Preface of Second Edition

On December 29, 1959, at the California Institute of Technology, Nobel Laureate Richard P. Feynman gave a talk at the Annual Meeting of the American Physical Society that has become one of the classic science lectures of the twentieth century. His talk "There's Plenty of Room at the Bottom" presented a technological vision of extreme miniaturization several years before the word "chip" became part of the lexicon. He talked about the problem of manipulating and controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature, building nanoobjects atom by atom or molecule by molecule. Since the 1980s, many inventions and discoveries in the fabrication of nanoobjects have been testaments to his vision.

In a January 2000 speech, also at the California Institute of Technology, President William J. Clinton talked about the exciting promise of nanotechnology and the importance of expanding research in nanoscale science and technology more broadly. Later that month in his State of the Union Address, he announced an ambitious $497 million federal, multiagency National Nanotechnology Initiative (NNI) in the FY 2001 budget and made the NNI a top science and technology priority (Anonymous, 2000). The objective of this initiative was to form a broad-based coalition in which academia, the private sector, and local, state, and federal governments work together to push the envelope of nanoscience and nanoengineering to reap nanotechnology's potential social and economic benefits.

In January 2003, following the creation of the NNI, the US Senate in the 108th Congress introduced a bill to establish a National Nanotechnology Program. On December 3, 2003, President George W. Bush signed into law the 21st Century Nanotechnology Research and Development Act (NRDA) (Public Law 108–153). The legislation put into law programs and activities supported by the NNI. The bill gave nanotechnology a permanent home in the federal government and authorized $3.7 billion to be spent in the 4-year period beginning in October 2005. The funds were used to provide grants to researchers, coordinate R&D across six agencies, establish interdisciplinary research centers, and accelerate technology transfer into the private sector.

Regarding international activities in early stages, in 2002 the European Union (EU) made nanosciences and nanotechnologies a priority in the Sixth Framework Program (FP6) for the period 2003–2006. They had also dedicated small funds in the FP4 and FP5 programs before. FP6 was tailored to

help better structure European research and to cope with the strategic objectives set out in the Lisbon Strategy Development Plan of 2000. Japan identified nanotechnology as one of its main research priorities in 2001. The funding levels increased from $400 million in 2001 to around $950 million in 2004. In 2003, South Korea embarked on a 10-year program with around $2 billion in public funding, and Taiwan had committed around $600 million in public funding over 6 years. Russia, Singapore, and China also started to invest on a large scale.

Through FY 2015 in the USA, federal R&D investment has been about $20 billion, with annual investment in FY 2015 of about $1.5 billion, and more than double that by the private sector. The revenues from nano-enabled products continue growing, with over $200 billion in FY 2012 in the USA alone and over $700 billion worldwide. This represents an impressive return on investment.

Nanotechnology refers to any technology done on a nanoscale that has applications in the real world. It is defined as the control or restructuring of matter at the atomic and molecular levels in the size range of about 1–100 nm. The underlying science is referred to as nanoscience. The properties of matter at the nanoscale are different from those at a larger scale. When the dimensions of a material are reduced from a large size, the properties remain the same at first, then small changes occur. Finally, when the size drops below 100 nm, dramatic changes in properties can occur. The unique physical and chemical properties of nanomaterials can be exploited for commercial applications and for novel performance that benefits society. The discovery of novel materials, processes, and phenomena at the nanoscale and the development of new experimental and theoretical techniques for research at the end of the twentieth century provided fresh opportunities for the development of innovative nanosystems and nanomaterials. This field is opening new venues in science and technology.

Nanotechnology encompasses nanomanufacturing and application of physical, chemical, and biological systems at scales ranging from individual atoms or molecules to submicron dimensions, as well as the integration of the resulting nanostructures into larger systems. It spans across scientific fields, including chemistry, physics, material science, engineering, and manufacturing. Its impact on our society and economy in the twenty-first century is comparable to that of semiconductor technology, information technology, or cellular and molecular biology in the twentieth century. The integration of nanotechnology into larger systems has given breakthrough solutions to many current environmental, medical, and industrial problems, including smart materials, nanomanufacturing, electronics, drug delivery, energy and water, biotechnology, information technology, and national security. Nanotechnology will have a profound impact on our economy and society; it is a modern industrial revolution. Nanotechnology represents a megatrend, bringing disruptive innovation. It has become a general purpose technology, being applicable across various industrial sectors.

There has existed a need for a multidisciplinary, system-oriented approach to design and manufacturing of micro/nanodevices which function reliably. This can only be achieved through the cross-fertilization of ideas from

different disciplines and the systematic flow of information and people among research groups. A broad-based *Springer Handbook of Nanotechnology* was published with the first edition in April 2004, second edition in 2007, and the third edition in 2010. It presents an overview of nanomaterial synthesis, micro/nanofabrication, micro- and nanocomponents and systems, scanning probe microscopy, reliability issues (including nanotribology and nanomechanics) for nanotechnology, and various industrial applications including biomedical applications. A two-volume *Springer Handbook of Nanomaterials Properties* was launched in 2014.

A four-volume *Encyclopedia of Nanotechnology* was launched in 2012 with 325 essays written by experts in the field from academia, national research labs, and industry, and from all over the world. The objective of this encyclopedia was to introduce a large number of terms, devices, and processes. For each entry or essay, a brief description is provided by experts in the field. The entries were written by a large number of internationally recognized experts in the field, from academia, national research labs, and industry, and from all over the world. The *Encyclopedia of Nanotechnology* has provided a comprehensive and multidisciplinary reference to the many fields relevant to the general field of nanotechnology. The encyclopedia focuses on engineering and applications with some coverage of science of nanotechnology. It is a comprehensive and genuinely international reference work and is aimed at graduate students, researchers, and practitioners. Given the explosive growth in nanoscience and nanotechnology, we offer an updated and expanded second edition.

The development of the encyclopedia was undertaken by an Editorial Board, who were responsible for the focus and quality of contributions, and an Advisory Board, who were responsible for advising about the selection of topics.

The *Encyclopedia of Nanotechnology* is available both in a print version and an online version. The print version of the encyclopedia contains four volumes with a total of 426 entries and about 4944 pages. The online version of the encyclopedia is expected to be updated periodically. The editor-in-chief and all editors thank the large number of authors for making contributions to this major reference work. Thanks are also due to the referees who meticulously read the entries and made their recommendations.

Powell, Ohio **Bharat Bhushan**
August 2016

Preface of First Edition

On December 29, 1959, at the California Institute of Technology, Nobel Laureate Richard P. Feynman gave a speech at the Annual meeting of the American Physical Society that has become one of the twentieth-century classic science lectures, titled "There's Plenty of Room at the Bottom." He presented a technological vision of extreme miniaturization in 1959, several years before the word "chip" became part of the lexicon. He spoke about the problem of manipulating and controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature, building nanoobjects atom by atom or molecule by molecule. Since the 1980s, many inventions and discoveries in the fabrication of nanoobjects have been testament to his vision. In recognition of this reality, National Science and Technology Council (NSTC) of the White House created the Interagency Working Group on Nanoscience, Engineering and Technology (IWGN) in 1998. In a January 2000 speech at the same institute, former President W. J. Clinton spoke about the exciting promise of "nanotechnology" and the importance of expanding research in nanoscale science and technology, more broadly. Later that month, he announced in his State of the Union Address an ambitious $497 million federal, multiagency National Nanotechnology Initiative (NNI) in the fiscal year 2001 budget and made the NNI a top science and technology priority. The objective of this initiative was to form a broad-based coalition in which the academe, the private sector, and local, state, and federal governments work together to push the envelope of nanoscience and nanoengineering to reap nanotechnology's potential social and economic benefits.

The funding in the USA has continued to increase. In January 2003, the US Senate introduced a bill to establish a National Nanotechnology Program. On December 3, 2003, President George W. Bush signed into law the 21st Century Nanotechnology Research and Development Act. The legislation put into law programs and activities supported by the (NNI). The bill gave nanotechnology a permanent home in the federal government and authorized $3.7 billion to be spent in the 4-year period beginning in October 2005, for nanotechnology initiatives at five federal agencies. The funds have provided grants to researchers, coordinated R&D across five federal agencies (National Science Foundation (NSF), Department of Energy (DOE), NASA, National Institute of Standards and Technology (NIST), and Environmental Protection Agency (EPA)), established interdisciplinary research centers, and accelerated

technology transfer into the private sector. In addition, the Department of Defense (DOD), Homeland Security, Agriculture and Justice, as well as the National Institutes of Health (NIH) also fund large R&D activities. They currently account for more than one-third of the federal budget for nanotechnology.

The European Union (EU) made nanosciences and nanotechnologies a priority in the Sixth Framework Program (FP6) in 2002 for the period 2003–2006. They had dedicated small funds in FP4 and FP5 before. FP6 was tailored to help better structure European research and to cope with the strategic objectives set out in Lisbon in 2000. Japan identified nanotechnology as one of its main research priorities in 2001. The funding levels increased sharply from $400 million in 2001 to around $950 million in 2004. In 2003, South Korea embarked upon a 10-year program with around $2 billion of public funding, and Taiwan has committed around $600 million of public funding over 6 years. Singapore and China are also investing on a large scale. Russia is well funded as well.

Nanotechnology literally means any technology done on a nanoscale that has applications in the real world. Nanotechnology encompasses production and application of physical, chemical, and biological systems at scales, ranging from individual atoms or molecules to submicron dimensions, as well as the integration of the resulting nanostructures into larger systems. Nanotechnology is likely to have a profound impact on our economy and society in the early twenty-first century, comparable to that of semiconductor technology, information technology, or cellular and molecular biology. Science and technology research in nanotechnology is leading to breakthroughs in areas such as materials and manufacturing, nanoelectronics, medicine and healthcare, energy, biotechnology, information technology, and national security. It is widely felt that nanotechnology will be the next industrial revolution.

There is an increasing need for a multidisciplinary, system-oriented approach toward designing and manufacturing micro/nanodevices which function reliably. This can only be achieved through the cross-fertilization of ideas from different disciplines and the systematic flow of information and people among research groups. Reliability is a critical technology for many micro- and nanosystems and nanostructured materials. The first edition of a broad-based *Handbook of Nanotechnology* from Springer was published in April 2004, the second edition in 2007, and the third edition in 2010. It presents an overview of nanomaterial synthesis, micro/nanofabrication, micro- and nanocomponents and systems, scanning probe microscopy, reliability issues (including nanotribology and nanomechanics) for nanotechnology, and various industrial including biomedical applications.

The field of nanotechnology is getting a strong foothold. It attracts people from various disciplines including science and engineering. Given the explosive growth in nanoscience and nanotechnology, this *Encyclopedia of Nanotechnology* is being launched with essays written by experts in the field from academia and industry.

The objective of this encyclopedia is to introduce a large number of terms, devices, and processes. For each entry, a brief description is provided by experts in the field. The entries have been written by a large number of

internationally recognized experts in the field, from academia, national research labs, and industry.

The *Encyclopedia of Nanotechnology* is expected to provide a comprehensive and multidisciplinary reference to the many fields relevant to the general field of nanotechnology. The encyclopedia focuses on engineering and applications with some coverage of the science of nanotechnology. It aims to be a comprehensive and genuinely international reference work and is aimed at graduate students, researchers, and practitioners.

The development of the encyclopedia was undertaken by an Editorial Board, who were responsible for the focus and quality of contributions, and an Advisory Board, who were responsible for advising about the selection of topics.

The print version of the encyclopedia contains four volumes with a total of **325** entries and about **3068** pages. The encyclopedia is also available online. Editors expect to update it periodically. The editor-in-chief and all the editors thank a large number of authors for making contributions to this major reference work. We also thank the referees who meticulously read the entries and made their recommendations.

Bharat Bhushan

About the Editor

Dr. Bharat Bhushan received an M.S. in Mechanical Engineering from the Massachusetts Institute of Technology in 1971; an M.S. in Mechanics and a Ph.D. in Mechanical Engineering from the University of Colorado at Boulder in 1973 and 1976, respectively; an MBA from Rensselaer Polytechnic Institute at Troy, NY, in 1980; Doctor Technicae from the University of Trondheim at Trondheim, Norway, in 1990; a Doctor of Technical Sciences from the Warsaw University of Technology at Warsaw, Poland, in 1996; and Doctor Honouris Causa from the National Academy of Sciences at Gomel, Belarus, in 2000, and University of Kragujevac, Serbia, in 2011. He is a registered professional engineer. He is presently an Ohio Eminent Scholar and The Howard D. Winbigler Professor in the College of Engineering, and the Director of the Nanoprobe Laboratory for Bio- and Nanotechnology and Biomimetics (NLB^2) and affiliated faculty in John Glenn College of Public Affairs at the Ohio State University, Columbus, Ohio. In 2013–2014, he served as an ASME/AAAS Science and Technology Policy Fellow, House Committee on Science, Space and Technology, United States Congress, Washington, DC. His research interests include fundamental studies with a focus on scanning probe techniques in the interdisciplinary areas of bio/nanotribology, bio/nanomechanics and bio/nanomaterials characterization and applications to bio/nanotechnology, and biomimetics. He is an internationally recognized expert of bio/nanotribology and bio/nanomechanics using scanning probe microscopy and is one of the most prolific authors. He is considered by some a pioneer of tribology and mechanics of magnetic storage devices. He has authored 8 scientific books, 90+ handbook chapters, 800+ scientific papers

(Goggle Scholar h-index – 105+ with 50k+ citations; Web of Science h-index – 80+; ISI Highly Cited Researcher in Materials Science since 2007 and in Biology and Biochemistry since 2013; ISI Top 5 % Cited Authors for Journals in Chemistry since 2011), and 60+ technical reports. He has also edited 50+ books and holds 20 US and foreign patents. He is coeditor of Springer NanoScience and Technology Series and coeditor of Microsystem Technologies, and Member of Editorial Board of PNAS. He has given more than 400 invited presentations on six continents and more than 200 keynote/plenary addresses at major international conferences.

Dr. Bhushan is an accomplished organizer. He organized the first Symposium on Tribology and Mechanics of Magnetic Storage Systems in 1984 and the first International Symposium on Advances in Information Storage Systems in 1990, both of which are now held annually. He organized two international NATO institutes in Europe. He is the founder of an ASME Information Storage and Processing Systems Division founded in 1993 and served as the founding chair during 1993–1998. His biography has been listed in over two dozen *Who's Who* books including *Who's Who in the World*. He has received more than two dozen awards for his contributions to science and technology from professional societies, industry, and US government agencies including Life Achievement Tribology Award and Institution of Chemical Engineers (UK) Global Award. His research was listed as the top ten science stories of 2015. He is also the recipient of various international fellowships including the Alexander von Humboldt Research Prize for Senior Scientists, Max Planck Foundation Research Award for Outstanding Foreign Scientists, and Fulbright Senior Scholar Award. He is a foreign member of the International Academy of Engineering (Russia), Byelorussian Academy of Engineering and Technology, and the Academy of Triboengineering of Ukraine; an honorary member of the Society of Tribologists of Belarus and STLE; a fellow of ASME, IEEE, and the New York Academy of Sciences; and a member of ASEE, Sigma Xi, and Tau Beta Pi.

Dr. Bhushan has previously worked for Mechanical Technology Inc., Latham, NY; SKF Industries Inc., King of Prussia, PA; IBM, Tucson, AZ; and IBM Almaden Research Center, San Jose, CA. He has held visiting professorship at University of California at Berkeley; University of Cambridge, UK; Technical University Vienna, Austria; University of Paris, Orsay; ETH Zurich; EPFL Lausanne; Univ. of Southampton, UK; Univ. of Kragujevac, Serbia; Tsinghua Univ., China; Harbin Inst., China; and KFUPM, Saudi Arabia.

Definition

Density Functional Theory (DFT) is an exact theory in which the electronic charge density is the basic quantity used to determinate the ground state properties of a many-body quantum system [1, 2]. Such a theory is an alternative formulation of the Schrödinger picture of quantum mechanics and represents a fundamental breakthrough in the application of computer simulation to material science and to nanosystems in particular. In the last decades, DFT-based analysis showed a quantitative predictive role and has been successfully employed in the study of molecules, crystals, and nanostructured materials. DFT calculations permit to investigate phenomena at an atomic scale hardly accessible by other techniques, emerging as a fundamental tool for complementing experimental investigations and for addressing open issues regarding nanomaterials and novel design processes [3, 4]. The DFT methodology is an ab initio (or first principles) approach, since no parameter characterizing the Hamiltonian of the system is tuned to empirical data and simulations results are thus free from empirical hints.

Introduction and DFT Foundations

The chemical and physical properties of materials both at the macro- and nano-scale strongly depend on the fundamental interactions holding together atoms and electrons present in the structure. A complete understanding of the material properties rests upon being able to accurately describe the electronic structure of the system, or, in other words, to solve the Schrödinger equation for the Hamiltonian characterizing the system. Unfortunately, solving this equation is not possible without making some physical assumptions that decrease the mathematical complexity of the problem. One of the most important approximations considered in the quantum treatment of materials consists of the so-called Born-Oppenheimer or adiabatic approximation: considering the three orders of magnitude difference between nuclei and electron masses (and De Broglie wavelengths), only the electrons are regarded as quantum particles and it is accepted

B. Bhushan (ed.), *Encyclopedia of Nanotechnology*,
DOI 10.1007/978-94-017-9780-1

that the motion of the nuclei does not influence the electron dynamics (nuclei are considered fixed in space). Within this hypothesis, the description of correlated nuclei and electrons can be decoupled so that the wave function Ψ of an N-electron system depends only on the electron coordinates, namely, Ψ (r_1, r_2, …, r_N) = Ψ ({r}), and the nuclei positions enter only as parameters. The Hamiltonian operator $\hat{H}$ for the electrons at a fixed nuclear configuration can be written in the compact form:

$$\hat{H} = \hat{T} + \hat{V}_{ee} + \hat{V}_{ext} \tag{1}$$

where $\hat{T}$ is the kinetic energy operator, $\hat{V}_{ee}$ the operator corresponding to the electron–electron interactions, and $\hat{V}_{ext}$ the external potential operator typically defined by the Coulomb attractive potential due to nuclei. Despite the simplifications introduced, when the form of the interaction potentials are known, the many-body Schrödinger equation $\hat{H}\Psi = E\Psi$ for the electrons cannot be solved analytically and it is not numerically manageable because of the prohibitive number of degrees of freedom. Density Functional Theory, which was elaborated in 1960s by Hohenberg and Kohn, together with the ansatz made by Kohn and Sham has provided a way to obtain the ground state properties for real systems of many electrons, starting from the general Hamiltonian reported in Eq. 1.

Theoretical Background

Density Functional Theory (DFT) takes its historical root in the Thomas-Fermi model [1] and has its solid mathematical justification in the Hohenberg-Kohn theorems [1, 2]. These theorems and their corollaries prove rigorously that the electronic charge density, $\rho(r)$, can be used as the only basic variable to obtain the ground state properties of a system of N interacting electrons moving in an external potential $v_{ext}(r)$. In particular, it can be demonstrated that the total energy of a quantum system is a functional of the electron density $\rho(r)$ only: knowing the electron density explicitly implies having a complete physical description of the system and it is equivalent to know its ground state wave function ($\psi_0[\rho]$). The energy functional can be written as:

$$\begin{aligned} E[\rho] &= E[\rho] + \int v_{ext}(r)\rho(r)dr \\ \text{with } F[\rho] &= T[\rho] + V_{ee}[\rho] \end{aligned} \tag{2}$$

In Eq. 2, the functional $E[\rho]$ is organized in two parts: a term depending on the external potential or, in other words, by the specific material and structure under investigation, and the functional $E[\rho]$ which is the same for all the physical systems (atoms, molecules, solids, or nanostructures) and it is called universal functional. In quantum mechanics the electron charge density $\rho(r)$ is defined as:

$$\rho(r) = N\int \dots \int |\Psi(\{r\})|^2 dr_2 \dots dr_N \tag{3}$$

and obeys the condition $\int \rho(r)dr = N$ in order to represent the number of electrons per unit volume for a given state (in Eq. 3 and throughout the chapter atomic units are used). The second Hohenberg-Kohn theorem states that the exact ground state energy of a system is the global minimum value of the functional $E[\rho]$ and that the density that minimizes this functional corresponds to the exact ground state density ρ_0. In this context, if ρ_0 is unknown, the best estimate of the ground state properties can be obtained following a variational approach by minimizing the energy functional $E[\rho]$ calculated with respect to a trial density. The latter condition can be expressed considering that also the wave function of the system is a functional of the density, and the total energy of the system can be written as:

$$E[\rho] = \langle \Psi[\rho]\hat{H}|\Psi|[\rho]\rangle \tag{4}$$

the ground state charge density ρ_0 results from:

$$\rho_0 = \min_{\rho} E[\rho]. \tag{5}$$

The Hohenberg and Kohn formulation has in principle a very general validity but it is impractical since the exact form of the universal

functional $E[\rho]$, is not known. A decisive step toward its practical applications was made possible thanks to the ansatz by Kohn-Sham (KS); according to their hypothesis, the interacting electron systems can be replaced with an auxiliary system of independent electrons characterized by the same ground state charge density, ρ_0, as the original one. For the auxiliary system the energy functional, $E[\rho]$, can be written as:

$$E[\rho] = T_s[\rho] + \frac{1}{2}\int\int \frac{\rho(r)\rho(r')}{|r-r'|} dr dr' + \int v_{ext}\rho(r)dr + E_{xc}[\rho] \tag{6}$$

where $T_s[\rho]$ is the kinetic energy term of noninteracting electrons, $1/2\int\int \rho(r)\rho(r')/|r-r'|drdr'$ is a classical term representing the Coulomb repulsion between two continuous charge distributions (Hartree term), while $E_{xc}[\rho]$ is the "exchange and correlation" term in which all the many-body effects of the original interacting system are included. For the noninteracting electrons, the wave function is expressed by $\Psi = \psi(r_1)\psi(r_2)\ldots\psi(r_N)$ and the charge density $\rho(r)$ becomes

$$\rho(r)\sum_i f_i|\psi_i|^2, \mathrm{i} = 1, \ldots, \mathrm{N} \tag{7}$$

where ψ_i are the single-particle wave functions and f_i are the occupation numbers. Once the density of the auxiliary system is obtained, one knows also the ground state density of the original interacting system. The minimization of Eq. 6 with respect to ρ yields a set of N ground state single-particle Schrödinger-like equations that reads:

$$\left(-\frac{1}{2}\nabla^2 + \int\frac{\rho(r')}{|r-r'|}dr' + v_{ext}(r) + \frac{\delta E_{xc}[\rho]}{\delta\rho(r)}\right)\psi_i^{KS} = \varepsilon_i^{KS}\psi_i^{KS}, i = 1, \ldots, N \tag{8}$$

It is worth to remark that the eigenvalues (ε_i^{KS}), and the wave functions (ψ_i^{KS}) calculated in Eq. (8) are referred to a Kohn-Sham system and are not those relative to the real system of interacting electrons, yet, following Eq. 7, ψ_i^{KS} are used to obtain the correct density. The main intricacy of Eqs. 6 and 8 is related to the fact that the explicit dependence of $E_{xc}[\rho]$ on the electron density is not known, thus, even if the KS ansatz has reduced the complexity of the original many-body problem, the correct ground state is still not achievable. Following the work by KS, many approximations to $E_{xc}[\rho]$ have been proposed in literature and these are usually classified as a "Jacob's ladder of DFT" [5] which goes from lower accuracy (lower steps) to the exact unknown form (highest step). The simplest construction of $E_{xc}[\rho]$ is represented by the Local Density Approximation (LDA) in which $E_{xc}[\rho]$ is taken so that $\delta E_{xc}[\rho]/\delta\rho$ is equal to the exchange and correlation energy density of a homogeneous electron gas, $\varepsilon_{xc}^{\mathrm{hom}}$, at the density of the auxiliary system at point r of space. The quantity $\varepsilon_{xc}^{\mathrm{hom}}(\rho(r))$ has an analytical expression, that, once substituted in Eq. 8 allows finding the eigenfunctions of the auxiliary system. Many approximations other than LDA are available for $E_{xc}[\rho]$; one of the most commonly used consists of the Generalized Gradient Approximation (GGA) in which the exchange and correlation energy density term has an explicit dependance also on the density gradient $|\nabla\rho(r)|$. Several expressions for such dependence have been proposed in literature. Both LDA and GGA functionals suffer from being approximations of the true energy functional and, for this reason, they fail in describing physical phenomena in which electron correlation has an important role as for example Van der Waals forces or strongly correlated systems such as the d-shells of transition metals. To overcome the limits of KS-DFT formulation, several post-DFT methods have been developed; for example, the LDA + U (or GGA + U) approximation in which an on-site Hubbard-like correction (U) is added to the strongly correlated electrons [6], or the GW approach in which Green functions are used to evaluate self-energy corrections on single particle eigenvalues [7]. Finally, we mention that DFT, which is a ground state theory, has been extended to a time dependent formulation (TD-DFT) to provide a solid methodology to study the excited state properties of a many-body system in the presence of an external time dependent potential [8].

Numerical Details

Once the Exchange and Correlation term is made explicit, the KS wave functions ψ_i^{KS} (and the ground state charge density ρ_0) can be obtained by solving self-consistently the set of nonlinear differential equations (8). In the iterative solution procedure, the wave function is generally represented as a linear combination of basis set functions yielding a matrix representation of the Hamiltonian. This choice transforms the solution of partial integro-differential equations into a diagonalization problem, for which many standard algorithms have been largely tested and developed. Traditionally many DFT codes, implemented to calculate the electronic structure of materials, have been developed to deal with crystalline solids, that is, with periodic arrangements of atoms in a Bravais lattice and consequently yielding $v_{ext}(r)$ appearing in Eq. 8 also periodic. In this case, according to the Bloch's theorem [9], the KS eigenfunctions can be expressed as Bloch states denoted by a wave vector $\vec{k}$ within the first Brillouin Zone (BZ). A convenient basis set to expand these wave functions consists of the plane waves (PWs) basis set. Since the system is periodic, not all the PWs appear in the expansion but only those having a wave vector belonging to the reciprocal lattice of the crystal. In principle one would have to include an infinite number of functions to express the solution of the KS eigenvalue equation; in practice it is enough to limit the expansion to a finite subset of the basis set space once the accuracy of the subset has been proved. In the case of nonperiodic systems, like molecules, surfaces, or nanostructures, one can still effectively adopt a finite PWs basis set and use all the established numerical strategies deviced for 3-D periodic structures, if one adopts a supercell approach [2]. With the term "supercell" one indicates a 3-D periodic cell that contains the nonperiodic (or partially periodic) structure and a vacuum region. The cell sizes along the periodic directions correspond to the lattice parameters of the structure in those directions, while in the other directions the cell size has to be large enough to accommodate the finite structure and the vacuum. Periodic boundary conditions are applied to the supercell, in this way the structure is repeated in space even if it is not fully periodic; if the vacuum size is large enough the replicas along the nonperiodic directions can be considered to be isolated. Indeed, the increment of the cell size to create a reliable system increases the computational cost, thus a compromise has to be reached to obtain the desired accuracy. One of the most used methods, employed to decrease the size of the basis set (and thus reducing the computational cost) is represented by the so-called "pseudopotential" approximation [10]. According to this approximation the electrons tightly bound to the nuclei and not involved in bond formation (core electrons) are "frozen" into the core and their effect on the other electrons (valence electrons) is included in an effective way into the external potential ($v_{ext}(r)$). The pseudopotential represents an electrostatic potential that contains the effect of the bare ionic charge screened by the core electrons and it is characterized by pseudo-wavefunctions that, in the core region, are smoother than the wave functions of the bare nuclear potential and, for this reason, require less PWs to be expanded.

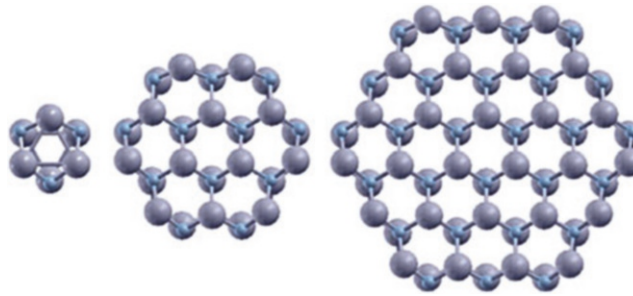
Once the solutions of the KS equations are obtained, it is possible to calculate any physical quantity of interest for the investigated system. For the case of periodic structures many properties such as the counting of electrons in bands, total energy, density, etc., are obtained by summing over all the states labeled by $\vec{k}$ in the BZ. For a general function $F_i(\vec{k})$ associated with a certain physical quantity, the average value $\overline{F}_i$ is defined as:

$$\overline{F}_i = \frac{1}{\Omega_{BZ}} \int_{BZ} F_i\left(\vec{k}\right) d\,\vec{k} \tag{9}$$

where i denotes discrete states for each $\vec{k}$, Ω_{BZ} is the BZ volume, and the integral is extended over the entire BZ. In computer codes, accurate integration is performed by summation over discrete set of points in the BZ. One of the methods that has been largely used to sample the BZ is the one proposed by Monkhorst and Pack [2]. This method consists of constructing a uniform grid of points indicated by three integer numbers (n_1, n_2, n_3) that define the mesh discretization

along the reciprocal space axis. If these points are chosen carefully and the grid is fine enough, the error in the estimate of $\overline{F}_i$ is small and the integral is well approximated by the summation. Finally once the ground state density of the KS system is known, according to the Hellmann-Feynman theorem [2], it is possible to calculate analytically the forces acting on each atom of the structure. Thus, if the structure is not at its equilibrium geometry, atoms can be moved and systems relaxed following the calculated forces until a selected threshold value is reached.

DFT Applications to Nanostructures



In the following the application of DFT to the investigation of the structural and electronic properties of a particular type of nanostructures, namely, one-dimensional nanowires (NWs) is presented. Understanding how the properties of a material change when it is reduced to a nanostructure is important for a wide range of scientific and technological applications as well as for basic science. The reduction to nanometers in the size of a semiconductor [11] demands theoretical approaches based on an atomistic description of a material; first principles–based approaches have demonstrated to be capable of exploring the electronic structure of bulk materials and small nanostructures with highly predictive character reaching a degree of detail that can hardly be achieved with experimental techniques. In particular, DFT simulations have played a major role in the study of electron confinement, and in determining how the band gap, the optical properties, and the electronic transport change at the nanoscale. In the last years, many different materials have been studied ranging from low (e.g., Ge, Si, InN) to wide band gap (e.g., ZnO, SiC) semiconductor, in the form of both simple and core/shell wires. Hereinafter the results for simple nanowires are discussed for a particular type of a technologically important material: Indium Nitride (InN). More in detail the effects of size reduction on the energy gap of the material are presented and the changes induced by surface termination on the electronic properties of the nanostructure are analyzed.

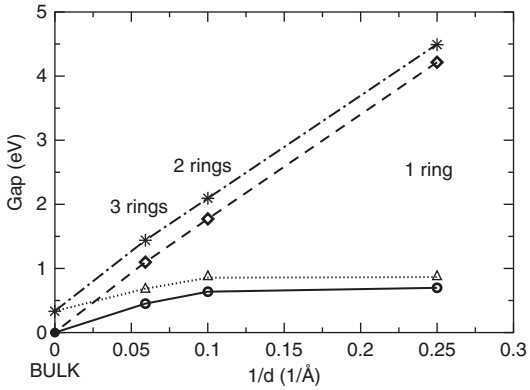
DFT Simulations of InN Nanowires

Group-III nitrides represent a material class with promising electronic and optical properties [12]. Among these, InN exhibits the narrowest band gap of about 0.67 eV at low temperatures, the lowest effective electron mass, and the highest peak drift velocity and electron mobility. InN nanowires have been proposed for applications in new generation integrated systems like quantum wire transistors with the aim of reducing the power consumption in large-scale integrated circuits. Due to their high surface to volume ratio, nanowires are also potential candidates for sensor applications and they have been proposed as key elements in new generation solar energy harvesting devices such as dye sensitized or other hybrid solar cells. A crucial role for applications of InN nanowires as novel nanoelectronic devices is played by a quasi-two-dimensional electron accumulation layer around the wire. To fully exploit the potential of InN nanowires, their physical properties have to be understood in depth.

Here the LDA and LDA + U results are discussed for wurtzite InN NWs [13] of increasing diameter with both clean and hydrogenated surfaces of three sizes (see Fig. 1): NW1 has one atom ring and a diameter d ≈ 4.1 Å, NW2 has two rings and a diameter d ≈ 10.6 Å, while NW3 has three rings and a diameter d ≈ 17.6 Å. By construction, these NWs have hexagonal cross-section and present nonpolar $(1\overline{1}00)$ facets, in agreement with experimental observation. Typically for a DFT simulation, due to the numerical approximations adopted to solve the KS equations presented previously, accuracy of the results has to be checked carefully once the following computational conditions have been chosen:

- Pseudopotentials needed to describe the external potential felt by the valence electrons.
- Size of the plane waves basis set employed to expand the one-electron wave function. This is expressed by an energy cutoff that corresponds to the highest kinetic energy (lowest wave vector) of the PWs included in the expansion.
- Convergence criteria on the total energy of the system and on the forces acting on the atoms in

Ab Initio DFT Simulations of Nanostructures, Fig. 1 Ball and stick representation of the investigated InN nanowires: *left* – 1 ring NW (d ≈ 4.1 Å), *middle* – 2 rings NW (d ≈ 10.6 Å), *right* – 3 rings NW (d ≈ 17.6 Å). *Large balls* represent In atoms, *small balls* represent N atoms

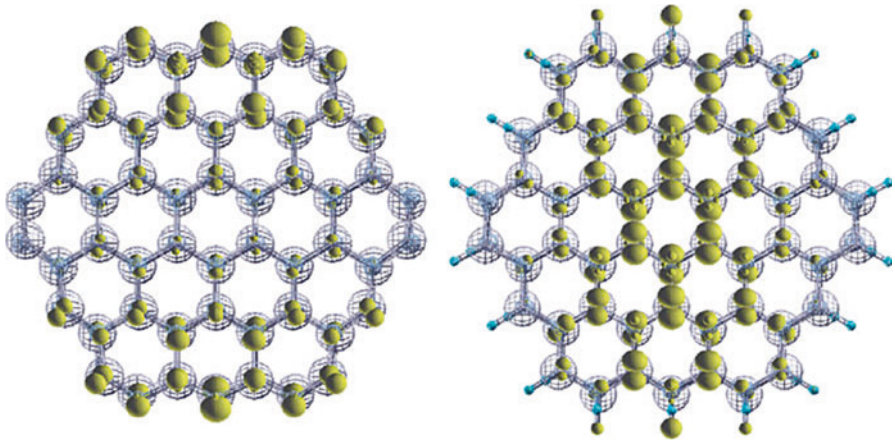


the case of structural relaxation based on Hellman-Feynman forces.
- Accuracy of the Monkhorst-Pack grid used to sample the Brillouin Zone of the periodic structure.
- Vacuum size in the supercell, in the case of structures that are nonperiodic in one or more dimensions (e.g., surfaces, nanowires, quantum dots, etc.).

To simulate InN 1-D nanostructures previously mentioned, the supercell approach was used: in this case the nanostructures are periodic only along the NW axis (*z*), thus large supercells have to be employed to accommodate enough vacuum space surrounding the wire (i.e., ∼ 10 Å) in the directions perpendicular to the NW axis. The integration over the Brillouin Zone was performed using a (1 × 1 × 6) k-point grid. All the structures were fully relaxed until the forces acting on the atoms were less than 10^{-3} Ry/bohr. The lattice parameter along the direction of the NW axis can be optimized by varying the cell size along that direction and relaxing all the atomic positions. The minimum energy structure is then obtained by fitting the total energy values with a polynomial fit. It has been found that in nanowires two main relaxation mechanisms occur: the lattice parameter along the NW axis changes with respect to the bulk value and the atoms at the NW surfaces relax.

The lattice constant along the NW axis increases decreasing the NW diameter and, except for the smallest diameter NW1, the behavior appears to be linear. While the NWs elongate along their axis, the lattice contracts in the perpendicular directions. This behavior has been observed also for other more ionic compound such as ZnO [14]. After relaxation, changes of InN bonds occur at the nanowire surface: the InN bond length becomes 2.05 Å (shorter than InN length in bulk of ∼ 0.1 Å) and it tilts by about 9.5°, with the In atoms relaxing inward. Upon hydrogenation the In–N bond length recovers its bulk value (∼2.18 Å), but the In–N bond tilting is now opposite to the clean case (∼5–6°), due to the moving out of the In atom.

In Fig. 2, the band gap dependence on the inverse of the NW diameter (1/d) for NWs with clean and hydrogenated surfaces is reported. It can be noted that in both LDA and LDA + U approaches the dependence of quantum confinements is almost linear and that the inclusion of the Hubbard (U) correction determines a rigid shift of the band gap (about 0.2 eV for NWs with clean surfaces and 0.35 eV for NWs with hydrogenated surfaces) that depends only slightly on the NW diameter. The larger energy gaps observed in the case of nanowires with hydrogenated surfaces imply that quantum confinement effects are more noticeable in passivated NWs and that one might expect to see spectroscopic differences in experiments performed in different environments (e.g., solution vs ultra high vacuum). LDA and LDA +U predict similar confinement effects also in terms of charge density distribution when comparing nanowires with clean and hydrogenated surfaces.



In the latter case, due to surface dangling bonds saturation, the electronic charge density accumulates in the center of the wire, while in nanowires with clean surfaces the density is more delocalized on the surface atoms. This effect is visible in Fig. 3 where the electronic charge density isosurface of the highest occupied state for NW3 is shown for clean and hydrogenated surfaces.

Ab Initio DFT Simulations of Nanostructures, Fig. 2 Band gap versus inverse diameter (1/d) of InN nanowires with clean surface indicated by *solid* (LDA) and *dotted* (LDA + U) *lines*, and for hydrogenated nanowires indicated by *dashed* (LDA) and *dashed-dotted* (LDA + U) *lines*

Conclusion

In conclusion, first principles DFT electronic structure calculations can be effectively used to systematically investigate the relative stability and electronic properties of nanostructures with clean, reconstructued, or passivated surfaces. In the case of Nanowires one can also consider the effects of the growth direction and of the diameter. Electronic properties of NWs, including band gaps, band structures, and effective masses, are usually found to depend sensitively on all the NW structural parameters. In many cases, the size dependence of the band gap depends on the growth direction of the NW, and the band gaps for a given size also depend on surface structure; moreover NWs with clean surfaces have HOMO orbitals localized on the facets and exhibit smaller band gaps. DFT calculations demonstrate the extremely rich nature of the electronic properties of nanostructures and NWs in particular and have a unique role in describing confinement effects in these small dimension systems. By changing the growth direction and NW diameter, or tuning the surface structure via chemical or physical methods, it is possible to engineer NWs with a wide range of technologically important electronic properties.

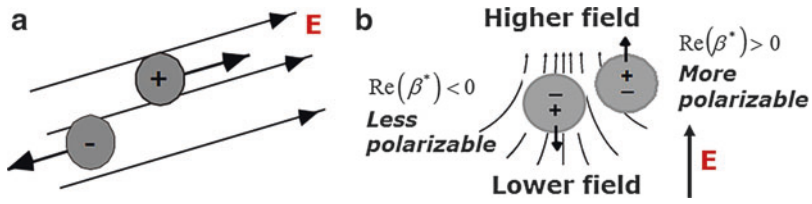
Dielectrophoretic phenomena; Dipolar particle chaining; Dipole–dipole particle interaction; Field-driven particle assembly; Suspension interaction with external AC field gradient

Definition

The total force exerted on a polarizable particle by a spatially nonuniform electrical field is the sum of the electrophoretic force (product of the net particle charge and the field strength) and the dielectrophoretic force (product of the particle dipole moment and the field strength gradient). Electrophoretic force effects vanish in an alternating current (AC) field of a sufficiently high frequency due to the zero time average over the field oscillations. In contrast, dielectrophoretic force operates in AC fields as its averaging yields a

nonzero value whose magnitude is the product of the particle volume, the gradient of the time-average squared field strength, and the relative particle polarization at the field frequency. Depending on whether the particle is more or less polarizable than the suspending fluid, it migrates toward the regions of high field strength (positive dielectrophoresis) or low field strength (negative dielectrophoresis).



AC dielectrophoresis is becoming one of the major techniques for micro- and nanoscale systems. As one of its major features is the ability to concentrate particles, AC dielectrophoresis in suspensions is controlled not only by the interaction of particles with an externally applied field but also by the dipole–dipole forces between the polarized particles which acquire dipole moments as exposed to an electrical field. The main effect of the interparticle dipolar interactions is that they, if sufficiently strong, cause a suspension to undergo reversible transitions from a random arrangement of particles into a variety of ordered aggregation patterns. This trend has been long recognized and exploited in electrorheology to initiate the fluid–solid transition by applying a sufficiently strong field to a suspension. Control of multiparticle interactions driven by the interplay of dielectrophoretic and dipolar forces was shown to provide a powerful way to manipulate suspensions.

Overview

Dielectrophoresis, the term coined by Pohl [1], is the motion of an object under the force resulting from an electrical field gradient. Application of AC dielectrophoresis is based on differentiation of dielectric and conducting properties of objects to allow their separation and identification. To enable the dielectrophoretic manipulation of particles and macromolecules, the applied AC field should be sufficiently strong to dominate the thermal Brownian motion. However, a high electrical field also gives rise to undesirable processes in the suspending fluid, such as electrolysis, electroosmosis, thermal convection, and electrothermal flow caused by the variation in the fluid conductivity, permittivity, and density due to Joule heating. Estimation of the orders of magnitude of the various forces experienced by a particle and a fluid in dielectrophoretic micro-fluidics indicates that AC dielectrophoresis would prevail in small-scale devices and for sufficiently high field frequencies.

Compared to other available methods, AC dielectrophoresis is becoming one of the major methods for control and manipulations of particles and macromolecules in micro- and nanofluidics. Its main advantages include the use of an electrical field which requires no moving parts and employing polarization forces acting on a fine particle that are insensitive to the particle charge which is difficult to control. Therefore, dielectrophoresis-based techniques offer easy adaptability to electronics and can be incorporated more favorably into micro-systems to integrate multiple analytical methods down to chip format. A wide variety of dielectrophoretic micro-devices have been developed to address challenges in materials science, analytical chemistry, and life science, such as assembling nanoparticles, separating polydisperse particle suspensions into homogeneous subpopulations, manipulating and concentrating biologically relevant molecules, distinguishing dead and living cells or ill and healthy cells, etc. [2].

Since particles undergoing dielectrophoresis acquire a dipole moment, they interact with one another through dipole–dipole forces. It is well known that, because of dipolar interactions, polarized particles have a tendency to align rapidly along the field direction and to form chains that subsequently coalesce into thicker columns. This phenomenon causes a colloidal dispersion to undergo a reversible fluid–solid transition and exhibit a yield stress at low shear rates (often referred to as electrorheological effect) [3]. Recent studies reveal that, due to the particle confinement at the microscale, synergism of dielectrophoretic and dipole forces provides a powerful way to control and manipulate particles in micro-devices and extends the use of dielectrophoresis to the nanoscale for various applications ranging from nano-biotechnology to molecular electronics.

AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 1 (**a**) Electrophoresis. (**b**) Dielectrophoresis

Basic Methodology

Electrical Force Acting on an Individual Particle

The force exerted by an electrical field on a particle consists of two terms:

$$\mathbf{F} = Q\mathbf{E} + (\mathbf{P} \cdot \nabla)\mathbf{E} \tag{1}$$

where Q is the particle charge and $\mathbf{P}$ is the particle dipole moment. The first term in Eq. 1 is the *electrophoretic force*, which causes a charged particle subjected to a direct current (DC) field to travel along the electrical lines (Fig. 1a), whereas the other term is referred to as the *polarization force* or very often as the *dielectrophoretic force*. In contrast to the electrophoretic force, the latter acts on both neutral and charged particles. Equation 1 represents the first terms in the expansion of the net electrical force acting on the induced charges in a polarized particle as a power series in the field gradient. When the particle dimensions become comparable to a characteristic length scale of an array of microelectrodes, the presence of the particle modifies the overall electrical field, and the dipole approximation in Eq. 1 is unreliable. The significance of higher-order terms in Eq. 1 for different electrode configurations is analyzed through comparison against the net force computed by integrating the Maxwell stress tensor over the particle surface [4]. Higher-order terms in the net electrical force exerted on a nonspherical particle (which includes the majority of biological particles) appear to be more significant due to the shape dependence of the particle polarization.

The polarization of a not perfectly insulating or perfectly conducting particle depends on the time variation of the applied electrical field over some characteristic time interval in the recent past. In particular, for a suspended sphere when the speed with which charge carriers rearrange themselves in response to an applied field is independent of the field strength, it becomes

$$\mathbf{P} = 3v_p\varepsilon_0\varepsilon_f \int_{-\infty}^{t} \overline{\beta}(t-t')\mathbf{E}(t')dt' \tag{2}$$

where v_p is the particle volume, ε_0 is the vacuum permittivity, ε_f is the fluid dielectric constant, and $\overline{\beta}(t)$ describes the dielectric relaxation. The real and imaginary parts of the Fourier transform of $\overline{\beta}(t)$ describe the interaction of a particle with an oscillating (AC) field of the frequency $\omega = 2\pi v$ where v is given in Hz:

$$\mathrm{Re}(\beta^*) + i\mathrm{Im}(\beta^*) = \int_0^{\infty} \overline{\beta}(t)e^{-i\omega t}dt \tag{3}$$

A model of a perfect dielectric assumes that the polarization responds instantaneously to an applied field so that $\overline{\beta}(t) = C_1\delta(t)$ with some constant C_1 and $\delta(t)$ being the Dirac delta function. In this case, Eq. 3 yields $\mathrm{Re}(\beta^*) = C_1$ and $\mathrm{Im}(\beta^*) = 0$. The opposite extreme of a perfectly conducting material corresponds to the polarization proportional to the rate of the time variation of an applied field so that $\overline{\beta}(t) = C_2\delta'(t)$ with some constant C_2 and $\delta'(t)$ being the derivative of the delta function, in this case, $\mathrm{Re}(\beta^*) = 0$ and $\mathrm{Im}(\beta^*) = \omega C_2$. When the electrical properties of the particle and that of the suspending fluid (i.e., their dielectric constants, ε_p and ε_f, and conductivities, σ_p and σ_f) are frequency independent, the Maxwell–Wagner theory [5, 6] yields the following expression for β^* often referred to as the Clausius–Mossotti factor:

$$\mathrm{Re}(\beta^*) = \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + 2\varepsilon_1} + \frac{3(\varepsilon_1\sigma_2 - \varepsilon_2\sigma_1)(\sigma_2 + 2\sigma_1)}{\left[(\sigma_2 + 2\sigma_1)^2 + \omega^2(\varepsilon_2 + 2\varepsilon_1)^2\right](\varepsilon_2 + 2\varepsilon_1)} \quad (4)$$

$$\mathrm{Im}(\beta^*) = -\frac{3\omega(\varepsilon_1\sigma_2 - \varepsilon_2\sigma_1)}{(\sigma_2 + 2\sigma_1)^2 + \omega^2(\varepsilon_2 + 2\varepsilon_1)^2}. \quad (5)$$

Similar expressions are available for ellipsoidal particles [5, 6]. Equations 4 and 5 indicate that a particle responds according to its dielectric constant at sufficiently high frequencies and conductivity at sufficiently low frequencies and DC field:

$$\mathrm{Re}(\beta^*) \to \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + 2\varepsilon_1} \text{ and } \mathrm{Im}(\beta^*) \to 0 \text{ as } \omega \to \infty$$

$$\mathrm{Re}(\beta^*) \to \frac{\sigma_2 - \sigma_1}{\sigma_2 + 2\sigma_1} \text{ and } \mathrm{Im}(\beta^*) \to 0 \text{ as } \omega \to 0$$

There have been extensive theoretical and experimental studies of polarization of particles and macromolecules subjected to spatially uniform electrical fields [5]. It is found that the polarization of a fine particle and a macromolecule dispersed in a fluid strongly depends on its structure, fluid properties, and interface characteristics. There are no simple models containing a few adjustable parameters capable to characterize the dependence of Re(β*) and Im(β*) on the applied frequency and electrical and physical properties of the particle and the fluid. Dielectric relaxation spectroscopy that employs spatially uniform low fields (~1 V/mm) is used to measure the polarization of a colloidal dispersion to obtain data on the frequency dependence of an individual particle polarizability. Specifically, β* can be calculated from experimental data on the concentration and frequency dependence of the complex dielectric permittivity of the colloidal dispersion, ε_s^*, and the suspending fluid, ε_f^*, using the Maxwell-Garnett expression (Eq. 6) (often referred to as the Lorentz–Lorenz model) for a dilute suspension of spheres [5]:

$$\left(\varepsilon_s^* - \varepsilon_f^*\right) / \left(\varepsilon_s^* + 2\varepsilon_f^*\right) = \beta^*(\omega)\, c \quad (6)$$

where c is the particle volume fraction. Polarizability measurements enable quantitative predictions of dielectrophoretic phenomena in a colloidal dispersion subjected to strong fields (~ kV/mm) since the field dependence of β*(ω) usually appears to be insignificant.

As the dipole moment **P** is proportional to the field strength in Eq. 2, the second term in Eq. 1 appears to be proportional to the square of the applied field. This implies that under the action of an AC electrical field, the dielectrophoretic force yields a nonzero time-average value [1, 6]:

$$\left\langle \mathbf{F}_{dep} \right\rangle = \frac{3}{2}\varepsilon_0\varepsilon_f v_p \mathrm{Re}[\beta^*(\omega)]\nabla E_{rms}^2(\mathbf{r}) \quad (7)$$

where $\langle\,\rangle$ denotes averaging over the period of the field oscillations and E_{rms} is the root mean square of the local electrical field strength. This force causes a particle to move to the regions of high field strength (*positive* dielectrophoresis) or low field strength (*negative* dielectrophoresis), depending on whether the particle is more ($\mathrm{Re}(\beta^*) > 0$) or less ($\mathrm{Re}(\beta^*) < 0$) polarizable than the suspending fluid (Fig. 1b).

Single-Particle Model of Dielectrophoresis

A single-particle model ignores the interparticle interactions and considers only the dielectrophoretic, Eq. 7, and hydrodynamic forces exerted on a polarized particle. The Reynolds numbers for the fluid flow $\mathrm{Re}_f = \rho_f |\mathbf{v}_f| d/\eta_f$ and for the particle motion relative to the fluid $\mathrm{Re}_p = \rho_p |\mathbf{u} - \mathbf{v}_f| a/\eta_f$, where $\mathbf{v}_f$ is the local fluid velocity, $\mathbf{u}$ is the local particle velocity, and ρ_p and ρ_f are, respectively, the particle and fluid densities, are usually very small. The hydrodynamic force exerted on a spherical particle is given by the Stokes equation since the contribution of the inertial and Basset forces to the transient regimes of the particle motion relative to the fluid is typically negligible in comparison with the viscous forces [5]. With these assumptions, the force balance for a spherical particle flowing through a field region yields

$$\frac{d\mathbf{r}}{dt} = \mathbf{u} \text{ with } \mathbf{r}|_{t=0} = \mathbf{r}_0 \tag{8}$$

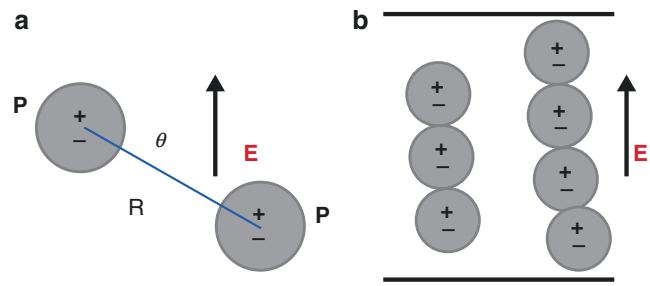
$$\text{with } 6\pi\eta_f a\left[\mathbf{u} - \mathbf{v}_f(\mathbf{r})\right] = 2\pi\varepsilon_0\varepsilon_f a^3 \mathrm{Re}(\beta^*)\nabla E^2_{rms}(\mathbf{r}) + \frac{4}{3}\pi\left(\rho_p - \rho_f\right)a^3\mathbf{g}$$

where $\mathbf{g}$ is the gravitational acceleration and $\mathbf{r}(t)$ is the displacement of a particle initially at $\mathbf{r}_0$. To find the local values of the fluid velocity $\mathbf{v}_f(\mathbf{r})$ and the field gradient $\nabla E^2_{rms}(\mathbf{r})$, Navier–Stokes' equations for the fluid flow and Laplace's equation for the electrical field are solved for the dielectrophoretic device without particles. A gradient of an electrical field in Eq. 8 can be estimated as $\nabla E^2_{rms} \sim E^2_{rms}/d$, where d is the characteristic length of the field variation. Equation 8 provides a scale of time it takes a particle to travel the distance d relative to the fluid under the action of the dielectrophoretic force.

$$\tau_d = \frac{3\eta_f d^2}{a^2\varepsilon_0\varepsilon_f|\mathrm{Re}(\beta^*)|E^2_{rms}} \tag{9}$$

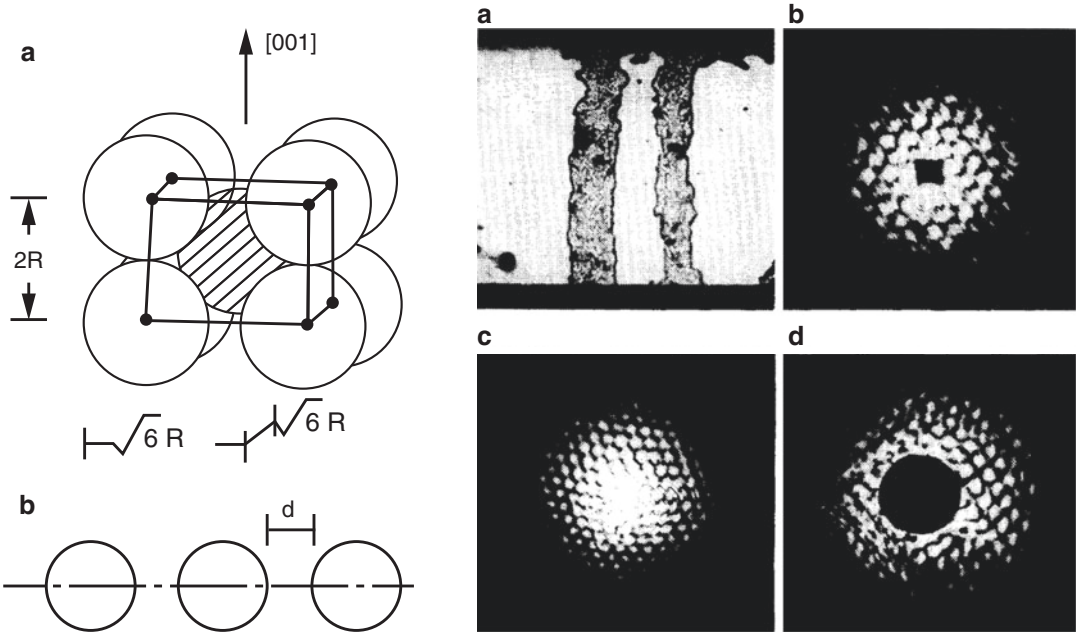
Three nondimensional parameters of Eq. 8 characterize the particle motion: the ratio of the dielectrophoretic time, Eq. 9, to the average fluid residence time, $\tau_d Q/(AL)$, where L is the characteristic length along the flow streamlines, Q is the volumetric flow rate, and A is the channel cross-sectional area; the ratio L/d, and the ratio of the gravitational and dielectrophoretic forces $G = 2\left(\rho_p - \rho_f\right)gd^3/3\varepsilon_0\varepsilon_f|\mathrm{Re}(\beta^*)|V^2_{rms}$. Predictions of Eq. 8 for the motion of polarized particles are limited to very dilute suspensions when the electrical and hydrodynamic interactions between particles are negligible [7].

Predictions of the dielectrophoretic migration and rotation of a nonspherical polarizable particle require considering the balance of hydrodynamic and electrical forces and torques exerted on the particle by an electrical field and a flowing fluid.



Structural Transitions in Suspension Subjected to Spatially Uniform Electrical Field

When an electrical field is applied to a polarized suspension, each particle acquires a dipole moment given by Eq. 2. The dipole–dipole interparticle interactions decay with the inverse cube of separation distance and, depending on the relative orientation of the dipoles, vary from attraction to repulsion [5, 6]. When the dielectric constants and conductivities of the particles and the suspending fluid are frequency independent, the time-average energy of the dipole–dipole interaction between two spheres subjected to an AC field is [8]



$$W_{dd} = \varepsilon_0\varepsilon_f v_p \Psi_\omega E^2_{rms}(a/\mathrm{R})^3\left(1 - 3\cos^2\theta\right) \tag{10}$$

where a is the particle radius, R is the center-to-center separation between the particles, θ is the angle between the line connecting the particle centers and the electrical field line (Fig. 2a), E_{rms} is the root mean square of the electrical field strength, and the function Ψ_ω characterizes the electrical energy of the interparticle interaction that depends on the field frequency and electrical properties of the particles and the suspending fluid. A rough estimate yields $\Psi_\omega \sim 3\mathrm{Re}(\beta^*)^2$ for a relatively small $\mathrm{Im}(\beta^*)$.

When the dipolar interparticle interactions exceed the randomizing Brownian motion,

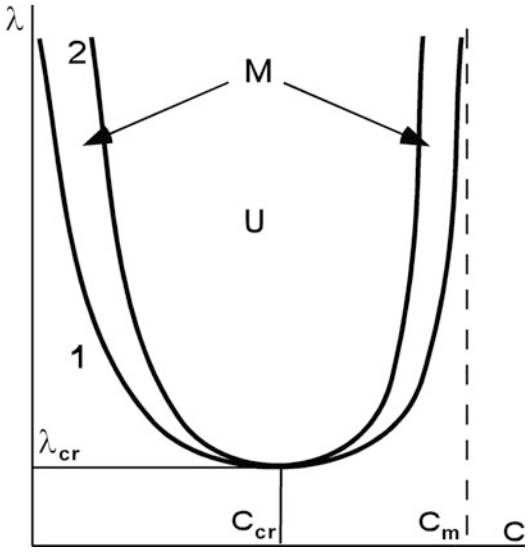
electrically induced particle rearrangement would occur. A head-to-tail configuration with $\theta = 0$ or $\theta = \pi$ in Eq. 10 is the lowest energy configuration of two polarized particles. Therefore, dipolar interactions in suspensions exposed to a spatially uniform electrical field cause particles to form chains along the applied field direction (Fig. 2b). Computer simulations for the electrical energy of a suspension of spherical particles treated as a system of point dipoles demonstrate that the zero-temperature ground state of the suspension (i.e., neglecting entropy) is a body-centered tetragonal (bct) structure. This prediction was validated in experiments (Fig. 3; [9]). However, the long-range nature of dipole–dipole interactions, Eq. 10, leads to coarsening of the chains/columns into sheets (Fig. 4; [10]) that eventually transform into a bct lattice of strings [3, 11, 12].

A thermodynamic theory [8, 13] provides an estimate of conditions under which polarizable particles would aggregate. This theory yields the following expressions for the chemical potential μ_p and the osmotic pressure Π_p of the particles averaged over the period of the field oscillations [8]:

$$\mu_p = \left(k_B T / v_p\right)\left(df_0/dc\right) - \varepsilon_0 \left(\partial \varepsilon_s'/\partial c\right)_{\omega t_c} \left\langle E^2/2 \right\rangle \tag{11}$$

$$\Pi_p = k_B T c Z / v_p + \varepsilon_0 \left[\varepsilon_s' - c\left(\partial \varepsilon_s'/\partial c\right)_{\omega t_c}\right] \left\langle E^2/2 \right\rangle \tag{12}$$

where $f_0 = c \ln \frac{c}{e} + c \int_0^c \frac{Z-1}{c} dc$, $k_B T$ is the thermal energy, Z is the suspension compressibility factor, and $\left(\partial \varepsilon_s'/\partial c\right)_{\omega t_c}$ is the derivative of the real part of



AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 4 Silica spheres (0.525 μm radius, polydispersity in size 1.8 %) in a mixture of water and glycerol. Sheet structure. The field strength is 1.2 kV/mm and the field has been on for ~30 min. (**a**) *x*–*z* Confocal micrograph (raw data). There is a sheet of particles seen in the left side of the image, with a single chain of particles to the right of it. The bottom of the image is closest to the objective lens of the microscope. It should be noted that since only the cores of the silica spheres fluoresce, touching spheres are seen as separated. It is the anisotropic point spread function that causes the spherical fluorescent cores to appear ellipsoidal. Note also that the intensity and resolution diminish away from the lens due to spherical aberration. (**b**) View of a sheet seen face on. The image is taken from a rendering of reconstructed 3D raw data such as seen in (**a**). The white scale bar is 2 μm. The bottom row of spheres is touching the glass electrode (the electrode is perpendicular to the image), and the electric field is upwards. The spheres are hexagonally close packed within a sheet. The smallest angle between nearest neighbors and the field is +/−30°, except for the first two layers adjacent to the electrode, where nearest neighbors are aligned along the field. (**c**) Side view of the same sheet object (Reprinted with permission from Ref. [10]. Source: http://scitation.aip.org/content/aip/journal/jcp/112/8/10.1063/1.480933. Copyright 2014 AIP Publishing)

the suspension dielectric permittivity ε_s^* taken at a constant value of ωt_s with t_s being the relaxation time of the particle polarization. The first terms in Eqs. 11 and 12 refer to the free energy and the osmotic pressure in the absence of an external electrical field. The other terms represent the interaction of particles with the external electrical field and the particle–particle dipole interactions. The concentration dependence of Z is described by the Carnahan–Starling equation for a suspension of spheres in a disordered state [5]. Equations 11 and 12 express the critical conditions beyond which a random arrangement of particles becomes unstable in a spatially uniform AC field in terms of the particle volume fraction c and the dimensionless parameter $\lambda = \varepsilon_0 \varepsilon_f \langle E^2 \rangle v_p / k_B T$ that characterizes the ratio of electrical and thermal energies. The phase diagram of a polarizable suspension in terms of particle concentration versus relative field strength is similar to the phase diagram of concentration versus temperature of two liquids which are completely miscible only above a certain temperature. The simplest suspension phase diagram corresponding to the case of small Im(β^*) is sketched in Fig. 5 [7], in which the spinodal separates the metastable regime **M** (slow phase transition) from the unstable regime **U** (fast phase transition) in the two-phase region. On the curve separating two-phase and single-phase regions in Fig. 5, the chemical potentials and the osmotic pressures of particles in the coexisting phases are equal. The critical point on the spinodal curve, c_{cr} and λ_{cr}, coincides with the inflection point of μ_p as a function of c [8]:

$$\frac{\partial \mu_p}{\partial c} = \frac{\partial^2 \mu_p}{\partial c^2} = 0 \text{ with } \frac{\partial^3 \mu_p}{\partial c^3} > 0$$

The single-phase region of the phase diagram (at $\lambda < \lambda_{cr}$) represents a suspension with the

random spatial arrangement of particles, whereas the two-phase region (at $\lambda > \lambda_{cr}$) corresponds to the appearance of the field-induced separation of a suspension in regions enriched with and depleted of particles. The critical point and the coexistence and spinodal lines on the phase diagram are found to be sensitive to the concentration dependence of the second derivative of the suspension dielectric permittivity $\partial^2 \varepsilon_s' / \partial c^2$ [14]. Describing structures formed by particles is beyond the scope of the thermodynamic theory [8, 13] and requires molecular dynamics simulations [11, 12].

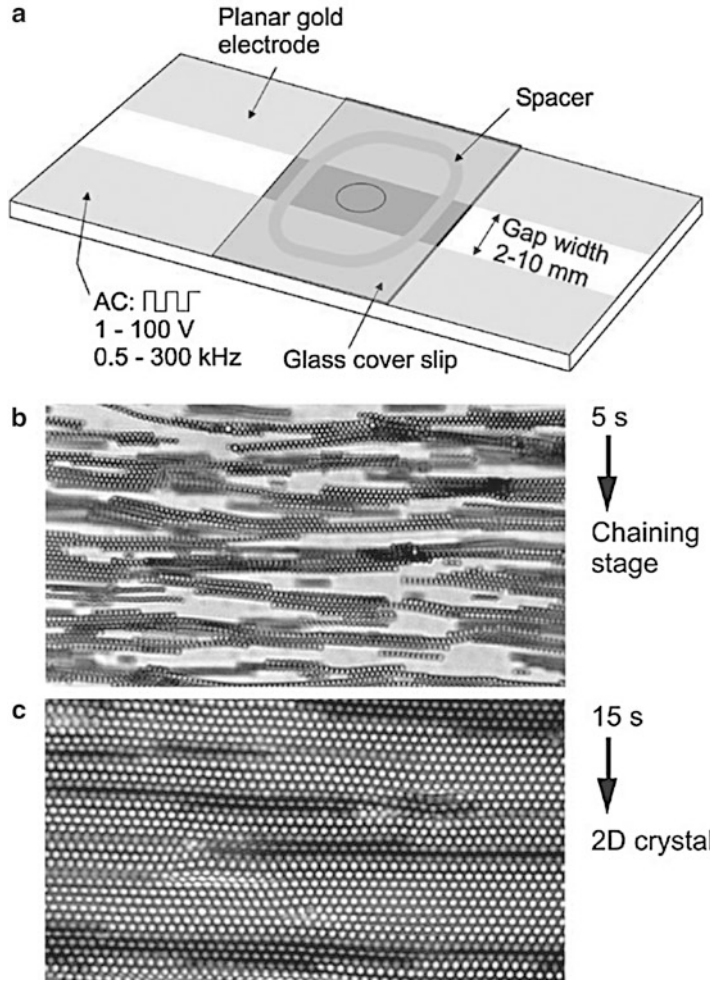
Key Research Findings

Synergism of AC Dielectrophoresis and Dipolar Interactions



Figures 6, 7, 8, and 9 from Refs. [15–18] demonstrate that the synergism of the dielectrophoretic and dipole–dipole forces provides an efficient tool for the organization and assembly of particles into functional structures. Under such conditions, the interaction of particles with an external field, Eq. 7, in a suspension is exposed to a spatially nonuniform AC electrical field that is accompanied with the interparticle dipole–dipole interactions, Eq. 10, as each particle acquires a dipole moment.

As the dipolar interparticle force is $\langle \mathbf{F}_{dd} \rangle = -\nabla W_{dd}$, Eqs. 7 and 10 yield the following estimate for the ratio of the dipole–dipole and dielectrophoretic forces:

$$\frac{\langle \mathbf{F}_{dd} \rangle}{\langle \mathbf{F}_{dep} \rangle} \sim \frac{6|\mathrm{Re}(\beta^*)|a^3 d}{R^4} \tag{13}$$

where the field gradient is estimated as $\nabla E_{rms}^2 \sim E_{rms}^2/d$ and R can be estimated as $a/c^{1/3}$. The interparticle interactions can be neglected if the ratio in Eq. 13 is small that occurs at a very low particle concentration. This situation corresponds to the single-phase region in the suspension phase diagram in Fig. 5. When the local values of the particle concentration and the field strength in certain regions of a dielectrophoretic device fall into the two-phase region of the suspension phase diagram in Fig. 5, dielectrophoresis of the particles would be accompanied by field-induced structural transitions caused by the interparticle dipolar interactions [13]. The kinetics of these transitions depends on the ratio of two time scales: τ_a and τ_d, given in Eq. 9. The former refers to the

AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 8 A suspension of 1-μm PMMA particles in decalin in the "dielectrophoretic bottle." The schematic diagram shows the capacitor plates (outside the cover slips) and the electric field lines. The particle concentration can be varied from less than 1 % to above the crystallization concentration ~0.54. The confocal images on the left and right illustrate the density profile about ten particle layers up from the bottom cover slip. The middle image was taken at ~5 layers in, where the density is slightly higher due to gravity sedimentation (Reprinted with permission from Ref. [17]. characteristic time for the field-induced structure formation in a suspension subjected to a spatially uniform field [8]:

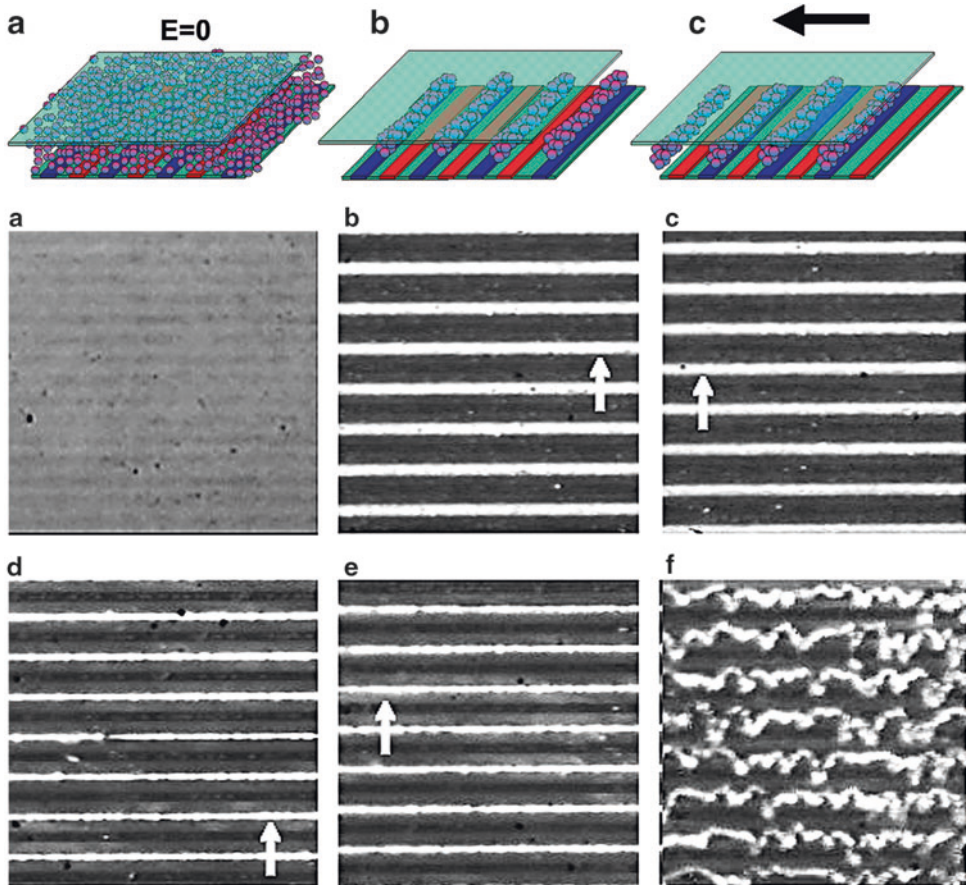
$$\tau_a \approx \frac{\eta_f}{\varepsilon_0 \varepsilon_f [\mathrm{Re}(\beta^*) E_{rms}]^2} \xi \text{ and } \frac{\tau_d}{\tau_a} \approx \frac{3d^2 |\mathrm{Re}(\beta^*)|}{a^2 \xi(c)} \tag{14}$$

where η_f is the viscosity of the suspending fluid and $\xi \approx 0.4\left[(\pi/6c)^{5/3} - 1\right]$ is a coefficient that depends on the volume fraction of the particles.



The regime $\tau_d << \tau_a$ corresponds to *heterogeneous aggregation*. Under these conditions typical of dilute suspensions, the particles are forced to accumulate in certain areas of the dielectrophoretic device and then to undergo field-induced structural transitions. The regime $\tau_d >> \tau_a$ corresponds to *homogeneous aggregation* in which macroscopic redistribution of particles during field-induced structural transitions is negligible. This regime is typical of applications of electrorheological effect [3].

Macroscopic Models

The mean-field model [7, 19] expresses the electrical and hydrodynamic interparticle interactions in terms of the instantaneous local electrical fields, particle concentrations, and flow velocities. It is based on coupled quasi-steady equations for an electrical field, Eq. 15, plus momentum balance and continuity equations for a suspension, Eq. 16, and the equation for the field and flow-driven particle motion, Eq. 17. These equations are averaged over the field oscillations. The suspension is approximated as a Newtonian fluid with a concentration-dependent viscosity. When local values of the particle concentration and electrical field lie within the single-phase region of the suspension phase diagram in Fig. 5, the electrical force exerted on the particles and the particle velocity relative to the suspending fluid in these equations are given by the particle chemical potential μ_p, Eq. 11.

Field equations

$$\nabla \cdot \varepsilon_s^*(\omega, c) \nabla \phi_\omega^* = 0 \text{ with } \mathbf{E}_\omega^* = -\nabla \varphi_\omega^* \tag{15}$$

AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 9 The schematic diagram shows conveyor belt building of large-scale multiparticle structures. Formation [(**a**) and (**b**)] and transportation [(**b**) and (**c**)] of the particle structures by energizing (*red*) and grounding (*blue*) electrodes. Photos show 1 % (*v*/*v*) suspension of 3.1-μm latex beads in a chamber equipped with two-electrode array dielectrophoretic chip energized with 5 V_{rms}/1 MHz, chamber top grounded. (**a**) Initially, the electrodes were barely visible through the suspension. (**b**) Beads were concentrated into columns (seen as *white*) in the low-field regions caused by energizing electrode array 1 and grounding array 2 and then (**c**) were moved to other low-field regions by grounding array 1 and energizing array 2. Columns were formed by energizing array 1 and grounding array 2 and (**e**) were translated by moving the chip with velocity 4.3 μm/s using the stage but (**f**) were destabilized at a chip velocity of 700 μm/s. *White arrows* on (**b**) and (**c**) as well as (**d**) and (**e**) indicate the sequential positions of the same column, respectively. Chamber height: [(**a**)–(**c**)] ~100 μm and [(**d**)–(**f**)] ~50 μm. (Reprinted with permission from Ref. [18]. Source: http://scitation.aip.org/content/aip/journal/apl/90/15/10.1063/1.2721238. Momentum balance and continuity equations

$$\rho_s\left(\frac{\partial \mathbf{v}}{\partial t}+\mathbf{v}\cdot\nabla\mathbf{v}\right)=-\nabla p+\nabla\cdot\eta_s(c)\left(\nabla\mathbf{v}+\nabla\mathbf{v}^T\right)$$
$$-c\nabla\mu_p+c\left(\rho_p-\rho_f\right)\mathbf{g}\ \text{and}\ \nabla\cdot\mathbf{v}=0 \qquad (16)$$

Particle motion

$$\frac{\partial c}{\partial t}+\nabla\cdot\left(c\mathbf{v}+\mathbf{j}_p\right)=0\ \text{with}$$
$$\mathbf{j}_p=\frac{c(1-c)^2 v_p}{6\pi a\eta_s(c)}\left[-\nabla\mu_p+\left(\rho_p-\rho_f\right)\mathbf{g}\right] \qquad (17)$$

where $\varepsilon_s^*(\omega, c)$ is the complex dielectric permittivity of a suspension as a function of the field

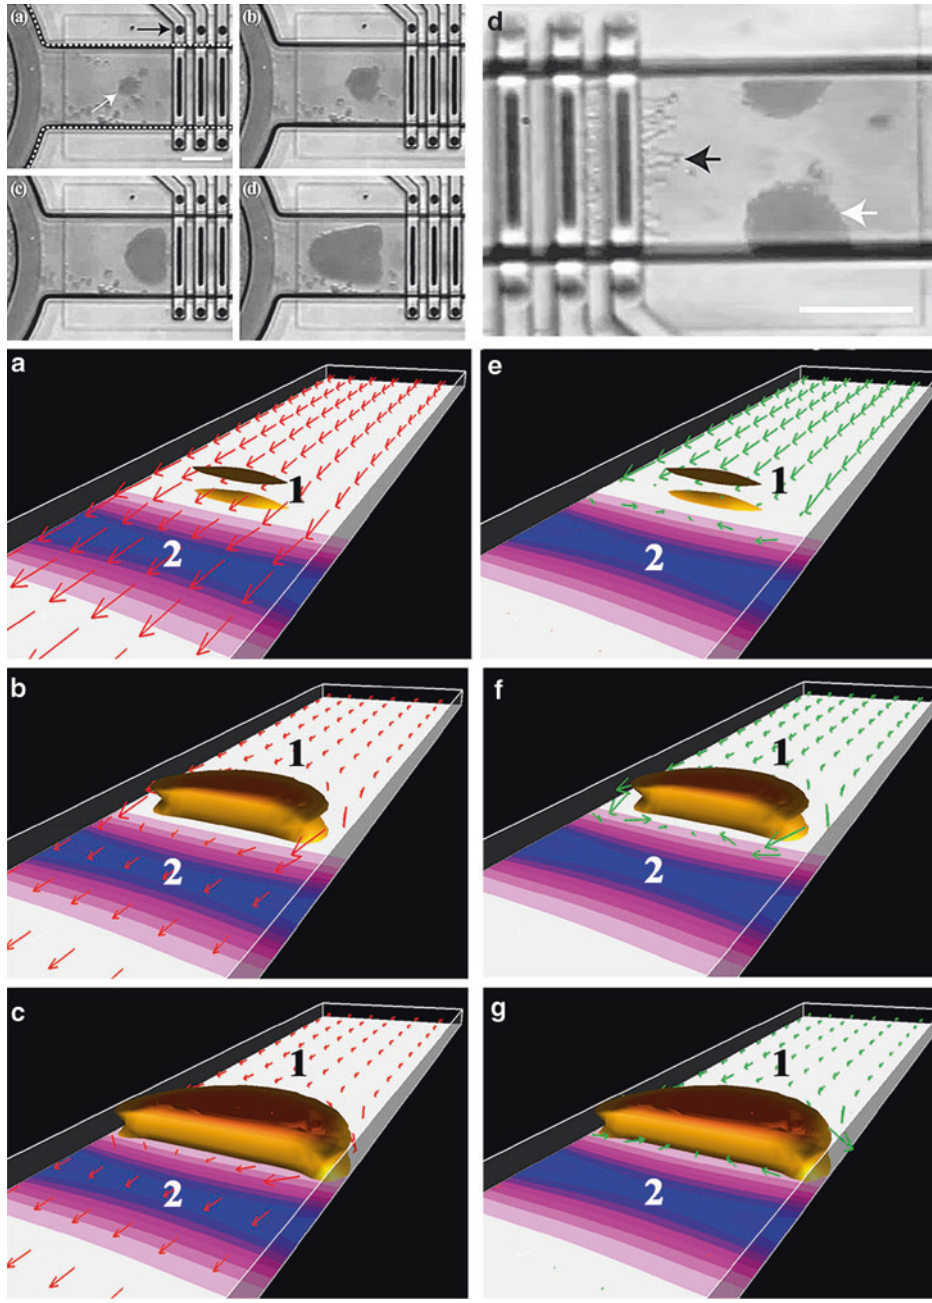
frequency ω; the particle concentration c, $\mathbf{E}^*_\omega$, and φ^*_ω are, respectively, the Fourier components of the electrical field and potential; v and p are the suspension velocity and pressure; and $\rho_s = (1-c)\rho_f + c\rho_p$ and $\eta_s = \eta_f\hat{\eta}(c)$ are the suspension density and viscosity with $\hat{\eta} = (1-c/c_m)^{-n}$ where $n \approx 2$ and $c_m \sim 0.68$ is the concentration of spheres at random close packing. The particle chemical potential μ_p, Eq. 11, is a function of the particle concentration c and oscillation-averaged field strength $\langle E^2\rangle = \left|\mathbf{E}^*_\omega(\mathbf{r})\right|^2/2$. The factor $(1-c)^2$ in the expression for the particle flux $\mathbf{j}_p$ in Eq. 17 represents the hindrance function that slows down the particle mobility.

The effects of the particle arrangement on the local field strength are included in the model via the particle concentration dependence of $\varepsilon^*_s(\omega, c)$ in Eq. 15. Equations 16 and 17 incorporate the interparticle electrical interactions in terms of the field and concentration dependence of the particle chemical potential, Eq. 11. The interparticle hydrodynamic interactions are included in terms of the concentration dependence of the suspension viscosity and the hindrance function.

Hydrodynamic equations for local values of the particle concentration and electrical field in the two-phase region of the phase diagram in Fig. 5 are formulated for relatively fast local phase separation, i.e., $\tau_d >> \tau_a$ in Eq. 14 at a local particle concentration. Under these conditions, the value of the chemical potential is the same in coexisting phases and is specified as a function of λ by the coexistence curve of the phase diagram. The particle concentrations in both phases, c_1 and c_2, are also specified as functions of λ by expressions [8]

$$\mu_p(c_1) = \mu_p(c_2) \text{ and } \Pi_p(c_1) = \Pi_p(c_2) \quad (18)$$

The volume fraction of the high concentration phase ψ is given by the lever rule $c_2\psi + c_1(1-\psi) = c$ as a function of c and λ. For simplicity, the model ignores the explicit dependence on ψ of the complex dielectric permittivity, viscosity, and hindrance function for this zone. These parameters are obtained by the same way as in the single-phase region. Under these conditions, the two-phase model consists of Eqs. 15, 16, and 17 in which the chemical potential is now specified as a function of the field strength, $\mu_p = \mu_p(\lambda)$, through solution of Eq. 18. Notice that the spatial gradient of the particle chemical potential $\nabla\mu_p$, considered as a function of the local particle concentration and the relative field strength, experiences an abrupt change when the suspension undergoes the local field-driven phase transition, i.e., when the point $c(\mathbf{r}, t)$, $\lambda(\mathbf{r}, t)$ representing the local suspension composition and field strength in the phase diagram, Fig. 5, crosses the coexistence curve.



For the limiting case of a dilute suspension for which $c \to 0$, Eqs. 15 and 16 reduce to the field and flow equations for the suspending fluid in a dielectrophoretic device, while Eq. 17 yields

$$\frac{\partial c}{\partial t} + \nabla\cdot\left[c\left(\mathbf{v}_f + \mathbf{u}_e\right)\right] = D_B\Delta c \text{ with}$$

$$\mathbf{u}_e = \frac{v_p}{6\pi a\eta_f}\left[\frac{3}{2}\varepsilon_0\varepsilon_f \mathrm{Re}(\beta)\nabla E^2_{rms} + \left(\rho_p - \rho_f\right)\mathbf{g}\right] \quad (19)$$

where $\mathbf{u}_e$ is the velocity of a particle relative to the fluid under the action of the dielectrophoretic and gravity forces and $D_B = k_BT/6\pi a\eta_f$ is the particle Brownian diffusion coefficient. When Brownian motion is insignificant, Eq. 19 leads to the single-particle model, Eq. 8. Another limiting case is the equilibrium state of neutrally buoyant particles subjected to a spatially nonuniform AC field [13], for which Eqs. 15, 16, and 17 yield $\mathbf{v} = \nabla p = 0$ and $\nabla\mu_p(\mathbf{r}) = 0$ where μ_p is given by Eq. 11. This spatial distribution of the particles is reached when the chemical potential of a particle becomes independent of position. The equation $\nabla\mu_p(\mathbf{r}) = 0$ represents c as a function of $\langle E^2\rangle$ along the curve of constant μ_p on the suspension phase diagram, Fig. 5.

Equations 15, 16, 17, and 18 require no fitting parameters provided that particle properties are measured independently. Simulations of front formation and propagation using independently measured data for the fluid and particle properties are quantitatively consistent with experimental data (Figs. 10 and 11). Numerical simulations and

AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 10 (*Top left*) The photo shows dielectrophoresis (10 V pp, 30 MHz) of 1-μm polystyrene beads in deionized water accompanied by a phase separation (*white arrow*). asymptotic analysis of these equations reveal two limiting regimes for the dielectrophoretic formation of a sharp concentration front seen in Figs. 9, 10, and 11. One of them is the quasi-equilibrium regime in which dielectrophoresis is accompanied by field-driven phase separation leading to an abrupt change in particle concentration [13]. The position and the magnitude of the concentration front are then determined by the balance of the dielectrophoretic, dipole–dipole, and steric forces. The other is a hydrodynamic mechanism which operates through the balance of the dielectrophoretic and hydrodynamic forces. The position and the magnitude of the concentration jump are governed by the rapid local growth of the suspension viscosity due to the particle accumulation near the front which slows down the field-driven particle motion by decreasing their mobility, proportional to $(1-c)^2/\hat{\eta}(c)$. The concentration front forms in both the single-phase and the two-phase states of a suspension and travels with the speed that increases with increasing applied voltage. In contrast to the front formation due to the field-driven phase transition, the hydrodynamic mechanism can operate only in an unsteady regime of dielectrophoresis and will cease when the particle spatial distribution reaches the equilibrium.

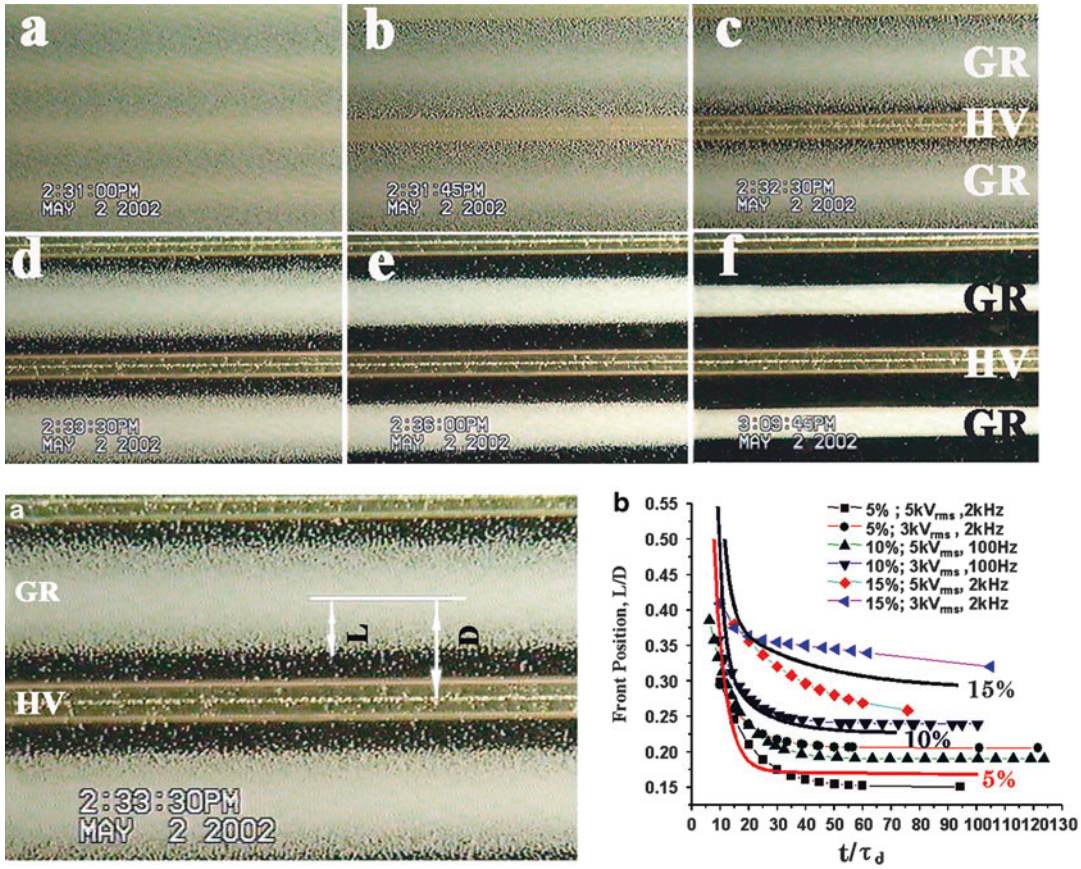
Microscopic Models

Direct numerical simulations of the motion of interacting particles require the solution of Laplace's equation for the electrical field and Navier–Stokes' equations for the fluid flow in a dielectrophoretic device that consider the presence of all particles. The electrical and hydrodynamic forces and torques exerted on each particle are then computed by integrating the Maxwell stress tensor and the hydrodynamic stress tensor over the particle surface. As the particle positions change continuously, the solution of Laplace's and Navier–Stokes' equations is carried out at each simulation time step. The capabilities of current computers limit direct numerical simulations to a system of two or three particles.

A microscopic approach [20] for modeling the motion of interacting spherical particles is implemented by presenting the total electrical field $\mathbf{E}_{tot}(\mathbf{r}_i)$ exerted on a particle in the location $\mathbf{r}_i$ as the external field in this point $\mathbf{E}_{ext}(\mathbf{r}_i)$ plus the contributions of dipoles induced in other particles:

$$\mathbf{E}_{tot}(\mathbf{r}_i) = \mathbf{E}_{ext}(\mathbf{r}_i) + \sum_{j\neq i} \mathbf{E}_j(\mathbf{r}_i) \text{ for } i = 1, \cdots, N \tag{20}$$

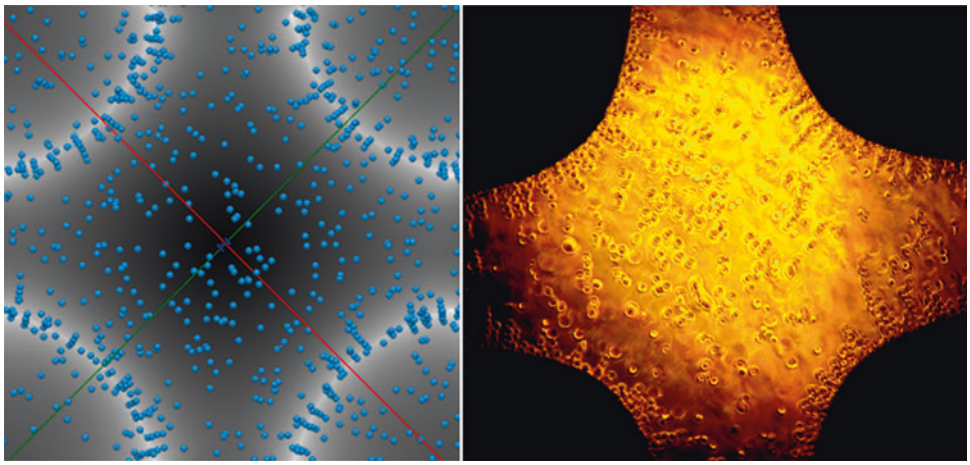


$$\text{with } \mathbf{E}_j(\mathbf{r}_i) = \frac{1}{4\pi\varepsilon_0\varepsilon_f r_{ij}^3}\left[3\mathbf{n}\left(\mathbf{n}\cdot\mathbf{P}_j\right) - \mathbf{P}_j\right] \text{ and}$$

$$\mathbf{P}_i = 3v_p\varepsilon_0\varepsilon_f\beta^*\mathbf{E}_{tot}(\mathbf{r}_i)$$

where $\mathbf{P}_i$ and $\mathbf{P}_j$ are, respectively, the dipoles of particles at the locations $\mathbf{r}_i$ and $\mathbf{r}_j$, $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$, $\mathbf{n} = \mathbf{r}_{ij}/r_{ij}$, and $\mathbf{E}_j(\mathbf{r}_i)$ is the electrical field generated by the particle at the location $\mathbf{r}_j$. The external field $\mathbf{E}_{ext}(\mathbf{r}_i)$ is computed for a dielectrophoretic device without particles. The effects of the particle dipole–dipole interactions are simulated by solving coupled Eq. 20 for all particles. The electrical energy of the instantaneous particle configuration is then computed as

$$U(\{\mathbf{r}_1, \cdots, \mathbf{r}_N\}) = \sum_i U_{eff}(\mathbf{r}_i) + \sum_{j\neq i} U_{eff}\left(\mathbf{r}_i, \mathbf{r}_j\right)$$



AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 10 (continued) upper right-hand corner to the lower left-hand corner. The color band (2) indicates the variation of E^2 along the channel bottom (*white* for up to 1.3 kV^2/cm^2, *pink* for 1.3–2.7 kV^2/cm^2, and *blue* for 10.6–11.9 kV^2/cm^2), whose maximum is located near the first electrode. The time is (**a**, **e**) 10, (**b**, **f**) 70, (**c**, **g**) 180, and (**d**, **h**) 120 s. The computed values for c_{max} in the bolus [in %(v/v)] are (**a**) 8.73, (**b**) 45.4, (**c**) 56.4, and (**d**) 54.1. In (**a**–**d**), the *red arrows* show the relative magnitude of the flow velocity [$v_{max\ at\ t=0}$ = 36 μm/s; v_{max} = (**a**) 49.8, (**b**) 106.3, (**c**) 110.4, and (**d**) 139.9 μm/s]. In (**e**–**h**), the green arrows show the relative magnitude of the particle velocity, $v_{p,max\ at\ t=0}$ = 36 μm/s, $v_{p,max}$ = (**e**) 45.2, (**f**) 78.8, (**g**) 151.4, and (**h**) 171.6 μm/s (Reprinted with permission from Ref. [19]. Source: http://scitation.aip.org/content/aip/journal/apl/83/23/10.1063/1.1629789. Copyright 2014 AIP Publishing)

AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 11 (*Top*) Negatively polarized neutrally buoyant spherical polyalphaolefin 87-μm particles in Mazola corn oils. The particle distribution in a suspension with 10 % (v/v) particle concentration (**a**) before and (**b**)–(**f**) following the application of a field 5 kV rms, 100 Hz at t= (**b**) 45 s, (**c**) 90 s, (**d**) 150 s, (**e**) 300 s, and (**f**) final state, ~39 min. The electrode width is 1.6 mm. HV and GR refer to the high-voltage and grounded electrodes, respectively. (*Bottom*) (**a**) The photograph illustrates how the front position L was measured; D =3.6 mm. (**b**) The experimental data (symbols) and computational results (*solid lines*) of the electrohydrodynamic model Eqs. 15, 16, 17, and 18 for the front propagation in suspensions with 5 %, 10 %, and 15 % (v/v) particle concentrations for different voltages and frequencies of the applied fields. The experimental data and the simulation results are plotted against a nondimensional time, t/τ_d, with τ_d given by Eq. 9 with $E_{rms}^2 = V_{rms}^2/d$ where d is the electrode width and V_{rms} is the root mean square of the applied AC voltage (Reprinted with permission from Ref. [7]. Source: http://journals.aps.org/pre/abstract/10.1103/PhysRevE.69.021402. Copyright 2014 by the American Physical Society)

where $U_{eff}(\mathbf{r}_i)$ is the energy of the dipole $\mathbf{P}_i$ in the electrical field $\mathbf{E}_{tot}(\mathbf{r}_i)$ and $U_{eff}(\mathbf{r}_i, \mathbf{r}_j)$ is the electrical energy of two dipoles $\mathbf{P}_i$ and $\mathbf{P}_j$. A Monte Carlo method that employs a stochastic sequence of single-particle displacement events is used for simulating the equilibrium arrangement of N particles subjected to a spatially nonuniform external field [20]. Specifically, a randomly selected particle displacement $\Delta\mathbf{r}_i$ is accepted if the difference between the energies of the new and old configurations $\Delta U = U(\{\mathbf{r}_1, \cdots, \mathbf{r}_i + \Delta\mathbf{r}_i, \cdots, \mathbf{r}_N\}) - U(\{\mathbf{r}_1, \cdots, \mathbf{r}_N\})$ is negative. Equation 20 includes the effects of the particle arrangement on the local field strength. However, the model predictions are limited to the equilibrium arrangement of particles, Fig. 12 [20], since the dynamics of the field-driven particle motion is not considered.

In approach [21], modeling the motion of interacting spherical particles is implemented by

AC Dielectrophoresis and Dipolar Interactions for Particle Manipulation, Fig. 12 (*Left*) Top view of the final spatial distribution of the Monte Carlo simulation with superimposed intensity map of the electric field $|\mathbf{E}_{rms}(\mathbf{r})|$. presenting the total force exerted on each spherical particle as

$$\mathbf{F}_{tot}(\mathbf{r}_i) = \mathbf{F}_{ext}(\mathbf{r}_i) + \sum_{j \neq i} \mathbf{F}_{i,j}(\mathbf{r}_i) \text{ for } i = 1, \cdots, N \tag{21}$$

where the dielectrophoretic force $\mathbf{F}_{ext}(\mathbf{r}_i)$ is calculated using Eq. 7 with the external electric field $\mathbf{E}_{ext}(\mathbf{r}_i)$ and the forces $\mathbf{F}_{i,j}(\mathbf{r}_i)$ acting on this particle by other particles are computed as

$$\mathbf{F}_{i,j}(\mathbf{r}_i) = \frac{3}{4\pi\varepsilon_0\varepsilon_f r_{ij}^4}\left[\mathbf{n}_{ij}\left(\mathbf{P}_i \cdot \mathbf{P}_j\right) + \left(\mathbf{n}_{ij} \cdot \mathbf{P}_i\right) \cdot \mathbf{P}_j + \left(\mathbf{n}_{ij} \cdot \mathbf{P}_j\right)\mathbf{P}_j - 5\mathbf{n}_{ij}\left(\mathbf{n}_{ij} \cdot \mathbf{P}_i\right)\left(\mathbf{n}_{ij} \cdot \mathbf{P}_j\right)\right]$$

with $\mathbf{P}_i = 3v_p\varepsilon_0\varepsilon_f\beta^*\mathbf{E}_{ext}(\mathbf{r}_i)$. The external field $\mathbf{E}_{ext}(\mathbf{r}_i)$ is also computed for a dielectrophoretic device without particles. This model does not include the effects of the particle arrangement on the local field strength. If the interparticle hydrodynamic interactions are neglected, the velocity of each particle is calculated using the equation for Stokes drag force and Eq. 21 for the total electrical force $\mathbf{F}_{tot}(\mathbf{r}_i) = 6\pi\eta_f a\mathbf{u}_i$. The simultaneous displacements of interacting particles are then computed using the following coupled equations:

$$\frac{d\mathbf{r}_i}{dt} = \mathbf{u}_i \text{ with } \mathbf{r}_i|_{t=0} = \mathbf{r}_{0,i} \text{ for } i = 1, \ldots, N$$

where $\mathbf{r}_{0,i}$ is the initial particle position.

Simulations [20, 21] within the framework of pairwise models, Eqs. 20 and 21, demonstrate that the effects of the dipole–dipole interactions play a crucial role in the evolution of particles even at a concentration lower than concentrations typically used in dielectrophoretic devices. Microscopic simulations can be used for evaluation of experimental conditions (e.g., electrode configuration, applied voltage and frequency, particle concentration, etc.) under which the contribution of interparticle interactions is insignificant.

Future Direction for Research

Dielectrophoresis is becoming one of the major methods for control and manipulations of micro- and nano-sized particles in various applications. Rapid advances in manufacturing technologies and new materials open the avenue for the fabrication of sophisticated dielectrophoretic devices to address challenges in materials science, analytical chemistry, and life science. The greatest

challenge is to understand the role of electrical and hydrodynamic interparticle interactions in directing and controlling dielectrophoresis in a colloidal dispersion.

Definition

AC electrokinetics is the name given to a group of techniques that utilize alternating (AC) electric fields to move dielectric particles in suspension. AC electrokinetics of nanoparticles refers to methods of exerting electrical force and/or torque on particles of nanometer dimensions, examples of which are viruses, macromolecules, and colloidal particles.

Introduction

Dielectrics do not bear a net charge but rather polarize when subjected to electric fields. When dielectric particles in suspension are subjected to electric fields, polarization results in charge accumulation at the particle/electrolyte interface. Electrode polarization may also occur, giving rise to the buildup of a double layer of ions and counterions at the electrode/electrolyte interface. Particle polarization is represented by effective dipole and higher-order moments. AC electrokinetic forces and torques on particles result from interactions of an applied electric field with the effective moments. Electric field-induced fluid motion is also studied under AC electrokinetics due to the important effect it can have on particle behavior. Electric field interactions with the double layer and gradients in fluid permittivity and conductivity (resulting from localized heating of the medium) are the main factors causing fluid motion under AC electric fields.

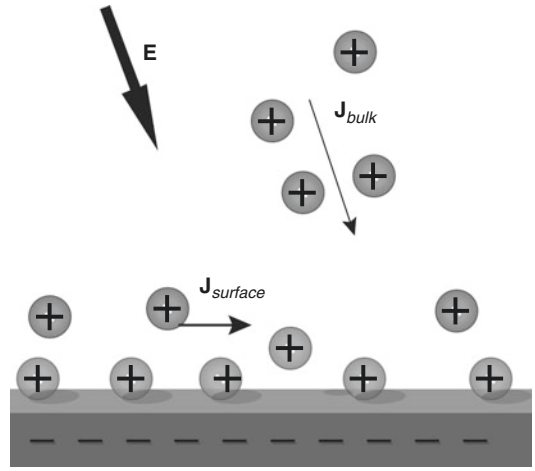
AC electrokinetic techniques are particularly fitted to lab-on-a-chip applications where multiple processes involving manipulation, separation, or characterization of biological particles, mostly dielectrics, are integrated onto a single chip. The direction and magnitude of AC electrokinetic forces and torques can be easily controlled by varying electric field frequency and geometry. The techniques are advantageous over alternative means of moving particles in their noninvasive nature and easy integration onto micro-devices, not relying on any moving parts.

