systems [25], where they are being developed for super compact and ultrahigh-recording-density magnetic disk drives.



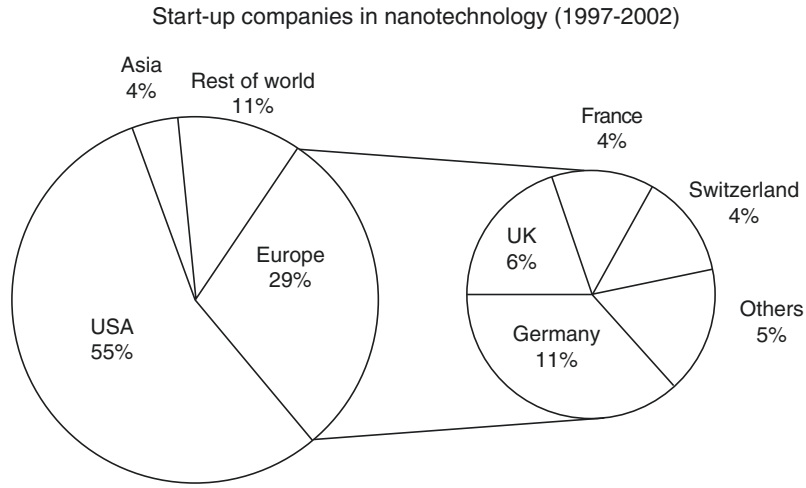
Nanotechnology, Fig. 4 Breakdown of public and private expenditures in nanotechnology R&D in 2004 in various countries [8]

NEMS are produced by nanomachining in a typical top-down approach and bottom-up approach, largely relying on nanochemistry [4, 26–32]. Examples of NEMS include microcantilevers with integrated sharp nanotips for scanning tunneling microscopy (STM) and atomic force microscopy (AFM), quantum corral formed using STM by placing atoms one by one, AFM cantilever array for data storage, AFM tips for nanolithography, dip-pen lithography for printing molecules, nanowires, carbon nanotubes, quantum wires (QWRs), quantum boxes (QBs), quantum-dot transistors, nanotube-based sensors, biological (DNA) motors, molecular gears by attaching benzene molecules to the outer walls of carbon nanotubes, devices incorporating nm-thick films (e.g., in giant magnetoresistive or GMR read/write magnetic heads and magnetic media) for magnetic rigid disk drives and magnetic tape drives, nanopatterned magnetic rigid disks, and nanoparticles (e.g., nanoparticles in magnetic tape substrates and magnetic particles in magnetic tape coatings).

Nanoelectronics can be used to build computer memory using individual molecules or nanotubes to store bits of information, molecular switches, molecular or nanotube transistors, nanotube flat-panel displays, nanotube integrated circuits, fast logic gates, switches, nanoscopic lasers, and nanotubes as electrodes in fuel cells.

BioMEMS/BioNEMS are increasingly used in commercial and defense applications (see, e.g., [4, 33–39]. They are used for chemical and biochemical analyses (biosensors) in medical diagnostics (e.g., DNA, RNA, proteins, cells, blood pressure and assays, and toxin identification) [39], tissue engineering [40], and implantable pharmaceutical drug delivery [41, 42]. Biosensors, also referred to as biochips, deal with liquids and gases. There are two types of biosensors. A large variety of biosensors are based on micro/nanofluidics. Micro/nanofluidic devices offer the ability to work with smaller reagent volumes and shorter reaction times, and perform analyses multiple times at once. The second type of biosensors includes micro/nanoarrays which perform one type of analysis thousands of times. Micro/nanoarrays are a tool used in biotechnology research to analyze DNA or proteins to diagnose diseases or discover new drugs. Also called DNA arrays, they can identify thousands of genes simultaneously

Nanotechnology, Fig. 5 Breakdown of (**a**) worldwide publications and (**b**) worldwide patents (European Commission 2003)



[35]. They include a microarray of silicon nanowires, roughly a few nm in size, to selectively bind and detect even a single biological molecule, such as DNA or protein, by using nanoelectronics to detect the slight electrical charge caused by such binding, or a microarray of carbon nanotubes to electrically detect glucose.

After the tragedy of September 11, 2001, concern of biological and chemical warfare has led to the development of handheld units with bio- and chemical sensors for detection of biological germs, chemical or nerve agents, and mustard agents, and chemical precursors to protect subways, airports, water supply, and population at large.

BioMEMS/BioNEMS are also being developed for minimal invasive surgery including endoscopic surgery, laser angioplasty, and microscopic surgery. Other applications include implantable drug-delivery devices – micro/nanoparticles with drug molecules encapsulated in functionalized shells for site-specific targeting applications, and a silicon capsule with a nanoporous membrane filled with drugs for long-term delivery.

Various Issues

There is an increasing need for a multidisciplinary, system-oriented approach to the manufacturing of micro/nanodevices which

Nanotechnology, Fig. 6 Breakdown of start-up companies around the world (1997–2002) (CEA, Bureau d'Etude Marketing)

function reliably. This can only be achieved through the cross-fertilization of ideas from different disciplines and the systematic flow of information and people among research groups. Common potential failure mechanisms for MEMS/NEMS requiring relative motion that need to be addressed in order to increase their reliability are: adhesion, friction, wear, fracture, fatigue, and contamination [4, 43–46]. Surface micro/nanomachined structures often include smooth and chemically active surfaces. Due to large surface area to volume ratio in MEMS/NEMS, they are particularly prone to stiction (high static friction) as part of normal operation. Fracture occurs when the load on a microdevice is greater than the strength of the material. Fracture is a serious reliability concern, particularly for brittle materials used in the construction of these components, since it can immediately or would eventually lead to catastrophic failures. Additionally, debris can be formed from the fracturing of microstructures, leading to other failure processes. For less brittle materials, repeated loading over a long period of time causes fatigue that would also lead to the breaking and fracturing of the device. In principle, this failure mode is relatively easy to observe and simple to predict. However, the material properties of thin films are often not known, making fatigue predictions error-prone.

Many MEMS/NEMS devices operate near their thermal dissipation limit. They may encounter hot spots that may cause failures, particularly in weak structures such as diaphragms or cantilevers. Thermal stressing and relaxation caused by thermal variations can create material delamination and fatigue in cantilevers. In large temperature changes, as experienced in the space environment, bimetallic beams will also experience warping due to mismatched coefficients of thermal expansion. Packaging has been a big problem. The contamination that probably happens in packaging and during storage also can strongly influence the reliability of MEMS/NEMS. For example, a particulate dust landed on one of the electrodes of a comb drive can cause catastrophic failure. There are no MEMS/NEMS fabrications standards, which make it difficult to transfer fabrication steps in MEMS/NEMS between boundaries.

Obviously, studies of determination and suppression of active failure mechanisms affecting this new and promising technology are critical to high reliability of MEMS/NEMS and are determining factors in successful practical application.

Adhesion between a biological molecular layer and the substrate, referred to as "bioadhesion," and reduction of friction and wear of biological layers, biocompatibility, and biofouling for BioMEMS/BioNEMS are important.

Mechanical properties are known to exhibit a dependence on specimen size. Mechanical property evaluation of nanometer-scaled structures is carried out to help design reliable systems since good mechanical properties are of critical importance in such applications. Some of the properties of interest are: Young's modulus of elasticity, hardness, bending strength, fracture toughness, and fatigue life. Finite element modeling is carried out to study the effects of surface roughness and scratches on stresses in nanostructures. When nanostructures are smaller than a fundamental physical length scale, conventional theory may no longer apply, and new phenomena emerges. Molecular mechanics is used to simulate the behavior of a nano-object.

The societal, ethical, political, and health/safety implications are getting major attention [12]. One of the prime reasons is to avoid some of the public skepticism that surrounded the debate over biotech advances such as genetically modified foods, while at the same time dispelling some of the misconceptions the public may already have about nanotechnology. Health/safety issues need to be addressed as well. For example, one key question is what happens to nanoparticles (such as buckyballs or nanotubes) in the environment and are they toxic in the human body, if digested.

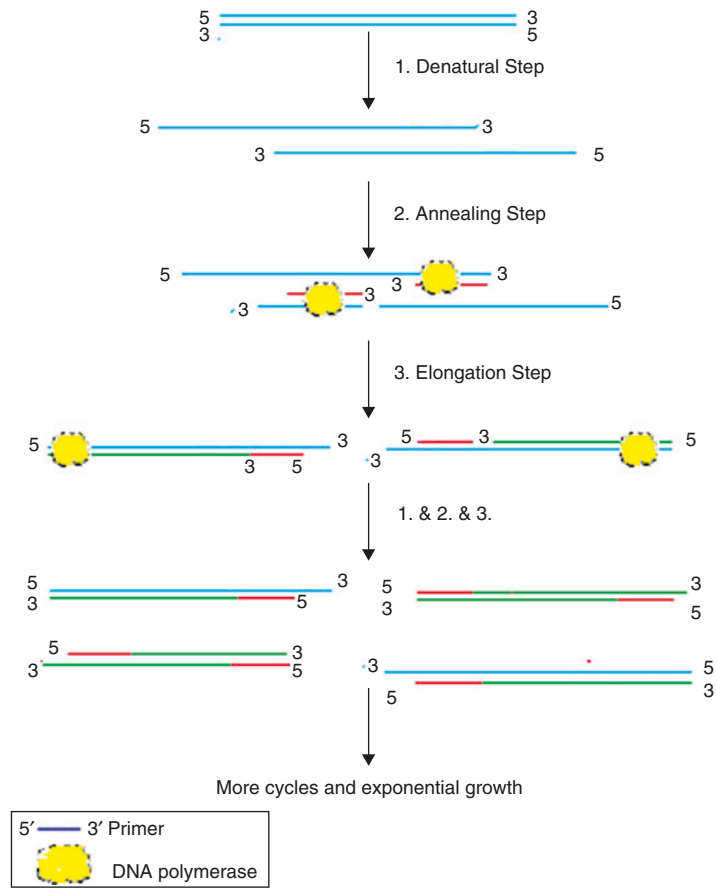
Definition



Polymerase chain reaction (PCR) is the most prevalent technology used in modern molecular biology research. Generally, it is a technique to amplify the amount of a piece of DNA with a specific sequence. Although the PCR technique is mature, improvement of its efficiency is still an emerging area of research. Recently, nanotechnology is getting more attention in this application. Several nanometer-sized materials such as carbon nanotubes, gold nanoparticles, quantum dots, and metal oxide nanoparticles have been employed.

Introduction

The polymerase chain reaction (PCR) technique is a series of chemical processes to exponentially amplify the number of a specific DNA sequence, producing hundreds of thousands of copies of DNA from a low original sample concentration. This revolutionary technique was first developed by Dr. Kary Mullis in 1983 [1]. Since then, it has been broadly utilized in medical, biomedical, and biological research fields for a variety of applications [2, 3]. In year 2013, the market of global polymerase chain reaction (PCR) with related products had reached US $6 billion with 6–10 % compound annual growth rate (CAGR) [4]. The growth include DNA sequencing, DNA cloning, identification of functional genes, the disease diagnosis, and the identification of genetic fingerprints associated with the PCR technique.

A basic PCR reaction needs several components in the mixture reagent. These include:

(a) A small amount of original DNA (mRNA in some applications) as a template which contains the oligonucleotide segment to be amplified.
(b) Primers. These are short sequences of oligonucleotides in which their sequences are designed complementary to the specific site of the template DNA. Two primers are used for one amplification process and each primer complementary binds to one strand of the paired DNA template at the opposite ends of the segment.
(c) DNA polymerases. These are the enzymes that perform DNA synthesis in the amplification process. The Taq polymerase is most prevalently used in the conventional PCR process and other polymerases are also used on different applications.
(d) Deoxynucleotide triphosphates (dNTPs). These are the building blocks of DNAs which are polymerized by the enzyme (polymerase) complementary to the sequence of DNA templates.
(e) Buffer solution. This is the salt solution to provide an optimum condition for DNA synthesis. Divalent cations such as Mg2+ or Mn2+ are normally used in the buffer solution

Nanotechnology Applications in Polymerase Chain Reaction (PCR), Fig. 1 Schematic illustration of the PCR amplification processes

to mediate DNA mutagenesis or decrease the error rate of the DNA polymerase.

The technique is based on the cycles of repeated temperature changes of the reactant in reaction tubes or plates. The thermal cycling is normally carried out in a thermal cycler which performs heating and cooling on the reactants. A typical PCR process consists of 20–40 cycles, with each cycle consisting of three basic heating and cooling steps on discrete temperatures. The temperatures employed and the duration of specific temperature in a cycle depend on the reactant used in the mixture for each specific process. In a conventional PCR process, as the first step (or called as denature step), the mixture is heated up to 94–98 °C for 20–30 s to break hydrogen bonds between complementary double-stranded DNA (templates) and yield single-stranded DNA molecules. In the second step (or called as annealing step), the temperature of the solution is lowered to 50–65 °C for 20–40 s allowing the primers to bind to the separated strands of DNA template. Sequentially, the enzyme (DNA polymerase) binds to the hybridization sites of primer and template to initiate DNA amplifications. In the next step (also called the extension/elongation step), the temperature of solution is risen to a temperature at which the enzyme has its optimum activity. A temperature of 72 °C is used for the commonly used Taq polymerase. At this step, the amount of DNA is doubled due to the enzyme synthesizing a new complementary strand to each DNA template by polymerizing dNTPs in 5′–3′ direction. These three basic steps form a cycle, and repetitions of this cycle lead to exponential amplification of the amount of DNA fragments. Figure 1 schematically shows a conventional PCR process.

Variations on the Basic PCR Technique

PCR is such a powerful technique to provide a relatively easy, efficient method to amplify the amount of desired DNA sequence. Since it was invented, many modifications to tailor the basic PCR thermal cycle approach to fit specific applications have been made. The features of these modified techniques are summarized in Table 1.

Nanotechnology in PCR

Although the PCR technique is mature and has been broadly employed in various applications, there is still an effort to improve the specificity and efficiency of it by using different advanced technologies. In the nanotechnology, the development and discovery of more applications of nanoparticles is an emerging area of research. Nanoparticle-assisted PCR has attracted more attentions, and many nanomaterials have been studied for their potential in developing better PCR technique. Various types of nanoparticles such as carbon nanotubes, metal nanoparticles (especially gold nanoparticles), semiconductor quantum dots, and metal oxide nanoparticles have been introduced into PCR, and their effect on reaction efficiency is studied. Some studies showed these nanoparticles dramatically improve PCR in efficiency and specificity, but some studies showed contrary results. In this entry, the development of the technique which employed the nanoparticles in PCR would be introduced. The different types of nanoparticles utilized in the studies and their effect in assisting PCR as well as mechanisms will be discussed.

Carbon Nanotubes

Gao et al. [14] investigated the effects of single-walled carbon nanotubes (SWCNTs) on PCR. Their results showed the amount of PCR product increased by adding single-walled carbon nanotubes into the PCR reactant mixture. They further discovered that adding higher concentrations of SWCNTs (>3 ug/ul) reversed the effect (amount of PCR product decreased). Using SEM and HRTEM, they showed that DNA templates and Taq enzymes were attached to bundles of SWCNTs. XPS results further suggested that there might be a chemical reaction between SWCNTs and components in PCR solution. The authors concluded that the SWCNTs have the potential to act as catalysts in the solution, which increased the yield of PCR products.

Zhang et al. [15] had done the similar study and reported the beneficial effect of using single-walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs) to enhance the amplification efficiency of long PCR up to 14 kb. Rather than the pristine carbon nanotubes, the authors employed the CNTs with surface functionalization. Both hydroxylic and carboxylic functionalized CNTs had been studied and had similar enhancing effects of long PCR.

Shi et al. [16] demonstrated using polyethyleneimine (PEI)-modified multiwalled carbon nanotubes (MWCNTs) to improve the efficiency of PCR. The authors tried three different polarities of PEI on MWCNTs and examined their influences on PCR. They discovered that only the MWCNTs with positive and negative PEI have effects on PCR efficiency but not the neutral PEI sample. In addition, positive PEI-coated MWCNTs had stronger effects than the negative PEI-coated MWCNTs. The authors speculated the effects might be from thermal conductivity of MWCNT and electrostatic interactions between PCR components and positive-charged molecules on MWCNTs.

The opposite effect on CNTs enhancing PCR had also been reported. Yang et al. [17] studied the effects of multiwalled carbon nanotubes and single-walled carbon nanotubes functionalized with and without carboxylic groups on PCR. Their results showed that CNTs reduced the efficiency of PCR. From their report, the inhibition effect on PCR was increased in the order of CNT-COOH > pristine CNT and SWCNT > MWCNT. The authors attributed the inhibition effect of nanomaterials on PCR to the decrease of the DNA polymerase activity, which they believed to be a significant effect of how nanomaterials impact biological systems.

Nanotechnology Applications in Polymerase Chain Reaction (PCR), Table 1 Variation techniques based on PCR process

Name	Functions	References
1. Quantitative PCR (qPCR)	A technique used to quantify the PCR products during the amplification cycles. Because the measurement is in "real time" of amplification, it is also called quantitative real-time PCR (qRT-PCR). The technique employed the fluorescent dyes in the PCR solution to measure the amount of amplified products in the log phase of the reaction before the plateau. The commonly used dyes are SYBR Green or TaqMan which is a DNA probe containing a fluorophore	[5]
2. Reverse transcription PCR (RT-PCR)	A preferred technique used to detect and quantify mRNA. In mRNA detection applications, the target RNA needs to be amplified by PCR. Thus, RNA samples need to be first reverse transcribed into cDNA by reverse transcriptase, and cDNA sequences will be amplified by PCR. This technique is widely used in profiling of gene expressions	[6]
3. Polymerase cycling assembly (PCA)	A technique to synthesize long DNA sequences by a PCR. It employed a pool of oligonucleotides with designed short overlapping sequences in each piece of oligonucleotide. Rather than using two primers, this technique uses multiple short oligonucleotides which are part of the single strand of the target sequences. During the elongation cycle, the rest of sequences will be filled in by polymerase. The technique is popular for the production of synthetic genes and even synthetic genomes	[7]
4. Helicase-dependent amplification	This technique is similar to traditional PCR but uses a constant temperature instead of temperature cycling in denaturation and annealing steps. Rather than thermal denaturation, a DNA helicase is used to separate the double strand of DNA which provides single-stranded DNA template for primers and polymerase binding	[8]
5. Hot start PCR	A modified process to reduce nonspecific amplification of DNA by inactivating the Taq polymerase at a lower temperature in the initial stages of the conventional PCR. It can be performed manually by adding a primer to start amplification after heating the reaction components to the melting temperature. Common methods for this technique include chemical modifications, wax-barrier methods, inhibition by a Taq-directed antibody, and by the presence of covalently bound inhibitors. Due to lack of nonspecific hybridization of primers to template, the amplified DNA bands tend to be cleaner	[9]
6. Methylation-specific PCR (MSP)	A technique is used to detect methylation of CpG islands in the genomic DNA. DNA is first treated with sodium bisulfite, which converts unmethylated cytosine bases to uracil. A special primer is designed to distinguish methylated from unmethylated DNA. The process takes advantage of the sequence differences resulting from bisulfite modification. MSP using qPCR can also be performed to obtain quantitative rather than qualitative information about methylation	[10]
7. Allele-specific PCR	It is a variation of the PCR which is used as a diagnostic or cloning technique to identify single-nucleotide polymorphism (SNPs) (single-base differences in DNA). It requires prior knowledge of a DNA sequence and differences between alleles. The allele-specific PCR uses primers whose 3′ ends encompass the SNP	[11]
8. Solid-phase PCR	In a solid-phase PCR (SP-PCR), the amplification takes place directly on a solid substrate. The technique encompasses multiple modifications, including polony amplification where PCR colonies are derived in a gel matrix, bridge PCR in which primers are covalently linked to a solid-support surface, and conventional solid-phase PCR in which an asymmetric PCR is employed. A primer is immobilized on a solid support which has the sequence matching one of the aqueous primers	[12, 13]

Gold Nanoparticles

Nanometer-sized gold particles (Au-NPs) and its counterparts with different surface modifications had also been studied of their influences on PCR. Hu et al. [18] reported that nanogold significantly improved the specificity and yield of PCR. The author attributed the enhancement to the greater affinity of Au-NPs to single-stranded DNA (ssDNA) than to double-stranded DNA (dsDNA) which reduced the mispairing of nucleotides to the template sequence in the elongation step. In their other work [19], the authors did the multiple rounds of PCR with 10 nm Au-NPs. The result showed that the Au-NPs effectively enhanced the specificity and yield of error-prone amplification. As the result showed, after six rounds of amplification, the target band was still manifested by a single bright band in gel electrophoresis. However, the target band disappeared after four rounds of amplification of the sample without adding Au-NPs. This study has shown that with Au-NP enhancement, a large amount of target DNA can be produced even with very low copies of original DNA samples. Liu et al. [20] had done the similar study using 13 nm Au-NPs in the PCR reagent and discovered the efficiency was increased. In this study, the authors also compared different PCR systems by using different DNA polymerases, various DNA sizes for amplification, and complex samples. Their results demonstrated that Au-NPs increased the efficiency from fivefold to tenfold in a conventional PCR and by 104-fold in a real-time PCR. The authors hypothesized that the enhancement is due to the excellent heat transfer property of the Au-NPs in PCR solution.

In addition to the bare Au-NPs, the surface-modified Au-NPs had also been studied with their influences on PCR. He et al. [21] reported using poly(diallyldimethylammonium) chloride (PDDA) molecule on Au-NPs to improve the efficiency and specificity of PCR. The authors used positive-charged PDDA, neutral PDDA, and negative-charged PDDA on Au-NP and discovered all these three modifications will enhance the efficiency of the PCR. In the mechanism study, the authors discovered that the positive-charged PDDA-modified Au-NP had the highest efficiency on PCR. It was speculated that the surface modifications with PDDA molecule would cause interactions between Au-NPs and components in PCR, which enhanced the specificity of molecule recognitions and further increased the efficiency. In addition, positive PDDA molecules caused stronger electrostatic attractions on negative-charged PCR components and thus induced higher efficiency enhancement than the other counterparts did. Shi et al. [22, 23] also reported the similar discovery of enhancement of PCR efficiency with surface-modified Au-NPs. In their study, the authors used poly(amidoamine) (PAMAM) dendrimer-grafted Au-NPs as the efficiency enhancer on PCR. The authors drew the same conclusion as He's group that the modified molecules on Au-NPs induced more interactions between PCR components and as the matter of fact enhancing the efficiency. The authors also provided a sophisticated model that PCR efficiency enhancement was mainly beneficially by the good thermal conductivity of Au-NPs, which enhanced local heat transfer rate and reduced mispairing between primers and templates. Further study will be conducted by the authors.

Although Au-NP-enhanced PCR had been investigated, different results had been reported. Emslie et al. [24] reported the contrary results from their study. The authors investigated the efficiency of real-time quantitative polymerase chain reaction (qPCR) by adding Au-NPs into the PCR solution. It was found that Au-NPs affect the qPCR amplification due to fluorescence quenching by Au-NPs. Rather than the quenching effect, it was discovered that Au-NPs destabilized the double-stranded PCR products which further reduced the efficiency of qPCR. In contrast to those previous reports, Willson et al. [25] discovered that Au-NPs suppressed the amplification of longer products and rather enhanced the amplification of shorter products. In their discovery, when Au-NPs were added in the PCR solution, some of the DNA polymerases were nonspecifically absorbed on nanoparticles and thus reduced the amount of polymerase and the efficiency of amplification. In their recent report, Hu et al. [26] also discovered that the Au-NPs can

enhance the PCR efficiency only by employing native Taq polymerase. No improvement was found in a PCR based on the recombinant Taq polymerase. However, the underlying mechanism was still unclear.

Yeow et al. [27] had done the study of the proposed mechanism for Au-NPs affecting the PCR. The authors studied the PCR efficiency with different Au-NP sizes (5 nm, 10 nm, and 20 nm) and different concentrations. Evidence from their study showed that the possible mechanism for Au-NPs affecting the PCR is through DNA polymerase-Au-NP binding which modulated the enzyme activity for the amplification. Besides, the binding strongly related to the total surface area of the nanoparticles in the reaction solution.

Semiconductor Quantum Dots

Another type of nanoparticles such as semiconductor quantum dots (QDs) has been studied in affecting the PCR efficiency. Li et al. [28] reported that the QDs dramatically improved the yield and specificity of PCR. In their study, by employing mercaptoacetic acid (MAA)-coated QDs, yield and specificity of PCR enhanced even at lower annealing temperature. Rather than MAA surface-coated QDs, streptavidin surface-modified QDs also effectively improved the specificity of PCR which demonstrated that the effect was not due to the molecules of surface modification but instead due to the QDs itself. Further study is needed to discover the underlying mechanism. Another study using QDs in PCR was done by Xu et al. [29]. In this study, the authors also discovered that the QDs could increase the specificity of the PCR at different annealing temperatures. Thus, as the authors concluded, this method could make the PCR widely applicable, especially in the multi-round PCR with different annealing temperatures.

Guan et al. [30] discovered different effects of QDs using different polymerase systems. The PCR efficiency was reduced by introducing high-concentration QDs in reagents, but this effect was reversed in Ex PCR systems using Ex Taq polymerase. The mechanism was unknown. The same group also discovered the QDs were able to enhance fluorescence signals without interrupting the DNA amplification in real-time PCR. Zheng et al. [31, 32] studied the influences of the water-soluble CdTe quantum dots in the hot start (HS) PCR reaction. Their results showed the higher amplicon yields and reduced nonspecific amplification on hot start PCR with premix PCR reagents and QDs. The study also discovered the effects are reversible by increasing the polymerase concentration in the PCR reagent, which demonstrated the interactions between QDs and the polymerase. Further investigation of the working mechanism was conducted.

Other Nanoparticles

Several different types of nanoparticles have also been studied of their effects in PCR. Mahapatra et al. [33] recently reported that the TiO_2 nanoparticles with the size of 25 nm diameter significantly enhanced the PCR efficiency even with various types of templates (i.e., plasmid DNA, genomic DNA, and complementary DNA). Besides, the yield was also enhanced by utilizing TiO_2 nanoparticles in the PCR. Investigations of the mechanism by simulations showed evidences of fast and efficient heat transfer in the PCR solution in the presence of TiO_2 nanoparticles to enhance the PCR efficiency. Consistent with the simulation results, experimentally, the authors observed the increase of denaturation of genomic DNA in the presence of TiO_2 nanoparticles in PCR solution which indicated higher thermal conductivity through the reaction buffer. This technique may be useful for reduction of the overall PCR reaction time and further enhanced the efficiency and specificity of PCR in a variety of samples.

The platinum nanoparticles have also been evaluated to optimize DNA amplification on PCR. Ventimiglia et al. [34] demonstrated that the (beta-cyclodextrins) capped platinum NPs were able to increase the PCR efficiency. The authors discovered the enhancement was directly caused by the metal thermal efficiency and was

not influenced by the properties of capping agents. In addition, the reduction of the reagent's concentration was another benefit by applying metal NPs on PCR.

The effect of C-60 on PCR was studied by Jiang et al. [35] using a qPCR system. The authors reported a dramatical enhancement of the qPCR at the beginning of the exponential phase but a significant inhibition at the plateau region. In addition, the resulting melting curve demonstrated that C-60 decreased the melting temperatures (Tm) of the template DNA fragments. The authors hypothesized this is due to the enhancement of qPCR efficiency by C-60 in the initial phase of PCR. However, when there is more DNA amplicon in solution, C-60 can disrupt DNA replication by binding to DNA to decrease the access of templates and changing the conformation of DNA templates which reduced the amplification efficiency at the later cycles of the reaction.

Conclusion

Although the utilization of nanoparticles in conventional PCR is just emerging, the potentials to enhance the process have been demonstrated by some of the works. Due to its excellent thermal conductivity, high surface-to-volume ratio, and high affinity to bind molecules on surface, nanoparticle-assisted PCR can greatly reduce the total process time and specificity of the process. This is critical for the technique to be used in medical diagnosis and infield detection applications. In addition, due to the high efficiency of process with NP enhancement, less amount of expensive reagents is needed which significantly reduce the experimental costs. However, until now, the NP-assisted technology has not yet been revolutionized in practice. To enable users to embrace the technique, future development in identifying type of NPs, size of NPs, concentration of NPs in PCR reagent, and specific PCR components are all essential. In addition, optimization of process design to maximize the enhancements and further reduce the time and cost of the process is also important to evolve this technology out of research and to be used routinely.

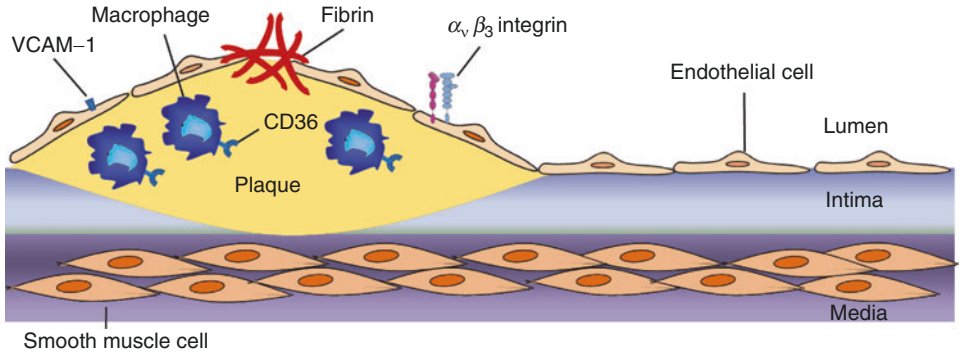
Definition

Nanomolecular imaging is a new type of imaging with a combination of nanomaterial and molecular biology, using nanoparticles to visualize, characterize, and measure biological processes at molecular and cellular levels in living systems, including radiotracer imaging/nuclear medicine, magnetic resonance (MR) imaging, MR spectroscopy, optical imaging, ultrasound, and other nanomolecular imaging.

Overview

Recently, the emergence of nanomolecular imaging has set the stage for an evolutionary leap in the diagnosis and therapeutics of diseases such as cancer and neurological and cardiovascular diseases (CVDs) [1–3]. CVD is the leading cause of morbidity and mortality in the world. The pathology underpinning CVD is chronic inflammation involving the injury of arterial wall, the infiltration of leukocytes, and the remodeling of vasculature. The main benefits of nanomolecular imaging are derived from the combination of cell type-specific molecular-based, molecular-molecular recognition with nanoparticle-based probes, leading to accurate and high resolution of diseased sites and to the early diagnosis and treatment for CVDs, including atherosclerosis, thrombosis, and myocardial infarction [4–6]. The progress in nanomolecular imaging will play an important role not only in molecular imaging, but also in the development of biosensors, biomarkers, and new drug delivery system.

Nanoparticles are defined as ranging from 5 to 700 nm in diameter and can enter the cells and function inside the cells (such as generation of intracellular imaging and targeting-specific molecular pathways) [4] (see Nanoparticles). For example, new types of nanoparticles have been recently introduced to generate contrast enhancement and improved sensitivity, such as infrared dyes and quantum dot (QD) nanocrystals for optical imaging [7], gold colloids or radiotracer-based nanoassemblies for X-ray contrast [4], gas-filled microbubbles for contrast using ultrasound [8], and nanoparticles of gadolinium or iron oxide for magnetic resonance contrast [4]. These abilities open up a large number of exciting possibilities for early detection, the potential treatment of disease, and a novel type of drug delivery system. Nanomolecular imaging has also been applied to imaging techniques including luminescence imaging and spectroscopy. Indeed, current imaging device can be applied for nanomolecular imaging, such as positron emission tomography (quantitative PET) and magnetic resonance spectroscopy (MRS), magnetic resonance spectroscopic imaging (MRSI), diffusion magnetic resonance imaging (dMRI), and functional magnetic resonance imaging (fMRI).



Key Research Findings

Nanomolecular Imaging and Potential Therapy in Cardiovascular Disease

CVD is the largest cause of mortality in the world, accounting for about 40 % of deaths. CVD occurs at a higher rate in diabetes with mortality exceeding 50 %. Risk factors, such as visceral obesity, hypertension, and dyslipidemia, are all associated with increased risk of CVD. The major underlying disease of most CVDs is atherosclerosis, characterized by a complex multifactorial pathophysiology such as the slow accumulation of lipid and inflammatory products in the vessel wall that further leads to calcification and fibrosis in atherosclerotic plaques. Inflammation in the vessel wall is now considered to play an essential role in the initiation, progression, and the final steps of atherosclerosis, namely, plaque destabilization and eventually plaque rupture (Fig. 1) [9]. Atherosclerotic plaques can be divided into two types: stable plaque and unstable plaque (a vulnerable plaque, causing myocardial infarction and stroke). Unstable plaques are at higher risk for plaque disruption, characterized by fibrous cap rupture, ulceration following spontaneous denudation of the endothelium, or intraplaque hemorrhage. This plaque disruption leads to local thrombus formation and vessel occlusion, recognized as the proximate cause of the majority of clinical CVD events such as a heart attack or stroke. Although there have been significant advances in vascular imaging (such as intravascular ultrasound and MRI), current imaging methods are still insufficiently capable for elucidating plaque composition. Therefore, it is critical to develop novel techniques to identify vulnerable plaques. In recent years, nanomolecular imaging provides exciting opportunities to identify vulnerable plaque to reduce the risk of acute coronary syndromes.

Endothelial Cells

The initiating event for the development of atherosclerosis is the endothelial layer inflammation

Nanotechnology in Cardiovascular Diseases, Fig. 1 The structure of plaque in atherosclerosis. *VCAM-1* vascular cell adhesion molecule-1

or dysfunction. Increased adhesiveness of the endothelium leads to the infiltration of leukocytes which could engulf oxidized lipid particles and develop into inflammatory foam cells [10]. These processes can be determined by measuring inflammatory markers, such as vascular cell adhesion molecule-1 (VCAM-1), a molecule found in blood vessel walls at the onset of inflammation – a first stage in the development of atherosclerotic plaques. Kelly et al. identified VCAM-1 internalizing peptide-28 nanoparticles (VINP-28), a novel VCAM-1 peptide affinity ligand from phage display that undergoes internalization and trapping in cells that express VCAM-1, resulting in higher signal amplification ion [11]. That offers an opportunity for detecting early atheromata (fatty streak-like lesions) and targeting VCAM-1-expressing cells of human carotid atherosclerotic plaques.

Macrophages

Macrophages have emerged as a key component of atherosclerosis, which accumulate cholesterol esters to form lipid-laden foam cells in the arterial intima and generate proteinases that lead to plaque destabilization and rupture. The accumulation of macrophage in the subendothelial space could be observed through all stages of vascular lesion development, and the increased macrophage density is associated with lesion progression and rupture [9]. Additionally, the macrophage may serve as an ideal target for the detection and potential therapy of vulnerable inflamed lesions. Recently, macrophage-specific lipid-based nanoparticles were created which improved cardiac magnetic resonance detection and characterization of human atherosclerosis [12]. These nanoparticles were made from phospholipids, a surfactant (Tween 80), and an aliphatic gadolinium complex, which targets CD36, a macrophage class B scavenger receptor. The macrophage-specific (CD36) nanoparticles bind human macrophages and improve cardiac magnetic resonance (CMR) detection. A light-activated theranostic nanoagent for targeted macrophage ablation was invented [13]. This nanoparticle was based upon cross-linked dextran-coated iron oxide (CLIO). It was modified with near-infrared fluorophores and light-activated therapeutic moieties. The therapeutic component was activated at 650 nm and could result in eradication of inflammatory macrophages. Moreover, other potential targets, such as scavenger receptor class B type 1 (SRB1), lectin-like oxidized LDL receptor-1 (LOX-1), receptor for advanced glycation end products (RAGE), and urokinase-type plasminogen activator (uPA) receptor, could be more efficacious and provide an integrated imaging and therapeutic nanoplatform for atherosclerosis [14–17].

Atherosclerotic Plaque

A major component of atherosclerosis plaques is fibrin, which forms the fibrils that entangle the blood platelets and seal up the rent in the artery wall. Fibrin deposition is one of the earliest signs of plaque rupture or erosion and intraplaque

hemorrhage. Densely packed fibrin-targeted nanoparticles can be detected by scanning electron micrographs (SEM) [18]. These nanoparticles were formulated with gadolinium DTPA-bis-oleate (Gd-DTPA-BOA) and presented a highly detectable, homogeneous T1-weighted contrast enhancement that improved with increasing gadolinium level. Higher-resolution scans and scanning electron microscopy revealed that the nanoparticles were present as a thin layer over the clot surface. Then, the development of other matrix-targeted nanoparticles could provide accurate detection and localization of matrix deposits and may allow early, direct identification of vulnerable plaques.

Angiogenesis

In atherosclerosis, angiogenesis is not only related to plaque growth, but also related to plaque instability and rupture. Integrins, cell surface receptors involved in cell-cell and cell-matrix interaction, such as $\alpha_v\beta_3$, are associated with angiogenesis and have been extensively used as a target for nanomolecular imaging [19]. Patrick Winter et al. developed a paramagnetic nanoparticle contrast agent targeted specifically to $\alpha_v\beta_3$ integrins to permit noninvasive molecular imaging of plaque-associated angiogenesis. Moreover, $\alpha_v\beta_3$ integrin-targeted paramagnetic nanoparticles can deliver fumagillin and elicit a marked antiangiogenic response with a minimal drug dosage [19].

Future Directions for Research

Nanomolecular imaging is a new evolving field, which represents the beginning of a revolutionary new age for the clinicians to enhance the diagnosis and treatment of the cardiovascular diseases relying on the powerful imaging probes and hardware. While it is still in the developing phase, the nanomolecular imaging has resulted in lots of nanoparticles that vary in size, shape, change, chemistry, coating, and solubility. More importantly, nanomolecular imaging must utilize the progress of molecular and cellular biology in pathological conditions. At the same time, the potential toxicity of these nanoparticles should also be paid more attention to [20] (see "▶ Cellular Mechanisms of Nanoparticle Toxicity" and "▶ Nanoparticle Cytotoxicity"). The nanoimaging agent synthesis requires the efforts on their subsequent translation to clinical practice. The rapid growth of nanomolecular imaging will change the field of imaging and imaging-guided interventions for cardiovascular diseases.

Nanotechnology in Pulmonary Disease

James C. Bonner
Department of Biological Sciences, North Carolina State University, Raleigh, NC, USA

Definition

Nanotechnology in pulmonary disease encompasses the potential human health risks from occupational, environmental, or consumer exposure to engineered nanomaterials as well as the therapeutic benefits of nanomaterials for drug delivery to treat pulmonary diseases, enhance medical imaging of lung diseases, or provide tissue engineering for regenerative medicine.

Introduction

Engineered nanomaterials (ENMs) are intentionally manufactured nanoparticles with at least one dimension <100 nm that can be mass produced with a high degree of conformity in size and shape. The risk of ENMs to human health, specifically pulmonary disease, is not yet known due to the relative infancy of the nanotechnology revolution. However, studies with rodents that show adverse pro-inflammatory, pro-fibrogenic, and carcinogenic effects suggest that at least some ENMs will pose a human health hazard. Also, the utility of ENMs for therapies aimed at the treatment of pulmonary diseases in an early stage of development. Naturally occurring nanoparticles (e.g., nanoscale volcanic dust) or nanoparticles from anthropogenic sources but not intentionally manufactured (e.g., diesel exhaust ultrafine particles) are not ENMs as defined in the context of this essay and are therefore not discussed.