It was long believed that for sub-micrometer particles, AC electrokinetic forces would be overwhelmed by thermal effects such as Brownian motion. The strong electric fields required to exert sufficient electrical force to dominate particle behavior at the nanometer scale were believed to generate excessive heat giving rise to strong fluid motion that would hinder AC electrokinetic interactions. Thanks to fabrication techniques that realized micro- and nano-electrode geometries, electric fields of sufficient strength to overcome Brownian motion of nanoparticles could be generated with the application of modest voltages, avoiding excessive heating of the suspension.

AC Electric Field Interactions with Nanoparticle Suspensions

When an electric field is applied to dielectric particles in suspension, surface charge accumulates

at interfaces between the dielectrics due to the differences in electrical properties. Since the polarizabilities of each dielectric are frequency dependent, the magnitude of the surface charge is also frequency dependent, and the total (complex) permittivity of the system exhibits dispersions solely due to the polarization of the interfaces. This is referred to as the Maxwell-Wagner interfacial polarization. For a spherical particle of radius R, the effective dipole moment is given by



$$\boldsymbol{p} = 4\pi\epsilon_m R^3 [K(\omega)]\boldsymbol{E} \tag{1}$$

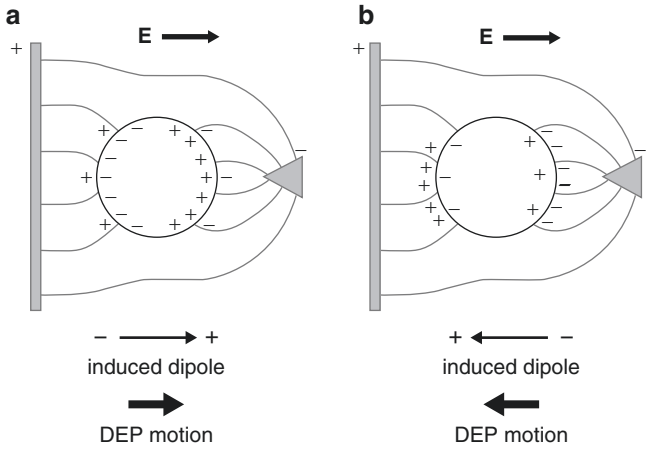
where ω is the frequency of the applied electric field $\boldsymbol{E}$ and $K(\omega)$, known as the Clausius-Mossotti factor, describes a relaxation in the polarizability of the particle with a relaxation time

$$\tau_{MW} = \frac{\epsilon_p + 2\epsilon_m}{\sigma_p + 2\sigma_m} \tag{2}$$

The angular frequency $\omega_{MW} = 2\pi f_{MW} = 1/\tau_{MW}$ is often referred to as the Maxwell-Wagner relaxation frequency.

During the first half of the twentieth century, dielectric spectroscopic measurements of suspensions of nanoparticles identified that the Maxwell-Wagner relaxation frequency for charged nanoparticles was higher than expected. Later, O'Konski [1] showed that the dielectric properties of nanoparticles in this frequency regime were dominated by surface conductance effects. The high value of particle conductivity determined from dielectric measurements was explained by the inclusion of a surface conductance component in the derivation of the particle's dipole moment. The model developed by O'Konski is shown in Fig. 1. He assumed that the flux due to the transport of charge carriers, associated with the fixed charge on the particle surface, could be added to the flux due to the transport of bulk charge to and from the surface. With this assumption, he derived the potential around the spherical particle and derived the equation for the dipole moment of a dielectric sphere (Eq. 1) but with the particle conductivity given by the sum of the bulk conductivity of the particle and a surface conductivity term

AC Electrokinetics of Nanoparticles, Fig. 1 Schematic of the mechanism with which surface conductance affects interfacial polarization of nanoparticles in suspension. The AC electric field produces both a bulk flow of ions and a surface flow around the particle



$\sigma_p = \sigma_{p,\,\text{bulk}} + \sigma_{p,\,\text{surface}}$. The surface conductivity of the particle is given by

$$\sigma_{p,\,\text{surface}} = \frac{2K_s}{R} \tag{3}$$

where K_s is the surface conductance.

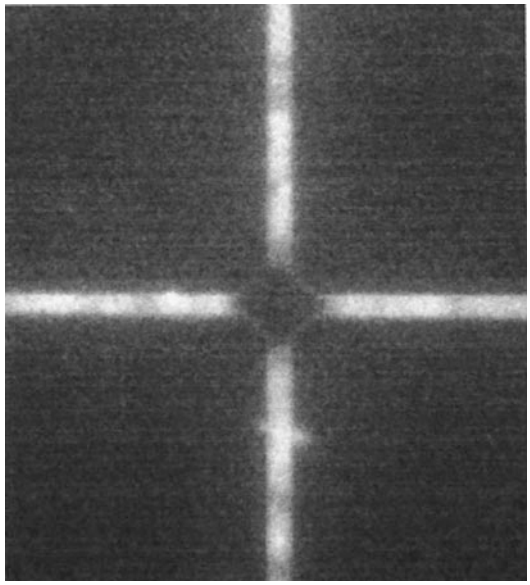
AC Electrokinetic Techniques

Dielectrophoresis (DEP): Fig. 2 shows the underlying principle of dielectrophoresis as the most widely used of AC electrokinetic techniques. The gradient in electric field strength gives rise to unequal forces experienced by polarization charges at the particle/electrolyte interface, hence a net force on the particle moving it toward or away from regions of high field intensity depending on whether the particle is more or less polarizable than the suspending medium. Polarization charges at dielectric interfaces form induced dipole and higher-order moments. As shown in Fig. 2, the notion of an induced dipole helps better visualize the direction of dielectrophoretic force on particles. The particle would move toward or away from regions of high electric field strength when the induced dipole is

AC Electrokinetics of Nanoparticles, Fig. 2 Dielectrophoresis – interaction of a nonuniform electric field with a dielectric particle in suspension gives rise to unequal forces experienced by polarization charges at the particle/electrolyte interface. The result is a net dielectrophoretic force that moves the particle (**a**) toward or (**b**) away from regions of high electric field intensity depending on whether the particle is more or less polarizable than its suspending medium

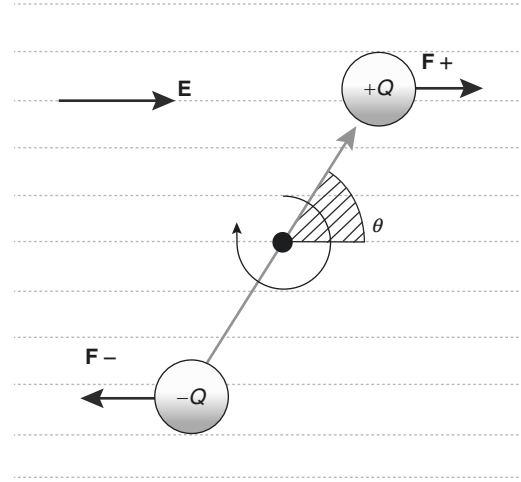
aligned with or against the electric field, respectively. In more complex geometries, particularly those involving nonspherical particles subjected to highly divergent electric fields, higher-order moments will need to be accounted for as they could contribute notably to the DEP force on particles [2, 3].

If particle dimensions are smaller than a characteristic length scale of electric field nonuniformity, higher-order terms can be neglected, and the time-averaged dielectrophoretic force on a spherical particle of radius R suspended in a fluid of dielectric constant ϵ_m is given by [4]



$$\langle \boldsymbol{F}_{DEP} \rangle = \pi \epsilon_m R^3 Re[K(\omega)] \nabla |\boldsymbol{E}|^2 \qquad (4)$$

It is understood from Eq. 1 that the dielectrophoretic force scales with particle volume and also inversely with the cube of a characteristic dimension of the electrode geometry. It is due to the latter proportionality that micro- and nanoelectrode geometries are capable of exerting electric fields of sufficient strength to move particles as small in volume as nanoparticles, overcoming Brownian and field-induced fluid motion.



Although first observations of the effect date back to earlier times, Pohl was the first to use the term dielectrophoresis for the force exerted by a nonuniform electric field on a dielectric [5]. He observed coagulation of carbon particles from a polymer solution upon application of a DC or AC electric field. Pohl used the term "dielectrophoresis" to distinguish the effect from electrophoresis, which describes motion of charged particles under DC (and not AC) electric fields.

Since its advent, dielectrophoresis has been used in a broad range of applications. Separation, as a fundamental part of many processes in micro-total-analysis systems (μTAS), has been diversely and controllably accomplished using dielectrophoresis. The dependence of the dielectric properties of particles on their structure and composition has broadened the applicability of DEP-based separation techniques. In electrode geometries with well-defined regions of electric field maxima and minima, particles of different properties can be separated into subpopulations. Figure 3 shows the collection of 280 nm tobacco mosaic viruses (TMV) in a polynomial electrode configuration [6]. As the TMV particles are more polarizable than the suspending medium, they gather at electrode edges where the electric field is strongest.

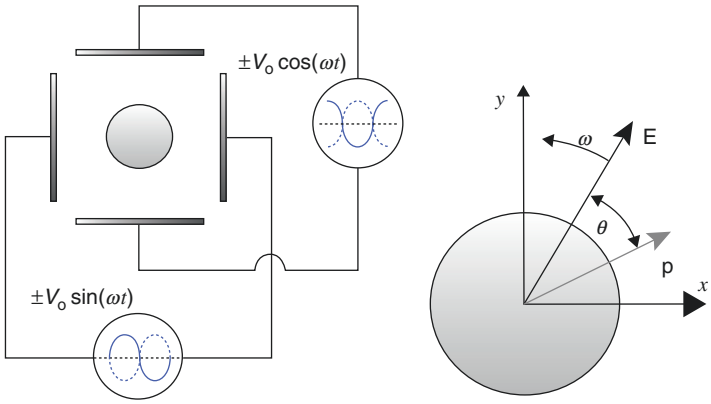
Dielectrophoresis has been used extensively for manipulation and characterization of

AC Electrokinetics of Nanoparticles, Fig. 3 Dielectrophoretic collection of nanoparticles – applying a 6 MHz AC electric field leads to the collection of 280 nm tobacco mosaic viruses (*TMV*) at the electrode edges where the field is strongest [4]

AC Electrokinetics of Nanoparticles, Fig. 4 Principle of electro-orientation – in a uniform field **E** (indicated by the vector and the *dotted field lines*), the two charges experience equal and opposite forces resulting in a torque about the center point of the dipole

nanoparticles. One of the most notable application areas is diagnostics and healthcare, toward which a huge amount of effort has been directed involving sub-micrometer biological particles such as viruses, DNA, and chromosomes [7]. Dielectrophoresis has also been used for separation of metallic from semiconducting carbon nanotubes [8], assembly of nanoparticles into micro-wires [9], and three-dimensional focusing of nanoparticles in microfluidic channels [10]. With the emergence of nano-electrode geometries, there is huge prospect for further applications involving dielectrophoresis of nanoparticles including the fabrication of a new generation of electronic devices and sensors [7].

Electro-orientation: As shown in Fig. 4, when a dipole sits in a uniform field, each charge on the dipole experiences an equal and opposite force tending to align the dipole with the electric field. The effect can also be observed in nonuniform and rotating electric fields and is the basis of a phenomenon known as electro-orientation.



A dielectric particle of no net charge in a uniform electric field will be subject to no net force but will experience a torque given by

$$\Gamma = \boldsymbol{p} \times \boldsymbol{E} \tag{5}$$

This torque always tends to align the dipole with the electric field. However, small dipoles, such as those of nanoparticles, will not completely align with the field due to the dominating effect of Brownian motion. In typical dielectric spectroscopy measurements, the electric fields are only of sufficient magnitude to align individual molecules by fractions of degrees, but the total effect of alignments of many molecules gives rise to a large net or average alignment [11].

In AC electric fields, electro-orientation is frequency dependent with nonspherical particles orienting along different axes in different frequency ranges. The set of crossover frequencies is referred to as the orientation spectrum. The orientation spectra of elongated biological particles such as erythrocytes and bacteria have been used to study the dielectric properties of these particles [12].

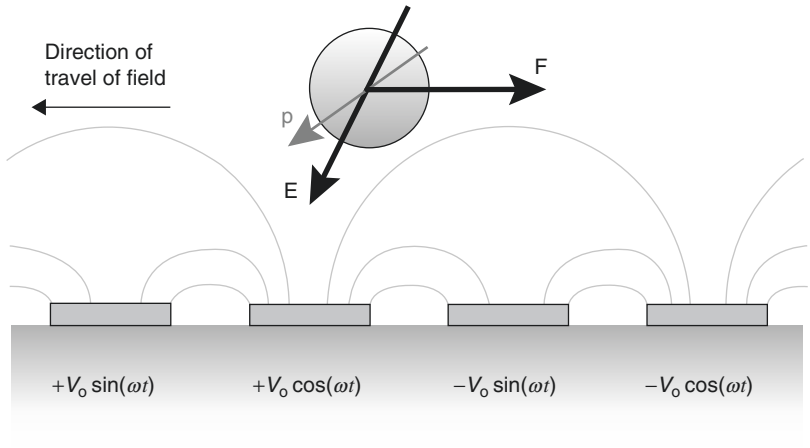
Electro-rotation (**ROT**): Dielectric particles subjected to rotating electric fields experience a

AC Electrokinetics of Nanoparticles, Fig. 5 Electro-rotation – (**a**) A schematic diagram of an electro-rotation setup. Four signals, successively 90° out of phase, are applied to four electrodes encircling the particle. (**b**) Schematic diagram showing how the induced dipole moment of a particle lags behind a rotating applied electric field

torque based on a principle which is somewhat different from that of electro-orientation. As mentioned previously, applying an electric field to a dipole will result in the exertion of a (electro-orientational) torque that tends to align the dipole with the electric field. Alignment of the dipole with the electric field vector will not be immediate as it takes a finite amount of time for polarization charges to move toward the particle/electrolyte interface and form a dipole. In a rotating electric field, where the field vector changes direction, this time delay gives rise to a (electro-rotational) torque, as shown in Fig. 5. The figure also shows an example electro-rotation setup, where voltages of 90° phase differences are applied to successive electrodes encircling the particle to generate a rotating electric field.

The first order electro-rotational torque on a spherical particle of radius R is given by [13]

$$\Gamma_{ROT} = -4\pi\epsilon_m R^3 Im[K(\omega)]|\boldsymbol{E}|^2 \qquad (6)$$



where $Im[K(\omega)]$ denotes the imaginary part of the Clausius-Mossotti factor. The particle will rotate with or counter to the applied field depending on whether $Im[K(\omega)]$ is negative or positive, respectively. Accounting for viscous drag force from the suspending fluid, the rotation rate of the particle is given by [13]

$$\Omega = -\frac{\epsilon_m Im[K(\omega)]|\boldsymbol{E}|^2}{2\eta} \qquad (7)$$

where η denotes fluid viscosity. Variations with frequency of the rotation rate are referred to as electro-rotation spectra.

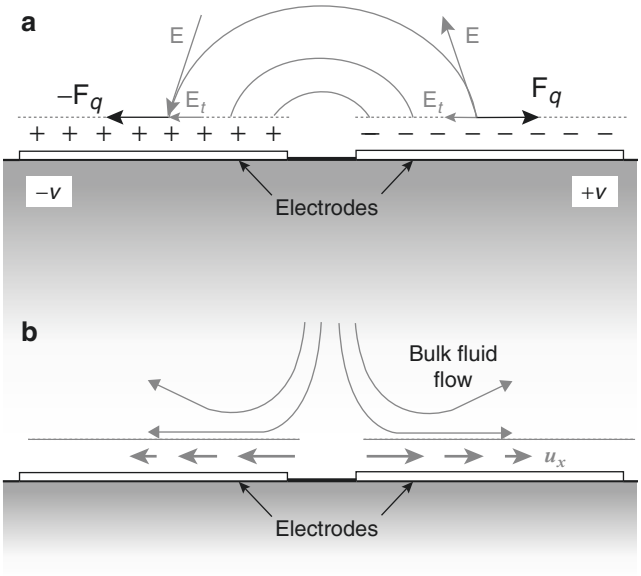
Two important distinctions can be readily identified from a comparison of Eqs. 1 and 3 for dielectrophoretic force and electro-rotational torque. Firstly, the ROT torque is proportional to the square of the electric field magnitude, while the DEP force is a function of the gradient of the square of the field magnitude – and is therefore zero in uniform electric fields. Secondly, the electro-rotational torque depends on the imaginary rather than the real part of the Clausius-Mossotti factor. As a result, particles may experience both dielectrophoresis and electro-rotation with the relationship between the two determined by the dielectric properties of the particles and their suspending media.

Initially observed as a nuisance in cell electrofusion procedures, electro-rotation has since developed into a useful means of measuring dielectric properties and membrane electrical parameters of biological particles. Rotational spectra are analyzed to determine fundamental cell properties and to monitor changes in these properties upon different types of treatments [12]. Among the major works done on electro-rotation of nanoparticles are investigations by Washizu and co-workers into the torque-speed behavior of the flagellar motor mechanism of bacterial cells [14]. In a more recent work, electro-rotation and electro-orientation of metal nanowires were studied experimentally and theoretically [15].

AC Electrokinetics of Nanoparticles, Fig. 6 Traveling-wave dielectrophoresis – schematic diagram of a linear traveling-wave dielectrophoresis array and the consecutive phase-shifted signals required to generate the traveling electric field. Also shown are the approximate field lines for time $t = 0$, the electric field, and the dipole moment induced in the particle together with the force on the particle

Traveling-wave dielectrophoresis (twDEP): Traveling-wave DEP can be considered as the linear analog of electro-rotation where voltages of 90° phase difference are applied to successive electrodes that are laid out as tracks, rather than being arranged in a circle. This generates an electric field wave which travels along the electrodes. The dipole induced in the particle moves with the electric field but lags behind the field, as in electro-rotation. As shown in Fig. 6, the result is the induction of a force, rather than a torque, given – for a spherical particle of radius R – by [16]

$$\boldsymbol{F}_{twDEP} = -\frac{4\pi\epsilon_m R^3 Im[K(\omega)]|\boldsymbol{E}|^2}{\lambda} \qquad (8)$$



where λ is the wavelength of the traveling wave. The negative sign in Eq. 8 indicates that, as shown in Fig. 6, the twDEP force propels particles in the opposite direction to the moving field vector. For a finite twDEP force to be exerted on a particle, two criteria need to be met: (a) the particle must experience a DEP force that levitates it above the electrode array, and (b) some loss mechanism needs to be present for the imaginary part of the Clausius-Mossotti factor to be nonzero.

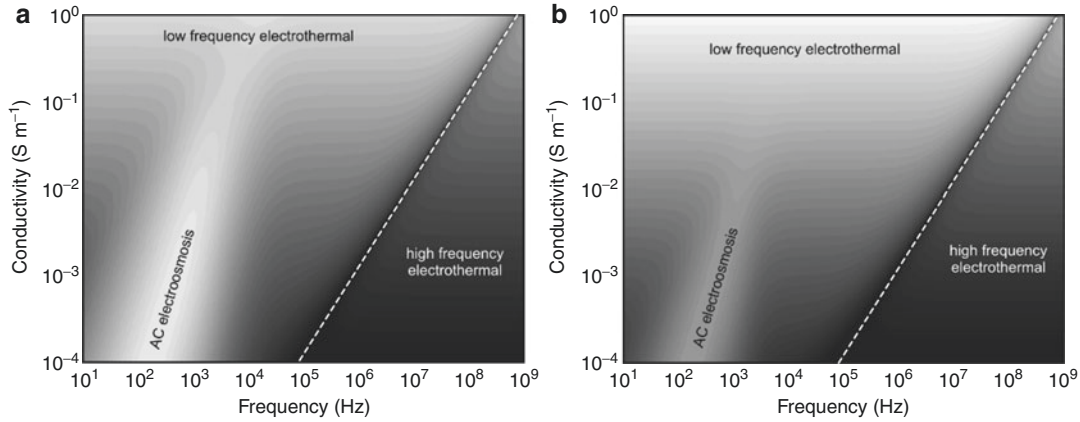
Masuda et al. [17] were the first to describe the principles of traveling-wave DEP. Since then, twDEP has been used for characterizing and separating cells and microorganisms [18]. Nanoparticle manipulation and separation has also been accomplished using the traveling electric field above interdigitated electrodes [19].

AC Electrokinetic Fluid Motion

AC electroosmosis (ACEO): AC electric fields applied to a suspension of dielectric particles can give rise to fluid motion, in an effect known as AC electroosmosis [20]. The effect arises from interaction of the electric field with charges at the double layer and is only observed if the field is nonuniform.

The mechanism for AC electroosmosis is shown in Fig. 7. Applying equal and opposite voltages to successive electrodes gives rise to the electric field $\boldsymbol{E}$ with tangential component $\boldsymbol{E}_t$ outside the double layer and an induced charge on each electrode. The induced charge experiences a force $\boldsymbol{F}_q$ due to the action of the tangential field, resulting in fluid flow. Figure 7a shows the system for one half-cycle of an AC field. In the other half-cycle, the sign of the potential, that of the induced charge, and the direction of the tangential field are all opposite. As a result, the direction of the force vector remains the same giving a nonzero

AC Electrokinetics of Nanoparticles, Fig. 7 AC electroosmosis – (**a**) schematic diagram outlining the mechanism of AC electroosmosis. (**b**) The interaction of the tangential field at the surface with the charge in the double layer gives rise to a surface fluid velocity and a resulting bulk flow



time-averaged force and steady-state fluid flow occurs, as shown in Fig. 7b.

Electrothermal fluid flow: At higher frequencies (>100 kHz), AC electroosmotic flow is negligible and the dominant fluid flow is due to electrothermal effects. This type of flow requires temperature gradients in the fluid and these can be generated both by internal and/or external sources. The internal source is Joule heating, where the electric field causes power dissipation in the fluid and the corresponding temperature rise diffuses through the system. This gives rise to gradients in the conductivity and permittivity; the electric field acts on these gradients to give a body force on the fluid and consequently a flow. In this case, the velocity of the flow is proportional to the temperature rise in the fluid, which is in turn proportional to the conductivity of the electrolyte and the magnitude of the electric field. As a result, this type of fluid flow occurs mainly at high electrolyte conductivities.

Apart from the conductivity dependence of the electrothermal effect, the magnitude of the flow is also frequency dependent. The ratio of low- to high-frequency limiting values is approximately 10:1, and the flow changes magnitude and direction at a frequency of the order of the charge relaxation frequency of the medium. The change in the velocity of the fluid as a function of the two parameters, frequency of the applied field and conductivity of the electrolyte, is complicated and is summarized in Fig. 8. In these plots, the logarithm of the magnitude of the flow velocity is indicated by a gray scale as a function of the conductivity of the electrolyte and frequency of the field, for two applied voltages. Both figures demonstrate the regions in which strong fluid flow occurs and also which regions might be "safe" from fluid motion.

Review of AC Electrokinetic Forces on Nanoparticles

As described through the different mechanisms responsible, particle behavior under AC electric fields is determined by a variety of factors. The total force on any particle is given by the sum of many forces including Brownian, dielectrophoretic, and hydrodynamic forces, the latter arising from fluid motion. These forces can be comparable to, or in certain circumstances much stronger than, the dielectrophoretic force exerted on the particle. At certain combinations of medium conductivity and electric field frequency and strength, the hydrodynamic forces can dominate particle behavior. Under other experimental conditions, these forces are negligible, and as a result,

AC Electrokinetics of Nanoparticles, Fig. 8 Schematic frequency/conductivity maps of the two types of electric field-driven fluid flow: AC electroosmosis and electrothermal. The *white dotted line* indicates the frequency at which electrothermal flow changes direction. The velocities are plotted on a log gray scale and were determined for the same position (10 μm from the edge of the electrode) and applied signals: (**a**) 1 V and (**b**) 10 V on each electrode. Note that the ratio of AC electroosmotic flow is much less at 10 V

small changes in the dielectric properties of the particles can be detected and measured by DEP.

Ramos and co-workers have conducted order-of-magnitude calculations for the forces on nanoparticles in AC electric fields [21]. It has been shown that for low-conductivity suspensions, Joule heating has little effect on system temperature and is therefore negligible. With ±10 V applied to a microelectrode system with a medium conductivity of 10 mS/m, temperature rises of the order of only 1 °C have been observed. In contrast, electrothermal forces have been shown to be of sufficient strength to compete with the dielectrophoretic force. However, it is important to note that the DEP force varies much more rapidly than electrothermal forces upon proximity with electrode edges. Applying ±5 V to a system of parallel finger microelectrodes and a 10 ms/m-conductivity suspension of 282 nm particles has been shown to generate a fluid velocity of 5 μm/s against a DEP-induced velocity of 1.8 μm/s. Near electrode edges, DEP-induced and electrothermal velocities have been reported to be 200 μm/s and 50 μm/s, respectively. Changes in fluid density arising from field-induced temperature gradients have been shown to be on the order of 0.01 % per degree. As a result, natural convection has been found to be very small compared to electrothermal and DEP forces.

Brownian motion was for long considered the biggest obstacle in AC electrokinetic motion of sub-micrometer particles. Pohl had estimated that electric field strengths required to overcome Brownian motion of nanoparticles would (a) not be realizable and (b) lead to excessive heating, and hence electrothermal motion, of the fluid, thereby hinders DEP motion of particles [2]. Experimental findings have shown that Pohl had largely overestimated the electric field strength required to overcome thermal effects, the reason being his comparison of thermal energy with dielectrophoretic *potential* rather than *force*, the latter being the gradient of the former [6]. It has been shown that DEP forces required to overcome Brownian motion of nanoparticles are in the sub-pico-newton range and can be easily generated using micro- and nano-electrode geometries by application of voltages modest enough to avoid excessive heating of the medium. The observable deterministic force required to move a 282 nm particle has been found to be of the order of 0.01 pN over a 1-s time frame of observation, requiring an electric field on the order of 100 kV/m, which can be generated by applying voltages on the order of 1 V across a 10 μm gap.

In summary, although hydrodynamic effects can complicate AC electrokinetic motion of nanoparticles, it has been shown that the forces

can be predicted and therefore controlled. Consequently, it is expected that recent technological advances in AC electrokinetics could be applied, together with field-induced fluid motion, to develop new methods for the characterization, manipulation, and separation of nanoparticles.

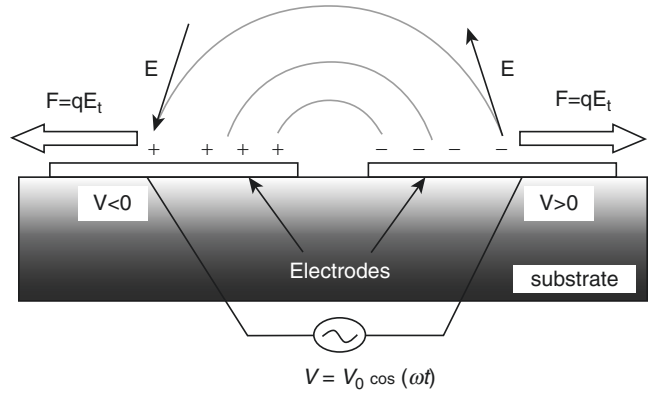
Induced charge electroosmosis

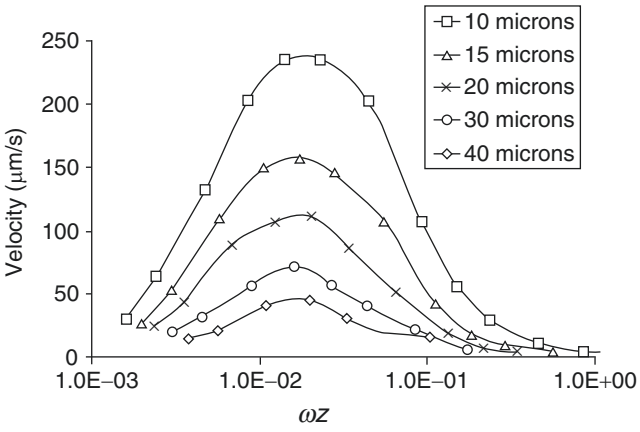
Definition

Microelectrode structures subjected to AC voltages can generate flow of aqueous solutions by the action of the AC field on the charges induced by itself at the electrode-electrolyte interface, i.e., induced charges in the electrical double layer (EDL). The phenomenon is called *AC electroosmosis* (ACEO) in analogy with the "classical" electroosmosis, where fluid flow is generated by the action of an applied electric field on the mobile charge of a given solid-liquid interface [1]. The main difference is that the applied field in ACEO is responsible for both inducing the charge and pulling on it. The term induced-charge electrokinetics (ICEK) has been proposed to refer to all phenomena where the electric field acts on the electrical double layer induced by itself [2].



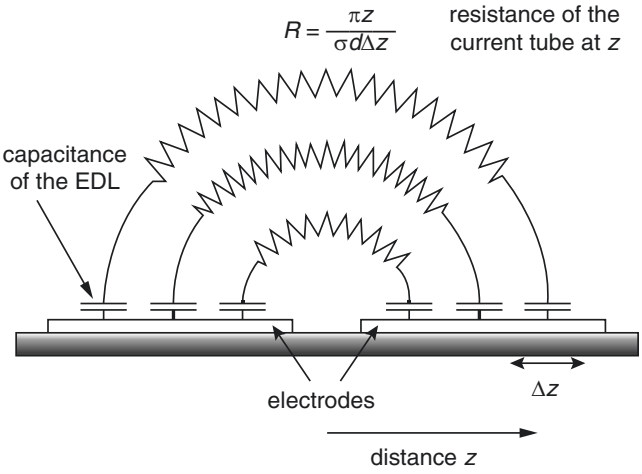
Basic Mechanism

Possibly, the simplest system for the study of AC electroosmosis consists of a couple of coplanar electrodes covered by an aqueous electrolyte. The electrodes are subjected to a harmonic potential difference of amplitude V_0 and frequency ω, $\boldsymbol{V(t) = V_0 \cos(\omega t)}$. Figure 1 shows a sketch of the physical system at a given time of the AC signal cycle. The applied field attracts counterions at the solid-liquid interfaces with a certain delay, and since the electric field is nonuniform, there appears an electrical force pulling the liquid outward $\boldsymbol{F = qE_t}$ ($\boldsymbol{E_t}$ is the component of the electric field tangential to the electrode surfaces). Note that in the other half cycle both the tangential field and the induced charge change sign and, therefore, the force direction remains the same and the time-averaged force is nonzero.



The fluid velocity generated by this mechanism is frequency dependent. At low frequencies the electrical charges have sufficient time to completely screen the electric field at the electrodes; the electric field in the electrolyte bulk vanishes and so does the induced velocity. In this view, the electrodes are supposed to be perfectly polarizable, i.e., no faradaic currents occur. At high frequencies the electrical charges have no time to follow the electric field, the induced charge at the electrode tends to zero, and therefore, the electrical force is negligible. The theoretical expectation for the velocity versus frequency plot is a bell-shaped curve, in accordance with the experimental observations (Fig. 2).

Simple Model for Small Voltages



The electroosmotic velocity generated at metal surfaces can be computed from the Helmholtz-Smoluchowski formula, $\boldsymbol{v_{HS} = \varepsilon \zeta E_t / \eta}$, where ε is the dielectric constant of the electrolyte, ζ is the zeta potential of the solid-liquid interface (i.e., voltage drop across the electrical double layer), and η is the liquid viscosity. For small voltage amplitudes, the relation between ζ and the charge

AC Electroosmosis: Basics and Lab-on-a-Chip Applications, Fig. 3 RC-circuit model for computing the charge density in the electrical double layer as a function of the position on the electrodes. The resistance of the liquid is modeled by the resistors. The capacitance of the electrical double layer is represented by the capacitors

in the EDL is linear, and the formula reads $v_{HS} = \sigma_q \lambda_D E_t / \eta$, with λ_D the Debye length and σ_q the charge per unit area in the EDL.

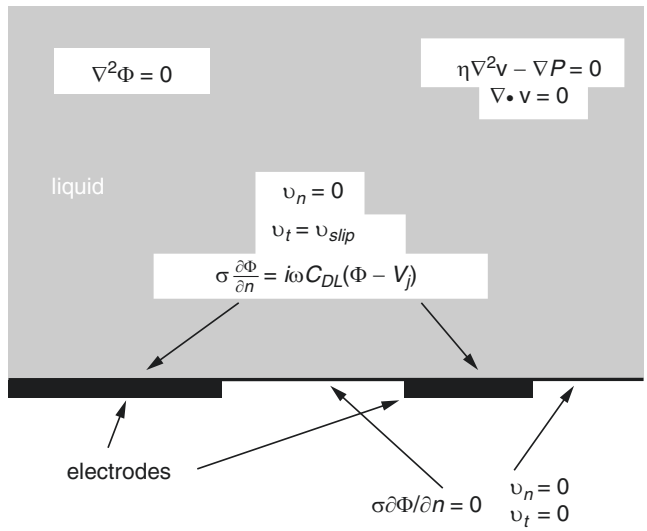
In ACEO, σ_q is the induced charge in the EDL by the AC potential. A constant (non-oscillating) term in the charge on the electrode-electrolyte interface is not considered although it might exist, the so-called intrinsic surface charge. However, in this linear model, the time-average velocity due to that charge is zero. In the system of symmetric electrodes, σ_q can be computed from the RC-circuit model shown in Fig. 3. In this model the electrical current in the electrolyte is discretized in current tubes of semicircular shape and width Δz. The resistance of one of these tubes is $R = \pi z / \sigma d \Delta z$, where z is the distance to the interelectrode gap center, σ the electrolyte conductivity, and d the depth of the electrodes. The electrical current in the tubes charges the electrical double layer, represented in this model by a distributed capacitor with a capacitance per surface area that, at low amplitudes, can be estimated from the Debye-Hückel theory as $\varepsilon d \Delta z / \lambda_D$. The value of σ_q at any position can be computed from $\sigma_q = \varepsilon V_d / \lambda_D$, where V_d is the voltage drop across the EDL, and it is a function of the position z:

$$V_d(z) = \frac{V_0}{1 + j\omega\pi\varepsilon z / \sigma\lambda_D} \tag{1}$$

and the tangential electric field is obtained from $E_t = -\partial V_d / \partial z$. The time average of the Helmholtz-Smoluchowski formula reads:

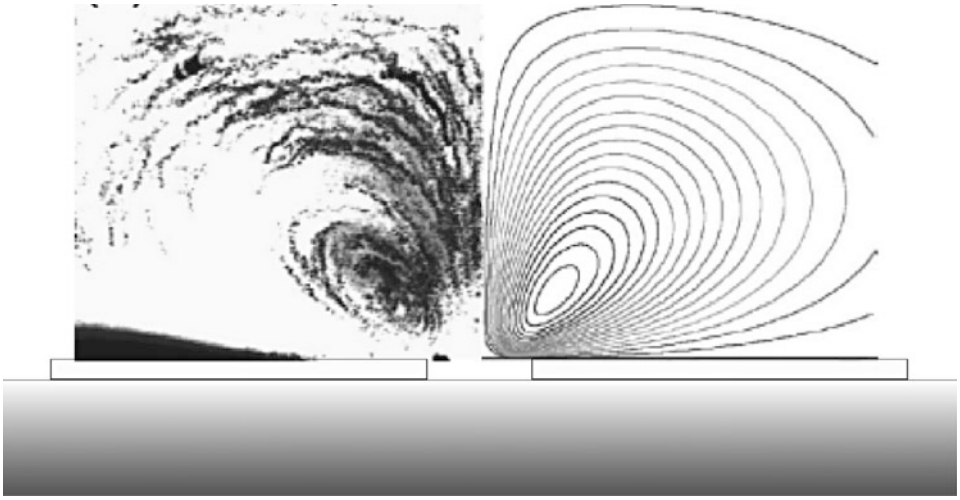
$$\langle v_{HS} \rangle = \frac{1}{2}\mathrm{Re}\left[\frac{\sigma_q E_t^* \lambda_D}{\eta}\right] = \frac{\varepsilon V_0^2 \Omega^2}{8\eta z\left(1+\Omega^2\right)^2} \quad (2)$$

where * indicates the complex conjugate and the nondimensional frequency Ω is written as $\Omega = \omega\pi\varepsilon z/2\sigma\lambda_D$. Maximum velocity is predicted for $\Omega = 1$, i.e., $\omega_{\max} = 2\sigma\lambda_D/\pi\varepsilon z$. The frequency for maximum velocity is dependent on position on the electrode z, and the electroosmotic velocity vanishes for either $\Omega << 1$ or $\Omega >> 1$, as expected. The model is in qualitative agreement with experimental measurements [3].



A rigorous study of ACEO flows for small potentials can be found in Ref. [4], where the electrokinetic equations are solved in the limit of thin electrical double layer, i.e., the Debye length is much smaller than the size of the electrodes. In this limit, the fluid velocity in the liquid can be obtained from Stokes equation with boundary condition of slip velocity on the electrodes, the electroosmotic velocity. For electrode j, subjected to a harmonic potential $V(t) = \mathrm{Re}\left[V_j \exp(i\omega t)\right]$, the slip velocity is computed according to

$$v_{\mathrm{slip}} = -\frac{\varepsilon}{4\eta}\Lambda\frac{\partial\left|\Phi - V_j\right|^2}{\partial s} \quad (3)$$



where s is the coordinate tangential to the electrode surface and Φ is the electric potential phasor evaluated at the level of the electrodes (the electric potential in the liquid is written as $\phi(t) = \mathrm{Re}[\Phi\exp(i\omega t)]$). The parameter Λ appears to account for the effect of a compact layer on the electrodes, acting as a capacitor in series with the Debye layer and, as a consequence, diminishing the voltage drop across the latter [5], $\Lambda = C_s/(C_s + C_d) \leq 1$, where C_s and C_d are the capacitances of the compact and Debye layers, respectively.

Thus, it is first required to solve the electric potential in the bulk of the liquid, which is solution of Laplace equation with specific boundary conditions, as shown in Fig. 4. Charge accumulation at the electrode-electrolyte interface yields the following boundary condition:

$$\sigma\frac{\partial\Phi}{\partial n} = i\omega C_{DL}\left(\Phi - V_j\right) \quad (4)$$

AC Electroosmosis: Basics and Lab-on-a-Chip Applications, Fig. 4 Equations and boundary conditions for computing the fluid velocity generated by ACEO. Indexes n and t indicate normal and tangential component, respectively. The electric potential is obtained from Laplace equation with specific boundary conditions at the electrodes. From the solution of the potential at the level of the electrodes, the slip velocity is computed with Eq. 3 and introduced as boundary condition in solving Stokes equation for the fluid velocity

where **n** is the coordinate normal to the electrode surface and σ is the liquid conductivity and the total capacitance of the double layer is given by $C_{DL} = C_s C_d/(C_s + C_d)$. Zero normal current, $\partial\Phi/\partial\mathbf{n} = 0$, is imposed at the other boundaries of the domain. Figure 5 shows a comparison of experimental streamlines obtained using fluorescent particles as tracers and streamlines computed with this model [5].

Limiting Effects

The simple model presented in the previous section is rigorous for voltages of the order of $k_B T/e \sim 25$ mV or smaller. For these voltages, the Debye-Hückel approximation is valid, and the capacitance of the EDL per unit area is given by ε/λ_D. This does not hold true at higher voltages, and analytical models become more complicate, especially when the finite size effect of ions must be considered [6].

Another simplification is that the electrodes are considered to be perfectly polarizable, meaning that there is no charge transfer from the electrode to the electrolyte or vice versa. However, faradaic currents appear for increasing voltage, and it has been found to have an important influence in the flow [7].

Finally, there are more limitations not related to the amplitude of the applied voltage. The simple model does not consider the possible existence of an oxide layer on top of the electrode, the so-called compact layer. Very good fit to experimental results was obtained when this layer was taken into account [5]. In addition, the effect of ionic adsorption on the compact layer can reduce the slip velocity [8, 9]. In general, ACEO flow of electrolytes with high ionic strength (greater or equal to 100 mM) has not been reported. It seems that there are fundamental limitations around this ionic strength related to steric effects at high electrolyte concentrations as well as problems with the generation of faradaic reactions.

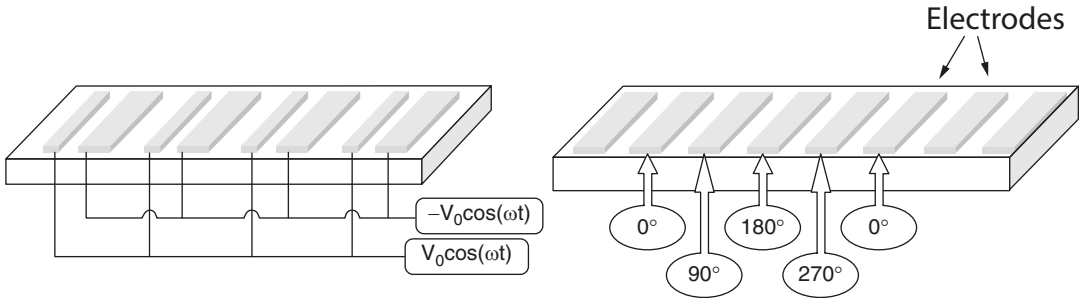
Applications for the Lab-on-a-Chip

Current clean room technologies allow for the fabrication of complex microelectrode structures and their integration in microfluidic devices. Therefore, AC electrokinetic phenomena represent an opportunity for performing standard operations in lab-on-a-chip systems. In particular, AC

electroosmosis has been demonstrated to be useful for the following applications:

ACEO Pumping and Mixing

The example of two coplanar electrodes of the same size is perhaps the easiest system to illustrate the mechanism of ACEO. As a consequence of the symmetry of the system, no net pumping of fluid is produced. The flow rolls on top of the two electrodes are identical and cancel each other. However, as predicted in [10], any electrode array with some asymmetry will lead to net pumping of the electrolyte.



Two different electrode arrays have been broadly explored for achieving net pumping of fluid; see Fig. 6. When pairs of asymmetric electrodes are used, the flow roll on top of the larger electrode dominates and net flow is created (from left to right in the figure) [11, 12]. Ref. [13] demonstrates a microfluidic pump consisting of a long serpentine microchannel lined with 3D stepped electrode arrays, allowing to achieve high pressures with voltages around 1 V_{rms}. Because the ACEO pump employs low voltage, it has potential applications in portable and/or implantable biomedical microfluidic devices. A different strategy to break the symmetry is the application of a traveling-wave electric potential [14, 15]. In experiments, this is implemented by using an array of equal size electrodes and applying a sinusoidal potential to each electrode but with a phase lag of 90° between neighbors. Net flow is achieved in the same direction of the traveling wave (left to right in the figure). A common feature of both arrays is that the flow direction is reversed for sufficiently high voltages [16]. This observation cannot be explained by the standard ACEO model, and limiting effects like ion crowding and faradaic currents should be accounted for.

The predominant laminar character of the flow in microfluidics makes mixing a slow process. Refs. [17, 18] show how AC electroosmosis can be exploited for generating micro-vortices locally and enhancing the mixing.

Transport and Aggregation of Particles and Molecules

AC electroosmotic flows have also been used in combination with other forces (dielectrophoresis in most cases) for concentration of bio-particles. The flow is used to bring and concentrate the particles on top of the electrodes, while the other forces are used for holding them [19]. For example, ref. [20] demonstrates ACEO for concentrating DNA molecules; the generated bulk flow was able to transport DNA molecules from a large effective region to the electrode surface. In ref. [21], ACEO combined with dielectrophoresis is employed for the sorting of ZnO nanoparticles with two different morphologies (nanowires and cubic shape).

The detection times for heterogeneous immunoassays can be very long if analytes have to travel only by diffusion to the device surface, where they then bind or react with surface-bound receptors. Ref. [22] demonstrates that the fluid flow generated by ACEO can enhance the analyte

AC Electroosmosis: Basics and Lab-on-a-Chip Applications, Fig. 6 Microelectrode structures for pumping of electrolytes. (*Left*) Array of asymmetric couples of electrodes subjected to a harmonic potential. (*Right*) Array of equal size electrodes subjected to a 4-phase traveling-wave potential

transport and reduce the detection time. Ref. [23] shows how a thin metal layer on a cantilever can generate ACEO vortices and increase concentration of bio-particles before detection.

Promising results have recently been obtained by using transparent semiconductors that become conductors when light is projected on them. In this way, light patterns created at will on the substrate will function as electrodes and, for example, allow for dynamic and in-situ concentrations of particles. Ref [24] showed the light patterning of 31,000 microfluidic ACEO vortices on a featureless photoconductive surface which were able to concentrate and transport micro- and nanoscale particles.

Acoustic Contrast Factor

Andreas Lenshof and Thomas Laurell
Department of Biomedical Engineering, Lund University, Lund, Sweden

Definition

The acoustic contrast factor (Φ) governs whether an object will be affected by the acoustic radiation force in an acoustic standing wave field [1]. It is comprised of the density and speed of the sound of the object (ρ_p and c_p) and the surrounding medium (ρ_0 and c_0), as seen in the equation below. A positive contrast factor means that the object will move to a pressure node, while a negative factor will move the object toward a pressure antinode:

$$\Phi = \frac{\rho_p + \frac{2}{3}(\rho_p - \rho_0)}{2\rho_p + \rho_0} - \frac{1}{3}\frac{\rho_0 c_0^2}{\rho_p c_p^2}$$

Acoustic Nanoparticle Synthesis for Applications in Nanomedicine

Aisha Qi, Peggy Chan, Leslie Yeo and James Friend
Micro/Nanophysics Research Laboratory, RMIT University, Melbourne, VIC, Australia

Synonyms

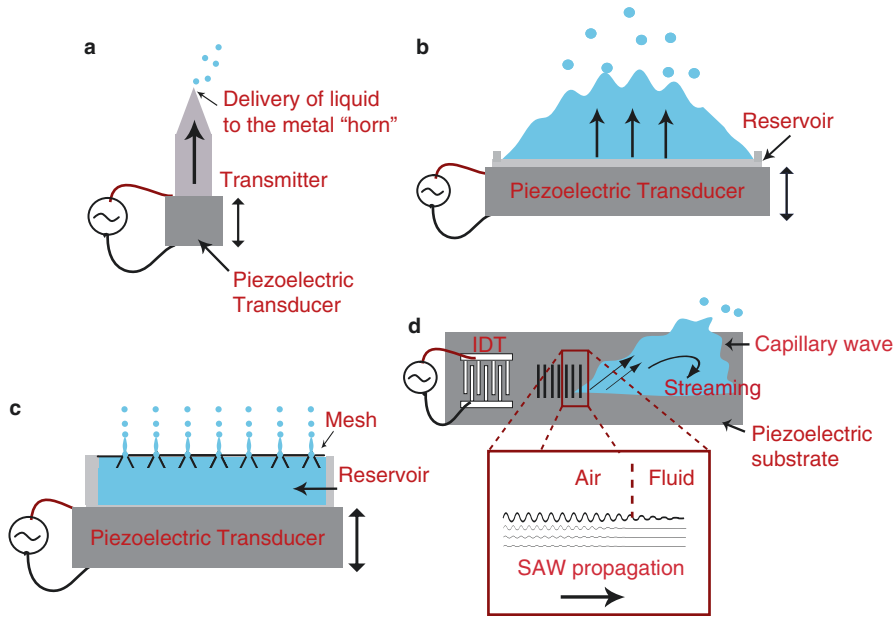
Drug delivery and encapsulation; Nanocarriers; Nanomedicine; Polymer nanocapsules; Sound propagation in fluids; Ultrasonic atomization

Definition

Sound wave propagation arising from the high-frequency acoustic irradiation of a fluid can generate considerable stresses at the free surface of the fluid leading toward its destabilization and subsequent breakup. If the fluid comprises a polymer solution, the evaporation of the solvent from the aerosols that are generated as a consequence of the atomization process leaves behind a solidified polymer core with submicron dimensions. Here, any discussion of nanoparticle synthesis due to chemical reactions driven by sound waves, i.e., sonochemistry, is omitted and the discourse is limited to the physical synthesis of such nanoparticles due to the atomization of polymer solutions into a gas, typically dry air.

Overview

The synthesis of functional nanoparticles is an area of tremendous interest, particularly from the standpoint of many industry applications from catalysis, optics, and electronics to biomolecular



sensing, regenerative medicine, and pharmaceutical science. In the latter, there are several challenges that current drug delivery technologies and systems face. For example, the low solubility of many drugs in biological environments prevents their absorption and distribution in vivo [1, 2]. While drug solubility limitations can be circumvented through chemical structure modification or the introduction of surfactant, the former often requires expensive and complicated procedures whereas the latter may not only increase the dosage volume but is also associated with toxicity problems [1]. In addition, the delivery of most drugs cannot be localized to target a site of interest, leading to undesirable side effects or immune responses when taken up by uninfected tissues and organs. Further, drugs are often susceptible to decomposition, enzymatic degradation, aggregation, or denaturation, thus either reducing their shelf life or their efficacy in vivo.

Nanoparticle-based delivery systems, however, offer the possibility of addressing some of these issues. For example, the drug dissolution rate can be increased by reducing the particle size [1, 2]. Tumor tissues are characterized by leaky vasculature and poor lymphatic clearance; due to their subcellular dimensions, nanoparticles are able to preferentially accumulate in tumor tissue through an enhanced permeation and retention (EPR) effect [3]. As an attractive alternative to conventional invasive surgical procedures, nanoparticles have also been reported to be able to cross the blood–brain barrier to be administrated into the central nervous system [1].

The encapsulation of drugs within the polymer nanoparticle not only acts as a protective layer surrounding the drug from hostile in vivo environments but also enables the drug to diffuse out slowly over extended periods. Such controlled release as well as direct local targeting of diseased regions can also be further tuned by judicious choice of the polymeric excipient chemistry, comonomer ratios, and their degradability in certain regions. Further site-specific targeting can be achieved by functionalizing the nanoparticle surface with tissue-specific or cell-specific ligands to increase uptake into receptor expressing cells [3]. Alternatively, it is straightforward to chemically modify the nanoparticle surface to actively target a diseased site by attaching a surface-bound ligand, e.g., monoclonal antibodies or polymeric conjugates that specifically bind to target cells [1].

There are numerous routes for nanoparticle synthesis, all of which can be broadly delineated into three general approaches. Mechanical milling techniques are widely used commercially but are typically confined to industrial applications such as ceramics and paints due to contamination issues. While the level of impurities can be reduced, for example, by carrying out the process in vacuum, this is expensive and the powders are often polydispersed. Wet chemical deposition and precipitation techniques involve phase separation and include crystallization and sol–gel processing. Polymeric nanoparticles can be synthesized using emulsion (solvent extraction/evaporation) and self- or directed-assembly methods. These are usually batch operations and mass production can lead to scale up in complexity and cost. Moreover, while these methods allow for size and size distribution reproducibility, controlling these parameters is difficult. Gas phase evaporation and condensation techniques, on the other hand, encompass a range of methods that include combustion flame pyrolysis, plasma chemical vapor deposition, and laser ablation as well as spray drying. As with all aerosol processing strategies, spray drying is typically straightforward, fast, and allows high throughput, producing dried nanoparticles by atomizing a solution into micron or submicron-sized aerosols which then rapidly pass through a drying configuration. By removing the solvent either through evaporation or extraction using a hardening agent [4–6], the material of interest, e.g., proteins, peptides, and a wide range of polymers, can solidify into dried particles usually with desired dimensions and morphologies governed by the parent aerosol [7].

Other aerosol processing techniques include hydrodynamic flow focusing and electrospraying. Hydrodynamic flow focusing generates droplets by forcing liquid through an orifice using direct pressure or a fast moving air stream [8], although this typically results in an uneven and large particle size distribution. As such, it is typically used

Acoustic Nanoparticle Synthesis for Applications in Nanomedicine, Fig. 1 Different conceptual configurations for ultrasonic atomization. (**a**) Indirect bulk vibration driven by a piezoelectric transducer via a metallic horn on which the working fluid drop is deposited. (**b**) Direct bulk vibration transmitted to the fluid drop placed on the piezoelectric transducer. (**c**) Use of micron-sized nozzles and orifices to drive ultrasonic microjets. (**d**) Transmission of surface vibration energy in the form of SAWs into a fluid drop to drive interfacial destabilization

by the food industry, for example, in the manufacture of milk powder, in which stringent particle size requirements are not essential. Electrospraying, on the other hand, employs large voltages to stretch and pinch off aerosol droplets from a liquid meniscus at the tip of a metal capillary [9]. While this produces aerosol droplets and polymeric nanoparticles with a uniform size distribution, the throughput is generally low and the large electric fields required not only poses safety hazards but could also result in molecular lysis, although these could potentially be circumvented using high-frequency AC fields [10].

New technologies for nanoparticle synthesis and drug encapsulation, however, have not kept up with the rapid advances achieved in nanomedicine, particularly, from the standpoint of drug discovery and formulation. The rest of this entry is concerned with atomization processes via acoustic means for polymeric nanoparticle synthesis and recent advances in this field that allow it to be exploited as a powerful tool for drug delivery.

Ultrasonic Atomization

Ultrasonic atomization generally refers to a method for aerosol production induced by irradiating a fluid in order to destabilize its interface with acoustic energy at driving frequencies between 20 kHz to a few MHz [11], although novel technologies such as surface acoustic waves (SAWs) allow operation at higher frequencies above 10 MHz [12]. The source of the acoustic energy is usually a piezoelectric transducer driven by an alternating electrical signal. Ultrasonic atomization therefore typically encompasses both indirect and direct vibration-induced atomization [11, 13], ultrasonic microjetting [14], and, more recently, SAW atomization [15]. Figure 1 illustrates these various conceptual strategies that are generally classified as ultrasonic atomization methods, the difference between these arising through the mechanism by which the acoustic energy is introduced or the way in which the aerosol droplets are produced. For example, *bulk* vibration energy is transferred

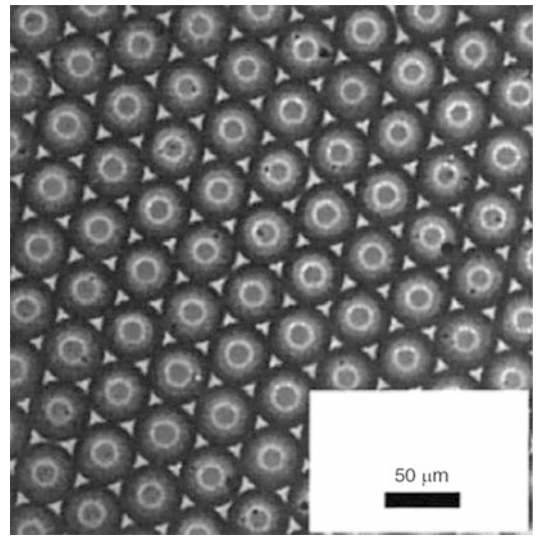
indirectly from the piezoelectric transducer to the fluid drop to be atomized through a metallic horn (Fig. 1a) or directly to the sessile fluid drop placed on the piezoelectric substrate (Fig. 1b). Nozzles and orifice plates from which fluid jets emanate that subsequently break up into aerosol droplets can also be used in an extension of the indirect method to provide finer control over the final droplet size (Fig. 1c). Alternatively, a nozzle can assume the place of the horn in the direct method in Fig. 1a, with the fluid issuing through the needle instead of placing the fluid on the horn. Nozzles or orifices however tend to clog over time and require constant cleaning; the pressure drop is also significantly increased, and hence more power is typically required to drive the atomization process. Alternatively, the *surface* vibration in the form of SAWs can couple acoustic energy into a fluid drop sitting on the piezoelectric substrate to effect interfacial destabilization (Fig. 1d). The operating principle and governing mechanisms that underpin ultrasonic atomization (cavitation or capillary wave destabilization) are discussed in detail in Yeo et al. [12].

The average diameter D of the aerosol droplets produced depends on the most unstable wavelength λ of the capillary wave instability that is induced, specified by the Kelvin equation, which essentially arises from a dominant force balance between the stabilizing capillary stresses and the destabilizing stress imposed by the vibration:

$$D \approx C_1\lambda \approx C_2\left(\frac{2\pi\gamma}{\rho f_c^2}\right)^{\frac{1}{3}}, \tag{1}$$

where γ and ρ are the surface tension and density of the fluid, respectively, and f_c is the capillary wave frequency. C_1 and C_2 are empirically determined coefficients commonly used to fit the experimental data to the predictions, and vary widely in the literature, although they are typically of order unity. It should be noted that Kelvin's theory does not provide a way in which the capillary wave frequency is related to the forcing frequency due to the acoustic vibration, and the usual assumption made (see, for example, [15]) is that the capillary waves are excited at a subharmonic frequency that is one half of the forcing frequency, i.e., $f_c = f/2$. Recent studies have however shown that this may not always be true and that the capillary wave frequency can be predicted from a dominant balance between capillary and viscous stresses, at least for a sessile drop or thick liquid film [12, 15]:

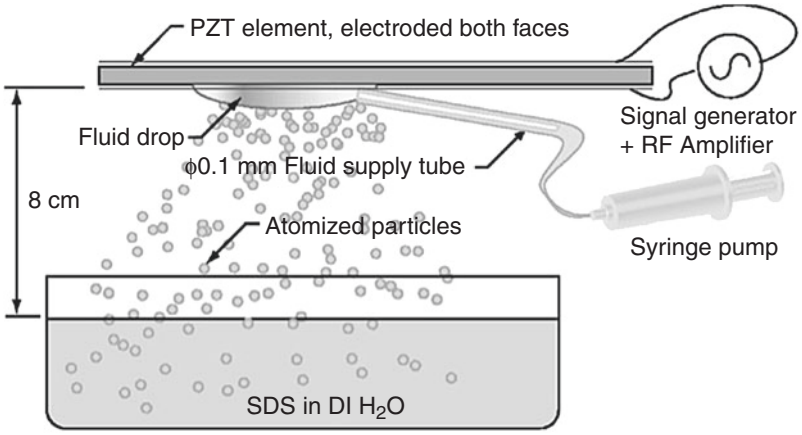
$$f_c \sim \frac{\gamma}{\mu L}, \tag{2}$$



where μ is the viscosity of the fluid and L is the characteristic length scale of the drop or film. A correction factor $(H/L)^2$, wherein H is the characteristic height scale, can be included to account for the geometry of the parent drop, in particular, the axial capillary stress, when substituting Eq. 2 into Eq. 1 [15].

SAWs, generated by applying an oscillating electrical signal to the interdigital transducer electrodes patterned onto a piezoelectric substrate (Fig. 1d), the gap and width of which specifies the SAW wavelength and hence the resonant frequency (typically 10–100 MHz), have also been shown as an effective mechanism for atomizing drops. Essentially, SAWs are nanometer order amplitude ultrasonic waves that are confined to and propagate along the substrate surface in the form of a Rayleigh wave. Owing to high MHz order frequencies and substrate displacement velocities, on the order of 1 m/s in the vertical direction perpendicular to the substrate, substrate accelerations on the order of 10^7 m^2/s arise. This, together with the strong acoustic streaming that is induced within the fluid drop placed on the substrate, leads to fast destabilization and breakup of the drop free surface to produce 1–10 μm dimension aerosol drops [15], as illustrated in Fig. 1d. One advantage of the SAW atomization over its ultrasonic counterparts is the efficient energy transfer mechanism from the substrate to the liquid – unlike bulk vibration, most of the acoustic energy of the SAW is localized within a region on the surface of the substrate about 3–4 wavelengths thick (a SAW wavelength is typically on the order of 100 μm) and is transferred to the liquid drop to drive the atomization. Consequently, it is possible to atomize fluids using the SAW at input powers of

around 1 W, which is one to two orders of magnitude smaller than that required using other ultrasonic methods. Another advantage of the SAW is the high frequencies (>10 MHz) that can be assessed. The timescale associated with the period (inverse frequency) of the oscillating acoustic and electromechanical field at these frequencies is much shorter than the hydrodynamic timescale $\mu L/\gamma \sim 10^{-4}$ s as well as the 10^{-5}–10^{-6} s relaxation timescales (inverse of the strain rate) associated with shear-induced molecular lysis [12]. In addition, it is not possible to induce cavitation, which is known to cause molecular lysis, at the low powers and high frequencies associated with SAW atomization [15].



Synthesis of Polymeric Microparticles and Nanoparticles

Early work to demonstrate the possibility of synthesizing polymeric particles, albeit with micron dimensions, was reported by Tsai et al. [16] and Berkland et al. [4]. The apparatus in both studies is similar, based on concept known as two-fluid atomization. A piezoelectric transducer is used to vibrate a nozzle or orifice from which a jet comprising the working fluid issues and which subsequently suffers from Rayleigh-Plateau instabilities to break up into individual aerosol droplets. In a manner similar to the Kelvin equation given in Eq. 1, the droplet diameter is controlled by the most unstable wavelength of the axisymmetric instability, which can be predicted from a dominant force balance between the inertia imposed on the jet and the capillary stresses that stabilize it, and is a function of the diameter of the undisturbed jet, which is slightly larger than the nozzle or orifice diameter. In both cases, an external annular stream surrounding the nozzle through which the liquid jet issues is employed. The annular sheath fluid consists of air in the former and an immiscible carrier liquid that does not dissolve the polymer solution in the latter. In both cases, the sheath fluid, whether air or a second immiscible liquid, is flowed much faster than the jetting fluid although the underlying reason provided for its necessity differs. In the former, the airflow is suggested to vibrate in resonance with the vibrating nozzle due to the coaxial annular arrangement, resulting in a magnification of the amplitude of the capillary waves on the liquid jet. In the latter, the interfacial shear imposed by the carrier fluid surrounding the jet is suggested to aid the primary breakup of the jet away from its parent fluid at the orifice, allowing the production of droplets one order of magnitude smaller. 40 μm diameter xanthan gum particles were synthesized in the former when driven at a fundamental resonant frequency of 54 kHz through a 0.93 mm nozzle whereas 5–500 μm diameter poly(d,l-lactic-*co*-glycolic acid) (PLGA) particles (Fig. 2) were synthesized in the latter when driven at frequencies between 19 and 70 kHz through 60 and 100 μm diameter orifices. The carrier fluid, poly (vinyl alcohol), in which the PLGA particles were collected and solidified within, however, remained on the surface of the particles, which could potentially affect physical and cellular uptake [3].

[4]. Copyright (2001) Elsevier)

Forde et al. [17] subsequently showed the possibility of synthesizing poly(ε-caprolactone)

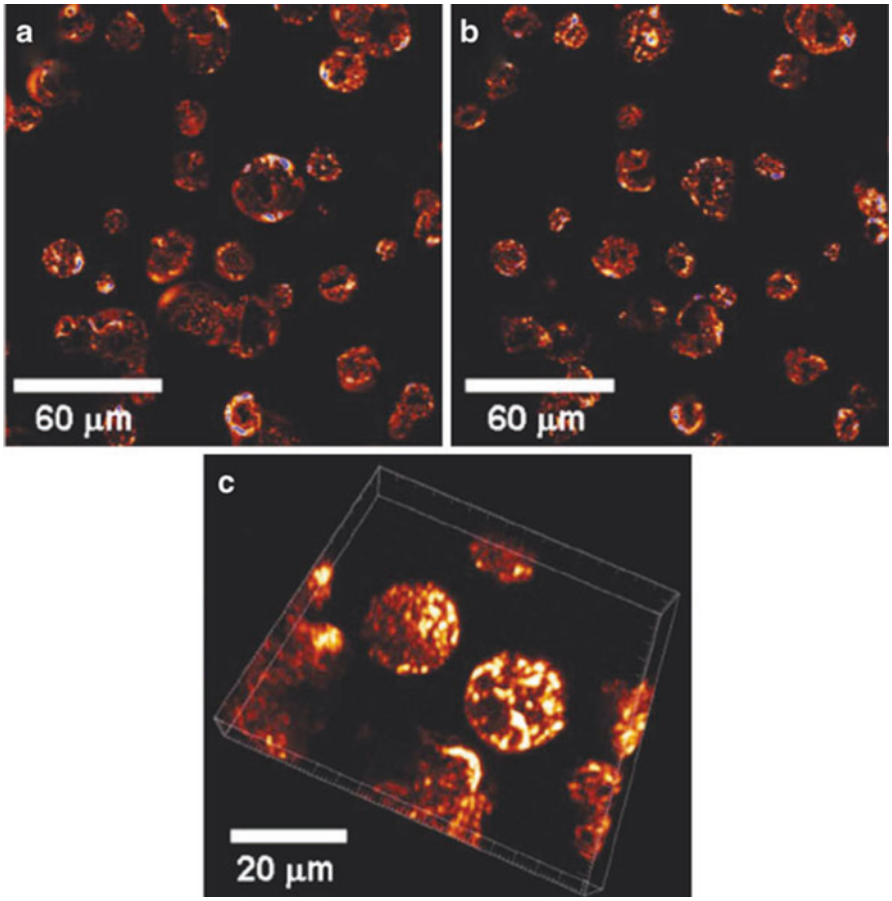
[19]. Copyright (2008) Institute of Physics)

(PCL) *nano*particles around 200 nm in dimension by atomizing a PCL/acetone solution using the direct method shown in Fig. 1b involving a piston-vibrated hard lead zirconate titanate piezoelectric disk between 1 and 5 MHz, as illustrated in Fig. 3. The nanoparticle diameter D_p can be estimated from volume considerations [18]:

$$D_p \approx D\left(\frac{C}{\rho}\right)^{\frac{1}{3}}, \tag{3}$$

wherein C denotes the initial polymer concentration, such that it is possible to tailor the nanoparticle size by tuning the aerosol size through its physical properties as well as the geometry of the parent drop, as suggested by Eq. 2.

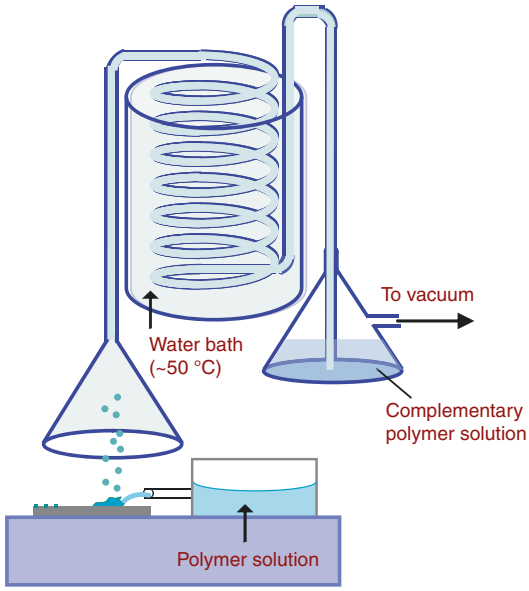


Polymeric nanoparticles have also been produced using SAW atomization. Friend et al. [19] demonstrated the synthesis of 150–200 nm clusters of 5–10 nm PCL nanoparticle aggregates, as shown in Fig. 4, the cluster size being weakly dependent on several parameters such as the surfactant used and the drying length. The grape-bunch-like cluster morphology was attributed to nonuniform solvent evaporation during in-flight

drying of the droplets that drive a thermodynamic instability. This results in spinodal decomposition and phase separation, which gives rise to separate regions that are polymer-rich and solvent-rich. The polymer-rich regions then solidify more rapidly, creating nucleation sites that lead to the formation of a cluster of PCL molecules until a critical nucleation size is attained, estimated from classical nucleation theory to be around 10 nm and consistent with the 5–10 nm nanoparticles observed. In addition to PCL, 1–10 μm dimension protein (bovine serum albumin and insulin) aerosols have been generated using the SAW, which evaporate in flight to form 50–100 nm nanoparticles [18].

Drug Encapsulation

Early work on drug encapsulation via ultrasonic atomization was carried out by Felder et al. [5], who showed the possibility of encapsulating protein and peptides into poly(lactic acid) (PLA) and PLGA directly using ultrasonic atomization. The polymer solution was sonicated with a protein (bovine serum albumin; BSA) or peptide solution (2–10 % w/w concentration) to create a stable water-in-oil emulsion, which was then atomized into a beaker in which hardening agent (octamethylcyclotetrasil, hexane, isopropyl myristate, or water) was agitated to yield 10–100 μm order microparticles. This solidification method relies on *solvent extraction* and hence polymer desolvation within the hardening agent as opposed to *solvent evaporation* in-flight used in the other methods reported here. While smaller nanoparticles on the order of 100 nm diameter were also reported, it is not clear whether these contained any encapsulated material, as the authors only reported size distribution data for the naked PLA and PLGA particles. It would, however, be consistent with the other studies reported below that encapsulated particles are generally of micron-order dimension due to the size of the peptides and proteins within. The frequency at which the ultrasonic atomization was carried out was also unspecified. Reported encapsulation efficiencies, obtained by dissolving the polymer particles in the original solvent (or an acetonitrile/chloroform mixture) to release the encapsulated material which is then recovered on a 200 nm cellulose filter followed by elution with phosphate buffered saline and quantitative characterization using a spectrofluorometer (protein) or through a HPLC assay (peptides), were typically low, between 10 % and 35 %. This was attributed to comparable extraction rates between that of the aqueous phase in which the protein or peptide resides with that of the polymer solvent through diffusion and partitioning. Consequently, the protein or peptide is removed during washing. When a different peptide which is only weakly soluble in water was encapsulated, the efficiency was observed to increase to 63 % and 93 %. As such, it is instructive to note here that encapsulation efficiencies are therefore likely to be higher if solvent evaporation is used as the polymer desolvation method instead of solvent extraction, since the solvent is much more likely to be removed rapidly through evaporation while in flight at a rate much faster than that of water, therefore resulting in more efficient encapsulation of the aqueous phase and the proteins or peptides within the fast solidifying polymer shell.

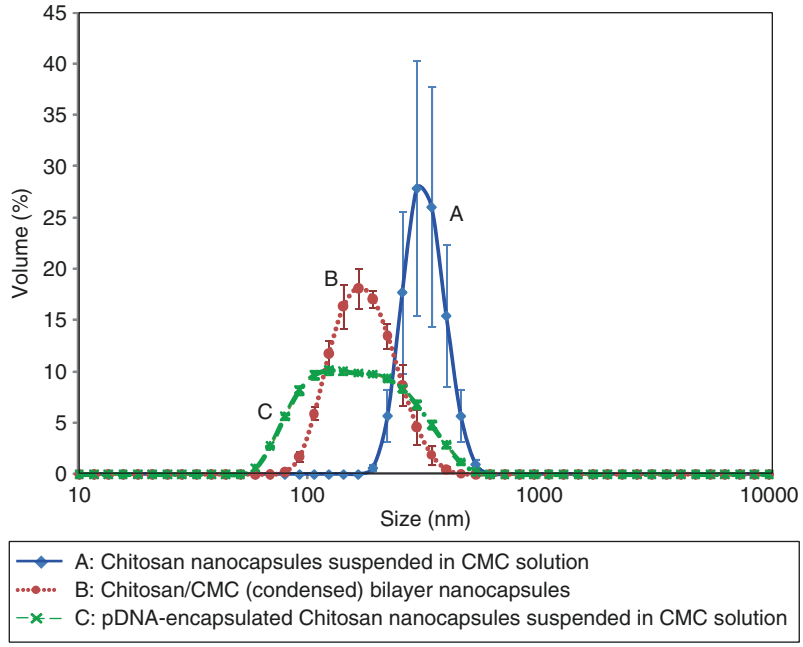


BSA was also encapsulated in PLGA using 100 kHz ultrasonic atomization of a similar water-in-oil emulsion in a study by Freitas et al. [6]. The solvent was evaporated and the solidified particles were collected and further desolvated in an agitated aqueous solution and subsequently recovered using a filter. To allow for aseptic encapsulation conditions, the conventional spray dryer unit was shortened by running the unit under near-vacuum conditions instead of using hot air, and the cyclone unit that is usually present in spray dryers was replaced by an aqueous collection bath; in that way, the entire unit can be placed within a laminar flow chamber. Again, the particles were in the micron dimension (13–24 μm mean diameter). As expected due to the use of solvent evaporation over solvent extraction, the BSA encapsulation efficiencies were higher, around 50–60 % compared to 10–35 %, which the authors claim could be improved if BSA loss in the aqueous collection solution was replaced by a fluid which is a nonsolvent for

[18]. Copyright (2009) American Institute of Physics)

BSA. Alternatively, they suggest reducing the polymer concentration.

Plasmid DNA (pDNA) and poly(ethyleneimine) (PEI) complexes were encapsulated within 10–20 μm diameter PLGA microparticles using a 40 kHz ultrasonic atomizer [20]. Solvent extraction via a poly(vinyl alcohol) hardening agent was used in this case. Encapsulation efficiencies in a wide range between 20 % and 90 % were reported, with lower polymer concentrations and higher pDNA-PEI volume fractions giving higher efficiencies; contrary to prior claims, the authors however did not find significant dependence of the encapsulation efficiency on the N/P ratio (N referring to the nitrogen content and P referring to the DNA phosphate content of the pDNA-PEI complex). These values were however obtained by subtracting the mass of pDNA remaining in the hardening agent, measured using a spectrofluorometer, from that in the feedstock, which does not take into account loss of pDNA in the environment during atomization, the amount of unatomized pDNA left on the atomizer as well as the pDNA that resides on the surface of the particles instead of being encapsulated within. The authors also investigated the post-atomization structural integrity of the pDNA using gel electrophoresis due to the susceptibility of pDNA to shear degradation, and found 80 % retention of the pDNA in supercoiled

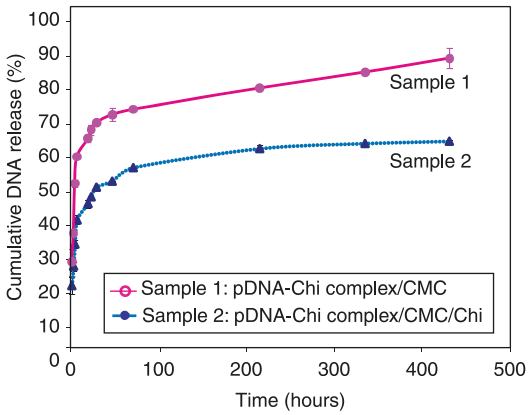


Acoustic Nanoparticle Synthesis for Applications in Nanomedicine, Fig. 6 Schematic illustration of the SAW atomization setup involving a single atomization–evaporation–resuspension step used to deposit a single polymer layer and to resuspend it in a complementary polymer solution. The step is repeated to deposit subsequent layers for as many layers as required

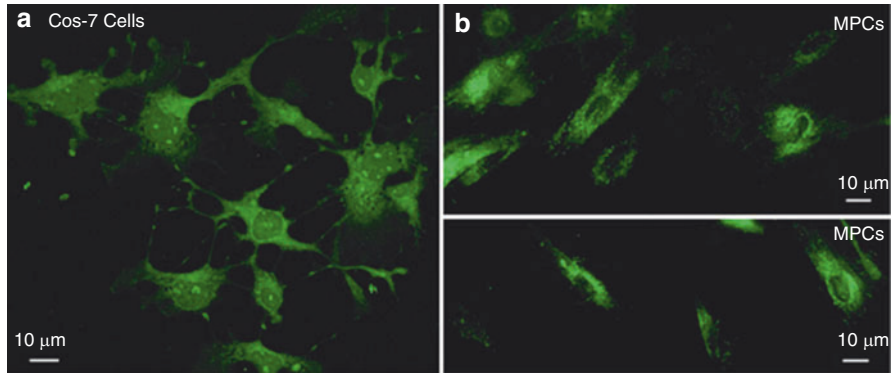
conformation. This was attributed to cationic complexation between pDNA and PEI, which reduces its size and hence the possibility of shear-induced degradation (when naked pDNA was assessed, only 8 % of this remained supercoiled). Nevertheless, PEI has been known to induce cytotoxic effects and hence its use may be limited for gene transfection and delivery. An alternative mitigation strategy involving multilayer polymer nanoparticles will be discussed in the next section.

Alvarez et al. [18] later demonstrated the encapsulation of BSA in PCL particles using SAW atomization. With 10 MHz SAWs, the particle sizes had a mean of 23 μm whereas this decreased to around 6 μm with 20 MHz SAWs. Proof of encapsulation was acquired through confocal image slices of the particles showing the fluorescently tagged BSA appearing not only at the top and bottom of the cross-sectional slices across the particle but also in the particle center, thus verifying that the BSA was entrapped within and not simply bound to the surface of the particle (Fig. 5). The encapsulation efficiency value reported was slightly different compared to other

Acoustic Nanoparticle Synthesis for Applications in Nanomedicine, Fig. 7 Dynamic light scattering measurements of (**a**) single-layer chitosan nanoparticles, (**b**) bilayer chitosan and CMC nanoparticles, and (**c**) pDNA encapsulated chitosan nanoparticles



studies in that 54 % of BSA from the feedstock was found to be encapsulated with its chemical structure intact (as opposed to the total BSA content encapsulated reported in previous studies). Thus, the total encapsulation efficiency value could be significantly higher (if a comparison were to be made with the values in Felder et al. [5] and Freitas et al. [6]). As discussed above, the high-frequency operation of the SAW limits the amount of shear and cavitation damage caused to the molecules, and constitutes a considerable advantage of using SAWs over conventional ultrasonic atomization.



Multilayer Nanoparticle Synthesis and Encapsulation

Multilayered polymer particles offer significant advantages over a particle comprising a single layer. Layers of different polymers with varying chemistry and hence degradation profiles offer the possibility of tuning the drug release over time and in different physiological regions, therefore affording tremendous opportunities for targeted and controlled release delivery. Very recently, SAW atomization has been exploited to demonstrate the potential for rapidly synthesizing nanoparticles with alternating layers of complementary polymers of opposing charge [21]. This is done through a variation of the usual procedure of atomizing an initial polymer solution followed by evaporated-assisted solidification to produce a single-layer polymer nanoparticle. In addition, however, the solidified polymer particle is collected in a solution in which the second polymer is dissolved (Fig. 6), which is then re-atomized and dried to deposit the second polymer layer over the initial polymer core. By collecting the two-polymer-layer nanoparticle in a solution comprising the polymer to form the third layer and re-atomizing, a further layer can be deposited. The atomization–evaporation–resuspension procedure is then repeated for as many times as the number of layers desired. The requirement of the polymers comprising alternating layers is that each successive polymer must be complementary to the previous polymer, i.e., they must have opposing charges. In addition, the polymer making up the subsequent layer must be soluble in a solvent that cannot dissolve the polymer making up the previous layer. Up to eight layers of alternating chitosan (or PEI) and CMC layers were synthesized; proof of the deposition of successive layers was provided by visual inspection (atomic force microscopy), charge characterization (reversal of the zeta-potential after the deposition of each successive layer), Fourier transform infrared spectrometry showing ionic complexation between the deposited layers, and fluorescence measurements of labeled polymers. In addition, pDNA was also encapsulated within the multilayer polymeric nanoparticles to demonstrate the therapeutic capability of the nanoparticles in particular for gene therapy.

Figure 7 shows the size distribution of negatively charged chitosan and positively charged CMC polymer bilayer particles. The decrease in size upon deposition of the second CMC layer over the chitosan core or the encapsulated pDNA can be attributed to ionic complexation that tends to compact the particle size. Even with encapsulation, however, the size of the particles remains in the 100–200 nm range, which is a significant advance over the micron-sized particles obtained whenever a therapeutic molecule is encapsulated

(see previous section). In targeted cancer therapy, for example, the mean vascular pore size of most human tumors is around 400 nm [1], and hence extravasation is likely to be more effective with the multilayer nanoparticle drug carriers synthesized through this technique. Figure 8 shows in vitro release profiles of the pDNA, showing the possibility for slowing and hence controlling the release with the deposition of an additional layer. Good in vitro DNA transfection is also demonstrated in COS-7 and human mesenchymal progenitor cells, as seen in Fig. 9.

Definition

Acoustic trapping is the immobilization of particles and cells against a flow in the node of an ultrasonic standing wave field.

Overview

Acoustic trapping has been shown to be a gentle way of performing noncontact immobilization of cells and particles in microfluidic systems. Localized ultrasonic standing waves are created in microfluidic channels, cavities, or other small, confined spaces creating pressure nodes that attract and hold particles and cells. Commonly, structures in the range of a couple of 100 μm are used, corresponding to acoustic frequencies in the MHz range.

Background

Some 30 years ago, NASA and ESA started to develop containerless processing, and one of several possible techniques was acoustic trapping/levitation [1]. These open-air levitators, still in use today, are rather large instruments that create a standing wave in air and make it possible to position and levitate liquid droplets or small and light solid matter. The use of radiation forces on particles and cells in liquid suspensions has been a more common approach than the open-air levitators however. Baker showed in 1972 that a band formation owing to the radiation forces could be observed when subjecting erythrocytes to a 1 MHz standing wave in polystyrene containers [2]. Since then, the technique has been refined and successfully incorporated into the lab-on-a-chip field as one of several methods to control cells and particles in laminar flows.

Theory

In order to create an efficient standing wave, the geometry of the channel/cavity must match the actuation frequency of the transducer. To create a single pressure node, the length of the resonance cavity should be $\lambda/2$, where λ is the wavelength of the ultrasound in the media. To increase the trapping capacity, this can then be scaled so that the number of pressure nodes where objects can be trapped is equal to $n*\lambda/2$. For water-based buffers, the sound velocity is typically 1,500 m/s. So in

order to create a standing wave at 2 MHz, the resonance cavity should be 375 μm (v/2f).

The most dominant force in play is the *primary radiation force* (Eq. 1) that is proportional to the particle volume (V_c) and is thus strongly size dependent [3]. The force also depends on the acoustic wavelength (λ), the acoustic pressure amplitude (p_0), and the particles' position in the acoustic wave (x). The *acoustic contrast factor* (Eq. 2) is dependent on the density and compressibility of both the particle (ρ_c, β_c) and the medium (ρ_w, β_w):

$$F_r = -\left(\frac{\pi p_0^2 V_c \beta_w}{2\lambda}\right) \cdot \phi(\beta, \rho) \cdot \sin(2kx) \quad (1)$$

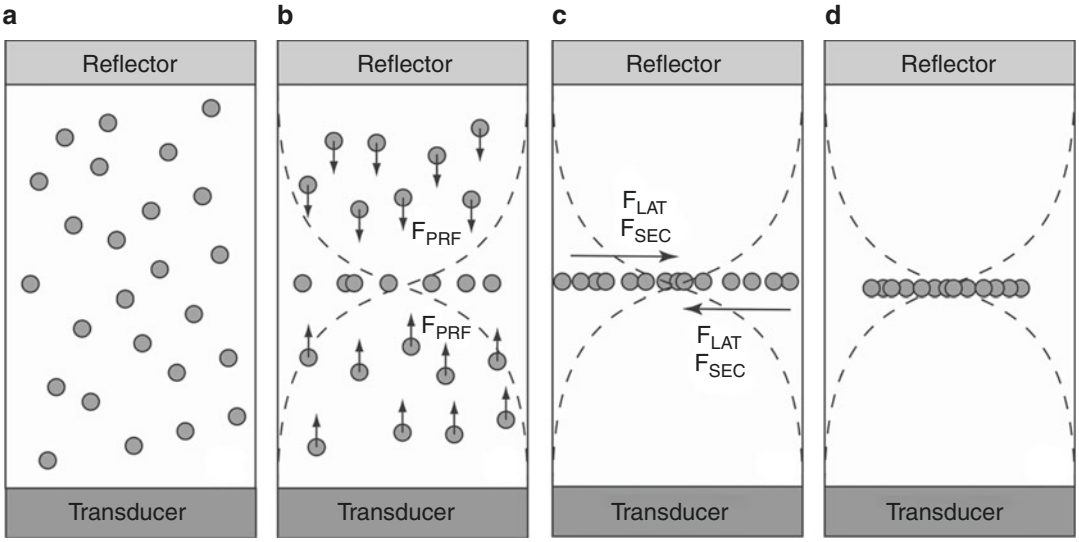
$$\phi(\beta, \rho) = \frac{5\rho_c - 2\rho_w}{2\rho_c + \rho_w} - \frac{\beta_c}{\beta_w} \quad (2)$$

The acoustic contrast factor can change the direction of the force so that, depending on the material parameters, an object may be pushed toward the pressure node or the pressure antinode. For most cells and particles, the force will be directed toward the pressure node however. *Acoustophoresis* uses this factor to enable separation between different cell types that may differ in density and/or compressibility.

While the *primary radiation force* is responsible for moving an object into the pressure node or antinode, it is the lateral component of it that enables acoustic trapping. The acoustic radiation force is based on both the pressure and the velocity gradient in the standing wave, and in order to create an efficient trapping system, a large gradient is required. The force resulting from the lateral velocity gradient for a dense particle with a radius, R, situated in the pressure node of a standing wave with constant amplitude gradient was expressed by Gröschl as [4]

$$F_{\text{Lat}} = \pi\rho\omega^2 R^2 \hat{u}_0 \hat{u}_m \quad (3)$$

where ρ is the medium density and the angular frequency of the ultrasound, u_0, is the displacement amplitude at the center of the particle, while u_m is the difference in amplitude between the center and the edge of the particle. As can be seen, the larger the amplitude difference between the center and the edge of the particle, the larger the trapping force.



There are also *secondary interparticular forces* that arise when the incident sound wave is scattered on the objects in the standing wave. These forces only act on short distances but help to form a cluster of the objects and keep them together (Fig. 1).

System Design

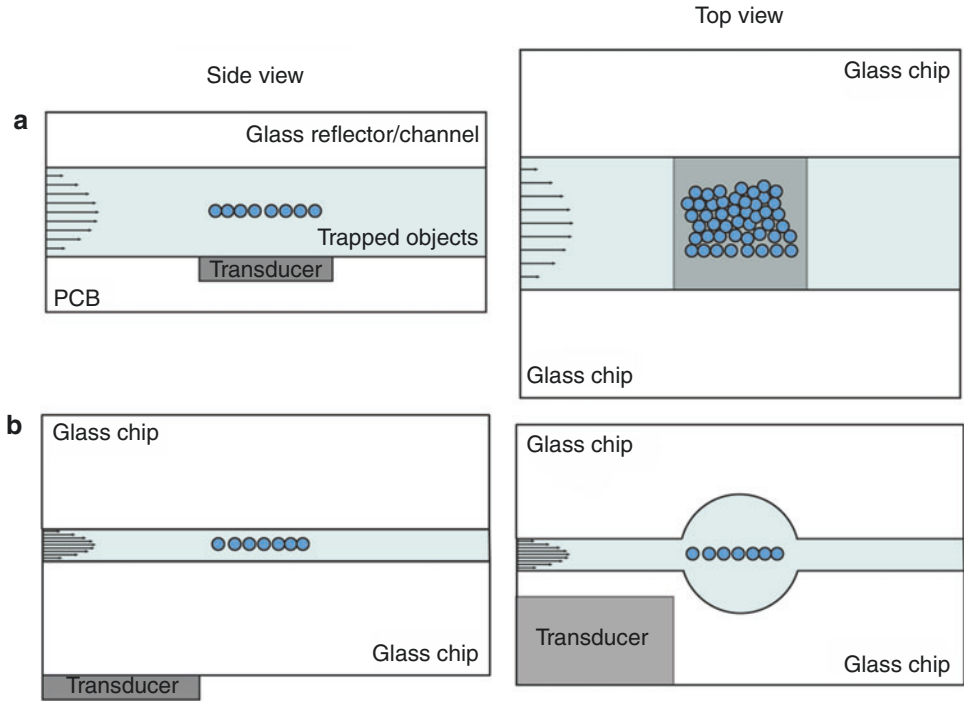
An acoustic trap is usually designed to either use a localized pressure field or create a localized resonance. An example of a localized pressure field would be a small transducer that couples sound to a fluid only in a small portion of a channel, also called a layered resonator. The alternative approach is to actuate the entire chip and design a resonance cavity on the chip that matches the actuation frequency. The standing wave will then only exist where the geometry matches the standing wave criteria. Another alternative that has not been as common as the other two designs is the use of focused transducers. By focusing the ultrasound into a very narrow beam and then reflecting the wave in the focal plane, a hemispheric standing wave that can trap and hold objects can be created [6] (Fig. 2).

Designs Using Local Resonance Cavities

Designs that use a transducer coupled directly or through a matching layer to the fluid typically have a larger trapping capacity than the cavity approach. However, since the cavity trap is usually created using photolithographic techniques, it is easy to array and to integrate with other sample processing steps on the chip. An example of a cavity array was presented by Vanherberghen et al. where a 10 × 10 array was used for aggregating cells for isolated cell studies using microscopy [7] (Fig. 3).

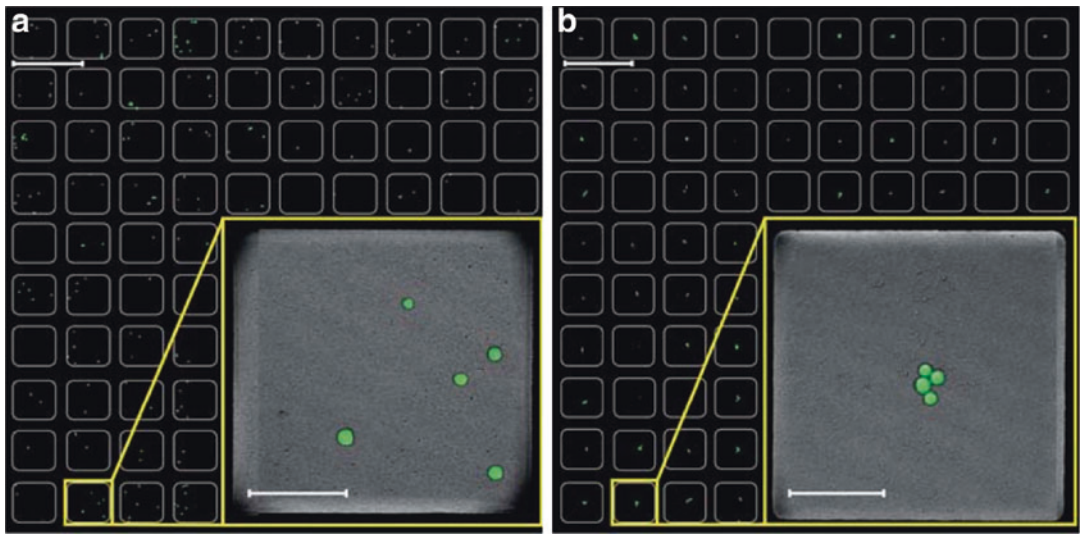
Acoustic Trapping, Fig. 1 A schematic image demonstrating how different acoustic forces act on particles in a standing wave. (**a**) Before activating the ultrasound, particles will be evenly distributed in the channel. (**b**) When activating the ultrasound, the particles will be moved into the pressure node by the primary radiation force. (**c**) Lateral forces will then focus the particles to the center of the sound field. Once the distance between the particles is short enough, secondary interparticular forces will create an attractive force between the particles and pull the cluster firmer together. (**d**) The end result is a centered, levitated cluster of particles situated in the middle of the resonance cavity (Reprinted from Evander [5] with permission from the author)

Designs Using a Localized Transducer



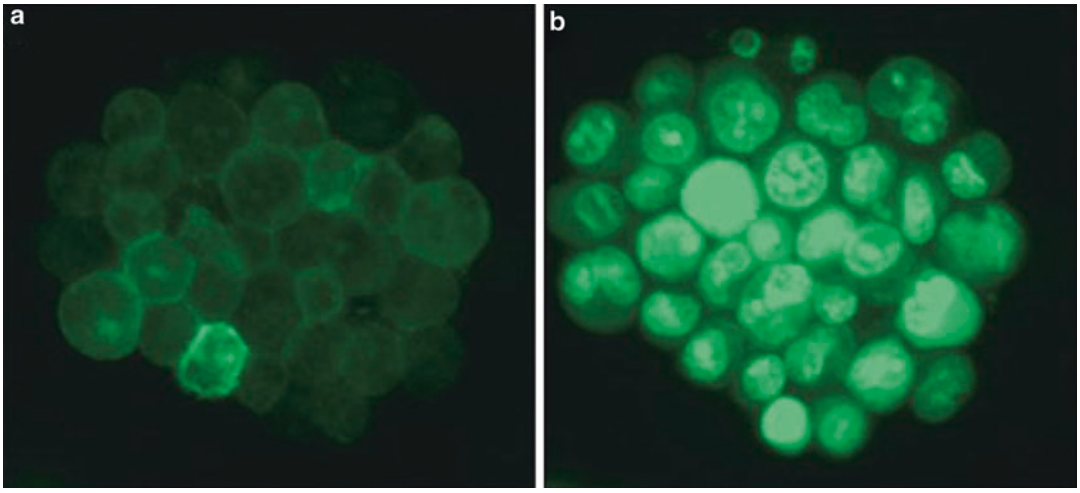
Spengler and Coakley presented a trapping system that used a layered design in 2000 [8]. By using a PTFE spacer and a glass reflector, they were able to study cell aggregates in a standing wave at 1.93 MHz. This system was later redesigned to a stainless steel system using a matching layer to couple the ultrasound into the resonator and used for studies of cell membrane spreading [9].

An alternative to using a matching layer is to integrate the transducer in the bottom of a microfluidic channel. A system based around a miniature transducer that was embedded in a printed circuit board was presented by Evander et al. in 2007 [10]. A glass lid with a microfluidic channel was placed on top of the printed circuit board, and a standing wave was formed above the transducer in the channel. To test the system, yeast cells were grown in the standing wave, and an online viability assay was performed on trapped neural stem cells (see Fig. 4).

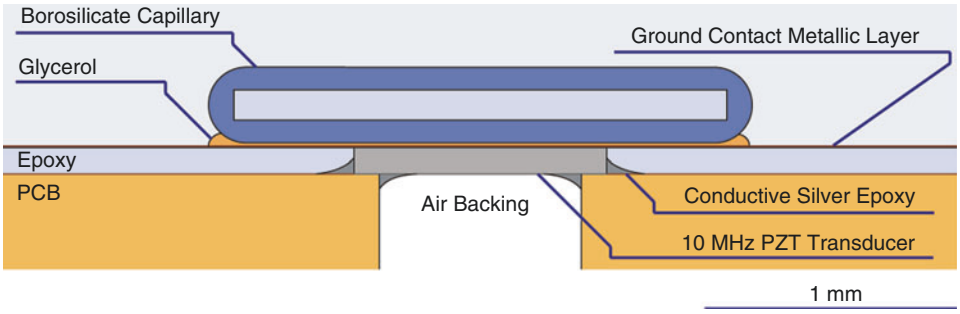


A further development of the trapping system was presented by Hammarström et al. [11]. Instead of etched microfluidic channels, a square borosilicate capillary was coupled to an external miniature transducer through a thin glycerol layer (see Fig. 5). Using commercially available capillaries both lowers the production costs and allows for disposable channels for more sensitive analysis.

Cell Viability



Several studies have shown that ultrasonic levitation does not seem to have any negative effects on live cells. Hultström et al. cultured cells that had been levitated for over an hour and studied the doubling times of the cells [12]. No direct or delayed damage could be detected on the cells. Bazou et al. performed a study on mouse embryonic stem cells and confirmed that they could see no changes in gene expression after ultrasonic treatments up to 1 h and the cells maintained their pluripotency [13].



Acoustic Trapping, Fig. 2 (**a**) An acoustic trapping approach using a small transducer that creates a very localized pressure field in a channel. The transducer is embedded into the bottom of the fluidic channel and creates a large pressure gradient over a small area; (**b**) An example of an acoustic trapping cavity. Here, the entire chip is actuated, and a standing wave is created only where the geometry matches the ultrasound

Acoustic Trapping, Fig. 3 The 10 × 10 ultrasonic cavity array presented by Vanherberghen et al. [7]. Acoustic Trapping, Fig. 4 Neural stem cells, HiB5-GFP, trapped in an acoustic standing wave. In (**a**) the cells have just been trapped in the standing wave, and in (**b**) the cells have been levitated for 15 min after which they were perfused with acridine orange to test for viability. The increase in fluorescence indicates that the cells are still viable (Reprinted and modified with permission from Evander [10]. Copyright 2007 American Chemical Society)

Acoustic Trapping, Fig. 5 The trapping platform presented in [11] uses a square borosilicate capillary as microfluidic channel and resonance cavity. A system with an external transducer and off-the-shelf capillaries has a lower production cost and is also compatible with more sensitive assays where disposable channels must be used (Reproduced with permission from The Royal Society of Chemistry: http://dx.doi.org/10.1039/c004504g)

Future Directions of the Field

The main research focus has so far been on technology development, but as the robustness of the systems is steadily increasing, more application-driven development can be expected. Further work aimed at integrating the trapping systems with other lab-on-a-chip systems can also be expected as well as an ambition to increase the particle size range that can be manipulated, in particular toward smaller objects such as bacteria. A lot of effort is also focused on controlling trapped clusters in three dimensions through the use of transducer matrix with phase and frequency control. These platforms will open up for exciting new applications where it will be able to have full control over clusters and perhaps single cells in microfluidic platforms.

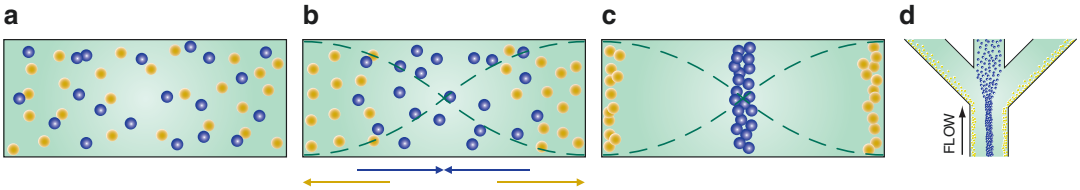
Acoustophoresis



Andreas Lenshof and Thomas Laurell
Department of Biomedical Engineering, Lund University, Lund, Sweden

Definition

"Acoustophoresis" means migration with sound, i.e., "phoresis" (migration) and "acousto" (sound waves) are the executors of the movement. In related concepts, electric forces move particles in electrophoresis and magnetic forces in magnetophoresis [1]. Acoustophoresis is a non-contact and label-free mode of manipulating particles and cell populations and allows for implementation of several separation modes [2]. The technology is currently finding increased applications in bioanalytical and clinical applications of cell handling and manipulation. An extensive tutorial series on acoustophoresis was recently published by Royal Society of Chemistry [3].

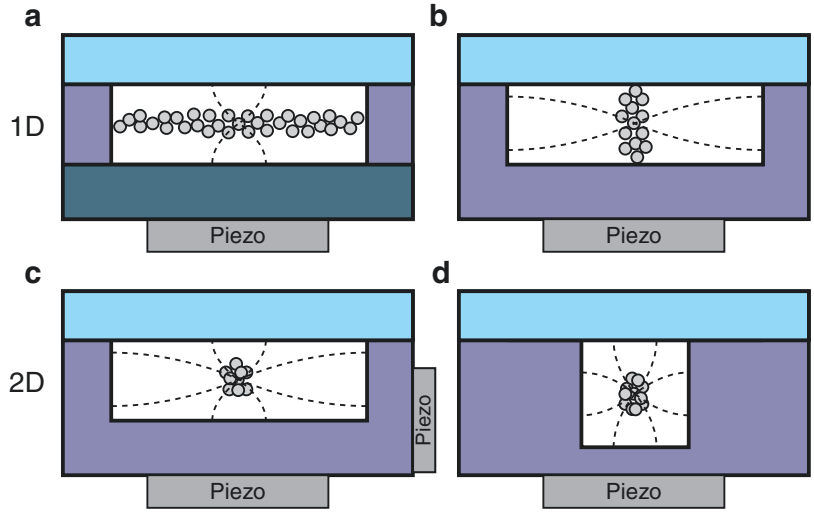
Theory

Particles in suspension exposed to an acoustic standing wave field will be affected by an acoustic radiation force [4]. The force will cause the particle to move in the sound field if the acoustic properties of the particle differ from the surrounding medium. The magnitude of the movement depends on factors, such as the size of the particle, the acoustic energy density, and the frequency of the sound wave. The direction of the particle movement is dependent on the density and speed of sound of the particle as well as the liquid media. In an acoustic standing wave generated in a liquid (e.g., water)-filled channel with wall boundaries of dense materials such as metal, silicon, or glass, a standing wave pressure maxima will form at the walls/fluid interface. If the width of the channel is matched to half a wavelength, a pressure node will form in the center of the channel.

Acoustophoresis, Fig. 1 Illustration of particles with different sign of the acoustic contrast factor being exposed to an acoustic stranding wave field. The radiation force move the particles with positive contrast factor (*blue*) to the pressure node located in the center of the channel, while the particles with negative contrast factor (*yellow*) move to the antinodes at the channel side walls, (**a-c**). The laminar flow enables separation of the two particle types using a trifurcation at the end of the channel (**d**)

The most predominant acoustic force acting on microparticles in an acoustic standing wave is the primary axial acoustic radiation force (PRF), Eq. 1. The magnitude of the PRF is dependent on the acoustic energy density, E_{ac}, and the radius, a, of the particle. The direction of the particle movement depends on the acoustic contrast factor Φ, which comprises the inherent physical properties of the cell or particle, such as the density, ρ_p, and speed of sound, c_p, relative to the properties of the surrounding medium, ρ_0 and c_0. The sign of the acoustic contrast factor defines the direction of the movement.

$$F_y^{rad} = 4\pi k a^3 E_{ac} \Phi \sin(2ky) \tag{1}$$



$$\Phi = \frac{\rho_p + \frac{2}{3}(\rho_p - \rho_0)}{2\rho_p + \rho_0} - \frac{1}{3}\frac{\rho_0 c_0^2}{\rho_p c_p^2} \tag{2}$$

As shown in Fig. 1, most rigid cells and particles (blue particles) have a positive contrast factor and are moved to the pressure node located in the center of the channel. Liquid vesicles or air bubbles will move to the antinodes at the wall (yellow particles). If the size of the flow channel is in microdomain, the flow conditions are generally laminar, and the particles passing through the standing wave field will be moved to their nodal position and remain in that position throughout the flow channel even after exiting the sound field. By terminating the flow channel with a trifurcation, it is possible to separate and/or concentrate the particles from the medium; see Fig. 1d.