Engineered Nanomaterials Causing Pulmonary Disease

Potential adverse effects of ENMs on the respiratory tract and lungs may occur in occupational settings from airborne nanoparticles released during the manufacturing process, during exposure of nanoparticles released from consumer products containing ENMs, or from exposure to ENMs released into the environment. The most likely route of exposure to ENMs resulting in pulmonary disease is inhalation, but other routes of exposure (dermal, ingestion) should not be excluded.

Pulmonary Fibrosis

Pulmonary fibrosis is a fatal disease characterized by the progressive accumulation of extracellular

matrix proteins produced by activated lung myofibroblasts [1]. A variety of environmental toxic agents such as asbestos and certain metals (Ni, Co) cause pulmonary fibrosis in humans. While pulmonary fibrosis has yet to be associated with ENMs, many ENMs have the potential to cause pulmonary fibrosis, including carbon-based ENMs (carbon nanotubes, carbon nanofibers, and graphene) and metal nanoparticles (Co, Ni, Fe). A rapidly growing body of evidence indicates that carbon nanotubes (CNTs), either single-walled CNTs (SWCNTs) or multiwalled CNTs (MWCNTs), cause pulmonary fibrosis in rodents when delivered to the lungs by inhalation exposure, intratracheal instillation, or pharyngeal aspiration [2]. The underlying mechanisms of fibrogenesis induced by CNTs and other pro-fibrogenic ENMs likely involve several factors. First, the generation of reactive oxygen species (ROS) is important to tissue injury and the activation of resident cells (e.g., macrophages and epithelial cells) during pulmonary fibrosis. Second, the activation of lung cells by ROS drives the production of pro-fibrogenic soluble mediators including platelet-derived growth factor (PDGF), osteopontin (OPN), and transforming growth factor (TGF)-β1 which then drive myofibroblast growth, migration, and collagen deposition, respectively [1]. Certain physiochemical features also determine the fibrogenic potential of CNTs. For example, like asbestos fibers, the length of CNTs has been proposed as an important determinant of fibrogenic potential, and rigid MWCNT tubes longer than 15 or 20 μm are difficult to clear from lung tissues via macrophage-mediated mechanisms [2]. However, long SWNCT can fold and might be cleared more effectively by macrophages. Second, the composition of CNTs is an important determinant of fibrogenicity. Metal catalysts (e.g., nickel, cobalt, iron) are used in the manufacture of CNTs, remain within the tube structure post-synthesis, and have the potential to generate reactive oxygen species (ROS).

A wide spectrum of metal nanoparticles (Fe, Co, Ni, Zn, TiO_2) pose a significant risk for pulmonary fibrosis, especially in occupational settings where relatively high concentrations of these ENMs might be inhaled during the manufacturing process. Also, as mentioned above, some metal nanoparticles (Ni, Co, Fe) are used in chemical vapor deposition reactions to grow CNTs. A large body of literature already exists on metal-induced pulmonary diseases, including pulmonary fibrosis, in humans and rodents [3]. For example, Co and Ni are known causes of "hard metal disease" and "metal fume fever" in workers exposed during welding and other industrial applications. It is also known that Fe mediates asbestos-induced pulmonary fibrosis (i.e., asbestosis). Therefore, it is not surprising that ENMs composed of these same metals would also have fibrogenic potential. In particular, nanometals could be more fibrogenic based on the fact that they have greater surface area per unit mass and therefore have the capacity to generate higher levels of ROS than larger metal particles.

Obstructive Airway Diseases: Asthma and COPD

Obstructive airway diseases include asthma and chronic obstructive pulmonary disease (COPD) [4]. Both diseases have genetic and environmental components. Asthma is an allergen-induced Th2 immune-mediated chronic airway disease characterized by eosinophilic inflammation, mucous cell metaplasia, smooth muscle thickening, and airway fibrosis. Chronic airway remodeling in asthma is accompanied by acute episodic bronchospasm in response to allergens or other environmental factors that narrows airways and limits pulmonary function. COPD, caused primarily by cigarette smoking or inhalation of smoke from burned biomass, is a Th1 immune-mediated lung disease that includes chronic bronchitis and emphysema (progressive degradation of the alveolar walls of the lung).

Some ENMs have been reported to either cause or exacerbate allergic airway disease in rodents, suggesting that they may pose a risk for asthma [5]. Altered airway flow in patients with asthma or COPD may increase airway deposition and

relative deposited concentration of inhaled ENMs as compared to healthy individuals. Also, the physicochemical characteristics of ENMs (e.g., aggregation status, surface charge) could be affected by the presence of mucus and cellular debris in diseased airways. Also, individuals with asthma or COPD have impaired mucociliary clearance and therefore might not be expected to remove inhaled ENMs as effectively as healthy individuals. The presence of activated inflammatory cells and structural airway cells may alter the response to ENMs. Several studies indicate that ENMs exacerbate or cause allergic airway inflammation and remodeling in the lungs of mice [6]. For example, airway fibrosis in mice is increased by the combination of ovalbumin allergen and MWCNTs, whereas ovalbumin or MWCNTs alone do not significantly increase airway fibrosis, suggesting that MWCNTs pose a hazard to individuals with allergic lung inflammatory diseases such as asthma. Intratracheally administered MWCNTs significantly increased ovalbumin-induced T-lymphocyte proliferation and amplified lung Th2 cytokines and chemokines compared to ovalbumin exposure alone. SWCNTs also exacerbate murine allergic airway inflammation via enhanced activation of Th2 immunity, increased oxidative stress, and inappropriate activation of antigen-presenting cells such as dendritic cells. MWCNTs delivered to the lungs of mice may also induce allergic responses through B-cell activation and production of IgE in the absence of any allergen preexposure.

In addition to CNTs, certain metal nanoparticles could pose a risk for the development of asthma or COPD. For example, Ni nanoparticles delivered to mice cause airway mucous cell metaplasia and mucus overproduction; this effect is greatly enhanced in mice lacking the transcription factor T-bet, a spontaneous mouse model of asthma [7]. While the potential human health impact of metal ENMs has yet to be established, the known adverse effects of a variety of metals on asthma suggest that some metal ENMs will either exacerbate or cause asthma.

Lung Cancer and Mesothelioma

Some ENMs show carcinogenicity in rodents and have the potential to cause either lung cancer or mesothelioma (cancer of the pleural lining surrounding the lungs) in humans. However, as with other pulmonary diseases, no ENM has yet to be linked to lung cancer or mesothelioma in humans. A number of studies have focused on the genotoxicity and potential carcinogenicity of CNTs and these have been reviewed [8, 9]. Both SWCNTs and MWCNTs cause genotoxic effects in certain in vitro cell culture systems. SWCNTs cause fragmented centrosomes, multiple mitotic spindle poles, anaphase bridges, and aneuploid chromosome number in cultured primary or immortalized human airway epithelial cell types. MWCNTs induce apoptosis in mouse embryonic stem cells and activate the tumor suppressor protein p53, a marker of DNA damage. CNTs also cause genotoxic effects in vivo. Long and thick MWCNTs cause more DNA damage in the lungs of mice compared to short and thin MWCNTs. Intraperitoneal injections of COOH-functionalized MWCNTs in mice cause structural chromosome aberrations, DNA damage, and micronuclei formulation compared to non-functionalized "pristine" MWCNTs. On the other hand, polyethylene glycol (PEG)-coated SWCNTs reduce genotoxicity in neuronal PC12 cells. Therefore, the degree of genotoxicity caused by modification of CNTs depends on the specific type of functionalization. Since genotoxicity plays a role in the development of cancer, genotoxicity screening-level assays have been developed to predict the potential carcinogenicity of a wide variety of ENMs.

Nanotechnology for Therapeutic Treatment of Pulmonary Diseases

While ENMs generated by nanotechnology will pose some risk to human health as described above through occupational or environmental exposures, other types of ENMs intentionally designed for nanomedicine platforms will offer

significant benefits for improving drug delivery and therapy of respiratory diseases. ENMs have been of great interest for some time as they can be designed to simultaneously carry a drug payload, specifically target features of diseased tissues, and carry an imaging molecule to track drug accumulation and clearance in tissues. Moreover, they can be engineered for more sustained drug delivery to improve pharmacokinetics and reduce the overall amount of drug administered during treatment of disease. A variety of ENMs have been investigated in animal models as tools to improve the therapeutic efficacy of drugs or genes delivered to the lung or other organ systems [10].

The nanotechnology platform for drug delivery contains a number of very different types of nanoscale structures with widely varying properties, including dendrimers, fullerenes, polymeric NPs, nanometals, and carbon nanotubes. Nanoparticles that have been investigated for drug delivery fall into two broad categories: organic "soft" nanoparticles (e.g., dendrimers and liposomes) and "hard" nanoparticles that are produced from carbon, silver, gold, or zinc in a variety of shapes (e.g., spheres, tubes, rods, wires) [11]. Nano-based drug delivery systems offer the potential for improved efficacy of treatment. ENMs are desirable because they easily enter cells and they can be designed to interact with specific cellular structures (e.g., receptors) to allow for accumulation within specific regions of the cell. ENMs can also be designed as pH-labile structures so that they degrade within the more acidic microenvironment of the cell to release drug payloads. Biocompatible ENMs that are used for drug delivery, such as poly-(ethylene glycol)-*poly*lactide co-glycolide copolymer (PEG-PLGA) nanoparticles, generally have low toxicity but often do not persist in tissues long enough for sustained drug or gene payload delivery. Nevertheless, PEG-PLGA NPs might be useful for delivering metabolic inhibitors of inflammation for the treatment of pulmonary diseases such as COPD or hypertension [12].

CNTs are durable and persist in tissues after administration by aerosol inhalation. An attractive property of CNTs, particularly SWCNTs, is that the tube- or fiber-like structure allows for extensive functionalization and loading of cargo. The versatile physicochemical features of CNTs allow for covalent and noncovalent functionalization to simultaneously carry several agents: (1) a drug, (2) an imaging agent (to track the course of delivery), and (3) a specific targeting agent (e.g., antibody selective for diseased tissue) [13]. Despite the versatility of CNTs as delivery platforms, some of the same unique properties that make CNTs desirable for therapeutic applications also make them potentially toxic. Thus, it is currently unclear whether the toxic effects of CNTs might ultimately outweigh any beneficial effects as drug delivery systems [14]. If CNTs are to be ultimately developed as a viable drug delivery platform, functionalization will be required to ameliorate toxicity, minimize the risk of side effects, and target therapeutic agents to the desired organs, tissues, or cells. A better understanding of how these nanomaterials interact at the nanoscale level with biological systems (i.e., the subcellular architecture) will be essential, along with adequate in vitro screening techniques to predict toxicity and thereby allow for safe design of ENMs in drug delivery for lung diseases [15].

For effective therapy, it is desirable to have a nanoparticle delivery system that remains in the target tissues long enough to achieve sustained and targeted release of drug, but nanoparticle persistence in tissues for too long will increase the possibility of toxic side effects and pathogenesis. Biodegradable nanoparticles are currently considered to be the best choice for targeted drug delivery, but biopersistent nanoparticles might also be considered valuable if they are cleared from tissues quickly enough to minimize exposure and retention [16]. Durability and degradation half-life must therefore be carefully considered in the intelligent design of ENMs to maximize beneficial pharmacologic effects while minimizing pathogenic side effects. Also, increasing solubility and decreasing aggregation status through functionalization will likely be important for developing ENMs as delivery platforms.

A variety of types of nanoparticles (lipid, cerium oxide, gold, iron oxide, super

paramagnetic iron oxide, lipid-polycation-DNA, silica-overcoated magnetic cores, and polyethylene glycol phosphatidylethanolamine) have been investigated for the treatment of lung cancer [17]. Nanoparticles can enhance drug delivery by encapsulation against immune response, increasing cellular uptake and tissue penetration, target selectivity, and specificity, promoting apoptosis, and blocking pathways for cancer initiation and progression. Nanoparticles have the ability to selectively accumulate in tumor tissue. The vasculature supplying tumors is often leaky due to loss of tight cell–cell contact between endothelial cells lining the capillaries, and these endothelial cell gaps (0.5–2.5 μm) allow circulating nanoparticles to exit the capillary and selectively accumulate in the tumor tissue [11]. In addition, nanoparticles remain in tumor tissue longer since there is poor lymphatic drainage surrounding tumors, which impedes nanoparticle clearance.

In addition to the ENMs mentioned above, CNTs could also offer potential for the treatment of lung cancer [18]. Tumor-targeted SWCNT constructs have been synthesized from water-soluble CNTs by covalent attachment of tumor-specific monoclonal antibodies [19]. Moreover, this strategy may be used along with thermal ablation of cancer cells by selectively heating CNTs taken up by cancer cells with infrared radiation [20]. While fibrotic reactions may still be a risk of these functionalized CNT platforms in some patients, overall the benefits could outweigh the risks. Other issues will also ultimately determine the potential success of treatment strategies that might utilize carbon nanotubes, such as costs of CNTs versus current biopolymers or other types of nanoparticles. In the words of Paracelsus (1493–1541), "the right dose differentiates a poison and a remedy." The success of CNTs in drug delivery will be achieved by using the lowest possible dose combined with single tube dispersibility, functionalization to target and/or carry a therapeutic agent, and biodegradability to avoid long-term chronic side effects.

Individuals with preexisting pulmonary diseases such as asthma and COPD represent susceptible populations to ENM exposures. However, these are also some of the same individuals that might benefit from improved drug delivery strategies or novel imaging techniques using nanotechnology. A major challenge for drug delivery in chronic airway diseases such as asthma and COPD is penetration through a thick layer of dense mucus that lines the airways. The hydrophobic and electrostatic forces within the mucus layer are highly effective in trapping particles and preventing access to the airway epithelium. Penetration through mucus can be achieved by properly modifying the size and charge of the nanoparticle. Coating particles with a high density of low molecular weight polyethylene glycol (PEG) renders the surface of the particle neutrally charged and improves transport of particles across the mucus layer [11].

ENMs may be effective in the treatment of infectious diseases that cause lung injury. For example, tuberculosis is a fatal respiratory infectious disease that represents a global threat and current oral antituberculosis therapy is limited by systemic toxicity [21]. Nanotechnology represents a promising strategy in the development of inhaled drug delivery systems for the treatment of TB. Nanocarriers (polymeric nanoparticles, solid lipid nanoparticles, nanoliposomes, and nanomicelles) can improve the drug effectiveness and decrease systemic side effects by targeting the drug to the infected area and sustaining release in a prolonged manner.

Conclusions

Nanotechnology is a "double-edged sword" for pulmonary diseases since some ENMs will likely cause pulmonary diseases or exacerbate preexisting disease when encountered in occupational or environmental exposure settings, while others will be highly beneficial for therapeutic applications in nanomedicine. The potential risks to human health and the environment should be carefully considered when designing ENMs for industrial purposes, consumer products, or nanomedicine. There are numerous physicochemical factors (e.g., aspect ratio, surface charge, biodegradability, etc.) that must be considered in the design of functional and safe ENMs for a wide

variety of applications. Because of the infancy of the field of nanotechnology, there are no epidemiologic data to indicate health hazards for ENMs.

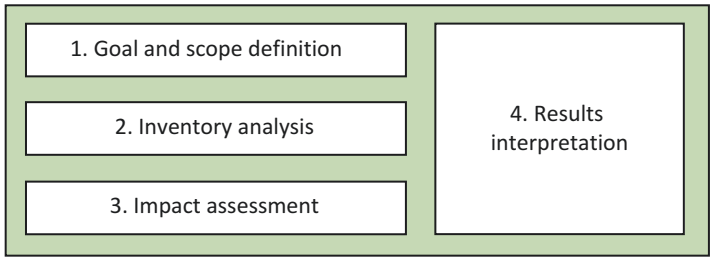
Environmental impact assessment

Definition

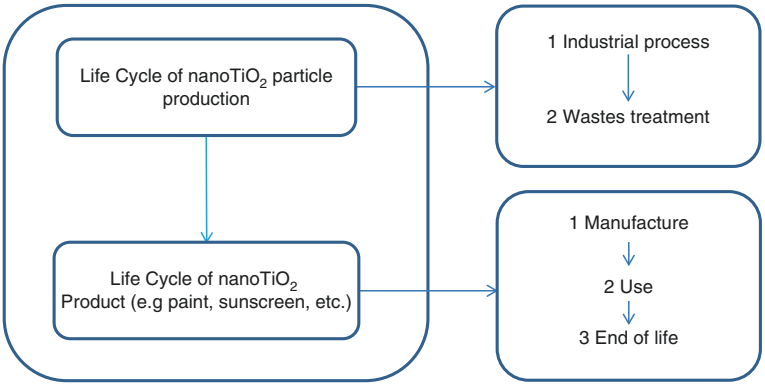
Life cycle assessment (LCA) is a standard tool/method (ISO14040, 14044 -2006-) which aims at addressing environmental problems of a product over its life cycle (from cradle to grave).

In the context of nano-TiO_2, the term "life cycle" can be applied to the step of the NP production on its own, which includes an industrial process phase and a waste treatment phase, or it can be applied to the step of nanoparticles incorporation.



Introduction: Framework and Concept

Nano-TiO_2 represents the second most important part of ENM production worldwide (550–5,500 t/year) and in Europe (55–3,000 t/year) and the most important part in the USA (7,800–38,000 t/year). In the environment, TiO_2 is a mineral which can be found in the state of ilmenite ($FeTiO_3$), rutile (TiO_2), sphene ($CaSiTiO_5$), etc., ilmenite and rutile being the predominant forms of TiO_2, which occurs as three different crystalline phases: anatase, rutile, and brookite. Anatase and rutile are the most commonly encountered ones. At the macroscale [250–350 nm], TiO_2 is used as a pigment for surface coatings, for example, but also in non-pigment applications as a fluxing agent, slag former, etc. At the nanoscale [$<$100 nm], TiO_2 is not inert and finds its applications as a UV light attenuator and as a catalyst. Emerging applications of nano-TiO_2 use its conductive, catalytic, and photocatalytic properties for applications in environmental remediation, including degradation or adsorption of contaminants from surface water, groundwater, and air. However, even if more and more studies were performed on nano-TiO_2 in the last decade, high uncertainties remain regarding their fate and behavior in the environment and their toxicological effects. High uncertainties also remain regarding the methodological approaches to model these parameters in the aim of assessing their environmental impacts and their risks. Consequently, a framework able to deal with these uncertainties is needed for the environmental assessment of nano-TiO_2.



Several tools are used to understand the environmental impacts of products or substances, such as substance flow analysis (SFA), chemical risk assessment, and life-cycle assessment. These tools include the whole life cycle of the product or substance in their analysis. LCA, described as an environmental impact assessment tool for products, processes, or services over their whole life cycles [8], and risk assessment (RA), defined as the process of assessing magnitudes and probabilities of human activities or natural catastrophes adverse effects, are two methodologies used to assess the impacts and risks of substances in the environment. Today, there is consensus among scientists on combining these two tools in order to overcome their respective limitations. LCA is conducted in four stages following the requirements of the ISO 14040: the determination of the goal, scope, and system boundaries, the inventory analysis of inputs and outputs, the assessment of environmental impacts, and the interpretation of results with proposals for improvement (Fig. 1).

The term "life cycle" refers to the extraction and transformation of raw materials, as well as the manufacture, the transformation, and the distribution, use, and end-of-life steps of products.

In the context of nano-TiO_2 (Fig. 2), the term "life cycle" can be applied to the step of the NP production on its own, which includes an industrial process phase and a waste treatment phase, or it can be applied to the step of nanoparticle incorporation into different nanomaterials which are

Nano-TiO_2 Life-Cycle Assessment Perspective, Fig. 1 Life-cycle assessment framework [8]

Nano-TiO_2 Life-Cycle Assessment Perspective, Fig. 2 LCA methodological approach of nano-TiO_2

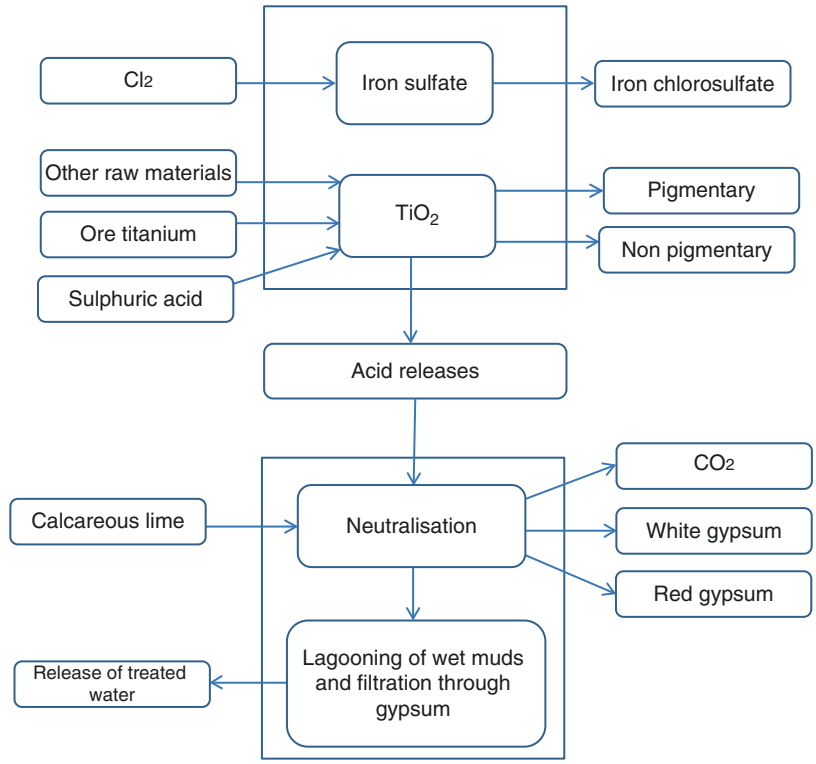
then used in different products. In this case the cycle includes the manufacture, the use, and the end of life of the nanoproduct. The term "life cycle" can also consider both nanoparticle and nanoproduct LCAs, which are then the two subsystems of the global life cycle.

This entry presents in the first section the life-cycle assessment methodological approach of the nano-TiO_2 particle production and in the second section the current research on the parameters needed for determining the nano-TiO_2 characterization factor in their life-cycle impact assessment.

Life-Cycle Assessment Applied to a TiO_2 NP Production Site

Goal and Scope of the Study

The LCA was conducted following the requirements of the ISO 14040 [8] with this aim of quantifying the environmental impacts related to an industrial TiO_2 production site. In this case the system could be illustrated as in Fig. 3, taking into account both the production process and the treatment of acid effluents.



Focusing on the production workshop, the limits of the studied system are represented in Fig. 4. Two sectors are under study: the first one called "black part" includes titanium ore (as input) and its successive treatments, excluding fabrication of iron chlorosulfate from the scope of the study. At the exit of this first sector, a solution of titanyl sulfate has been obtained and can then be treated in a second sector called "white part," including the hydrolysis of the solution leading to the crystallization of titanium dioxide and different washings removing impurities such as iron, chromium, or vanadium.

Then the titanium gel is moved towards different workshops according to the wanted final product. The "anatase" shop produces microparticles of titanium, whereas the "ultrafine" workshop produces nanoparticles of titanium, either on the GT or the DT production lines (Fig. 4).

The selected functional unit (FU), quantifying the function of the system and being the unit to which all impact factors are related, is 1 t of produced nanoparticles.

Data Inventory

A data inventory was obtained from the existing titanium production plant, from a functioning balance of a site among a 10-year period. These data

Nano-TiO_2 Life-Cycle Assessment Perspective, Fig. 3 Simplified scheme of TiO_2 industrial process and materials

came from a reliable source but are global and nonspecific to the nano-titanium workshop. However, it has been possible to distinguish some air emissions related to the "black sector," "white sector," and "ultrafine sector" and other air emissions (called global air sector) related to the other sectors of the plant. Concerning the wastewaters, the data are global (for the whole plant).

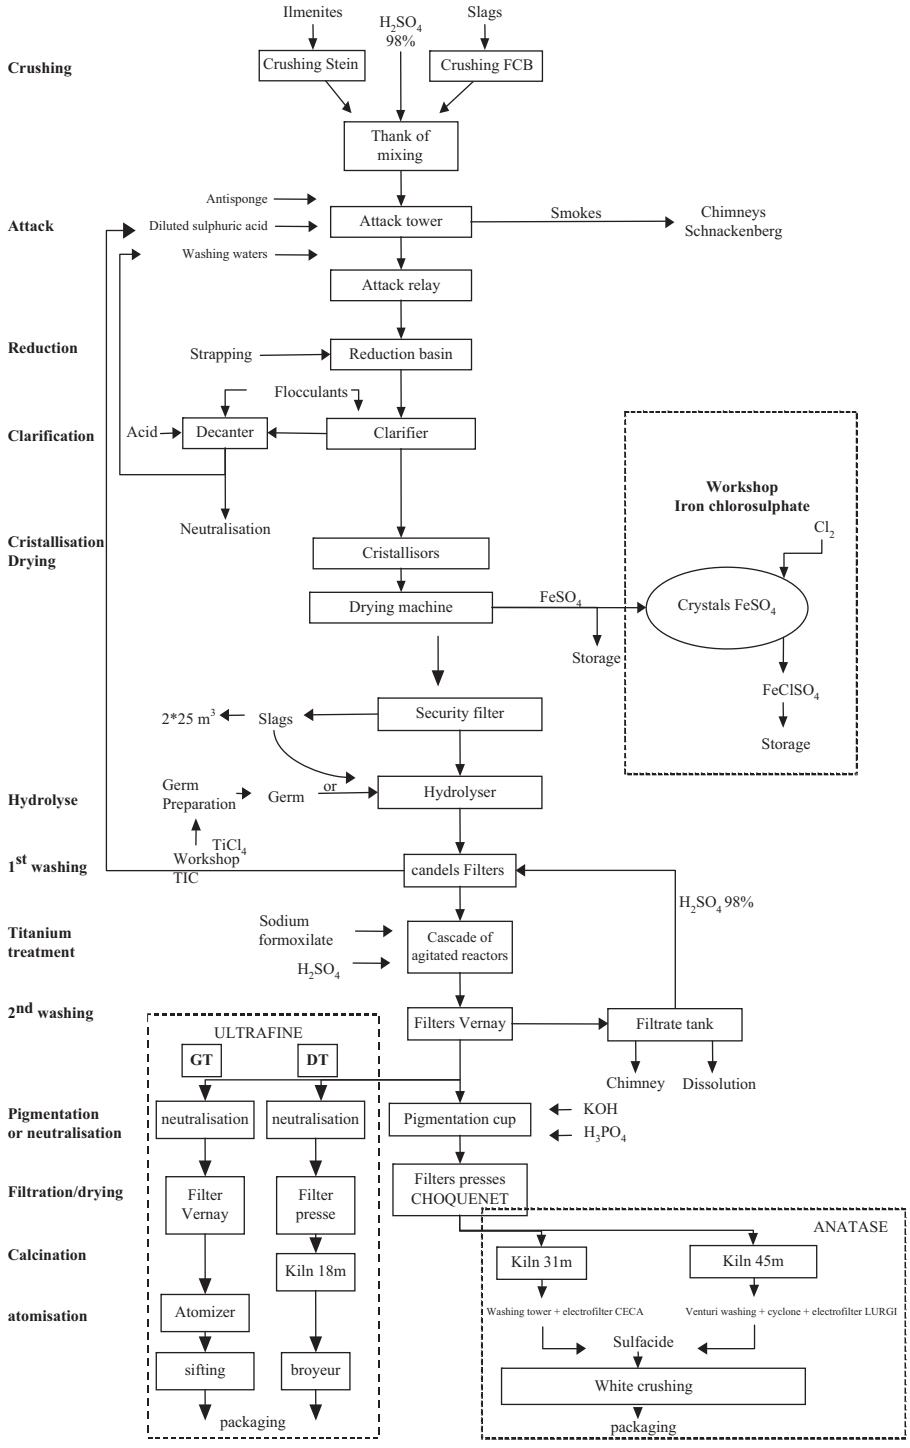
The data inventory is reported in Tables 1 and 2.

Impact Assessment

In the impact assessment stage (LCIA), inventory data are assigned to different impact categories. The calculation of category indicators (CIs) is achieved using characterization factors (CFs).

The category indicator is usually expressed with the following equation, which is the numerical expression of the life-cycle inventory result conversion (Eq. 1) [7]:

$$C_i = \sum_{e=1}^{e=m} \sum_{x=1}^{x=n} CF_{i,x,e} \cdot M_{x,e} \qquad (1)$$



where C_i is the impact score for category i, $M_{x,e}$ the substance mass (LCI results), and $CF_{i,x,e}$ the characterization factor of impact category i for substance x due to an emission to compartment e (dimensionless).

and

$$CF = EF \times FF \qquad (2)$$

where CF is the characterization factor of the impact category, EF is the effect factor of a substance x, and FF is the fate factor of the substance x.

Many LCIA calculation methods/models are available, each providing different CFs. In this study the LCA SIMAPRO software v.7.3.3 (Pre Consultants B.V) has been used with the Ecoinvent database within the program. The study performed an environmental evaluation according to the Impact 2002+ assessment method which offers an attractive implementation of a combined midpoint/damage approach via 14 midpoint categories to four damage categories

	Pollutant flows of TiO_2 particles kg/h: denox atomizer	0.026	0.133	0.687	0.28

but also according to EPD 2008 v1.03 which describes the environmentally relevant physical flows to and from a product system and its subsystems.

Thus, the environmental impact contributions of the **TiO_2 white sector**, the **TiO_2 black sector**, the **TiO_2 ultrafine sector**, the **TiO_2 global air**, and the **TiO_2 global wastewater** have been assessed (Fig. 5). This industrial system shows that impacts are related to the TiO_2 global air that is to say to the atmospheric emissions not assigned to white, black, or ultrafine sector but depending on the other workshops of the plant. The TiO_2 black sector induces no impact; this is due to low quantities of pollutants emitted that are negligible compared to other workshops. Concerning the "respiratory inorganic" effects, the TiO_2 white sector contributes to 50 % of the observed impacts, followed by TiO_2 global air (29 %) and the ultrafine workshop. The emissions of the TiO_2 white sector depend on the SO_2 emissions and on the ore dusts. The ultrafine shop contributes to 21 % of this impact, but high uncertainty remains regarding the nano-TiO_2 particle fate and behavior in the environment and their toxicological effects. For the "respiratory organic" effects, which include all the carbon-based molecules, the TiO_2 global air sector

Analysis 1p "Global Industrial process" Method Impact 2002+/Characterization

Analysis 1p "Global Industrial process" Method EPD 2008/Characterization

Nano-TiO_2 Life-Cycle Assessment Perspective, Fig. 5 Impact assessment results

represents 100 % of this impact category. The different workshops of the industrial process should contribute to this impact category, but due to the lack of data, it was impossible to quantify their emissions and the different contributing molecules. The terrestrial and aquatic acidification depends on SO_2, NO_x, and chlorine emissions which have effects in series, the TiO_2 "global air" subsystem generating the highest impact. In the other workshops, SO_2 alone contributes to these categories, implying a moderated influence. Regarding the aquatic acidification, a question remains about the non-contribution of the TiO_2 global wastewater to this impact, as it has been noted that chlorine was released into water. The global warming is due to the emissions of the TiO_2 global air sector: CO_2, CO, CH_4, and NMVOC (non-methane volatile organic compounds). The data allowing the assessment of the global warming by sector (black and white sectors) being unavailable, only the global warming applied to the whole process has been appreciated.

The results obtained with the EPD 2008 method are illustrated for four impact categories: global warming, photochemical oxidation, aquatic acidification, and eutrophication (Fig. 5). The TiO_2 global air part induces most of the calculated impact. Concerning the global warming and the aquatic acidification, the results are similar to those of the Impact 2002+ method. The contribution to the eutrophication impact category is of 40 % for the TiO_2 global wastewater sector and 60 % for the TiO_2 global air sector, NO_x, N_2O, and Ptotal being the main contributors. Other molecules have only a limited influence in this process. These are releases induced by the whole site, so the analysis is not limited to the production of nano-TiO_2.

Conclusion of the Study

The LCA approach can provide useful information about the main environmental impacts, but the main problem encountered is the lack of data. During the study, the difficulties are of different orders, linked to databases or physicochemical characterization of nanoparticles. The lack of data for each manufacturing process has failed to allow a cross-process comparison: apart from a few sectoral data, most of the data was aggregated over the whole production site. This study focuses on a specific TiO_2 life-cycle stage excluding the effect and the fate of nano-TiO_2 because of the lack of information. The impact calculations are based only on the inputs and outputs of the process (excluding nanoparticles). LCA needs experimental data on characteristics and toxicity of nano-TiO_2 to address all life-cycle stages. It seems necessary to determine which of their properties need to be characterized in priority.

Overview of Necessary Data to Complete a Nano-TiO_2 LCA

The behavior of TiO_2 NMs in environmental compartments relies on their specific properties. Among them, seven have been identified as primordial: crystal phase, shape, primary (as received) size and size distribution, subsequent aggregation state, number concentration, surface area, and surface reactivity (charge and chemistry). This section shows how these characteristics are interrelated and why they are important in the modeling of TiO_2 NP behavior in biotic and abiotic media.

Crystal Phase

TiO_2 is naturally present in three different crystalline phases; the different lattice structures induce differences in mass densities and in reactivity. These differences in reactivity lead to different modes of toxicity. For example, amorphous TiO_2 can produce more reactive oxygen species (ROS) and oxidative stress to organisms than anatase. However, it has been pointed out that the media in which NPs are placed play a role in the generation of ROS.

Shape

In water, the shape of NMs, and the volume they occupy, will mostly influence their gravitational settling, their collision frequencies, and their aggregation. This will affect their sedimentation and finally their final concentrations in the water column and in the sediment. On a toxicity viewpoint, it has been proposed that "fibers" (particles with a diameter-to-length ratio higher than 1:3) have "extended" dimensions and generally lead to

inflammatory responses of the immune system. Thin fibers have a small aerodynamic diameter and can be deposited beyond the ciliated airways in the respiratory tract, but they cannot be entirely processed by immune processes such as phagocytosis [2, 3]. It has also been found that TiO_2 NMs with a length higher than 15 μm cannot be processed by lung macrophages, leading to inflammation [6].

Size and Size Distribution

Smaller particles present higher surface/mass ratio, also called specific surface area. So by definition, the variation of the size of a particle affects its specific surface area. Higher specific surface area leads to higher reactivity, although this phenomenon can be altered by coatings. Thus, a diminution in size has been found to enhance aggregation of spherical anatase TiO_2 NPs and sorption of organic matter. Size also influences the NP dissolution rates, through surface area, surface curvature, and roughness, and alters their transport. A decrease in size will lead to higher diffusion velocity, while increasing size induces higher gravitational settling.

In soils, larger aggregates are more influenced by gravity forces and are more likely to attach to soil particles. These large aggregates are prone to pore straining and may lead to soil clogging.

The point of zero charge (PZC) can be assimilated to the surface charge of nanoparticles (see section "Surface Charge and Chemistry"). It also appears to be affected by the size of the NPs. It has been shown that the PZC of rutile and anatase TiO_2 NPs increases towards higher pH values with decreasing size in water, whatever the shape of the NPs. Nano-TiO_2 aggregates when the solution pH is close to the PZC, whereas nano-TiO_2 remains free at very basic and very acidic pH values.

In organisms, the size of NMs affects their toxicity firstly because of their different transport abilities. Smaller particles will be deposited further in the respiratory tract, passing through the ciliated airways, and will have more ability to pass cell membranes and enter the blood circulation. In the same way, smaller TiO_2 NPs (smaller primary diameter) penetrate deeper into the wheat root and are more readily translocated to the shoot of the plant [15]. Decreasing particle size also induces more structural defects and more reactive groups on the surface, leading to prooxidant effects. An increased toxicity of TiO_2 NPs has been found to *Escherichia coli* and *Pseudomonas aeruginosa* with size decreasing from 30 to 10 nm [9]. Similarly, an increased cytotoxicity of TiO_2 NPs has been showed with decreasing size in murine macrophages, which was related to increasing surface area [20].

However, several studies demonstrated that the assumption that smaller particles induce higher toxicity is not true in all cases [11, 17, 19].

Specific Surface Area

The specific surface area of NPs does not depend only on their size but also on their porosity and surface roughness. Higher specific surface area (surface over mass ratio) leads to enhanced reactivity (e.g., dissolution and aggregation), and it can induce higher deposition on soil particles. Higher specific surface area also induces higher biologic activity per given mass of NP.

Thus, numerous links have been found between specific surface area and NP toxicity, and it is considered as a critical driver of NP toxicity. However, current sampling and analysis methodologies rely on the mass of substances.

Surface Charge and Chemistry

The surface charge of NPs is affected by the pH and the ionic strength of the surrounding medium. It is measured as the zeta potential, which is "the potential at the slipping plane that separates the stationary and mobile phases in tangential flow of the liquid with respect to the surface" [12]. The z-potential is one of the factors controlling electrostatic repulsion: increasing net charge of the surface leads to increasing repulsion between NPs and to lower aggregation rates. A null z-potential is referred to as the point of zero charge (PZC) and favors aggregation; suspensions are said to be stable when the zeta potential of the NPs is higher than 30 mV in absolute value. The charge of NPs also controls their transport in porous media, and it has been shown that positively charged NPs were more readily retained into a sand or soil column than negatively charged particles.

The z-potential of NPs influences their oxidative potential and the production of ROS, inducing increased cytotoxicity and inflammatory effects with increasing charge. However, it has been pointed out that even if increasing charge usually leads to easier uptake of NPs by lysosomes and increased cytotoxicity, z-potential is not a predictor of nanotoxicity, because the charge at specific spots of the NP surface is also a significant contributor to toxicity, as they will determine precisely their penetration into cells.

The solubility of NPs is also an important parameter to take into account when assessing their toxicity. Firstly, it conditions their persistence in the media and in the organism. Secondly, the release of ions increases the oxidative potential and prooxidant effects. Finally, the ions themselves can be toxic, depending on the composition of the NP and on the target organism. TiO_2 NP solubility is low, so that they tend to accumulate in soils and water, leading to high potential bioaccumulation in organisms.

Concentration

Concentration is usually expressed as a mass/volume ratio. However, in the case of NMs, the mass might not be the best metric to use in fate modeling and toxicity assays. Indeed, it has been showed that for the same mass dose, NPs induce higher toxicity than their bulk counterparts, due to higher specific surface area. Debate is still ongoing about the best metric to use, but particle number concentration and available surface area appear as best appropriate. However, Pauluhn [16] showed that the mass-based exposure intensity (actual concentration × duration of exposure) of NPs is a better dose metric for lung burden than surface area (BET surface area × duration of exposure). No correlation between the pulmonary toxicity of TiO_2 NPs to rats and the surface area of the NPs has been found. This could be due to the high aggregation state that was reported.

On the one hand, higher number concentration of particles in a same volume leads to higher collision rates and to higher aggregation rates. The size of NM aggregates is then increased, and deposition is enhanced. Higher number concentration also induces higher chances of contact with organisms and higher potential toxicity. On the other hand, if the NP aggregates are large enough, their entrance in organisms, e.g., via dermal penetration, may be less likely.