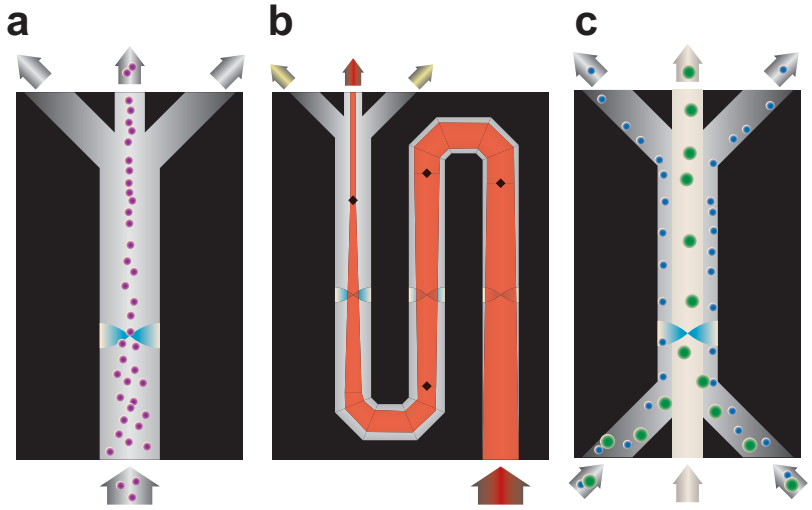
Beside the primary axial radiation force, also secondary forces act on particles in a standing wave field [5]. These interparticle forces can mostly be negligible as they are only effective when particles are very close to each other. The secondary forces assist in particles forming clusters which are less common in continuous flow systems but are useful in stagnant systems which rely on agglomeration and sedimentation to clarify medium [6].

When designing flow channels with dimensions that match a half wavelength in the MHz frequency regime, conventional microfabrication offers simple means of fabricating acoustophoresis chips typically in glass or silicon or other high Young's modulus materials.

There are several ways of actuating an acoustophoresis chip. The most straightforward approach is to set up the standing wave between a coupling layer bonded to the transducer and the opposing channel wall, commonly referred to as a layered acoustic resonator (Fig. 2a). This creates an acoustic nodal plane perpendicular to the wave propagation. Another way is to place the transducer underneath the entire separation system or at any location on the chip surface where space is available. This causes the whole acoustophoresis chip to be actuated, not just the separation channel, but this mode of actuation requires the chip material allow waves to propagate without too much losses. By matching the actuation frequency to the channel dimension, it is possible to obtain a standing wave horizontally or vertically or in both directions in the microchannel (Fig. 2b). Two-dimensional focusing can be obtained either using two transducers of different frequencies or using a single transducer if the cavity has height to width proportions (Fig. 2c, d).

Acoustophoresis, Fig. 2 Two ways of actuation of the resonator system. (**a**) Layered resonator where the standing wave is generated in the direction of the primary direction of actuation. (**b**) Transversal resonance. The resonance is created perpendicular to the primary direction of actuation. (**c**) Two-dimensional focusing in a rectangular channel using transducers of two different frequencies. (**d**) Two-dimensional focusing in a square channel using a single transducer

The use of two-dimensional acoustic standing wave systems to pre-align sample before affecting them in a secondary acoustic separation or concentration step has shown to give superior performance over one-dimensional systems [7, 8]. This is due to the particles being forced to a common position in the flow and are thus all exposed to the same flow profile and Stoke's drag, which isolates the particles from the effect of most of the external flow factors, and the acoustic effects become prominent [9].



Applications

Acoustophoretic Enrichment and Depletion of Cells and Particles

Acoustophoretic enrichment/concentration of a sample is the most straightforward operation as most cells and particles easily focus on pressure nodes and thus deplete the surrounding medium of solid matter. By using flow splitters such as a trifurcation, the particle dense fraction in the central pressure node can be collected via the middle outlet of the trifurcation (Fig. 3a). Likewise, cell and particle depletion from a fluid is also obtained with the chip configuration of Fig. 3a if the fluid of interest is collected from the side branches.

However, like many microfluidic devices presented in the literature, acoustophoretic systems display problems in handling fluids of high concentrations, such as whole blood. Plasmapheresis, i.e., the removal of the cellular content from the blood plasma, is a quite common microfluidic procedure where free plasma is desired for further diagnostic purposes. Commonly, these devices are forced to work with dilute blood samples, which deteriorate the plasma composition from an analytical point of view. The acoustical chips presented earlier are no exception, and the plasma separation efficiency is known to decrease significantly when the hematocrit is increased above 5–10 %).

Means to handle samples with higher amounts of cellular content/hematocrit can be realized by a sequential acoustophoretic enrichment and partial removal of enriched cells from the standing wave node region [10]. This requires a microchannel configuration that extends over a longer distance such that the duration in the acoustic field is sufficiently long to focus cells between each point of cell removal. Figure 3b shows a schematic of a

Acoustophoresis, Fig. 3 (**a**) An acoustophoretic concentrator. The particles are concentrated in the central pressure node, while particle-depleted fluid exits to the sides. (**b**) Depletion of high cell or particle contents. Acoustically concentrated particles leave outlets in the bottom of the chip (*black diamonds*) thus lowering the particle load until eventually all particles can be removed through the central duct of the trifurcation outlet. This mode of operation is suitable for plasmapheresis of whole blood. (**c**) Wash or fractionation of cells. Sample enters the separation channel from the side branches and becomes laminated against the side walls. Clean buffer enters through the central inlet. The acoustic radiation force moves the large cells into the clean buffer and thus completes a wash in form of a medium switch

chip surface conservative meander style layout, where focused blood cells are partially removed at each outlet in the center of the channel bottom indicated as dark squares. At the end of the meander structure, the concentrations of blood cells are sufficiently low for all remaining cells to be removed via the central outlet, and the clean plasma fraction can be extracted from the side branches of the trifurcation.

Acoustophoretic Cell Washing

Microchip acoustophoresis can be configured to perform buffer exchange operations by adding two extra inlets on each side of an acoustophoresis channel. The sample solution is supplied via the side inlets, while a clean buffer is provided via the central channel inlet (Fig. 3c). Cells/particles are acoustophoretically moved from their original sample stream along the channel side wall into the central, particle-free medium stream thus exchanging the medium the particles are suspended in [11]. The typical buffer exchange efficiency displays performance data equal or better than conventional centrifugation steps and allows continuous flow-based operation, where several sequential wash steps can be implemented depending on the requirements on the wash efficiency [12]. Acoustophoretic cell and particle washing has been demonstrated for red blood cell washing in glass chips [13] and in washing of microbeads used to selectively affinity capture bacteriophages in a large phage library [14] as well as extraction of phosphopeptides from protein digests using metal ion affinity specific microbeads [12] and more recently also as a means of performing stain and wash unit operations in flow cytometry applications [15].

Acoustophoretic Separation/Fractionation

Acoustophoretic separation can be performed in two modes where:

(a) The species to be separated display different signs of the acoustic contrast factor and hence gather in the acoustic pressure node and antinode, respectively, so-called binary separation.
(b) The rate of acoustophoretic transport of a cell or particle into a pressure node determines the

lateral position in the flow stream of a given cell or particle type as they leave the separation zone, and thus, the acoustophoretic mobility determines the outcome of the separation, so-called free flow acoustophoresis – FFA.

An early clinical application of microchip-integrated acoustophoretic binary separation targeted blood wash in open-heart surgery. Patient bloodshed during the surgery is contaminated by lipid microemboli from tissue undergoing surgery and has to be removed prior to autologous re-transfusion to the patient. Jönsson et al. [16] demonstrated that acoustophoresis can remove the lipid microemboli from blood, utilizing the fact that erythrocytes display a positive acoustic contrast factor ($\sim +0.05$), while lipid particles have negative contrast factor (~ -0.18). Hence, the blood cells and the lipid vesicles will move to different lateral positions in the acoustic standing wave field and can thus be separated from each other as they pass through the acoustic separation channel (Fig. 1d) following the principles of binary separation.

Binary separation has also been demonstrated as an efficient sample preprocessing step in milk quality control where the lipid emulsion was removed by binary acoustophoresis, enabling online Fourier transform infrared spectroscopic analysis of lactose and protein content of the milk [17].

When performing separation based on free flow acoustophoresis (FFA), the major factor that influences separation outcome is the primary axial radiation force which is dependent on the size, density, and speed of sound of the particle; see Eq. 1. This commonly means that larger particles will experience a larger acoustic force than smaller-sized particles, and thus, size fractionation can be performed by acoustophoresis. Petersson et al. demonstrated successful FFA of suspensions with mixed particle sizes by tuning the acoustic force and the flow rate such that the largest particles reached the pressure node shortly before entering the center outlet, and hence, laterally from the center to the side wall, a gradient of particle sizes were located, which could be routed to individual outlets of the acoustophoresis chip [18].

By manipulating the density of the medium through the addition of a buffer that alters the fluid density, it is also possible to improve separation conditions between species that display similar acoustophoretic mobility. Buffer density manipulation in combination with the FFA fractionation device demonstrated different separation profiles of fractionation of erythrocytes, platelets, and leucocytes [18].

Free flow acoustophoresis has also been demonstrated in the preparation of peripheral blood progenitor cells from apheresis product. Platelets are an unwanted contaminant when the apheresis instrument continuously separates the buffy coat from the whole blood as they compromise the subsequent immunomagnetic extraction of stem cells from the apheresis product. Acoustophoresis can be used to solve this problem using the same chip design as in Fig. 3c where sample enters the channel at the side inlets and clean buffer enters centrally [19]. The acoustophoretic force on the platelets is very low and thus proceeds with the laminar flow along the channel side walls, while the larger leukocytes and the few remaining erythrocytes present in the apheresis product are focused on the center of the channel and exited through the central outlet as a platelet-depleted fraction [19].

Some cells, however, do not differ enough in acoustic properties to be separated by acoustic standing waves alone. By introducing affinity beads that target certain cell types, the combined bead-cell complex will experience a larger acoustic force than the unbound cells which enables a separation of the targeted cells [20].

Summary

Microchip acoustophoresis offers simple means to non-contact handling/processing of cells in continuous flow mode. Acoustophoresis is to a large extent independent of surface charge, ionic strength, and pH variations (within physiological conditions). It is also a non-perturbing technique

in the sense that cells are not experiencing any major stress when undergoing acoustophoresis as seen in several viability studies [19–21].

Active Carbon Nanotube-Polymer Composites

Jian Chen
State Key Laboratory of Transducer Technology, Institute of Electronics, Chinese Academy of Sciences, Beijing, People's Republic of China

Synonyms

Smart carbon nanotube-polymer composites

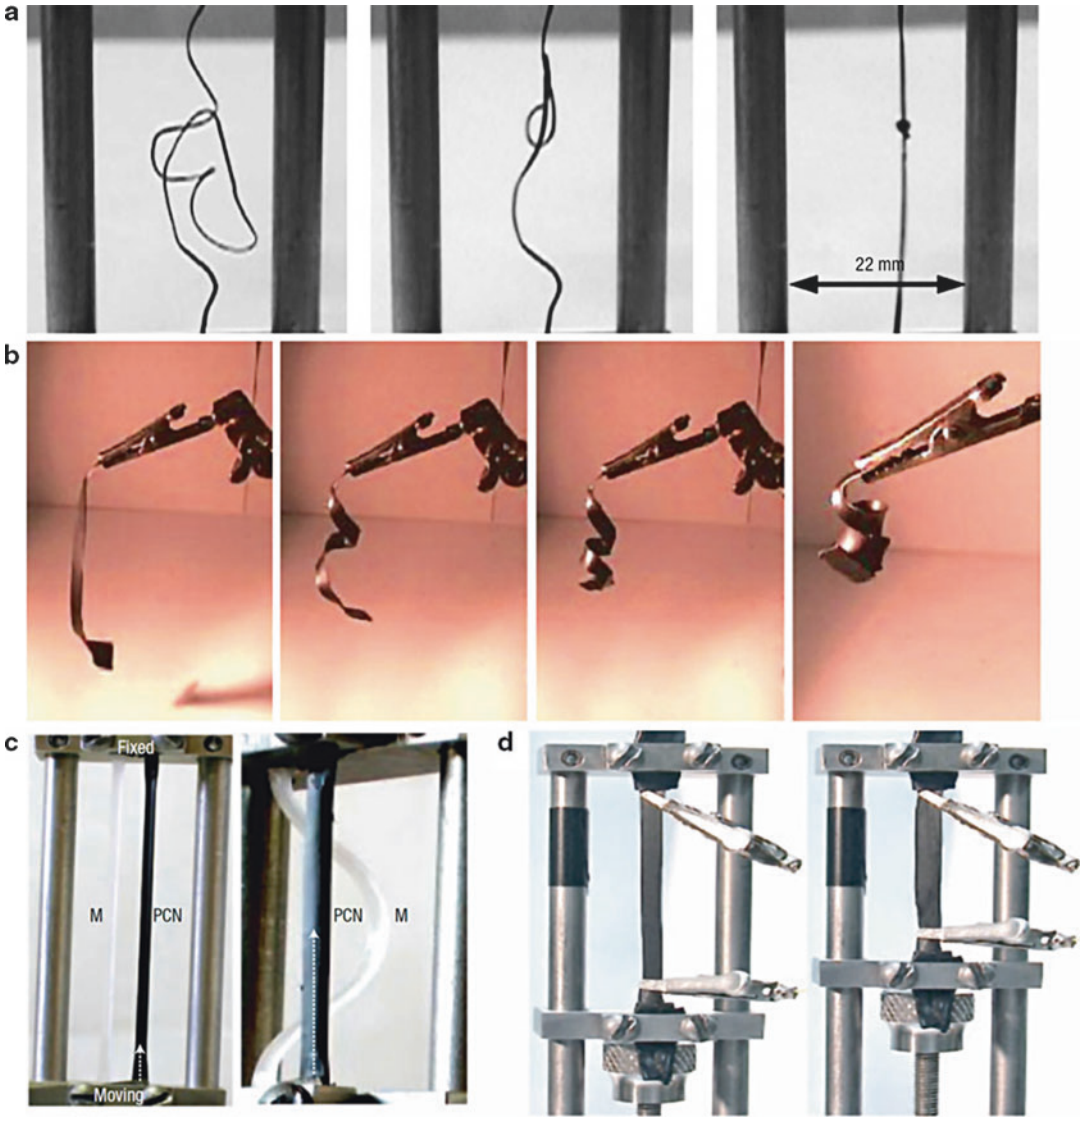
Definition

Active carbon nanotube-polymer composites are carbon nanotube-polymer composites that display active material functions such as actuation and sensing.

Introduction

Carbon nanotubes (CNTs) represent a rare class of materials, which exhibit a number of outstanding properties in a single material system, such as high aspect ratio, small diameter, light weight, high mechanical strength, high electrical and thermal conductivities, and unique optical and optoelectronic properties. CNTs are recognized as the ultimate carbon fibers for high-performance, multifunctional polymer composites, where an addition of only a small amount of CNTs, if engineered appropriately, could lead to simultaneously enhanced mechanical strength and electrical conductivity [1, 2]. While most efforts in the field of CNT-polymer composites have been focused on passive material properties such as mechanical, electrical, and thermal properties, there is growing interest in harnessing active material functions such as actuation, sensing, and power generation in designed CNT-polymer composites. The synergy between CNTs and the polymer matrix has been judiciously exploited to create highly desirable active material functions. In this entry, recent progress in active CNT-polymer composites is briefly highlighted with a focus on smart materials and infrared (IR) sensors.

Shape-Memory CNT-Polymer Composites



Shape-memory polymers (SMPs) are polymeric smart materials that can memorize a temporary shape and are able to return from a temporary shape to their permanent shape upon exposure to an external stimulus such as heat [3]. Compared with shape-memory alloys and ceramics, SMPs offer a number of distinctive advantages, which include high recoverable strain (up to 400 %), low density, ease of processing and the ability to tailor the recovery temperature, programmable and controllable recovery behavior, and low cost. Such advantages could enable a broad spectrum of demanding applications including deployable space structures, morphing wings, information storage, smart textiles, biomedical devices, and drug delivery.

Although SMPs show promising shape-memory effects, several major issues remain to be addressed: (1) slow recovery speed; (2) low recovery stress; nnn lack of remote control. Vaia and coworkers demonstrate that the addition of multiwalled CNTs (MWNTs) into a thermoplastic polyurethane matrix (Morthane) could address these issues simultaneously (Fig. 1) [4]. The low recovery speed (up to several minutes) of thermal-responsive SMPs originates from their intrinsically low thermal conductivity (<0.3 $Wm^{-1}K^{-1}$) [3]. Therefore, the heat transfer from an external heating source to the core of a SMP sample will take considerable amount of time. Vaia and coworkers show that non-radiative decay of IR photons absorbed by the nanotubes raises the internal temperature, melting strain-induced polymer crystallites (which act as physical cross-links that secure the deformed shape), and remotely trigger the release of the stored strain energy. The 1 wt% MWNT-Morthane nanocomposite displays a rapid shape-recovery within 5 s upon exposure to an IR light (Fig. 1b). Comparable effects occur for electrically induced actuation associated with Joule heating of the matrix when a current is passed through the conductive percolative network of the nanotubes within the resin in a 16.7 wt% MWNT-Morthane nanocomposite (Fig. 1d).

The low recovery stress of thermal-responsive SMPs originates from their intrinsically low modulus [3]. CNTs have proven to enhance the mechanical properties, particularly modulus, of various polymers. For example, 8.5 wt% MWNTs could increase the room temperature rubbery modulus of Morthane by a factor of 5 [4]. In fact, incorporation of 5 wt% of MWNTs into polyurethane SMPs results in an increase of the recovery stress by $\sim$ 230 % [4].

CNT-Polymer Composite Actuators

Polymeric actuators are polymers that deform in response to an external stimulus such as heat, light, or electric field, and they normally recover their original shapes after the stimulus is terminated [5]. Potential applications of polymeric

Active Carbon Nanotube-Polymer Composites, Fig. 1 (**a**) Stretched (800 %) Morthane ribbon containing 1 wt% MWNTs, tied into a loose knot and heated at 55 °C. The knot closes on strain recovery. (**b**) Strain recovery and curling of the 1 wt% MWNT-Morthane nanocomposite ribbon upon IR irradiation within 5 s. (**c**) Comparison of the stress recovery before (*left*) and after (*right*) remote actuation by IR irradiation. Neat Morthane (*M*) bends and does not recover. In contrast, a 1 wt% MWNT- Morthane nanocomposite (*PCN*) contracts on exposure to IR irradiation (*arrow* indicates moving direction). actuators include artificial muscles, mini- and microrobots, "smart skins," pumps, and valves in microfluidic systems for drug delivery, ventricular assist devices for failing hearts, and sensors for mechanical strain, humidity, and gases. Researchers have recently demonstrated that the synergistic combination of CNTs and a suitable polymer matrix could lead to promising CNT-polymer composites with either new or significantly enhanced actuation properties.

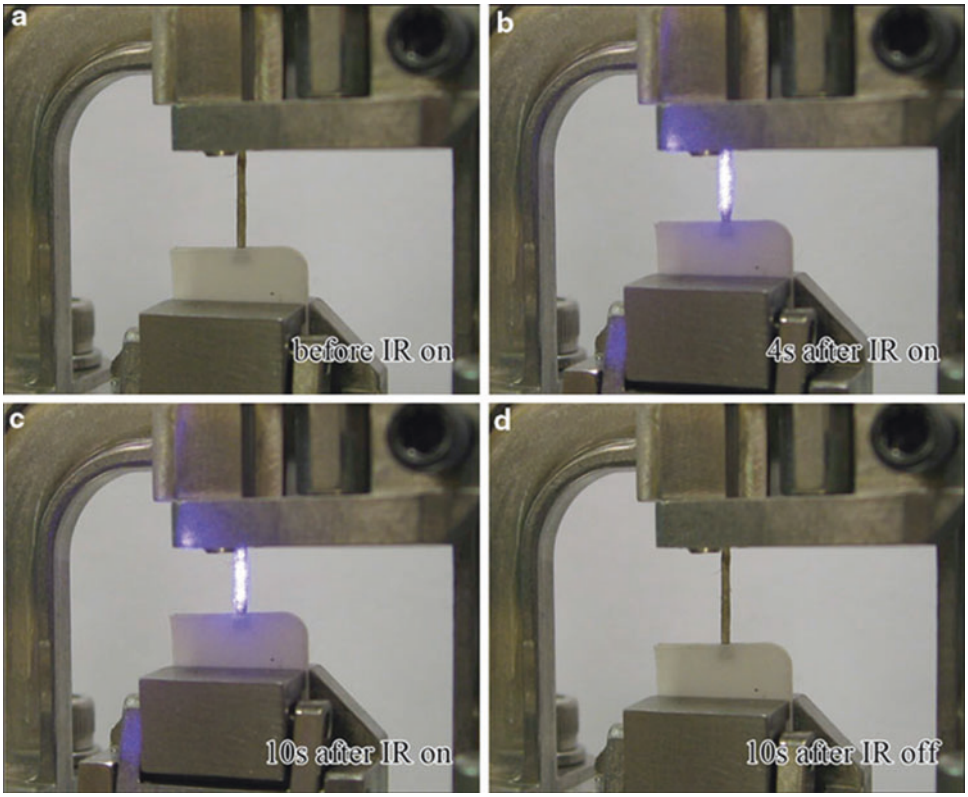
Nematic liquid crystalline elastomers (LCEs) have fascinated scientists and engineers



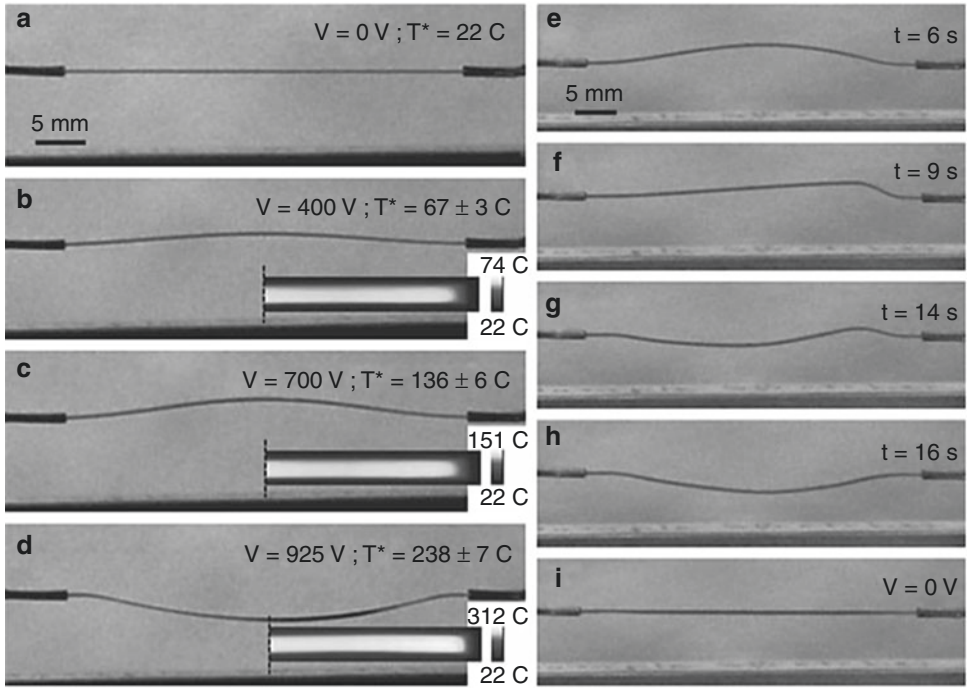
continually since 1981 when they were first synthesized by Finkelmann and coworkers [6]. LCEs bring together, as no other polymer, three important features: orientational order exhibited by the mesogenic units in amorphous soft materials; topological constraints via cross-links; and responsive molecular shape due to the strong coupling between the orientational order and the mechanical strain [7]. Acting together, they create many new physical phenomena that can lead to many potential applications. Nematic LCEs can dramatically and reversibly elongate or contract in response to temperature changes; however, this type of LCE actuator tends to have a slow response time due to the low thermal conductivity of LCEs and cannot be actuated remotely, thereby limiting its potential applications.

Terentjev and coworkers have studied the rich photomechanical behavior of three types of MWNT-elastomer nanocomposites irradiated with near-IR light, including polydimethylsiloxane, styrene–isoprene–styrene, and a nematic LCE with a polysiloxane backbone [8, 9]. They show that these composite materials have the novel ability to change their actuation direction, from expansive to contractive response, as greater imposed strain is applied to the sample.

Unlike MWNTs, which have featureless visible/near-IR absorption, single-walled CNTs (SWNTs) show strong and specific absorptions in the visible/near-IR region owing to bandgap transitions [10]. Recent advances in nanotube separation make it possible to obtain enriched single-chirality SWNTs with strong and narrow optical absorptions, which may ultimately offer unique opportunities for the wavelength-selective IR actuation of LCE nanocomposites. The effective use of SWNTs in polymer-composite applications strongly depends on the ability to disperse them uniformly in a polymer matrix without destroying their integrity. Pristine SWNTs are incompatible with most solvents and polymers, which lead to poor dispersion of the nanotubes in solvents and polymer matrices. Chen and coworkers have recently developed a versatile, nondamaging chemistry platform that enables them to modify specific CNT surface properties, while preserving the CNT's intrinsic properties [11]. They have discovered that rigid, conjugated macromolecules, for example, poly(*p*-phenyleneethynylene) (PPE), can be used to noncovalently functionalize and solubilize CNTs and disperse CNTs homogeneously in polymer matrices [2, 11].

Chen and coworkers have recently reported the reversible IR actuation behavior of a new type of nematic SWNT-LCE nanocomposite using PPE-functionalized SWNTs (PPE-SWNTs) as a filler in a LCE matrix with side-on mesogenic units [12]. The SWNT-LCE nanocomposites have been prepared through a two-stage photopolymerization process coupled with a "hotdrawing" technique, which enable the fabrication of relatively thick films (∼160–260 μm). The excellent dispersion of PPE-SWNTs in the LCE matrix has allowed them to observe a significant and reversible IR-induced strain (∼30 %) at very low SWNT loading levels (0.1–0.2 wt%, Fig. 2). The effects of various parameters have been investigated, including the degree of pre-alignment, the loading level of the SWNTs, and the curing time. In SWNT-LCE composites, semiconducting SWNTs can efficiently absorb and transform IR light into thermal energy, thereby serving as numerous nanoscale heaters being uniformly embedded in the LCE matrix. The absorbed thermal energy then induces the LCE nematic-isotropic phase transition, which leads to the shape change of the nanocomposite film. The IR strain response of SWNT-LCE nanocomposites increases with an increasing SWNT loading level and a higher degree of hot-drawing, and decreases with longer photocuring [12].

Electric field driven pure nematic LCE actuators have not been developed because the characteristic rotation energy density is too low compared with the characteristic resistance energy density from the rubbery elastic network due to the low anisotropic dielectric permittivity of the LCEs, even under a very high electric field [13]. However, adding CNTs with high anisotropic polarizability into the LCEs, aligned along the uniaxial director of a monodomain nematic elastomer network, the CNT-LCE nanocomposites below the conductivity percolation threshold can achieve an effective dielectric anisotropy many

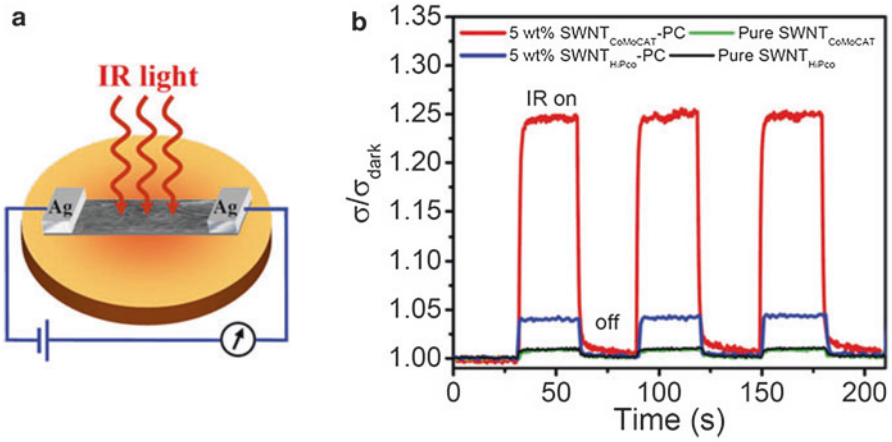


Active Carbon Nanotube-Polymer Composites, Fig. 2 IR actuation of a 0.2 wt% SWNT-LCE nanocomposite film: (**a**) before the IR was turned on; (**b**) after the IR was turned on for 4 s; (**c**) after the IR was turned on for 10 s; (**d**) the film returned to its original length with the IR beam turned off (Reprinted by permission from Wiley-VCH Verlag GmbH & Co. KGaA [12])

orders of magnitude higher than the LCEs alone [13]. Therefore, introducing highly polarizable anisotropic CNTs into the LCE will lead to a significantly enhanced electromechanical effect and make electrical-field driven LCE actuators possible. Terentjev and coworkers have demonstrated, for the first time, a large electromechanical response (uniaxial stress of $\sim$ 1 kPa in response to a constant field of $\sim$ 1 MV/m) in nematic LCEs filled with a very low ($\sim$0.0085 wt%) concentration of MWNTs, pre-aligned along the nematic director at preparation [13]. However, the response stress in the isostrain conditions shows a linear dependence on the applied field E, instead of E^4 that would be expected from a CNT rotation-induced electromechanical response, a puzzling finding to the researchers as stated in the original paper [13].

Park and coworkers have investigated the electromechanical properties of a 0.05 wt% SWNT/LaRC-EAP (Langley Research Center-ElectroActive Polyimide) composite, which forms an intrinsic unimorph during the fabrication process to actuate without the need for additional inactive layers [14]. The 0.05 wt% SWNT/LaRC-EAP exhibits a large strain ($\sim$2.6 %) at a low driving voltage ($<$1 MV/m) while possessing excellent mechanical and thermal properties. The out-of-plane strain is proportional to the square of the electric field E, which suggests that the actuation mechanism of the SWNT/LaRC-EAP composite is primarily due to electrostriction [14].

The addition of CNTs also enables electrically stimulated thermo-mechanical actuation via electrical Joule heating when the loading level of CNTs is above its electrical conductivity



Active Carbon Nanotube-Polymer Composites, Fig. 3 (**a**–**d**) Deflection of a 0.5 vol% SWNT-CP2 beam (L = 4 cm; d = 140 μm; w = 1.9 mm) as a function of applied voltage and temperature. For $T^* < T_g$ (~220 °C), thermal expansion induces a positive deflection in the beam due to a buckling instability (**b**, **c**). At $T^* \approx T_g$, mechanical softening promotes a deflection inversion as gravity becomes the dominant force acting on the beam (**d**). Sample temperature was determined at each voltage using the thermal images shown inset; (**e**–**i**) Deflection of a 0.5 vol% SWNT-CP2 beam as a function of time at V_{th} (voltage where T* is first observed to exceed T_g). The sample initially buckles as a result of thermal expansion (**e**); however, as the sample temperature continues to increase, the sample kinks (**f**, **g**), and then eventually sags under its own weight at T_g (h). Once the voltage is removed, the beam reversibly actuates back to its original form (**i**) (Reprinted by permission from Wiley-VCH Verlag GmbH & Co. KGaA [15])

percolation threshold. Vaia and coworkers have studied the electrothermal properties of SWNT-polyimide (CP2) nanocomposites (Fig. 3) [15]. They show that the reversible softening associated with temperature transitions through T_g can provide substantial strain increases ($\Delta S \approx 4$ %) over relatively small changes in applied electric field ($\Delta E \approx 0.01$ MV/m).

CNT-Polymer Composite IR Sensors

Organic electronic materials offer ease of materials processing and integration, low cost, physical flexibility, and large device area as compared to traditional inorganic semiconductors. Optoelectronic materials that are responsive at wavelengths in the near-infrared (NIR) region (e.g., 800–2,000 nm) are highly desirable for various demanding applications such as telecommunication, thermal imaging, remote sensing, thermal photovoltaics and solar cells [16]. SWNTs have strong absorptions in the NIR region owing to the first optical transition (S_{11}) of semiconducting nanotubes [10]. The inverse diameter dependence of S_{11} optical transition energy enables the wavelength-tuning of SWNT's NIR absorptions, which, coupled with the rapid progress in nanotube separation, will ultimately allow the development of SWNT IR sensors tailored to specific

Active Carbon Nanotube-Polymer Composites, Fig. 4 (**a**) Schematic experimental setup. IR light covers all sample area. (**b**) Relative conductivity (σ/σ_{dark}) response of SWNT-PC nanocomposites to the on/off IR illumination (power intensity: 7 mW/mm^2)

regions of the NIR spectrum. There are a number of reports on the IR photoelectrical property of SWNT films. Levitsky and coworker have demonstrated that the arc-produced SWNT ($SWNT_{arc}$) film is capable of generating a very weak photocurrent upon continuous-wave IR illumination (12 mW/mm^2) in the air at room temperature, and the current increase upon IR illumination is only about 0.2 % [17]. In addition, they have observed a dark current drift due to oxygen adsorption and a relatively slow rise/decay (~4–5 s relaxation time) of the photocurrent in response to the on/off illumination. Haddon and coworkers have reported that the IR photoresponse in the electrical conductivity of a $SWNT_{arc}$ film is dramatically enhanced when the nanotube film is suspended in vacuum at low temperature (e.g., 50 K) [18].

Chen and coworkers have discovered that the IR photoresponse in the electrical conductivity of SWNTs is dramatically enhanced by embedding SWNTs in an insulating polymer matrix such as polycarbonate (PC) in the air at room temperature (Fig. 4) [19, 20]. In contrast to the gradual photoresponse and weak conductivity change (1.10 %) observed in a HiPco®-produced SWNT ($SWNT_{HiPco}$) film in the air at room temperature, the 5 wt% $SWNT_{HiPco}$-PC nanocomposite under the same IR illumination (power intensity: 7 mW/mm^2) shows a sharp photoresponse and strong conductivity change (4.26 %) [19]. The dark current drift owing to oxygen adsorption is also minimized by embedding nanotubes in the polymer matrix. They have shown that semiconducting SWNTs are critical to the IR photoresponse of nanotube materials [19, 20]. They have also demonstrated that both SWNT types and nanotube-matrix polymer-nanotube junctions have profound impact on the IR photoelectrical property of SWNT-polymer composites [20]. Composite IR sensors based on CoMoCAT®-produced SWNTs ($SWNTs_{CoMoCAT}$) significantly outperform those based on $SWNTs_{HiPco}$. The 5 wt% $SWNT_{CoMoCAT}$-PC nanocomposite demonstrates a very strong conductivity change of 23.45 % upon the IR illumination (7 mW/mm^2) in the air at room temperature [20], which is 5.5 times of that (4.26 %) observed in the 5 wt% $SWNT_{HiPco}$-PC composite film [19], nearly 27 times of that (0.88 %) observed in the pure $SWNT_{CoMoCAT}$ film [20], 21 times of that (1.10 %) observed in the pure $SWNT_{HiPco}$ film [19], and 117 times of that (0.2 %) observed in the pure $SWNT_{arc}$ film in the air at room temperature (12 mW/mm^2) [17]. In addition, the 5 wt% $SWNT_{CoMoCAT}$-PC composite film shows a

detectable IR photoresponse at a light intensity as low as 23.4 μW/mm^2 [20].

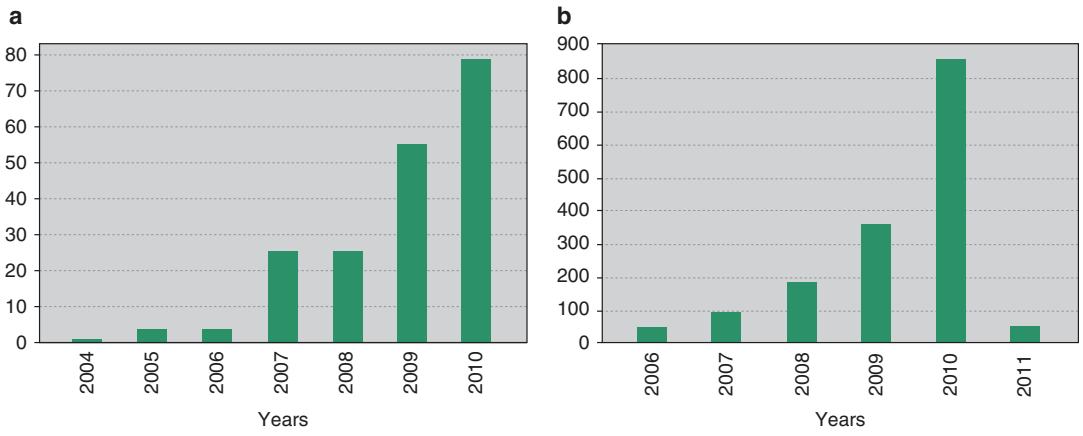
Active nanoantenna system



Definition

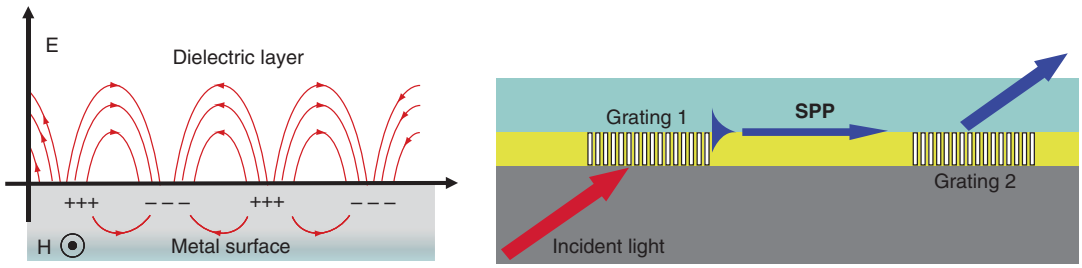
Active plasmonic devices combine plasmonic systems and a physical or chemical control input.

Main Text

Published papers using the term "active plasmonics" and citations of those papers are shown in Fig. 1a, b. The first papers explicitly devoted to this new field were published in 2004 and 2005, even though many previous publications had already pointed out the need for such devices. The growth of these two curves clearly demonstrates that breakthroughs have been achieved in the last 5 years and that many new devices will briefly be demonstrated.

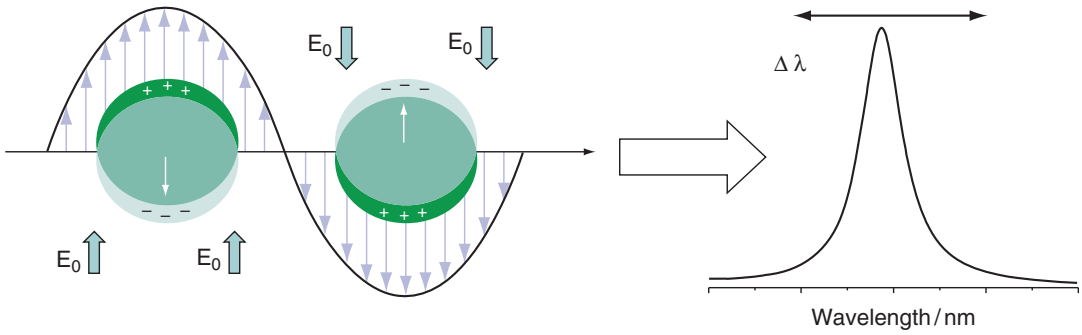
Active plasmonic systems generally use two components: one of them supporting *Localized Surface Plasmons* (LSP) or *Surface Plasmon Polaritons* (SPPs) [1]. One needs to distinguish two types of approaches. In the first approach, the plasmonic component acts as an input in order to control or tune the properties of the second component. Such active plasmonic systems are widely studied but do not belong to the field of active plasmonic devices as described in this Essay. Surface Enhanced Raman Spectroscopy (SERS) is an example of such approaches using an extreme light concentration in order to develop a highly sensitive analysis that can now even detect single molecules [2]. In the second approach, the second component is used in order to control, switch, or tune the properties of the plasmonic component, and the plasmonic response to the external stimulus is the output of the device. This review will be devoted only to this second approach, even though some examples of plasmonic systems

Active Plasmonic Devices, Fig. 1 Histogram of (**a**) published papers and (**b**) number of citations of papers including terms "active plasmonics"



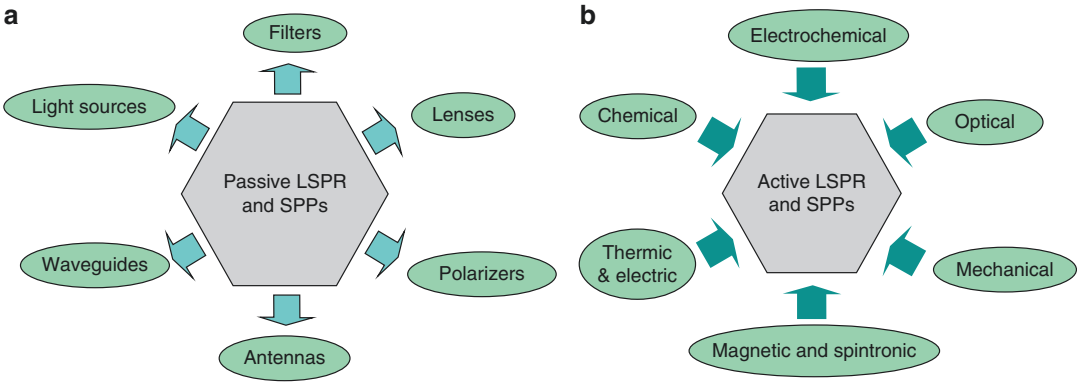
using the first approach will be given when they are of interest in the design of active devices.

Surface Plasmons: Qualitative Description



In order to understand the evolution depicted in Fig. 1 and the tremendous research and technological opportunities of this new field, one has first to have in mind why in the last decade passive plasmonic devices have been studied so much and what kinds are of interest.

Briefly, they can be divided in two classes.

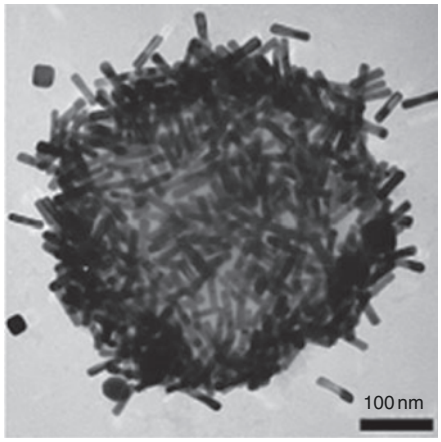


- Those using SPPs, i.e., electromagnetic waves coupled to the coherent oscillation of free-charge carriers at the interface between a dielectric and a conductor (Fig. 2). SPPs propagate along subwavelength nanostructured metals or semiconductors and are often referred to as low-dimensional waves due to the strong confinement of the electromagnetic field on the surface [3].
- Those using LSPs, some metal NanoParticles (NPs) exhibit coherent but confined oscillations of the quasi-free electrons in the conduction bands (Fig. 3). When the characteristic frequency of these oscillations coincides with that of the light excitation, the response of the metallic NPs becomes resonant and strong absorption in the visible and near-infrared range occurs (so-called localized surface plasmon resonance, LSPR). The frequency of LSPR strongly depends on the size, shape, spacing of the particles, and on the dielectric constants of the substrate and surrounding medium [4].

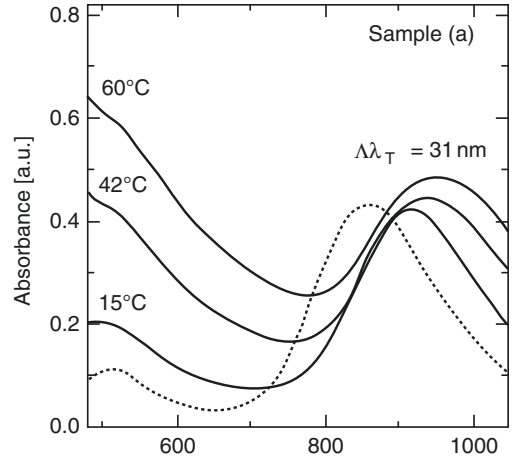
Active Plasmonic Devices, Fig. 2 SPs propagating along the interface between metal and dielectric materials. These waves have a combined electromagnetic and surface charge character. Schema of a plasmonic signal, coupled to and from the waveguide by gratings on a metallic layer

Active Plasmonic Devices, Fig. 3 Schema of the localized oscillations of electrons exposed to an electric field. The electrons are shifted, and the polarization charges on opposite surface elements apply a restoring force on the electrons. The extinction spectra of NPs shows the localized surface plasmons resonance peak which shift with the shape, size, and spacing of particles

Active Plasmonic Devices, Fig. 4 (**a**) Major plasmonic devices. (**b**) Overview of major routes for the development of active plasmonics



Because of surface plasmons capability to enhance electric fields in the very close vicinity of NP structures or to localize and guide light in metallic structures, plasmonics allows the manipulation of the flow of light and its interaction with matter at the nanoscale. In this sense, NPs work in a similar way to that of antennas in radio and telecommunication systems, but at optical frequencies, i.e., at frequencies corresponding to typical electronic excitations in matter. Plasmonics also offer an opportunity to merge photonics and electronics at nanoscale dimensions to obtain unusual optical properties and opportunities for unprecedented levels of synergy between optical and electronic functions. Figure 4a depicts the main passive devices already demonstrated, including light sources, filters, waveguides, lenses, plasmonic antennas, and polarizers [5].



Nevertheless, in order to become a high valuable technology, plasmonics needs switches, modulators, and routers. Indeed, such active plasmonic systems are needed to achieve functional Surface Plasmons (SP) circuits that will, for instance, first convert light into SPs using nanoantennas; SPP would then propagate along SP waveguides and be processed by logic elements before being converted back to light using nanoscopic sources. Active plasmonic devices can thus be the basic building blocks for an alternative technology capable of writing, reading, storing, and processing information at the nanoscale. Figure 4b show the various types of physical and chemical external stimuli already demonstrated to control passive plasmonic devices. Currently, their number is expanding.

Many recent reviews [1] have been devoted to passive plasmonics, and this contribution will only describe active plasmonic devices, and few aspects of theoretical background will be used to define and understand strategies to reversibly switch or modulate plasmons.

Controlling Localized Surface Plasmons

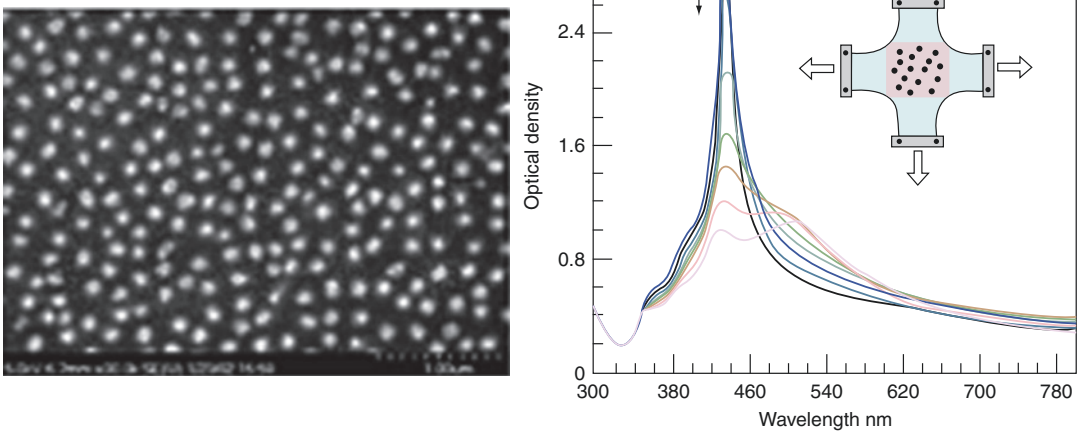
The frequency of LSPR depends mainly on the size, shape, and spacing of the particle and on the dielectric constants of the substrate and surrounding medium. Adding to a LSPR-based plasmonic system, an external stimulus that will tune the size, the shape, the spacing of the particle or the dielectric functions of the surrounding medium can therefore lead to active plasmonic devices. Some strategies will easily allow reversibility; others based on tuning the size and shape of the NPs will be less successful for reversible control. Of particular interest is the recent discovery of mixed exciton-plasmon states in metal-molecule complexes, which makes them promising candidates for active molecular plasmonic devices.

UV-Vis spectra of hybrid sample at 15 °C (swollen state), at 42 °C, and at 60 °C (collapsed state) (Reprinted with permission from Karg et al. [6])

Thermally Driven Active Plasmonic Devices

The LSPR is not tuned by changing the temperature of a substrate. A thermoresponsive layer surrounding NPs could be use to design *thermally driven active plasmonic devices*. Most examples use thermoresponsive polymers, inorganic layers, and liquid crystals in which the thermal effect induces a variation of the spacing between the NPs or of the dielectric function of the surrounding medium. For all these systems, a temperature-driven phase transition is observed and induces a plasmon resonance shift.

Several systems based on the thermally induced and reversible collapse of poly (N-isopropylacrylamide), pNIPAM have been reported (Fig. 5) [6]. Inorganic composites were also used. For example, Metal–VO_2 nanocomposites have shown LSPR shifts of about 50 nm for a temperature variation of 95 °C.



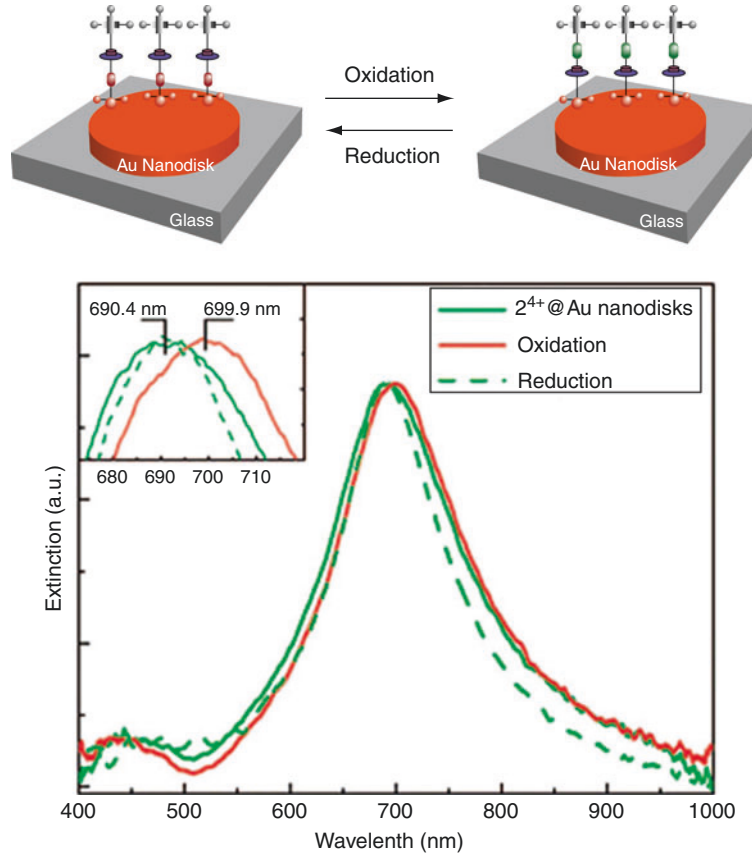
Other thermoresponsive active plasmonic devices have been developed using liquid crystals (LCs). LCs are unique materials that show such characteristic properties as self-organization, fluidity with long-range order, cooperative motion and alignment change with various external stimuli (temperature, electric fields, etc.) at surfaces and interfaces. Thereby, the modulation of alignment of LCs gives rise to a change in optical properties, which forms the basis of LC displays (LCDs) [7]. The LSPR in anisotropic media such as liquid crystals are strongly dependent on the local ordering of the media, and that induced orientational transitions of the liquid crystal may be used to tune the optical properties of metallic NPs.

Mechanical Input

An alternative approach is to fabricate plasmonic structures on mechanically tunable substrates. In most of the cases, small metallic nanospheres have been deposited on stretchable elastomeric films like polydimethylsiloxane (PDMS). As the film is stretched to different degrees, the intensity of plasmon resonance rapidly decreases, and a new band appears at higher wavelength (Fig. 6).

Chemically Driven Plasmonic Devices

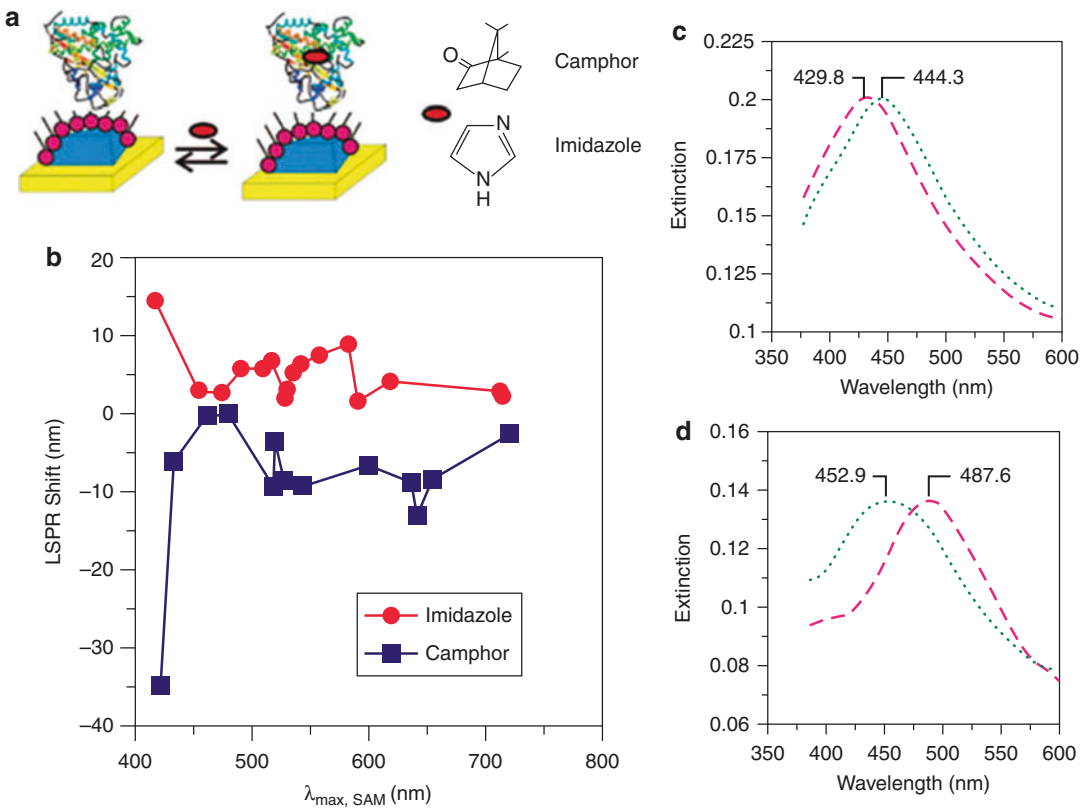
LSPR modulation using molecular recognition is a mature technology that is widely used to design sensors and biosensors. The LSPR of isolated NP shows limited sensitivity of absorption spectra (for small colloidal 5–20 nm nanoparticles), to molecular or biomolecular recognition events due to the small changes of the refractive index of the surrounding medium induced by the molecular recognition events. Additionally, the LSPR wavelength and the UV-Vis absorption of the molecules do not match in most cases.



Active Plasmonic Devices, Fig. 6 SEM image of the 2D array of Ag nanoparticles into PDMS. Extinction spectra of the array as a function of the stretching force. *Red curve* represents the film stretched 50 % from its original, nonstretched state (*black curve*) (Reprinted with permission from Journal of American Chemical Society, Malynych and Chumanov [8])

However, LSPRs are highly sensitive to interparticle spacing, originated from the near-field plasmon coupling of nanoparticles. The strength of the effect falls rapidly with distance; at separations above 2.5 times the particle size, the nanoparticles behave essentially as isolated clusters. In particular, particle aggregation results in a pronounced red shift of the LSPR peaks, and most of the applications for sensors are based on this distance variation, resulting in the change of their plasmon coupling. Recent reviews [9] have described the large body of research on plasmon-based sensors. Indeed, even though such devices can be considered as active plasmonic devices, their purpose is not to control LSPR but to use LSPR as a transduction of the molecular events occurring at the NP surface. This part will only focus on some recent systems illustrating the various chemical stimuli which tuned LSPR.

As first examples, the pH of a solution could act as a chemical input. In a typical configuration, metal nanoparticles are immobilized as a monolayer on a glass substrate, while a polymer material is either deposited on the top of the nanoparticles monolayer or between nanoparticles. PH-induced conformational changes will alter the interparticle distance and, hence, the strength of plasmon coupling. The variation of the nanoparticles–island distance was limited to 1–20 nm, which corresponds to the optimal distance between metal nanoparticles for electromagnetic coupling. Reversible operation was achieved by returning the pH and optical properties of the system to the initial state.



Electroactive molecular machines with grafted NPs have also been used but, in this case, the input was a chemical chosen to reduce or oxidize the electroactive machine. Zheng et al. recently showed that a gold nanodisc array, coated with bistable, redox-controllable [2]rotaxane molecules, when exposed to chemical oxidants and reductants, undergoes reversible switching of its plasmonic properties (Fig. 7) [10]. These observations suggest that the nanoscale movements within surface-bound "molecular machines" can be used as the active components in plasmonic devices. One has, nevertheless, to note that the observed LSPR shifts were rather small (10 nm) due to the small change of monolayer's effective refractive index and the very thin molecular film.

Active Plasmonic Devices, Fig. 7 Schematic of working principle of the molecular-machine-based active plasmonics. Extinction spectra recorded from Au nanodisks in air during the redox process (Reprinted with permission from Zheng et al. [10])

In these previous examples, the molecules used did not absorb light near the nanoantenna extinction. New phenomena occur when LSPR and molecular absorption coincide. When the peak position of the NPs LSPR did not overlap with the molecular resonance, a small shift (20 nm for example) was observed upon monolayer deposition, whereas a higher shift is observed when the LSPR peak partially overlaps with the molecular resonance [11]. The oscillatory dependence of the peak shift on wavelength was shown to track with the wavelength dependence of the real part of the refractive index of the monolayer, as determined by a Kramers–Koenig transformation of the molecular resonance absorption spectrum.

The influence of surrounding adsorbates is important even for monolayers as explained above or at low-coverage adsorption. In such cases, it is difficult to estimate the dielectric constant and an atomistic description is needed [12]. Thus, the influence of molecular adsorbates on the absorption spectra of spherical NPs was investigated using arbitrary coupling to the surface and changing the molecular excitation characteristics through its HOMO–LUMO gap. For the weak adsorption regime, the adsorbates influenced the resonance width; the resonance energy, however, is increased by less than 10 nm. For strong coupling to the surface, and when the excitation of the adsorbates becomes lower in energy than that of the plasmon, it was shown that the peak splits into two excitations. The higher-energy broad peak was shown to be located at the particle surface and was, therefore, attributed to plasmonic excitation. The lower-energy excitation was located over the adsorbates and was attributed to an in-phase oscillation of molecular dipoles on opposite sites of the NP. This new excitation is similar to a completely symmetric molecular exciton, in which molecular dipole oscillations couple

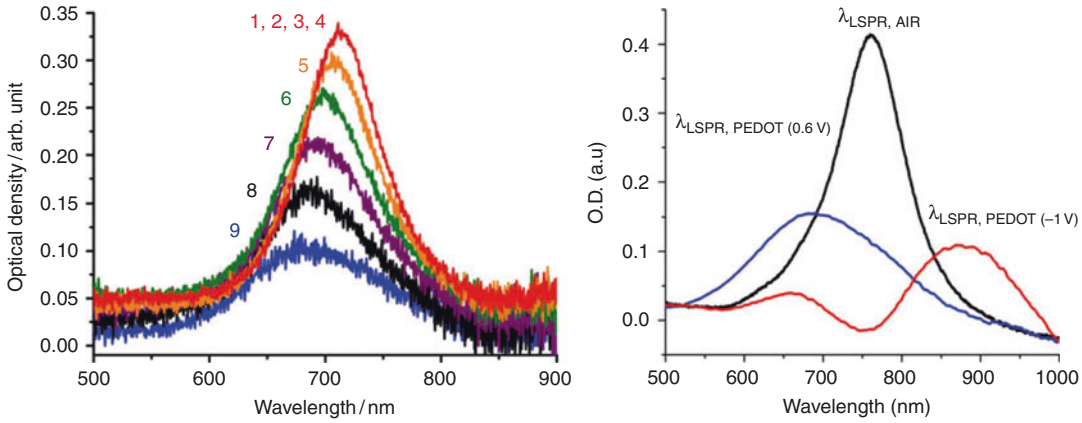
Active Plasmonic Devices, Fig. 8 Schematic representation of small molecule binding to receptors on functionalized Ag nanoparticles (*below*). The wavelength-dependent LSPR shift induced by inhibitor (*red line with dots*) and substrate (*blue line with squares*). LSPR spectra of NPs with cytochrome before (*dashed line*) and after (*dotted line*) substrate (*up*) or inhibitor (*down*) binding (Reprinted with permission from Zhao et al. [13])

in-phase. However, the electrostatic coupling between molecular dipoles occurs through the metallic particle, allowing very significant interaction at large distances.

Strong coupling of chromophore and plasmon resonances has been exploited for molecular sensors. Zhao et al. showed an extreme LSPR shift for isolated NPs due to small changes in the resonances of a chromophore that are induced by binding an additional analyte [13]. In this case, the binding of substrate or inhibitor molecules to a cytochrome caused its absorption band to shift to shorter or longer wavelengths, respectively, and to be *off-resonance* with the plasmon, which was at the origin of a huge LSPR shift for isolated NP (Fig. 8).

The creation of such responsive plasmonic devices by coupling a chromophore to the plasmon through absorption overlap with the wavelength of the LSPR is an important new research trend for applications in molecular sensing and active plasmonics. Excitons and plasmons are the two main excited states of matter. Understanding their interactions is likely to become a very important research field. It yields to mixed exciton-plasmon states, so-called hybidized states. Indeed, when excitons of molecules, such as in J-aggregates, resonate with the plasmon modes of metal NPs, new peaks appear in the extinction spectra. These peaks are governed by the strength of the coupling between excitons and plasmons, and strategies based on tuning this strength, through some physical or chemical input, have recently been reported and considerably widen the opportunities to reach active molecular plasmonic devices. Change of the

angle of incident light or change of the geometry of the NPs was used to control the coupling strength. For strong coupling, the LSPR splits into two bands upon adsorption of the J-aggregates. Reversible tuning of the coupling strength was not obtained since tuning was generated using the flexible geometry or changing the incident angle. Based on these recent results, the reversible tuning of exciton–plasmon coupling using other stimuli will be an easy and flourishing means to develop active plasmonic devices.



Electrochemically Driven Active Plasmonic Devices

Nanoelectrochemistry is rapidly expanding its frontiers toward many new aspects including redox-gated molecular junctions and photovoltaic integrated systems. In this context, electrochemical switching is a useful tool to reversibly control the properties of metallic NPs.

Electrochemistry on nanostructured electrodes supporting LSPR, used as the working electrode, has been widely investigated. Sweeping or changing the potential of such an electrode in an electrolyte usually yields very small LSPR wavelength shifts. Ung et al. were the first to monitor the position of the surface plasmon band of silver colloids as a function of the applied potential [14]. The SP shift amounted to 10 nm/V in the potential regime dominated by double-layer charging. With various electroinactive organic shells a higher blue shift could be obtained. The LSPR shift was attributed to the increased of metal plasma frequency due to the excess stored electrons.

Changing the spacing of the particle through electrochemistry has not yet been widely used, probably because reversibility is not easy to obtain. Electrochemical etching induces LSPR wavelength modulation but is unlikely to be used for reversible active plasmonic devices. On the contrary, reversible control through electrochemistry of the surrounding dielectric medium is easy to obtain. Deposition on the NPs of an electroactive thin film or of an electroactive monolayer makes it possible to trigger LSPR through the oxidoreduction properties of the deposited layer and thus through the applied potential to the electrode. For example, Ag NPs, arranged in closely spaced two-dimensional arrays, were coated by a thin film of tungsten oxide [15]. WO_3 is a well-known electro-active electrochromic material that undergoes a reversible redox process to form reduced tungsten oxide. Reduced and oxidized forms of WO_3 have different electrical conductivities and thus different dielectric functions. By switching the externally applied potential, the optical extinction signal was reversibly modulated and a blue shift was observed.

Following that, Lacroix et al. reported the use of electroactive conductive polymer (CP) thin layers deposited on gold gratings [16]. In a first study, they used polyaniline (PANI) because such films exhibit ultrafast switching (around 1 μs, RC limited) between their reduced non-conductive state and their oxidized conductive state. Blue shift was observed from $\lambda_{LSP} = 633–571$ nm, below that of λ_{LSP} observed in air (593 nm), accompanied by a strong damping of LSPR. This reversible effect was observed repeatedly for more than 1 h. The interpretation lies in the switching of the dielectric constant ε of PANI. When PANI is in its reduced state, ε is real, whereas in its oxidized state, ε is complex ($\varepsilon = \varepsilon_{Re} + i\,\varepsilon_{Im}$). Moreover, oxidized metallic PANI samples follow a Drude-like behavior [1] with a plasma frequency $\omega_p = 2$ eV yielding a simplified expression of ε_{Re} given by $\varepsilon_{Re} = \varepsilon\propto - (\omega_p/\omega)$ [2]. The imaginary part of the dielectric constant can be expressed as $\varepsilon_{Im} = (2\sigma\lambda/c)$, where λ is the vacuum wavelength of incident light, σ the wavelength-dependent conductivity, and c the speed of light. The electrochemical switching of PANI thus generates a large change in both the real and the imaginary part of the dielectric function of the material around the nanoparticles. The large blue shift can be attributed to a decrease in the real part of the dielectric constant at wavelength around 632.8 nm, whereas switching in the imaginary part of the dielectric constant (from zero to a finite value) induces quenching and damping of the LSP. In a second step, they showed that the LSPR in such a PANI/gold NP hybrid material exhibits a progressive damping as a function of the applied potential, as evidenced in

Active Plasmonic Devices, Fig. 9 (*Left*) Extinction spectra of prolate gold grating under x-polarized light and polarization from −500 to 500 mV (Reprinted with permission from Leroux et al. [17]). (*Right*) Extinction spectra of prolate gold particle grating (X polarized light) in air (*black curve*); overcoated with a PEDOT/SDS film in its oxidized state (*blue curve*); overcoated with a PEDOT/SDS film in its reduced state (*red curve*) (Reprinted with permission from Stockhausen et al. [18])

Fig. 9 (left). These results clearly show that the observed modulations of the LSPR are closely related to the charge-carrier density injected into the conductive polymer through electrochemical doping.

More recently, poly(3,4-ethylenedioxythiophene) (PEDOT) was used to shift the LSPR of gold NP arrays [18]. Figure 9 shows the giant red shift from 685 to 877 nm under polarization at −1.0 V. The reversible shift between reduced and oxidized states is 192 nm. Such a giant plasmon resonance shift, covering almost half of the visible spectrum, is, to the best of our knowledge, unique.

Bringing together two systems used in two emerging scientific areas with important applications, i.e., plastic electronics and plasmonics, can thus yield new active plasmonic devices. In this context, it is important to evaluate the potentialities and the flexibility of such devices. CPs can be tailored at will in order to change their switching potential or the variation of their dielectric constant upon switching which will give electrochemically driven plasmonic devices with tunable optical properties. Switching speed is another key point for photonics application and in the present case, switching times of the LSPR in the millisecond range have been observed. Electrode size reduction allows switching times in the microsecond range, and it can thus be predicted that switching frequencies in the MHz range could be easily obtained. Moreover, the external stimuli inducing CP switch is not restricted to the electrochemical input. CPs can also be doped using light, and all-optical solid-state devices using CPs for controlling plasmonic systems are likely to be demonstrated in the near future. Finally, other plasmonic systems, such as waveguides or nanoscopic light sources, can also be combined with plastic electronic components providing a wide range of active plasmonic components for solid-state nanophotonics.

Electric Field-Driven Active Lasmonic Devices

Another input for controlling LSPR is the application of an external electric field. The applied voltage can then be used to exert direct control over an electrooptically active dielectric medium, changing its refractive index and thus the SPR modes at the metal/dielectric interface. Using an electric field as an input could lead to faster switches than thermally, mechanically, chemically, or electrochemically driven systems, and is especially significant because both plasmonic and electric signals can be guided in the same metallic circuitry.

Coupling LSPR devices and organic field-effect transistors has not yet been reported but is

likely to be developed in the next couple of years. On the contrary, many studies have used liquid crystals (LC) or ferroelectric films. In all these cases, shifts have been observed, and the spectral position of the surface plasmon resonances depends on the applied voltage. The variations of the local density of the LC molecules and/or changes in the refractive index in the active films provide a sufficient effect to modulate the LSPR of gold nanostructures. The switching time for the system was in the order of ms.

Optically Driven Active Plasmonic Devices

Light-driven plasmonic devices have several potential advantages: they could operate faster, light can be used for inducing (writing) as well as detecting (reading) the behavior of plasmonic devices; and they can be integrated in future all-optical plasmonic circuits. Efficient methods to achieve optically driven plasmonic devices have been developed and are based on tuning the spacing between particles or the dielectric constant of the surrounding medium.

In this context, it is worth mentioning that there are a number of reports on photosensitive Au NPs with surface coating with small molecules bearing a photochromic moiety. In the case of colloidal metallic NPs, azobenzene trans-cis photoisomerization was used to induce NP aggregation, resulting in the change of the interparticle distance and a shift of the surface plasmon resonance. Sidhaye et al. reported the red shift (close assembly of particles) and the blue shift (loose assembly of the gold nanoparticles) of the surface plasmon peak position ($\Delta\lambda = 80$ nm) induced by the reversible manipulation of interparticle spacing in gold nanoparticle networks connected with azobenzene derivatives [19]. Isomerization yields and switching speeds in such devices remain clear limitations, even though lowering the surface coverage of azobenzene provided more free space for isomerization to take place and enhanced the LSPR shift. Reversibility was clearly demonstrated.

Finally, several studies described the use of specific photoresponsive liquid crystals due to their large and controllable birefringence [7]. The surrounding media was homogeneous mixtures of a liquid crystal and a photoswitchable molecule such as azobenzene. Upon photoirradiation, the LCs undergo a phase transition and a change in their refractive index, leading to a LSPR shift of few of tens nm (for Gold arrays). Reversibility was demonstrated, and a response time in the second range was observed.

Magnetic and Magneto-optic Driven Active Plasmonic Devices

The study of the excitation of SPs on ferromagnetic materials has recently attracted much interest not only from a fundamental point of view but also because of the possibility of realizing spin-plasmonic devices, bringing together the rapidly developing plasmon technology and the field of spintronics. Active spin-plasmonic devices have been developed for controlling SPP and will be briefly reviewed in the next part of this essay. To the best of our knowledge, the only study, combining LSPR and magneto-active materials, have been recently reported by Du et al., using spherical and elliptical nanocylinders [20]. However, they focused on how plasmons can enhance the magneto-optical properties of a thin magnetic metal layer (Co, Ni or Fe). Active control of the LSPR using magnetic layers remains to be demonstrated.

Controlling Surface Plasmon Polaritons

Surface plasmon polaritons (SPPs) are electromagnetic waves coupled to the coherent oscillation of free charge carriers at the interface between a dielectric and a conductor. The propagation length of SPPs depends on the metal, even though resistive heating losses in metals can severely limit the performance of devices. Several passive plasmonic devices, such as waveguides, and nanoscopic light sources have been demonstrated. In the latter system, the light could be transmitted through holes with lateral dimensions smaller than half the incident wavelength, while classical theory predicts orders-of-magnitude less transmission (extraordinary or enhanced optical transmission [EOT]) [3]. For a better efficiency, the metal should be corrugated with a periodic

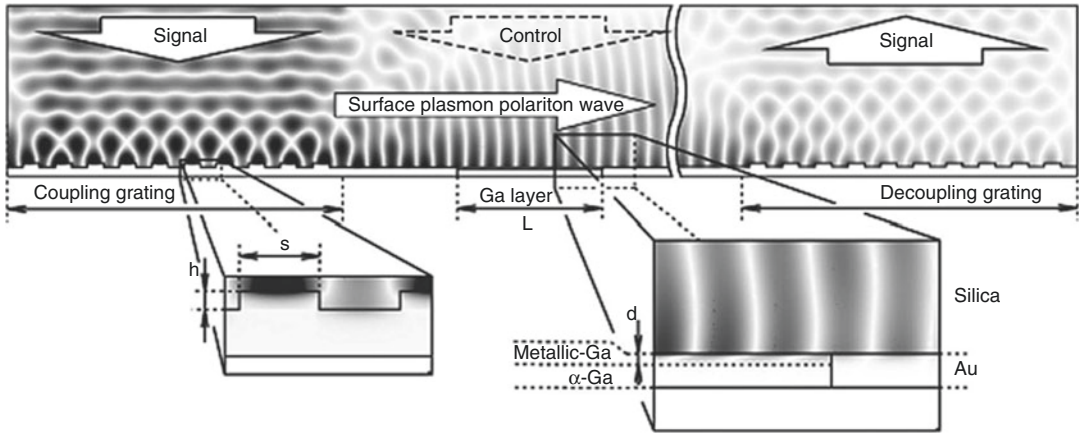
structure such as an array of holes or a single hole surrounded by grooves.

In order to fully exploit the possibilities of such SPP-based plasmonic devices, it is necessary to achieve active control. Since SPP fields are strongly confined, they are again very sensitive to refractive index changes within a few tens of nanometers of the surface. As a consequence, many strategies used to control SPPs are similar to those used for LSPR tuning.

Most systems are solid-state devices avoiding the use of liquid, and when molecules are used, they are deposited as thin films and not used in solution which excludes, to some extent, PH or redox input. A notable exception lies in Surface Plasmon Resonance (SPR) spectroscopy which is very sensitive and widely used to design sensors and biosensors [9]. Readers are directed toward other reviews for many examples of such system. One of the considered configuration replaces the "dielectric" layer in the structure with an active thin film which can be artificially doped by suitable inputs and allows the dynamic modulation of the SPP wavevector [5]. One of the first examples was demonstrated by Krasavin and Zheludev in [21] and will be described in the optical input section.

Inorganic semiconducting materials supporting SPP are also used, whereas metal NP remains the main basic blocks for LSPR devices. Indeed, as the carrier densities in semiconductors are much lower than those in metals, the plasma frequency is much smaller, being typically at mid- or far-infrared frequencies. The main advantage of semiconductors is that their carrier density and mobility, and consequently the SPPs, can be easily controlled by many external stimuli (thermal, electrical, and optical excitation).

Thermally Driven Active Plasmonic Devices



Nikolajsen's group fabricated and characterized thermo-optic Mach–Zender interferometric modulators (MZIMs) and directional-coupler switches (DCSs) at telecom wavelengths [22]. MZIMs and DCSs operation utilize the SPP waveguiding along thin gold stripes embedded in polymer and heated by electrical signal currents. The operation of a thermo-optic MZIM is based on changing the SPP propagation constant in a heated arm resulting in the phase difference of two SPP modes that interfere in the output Y-junction. By sandwiched, the stripes between a thick layer of benzocyclobutene, they observed the modulation of the SPP propagation (extinction ratio of 35 dB for a 8 mW electrical power). This achieved driving power was considerably lower than that of conventional thermo-optic MZIMs.

In the field of EOT, ordered arrays of nanoapertures have been considered as field enhancers and controllers for near-field electromagnetic waves. The EOT transmission takes place in a double-layer structure (a metal-oxide layer). The characteristics of the transmission spectra are fixed by the dielectric constants of the materials that bound the array and by the hole's depth and pitch. Using a specific oxide layer in which semiconductor–metal transition is observed; the transmission of light incident on a metallic nanoholes array is modulated by switching, at transition temperature, the oxide layer between metallic and semiconducting phases with distinctly different dielectric functions.

Electric Field-Driven Active SPP Devices

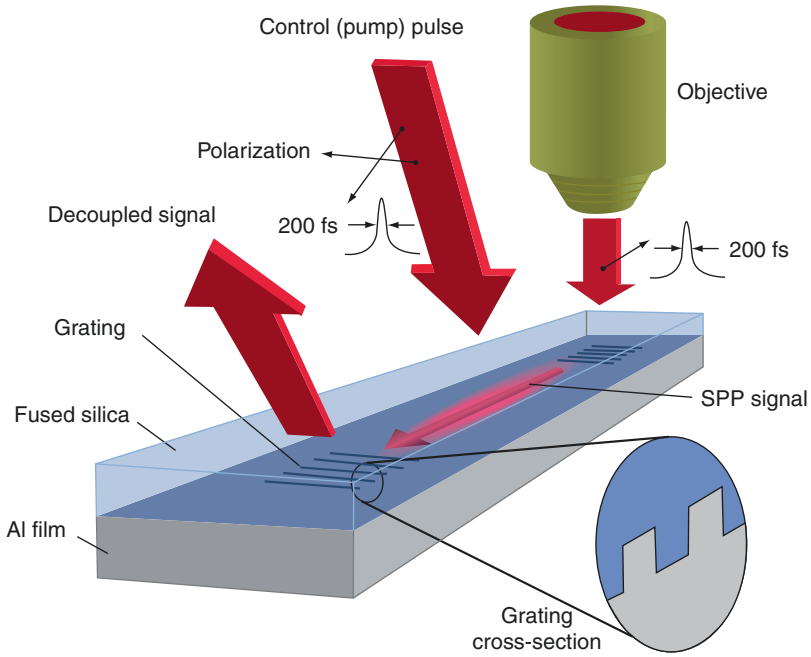
Replacing the "dielectric" layer in the structure with an electro active thin film (for example barium titanate or GaAs layer) allows the dynamic modulation of the SPP wavevector. Under an electric field, the orientation of ferroelectric domains is affected by film stresses. Thus, the SPP waves are modulated by the switch of the in-plane to out-of-plane domains.

Coupling field-effect transistor with plasmonic devices supporting SPP has not yet been widely developed. In 2009, a Metal-Oxide-Semiconductor (MOS) field-effect plasmonic modulator has nevertheless been demonstrated with a device operating at 1.55 μm [23]. A four layer metal-MOS–metal (Ag-SiO_2-Si-Ag) waveguide structure supporting both photonic and plasmonic modes was fabricated. Its transmission coefficient is determined by interference between the two modes. When the MOS is driven into accumulation under a bias of 0.75 V, the Si index changes and the photonic mode is cut off, which leads to transmission modulation. Switching time of 10 ns has been demonstrated

Active Plasmonic Devices, Fig. 10 Representation of gold waveguide containing a Ga switching layer (Reprinted with permission from Krasavin and Zheludev [21])

(limited by the experimental apparatus), but gigahertz frequencies could be reachable.

Optically Field-Driven Active SPP Devices



Due to the optical properties of dielectric layer, the switching may be achieved by external optical excitation through a phase transition in the layer section. For example, Krasavin et al. investigated the control of a dielectric waveguides containing a gallium section a few microns long (Fig. 10).

In such a waveguide, the SPP waves propagated at the interface between the metal film and silica substrate, through the gold and gallium sections, but the transmitted SPP wave was attenuated due to the mismatch of dielectric characteristics. The transition of the gallium layer from the semiconductor solid phase to the metallic liquid phase changes the local refractive index and provides a high-contrast modulation of the SPP propagation. This system could also be thermally driven. A fluence about 10 mJ/cm [2] was needed to induce the Ga-phase transition. Since this first work, many studies have been done in order to implement such system in different active plasmonic devices.

The use of photochromic (PC) molecules was developed by several groups. Among many interesting examples is the use of spyropyran, which are mixed with PMMA and deposited on top of the aluminum layer. Spiropyrans are PC molecules that can undergo a ring-opening reaction and can reversibly be switched between transparent and absorbing states using a free space optical pump. In the transparent (signal "on") state, the SPPs freely propagate through the molecular layer, and in the absorbing (signal "off") state, the SPPs are strongly attenuated (26 % of the original intensity). Upon exposure with 532 nm green light, the signals go back up to 90 %. Therefore the switch was very reproducible but slow, and the incomplete recovery of the signal was attributed to degradation.

With sub-microsecond or nanosecond response times at best, these techniques are likely to be too slow for future applications in data transport and processing fields. Few groups are working to develop some solutions to control or modulate a femtosecond optical frequency plasmon pulses by direct ultrafast optical excitation of the metal. MacDonald's group have discovered a nonlinear interaction between a propagating SPP and light that takes place in the skin layer of the metal surface along which the plasmon wave is propagating [24]. A femtosecond optical pulse incident on the metal surface disturbs the equilibrium in the energy–momentum distribution of electrons, thereby influencing SPP propagation along the surface (Fig. 11).

The transient effect of control pulse excitation on the propagation of the SPP signal was monitored by varying the time delay between the SPP excitation and optical pump pulses.

Active Plasmonic Devices, Fig. 11 Schematic representation of SPP modulation by ultrafast pulse in a Al-silica waveguide (Reprinted with permission from MacDonald et al. [24])

Two components were observed in the transient pump-probe interaction. The "fast" component was only seen where the pump polarization has a component parallel to the direction of SPP propagation with a magnitude of around 7.5 % for pump fluence of 10 mJ cm^{-2}. On the contrary, the "slow" component was a characteristic decay time of about 60 ps and reaches about 4 % of magnitude at the same fluence. The ultrafast femtosecond switching times and modest switching energy reported here open the gates to the exploration of what can ultimately be achieved in nonlinear plasmonics and active plasmonic switching, in particular for the purposes of high-bandwidth interconnects, plasmon–polariton modulation, all-plasmonic switching.

Spin Coupling SPP

A first proposal for a spin-plasmonic device was reported by Chau et al. [25]. The properties of a gigahertz magnetoplasmon optical modulator based on a bismuth-substituted yttrium iron garnet system are studied, showing the possibility of achieving a high-speed magneto-optic modulation of improved efficiency compared to bulk devices. This system is characterized by relevant magneto-optical properties (with Faraday rotations as high as 1°/μm). However, the high absorptions of this material in the visible range of wavelengths represent one of the major limitations in its application in devices. In 2007, the first experimental evidence of a spin-dependent transport in spin-plasmonic media was given by the same group, showing a magnetic manipulation of near-field-mediated light transport via the electron spin. They demonstrated that ferromagnetic particles coated with nonmagnetic metal nanolayers exhibit an enhanced magnetic field controlled attenuation of the electromagnetic field propagated through the sample. The mechanism is related to dynamic, electromagnetically induced electron spin accumulation in the non-magnet. Since 2007, many studies have been done based on core shell metal/magnetic material/metal or magnetic material/metal/magnetic material nanosandwichs system demonstrating a strong coupling between the plasmon resonance and the magneto-optics activity.

Future Directions for Research

Active plasmonic is still in its infancy, even though controlling LSPR and SPP by various

external stimuli has been widely successful. Many new devices are likely to be fabricated shortly. Strategies are similar, but some of them have only been used in order to control one kind of plasmonic device. Switching speed measurements in LSPR-based systems are still lacking, whereas SPP control does not yet use plastic electronic components. It can be anticipated that works on LSPR and SPP control will feed each other, and that active molecular plasmonic devices will lead to a wealth of new important results.

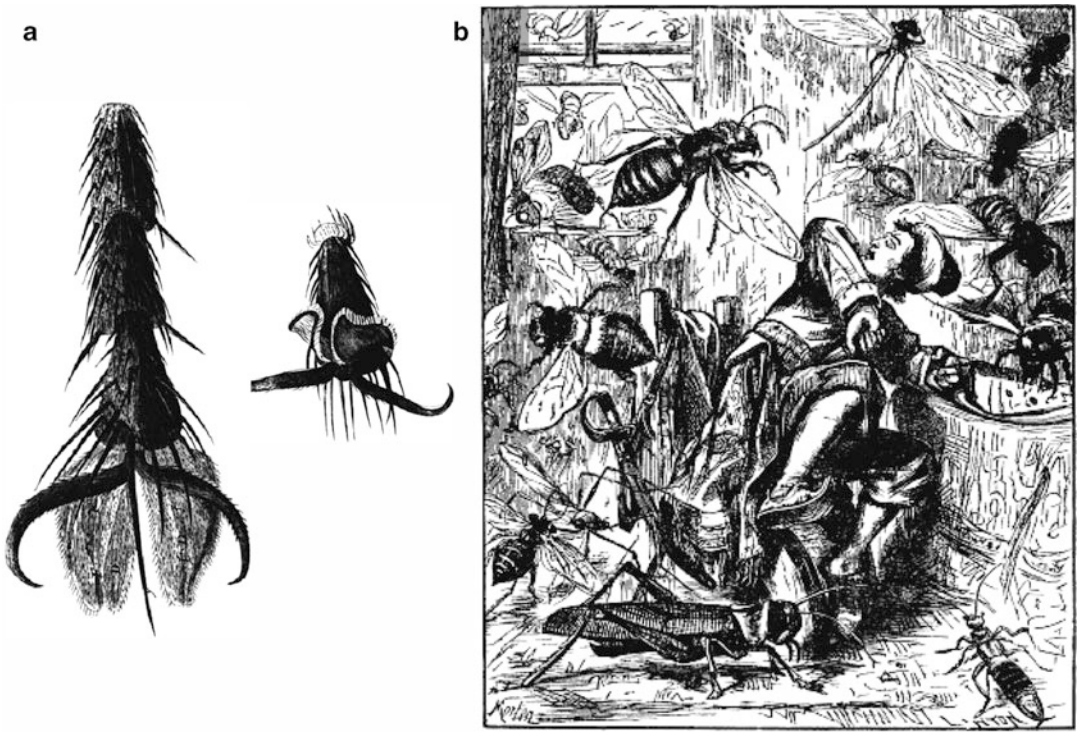
Definition

Mechanisms of adhesion in insects.

The Fascination of Insect Adhesion

For hundreds of millions of years, insects have been inhabiting almost every part of the world, and different species have developed adaptations to very successfully survive in almost all ecosystems.

The ability to survive in ecosystems obviously depends on many different and complex biological and non-biological factors. One very important skill however is the ability to safely walk and stick to many different types of surfaces. Insects have brought this ability to almost perfection, and their feet have inspired authors and scientists for centuries.



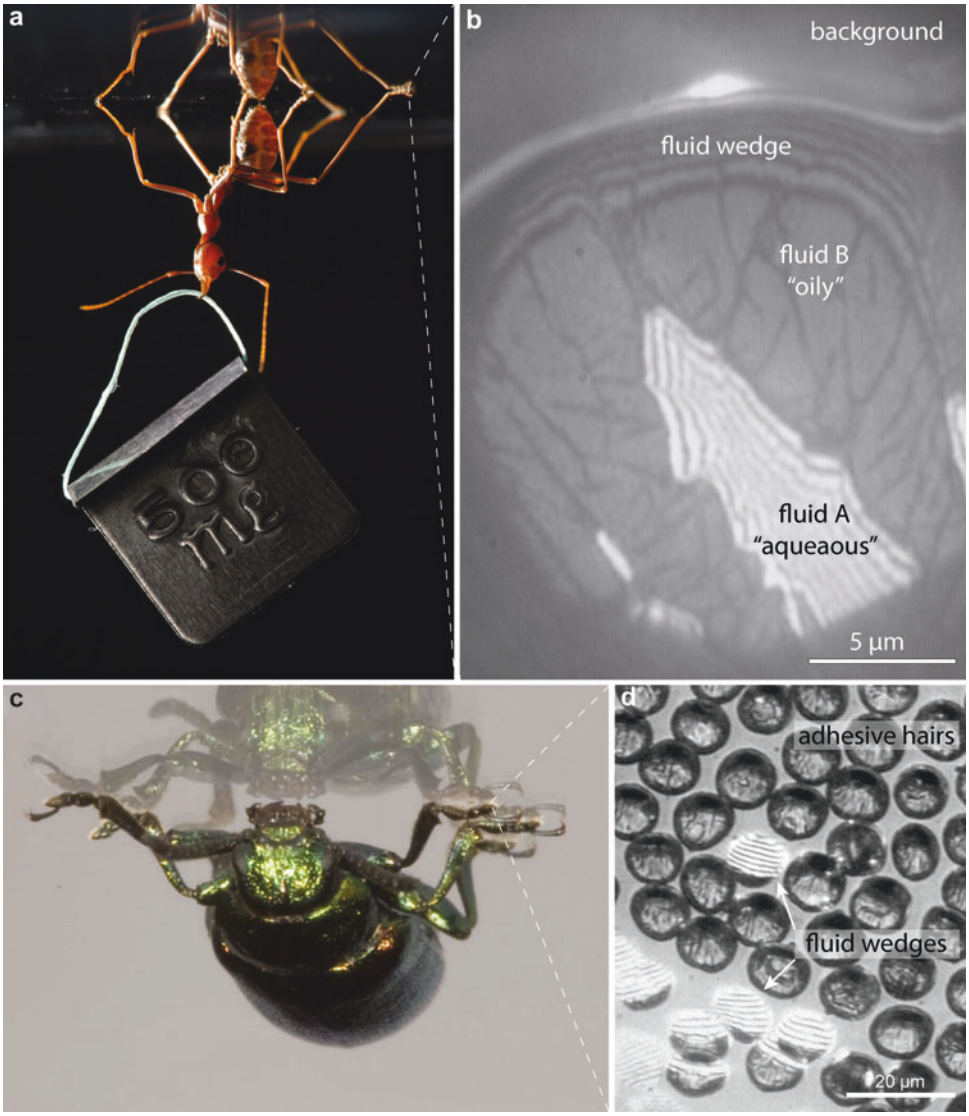
In the beginning of the seventeenth century, soon after the invention of the microscope, researchers were able to study the details of adhesive mechanisms for the first time. Quickly, a lively discussion started into how insects are able to stick to and walk on many kinds of surfaces. Many hypotheses about insect adhesion, from "gluten-filled sponges," the interlocking of fine hairs, suction cups to adhesive secretions, have been proposed over the last two centuries (see Fig. 1a and 1b) [1, 3–7].

In recent years more elaborate microscopes and better analytical tools have become available, and the interest of biologists and engineers in biological and biomimetic adhesives has increased [8–13]. Imaging techniques such as atomic force microscopy (AFM) and various different types of scanning electron microscopy (SEM) now allow biologists to analyze sensitive biological samples on a nanometer scale. Nevertheless, the detailed mechanisms allowing insects to safely adhere to surfaces are still not fully understood.

Adhesive Organs in Insects

Despite the insects' ecological importance and astounding diversity, insect adhesion is surprisingly still understudied, compared to the natural adhesives of a small number of animals such as geckos and mussels. Although at first glance the wide variety of insect adhesive organs appears very different, many of them are functionally quite similar, combining versatility with reliability and controllability.

In their natural environment the surfaces which climbing insects encounter can change fundamentally from one step to the next. Insect foot pads are however not only versatile and work on many surfaces, but can also produce remarkable high attachment forces with only moderate adhesive stresses. Some insects, such as the Asian weaver ant *Oecophylla smaragdina*, can carry loads of more than 100 times body weight when walking upside down on a smooth substrate (see Fig. 2a).

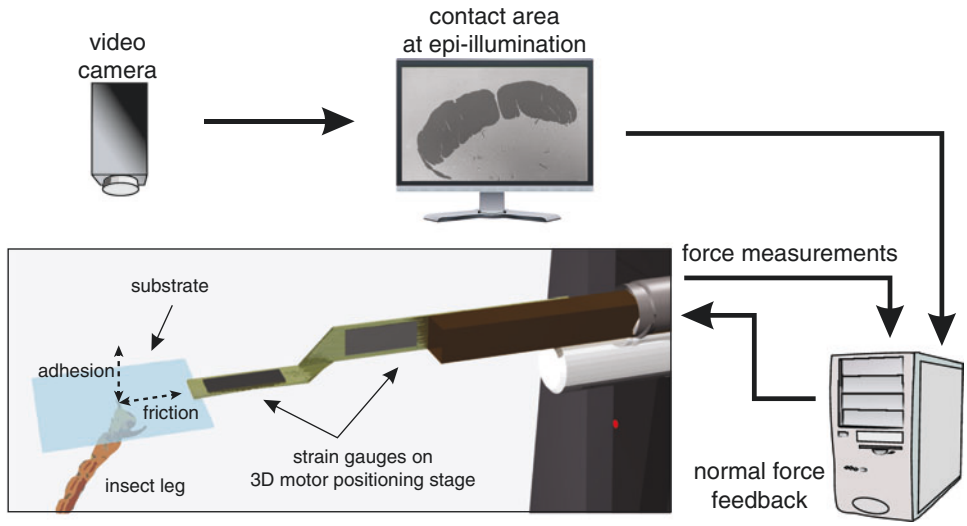


Adhesion in Insects, Fig. 1 (**a**) Probably one of the first drawings of the adhesive feet of a fly published by Robert Hooke in 1665. "The foot of a Fly [. . .] is of a most admirable and curious contrivance" (Figure adapted from [1], public domain). (**b**) When traveling the land of Brobdingnag, Captain Lemuel Gulliver is attacked by giant wasps on the breakfast table and notes "I could easily trace that viscous matter, which, our naturalists tell us, enables those creatures to walk with their feet upwards upon a ceiling" (Figure adapted from [2], public domain)

Although such high adhesive forces of many insects are fascinating, to really understand the principles of insect attachment forces, it is necessary to (i) measure the forces generated by a single adhesive pad, (ii) relate these forces to the respective contact area (to calculate the stresses), and (iii) take into account the chemical and mechanical properties of the surface (wettability, roughness). Biomechanical measurements of the attachment forces also require a precise real-time control of the normal force and, in case of dynamic measurements, also of the adhesive pad's sliding speed. A schematic drawing of a setup used to comprehensibly characterize the attachment forces of a single adhesive pad is shown in Fig. 3.

Although many modern artificial adhesives can outperform insect attachment forces, the feet of insects are still unmatched in respect to their rapid controllability. Insects use their dynamic adhesive organs to attach and detach their feet countless times during their lifetime. Looking at the fast locomotion of many insects, it becomes clear that their adhesive organs thus must be well adapted to rapid attachment and detachment on many different surfaces. Each of these steps also bears the risk of not only damaging but also contaminating the adhesive organ, which results in a loss of adhesion.

One of the most basic biological structures for adhering to a substrate is a pair of sickle-shaped claws at the end of each foot. Such claws can be found in a variety of different sizes and shapes in many vertebrates and most arthropods. Claws are used to grip and interlock on rough surfaces, where their function is determined by their stiffness and shape and in particular by the radius of their tip.



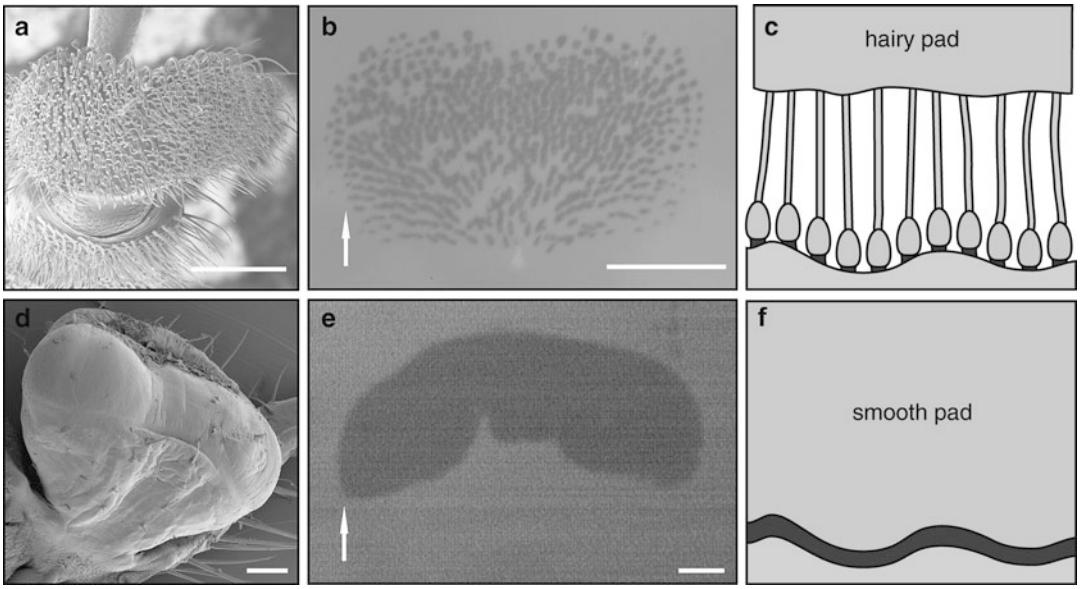
Adhesion in Insects, Fig. 2 (**a**) Asian weaver ant (*Oecophylla smaragdina*) holding more than 100 times its body weight upside down on a smooth surface. (**b**) IRM of adhesive contact zone of the ant's pad with the two-phasic adhesive fluid showing aqueous droplets (fluid A) within a hydrophobic continuous fluid (fluid B). (**c**) Leaf beetle (*Gastrophysa viridula*) and (**d**) IRM of discoidal adhesive setae in contact with glass. Interference fringes show hairs in partial contact. Setae appear darker on the side of the stalk (Insect photographs with kind permission by T. Endlein. Figure adapted with permission from own work [14])

However, if the surface asperities are smaller than the diameter of the claw tip and the claws cannot insert into the material, the adhesive pads will fail. Hence, to stick to smooth and stiff natural substrates, such as stones or leaves, insects and other arthropods have to use adhesive pads.

Hairy Versus Smooth Adhesive Pads

The adhesive organs of insects, like all parts of their exoskeleton, are almost entirely made of cuticle. Although cuticle is a material known for its variability, exoskeletal parts are mostly orders of magnitude stiffer than required by the

Adhesion in Insects, Fig. 3 Schematic illustration of an experimental setup for in vivo measurement of adhesion and shear stress (friction) on single adhesive pads of insects. A force transducer with attached surfaces can be moved in three dimensions using a computer-controlled translation stage. A feedback system controls normal forces in real time during friction measurements. The contact areas of the adhesive pads are imaged from above under reflected light using digital cameras synchronized with the force measurements. This allows the calculation of shear stress from force measurements (Figure adapted with permission from own work [15])



"Dahlquist criterion" (a Young's modulus of 100 kPa), which is usually considered as the upper limit for "tacky" materials.

To reduce the effective stiffness of the adhesive organ cuticle, two types of adhesive systems have evolved several times in insects: "hairy" (fibrillar) and "smooth" pads (see Fig. 4a and 4d). Both systems provide attachment to most rough and smooth surfaces by maximizing the contact area [16, 17].

The hairy adhesive pads on the feet of flies, beetles (see Fig. 2c), and spiders are densely covered with arrays of flexible *setae*, with each of the setae making close contact to the substrate separately (see Fig. 4b and 4c) [18, 19]. In most hairy pads these setae only end in a single terminal element; however, in some beetles they can branch toward the tip. Even within one tarsus or between the sexes of one species, these terminal elements can vary in shape and size [20]. Recently, it has been shown that in beetles the setae show a decreasing stiffness of the cuticle toward the tip of the setae [21].

Smooth pads of insects increase the contact area by adapting as a whole to the surface roughness (see Fig. 4e and 4f) [22, 23]. They can be found in many groups of insects such as ants, bees, stick insects, grasshoppers, true bugs, and cockroaches [24]. A soft cuticular sac (arolium) is located between the claws on the pretarsus of the insect leg and shows the presence of a specialized ultrastructure, which can deform and mold to rough surface profiles (see Fig. 4f). Within the arolium, cuticular rods are oriented almost perpendicular to the surface plane and branch out into finer fibers toward the pad surface. Again, this ultrastructure can be found in many insect orders and even in the toe pad epidermis of tree frogs. Some insect orders, such as Hymenoptera, Thysanoptera, or Mecoptera, also show additional adaptations, such as an unfoldable arolium.

In addition to the pre-tarsal arolium, some insect orders such as Blattodea, Heteroptera, Hymenoptera, Orthoptera, Phasmatodea, and Plecoptera have tarsal pads called euplantulae, which are specialized for fundamentally different functions.

Adhesion in Insects, Fig. 4 (**a**) Adhesive pad morphology of a "hairy" pad from a male dock beetle (*G. viridula* and **d**) and a "smooth" adhesive pad from an Indian stick insect (*C. morosus*). Epi-illumination can be used to visualize the contact area of the adhesive pads in contact with glass (**b**, **e**). *Arrows* indicate distal direction. Subfigures **c** and **f** show a schematic view of the close contact of the hairy and smooth pads. Note that in both cases the contact zone is mediated by an adhesive fluid (dark). On rough surfaces many single adhesive hairs adapt to the surface asperities and allow the adhesive pad to form close contact. The soft arolium of smooth adhesive pads adapts as a whole to the surface asperities on rough substrates (Figure adapted with permission from own work [14])

In stick insects (*Carausius morosus*), for example, arolia are only in contact with the surface when the insect is hanging upside down. When standing upright, the insects rested on their proximal euplantulae. Single-pad force measurements suggest that, strictly speaking, only arolia are "true" adhesive pads that stick to the substrate, while euplantulae are specialized "friction pads" [23].