Agglomeration and Aggregation State

Larger particles and aggregates tend to bind more weakly than smaller ones. The type of forces entailed in aggregation is determined by the size of the NPs. If the forces between particles are weak, then the attraction process is called agglomeration; in contrary when the forces are stronger, the process is called aggregation. It was found that aggregates of 21 nm NPs present weaker bounds than 5 nm NPs, thus deagglomerating more readily and resulting in a higher final pulmonary toxicity than that of 21 nm NPs [10].

NP aggregation state and their size distribution are important parameters controlling their behavior. Larger aggregates have a higher mass and higher volume than the NPs they are composed of, so they are more affected by the gravitational and buoyant forces acting on them, leading to enhanced settling rate. On the opposite, their diffusion is decreased with increasing size. The aggregation state also affects the surface area of the NM: large and dense aggregates have smaller specific surface area than porous and small aggregates, leading to lower reactivity. Moreover, larger aggregates are more readily filtered in porous media and show higher retention in sand and soil.

The aggregation state of NPs also affects their biouptake. It is generally considered that larger aggregates penetrate less easily into organisms. Furthermore, Li et al. [13] showed that heteroaggregation of TiO_2 NPs with algal cells lead to decreasing food availability and quality for *Ceriodaphnia dubia*.

This section shows that there is no absolute trend determining what property explains best the TiO_2 NM behavior. It is clear that the chemical composition and crystal phase should be determined in priority, but other properties such as size, particle number, and surface area are important in the understanding of the NM behavior, and many of them are intermingled. Adapted exposure and TiO_2 fate modeling are necessary to assess the environmental impact of TiO_2 NM during all life-cycle stages.

Conclusion

Today there is consensus among authors that large benefits arise from the combination of LCA and RA approaches. This combination could help at identifying the fate and effect factors which determine the characterization factor of an impact category and at calculating exposure levels and the potential damage of NPs on environment and human health along the life cycle.

Combining RA and LCA would allow overcoming their respective limitations. Indeed, environmental risk assessment (ERA) generally considers ecotoxicity only, so that negative impacts on other categories (such as climate change) that could arise from the mitigation of ecotoxicity are not acknowledged. The wide range of impact categories in LCA allows stakeholders to have a more comprehensive view of the system under study [1]. In the same way, the consideration of all emissions over the whole life cycle of the substance, as it is the case in LCA, would make RA a more powerful decision support [4, 5, 14] and would also allow improving the life-cycle processes [18]. The time- and site-specific design of ERA would also benefit to LCA, reducing result uncertainties.

Definition

The word "Tribology" was coined in 1966. It is derived from the Greek word *tribos*, meaning rubbing so the literal translation would be the science of rubbing. However, it encompasses studies of surface characterization, adhesion, friction, wear, and lubrication. According to Webster dictionary, Tribology is defined as the science and technology of interacting surfaces in relative motion and of the related subjects and practices. Tribology is an interdisciplinary field. Rather complex surface interactions in a tribological interface require knowledge of various disciplines including physics, chemistry, mechanical engineering, solid mechanics, materials science, rheology, applied mathematics, and reliability. At most interfaces of technological relevance, contact occurs at numerous asperities. It is of importance to investigate a single asperity contact in the fundamental tribological studies and thus emphasizing the importance of nanotribology.

Introduction

The mechanisms and dynamics of the interactions of two contacting solids during relative motion, ranging from atomic- to microscale, need to be understood in order to develop fundamental understanding of adhesion, friction, wear, indentation, and lubrication processes. For most solid–solid interfaces of technological relevance, contact occurs at multiple asperities. Consequently, the importance of investigating single asperity contacts in studies of the fundamental micro/nanomechanical and micro/nanotribological properties of surfaces and interfaces has long been recognized. The recent emergence and proliferation of proximal probes, in particular scanning probe microscopes (the scanning tunneling microscope and the atomic force microscope), the surface force apparatus, and of computational techniques for simulating tip-surface interactions and interfacial properties, has allowed systematic investigations of interfacial problems with high resolution as well as ways and means for modifying and manipulating nanoscale structures. These advances have led to the appearance of the new field of nanotribology, which pertains to experimental and theoretical investigations of interfacial processes on scales ranging from the atomic- and molecular-scale to the microscale, occurring during adhesion, friction, scratching, wear,

Nanotribology, Table 1 Comparison of typical operating parameters in SFA, STM and AFM/FFM used for micro/nanotribological studies

Operating parameter	SFA	STM[a]	AFM/FFM
Radius of mating surface/tip	~10 mm	5–100 nm	5–100 nm
Radius of contact area	10–40 μm	N/A	0.05–0.5 nm
Normal load	10–100 mN	N/A	<0.1–500 nN
Sliding velocity	0.001–100 μm/s	0.02–200 μm/s (scan size ~ 1 × 1 nm to 125 × 125 μm; scan rate <1–122 Hz)	0.02–200 μm/s (scan size ~ 1 × 1 nm to 125 × 125 μm; scan rate <1–122 Hz)
Sample limitations	Typically atomically–smooth, optically transparent mica; opaque ceramic, smooth surfaces can also be used	Electrically-conducting samples	None of the above

indentation, and thin-film lubrication at sliding surfaces [2, 4–8, 10–12, 15, 18, 22, 25]. Proximal probes have also been used for mechanical and electrical characterization, in situ characterization of local deformation, and other nanomechanics studies.

Nanotribological and nanomechanics studies are needed to develop fundamental understanding of interfacial phenomena on a small scale and to study interfacial phenomena in micro/nanostructures used in magnetic storage devices, nanotechnology, and other applications [1–12]. Friction and wear of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally coated with molecularly thin films. Nanotribological and nanomechanics studies are also valuable in the fundamental understanding of interfacial phenomena in macrostructures, and provide a bridge between science and engineering.

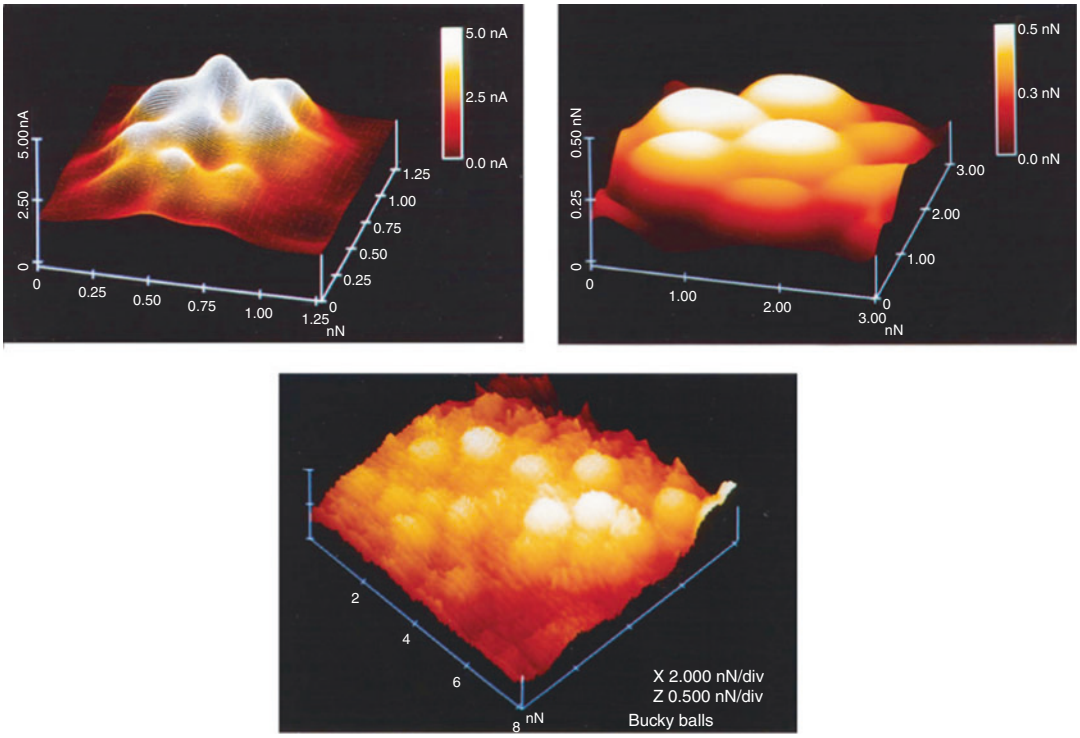
The surface force apparatus (SFA), the scanning tunneling microscopes (STM), atomic force and friction force microscopes (AFM and FFM) are widely used in nanotribological and nanomechanics studies. Typical operating parameters are compared in Table 1. The SFA was developed in 1968 and is commonly employed to study both static and dynamic properties of molecularly thin films sandwiched between two molecularly smooth surfaces. The STM, developed in 1981, allows imaging of electrically conducting surfaces with atomic resolution, and has been used for imaging of clean surfaces as well as of lubricant molecules. The introduction of the AFM in 1985 provided a method for measuring ultra-small forces between a probe tip and an engineering (electrically conducting or insulating) surface, and has been used for morphological and surface roughness measurements of surfaces on the nanoscale, as well as for adhesion measurements. Subsequent modifications of the AFM led to the development of the FFM, designed for atomic-scale and microscale studies of friction. This instrument measures forces in the scanning direction. The AFM is also being used for various investigations including scratching, wear, indentation, detection of transfer of material, boundary lubrication, and fabrication and machining. Meanwhile, significant progress in understanding the fundamental nature of bonding and interactions in materials, combined with advances in computer-based modeling and simulation methods, has allowed theoretical studies of complex interfacial phenomena with high resolution in space and time. Such simulations provide insights into atomic-scale energetics, structure, dynamics, thermodynamics, transport, and rheological aspects of tribological processes.

The nature of interactions between two surfaces brought close together, and those between

Nanotribology, Fig. 1 Schematics of an engineering interface and scanning probe microscope tip in contact with an engineering interface

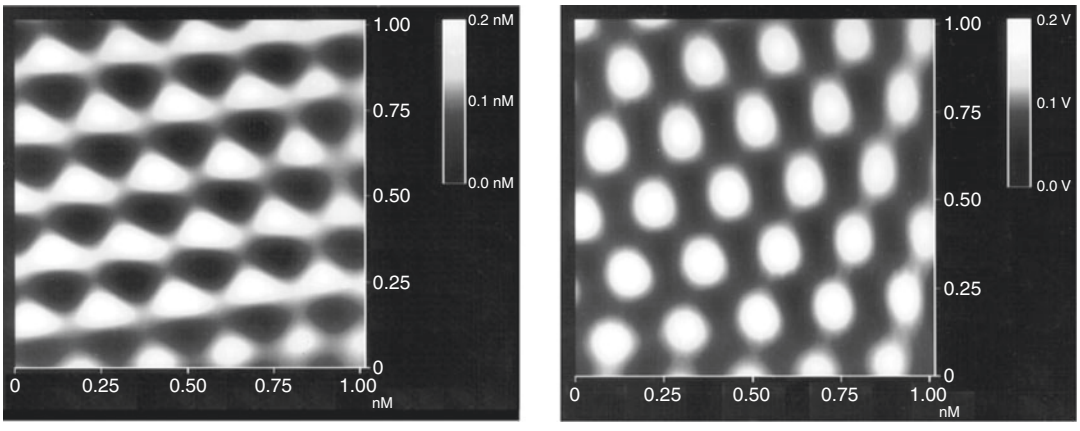
two surfaces in contact as they are separated, have been studied experimentally with the surface force apparatus. This has led to a basic understanding of the normal forces between surfaces, and the way in which these are modified by the presence of a thin liquid or a polymer film. The frictional properties of such systems have been studied by moving the surfaces laterally, and such experiments have provided insights into the molecular-scale operation of lubricants such as thin liquid or polymer films. Complementary to these studies are those in which the AFM tip is used to simulate a single asperity contact with a solid or lubricated surface, Fig. 1. These experiments have demonstrated that the relationship between friction and surface roughness is not always simple or obvious. AFM studies have also revealed much about the nanoscale nature of intimate contact during wear, indentation, and lubrication.

Overview



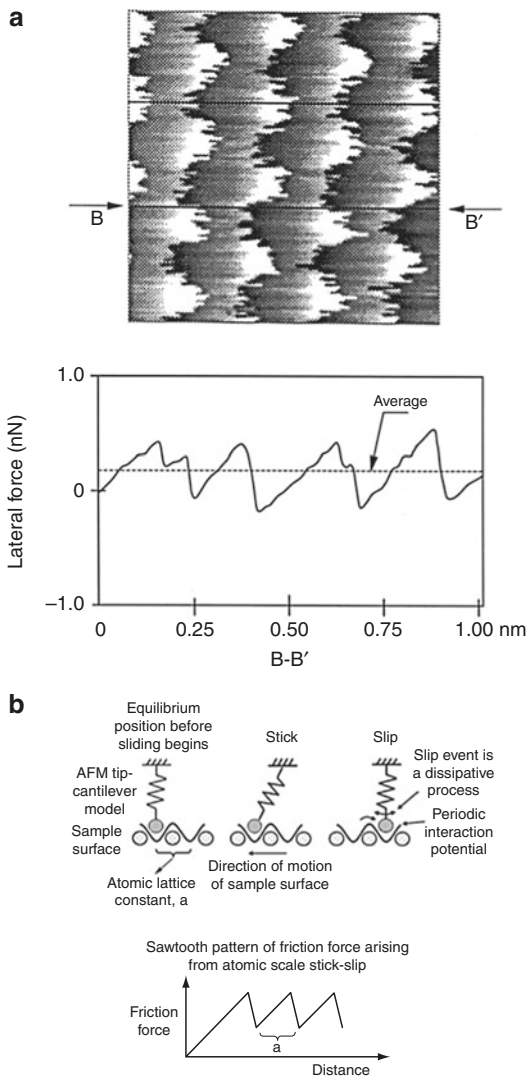
Surface Imaging, Friction, and Adhesion

Surface height imaging down to atomic resolution of electrically conducing surfaces can be carried out using an STM. An AFM can also be used for surface height imaging and roughness characterization down to nanoscale. Figure 2 shows a sequence of STM images at various scan sizes of solvent-deposited C60 film on a 200-nm thick gold-coated freshly cleaved mica [13]. The film consists of clusters of C60 molecules with 8 nm in diameter. The C60 molecules within a cluster appear to pack in a hexagonal array with a spacing of about 1 nm; however, they do not follow any long range order. The measured cage diameter of the C60 molecule is about 0.7 nm, very close to the projected diameter of 0.71 nm.



In an AFM measurement during surface imaging, the tip comes in intimate contact with the sample surface and leads to surface deformation with finite tip-sample contact area (typically few atoms). The finite size of contact area prevents the imaging of individual point defects, and only the periodicity of the atomic lattice can be imaged. Figure 3 shows the topography image of freshly cleaved surface of highly oriented pyrolytic graphite (HOPG) [24]. The periodicity of the graphite is clearly observed.

To study friction mechanisms on an atomic scale, a freshly cleaved HOPG has been studied by Mate et al. [21] and Ruan and Bhushan [24]. Figure 4a shows the atomic-scale friction force map (raw data), and Fig. 3 shows the friction force maps (after 2D spectrum filtering with high frequency noise truncated) [24]. Figure 4a also shows line plot of friction force profiles along some crystallographic direction. The actual shape of the friction profile depends upon the spatial location of axis of tip motion. Note that a portion of atomic-scale lateral force is conservative. Mate et al. [21] and Ruan and Bhushan [24] reported that the average friction force linearly increased with normal load and was reversible with load. Friction profiles were similar during sliding of the tip in either direction.



During scanning, the tip moves discontinuously over the sample surface and jumps with discrete steps from one potential minimum (well) to the next. This leads to a saw-tooth-like pattern for the lateral motion (force) with a periodicity of the lattice constant. This motion is called stick–slip movement of the tip [5, 8, 12, 21, 23]. The observed friction force includes two components – conservative and periodic, and nonconservative and constant. If the relative motion of the sample and tip were simply that of two rigid collections of atoms, the effective force would be a conservative force oscillating about zero. Slow reversible elastic deformation would

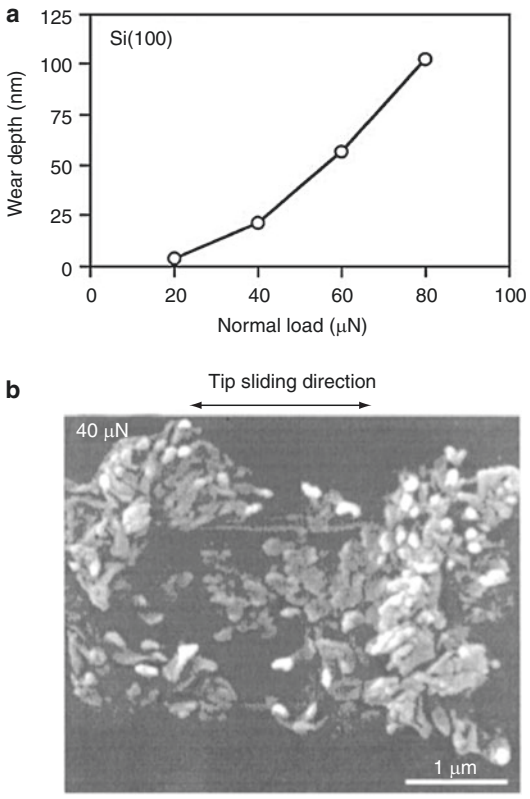
Nanotribology, Fig. 3 *Gray*-scale plots of surface topography and friction force maps (2D spectrum filtered), measured simultaneously, of a 1 × 1 nm area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction



Nanotribology, Fig. 4 (**a**) *Gray* scale plot of friction force map (raw data) of a 1×1 nm^2 area of freshly cleaved HOPG, showing atomic-scale variation of friction force. High points are shows by *lighter color*. Also shown is line plot of friction force profile along the line indicated by *arrows*. The normal load was 25 nN and the cantilever normal stiffness was 0.4 N/m [23], and (**b**) schematic of a model for a tip atom sliding on an atomically flat periodic surface. The schematic shows the tip jumping from one potential minimum to another, resulting in stick–slip behavior

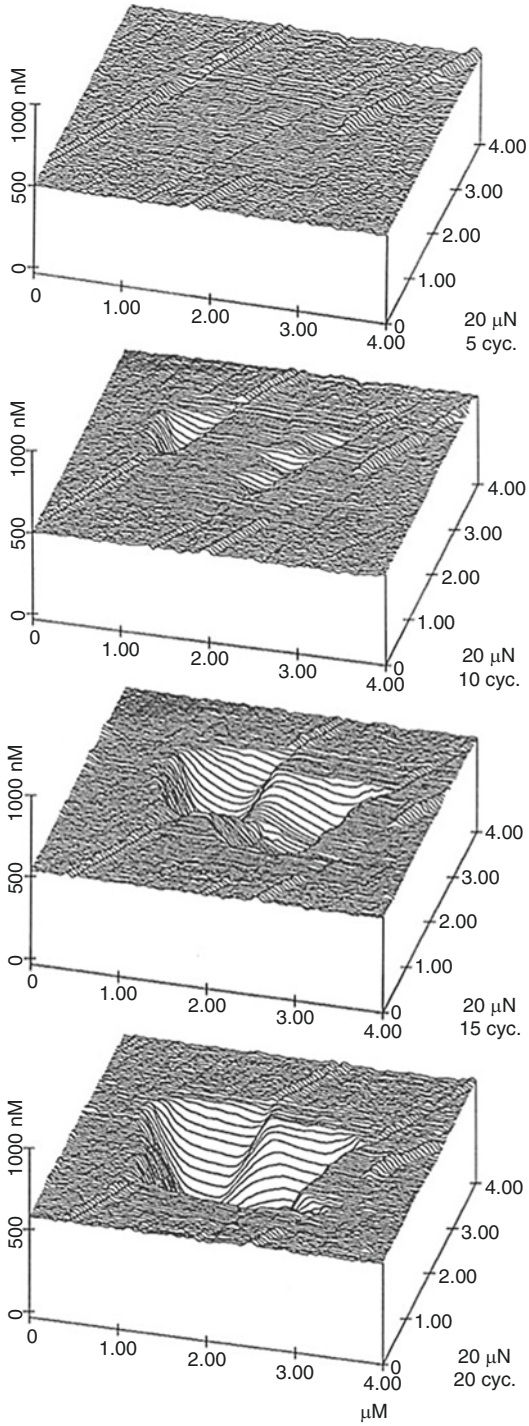
also contribute to conservative force. The origin of the nonconservative direction-dependent force component would be phonon generation, viscous dissipation, or plastic deformation.