The large number of insect groups with smooth pads, compared to the smaller number of groups with hairy pads, and the structural diversity of the smooth pads in different insect orders, led to the suggestion that smooth pads probably appeared earlier in insect evolution and represent a more "basic" evolutionary adhesive structure and have independently evolved several times [19]. "Hairy" structures however can also be found in many other biological adhesive pads such as lizards and spiders, indicating a general evolutionary "favorable" attachment design for surface attachment [8].

Insect Adhesive Fluid

Despite their different morphology, hairy and smooth adhesive pads of insects both secrete adhesive fluid into the contact zone (see Fig. 2b and 2d). Within the last three centuries, many scientific hypotheses about the role of the adhesive fluid were proposed and tested.

In 1833 Blackwall placed insects in evacuated air cylinders and showed that air pressure does not affect the insects' ability to adhere to smooth surfaces [3]. This experiment was initially thought to disprove the popular "suction cup" hypothesis; however, Blackwall also noticed that small quantities of condensed water vapor, oil or wheat, pulverized chalk, and gypsum prevented insects and spiders from sticking to clean glass surfaces. This observation leads him to the conclusion that ". . .these facts, far from corroborating the mechanical theory, appeared quite inexplicable, except on the supposition that an adhesive

secretion is emitted by the instruments employed in climbing." This appears to be one of the first experimental scientific approaches to understand the function of the insects' adhesive fluid.

Until now adhesive secretions have been found in all insect groups studied to date, including smooth pads of cockroaches, ants, and stick insects, as well as in hairy pads of flies, bugs, and beetles [14]. Adhesive fluids are also known from other organisms such as tree frogs and bats, and recent work has demonstrated that even the adhesive pads of spiders, mites, and other arachnids can secrete a fluid. This leaves geckos and anoles currently as the only known representatives of "dry" adhesive pads in nature.

Although the adhesive fluids secreted by the attachment organs of insects were discovered and described several hundred years ago, their chemical composition, mechanisms of secretion, and biological function are still not fully understood.

Composition and Secretion of Adhesive Fluid

For the smooth pads of stick insects, cockroaches, and ants, it has been shown that the adhesive fluid is a two-phasic microemulsion, consisting of a hydrophilic, volatile dispersive phase within a hydrophobic and evaporation-persistent continuous phase (see Fig. 2b). Chemical analyses of hydrophobic footprint droplets in smooth and hairy systems show the presence of long-chained hydrocarbons (mainly C_{22} to C_{29} n-alkanes and n-alkenes [25, 26], as well as more polar fatty acids, carbohydrates, and amino acids. As many of these substances are found in other parts of the insects' cuticle, it is still unclear whether and to what extent the adhesive fluid differs in composition from the general lipid cover of the cuticle. While a similarity between footprint chemicals and cuticular waxes was reported for beetles, differences were shown for locusts and flies [26, 27].

Deposited footprint droplets of stick insects and weaver ants are highly persistent against evaporation, remain present even after rinsing them with water, and show high refractive indices typical of hydrocarbons ($n_{fluid} = 1.47$, fluid B) [24]. When in contact with glass, droplets of the emulsion's disperse phase (fluid A) are noticeable as bright spots with a much lower refractive index. These small droplets rapidly evaporate when approaching the edge of the contact zone. Although the two-phasic nature of adhesive fluid has been found for several insect groups and mites with smooth adhesive pads, there is still no clear experimental evidence for the presence of two fluid phases in the hairy pads of insects and arachnids [28].

The secretion mechanism of the adhesive fluid is still unclear for both hairy and smooth pads. In smooth pads, it is so far only known that the secretion relies on simple physical principles, allowing for passive control of fluid volume within the contact zone. Footprints left by freely climbing insects are much smaller than those left during consecutive experimental press-downs, suggesting that insects can conserve secretion by minimizing contact area and by recovering fluid during detachment [29].

Biomechanical Function of the Adhesive Fluid: Self-Cleaning, Adhesion, and Friction

Typical cuticle secretions form an important protective barrier against evaporation and are used for intra- and interspecies communication. The main functions of the fluid secreted by adhesive pads however are self-cleaning of the pads and improvement of attachment forces [29].

Adhesion Forces

Insects climbing on a surface have to generate both adhesion (perpendicular to the substrate) and friction forces (parallel to the substrate). For simplicity, fluid-based adhesion is often modeled using two flat, undeformable surfaces mediated by a thin layer of fluid. The adhesion observed between the surfaces of such a model is the sum of three components: the fluid's surface tension, the Laplace pressure, and the *Stefan* adhesion:

$$F_{\text{adh}} = \underbrace{F_{\text{surface tension}} + F_{\text{Laplace pressure}}}_{\text{capillary forces}} + F_{\text{viscous forces}} \tag{1}$$

Using a few experimentally accessible parameters such as mediating fluid height, viscosity, contact

angle, etc., this model can be used to discuss and qualitatively predict a few characteristic "features" of fluid-based adhesion. For example, one can predict that an increasing fluid height h between adhesive pad and surface would result in decreasing capillary adhesive forces. As a consequence, insects and all organisms with fluid-mediated attachment organs (including tree frogs) should minimize the secretion of adhesive fluid into the contact area to increase capillary adhesion on smooth surfaces.

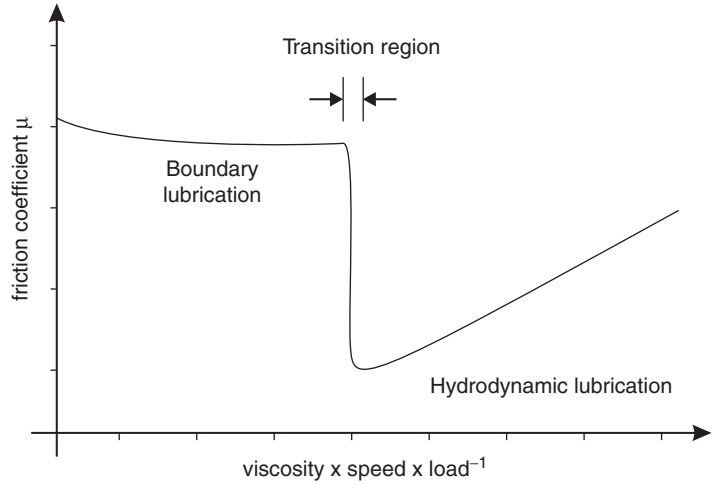
However, only very few natural surfaces are actually smooth. Experimental studies indeed show that the adhesive fluid actually plays a more important role in filling gaps between the pad and the surface, thus maximizing contact area and adhesion to rough substrates (see Fig. 3 and Refs. [18, 30]).

Besides the limitation to smooth surfaces, this simple adhesion model also bears several additional notable problems, in particular in light of the stiffness and deformability of the adhesive pads [31]. For example, at certain ratios of adhesive pad size and stiffness, the Young's modulus of the adhesive pad can play an important role in determining the capillary adhesion. In these models a softer adhesive pad or substrate with a lower elasticity deforms more easily at a given external force, which results in a larger contact area. This larger contact area again increases the radius of the mediating liquid's meniscus, which then increases the capillary force.

Friction Forces

In a fluid-mediated system with a continuous Newtonian fluid film, the friction forces between the substrates are often described using two basic principles: the surface tension of the mediating fluid and the laws of *hydrodynamic* lubrication.

However, the predicted contribution of surface tension toward the generation of friction forces is several orders of magnitude smaller than the shear stresses measured in smooth adhesive pads and thus is unlikely to explain the high friction forces generated by the adhesive pads of insects alone [18, 32, 33].



Similar to the *Stefan* adhesion, the "hydrodynamic lubrication" friction term takes into account the *viscosity* of the mediating fluid layer. Two parallel smooth surfaces with a distance of h sliding at a velocity v relative to each other generate the friction force

$$F_F = \eta_{\text{eff}} A \frac{v}{h} \tag{2}$$

where η_{eff} is the effective viscosity of the mediating fluid layer and A the size of the contact area. Again, similar to the time-dependent *Stefan* adhesion, this term shows that a simple fluid-mediated system at rest should not be able to generate any static friction. Also, hydrodynamic friction forces generated by a continuous fluid film of 90 nm height would be one order of magnitude smaller than the shear stresses observed in adhesive organs [24].

Thus, to date it is still not entirely clear how insects with a fluid-mediated adhesive pad generate the observed high friction forces, preventing them from sliding down smooth vertical substrates. Experimental results suggest that thixotropic (shear thinning) non-Newtonian properties of the adhesive emulsion could explain the presence of high static friction forces [15, 30].

A second, yet to be tested, hypothesis to explain the observed high friction forces in the adhesive pads of insect is the formation of local "dry" rubberlike direct contacts between the adhesive pad and the substrate. The classic *hydrodynamic* model only describes the friction observed with relative "thick" layers of lubricant ($\geq$0.5 μm), where neither the specific surface properties (roughness, surface energy) nor *Amonton's* law is involved. Friction forces generated by fluid layers thinner than five to ten molecular layers are usually modeled using the more complex *boundary lubrication* theory, where a decreasing film height and increasing number and area of direct contacts between the two substrates actually *increase* the friction coefficient. The range between the hydrodynamic model and the boundary lubrication model, where the mediating fluid layer is still lubricating the contact, however, allows a weak interaction between the surfaces and is mostly referred to as *elasto-hydrodynamic lubrication* (see Fig. 5).

Adhesion in Insects, Fig. 5 Schematic illustration showing regions of hydrodynamic and boundary lubrication of two fluid-mediated smooth surfaces and the resulting friction forces. With decreasing sliding velocity and increasing load, the mediating fluid film becomes thinner, allowing regions of direct contact between the two surfaces. Within the transition region, the friction coefficient rapidly increases, usually to a value smaller than unlubricated surfaces. This region is also referred to as *elasto-hydrodynamic* lubrication. It is not yet fully understood in which of the two "regions" the adhesive organs of insects operate

Within this range, areas with "dry" solid-like contact can form as a result of local "dewetting" of the adhesive fluid. Indeed, a similar mechanism has been proposed for the fluid-mediated adhesive toes found in tree frogs, where local "dewetting" might be responsible for the high friction forces. However, so far there is no experimental evidence for the occurrence of dewetting or direct contacts between adhesive pad and surface in smooth or hairy adhesive organs of insects.

Conclusion

Even after many years of research, several of the fundamental physical properties enabling insects to safely adhere to surfaces are still not fully understood. Simple fluid-mediated models based on capillary and viscosity are still often used to estimate the attachment forces generated by insect feet. However, newer experimental data and more comprehensive tribological models suggest that many aspects of these classic "microscopic" attachment models fall short in fully explaining the forces generated by the fluid-mediated adhesive pads of insects. To fully understand the physical principles, one thus has to extend these models to incorporate non-Newtonian properties of the adhesive fluid [15, 30] and also take into account possible more complex nano-tribological models, with boundary lubrication or other mechanisms resulting in points of "dry" contact between the pad and the surface.

Further fundamental experimental work, in particular a more accurate in vivo measurement of the mediating fluid's height and high-resolution single-leg force measurements on smooth substrates with well-known physical properties, is required to answer these questions and help to solve a century-old scientific question.

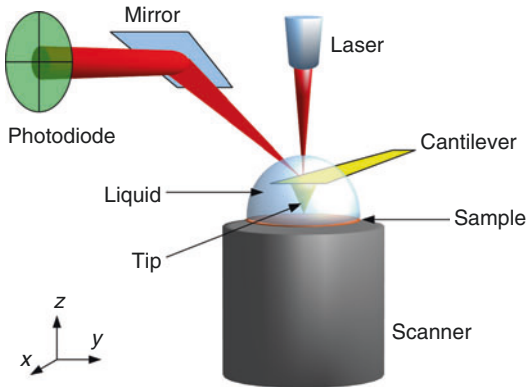
Definition



Atomic force microscopy (AFM) in liquids is the application of AFM in liquid environment, i.e., in which both the surface under investigation and the scanning probe are immersed in liquid.

Overview and Definitions

AFM is a microscopy technique that can provide three-dimensional images of virtually any surface at nanometer-scale resolution. It relies on the force between a sharp probe and the surface, which is detected while scanning the probe over the sample. Unlike many other microscopy techniques at such a resolution, it can readily be applied in liquid environment.

An atomic force microscope consists of a sharp probe ("tip") mounted on a microfabricated cantilever beam and a mechanism ("scanner") to scan the tip over the surface at subnanometer resolution [1], see Fig. 1. Typically, an optical detection scheme is used to detect the deflection of the cantilever. Via the spring constant of the cantilever, the cantilever deflection can be translated to a force between tip and sample. For a rectangular lever, the spring constant is given by

$$k = \frac{Et^3 w}{4l^3}, \tag{1}$$

AFM in Liquids, Fig. 1 Schematic of AFM in liquid. A sharp tip is scanned across the sample surface while the tip-sample interaction is monitored via the deflection of the cantilever to which the tip is attached. The sample is mounted on a (usually piezoelectric) scanner for three-dimensional positioning with sub-nanometer accuracy. The sample, the tip, and the cantilever are immersed in liquid. The bending of the cantilever is usually detected via a laser beam deflected on a position-sensitive detector (4-quadrant photodiode)

where E is the Young's modulus of the cantilever material (typically silicon or siliconnitride), and t, w, and l are its thickness, width, and length, respectively, which are in the micron range. Most cantilevers for AFM have spring constants between 0.01 and 100 N/m. In its most basic mode of operation, the deflection of the cantilever (and thus the tip-sample force) is kept constant by adjusting the vertical position of the sample with respect to the tip.

In most instruments, the cantilever deflection is recorded via the position of a laser beam that is deflected from the cantilever. Images of the surfaces are acquired by line-by-line scanning the surface, and tracing its surface contours on a false-color scale. For AFM in liquid, the surface and the cantilever are immersed in liquid. Typically, the minimum liquid volume is some tens of microliters, which can be either contained in a closed liquid cell, or in the shape of a droplet that is formed by capillary forces between the sample surface and the cantilever holder. In principle, the liquid can be of arbitrary nature, though the optical deflection detection in most microscopes limit their use to liquids that are transparent for (near infra-) red light.

AFM in Liquids, Table 1 Different modes of operation in AFM, with the parameter that is used to control the tip-sample distance while scanning over the surface

Mode of operation	Other common names	Control parameter
Static	Contact mode	Static deflection
Amplitude modulation (AM)	Tapping mode	Oscillation amplitude
	Intermittent contact, AC mode	
Frequency modulation (FM)	Noncontact (NC) AFM	Resonance frequency
Force spectroscopy	Force volume, quantitative imaging, peakforce tapping	Maximum force

There are many possible imaging modes of AFM and their names are rather confusing. They are divided into static mode and a variety of dynamic modes in which the cantilever is oscillating [2]. The latter are of particular importance when the lateral (drag) forces on the sample need to be minimized, e.g., for imaging DNA molecules that are loosely bound to a flat surface. The most common modes of operation in liquid are static or contact mode and amplitude modulation or tapping mode. In contact mode, the bending or deflection of the cantilever is used to detect the tip-sample force. In tapping mode, the cantilever is vertically oscillated above the sample, and the tip-sample interactions detected via the change (usually decrease) of amplitude of the cantilever oscillation. In variations along the same theme, the cantilever may be oscillated and tip-sample interactions are detected via changes in phase or resonance frequency of the cantilever [3]. Thus, the amplitude, phase, or frequency of the cantilever oscillation can be the control parameter that is used to keep the (average) tip-sample interaction constant, via continuous adjustment of the relative position of the tip with respect to the sample (or vice versa). An overview of the most relevant AFM modes in liquids is given in Table 1. Confusion may arise because the commonly used terms contact, intermittent-contact, and noncontact often – but not always – refer to a mode of operation (as referred to in Table 1), and not necessarily to the actual contact (or lack

of it) between the tip and the sample. As a particular example, FM ("noncontact") AFM in liquids is usually performed in the range of repulsive tip-sample interactions, with the tip in actual intermittent contact with the sample. In addition, if the amplitude is used to trace and control the tip-sample distance (i.e., tapping mode), the phase of the cantilever can be recorded simultaneously for phase imaging, which provides an additional means to measure tip-sample interactions. Or, in FM AFM, a frequency shift is used to trace elastic tip-sample interactions and control the tip-sample distance, while the oscillation amplitude can be kept constant by adjusting the cantilever drive signal. This cantilever drive signal then provides a simultaneous measure of the dissipative tip-sample interactions. In addition, the tip-sample force may be continuously probed by acquiring force-distance curves (force spectroscopy). Provided that these curves are acquired sufficiently fast, the maximum force in such a force curves (at smallest tip-sample separation) can be used as the control parameter for imaging the surface topography [4].

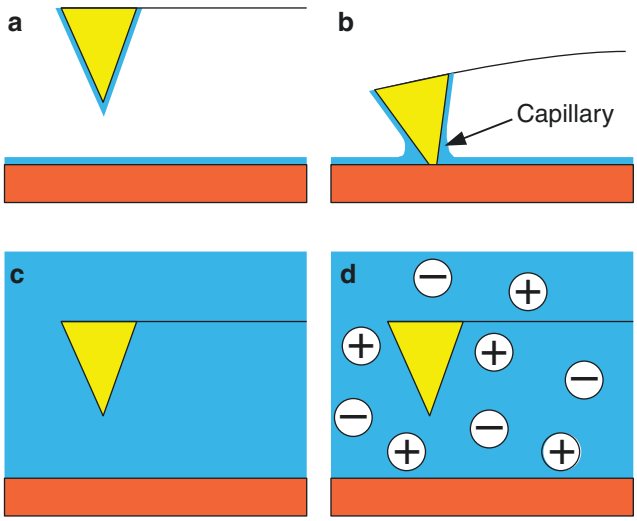
Physical and Chemical Principles

The spatial resolution of AFM critically depends on the sharpness of the tip and on the range of the tip-sample interactions. Ideally, only the very (nanometer-scale) end of the tip interacts with the surface, thus avoiding convolution effects due to interactions between the sample and the (micron-scale) bulk of the tip. The presence of long-range tip-sample forces is therefore decremental to the spatial resolution. On the other hand, the shorter the range of the tip-sample interaction, the more likely the tip is to enter in hard contact with the sample, which may damage the tip and/or the sample.

By immersing the tip and sample in liquid, it is not only possible to access scientifically and technologically interesting solid-liquid interfaces (including biological samples), but also to tune the tip-sample interactions by varying the ingredients of the liquid. In particular, the electrostatic sample interaction between the tip and a flat sample can be approximated by [5]:

$$F_{el} = g_\kappa \sigma_t \sigma_s e^{-\kappa z} + g_{2\kappa}\left(\sigma_t^2 + \sigma_s^2\right) e^{-2\kappa z}, \quad (2)$$

where g_κ and $g_{2\kappa}$ are constants that depend on the tip geometry and the dielectric properties of the medium, σ_t and σ_s are the surface charges of the tip and the sample, respectively, z is the tip-sample distance, and κ^{-1} the Debye screening length [6],



$$\kappa^{-1} = \sqrt{\frac{\varepsilon_0 \varepsilon_b k_B T}{2e^2 I}}. \quad (3)$$

In the latter, ε_0 is the permittivity of vacuum (8.854×10^{-23} F/m), ε_b the permittivity of the bulk solution (or the dielectric medium), k_B is the Boltzmann's constant (1.38×10^{-23} J/K), and T is the temperature in Kelvin. The parameter I is the ionic strength of the medium,

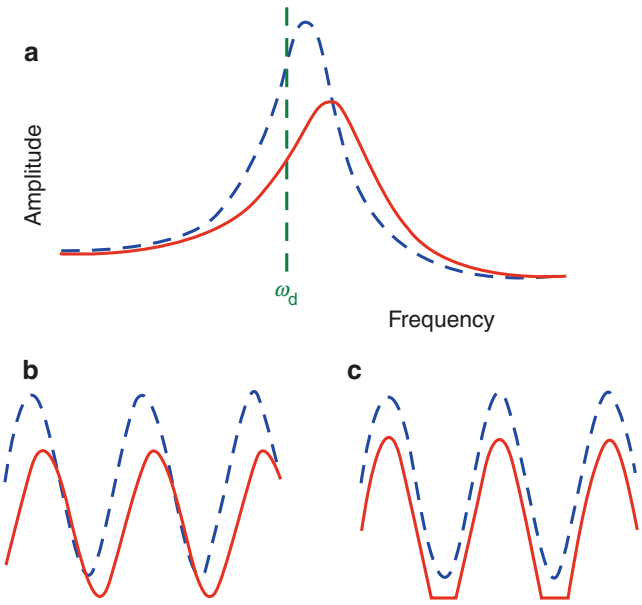
$$I = \frac{1}{2}\sum_i z_i^2 c_i. \quad (4)$$

where z_i is the valence of ion i and c_i is its concentration. The Debye length is historically written as an inverse length (i.e., κ has units of m^{-1}). In typical biological buffers, the Debye length is between 1 and 10 nm.

In a chemically reactive medium, σ_t and σ_s are generally not zero. For typical tip terminations such as silicon oxide or silicon nitride in water, $\sigma_t < 0$ at neutral pH. As can be seen from Eq. 2, the strength of the electrostatic tip-sample interaction depends on σ_t and σ_s. These can be changed by adding or removing solutes that react with or bind to the tip and sample surfaces. In aqueous solutions, this is most readily achieved by changing the pH (i.e., adding H_3O^+ or OH^-). Moreover, the dielectric properties – and in particular the ionic strength (Eq. 4) – of the medium can be tuned to control the range of the electrostatic tip-sample interaction. This provides a significant advantage over AFM in gaseous mediums and vacuum environment, and is one of the reasons why the first true atomic resolution (see below)

AFM in Liquids, Fig. 2 (**a**) Capillary forces for AFM in air arise due to the thin water layers that are usually present at both tip and sample under ambient conditions. (**b**) At small tip-sample distances, they pull the tip toward the surface to create a larger contact area and thus limit the lateral resolution. (**c**) In liquid environment, these capillary forces are absent. (**d**) Moreover, long-range electrostatic forces can be screened by ions in the liquid

AFM images were obtained, in contact mode, in aqueous environment rather than in vacuum or air [7].

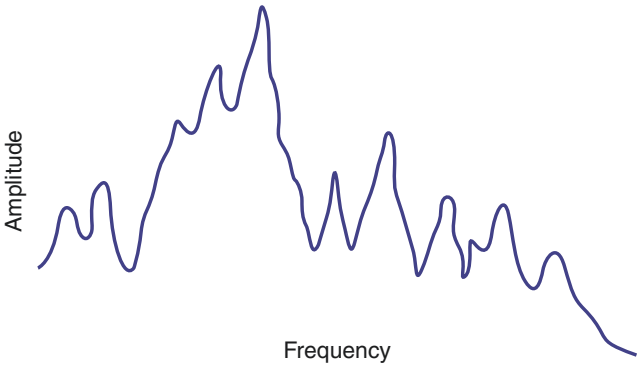


Compared to AFM in air, AFM in liquids has the additional advantage of preventing the capillary forces that arise from the humid coverage of both sample and tip under ambient conditions, as illustrated in Fig. 2. The capillary forces create a strong pull on the tip toward the sample at distances of many nanometers. On close approach, this results in a tip-sample contact area that covers many atoms at the surface, thus prohibiting high resolution. Under such conditions, AFM is likely to result in one of its most extensively documented artifacts: The apparent "atomic resolution" that results from the periodic interaction averaged over many atoms of tip and surface. This represents the atomic periodicity of the surface rather than individual atomic-scale features such as atomic defects (which are often used to demonstrate "true atomic resolution").

Apart from electrostatic and capillary forces, AFM in liquids is also (and not exclusively) sensitive to atomic bonding forces and hard-core repulsion, van der Waals interactions, dissolution/solvation forces, and general dissipative interactions.

The latter are particularly important in the dynamic modes of AFM operation. To illustrate this, it is helpful to depict the cantilever resonance for different elastic and dissipative interactions, see Fig. 3.

A repulsive (elastic) tip-sample interaction increases the effective spring constant of the cantilever and thus increases its resonance frequency, shifting the whole resonance curve to the right. Any dissipative interaction reduces the sharpness of the resonance curve and the maximum of the curve. The quality factor Q is the most common measure for this sharpness, defined as $\omega_0/\Delta\omega$, where ω_0 is the natural frequency of the resonator and $\Delta\omega$ the width of the resonance curve at $1/\sqrt{2}\times$ its maximum amplitude. In tapping mode, the driving frequency is usually set just below the resonance frequency, such that both elastic and dissipative interactions cause the amplitude to decrease when the tip comes into contact with the sample. In FM AFM, the shift in the resonance frequency provides a direct measure of the elastic interaction, and the conversion to a force is straightforward when the amplitude of the oscillation is (kept) constant [8]. The dissipated energy can be deduced from the energy that is required to maintain a fixed amplitude. Thus, tapping mode is sensitive to a mixture of elastic and dissipative tip-sample interactions, whereas FM AFM can track elastic and dissipative interactions separately (and simultaneously).



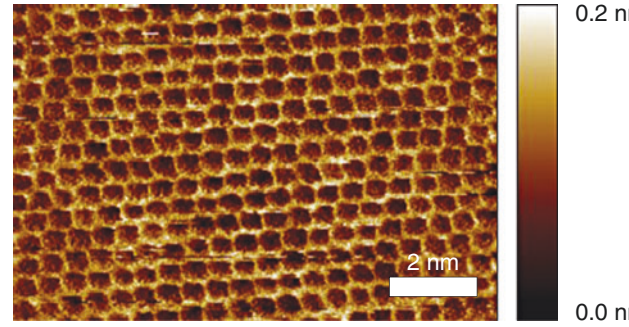
This analysis relies on the cantilever behaving as a simple harmonic oscillator, which is

AFM in Liquids, Fig. 3 (**a**) Schematic resonance curve of a freely oscillating cantilever (*dashed, blue curve*), based on a model of a simple harmonic oscillator. In the presence of a (repulsive) elastic tip-sample force as well as dissipative tip-sample interactions, the resonance shifts to higher frequencies, broadens and decreases in amplitude (*red curve*). At a fixed driving frequency ω_d, such as in tapping mode, the effects of elastic or dissipative interactions will cause the amplitude to decrease or increase, depending on the choice of ω_d. (**b**) Sinusoidal oscillation of a cantilever above the surface (*dashed, blue*). Close to the sample, the oscillation amplitude decreases and changes phase (*red*). (**c**) For heavily damped cantilever oscillations ($Q \sim 1$), however, the harmonic-oscillator analysis is not valid any more. The tip-sample interaction will only affect the bottom part of the oscillation, where the tip is closest to the sample

appropriate for $Q \gg 1$, typical for operation in vacuum $(Q \gtrsim 1000)$ and air $(Q \gtrsim 100)$. However, in liquid, viscous damping reduces Q to $\lesssim 10$. In particular, for softer cantilevers $k \lesssim 1\mathrm{N/m}$, $Q \approx 1$, and the contact between tip and sample will prevent the cantilever from following a harmonic, sinusoidal oscillation. The cantilever oscillation will simply be topped off at the bottom of the oscillation, at the closest tip-sample approach. In this case, significant information on the tip-sample interaction will be contained in higher harmonics of the oscillation. The interpretation of cantilever oscillation in terms of tip-sample forces thus becomes considerably more complicated.

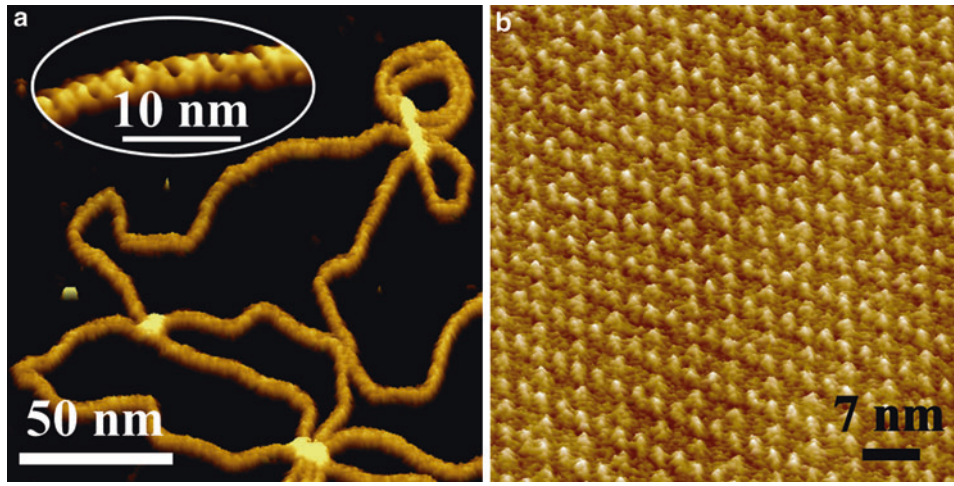
The low quality factor has another undesirable side effect for AFM operation that involves oscillating the cantilever. Cantilevers are usually driven by a small piezoelectric element that drives not only the cantilever itself, but also its (macroscopic) support chip and often the whole cantilever holder. In vacuum and air, the high Q singles out the cantilever resonance from other mechanical resonances in the instrument. In liquid, this is not the case anymore, and a typical excitation spectrum contains a so-called forest of peaks, i.e., a convolution of the broad cantilever resonance with many sharp(er) mechanical resonances from the microscope, as illustrated in Fig. 4. Again, this complicates the interpretation of the cantilever behavior in terms of a simple harmonic oscillator. It also makes the choice of optimum driving frequency much less straightforward (usually, this is done by trial and error). Moreover, since this excitation spectrum depends on the macroscopic geometry of the fluid cell, it is much more dependent on drift than the cantilever alone. For these reasons, there are a number of alternative methods to only drive the microscopic cantilever (and no macroscopic parts), such as

AFM in Liquids, Fig. 4 Excitation spectrum such as can be obtained for a cantilever in water that is actuated by piezoelectrically driving the cantilever holder rather than the cantilever alone. Note the contrast with the ideal resonance shape in Fig. 3a



magnetic and optical actuation. In the former, the cantilever is coated with a magnetic material and driven by an AC magnetic field; in the latter, an AC-modulated actuation laser locally heats the metal-coated surface of cantilever, which acts as a bimetal and thus transduces laser power to cantilever deflection. These and other methods have the disadvantage of adding complexity to the instrument and eventually to the microfabricated cantilever itself.

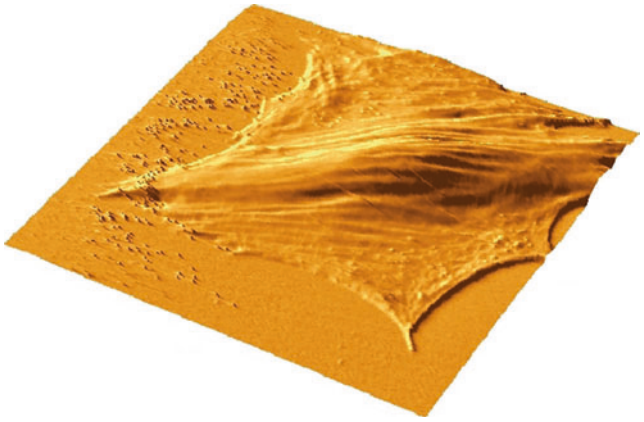
These concerns can partly be addressed by so-called Q-control or self-oscillatory methods [9], in which the signal from the cantilever oscillation itself is phase-shifted, amplified, and added to the actuation signal. This positive feedback is very familiar in electronic oscillatory circuits. It causes any change to the oscillation to ring for a longer time, stretching its effect over many oscillations. As a result the effective Q of the cantilever oscillation is enhanced, and the cantilever is forced to follow a perfectly harmonic, sinusoidal oscillation. As for problems related to the forest of peaks in nonideal cantilever excitation, these are not resolved by Q control, since the positive feedback does not distinguish between the cantilever resonance and other mechanical resonances. Q control or self-oscillatory methods can be applied to each mode of operation (see Table 1), but for tapping mode has the side effect of slowing down the measurement: Changes in amplitude occur at a timescale of $\sim Q/\omega_0$, unlike changes in phase or resonance frequency, which are instantaneous. In FM AFM, the cantilever can even entirely be driven by its phase-shifted and amplified thermal noise.



Applications

AFM has been used to probe a vast amount of interfaces between (hard and soft) condensed matter and liquids. It is of particular importance for the study of surfaces that are instable or show distinctly different behavior when taken out of the liquid, and for the study of dynamic processes that depend on an exchange of material (ions, macromolecules) between the surface and the liquid. AFM in liquids has been important for the study of, among others, crystal growth/dissolution, polymer science, and the behavior of liquids in confined geometries. The vast majority of its applications, however, lie in the life sciences [10]: For most biomolecular structures, aqueous solutions represent their natural environment. Their structures and functions are strongly dependent on the presence of water, a number of ions, and other macromolecules. The structure and function of biological samples can thus be studied at (sub)nanometer resolution while they are still "alive," and for varying liquid contents. The following represents some illustrative examples of the use of AFM in aqueous solutions on easily accessible samples, with a strong focus on biological applications.

Up to now, highest resolution AFM images in liquid have been obtained on atomically flat and inorganic surfaces, with calcite and muscovite mica as most common examples. On such surfaces, the lateral resolution can be less than an Ångström and the vertical resolution a few picometers. Though initially such resolution was only obtained in contact mode [7], more recently FM AFM has become popular as a method for atomic-resolution



AFM in Liquids, Fig. 5 Atomic-resolution image of mica in (aquaeous) buffer solution, obtained by FM AFM (Reproduced from Khan et al. [13], with permission)

imaging that is significantly less susceptible to thermal drift. One of the key steps toward high-resolution imaging in liquids was the development of low-noise deflection sensors [11, 12]. This has brought the measurement noise down to the thermal noise of the cantilevers, even for stiff and heavily damped cantilevers in liquid. As a result, surfaces can now be stably measured with Ångström amplitudes of cantilever oscillation. This enhances the sensitivity to short-range forces and yields images such as depicted in Fig. 5. Because it is flat, hydrophilic, and easily cleaved, mica is one of the substrates of choice for adsorbing molecules in AFM experiments in aqueous solutions.

AFM has been successful in imaging DNA as well as DNA-protein complexes. DNA is routinely adsorbed on mica, where it is generally assumed to adopt a two-dimensional projection of its original three-dimensional configuration [14]. Under optimum imaging conditions, the major and minor grooves of the DNA double helix can be resolved [15]. The rather flat geometry required for high-resolution AFM is a natural one for proteins that are embedded in a lipid membrane. In particular when two-dimensional crystals are available, such as for bacteriorhodopsin, high-resolution images can readily be obtained in the various modes of AFM operation [16]. DNA and bacteriorhodopsin represent some of the biomolecules that have been most often imaged at high resolution by AFM in liquid (Fig. 6).

AFM in Liquids, Fig. 7 $100 \times 100 \times 3\ \mu m^3$ contact-mode AFM topograph of an osteoblast (bone cell) adsorbed on a glass coverslip (Image courtesy Guillaume Charras)

On a completely different scale, AFM can image objects as large as whole cells (Fig. 7). Due to thermal fluctuations, vibrations, and the overall softness of the cell, the spatial resolution is considerably lower than that obtained on flat surfaces or molecules directly adsorbed on a hard substrate. As, for cell imaging, alone, the advantage of AFM over optical techniques is therefore limited.

AFM can also be used to deliberately probe sample properties other than structure [17]. Single molecules that are tethered between the tip and the substrate can be deliberately stretched, unfolded, and allowed to refold at controlled load force [18], similar to optical-tweezers experiments. Using the same force spectroscopy techniques, force-distance curves can be obtained on whole cells, yielding information about their local elasticity or – when using chemically modified tips – local binding sites for specific ligands [19].

Finally, fast AFM methods [20] have improved the image rate from the typical frame per minute up to many frames per second. This gives direct access to the kinetics of molecular-scale processes at nanometer resolution.

AFM force sensors; AFM tips

Definition

AFM probes are transducers that convert the interaction force with a sample surface into a deformation or a change of the vibrational state of the probe. Most probes consist of a sharp microtip and a force transducer. The former determines the lateral resolution of the AFM and the latter provides the force sensitivity.

Overview

A typical AFM probe consists of a sharp tip and a microcantilever, which plays the role of a force transducer. In this case, the interaction force between the tip and sample deflects the cantilever. The deflection can be detected by a displacement measurement method, such as an optical lever or interference techniques. Assuming that the deflection and the spring constant of the cantilever are Δz and k, respectively, the interaction force F is given by

$$F = k\Delta z. \tag{1}$$

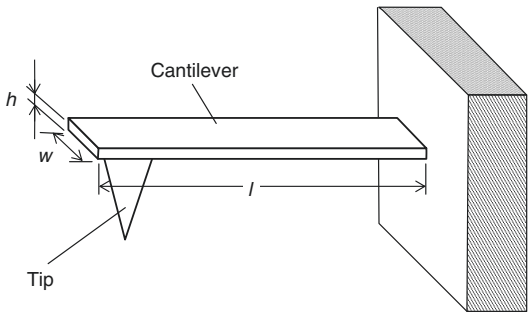
In contact AFM mode, the probe height is controlled so that the probe deflection is constant, which means that the interaction force does not change during the probe scanning. Mapping the controlled height can thus provide the topography of the sample.

In the early days, a metal foil with a glued microparticle or sharpened metal wire was used

as an AFM probe. Here, the particle or wire acted as a tip [1]. Improving the force sensitivity and reproducibility was not easy with those probes. Then, microfabricated cantilever probes were introduced [2]. These probes are made of silicon nitride or silicon and are produced by microfabrication techniques such as anisotropic chemical etching. Microfabricated probes enabled to improve the force sensitivity and expand the freedom of the probe design. They were also suitable for mass production. Therefore, microfabricated probes are the most common at present and various types of them are commercially available nowadays. Undoubtedly, the microfabricated probes have been playing an important role in AFM's becoming one of the most widely used methods in nanotechnology.

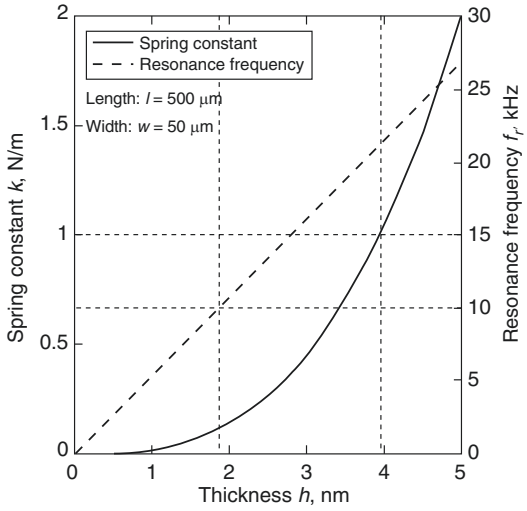
Probe Design

Since the specifications of the tip are rather limited by the fabrication method, the main part of the probe design is the force transducer, such as the rectangular micro cantilever sketched in Fig. 1. In addition to rectangular cantilevers, V-shaped cantilevers are widely used, especially in contact AFM mode. The force sensitivity of the probe should be high enough to detect weak interaction forces. From Eq. 1, the cantilever should convert a small force F into a large displacement Δz, which requires a small spring constant $k = F/\Delta z$. This means that higher sensitivity requires softer cantilevers. In addition to the force sensitivity, the robustness against mechanical disturbances from the environment should be considered. If the vibrations induced by the disturbances exceed the deflection due to the interaction force, the AFM signal is buried in the noise. The vibrations due to disturbances are amplified when the disturbance frequency is around the resonance frequency (natural frequency) of the probe. Since the disturbance frequencies are generally low, the resonance frequency should be set at a high value, typically larger than about 10 kHz. If the force transducer of the probe is simplified as a point mass and spring system, the resonance frequency is given by



$$f_r = \frac{1}{2\pi}\sqrt{\frac{k}{m}}, \tag{2}$$

where m is the mass of the transducer. The sensitivity needs low values of k whereas the robustness against the environmental disturbances requires high values of f_r. This means that low values of m are required. Therefore, the force transducer of the probe should be soft and small. If a rectangle cantilever is chosen as a force transducer, it has to be thin and small. Microfabricated cantilevers meet this demand and, for this reason, they became standard probes for AFM.



The design details of a rectangular cantilever are considered below. If the length, width, and thickness of the cantilever are l, w, and h, respectively, the spring constant k is given by

$$k = \frac{Ewh^3}{4l^3} \tag{3}$$

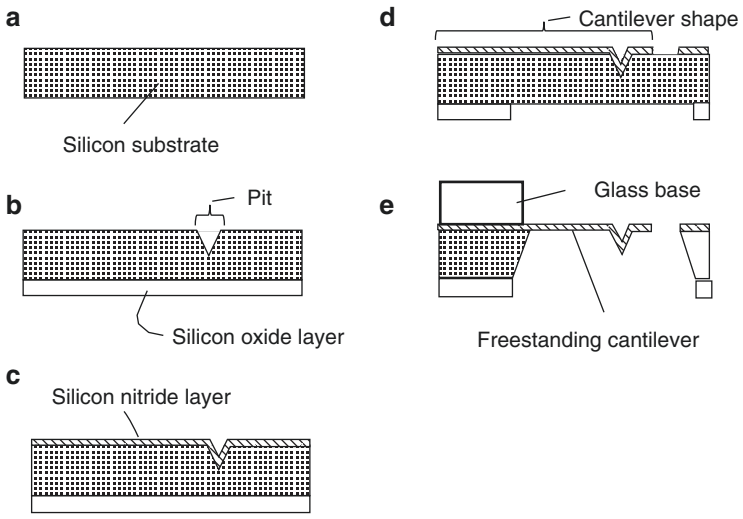
where E is the Young's modulus of the cantilever. It should be noted that the spring constant is proportional to $(h/l)^3$. This means that longer and thinner cantilevers can provide higher force sensitivity. The force F to be measured depends on the interaction between the tip and sample and the deflection Δz depends on the sensitivity of the displacement measurement method. Therefore, the spring constant k should be determined by considering the typical values of F and Δz for the targeted samples and the measurement system.

AFM Probes, Fig. 1 Schematic of a microcantilever probe

AFM Probes, Fig. 2 Thickness dependencies of the spring constant and resonance frequency of a microcantilever

On the other hand, the resonance frequency of a rectangular cantilever is given by

$$f_r = \frac{\lambda^2}{4\pi}\frac{h}{l^2}\sqrt{\frac{E}{3\rho}}, \tag{4}$$



where ρ is the density of the cantilever and λ is a constant that depends on the vibrational mode. For the first mode λ is about 1.875. It should be noted that the cantilever width is not included in Eq. 4. Since f_r is proportional to h/l^2, higher resonance frequencies f_r require shorter and thicker cantilevers. However, as described above, high sensitivity requires opposite conditions. Thus, a balance between the spring constant and the resonance frequency has to be found in designing the probe. An example for contact mode cantilevers is shown in Fig. 2, where the thickness dependencies of the spring constant and resonance frequency are plotted using Eqs. 3 and 4 for a length $l = 500$ μm and a width $w = 50$ μm, respectively. If a spring constant of less than 1 N/m and a resonance frequency larger than 10 kHz are selected, the former curve requires a thickness of more than 1.9 μm and the latter curve requires a thickness of less than 4.0 μm. Therefore, a thickness in the overlapping range should be selected. A probe with these dimensions is not easy to fabricate by conventional machining and requires micromachining techniques.

Measurements of the spring constant k and resonance frequency f_r are important for converting the measured deflection signal into a force signal. The resonance frequency f_r can be measured by varying the drive frequency as it is routinely done in commercial AFM equipments. However, the accurate measurement of the spring constant k is not easy. An approximate value can be calculated from the dimensions of the cantilever using Eq. 3. An experimental method using the thermal fluctuation was presented in Ref. [3].

Many types of AFMs using a vibrating cantilever have been developed, such as cyclic contact mode and non-contact mode AFMs. The probe vibrations can be induced using a quartz-oscillator. In this case, the resonance properties, especially the quality factor Q, are very important. The quality factor Q is defined as $Q = 1/2\zeta$, where ζ is the damping coefficient. A probe with a high Q is able to resonate effectively and its vibration is hard to damp. The minimum detectable force gradient in the frequency-modulation detection, which is widely used in highly sensitive AFMs such as non-contact AFMs and magnetic force microscopy, is given by

$$\left(\frac{\partial F}{\partial z}\right)_{\min} = \frac{2}{A}\sqrt{\frac{kk_BTB}{\omega_r Q}}, \tag{5}$$

where B, ω_r, and A are the measurement band width, resonance angular frequency, and vibration amplitude, respectively [4]. Higher force sensitivity requires a higher Q. Since the vibration damping of the probe is caused by the internal friction and by friction between the probe and environmental gas such as air, the quality factor Q usually depends on the probe structure and environment. Typical values of Q of silicon cantilevers are on the order of 10–100 in air whereas they can increase up to more than 10,000 in vacuum. A method to increase Q electronically was presented, where the deflection signal is fed back to the drive signal after the phase of the deflection signal is shifted by 90° [5].

AFM Probes, Fig. 3 Fabrication process of a microfabricated probe: (**a**) silicon substrate, (**b**) formation of pit for a microtip, (**c**) deposition of silicon nitride layer, (**d**) patterning of cantilever, and (**e**) removal of substrate

Probe Fabrication

At present, most of the probes are fabricated by microfabrication techniques and various types of probes have been designed. Moreover, a considerable number of them are commercially available because microfabricated probes are suitable for mass production. The fabrication methods have also been improved, corresponding to a general improvement of the probe quality. Here, the fabrication methods for two typical types of probes are outlined. We will first address the probes made of silicon nitride. These probes are widely used in contact AFM mode. The fabrication process is shown in Fig. 3 [6]. In this method, a small pit that is formed in a silicon substrate by anisotropic wet etching is used as a mold. The silicon oxide layer is formed as an etching mask for the later substrate removal (Fig. 3a, b). A silicon nitride film is deposited onto the substrate and the cantilever is patterned by lithography. At this point, the cantilever with tip is shaped (Fig. 3c, d). By attachment of the glass base by anodic bonding and removal of the silicon substrate by wet etching, a freestanding cantilever is obtained (Fig. 3e). Another type of probes are silicon cantilevers [7]. Silicon cantilevers are the most widely used probes in AFM and they are operated in various modes. By using the undercut etching of the underneath of a circular mask, a tip is formed. Then the cantilever is patterned. The substrate silicon is removed by wet etching with protection of the fabricated tip and cantilever. Sharpening the tip end can be achieved by thermal oxidation followed by oxide removal [6].

Future Directions for Research

In addition to standard silicon or silicon nitride cantilever probes, various types of probes have been recently introduced. In a piezoresistive probe a piezoresistive strain sensor is embedded with a silicon cantilever [8]. The embedded sensor detects the cantilever deflection and makes the detection system such as an optical lever unnecessary. This not only makes the setup compact but also provides easier operation in the special case of liquid or vacuum environments. Along the growth of microfabricated cantilever probes, probes that use a quartz-oscillator as a force transducer have also been developed. Various types of oscillators such as tuning fork or linear-extension resonators are used [9]. In many probes, a microtip is manually glued to the quartz-oscillator although the oscillator is microfabricated. Quartz-oscillator probes have advantages of high Q and large spring constant. The latter allows to avoid

the jump-in of the probe. In addition, quartz-oscillator probes provide self-sensing as piezoresistive probes.

As stated above, the improvement of the probes is essential for the development of AFM. Recent advances in micro/nanomachining are promoting this improvement, which is expected to open up new applications of AFM.

AFM, Noncontact Mode

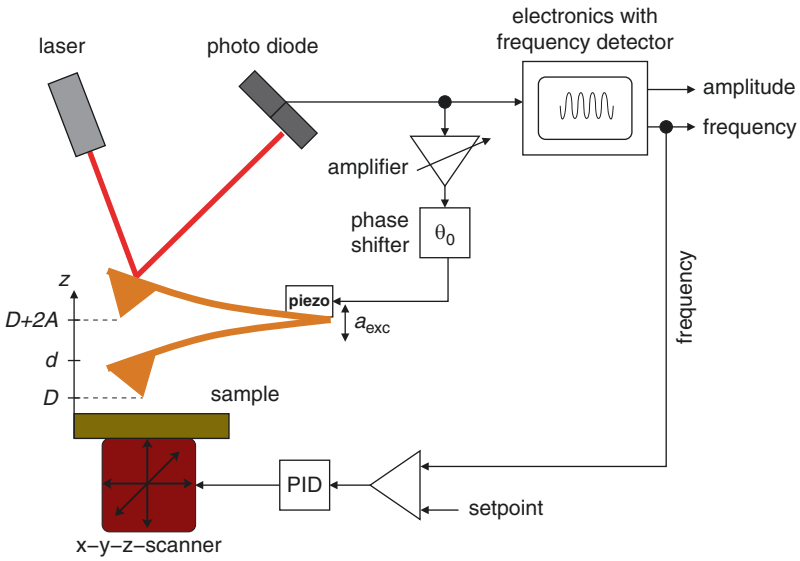
Hendrik Hölscher
Karlsruher Institut für Technologie (KIT), Institut für Mikrostrukturtechnik, Karlsruhe, Germany

Definition

The *noncontact atomic force microscopy* (NC-AFM) is a specific AFM technique primarily developed for application in vacuum where standard AFM cantilevers made from silicon or silicon nitride exhibit very high quality factors Q, what makes the response of the system slow if driven in AM or tapping mode (▶ AFM, Tapping Mode). The technique to oscillate the cantilever also in high Q environments is called *frequency-modulation* (FM) mode. In contrast to the tapping or AM mode typically applied in air or liquids, this approach features a so-called self-driven oscillator, which uses the cantilever deflection itself as drive signal, thus ensuring that the cantilever instantaneously adapts to changes in the resonance frequency. The NC-AFM technique is the method of choice to obtain true atomic resolution on non-conduction surfaces with an atomic force microscope.

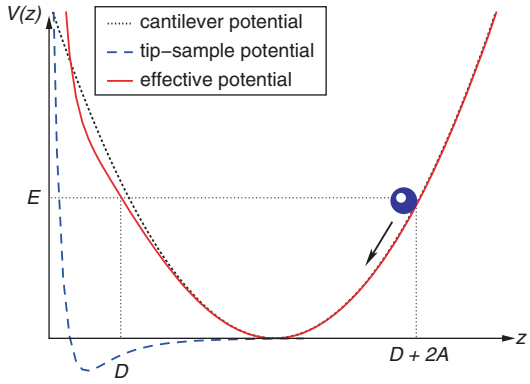
Overview

To obtain high resolution images with an atomic force microscope it is most important to prepare clean sample surfaces free from unwanted adsorbates. Therefore, these experiments are usually performed in ultra-high vacuum with pressures below 1×10^{-10} mbar. As a consequence most dynamic force microscope experiments in vacuum utilize the so-called *frequency modulation* (FM) detection scheme introduced by Albrecht



et al. [1]. In this mode the cantilever is self-oscillated, in contrast to the AM- or tapping-mode (▶ AFM, Tapping Mode). The FM-technique enables the imaging of single point defects on clean sample surfaces in vacuum and its resolution is comparable with the scanning tunneling microscope, while not restricted to conducting surfaces [2–6]. In the years after the invention of the FM-technique the term *non-contact atomic force microscopy* (NC-AFM) was established, because it is commonly believed that a repulsive, destructive contact between tip and sample is prevented by this technique.

Set-Up of FM-AFM



In vacuum applications, the Q-factor of silicon cantilevers is in the range of 10,000–30,000. High Q-factors, however, limit the acquisition time (bandwidth) of a dynamic force microscopy, since the oscillation amplitude of the cantilever needs a long time to adjust. This problem is avoided by the FM-detection scheme based on the specific features of a self-driven oscillator.

The basic set-up of a dynamic force microscope utilizing this driving mechanism is schematically shown in Fig. 1. The movement of microfabricated cantilevers is typically measured with the laser beam deflection method or an interferometer. A self-detecting sensor like a tuning fork do not need an additional detection sensor. In any case the amplitude signal fed back into an amplifier with an *automatic gain control* (AGC) and is subsequently used to excite the piezo oscillating the cantilever. The time delay between the excitation signal and cantilever deflection is adjusted by a time ("phase") shifter to a value of $\approx 90°$, since this ensures an oscillation at resonance. Two different modes have been established: The *constant amplitude*-mode [1], where the oscillation amplitude A is kept at a constant value by the AGC, and the *constant excitation mode* [7], where the excitation amplitude is kept constant. In the following, however, only the constant amplitude mode is discussed.

The key feature of the described set-up is the positive feedback-loop which oscillates the cantilever always at its resonance frequency f [8]. The reason for this behavior is that the cantilever serves as the frequency determining element. This is in contrast to an external driving of the cantilever in tapping mode by a frequency generator (▶ AFM, Tapping Mode). If the cantilever oscillates near the sample surface, the tip-sample interaction alters its resonant frequency, which is then different from the eigenfrequency f_0 of the free cantilever. The actual value of the resonant frequency depends on the nearest tip-sample distance and the oscillation amplitude. The measured

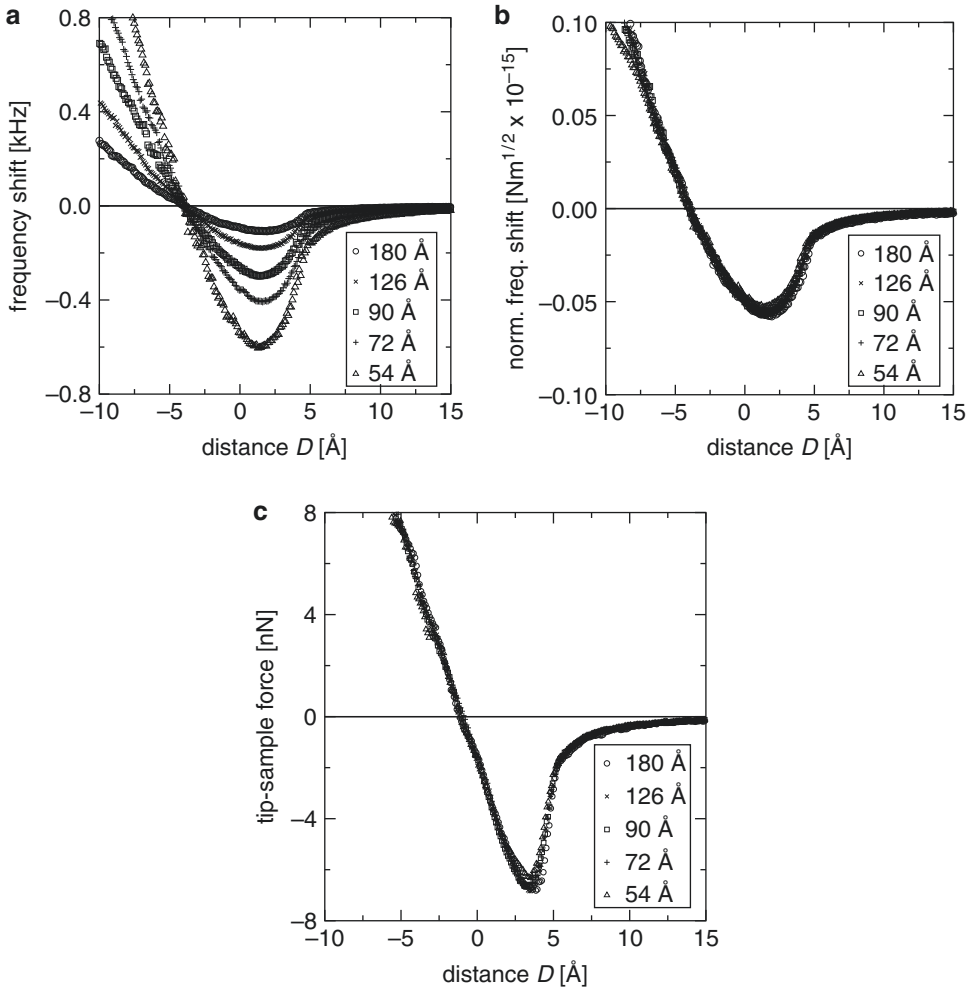
AFM, Noncontact Mode, Fig. 1 The schematic set-up of a dynamic force microscope based on the frequency modulation technique often used in UHV. A significant feature is the positive feedback of the self-driven cantilever. The detector signal is amplified and phase shifted before it is used to drive the piezo. The measured quantity is the frequency shift due to the tip-sample interaction, which serves as the feedback signal for the cantilever-sample distance

AFM, Noncontact Mode, Fig. 2 The frequency shift in dynamic force microscopy is caused by the tip-sample interaction potential (*dashed line*), which alters the harmonic cantilever potential (*dotted line*). Therefore, the tip moves in an anharmonic and asymmetric effective potential (*solid line*)

quantity is the *frequency shift* Δf, which is defined as the difference between both frequencies ($\Delta f := f - f_0$). For imaging the frequency shift Δf is used to control the cantilever sample distance. Thus, the frequency shift is constant and the acquired data represents planes of constant Δf, which can be related to the surface topography in many cases.

Origin of the Frequency Shift

Before presenting experimental results obtained in vacuum the origin of the frequency shift is analyzed in mode detail. A good insight into the cantilever dynamics is given by looking at the tip potential displayed in Fig. 2. If the cantilever is far away from the sample surface, the tip moves in a symmetric parabolic potential (dotted line), and its oscillation is harmonic. In such a case, the tip motion is sinusoidal and the resonance frequency is given by the eigenfrequency f_0 of the cantilever. If, however, the cantilever approaches the sample surface, the potential – which determines the tip oscillation – is modified to an effective potential V_{eff} (solid line) given by the sum of the parabolic potential and the tip-sample interaction potential V_{ts} (dashed line). This effective potential differs from the original parabolic potential and shows an asymmetric shape.



As a result of this modification of the tip potential the oscillation becomes anharmonic, and the resonance frequency of the cantilever depends now on the oscillation amplitude A. Since the effective potential experienced by the tip changes also with the nearest distance D, the frequency shift is a functional of both parameters ($\Rightarrow \Delta f := \Delta f(D, A)$).

Figure 3 displays some experimental frequency shift versus distance curves for different oscillation amplitudes [9]. The obtained experimental frequency shift versus distance curves show a behavior expected from the simple model explained above. All curves show a similar overall shape, but differ in magnitude in dependence of the oscillation amplitude and the nearest tip-sample distance. During the approach of the cantilever towards the sample surface, the frequency shift decreases and reaches a minimum. With a further reduction of the nearest tip-sample distance, the frequency shift increases again and becomes positive. For smaller oscillation amplitudes, the minimum of the $\Delta f(z)$-curves is deeper and the slope after the minimum is steeper than for larger amplitudes, i.e., the overall effect is larger for smaller amplitudes.

This can be explained by the simple potential model as well: A decrease of the amplitude A for a fixed nearest distance D moves the minimum of the effective potential closer to the sample surface. Therefore, the relative perturbation of the harmonic cantilever potential increases, which increases also the absolute value of the frequency shift.

Theory of FM-AFM

As already described in the previous subsection it is a specific feature of the FM-modulation technique that the cantilever is "self-driven" by a positive feedback loop. Due to this experimental set-up, the corresponding equation of motion is different from the case of the externally driven cantilever discussed for the tapping-mode. The external driving term has to be replaced in order to describe the self-driving mechanism correctly. Therefore, the equation of motion is given by

AFM, Noncontact Mode, Fig. 3 (**a**) Experimental frequency shift versus distance curves acquired with a silicon cantilever ($c_z = 38$ N/m; $f_0 = 171$ kHz) and a graphite sample for different amplitudes (54–180 Å) in UHV at low temperature ($T = 80$ K). (**b**) Transformation of all frequency shift curves shown in (**a**) to one universal curves using Eq. 6. The normalized frequency shift $\gamma(D)$ is nearly identical for all amplitudes. (**c**) The tip-sample force calculated with the experimental data shown in (**a**) and (**b**) using the formula Eq. 7

$$m\ddot{z}(t) + \frac{2\pi f_0 m}{Q}\dot{z}(t) + c_z(z(t) - d) + \underbrace{g c_z(z(t - t_0) - d)}_{\text{driving}} = F_{\text{ts}}[z(t), \dot{z}(t)]. \tag{1}$$

where $z := z(t)$ represents the position of the tip at the time t; cz, m, and Q are the spring constant, the effective mass, and the quality factor of the cantilever, respectively. $F_{\text{ts}} = -(\partial V_{\text{ts}})/(\partial z)$ is the tip-sample interaction force. The last term on the left describes the active feedback of the system by the amplification of the displacement signal by the *gain factor* g measured at the retarded time $t - t_0$.

The frequency shift can be calculated from the above equation of motion with the ansatz

$$z(t) = d + A\cos(2\pi f t) \tag{2}$$

describing the stationary solutions of Eq. 1. Again, it is assumed that the cantilever oscillations are more or less sinusoidal and develop the

tip-sample force F_{ts} into a Fourier-series. As a result the following equation for the frequency shift is obtained

$$\Delta f = \frac{1}{\pi c_z A^2} \int_{d-A}^{d+A} (F\downarrow + F\uparrow) \frac{z-d}{\sqrt{A^2-(z-d)^2}} dz \tag{3}$$

and the energy dissipation

$$\Delta E = \left(g - \frac{1}{Q}\frac{f}{f_0}\right) \pi c_z A^2. \tag{4}$$

Since the amplitudes in FM-AFM are often considerably larger than the distance range of the tip-sample interaction, apply the "large amplitude approximation" [10, 11] can be applied. This yields the formula

$$\Delta f = \frac{1}{\sqrt{2\pi}} \frac{f_0}{c_z A^{3/2}} \int_D^{D+2A} \frac{F_{ts}(z)}{\sqrt{z-D}} dz \tag{5}$$

It is interesting to note that the integral in this equation is virtually independent of the oscillation amplitude. The experimental parameters (cz, f_0, and A) appear as pre-factors. Consequently, it is possible to define the *normalized frequency shift* [10]

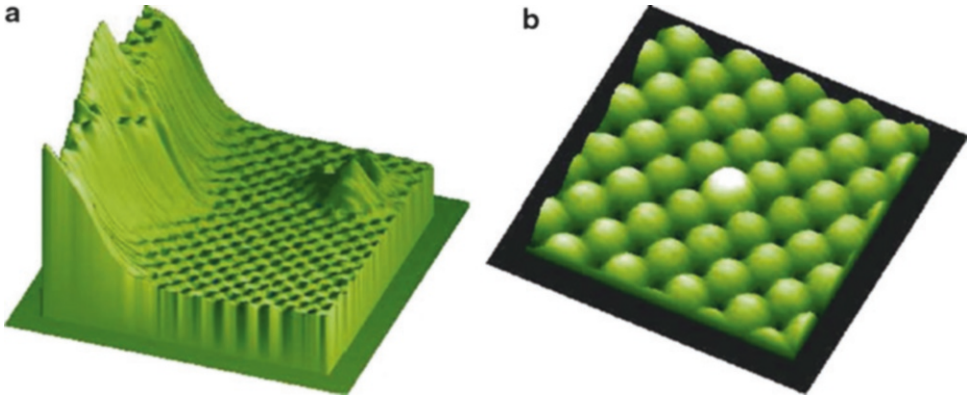
$$\gamma(z) := \frac{c_z A^{3/2}}{f_0} \Delta f(z) \tag{6}$$

This is a very useful quantity to compare experiments obtained with different amplitudes and cantilevers. The validity of Eq. 6 is nicely demonstrated by the application of this equation to the frequency shift curves already presented in Fig. 3a. As shown in Fig. 3b all curves obtained for different amplitudes result into one universal γ-curve, which depends only on the actual tip-sample distance D.

These equations help to calculate the frequency shift for a given tip-sample interaction law. The inverse problem, however, is even more interesting: *How can the tip-sample interaction be determined from frequency shift data?* Several solutions to this question have been presented by various authors and have lead to the *dynamic force spectroscopy* (DFS) technique, which is a direct extension of the FM-AFM mode [12].

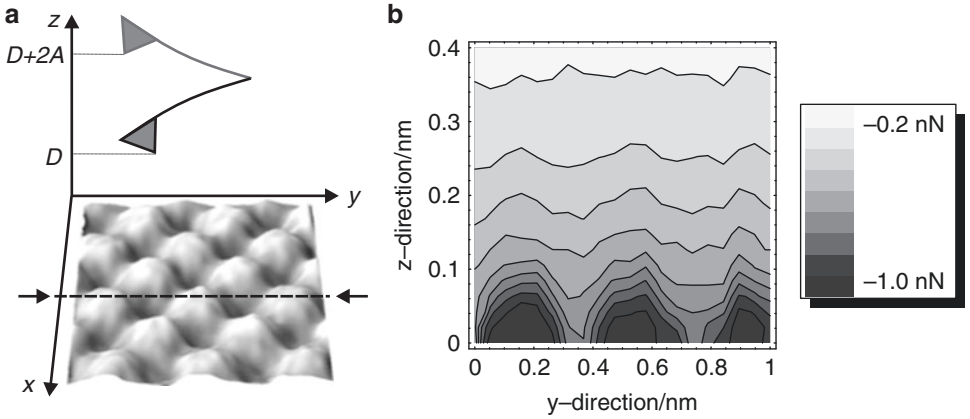
Here the approach of Dürig [11] is presented, which is based on the inversion of the integral Eq. 5. It can be transformed to

$$F_{ts}(D) = \sqrt{2} \frac{c_z A^{3/2}}{f_0} \frac{\partial}{\partial D} \int_D^{\infty} \frac{\Delta f(z)}{\sqrt{z-D}} dz, \tag{7}$$



which allows a direct calculation of the tip-sample interaction force from the frequency shift versus distance curves.

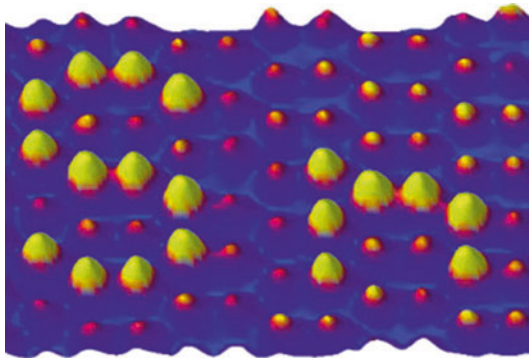
An application of this formula to the experimental frequency shift curves already presented in Fig. 3a is shown in Fig. 3c. The obtained force curves are nearly identical although obtained with different oscillation amplitudes. Since the tip-sample interactions can be measured with high resolution, dynamic force spectroscopy opens a direct way to compare experiments with theoretical models and predictions.



Applications of FM-AFM

The excitement about the NC-AFM technique in ultrahigh vacuum was driven by the first results of Giessibl [13] who achieved to image the true atomic structure of the Si(111)-7 × 7-surface with this technique in 1995. In the same year Sugawara et al. [14] observed the motion of single atomic defects on InP with true atomic resolution. However, imaging on conducting or semiconducting surfaces is also possible with the scanning tunneling microscope (STM) and these first NC-AFM images provided no new information on surface properties. The true potential of NC-AFM lies in the imaging of non-conducting surface with atomic precision. A long-standing question about the surface reconstruction of the technological relevant material Aluminium oxide could be answered by Barth et al. [15], who imaged the atomic structure of the high temperature phase of α-Al_2O_3(0001).

The high resolution capabilities of non-contact atomic force microscopy are nicely demonstrated



AFM, Noncontact Mode, Fig. 4 Imaging of a NiO(001) sample surface with a non-contact AFM. (**a**) Surface step and an atomic defect. The lateral distance between two atoms is 4.17 Å. (**b**) A dopant atom is imaged as a light protrusion about 0.1 Å higher as the other atoms (Images courtesy of W. Allers and S. Langkat, University of Hamburg; used with kind permission)

AFM, Noncontact Mode, Fig. 5 (**a**) Principle of 3D-force spectroscopy. The cantilever oscillates near the sample surface and measure the frequency shift in a x-y-z-box. The three dimensional surface shows the topography of the sample (image size: 10 Å × 10 Å) obtained immediately before the recording of the spectroscopy field. (**b**) The reconstructed force field of NiO(001) shows atomic resolution. The data is taken along the line shown in (**a**)

by the images shown in Fig. 4. Allers et al. [16] resolved atomic steps and defects with atomic resolution on Nickel oxide. Today such a resolution is routinely obtained by various research groups (for an overview see, e.g., Refs. [2–6]). Recent efforts have also been concentrated on the analysis of functional organic molecules, since in the field of nanoelectronics it is anticipated that in particular organic molecules will play an important role as the fundamental building blocks of nanoscale electronic device elements.

The concept of dynamic force spectroscopy can be also extended to 3D-force spectroscopy by mapping the complete force field above the sample surface [12]. Figure 5a shows a schematic of the measurement principle [17]. Frequency shift vs. distance curves are recorded on a matrix of points perpendicular to the sample surface. Using Eq. 7 the complete three-dimensional force field between tip and sample can be recovered with atomic resolution. Figure 5b shows a cut through the force field as a two-dimensional map.

AFM, Noncontact Mode, Fig. 6 Final topographic NC-AFM image of the process of rearranging single Sn-atoms on a Ge(111)-c(2 × 8) semiconductor surface at room temperature (Reproduced from [19])

If the NC-AFM is capable of measuring forces between single atoms with sub-nN precision, why should it not be possible to also exert forces with this technique? In fact, the new and exciting field of nanomanipulation would be driven to a whole new dimension, if defined forces can be reliably applied to single atoms or molecules. In this respect, Loppacher et al. [18] achieved to push on different parts of an isolated Cu-TBBP molecule, which is known to possess four rotatable legs. They measured the force-distance curves while one of the legs was pushed by the AFM tip and turned by 90°, thus being able to measure the energy which was dissipated during "switching" this molecule between different conformational states. The manipulation of single Sn-atoms with the NC-AFM was nicely demonstrated by Sugimoto et al. who manipulated single Sn-atoms on the Ge(111)-c(2 × 8) semiconductor surface (Fig. 6). By pushing single Sn-atoms from one lattice site to the other they finally succeeded to write the letter "Sn" with single atoms.

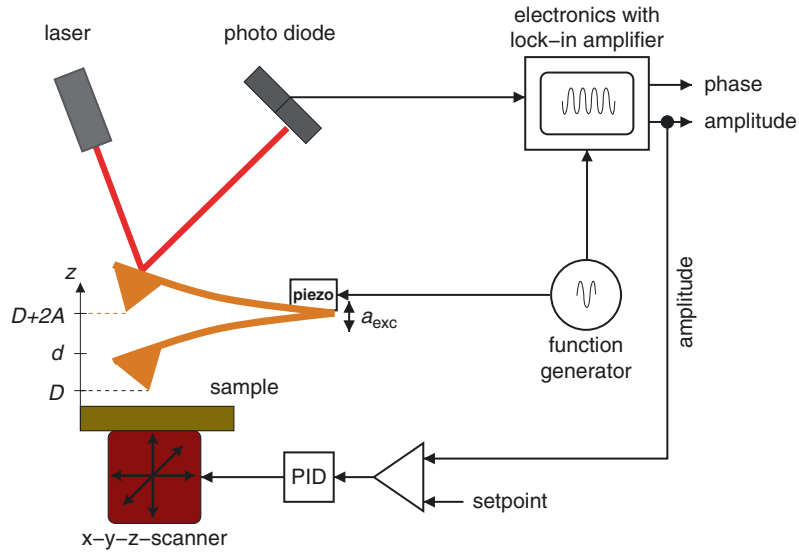
AFM, Tapping Mode

Hendrik Hölscher
Karlsruher Institut für Technologie (KIT), Institut für Mikrostrukturtechnik, Karlsruhe, Germany

Definition

The *tapping* or AM-mode is the most common dynamic mode used in atomic force microscopy. In dynamic mode AFM the cantilever is oscillated with (or near) its resonance frequency near the sample surface. Using a feedback electronic the cantilever sample distance is controlled by keeping either the amplitude or the phase of the oscillating cantilever constant. Since lateral tip–sample forces are avoided by this technique the resolution is typically higher compared to the classical contact mode AFM where tip and sample are in direct mechanical contact.

Overview



Since its introduction in 1986 [1], the *atomic force microscope* became a standard tool in nanotechnology. In early experimental setups, a sharp tip located at or near the end of a microstructured cantilever profiled the sample surface in direct mechanical contact (*contact mode*) to measure the force acting between tip and sample. Maps of constant tip–sample interaction force, which are usually regarded as representing the sample's "topography," were then recovered by keeping the deflection of the cantilever constant (▶ Friction Force Microscopy). This is achieved by means of a feedback loop that continuously adjusts the z-position of the sample during the scan process so that the output of the deflection sensor remains unchanged at a preselected set-point.

Despite the widespread success of contact mode AFM in various applications, the resolution was frequently found to be limited (in particular for soft samples) by lateral forces acting between tip and sample. In order to avoid this effect, it is advantageous to vibrate the cantilever in vertical direction near the sample surface. AFM imaging with an oscillating cantilever is often denoted as *dynamic force microscopy* (DFM) [2].

The cantilever dynamics are governed by the tip–sample interaction as well as by its driving method. For instance, the historically oldest scheme of cantilever excitation in DFM imaging is the external driving of the cantilever at a fixed excitation frequency chosen to be exactly at, or very close to, the cantilever's first resonance. For this driving mechanism, different detection schemes measuring either the change of the oscillation amplitude or the phase shift between driving signal and resulting cantilever motion were proposed. Over the years, the *amplitude modulation* (AM) or *tapping* mode, where the actual value of the oscillation amplitude is employed as a measure of the tip–sample distance, has been established as the most widely applied technique for ambient conditions and liquids.

Experimental Setup

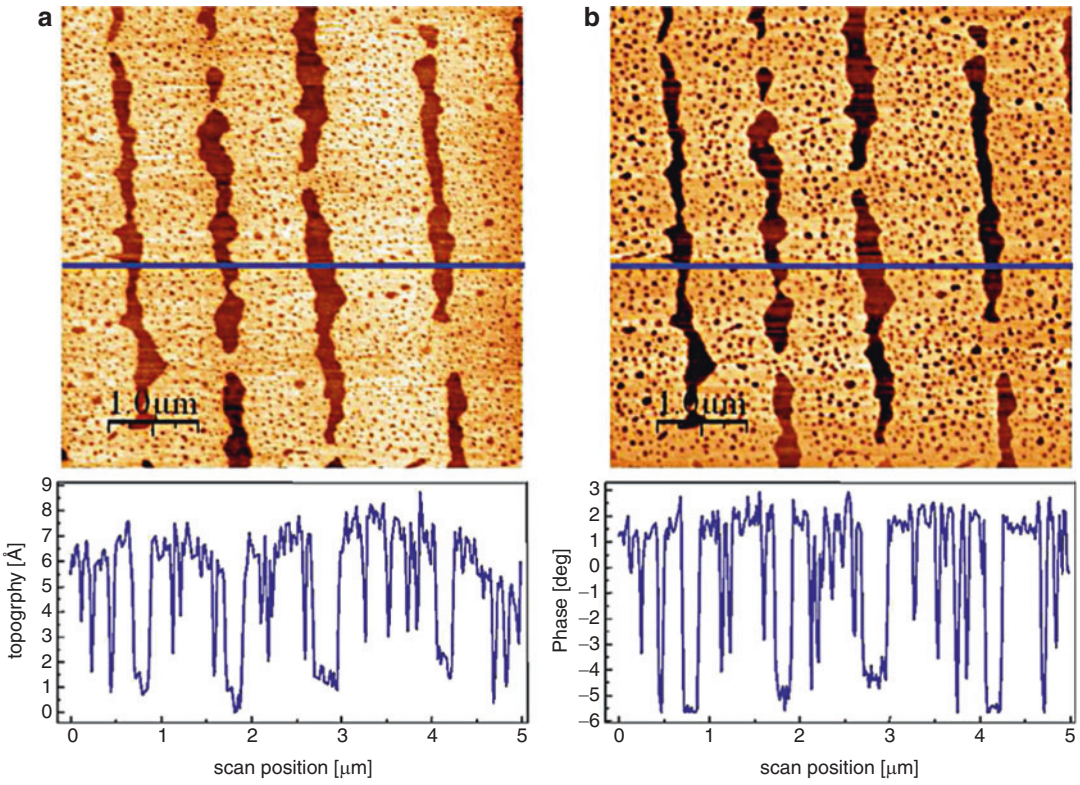
A schematic of the experimental setup of an atomic force microscope driven in amplitude modulation mode is shown in Fig. 1. In this mode the cantilever is vibrated close to its resonant frequency near the sample surface. Due to the tip–sample interaction the resonant frequency (and consequently also amplitude A and phase ϕ) of the cantilever changes with the cantilever sample distance d. Therefore, the amplitude as well as the phase can be used as feedback channels. A certain set-point for example, the amplitude is given, and the feedback loop will adjust the tip–sample distance such that the amplitude remains constant. The cantilever sample distance is recorded as a function of the lateral position of

AFM, Tapping Mode, Fig. 1 Setup of a dynamic force microscope operated in the tapping (or AM-) mode. A laser beam is deflected by the back side of the cantilever, and its deflection is detected by a split photo-diode. The cantilever vibration is caused by an external frequency generator driving an excitation piezo. A lock-in amplifier is used to compare the cantilever driving with its oscillation. The amplitude signal is held constant by a feedback loop controlling the cantilever sample distance

the tip with respect to the sample and the scanned height essentially represents the surface topography.

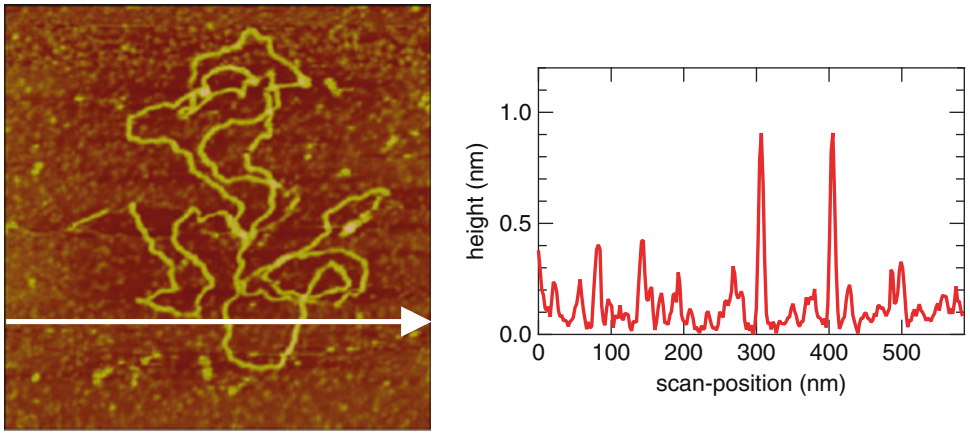
The deflection of the cantilever is typically measured with the laser beam deflection method. During operation in conventional tapping mode, the cantilever is driven with a fixed frequency and a constant excitation amplitude using an external function generator, while the resulting oscillation amplitude and/or the phase shift are detected by a lock-in amplifier. The function generator supplies not only the signal for the dither piezo; its signal serves simultaneously as a reference for the lock-in amplifier.

This setup is mostly used in air and in liquids. A typical image obtained with this experimental setup in ambient conditions is shown in Fig. 2. The phase between excitation and oscillation can be acquired as an additional channel and gives information about the different material properties of DPPC and the mica substrate. As shown at the end of the next section, the phase signal is closely related to the energy dissipated in the tip–sample contact.



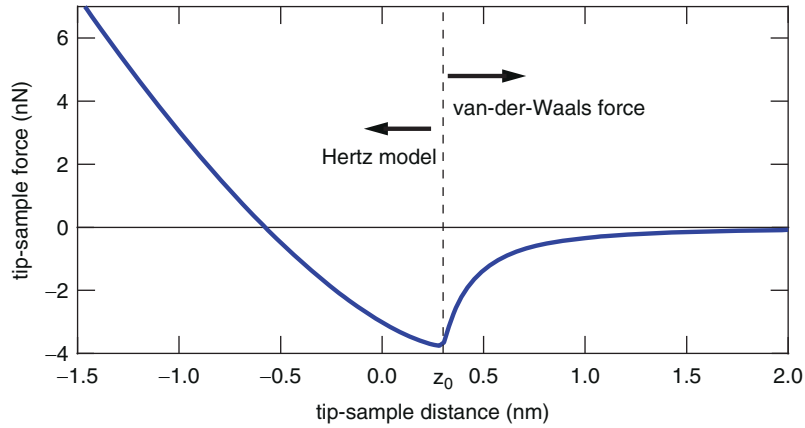
Due to its technical relevance the investigation of polymers has been the focus of many studies and high-resolution imaging has been extensively performed in the area of material science. Using specific tips with additionally grown sharp spikes Klinov et al. [3] obtained molecular resolution on a polydiacetylene crystal. Imaging in liquids opens up the avenue for the investigation of biological samples in their natural environment. For example, Möller et al. [4] have obtained high-resolution images of the topography of hexagonally packed intermediate (HPI) layer of *Deinococcus radiodurans* with tapping-mode AFM. A typical example for the imaging of DNA in liquid solution is shown in Fig. 3.

Theory of Tapping-Mode AFM



Many features observed in tapping-mode AFM can be described by a simple spring-mass model which includes the tip–sample interaction force.

$$m\ddot{z}(t) + \frac{2\pi f_0 m}{Q_0}\dot{z}(t) + c_z(z(t) - d) = \underbrace{a_d cz \cos(2\pi f_d t)}_{\text{external driving force}} + \underbrace{F_{ts}[z(t), \dot{z}(t)}_{\text{tip–sample force}}. \quad (1)$$



Here, $z(t)$ is the position of the tip at the time t; cz, m, and $f_0 = \sqrt{(c_z/m)}/(2\pi)$ are the spring constant, the effective mass, and the eigenfrequency of the cantilever, respectively. The quality factor Q_0 combines the intrinsic damping of the cantilever and all influences from surrounding media,

AFM, Tapping Mode, Fig. 2 (**a**) A dynamic force microscopy image of a monomolecular DPPC (l-α-dipalmitoyl-phophatidycholine) film adsorbed on mica. (**b**) The phase contrast is different between substrate and DPPC film. Equation 6 explains how this contrast is related to the energy dissipation caused by the tip–sample contact interaction

AFM, Tapping Mode, Fig. 3 Topography of DNA adsorbed on mica imaged in buffer solution by tapping mode AFM. The *right* graph shows a single scan line obtained at the position marked by an arrow in the *left* image

AFM, Tapping Mode, Fig. 4 Tip–sample model force after the DMT-M model for air Eq. 2 using the typical parameters: $A_H = 0.2$ aJ, $R = 10$ nm, $z_0 = 0.3$ nm, and $E^* = 1$ GPa. The *dashed line* marks the position z_0 where the tip touches the surface

such as air or liquid. The equilibrium position of the tip is denoted as d. The first term on the right-hand side of the equation represents the external driving force of the cantilever by the frequency generator. It is modulated with the constant excitation amplitude a_d at a fixed frequency f_d. The (nonlinear) tip–sample interaction force F_{ts} is introduced by the second term.

The actual tip–sample force is unknown in nearly all cases. However, in order to understand the most important effects it is often sufficient to apply the *DMT-M theory* [5]. In this approach it is assumed the tip is nearly spherical and that the noncontact forces are given by the long-range van-der-Waals forces while the contact forces are described by the well-known Hertz model. The resulting overall force law is given by

$$F_{\mathrm{DMT-M}}(z) = \begin{cases} -\dfrac{A_H R}{6z^2} & \text{for } z \geq z_0, \\ \dfrac{4}{3} E * \sqrt{R}(z_0 - z)^{3/2} & \text{for } z < z_0, \end{cases} \tag{2}$$

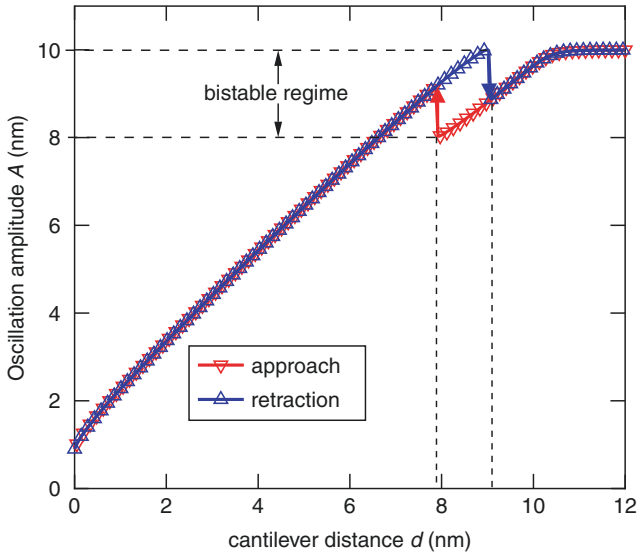
where AH is the Hamaker constant, E^* the effective modulus, and R the tip radius. At z_0 tip and sample come in contact. Figure 4 displays the resulting tip–sample force curve for this model.

For the analysis of dynamic force microscopy, experiments only on the steady states with sinusoidal cantilever oscillation are of interest. Consequently, the steady-state solution is given by the ansatz

$$z(t \gg 0) = d + A\ \cos(2\pi f_d t + \phi), \tag{3}$$

where ϕ is the phase difference between the excitation and the oscillation of the cantilever.

Here, the situation where the driving frequency is set *exactly* to the eigenfrequency of the cantilever ($f_d = f_0$) is analyzed. With this choice, which is also very common in actual DFM experiments, defined imaging conditions are given leading to a handy formula relationship between the free oscillation amplitude A_0, the actual amplitude A, and the equilibrium tip position d [6].



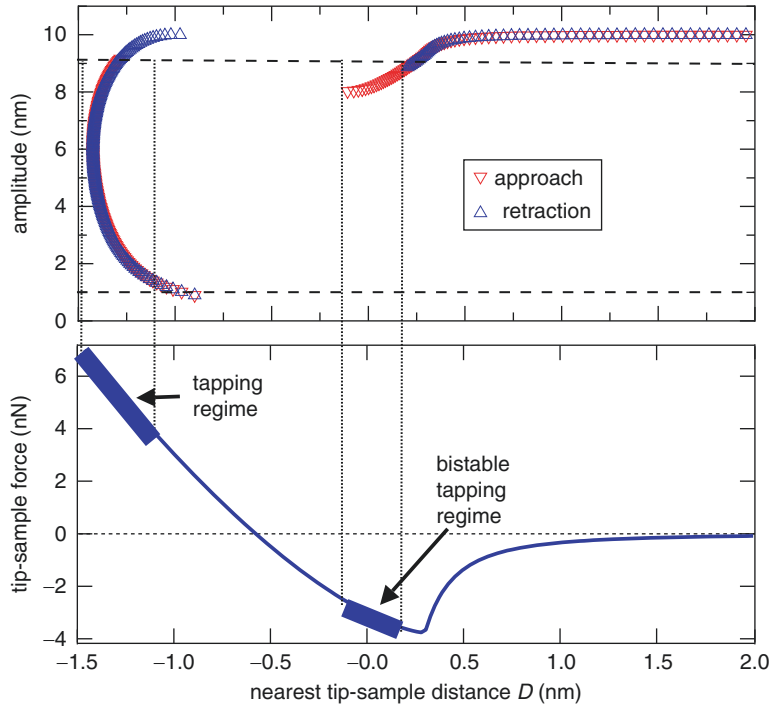
$$A_0 = A\sqrt{1 + (Q_0 I_+[d, A]^2}, \tag{4}$$

where

$$\begin{aligned} & I + (d, A) \\ &= \frac{2 f_d}{c_z A} \int_0^{1/f_d} F_{ts}[z(t), \dot{z}(t)] \cos(2\pi f_d t + \phi) dt \\ &= \frac{1}{p c_z A^2} \int_{d-A}^{d+A} (F_\downarrow + F_\uparrow) \frac{z - d}{\sqrt{A^2 - (z - d)^2}} dz. \end{aligned} \tag{5}$$

The function $I_+(d, A)$ depends on the actual oscillation amplitude A and cantilever–sample distance d and it is a weighted average of the tip–sample forces during approach and retraction ($F_\downarrow + F_\uparrow$).

The solution of this equation allows us to study amplitude versus distance curves as shown in Fig. 5 for a Q-factor of 300. Most noticeable, the



AFM, Tapping Mode, Fig. 5 Amplitude versus distance curve for tapping-mode AFM assuming the parameters $A_0 = 10$ nm, $f_0 = 300$ kHz, and the tip–sample interaction force shown in Fig. 4. The overall amplitude decreases the sample surface distance, but instabilities (indicated by *arrows*) occur during approach and retraction

tapping mode curve exhibits jumps between unstable branches, which occur at different locations for approach and retraction. The resulting bistable regime then causes a hysteresis between approach and retraction and divides the tip–sample interaction into two regimes. In order to identify the forces acting between tip and sample in these two regimes, the oscillation amplitude is plotted as a function of the nearest tip–sample distance in Fig. 6. In addition, the bottom graph depicts the corresponding tip–sample force (cf. Fig. 4). The origin of the nearest tip–sample position D is defined by this force curve. Since both, the amplitude curves and the tip–sample force curve, are plotted as a function of the nearest tip–sample position, it is possible to identify the resulting maximum tip–sample interaction force for a given oscillation amplitude.

During the approach of the vibrating cantilever toward the sample surface, there is discontinuity in the nearest tip–sample position D. This gap corresponds to the bi-stability and the resulting jumps in the amplitude versus distance curve. After the jump from the attractive to the repulsive regime has occurred, the amplitude decreases continuously. The nearest tip–sample position, however, does not reduce accordingly, remaining roughly between -0.8 and -1.5 nm. As a result, larger A/A_0 ratios do not necessarily result into lower tip–sample interactions, which is important to keep in mind while adjusting imaging parameters in tapping mode. For practical applications, it is reasonable to assume that the set-point of the amplitude used for imaging has been set to a value between 90 % and 10 % of the free oscillation amplitude. With this condition, one can identify the accessible imaging regimes indicated by the horizontal (dashed) lines and the corresponding vertical (dotted) lines. Therefore, in tapping mode, two imaging regimes are typically accessible: the *tapping regime* (left) and the *bistable tapping regime* (middle). The bistable imaging state is only accessible during approach. Imaging in this regime is indeed possible with the limitation that the oscillating cantilever might jump into the repulsive regime [7, 8].

In the above paragraphs, the influence of the tip–sample interaction on the cantilever oscillation was analyzed, the maximum tip–sample interaction forces based on the assumption of a specific model force was calculated, and subsequently possible routes for image optimization were discussed. However, in practical imaging, the tip–sample interaction is not a priori known. Therefore, several authors [9–14] suggested solutions to this inversion problem, but some of them need further technical equipment. However, most commercial systems give access to amplitude and

AFM, Tapping Mode, Fig. 6 A comparison between the maximum tip–sample forces (tip–sample forces acting at the point of closest tip–sample approach/nearest tip–sample position D) experienced by conventional "tapping mode" AM-AFM assuming the same parameters as in Fig. 5. The *upper* graph shows the nearest tip–sample position D versus the actual oscillation amplitude A for tapping mode. The graph at the *bottom* reveals the force regimes sensed by the tip. The maximal tip–sample forces in tapping mode are on the repulsive (tapping regime) as well as attractive (bistable tapping regime) part of the tip–sample force curve

phase versus distance data which already allows the reconstruction of the tip–sample force curve applying numerical procedures [11, 12, 14].

The energy dissipation caused by the tip–sample interaction can be easily calculated using the conservation of energy principle [15].

$$\Delta E = \left(\frac{1}{Q_0}\frac{f_d}{f_0} + \frac{a_\mathrm{d}}{A}\sin\phi\right)\pi c_z A^2. \qquad (6)$$

Since all parameters – except the phase ϕ – are constant during scanning, this formula shows that the energy dissipation is roughly proportional to $\sin\phi$ as already mentioned in the caption of Fig. 2.

Definition

Aluminum-based nano-adjuvants are insoluble aluminum salts used in human and animal vaccines for the effective stimulation of the immune system against infectious diseases.

Introduction

Vaccination remains one of the most effective tools to prevent infectious disease [1–3], and adjuvants based on aluminum salts are commonly

used in vaccines to provide an efficient and long-lasting protective immunity against infectious agents. In 1926, Glenny et al. demonstrated that injection of aluminum potassium sulfate with diphtheria toxoid could induce a stronger antibody response than soluble toxoid in guinea pigs [4]. Since then, aluminum-based adjuvants have been widely used in both human and veterinary vaccination against infectious diseases [5] and are being evaluated for immunotherapy against cancer. Aluminum-based adjuvants generally induce a strong Th2 immune response, with little or no Th1 immune response. While it is known that aluminum adjuvants tightly bind to antigens and provide slow release of antigens as a result of these materials' astringent characteristics, the specific mechanistic details of how the physicochemical properties of these materials lead to immunopotentiation has just begun to emerge [6].

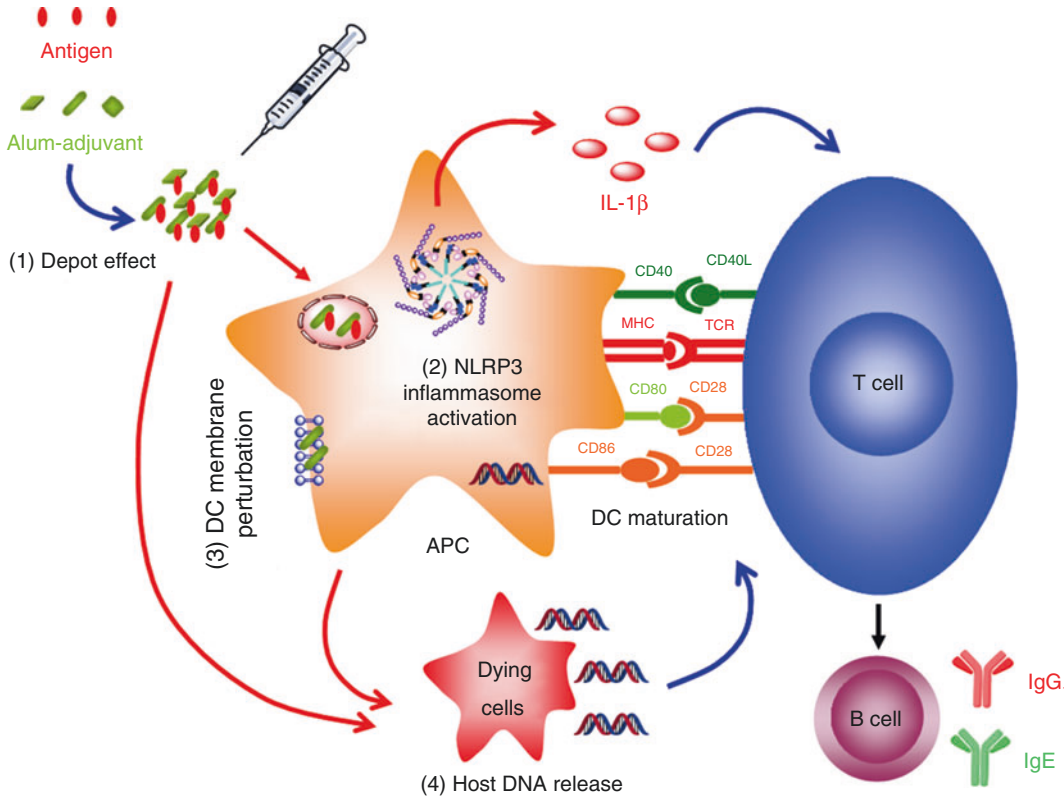
Aluminum-Based Nano-adjuvants in Licensed Vaccines

Aluminum-based vaccine adjuvants have been in routine use in human vaccination against various infectious diseases including DTaP (diphtheria, tetanus, acellular pertussis), human papillomavirus and penumococcal disease, hepatitis A, and hepatitis B for over 80 years (Table 1) [7]. Depending on the commercial source, they may be composed of aluminum hydroxide (Alhydrogel), aluminum phosphate (Adju-Phos), aluminum potassium sulfate (Alum), aluminum hydroxyphosphate sulfate (AHSA), or a mixture of aluminum and magnesium hydroxides (Imject Alum, commonly used for experimental and basic immunological studies) (Table 1) [5, 7, 8]. These commercially available aluminum salts have different physicochemical properties [6]. For example, aluminum hydroxides are needlelike particles with diameters of 2 nm, while aluminum phosphates are platelike particles with a primary size of 50 nm. However, their names sometimes do not correctly describe their adjuvant structures. X-ray diffraction analysis, energy-dispersive spectroscopy and infrared spectroscopy have identified aluminum hydroxide adjuvant as crystalline aluminum oxyhydroxide, AlOOH; and aluminum phosphate is determined as amorphous aluminum hydroxyphosphate, $Al(OH)_x(PO_4)_y$ [6]. The amount of aluminum adjuvants used in the currently licensed vaccines varies from 0.85 to 0.125 mg per dose in the USA, and a 1-year-old baby who receives a complete series of recommended vaccines may have 1.6–4.1 mg of aluminum [7]. Although there are concerns on the high dose of aluminum adjuvants in vaccines for human use, they have been showing a safe profile up to date [9].

Mechanisms of Aluminum-Based Nano-adjuvant-Induced Immune Responses

Despite of the wide usage for over 80 years as adjuvants in vaccines, the detailed mechanisms of how aluminum-based adjuvants enhance adaptive immunity and exert their adjuvant effect remain unclear, and several mechanisms are proposed (Fig. 1). Firstly, upon mixing, antigens may be retained at the injection site either by being adsorbed by the aluminum containing adjuvant or by being trapped in the void spaces within the adjuvant aggregates to form a local higher concentration of antigen, which could allow retaining and a slower release of antigen in the body for prolonged and effective stimulation of the immune system, an effect referred to as the "depot effect" [10]. However, the depot effect has been challenged, with the evidence showing that the excision of injection site did not interfere with the development of immune response [11]. Recently, it has been shown that aluminum adjuvants could activate the nucleotide binding and oligomerization, leucine-rich repeat, pyrin domain-containing 3 (NLRP3) inflammasome, and IL-1β production, which could explain its ability to induce local inflammation, recruitment of antigen-presenting cells (APCs), enhanced antigen uptake, dendritic cell (DC) maturation, and stimulation of T-cell activation and differentiation [12, 13]. However, there is disagreement about the necessity of this pro-inflammatory response pathway in generating adjuvant effects in vivo [14], with NLRP3-deficient mice

Aluminum-Based Nano-adjuvants, Table 1 Types of alum salts used in licensed vaccines [7, 8]



Vaccine (trade name)	Manufacturer	Type of aluminum salts
Anthrax (BioThrax)	Emergent BioSolutions, Inc.	Aluminum hydroxide
DT (Sanofi)	Sanofi Pasteur Limited	Aluminum potassium sulfate
DTaP (Daptacel)	Sanofi Pasteur Limited	Aluminum phosphate
DTaP-IPV (Kinrix)	GlaxoSmithKline Biologicals	Aluminum hydroxide
DTaP-HepB-IPV (PEDIARIX)	GlaxoSmithKline Biologicals	Aluminum hydroxide, aluminum phosphate
DTaP-IPV/Hib (Pentacel)	Sanofi Pasteur Limited	Aluminum phosphate
Hib (PedvaxHIB)	Merck & Co., Inc	Aluminum hydroxyphosphate sulfate
Hib/Hep B (Comvax)	Merck & Co., Inc	Aluminum potassium sulfate

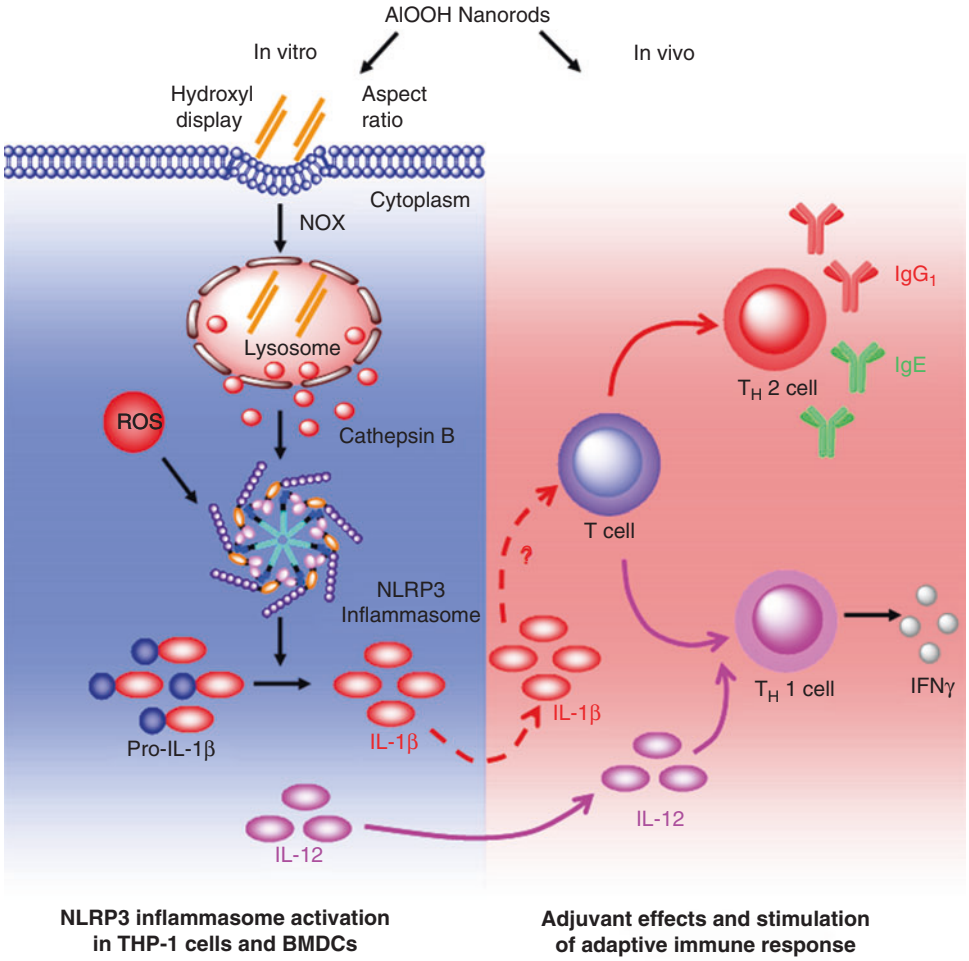
mounting a normal OVA-specific IgG_1 response [15]. Studies have demonstrated that aluminum hydroxide could induce cytotoxicity and host DNA release at sites of immunization [16, 17], which mediate the adjuvant effect for Th2-biased adaptive immune responses (Fig. 1). In addition, it has been shown that aluminum adjuvants are able to perturb the DC membrane as a way of providing immune stimulation [18]. One possible reason for these discrepancies is the existence of different adjuvant mechanisms by which aluminum adjuvants boost in vivo immune responses. Also, different types and/or structures of aluminum adjuvants were used in these studies. An adjuvant with rigorously controlled structure is needed to address the controversy regarding the mechanisms of the adjuvants' immunopotentiating effects in vivo.