The stick–slip on the atomic scale discussed above is the result of the energy barrier required to be overcome for jumping over the atomic corrugations on the sample surface. It corresponds to the energy required for the jump of the tip from a stable equilibrium position on the surface into a neighboring position. The perfect atomic regularity of the surface guarantees the periodicity of the lateral force signal, independent of actual atomic structure of tip apex. Few atoms (based on the magnitude of the friction force, less than 10), on a tip sliding over an array of atoms on the sample, are expected to go through the stick–slip. For simplicity, Fig. 4b shows a simplified model for one atom on a tip with a one-dimensional spring mass system. As the sample surface slides against the AFM tip, the tip remains "stuck" initially until it can overcome the energy (potential) barrier, which is illustrated by a sinusoidal interaction potential as experienced by the tip. After some motion, there is enough energy stored in the spring which leads to "slip" into the neighboring stable equilibrium position. During the slip and before attaining stable equilibrium, stored energy is converted into vibrational energy of the surface atoms in the range of 1,013 Hz (phonon generation) and decays within the range of 10–11 s into heat. (A wave of atoms vibrating in concert is termed a phonon.) The stick–slip phenomenon, resulting from irreversible atomic jumps, can be theoretically modeled with classical mechanical models [27, 28]. The Tomanek-Zhong-Thomas model [27] is the starting point for determining friction force during atomic scale stick–slip. The AFM model describes the total potential as the sum of the potential acting on the tip due to interaction with the sample and the elastic energy stored in the cantilever. Thermally activated stick–slip behavior can explain the velocity effects on friction.

Wear

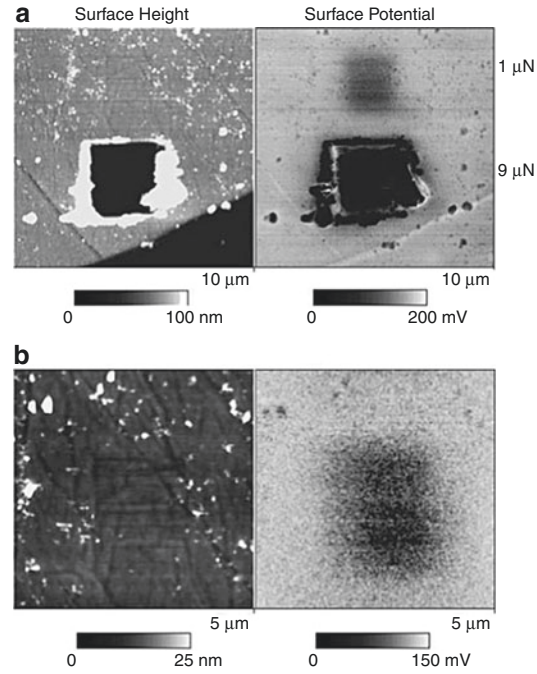
By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. Figure 5a shows the effect of normal load on wear depth on Si(100). Note that wear depth is very small below 20 μN of normal load [29]. A normal load of 20 μN corresponds to contact stresses

Nanotribology, Fig. 5 (**a**) Wear depth as a function of normal load for Si(100) after one cycle [29], and (**b**) secondary electron image of wear mark and debris for Si(100) produced at a normal load of 40 μN and one scan cycle



comparable to the hardness of silicon. Primarily, elastic deformation at loads below 20 μN is responsible for low wear. Uniform material removal at the bottom of the wear mark has been reported. An AFM image of the wear mark shows small debris at the edges, probably swiped during AFM scanning. This indicates that the debris is loose (not sticky) and can be removed during the AFM scanning.

Next, the mechanisms of material removal were examined on a microscale in AFM wear experiments [29]. Figure 5b shows a secondary electron image of the wear mark and associated wear particles. The specimen used for the scanning electron microscope (SEM) was not scanned with the AFM after initial wear, in order to retain wear debris in the wear region. Wear debris is clearly observed. In the SEM micrographs, the wear debris appears agglomerated because of high surface energy of the fine particles. Particles appear to be a mixture of rounded and so-called cutting type (feather-like or ribbon-like material). Zhao and Bhushan [29] reported an increase in the number and size of cutting type particles with the normal load. The presence of cutting type particles indicates that the material is removed primarily by plastic deformation.



To better understand the material removal mechanisms, Zhao and Bhushan [29] used transmission electron microscopy (TEM). The existence of dislocation arrays observed by them confirms that material removal occurs by plastic deformation. It is concluded that the material on microscale at high loads is removed by plastic deformation with a small contribution from elastic fracture.

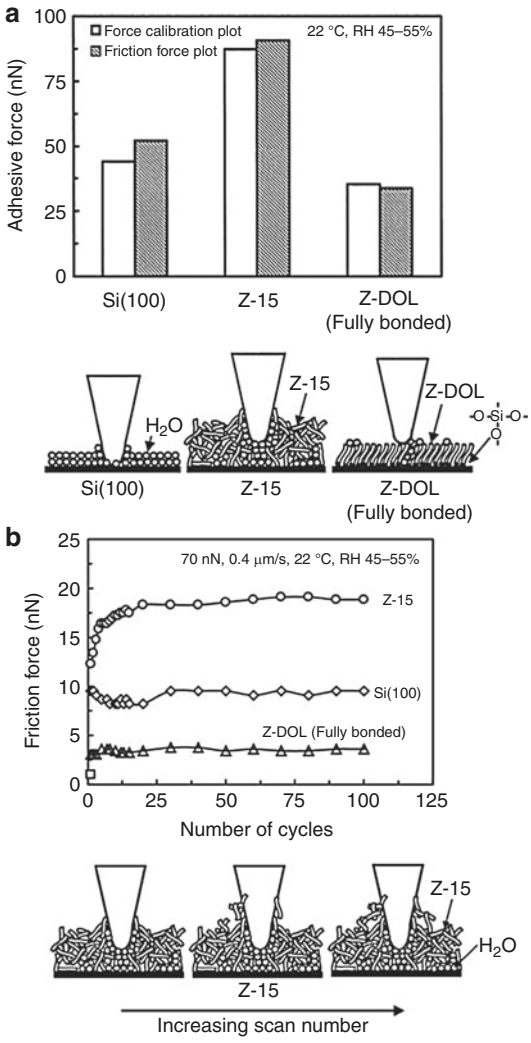
To understand wear mechanisms, evolution of wear can be studied using AFM. Figure 6 shows evolution of wear marks of a DLC-coated disk sample. The data illustrate how the microwear profile for a load of 20 μN develops as a function of the number of scanning cycles [14]. Wear is not uniform, but is initiated at the nanoscratches. Surface defects (with high surface energy) present at nanoscratches act as initiation sites for wear. Coating deposition also may not be uniform on and near nanoscratches which may lead to coating delamination. Thus, scratch-free surfaces will be relatively resistant to wear.

Wear precursors (precursors to measurable wear) can be studied by making surface potential measurements [17]. The contact potential difference, or simply the surface potential between two surfaces depends on a variety of parameters such as electronic work function, adsorption, and oxide layers. The surface potential map of an interface gives a measure of changes in the work function which is sensitive to both physical and chemical conditions of the surfaces including structural and chemical changes. Before material is actually removed in a wear process, the surface experiences stresses that result in surface and subsurface changes of structure and/or chemistry. These can cause changes in the measured potential of a surface. An AFM tip allows mapping of surface potential with nanoscale resolution.

Nanotribology, Fig. 6 Surface plots of diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated [14]

Nanotribology, Fig. 7 (**a**) Surface height and change in surface potential maps of wear regions generated at 1 μN (*top*) and 9 μN (*bottom*) on a single crystal aluminum sample showing bright contrast in the surface potential map on the worn regions. (**b**) Close up of *upper* (low load) wear region [17]

Surface height and change in surface potential maps of a polished single-crystal aluminum (100) sample, abraded using a diamond tip at loads of 1 and 9 μN, are shown in Fig. 7a (Note that the sign of the change in surface potential is reversed here from that in DeVecchio and Bhushan [17]). It is evident that both abraded regions show a large potential contrast (∼0.17 V), with respect to the non-abraded area. The black region in the lower right-hand part of the topography scan shows a step that was created during the polishing phase. There is no potential contrast between the high region and the low region of the sample, indicating that the technique is independent of surface height. Figure 7b shows a close up scan of the upper (low load) wear region in Fig. 7a. Notice that while there is no detectable change in the surface topography, there is nonetheless, a large change in the potential of the surface in the worn region. Indeed, the wear



mark of Fig. 7b might not be visible at all in the topography map were it not for the noted absence of wear debris generated nearby and then swept off during the low load scan. Thus, even in the case of zero wear (no measurable deformation of the surface using AFM), there can be a significant change in the surface potential inside the wear mark which is useful for the study of wear precursors. It is believed that the removal of the thin contaminant layer including the natural oxide layer gives rise to the initial change in surface potential. The structural changes, which precede generation of wear debris and/or measurable wear scars, occur under ultra-low loads in the top few nanometers of the sample, and are primarily responsible for the subsequent changes in surface potential.

Boundary Lubrication

The classical approach to lubrication uses freely supported multimolecular layers of liquid lubricants [1, 5, 8, 16]. The liquid lubricants are sometimes chemically bonded to improve their wear resistance [1, 5, 8]. Partially chemically-bonded, molecularly-thick perfluoropolyether (PFPE) films are used for lubrication of magnetic storage media because of their thermal stability and extremely low vapor pressure [1]. Chemically-bonded lubricants are considered as potential candidate lubricants for MEMS/NEMS. Molecularly-thick PFPEs are well suited because of the following properties: low surface tension and low contact angle which allow easy spreading on surfaces and provide hydrophobic properties; chemical and thermal stability which minimize degradation under use; low vapor pressure which provides low out-gassing; high adhesion to substrate via organic functional bonds; and good lubricity which reduces contact surface wear.

For boundary lubrication studies, friction, adhesion, and durability experiments have been performed on virgin Si (100) surfaces and silicon surfaces lubricated with various PFPE lubricants [19, 26]. Results of two of the PFPE lubricants will be presented here, which are –Z-15 (with -CF_3 nonpolar end groups), CF_3–O–(CF_2–CF_2–O)$_m$–(CF_2–O)$_n$–CF_3 (m/n ∼ 2/3) and Z-DOL (with –OH polar end groups), HO–CH_2–CF_2–O–(CF_2–CF_2–O)$_m$–(CF_2–O)$_n$–CF_2–CH_2–OH (m/n ∼ 2/3). Z-DOL film was thermally bonded at 150 °C for 30 min and unbonded fraction was removed by a solvent (BW) [1]. The thicknesses of Z-15 and Z-DOL films were 2.8 and 2.3 nm, respectively. Lubricant chain diameters of these molecules are about 0.6 nm and molecularly thick film generally lie flat on surfaces with high coverage.

The adhesive forces of Si(100), Z-15, and Z-DOL (BW) measured by force calibration plot and friction force versus normal load plot are summarized in Fig. 8a [20]. The data obtained by these two methods are in good agreement. Figure 8(a) shows that the presence of mobile Z-15 lubricant film increases the adhesive force as compared to that of Si(100) by meniscus formation. Whereas, the presence of solid-like phase of the Z-DOL (BW) film reduces the adhesive force as compared to that of Si(100) because of the absence of mobile liquid. The schematic (bottom) in Fig. 8a shows relative size and sources of meniscus. It is well known that the native oxide layer (SiO_2) on the top of Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed on this surface. The condensed water will form meniscus as the tip approaches the sample surface. The larger adhesive force in Z-15 is not only caused by the Z-15 meniscus alone, the non-polarized Z-15 liquid does not have good wettability and strong bonding with Si(100). Consequently, in the ambient environment, the condensed water molecules from the environment will permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules present on the substrate. The interaction of the liquid lubricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles. This dewetting allows water molecules to be adsorbed on the Si(100) surface along with Z-15 molecules. And both of them can form meniscus while the tip approaches to the surface. Thus the dewetting of liquid Z-15 film results in higher adhesive force and poorer lubrication performance. In addition, as the Z-15 film is pretty soft as compared to the solid Si(100) surface, and penetration of the tip in the film occurs while pushing tip down. This results in the large area of the tip wetted by the liquid to form the meniscus at the tip-liquid (mixture of Z-15 and water)

Nanotribology, Fig. 8 (**a**) Summary of the adhesive forces of Si(100) and Z-15 and Z-DOL (BW) films measured by force calibration plots and friction force versus normal load plots in ambient air. The schematic (*bottom*) showing the effect of meniscus, formed between AFM tip and the surface sample, on the adhesive and friction forces [19], and (**b**) Friction force versus number of sliding cycles for Si(100) and Z-15 and Z-DOL (BW) films at 70 nN, 0.4 μm/s, and in ambient air. Schematic (*bottom*) shows that some liquid Z-15 molecules can be attached onto the tip. The molecular interaction between the attached molecules onto the tip with the Z-15 molecules in the film results in an increase of the friction force with multi scanning [20]

interface. It should also be noted that Z-15 has a higher viscosity compared to water, therefore Z-15 film provides higher resistance to motion and coefficient of friction. In the case of Z-DOL (BW) film, both of the active groups of Z-DOL molecules are mostly bonded on Si(100) substrate, thus the Z-DOL (BW) film has low free surface energy and cannot be displaced readily by water molecules or readily adsorb water molecules. Thus, the use of Z-DOL (BW) can reduce the adhesive force.

To study the durability of lubricant films at nanoscale, the friction of Si(100), Z-15, and Z-DOL (BW) as a function of the number of scanning cycles are shown in Fig. 8b [19]. As observed earlier for adhesive force, friction force of Z-15 is higher than that of Si(100) with the lowest values for Z-DOL(BW). During cycling, friction force of Si(100) shows a slight decrease during initial few cycles then remains constant. This is related to the removal of the native oxide layer. In the case of Z-15 film, the friction force shows an increase during the initial few cycles and then approaches to higher and stable values. This is believed to be caused by the attachment of the Z-15 molecules onto the tip. After several scans, the molecular interaction reaches an equilibrium and after that the friction force remains constant. In the case of Z-DOL (BW) film, the friction force starts out to be low and remains low during the entire test for 100 cycles. It suggests that Z-DOL (BW) molecules do not get attached or displaced as readily as Z-15.

Closure

For most solid-solid interfaces of technological relevance, contact occurs at multiple asperities. A sharp AFM/FFM tip sliding on a surface simulates just one such contact. However, asperities come in all shapes and sizes. AFM/FFM are used to study various tribological phenomena, which include surface roughness, adhesion, friction, scratching, wear, indentation, detection of material transfer, and boundary lubrication. Measurement of atomic-scale friction of a freshly-cleaved highly-oriented pyrolytic graphite exhibits the same periodicity as that of the corresponding topography. Relevant friction mechanism is atomic-scale stick–slip.

Wear rate on the microscale for single-crystal silicon is negligible below 20 μN and is much higher and remains approximately constant at

higher loads. Elastic deformation at low loads is responsible for negligible wear. Most of the wear debris is loose. SEM and TEM studies of the wear region suggest that the material on the microscale is removed by plastic deformation with a small contribution from elastic fracture; this observation corroborates with the scratch data. Evolution of wear has also been studied using AFM. Wear is found to be initiated at nanoscratches. For a sliding interface requiring near-zero friction and wear, contact stresses should be below the hardness of the softer material to minimize plastic deformation and surfaces should be free of nanoscratches. Further, wear precursors can be detected at early stages of wear by using surface potential measurements. It is found that even in the case of zero wear (no measurable deformation of the surface using AFM), there can be a significant change in the surface potential inside the wear mark which is useful for study of wear precursors.

Boundary lubrication studies and measurement of lubricant-film thickness with a lateral resolution on a nanoscale can be conducted using AFM. For chemically bonded lubricant films, the adsorption of water, the formation of meniscus and its change during sliding, and surface properties play an important role on the adhesion, friction, and durability of these films.

Investigations of adhesion, friction, wear, scratching and indentation on nanoscales using the AFM can provide insights into failure mechanisms of materials. Coefficients of friction, wear rates and mechanical properties such as hardness have been found to be different on the nanoscale than on the macroscale; generally, coefficients of friction and wear rates on micro- and nanoscales are smaller, whereas hardness is greater. Therefore, micro/nanotribological studies may help define the regimes for ultra-low friction and near zero wear. These studies also provide insight to atomic origins of adhesion, friction, wear, and lubrication mechanisms.

Nanotribology Applications in Microprojector Technology

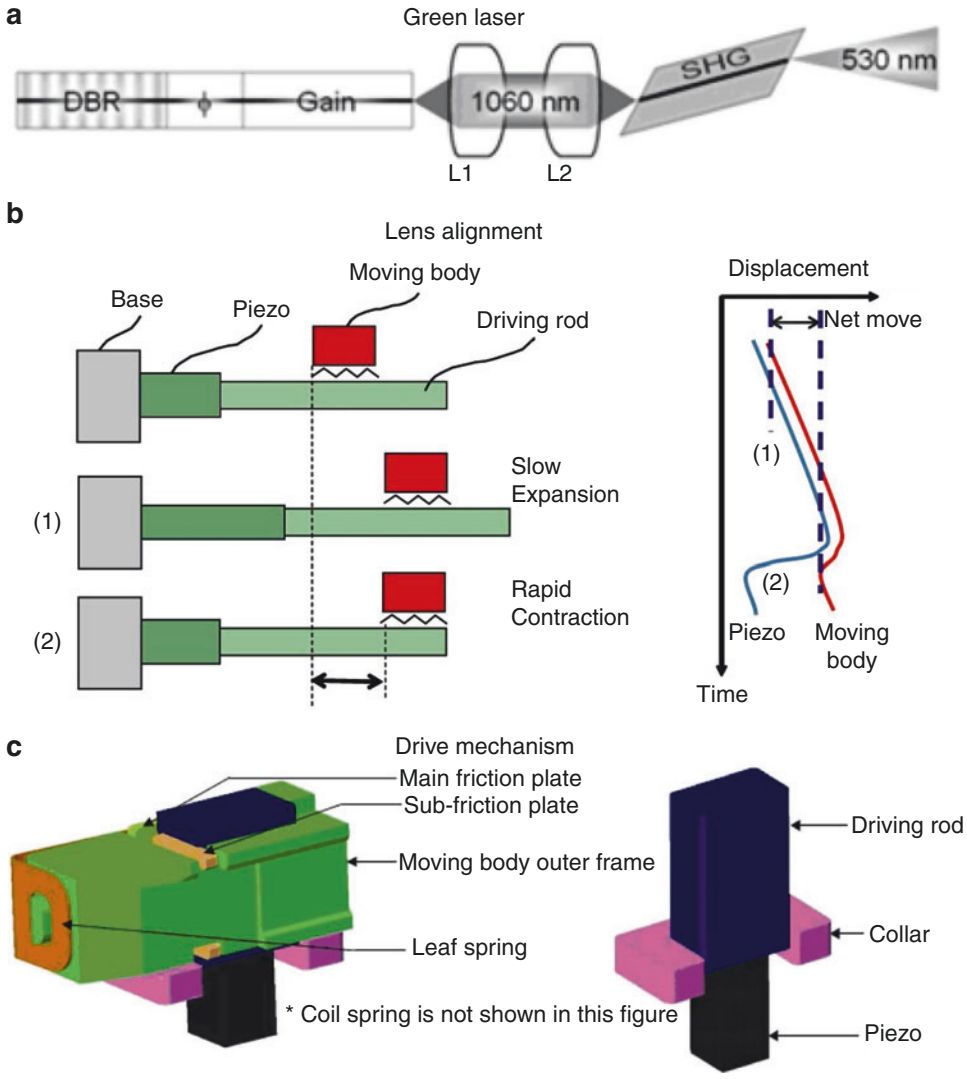
Satish C. Chaparala and Vikram Bhatia
Science and Technology, Corning Incorporated
SP-PR-02-1, Corning, NY, USA

Definition

Microprojectors are being developed to project a larger image from a smaller display in handheld electronic devices such as cell phone, handheld PDA, etc. The technology associated with microprojectors has several applications of nanotribology and those are described in this entry.