Engineered AlOOH Nanorods as Vaccine Adjuvants

A recent study sheds light on the detailed mechanism of aluminum adjuvant-induced immune responses using engineered aluminum oxyhydroxide (γ-AlOOH, boehmite) nanoparticles [19]. In this study, AlOOH nanoparticles were synthesized with precisely controlled shape, crystallinity, and hydroxyl content, which have been shown to play important roles in the induction of immune responses.

Aluminum-Based Nano-adjuvants, Fig. 1 Mechanisms of aluminum-based nano-adjuvant-induced immune responses, including (*1*) the depot effect, (*2*) NLRP3 inflammasome activation, (*3*) DC membrane perturbation, and (*4*) host DNA release, which promote DC maturation and enhance adaptive immune responses

AlOOH nanorods with higher hydroxyl contents lead to increased reactive oxygen species (ROS) generation that induced stronger NLRP3 inflammasome activation and IL-1β production compared to polyhedron- and plate-shaped particles as well as commercial Imject Alum in both THP-1 macrophages and bone marrow-derived dendritic cells (BMDCs) in vitro (Fig. 2) [19]. Interestingly, AlOOH nanorods were also able to induce the maturation of BMDCs as indicated by the expression of surface maturation markers including MHC II, CD80, and CD86. The in vitro results were corroborated by in vivo studies using ovalbumin (OVA) as a model antigen. It was shown that vaccination with AlOOH nanorods bounded with OVA exhibited higher antibody production including OVA-specific IgG_1 and IgE in mice compared to commercial Imject Alum. Adoptive transfer was also conducted to confirm the role of DCs in which ex vivo activation of BMDC by AlOOH nanorods could induce a stronger adjuvant effect than Alum in intact animals. It is interesting to note that in addition to the boosting of IL-1β production, AlOOH nanorods could also increase IL-12 production in BMDCs, which suggests that it is possible to induce Th1 cytotoxic immune responses including the generation of CD4- and CD8-positive T cells and the production of IFN-γ by these particles (Fig. 2) [19]. These results show that the engineered design of aluminum adjuvants in combination with property-activity analysis can be used to design more potent aluminum-based adjuvants to induce strong Th2 and potential Th1 immune responses. In addition, it is possible to use AlOOH nanorods as reference

Aluminum-Based Nano-adjuvants, Fig. 2 Engineered AlOOH nanorods as vaccine adjuvants

materials to study whether the paradoxical outcomes in different mechanistic studies could be due to the differences in the physicochemical properties of various aluminum-based materials that were used previously.

Future Directions

Aluminum vaccine adjuvants can generally induce strong Th2 immune responses with little or no Th1 immunity. However, Th1 cytotoxic responses are needed for clearance of viral infections and tumor cells. To achieve the goal of activating Th1 responses, additional stimuli including Toll-like receptor (TLR) agonists are needed. Triggering of certain TLRs (e.g., TLR4, 7, and 9) could stimulate the production of cytokines/chemokines and type I interferons (IFNs) that promote the immune system to activate Th1 responses to eliminate exogenous pathogens. Clinical trials involving individual TLRs suggest that TLR ligands can be safe and effective vaccine adjuvants, with vaccines already licensed in the USA and Europe containing such ligands [20]. Therefore, using engineered nanoparticles including AlOOH nanorods together with TLR agonists, it is possible to develop combinatorial

vaccine adjuvants to direct the T-cell differentiation toward Th1 cytotoxic responses for more effective prevention of infectious diseases and treatment of cancer in clinics.

Anchor Loss in MEMS/NEMS

Zhili Hao

Clamping loss; Support loss

Definition

Anchor loss is part of vibration energy in a MEMS/NEMS resonator that is dissipated through its anchor/anchors.

Background

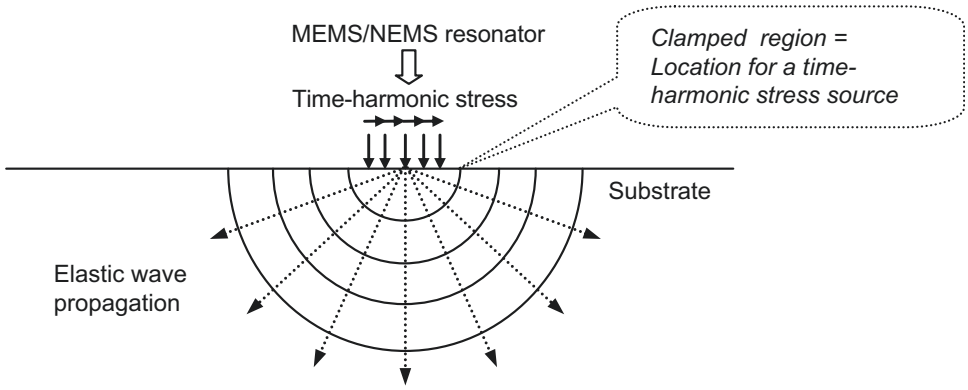
Generally speaking, a MEMS/NEMS resonator is comprised of two fundamental elements: a micro/nano-mechanical structure and its integrated transducers for converting a mechanical signal to an electrical one or vice versa. Electrostatic transducers and piezoelectric transducers are the two types of transducers commonly employed for MEMS/NEMS resonators. In most cases, anchor loss is of great concern to a resonator with electrostatic transducers and thus needs to be examined. In contrast, interfacial damping is significant in a resonator with piezoelectric transducers, while its anchor loss is not a concern. Therefore, only anchor loss in a resonator with electrostatic transducers is examined here.

The mechanical behavior of a MEMS/NEMS resonator can be described by the second-order mechanical system. By operating a MEMS/NEMS resonator in one of its vibration modes, many functions have been realized, including sensing acceleration and rotation rate [1], processing wireless signals, and serving as a time/frequency keeper [2, 3]. From the mechanical design perspective, two key design parameters for a MEMS/NEMS resonator are the resonant frequency and the mechanical quality factor (Q). While the resonant frequency is application dependent, a high Q is highly desirable in most cases, simply because a high Q in these resonators directly translates to high performance of the final resonator products, including high sensitivities, better bias stability, and improved frequency selectivity.

Owing to its small size, it is feasible to package a MEMS/NEMS resonator in vacuum and thereby eliminate air damping. Then, anchor loss, thermoelastic damping (TED), and surface loss come to the fore and determine the Q of a resonator. The overall measured Q of a resonator operating in vacuum is given by [4]:

$$\frac{1}{Q_{\text{measured}}} \cong \frac{1}{Q_{\text{anchor}}} + \frac{1}{Q_{\text{TED}}} + \frac{1}{Q_{\text{surface}}} \tag{1}$$

Physical Mechanism



In a MEMS/NEMS resonator, its micro/nano-mechanical structure is fixed on a substrate. During its vibrations, the structure exerts a time-harmonic stress on the substrate through its clamped region (Fig. 1). Acting as an excitation source, this time-harmonic stress will excite elastic waves propagating into the substrate. Part of the vibration energy of the structure, which is dissipated through elastic wave propagation into the substrate, is commonly referred to as anchor loss [5–7]. Then, the Q related to anchor loss of a resonator is defined as:

$$Q_{\text{anchor}} = 2\pi \frac{W}{\Delta W_{\text{anchor}}} \tag{2}$$

where ΔW_{anchor} denotes the energy dissipated through the anchor per cycle of vibration and W denotes the maximum vibration energy stored per cycle of vibration in a resonator.

Theory

Anchor loss involves both the micro/nano-mechanical structure and the substrate, with the

Anchor Loss in MEMS/NEMS, Fig. 1 Physical mechanism of anchor loss in a MEMS/NEMS resonator – elastic wave propagation in the substrate with the clamped region as the excitation source [5]

latter being extremely large in relation to the former. Thus, the difficulty in calculating anchor loss lies in the fact that unlike the micro/nano-mechanical structure, the substrate is virtually a semi-infinite medium and cannot be easily incorporated into finite element analysis (FEA) software [5]. In order to calculate anchor loss in a resonator at the design stage, numerical algorithms have been developed that tackle the semi-infinite geometry of the substrate. However, such numerical algorithms are not only extremely computationally intensive but also not efficient at providing insights on how anchor loss is affected by resonator design parameters so as to modify a resonator design for achieving a higher Q. With the goal of providing the reader with the general concept of how anchor loss is calculated, the related theoretical analysis is described here.

To gain insights on how anchor loss in a resonator varies with resonator design parameters, a separation-and-transfer method has been developed to calculate anchor loss [5–7]. The two fundamental assumptions underlying this method are given below:

1. There is negligible interference between the elastic vibrations in a resonator and the elastic wave propagation in its substrate.
2. All the vibration energy of a resonator entering the substrate is not returned to the resonator (i.e., no reflection from the substrate boundaries) and therefore is considered to be lost.

Accordingly, the micro/nano-mechanical structure and the substrate are separated first, and then the time-harmonic stress from the structure is transferred to the substrate for elastic wave excitation through the clamped region. Thus, anchor loss is formulated as the integral of the product of the time-harmonic stress from the structure and the time-harmonic displacement on the substrate, across the clamped region over one cycle of vibration:

$$\Delta W_{\text{anchor}} = \pi \cdot \int_{\text{clamped region}} \text{stress} \times \text{displacement} \tag{3}$$

where π is due to the time-harmonic nature of vibrations; stress and displacement represent the amplitudes of the two time-harmonic parameters. To calculate anchor loss in a resonator, one needs to calculate the time-harmonic stress at the clamped region and the time-harmonic displacement on the substrate across the clamped region. Once the ΔW_{anchor} is known, the Q_{anchor} can be obtained using Eq. 2.

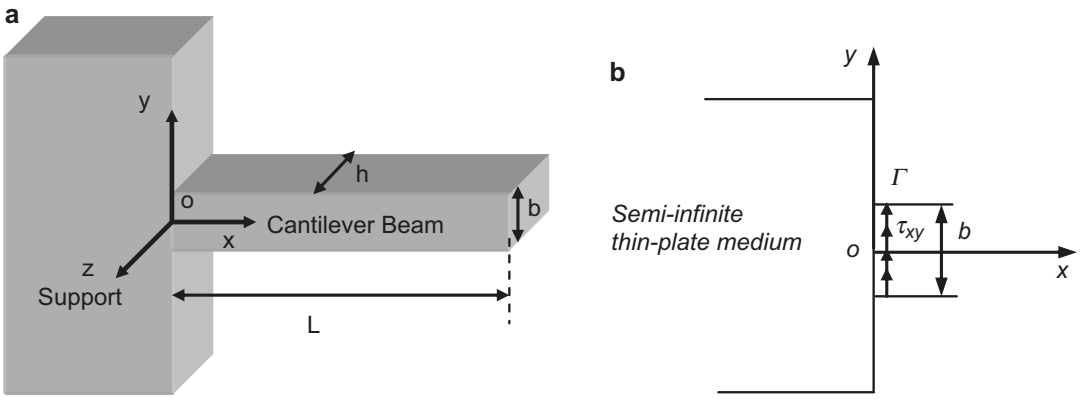
Based on the first assumption, the classic vibration theory can be utilized to describe the elastic vibrations in a resonator, where the clamped region has zero displacement but suffers from a time-harmonic stress. As to a resonator taking a regular geometry, a closed-form expression for the time-harmonic stress at the clamped region can be obtained, as well as the maximum vibration

energy stored in the resonator. In contrast, as to a resonator taking an irregular geometry, FEA software is needed to obtain the time-harmonic stress at the clamped region and the maximum vibration energy stored in the resonator. The second assumption translates to treating the substrate as a semi-infinite medium. Then, one can utilize the large body of literature on the investigation of the time-harmonic displacement on a semi-infinite or infinite elastic medium [8], which were originally developed for other applications (e.g., earthquake and acoustic emission) over the past century, to find out the time-harmonic displacement on the substrate, corresponding to the time-harmonic stress from the vibrations of a resonator. To illustrate how anchor loss is calculated using the separation-and-transfer method, an example on anchor loss in a cantilever beam resonator is given below [5].

Analytical Model of Anchor Loss in a Cantilever Beam Resonator

A cantilever beam resonator is fixed at one end (Fig. 2a). The length, width, and thickness of the resonator are denoted by L, b, and h, respectively. It operates in one of its in-plane (x-y plane) flexural modes. It is assumed that the dimensions of the substrate in the x-y plane are much larger than those of the beam resonator. For simplicity, it is also assumed that both the beam and the substrate are made of the same isotropic and homogeneous material. The in-plane flexural vibrations of the beam resonator are governed by the following equation:

$$\frac{\partial^4 y}{\partial x^4} = -\frac{\rho \cdot S}{E \cdot I} \cdot \frac{\partial^2 y}{\partial t^2} \tag{4}$$



where E and ρ denote Young's modulus and density of the beam; I and S are the moment of inertia and cross-section area of the beam, respectively. When this beam resonator undergoes time-harmonic vibrations, one can assume:

$$y(x,t) = Y(x) \cdot e^{-\omega \cdot t} \tag{5}$$

where ω denotes the angular frequency of the vibrations. The angular frequency, ω, of the beam resonator is:

$$\omega = \frac{\pi^2 \cdot \beta^2}{L^2} \cdot \sqrt{\frac{E \cdot I}{\rho \cdot S}} \tag{6}$$

where β is the mode constant. The vibration mode shape of the resonator is:

Anchor Loss in MEMS/NEMS, Fig. 2 (**a**) Schematic of a cantilever beam resonator [6]; (**b**) the semi-infinite thin-plate medium of thickness, h, subjected to a time-harmonic shear stress from the cantilever beam resonator [5] (drawn out of proportion for clear illustration)

$$Y(x) = \frac{U}{2}\left\{\cosh\left(\beta\pi \cdot \frac{x}{L}\right) - \cos\left(\beta\pi \cdot \frac{x}{L}\right) + \chi \cdot \left(\sinh\left(\beta\pi \cdot \frac{x}{L}\right) - \sin\left(\beta\pi \cdot \frac{x}{L}\right)\right)\right\} \tag{7}$$

where $U/2$ denotes the vibration amplitude and χ denotes the mode shape factor.

Accordingly, the stored maximum vibration energy in the resonator can be expressed as:

$$W = \frac{1}{8}\rho \cdot S \cdot L \cdot \omega^2 \cdot U^2 \tag{8}$$

Through its clamped end, this beam resonator exerts a vibrating shear force, Γ, on its substrate over the clamped region, $x = 0, |y| \le b/2$ (Fig. 2b):

$$\Gamma = E \cdot I \cdot U \cdot \left\{\frac{\pi \cdot \beta}{L}\right\}^3 \cdot \chi \tag{9}$$

This shear force is assumed to be uniformly distributed across the clamped region, acting as a source to excite elastic waves propagating into the substrate. Hence, the excitation shear stress source, τ_{xy}, at the clamped end becomes:

$$\tau_{xy} = \frac{\Gamma}{b \cdot h}, \ |y| \le b/2; \ \tau = 0, \ |y| > b/2 \tag{10}$$

The substrate is treated as a semi-infinite thin-plate medium of thickness, h, and the elastic waves, excited by the shear stress source, are governed by the 2D in-plane elastic wave equations:

$$\frac{\partial^2 u_x}{\partial t^2} = c_L^2 \cdot \frac{\partial^2 u_x}{\partial x^2} + c_T^2 \cdot \frac{\partial^2 u_x}{\partial y^2} + \left(c_L^2 - c_T^2\right) \cdot \frac{\partial^2 u_y}{\partial x \partial y} \tag{11a}$$

$$\frac{\partial^2 u_y}{\partial t^2} = c_L^2 \cdot \frac{\partial^2 u_y}{\partial y^2} + c_T^2 \cdot \frac{\partial^2 u_y}{\partial x^2} + \left(c_L^2 - c_T^2\right) \cdot \frac{\partial^2 u_x}{\partial x \partial y} \tag{11b}$$

where u_x and u_y are the displacements along the x-axis and y-axis, respectively. The propagation velocities for longitudinal (c_L) and transverse waves (c_T) are given by:

$$c_L^2 = \frac{E}{\rho \cdot (1 - \upsilon^2)}, \ c_T^2 = \frac{E}{2\rho \cdot (1 + \upsilon)} \tag{12}$$

The Poisson's ratio of the thin plate is denoted by υ. The shear stress source, Eq. 10, serves as the boundary condition for the two governing equations, Eq. 11. Through the related mathematical manipulations on Eqs. 10 and 11, the average displacement amplitude along the y-axis (shear stress direction) over the clamped region can be obtained:

$$\begin{aligned} v_{x=0,|y|\le b/2} &= \frac{4 \cdot b \cdot \tau}{\pi \cdot E} \cdot \frac{1+\upsilon}{1-\upsilon} \cdot \Psi \text{ with } \Psi \\ &= \int_0^\infty \frac{\sqrt{\zeta^2 - (c_L/c_T)^2}}{\left\{2\zeta^2 - (c_L/c_T)^2\right\}^2 - 4\zeta^2 \cdot \sqrt{\zeta^2 - (c_L/c_T)^2} \cdot \sqrt{\zeta^2 - 1}} \cdot d\zeta \end{aligned} \tag{13}$$

where $\zeta = \xi c_L/\omega$, with ξ being the variable of the Fourier transform. The imaginary part of the integral of (13) contributes to anchor loss and is numerically calculated to be 0.336 (assuming $\upsilon = 0.28$).

After the average displacement amplitude incurred by the shear stress over the clamped region is determined, the amount of energy loss per cycle from the anchor of the beam resonator can be explicitly calculated as:

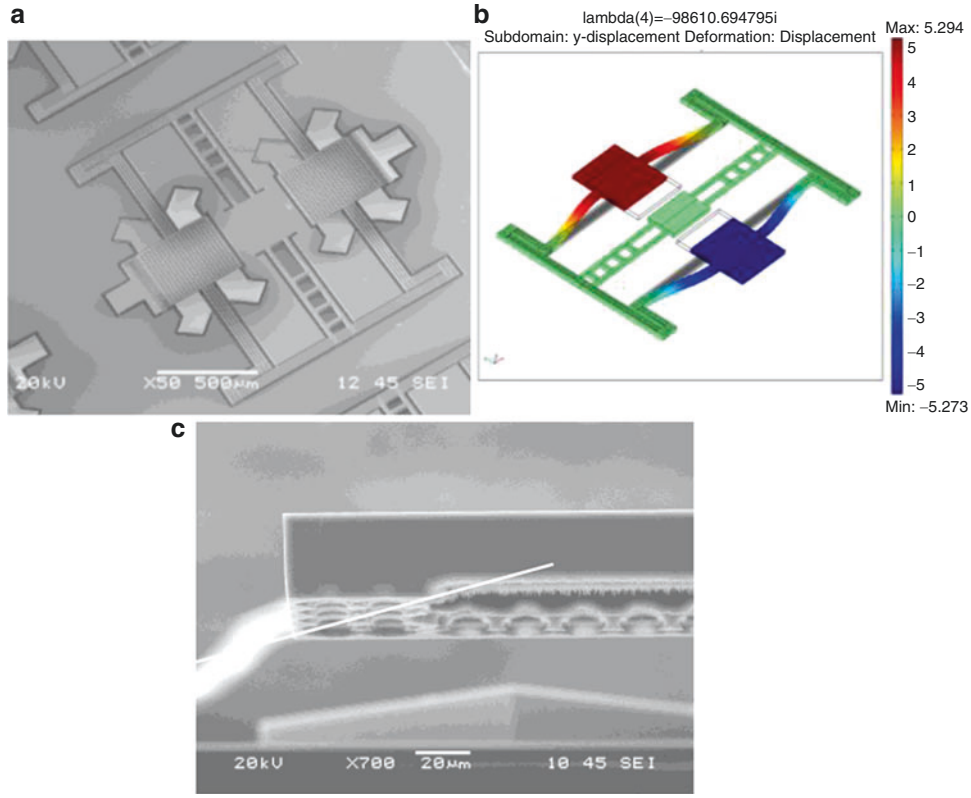
$$\Delta W_{\text{anchor}} = \pi \cdot \Gamma \cdot v_{x=0,|y|\le b/2} \tag{14}$$

By combining Eqs. 2, 8, and 14 a closed-form expression for the Q_{anchor} of a cantilever beam resonator is obtained:

$$Q_{\text{anchor}} = \left[\frac{0.24 \cdot (1-\upsilon)}{(1+\upsilon)\cdot \Psi}\right] \cdot \frac{1}{(\beta \cdot \chi)^2} \cdot \left[\frac{L}{b}\right]^3 \quad (15)$$

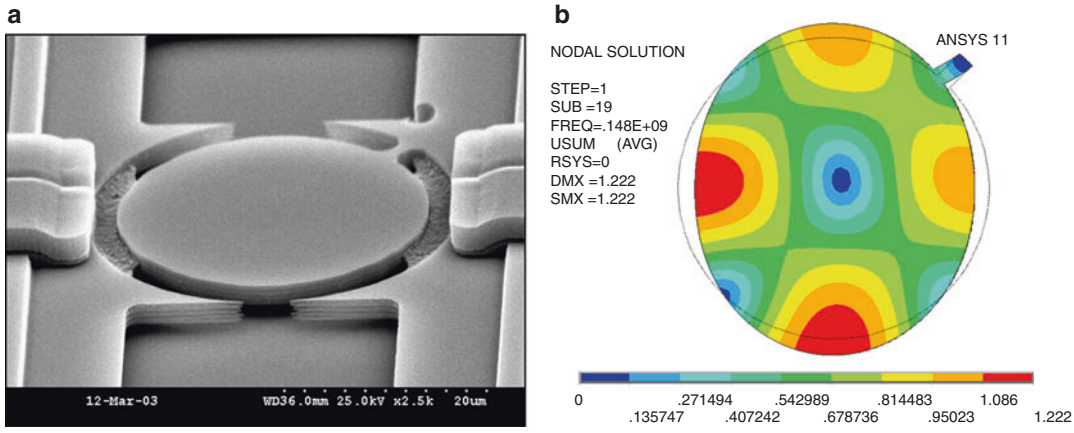
This expression clearly relates the Q_{anchor} of a cantilever beam resonator to its design parameters, indicating that a high ratio of length/width yields a high Q_{anchor}. Finally, it is worth mentioning that closed-form expressions for the time-harmonic displacement on different substrate configurations of MEMS/NEMS resonators under varying time-harmonic stress sources are available in the literature [5, 8].

Sometimes, a resonator, such as a tuning-fork gyroscope [1], is relatively large, and then the substrate cannot be effectively treated as a semi-infinite medium. Meanwhile, depending on how the substrate is mounted on its surroundings, its boundaries may reflect part of dissipated vibration energy into the resonator. Furthermore, the fabrication technology employed could severely affect how a resonator is fixed on a substrate through its anchor/anchors [9] and vary the time-harmonic stress at its anchor/anchors [10] and thus plays a critical role in determining anchor loss. As such, a theoretically calculated Q_{anchor} is perhaps best suited for providing the design guidelines for improving the Q_{anchor} of a resonator, rather than accurately estimating its value.



Key Research Findings

While surface loss is not much relevant to a resonator design, both anchor loss and TED can vary dramatically with a resonator design [6]. Thus, at the resonator design stage, both anchor loss and TED need to be examined for achieving a high Q. Different from anchor loss, TED is confined within a resonator and thus imposes the fundamental limit on the achievable Q of a resonator. As compared with anchor loss, TED is relatively easy to calculate with great accuracy in FEA software [11], in the sense that fabrication variations do not affect the calculated Q_{TED} in a resonator as much as the calculated Q_{anchor}. Accumulated from the analytical and experimental studies on both TED and anchor loss, the following two conclusions have been well established:



1. As to a resonator operating in one of its bulk modes, anchor loss is the sole dominant loss, while TED is completely negligible.
2. As to a resonator operating in one of its flexural modes, both anchor loss and TED could be dominant losses, depending on the resonator design and fabrication variations.

According to the theory of anchor loss, the essence for improving the Q_{anchor} of a resonator is to minimize the reaction force (or time-harmonic stress) at the clamped region of a resonator and minimize the displacement on the substrate across the clamped region. It is worth mentioning that the displacement on the substrate is caused by the reaction force and thus is proportional to the reaction force. Then, reducing the reaction force at the clamped region will coincidently reduce the displacement on the substrate.

To minimize the reaction force in a resonator, two common strategies are (1) to design a symmetrical mechanical structure operating in a vibration mode that is symmetric to its anchor and (2) to fix a resonator to one of its resonant nodes through a slim support beam. An example of the first strategy is a multiple-beam tuning-fork gyroscope (Fig. 3). In this gyroscope, a symmetric multiple-beam tuning-fork structure is fixed at its center and one of its operation modes is symmetric to the anchor. An example of the second strategy is a disk resonator operating in its elliptic bulk mode (Fig. 4) [12, 13]. In theory, a resonant node is a point with no dimension, and thus a support beam should be designed as slim as possible. Meanwhile, care needs to be taken to ensure that adding a support beam does not affect the operation mode of the main structure (disk). To minimize the displacement on the substrate across the anchor region, one strategy is to use a substrate with a higher elasticity so that a reaction force of the same amplitude gives rise to a smaller displacement on the substrate. Alternatively, using a

Anchor Loss in MEMS/NEMS, Fig. 3 (**a**) Scanning electron microscope (*SEM*) picture of a multiple-beam tuning-fork gyroscope [9]; (**b**) one of the operation modes of the gyroscope symmetric to its anchor [9].(**c**) SEM picture of the multiple-beam tuning-fork structure undermined by fabrication variations [9]

Anchor Loss in MEMS/NEMS, Fig. 4 (**a**) SEM picture of a disk resonator [13]; (**b**) the elliptic bulk mode of the disk resonator fixed at one of its resonant nodes through a slim support beam to the substrate [12]

material with high elasticity for a resonator will increase the maximum vibration energy in the resonator and consequently increase the Q_{anchor}, although not necessarily reducing anchor loss [14].

Although the abovementioned design strategies for improving the Q_{anchor} have been well established, practical obstacles for implementing them arise mainly from the fabrication technologies employed to produce MEMS/NEMS resonators. For instance, the multiple-beam tuning-fork structure can be designed with a perfect symmetric structure, but unavoidable fabrication variations render a fabricated gyroscope with a non-perfect symmetric structure (Fig. 3). Such a non-perfect symmetric structure gives rise to a relatively large reaction force at the anchor and consequently a relatively low Q_{anchor}. Moreover, fabrication variations vary with individual resonators of identical design and made from the same fabrication run. When anchor loss is a dominant loss in a resonator, the measured Qs of these individual resonators can vary dramatically. Thus, for those resonators with anchor loss being a dominant loss, fabrication technologies employed play a critical role in determining their ultimate Q, which might be quite different from the calculated value. Although electrostatic tuning has been introduced for compensating for the unsymmetry in a fabricated structure, implementing this compensation strategy has proven to be extremely challenging. Similarly, owing to fabrication variations, a support beam is not perfectly located at a resonant node, yielding a relatively large reaction force. Silicon is a commonly used building material for a resonator and its substrate, owing to its low cost and mature fabrication technologies. Replacing silicon with other materials, such as diamond, would lead to high cost of final resonator products. As such, minimizing the reaction force of a resonator is perhaps the most cost-effective and practical strategy to improve the Q_{anchor} of a MEMS/NEMS resonator.

Future Directions of the Field

Currently, the physical mechanism of anchor loss is well understood and the strategies for improving the Q_{anchor} of a MEMS/NEMS resonator are well established. The main research focus has so far been on fabrication technology development for reducing fabrication variations among fabricated MEMS/NEMS resonators so as to reduce performance variations and the Q_{anchor} variations among them and replacing silicon with other desirable materials for increasing the Q_{anchor} of MEMS/NEMS resonators.

Definition

Originally, the term "angiogenesis" was strictly confined to describe the sprouting of blood vessels from preexisting capillaries or post-capillary venules. Presently, angiogenesis refers to the molecular and cellular mechanisms leading to the formation and remodeling of vascular tree occurring during embryo development and in adult life. However, this term often includes the concept of vasculogenesis. Vasculogenesis indicates the earlier events of the formation of the cardiovascular system and is characterized by the assembly of a primitive vascular plexus constituted by angioblasts, which are believed to arise from the hemangioblast, a common precursor for endothelial and hematopoietic lineages.

There are two other general concepts that strictly parallel angiogenesis. The first is arteriogenesis, which describes the growth of functional collateral arteries from preexisting arterio-arteriolar anastomoses in response to ischemic injuries. The second is lymphangiogenesis, which illustrates the formation of the lymphatic system. This forms a unidirectional network of blind-ended terminal lymphatic vessels that collect the protein-rich fluid that exudes from blood capillaries and then drain through a conduit system of collecting vessels, lymph nodes, lymphatic trunks and ducts into the venous circulation.

Introduction

The notion that blood circulation is indispensable for bringing nutrients to the organs and for organism growth has been known for millennia. However, the connected concept – that growth of blood vessels may promote disease – is more recent [1, 2].

The perception that tumor growth is linked to an increased vascularization took place in the mid-twentieth century. In 1971, Judah Folkman gave the first formal demonstration that tumors release soluble molecules able to recruit from surrounding tissue capillaries, which enable cancer to growth over few millions of cells, infiltrate the normal parenchyma, and colonize distant organs. These observations opened an extraordinary research area that is far to be completely exploited and is at the frontier of the molecular medicine. The greatest achievement of these studies has been made over the past years in targeting angiogenesis for human therapy. In particular, in the 2004 vascular-endothelial growth factor (VEGF)-A removal by the humanized monoclonal antibody bevacizumab and by the specific aptamer pegaptanib was, respectively, approved for the treatment of metastatic colorectal cancer and exudative retinopathy [3]. Currently more than 50 anti-angiogenic compounds are in clinical trials. However, clinical experience has shown that the antivascular effect of bevacizumab as well as of other anti-angiogenic compounds are often transient or even negligible [4, 5], indicating that new knowledge is required to better understand the complexity of vascular formation and to properly select responder patients.

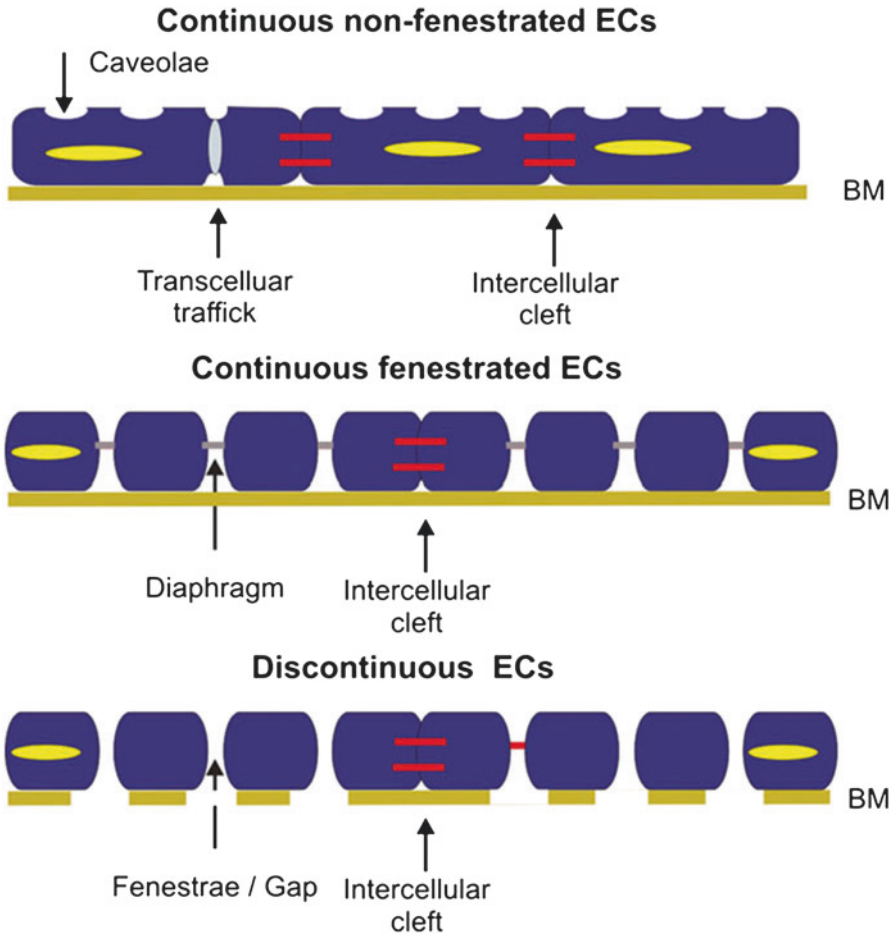
Nevertheless the impact of angiogenesis in medicine overcomes oncology and is extended to other relevant pathologies including ischemic diseases, chronic inflammatory diseases,

Angiogenesis, Table 1 Human diseases characterized by abnormal vascularization

Organs	Diseases
Whole body	Cancer, autoimmune diseases, ischemic diseases, diabetes, infections
Vessels	Vascular malformations, cavernous hemangiomas, hemangiomas, atherosclerosis, hereditary hemorrhagic telangiectasia, Di George syndrome, glomerulonephritis, transplant arteriopathy
Adipose tissue	Obesity
Skin	Psoriasis, warts, blistering disease, allergic dermatitis, scar keloid, pyogenic granulomas
Eye	Persistent hyperplastic vitreous syndrome, Norrin disease, exudative retinopathy, retinopathy of prematurity
Lung	Primary pulmonary hypertension, asthma, nasal polyps
Intestines	Inflammatory bowel disease, ascites, periodontal diseases
Reproductive system	Endometriosis, ovarian cysts, ovarian hyperstimulation
Bone, joints	Arthritis, synovitis, osteomyelitis, osteophyte formation

metabolic disorders, obesity, some mendelian inherited diseases, reproductive disorders, and bone diseases (Table 1).

The Morpho-Functional Vascular Unit



Arteries, veins, and capillaries share a common structure (tunica intima) characterized by endothelial cells (EC) that line vascular lumens and are surrounded by the basement membrane (BM) constituted by extracellular matrix proteins and complex sugars (i.e., heparan sulfates, proteoglycans). The external face of tunica intima is covered by vascular smooth muscle cells and pericytes (mural cells) that form a multilayer wall of different size (thinner in the veins and ticker in the arteries), named tunica media. In capillaries, pericytes do not form a continuous layer but they are scattered and embedded in the BM. Mural cells exert key roles in multiple microvascular processes, including: (1) endothelial cell proliferation and differentiation, (2) contractility and tone, (3) stabilization and permeability, and (4) morphogenesis and remodeling during disease onset [6, 7].

EC thickness varies from less than 0.1 μm in capillaries and veins to 1 μm in the aorta and in arteries they are aligned in the direction of blood flow and this remodeling occurs in response to hemodynamic shear stress. On the contrary in vasculature characterized by a slow blood stream, endothelial shape may be irregular, rounded, or elliptical. Endothelium may be continuous or discontinuous (Fig. 1). Continuous endothelium, in turn, is fenestrated or nonfenestrated. Nonfenestrated continuous endothelium is found in arteries, veins, and capillaries of the brain, skin, heart, and lung. Fenestrated continuous endothelium occurs in tissues that are characterized by increased filtration or increased transendothelial transport, including exocrine and endocrine glands, gastrointestinal mucosa, and kidney. Fenestrae are transcellular pores (∼70 nm in diameter) that develop through the whole thickness of the cell and have a thin 5–6 nm nonmembranous diaphragm across their aperture.

Discontinuous endothelium characterizes capillaries of sinusoidal vascular beds (i.e., liver and bone marrow). It is characterized by large fenestrations (100–200 nm in diameter) that lack a diaphragm and contain gaps (or large holes) within individual cells.

The regulation of these kinds of EC-EC interactions occurs at two types of intercellular junctions: the tight junctions (also named *zona occludens*), which are mainly located at the apical region of the intercellular cleft and the adherens junctions (*zona adherens*). Zonula occluden-1, occludin, claudin, and JAM are the major elements of tight junctions, while vascular-endothelial cadherin is a specific constituent of adherens junctions and its clustering at cell-cell contacts promotes the formation of multimolecular complexes that comprise signaling, regulatory, and scaffold proteins.

In physiologic and pathological conditions, the above-described structural features of endothelium contribute to maintain the fluid and the cellular homeostasis between blood and tissues. Actually, the vascular system needs to be

Angiogenesis, Fig. 1 Morphology of capillaries. Capillaries in different anatomical districts have different morphology. Continuous nonfenestrated EC is mainly found in skin, heart, muscle, brain, and lung. It regulates the passage of molecules through transendothelial channels or by caveolae-mediated transcytosis. Continuous fenestrated ECs characterize glomerulus, endocrine glands, and intestines and demonstrate greater permeability to water and small molecules but do not allow the passage of larger macromolecules by using diaphragms as molecular filters. Discontinuous endothelium is present in liver, bone marrow, and spleen and has fenestrae (without diaphragms), gaps, and partially structured BM. The intercellular cleft represents tight junctions or adherens junctions

sufficiently permeable to allow the ready exchange of small molecules (gases, nutrients, waste products) with the tissues. Plasma proteins also need to cross the normal vascular barrier, at least in small amounts. Albumin, for example, transports fatty acids and vitamins and immunoglobulin antibodies are required for host defense. The passage of small molecules across the endothelial layer is almost passive and has to take into account three parameters: hydraulic conductivity, reflection coefficient, and diffusion. Diffusion is the most important of these for the exchange of small molecules and is driven by the molecular concentration gradient across vascular endothelium (Fick equation). On the other hand, filtration is much more important than diffusion for the flux of large molecules such as plasma proteins and is determined by the Starling equation.

On structural point of view, endothelial permeability is mediated by the so-called transcellular and paracellular pathways – that is, solutes and cells can pass through (transcellular) or between

(paracellular) EC. While the paracellular route restricts the passage of solutes larger than 3 nm in radius, transcellular vesicle trafficking selectively transports macromolecules such as albumin across the endothelium. Transcellular passage (transcytosis) is an energy-dependent mechanism that requires either cell fenestration or a complex system of transport vesicles, which includes caveolae and organelles called vesiculo-vacuolar organelles (VVO). These organelles, or similar structures, can also fuse and appear as channels that traverse single cells and allow the passage of leukocytes and solutes through the endothelium. Caveolae are 70-nm membrane-bound, flask-shaped vesicles that usually open to the luminal or abluminal side of the EC membrane. They are enriched in cholesterol and some, but not all, caveolae possess a thin diaphragm similar to that found in fenestrae. The density of caveolae is far greater in capillary endothelium (up to 10,000 per cell) compared with other vessels and their number is highest in continuous nonfenestrated endothelium. A notable exception is the blood–brain barrier, where caveolae are rare, which reflects the protective role of this vascular bed for the brain.

VVOs are comprised of hundreds of cytoplasmic vesicles and vacuoles that together form an organelle that traverses venular endothelial cytoplasm from lumen to albumen. VVOs often extend to inter-endothelial cell interfaces and their individual vesicles commonly open to the inter-endothelial cell cleft. The vesicles and vacuoles comprising VVOs are linked to each other and to the luminal and abluminal plasma membranes by stomata that are normally closed by thin diaphragms that appear similar to those found in caveolae and fenestrae.

The paracellular pathway, by contrast, is mediated by the coordinated opening and closure tight junctions and adherens junctions, and is mainly operative during pathological conditions, in which this barrier is altered by the release of permeability factors (acute and chronic inflammatory injury) or by an abnormal and chaotic vascularization (i.e., tumor angiogenesis).

The Morpho-Functional Vascular Unit in Pathological Settings

The formation of vascular bed depends from well-regulated circuits that involve soluble molecules with inducing and inhibiting activity, mechanical forces, different cell types and features of the extracellular matrix. The final result of these dynamic interactions is the ordered distribution of capillaries (the intercapillary distance ranged from ∼100 to ∼150 μm) allowing the appropriate cell oxygenation on the basis of local pO_2 and O_2 coefficient diffusion [6–8].

In pathological settings (i.e., tumor, chronic inflamed tissues, wound healing, postischemic revascularization) this homeostatic balance is disturbed leading to the formation of vessels with functional and structural defects.

In pathological tissues and in particular in tumors, vessels are dilated, tortuous, and show a chaotic spatial distribution. Normal vascular tree is characterized by vessels with decreasing diameter and by dichotomous branching, but tumor vessels are unorganized with trifurcations and irregular diameters. Endothelial phenotype is also modified in tumors. Large discontinuities characterize inter-endothelial junctions, as well as the increased numbers of fenestrae and VVOs and alterations or lack of BM. Similarly, mural cells are poorly distributed and show defects in association with vessel wall. The molecular and cellular mechanisms causing these abnormal vascular architectures are largely unknown, but the imbalance of pro- and anti-angiogenic associated with mechanicals stresses is believed to be instrumental in achieving these features.

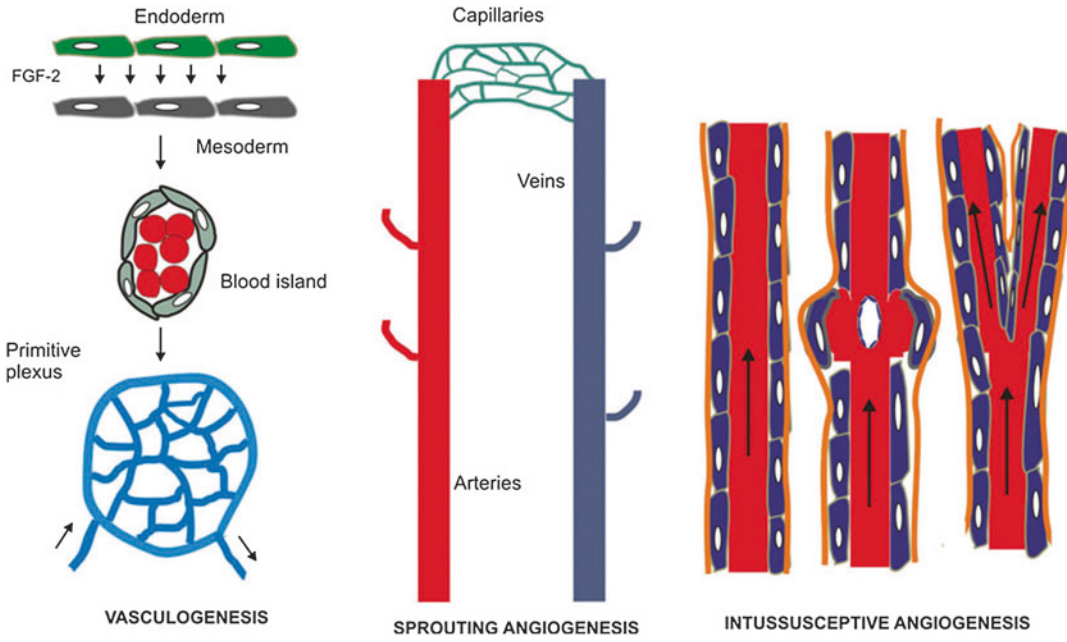
These structural alterations are accountable for some features of tumor microenvironment. In normal tissues permeation of hydrophilic solutes is progressively restricted with increasing molecular size, as by a sieve, with many openings 8 nm and a few 40–60 nm wide. In solid tumors vascular permeability is generally higher allowing (≥80–90 nm) or facilitating (≥10 nm) the extravasation of molecules with sizes that in general are retained. The blood flow is irregular because the flow resistance, which depends from vascular

geometry and blood viscosity, is increased. Focal interruption of vessel wall may also compromise the downstream blood flow. As a result, overall perfusion rates (blood flow rate per unit volume) in tumors are lower than in healthy organs. Blood flux is erratically distributed and fluctuates with time causing a jeopardized perfusion.

The increased permeability abolishes the differences between hydrostatic and colloid osmotic pressures that characterize normal tissues. As a result, tumors show interstitial hypertension and reduction of transmural pressure gradient and convection across tumor vessel walls. Consequently, the increased permeability connected with the interstitial hypertension reduces pressure difference between up and down stream of blood vessels and leads to blood flow stasis.

The final consequences of these functional abnormalities takes place at metabolic level leading to hypoxia and acidosis. Tumor vessels fail to adequately deliver oxygen and nutrient as well as to remove wastes. The imbalance of vascular network development and tumor cell proliferation results in the formation of hypovascular regions in tumors. Since tissue diffusion limit of oxygen is 80–200 μm, the regions far from blood vessels become hypoxic. Extracellular acidosis is a consequence of hypoxia and Warburg effect (cancer cells produce energy through glycolysis also in the presence of adequate amount of oxygen). When pO_2 is low, the metabolic process (glycolysis followed by oxidative phosphorylation) sustaining oxidative demolition of glucose and ATP production decreases its efficiency. Actually, in the absence of oxygen, the end product of glycolysis, pyruvic acid, does not proceed toward oxidative phosphorylation but it is reduced to lactic acid. This metabolite, together carbonic acid generated by growing cells, accounts for the reduction of extracellular pH in tumors.

The above-described metabolic and functional characteristics render the microenvironment hostile, leading to a genetic selection that favors the most aggressive and malignant cancer cells. Finally, the combination of acidosis (which may modify the polarity of hydrophilic compound) with the blood stasis and the increased interstitial pressure hinders the delivery and efficacy of therapeutic agents to tumors.

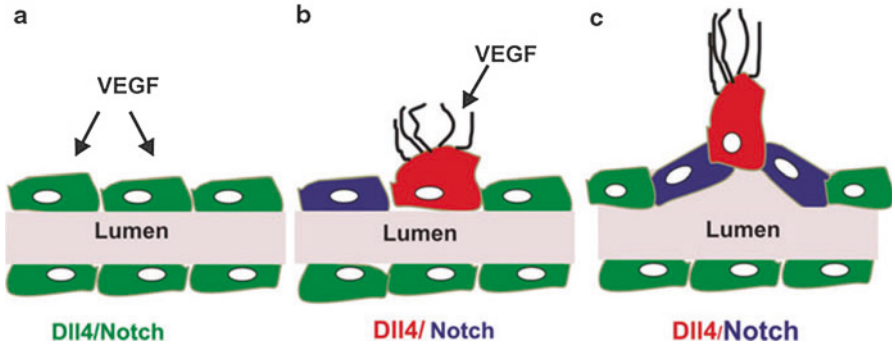


The Mechanisms of Angiogenesis

Mesenchymal cells differentiate in angioblasts, which undergo vasculogenesis where they aggregate and form a primitive vascular network firstly located into extraembryonic tissues and then invading the embryo. As vessels begin to be remodeled, they undergo localized proliferation and regression, as well as programmed branching and migration into different regions of the body. They need to be specified into different calibers and types of vessel, including division into arteries, veins, and lymphatics, with further subdivision into large vessels, venules, arterioles, and capillaries. In addition, they need to recruit supporting mural cells and create the optimal extracellular matrix to ensure the stability of the vessels formed. Pulsatile and shear stress forces mediated by heart beats are instrumental for capillary branching and pruning. The establishment of final vascular architecture is characterized by four different mechanisms, which are also present in adult life: (1) formation of primitive and immature plexus, (2) stabilization of primitive plexus, (3) remodeling toward the final architecture, and (4) vascular specialization. Molecules involved in these steps are summarized in Table 2 [9–12].

Formation of primitive and immature vascular plexus – During embryo development, the nascent capillary network is generated by combining vasculogenesis and angiogenesis. Vasculogenesis describes the *de novo* formation of vascular plexus. Mesenchymal cells are stimulated by soluble molecules (i.e., Indian hedgehog, basic fibroblast growth factor, bone morphogenic protein 4) released by endodermal cells to differentiate in vascular-endothelial growth receptor-2 (VEGFR-2)-positive cells. In extraembryonic yolk sac, these cells form hemangioblast, the common precursor of vascular and hematopoietic system. Primitive endothelial and hematopoietic cells coalesce to form blood islands. The outer cells of the blood islands are endothelial, whereas the inner cells give rise to hematopoietic progenitors.

Angiogenesis, Table 2 Most important molecules involved in angiogenesis



Angiogenic inducers (ligand/receptor)	
VEGF-A/VEGFR-1	Negative regulation of embryonic angiogenesis. Later, VEGFR-1 acts as decoy receptor. Recruitment of monocytes and macrophages
VEGF-A/VEGFR-2	Regulation of proliferation, permeability, migration, and survival of ECs. ECM remodeling. EC differentiation and specialization (i.e., fenestrae formation). The activity of VEGFR-2 is modulated by association with co-receptors (neuropilins, VE-cadherin, αvβ3 integrin). VEGF-A isoforms contribute to vascular patterning
Placental growth factor/VEGFR-1	Regulation of pathological angiogenesis (i.e., tumor, collateral formation, wound healing). Contribution to hematopoiesis. Recruitment of inflammatory cells
VEGF-B/VEGFR-1	Cardiac vascularization
VEGF-C or VEGF-D/VEGFR-2 and/or VEGFR-3	Control of lymphangiogenesis in physiologic and pathological settings. Modulators of vascular angiogenesis
Notch/Dll4 or Jagged	Control of EC tip formation in sprouting angiogenesis. Differentiation and recruitment of mural cells. Venous-arterial differentiation
Angiopoietins/Tie-2	Regulation of the relationships between mural cells and EC. Regulation of vessel stabilization. Accessory role in lymphangiogenesis. Activation of inflammatory cells
TGFβ/ALK or endoglin	Production of ECM and proteases. Venous-arterial differentiation. Mural cell differentiation. Control of EC proliferation and migration
PDGFs/PDGF receptors	Differentiation, survival, and recruitment of mural cells
Ephrin B2/EphB4	Venous-arterial differentiation. Vascular branching
Slits/Robo	Formation of primitive plexus. Vascular stabilization. Control of EC motility
Netrins/UNC5B	Negative control of sprouting angiogenesis. Regulation of vascular branching
Semaphorins/plexins-Neuropilins	Regulation of vascular morphogenesis. Inhibition of EC adhesion and migration. Anti-angiogenic effect in tumor angiogenesis
Hepatocyte growth factor/Met	Regulation of pathological angiogenesis. Collateral formation
Chemokines/Chemokine receptors	Members that contain the "ELR" motif are potent promoters of angiogenesis via binding and activating CXCR2 on ECs. In contrast, members, in general, those lack the ELR motif (ELR-) are potent inhibitors of angiogenesis, and bind to CXCR3 on ECs
Endogenous angiogenic inhibitors	
Tumstatin, arresten, and canstatin	They are cryptic angiostatic peptides released by collagen type IV during ECM proteolysis in sprouting angiogenesis
Endostatin	A cryptic angiostatic peptide released by collagen type XVIII during ECM proteolysis in sprouting angiogenesis
Angiostatin	A plasminogen fragment produced during sprouting angiogenesis. It Inhibits EC migration and proliferation and induces apoptosis
Vasostatin	Vasostatin is an N-terminal fragment of the calreticulin. It inhibits angiogenesis presumably by binding to laminin and blocking EC adhesion and proliferation
Thrombospondin	It inhibits EC proliferation and migration by interacting with CD36 molecule
2-methoxyestradiol	It inhibits angiogenesis by reducing EC proliferation and inducing EC apoptosis
Histidine-rich glycoprotein	It inhibits tumor angiogenesis by preventing release of angiogenic factors from the matrix and inhibiting growth factor-induced EC migration
Pigment epithelial-derived factor	It is released by retinal pigment epithelium and causes EC apoptosis
Maspin	It is a serpin inhibitor of serine-proteases with anti-angiogenic activity in tumor
PEX	It is a fragment of metalloproteinase-2 that prevents its collagenolytic activity during sprouting angiogenesis
Fibulin 5	It is a ECM protein that antagonizes VEGF activities and enhances that of thrombospondin
Interferons (α,β,γ)	They inhibit angiogenesis by multiple and direct effects on EC or by modulating innate immunity

Angiogenesis, Fig. 2 Vasculature assembly. *Vasculogenesis* starts when mesenchymal cells stimulated by soluble molecule released by endoderm differentiate into EC precursors (hemangioblasts and angioblasts) and form the blood islands (*left*). Fusion of blood islands leads to formation of primary capillary. *Sprouting angiogenesis*. Blood circulation is established and primary plexi are remodeled into a hierarchical network of arteries, capillaries, and veins. Sprouting angiogenesis starts when a gradient of VEGF triggers the detachment of EC-EC contacts leading EC to proliferate and migrate. The nascent capillaries undergo maturation characterized by reorganization of ECM and recruitment of mural cells. This step parallels the selection of the proper trajectory for the best blood supply. *Intussusception*. The division of vessels through the insertion of tissue pillars is an alternative mechanism that leads to the expansion of blood vessels in several organs. Little is known about the function or regulation of intussusceptive growth but the process seems to involve EC growth, motility, and remodeling of ECM

The endothelial-lined blood islands fuse to generate *de novo* a primary capillary plexus. This process is named vasculogenesis. In intra-embryonic tissues, VEGFR-2-positive mesenchymal cells differentiate into angioblasts which directly aggregate into the dorsal aorta or cardinal vein, without a plexus intermediate. These large vessels then undergo connection with the primitive vascular network.

Besides vasculogenesis, sprouting and intussusceptive angiogenesis take place (Fig. 2). Sprouting angiogenesis if facilitated by hypoxia, which upregulates the transcription of a large set of pro-angiogenic genes. EC loose the cell-cell contacts and vessels become leaky. The BM is digested by the release of specific proteases (metalloproteases) and a specific suppression of protease inhibitors allowing EC migration and proliferation. Intriguingly, BM cleavage can produce multiple anti-angiogenic molecules that counteract and balance the effect of angiogenic inducers thus allowing an accurate vascularization. The sprouts reorganize internally to form a vascular lumen and are finally connected to other capillary segments. VEGF signaling is critically important in this process, as it promotes endothelial cell proliferation and modulates migration. Angiopoietin-2, in the presence of VEGF, facilitates sprouting angiogenesis because it contributes in dismantling cell contacts. The pivotal effect of VEGF in sprouting angiogenesis is regulated by Notch receptors and their Delta-like-4 (DLL4) and Jagged-1 ligands to allow a specific focalization of capillary area from which a new capillary stems. The fine-tuning activity between VEGF and DLL4 allows the selection of the tip

Angiogenesis, Fig. 3 Tip cell selection in sprouting angiogenesis. (**a**) At the beginning of VEGF stimulation ECs most probably contain equal amount of Dll4 and its receptor Notch. (**b**) Tip selection occurs by increasing Dll4 expression in a specific EC (*red* cell) stimulated by VEGF. As consequence, Notch is upregulated in neighboring cells (*blue*), which inhibit the expression of VEGF receptors. (**c**) This modulation allows tip cells reacting strongest to VEGF signaling and acquiring sprouting phenotype whereas tip cell behavior is suppressed in Jag1-expressing (stalk) cells (*blue*), which form the base of the emerging sprout

EC, which is devoid of proliferative activity and drives the sprout by emitting filopodia. Initially, Dll4 and Notch signaling are thought to be balanced in EC until presumptive tip cells eventually increase Dll4 expression in response to VEGF signaling. Consequently, Notch is upregulated in neighboring cells, which inhibits the expression of VEGF receptors and the tip cell differentiation. Thus, Dll4-expressing tip cells react strongest to VEGF signaling and acquire a motile, invasive, and sprouting phenotype whereas tip cell behavior is suppressed in Jag1-expressing (stalk) cells, which form the base of the emerging sprout. Reduced levels of DLL4 or blocking of Notch signaling enhance the formation of tip cells, resulting in dramatically increased sprouting and chaotic angiogenesis. The principle in which a differentiating cell represses the differentiation of adjacent cells is called lateral inhibition (Fig. 3).

More recently ephrins and wnt pathway has been demonstrated to modulate tip cell dynamics. Although little is known about the lumenization of blood vessels, there is strong evidence for the involvement of pinocytosis and vacuole formation. High-resolution time-lapse imaging has established that the lumen in these ECs is formed by intracellular and, subsequently, intercellular fusion of large vacuoles.

Intussusception (growth within itself) is an alternative to the sprouting mode of angiogenesis. The protrusion of opposing microvascular walls into the capillary lumen creates a contact zone between ECs. The endothelial bilayer is perforated, intercellular contacts are reorganized, and a transluminal pillar with an interstitial core is formed, which is soon invaded by myofibroblasts and pericytes leading to its rapid enlargement by the deposition of collagen fibrils. When a primitive capillary plexus is generated by vasculogenesis or sprouting, intussusception is triggered and is responsible for rapid vascular growth and optimal remodeling.

Stabilization of primitive plexus – Blood perfusion of nascent capillaries requires their maturation. This step is mainly characterized by recruitment of mural cells and remodeling of extracellular matrix (ECM). Mural cells are recruited by molecules released by EC and in particular by platelet-derived growth factors (PDGF) and sphingosine-1 phosphate, which, respectively, bind the tyrosine kinase PDGF receptor and the seven spanning domains endothelial differentiation sphingolipid G-protein-coupled receptor-1. Compelling support for this hypothesis comes from mouse genetic models in which the modification of the expression of these molecules impair the correct relationships between mural cells and EC and alter production of ECM. Mural and stroma cells produce angiopoietin-1 (Ang-1), which binds the tyrosine

kinase receptor, Tie2 on endothelial cells, resulting in enhanced EC-mural cell interactions leading the vessels leak-resistant. A homolog, Ang-2, appears to antagonize Ang-1, relaxing these interactions and triggering BM degradation in preparation for angiogenic sprout. Transforming-growth factor β promotes the differentiation of mesenchymal cells into mural cells and contributes to ECM production. Mutations in endoglin and activin-like kinase, two receptors of transforming-growth factor β, cause hereditary hemorrhagic telangiectasia, a disease that is characterized by capillary dilatation, microaneurysms, and bleeding.

Interactions between ECs and their surrounding BM and ECM are critical for vascular maturation and occur through specialized adhesive receptors named integrins. The importance of these connections are underscored by the vascular defects seen in mice deficient in some types of integrins and various BM constituents such as type IV collagen, fibronectin, and laminins. Interestingly, the adhesion of EC to BM through integrins mediates anti-apoptotic signals that are instrumental to avoid vessel regression. Actually, anti-integrin molecules, including specific antibodies, have anti-angiogenic effects. Besides an adhesive role, integrins act as co-receptors of several tyrosine kinase receptors involved in angiogenesis modulating their activities. Following BM assembly, vessels are stabilized by cross-linking of ECM components and associated proteins by transglutaminase-2-mediated lysine bonds. The ECM cross-linking activity leads to inhibition of angiogenesis by increasing ECM stiffness and deposition.

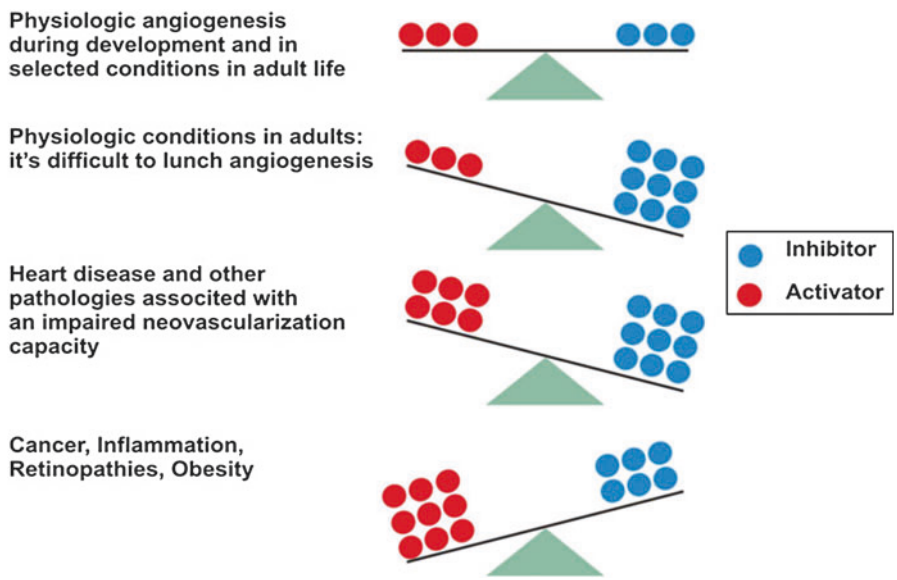
Remodeling toward the final architecture – The transition from the plexus to the vascular tree is characterized by regression and pruning of some vascular segments, new branching, remodeling, and navigation to build the most appropriate network to distribute oxygen, nutrients, and wash catabolites off. This step is regulated by the combined activities of physical forces, axon guidance cues, and ECM features. Using in vivo molecular imaging associated with genetic and vascular grafting studies it has been established that physical cues drive guidance of lumenized vessel sprouts. ECs are subjected to tension created by cell-cell and cell-ECM interactions or by blood flow (shear stress) and pressure (circumferential wall stress). Interestingly, the absence of blood flow or sufficient tensions promotes vascular regression. Physical stimuli must be sensed by cells and transmitted through intracellular transduction pathways to the nucleus, resulting in gene expression. However, how cells sense biomechanical stimuli is still under debate. Several hypotheses experimentally supported have been proposed. They include the capacity of heterotypic (integrin-mediated cell-ECM) and homotypic (VE-cadherin mediated EC-EC interaction) adhesive receptors to link the internal cytoskeleton and provide mechanical coupling across the cell surface, including ion- channel opening [13].

As above mentioned, proteases released by angiogenic EC modify the structure of ECM during the formation of primitive plexus. Furthermore, this mechanism occurs also during the remodeling phase leading to pro- or anti-angiogenic activities. This stimulatory effect may be due to decreasing the density of extracellular matrix proteins, and/or by exposing cryptic binding sites within matrix molecules that promote migration. In contrast, the action of proteases can be anti-angiogenic, due to their ability to generate fragments of matrix molecules that have pro-apoptotic properties not possessed by the intact molecule. Therefore the characteristics of surrounding ECM may favor the progression or the regression of primitive capillary network. On the other hand ECM elements, and in particular fibronectin, collagens, laminins, and heparan sulfates, participate in vascular stabilization and patterning as demonstrated by specific vascular defects (increase in lumen size, edema, leakage, vessel rupture) in mouse genetic models.

ECM also affects the availability of angiogenic regulators. For instance, different isoforms of VEGF-A, characterized by increased affinity to ECM, form specific gradients required for vessel patterning. Similarly, fibroblast growth factor-2 may be sequestered by ECM and released to cell surface by proteolysis. Generally, ECM and proteolytic activities adapt the strength and the

duration of angiogenic signals and train ECs to initiate fine-tuned and specific signal genetic programs regulating vascular patterning.

During the remodeling step, vessels select specific trajectories leading to an optimal spatial distribution instrumental for the molecular exchanger in the tissues. This strategy is shared with the nervous system, in which axon guidance molecules are responsible for guiding the navigating axon toward its target area. Indeed ECs and neurons share some fundamental mechanisms during the formation of their networks. On an anatomical point of view, in several tissues (skin, muscles, intestine) nerves and larger blood vessel align into two parallel structures and genetic studies indicate that peripheral nerves in the dermis provide a spatial template for the growth and differentiation of arteries. During axon navigation, growth cones project numerous filopodia as shown in endothelial tip cells that actively extend and retract in response to extracellular cues. Four ligand-receptor pairs of guidance cues are known to play attractive of repulsive effects in nervous and vascular systems: ephrins/Eph, semaphorins/plexins-neuropilins, slit/Robo, and netrins/UNC-DCC. Many studies performed in genetic modified mice or zebrafish clearly indicate that these molecules mainly act in defining the final shape and architecture of vessels in body tissues.



Vascular specialization – The paradigmatic example of this concept is the differentiation of arteries and veins. During vascular development cardiac work presses high-pressure blood flow through large diameter arterial vessels, which acquire an extensive supporting system of mural cells. Blood comes back to the heart with low pressure through veins, which develop *venous valves* to prevent blood from flowing back. Therefore hemodynamic forces have a crucial role in defining arterial and venous circulation. These mechanisms are strictly intermingled with early genetic determinant. The landmark of arterial–venous cell fate is the expression of ephrinB2 and EphB4, respectively, in plasma membrane of arterial and venous ECs. The interactions between these two markers are essential for proper vascular development. However, the expression of these molecules is differently controlled. VEGF upregulates the Notch pathway that through hesr1/hesr2 transcription factors leads to arterial specification via EphrinB2 activation. In veins, COUP-TFII is required for strong expression of EphB4 and venous differentiation. Therefore it seems that molecular differences between arteries and veins are predetermined but the final fate is contributed by epigenetic and physical cues indicating a prominent plasticity of the system.

The vascular architecture has definite features in different organs to respond to specific needs in terms of nutrient requirements and transport [14]. For instance, the filtration barrier of glomerular endothelial cells in kidney results from the presence of continuous fenestrations allowing bulk fluid and anionically charged molecules to be filtered and facilitates movement of cationically charged molecules. The sinusoidal hepatic system is characterized by discontinuous endothelium with sieve-like pores (∼100 nm diameter) and nondiaphragmatic fenestrae, which regulate the permeability and the blood flow in hepatic sinusoids. Endocrine organs have fenestrated capillaries that contain pores sometimes lined with thin diaphragms. These structures are thought to allow increased transport of long-range hormones between extravascular cells and blood. In contrast to the fenestrated vascular beds present in high-transport organs, brain capillaries are linked by extensive tight junctions that restrict transendothelial movement.

These differences are furtherer envisaged by specific patterns of gene expression orchestrated by mechanisms largely unexplored. It is emerging the existence of angiogenic inducers specific for each organ. They include members of Wnt family and endocrine gland-VEGF.

The Mechanisms of Pathological Angiogenesis

In adult life, physiologic angiogenesis employs the same mechanisms illustrated above and occurs in endometrium during female cycle, in *corpus luteum* during reproductive cycle, in hypertrophic glands (i.e., breast during lactation), and in

Angiogenesis, Fig. 4 Homeostatic hypothesis in pathological angiogenesis. During embryonic development and in some process in adult life (i.e., female cycle, reproduction, lactation, muscle exercise), tissues express balanced amounts of activators and inhibitors of angiogenesis, which allow the formation of regular vessels. In other adult tissues, angiogenesis is repressed by an increased amount of inhibitors. Vascular regeneration may occur in ischemic tissues but usually it is insufficient to recover tissue oxygenation. On the other hand, tumors, obesity, chronic inflammatory diseases, and retinopathies are characterized by a prominent but chaotic angiogenesis. These different scenarios are associated with unbalanced ratios between activators and inhibitors

exercise-trained skeletal muscles. Several diseases are connected with and sustained by an abnormal angiogenesis. In some pathological settings, including tumors and chronic inflammatory diseases, abnormal angiogenesis results from an altered homeostasis between angiogenic inducers and inhibitors driven and sustained by specific pathogenic events. On the contrary, ischemic diseases are characterized by attempts to revascularize the necrotic area through angiogenesis and arteriogenesis (Fig. 4) [2, 15, 16].

Tumor angiogenesis – Oncogene-mediated cell transformation is necessary but not sufficient to promote metastatic and aggressive cancer. Tumor cell proliferation alone, in the absence of angiogenesis, can give rise to dormant, microscopic tumors of $\sim$1 mm^3 or less, but these in situ cancers are harmless to the host. Oncogene somatic mutations deeply modify the transcription profile of transformed cells, including the upregulation of VEGF and other growth factors often associated with the down-modulation of inhibitors of vessel formation (i.e., thrombospondin). Therefore the accumulation of genetic mutation along the tumor span-life progressively modifies the angiogenic homeostasis leading to the formation of a chaotic vasculature (see above). However the process of tumor angiogenesis is not limited to the altered production of factors in tumor cells and other mechanisms may occur. The angiogenic process may be partially sustained by EC precursors mobilized by bone marrow and migrated to the angiogenic site. Bone marrow participates to the angiogenic process by producing myeloid cells that differently modulate angiogenesis. For example, macrophages have long been characterized as a highly plastic cell type capable of tumor-suppressive or tumor-promoting effects, depending on the polarization state (M1 vs. M2). Tie2-expressing monocytes have also been reported to promote tumor growth through secretion of angiogenic factors, as also demonstrated for neutrophils and platelets. Interestingly the accumulation of $CD11b^{+}Gr1^{+}$ cells in mice has been associated with the refractoriness to anti-VEGF therapies.

At least in their early phase, some tumors do not mediate sprouting angiogenesis but they utilize preexisting vessels. For instance, brain tumors are highly vascularized and vessels have a similar phenotype than normal brain. Vessels are surrounded, co-opted by tumor cells, and no sprouts are observed (co-option mechanism). Later, when the tumor mass collapses normal capillaries, hypoxia takes places and activates a VEGF-mediated sprouting angiogenesis.

In some tumors and in particular in colon-rectal cancers, the capillary wall is often constituted by EC and tumor cells (mosaic vessel). This scenario may be induced by the endothelial migration during rapid vessel growth without sufficient proliferation to complete the endothelial lining, leaving cancer cells exposed to the lumen. Second, ECs could be shed from the vessel lining, leaving exposed tumor cells. Third, migrating tumor cells could invade the vessel wall, displacing endothelial cells from the lining.

Finally vascular mimicry describes the potential of tumor cells (i.e., in melanomas) or cancer stem cells (at least in glioblastoma) to differentiate in EC with a mixed phenotype and be able to form functional vessels. Despite a significant body of literature, vascular mimicry is not yet a universally accepted mechanism, as the concept has been challenged by several investigators.

Arteriogenesis – The development of an arterial circulation circumventing the occlusion of a large artery from preexistent small arterioles is named arteriogenesis and occurs exclusively in adult injured tissues. It shares some features with angiogenesis, but the pathways leading to it are different. Furthermore arteriogenesis is potentially able to fully replace an occluded artery whereas angiogenesis cannot. As demonstrated in embryonic arterial differentiation, a pivotal role in arteriogenesis is played by physical forces and in particular by shear stress. It is proportional to blood flow velocity and inversely related to the cube of the collateral vessel radius Therefore, since growth increases the collateral vessel radius, shear stress falls quickly. This may be the reason why arteriogenesis arrests without a completed vascularization of ischemic tissue. Collateral vessels of an occluded artery show activated ECs, able to release molecules involved in the recruitment of circulating monocytes, in vascular proliferation and remodeling (proteases, Notch ligands, integrins, VEGF, angiopoietins, fibroblast growth factors) and in control of vascular tone (nitric oxide). Furthermore these collaterals are leaky. A similar activation is observed in smooth muscle cells, which undergo a massive proliferation. Therefore it seems to be conceivable to hypothesize that high fluid shear stress starts at least two signaling mechanisms: one that attracts bone marrow-derived cells for remodeling and another that causes endothelial and smooth muscle cells to enter the cell cycle, leading to proliferation.

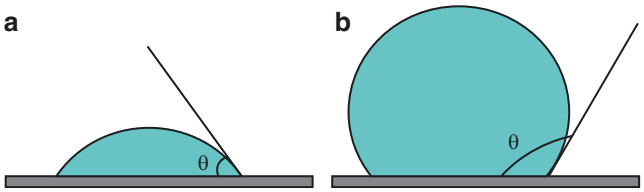
Antifogging Properties in Mosquito Eyes

Xuefeng Gao
Suzhou Institute of Nano-Tech and Nano-Bionics, Chinese Academy of Sciences, Suzhou, People's Republic of China

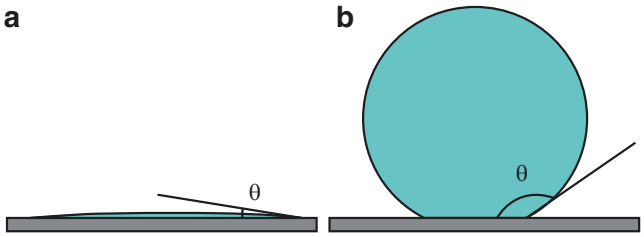
Definition

Fogging occurs when vapor condenses into droplets on condensation nuclei (e.g., dust) or exposed objects (e.g., glass and plastics) with diameters larger than 190 nm, namely, half of the shortest wavelength of visible light. These droplets can firmly stick to the surface of optical transparent materials so as to reduce the visibility by light scattering and reflection, which are undesired. Antifogging is to avoid condensed water droplets on a surface. Antifogging properties in mosquito eyes present a novel surface nonstick superhydrophobicity for micrometer-size water droplets [1].



Overview

Surface wettability is a very common but important surface property closely related to the chemical composition and microstructures of material surfaces. According to the affinity of water to material chemicals, the wettability may be simply divided into the hydrophobicity and hydrophilicity. The intrinsic contact angle θ of a water droplet on a smooth solid surface is given by the classical Young's equation:



$$\cos\theta = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \quad (1)$$

where γ_{SL}, γ_{SV}, γ_{LV} are the interfacial free energies per unit area of the solid–liquid, solid–gas, and liquid–gas interfaces, respectively. The higher surface energy of solid materials means a lower contact angle with water, and vice versa. Generally, one defines that a surface with $\theta < 90^\circ$ is called a hydrophilic surface; conversely, a surface with $\theta > 90^\circ$ is called the hydrophobic (Fig. 1). Note that glass and PMMA are two kinds of most widely used optical transparent materials, both of which are hydrophilic with water contact angles of about 30° and 68°, respectively.

Water vapor easily condenses in the form of tiny droplets on any flat surface made of hydrophobic and hydrophilic materials once its temperature is lower than the dew point. Strictly speaking, the water condensed on exposed objects such as plastic and glass should be called dew although the formation of fog and dew virtually follows the same thermodynamic principles. However, for material sciences and engineering,

the measures of preventing the moisture condensation on optical transparent materials are customarily called antifogging while those aiming at other opaque materials such as metals and paints are called antidewing. It is known that the ordinary wettability makes the condensed water droplets firmly stick to the surfaces once contacting, which generates light scattering and reflection so as to greatly blur the visual field. It often occurs that the eyeglasses fog up when one comes inside on a cold day. This is because the eyeglasses have been cooled outside down to a temperature that is below the dew point and the moisture in the inside air will come in contact with the cooled eyeglasses and condense into tiny droplets. Similar phenomena can frequently occur on the aluminum heat exchange fins in air conditioners, resulting in higher energy consumption and mildew wind. Besides, other side effects caused by moisture condensation are often neglected, for example, the corrosion of metal, the swelling and peeling of paints, and the attachment of dust particles.

Up to now, most antifogging coatings reported are highly hydrophilic, aiming at protecting the optical transparency. A known example is the use of photocatalytic TiO_2 nanoparticle coatings that become superhydrophilic under UV irradiation [2]. Besides, a three-dimensional capillary effect was adopted to achieve superhydrophilic properties by constructing porous nanostructures from layer-by-layer assembled nanoparticles [3]. The key to these two wet-style antifogging strategies is to make these condensed droplets rapidly spread into a uniform thin film, which can avoid the light scattering and reflection. However, many other problems caused by adsorption of moisture are hard to solve by the superhydrophilic approach due to its inherently wet nature. Thus, a dry-style antifogging technique that can prevent the condensed drops from sticking to the material surface is highly desired, which may be developed into multifunctional coatings such as antifogging, antirust, and antifouling.

Basic Principles

Fogging of material surfaces generally forms via the impact of fog drops suspending in air or the direct condensation of moisture. The antifogging property can be achieved by changing the water affinity of the material surfaces toward the two extremities, as shown in Fig. 2. One is the superhydrophilic approach, with a water contact

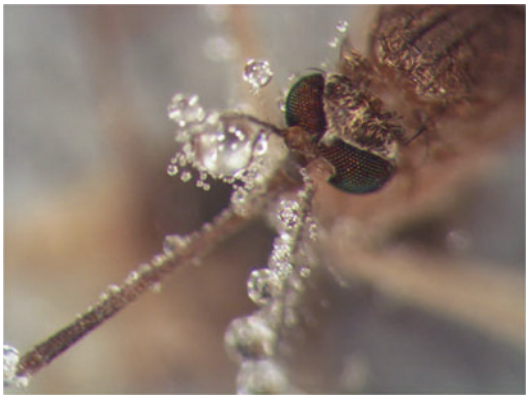
Antifogging Properties in Mosquito Eyes, Fig. 3 Two types of superhydrophobic states. (**a**) Wenzel's model with water trapping into the intervals of structures on surface. (**b**) Cassie's model without any water trapping

angle close to 0° [2, 3]. The other is the nonstick superhydrophobic approach, with a contact angle close to 180° and extremely low adhesion for micrometer-size water droplets [1]. The first strategy is now well understood. Thus, we mainly intend to introduce the possibility of the superhydrophobic strategy in this text.

With the advance of nanofabrication techniques, one can easily construct micro- and nanostructures on the surfaces of different materials, which provide the possibility to study and modulate surface wettability toward the nonstick superhydrophobicity. The real material surfaces are actually not ideally smooth at atomic and molecular scale, which means that the classic Young's equation is not suitable in analyzing their water contact angles. Thus, Wenzel [4] proposed a theoretical model describing the apparent contact angle θ_W on a rough surface and modified Young's equation as follows:

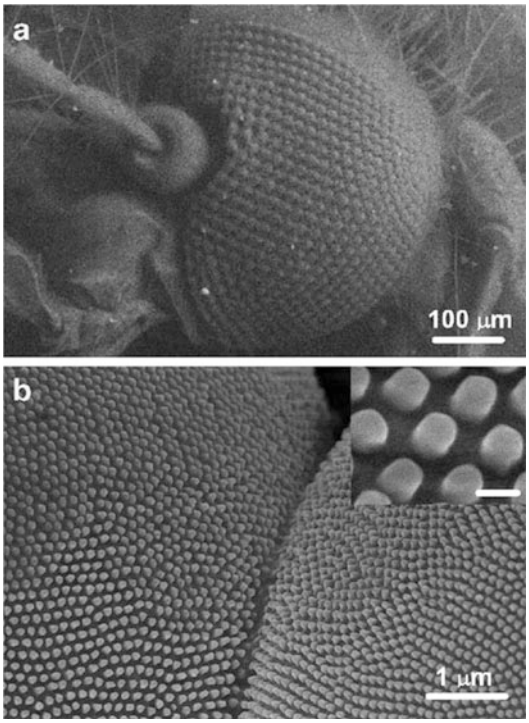
$$\cos\theta_W = \frac{r(\gamma_{SV} - \gamma_{SL})}{\gamma_{LV}} = r\cos\theta \qquad (2)$$

where r is a roughness factor, defined as the ratio of the actual area of a rough surface to the geometric projected area. Apparently, this factor is always larger than unity and the hydrophobicity of a rough surface can be augmented by the increase of the solid–liquid contact area. However, such mechanism brings about very strong water adhesion, as shown in Fig. 3a. Thus, Wenzel model may be effective in the case of superhydrophobic surfaces with microscopic large interspaces or hollows enabling the water penetration but inapplicable to the development of nonstick and antifogging materials.



Air is an effective hydrophobic medium with a water contact angle ~180° [5]. As the air phase can be stably trapped into the microscopic hollows, a rough hydrophobic surface may be considered a composite surface composed of air and solid. Accordingly, the contact angle θ_C of a water droplet on the composite surface can be given by Cassie and Baxter's equation [5] as follows:

$$\begin{aligned}\cos\theta_C &= f\cos\theta + (1-f)\cos 180^\circ \\ &= F(\cos\theta + 1) - 1\end{aligned} \qquad (3)$$



where f and $(1 - f)$ represent the area fraction of solid and trapped air, respectively; θ is the intrinsic contact angle of solid materials. Clearly, the hydrophobicity of a rough surface can be amplified by the decrease of the solid–liquid contact area (Fig. 3b). It has been reported that the surface adhesion of a superhydrophobic surface is governed by van der Waals attraction at the solid–liquid interfaces and the capillary force caused by the curving of the liquid–air interfaces [6]. Thus, it is theoretically possible that the nonstick superhydrophobic property can be obtained by fine surface nanoengineering for the antifogging purpose.

Key Research Findings

Lotus leaves are a sort of classic examples of natural nonstick superhydrophobic with a water contact angle >160° and a sliding angle <5°, exhibiting remarkable raindrop self-cleaning ability. Recent bionic research has clearly revealed that such property is attributed to the cooperative

Antifogging Properties in Mosquito Eyes, Fig. 4 A photograph of antifogging mosquito eyes (*C. pipiens*). Even though they are exposed to moisture, the surface of the eyes remains dry and clear while the surrounding hairs nucleate many drops

effects of the hierarchical micropapillae and branch-like nanostructures and the low-surface-energy wax [7, 8]. Up to now, much efforts have been made toward the bio-mimetic fabrication of the lotus-like nonstick superhydrophobic materials, which was designed for various applications such as self-cleaning and drag-reduction [9]. The emergence of such nonstick superhydrophobic technique was expected to be able to effectively solve the fogging problem. However, there are no reports on man-made dry-style antifogging coatings. Recently, researchers from General Motors have reported that the surface of lotus leaves becomes wet with moisture because the micrometer-size fog drops can easily trap in the interspaces among micropapillae [10]. Thus, the lotus-like microstructures are unsuitable for the creation of superhydrophobic antifogging coatings, and a new inspiration from nature is desired for solving this problem.

Recently, Gao et al. reported a novel dry-style antifogging strategy, inspired by the eyes of mosquitoes, *Culex pipiens*, which have ideal superhydrophobic properties (Fig. 4), providing an effective protective mechanism for maintaining clear vision in a humid habitat. As shown in Fig. 5, scanning electronic microscopic (SEM) observation reveals that the mosquito eye is a compound structure composed of hundreds of micro-hemispheres, which act as individual sensory units called ommatidia. These ommatidia are uniform with a diameter of ca. 26 μm and organize in a hexagonal close-packing (hcp) arrangement. The surface of each ommatidium was covered with numerous nanoscale nipples. These uniform nanonipples, with diameters of (101.1 ± 7.6) nm and interparticle spacings of (47.6 ± 8.5) nm, are organized in an approximately hexagonal non-close-packed (ncp) array.

According to Cassie's principle for surface wettability, such hierarchical micro- and nanostructures may be considered as heterogeneous curved surfaces composed of air and solids. Similar to the surfaces of lotus leaves [7, 8], air may be trapped in the spaces between the nanonipples and micro-hemispheres to form a stable air cushion that acts as an effective water barrier, greatly reducing the contact of tiny fog

drops with the eye surface. Chandler and co-workers have reported that it is theoretically difficult for a hydrogen-bonded network of water molecules to invade the voids in nanomaterials such as parallel hydrophobic plates with a critical separation of ca. 100 nm at room temperature and atmospheric pressure [11]. As a result, air is firmly trapped in the small voids between these neighboring nanonipples, which possess an average interparticle spacing of 47.6 nm. In this case, water surface tension is strong enough to cause the micrometer-sized fog drops to contract, assuming a perfect spherical shape due to their negligible weight. Moreover, the loose arrangement of nanonipples makes an extremely discrete and nonplanar triple-phase (liquid–air–solid) contact line, which is energetically favorable for driving the spherical fog drops effortlessly from the surface [12–15]. Thus, the combination of the ncp nipples at the nanoscale and hcp ommatidia at the microscale on the surface of mosquito eyes may induce ideal antifogging properties via a superhydrophobic approach.

Although mosquito eyes and lotus leaves are both superhydrophobic, the difference in their surface microstructures gives rise to different biological behavior: the former is antifogging for microscale fog drops while the latter is self-cleaning for millimeter-scale raindrops. It has been reported that the arrangement of lotus papillae at the microscale is random and diffuse with a spacing larger than fog drop diameters. Accordingly, the tiny fog drops are easily trapped in the spaces between the papillae so that the lotus leaf surface may become wet during a long exposure to moisture. In comparison, the mosquito ommatidia at the microscale assume a compact hcp arrangement with triangular voids less than 3 μm, which effectively prevent the plunge of fog drops, while the hexagonal ncp nanonipples trap a stable air cushion, thus preventing microscale fog drops from condensing on the corneal surface.

It is noteworthy that similar nanonipple array structures have also been found on other insects, such as moth eyes and cicada wings [16–19]. Detailed microscopic investigations of these nanonipples indicate that they have in common a characteristic tapered configuration, with periods in the range of 180–250 nm [16–18]. Interestingly, such nanostructures can have other biological functions such as anti-adhesive and broadband antireflective properties [16–19]. Inspired by these, one can develop advanced (multi-) functional interfacial materials. For example, the bio-inspired self-cleaning and zero-reflective coatings can greatly enhance the photoelectric conversion efficiency of solar cells. Many efforts have been made in fabricating nanotaper (e.g., nanonipple and nanocone) arrays by self-masked and masked reactive ion etching techniques [20]. However, the dry-style antifogging properties of these nanostructures have not been reported so far.

Future Directions for Research

The superhydrophobic antifogging technique can keep material surfaces dry, and thus is very attractive as comparing with other antifogging techniques. Nowadays, how to quantitatively measure the interaction of nanostructure surfaces with moisture and condensed drops remains a great challenge. In the near future, one should develop a widely accepted method. There are no successful reports on man-made dry-style antifogging coatings based on the current nonstick superhydrophobic techniques. Accordingly, continuous efforts should be made in designing and fabricating the nonstick superhydrophobic surfaces for microscale water drops. At the same time, their potential physical mechanism is under scrutiny, which is helpful to further guide the experimental research. Finally, when the dry-style antifogging technique is developed for practical applications, it becomes increasingly important to build up low-cost and large-scale nanomanufacture techniques and endow the robust nanofilms with excellent anti-wear, anti-aging properties as well as durability, in order to ensure functioning over longer operation periods.

Definition

Nanofluidics studies the properties and transport phenomena of fluid in nanoscale, which typically ranges from 1 to 100 nm. The applications of nanofluidics employ those properties and transport phenomena either for real-life needs or to support other fields of research.

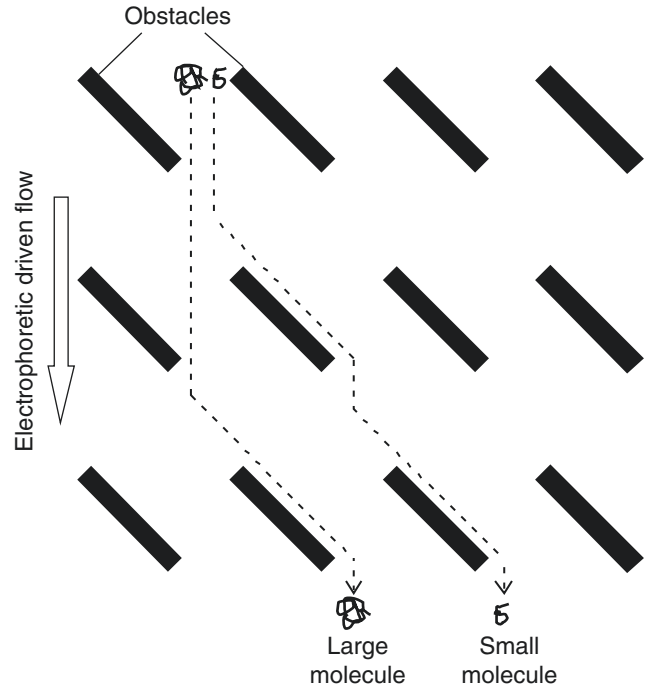
Overview

The transport of fluid confined in nanoscale structures (1–100 nm) possesses many interesting unique characteristics so that it promises various applications in science and technology. In history, people have applied the principle of transport in nanoscale to perform chromatography with porous materials. In chromatography, a mobile phase, usually liquid or gas, is driven through a static phase, or matrix, usually in solid. Due to difference in affinity of the particles in the mobile phase to the surface of the matrix, different kinds of particles will move to a different distance. By observing the pattern that the particles form, one can point out the composition of the particles in the mobile phase. Because the surface affinity plays a key role in chromatography, it is preferable for the matrix to have large area-to-volume ratio. Natural nanoporous materials satisfy well this criterion. The driving force in chromatography may be of various kinds, such as pressure driven, capillary, and electrophoresis. In techniques such as paper chromatography, the capillary is preferred because of its simplicity. However, in nanoporous material, where viscous force becomes more important, the capillary and pressure-driven chromatography turn out to be less effective. In such case, the electrophoresis is more favorable. Electrophoresis phenomenon describes the movement of particles submerged in fluids under the influence of the electrostatic field. The movement happens because of the electric charge associated with the intersurface of fluid and solid. Due to the chemical affinity, the defects in the crystalline structure of the solid surface, and the adsorption, the ions of the fluid attach to the solid surface. This process is generally selective. Therefore, the intersurface between the fluid and the solid gains a net charge. The thickness of this charge layer is usually represented by the Debye's length $\kappa^{-1} = \sqrt{\epsilon\epsilon_0 kT/e^2 \sum_i z_i^2 n_i}$. For large objects, the effect of this charge layer is negligible. However, for small particles, where the surface-over-volume ratio is high, the charged surface becomes more important. When an external electric field is applied, the charged particles move.

Chromatography

Gel electrophoresis is traditionally used to analyze the biomolecules such as DNA, RNA, or proteins. The gel is a porous matrix, usually made from polymer. Several wells are punched in the gel to hold the analyte. When the external electric field is applied, the analyte moves across the gel. Because of the difference in size, mass, shape, and charge of the molecules, different kinds of the molecules migrate to different distances. The molecules are

then stained and then observed to obtain the information about the molecular distribution. For small molecules such as proteins or shorter DNA, the polyacrylamide gel is preferred. For the molecules whose size is about 100 bases, the carbohydrate-based matrix agarose is used. However, conventional gel electrophoresis shows to be less effective for large molecules.

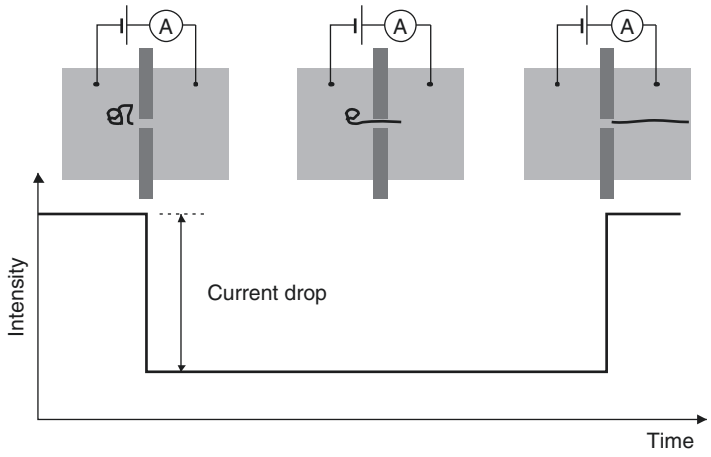


With the introduction of new devices, which is better controlled and fabricated, the applications of nanofluidics are widely expanded. General perspectives of these new devices and their application were given by Abgrall and Nguyen [1]. Random patterns of the porous material can be substituted by more regular fabricated pillar arrays. Bakajin et al. introduced an improving technique to separate DNA strands using switching electric fields [2] along different orientations. The DNA strands react with the electric field by first realigning their orientation and then migrating along the direction of the electric field. Longer strands take more time to realign; therefore, they have less time to migrate in a cycle. The shorter strands therefore migrate through longer distances than the long ones. The authors demonstrated the separation of 100-kbp DNA in 10 s.

However, in the pillar array design, the large molecules tend to clog the array and easily break up. Baba et al. introduced a new structure to solve the problem [3]. The structure consists of parallel wide channels connected with narrower channels run perpendicular from the wide channels. Electrophoresis is used to drive molecules along the wide channels. Molecules smaller than the narrow channel can enter the narrow channel by Brownian motion, while the large molecules remain in the wide channels. As a result, the large molecules migrate in faster than the small molecules. Han et al. performed a series of studies in DNA separation in entropic trap [4]. The entropic trap is a pattern of alternative deep (1.5–3-μm) and shallow (75–100-nm) regions. The molecules were driven across the pattern by electrophoresis technique. The system showed effective separation of long-chain DNA. The depth value can be changed to optimize for different size range of molecules. The devices showed to be effective in separating long DNA (5–200 kbp) within 30 min. This principle is also applied to separate protein or smaller DNA in similar devices [1].

Chromatography methods can also be performed in well-defined microchannels or nanochannels rather than in porous material. Various studies have been carried out to establish the relation between the species retention and coefficient of dispersion as functions of Debye's length and the species charge [1]. The channel size is crucial in electrophoresis separation effect. Pennathur and Santiago [5] introduced an investigation on the electrokinetic transport in nanochannels. The investigation described a complete dependence of the effective mobility of species in electrophoretic motion on the bulk electrolyte mobility values, zeta potential, ion valence, and background electrolyte concentration. From this theory, the authors suggested a method called electrokinetic separation by ion valence. This method determines the ion valence and the ion mobility by comparing transport motion of species in micro- and nanochannels.

Beside electrophoresis, pressure-driven flow can also be used in DNA chromatography, as demonstrated by Wang et al. [6]. The DNA sample was injected into the 500-nm channel. The sample was pushed along the channel with pressure. The longer molecules migrate faster than the shorter ones. Real demonstration with DNA sample from *Arabidopsis* showed that this method is effective. The method, therefore, also promises a great potential to be used for protein and other biomolecules.



Other concepts such as shear-driven separation and anisotropic continuous-flow separation are also used to separate DNA. Shear-driven separation employs the relative movement of two parallel substrates separated by a spacer. This method does not require a high pressure as in pressure-driven separation. It also does not use electric field as in electrokinetic-driven method; therefore, it is suitable for samples which are sensitive to electric field. It is also faster than electrokinetic-driven method to reach the optimal velocity for separation. Experiments with dyes showed effective separation within only 0.2 s and over a distance of 1.8 mm [7].

Applications of Nanofluidics, Fig. 1 Array of oblong obstacle used to sieve biomolecules. The smaller molecules suffer more from diffusion and deflect further from the electrophoretic direction

Continuous-flow separation technique offers advantage such as real-time monitoring or integration of signal over time. Duke and Austin [8] introduced a sieving mechanism for biological molecules. A stream of molecules is driven by electrophoresis along a sieve consisting of oblong obstacle in oblique direction (Fig. 1). Besides the electrophoretic movement, the molecules also move orthogonally depending on their diffusion coefficient. Therefore, the molecules with different sizes follow different trajectories. This principle was tapped to sieve the DNA molecules of different sizes [1]. Huang et al. also used an array of pillars for sieving, but instead of natural diffusion process, a weaker electric field pulse is used to sieve the molecules [9]. The sieving action is done by alternating strong and weak electric field pulses in different directions. Because of the apparent similarity between the sieving phenomenon and optical dispersion, the author proposed the term "DNA prism" for the device. Using this DNA prism, separation of DNA with sizes in the range of 61–209 kbp was completed within 15 s. The principle can be applied with different shapes and arrangements of the obstacles to optimize the sieving effect. Fu et al. [10] introduced a device with parallel deep channels connected by perpendicular nanochannels. The macromolecules such as DNA and proteins are driven by diagonal electric field. One component of the electric field drives the molecules along the deep channels, while the other component leads the molecules to jump from one deep channel to another through the nanochannels. The molecules jump more or less frequently depending on their size. As a result, channels with different depths contain molecules of different size ranges.

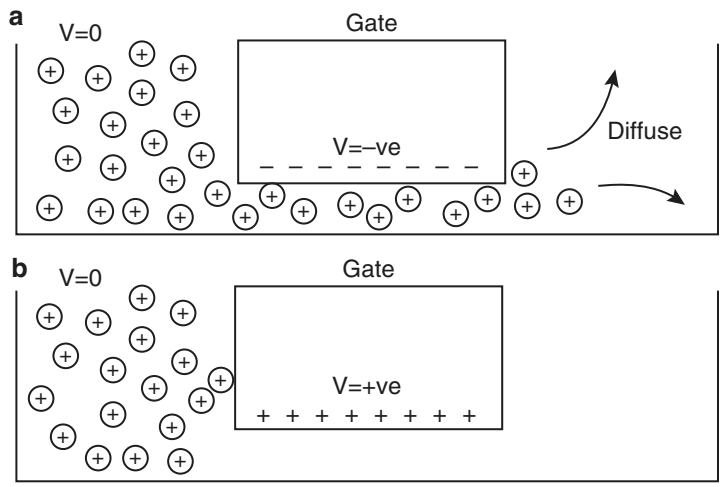
Separation effect such as in chromatography is usually used for analysis purpose. However, it is also useful in preparation of solution, thanks to the electrokinetic mechanism. Kuo et al. demonstrated the delivery of analyte from one microchannel (injection) to another (collection) [11]. The rate of delivery is controlled by bias voltage across two microchannels and the type of analyte. Different configurations of voltages (specified, ground, or float) at four ends of the injection and collection channels shows different levels of control. Karnik et al. [12] realized the nanofluidic transistor circuit to control the

Applications of Nanofluidics, Fig. 2 Translocation of DNA molecules through a nanopore, causing a drop in electric current intensity

transport of protein between microchannels by connecting nanochannels, serving as the gate. The electric field across the gate is controlled with electrode. The gate then can be switched on or off to control the delivery. Microfabricated porous membrane and nanochannels were used as electrical current passages incorporated in the microchannel system; preconcentration with a factor of up to millions can be reached [1].

Single-Molecule Analysis

The size of the nanoscale structures allows them to capture less and less molecules, approaching the goal of handling individual macromolecules for analysis. With recent advances in nanotechnology, the single-molecule sensing technique has improved significantly. Conventionally, molecules such as DNA are handled in porous material. The properties of the molecules are studied statistically on a large population, usually obtained after amplification processes, such as polymerase chain reaction (PCR). The well-defined nanostructure allows the study of the motion of individual DNA. The obtained information is then more specific than that with statistical approach.



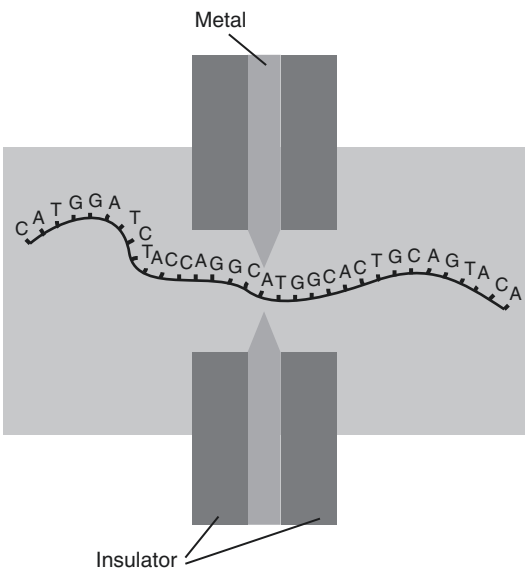
When driven into the nanochannels, the DNA molecules separate from one another. Fluorescent-labeled technique was used to capture the individual images of each molecule. By correlating the photon burst size obtained with the length of the DNA, the length of each molecule can be measured. This technique also can be used to count the number of protein bound to DNA using integrated photon molecular counting method. It was shown that the minimum channel size required to stretch a DNA molecule not only depends on the length of the DNA but also on the ionic strength of the buffer [1]. In a study performed by Krishnan et al. [13], the DNA molecules introduced by capillary filling in a nanochannel were observed to extend at the edge of the channel. This phenomenon promises a simple way to stretch the DNA molecules. However, the physics of this phenomenon is still unknown. Zevenbergen et al. [14] introduced a device to perform redox reaction of molecules in a nanodevice. The solution is filled in a nanochannel with two electrodes on top and at the bottom. The potential of each electrode can be adjusted individually with respect to a reference Ag/AgCl electrode immersed in the solution. The product generated at one electrode becomes the reactant at the other electrode and vice versa. The process is called redox cycling. The redox cycling enables one molecule to contribute many electrons to the induced current, making it possible to detect a small number of molecules by measuring the induced current. The amplification factor up to 400 and a resolution down to 70 molecules were detected.

Figure 2 explains the principle of reading information of individual DNA strand using its translocation through a nanopore. The DNA moves

through the nanopore under an applied electric field. During the movement, the DNA partially blocks the pore. The ionic movement along the pore reduces, leading to a drop in the electric current. If the molecules move across the pore individually, each down peak of the current associates with one translocation. With the nanopore small enough, the DNA passes across the nanopore linearly. Then, the DNA length can be deduced from the time of the translocation. However, the traveling speed depends both on the composition (A, C, G, or T) and the orientation (3′ or 5′) of the DNA [1]. Therefore, measuring the length of DNA is not a simple problem, unless the interaction between the nanopore and the molecules is well understood. To analyze such an interaction, Keyser et al. [15] placed a double-stranded RNA molecule attached to a bead by optical tweezers near the nanopore. The strand was pulled into the pore by electric field, but the optical restoring prevents the complete translocation of the molecules. The optical restoring force causes a dislocation of the beads which can be measured. The translocation also caused a drop in electric current. Correlation between the dislocation of the bead and the electric current drops reveals the interaction between the molecules and the nanopore. The information of such interactions provided tools for further studies in single-molecule DNA sequencing.

Nanofluidic Electronics

Applications of nanofluidics require the fluid flow controlling in nanoscale, where most of conventional fluid controlling methods are impossible to implement. Electrokinetic properties of the fluid in nanoscale inspire the use of electric field to control the fluid, similar to its use in controlling the electric current in diodes and transistors; this idea leads to the concept of nanofluidic electronics [1]. In a nanochannel, it is easier to create a strong electric field with a relatively small value of electric potential. The electric field in the nanochannel attracts or repulses the counterions or coions. Therefore, the flow of counterions and coions through the channels can be switched on or off. This principle is illustrated in Fig. 3. Gajar et al. [16] introduced the concept of ionic liquid-channel field-effect transistor, which uses the electric field at the gate to control the concentration ratio of cation and anion. For demonstration with solution of KCl in glycerol in 88-nm-thick channel, when the gate voltage changed from 0 to 25 V, the anion/cation ratio increases by 17.2, the conductance increases by 5.2. This device is not meant to substitute traditional transistor in electronic circuit but to inspire the possibility that the flow of chemical can be logically controlled, which gives great advantage in process automation. The same principle was also employed by



Applications of Nanofluidics, Fig. 3 Working principle of field-effect nanofluidic transistor. (**a**) A negative gate potential attracts cations in the nanochannel, making them possible to pass through the channel. (**b**) A positive gate potential repulses the cations from the nanochannels, blocking the flow of cations through the channel

other authors to control the transport of proteins or in the field-effect transistor biosensors [1]. The transistor principle can also be realized with carbon nanotube instead of nanochannels [17]. Especially, surface treatment of the nanotube can modify the polarity of the transistor; therefore, many types of transistor structures can be made in a similar way. Besides the transistor, the idea of nanofluidic diodes was also demonstrated with both nanochannels and nanotubes [1].

Future Directions

Apart from these broadly developed applications, nanofluidics suggests many other applications. The ability to control the diffusivity makes it greatly advantageous in drug delivery in vivo [1]. The diffusivity of the chemicals can be controlled by changing the size and shape of the porous pore. Therefore, it is possible to determine the lag time after which the drug will release, as well as the drug-releasing rate. Gersborg-Hansen et al. [18] integrated the microfluidic channels in a resonator for dye laser. The laser wavelength can be alternated by changing the dye or solvent. Theoretical models have been developed to directly read the sequence of a DNA molecule as it moves linearly through the nanopore like the magnetic tape reading in a tape deck [1], as illustrated in Fig. 4. The nanostructures for energy emerge as a promising field, as the need for new source of energy is increasing. It was showed that conversion of hydrostatic to electrical energy has a maximum efficiency of 12 % with aqueous-based solutions of lithium ions [19]. In practice, a lower efficiency was achieved in preliminary experiments but the conditions to improve the efficiency were also sketched out [1]. Current prototypes of fuel cell are mainly based on proton exchange across the membranes. However, because of the enrichment of counterions in a nanochannel, Liu et al. [20] proposed the use of fabricated nanochannels to substitute the porous membranes in fuel cell.

Applications of Nanofluidics, Fig. 4 Reading of DNA sequence as the DNA moves through a nanopore. Preliminary theoretical principles for such an application have been already sketched out

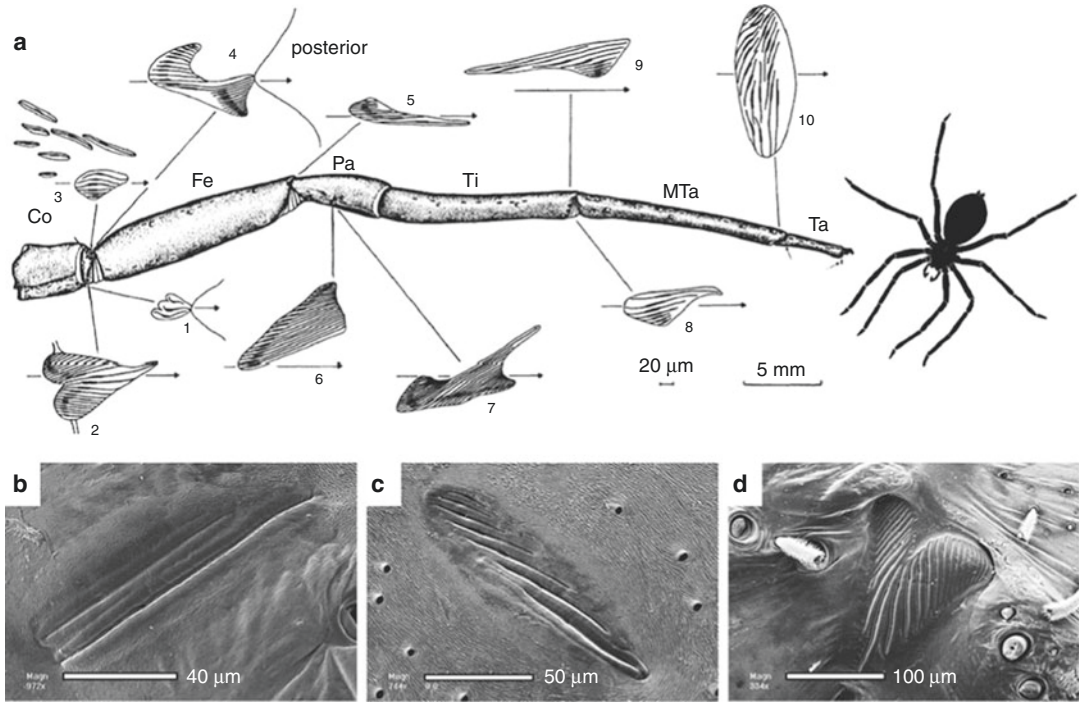
Definition

Arthropods have highly refined sensors which provide them with a detailed picture of the mechanical events going on in their exoskeleton. These exoskeletal strain sensors are innervated holes embedded in the stiff cuticle that locally increase compliance when the exoskeleton is loaded by internal or external forces. Their deformation in the nanometer range suffices to set off nervous impulses. Arthropod strain sensors are called slit sensilla in arachnids and campaniform sensilla in insects. Their function is particularly closely linked to locomotion.

Introduction



Arthropods are well informed about the mechanical events in their outside and inside worlds. They have numerous highly developed sense

organs which respond to a large variety of mechanical events such as tactile, acoustic, vibratory, and airflow stimuli. Whereas their proprioreceptive sensors tell them about self-generated mechanical stimuli like the position and movements of joints and hemolymph pressure, exteroreceptive sensors keep them informed about the external world. In both cases it is in particular changing conditions as opposed to stationary ones which they respond to and use for the guidance of their behavior.

This chapter deals with a sense alien to us humans and specifically linked to the cuticular *exoskeleton*, a structure most typical of arthropods and of dominant importance in regard to their behavior and way of life. The exoskeletons of insects and spiders and related animals not only provide mechanical support and protection and attachment sites for the musculature. They also advertise the animal to mates and conspecifics or conceal it from predators if adequately shaped and colored. In addition to all that, the exoskeleton carries tens or even hundreds of thousands of sensory organs, called sensilla, and has a particular sensory function not known in vertebrates. Embedded into their exoskeleton, insects and arachnids have *strain sensors* which may be considered analogous to technical strain gauges (reviews [1, 2]). These biological strain gauges form tiny holes in the cuticular exoskeleton which represent areas of increased mechanical compliance and locally amplified deformation. When the exoskeleton is loaded by internal or external forces, the resulting minute strains in the cuticle deform the sensors. This deformation in turn elicits nervous responses by straining the dendritic membrane of sensory cells attached to them [1, 3]. Apart from actually measuring strains, the biological strain sensors have control functions as parts of reflex and more complex nervous circuits which help the animal to detect substrate engagement, to temporally and spatially control its movements and posture, to adapt them to different environments, and to avoid overloading of the exoskeleton [2, 4, 5]. In night-active spiders it was shown that exoskeletal strain sensors even help the animal to remember motion sequences which it can later use to find back to a starting point where they might have lost a prey animal or where they usually return to as their home site or retreat. The zoologists refer to such a remarkable way of orientation as kinesthetic or idiothetic orientation [1, 6].

The largest *number* of strain sensors so far known in an arthropod is that found in the spider *Cupiennius salei* [1, 7]. The presence of some 3300 strain sensors suggests that there is much detail in the picture the spider receives about the spatiotemporal patterns of the mechanical events going on in its exoskeleton. The vast majority of the sensors (86 %) are embedded in the stiff sclerotized cuticle of the walking legs and pedipalps whose mechanical properties are close to that of bone with a Young's modulus of around 18 GPa [8]. The *slit sense organs or slit sensilla*, as the strain sensors are called in spiders and their arachnid relations because of their slit-like form, have aspect ratios (length *l*/width *b*) of up to more than 100, being from 8 to 200 μm long and 1–2 μm wide. They come in different configurations as individual slits, loose groups of slits, and so-called lyriform organs (Figs. 1 and 2). The latter are the most intriguing type of slit sensilla. Lyriform organs, of which *Cupiennius* has 144 (the majority on the legs, Figs. 1a and 2a), consist of arrays of up to about 30 slits of different length closely arranged in parallel. Some of these organs show bizarre outlines which substantially impact their mechanical behavior and as a consequence the information made available to the central nervous system.

In insects, the equivalent (analogous) strain sensors are called *campaniform sensilla* (Fig. 3). Their strain sensors usually form oval, more rarely round, holes in the cuticle which are covered by a dome-shaped cuticular membrane to which the dendrite of a mechanosensory cell attaches. The organs are called campaniform sensilla because the dendrite and the covering membrane remind of a bell and its clapper. In different campaniform sensilla the aspect ratios range from 1 (round) to rarely more than 3 [1]. The most complete mapping of campaniform sensilla is available for a fly (*Calliphora vicina*), where a total of about 1200 such campaniform sensilla were found [9, 10]. Similar to arachnid slit sensilla campaniform

Müllan) *Co* coxa, *Fe* femur, *Pa* patella, *Ti* tibia, *MTa* metatarsus, *Ta* tarsus

sensilla occur as single sensilla, loose groups, and what Grünert and Gnatzy [10] referred to as fields. In *Calliphora vicina* there were 86 single campaniform sensilla, 52 groups consisting of 3–32 sensilla with a total of 350 sensilla, and 12 fields with a total of 730 sensilla. As much as 55 % (about 730) of all campaniform sensilla were located on the halteres (see Fig. 3a and below) arranged in 10 of the 12 sensilla fields, about 250 sensilla were on the wings and ca. 210 on the walking legs underlining their central role in the coordination of locomotion.

Like in the case of technical strain gauges, the *mechanical parameter measured* depends to a large extent on the sensor's location and arrangement in the exoskeleton. In arthropods, strain sensors tell the animals about sources of load such as muscle contraction, hemolymph pressure, vibration of the substrate they are sitting on, wing deformation during flight due to aerodynamic forces and – in the case of dipteran flies – the Coriolis forces generated during flight (see section "Sensor Arrays"). A special case are insect strain sensors closely associated with the base of wind-detecting sensory hairs and responding when these are strongly stimulated.

After a short description of some functional principles of individual arthropod strain sensors, the main focus of this chapter will be on the intriguing questions of what the mechanical implications of the strange patterns of sensor arrangement in the lyriform organs may be and how nature managed to successfully maintain the mechanical intactness of the exoskeleton using holes as sensory structures (which an engineer always tends to avoid because of stress concentration problems leading to cracks and fracture). As experimental analyses and Finite Element modeling show, quantitative predictions can be made in regard to the mechanical effects of a number of morphological features which are

Müllan)

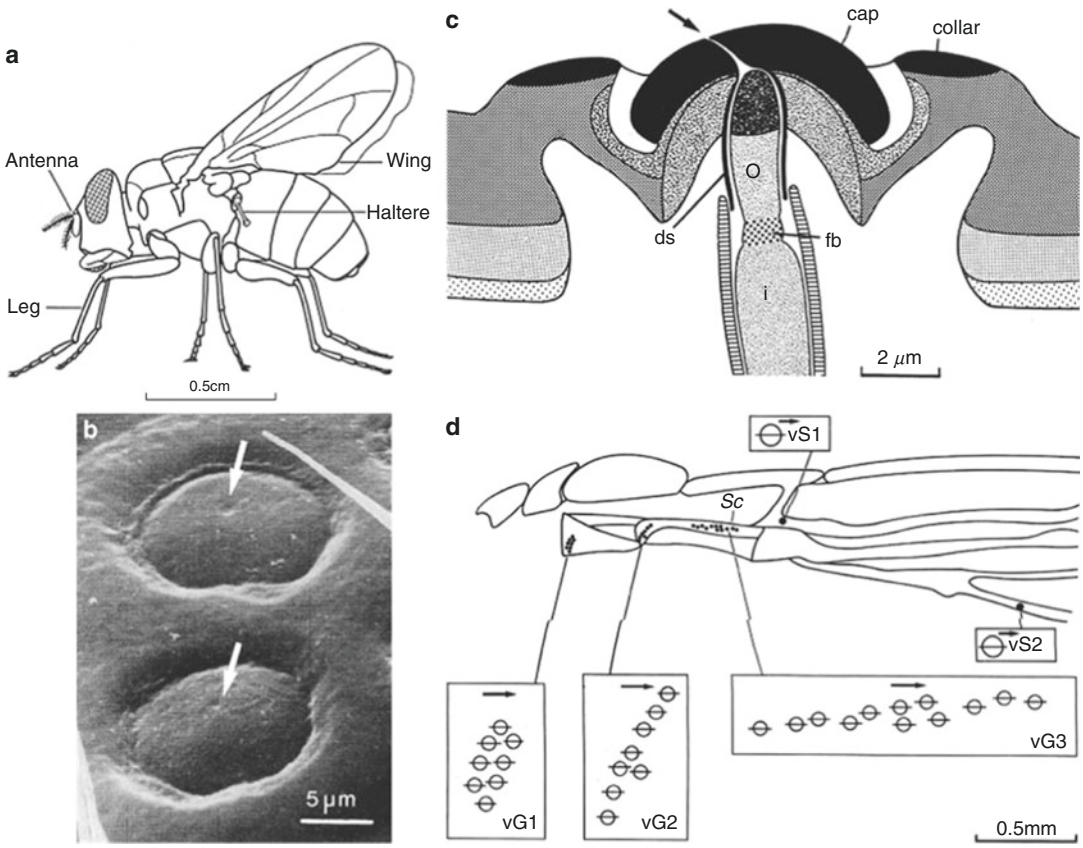
indeed seen to vary in nature. These predictions will be a valuable basis for the design of bio-inspired synthetic sensors used for technical applications.



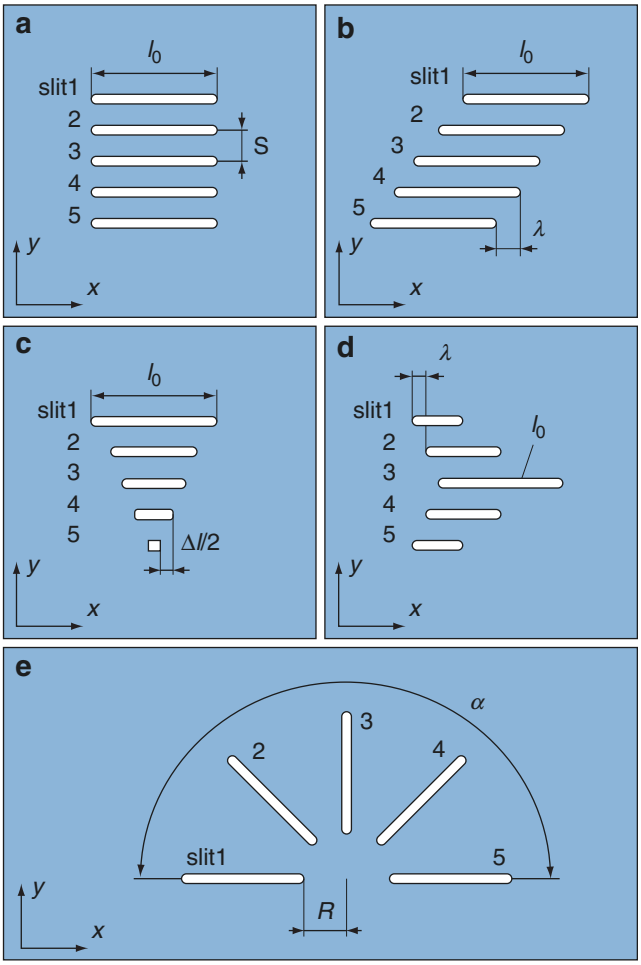
Form and Function

Individual Sensors

According to experimental studies the adequate stimulus of slit sensilla is compressive loading [1]. As demonstrated by Finite Element analyses [11] and earlier pioneering experiments with polymer models [1, 12], several different geometrical parameters affect stimulus transformation and thus the mechanical sensitivity of a slit. One of these parameters is (a) *orientation* in regard to load direction. Single slits are highly directional and best suited for detecting compressive stresses acting normal to their long axis. The same applies to oval campaniform sensilla responding to compression at right angles to their long axes [13]. The other parameter to which slit compression is most sensitive is (b) *slit length l* which indeed varies between about 8 and 200 µm in *Cupiennius* and is the most appropriate parameter to adjust slit compression. Slit length linearly scales with slit face displacement, that is, magnitude of stimulation. A slit's directionality increases with aspect ratio and slit length as well. Remarkably, the (c) *aspect ratio* (*l*/*b*) of slits plays a minor role in this context when assuming values between 20 and 100. However, when comparing a slit of aspect ratio 1 (reminding of some insect campaniform sensilla) with a reference slit of aspect ratio 100 (well within the range of arachnid slit sensilla) the deformation in the former exceeds that of the latter by 50 %. This is mainly due to the area covered by such round sensilla, which is about 80 times larger than in case of a sensor with an aspect ratio of 100. Similarly, (d) capped rectangular slits are compressed more than elliptic holes of identical aspect ratio due to their larger area. Apart from straight slits there are (e) C- and S-shaped slit geometries which, as a rule of thumb, are less mechanically sensitive than the straight slit under normal compressive loading. If one had to adjust/modify the mechanical sensitivity in a synthetic slit sense organ the primary parameter to adjust is slit length. Since slit deformation, which ultimately induces strains in the dendritic membrane and thus nervous activity, is largest in the middle along the slit's long axis mechanical sensitivity could also be adjusted (reduced) by moving the (f) dendrite attachment site toward the slit's ends.

Sensor Arrays

By forming arrays of slits in the lyriform organs, the measurement capabilities at a particular



Arthropod Strain Sensors, Fig. 3 Insect campaniform sensilla. (**a**) The fly *Calliphora vicina*. Note halteres which are modified wings. (**b**) Scanning electron micrograph of two campaniform sensilla on the fly leg. (**c**) Schematic drawing of section through stimulus conducting structures of a campaniform sensillum. location of the exoskeleton can be substantially increased. What is it that a lyriform organ can do more and better than a single slit?

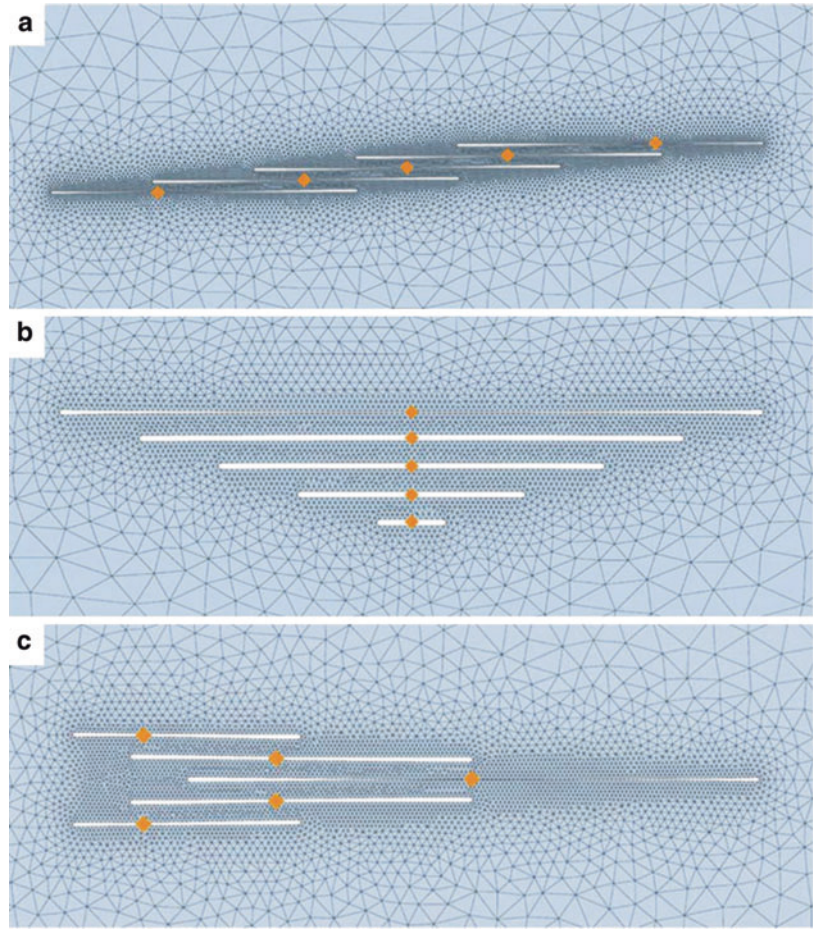
Due to limited spatial resolution, it is quite difficult to reveal the mechanical tricks underlying the various arrangement patters found in spider lyriform organs by direct observation. Modeling again has helped to better understand the principles [11, 12, 14]. Whereas the analytical approach of Kachanov, developed within fracture mechanics to calculate stress intensity factors at the tips of interacting cracks, can be applied to single slits and loose groups of slits (where the distance S between slits is larger than about ½ slit length l), there are difficulties with lyriform organs where typically $S < 0.05\ l$ [15]. A more efficient way to study the mechanical properties of a large variety of slit shapes, positions, and orientations in lyriform organs is finite element analysis. Thus the effects of lateral spacing (S), longitudinal shift (λ), and length gradation (Δl) on slit deformation could be studied under uniaxial normal load (in plane, normal to long axis of longest slit in the array) (Fig. 4). In short, some basic results are the following.

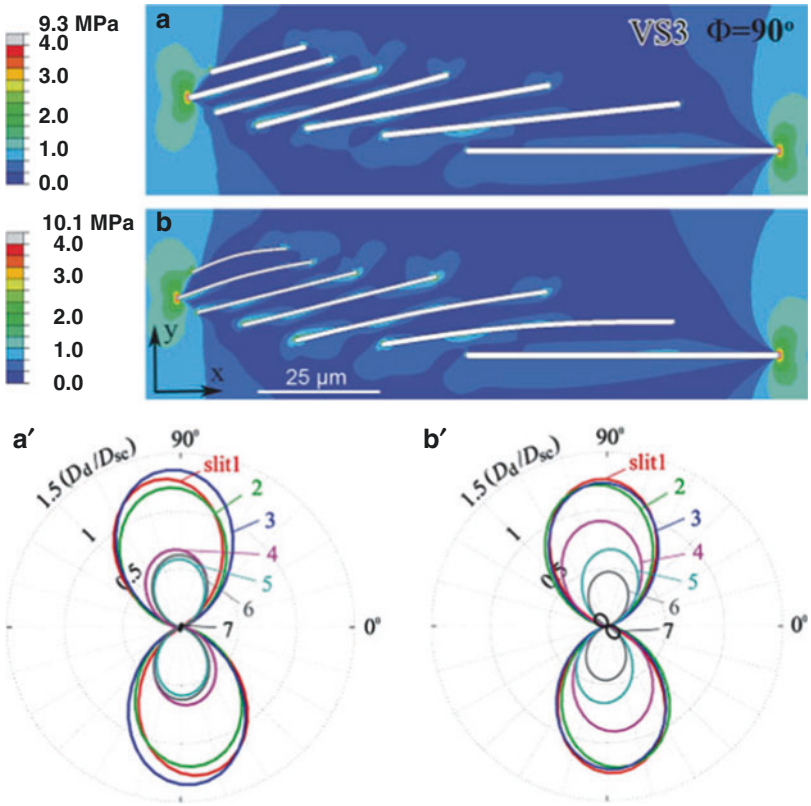


(1) For a group of parallel slits of equal length and as closely spaced as in real lyriform organs the inner slits are much less compressed than the

Arthropod Strain Sensors, Fig. 4 Some of the patterns of planar models studied by FE analysis. (**a**) Non-staggered array of five slits, (**b**) oblique bar arrangement, (**c**) triangular arrangement, (**d**) heart shaped arrangement, and (**e**) fan like arrangement. l_0 length of longest slit in array; S distance to neighboring slit; λ longitudinal shift between neighboring slits (From Ref. [11], with permission)

peripheral ones. The reason for this is the shielding effect of the outer slits which are deformed much more. (2) Slit compression may be larger by up to several hundred percent than that of a single slit if there is a longitudinal shift between slits. A longitudinal shift between neighboring slits is typical of natural lyriform organs; actually no case without it is known. (3) By arranging slits with different length in a group, mechanical sensitivity can be fractionated and the range of absolute and directional mechanical sensitivity of the entire organ extended. Each of the individual slits in one lyriform organ is innervated independently. Details are found in the papers by Hößl et al. [11, 14].

Considering different typical outlines of lyriform slit arrays (represented by five slits in the FE models) provides some answers to the question initially asked: What can a lyriform array do more or better than a single slit? A few examples shall illustrate this (Figs. 4 and 5). (1) In the "oblique bar" array the slits have the same length l but are longitudinally shifted by λ. The level of slit face displacement is similar in all slits and considerably larger than that of a single slit as long as $0.25 \leq \lambda/l \leq 2.5$. One might speculate that by such an arrangement and the central nervous convergence of the corresponding nervous information the signal-to-noise ratio (an ever-present problem in both biological and technical sensing) may be enhanced. (2) Another typical array has a "triangular outline" with slits of decreasing length where the shorter slits are strongly shielded at length gradations $\Delta l/l0 \geq 0.1$ (Δl, length



Arthropod Strain Sensors, Fig. 5 Deformed configurations of three finite element models subjected to uniaxial compressive load at right angle to slit long axes. The displacements are scaled up. (**a**) Oblique bar array with similar mid slit compression for all of the slits. (**b**) Triangular formation with linear gradation of slit length; note considerable shielding effect. (**c**) Heart-shaped array, where maximum slit deformation is not in the middle along the slits. Orange diamonds mark position of maximum compression (From Ref. [11], with permission)

difference of neighboring slits; l_0, length of longest slit) and will respond to relatively large strains (loads, respectively) only. The widely differing mechanical response in a triangular array suggests that it serves to maximize the range of signal magnitude the organ can cope with and exhibits a pronounced range fractionation. (iii) A third type of array is referred to as "heart-shaped" (Figs. 4 and 5). Similar to fan-like configurations with slit axes diverging in different directions, which are indeed known to occur in nature, one achieves sensitivity over a wide range of loading angles with heart-shaped arrays. This implies that even with particular types of parallel slit arrangements the range of effective load directions can be considerably enlarged. It also implies that such an array fractionates the stimulus both in regard to magnitude and direction. As Fig. 6 demonstrates, small differences in the shape and arrangement of slits in a lyriform array may affect the deformation pattern substantially.

The most spectacular arrays of insect campaniform sensilla are those at the base of the halteres of flies (Diptera) [9]. The halteres are club-shaped structures derived from the second pair of wings which oscillate during flight and work like gyroscopes, stimulated by Coriolis forces due to body rotations and providing inertial sensory information for flight control with very high temporal resolution [16] (Fig. 3a).

Vincent et al. [17] used finite element modeling to see stress concentration levels in order to analyze the reduction of the material strength by the "campaniform" holes. Their model was a multiple hole arrangement derived from a sensilla field on the base of the fly haltere and consisting of 4 rows

Arthropod Strain Sensors, Fig. 6 FE simulation of the directional sensitivities of the seven slits making up a lyriform organ on the spider leg of the oblique bar type. (**a**, **b**): Von Mises equivalent stresses (*MPa*) under loads normal to the long axis of slit 1, the longest slit in the array. (**a'**, **b'**): Directional mechanical sensitivity to uniaxial compressive loads in the simple (**a**) and more detailed (**b**) model formed according to scanning electron micrographs of the original organ. The mechanical sensitivity is given as the ratio between the deformation at the position of the dendrite (*Dd*) and the deformation in the middle of an isolated single slit (*Dsc*). Note the even fractionation of sensitivity among the slits in **b'** (From Ref. [14], with permission)

of 5 sensilla each (aspect ratio of sensilla 6.5). They found the maximum von Mises stress to be about 10 times higher than in case of the plate with no hole (stress concentration factor 11.1), whereas in case of the single hole it was only 4. Strain amplification in the multiple hole model was predicted to be $\times 8.75$ parallel to the loading. The effect of the aspect ratio, orientation of the holes, and the influence of other holes in the vicinity (distance between holes) were not studied.

Naturally Occurring Loads and Strains

An intriguing question is that of naturally occurring strains in the arthropod exoskeleton. It is these strains which must have shaped the evolution of the sensors receiving them. Again it is large spiders (*Cupiennius salei*; *Aphonopelma* spec.) where the corresponding quantitative measurements were done in some detail on the legs (where most of the sensilla are found) in living animals. Here the focus will be on just a few values. More details are found in the original literature [1, 8].

The three main sources of load are (1) *hemolymph pressure* which spiders use to extend their legs at joints lacking extensor muscles, (2) contraction of the *musculature* which is concentrated proximally in the legs so that the forces of inertia are kept low in these long and slender structures, and (3) *external sources* such as gravity and

substrate vibration. Under the conditions of slow walk at speeds of 1–10 cm/s the strains found at the site of lyriform organs varied between −13 and −20 με in a particular leg but differed in time course at different positions, relative to the walking pattern. Whereas one organ was stimulated during the stance or load bearing phase signaling muscle force (up to 200 mN) during joint flexion (strain due to resisted muscle action) another one responded to the increased hemolymph pressure (up to 5.3 kPa) during leg extension (swing phase). Since in areas without slit sensilla the strains occurring simultaneously may be significantly higher the conclusion is that lyriform organs are not necessarily located at sites of particularly high strain. In the given case the cyclical change of leg loading and thus the sensory timing of leg movements and the phases of walking seem to be a biologically more relevant aspect.

During situations like rapid starts and stops and jumps one would expect particularly high strain values. At a walking speed of 30 cm/s strains as high as −360 με were indeed measured in the cuticle of the joint region during the stance phase. During starts and stops and jumps the high accelerations imposed loads similar to those found during rapid walks. Clearly at least many of the lyriform organs are in regions with strongly varying strains and high peak loadings. According to both the model studies referred to above and electrophysiological analyses (see below), the lyriform organs are well adapted to monitor such variable load conditions and to avoid dangerous peaks by eliciting synergic reflexes [4].

Physiological Properties

For a lyriform organ on the spider leg tibia identified as HS-8 [7], which belongs to the "triangular" type (Fig. 3), the available analyses include FE-modeling, studies of organ deformation in the living animal using white light interferometry [14] and electrophysiological experiments [18]. By a comparison of all these data it turns out that the values for slit compression predicted by the FE analysis are very close to those obtained by direct measurement. At the electrophysiologically determined thresholds, where action potentials are elicited in the sensory cells, slit face displacements are as small as 1.7 nm. Clearly, physiologically relevant measurements down to the nanometer level are possible even in a material with a modulus of elasticity close to that of bone. The sequence of slits in the organ in regard to the magnitude of their deformation (and therefore sensitivity) follows slit length and is the same both in the FE models and in the interferometric measurements. Electrophysiologically determined threshold values differed by more than 40 dB (×100) among the slits of organ HS-8 and the linear parts of their working ranges complemented each other, thereby considerably increasing the linear range and range of high increment sensitivity of the entire lyriform organ as compared to a single slit [18].

Readers interested in the cellular mechanisms of mechanotransduction in slit sensilla are referred to reviews by French and Torkkeli [1, 3]. Zill et al. [2] reviewed the role of insect campaniform sensilla in load sensing and the control of posture and locomotion in some detail.

The Problem of Embedding Holes and Synthetic Sensors

Considering the basically simple design of arthropod strain sensors and the enormous range of their properties achieved by adjusting just a few parameters (whose relevance is understood quantitatively at least in slit sensilla), they are indeed of interest as models for the design of bio-inspired synthetic strain sensors for technical applications. Bio-inspired arrays would allow a highly resolved analysis of strains at small areas of particular interest and help the process of economizing (which is what natural evolution does) by saving material, weight, and energy. A network of sensors could help the decentralized steering of a robot and its feedback control in adaptive locomotion in particular in uneven terrain.

As embedded sensors [19] they would not cause a problem by being attached to the outside of a piece of material under load and thereby changing its mechanical properties in particular if the material studied is very thin. There are attempts to design high-performance MEMS sensors inspired by fly campaniform sensilla but the gap between the refinement and performance of the natural sensor and the engineered one is still considerable [17, 20].

In engineering one would normally try to avoid micro-holes like those of arthropod strain sensors because they are sources of stress concentration and the initiation of cracks. Obviously nature has found ways to effectively use holes for sensory purposes without endangering the intactness and provoking fracture of the material they are embedded in. There are several reasons why in nature the intactness of the material obviously is not a problem. (1) As already said the strain sensors not only measure strains but are also part of feedback loops and nervous circuits which can be used to avoid dangerous loads. (2) The resistance to tensile and pressure forces is increased close to the slits by an increased thickness of the stiff exocuticle around the opening (Fig. 2a). (3) The arthropod cuticle is a fiber-reinforced laminate material with the fibers arranged in layers parallel to the surface. Near the slits the fibers deviate from their arrangement parallel to the surface and follow a course reminiscent of the stress lines near a notch subjected to tensile force or pressure. They curve inward like the lines of greatest principal stress conforming to the contours of the slit. Thus the load-bearing capacity of the cuticle is largest in the direction of the greatest principal stress (Fig. 2b). (4) The sensory holes are not holes drilled into a homogeneous material but shaped within a fibrous laminate composite material while the exoskeleton is laid down. In line with this the chitinous microfibers are not interrupted by the hole but molded around it (Fig. 2b). (5) The ends of the notches are not sharp-edged but rounded (Fig. 2b).

The stress concentration factors SCF (local maximum equivalent stress/far-field stress) seen in the models of slit sense organs (which do not fully describe the natural case because they are homogeneous, in-plane isotropic plates of constant thickness) are about 22 at the ends of an isolated slit of aspect ratio 100 and only 4.2 when the aspect ratio is reduced to 2.5. For ellipses with aspect ratios of 2.5 as found in insect campaniform sensilla the SCF is about 6.5. For the lyriform groups highest SCFs were in the range between about 15 and 25 [14, 17].

Artificial vision; Bionic eye; Electronic visual prosthesis; Epiretinal implant; Retina implant; Retina silicon chip; Sub-retinal implant; Visual prosthesis

Definition

A device intended to restore the vision in patients suffering from vision loss caused by retinal disorders by replacing or improving the natural retina function or the vision pathway.

Visual Prosthesis for Retinal Disorders

Visual prostheses are currently under development by the scientific and industrial communities aimed to restore the vision for people suffering from retinal disorders such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD). Several types of visual prosthesis have been developed to date by different groups using different approaches. All approaches focus on developing a so called "artificial retina."

The artificial retina includes a device intended to mimic the function of the photoreceptors in the natural retina. The natural retina is made of several layers. In retinal disorders, such as RP and AMD, the photoreceptor layer is compromised. The photoreceptor layer comprises photoreceptor cells that are responsible for capturing the incoming light and transforming it into electrical pulses that will travel to the brain where the image will be created. The artificial retina approach is based on the finding that, although the photoreceptor layer is dysfunctional, the rest of the retina (bipolar and ganglion cells) and the visual pathway is still capable of transmitting the visual information, as electrical pulses, to the brain.

This entry focuses on the Department of Energy's (DOE) artificial retina because it has been successfully developed and commercialized, although other prototypes using different approaches are being developed by other groups worldwide [1].

DOE Epiretinal Device Function

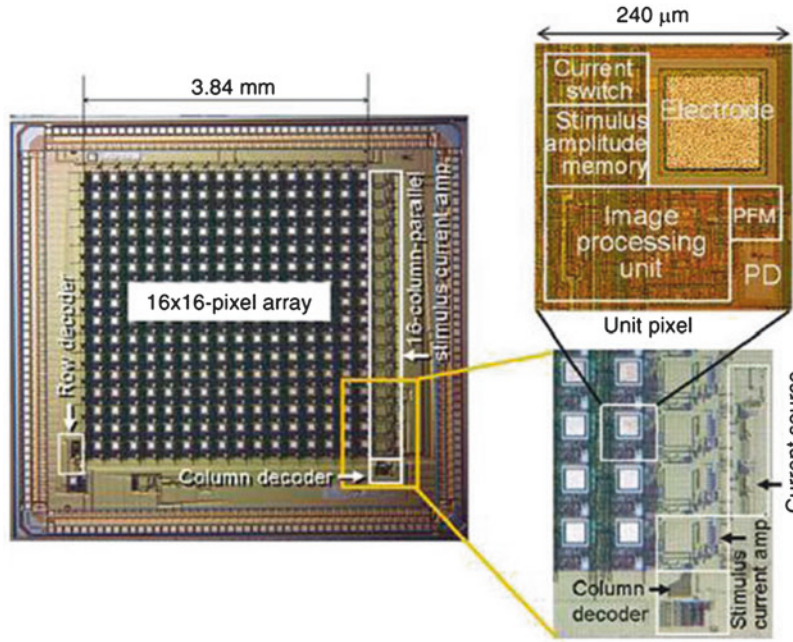
As with the natural retina, an artificial retina should be able to transform the light (a flow of photons) into an electrical pulse (a flow of electrons). This is performed by a camera mounted on a glass connected to a video processing unit (VPU) that is located on the belt of the patient. The camera receives the visual information and transmits this information to a VPU that converts this information into a digital format in the form of pixels that are sent to the internal unit. The internal unit uses a stimulator system to generate electrical pulses that activate the neuron cells through a microelectrode array placed in contact with the bodies of these neurons (the group of neurons that are thought to be activated are the ganglion cells). These cells trigger an electrical wave called action potential that transports the visual information codified in electric pulses through the optic nerve to the occipital cortex of the brain where the image percept is created.

Main Components of the DOE Artificial Retina

The device can be divided in two parts, an external component and an internal component:

External Components

Camera: A CCD camera, located on glasses used by the patient, collects the visual information in the form of pixels sending this information to a microprocessor located in the patient belt.



Microprocessor: A microprocessor is placed on the patient's belt in order to capture the visual information (pixels) and transforms it into electronic signals. This part of the device is located externally allowing adjustments of the visual information to send the most accurate data to the internal unit. In this manner, the ophthalmologist could evaluate the patient's vision and modify it accordingly.

Battery: A battery is placed externally to provide energy to the external microprocessor, but also to send energy wirelessly to the internal unit. Having an external battery is an important requirement since a battery located inside would have more constraints such as being of small size, and its replacement could demand frequent surgeries plus the fact that a battery inside the eye would require stringent bio-isolation from the eye to prevent eye rejection.

Internal Components

Transmitting Unit: Using a special algorithm, the internal unit codifies the electronic signals sent by the microprocessor and send electrical pulses through a stimulator to the microelectrode array located at the retina surface via wire connection. The power to supply this unit is provided wireless by the external component.

Microelectrode array: Microelectrodes are the interface between the device and the visual system that are responsible for stimulating the neurons that will transport the visual stimulus to the brain. Microelectrodes are micrometer size structures ranging from flat circular platinum discs to elongated sharp pyramidal structures, in the size ranging between 250 and 500 μ in diameter, responsible for transmitting the electrical pulses

Artificial Retina: Focus on Clinical and Fabrication Considerations, Fig. 1 Photograph of the internal unit with the microelectrode array and the stimulator circuit (With permission from Springer, from Ref. [4])

coming from the microstimulators to the neurons, which become activated and transport the electrical pulses to the brain. To date, microelectrode arrays have been developed, featuring 16, 64, and 200 microelectrodes. The 64 microelectrode array is currently the first artificial retina implanted commercially in blind people, first in Europe, where Second Sight has obtained approval for commercial implantation of the epiretinal device. Several kinds of microelectrodes have been developed for retina prosthesis. Desired features for retina microelectrodes are low impedance which means easy transfer of electrical pulses to the neurons, biocompatibility, or an acceptable tissue response to the implant, long lifetime to avoid additional surgeries, and flexibility (that means, adaptation of the implant to the curvature of the eyeball without hindering the electrode-neuron distance that could promote heating effects if they are too close or could not activate the neurons if they are too separate). Miniaturization of electrodes is highly desirable and currently under development as the larger number of electrodes allows to achieving higher resolution of the image. The problem, which a tough one, is that impedance increases as electrode size becomes smaller. As impedance increase, voltage should increase to deliver the same amount of charge to the neurons, resulting in an increase in energy consumption, and concurrently an increase in heat dissipation, which could damage the surrounding tissue.

Wireless Transfer of Information and Energy between External and Internal Units: In the current epiretinal devices, both information and energy communication between the external and internal units transmitted via electromagnetic signals wirelessly and coupled to the microchip via inductively coupling coils. Inductively coupling coils are conductive wires built up as coils that work based on the physical phenomena of electromagnetic induction by which an electric current flowing in one coil induces a voltage on the other coil by the electromagnetic field created in the former by the current flow. One of the coils is located in the external component while the other is located in the internal component (Fig. 1).

Materials Used in the DOE Artificial Retina

Silicon: Silicon is the current material used in most of the microelectronic components and

microfabrication processes. In the artificial retina, microprocessors are necessary for translating the visual stimulus into an electric signal. Also, the internal unit has a microchip stimulator to deliver the electric signal to the microelectrodes.

Diamond: In the DOE artificial retina prototype, a novel diamond material known as Ultrananocrystalline Diamond (UNCD) is being investigated in thin film form to provide a hermetic/bioinert/biocompatible coating to encapsulate the silicon microchip to enable implantation inside the eye. The UNCD film provides a coating extremely resistant to the corrosive environment of the eye saline, which otherwise would attack the silicon material underneath dissolving it [5].

Polymers: Some polymers including polyimide, parylene, and silicone have been tested to provide a flexible platform to deposit microelectrodes. In this manner, it is possible to adjust the microelectrode array to the curvature of the eye reducing the distance between the device and the neurons which results in lower voltage thresholds to activate the neurons decreasing power consumption.

Metals

Gold: gold is being used as one of the noble metals for wires to connect the microelectrode array to the pads where the current is delivered from the internal electronic unit that drives the energy provided wireless by the external battery.

Platinum: Platinum is being used as the material for microelectrodes. Key properties that make platinum an optimum candidate as microelectrode material includes its capacity to transfer electrical charge to the neurons (low impedance), its biocompatibility, and its durability. A potential problem of Pt, which has not been investigated in detail, is the catalytic properties of Pt. As the size of the Pt electrodes becomes smaller, the catalytic properties of Pt becomes bigger. Under the liquid environment of the eye, this could increase the risk of unwanted electrochemical reactions.

Indium Tin Oxide: material used for leads

Silicon Nitride: material used as insulator layer

Silicon Oxide: material used as insulator layer

Fabrication Process of the DOE Artificial Retina

Due to the tiny and delicate space that occupies the retina inside the eyeball, miniaturization technologies are deemed extremely necessary to create complex devices with integrated functionality. Some of the miniaturization techniques currently used to develop an artificial retina are:

Photolithography: Photolithography is a technique developed to imprint micro and nano patterns using a photosensitive polymer that when exposed to UV light it could reproduce a pattern imprinted in a mask over a substrate like silicon.

Reactive Ion Etching (RIE): Once a photolithography pattern is created, in order to etch away the parts that do not correspond to the pattern, an etching technique is needed. RIE is a technique that uses high-energy ions, radicals, and electrons created in plasma and accelerated toward the substrate to enhance chemical reactions of the reactive atoms in the system to produce directional (anisotropic) etching of the substrate.

Electroplating: Electroplating is a technique that allows growing metals to create microstructures such as the platinum discs microelectrode array.

Thin Film Deposition (Sputtering, Physical Evaporation, Chemical Vapor Deposition): Sputtering, physical evaporation, and chemical vapor deposition techniques are used to produce films with thickness from a few nanometers ($1\ \text{nm} = 10^{-7}$ cm) to a few microns ($1\ \mu\text{m} = 10^{-4}$ cm). For the components of the artificial retina, different type of films are used for different purposes. In the hermetic encapsulation of the microchip to provide bioinertness (UNCD films), in the metal contacts to allow current passage to the microelectrodes (platinum films), and insulation layers to minimize or eliminate leakage currents that could promote unwanted electrochemical reactions within the biological media of the eye.

Most of these techniques are carried out in special facilities known as clean room designed to keep the air free from dust particles, preserving the surface of the retina components free from contaminants (dust and other species).

Laboratory Studies for Assessing Retina Structure and Function

In Vitro and In Vivo Testing

In vitro and vivo testing of biomedical devices becomes of critical importance to accomplish the goal of developing a safe and effective commercial device. In vitro systems could provide valuable information regarding electrical requirements that are needed to activate ganglion cells and thus the visual pathway. Electrophysiological techniques are used to study and assess the response of the artificial retina components to electrical stimulus and are some of the laboratory techniques to perform analysis of the artificial retina performance. Electrophysiological studies are based on recording electric potentials of the retina neurons. Electric potentials (EP) are electric waves that travel through the neurons carrying information. In this case, visual information is codified by frequency and amplitude changes of the potentials. In retina diseases such as RP and AMD, it is found that electrical potentials are altered and therefore become an important tool to perform a diagnosis of retina disease. In the same manner, the EPs allow an electrical characterization of artificial retina performance by analyzing the effect of microelectrodes stimulation on the activation of retina neurons. The technique developed to record EPs on retina cells is called *Electroretinogram. In order to perform an Electroretinogram* it is necessary to mount electrodes in the ocular surface to be able to record electric potentials in the neurons of the retina. A more invasive technique, called intraocular electroretinogram, consists of placing an electrode inside the eye, near the retina surface. In spite of providing useful information during the stage of animal testing, the clinical utility of Electroretinogram remains controversial.

In addition to the microelectrode system, the experimental setup to perform these types of experiments includes isolating the retina from the eyeball of an animal (i.e., salamander). The retina tissue is stimulated by a microelectrode array displayed in such a way to contact the retina neurons. In this manner, it is possible to record the electrical activity of a group of neurons (i.e., bipolar cells, ganglion cells) after an electric pulse is applied through a microelectrode array. Before performing studies in human subjects, it is necessary to evaluate the safety and effectiveness of the artificial retina in an *animal model*. An animal model mimics the human disease in an animal. Animal models of RP and AMD have been developed to assess the safety and effectiveness of an artificial retina [6].

Clinical and Surgical Considerations

Device Implantation

The eye is divided in two main compartments, the anterior compartment composed of the cornea, iris, and lens, and the posterior segment composed of the sclera, choroid, retina vitreous, and optic nerve. In order to implant the artificial retina, it becomes mandatory to access the posterior compartment of the eye, which is filled with a gelatinous substance known as vitreous. Being able to place the device on the retina surface (epiretinal) requires to remove the vitreous out of the posterior chamber while simultaneously keeping the pressure of the eye constant to avoid the collapse of the eyeball. The procedure is called vitreoretinal surgery and is done by performing three incisions on the sclera, one for introducing an illuminating system, another one for introducing a cannula to insert the device and cut the vitreous (it is not possible to suction it because it could track the retina and produce a retinal detachment, therefore it should be cut first and then aspirated), and the last incision for infusing liquid to keep the intraocular pressure constant while the small pieces of vitreous are aspirated. The device is fixed to the surface of the inner part of the retina using a tack that keeps the device in place avoiding any displacement [7].

Clinical Assessment of a Patient with an Artificial Retina

Vision Before Surgery

Patients with RP initially suffer from night blindness. As the disease progress, patients start to relate symptoms associated with peripheral loss

of rods such as inability to see pedestrians while they are driving. In addition, a difficulty in seeing the light impedes the patient from reading. At more advances stages, the patient loses independency because they are only able to see a small center region of the visual field (tunnel vision) and they are not able to walk by themselves. The patient with MD on the other hand consults for central vision impairment such as vision blurring, or a scotoma, which is a patch in the center of the visual field. At later stages, in both diseases, blindness could be the final outcome. Therefore, an artificial retina could restore partial vision for these patients enhancing their quality of life significantly. Computer simulations indicate that in order for a blind person to recover basic visual capabilities such as face recognition, reading, and independent mobility, the artificial retina should have at least 1,000 electrodes in order to create an image of 1,000 pixels. Current technologies have not overcome this challenge yet because miniaturization of electrodes is difficult. However, improvement of everyday life activities performance has been observed in patients that were implanted with the device with 60 electrodes [1].

Clinical Studies to Assess Retina Structure and Function

OCT (Optical Coherence Tomography): OCT is a clinical technique that allows the measurement of the thickness of the retina. When an artificial retina is implanted, OCT brings about useful information about distance between microelectrodes and the retina surface which is an important parameter, since in order to obtain a neural response the microelectrode array should be placed in close proximity to the group of neurons. In addition, if the microelectrode array is placed too far apart from the retina neurons the system consumes more power and dissipates more heat, increasing the chances of tissue damage.

Fundus Photo: Fundus refers to the inside back part of the eye where the retina is located. A special tool called ophthalmoscope allows the physician to take pictures of this part of the eye obtaining valuable information of the status of the retina tissue affected by RP or AMD.

Fluorescein Angiogram

This technique allows visualization of retina vessels by injecting a fluorophore inside the artery vessels. It is a useful technique for diagnosis of RP.

Clinical Performance After Artificial Retina Implantation

After implantation with an artificial retina containing 16 microelectrodes, patients were capable of discerning light and dark patterns (called phospenes) and localizing the spatial origin of the phospenes (which microelectrode was stimulated), whereas with the new generation of 64 microelectrodes the patients were capable of performing spatial motor task where visual input results are of critical importance to perform motor activities. In order to assess visual performance in these patients, several specific test including psychophysical studies, specific questionnaires, and subjective perceptions are being used, and new strategies to objectively assess visual function in patients implanted with an artificial retina are being pursued.

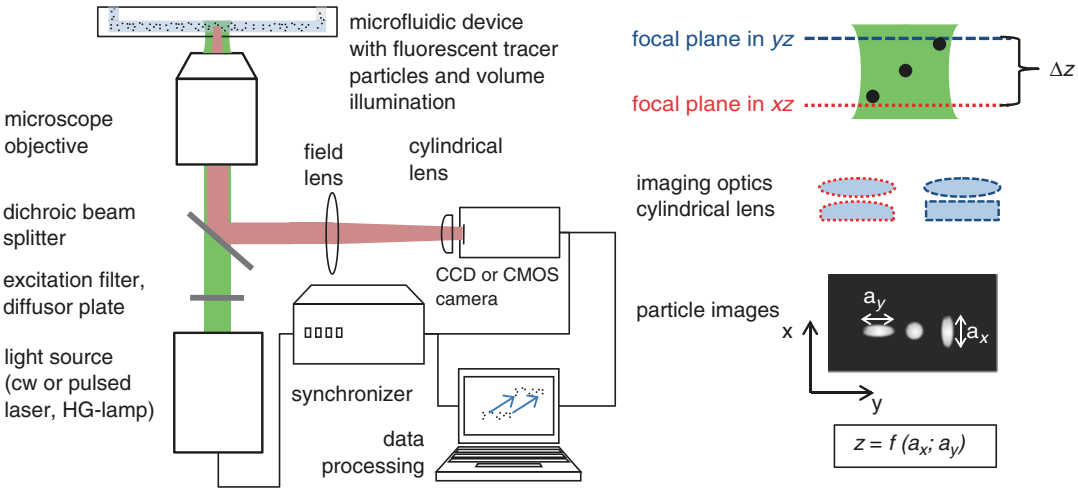
Definition

Astigmatism particle imaging is an optical method to determine the instantaneous volumetric position of spherical particles in a volume of transparent medium using only a single camera view. The method is mainly applied in microfluidics to measure the velocity and trajectories of tracer particles that follow the fluid motion. However, recently it could be shown that this measurement principle without bias errors due to the depth of correlation and spatial averaging is well suited to reconstruct the arbitrary-shaped interface of mixing layers in a micromixer with extended high precision.



Optical Principle

Astigmatic imaging is a way to break the axis symmetry of an optical system, thus allowing for the depth coding of particle positions in 2D images. Among the manifold of 3D3C methods recently developed, it can be classified as a method that makes use of the particle defocus without using an extra aperture [13]. The word astigmatism is based on the Greek language description for not (a-) point-shaped (-stigma). An optical system that features astigmatism has two focal planes, and the astigmatic image of a point source is thus an ellipse as shown in Fig. 1. Astigmatism is commonly used for technical applications, e.g., autofocus systems in CD, DVD, or Blu-ray players, to measure the distance between the rotating disk and the reader head.

One approach producing an astigmatic image aberration is the use of a tilt angle between the measurement plane or volume and the camera, which results in off-axis imaging. This method is often not applicable due to the fixed optical axis in microscopes and requires complex calibration procedures. However, another more elegant method is the use of cylindrical lenses. Already in 1994, Kao and Verkman [7] applied this technique to measure the position of fluorescent particles in living cells. The basic principle and the implementation to a standard epi-fluorescence microscope are shown in Fig. 2. The only difference from a standard microparticle image

Astigmatic Microparticle Imaging, Fig. 1 Schematic of astigmatism caused by off-axis imaging and the appearance of the image at various distances between the two focal planes, according to [5]

Astigmatic Microparticle Imaging, Fig. 2 Schematic of the astigmatism technique integrated in an inverted epi-fluorescence microscope (*left*) and principle schematic of the imaging with the cylindrical lens, according to [13]. The width a_x and height a_y of the particle images can be related to the axial (depth) position z (*right*)

velocimetry (μPIV) system [12] is the cylindrical lens, which is installed in front of the camera chip as shown in Fig. 2. As for standard μPIV, the transparent flow of interest is usually seeded with monodisperse spherical fluorescent tracer particles that follow the flow faithfully. The whole microfluidic channel is then illuminated twice by a laser or another bright light source (continuous or pulsed). To homogenize the beam profile often, a diffuser plate is used. A dichroic beam splitter is applied to allow only short wavelength light to pass through (indicated in green in Fig. 2), if a white light source is used. This short wavelength light is then absorbed by the tracer particles' fluorescent dye, and longer wavelength light (indicated in red) is emitted. The dichroic

filter is now used to reject direct reflections of the microfluidic device and only allow the emitted red light to contribute to the signal. A combination of a field lens and the cylindrical lens is used to image the particles on a digital CCD (charge-coupled device), CMOS or sCMOS ((scientific) complementary metal-oxide semiconductor), or intensified camera. On the right side of Fig. 2, the imaging of the particles is schematically shown. The curvature of the cylindrical lens acts in one direction only. Therefore, two distinct focal planes are produced. In the left (red dotted) schematic, the cylindrical lens causes a shortening of the distance between the focal plane and the objective lens. Particles that are close to this focal plane show a sharp and small extension in the x-direction (a_x) and a larger stretched one in the y-direction (a_y), thus producing an oblate-shaped particle image. On the right side of the schematic (blue dashed), the cylindrical lens is rotated by 90°. The focal plane is now further away from the objective lens. a_y is thus smaller than a_x, resulting in a prolate-shaped particle image. The particle image width and height can now be related to the depth position z by a proper calibration.

Data Evaluation and Calibration

Since the volumetric particle position is used later to estimate the velocity or fluid interfaces, the accuracy of the method relies on the precise determination of the particle's position. For the in-plane, or x- and y-direction, an in-plane calibration by means of a grid, or a known object, can be performed. The in-plane position can later be determined with sub-pixel accuracy by either a two-dimensional Gauss fit or via a correlation with a Gaussian, where the latter method is much faster. The width and height of the particle images are identified by either a two-dimensional Gauss fit or the autocorrelation function of the particle image. These algorithms have shown accurate results, even for high noise levels for particle images that extend at least three pixels in both directions [2]. Since the technique relies on the exact determination of the particle images' shapes, at least an 8-bit or better sampling is necessary to yield reliable results. Once a_x and a_y are known, a relationship with the depth distance is necessary. If the particles' diameter distribution is very coarse, the difference $a_x - a_y$ [1] or the ratio a_x/a_y [2] can be used as an independent criteria. The trust region is then limited to the linear region between the two focal planes. For a narrow particle diameter distribution, a direct fit of a_x and a_y can be used to substantially extend the measurement depth. A model of the particle image diameter, as a function of the distance z from the in-focus plane, can be applied for this purpose [9]. Under the assumption that the geometric image of the particles and the effect of diffraction and defocusing can be approximated by a Gaussian function, and that the working distance of the lens is significantly larger than z, the particle image diameter can be estimated by the following equation [14]:

$$a(z) = M\sqrt{d_p^2 + 1.49\lambda^2\left(\frac{n_0^2}{\mathrm{NA}^2} - 1\right) + 4z^2\left(\frac{n_0^2}{\mathrm{NA}^2} - 1\right)^{-1}} \tag{1}$$

where d_p denotes the particle diameter, λ is the wavelength of emitted light, n_0 the refractive index of the immersion medium of the lens, and M and NA are the magnification and numerical aperture of the lens, respectively. Equation 1 represents an arc of a hyperbola. The function can be used to extend the measurement depth beyond the two focal planes, and the fit is applied to the measured data itself:

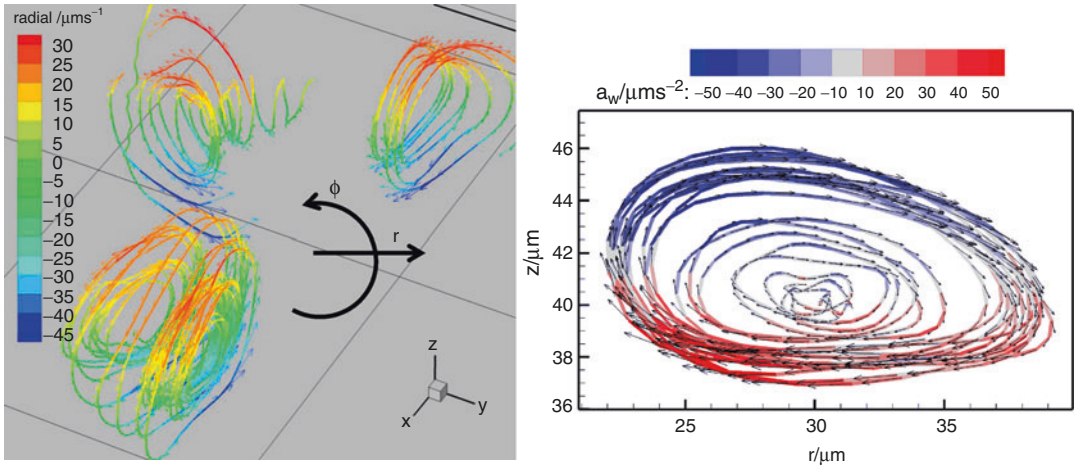
$$\begin{aligned} a_x(z) &= \sqrt{c_1^2(z - F_{xz})^2 + c_2^2} + c_3 \quad a_y(z) \\ &= \sqrt{c_4^2(z - F_{yz})^2 + c_5^2} + c_6 \end{aligned} \tag{2}$$

F_{xz} and F_{yz} denote the positions of the respective in-focus planes for the x- and y-directions, and $c_{1\ldots6}$ are parameters for the fit function. Particles that are beyond the in-focus planes can be taken into account by this fit, and thus the measurement volume is not restricted to the linear region between the in-focus planes. The distance between F_{xz} and F_{yz} in physical space can be

determined automatically by scanning a grid reticule through the volume. The axial position of F_{xz} and F_{yz} can be measured by a fit of a focus function (e.g., rms of the intensity) with submicron resolution. If additional image aberrations are present and the focal planes are not completely flat, these aberrations will also be estimated by the procedure, and the final results can be corrected for this systematic error. The validity of the model was tested on simulated and real data [3]. The advantages of the intrinsic calibration are the following:

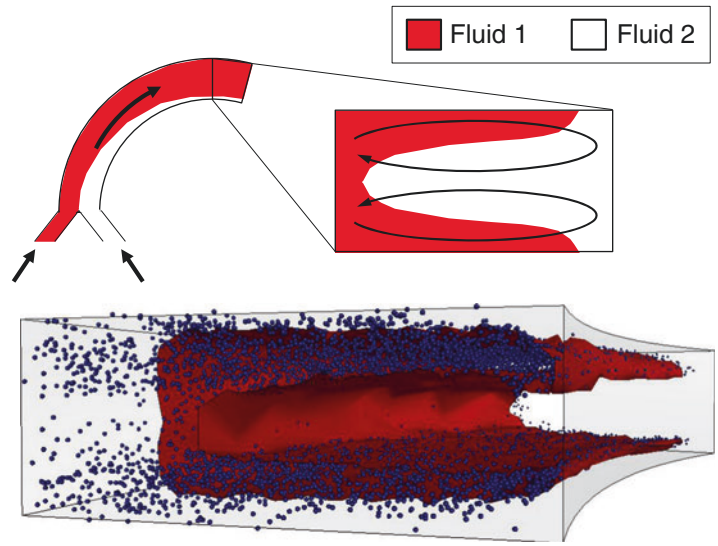
- The measurement volume depth is not limited by the distance between the two in-focus planes.
- The optical path through the different media does not change from calibration to experiment.
- All data points are taken into account, and thus the calibration is statistically relevant to a high degree.

Nevertheless, the distance between the two in-focus planes Δz is the quantity that primarily defines the depth of the measurement volume. It can be adjusted by the focal length of the cylindrical lens or the distance between the imaging lens of the CCD and the cylindrical lens [1]. The specific measurement volume is finally dependent on the specific optical arrangement of the whole microscope and the magnification [1]. Increasing the magnification gives lower Δz for the same cylindrical lens, whereas decreasing the focal length of the cylindrical lens increases the measurement volume by approximately $1/f_{\mathrm{cyl}}$ [3].



Applications

In general, the astigmatic imaging approach based on cylindrical lenses is very easy to apply and allows for the low cost extension of existing 2D measurement systems to fully 3D measurements without changing the illumination light path. Knowing the particle positions in the volume at two different time instants t and $t + \Delta t$ allows for an estimation of the first-order approximation of the particles' velocity. To find matching particles, several elaborate tracking schemes can be used [10, 16]. Despite the necessity for lower seeding concentration to avoid particle image overlapping, the major benefits of a 3D tracking scheme opposed to correlation-based methods are the following:



- Out-of-focus particles do not bias the velocity estimate by the depth of correlation effect [9].
- In-plane gradients and out-of-plane gradients are not averaged over interrogation volumes [6].
- The spatial resolution can be increased by taking a larger number of images.

The tracking approach was applied in recent investigations to measure flow velocities in micron-sized channels [1, 2] and close to the electrode during electrochemical metal deposition [15]. A comparison with standard and stereoscopic μPIV showed a similar uncertainty for the in-plane velocity components but an almost two times lower uncertainty for the out-of-plane component using A-μPTV [4]. Using time-resolved image sampling, the temporal and spatial evolution of the particle trajectories in an electrothermally generated microvortex was measured in a microvolume of 50 µm in depth without traversing [8]. Selected trajectories are shown in a volumetric representation on the left side of Fig. 3. The three-dimensional structure of the vortex and the mechanisms of particle trapping inside the vortex could be studied, and the results were used to validate the numerical boundary conditions for a simulation of such a scenario. Since the particle trajectories were sampled with sufficient temporal resolution, Lagrangian accelerations were also measured as shown on the right side of Fig. 3.

Astigmatic particle imaging can also be used to estimate the boundary of two mixing fluid regions of arbitrary shape or to reconstruct the three-dimensional shape of particle-seeded stream tubes. The volumetric topology of the interface can be estimated from the measured 3D positions of the particles. Algorithms based on Delaunay triangulation and numerical diffusion have been examined to perform the surface reconstruction [11].

Astigmatic Microparticle Imaging, Fig. 3 Selected trajectories in an electrothermally driven microvortex, color coded with the radial velocity (*left*). Representation of one trajectory in the *rz*-plane, color coded with the axial acceleration (*right*)

Astigmatic Microparticle Imaging, Fig. 4 Reconstruction of the mutual interface between two mixing fluids in a microfluidic mixer using the volumetric distribution of tracer particles. The flow is laminar and the convective mixing is induced by secondary flows established as a consequence of the channel curvature

The accuracy and resolution of the reconstruction are limited by the maximum particle density achievable and the error of the particle position determination. However, for steady flows (as typical in microfluidics), any desired accuracy can be achieved for a sufficient large number of samples. A classic example in which this approach is useful is the characterization of passive microfluidic mixers, where the topology of the mutual interface between the two mixing fluid streams plays an important role. In this case, one of the two mixing fluids is seeded with a homogeneous distribution of tracer particles. A typical result for the case of a micromixer, based on a curved microchannel, is shown in Fig. 4.

The cross section of the microchannel was $200 \times 70\ \mu m^2$, and the average particle concentration was set to 0.023 particles/μm^3, resulting in a resolution of 2.5 µm in the optical-axis direction with a maximum estimated error of 5.5 µm [11].

Conclusion and Future Aspects

It is obvious that astigmatic particle imaging is a technique that provides the instantaneous volumetric position of particles in a transparent medium with high precision. The displacement between two successive recordings can be used to estimate the volumetric three-component velocity field. In addition, the Lagrangian velocity and acceleration of the particle can be measured for sufficiently high sampling rates without systematic errors due to the depth of correlation and spatial averaging as typical for μPIV. The positions of the particles can also be used to estimate their volumetric distribution and to analyze the mixing of fluid streams [11], particle agglomeration, trapping, deposition, or other process engineering-relevant phenomena. Since not only the position but also the intensity of the particle images can be measured, other possible extensions of the technique are the measurement of temperature, pH value, or even pressure by particles that show a sensitivity in the fluorescence signal to these quantities.

Definition

Atomic force microscopy (AFM) is a scanning probe technique used to measure very small forces (as low as <1 nN) and produce very high resolution, three-dimensional images of sample surfaces. The AFM is capable of investigating surfaces of both conductors and insulators on the atomic scale. Aside from topographic imaging, the AFM is used in a wide variety of applications, including, but not limited to, the measurement of mechanical properties, chemical forces, electrical properties, among others.

Overview

Gerd Binnig and his colleagues developed the AFM in 1985. It is capable of investigating surfaces of scientific and engineering interest on an atomic scale [1]. As shown in Table 1, it belongs to a general class of related instrumental techniques that are used in determining surface nanotopography, nanomechanical, and nanotribological properties, such as the surface force apparatus (SFA), the scanning tunneling microscopes (STM), and the friction force microscope (FFM). The SFA was developed in 1968 and is commonly employed to study both static and dynamic properties of molecularly thin films sandwiched between two molecularly smooth surfaces. The STM, developed in 1981, allows imaging of electrically conducting surfaces with atomic resolution, and has been used for imaging of clean surfaces. AFM/FFM techniques have the advantage of imaging all types of sample surfaces, regardless of its roughness or electrical properties, unlike the SFA or STM.

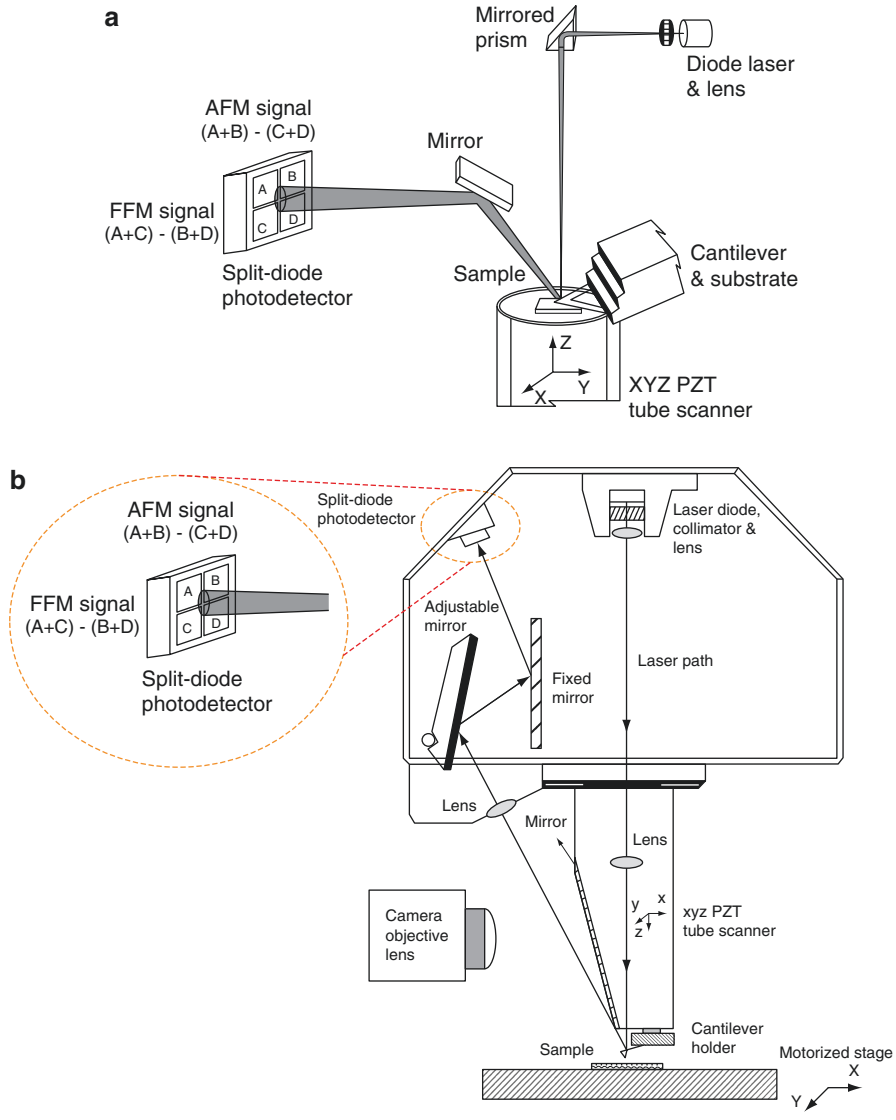
The AFM relies on a scanning technique to produce very high resolution, three-dimensional images of sample surfaces. It measures ultrasmall forces (less than 1 nN) present between the AFM tip surface mounted on a flexible cantilever beam and a sample surface. These small forces are obtained by measuring the motion of a very flexible cantilever beam having an ultrasmall mass, by a variety of measurement techniques including optical deflection, optical interference, capacitance, and tunneling current. The deflection can be measured to within 0.02 nm, so for a typical cantilever spring constant of 10 N/m, a force as low as 0.2 nN can be detected. To put these numbers in perspective, individual atoms and human hair are typically a fraction of a nanometer and about 75 μm in diameter, respectively, and a drop of water and an eyelash have a weight of about 10 and 100 nN, respectively.

In the operation of high-resolution AFM, the sample is generally scanned rather than the tip because any cantilever movement would add vibrations. AFMs are available for measurement of large samples, where the tip is scanned and the sample is stationary. To obtain atomic resolution with the AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. For high lateral resolution, tips should be as

Atomic Force Microscopy, Table 1 Comparison of typical operating parameters in SFA, STM, and AFM/FFM used for micro/nanotribological studies

Operating parameter	SFA	STM[a]	AFM/FFM
Radius of mating surface/tip	~10 mm[b]	5–100 nm	5–100 nm
Radius of contact area	10–40 μm	N/a	0.05–0.5 nm
Normal load	10–100 mN	N/a	<0.1–500 nN
Sliding velocity	0.001–100 μm/s	0.02–200 μm/s (scan size ~1 nm × 1 nm–125 μm × 125 μm; scan rate <1–122 Hz)	0.02–200 μm/s (scan size ~1 nm × 1 nm–125 μm × 125 μm; scan rate <1–122 Hz)
Sample limitations	Typically atomically–smooth, optically transparent mica; opaque ceramic, smooth surfaces can also be used	Electrically conducting samples	None of the above

[a]Can be used for atomic-scale imaging
[b]Since stresses scale with the inverse of tip radius, SFA can provide very low stress measurement capabilities



sharp as possible. Tips with a radius ranging from 5 to 50 nm are commonly available. Aside from topographic imaging, the AFM is also widely used for the characterization of surface/near-surface properties such as friction, adhesion, scratch, wear, fabrication/machining, electrical properties (such as surface potential, resistance, capacitance, tunneling current, electric field gradient distribution), local deformation, nanoindentation, local surface elasticity, viscoelasticity, and boundary lubrication.

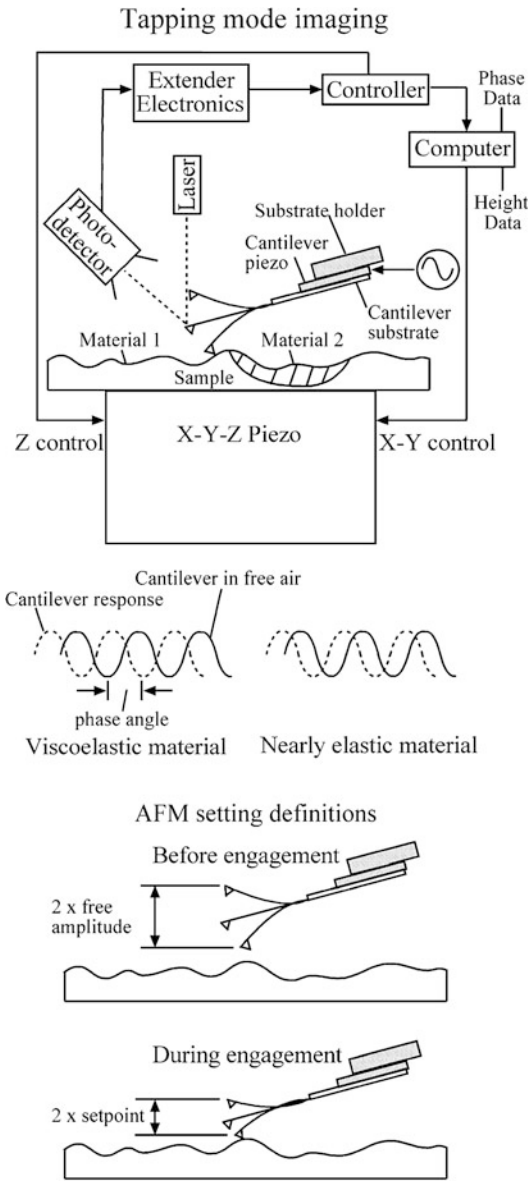
Various measurement techniques using atomic force microscopy are described next.

Description of Various Measurement Techniques

Surface Roughness and Friction Force Measurements

The AFM is widely used for surface height imaging and roughness characterization down to the nanoscale. Commercial AFM/FFM is routinely used for simultaneous measurements of surface roughness and friction force [2–4]. These instruments are available for measurement of small samples and large samples. In a small sample AFM shown in Fig. 1a, the sample, generally no larger than 10 mm × 10 mm, is mounted on a piezoelectric crystal in the form of a cylindrical tube (referred to as a PZT tube scanner) which consists of separate electrodes to scan the sample precisely in the X–Y plane in a raster pattern and to move the sample in the vertical (Z) direction. A sharp tip at the free end of a flexible cantilever is brought in contact with the sample. Normal and frictional forces being applied at the tip-sample interface are measured using a laser beam deflection technique. A laser beam from a diode laser is directed by a prism onto the back of a cantilever near its free end, tilted downward at about 10° with respect to the horizontal plane. The reflected beam from the vertex of the cantilever is directed through a mirror onto a quad photodetector (split photodetector with four quadrants). The differential signal from the top and bottom photodiodes provides the AFM signal which is a sensitive measure of the cantilever vertical deflection. Topographic features of the sample cause the tip to deflect in the vertical direction as the sample is scanned under the tip. This tip deflection will change the direction of the reflected laser beam, changing the intensity difference between the top and bottom sets of photodetectors (AFM signal).

Atomic Force Microscopy, Fig. 1 Schematics (**a**) of a commercial small sample atomic force microscope/friction force microscope (*AFM/FFM*) and (**b**) of a large sample AFM/FFM



In the AFM operating mode called the contact mode, for topographic imaging or for any other operation in which the applied normal force is to be kept constant, a feedback circuit is used to modulate the voltage applied to the PZT scanner to adjust the height of the PZT, so that the cantilever vertical deflection (given by the intensity difference between the top and bottom detector) will remain constant during scanning. The PZT height variation is thus a direct measure of the surface roughness of the sample.

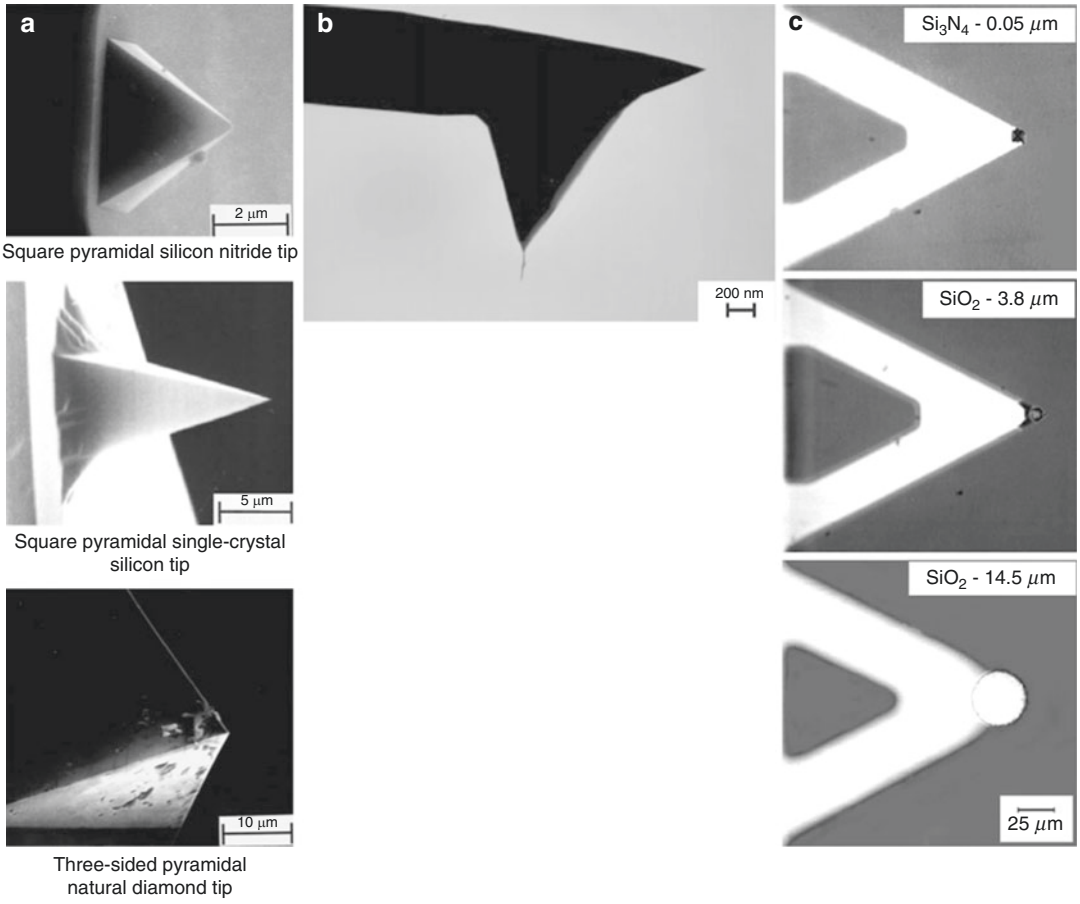
In a large sample AFM, both force sensors using optical deflection method and scanning unit are mounted on the microscope head, Fig. 1b. Because of vibrations added by cantilever movement, lateral resolution of this design can be somewhat poorer than the design in Fig. 1a in which the sample is scanned instead

of cantilever beam. The advantage of the large sample AFM is that large samples can be measured readily.

Aside from contact mode, most AFMs are equipped with dynamic operational mode capabilities, such as the amplitude modulation mode and the frequency modulated mode (also referred to as the self-excitation mode), which also can be used for surface roughness measurements. It should be noted that these dynamic modes could be implemented as an intermittent contact or noncontact imaging experiments. The amplitude modulation mode, also referred to as "tapping mode" will be described further below, as it is the most widely used among the dynamic modes of AFM operation.

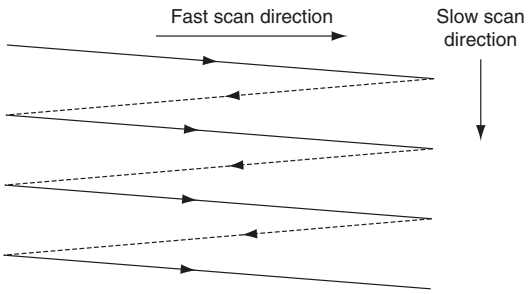
During a surface scan in tapping mode, the cantilever/tip assembly with a normal stiffness of 20–100 N/m (tapping mode etched Si probe or TESP) is sinusoidally vibrated at its resonance frequency (350–400 kHz) by a piezo mounted above it, and the oscillating tip slightly taps the surface. The piezo is adjusted using feedback control in the Z-direction to maintain a constant (20–100 nm) oscillating amplitude (setpoint) and constant average normal force, Fig. 2 [2–4]. The feedback signal to the Z-direction sample piezo (to keep the setpoint constant) is a measure of surface roughness. The cantilever/tip assembly is vibrated at some amplitude, here referred to as the free amplitude, before the tip engages the sample. The tip engages the sample at some setpoint, which may be thought of as the amplitude of the cantilever as influenced by contact with the sample. The setpoint is defined as a ratio of the vibration amplitude after engagement to the vibration amplitude in free air before engagement. A lower setpoint gives a reduced amplitude and closer mean tip-to-sample distance. The amplitude should be kept large enough so that the tip does not get stuck to the sample because of adhesive attractions. Also, the oscillating amplitude applies less average (normal) load as compared to contact mode and reduces sample damage. The tapping mode is used in topography measurements to minimize effects of friction and other lateral forces, and is well suited for topographic imaging of soft surfaces.

Atomic Force Microscopy, Fig. 2 Schematic of tapping mode used to obtain height and phase data and definitions of free amplitude and setpoint. During scanning, the cantilever is vibrated at its resonance frequency and the sample X-Y-Z piezo is adjusted by feedback control in the Z-direction to maintain a constant setpoint. The computer records height (which is a measure of surface roughness) and phase angle (which is a function of the viscoelastic properties of the sample) data



For measurement of friction force at the tip surface during sliding, left hand, and right hand sets of quadrants of the photodetector are used.

In the so-called friction mode, the sample is scanned back and forth in a direction orthogonal to the long axis of the cantilever beam. A friction force between the sample and the tip will produce a twisting of the cantilever. As a result, the laser beam will be reflected out of the plane defined by the incident beam and the beam reflected vertically from an untwisted cantilever. This produces an intensity difference of the laser beam received in the left hand and right hand sets of quadrants of the photodetector. The intensity difference between the two sets of detectors (FFM signal) is directly related to the degree of twisting and hence to the magnitude of the friction force. One problem associated with this method is that any misalignment between the laser beam and the photodetector axis would introduce error in the measurement. However, by following the procedures developed by Ruan and Bhushan [5], in which the average FFM signal for the sample scanned in two opposite directions is subtracted from the friction profiles of each of the two scans, the misalignment effect is eliminated. This method provides three-dimensional maps of friction force. By following the friction force, calibration procedures developed by Ruan and Bhushan [5], voltages corresponding to friction forces can be converted to force units [6]. The coefficient of friction is obtained from the slope of friction force data measured as a function of normal loads typically ranging from 10 to 150 nN. This approach eliminates any contributions due to the adhesive forces [2–4]. For calculation of the coefficient of friction based on a single-point measurement, friction force should be divided by the sum of applied normal load and intrinsic adhesive force. Furthermore it should be pointed out that for a single asperity contact, the coefficient of friction is not independent of load.



Surface roughness measurements in the contact mode are typically made using a sharp, microfabricated square-pyramidal Si_3N_4 tip with a radius of 30–50 nm on a triangular cantilever beam (Fig. 3a) with normal stiffness on the order of 0.06–0.58 N/m with a normal resonant frequency of 13–40 kHz (silicon nitride probe or NP) at a normal load of about 1–50 nN, and friction measurements are carried out in the load range of 1–100 nN. Surface roughness measurements in the tapping mode utilize a stiff cantilever with high resonance frequency; typically a square-pyramidal etched single-crystal silicon tip, with a tip radius of 5–10 nm, integrated with a stiff rectangular silicon cantilever beam (Fig. 3a) with a normal stiffness on the order of 17–60 N/m and a normal resonance frequency of 250–400 kHz (TESP), is used. Multiwalled carbon nanotube tips having a small diameter (few nm) and a length of about 1 μm (high aspect ratio) attached on the single-crystal silicon, square-pyramidal tips are used for high- resolution imaging of surfaces and of deep trenches in the tapping mode (noncontact mode) (Fig. 3b) [3, 4]. The MWNT tips are hydrophobic. To study the effect of the radius of a single asperity (tip) on adhesion and friction, microspheres of silica with radii ranging from about 4 to 15 μm are attached at the end of cantilever beams. Optical micrographs of two of the microspheres at the ends of triangular cantilever beams are shown in Fig. 3c.

The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern, Fig. 4. Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. Scan sizes ranging from less than 1 nm × 1 nm to 125 μm × 125 μm and scan rates from less than 0.5–122 Hz typically can be used. Higher scan rates are used for smaller scan lengths. For example, scan rates in the fast and slow scan directions for an area of 10 μm × 10 μm scanned at 0.5 Hz are 10 μm/s and 20 nm/s, respectively.

In an AFM measurement during surface imaging, the tip comes in intimate contact with the sample surface and leads to surface deformation with finite tip-sample contact area (typically few atoms). The finite size of contact area prevents the imaging of individual point defects, and only the periodicity of the atomic lattice can be imaged. Figure 5 shows the topography and friction force images of a freshly cleaved surface of highly oriented pyrolytic graphite (HOPG) [2–4]. The atomic-scale friction force of HOPG exhibited the same periodicity as the corresponding topography.

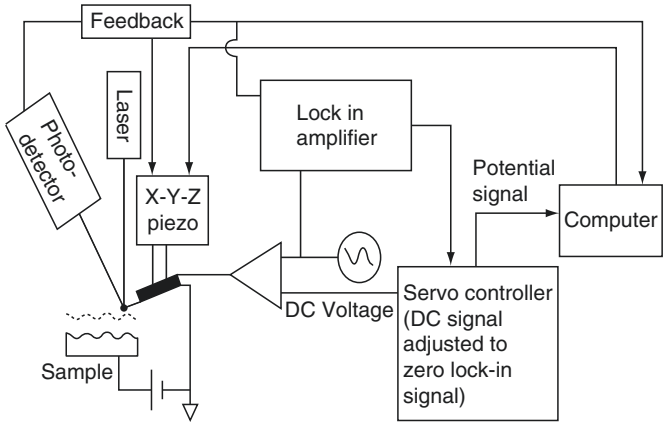
Atomic Force Microscopy, Fig. 4 Schematic of triangular pattern trajectory of the tip as the sample (or the tip) is scanned in two dimensions. During scanning, data are recorded only during scans along the solid scan lines

Adhesion Measurements

Adhesive force measurements are performed in the so-called force calibration mode. In this mode, force-distance curves are obtained. An example is shown in Fig. 6 for the contact between a Si_3N_4 tip and a single-crystal silicon surface. The horizontal axis gives the distance the piezo (and hence the sample) travels, and the vertical axis gives the tip deflection. As the piezo extends, it approaches the tip, which is at this point in free air and hence shows no deflection. This is indicated by the flat portion of the curve. As the tip approaches the sample within a few nanometers

Atomic Force Microscopy, Fig. 5 (**a**) Gray-scale plots of surface topography and friction force maps (2D spectrum filtered), measured simultaneously, of a 1 nm × 1 nm area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction and (**b**) schematic of superimposed topography and friction maps from (**a**); the symbols correspond to maxima. Note the spatial shift between the two plots [3, 4]



Atomic Force Microscopy, Fig. 6 Typical force-distance curve for a contact between Si_3N_4 tip and single-crystal silicon surface in measurements made in the ambient environment. Snap-in occurs at point A; contact between the tip and silicon occurs at point B; tip breaks free of adhesive forces at point C as the sample moves away from the tip

(point A), an attractive force exists between the atoms of the tip surface and the atoms of the sample surface. The tip is pulled toward the sample and contact occurs at point B on the graph. From this point on, the tip is in contact with the surface and as the piezo further extends, the tip gets further deflected. This is represented by the sloped portion of the curve. As the piezo retracts, the tip goes beyond the zero deflection (flat) line because of attractive forces (van der Waals forces and long-range meniscus forces), into the adhesive regime. At point C in the graph, the tip snaps free of the adhesive forces and is again in free air. The horizontal distance between points B and C along the retrace line gives the distance moved by the tip in the adhesive regime. This distance multiplied by the stiffness of the cantilever gives the adhesive force. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis in the PZT tube [2–4].

Scratching, Wear, and Fabrication/Machining

For microscale scratching, microscale wear, nanofabrication/nanomachining, and nano-indentation hardness measurements, an extremely hard tip is required. A three-sided pyramidal

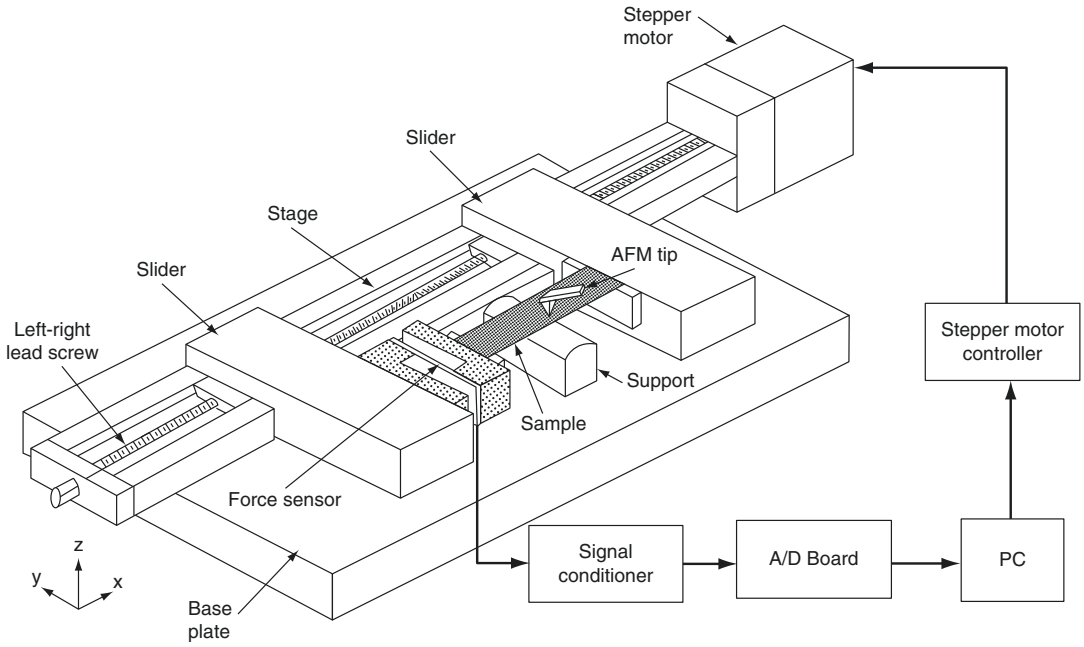
Atomic Force Microscopy, Fig. 7 Schematic of lift mode used to make surface potential measurement. The topography is collected in tapping mode in the primary scan. The cantilever piezo is deactivated. Using topography information of the primary scan, the cantilever is scanned across the surface at a constant height above the sample. An oscillating voltage at the resonant frequency is applied to the tip and a feedback loop adjusts the DC bias of the tip to maintain the cantilever amplitude at zero. The output of the feedback loop is recorded by the computer and becomes the surface potential map

single-crystal natural diamond tip with an apex angle of 80° and a radius of about 100 nm mounted on a stainless steel cantilever beam with normal stiffness of about 25 N/m is used at relatively higher loads (1–150 μN), Fig. 3a. For scratching and wear studies, the sample is generally scanned in a direction orthogonal to the long axis of the cantilever beam (typically at a rate of 0.5–50 Hz) so that friction can be measured during scratching and wear. The tip is mounted on the cantilever such that one of its edges is orthogonal to the long axis of the beam; therefore, wear during scanning along the beam axis is higher (about 2–3 x) than that during scanning orthogonal to the beam axis. For wear studies, an area on the order of 2 μm × 2 μm is scanned at various normal loads (ranging from 1 to 100 μN) for a selected number of cycles [2, 4].

Scratching can also be performed at ramped loads and the coefficient of friction can be measured during scratching [2–4]. A linear increase in the normal load approximated by a large number of normal load increments of small magnitude is applied using a software interface (such as the lithography module in Nanoscope) that allows the user to generate controlled movement of the tip with respect to the sample. The friction signal is tapped out of the AFM and is recorded on a computer. A scratch length on the order of 25 μm and a velocity on the order of 0.5 μm/s are used and the number of loading steps is usually taken to be 50.

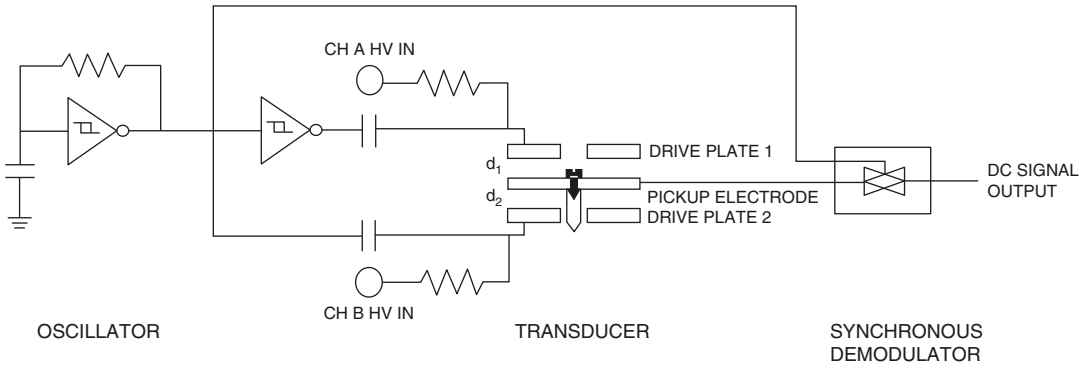
Nanofabrication/nanomachining is conducted by scratching the sample surface with a diamond tip at specified locations and scratching angles. The normal load used for scratching (writing) is on the order of 1–100 μN with a writing speed on the order of 0.1–200 μm/s [2–4, 7].

Electrical Properties Measurements



The use of a conductive tip in AFM experiments enables the mapping of surface or subsurface electrical properties of materials. Various AFM-based electrical characterization methods have been developed, such as scanning Kelvin probe force microscopy, scanning impedance microscopy, scanning capacitance microscopy, piezoresponse force microscopy, conductive AFM, scanning spreading resistance microscopy, and scanning gate microscopy. As an example, scanning Kelvin probe force microscopy, which is used for the measurement of the surface potential, is described below.

Mapping of the surface potential is made in the so-called lift mode (Fig. 7). These measurements are made simultaneously with the topography



scan in the tapping mode, using an electrically conducting (nickel-coated single-crystal silicon) tip. After each line of the topography scan is completed, the feedback loop controlling the vertical piezo is turned off, and the tip is lifted from the surface and traced over the same topography at a constant distance of 100 nm. During the lift mode, a DC bias potential and an oscillating potential (3–7 V) is applied to the tip. The frequency of oscillation is chosen to be equal to the resonance frequency of the cantilever (~80 kHz). When a DC bias potential equal to the negative value of surface potential of the sample (on the order of ±2 V) is applied to the tip, it does not vibrate. During scanning, a difference between the DC bias potential applied to the tip and the potential of the surface will create DC electric fields that interact with the oscillating charges (as a result of the AC potential), causing the cantilever to oscillate at its resonance frequency, as in tapping mode. However, a feedback loop is used to adjust the DC bias on the tip to exactly nullify the electric field, and thus the vibrations of the cantilever. The required bias voltage follows the localized potential of the surface [8].

In Situ Characterization of Local Deformation Studies

In situ characterization of local deformation of materials can be carried out by performing tensile, bending, or compression experiments inside an AFM and by observing nanoscale changes during the deformation experiment [2–4]. In these experiments, small deformation stages are used to deform the samples inside an AFM. In tensile testing of the polymeric films carried out by Tambe and Bhushan [9], a tensile stage was used (Fig. 8). The stage with a left-right combination lead screw (that helps to move the slider in the opposite direction) was used to stretch the sample to minimize the movement of the scanning area, which was kept close to the center of the tensile specimen. One end of the sample was mounted on the slider via a force sensor to monitor the tensile load. The samples were stretched for various strains using a stepper motor and the same control area at different strains was imaged. In order to better locate the control area for imaging, a set of four markers was created at the corners of a 30 μm × 30 μm square at the center of the sample by scratching the sample with a sharp silicon tip.

Atomic Force Microscopy, Fig. 8 Schematic of the tensile stage to conduct in situ tensile testing of the polymeric films in AFM

Atomic Force Microscopy, Fig. 9 Schematic of a nano/picoindentation system with three-plate transducer with electrostatic actuation hardware and capacitance sensor [10]

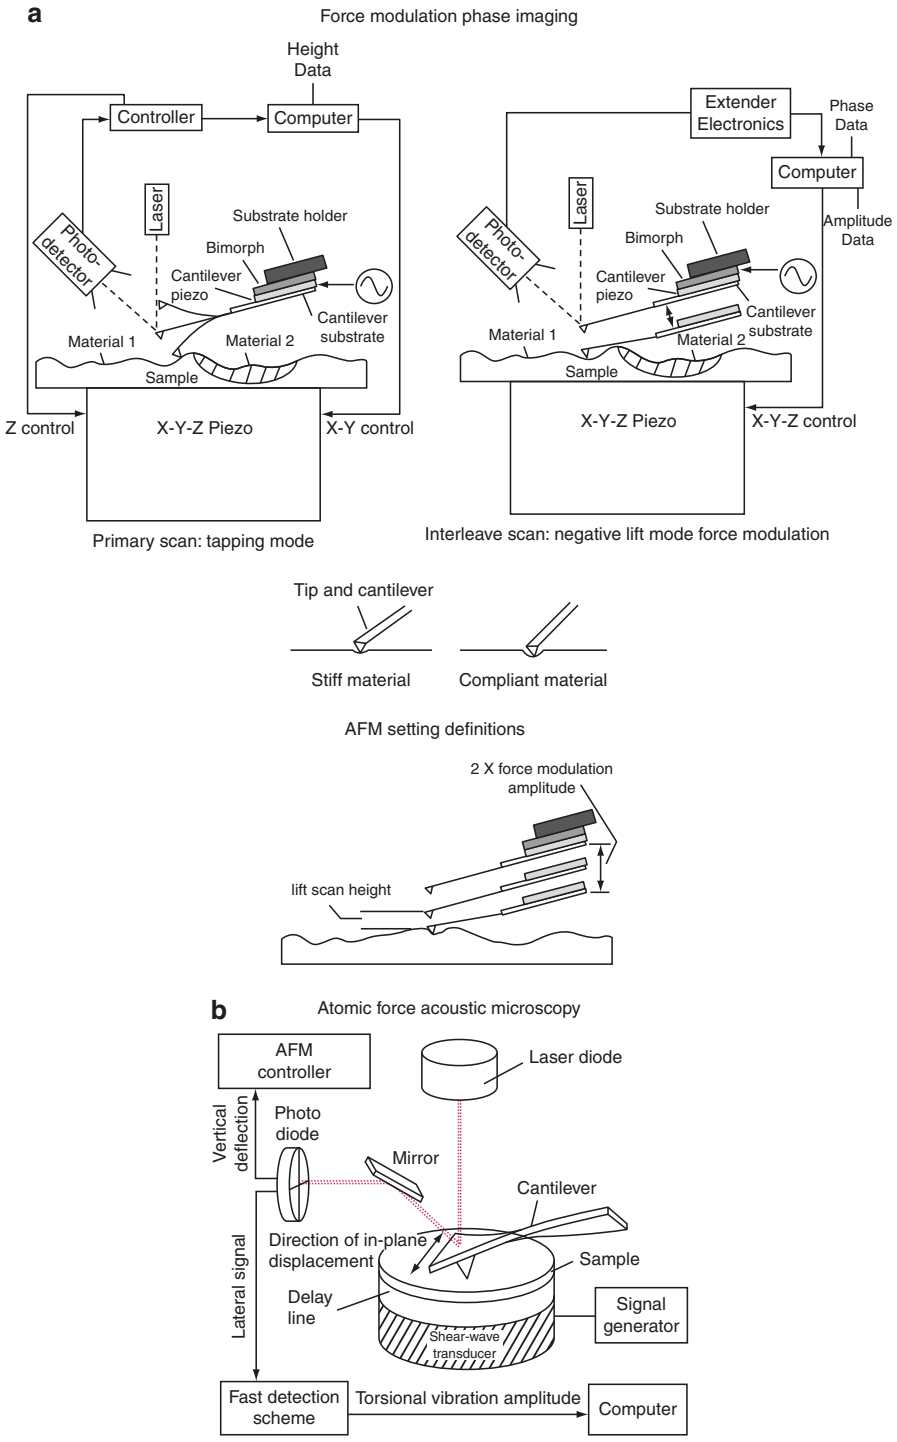
The scratching depth was controlled such that it did not affect cracking behavior of the coating. A minimum displacement of 1.6 μm could be obtained. This corresponded to a strain increment of 8×10^{-3} % for a sample length of 38 mm. The maximum travel was about 100 mm. The resolution of the force sensor was 10 mN with a capacity of 45 N. During stretching, a stress–strain curve was obtained during the experiment to study any correlation between the degree of plastic strain and propensity of cracks.