Introduction to Microprojector Technology

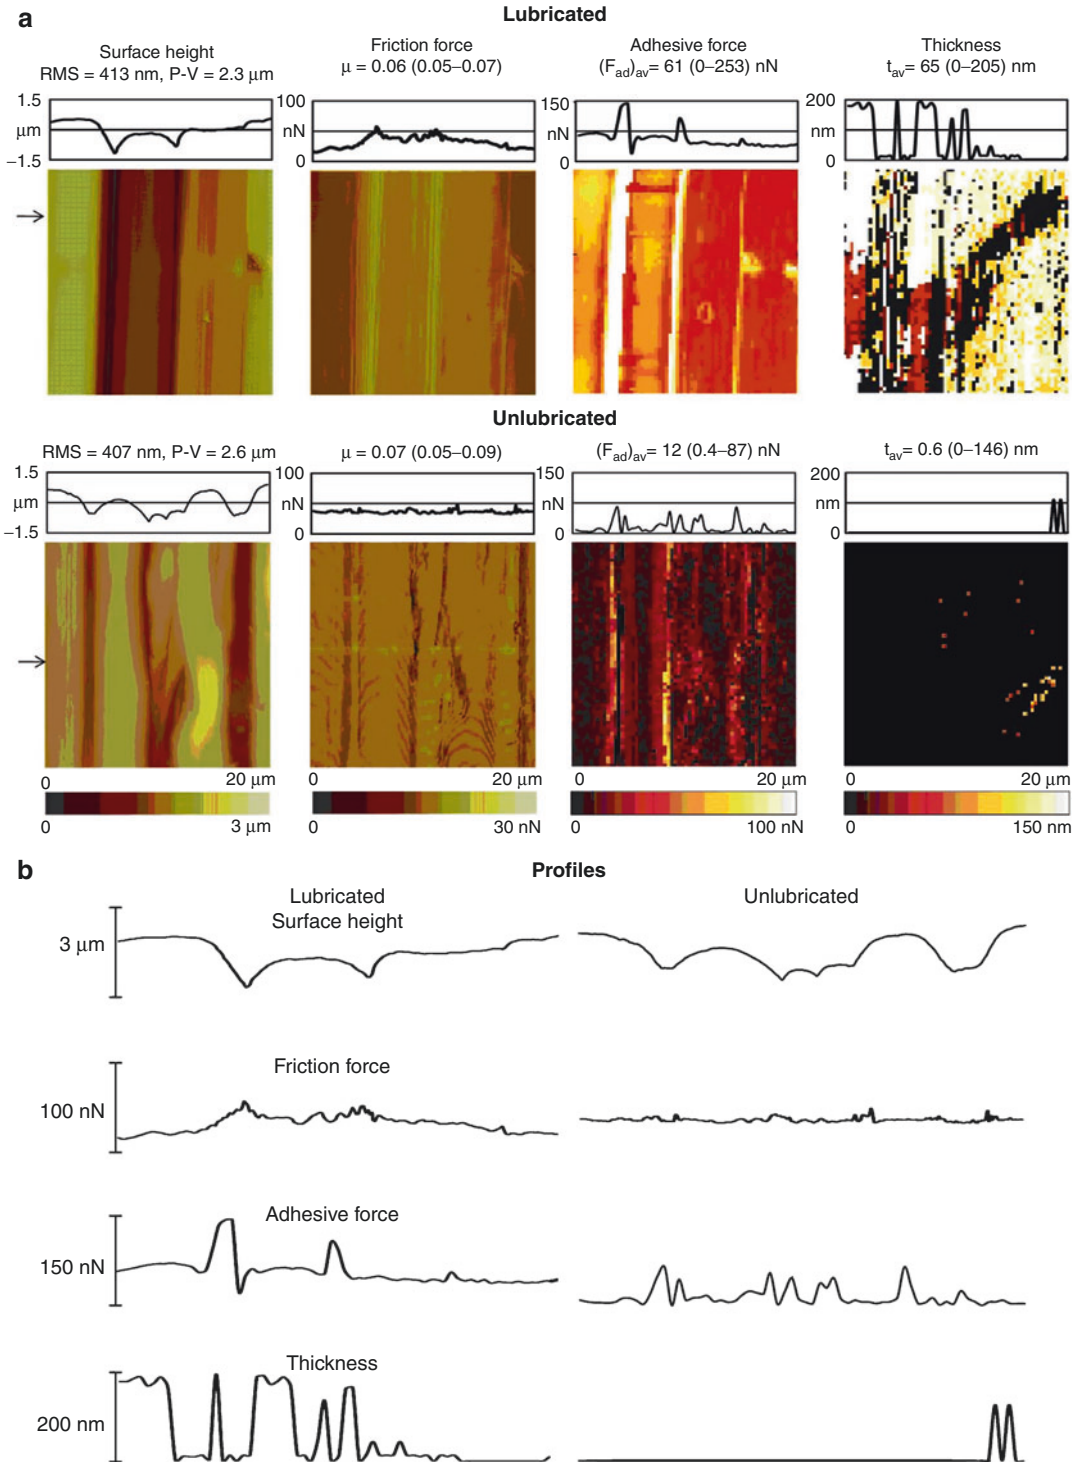
The capacity of high-speed wireless networks has enabled carriers to provide multimedia services to consumers such as web browsing, live television and gaming, etc. At the same time, the electronics industry is driving toward miniaturization which in turn led to the smaller size of displays on the electronic devices. The smaller display limits the full utilization and enjoyment of these services. Microprojectors have been proposed to address this issue. These devices can either be as an accessory to any electronic device or an embedded component within a mobile device. These are expected to provide images of the size of A4 paper and larger in indoor lighting conditions. The challenge is to develop the correct microprojector configuration to balance size, cost, performance, and efficiency [1]. For instance, currently, the thickness of the projector could be in the range of 7–14 mm that results in overall projector volume between 10 and 20 cm^3. Brightness is obviously a very important attribute of a microprojector. While the current range of products offers 5–10 lm of brightness, 50 lm is required to provide enough brightness in all lighting conditions. Focus-free operation is another desirable attribute and this is possible with the projectors that have lasers as light sources. Resolution is expected to continue to grow as product technology improves. The wide-screen format is typically acceptable for viewing video content. Similar to brightness, contrast is also an important attribute that makes the difference between washed-out images and crisp, dramatic-looking images [2]. These trade-offs are primarily driven by the choices of light source and imaging mechanism.



The microprojector technology has two major components in the optical engine: (1) light source and (2) image-producing technology. Optical engines are modules that combine the red-green-blue (RGB) light sources and an imaging element or elements. Optical engines accept an electronic input video signal and project an optical image. Optical engines do not contain power sources or any other functional elements such as wireless communication chips. Three primary colors, namely, red, blue, and green are required to create full color images. The light sources in the projection technology would be semiconductor devices that emit these colors. These devices could be either light-emitting diodes (LEDs) or lasers.

Like a normal diode, when an LED is forward biased or, in other words, switched on, electron combines with a hole, falls into a lower energy level, thereby releasing the energy in the form of photon. The color of the emitted light depends on the energy gap of the semiconductor. Red, blue, and green LEDs are commercially available. LEDs have several advantages that include low energy consumption, longer lifetime, smaller size, faster switching, and good reliability, typically lasting a few years. However, LEDs have higher etendue. Etendue is a property of an optical system that describes how "diverged" the light is in area and angle. Because of high etendue of LEDs, large optical elements (e.g., lenses, etc.) have to be used in the package to collect all the light that is emitted from LED, which in turn increases the size of the projector. If the projector volume is designed to be small using smaller optical elements, some of the optical power (larger angles) will be lost, which in turn decreases the conversion efficiency of the package. Lasers can be used to overcome this problem. A laser is a device that emits light through a process of optical amplification based on the stimulated emission of photons. Laser light is spatially and temporally coherent. Red and blue lasers are commercially available for applications to the optical read/write products such as DVD players, whereas green has been a challenge to produce through currently available processes and materials. A green laser is often referred to as the "keystone" component to enable laser-based mobile projection. Extensive research has been conducted to develop native green lasers using either III-V or II-VI compound semiconductors. Recent technological advancements have led to creation of native green laser light by Sumitomo, Osram, and others. For instance, Sumitomo succeeded in producing 2.4 mW of optical power at 520 nm at room temperature continuous wave lasing of InGaN-based green LEDs on semipolar GaN substrates [3]. Native green lasers are easier to control and could potentially demonstrate greater temperature stability, a smaller form factor, and higher modulation capability at several 100 MHz. However, there has not been sufficient reliability data of these devices under operating conditions. While the native green lasers are under development, a synthetic green laser has already been developed based on frequency doubling of 1,060 nm IR light using second harmonic generation crystal by various companies such as Corning [1, 4–6].

The second critical component of a microprojector is image-producing technology. There are three main image-producing technologies: (1) scanners, (2) digital light processing (DLP), and (3) liquid crystal on silicon (LCOS). Scanners are based on two-dimensional pixel-by-pixel scanning, typically using a single MEMS mirror and uses modulated laser beams as the light source. The image remains in focus at any projection distance and the projector consumes relatively low power [2, 7]. DLP uses millions of tiny mirrors, one for each pixel, to reflect light. This technology involves modulating the image by tilting the mirrors either into or away from the lens path. It is a "reflective" technology and can use either lasers or LEDs as light sources. DLP projection technology using LED as light source is already commercialized. LCOS combines the idea of a DLP which is a reflective technology but uses liquid crystals instead of individual mirrors. In LCOS, liquid crystals are applied to a reflective mirror substrate. As the liquid crystals are modulated based on the incoming video signal, the light is either reflected from the mirror below or blocked. This modulates the light from either laser or LED sources and creates the image. Any feasible combination of these three technologies with either lasers or LEDs could project an image. Finally, all these components can be either wrapped in a case (skin) and sold as a companion projector or embedded in a handset. Projector contains an optical engine, power source, and "industrial design or skin."



Synthetic Green Laser Package

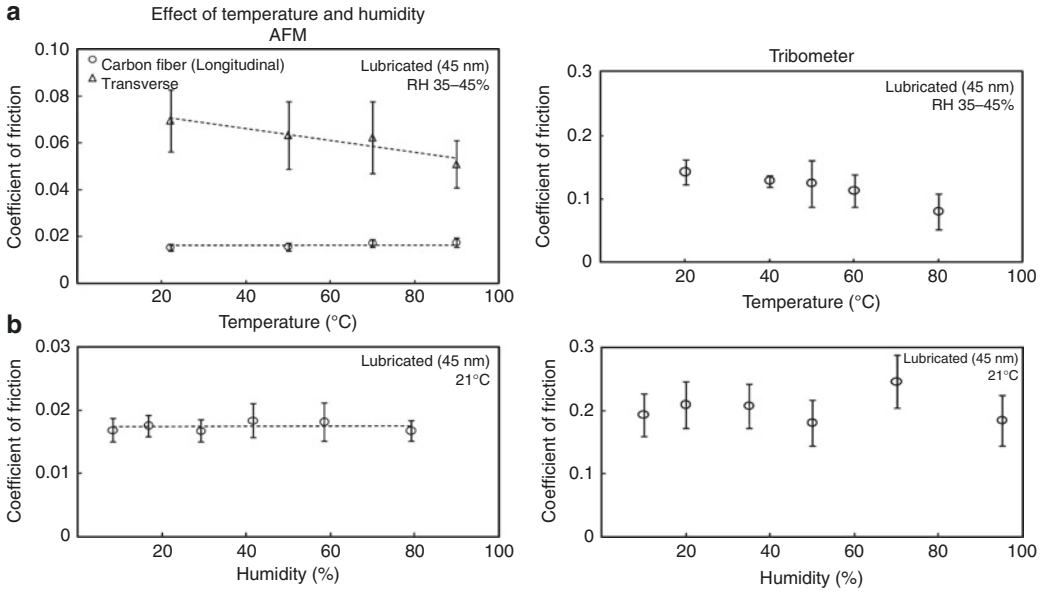
Until now, a detailed introduction to various projection technologies and components involved in the microprojector product has been provided. The next focus of this entry would be on the keystone component of a laser-based microprojector, which is a green laser optoelectronic

Nanotribology Applications in Microprojector Technology, Fig. 1 Schematic of (**a**) the green laser architecture, (**b**) the operation, and (**c**) the construction of the drive mechanism used in the green laser

package developed by Corning Incorporated and specifically, the role of nano-tribology in its development. Several key tribology design studies will be presented. A frequency doubling technique is used to produce a compact green laser. A distributed bragg reflector (DBR) laser diode generated 1,060 nm wavelength light is passed through second harmonic generating (SHG) crystal resulting in 530 nm green light. Corning's green laser architecture is shown in the Fig. 1 [1, 4, 8]. As can be seen from the figure, there are two lenses in this configuration. The first lens that is in front of the IR laser diode is used to collimate the light beam that emits from the laser diode. The second lens converges the collimated beam onto the waveguide in SHG. Exposure to the operating environment, which can be at a temperature as high as 60 °C and at 75 % relative humidity (RH), can cause lens misalignment and affect optical output. To correct for this, the green laser module uses an adaptive optics component with a drive mechanism to align the optics and

Nanotribology Applications in Microprojector Technology, Fig. 2 (continued)

N

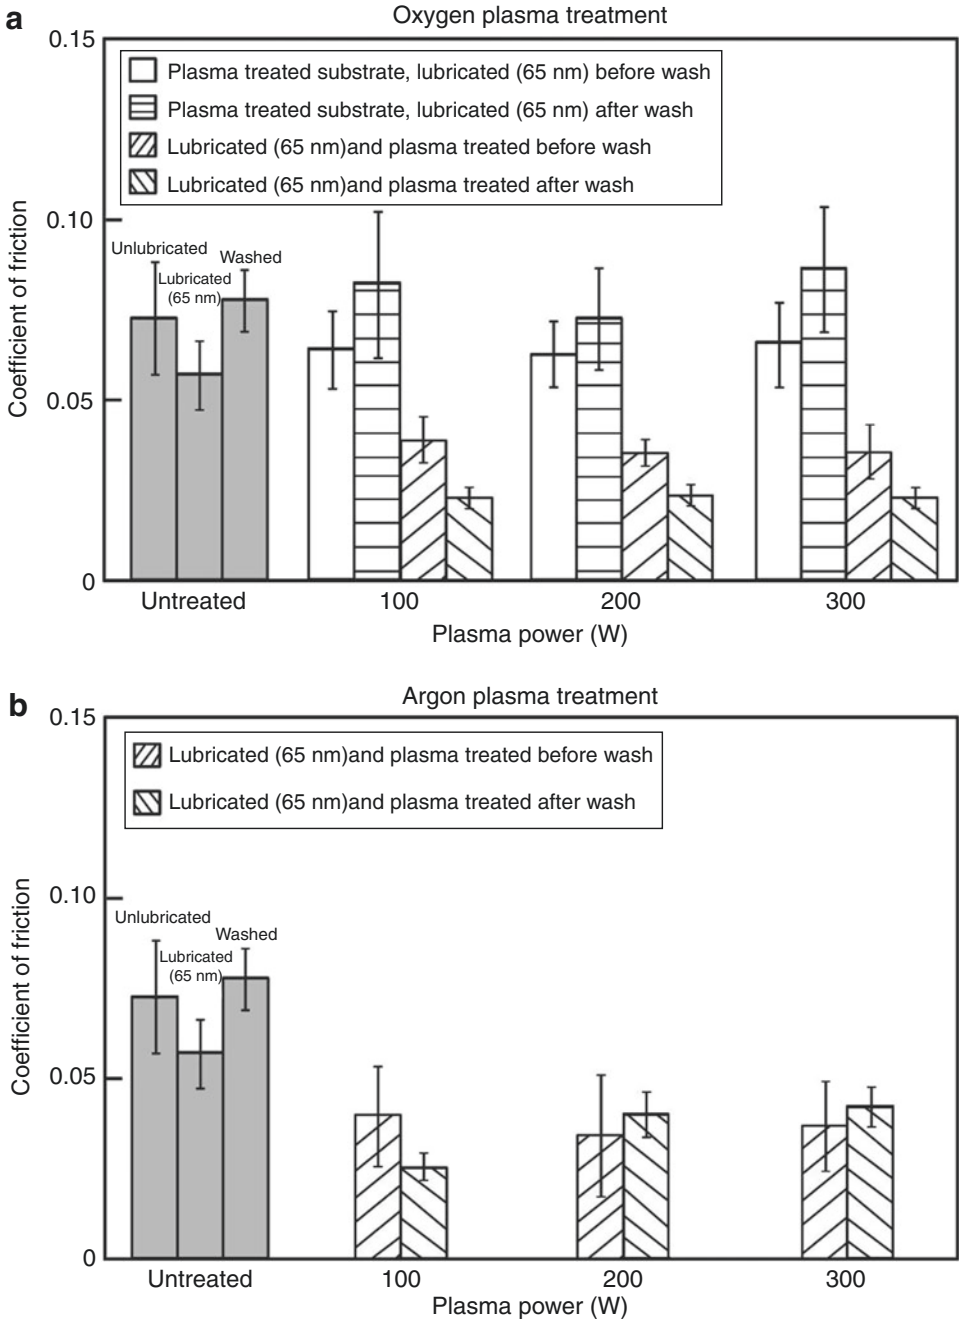


maintain constant power output with time and temperature. Lens alignment along the x- and y-axes is made by using adaptive optics, represented by L_1 and L_2 in the figure below. This adaptive optics component is referred to as smooth impact drive mechanism (SIDM) developed by Konica Minolta. Schematics of the operation and construction of this drive mechanism are shown in Fig. 1. The main components of the drive mechanism are the piezoelectric element, driving rod, moving body, and the friction plate. During operation, a rectangular waveform with a given voltage, frequency, and number of cycles is applied to the piezo element. The rectangular waveform is then converted to a sawtooth motion by the mechanical transfer function of the piezo. On the gentle upward slope, the rod carries the moving body due to friction ("stick" operation), while on the rapid falling slope, the rod "slips" due to inertia. The net displacement is the minimum movement of the drive mechanism. This is repeated until the desired amount of displacement is achieved [4].