Nanoindentation Measurements

For nanoindentation hardness measurements the scan size is set to zero, and then a normal load is applied to make the indents using the diamond tip. During this procedure, the tip is continuously pressed against the sample surface for about 2 s at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the initial and the final surface topography, at a low normal load on the order of 100–500 nN using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents [2–4].

Direct imaging of the indent allows one to quantify piling up of ductile material around the indenter. However, it becomes difficult to identify the boundary of the indentation mark with great accuracy. This makes the direct measurement of contact area somewhat inaccurate. A technique with the dual capability of depth-sensing as well as in-situ imaging, which is most appropriate in nanomechanical property studies, is used for accurate measurement of hardness with shallow depths [2–4, 10]. This nano/picoindentation system is used to make load-displacement measurement and subsequently carry out in-situ imaging of the indent, if required. The indentation system, shown in Fig. 9, consists of a three-plate transducer with electrostatic actuation hardware used for direct application of a normal load and a capacitive sensor used for measurement of vertical displacement. The AFM head is replaced with this transducer assembly while the specimen is mounted on the PZT scanner, which remains stationary during indentation experiments. The transducer consists of a three (Be-Cu) plate capacitive structure, and the tip is mounted on the center plate. The upper and lower plates serve as drive electrodes, and the load is applied by applying appropriate voltage to the drive electrodes. Vertical displacement of the tip (indentation depth) is measured by measuring the displacement of the center plate relative to the two outer electrodes using capacitance technique. Indent area and consequently hardness value can be obtained from the load-displacement data. The Young's modulus of elasticity is obtained from the slope of the unloading curve.

Localized Surface Elasticity and Viscoelasticity Mapping



Localized Surface Elasticity. Indentation experiments provide a single-point measurement of the

Young's modulus of elasticity calculated from the slope of the indentation curve during unloading. Localized surface elasticity maps can be obtained using dynamic force microscopy, in which an oscillating tip is scanned over the sample surface in contact under steady and oscillating load. Lower frequency operation mode in the kHz range, such as force modulation mode [11] or pulsed force mode [12], are well suited for soft samples such as polymers. However, if the tip-sample contact stiffness becomes significantly higher than the cantilever stiffness, the sensitivity of these techniques strongly decreases. In this case, the sensitivity of the measurement of stiff materials can be improved by using high-frequency operation modes in the MHz range with a lateral motion, such as acoustic (ultrasonic) force microscopy, referred to as atomic force acoustic microscopy (AFAM) or contact resonance spectroscopy [13]. Inclusion of vibration frequencies other than only the first cantilever flexural or torsional resonance frequency also allows additional information to be obtained.

In negative lift mode force modulation technique, during primary scanning height data is recorded in tapping mode as described earlier. During interleave scanning, the entire cantilever/tip assembly is moved up and down at the force modulation holder's bimorph resonance frequency (about 24 kHz) at some amplitude, here referred to as the force modulation amplitude, and the Z-direction feedback control for the sample X-Y-Z piezo is deactivated, Fig. 10a [11]. During this scanning, height information from the primary scan is used to maintain a constant lift scan height. This eliminates the influence of height on the measured signals during the interleave scan. Lift scan height is the mean tip-to-sample distance between the tip and sample during the interleave scan. The lift scan height is set such that the tip is in constant contact with the sample, that is, a constant static load is applied. (A higher lift scan height gives a closer mean tip-to-sample distance.) In addition, the tip motion caused by the bimorph vibration results in a modulating periodic force. The sample surface resists the oscillations of the tip to a greater or lesser extent depending upon the sample's stiffness. The computer records amplitude (which is a function of elastic stiffness of the material). Contact analyses can be used to obtain a quantitative measure of localized elasticity of soft surfaces [3, 4]. Etched single-crystal silicon cantilevers with integrated tips (DI force modulation etched Si probe or FESP) with a radius of 25–50 nm, a stiffness of 1–5 N/m, and a resonant frequency of 60–100 kHz, are commonly used for the measurements. The scanning rate could be set between 0.1 and 2 Hz along the fast axis.

In the AFAM technique [13], the cantilever/tip assembly is moved either in the normal or lateral mode, and the contact stiffness is evaluated by comparing the resonance frequency of the cantilever in contact with the sample surface to those of the free vibrations of the cantilever. Several free resonance frequencies are measured. Based on the shift of the measured frequencies, the contact stiffness is determined by solving the characteristic equation for the tip vibrating in contact with the sample surface. The elastic modulus is calculated from contact stiffness using Hertz analysis for a spherical tip indenting a plane. Contact stiffness is equal to 8 multiplied with the contact radius and the reduced shear modulus in shear mode.

In the lateral mode using the AFAM technique, the sample is glued on cylindrical pieces of aluminum, which serves as ultrasonic delay lines coupled to an ultrasonic shear wave transducer, Fig. 10b [14]. The transducer is driven with frequency sweeps to generate in-plane lateral sample surface vibrations. These couple to the cantilever via the tip-sample contact. To measure torsional vibrations of the cantilever at frequencies up to 3 MHz, the original electronic circuit of the lateral channel of the AFM (using a lowpass filter with limited bandwidth to few hundred kHz) was replaced by a high-speed scheme which bypasses the lowpass filter. The high- frequency signal was fed to a lock-in amplifier, digitized using a fast A/D card, and fed into a broadband amplifier, followed by an rms-to-dc converter and read by a computer. Etched single-crystal silicon cantilevers (normal stiffness of 3.8–40 N/m) integrated tips are used.

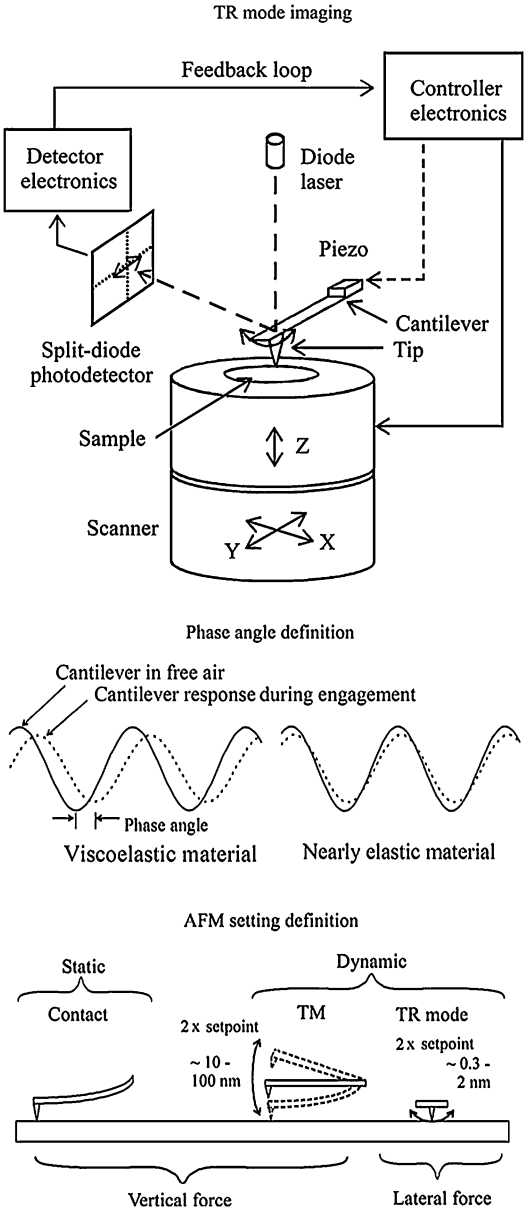
Atomic Force Microscopy, Fig. 10 (**a**) Schematic of force modulation mode used to obtain amplitude (stiffness) and definitions of force modulation amplitude and lift scan height. During primary scanning, height data is recorded in tapping mode. During interleave scanning, the entire cantilever/tip assembly is vibrated at the bimorph's resonance frequency and the Z-direction feedback control for the sample X-Y-Z piezo is deactivated.

Viscoelastic Mapping. Another form of dynamic force microscopy, phase contrast microscopy, is used to detect the contrast in viscoelastic (viscous energy dissipation) properties of the different materials across the surface [15–18]. In these techniques, both deflection amplitude and phase angle contrasts are measured, which are measures of the relative stiffness and viscoelastic properties, respectively. Two phase measurement techniques – tapping mode and torsional resonance (TR) mode – have been developed, and are described below.

In the tapping mode (TM) technique, as described earlier, the cantilever/tip assembly is sinusoidally vibrated at its resonant frequency, and the sample X-Y-Z piezo is adjusted using feedback control in the Z-direction to maintain a constant setpoint, Fig. 3 [15]. The feedback signal to the Z-direction sample piezo (to keep the setpoint constant) is a measure of surface roughness. The extender electronics is used to measure the phase angle lag between the cantilever piezo drive signal and the cantilever response during sample engagement. As illustrated in Fig. 3, the phase angle lag (at least partially) is a function of the viscoelastic properties of the sample material. A range of tapping amplitudes and setpoints is used for measurements. Commercially etched single-crystal silicon tip (TESP) used for tapping mode, with a radius of 5–10 nm, a stiffness of 20–100 N/m, and a resonant frequency of 350–400 kHz, is normally used. Scanning is typically set between 0.1 and 2 Hz along the fast axis.

In the torsional mode (TR mode), a tip is vibrated in the torsional mode at high frequency at the resonance frequency of the cantilever beam. An etched single-crystal silicon cantilever with integrated tip (FESP) with a radius of about 5–10 nm, normal stiffness of 1–5 N/m, torsional stiffness of about 30 times normal stiffness and torsional resonant frequency of 800 kHz is typically used. A major difference between the TM and TR modes is the directionality of the applied oscillation – a normal (compressive) amplitude exerted for the TM and a torsional amplitude for the TR mode. The TR mode is expected to provide good contrast in the tribological and mechanical properties of the near-surface region as compared to the TM. Two of the reasons are as follows. (1) In the TM, the interaction is dominated by the vertical properties of the sample, so the tip spends a small fraction of its time in the near field interaction with the sample. Furthermore, the distance between the tip and the sample changes during the measurements, which changes interaction time and forces, and affects measured data. In the TR mode, the distance remains nearly constant. (2) The lateral stiffness of a cantilever is typically about two orders of magnitude larger than the normal (flexural) stiffness. Therefore, in the TM, if the sample is relatively rigid, much of the deformation occurs in the cantilever beam, whereas in the TR mode, much of the deformation occurs in the sample. A few comments on the special applications of the TR mode are made next. Since most of the deformation occurs in the sample, the TR mode can be used to measure stiff and hard samples. Furthermore, properties of thin films can be measured more readily with the TR mode. For both the TM and TR modes, if the cantilever is driven to vibrate at frequencies above resonance, it would have less motion (high apparent stiffness), leading to higher sample deformation and better contrast. It should be further noted that the TM exerts a compressive force, whereas the TR mode exerts torsional force, therefore normal and shear properties are measured in the TM and TR modes, respectively.

In the TR mode, the torsional vibration of the cantilever beam is achieved using a specially designed cantilever holder. It is equipped with a piezo system mounted in a cantilever holder, in which two piezos vibrate out-of-phase with



Atomic Force Microscopy, Fig. 10 (continued) During this scanning, height information from the primary scan is used to maintain a constant lift scan height. The computer records amplitude (which is a function of material stiffness) during the interleave scan, and (**b**) Schematic of an AFM incorporating shear wave transducer which generates in-plane lateral sample surface vibrations. Because of the forces between the tip and the surface, torsional vibrations of the cantilever are excited [14]. The shift in contact resonance frequency is a measure of contact stiffness

respect to each other. A tuning process prior to scanning is used to select the torsional vibration frequency. The piezo system excites torsional vibration at the cantilever's resonance frequency. The torsional vibration amplitude of the tip (TR amplitude) is detected by the lateral segments of the split-diode photodetector, Fig. 11 [18]. The TR mode measures surface roughness and phase angle as follows. During the measurement, the cantilever/tip assembly is first vibrated at its resonance at some amplitude dependent upon the excitation voltage, before the tip engages the sample. Next, the tip engages the sample at some setpoint. A feedback system coupled to a piezo stage is used to keep a constant TR amplitude during scanning. This is done by controlling the vertical position of the sample using a piezo moving in the Z direction, which changes the degree of tip interaction. The displacement of the sample Z piezo gives a roughness image of the sample. A phase angle image can be obtained by measuring the phase lag of the cantilever vibration response in the torsional mode during engagement with respect to the cantilever vibration response in free air before engagement. The control feedback of the TR mode is similar to that of tapping, except that the torsional resonance amplitude replaces flexural resonance amplitude [18].

Chen and Bhushan [16] used a variation to the approach just described (referred to as mode I here). They performed measurements at constant normal cantilever deflection (constant load) (mode II) instead of using constant setpoint in the mode I approach. Their approach overcomes the meniscus adhesion problem present in mode I, and reveals true surface properties.

Song and Bhushan [19] presented a forced torsional vibration model for a tip-cantilever assembly under viscoelastic tip-sample interaction. This model provides a relationship of torsional amplitude and phase shift with lateral contact stiffness and viscosity, which can be used to extract in-plane interfacial mechanical properties.

Various operating modes of AFM used for surface roughness, localized surface elasticity, and viscoelastic mapping, and friction force measurements are summarized in Table 2.

Atomic Force Microscopy, Fig. 11 Schematic of torsional resonance mode shown at the *top*. Two examples of the phase angle response are shown in the *middle*. One is for materials exhibiting viscoelastic (*left*) and the other nearly elastic properties (*right*). Three AFM settings are compared at the *bottom*: contact, tapping mode (*TM*), and TR modes. The TR mode is a dynamic approach with a laterally vibrating cantilever tip that can interact with the surface more intensively than other modes. Therefore, more detailed near-surface information is available

Atomic Force Microscopy, Table 2 Summary of various operating modes of AFM for surface roughness, stiffness, phase angle, and friction

Operating mode	Direction of cantilever vibration	Vibration frequency of cantilever (kHz)	Vibration amplitude (nm)	Feedback control	Data obtained
Contact	N/a			Constant normal load	Surface height, friction
Tapping	Vertical	350–400	10–100	Setpoint (constant tip amplitude)	Surface height, phase angle (normal viscoelasticity)
Force Modulation	Vertical	10–20 (bimorph)	10–100	Constant normal load	Surface height, amplitude (normal stiffness)
Lateral	Lateral (AFAM)	100–3,000 (sample)	~5 (sample)	Constant normal load	Shift in contact resonance (normal stiffness, friction)
TR mode I	Torsional	~800	0.3–2	Setpoint (constant tip amplitude)	Surface height, phase angle (lateral viscoelasticity)
TR mode II	Torsional	~800	0.3–2	Constant normal load	Surface height, amplitude and phase angle (lateral stiffness and lateral viscoelasticity)
TR mode III	Torsional	>800 in contact	0.3–2	Constant normal load	Shift in contact resonance (friction)

Boundary Lubrication Measurements

AFM can be used to study nanoscale boundary lubrication properties, mainly adhesion, friction, and wear (or durability). Adhesive forces at the nanoscale can be measured in the force calibration mode, as previously described. The adhesive forces can also be calculated from the horizontal intercept of friction versus normal load curves at a zero value of friction force [20]. For friction measurements, the unlubricated and lubricated surfaces (such as silicon wafers, bulk metal or metallic films, ceramics and polymer films, among others) are typically scanned using a Si_3N_4 or Si tip over scan length of 2–10 μm with the normal load ranging from 5 to 150 nN. Velocity effects on friction are studied by changing the scan frequency from 0.1 to 60 Hz. As an example, if the scan length is maintained at 2 μm, the sliding velocity then varies from 0.4 to 240 μm/s. To study the durability properties, the friction force and coefficient of friction are monitored during scanning at an arbitrary nanoscale normal load (on the order of 10–100 nN) and a predefined scanning speed for a desired number of cycles [20].

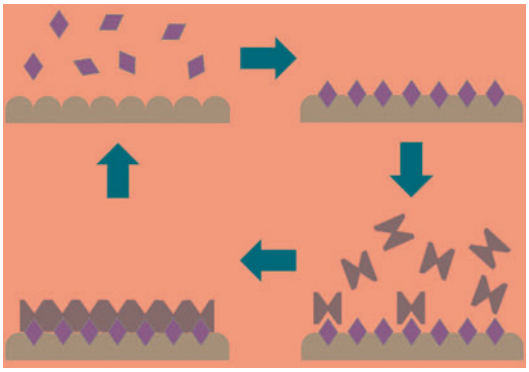
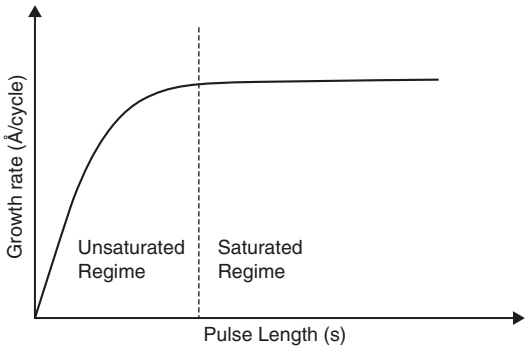
Definition



Atomic layer deposition is a method of thin film growth related to chemical vapor deposition whereby two or more vapor-phase precursor chemicals are individually and sequentially introduced to a substrate surface via discrete precursor pulses that are separated by purge steps. Each precursor pulse must yield saturative, self-limiting growth of a monolayer or sub-monolayer of the desired material if an ALD mechanism is operant. The resultant film exhibits excellent thickness uniformity and conformality, even on highly complex and demanding nanoscale substrate features, with the process affording an excellent degree of thickness control at the sub-nanometer level.

Introduction

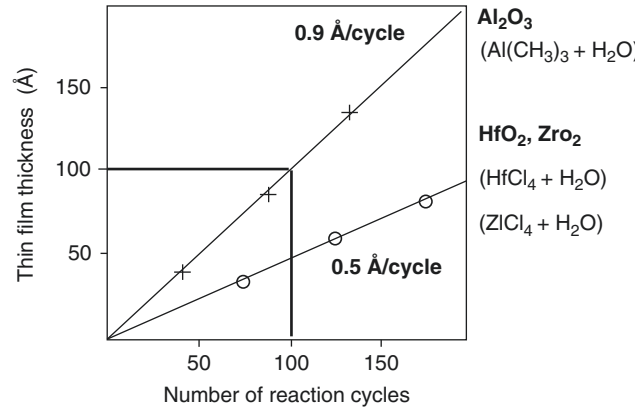


Atomic layer deposition (ALD) is a technique for the deposition of thin films of solid-state or polymeric materials onto solid substrates from vapor-phase precursor chemicals. While it is closely related to the chemical vapor deposition (CVD) technique and is similar to it in important ways, it also has substantial differences that distinguish it from CVD. Unlike CVD, ALD achieves film growth via the introduction of two or more precursor chemicals separately in discrete pulses into a reaction chamber. As a result, gas-phase reactions are avoided and only surface chemisorbed species are present at the time of exposure to the subsequent precursor. Growth with each exposure is self-limited and saturative, with each deposition cycle giving controlled deposition and layer-by-layer growth. As a result ALD is able to coat difficult substrate features and has been identified with its ability to overcome technological problems in the microelectronics industry, as well as potential for contributing to new areas in nanotechnology. ALD was first developed in Finland in the mid-1970s by Tuomo Suntola for thin film electroluminescent display applications, but experienced an enormous resurgence in the 2000s, mostly due to the need to replace SiO_2 gate dielectrics with high-permittivity alternatives to allow for future scaling of capacitor structures in microelectronics [1]. ALD continues to find new possibilities for future applications as the need for high-quality coatings on ever-smaller nano-sized features expands.

Key Features of an ALD Process

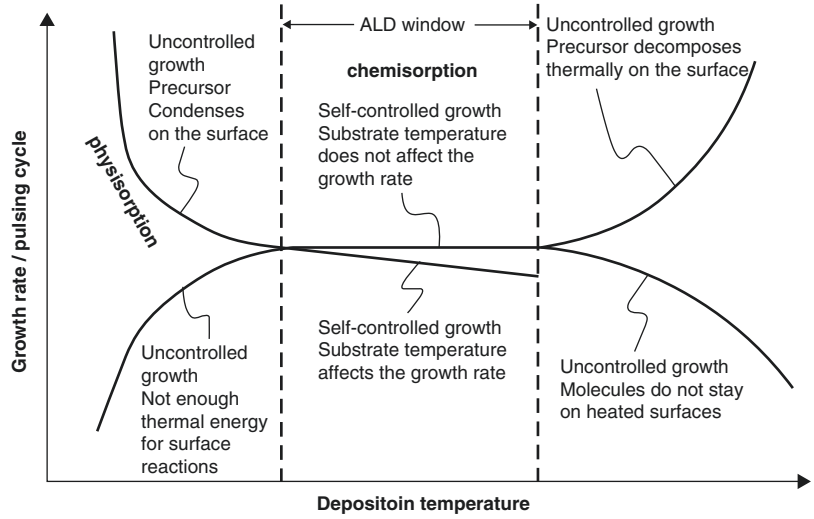
A number of key features are principal to the understanding of ALD [1–4]. Foremost is the concept of the ALD growth cycle. An ALD process is necessarily comprised of a sequence of pulses by which doses of precursor are delivered to a reaction chamber (see Fig. 1). In each pulse, a precursor is supplied in a dose sufficient to ensure reaction with every available surface site and over a time period that is long enough for the precursor vapor to effectively diffuse into substrate features and for reactions to occur on the surfaces that are present. The reaction between the precursor and the substrate must be self-limiting; the presence of excess precursor beyond that which is necessary for the reaction of all surface sites must not lead to additional film growth (Fig. 2). This behavior is often described as “saturative” growth and is the defining feature of ALD. A dose that has less than the required precursor amount to achieve this type of growth is considered “sub-saturative” and the

Atomic Layer Deposition, Fig. 1 A depiction of the ALD cycle. A precursor is alternately exposed to precursors that undergo self-limiting reactions with the surface. Repetition of the deposition cycle leads to layer-by-layer growth mechanism inherent to ALD



Atomic Layer Deposition, Fig. 2 ALD saturation curve. Each exposure of the substrate to precursor vapor leads to self-limiting growth, which is the defining feature of ALD. Any dose of sufficient size (here indicated by pulse length, which is one means of determining dose) leads to saturative growth whereby additional exposure does not lead to additional growth

resulting film is likely to not have the full characteristics expected of ALD. Additionally, it is crucial that no significant self-reaction or decomposition of the precursor occurs, as this may lead to an uncontrolled component of film growth.



Upon the conclusion of a precursor pulse, the deposition chamber is purged, typically by the combined treatment of the deposition chamber by an inert gas flow and evacuation. Depending on the design of the ALD system being used, the application of inert gas flow and vacuum may be stopped and resumed to create a purge phase, or may be continuous, with precursor vapor introduced to the inert gas flow intermittently, so as to make the inert gas flow function alternately as a carrier gas and purge gas. The former of these approaches may be advantageous in that the pulse period can be lengthened to increase the residence time and effectively incubate the substrate without wasting precursor. The latter method, however, often exhibits shorter deposition cycles, faster deposition times, and more effective purging. The purge step must be long enough and effective enough to ensure that gas-phase reactions between precursors are avoided. The failure to avoid gas-phase mixing of the precursors can result in uncontrolled poor-quality dual-source-type CVD film growth and the formation of particulates in the deposition chamber, both of which can have deleterious effects on the intended film function.

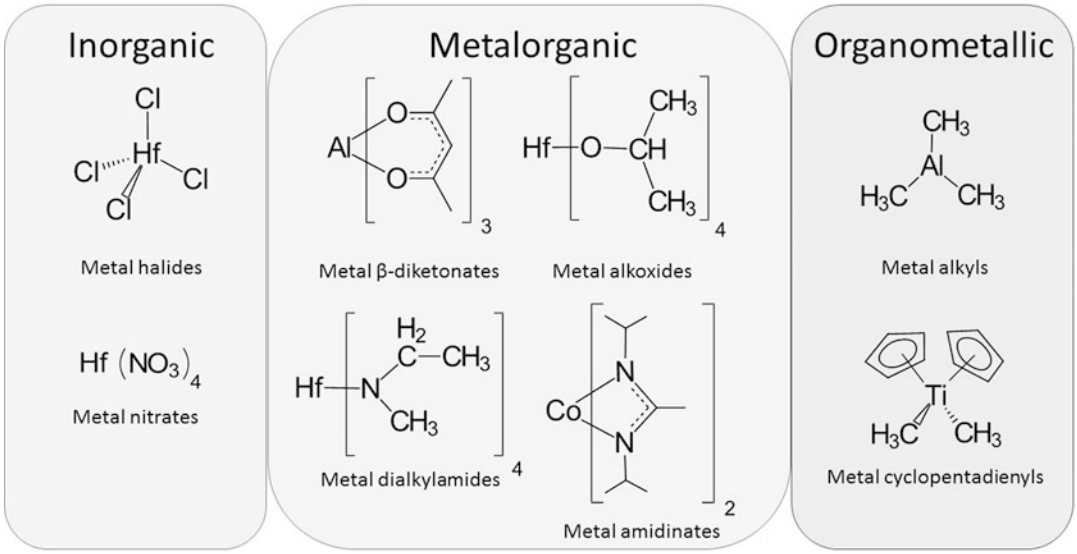
Following the above-described pulse and purge steps, the substrate is exposed to a second precursor chemical chosen to react rapidly and completely with the first precursor, which is now already reacted with the surface, to achieve the desired material. This is followed again by a purging step to remove excess precursor vapor and any gas-phase reaction by-products, thus completing the second "half reaction" of the ALD cycle. By the repetition of the ALD cycle, the layer-by-layer growth of the thin film is achieved. A constant growth rate per deposition cycle is a feature of every ALD process, and as a result, the thickness of deposited film varies linearly with the number of cycle repetitions. The number of necessary cycles for a given film thickness for a particular process operated at a specific temperature is easily determined and is the basis for the degree of thickness control inherent in ALD (see Fig. 3).

The influence of deposition temperature on the growth rate is another fundamental ALD concept. Depending on the mechanistic phenomena taking place during the deposition of the film, the growth rate may change considerably, sometimes with loss of the self-limiting growth necessary for ALD. The common modes of growth behavior are outlined in Fig. 4. The concept of an ALD

Atomic Layer Deposition, Fig. 3 ALD exhibits excellent control of film thickness. By selecting a number of deposition cycles appropriate to the desired thickness, precise control can be achieved. For a given process at a given temperature, the growth per cycle is constant. As a result, film thickness increases linearly with the applied number of deposition cycles

Atomic Layer Deposition, Fig. 4 Depiction of how growth rate per cycle varies with temperature. Some ALD processes have an "ALD window" or temperature range over which the growth rate is constant. At high or low temperatures, a number of phenomena can occur leading to a large increase or decrease in growth rate and the loss of ALD behavior

window, a temperature range over which the growth rate does not change with temperature, is important to ALD. It is a common misunderstanding that an ALD window is a required attribute of every ALD process and that ALD only exists within an ALD window. This is not true, however, and in fact many well-known ALD processes totally lack an ALD window. These processes instead will display a modest increase or decrease in growth rate over a temperature range where self-limiting growth is observed. Nevertheless, an ALD window is considered an attractive feature, as it affords a greater degree of reproducibility by mitigating the influence of small variations in temperature. Regardless of the presence or absence of an ALD window, there is frequently a more dramatic change in growth rate as the temperature moves to a regime where the growth is no longer self-limiting. At low temperatures, a process may undergo a sizable decrease in growth rate as the degree of thermal activation becomes insufficient to sustain effective surface reactions. Alternatively, an increase in growth behavior may be observed as a result of precursor condensation and/or physisorption leading to the association of multiple monolayers of precursor with the substrate surface, all of which become involved with film growth upon exposure to the following precursor. At high temperatures a similar departure from normal ALD conditions can occur as well. Most often an excessive temperature will lead to a large increase in growth rate as precursor



decomposition or self-reaction becomes a significant mode of film growth. High temperatures can also lead to a substantial drop in growth rate if precursor desorption from the surface becomes favorable. Both of these situations are likely to lead to loss of ALD growth.

Precursor Considerations

A number of factors are vital to the consideration of which precursor should be used for an ALD process [1–3]. Of primary importance is volatility. If a precursor compound cannot be effectively vaporized and delivered to the substrate surface in the gas phase, it will be impossible for the ALD process to proceed. A vapor pressure curve can be a very helpful tool in determining whether the volatility of a particular compound is suitable for effective delivery. Many precursors require heating to generate adequate vapor pressure for its delivery to the ALD chamber. The exact temperature required depends considerably on the configuration of the source delivery system used and the minimum vapor pressure requirement afforded by its design. A few precursors possess high enough vapor pressure at room temperature to ensure adequate dosing for ALD. These include some well-known examples such as trimethylaluminum (TMA), $Al(CH_3)_3$; titanium tetrachloride, $TiCl_4$; and diethylzinc, $Zn(CH_2CH_3)_2$. These provide the advantage not only of simplicity of delivery but also in allowing for low-temperature depositions of the corresponding metal oxides. Because the deposition temperature in a typical ALD reactor must exceed the temperature of the accompanying source delivery systems, low volatilization temperatures can help facilitate lower deposition temperatures. A further necessity of such low-temperature depositions – and for that matter, all ALD – is sufficient reactivity. In order for surface reactions to proceed via an ALD mechanism, both precursors must react rapidly and completely with the chemisorbed species left on the surface from the previous reaction. Insufficient reactivity may result in reduced growth rates, increased impurity content due to the inclusion of unreacted surface groups, and compromised film conformality and thickness uniformity. A third essential feature of an ALD precursor is thermal stability, that is, the inability of the precursor to undergo decomposition or self-reaction at a sufficient rate at the temperatures to which it is exposed to noticeably affect the quality of film growth. The lack of optimal thermal stability may result in uncontrolled single-source CVD-like growth and loss of ALD-type growth, oftentimes along with the loss of associated advantages of ALD. In addition to the three critical features of an ALD precursor, a number of other factors should be considered, such as availability, cost, ease of handling, the presence of undesired elements, the steric bulk of precursor molecules and its impact on film growth rate, reactivity and volatility of surface reaction by-products and their effects on the film and substrate, as well as environmental health and safety concerns.

Precursor Types

A variety of precursors exists for ALD and can be classified according to their key features [2, 3]. These features, as well as any associated advantages or disadvantages, must be considered carefully when determining the best process for a given application. Metal-containing precursors (i.e., for the delivery of the metal atoms to the growing film surface) can be divided into three categories: inorganic, metal-organic, and organometallic. Inorganic precursors are defined as those that do not contain carbon whatsoever. Typically inorganic precursors are restricted to metal halides, such as $TiCl_4$ for the growth of TiO_2 or TiN, but other examples exist as well, that is, the growth of HfO_2 from hafnium nitrate, $Hf(NO_3)_4$. Metal-organic precursors are those that contain one or more metal atoms and also contain at least one carbon-containing ligand bound to the metal through a heteroatom such as nitrogen or oxygen. Figure 5 shows common examples of metal-organic precursors. Classes of metal-organic precursors include alkoxides, amides, and amidinates. Such precursors are noted for their high volatility and good reactivity, although

Atomic Layer Deposition, Fig. 5 An overview of ALD precursor types and examples of each

many suffer from suboptimal thermal stability and exhibit a loss of ALD growth when the thermal budget has been exceeded. Due to this combination of characteristics, metal-organic precursors can be expected oftentimes to give ALD growth at the lower end of the range typical for ALD processes. Organometallic precursors are those that contain direct metal–carbon bond. Figure 5 shows common examples of organometallic precursors. These precursors primarily consist of metal alkyls, such as TMA, or cyclopentadienyl (Cp) compounds, such as dichlorohafnocene, $HfCp_2Cl_2$, or compounds containing both ligand types, such as dimethylhafnocene, $HfCp2(CH_3)_2$. Organometallic compounds typically have fairly good to excellent volatility, good to excellent reactivity, and excellent thermal stability. Their primary drawback is the limited availability of these compounds for many metals. For some organometallic compounds, high cost can also be an additional disadvantageous factor.

Besides metal-containing precursors, one must give proper consideration to the nonmetal precursor as well. A good nonmetal precursor must abide by all of the conditions and requirements for a good metal-containing precursor. Although many of the most commonly used nonmetal precursors are compressed gases where volatility is not an issue of concern, some nonmetal precursors are liquids, or perhaps even solids. In this case, good volatility is essential. Likewise, good thermal stability and reactivity are necessary, but due to the nature of the simple and robust nonmetal precursors commonly employed, only the second of these properties is usually a constraint. The reactivity of the nonmetal precursor must be appropriately matched to the metal-containing precursor and ideally should react in a vigorous and complete way that precludes the incorporation of impurities, as well as having oxidative or reductive properties adequate for achieving the desired oxidation state of material. Typically, metal oxide processes employ either H_2O or ozone. The use of H_2O commonly affords the metal oxide product by means of protonolysis and loss of the ligands bound to the metal of the adsorbed metal-containing precursor, along with replacement of the ligands by a hydroxyl group. The hydroxyl groups will then dominate the surface, making it amenable to reaction with the subsequent reintroduction of the metal-containing precursor. Ozone operates by a different mechanism, however, where the ligands undergo oxidation to CO_2 and H_2O, the latter of which is presumed to regenerate a hydroxyl-terminated surface. Ozone also brings with it a much greater

oxidative power than water, and its use typically assures that the resulting material will be in the highest accessible oxidation state. There are other precursors that have seen use for oxide growth, such as H_2O_2 and N_2O, but these are only used rarely. Oxygen (O_2) is typically not used in the growth of oxides, as its oxidative power and capability of promoting oxide growth are low at the temperatures used for ALD. Oxygen has been used extensively, however, in the growth of ALD films of the noble metals, where the combustion of organic ligands and the resulting reduction of the metal atoms are featured. The deposition of nitrides and sulfides is achieved most frequently using ammonia and hydrogen sulfide, respectively, which are analogous to water in that they are "hydrides" of their respective nonmetals and undergo protonolysis and ligand replacement reactions to achieve film growth.

Materials Grown by ALD

An ever-increasing variety of materials are available for growth by ALD. Comprehensive review articles exist that list and describe all known processes in detail [1–5]. It is beyond the scope of this entry to exhaustively list these processes, describe, and give references for them. Instead, a general overview of the materials according to type will be given, and the reader is encouraged to consult the recommended reviews for leading articles.

The large majority of ALD-grown materials are binary, that is, comprised of one metallic and one nonmetallic element. Metal oxides are easily the most common binary materials for which ALD processes are known and encompass a considerable portion of the periodic table. The oxides of the group 3 metals (Sc, Y, and lanthanide elements), group 4 metals (Ti, Zr, Hf), and several main group metals (Al, Mg, Zn) are particularly well represented, with many published studies and multiple processes developed from a variety of ligand types. Given the choice of available processes for these materials, ALD users can often select the process that best matches their needs and can choose optimal volatility, reactivity, and thermal stability from among the available precursors. Beyond these well-established processes are numerous others for which at least preliminary process studies have been published. These include nearly all of the first-row transition metal oxides, a few second- and third-row transition metal oxides (e.g., Nb_2O_5, Ta_2O_5, WO_3, RuO_2, RhO_2, IrO_2), as well as additional main group oxides beyond those mentioned earlier (e.g., B_2O_3, Ga_2O_3, In_2O_3, SiO_2, GeO_2). A representative list of known material processes is given in Table 1. Besides binary metal oxide processes, there are numerous examples of ternary (two metals and oxygen) and quaternary (three metals and oxygen) oxides that have been investigated. The metal titanates are the most

Atomic Layer Deposition, Table 1 An overview of known ALD materials (Based on information in Ref. [1])

Types	Materials
Metal oxides	Al_2O_3, TiO_2, ZrO_2, HfO_2, Ta_2O_5, Nb_2O_5, Sc_2O_3, Y_2O_3, MgO, B_2O_3, SiO_2, GeO_2, La_2O_3, CeO_2, PrO_x, Nd_2O_3, Sm_2O_3, EuO_x, Gd_2O_3, Dy_2O_3, Ho_2O_3, Er_2O_3, Tm_2O_3, Yb_2O_3, Lu_2O_3, $SrTiO_3$, $BaTiO_3$, $PbTiO_3$, $PbZrO_3$, Bi_xTi_yO, Bi_xSi_yO, $SrTa_2O_6$, $SrBi_2Ta_2O_9$,$YScO_3$, $LaAlO_3$, $NdAlO_3$, $GdScO_3$, $LaScO_3$, $LaLuO_3$, $Er_3Ga_5O_{13}$, In_2O_3, In_2O_3:Sn, In_2O_3:F, In_2O_3:Zr, SnO_2, SnO_2:Sb, ZnO, ZnO:Al, ZnO:B, ZnO:Ga, RuO_2, RhO_2, IrO_2, Ga_2O_3, V_2O_5, WO_3, W_2O_3, NiO, FeO_x, CrO_x, CoO_x, MnO_x, $LaCoO_3$, $LaNiO_3$, $LaMnO_3$, $La_{1-x}Ca_xMnO_3$
Metal nitrides	BN, AlN, GaN, InN, SiN_x, Ta_3N_5, Cu_3N, Zr_3N_4, Hf_3N_4, TiN, Ti–Si–N, Ti–Al–N, TaN, NbN, MoN, WN_x, WN_xC_y
Metal chalcogenides	ZnS, ZnSe, ZnTe, CaS, SrS, BaS, CdS, CdTe, MnTe, HgTe, La_2S_3, PbS, In_2S_3, Cu_xS, $CuGaS_2$, Y_2O_2S, WS_2, TiS_2, ZnS:M (M = Mn, Tb, Tm); CaS:M (M = Eu, Ce, Tb,Pb); SrS: M (M = Ce, Tb, Pb)
Metal pnictides	GaAs, AlAs, AlP, InP, GaP, InAs
Elements	Ru, Pt, Ir, Pd, Rh, Ag, W, Cu, Co, Fe, Ni, Mo, Ta, Ti, Al, Si, Ge
Others	CaF_2, SrF_2, MgF_2, LaF_3, ZnF_2, SiC, TiC_x, TaC_x, WC_x, $Ca_x(PO_4)_y$, $CaCO_3$, $Ge_2Sb_2Te_5$

frequently reported materials of this type and include examples such as $SrTiO_3$, $BaTiO_3$, $PbTiO_3$, and Bi_xTi_yO. Additionally, lanthanide-based ternary and quaternary materials are also well precedented, with accounts of the following in the literature: $YScO_3$, $LaAlO_3$, $NdAlO_3$, $GdScO_3$, $LaScO_3$, $LaLuO_3$, $Er_3Ga_5O_{13}$, $LaCoO_3$, $LaNiO_3$, $LaMnO_3$, and $La_{1-x}Ca_xMnO_3$. Besides stoichiometric multielement oxide films, doping of films by ALD is a frequently used approach. In fact due to its ability to precisely control film composition by setting a pulse sequence designed for the repeated introduction of a dopant-containing precursor, ALD is specially suited to the formation of thin films of such materials. Most of the work done to date has involved the doping of zinc, tin, or indium oxide with a single element, namely, ZnO:M, where M = B, Al, or Ga; SnO:M, where M = Sb; and In2O3:M, where M = Sn, F, or Zr.

After oxides, metal pnictides represent the second most explored group of ALD materials. Of these, nitrides have received by far the most attention. Metal nitride deposition by ALD generally falls into two categories: early transition metal nitrides and main group element nitrides. Many examples from the former group have metallic properties and have potential applications as an adhesion and barrier layers in microelectronics, thus creating a motivation for their study. Early transition metal nitrides include TiN, Ti–Si–N, Ti–Al–N, TaN, NbN, MoN, WN_x, and WN_xC_y. The remaining metal nitrides are semiconductor materials where the metallic element is from either group 13 or 14: BN, AlN, GaN, InN, and SiN_x. Other metal pnictides rather predictably fall into the category of III–V compound semiconductor materials: AlP, GaP, InP, AlAs, GaAs, and InAs.

In addition to the abovementioned material types that have been deposited by ALD, metal chalcogenides have been demonstrated for a number of metals. Upon examination, some trends become apparent: most of the grown films contain either group 2 or group 12 metals. Zinc is particularly well studied, as ZnS, ZnSe, ZnTe, and ZnS:M (M = Mn, Tb, Tm) are all known. Work on the group 2 metals, however, has been thus far restricted to sulfides and doped variants thereof, such as CaS, SrS, BaS, CaS:M, and SrS:M, where M = Ce, Tb, Pb. Other cases of metal chalcogenides are shown in Table 1.

The ALD of pure elements, particularly metallic elements, has been of increasing interest in recent years. Most of the attention has focused on processes for the "noble" metals, which are late transition metals which have a relatively unstable oxide and readily exist in the zero-valent metallic state. Although several notable noble metals have yet to be reported for ALD, elements such as Ru, Rh, Ir, Pd, and Pt have well-behaved processes. The noble metal ALD work has largely centered on the counterintuitive reduction of organometallic compounds using oxygen as the second precursor compound. Studies have indicated that the organic ligands undergo a combustion-like reaction in the presence of oxygen affording the reduction of the metal center and the production of CO_2 as a by-product. Other metal ALD processes have been based on the use of traditional reducing agents to ensure the formation of metallic species, including hydrogen, formaldehyde (as formalin), silanes, diborane, or the vapor of reductive metals such as zinc. Using such an approach, additional metals have been deposited, such as Cu and W, but with varying degrees of success. Recent advances have led to new processes that have started to make transition metal films feasible. Remote plasma ALD and radical-enhanced ALD are now actively being used to access metal films that were previously difficult or unknown by traditional thermal ALD methods. These include metals such as Ag, Ni, and others. This continues to be an active area of research and with time the number of ALD films in this category is likely to expand.

Molecular Layer Deposition

One variant of ALD that has gained considerable attention in recent years is what has become known as molecular layer deposition (MLD). MLD is essentially an ALD process where one or more of the sequential self-limiting surface reactions involve a molecular species that is deposited and itself becomes a layer in the

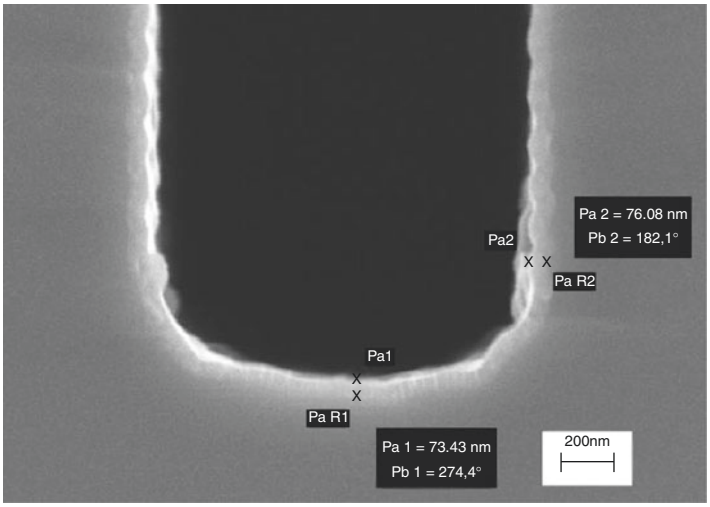
resulting film [4, 6]. MLD precursors are typically organic molecules that possess two or more reactive groups capable of undergoing ALD reactions. At least two such groups are needed in an MLD precursor, so that reaction can be achieved with the existing surface while generating a new surface that bears groups that are amenable to reaction with the precursor molecules of the subsequent precursor pulse. A precursor that contains only one such reactive group can react with the surface, but it will effectively terminate film growth due to the lack of ability to carry out subsequent reactions. Films grown by MLD generally fall into two categories: organic polymers and hybrid organic–inorganic materials.

To grow organic polymer films by MLD, many of the same principle apply for ALD. The precursors must be sufficiently volatile for gas-phase delivery. There must be no significant self-reaction or decomposition that leads to uncontrolled growth behavior – a fact that can become an even larger constraint for MLD than for ALD due to the nature of the precursors. Finally, the organic precursors must react with each other rapidly and completely within the time frame of an MLD growth cycle. This restricts MLD to those organic precursors that exhibit highly reactive functional groups. A common motif has been the reaction of a difunctional precursor molecule with two heteroatoms bearing protonizable hydrogen atoms (e.g., a diamine) with a second precursor that contains two functional groups that react vigorously with such functional groups (e.g., a diacid chloride or a dianhydride). An example of the diacid chloride and diamine MLD reaction is terephthaloyl chloride ($ClCOC_6H_4COCl$) and *p*-phenylenediamine ($NH_2C_6H_4NH_2$) to form the aromatic polyamide poly(*p*-phenylene terephthalamide) (PPTA). Similarly, films can be grown by pyromellitic dianhydride and the use of an amine such as ethylenediamine or *p*-phenylenediamine, to form the corresponding polyimide layers.

The MLD of hybrid organic–inorganic materials has been of increasing interest to researchers [4]. The approach for growing hybrid films is similar to that of other MLD films with one main difference: the precursor containing two or more groups with protonizable hydrogen atoms is reacted with a metal-containing compound having ligands that vigorously react with these functional groups. The obvious choice would be the use of TMA, which possesses methyl groups that are highly and irreversibly reactive toward such hydrogen atoms and, as has been described earlier, is amenable toward ALD growth. The reaction of TMA or other aluminum alkyl compounds with organic diols, such as ethylene glycol, leads to the formation of "alucones," which are the most well-studied class of MLD-grown hybrid inorganic–organic films. Alucone MLD processes have been described as robust and exhibiting the linear growth with a number of cycles expected of an ALD process [4]. By extension, other highly reactive metal alkyls should exhibit a similar ability to grow MLD organic–inorganic hybrids. "Zincones" have been formed by the MLD reaction of diethylzinc with organic diols with similar growth characteristics to those observed for the alucones [4]. The number and variety of available hybrid materials should be expected to increase rapidly in coming years as additional research is performed.

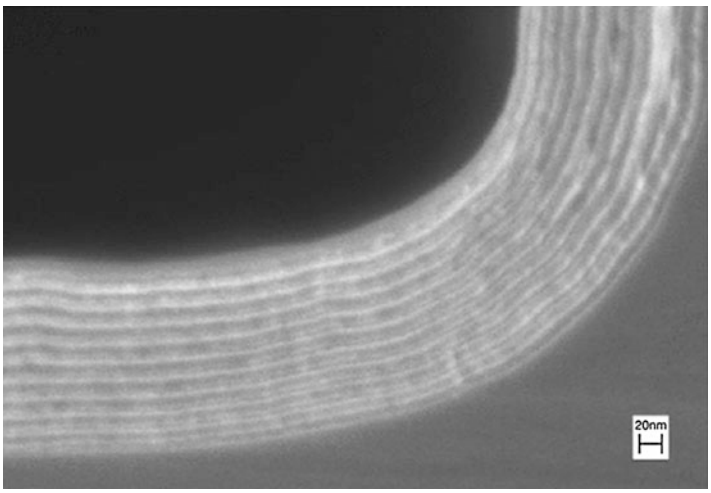
A number of obstacles exist for MLD processes [4, 6]. The vapor pressure requirements for an MLD precursor can substantially limit the available choice of organic precursor compounds that are suitable. Furthermore, the organic compounds typically under consideration nearly always have thermal stability limitations, which put an upper bound on the temperatures that can be used for volatilization, as well as putting an effective upper limit on the deposition temperature. Another problematic issue is the porous structure of the MLD-deposited films and the potential it creates for diffusion of precursor vapor into these small narrow features and – worse – the extra time required for the unreacted precursor to diffuse out during the purge step of the MLD process. This creates the possibility for gas-phase reactions that can lead to uncontrolled CVD and loss of the self-limiting growth mechanism. A further problem in MLD is the potential reaction of both functional groups of a precursor molecule with available surface reactive sites which can act to terminate or poison

growth and can perhaps alter the film characteristics. Double reactions of this type can be reduced or eliminated by selecting precursors with inherent conformational hindrances that greatly reduce the probability of this reaction type. Alternatively, the use of heterobifunctional precursors, where two chemically different reactive groups are present, has been used to limit the incidence of double reactions with the surface.



Plasma-Assisted ALD

Plasma-assisted ALD has experienced a trend toward increasing importance [1, 4, 7]. The central concept of plasma-assisted ALD differs from standard "thermal" ALD in that the reactivity of a precursor is increased by the application of plasma to generate radicals or other energetic species that can help promote reactions that might not otherwise progress by means of thermal activation alone. This advantage is commonly used to accomplish two ends: the reduction in deposition temperature of processes for which a thermal route is known and the ability to access difficult materials for which a thermal process may not be feasible or practical. In considering the former of these, the plasma-assisted process using TMA and O_2 plasma has been used to grow Al_2O_3 at low temperature, including down to room temperature, and has been shown to have improved dielectric properties relative to thermally grown Al_2O_3 ALD films [4]. An example of the latter type is TaN, which has not been grown in high quality by thermal-only methods, but has been achieved using an amido-/imido-based precursor and hydrogen radicals generated in a plasma source. The deposition of metal and metal nitride films is a common goal of plasma-assisted ALD processes, as these processes often require or benefit considerably from the advantages provided by plasma. Incidentally, it should be noted that plasma is always employed only for the generation of energetic nonmetal precursor species; it is not used with metal sources.



Plasma sources can be divided into two categories: direct plasma and remote plasma. Direct plasma sources are those where the substrate is directly exposed to the plasma, typically with the substrate resting on one of the plasma source electrodes [1]. Direct plasma is less commonly used in ALD due to drawbacks such as potential substrate damage. In remote plasma ALD, the substrate is situated some distance downstream from the plasma, with the energetic reactive species generated therein conveyed toward the substrate surface by the existing gas flow. The precursor pulse may contain a mixture of radicals and ions generated in the plasma, or in the case of a system that can be considered to be purely "radical-enhanced ALD," only radicals will be present as the reactive species.

Overview of Key Application Areas

Because of its ability to coat surfaces with exceptional control of thickness, excellent uniformity, and outstanding conformality and step coverage on complex and high aspect ratio surfaces (Fig. 6), ALD has found great potential for a range of applications [1, 8]. Foremost among these application areas is in microelectronics, where these three advantages are critical to the continued miniaturization of device features and the increase in performance demanded by Moore's law. Accordingly the ability to make coatings of advanced functional materials on increasingly challenging structures has proved valuable to the success of ALD, and microelectronics has been the major impetus for ALD technology development for the past two decades. Applications have generally fallen into three areas: (1) high-*k* dielectric gate oxide materials in metal oxide field effect transistors (MOSFET), (2) capacitor dielectrics in dynamic random access memory (DRAM), and (3) interconnect materials [1]. The driving force behind the use of high-*k* dielectrics in MOSFETs has been the need to replace SiO_2-based gate materials. The continual shrinkage of MOSFET features has led to a requirement that gate dielectric layers are only a few monolayers thick, which is a constraint that has allowed for tunneling and high leakage currents [1]. Alternate materials with high-permittivity values that can avoid the scaling problems inherent in SiO_2 have been a major focal

Atomic Layer Deposition, Fig. 6 ALD growth of Al_2O_3 in bottom of a 40:1 aspect ratio trench. ALD excels at coating challenging high aspect ratio features with uniform films and excellent conformality (Image: Picosun Oy proprietary)

Atomic Layer Deposition, Fig. 7 Nanolaminate thin film comprised of alternating layer of Al_2O_3 and TiO_2. Because of the stepwise methodology of ALD thin film growth, the deposition of nanolaminates and multicomponent composite materials is straightforward (Image: Picosun Oy proprietary)

point of ALD technology development. Hafnium oxide- and zirconium oxide-based materials have received the most attention, with phases containing silicon and nitrogen (HfSiON) considered the best solution for the near-term future [1, 8]. Active research continues on other materials that could become even better substitutes. DRAM production has also benefitted from the application of ALD. As with much of microelectronics, miniaturization has created a demand for DRAM features that are increasingly difficult to coat with the desired materials. Maintaining the required storage cell capacitance on a continually scaled down surface area and increasingly complex-shaped capacitor structure is a challenge to which ALD is particularly well suited. Capacitor dielectrics such as Hf–Al–O and nanolaminates of ZrO_2–Al_2O_3–ZrO_2 have seen recent use; however, it should be expected that the requirements of future technology nodes will necessitate the use of materials with a permittivity exceeding current benchmarks [1]. ALD is well suited to the deposition of such nanolaminate structures as shown in Fig. 7. Interconnects are another area where the application of ALD for microelectronics manufacture has been employed [1, 8]. Ruthenium and other noble metals have been grown by ALD and have been considered for seed layers for copper electroplating that can also act as an effective copper diffusion barrier. Early transition

metal nitrides have been evaluated also as copper diffusion barriers, but obstacles to their use remain. Tungsten processes based on the reduction of WF_6 have been used as seed layers for CVD tungsten contact plugs. Copper deposition for the formation of metallization seed layers is an attractive application area that continues to see active development and may eventually become a manufacturable process.

Optical applications represent a notable field where ALD has been used. ALD has the advantages of high uniformity, the ability to tailor refractive index, and film stress by combining several materials into one structure, all of which are appealing for optical devices [1, 8]. For planar optics, however, it seems unlikely that ALD will be helpful enough to overcome the traditional methods that have higher throughput. Optical designs that implement three dimensions into the structure, however, are more likely to gain from the use of ALD. For example, pillar structures of a selected arrangement have been conformally coated to produce microlens arrays, with integral interference filters incorporated via the deposition of an interference film stack [1]. Also ALD might be applicable to the fabrication of inverse opal photonic crystals, Fresnel zone plates for X-ray microscopy, and nanograting structures for polarizers and wave plates [1].

A variety of other application areas have also been explored. Due to the recent rapid miniaturization of magnetic read/write heads for inputting data onto hard disks, the deposition of conformal dielectrics by ALD has been implemented as insulating gap layers, as adhesion layers between the substrate and film stack, or as encapsulation layers [1, 8]. Thin film electroluminescent displays, which were the original application for which ALD was developed, continue to be a notable application area due to the necessity for defect-free films of uniform thickness. Doped metal sulfides, such as ZnS:Mn, are commonly used as the luminescent layer, whereas Al_2O_3 can be used as a passivation or protective layer [1]. Next-generation displays that incorporate organic light-emitting devices (OLEDs) have seen increasing use of ALD for thin film encapsulation of the device structure. The ALD films can be effective in limiting the rate of oxygen and water vapor permeation into the OLEDs, which can address one of the major factors limiting the useful lifetime of displays manufactured using this technology. Furthermore, MLD films can be used for flexible displays, where the ability to preserve the gas barrier properties over a surface that must endure repeated bending is required. ALD is also relevant to the development of photovoltaic applications. Transparent conductive oxides such as Al:ZnO have been deposited on complex or high surface area solar cells. Materials such as Al_2O_3 grown by ALD for passivation or charge recombination barrier layers have been of increasing importance. The application of ALD for solid-state 3-D Li-ion batteries has also been explored, where electrodes, current collectors, and electrolyte materials can all be potentially made using ALD thin films. Microelectromechanical systems (MEMS) are yet another area where ALD is experiencing a surge of interest. Because ALD can grow highly conformal and defect-free films on complex geometries, it can be used in MEMS components for wear-resistant, lubricating, anti-stiction, or charge-dissipating coatings [1, 9]. An emergent area of ALD research is in what could be described as nanotechnology: the coating of nano-sized features, such as those inside of porous materials, on the surface of nanowires, or onto nanotubes. Although the applications of this area are at this point largely prospective, the possibilities that could be realized are difficult to ignore. This topic has been the subject of a recent review to which the reader is referred for a detailed description [10].

Concluding Remarks

It is the purpose of this entry to give an overview of the basic principles, capabilities, and applications of ALD while referring the reader to several recent comprehensive review articles that treat specific areas in greater detail where relevant. In describing the unique qualities of ALD, it is apparent that the strong advantages of precise thickness control, thickness uniformity, and exceptional conformality lend themselves to a range of possible applications. Despite the fact

that ALD is an inherently slow deposition process, averaging around 1.0 Å/deposition cycle, the rapid miniaturization and increase in structural complexity of many devices has mitigated much of downside associated with its slowness. Correspondingly, these same developments have highlighted the need for ALD, as the limitations of traditional film growth methods have become an impediment to their future use in situations where challenging substrate features are involved. Additionally, in some areas, such as nanotechnology, ALD is likely to become a "critical enabler" that allows for unusual structures to be produced that would be unattainable by other methods. As such, the future for ALD is likely to yield new processes, novel research, and innovative use for an increasing number of applications.

Definition

MEMS actuators are a type of MicroElectroMechanical System (MEMS) that convert energy into motion. MEMS are systems that integrate mechanical and electrical components with dimensions on the order of micrometers. Therefore, the typical motions achieved by MEMS actuators are on the order of micrometers as well.

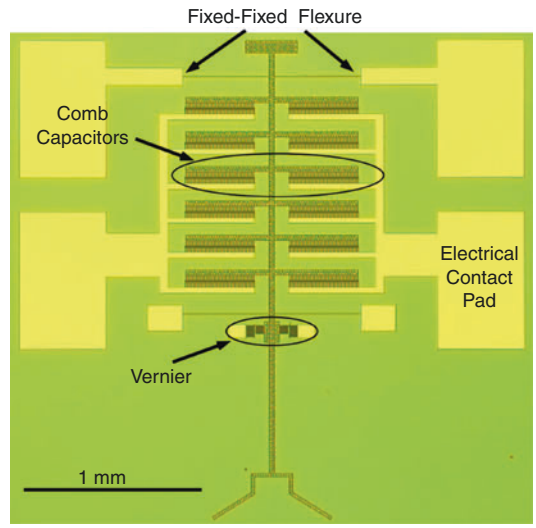
Overview



MEMS are systems that integrate mechanical and electrical components with dimensions on the order of micrometers. Though the concept of MEMS has existed since the 1960s, due to the advent of microfabrication techniques for miniaturizing electronic components, the term MEMS was not coined until 1986. Professors Jacobsen and Wood from the University of Utah devised this terminology in the course of writing a proposal to the Defense Advanced Research Projects Agency (DARPA) [1]. The term was then disseminated via a National Science Foundation (NSF) report, the Utah-held IEEE MEMS workshop in 1989, the IEEE/ASME *Journal of MEMS*, and subsequent DARPA MEMS funding solicitations. Since its inception, this term has gained wide acceptance as a catchall for microdevices in general.

MEMS actuators are a specific class of MEMS that convert energy into motion. The mechanisms by which energy is converted into motion are typically physical or chemical. Motion of the MEMS actuator can be used for positioning, open and closing valves, characterization of energy conversion processes, switching, and material characterization at the micro/nanoscale. A commercial application for positioning with MEMS actuators is that of Texas Instruments Digital Micromirror Device (DMD), wherein micromirrors are positioned (rotated) in order to direct light to create images in projectors for display applications. Opening and closing of (micro) valves is important for microfluidics and lab-on-a-chip applications. MEMS actuators can be configured to be energy storage devices or to detect quantities pertaining to energy conversion. Radio Frequency (RF) MEMS make use of MEMS actuators to create resonators for use in filters, reference oscillators, switches, switched capacitors, and varactors. Finally, MEMS actuators are commonly used to study material responses at the micro- and nanoscales. They are used to apply mechanical forces to materials in order to characterize their material properties mechanically.

Fabrication of MEMS actuators typically occurs via top-down fabrication methods. These methods begin with a larger piece of material, typically Si, and then shape the Si into the form of an actuator. Most MEMS actuators are extrusions of a 2-D pattern that are transferred into the Si via a photolithographic process. Three common methods by which MEMS actuators are fabricated are: Surface Micromachining, Silicon on Insulator (SOI) Surface Micromachining, and Single Crystal Reactive Etching and Metallization (SCREAM). Other processes exist, but many are a hybrid processes based in one of the prior mentioned processes.

This discussion of Basic MEMS Actuators will be broken into four parts. First, there will be a description of energy conversion mechanisms that generate forces; a specific discussion follows on comb capacitors and how they convert (electrical) energy into a force. Second, a discussion will ensue on how MEMS actuators convert the force into motion via a compliant structure. Third, methods for quantification of the motion will be discussed with specific emphasis on an integrated method for measurement of displacements. Finally, a brief description of the three main processes for fabrication of MEMS actuators will be given.

A MEMS actuator is depicted in Fig. 1. It uses comb capacitors for energy conversion into

Basic MEMS Actuators, Fig. 1 Basic MEMS Actuator that utilizes comb capacitors to generate force, a fixed-fixed flexure to guide the motion of the applied force, and a vernier to measure displacement

motion by deflecting a fixed-fixed beam flexure. Displacements of this actuator are measured using a vernier. All components mentioned will be discussed in detail here.

Energy Conversion into Forces and Motion

MEMS actuators convert different forms of energy into force and motion. For example, two electrically isolated parallel plates with an applied potential difference will develop an electrostatic force between the plates. If those plates are on flexible springs, then they will move toward one another. This type of energy conversion into motion is termed electrostatic actuation. Other types of actuators also use electrostatic actuation such as the nanotractor or inchworm actuator [2], scratch drive actuators [3], and the shuffle motor [4]. Beyond electrostatic actuators, many other actuators have been developed that use fluidic forces [5], magnetic forces [6], radiation pressure [7], piezoelectrics [8], shape-memory alloys [9], and thermal expansion [10].

Of particular importance for MEMS actuators is the way with which these forces scale with length; they scale differently due to the different physics involved. Table 1 displays a list of common forces and quantities that are of interest for MEMS actuators and gives how they scale with length.

Table 1 displays the way with which each force scales with length. Variables containing a geometric length pertinent to the physical system are in parentheses and moved to the right-hand side of the equation. It is these quantities that are used to determine quantities' sensitivity to length scale. Note each entry in Table 1 is highly dependent on the configuration of the system. In addition to common forces generated in MEMS actuators, this table also includes gravity, van der Waals forces, inertia, and the mass moment of inertia for reference.

Interpretation of Table 1 is accomplished by comparing the exponents of the fourth column. These exponents are used to compare the importance of a given energy conversion process at different length scales. l^0 indicates that the force-generating mechanism is invariant with length scale. l raised to a positive power means that the property grows with increasing scale, while a negative power implies that the property grows with decreasing scale.

Energy conversion mechanisms with negative exponents will behave more favorably at smaller length scales. Of the mechanisms listed, the easiest to employ and control are thermal (l^2) and the electrostatic forces generated by comb capacitors (l^0). Further discussion on thermal actuators is contained in the thermal actuators entry in this encyclopedia. Comb versus parallel plate capacitors are explained in more detail in the subsequent section. When compared to how inertia scales (l^3), both thermal and electrostatic actuation schemes behave more favorably at smaller length scales. The mass moment of inertia is also displayed in Table 1. The exponent of five (sphere) implies that it diminishes at shorter length scales more rapidly than any of the other forces. Because inertial force and mass moment of inertia are relatively small, compared to common forces used in MEMS actuators, their dynamic responses are much faster than their macroscopic counterparts.

Electrostatic and thermal actuators scale favorably with decreasing length scales and are more easily implemented than most other methods. Therefore, they have considerably more popularity than other energy conversion methods. In the remainder of this encyclopedia entry, MEMS actuators that use electrostatic forces, in particular capacitance due to comb capacitors, will be the topic of discussion. Thermal actuators are more thoroughly discussed in their entry in this encyclopedia.

Comb Capacitors

In order to generate the force applied to the MEMS actuator, one of the more common methods is to use capacitors. The common methods are parallel plate capacitors and comb capacitors. Parallel plate capacitors have a capacitance equal to:

Basic MEMS Actuators, Table 1 Sensitivity of physical quantities to length scale

Physical quantities	Examples	Governing equation	Sensitivity to length scale
van der Waals [11] $\breve{A}$:= *Hamaker constant* A:= *Area* d:= *Distance between objects* r:= *Radius* r_i:= *Radius of object "i"* l = *Facing lengths of two objects*	*Case 1:* Two spheres	$F = \frac{\breve{A}}{6}\left(\frac{r_1 r_2}{r_1+r_2}\frac{1}{d^2}\right)$	l^{-1}
	Case 2: A sphere and a surface	$F = \frac{A}{6}\left(\frac{r}{d^2}\right)$	l^{-1}
	Case 3: Two cylinders	$F = -\frac{A}{8\sqrt{2}}\left(\sqrt{\frac{r_1 r_2}{r_1+r_2}}\frac{l}{\sqrt{d^5}}\right)$	l^{-1}
	Case 4: Two crossed cylinders	$F = \frac{A}{6}\left(\frac{\sqrt{r_1 r_2}}{d^2}\right)$	l^{-1}
	Case 5: Two Surfaces	$F = \frac{A}{6\pi}\left(\frac{1}{d^3}\right)$	l^{-3}
Viscous forces μ:= *Dynamic viscosity* V_0:= *Relative velocity*	*Case 1:* Two infinite plates	$F = \mu V_0\left(\frac{1}{d}\right)$	l^{-1}
	Case 2: Two finite plates	$F = \mu V_0\left(\frac{A}{d}\right)$	l^{1}
Electrostatic force $\in_r$:= *Relative static permittivity* $\in_0$:= *Vacuum permittivity* V_e:= *Electrical potential* h:= *out-of-plane thickness*	*Case 1:* Finite parallel plates at distance d	$F = \frac{\in_0 \in_r V_e^2}{2}\left(\frac{A}{d^2}\right)$	l^0
	Case 2: Comb drive [12]	$F = \frac{\in_0 \in_r V_e^2}{2}\left(\frac{h}{d}\right)$	l^0
Thermal expansion E_y:= *Young modulus of elasticity* α_T:= *Therma expansion coefficient* ΔT:= *Temperature change*	*Case 1:* Constrained column	$F = E_y\ \alpha_T\ \Delta T A$	l^2
Magnetic forces [13] μ_0:= *Vacuum permeability* d:= *Distance between wires* l:= *Length along wire* I_i:= *Current in wire "i"* A_0:= *Cross sectional area* A_S:= *Surface area* $\dot{Q}_S$:= *Surface heat flow rate* I_e:= *Electrical current*	*Case 1:* Constant current density with the boundary condition $\frac{I_e}{A_0}$ = cons.	$F = \frac{\mu_0}{2\pi}\frac{l}{d} I_1 I_2$	l^4
	Case 2: Constant heat flow through the surface of the wire with the boundary condition $\frac{\dot{Q}_S}{A_S}$ = cons.	$F = \frac{\mu_0}{2\pi}\frac{l}{d} I_1 I_2$	l^3
	Case 3: Constant temperature rise of wire with the boundary condition ΔT = cons	$F = \frac{\mu_0}{2\pi}\frac{l}{d} I_1 I_2$	l^2
Piezoelectric force [14] $\in$:= *Mechanical strain* E_e:= *Electrical field* e_p:= *Piezoelectric constant* $\frac{\text{Charge density}}{\text{Applied strain}}$ E_y^E := *Young modulus at constant* E_e	*Case 1:* 1-D unconstrained actuation	$F = -e_p V_e\left(\frac{A_0}{d}\right) + E_y^E \in (A_0)$	l^0 and l^2
Drag force ρ:= *Density* C_d:= *Drag coefficient* A_p:= *Projected are normal to flow*	*Case 1:* Infinite cylinder ($C_d = 0.47$)	$F = \frac{1}{2}\rho V_0^2 C_d\left(A_p\right)$	l^2
	Case 2: Flat plate perpendicular to flow ($C_d = 1.28$)

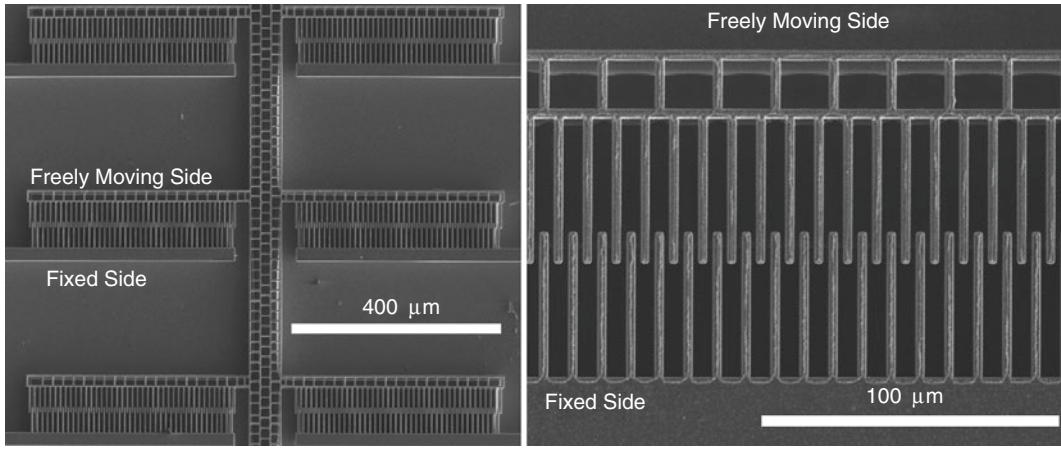
Physical quantities	Examples	Governing equation	Sensitivity to length scale
Inertia and weight g:= *Gravity* α:= *Acceleration* $\forall$:= Volume	*Case 2:* Inertia force	$F = \rho a(\forall)$	l^3
Mass moment of inertia ρ_l:= *Mass per unit length* ρ_A:= *Mass per unit area* ρ_V:= *Mass per unit volume* r:= *Radius*	*Case 1:* Sphere	$\bar{I} = \frac{8\pi}{15}\rho_V(r^5)$	l^5
	Case 2: Thin circular disk	$\bar{I} = \frac{\pi}{2}\rho_A(r^4)$	l^4
	Case 3: Slender bar	$\bar{I} = \frac{1}{12}\rho_l(l^3)$	l^3
Shape-memory alloy [9] v:= *Poisson's ratio* h_f:= *Shape-memory alloy film thickness* h_s:= *Substrate thickness* R_i:= *Initial radius of curvature* R_i:= *Radius of curvature of the substrate with SAM film*	*Case 1:* Force caused by shape-memory alloy on a substrate	$F = -\frac{E_y}{1-v}\left(\frac{A_0 h_s^2 (r_1 - r_2)}{6h_f r_1 r_2}\right)$	l^2

$$C_{pp} = \frac{\epsilon_0 A}{d} \tag{1}$$

where ϵ_0 is the permittivity of the material between the plates (usually air or vacuum), A is the area of parallel plate capacitor, and d is the gap between the parallel plates. The electrostatic energy is $\frac{1}{2}C_{pp}\ V^2$, where V is the voltage between the parallel plate capacitors. Taking its derivative with respective to the gap, the force is calculated to be

$$F_{pp} = -\frac{\epsilon_0 A V^2}{2d^2} \tag{2}$$

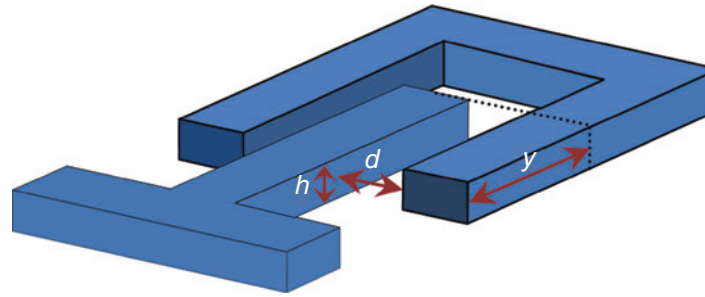
Note that F_{pp} is always attractive and is nonlinear in not only the voltage, but also in the gap between the parallel plates. This geometric nonlinearity makes control of actuators difficult and led to the development of comb capacitors [15].



SEM images of a comb drive array are shown in Fig. 2. Comb capacitors are arrays of interdigitated fingers. One side of the array is rigidly attached to the substrate, while the other is allowed to move via a flexure structure which will be discussed in the next section.

Comb capacitor drives typically have hundreds to thousands of combs to generate a desired force. For analysis purposes, Fig. 3 shows one unit of a comb drive. When connected to an external source, opposite charges gather on the surfaces of the comb fingers which generate an electric field (see Fig. 4). Note that along the vertical line of symmetry of Fig. 4 that the horizontal components to the right and left are equal and opposite. Thus, the net force due to the horizontal components is zero. The vertical components of the fringing field at the tip of the comb finger, however, are not balanced and a net attractive force results. The capacitance of an array of comb capacitors is found to be:

$$C_{cc} = 2n\frac{\epsilon_0 h y}{d} \tag{3}$$



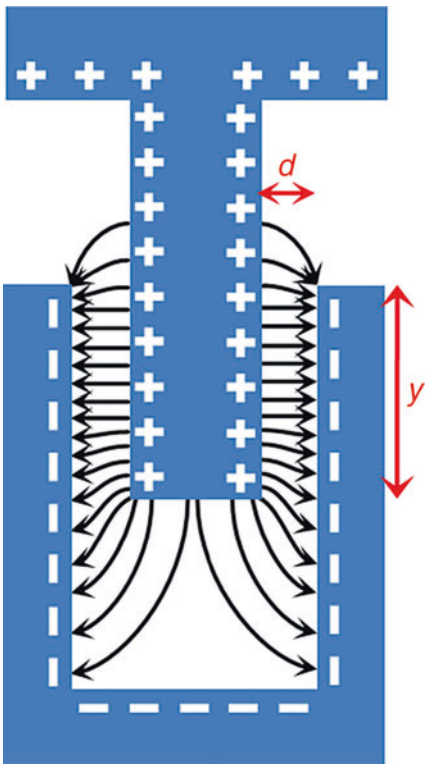
where n is the number of combs in the array, h is the depth of the comb, y is the overlap between the moving and fixed comb, and d is the gap between the moving and fixed comb. The attractive force generated by the comb capacitors when a voltage is applied is:

$$F_{cc} = \frac{n\epsilon_0 h}{d}V^2 \tag{4}$$

Basic MEMS Actuators, Fig. 2 Arrays of comb capacitors arranged symmetrically about the midline of a MEMS actuator (*left*). Closer view of a set of comb capacitors displaying the comb nature of the structure (*right*)

Basic MEMS Actuators, Fig. 3 A single unit of a comb drive actuator

The parameters in Eq. 4 are constant with the exception of the voltage. This type of relationship is more desirable than the relationship in Eq. 2, especially for dynamic excitation. Equations 3 and 4 are valid when the initial engagement of the comb is $>4d$ until the tip of the moving comb is within a distance $4d$ of the fixed side of the comb drive.



Comb drive fingers can be fabricated with various shapes to produce desired force-displacement relationships. For example, in [16] different comb capacitors have been designed, which exhibit linear, quadratic, and cubic response between force and displacement. The profiles of both stationary and moving fingers can be modified (as in Fig. 5), to obtain any desired force/displacement relationship. These types of responses between force and displacement are desirable because the spring constants used in many types of Basic MEMS actuators are nonlinear (see the subsequent section).

Spring Configurations for Basic MEMS Actuators

The force created by the conversion of energy is transmitted to a compliant structure (spring) via a stiff structure that traditionally comprises a majority of the mass – the proof mass. Though many different configurations have been used for the compliant structure, the two most common structures used are shown in Fig. 6. Figure 6a is a fixed-fixed (clamped-clamped) beam configuration, while Fig. 6b is referred to as the folded-beam flexure. Note that Fig. 6a is also referred to as a fixed-guided configuration. "*F*" in each of the figures represents the applied force onto the

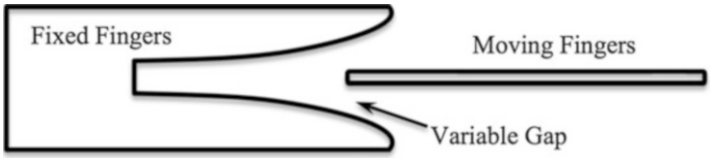
structure by a means of energy conversion, as is described in the previous section.

One-dimensional motion is often desired. Therefore, one direction is designed to be considerably more compliant than the two orthogonal directions. This typically leads to beams that have slenderness ratios greater than 100. Additionally, structures must be designed such that the guided motion is parallel to the force. This requires a configuration that is symmetric about the axis of motion. Thus, only even numbers of beams can be connected to the proof mass. An additional concern is that asymmetric loading may cause the structure to rotate if there are only two connections. Therefore, many designs will have four or more connections at the extremities of the actuator to avoid rotations.

Basic MEMS Actuators, Fig. 4 Electric field of a comb capacitor

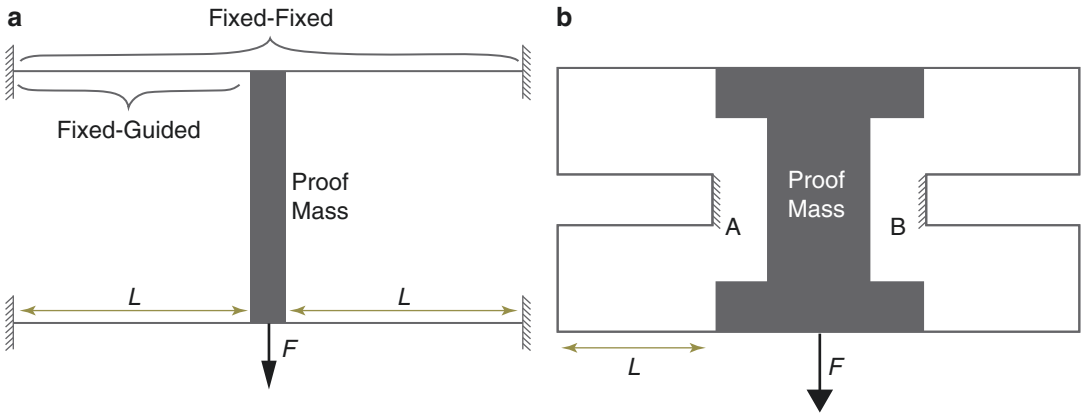
Analysis of a Fixed-Guided Beam Flexure

The linear response of fixed-guided configuration shown in Fig. 7 can be studied using the moment curvature relationship:



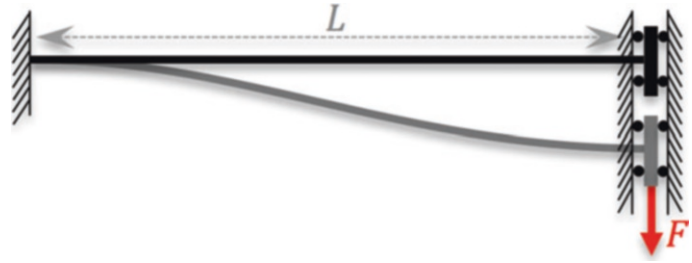
$$\frac{d^2v}{dx^2} = \frac{\mathrm{M}}{\mathrm{EI}} \tag{5}$$

where E is the elastic modulus, v is the deflection, and I is the second moment of inertia. The second moment of inertia for many MEMS structures is that of a rectangular cross section $\frac{hw^3}{12}$ where h and w are the height and width of the structure, respectively. The rectangular cross section is a result of the fabrication techniques used to make these devices (see "Fabrication Methods" section). Solving the ordinary differential equation, Eq. 5, one finds that:



$$F = \frac{12\,\mathrm{EI}}{L^3}\delta \tag{6}$$

where δ is the maximum deflection of the structure. Note that this solution is for a single fixed-guided beam (one half of a fixed-fixed beam). In order to find the solution for multiple fixed-guided beams as in Fig. 6a, springs constants are added in parallel, as appropriate. For example, for the structure shown in Fig. 6a, the spring constant would be 48 EI/L^3.



For small deflections, $\delta < w/4$, this relationship is sufficient for matching the true center line displacement of the fixed-guided beam with better

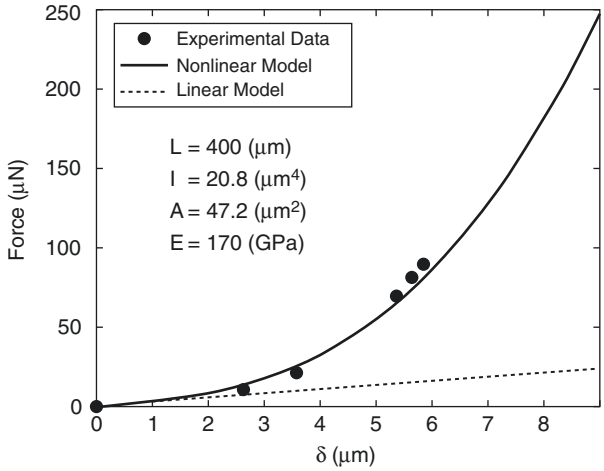
Basic MEMS Actuators, Fig. 5 Varying the shapes of the fixed and moving fingers of the comb capacitor results in modified force-displacement relationships

Basic MEMS Actuators, Fig. 6 Typical configurations for springs in MEMS actuators: (**a**) fixed-fixed or fixed-guided beam configuration and (**b**) folded-beam flexure configuration

Basic MEMS Actuators, Fig. 7 The fixed-guided beam fixed at one end (*left*) and guided on the other (*right*)

than 5 % accuracy. However, for larger deflections, stretching of the beam must be considered. Stretching of the beam induces an axial force F_x, which in turn results in an applied moment. This changes the moment in the ordinary differential equation to be solved. In order to solve this new equation, small displacement assumptions must be used in conjunction with Hooke's Law. These assumptions result in the following equations:

$$\delta = 2\left(\frac{2I}{A}\right)^{\frac{1}{2}}(u - \tanh u) \times \left(\frac{3}{2} - \frac{1}{2}\tanh^2 u - \frac{3}{2}\frac{\tanh u}{u}\right)^{-\frac{1}{2}} \tag{7}$$



$$F = \frac{8EI}{L^3}\left(\frac{2I}{A}\right)^{\frac{1}{2}} u^3 \left(\frac{3}{2} - \frac{1}{2}\tanh^2 u - \frac{3}{2}\frac{\tanh u}{u}\right)^{-\frac{1}{2}} \tag{8}$$

The parameter $u = \sqrt{\frac{F_x L^2}{4EI}}$ in Eqs. 7 and 8. No analytical solution is possible, because F_x is not known a priori. In practice, δ is commonly found in experiments. With δ, Eq. 7 can be solved for u. Next, F is found by inserting the previously determined value of u into Eq. 8. A more detailed solution is located in Frisch-Fay [17].

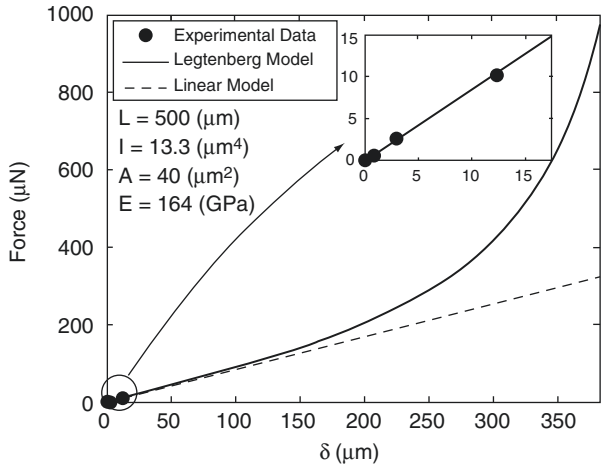


Figure 8 plots both the linear and nonlinear solution for the device shown in Fig. 1, which is schematically depicted in Fig. 6a. In addition to the derived solutions, experimental data are included on the plot. Data are taken by hanging calibrated weights from the device as is detailed in [18]. The width of the fixed-guided beams is 2 μm. Note that the nonlinear model diverges at about one-quarter of the value, that is, 500 nm.

Analysis of a Folded-Beam Flexure

The folded-beam flexure, Fig. 6b, is a variation of the fixed-guided beam configuration. Because the beams are folded, this structure experiences less axial stretch than the fixed-guided structure of Fig. 6a. However, for small deformations, the behavior is approximately the same and Eq. 6 can be used. Because there is less axial stretching in the folded-beam flexure, the linear range is

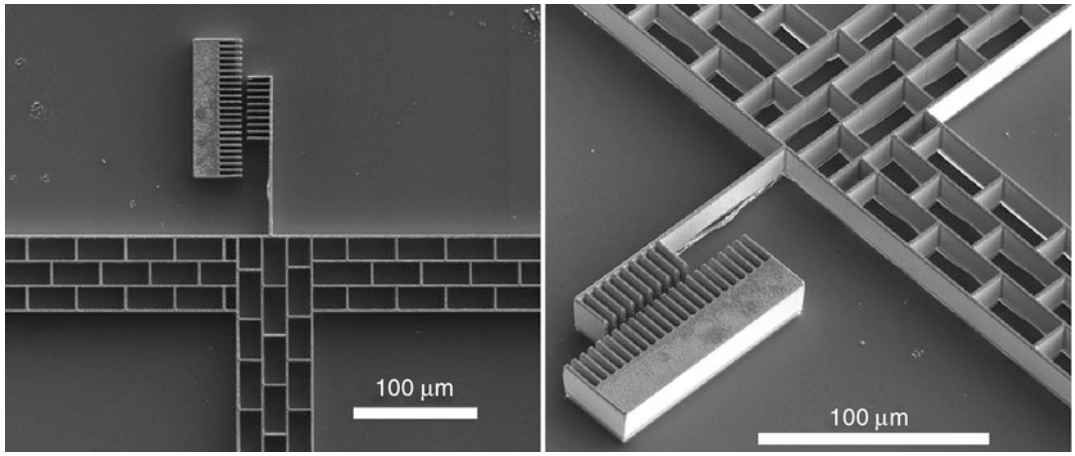
Basic MEMS Actuators, Fig. 8 Force versus displacement response for a fixed-guided beam that compares the linear and nonlinear models developed. Parameters used are for the actuator in Fig. 1. Experimental data are given as found using the method described in [18]

Basic MEMS Actuators, Fig. 9 Force versus displacement response for a folded-beam flexure that compares the linear and nonlinear models developed. Parameters used are for the actuator in Fig. 16. Experimental data are given as found using the method described in [18]

much larger for folded-beam flexures than for fixed-guided beam flexures. In order to find the solution for folded-beam flexure as in Fig. 6b, springs constants are added in series and parallel, as appropriate. For example, for the structure shown in Fig. 6b, the spring constant would be $24EI/L^3$.

For even larger deflections, elastica theory must be applied. Along the y-direction, the displacement and force are [19]:

$$\frac{L}{2}\sqrt{\frac{F_y}{EI}} = \int_{\phi_1}^{\frac{\pi}{2}} \frac{d\phi}{\sqrt{1-p^2\sin^2\phi}} \tag{9}$$



$$\delta = \sqrt{\frac{EI}{F_y}}\int_{\phi_1}^{\frac{\pi}{2}} \frac{2p^2\sin^2\phi - 1}{\sqrt{1-p^2\sin^2\phi}}\,d\phi \tag{10}$$

where:

$$\phi_1 = \sin^{-1}\left(\frac{1}{\sqrt{2p^2}}\right) \tag{11}$$

The solution method involves choosing p and finding ϕ_1 from Eq. 11. Then, the elliptic integrals of Eqs. 9 and 10, each of which depends only on p, are calculated.

Figure 9 plots both the linear and nonlinear solution for the device shown in Fig. 16. In addition to the derived solutions, experimental data are included on the plot. Data are taken by hanging calibrated weights from the device as is detailed in [18]. The width of the folded-beam flexure's

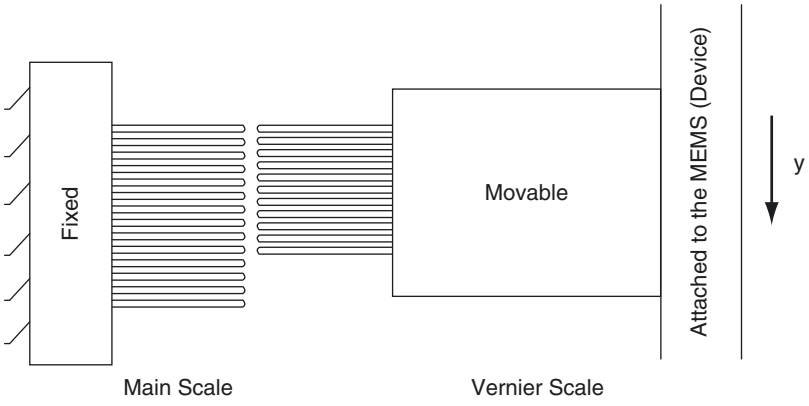
Basic MEMS Actuators, Fig. 10 SEM micrographs of a vernier for the measurement of displacement of a Basic MEMS Actuator

beams is 2 µm. Note that the nonlinear model diverges at almost 55 times the beam's thickness!

Motion Quantification

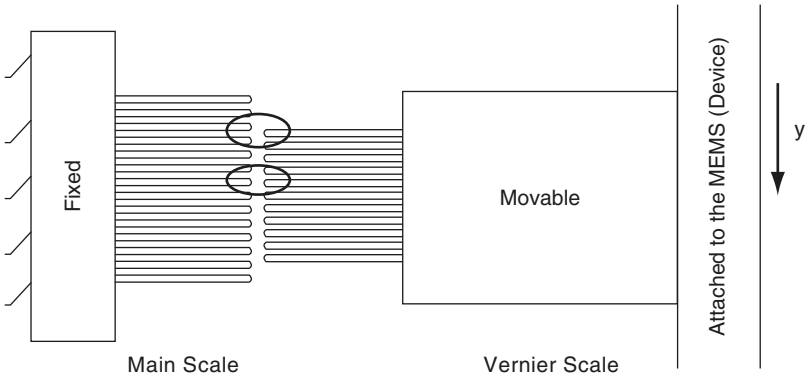
Many different schemes have been proposed for the quantification of the displacement of the MEMS actuators. The most common types include measuring capacitance, resistance, or interpreting an optical signal. Capacitance measurements are especially common when the method of actuation is by capacitors as well. By utilizing a high-frequency voltage on the capacitors, one can measure the impedance. Equation 1 is for the capacitance due to parallel plate capacitors and Eq. 3 is for comb capacitors. Both equations contain a term that relates the displacement to the capacitance of the MEMS actuator. Piezoresistance is also a common method because of the ease of measurement. Limitations of either capacitance or piezoresistance measurements include the sensitivity of the instrument and the ability to isolate the actuator from noise. Optical measurements can be broken into two main categories: inteferometric and vernier. Inteferometric techniques can make very sensitive measurements of displacement and (depending on the technique) may be limited only by thermal vibrations. A vernier is a simple method and can be co-fabricated into the device (see Fig. 10).

In order to measure the displacements of the springs, two sets of scales are incorporated in the design of the MEMS actuator. These are a fixed "main scale" that is attached to the substrate and a moving "vernier scale" that is integrated into the MEMS actuator (Figs. 10 and 11).



The vernier is an auxiliary scale, whose graduations are of different spacing from those of the main scale, but that bear a simple relation to them. The vernier scale of Fig. 11 has ten divisions that correspond in length to nine divisions on the main scale. Each vernier division is therefore shorter than a main-scale division by 1/10 of a main-scale division. Main-scale divisions are 5 µm apart. The Least Count (LC), which is defined as the smallest value that can be read on the vernier scale, is therefore:

$$LC = 5 \times \frac{1}{10} = 0.5\,\mu\text{m} \tag{12}$$



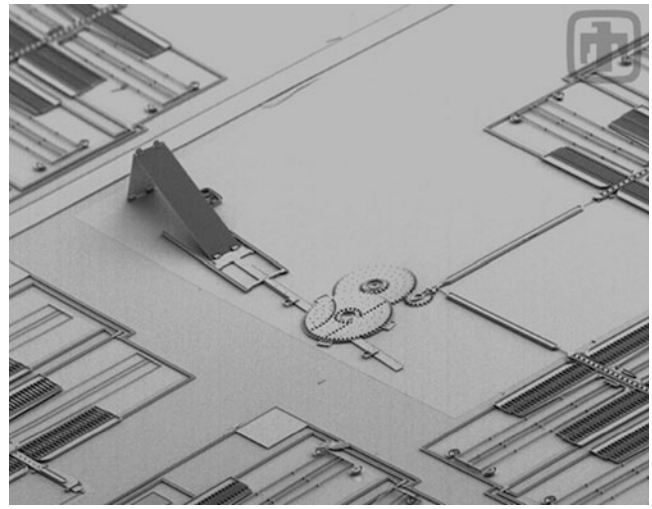
For example, in Fig. 12, the zero of the vernier scale is moved past two complete divisions of the main scale, and the fifth division of the vernier scale is aligned perfectly to the same fifth main-scale reading.

Therefore, the reading from the above setting would be:

- Main-scale divisions = 2
- Main-scale spacing = 5 µm

Basic MEMS Actuators, Fig. 11 Schematic of a vernier for measuring the displacement of a Basic MEMS Actuator

Basic MEMS Actuators, Fig. 12 Schematic of scale system, depicting a deflection of 12.0 μm



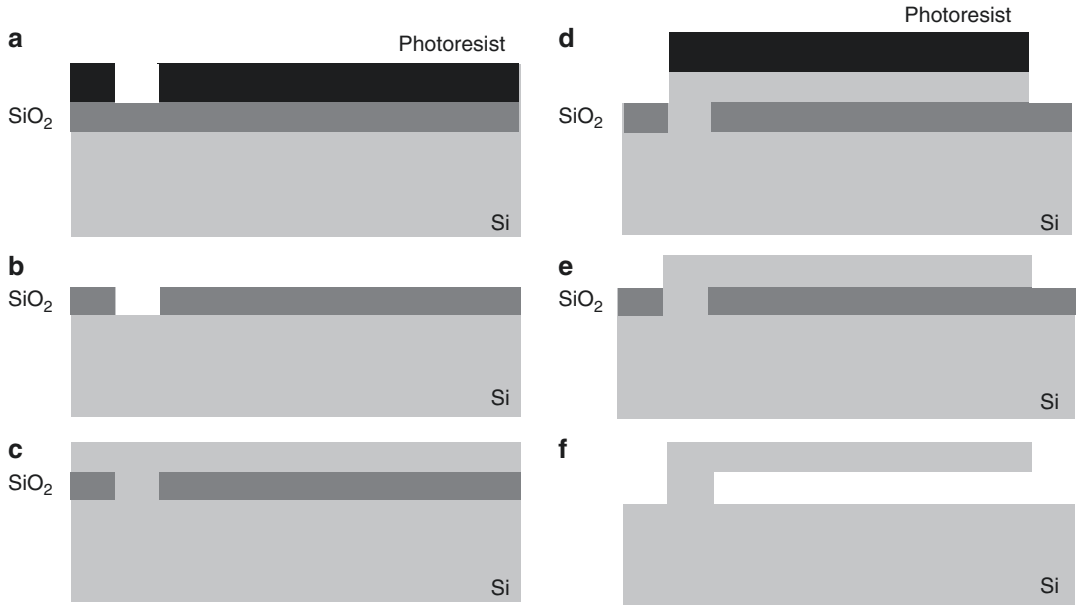
- Total main-scale reading = 2 × 5 μm = 10 μm
- Vernier-scale division that coincides with main scale = 4
- Least count of the vernier scale = 0.5 μm
- Total vernier-scale reading = 4 × 0.5 μm = 2.0 μm
- Total = main-scale reading + vernier-scale reading
- Total = 10 + 2.0 μm = 12.0 μm

Fabrication Methods

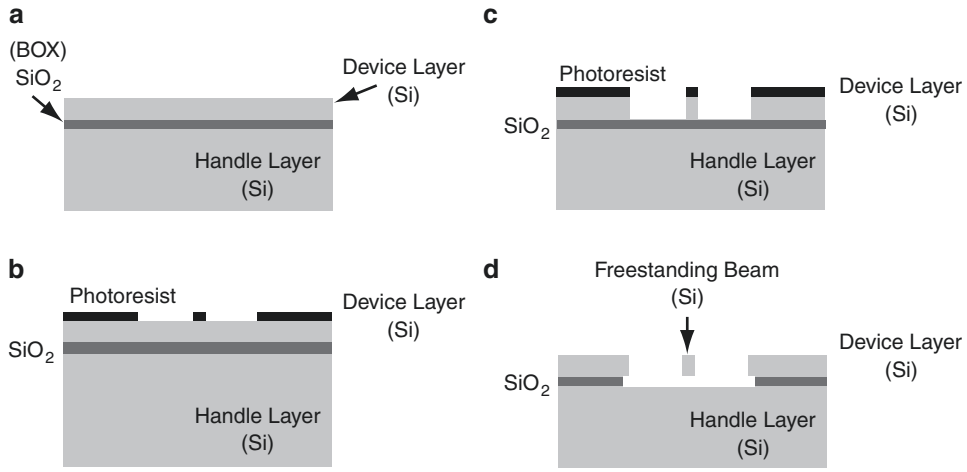
As mentioned previously, there are three main methods for fabrication of MEMS actuators: Surface Micromachining, SOI, and SCREAM [14]. It is important to emphasize that many other processes exist and new processes are being developed constantly. Modifications are typically introduced to accommodate for the actuators' ultimate application or for the type of energy conversion method that the actuator will be utilizing.

Surface micromachining is a process built by alternating the deposition and patterning of sacrificial layers and structural layers of material. Typically, the sacrificial layers are a type of silicate glass (Phospho-Silicate-Glass (PSG) or SiO_2). This layer is commonly referred to as the sacrificial oxide (sac-ox). The structural layers are often made of polycrystalline Si (poly-Si). After the deposition of each layer, that layer is patterned using a photolithographic process to define either holes through the sacrificial layer or physical features of the device in the case of a structural layer.