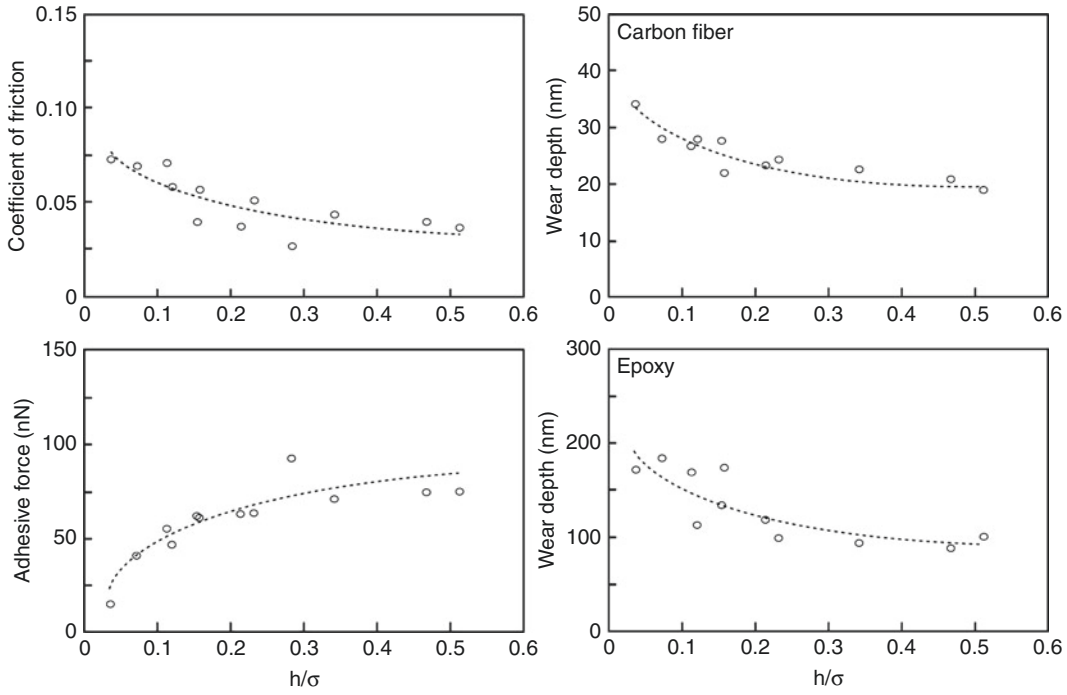
Carbon fiber reinforced plastic (CFRP) is used as a component for a wide variety of engineering applications, such as for aircraft structures, automobile, and solar cells, among many others [8–12]. In the drive mechanism, CFRP is the material used as the driving rod. For the friction plate, stainless steel is used. For the moving body, Zn alloy is used as the die-cast part, which is commonly used in automotive applications. Adaptive optics sliding components in microprojectors should be stable at an operating environment up to 60 °C and 75 % relative humidity. To improve tribological performance of the sliding components, perfluoropolyether (PFPE) lubricants are applied to the surfaces of the components. The ideal lubricant should be molecularly thick to protect the surface from wear, easily applicable, able to chemically bond to the surface, and insensitive to environment. PFPE lubricants are known to be most desirable as they have low surface tension, high contact angle, and high adhesion to the substrate allowing easy application and spreading onto the surface as well as providing hydrophobicity [13–19]. Their chemical and thermal stability and low vapor pressure provide low degradation and low outgassing. PFPEs have been extensively investigated, especially in the magnetic disk drive industry. It has been shown that they reduce friction and wear, resulting in lower disk drive failure. It is, therefore, very critical to conduct a comprehensive tribology study to understand the friction mechanisms and effect of temperature, humidity, plasma, etc., on the friction.

Applications of Nano-tribology

The following section presents several key findings from various nano-tribological studies made on the lubricant used in the adaptive optics component. A methodology to measure lubricant film thickness with a nanoscale resolution was developed. Atomic force microscopy (AFM) allows the simulation of a single asperity contact. The morphology measured by AFM is shown in Fig. 2. On the height images of the lubricated and unlubricated samples, the bright long columns are for the individual carbon fibers, and the dark ones for epoxy. The average surface roughness (RMS) of the lubricated CFRP is about 328 nm and that of the unlubricated is 406 nm. Even though both lubricated and unlubricated CFRPs have high average surface roughness, the lubricated sample surface has lower roughness than that of the unlubricated surface. The roughness difference between the lubricated and the unlubricated samples can be attributed to lubricant thickness.



Nanotribology Applications in Microprojector Technology, Fig. 2 (**a**) AFM maps for surface height, friction force, adhesive force, and film thickness distribution for lubricated and unlubricated CFRPs. Shown above each image is a cross section taken at a position denoted by the corresponding *arrows*. (**b**) 2-D cross-sectional profiles to correlate the surface morphology with friction force, adhesive force, and film thickness

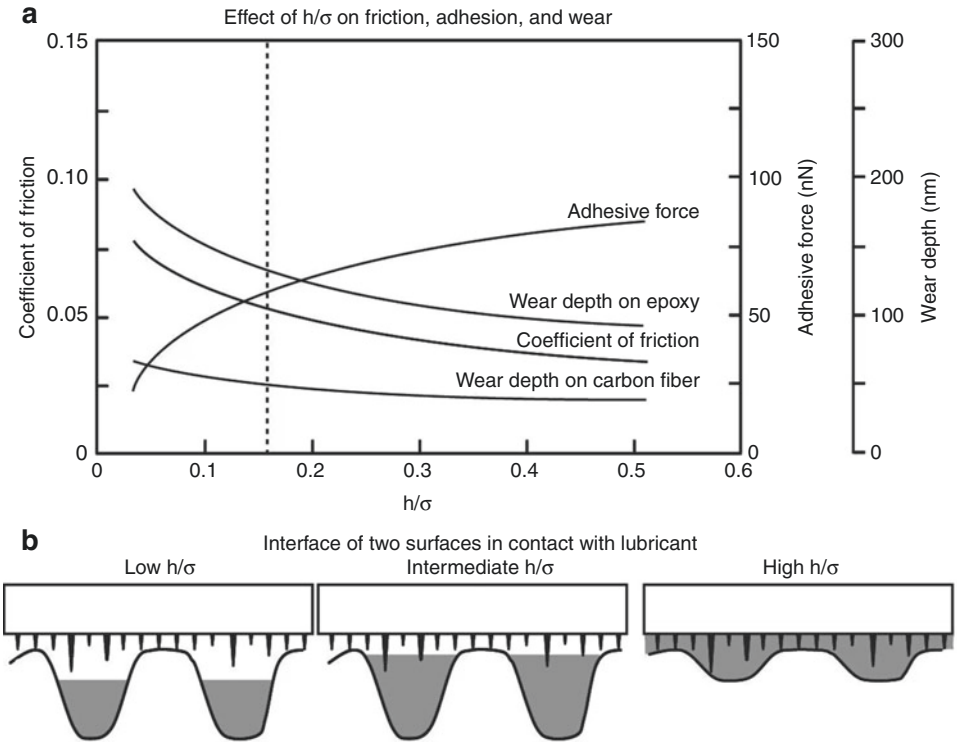


Nanotribology Applications in Microprojector Technology, Fig. 3 Effect of temperature and humidity on lubricated CFRP (average film thickness = 45 nm) using (**a**) AFM on carbon fiber in the longitudinal and transverse directions, and (**b**) tribometer

The degree of bonding was measured by measuring the film thickness before and after washing off the lubricant film. It was found that the lubricant was unbonded to the sample surfaces. Friction force, adhesive force, and lubricant thickness distribution correlate with surface morphology. Lubricant resides in the recessed epoxy regions which act as a lubricant reservoir. It is expected that lubricant will wick up during the operation and get transferred. Coefficient of friction on lubricated samples is lower than that on the unlubricated samples. The epoxy has a higher friction force than carbon fiber because of the presence of the lubricant. Wear depth of epoxy is found to be higher than on the carbon fiber. Effects of composite components, scan direction, length scale, temperature, and humidity were studied. Scanning in the transverse direction includes sliding on both the carbon fiber and the epoxy, and the friction data is close to that of epoxy. Regarding length scale effects, the coefficient of friction on larger length scales is higher due to larger contact area. Figure 3 shows the effect of humidity and temperature. Humidity does not affect the coefficient of friction due to the condensed water layer from the environment which is expected to be thin compared to lubricant thickness. However, increasing temperature leads to viscosity drop of the lubricant, resulting in the decrease in the coefficient of friction.

Thermal, UV, and oxygen and argon plasma treatments in order to allow chemical bonding of lubricant were studied. It was found that the effect of thermal treatment on the lubricant chemical bonding was not obvious. However, the thermal treatment reduced adhesive force and coefficient of friction because of solvent evaporation. For UV treatment, it was found that coefficient of friction, adhesive force, and lubricant thickness are unchanged. UV treatment does not affect chemical bonding of lubricant. For plasma treatment, it is observed that lubricant on the lubricated and subsequently plasma-treated samples is bonded to the surfaces. The plasma treatment also improves coefficient of friction and adhesive force. Lubricant film thickness was reduced by the plasma treatment. However, no difference is found between oxygen and argon plasma treatments. There is no difference between various power levels in plasma treatments either. It is found that

Nanotribology Applications in Microprojector Technology, Fig. 4 Effect of plasma power on coefficient of friction. (**a**) Oxygen and (**b**) argon plasma treatments were carried out. The first three *dark columns* are coefficient of friction on untreated samples. The next groups of columns are for plasma-treated samples. The *white blank* and *horizontally lined columns* in (**a**), which are not in (**b**), are for sample type #1. *Scatter bars* represent $\pm \sigma$ limits



Nanotribology Applications in Microprojector Technology, Fig. 5 The effect of h/σ on coefficient of friction, adhesive force, and wear depth on carbon fibers and epoxy regions at 30 μN of normal load. The *dotted lines* are the trend lines for the data

chemical bonding of lubricant to the sample surfaces due to plasma treatment helps to protect the carbon fiber areas of the CFRP rods from wear but not epoxy areas (Fig. 4).

Further studies revealed that the thermal and UV treatments do not improve wear for the CFRP rods. There is no measurable change in friction, adhesive force, and lubricant thickness after laser exposure to the samples. Therefore, it is believed that lubricant degradation by green and IR laser exposure does not occur or is negligible. Finally, wettability by contact angle measurement for unlubricated and lubricated CFRP rods was studied to simulate the effect of atmospheric humidity. It is found that, in advancing mode, unlubricated CFRP rods are hydrophilic, but the lubricated rods are hydrophobic. Contact angles increase with lubricant thickness. Therefore, humidity should have less effect on coefficient of friction on the lubricated samples. However, contact angle hysteresis is observed due to the large difference of advancing and receding contact angles. It could be explained by chemical heterogeneity caused by the high roughness and the composite effect of the CFRP rods. Finally, the interplay of surface roughness and film thickness of lubricant is optimized for low adhesion, friction, and wear. The effect of h/σ on friction, adhesion, and durability is studied. With an increase in h/σ, the uniformity of the lubricant distribution on the CFRP rods is improved, resulting in stable and reliable operation of the actual devices. Coefficient of friction and wear depth decrease with a decrease in h/σ, but adhesive force increases due to an increase in the amount of lubricant involved in surface interface and in the contact area between the two mating materials, and vice versa (Figs. 5 and 6).

Therefore, there is a trade-off in lubricant film thickness and surface roughness for optimum values of coefficient of friction, adhesive force, and durability. The ratio of the mobile fraction of lubricant film thickness to sample roughness should be decided by the requirement and functionality of the actual devices.

Conclusion

An introduction to microprojection technology and the components involved is provided. Specifically, a keystone component in laser-based microprojector, green laser package, developed by Corning Incorporated is considered in this study. Applications of nano-tribology in the development of adaptive optics component used in this package are detailed. The adaptive optics component involves sliding mechanical elements, and lubricant was used in between these elements. The tribological design has to be efficient in order for the adaptive optics component to function consistently. Therefore, a comprehensive study was done on tribological design of the lubricant and the surface characteristics of the sliding components. The design specifications obtained from this study were implemented in the final package design.

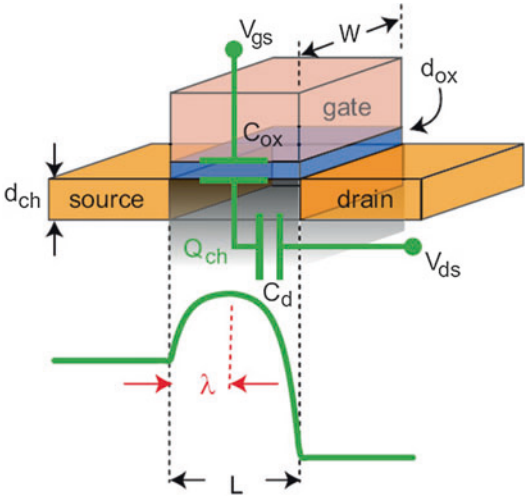
Nanowire-based field effect transistor (NWFET); Quantum kinetics; Realtime Green's function approach

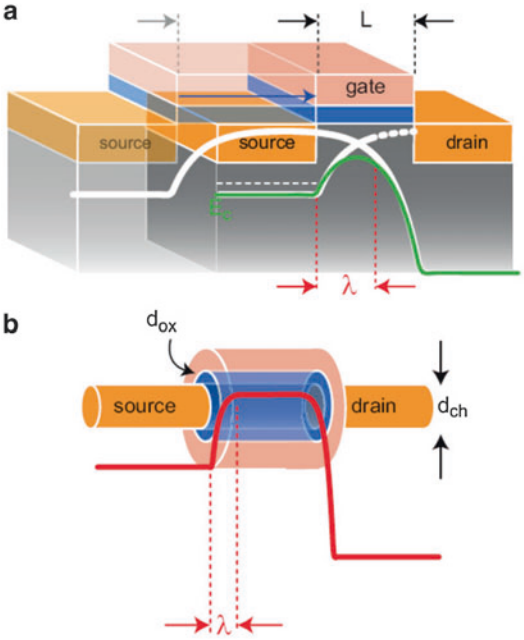
Definition

The nonequilibrium Green's function formalism (NEGF) is a quantum kinetic approach to nonequilibrium electronic transport in nanoelectronic devices. In principle, it is an exact many-body quantum mechanical approach which is able to describe Coulomb interaction and scattering effects in particular. In numerical implementations for the simulation of realistic device structures, however, the Coulomb interaction is often taken into account in terms of a mean field approximation, combined with a decoupled self-energy approximation.



Nanowire Field Effect Transistor

The continued downscaling of the geometric dimensions of metal-oxide-semiconductor field-effect transistors (MOSFET) [1] has been propelled by Moore's law over the last 40 years, i.e., by the promise of an exponential growth of the number of MOSFETs that fit on a single chip, by a strongly increasing circuit performance and reduced costs at the same time. However, when scaling down the channel length of a MOSFET, so-called short channel effects (SCEs) appear that lead to a loss of electrostatic integrity of the device resulting in an exponential increase of the static power consumption due to leakage (see, e.g., [2]).



Consider Fig. 1, which shows a schematic of a planar n-type MOSFET. The charge injected into the channel Q_{ch} is determined by the terminal voltages V_{gs} and V_{ds} that are capacitively coupled to the channel via the oxide and drain capacitances C_{ox} and C_{d}, respectively. Short channel effects appear the more Q_{ch} is influenced by C_{d} instead of C_{ox}, i.e., if both capacitances are of the same order $C_{\mathrm{ox}} \approx C_{\mathrm{d}}$. Approximating C_{ox} and C_{d} with the expression for a parallel-plate capacitor, one obtains

$$C_{\mathrm{ox}} = \epsilon_{\mathrm{ox}}\epsilon_0 \frac{W \cdot L}{d_{\mathrm{ox}}} \quad \text{and} \quad C_{\mathrm{d}} = \epsilon_{\mathrm{ch}}\epsilon_0 \frac{W \cdot d_{\mathrm{ch}}}{L} \tag{1}$$

where d_{ox}, d_{ch} denote the oxide and channel thicknesses and L, W are the channel length and width,

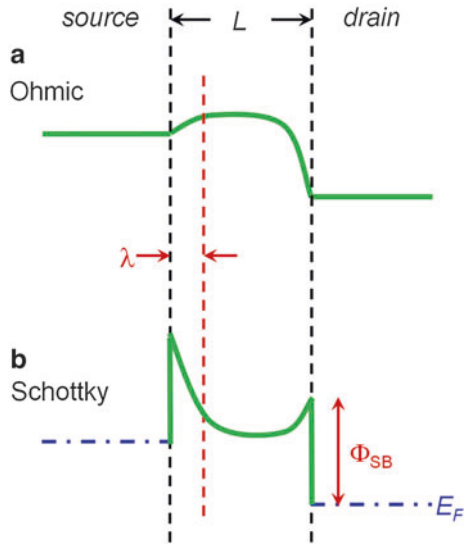
respectively (see Fig. 1). Then, from $C_{ox} \approx C_d$, one obtains $L \approx \lambda$, where the length scale

$$\lambda = \sqrt{\frac{\epsilon_{ch}}{\epsilon_{ox}} d_{ox} d_{ch}} \tag{2}$$

represents a screening length of potential variations within the channel (see Fig. 1). In fact, the spatial extent of the source-channel and channel-drain $p-n$ junctions in a MOSFET is on the order of λ, and thus, SCEs disappear if $L \gg \lambda$. For a given channel length L, this can be achieved by using high-k gate dielectrics with $\epsilon_{high-k} \gg \epsilon_{ox}$ as well as ultrathin gate dielectric and channel thicknesses. However, reducing the thicknesses of d_{ox} and d_{ch} is limited by gate leakage due to direct tunneling and threshold voltage variations due to quantization (see e.g., Ref. [3–5]). Therefore, for ultimately scaled MOSFETs, a multigate, nonplanar device architecture has to be employed such as Intel's trigate MOSFETs at the 22 nm node [6]. In particular, a cylindrical gate-all-around (GAA) transistor based on a nanowire with ultrathin diameter provides the best electrostatic integrity, i.e., the smallest values for λ. Comparing the capacitance of a coaxial system

$$C_{ox} = 2\pi\epsilon_0\epsilon_{ox} \frac{L}{\ln(1 + 2d_{ox}/d_{ch})} \tag{3}$$

with the approximation for



$$C_d = \epsilon_0\epsilon_{ch} \frac{\pi(d_{ch}/2)^2}{L} \tag{4}$$

one obtains [7]

$$\lambda = \sqrt{\frac{d_{ch}^2}{8} \frac{\epsilon_{ch}}{\epsilon_{ox}} \ln\left(1 + 2\frac{d_{ox}}{d_{ch}}\right)}, \tag{5}$$

where d_{ch} is the diameter of the nanowire (see Fig. 2).

In ultimately scaled FETs, the nanowire diameter needs to be on the order of a few nanometers only, which inevitably leads to one-dimensional (1D) electronic transport in the nanowires. On the one hand, 1D transport is beneficial for the performance of FETs since carrier scattering is

suppressed and the density-of-states limit can be approached when scaling the transistor yields performance benefits in terms of reduced dynamic power consumption of integrated circuits [8, 9]. On the other hand, in nanowires with small diameters, dopants become deactivated resulting in increased parasitic resistances of the source/drain extensions in a nanowire FET (NWFET) as has been shown experimentally by Bjoerk et al. [10]. In addition, the small volume of such nanowires leads to device-to-device variability due to random dopant distribution. As a result, metallic source/drain contact electrodes are being considered that allow circumventing all dopant-related issues. However, the Schottky barrier present at the metal–semiconductor interface yields deteriorated on- and off-state device behavior [11]. Fortunately, the tunneling of charge carriers through the Schottky barrier is increased as λ is decreased, and as a result, in ultimately scaled devices that require ultrathin d_{ch} and d_{ox}, the device performance is only slightly lower compared to FETs with (experimentally unrealizable) doped Ohmic source/drain contacts. Figure 3 shows the typical potential profiles within the channel of a NWFET with doped Ohmic source/drain contacts and Schottky contacts (with Schottky barrier height Φ_{SB}), respectively.