Figure 13 details a simple surface micromachining process for a cantilever beam. Each step (a–f) is a cross-sectional view for the structure. This is a common method of representing a microfabricated structure's process flow. This method typically revolves around an important feature of the final structure. Note that



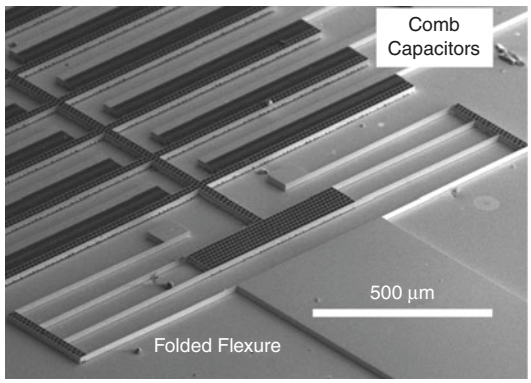
Basic MEMS Actuators, Fig. 13 A surface-micromachined set of Basic MEMS Actuators with comb capacitors and folded-beam flexure used to drive a gear train to raise a micromirror. Image courtesy of Sandia National Laboratories, SUMMiT™ Technologies, www.mems.sandia.gov



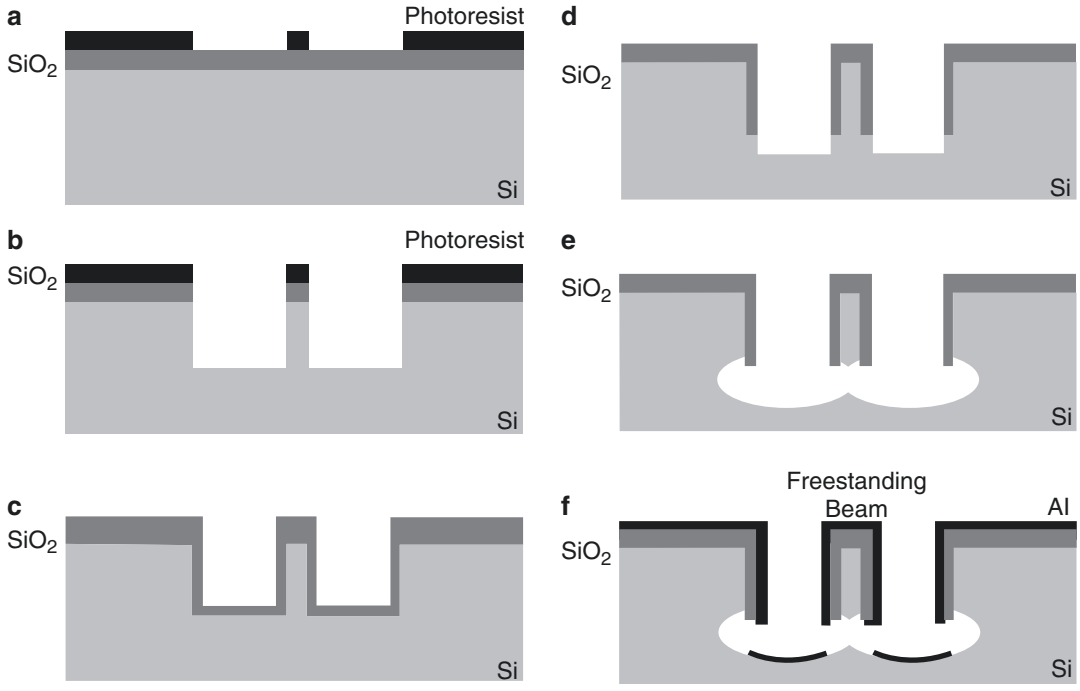
due to the nature of this process, numerous alternating layers of sac-ox and structural layers can be built up to form devices with multiple layers of functionality. One of the more common processes used for surface-micromachined MEMS is the SUMMiT process [20]. At the writing of this entry, the current process is entitled SUMMiT™ V, where V stands for five structural layers of poly-Si. An example of a SUMMiT surface-micromachined device is shown in Fig. 14. A device is displayed with a pair of orthogonal comb capacitors that turn gears and raise a micromirror out-of-plane.

SOI surface-micromachined devices are similar to the surface micromachining process previously described except that the process begins with an SOI wafer. SOI wafers are comprised of three layers: a handle layer, a buried oxide layer (BOX), and a device layer. The handle layer acts as a substrate for the BOX and device layer. BOX layers are the sacrificial layer to be removed by an oxide etch at the end of the process, whereas the device layer is the structural layer of Si for the actual MEMS. The device layer is a piece of single crystal Si, not poly-Si as in standard surface micromachining. Due to the nature of the SOI wafer, SOI surface micromachining is used to make single structural layer devices. The general process flow for an SOI surface-micromachined process is shown in Fig. 15. The freestanding beam in the Fig. 15d would be for any part of a MEMS actuator that is capable of movement. These freestanding beams however must be anchored to the substrate. This accomplished by having structures with larger cross sections that are not fully undercut by the HF etching process. The left and right side of the device layer in Fig. 15d are a partial view of cross section where the SiO_2 has not been fully undercut, thereby allowing for a physical connection between the device layer and handle layer. Note that the connections of the device to ground can be isolated electrically from one another. This is an important feature for placing biases on comb structures such as the one shown in Fig. 16. Although SOI surface micromachining and standard surface micromachining are similar, the device layer in the SOI process can have a broader range of thickness varying from 100's of nm to several 10's of μm. This is important because (1) layer thickness increases the actuator force and (2) a thick layer can make the out-of-plane stiffness of folded-beam suspension much greater, thereby minimizing unintended displacements.

The SCREAM process is a bulk processing method that utilizes a bulk piece of single crystal Si – a Si wafer. Typically, this process utilizes one mask (one photolithography step) as does SOI surface micromachining. In order to create free-standing structures, SCREAM utilizes the selectivity of etchants to certain deposited films and isotropic versus anisotropic etching.

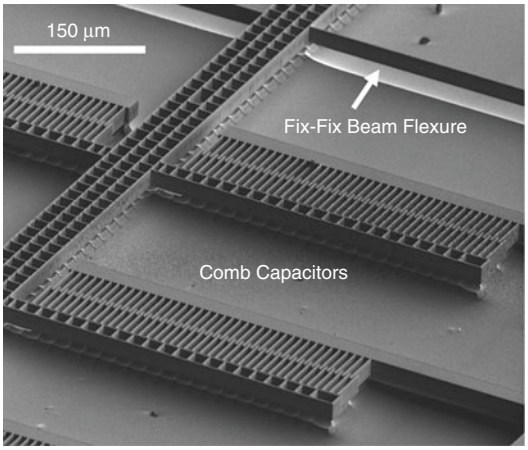


Basic MEMS Actuators, Fig. 14 Surface micromachining of a freestanding microcantilever: (**a**) deposition of a sacrificial SiO_2 layer on Si followed by photolithographic patterning, (**b**) removal of photo resist after etching, (**c**) poly-Si deposition, (**d**) photolithographic patterning and etching of Si to expose the sacrificial oxide layer, (**e**) microcantilever before release, and (**f**) etching the sacrificial oxide layer thus releasing the microcantilever



Basic MEMS Actuators, Fig. 15 Processing steps for the SOI surface micromachining process: (**a**) SOI wafer anatomy, (**b**) photolithographic patterning of device layer, (**c**) deep reactive ion etching of device layer, and (**d**) release of device by oxide etch

Figure 17 demonstrates the SCREAM process [21]. A Si wafer is the base substrate. SiO_2 is deposited on the surface of the Si. Photoresist is then patterned to define the 2D layout of the microactuator (Fig. 17a). Narrow features, approximately 1 μm, will be released (freed), while wider structures, approximately 100 μm or larger, will remain fixed to the substrate during the



release process. After patterning, the Si is etched anisotropically (vertically) typically via a deep reactive ion etch (DRIE) (Fig. 17b). The photoresist is then removed and a conformal layer of SiO_2 is deposited (Fig. 17c). This step is important to the process in that it places an electrical insulator on the sidewalls of the structures. The SiO_2 on the floor of the wafer is then back etched to expose the Si. A subsequent Si etch then isotropically removes Si from the floor (Fig. 17d). This etch is allowed to continue to the point where the two etch fronts from either side of the narrower structures are allowed to merge, thereby releasing the narrow structures (Fig. 17e). The wider adjacent structures are also undercut, but not released. In the final step, a metal is deposited (Fig. 17f). Metal is allowed to coat the top horizontal surface and vertical surfaces of the device. Depending on the layout of the device, the islands on the left and right of the freestanding beam can be electrically isolated from the beam and from one another, connect to one or the other, or connect to both. The isotropic etch of Si in step (e) allowed for the SiO_2 layer to shield the metal (Al) from coming into contact with the Si. If the metal of each structure had touched the Si, then the entire device would be shorted and no potential could be set up for actuation of the device. Figure 18 is an SEM

Summary

This encyclopedia entry covered the basics of MEMS actuators. The discussion was broken into four parts covering: energy conversion mechanisms for generation of force, compliant structures, motion quantification, and fabrication techniques. The section covering energy conversion mechanisms discussed the common mechanisms used in MEMS actuators and went into detail on electrostatic actuation. In particular, the salient features of parallel plate and comb capacitors were presented. Converted forces are used to move MEMS actuators to perform a host of applications. This motion occurs in controlled manner via a compliant structure. Two of the more common compliant structures used for MEMS actuators are fixed-guided beams and the folded flexure structure. Both the linear and nonlinear force versus displacement relationships are given for both of these common structures. Motion of the actuator is quantified in many different ways. Use of a simple co-fabricated vernier is detailed in this entry. Finally, the three main processes for fabrication of MEMS actuators were detailed. These included: Surface Micromachining, SOI, and the SCREAM processes.

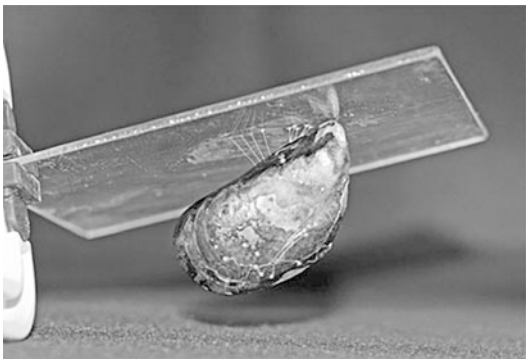
Synonyms

Cell adhesion; Mucoadhesion

Definition

Bioadhesion refers to the phenomenon where natural and synthetic materials adhere to biological surfaces. This adherence may or may not be associated with the use of a bioadhesive. Bioadhesion also refers to the incorporation of the biomaterial in the body, which is manifested by the formation of a biofilm on the biomaterial. A specific type of bioadhesion is referred to as mucoadhesion, where a mucous gel layer is formed on the surface of the biological surface during the adhesion process.

Occurrence



Depending on the chemical composition of the biomaterial and the function of the biological surface involved, bioadhesion may be desirable or undesirable. A few examples of the occurrence of bioadhesion interactions are described as follows.

Synthetic and Natural Biomaterial Interactions

The implantation of biomaterials to the body (in tissue engineering, orthopedics, or dental prostheses, among others) is an example of a situation where bioadhesion is desired. In this case, the bioadhesion between the biomaterial and the target organs lead to the formation of a biofilm (protein layer), which, in turn, facilitates the integration of the implant to the body. Studying the fundamental mechanisms that influence protein adhesion on biomaterials is of interest in the context of the "Vroman effect," which involves a series of adsorption and displacement of proteins on biomaterial surfaces. The proteins on the biomaterial surface interact with cells and influence their behavior. The formation of protein-containing adhesive complexes known as focal adhesions (or cell-matrix adhesions) determines cell migration, cell cycle progression, and eventual differentiation. The proteins involved in focal adhesions are sensitive to the properties of the underlying substrate, such as chemical composition and hydrophobicity [1, 2].

On the other hand, biofilm formation may not be considered as beneficial in some cases. For ocular (contact) lens applications, the formation of a biofilm on the surface of the polymeric lens leads to the accumulation of inflammatory cells, and is therefore undesired [3].

An example of bioadhesion between natural biomaterial surfaces involves lectins, which are proteins or glycoprotein complexes that can bind to polysaccharides (sugars). Lectins are found in both animals and plants. One of the common animal lectins is the calcium-dependent binding lectins (also referred to as "C-type"). One of these C-type lectins, the asialoglycoprotein lectins, is specific to liver cells and is involved in animal biological function [4]. Meanwhile, plant lectins are abundant and can be found in common plants such as tomato, soybeans, and kidney beans. Plant lectins are commonly regarded as toxins when they bind to animal cells. [4].

Bioadhesion, Fig. 1 Adhesion of a mussel on a glass slide, where multiple threads composed of the mussel adhesive protein were secreted by the animal to attach itself to the glass surface [5]

Mucoadhesion

The adherence of materials onto a mucous gel layer of a biological surface is referred to as mucoadhesion. A well-known example of mucoadhesion is the attachment of mussels to underwater surfaces (such as corals or ship surfaces). The animal's foot extends from its shell to secrete a pad of the mussel adhesive protein (MAP) on the underwater surface. The foot then retreats to the shell interior, leaving a thread that secures the mussel to the pad. As shown in Fig. 1, this process is repeated multiple times [5]. The MAP has been used as the model for the development of mucoadhesive materials.

Another important example of mucoadhesion pertains to drug-delivery systems, where the drug is carried in a bioadhesive system, which then adheres to the mucous gel layer located on the surface of the biological membrane. Examples of polymers used as bioadhesives include chitosan, poly(vinyl alcohol), poly(vinyl pyrrolidone), agarose, as well as the cellulose and poly(acrylic acid)-type polymers [4]. The mucous gel layer is composed mostly of water (approx. 95 % by weight), with the rest being the glycoprotein class known as mucins. The mucosal routes of

drug delivery include the eye, mouth, nose, vagina, rectum, and the gastrointestinal (GI) tract [6].

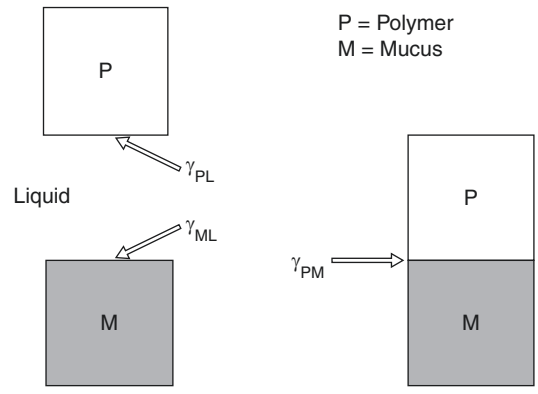
Medical Adhesives

Adhesives are used to close skin incisions, seal and strengthen tissues, stop the leakage of blood and other body fluids, and serve as an adjunct to staples or sutures. These adhesives can be used in various surgical operations such as cardiovascular, pulmonary, and gastrointestinal surgeries, among others. Medical adhesives could either be synthetic (such as cyanoacrylates) or naturally derived (such as fibrin sealants and bovine serum albumin-glutaraldehyde mixtures) [7]. In the case of cyanoacrylates, bonding occurs due to polymerization of the adhesive in the presence of hydroxyl groups in the environment. For the bovine serum albumin-glutaraldehyde glues, bonding takes place between the available lysine groups in the albumin and tissue surfaces and the aldehyde group in glutaraldehyde.

Dental Prostheses

Resin-based composites and polyacid-modified resin-based composites (compomers) are used to restore teeth damaged by cavities, fractures, erosion or aging. Moreover, adhesives are also used to repair fractured porcelain and composite restoratives. These adhesives are applied either to the enamel or to the dentin layer of the tooth requiring the restoration. Acrylic-based resins are used to restore human enamel. The enamel is pre-etched with acid (usually phosphoric acid) in order to create pores and increase surface wettability. The compositions of the enamel and dentin layers are widely different. Relative to enamel, dentin has much higher organic content, is less homogeneous, and more difficult to bond to restorative materials. As a consequence, the composition of adhesives intended for dentin is different from enamel adhesives. Dentin adhesives contain acrylic-based resins, such as bisphenol A-glycidyl methacrylate (BisGMA) and hydroxyethyl methacrylate (HEMA), but other components are present, such as a primer and a bonding agent, which are necessary to enhance bonding to dentin [8].

Key Research Findings



Bioadhesion Mechanisms

Interface Energetics

In systems exhibiting bioadhesion, the liquid environment influences the spreading of one material phase over another. Consider the case of a polymer surface adhering to the mucous gel layer on a biological membrane immersed in liquid medium (e.g., drug-delivery systems). Figure 2 is a schematic illustrating the interfacial energy components that should be considered in evaluating the thermodynamic work of adhesion of this system. During adhesion, a unit interface between the polymer and the liquid and between the mucus and the liquid vanishes, while an interface between the polymer and mucus forms. The thermodynamic work of adhesion (W_{PM}^{adh}) between the polymer and mucus is then defined as follows [6, 9]:

$$W_{PM}^{adh} = \gamma_{PM} - (\gamma_{PL} + \gamma_{ML}) \qquad (1)$$

where γ represent surface energies and the subscripts P, M, and L are for polymer, mucus, and liquid, respectively. A positive value for W_{PM}^{adh} is regarded to be a necessary condition to achieve successful bonding between the two surfaces.

Bioadhesion, Fig. 2 Schematic of the relevant interfacial energies (γ) that determine the formation of a bioadhesive bond, as illustrated for the adhesion between a polymer (*P*) and the mucus layer (*M*) on the biological membrane in the presence of a liquid medium (*L*) (Adapted from [6])

Chemical Interactions

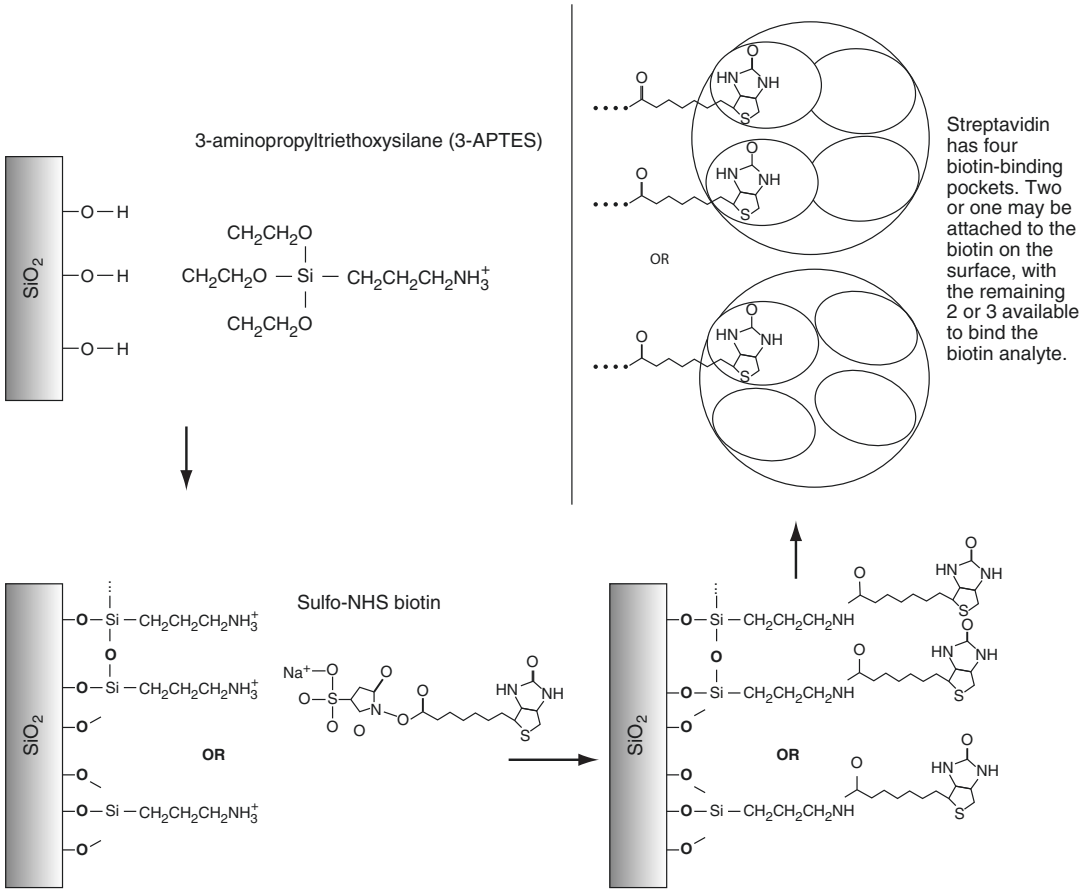
Various interactions between two chemically active surfaces (i.e., not inert) facilitate the bioadhesion process. Strong adhesion can occur if the two surfaces are capable of forming either covalent, ionic or metallic bonds. At the same time, weaker interaction forces, such as polar (dipole–dipole), hydrogen bonding, or van der Waals interactions (induced-dipoles), also aid in bonding the two surfaces [4, 9].

The case of mussel adhesion on underwater surfaces is an example of how the chemical composition of the contacting surfaces affects the adhesion mechanism. The initial interaction between the mussel and the underwater surface involves the removal of weak boundary layers (mostly water). If the underwater surface is nonpolar, the water boundary layer interacts through weak dispersive forces. Since the mussel adhesive protein (MAP) is larger than a water molecule, the protein experiences greater dispersive interactions with the nonpolar surface relative to water, leading to the displacement of the water boundary layer, and adhesion of the protein. In the case of polar underwater surfaces, the water boundary layer cannot be easily displaced. In this case, the MAP uses its hydrophilic amino acid side chains, which contain aminoalkyl, hydroxyalkyl, and phenolic groups (such as 3,4-dihydroxyphenylalanine or Dopa), all of which are capable of forming strong hydrogen bonds. Hence, the MAP is able to displace water and the mussel is able to adhere to polar underwater surfaces as well [10]. The unique chemical composition and properties of the mussel adhesive proteins have led to the development of synthetic analogs for potential use as mucoadhesives for drug-delivery systems.

Mechanical Effects

While interfacial contact and chemical bonding interactions are needed for the initial stages of bioadhesion, the interpenetration or interdiffusion between the molecules of the two contacting surfaces will maintain the adhesive bond. If a polymer is one of the contacting systems involved in the bioadhesion process, the interpenetration process involves the mobility of the individual chains and its entanglement in the opposing biological membrane. A related concept is the swelling capacity of the polymer, which is the ratio of the wet to dry weights. A high swelling capacity for a given polymer implies that it has greater chain mobility, and a higher tendency toward interpenetration [6].

For bioadhesion in dental prostheses, mechanical interlocking or interpenetration is the primary adhesive mechanism. When bonding to enamel, surface etching is performed to create micropores on the surface that will increase the penetration of the restorative material. Dentin, on the other hand, contains tubules that radiate from the pulp. These tubular structures facilitate the penetration of resin monomers into the dentin and their retention once the resin has been polymerized [11].



Interface Optimization

The contact between the two surfaces in contact during the bioadhesion process may be optimized using various physical, chemical, and mechanical methods.

Physical Processes

Plasma processing is a widely used technique for surface cleaning and modification of the surface chemical composition. The plasma, which is generated by applying an electric field to a low-pressure gas in vacuum, produces reactive species such as ions and free radicals. For surface cleaning purposes, the plasma breaks most organic bonds, such as C–H, C–C, C = C, C–O and C–N. In addition, if oxygen plasma is used, another cleaning mode is possible. The activated oxygen species (O•, O^+, O−, O_2^+, O_2−, O_3, among others) can combine with organic compounds to form H_2O, CO, CO_2, and low molecular weight hydrocarbons, thereby removing organic contaminants on the surface [12].

Surface modification through plasma processing can render the surface more hydrophilic or hydrophobic. If the gas used is oxygen or carbon dioxide, polar groups are introduced to the surface (such as –C–OH, −C = O and –COOH), enhancing surface hydrophilicity. The presence of more polar surface groups is valuable in enhancing adhesion, e.g., between proteins and

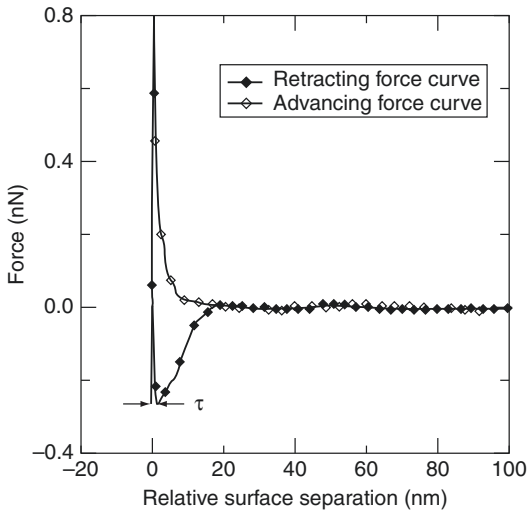
Bioadhesion, Fig. 3 Schematic showing the steps in the functionalization of silica surface with the protein streptavidin (Adapted from [13])

polymeric biomaterials used in tissue engineering applications. On the other hand, the use of fluorinated gases such as CF_4 in the plasma results in the introduction of a low surface energy polytetrafluoroethylene (PTFE)-like structure, enhancing surface hydrophobicity. This approach has been used to prevent the undesirable protein adhesion and the ensuing generation of inflammatory cells on poly(methyl methacrylate) contact lenses [3].

Chemical Functionalization

Specific functional groups can be attached to surfaces using chemical synthesis techniques to construct model systems for use in adhesion studies. An example is shown in Fig. 3, illustrating how a silica surface is chemically functionalized with the protein streptavidin [13]. In this illustration, the functionalization process consists of multiple steps, starting with the addition of the aminosilane 3-aminopropyltriethoxysilane (APTES) in order to introduce amine groups to the silica surface. This is then followed by reacting the surface with sulfo-*N*-hydroxysuccin-imido-biotin (abbreviated as biotin), which forms a covalent bond with the amine group of the APTES. In the final step, the protein streptavidin will bind to biotin. Streptavidin has a high affinity to biotin, and this interaction is regarded as one of the strongest non-covalent bonds known.

Mechanical Texturing



Surface modification through mechanical texturing is a simple and cost-effective method to roughen biomaterials and create anchor points

for enhanced adhesion. In this method, abrasive particles (such as silicon carbide or alumina) impinge on the biomaterial, and the resulting impact increases its surface roughness [14]. This method can be used on orthopedic implant materials such as titanium or cobalt/chrome.

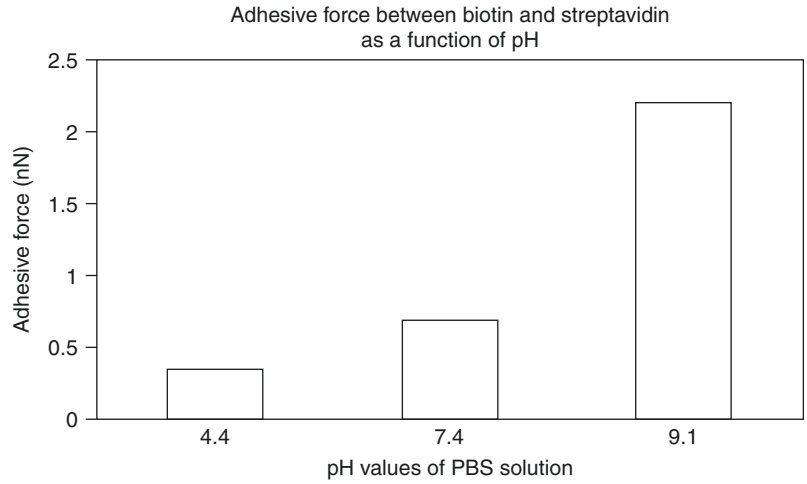
Characterization Methods

Nanoscale

Fundamental studies of bioadhesion at the nanoscale are conducted with atomic force microscopy (AFM). Aside from its high-resolution surface imaging capability, the AFM can measure forces in the pico- to nanonewton range, allowing for the detection of single molecule interactions [15, 16]. In AFM, force-distance curves for the contact between the probe and the sample surface can be obtained. An example is shown in Fig. 4, which corresponds to the interaction between the protein streptavidin and its ligand biotin while immersed in phosphate buffered saline (PBS) [17]. In this example, the AFM probe consisted of a cantilever with a glass microsphere functionalized with biotin on its end, where the biotin is covalently bonded to bovine serum albumin (BSA). The streptavidin was deposited onto a mica surface.

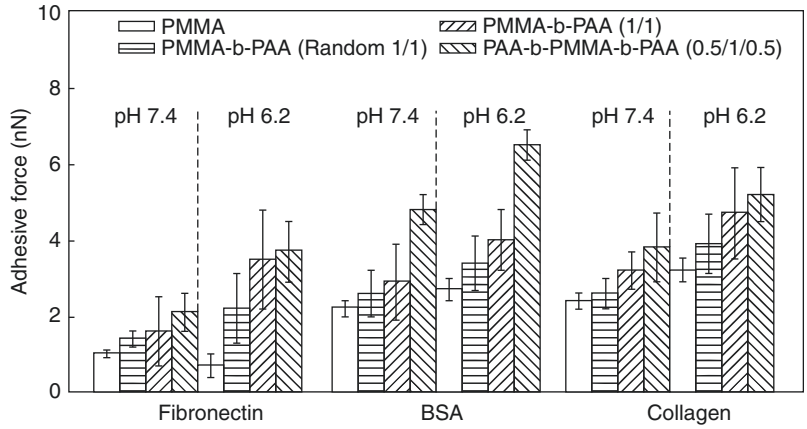
Bioadhesion, Fig. 4 Atomic force microscopy (*AFM*) force-distance curve between biotinylated bovine serum albumin and streptavidin surface imaged in phosphate buffered saline (*PBS*) medium (Adapted from [17])

The force-distance curve consists of two segments, namely, the advancing curve, which shows how the probe approaches the surface, and the retracting curve, which illustrates how the probe detaches from the surface. In the retracting force curve, a distinct snap-off point is observed, which corresponds to the force necessary to separate the tip from the sample surface. This is the measured adhesive force.



In Fig. 4, the quantity τ corresponds to the rupture period, the time over which the bond will break as related by the equation [17]:

$$F = [U - kT\ln(\tau/\tau_o)]\lambda \qquad (2)$$

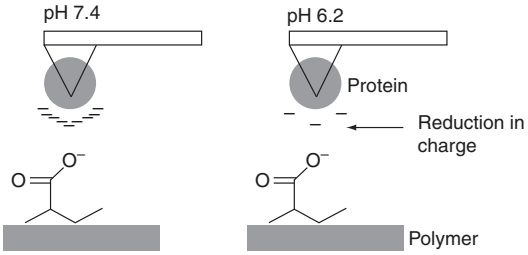


where F is the adhesive force, U is the bond energy, kT is the thermal energy, τ_o is the reciprocal of the natural frequency of oscillation, and λ is a parameter assumed to be equal to the effective rupture length.

The force resolution of the AFM enables it to detect differences on the net charge of biomolecules brought about by a change in the surrounding ionic environment. In another AFM study, Bhushan et al. [18] were able to demonstrate that the adhesion between streptavidin and biotin increases with the pH of the buffer solution, as shown in Fig. 5. This is related to the charge interactions between the two biomolecules. Streptavidin has an isolectric point of pH 5.5, such that it has a net positive charge at pH 4.4 and net negative charge at pH 7.4 and 9.1. The net negative charge in streptavidin facilitates adhesive interactions with the biotin molecule.

Force-distance curves can also be taken over a predefined area divided into an array of points, where the average adhesive force can be determined. This method is useful when analyzing the adhesive properties of next-generation biomaterials such as block copolymers, which have heterogeneous surface properties. Their morphology is a function of the composition and molecular weight of the individual blocks, as well as the spatial relationship of the blocks, for instance A-B block copolymers (or diblock) will have a different morphology than A-B-A block copolymers (or triblock), and so on. This variation in the morphology translates to observable differences

Bioadhesion, Fig. 5 Effect of pH on the adhesion between streptavidin and biotin as measured by AFM (Adapted from [18])



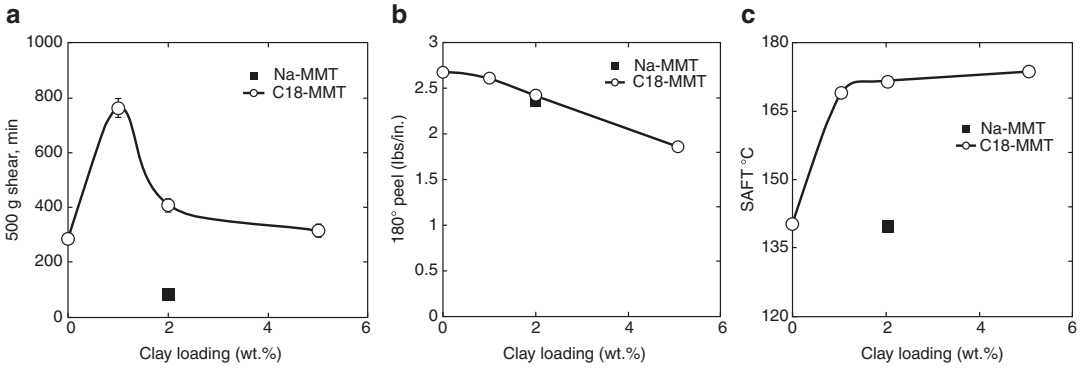
Bioadhesion, Fig. 6 AFM data on the average adhesive force for the interaction between block copolymers containing PMMA/PAA with the proteins fibronectin, BSA, and collagen (attached to functionalized AFM tips) in pH 7.4 (PBS) and pH 6.2 buffer media, with data for PMMA as a Ref. [2]

in the adhesive force. Figure 6 is a summary of the average adhesive force for the interactions between three proteins, namely, fibronectin, BSA, and collagen, on block copolymers composed of poly(methyl methacrylate) (PMMA) and poly(acrylic acid) (PAA), but with different block arrangements (random, diblock, and triblock) [2].

The data in Fig. 6 shows the variation of the adhesive force at two ionic environments, pH 7.4 (PBS) and pH 6.2, where it is seen that the liquid environment affects the adhesive force. At both buffer media, the highest average adhesive force was observed in the triblock copolymer (PAA-b-PMMA-b-PAA, where "b" denotes block copolymer), and the lowest force was obtained from the PMMA reference. The higher average adhesive force in the triblock copolymer surface can be due to greater ordering on its surface, which would expose more PAA-rich areas than it would for the diblock or random copolymer.

The average adhesive forces measured at pH 6.2 are higher throughout the entire series, relative to the PBS medium (pH 7.4) data. This is attributed to higher repulsion at pH 7.4 (or conversely, increased attractive forces at the lower pH). Chemical interactions between the protein and the polymer surface are influenced by the surface charges of the protein and the polymer itself. The amine groups of the proteins are protonated at both pH 7.4 and 6.2. But these proteins carry a net negative charge when immersed in either the pH 7.4 or 6.2 buffer media, since the isoelectric points of fibronectin,

BSA, and collagen are all lower than 6.2 [2]. There are more negative charges on the protein surface at pH 7.4 than at pH 6.2. Also, the acrylic acid chains are ionized (to acrylates) during the adhesive force mapping experiment as it is immersed in aqueous medium. The presence of negative charges on both the tip and sample surface leads to repulsive interactions. As illustrated in Fig. 7, the reduced repulsion between the acrylate groups in the acrylic acid and the smaller amount of surface negative charges in fibronectin, BSA and collagen at the lower pH increases the measured adhesion between the two surfaces [2]. At the higher pH (7.4), the proteins carry a greater net negative charge. Since the acrylic acid in the block copolymer is present in its ionized form, the repulsion from the negative charges present on both the protein and the polymer surface is more significant at pH 7.4 than at pH 6.2. This accounts for the higher adhesive force measured at pH 6.2. The results demonstrate how the AFM is able to measure the effect of the ionic environment on bioadhesion.



Bioadhesion, Fig. 7 Schematic illustrating the effect of pH on protein-block copolymer interactions (focusing on the effect of PAA, which is ionized at pH 7.4 and 6.2), showing negative charge reduction at lower pH conditions, which leads to decreased repulsion [2]

Macroscale

Standard ASTM characterization procedures, such as the peel test (ASTM D903-98), shear strength (ASTM D-3654), and shear adhesion failure temperature (SAFT, ASTM D4498-00), are conducted on interfaces where an adhesive is applied to the biomaterial. These tests are applicable to systems such as fibrin glues used in surgical operations and pressure-sensitive adhesives (PSA) intended for transdermal drug-delivery applications. Figure 8 shows examples of macroscale adhesion data on pressure-sensitive adhesives. The adhesive system investigated was poly(dimethylsiloxane) (PDMS). It was loaded with an organoclay based on montmorillonite (MMT) to form a composite material. The addition of the organoclay was shown to improve the shear strength and the SAFT, with a minimal reduction in the peel strength [19].

The flow-through method, which measures the flow rate needed to remove a bioadhesive-coated sphere, is a common macroscale experiment suited for the characterization of mucoadhesion of potential drug-delivery systems. A widely used

Bioadhesion, Fig. 8 Macroscale testing of bioadhesion. (**a**) Shear strength versus clay loading in pressure-sensitive adhesive (*PSA*) loaded with an organosilicate nanocomposite (C18-MMT); (**b**) 180° peel strength versus clay loading in the PSA; (**c**) shear adhesion failure temperature (*SAFT*) versus clay loading. Na-MMT denotes the pure clay used as the reference material [19]

biophysical assay involves the monitoring of molecular weight change through the variation in the sedimentation coefficient as measured by the analytical ultracentrifuge [20]. The Wilhelmy plate experiment is another technique for evaluating bioadhesion at the macroscale. Instead of having a liquid medium such as water (as used in surface tension measurements), it is replaced with either natural or synthetic mucus and the plate is coated with the polymer of interest [6, 14]. This method is useful for determining interfacial forces between mucus and polymer, as well as for the investigation of changes in bioadhesion properties over time.

Definition

Materials that are designed to bond interfaces for clinical applications.

Introduction

Bioadhesives can be broadly defined as materials that bond interfaces in biological or clinical situations. There are many well-known examples of biological adhesion including mussels or barnacles sticking to rocks, gecko lizards that walk on ceilings, and spider webs. Some examples of bioadhesion have detrimental consequences: Barnacles adhering to ship hulls are a significant problem for maritime operations, and bacteria will form adhesive biofilms that resist treatment resulting in significant harm to human health. These topics have been widely covered in the literature, and many excellent reviews on these topics have been written.

The main subject area of this entry is bioadhesives that are used in clinical situations to improve human health. While the proteins involved in mussel adhesion have been studied for clinical applications, most of the adhesives used clinically are synthetically derived. A notable exception to this is fibrin glue which will be discussed in detail. One of the reasons for this is that synthetic adhesives can offer a level of consistency and reproducibility that is not always possible from biologically derived materials. This entry will cover synthetic adhesives and fibrin glue and discuss some recent developments in nanostructured adhesives.

Applications and Clinical Problems

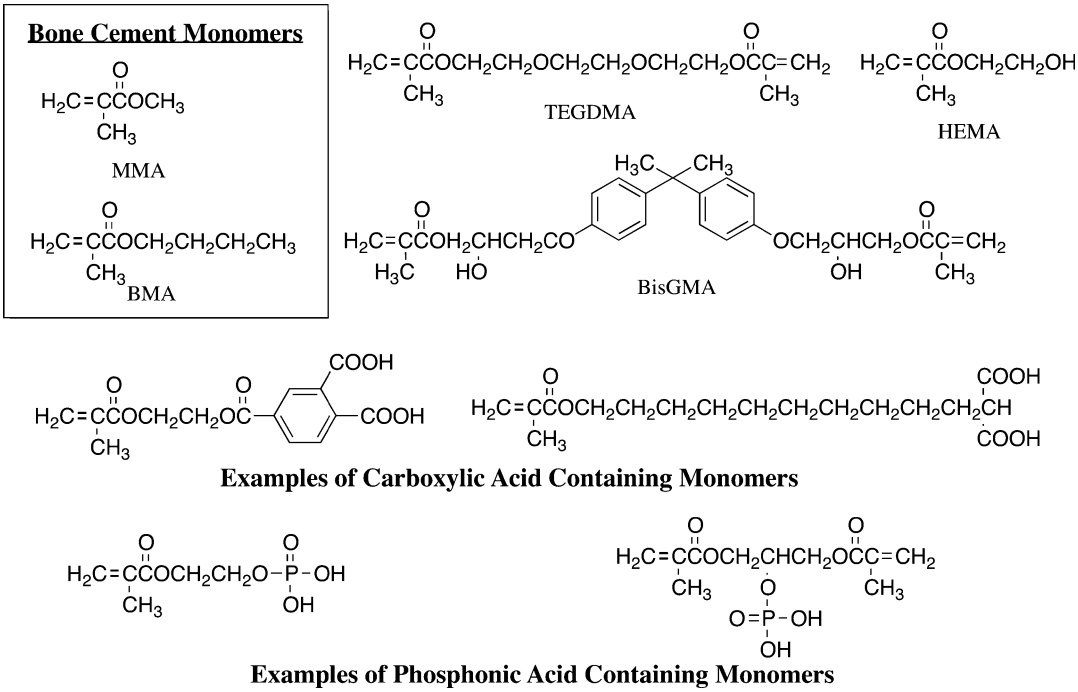
Bioadhesives are used in many situations: to adhere biological interfaces, a biological interface to a material or two material interfaces. Many types of materials are used as bioadhesives, and they can have a wide range of mechanical and physical properties depending on the application. For instance, methacrylate adhesives for dental and orthopedic applications are permanent and nondegradable, whereas most soft tissue adhesives such as cyanoacrylates and fibrin glue are temporary and degradable, while adhesives for maxillofacial prostheses and dentures are temporary, and the adhesives must allow for strong bonding until removal for daily cleaning is desired. In addition, bioadhesives must be resistant to biological attack such as hydrolysis, pH, temperature cycles, and enzymatic attack.

Adhesion is a multifaceted phenomenon involving mechanical locking and chemical interactions. For most hard tissue applications, mechanical locking is the dominant interaction that provides interfacial stability. The classic example is a dental amalgam that is bonded to the tooth almost exclusively by mechanical forces. Proper tooth preparation allows for a macroscale mechanical locking, and the malleable nature of the uncured amalgam allows for microscale mechanical locking with the tooth surface. The ability for an uncured adhesive to flow in-between the crevices and ridges of biological surface is important to establish a stable interface. Low viscosity is an important requirement for uncured bioadhesives and is the reason that most bioadhesives are lower-molecular-weight chemicals that are cured in vivo.

Chemical interactions play a significant role in determining the interfacial strength of a bioadhesive. The chemical composition of a bioadhesive will determine its ability to wet the surface of the substrate as well as its ability to form bonds with the substrate. Establishing a good mechanical interface requires the adhesive to wet the substrate, and poor wetting can result in voids/defects at the interface. As most biological surfaces are hydrophilic, low contact angle adhesives will flow into the crevices and ridges better than a hydrophobic adhesive. This will allow for good mechanical locking on the surface. Chemical interactions such as hydrogen bonding, polar interactions, ionic bonding, and covalent bonding will also play a role in determining the bond strength of a bioadhesive.

Recent Trends

Adhesives in Dentistry



Bioadhesives play a very important role in many aspects of clinical dentistry, binding restorations

to tooth structure, repair of restorations, binding of orthodontic appliances (braces) to teeth, and retention of dentures and maxillofacial prostheses. In restorative dentistry it is estimated that between 50 % and 70 % of procedures are for failed restorations. A significant mechanism of failure is secondary caries or tooth decay underneath the restoration. Most of these failures are directly or indirectly due to poor interfacial bonding between the restorative and the tooth structure. For this reason a great deal of research has focused on improving the adhesive interface between a restorative and the tooth structure. As this constitutes the vast majority of dental adhesion research, this will be the focus of the following discussion. It is important to note that the adhesives described can also be used for orthodontic applications and the repair of restorations or dental appliances. The chemistry and principles of adhesion are the same, and often only minor changes in formulation are made in order to adapt an adhesive to a different dental application.

Most of the adhesives used in clinical dentistry are based on methacrylate polymers and oligomers. A generic outline of a restorative procedure will illustrate how a dental adhesive is used. The clinician will grind away the caries (tooth decay) and expose the underlying dentin. The exposed dentin is coated with ground dentin, known as the "smear layer" that will prevent good bonding. The smear layer is etched away with a strong acid, normally phosphoric acid. The dental adhesive is then placed on the dentin and polymerized with visible light. An uncured composite restorative is then placed on the adhesive and polymerized by visible light. Current dental adhesives incorporate phosphorous-based acid groups that can simultaneously etch the smear layer and bond to the dentin, thus eliminating a step. A visible light-cured adhesive is used in this example; however, if the restoration is preformed to fit the defect, such as crown, precured composite, or a veneer, then a chemically cured adhesive is used. The light cannot penetrate to the adhesive layer, and the adhesive must be polymerized while in contact with the cured restorative to achieve the full adhesive potential.

Methacrylate systems offer many advantages over other curing chemistries and meet most of the requirements for clinical dentistry. As previously mentioned, it is desirable to start with lower-molecular-weight precursors and cure them in vivo. Methacrylate monomers can be cured by visible light within a minute; a longer time frame is not efficient from a practitioner's standpoint and not well tolerated by the patient. Functional groups are well tolerated in methacrylate polymerizations, and hydroxyl-, carboxyl-, and phosphorous-based acid groups can be incorporated as part of dental adhesives. Current formulations of methacrylate monomers and oligomers are stable and have a good shelf life, curing on command with visible light. In addition, most methacrylate polymers and monomers are well tolerated from a biological standpoint. While some concerns about these systems will be addressed later, most methacrylate monomers are considered nontoxic and acceptable for human use.

Early generation dental adhesives are characterized by the use of hydrophilic monomers such as triethylene glycol dimethacrylate (TEGDMA) and 2-hydroxy-ethyl-methacrylate (HEMA). Often a hydrophobic monomer such as (BisGMA) or fillers are added to enhance the mechanical strength of the adhesive. Subsequent generations have incorporated ionic groups such as carboxylic acid, phosphinic acid, and phosphonic acid to enhance bonding to the tooth structure. These acidic groups bind calcium and adhere to calcium-rich surfaces. Enamel and dentin have high levels of the calcium-based mineral hydroxyapatite, 40–50 % and over 90 %, respectively. So these acidic groups contribute significantly to the bonding to the tooth surface. The varied chemistry of adhesive monomers is due to the desire to control properties such as viscosity, mechanical strength, and bonding to the organic components of the tooth structure. The structures and formulations of many commercial and experimental adhesives are found in the literature, and examples of adhesive components are shown in Fig. 1 [1]. The monomers and initiators are often dissolved in a volatile organic solvent such as

Bioadhesives, Fig. 1 Monomers used in dental adhesives and bone cements

ethanol or acetone or a solvent-water combination. The solvent aids in allowing the monomers to penetrate into the dentin to achieve maximum bonding.

A significant focus of dental adhesive research has been on controlling secondary caries and preventing the breakdown of dentin. As was previously discussed, secondary caries is a major factor in the failure of dental restoratives that occurs at the adhesive interface. Chemical modifications and loading the adhesive with antibacterial agents have been employed to increase interfacial stability. Incorporating quaternary amines, silver nanoparticles and monomers derived from antibiotics have all demonstrated the ability to reduce secondary caries. Fluoride-releasing materials have also been successfully incorporated in adhesive formulations. The incorporation of chlorhexidine has also been used to stabilize the adhesive interface. Chlorhexidine has been shown to inhibit MMPs (matrix metalloproteinases) which are known to degrade dentin. Intact dentin is necessary to maintain a good adhesive interface so this has become an active area of research [2].

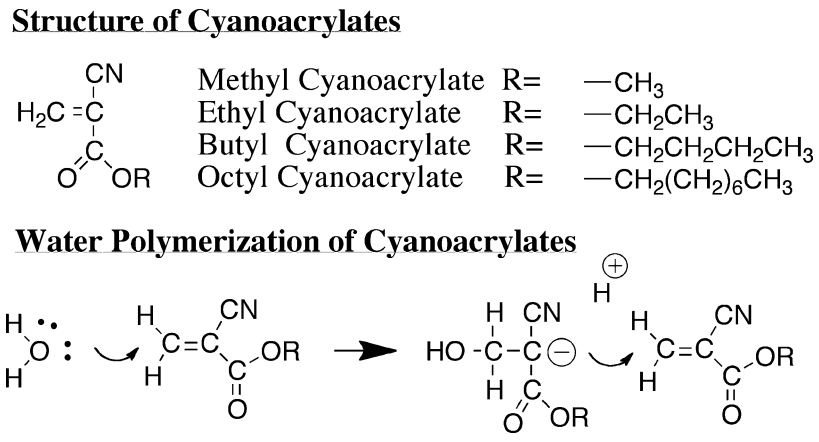
Dental adhesives and their monomers are considered bioacceptable and are approved for clinical use. However, recent studies in cell culture and animal models have raised some concerns about the unpolymerized monomers and breakdown products that can elute from the adhesive. One of the concerns involves these chemicals acting as endocrine disruptors. Bisphenol A, a known endocrine disruptor, is a precursor to BisGMA and is often detectable in BisGMA-based materials in trace amounts. Additionally, some of the visible light curable initiators such as camphorquinone have been implicated as endocrine disruptors. Unpolymerized methacrylate monomers, in particular TEGDMA and HEMA, are known to induce apoptosis in cell culture. This suggests that as unpolymerized monomer leaches from the adhesive, it will be toxic to the surrounding tissue. In addition, some of these same monomers have been shown to cause genetic damage in cell lines [3–5]. While these are areas of concern,

no human studies have demonstrated any significant negative impact on human health. However, as the definition of biocompatibility evolves, such concerns may need to be addressed.

Bone Cements

There are two main categories of bone cements, methacrylate-based cements and water-based calcium phosphate or calcium sulfate. The chemistry and use of bone cements are similar to dental adhesives. Bone cements are primarily used to affix implants into live bone. Bone implants are normally made from titanium, ceramic, or derived from a human source. None of these implants are malleable and will not form a mechanical bond to the bone. Stress will be placed on the implant bone interface soon after placement, and the bone will not regrow quickly enough to establish a good interface to handle the stress. Unpolymerized methacrylate bone cements will mold to the implant and bone upon implantation. Polymerization will harden the cement and form a mechanical lock.

Bone cements are formed by mixing liquid and solid components which initiates a polymerization reaction. The liquid is a mixture of methacrylate monomers, typically methyl methacrylate (MMA) and butyl methacrylate (BMA) along with a polymerization accelerator. The solid component is a fine powder of polymerized methyl methacrylate polymers or copolymers. The most common powder composition is a mixture of methyl methacrylate homopolymer and a copolymer of methyl methacrylate and styrene. The powder also contains a polymerization initiator, and upon mixing, the accelerator and initiator start the curing process. In addition, the powder may contain fillers to improve mechanical properties or antibiotics to prevent infection. Upon mixing, the cement has a doughy consistency allowing the clinician to place and mold the cement. The set cement is an interpenetrating network of the powder and polymerized monomers. This provides good mechanical properties that are needed to withstand the stresses across the interface.



The biological properties of the bone cement are considered to be acceptable. The major drawback is that the polymerization is exothermic and the heat generated can cause tissue damage. There are some concerns about the unpolymerized monomers being cytotoxic, but the long history and extensive use of these materials provides good evidence that they are safe [6, 7].

Water-based bone cements such as calcium phosphate are widely used clinically. They have some advantages over methacrylate bone cements such as better biocompatibility and producing less heat during curing. Calcium phosphate (CP)-based cements are known to resorb in contrast to methacrylate materials which are considered permanent. This is due to the fact that calcium phosphate is similar to the mineral structure of the bone, and the CPs can exist in many different morphologies. These different morphologies will affect the mechanical and biological properties of these materials. The primary drawback to CPs is mechanical properties, which are weaker than the methacrylate cements particularly in tensile strength.

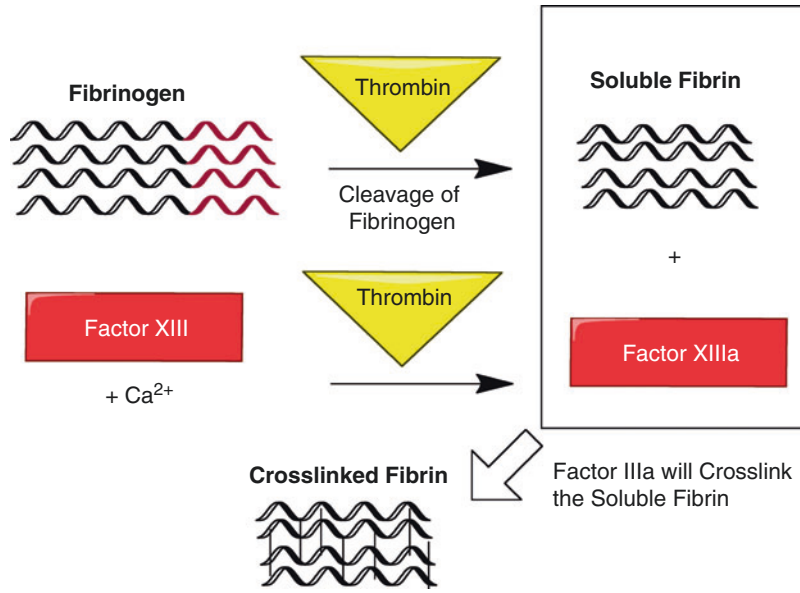
Bone cements, both methacrylate based and water based, have benefited from nanotechnology. Nanoscale fillers such as silica, magnesium oxide, and titania fibers have been used to reinforce methacrylate bone cements. Nanoscale silica demonstrated some physical property improvements but also a reduction in certain mechanical properties such as fatigue strength. The nanoscale magnesium oxide reinforcement demonstrated improved fracture toughness at the cement-bone interface, and it was demonstrated that the nanoscale magnesium oxide improved osteoblast adhesion. Both titania fibers and silicon carbide whiskers improved the fracture toughness and flexural strength at low loading levels. One of the important aspects of incorporating nanomaterials is having a good interface between the bone cement and nanomaterials.

Surgical and Wound Healing Applications

Clinical procedures often require the adhesion of tissue to close a wound or seal an incision after surgery. The applications can range from closing a wound on the skin to closing the small or large intestine after abdominal surgery. Suturing or stitching is a common technique to close wounds that is both labor intesive and requires skill and

Bioadhesives, Fig. 2 Structure and polymerization of cyanoacrylates

training. Surgical adhesives offer a quick, relatively simple alternative to suturing that is highly effective and in some cases superior to suturing. In some cases, sealing the wound immediately is important: For instance, athletes are typically not allowed to compete while they are bleeding. Adhesives offer a quick and convenient route to closing a wound or stopping bleeding.



Cyanoacrylates have been widely used as tissue adhesives particularly for external applications. The chemical structures of the common alkyl derivatives and the polymerization process are shown in Fig. 2. Cyanoacrylates are commonly known as "superglue" and are characterized by a rapid set and a strong adhesive bond. The double bond is electron deficient due to the attached cyano and ester groups. The result is that weak nucleophiles such as water can initiate the polymerization. Hydroxyl, amine, and thiol groups that are often found on tissue can also initiate polymerization. Upon contact with blood or tissue, polymerization will start. This is one of its attractive features; no initiator is needed and the rapid polymerization will stop bleeding and quickly seal a wound.

The degradation chemistry of cyanoacrylates is the biggest barrier that prevents broader clinical use. Hydrolysis of polycyanoacrylates will result in the release of formaldehyde and cyanoacetate. Both by-products are considered toxic and as a result, internal use is limited. The chemistry of the cyanoacrylates can be manipulated to reduce this toxicity. As the alkyl group on the cyanoacrylates becomes longer, the polymer is more hydrophobic and the rate of degradation is slower. While the by-products are still toxic, the overall effects are diminished because the rate of release is slow. Toxicity is a combination of the agent and concentration, so slower release will result in diminished toxicity to the tissue. Another result of a longer alkyl chain is that the polymerization rate is reduced. So the handling properties and degradation rate can be manipulated by mixing different ratios of cyanoacrylate monomers.

In addition to external wound closure, there are several clinical applications for cyanoacrylates. A cyanoacrylate-based product known as IntegueSeal is used to seal surgical sites to prevent infections. Upon curing, a barrier is formed that prevents bacteria from migrating to the infection site. Typically, wound sites are treated with iodine solution to reduce infection, and the application of cyanoacrylate after the iodine solution forms a barrier that prevents the iodine sterilization solution from evaporating and increases it effectiveness. In one clinical study, the rates of infection dropped to 53 % compared to 68.7 % with iodine alone [8]. Cyanoacrylates have also been used in ophthalmic and cardiovascular procedures, and it is being explored as a sealant for gastrointestinal surgery.

Fibrin Glue

Fibrin glue is a surgical sealant that is based on the chemistry and components of the blood-clotting cascade. The entire clotting cascade is very

Bioadhesives, Fig. 3 Overview of the final steps of the clotting process and the basic steps involved the formation of fibrin glue. Many more steps and factors are involved in the clotting process, but this is relevant to fibrin glue

complex and is controlled by multiple feedback mechanisms. Figure 3 shows the last few biochemical steps in clotting that are relevant to fibrin glue. In commercial formulations, fibrinogen and factor XIII are isolated from whole blood as are the thrombin components. In most cases, the fibrinogen is isolated from human blood, and the thrombin can be isolated from a human or bovine source. Batches of the components are often pooled from multiple sources to reduce variability and make a more consistent product. There are other factors involved in the setting process that are isolated with the fibrinogen and thrombin; they are usually referred to as fibrinogen and thrombin components. A solution of the fibrinogen is mixed with a thrombin solution containing calcium salts to initiate the biochemical cascade and thus form the fibrin glue.

Fibrin glue was developed from the observation that fibrinogen itself could be used to stop bleeding and help to close wounds. As it became feasible to isolate more components of blood, thrombin was added to enhance the effectiveness of the glue. Because the components of the glue are naturally derived, it is well tolerated by the body. There is no inflammatory response, the fibrin glue can be resorbed by the body, and the breakdown components are nontoxic. The major drawback is the potential of contamination from the biological source. Viruses and other pathogens can be transmitted along with fibrinogen and thrombin components. While no evidence of serious contamination has been documented and many decontamination protocols are utilized, the potential for contamination remains. Prions represent an area of potential concern and also highlight the unknown factors that may be responsible for disease transmission. Until a few decades ago, prions were not known as infectious agents, but their ability to cause disease is well documented. Bovine spongiform encephalopathy (BSE) could potentially be transmitted from bovine sources, as could the human variant Creutzfeldt-Jakob disease. The fact that sources are often pooled to produce the components can increase the risk of transmission.

Fibrin glue was approved for clinical use in the United States in the late 1990s and has been approved for use in Europe and elsewhere for almost two decades prior to that. Many surgical applications use fibrin glue such as cardiovascular surgery, neurosurgery, reconstructive surgery, and gastrointestinal surgery. Though it is beyond the scope of this entry, it is worth noting that fibrin glue is considered useful as a drug delivery carrier and a tissue engineering scaffold. In addition to previously stated convenience of tissue adhesives, there is documented clinical benefit to the use of

fibrin glue. One of the complications of lung surgery is the leakage of air from a closure site on the lung. In a clinical study, one patient group had the surgical site closed with a suture, and in the second group, the site was closed with a suture plus fibrin glue. The percentage of patients without air leakage for the first group was 34 % while fibrin glue group was 61 %. In another example, fibrin glue was compared with other agents, based on collagen, cellulose, or gelatin, to stop emergency bleeding following surgery. After 5 min, 92.6 % of the fibrin glue patients had stopped bleeding compared to 12.4 % of patients using the other methods [9, 10].

Polyethylene Glycol Adhesives

Polyethylene glycol (PEG) is widely used as a biomaterial due to its excellent biocompatibility and ability to resist protein adhesion. PEG and PEG derivatives have been explored as tissue adhesives and sealants. A number of commercial PEG-based tissue sealants have been produced [11]. PEG-based sealants have many different formulations and chemistries to promote adhesion and to control curing. A PEG with a star architecture cured with a thiol-succinimide combination was evaluated as an artery sealant. The adhesive had desirable mechanical and gelling properties and successfully stopped arterial bleeding in a rabbit model. Blends of PEG and natural hydrogels such as gelatin and polyesters have also been evaluated as bioadhesives. A visible light cure formulation of PEG and polylactic acid (PLA) was evaluated in cardiac surgery as a sealant. Similar PEG-PLA block copolymer systems have been proposed in the literature as tissue adhesives.

Polyurethane Adhesives

Polyurethanes have achieved utility as a bioadhesive due to the ability to create biodegradable polyurethane formulations. Typically, urethane monomers or prepolymers having pendant isocyanate moieties cure in the presence of moisture to form a thermoset adhesive. As the isocyanate moieties contact water, they will begin to react losing carbon dioxide and producing an amine group. The amine will add to isocyanate groups, that have not yet reacted with water, forming carbamates. The competitive reaction between the water and carbamate formation is balanced so that a thermoset is formed. The prepolymers can be prepared in several ways including reacting diols and triols with di- or triisocyanates in stoichiometries that form low-molecular-weight prepolymers and not thermoset materials.

Polyurethanes are widely used as commercial adhesives. Isocyanate monomers based on amino acids and prepolymers formed with degradable polyesters have allowed polyurethanes to be used in clinical settings. Lysine di- and triisocyanates are the basis of many biodegradable polyurethanes. Lysine is an amino acid that allows for the gradual breakdown of the resulting urethanes under physiological conditions. In many instances lysine diisocyanate is allowed to react with polylactic acid diols or polycaprolactone diols to form urethane prepolymers. In this manner any bioacceptable diol or triol can be incorporated into the polymer matrix to modify the physical, biological, or degradation properties. The urethane prepolymer or monomer is cured by contact with water as described above. Molecular level adhesion to tissue can be achieved because the native alcohols and amines can react with the isocyanate groups.

Bioadhesives Derived from Nanotechnology

Ophthalmological Applications

Dendrimers have been utilized to develop bioadhesives for ophthalmological applications and represent one of the few examples of nanotechnology applied to adhesives for clinical applications. Dendrimers are a class of highly branched polymers that can adopt a spherical conformation at higher generations. Dendrimers are characterized by being unimolecular, having a well-defined architecture, and formed from a highly controlled synthesis. The unimolecular and defined architecture allows for structure-property relationships to be well defined. So, by changing the chemistry of the dendrimers, the resulting architecture will be modified and lead to different properties. Due to its spherical nature, the terminal groups will

determine the interactions of the dendrimer with solvent, other dendrimers, surfaces, and biological moieties. Complete or partial modification of these terminal groups will have a significant impact on dendrimer properties. The core group and branching units will determine the arrangement and architecture of the terminal groups as well as the relative stiffness or the dendrimer itself. While these principles are generally true, dendrimers are not rigid spheres but rather molecules that are flexible and can react to its external environment. So the branching units can potentially contribute to the solubility of a dendrimer, for example.

The advantageous properties of dendrimers have led Grinstaff and coworkers to develop ophthalmologic sealants with them. The dendrimers are based on polyester chemistry that could hydrolytically degrade over time. The terminal groups were functionalized with methacrylate groups that allowed them to be visible light cured. Animal models have demonstrated that these materials serve well as adhesives for eye surgery. The investigators note little inflammation and high success rate comparable to standard suturing technique. The dendrimer adhesives also provide advantages over suturing. Suturing can further damage the delicate tissue of the eye, and the visible light-cured adhesive is more rapid than suturing. Additionally, the Grinstaff group has developed dendrimers that have peptides as terminal groups instead of methacrylates. The peptides can chemically link to the tissue of the eye and avoid any potential damage from the heat and light of methacrylate curing [12, 13].

Nanostructured Biological Adhesives

The application of nanotechnology to bioadhesives is a growing but relatively new area. Other than the dendrimer-based adhesives mentioned previously, nanotechnology has not made significant inroads to clinical bioadhesives. One aspect of bioadhesion that has incorporated nanotechnology is the creation of surfaces that can control cell and protein adhesion. It has been recognized that micro- and nanotopography can affect cell and protein adhesion in vitro. While much of the nanotopography has focused on surface roughness, there is a growing body of literature that is examining the role of well-defined nanostructured surfaces in controlling cell and protein adhesion. In particular, self-assembled monolayers [14] and nanopatterned surfaces [15, 16] have been used to control cell and protein adhesion.

Block copolymers provide a platform for creating a variety of nanostructures. While their use for many different applications has been well established, recent work has demonstrated that block copolymer morphology can be used to control protein and cell adhesion on a surface. Work by Bhushan and Schricker [17, 18] has demonstrated that varying surface nanomorphology through block copolymer design can affect protein adhesion. As shown in Table 1, varying the arrangement of the blocks while keeping the composition constant can affect protein adhesion. The protein adhesion is measured by covalently attaching a protein to an AFM tip and measuring the amount of force required to pull the tip away from the surface. For the polymethyl methacrylate

Bioadhesives, Table 1 Summary of the measured adhesive force

Material	Adhesive force (nN)					
	Fibronectin	Fibronectin	BSA	BSA	Collagen	Collagen
	(pH 7.4)	(pH 6.2)	(pH 7.4)	(pH 6.2)	(pH 7.4)	(pH 6.2)
PMMA	1.0 ± 0.1	0.7 ± 0.3	2.2 ± 0.2	2.7 ± 0.3	2.4 ± 0.2	3.2 ± 0.2
PMMA-co-PAA (1/1)[a]	1.4 ± 0.2	2.2 ± 0.9	2.6 ± 0.6	3.4 ± 0.7	2.6 ± 0.4	3.9 ± 0.8
PMMA-b-PAA (1/1)	1.6 ± 0.9	3.5 ± 1.3	2.9 ± 1.0	4.0 ± 0.8	3.2 ± 0.5	4.7 ± 1.1
PAA-b-PMMA-b-PAA (0.5/1/0.5)	2.1 ± 0.5	3.7 ± 0.8	4.8 ± 0.4	6.5 ± 0.4	3.8 ± 0.9	5.2 ± 0.7
PMMA-co-PHEMA (1/1)[a]	1.6 ± 0.3	3.4 ± 0.4	1.6 ± 0.4	4.2 ± 0.6	3.6 ± 0.8	5.1 ± 0.6
PMMA-b-PHEMA (1/1)	3.0 ± 0.2	4.4 ± 0.9	3.8 ± 0.4	3.7 ± 0.7	3.9 ± 0.7	5.0 ± 0.6
PMMA-b-PHEMA-b-PMMA (0.5/1/0.5)	4.2 ± 0.3	4.6 ± 1.0	3.3 ± 0.2	3.7 ± 0.4	4.0 ± 0.8	4.5 ± 1.0

[a]Random copolymer

(PMMA) and polyacrylic acid (PAA) block copolymers, an effect in the adhesion of fibronectin and bovine serum albumin (BSA) is observed at low pH but not neutral. However, for the PMMA and poly(2-hydroxy-ethyl-methacrylate) (PHEMA), the effect is observed at neutral pH but not at low pH.

Work by Cooper-White et al. [19, 20] has also demonstrated the use of block copolymers in controlling cellular behavior. Block copolymers of polystyrene and polyethylene oxide have been utilized to effect cellular and protein adhesion. In particular, as the domain sizes of the block changed, the cellular adhesion was affected.

Another application of nanotechnology to bioadhesion is the use of nanoparticles to bond hydrogels and soft tissues. Silica nanoparticles suspended in basic water were applied to a hydrogel surface. By placing another hydrogel on top of the nanoparticle-modified surface and applying pressure, a bond is formed. The polymer chains of the hydrogel will adsorb on the nanoparticle surface and act as a dynamic linker between the chains and the surface. In addition, this technique was used to bond two pieces of calf's liver [21]. This is an interesting use of the intrinsic surface area and size of nanoparticles to create an adhesive bond that would not be possible with larger-scale materials.

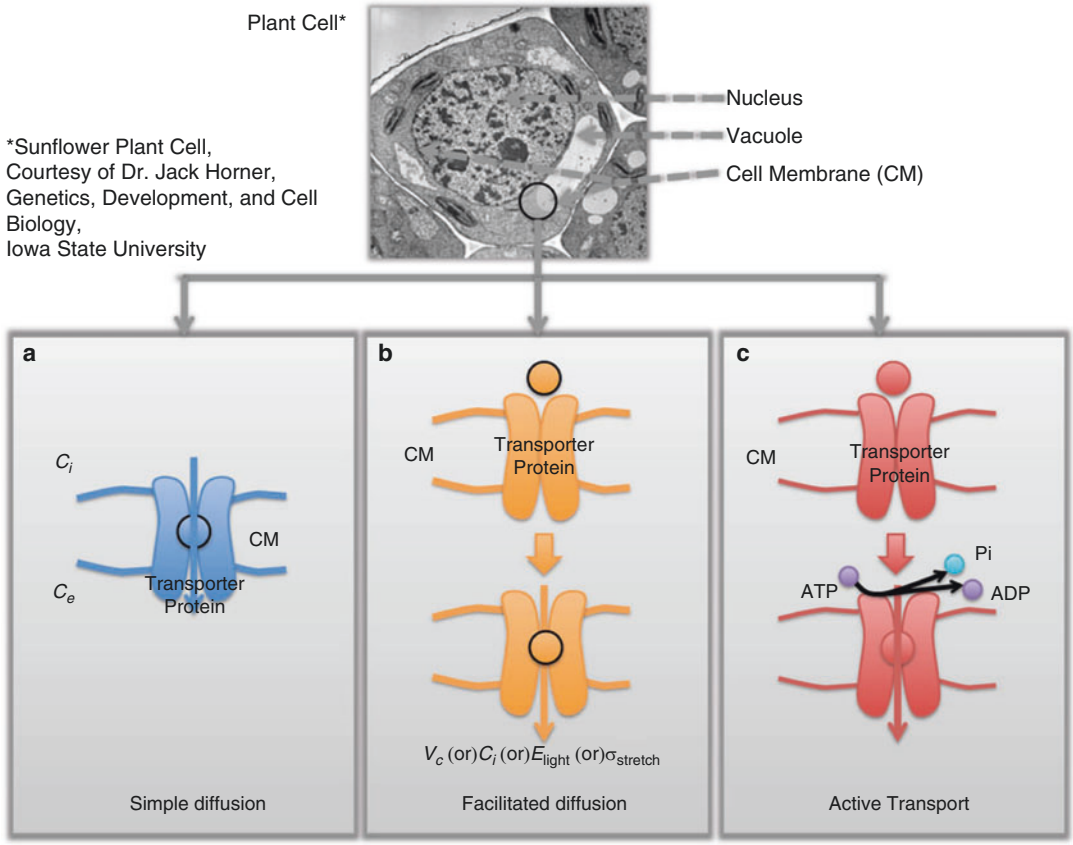
Definition

Bioderived smart materials are a category of ionic active materials that are fabricated from biological macromolecules and utilize the ion transport properties of cell membranes to couple multiple physical domains (chemical, electrical, mechanical, and optical). Owing to this coupling exhibited by biological macromolecules, bioderived smart materials are used as actuators, sensors, and energy harvesting applications.

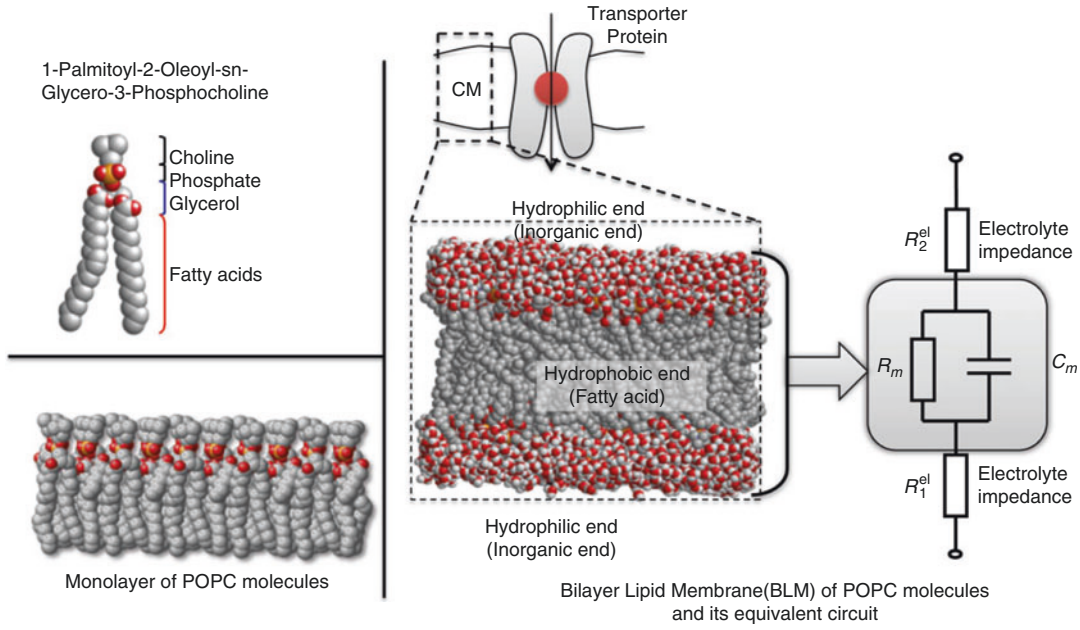


Cell Membrane Proteins: Transporter Macromolecules

The cell membranes of plant and animal cells are host to cholesterol and a variety of proteins that provide structural rigidity and serve as anchor points for cell attachment. In addition, some proteins serve as transporters and allow the cell to exchange ions and neutral molecules between the cell cytoplasm and its surroundings. The transport of species through a protein transporter in the cell membrane is driven by biological processes that have inspired the development of novel sensing, actuation, and energy harvesting concepts. This entry will provide the technical background on biological processes that have inspired the development of *bioderived smart materials* and discuss the system level concepts, fabrication, and characterization of these material systems. Specific emphasis will be given to novel actuation systems, sensing platforms, and recent advances in fabrication of these materials systems.

Transporter proteins are biological macromolecules embedded in cell membranes that convert electrical, mechanical, or chemical stimuli into ion transport and regulate chemoelectrical potentials across the membrane. It is this stimuli response of protein transporters that makes it viable for the development of a bioderived smart material using biological ion transport processes. The transport of ions through the transporter protein occurs via one of the following processes:

1. Simple diffusion
2. Facilitated diffusion
   (a) Voltage-gated diffusion
   (b) Ligand-gated diffusion
   (c) Mechanically gated diffusion
3. Active transport



These ion transport processes are illustrated in Fig. 1 and are used to classify protein transporters found in cell membranes. In simple diffusion, the protein transporter behaves like an open channel and allows diffusion of a species along a concentration gradient across the membrane. In facilitated diffusion, the protein transporter uses a gating signal such as light, electrical field, mechanical stretch (or) an analyte to open and conduct an ion or neutral molecule across the membrane. In active transport, the protein transporter uses the energy from biosynthetic molecules such as adenosine triphosphate (ATP) to transport ions across the membrane. Since active transporters expend chemical energy available in triphosphates, ions are transported across the membrane against an

Bioderived Smart Materials, Fig. 1 Protein transporters in plant cell membrane

existing concentration gradient. In addition to ion transport, active transporters establish the necessary chemoelectrical gradients required for facilitated diffusion across the membrane and provide the driving force for long-range ion and solute transport in plant and animal cells.

The mechanism for ion transport through the protein transporter is explained by its molecular composition and structural arrangement. The structural composition of the protein transporter is unique to a plant (or) animal cell membrane and hence transporters are unique in their ion transport function. The diversity of plant and animal cell membranes and the uniqueness of protein transporters found in the cell membranes lead to a large number of protein transporters that can be used as an active component in a bioderived smart material. Protein transporters ion proteins are formed from amino acids that are connected by a polypeptide bond. There are some 20 amino acids that form the majority of the protein transporters and have clearly identified C-C backbone and polar, nonpolar, and aromatic side chains. The linear network of polypeptide bonds has a well-defined two-dimensional structure and is woven (folded) into a three-dimensional structure in the cell membrane. The arrangement of amino acid side chains in the two-dimensional and three-dimensional structures contained within the protein transporters leads to hydrogen bonding, van der Waals, and steric interactions in response to external stimuli. This response in structural changes for an applied optical, electrical, mechanical, or chemical stimuli results in the formation of a conductive pathway for a specific ion to migrate across the membrane and results in an ionic current through the protein transporter and the cell membrane carrying the protein transporter. As a

Bioderived Smart Materials, Fig. 2 L-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine molecule, monolayer, bilayer, and equivalent electrical circuit

consequence of the ionic current, the protein transporter maintains and regulates the electrical potential across the membrane in response to the applied stimulus.

Bilayer Lipid Membranes: A Breadboard for Bioderived Smart Material Concepts

The fabrication of a bioderived smart material requires a membrane that can serve as a host to transporter proteins and exhibit coupling between multiple physical domains (chemical, electrical, mechanical, and optical). This membrane should have the structural properties of a cell membrane and assume the ion transport function imparted by the transporter protein. In addition, this membrane should be sufficiently modular to accommodate multiple proteins and provide a composite ion transport function. The current state of the art in bioderived smart materials uses the same macromolecules that form the cell membranes of plant and animal cells. These molecules, referred to as glycerophospholipids (also referred to as phospholipids or lipids), are extracted and purified from cell membranes and are amphiphilic in nature. Phospholipids comprise of an organic alkyl end group with one or few double bonds and a polar end group connected to each other via a glycerol-phosphate group. An example phospholipid molecule L-*p*almitoyl-2-*o*leoyl-sn-glycero-3-*p*hospho*c*holine (POPC) with an organic palmitoyl- oleoyl- and polar -choline end group is shown in Fig. 2. These molecules, owing to their amphiphilic nature assemble into a bilayer formed from stacked monolayers with the hydrophilic ends of the monolayer facing outside as shown in Fig. 2. This stacked arrangement of hydrophilic-hydrophobic-hydrophilic groups in the bilayer membrane offers high impedance for transport of ions and neutral molecules through the membrane. The bilayer lipid membrane (BLM) measures 6–10 nm in height, spans 10–20/μm^2 area, and serves as the host to various transporter proteins and forms the basic structure of a bioderived smart material. Since various transporter proteins with different ion transport functions can be incorporated in the BLM to provide a composite ionic function, the BLM becomes the breadboard for various smart material concepts.

Owing to their biological origin, the BLM with the protein transporter is referred to in this entry as the bioderived membrane.

In order to quantify the ionic current through the bioderived membrane in the presence of the stimulus, it is required to establish a measure of baseline ion transport (current) through the BLM and charge separation (electrical potential) across the membrane without the protein transporter. The conductance of the membrane is represented using a frequency-dependent complex impedance function and the membrane is modeled using electrical equivalents as shown in Fig. 2. The complex impedance is measured using electrical impedance spectroscopy (EIS) and fitted to an equivalent circuit. In the absence of protein transporters in the BLM, the membrane has a high electrical impedance (~**O** 0.1–1 GΩ.cm^2) and a capacitance of 1/μF.cm^{-2} [1, 2]. In the presence of protein transporters, the membrane assumes the transport properties of the protein and has markedly different conductance states. The impedance of the membrane with the protein in the presence of the stimuli measured using EIS and the conductance states through cyclic voltammetry (CV) and chronoamperometry (CA) establish the incorporation and functioning of the protein transporter in the membrane.

Concepts for Ionic Active Materials Using Bioderived Membranes

The design of smart materials system using protein transporters employs one or several of the previously discussed ion transport processes. In order to understand the energy conversion processes in a protein transporter and its performance as an ionic active material, it is necessary to quantify the work performed by the bioderived membrane for an applied input energy. The electrical work done by bioderived membranes from ion transport is

$$\Delta U_E = \int_0^q E dQ \tag{1}$$

where E is the electrical field established by the protein and dQ is the charge displacement through the membrane. The electrical field established across the membrane is given by $E = V/t_m$ where V is the transmembrane potential and tm is the thickness of the membrane. The charge displacement dQ is due to the ionic current i_c through the protein transporter embedded in the membrane and can be obtained from electrochemical measurements on the membrane. The ionic current results in altering the concentration of the ion across the membrane that sets up an additional transmembrane potential V_c give by

$$V_c^{\infty} = \frac{RT}{zF} \ln\left(\frac{C_e^{\infty}}{C_i^{\infty}}\right) \tag{2}$$

where $C_e^{\infty}, C_i^{\infty}$ are the concentration of the ion on either sides of the membrane at the end of the process and z is the valency on the transported ion. Similarly, the chemical energy gradient across the membrane due to a concentration gradient is given by

$$\Delta\mu = RT \ln\left(\frac{y_e^{\infty}}{y_i^{\infty}}\right) \tag{3}$$

where $y_e^{\infty}, y_e^{\infty}$ are the mole fractions of species y on either side of the membrane at steady state. The interconversion between chemical potential and electrical potential across the membrane shown in Eqs. 1, 2, and 3 occur via ionic currents through the protein transporter.

The ionic currents through the bioderived membrane can be written for various transport process from *phenomenological equations* as a function of one or more of the following as shown in Sundaresan et al. [3]

1. Applied transmembrane potential (V)
2. Chemical energy gradient ($\Delta\mu$)
3. Chemical energy released from biochemical reaction ($\Delta\mu$)

The diffusion ionic current through the membrane of area A and permeability constant P_m in the presence of concentration gradients Ce, C_i, and transmembrane potential V is given by Goldman-Hodgkin-Katz equation as

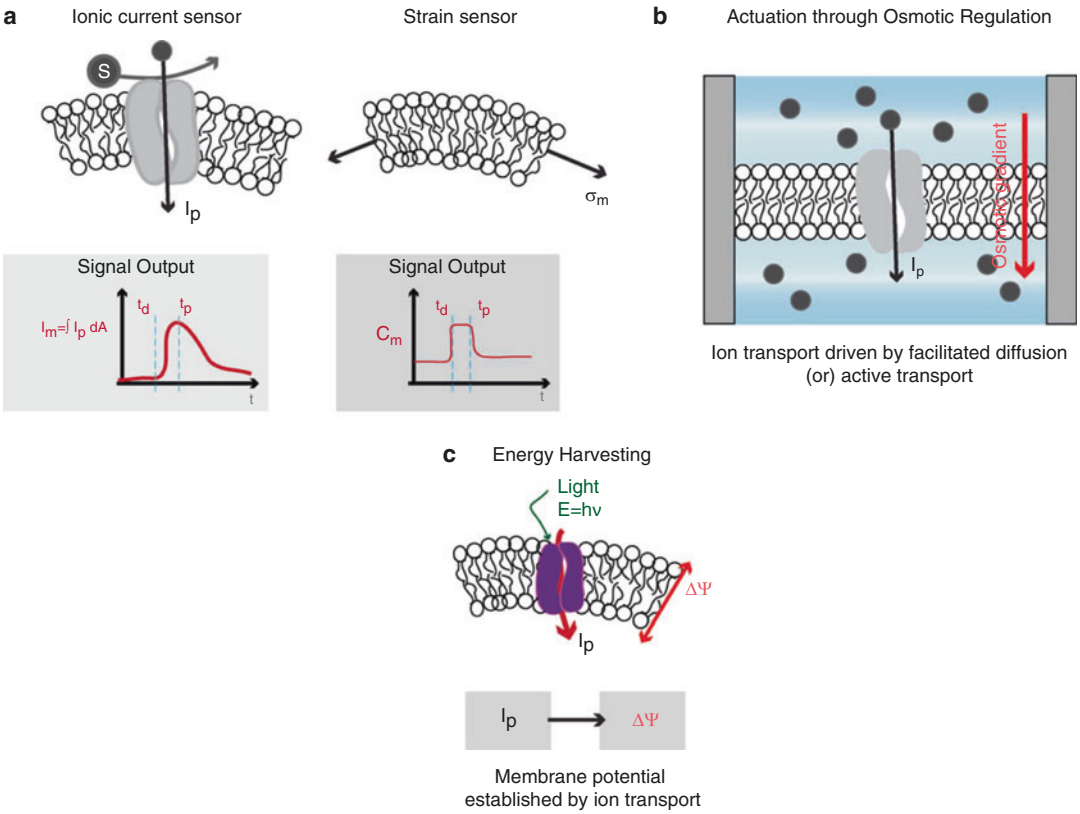
$$i_{diff} = -AP_mF\left(\frac{zFV}{RT}\right)\left(\frac{[C]_i - [C]_e e^{-\frac{zFV}{RT}}}{1 - e^{-\frac{zFV}{RT}}}\right). \quad (4)$$

The ionic current through the protein transporter via voltage-gated diffusion i_{vg} is given by

$$i_{vg} = 2\psi zekT\sqrt{[C]_e[C]_i} \times \frac{A_p}{\in d}\sinh\left(\frac{e(V - V_C)}{2kT}\right), \quad (5)$$

where ψ is the voltage gating coefficient, z is the valency of the transported species, e is the charge on the ion, A_p is the area of the ion conducting channel, and d is the length of the pore in the protein transporter. The ionic current through the protein transporter via active transport i_{pump} is given by

$$i_{\text{pump}} = Me\lambda\tanh\left(\frac{[F(-V - V_{\text{ATP}} + V_C]}{2kT}\right), \quad (6)$$



where M is the pump density in the membrane, z is the charge of the pumped ion, λ is the sum of the forward and backward reaction rates in the pump, V_c is the electrochemical gradient for the pumped ion given by Eq. 2, and k is Boltzmann constant.

The choice of transporter protein in bioderived materials depends on the nature of the stimulus to be detected for sensing, stimulus that is available for actuation and ambient energy source available for harvesting. This choice is also dependent on the ability to extract a protein transporter from a cell membrane and the ability to reconstitute the cell membrane-like structure on a synthetic platform. Thus, a bioderived membrane measuring 6–10 nm in thickness with finite number of transporter proteins supported or suspended on a solid substrate and membrane area of $\sim 10\ \mu m^2$ serves as the fundamental unit in a bioderived smart material. In an actuator, sensor, or energy harvesting device, a large number of such membranes with protein transporters are assembled to work in parallel as a smart material. An overview of concepts that use the bioderived membrane as the active component in sensors, actuators, and energy harvesting devices is shown in Fig. 3. The ionic currents through the membrane can be obtained from the ionic current through the transporter from expressions similar to Eqs. 4, 5, and 6 for the design of smart material systems.

Sensor: The bioderived membrane is used as the sensing element by monitoring the electrical response of the membrane in response to an applied stimulus. The bioderived membrane is formed with electrodes on either sides of the membrane on a synthetic substrate and packaged into a system for monitoring electrical current, transmembrane voltage, or electrical impedance. With the choice of an appropriate protein transporter, the sensor is tailored to respond to chemical analyte, bioelectrical sensors, mechanical strain, light, and temperature.

Actuator: A bioderived membrane is used to regulate the ionic concentration between two closed volumes in response to an applied stimulus. The ionic currents through the bioderived membrane sets up ionic and osmotic gradients across the membrane. This concentration gradient becomes an intermediate stimulus for osmotic regulation and movement of the solvent molecules (water) across the membrane. The bulk movement of water molecules leads to volumetric expansion of a closed volume that will lead to bulk stress in the material. The bulk stress generated in a closed volume encompassing the bioderived membrane is placed in a system that will lead to the development of a stack- or a bimorph-type actuator.

Energy Harvesting: The definition of an energy harvesting device has evolved over the last decade and is now defined as a system that converts ambient energy into electrical energy that can be stored locally and used later for powering electronic devices. In this context, a bioderived membrane generates a chemoelectrical potential from ion transport by varying the ionic concentration as shown in Eq. 2. The concentration gradient and the resulting chemoelectrical potential can be generated by active transport using incident light, consuming triphosphates (adenosine, guanosine), etc. Due to the nature of the ionic transport processes and the resulting gradient across the membrane, protein transporters behave like constant current power sources.

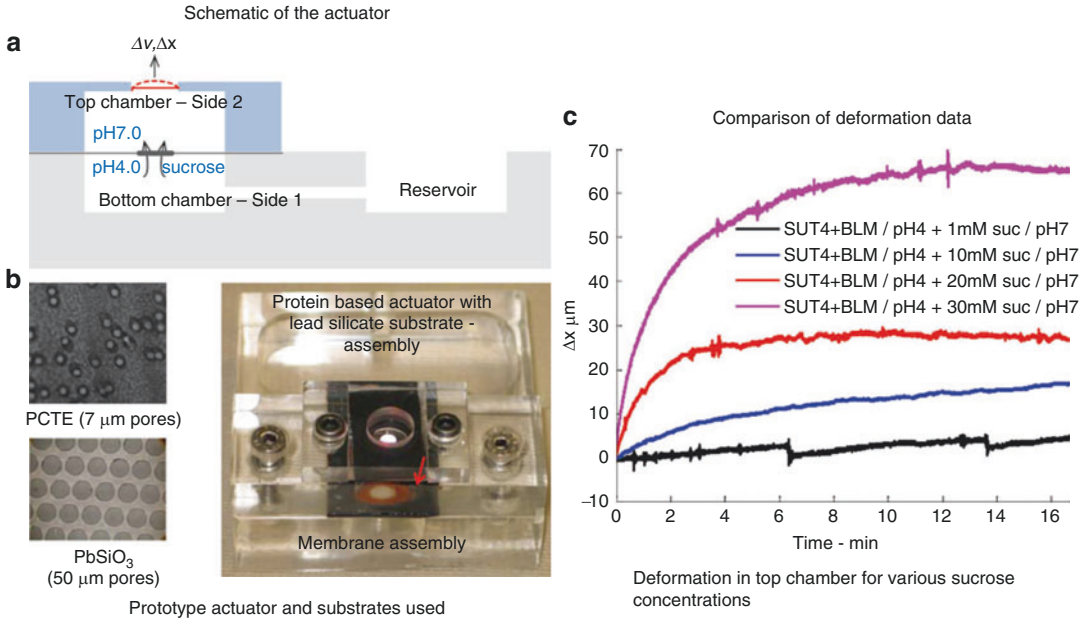
Fabrication Methods and Recent Advances

The methods to form BLM utilize the amphiphilic nature of the phospholipid molecule to produce a highly organized structure in the presence of an aqueous medium. In the past five decades, many techniques have emerged to assemble phospholipids into vesicles and planar BLM [1, 4–8]. Vesicles are hollow-spherical structures that are useful as carrier vehicles for chemical payloads. The planar configuration of the lipid membrane (planar BLM) permits access to both sides of the membrane and is preferred for the investigation of ion transport through transporter proteins. The bioderived smart materials typically use a planar BLM supported on a solid substrate (supported BLM) or suspended across the pores of a nanofabricated porous substrate (suspended BLM).

The tools and methods to fabricate a synthetic biological membrane trace its origin to the pioneering research by Mueller and Rudin and coworkers [1, 4] and Tien, Ottova, and coworkers [9]. The initial studies focused on forming planar BLMs from egg phospholipids across a 200-μm pore in a polymeric membrane with voltage-gated ion channels [4]. These initial experimental investigations and subsequent advances by Tien, Ottova, and coworkers were motivated by the need to create in vitro test platforms for analyzing the physiological and immunological function of cell membranes [10–12]. Recently, the experimental methods to form a BLM with proteins are motivated by the engineering applications of bioderived membranes. The anticipated applications for bioderived membranes have significantly influenced the fabrication methods and material choice in the past decade.

Bioderived Smart Materials, Fig. 4 (**a**) The regulated attachment method uses a flexible substrate and applied force to enable bilayer formation. (**b**) Membranes produced via the RAM enable single-channel measurements. (**c**) Modulating the applied force allows for reversible control on the size (area) of the bilayer

A consistent challenge in transitioning supported and suspended lipid bilayers into robust material platforms is the fragility and limited shelf life of the thin membrane. Various approaches have been investigated to stabilize lipid bilayers, including suspending bilayers across nanopores, tethering bilayers to solid surfaces, and sandwiching suspended membranes between water-swollen hydrogels. Among them, this entry will discuss a novel platform for reconstituting phospholipids into a BLM in a curable polymerizable structure. The method, referred to as droplet interface bilayer (DIB), utilizes the affinity of the hydrophobic tails to organic solvents (or) oils. The DIB technique first demonstrated by Funakoshi et al. [13] and then refined and expanded by Bayley et al. [14–16] showed that the stability of the bilayer can be improved by minimizing the direct interaction of phospholipids with a solid substrate. This leads to a BLM with improved longevity (DIBs lasted for days to weeks) and increased resistance to rupture. In this approach, a liquid-supported interface bilayer is formed by connecting two lipid-encased water droplets submerged in oil as shown in Fig. 4. The monolayers that make up the bilayer self-assemble at the oil–water interface surrounding each droplet and spontaneously "zip" together when the droplets are placed into contact. The formation of a lipid bilayer at this interface occurs by thinning when depletion flocculation removes excess oil from between the droplets. Using this principle, the amount of contact between two droplets can be modulated by the choice of oil.



Aside from advantages of simplicity and stability, the DIB embodiment affords the ability to form a biomolecular network of lipid bilayers by connecting more than two droplets. The ability of the DIB membrane to accommodate proteins makes it feasible to demonstrate selective transport across multiple interfaces formed from a network of droplets. The primary disadvantage of this method, though, is the need to dispense and position individual water droplets a task that becomes increasingly difficult for small droplets

(<100 μm). To remedy this limitation and to provide added support to the droplets themselves, Sarles and Leo recently developed an alternative technique called the regulated attachment method (RAM) for interface bilayer formation within a flexible, nonwetting solid substrate [17, 18]. Instead of positioning droplets individually, the RAM uses mechanical force applied to the flexible substrate to control the attachment of lipid-coated aqueous volumes contained in neighboring compartments. The applied force regulates the dimensions of the aperture separating the compartment as shown in Fig. 4a. With the initial design, increasing the force closes the aperture and separates the volumes. Relaxing this force, then, opens the aperture and allows the volumes to come into contact. The results of this method proved that, like DIBs, interface bilayers formed using RAM lead to stable membranes that exhibit high electrical resistances (>10GΩ) necessary for measuring single-channel and multiple-channel ion currents through proteins such as alamethicin (Fig. 4b). Further, the RAM enables the size of the bilayer (i.e., the area of contact) to be reversibly modulated after membrane thinning. It has been shown through experiments that the effective diameter of the bilayer formed from RAM technique could be varied by a factor of 5× by merely modulating compressive force (Fig. 4c). The flexibility of the regulated attachment method (RAM) provides additional advantages over earlier methods to form lipid bilayers, including the DIB approach. First, this method provides control of the size of the bilayer, independent of the sizes or shapes of the aqueous volumes. Sarles and Leo later utilized this advantage in forming interface bilayers between nonspherical hydrogels [19]. Second, supporting the aqueous volumes within a flexible substrate helps to reduce relative motion between the connected volumes under vibration and shock, making for a more portable system. With this added support, additional contents in the form of discrete aqueous droplets can be added to an existing lipid-coated volume via a microchannel or syringe without causing the membrane to rupture. This capability enables biomolecules (or other species) to be added to the membrane at a designated time after bilayer formation.

Bioderived Microhydraulic Actuators

Motion in biomolecules, especially protein transporters, is typically associated with conformational change in proteins and is of the order of few angstroms of displacement and/or angular rotation of the subunits in the protein transporter [20]. There are numerous challenges in coupling this mechanical motion resulting from three-dimensional conformational change of proteins to an external system and hence cannot be used for performing mechanical work. Another interesting example of chemomechanical actuation is the demonstration of kinesin motility on microtubules [21]. In this system, a kinesin-functionalized nanoparticle traverses along the length of a microtubule resulting from the rotation of kinesin dimer from ATP hydrolysis. Various research groups have used nanobeads functionalized with kinesin as platform for demonstrating this novel actuation concept. While this concept is significantly advanced than molecular motors, coupling this linear motion to generate force and volumetric strain has challenges in interfacing the bimolecular motion with a structure. In order to demonstrate a system that uses biomolecules to generate volumetric strain similar to ferroelectrics, electroactive polymers, a membrane-based hydraulic actuation concept was developed by Sundaresan and Leo [3].

The membrane-based microhydraulic actuator uses a BLM with ion transporters as shown in Fig. 5a, b. The chemomechanical actuator uses osmotic regulation between two chambers resulting from ion and sucrose transport through the bioderived membrane. The bioderived membrane is suspended across the pores of a microporous substrate and separates the contents of the two chambers and is reconstituted with a sucrose transporter protein (SUT4) extracted from *Arabidopsis thaliana*. The SUT4 protein, grown in and extracted from yeast cell membrane, is a cotransporter that transports proton and sucrose from the side of the membrane with higher proton and sucrose concentration. On applying a buffered proton gradient, the cotransporter balances the pH gradient with sucrose concentration gradient. The sucrose concentration gradient generates an

Bioderived Smart Materials, Fig. 5 (**a**–**b**) Schematic of a membrane-based chemomechanical actuator. (**c**) Deformation of cover plate in the actuator for various initial sucrose concentrations

osmotic gradient across the membrane and produces water transport through the membrane. The additional volume of fluid from osmotic regulation, demonstrated in Sundaresan et al. [22], builds pressure in the chamber, balances the osmotic gradient established by sucrose transport, and deforms a flexible wall in the chamber.

The mechanics of ion transport leading to an osmotic gradient due to a cotransporter is shown using phenomenological equations. The forces in the system during proton-sucrose cotransport through the membrane for actuation are chemical potentials ($\Delta\mu$) due to

1. Concentration gradient of proton ($\Delta\mu_p$)
2. Concentration gradient of sucrose ($\Delta\mu_s$) – cotransported specie
3. Osmotic gradient due to concentration gradients of charged species and nonelectrolytes

The proton and sucrose fluxes (ϕ_p, ϕs) through the membrane due to the applied concentration gradients across a membrane can be represented by phenomenological equations for ion transport formulated by Katachalsky et al. [23, 24].

$$\begin{aligned}\phi_s &= L_{s,s}\Delta\mu_s + L_{s,p}\Delta\mu_p \\ \phi_p &= L_{p,s}\Delta\mu_s + L_{p,p}\Delta\mu_p.\end{aligned} \tag{7}$$

Assuming unity values for activity coefficients, the chemical potentials that contribute to the flux are [25]

$$\begin{aligned}\Delta\mu_p &= RT\ln\left(\frac{C_1^p}{C_2^p}\right) \\ \Delta\mu_s &= RT\ln\left(\frac{C_1^s}{C_2^s}\right).\end{aligned} \tag{8}$$

The coefficients in the flux equations in Eq. 7 represent the coupling between proton and sucrose transport through the membrane. The coefficient $L_{s,s}$ represents the coupling between sucrose chemical potential and sucrose flux. The coefficient $L_{s,p}$ relates sucrose flux to the chemical potential due to proton and similarly, $L_{p,s}$ relates the proton flux to sucrose chemical potential. The coefficients $L_{s,p}$, $L_{p,s}$ are assumed equal due to the Onsager symmetry relationship [26]. The chemical potentials due to sucrose and pH gradients are assumed to balance each other as shown in Sundaresan and Leo [22] and the equilibrium

concentration of sucrose is obtained for various pH and sucrose gradients. For an infinite source of sucrose on side 1 of the membrane and zero initial concentration of sucrose on side 2 of the membrane, it is assumed that the concentration on side 1 of the membrane remains unchanged from the initial concentration. The concentration of sucrose on side 2 balanced by a buffered pH gradient at equilibrium is given by the expression

$$C_2^s = C_1^s 10^{\Delta pH}, \tag{9}$$

where $\Delta pH = pH_2 - pH_1$. In the presence of a limited source of sucrose on side 1 of the membrane as in the actuator, sucrose is transported through the membrane until the concentration gradient of sucrose balances the applied proton gradient. The balancing concentration as a function of the volume ratios. The number of moles of the sucrose on side 1 and side 2 at equilibrium is denoted by $n_1^s|_{eq}$ and $n_2^s|_{eq}$, respectively. The volume of the chamber on side 1 and side 2 of the membrane is represented by V_1 and V_2 and the volume ratio by $Vr = V_1/V_2$. At equilibrium condition the number of moles in the system is constrained by

$$n_1^s\big|_{eq} + n_2^s\big|_{eq} = V_1 c_1^s \tag{10}$$

The equilibrium concentration on side 2 of the membrane from Eq. 9 is rewritten in terms of the number of moles of the sucrose on both the sides of the membrane,

$$n_2^s\big|_{eq} = n_1^s\big|_{eq} \frac{V_r}{10^{\Delta pH}} \tag{11}$$

The concentration on side 1 at equilibrium condition is obtained in terms of the initial sucrose concentration on side 1 of the membrane by substituting the mass balance expression in Eq. 10 into Eq. 11

$$c_1^s\big|_{eq} = c_1^s \frac{V_r}{V_r + 10^{\Delta pH}}. \tag{12}$$

Similarly, the concentration of sucrose at equilibrium on side 2 of the membrane is

Bioderived Smart Materials, Table 1 Equilibrium concentration of sucrose on side 2 of the membrane in the actuator for pH4/pH7 applied across the membrane assembly

c_1^s mM (Initial)	1	10	15	20
$c_2^s\|_{eq}$ mM	90	900	1,360	1,810

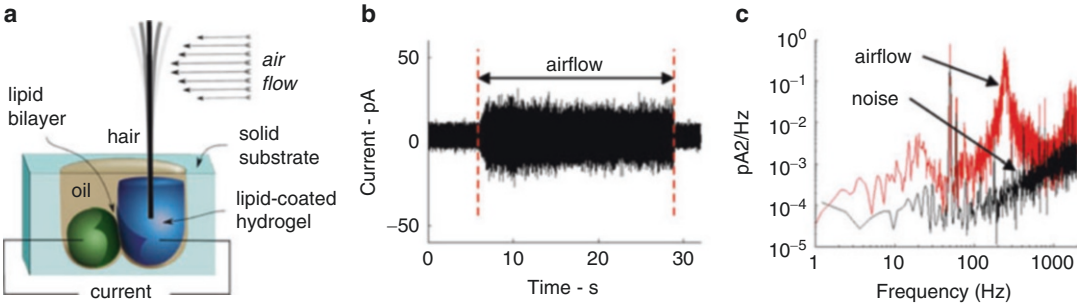
$$c_2^s\big|_{eq} = c_1^s \frac{10^{\Delta pH} V_r}{V_r + 10^{\Delta pH}}. \tag{13}$$

The equilibrium concentration of sucrose on side 2 of the membrane $c_2^s|_{eq}$ due to an imposed initial sucrose concentration (c_1^s) is computed for a volume ratio $V_r = 100$ in Table 1. It is observed from the table that the proton gradient concentrates sucrose on side 2 of the membrane. From the applied proton gradient and different initial concentration of sucrose on side 1 of the membrane, the membrane with cotransporter will develop different osmotic pressures on side 2 of the membrane within a finite duration. This analysis shows the feasibility to use concentration of sucrose as a control variable in the actuator with a cotransporter for modulating the force and deformation. A prototype chemomechanical actuator similar to the schematic in Fig. 5a was fabricated to demonstrate the concept of microhydraulic actuation using bioderived membranes. The porous glass plate is attached to a 500-μm Kapton film and sandwiched in between the two chambers with a rubber gasket. This serves as the supporting substrate for forming suspended BLM with SUT4 transporters. A clamping plate screwed onto the top chamber holds the PET (polyethylene terepthalate) coverplate that deforms out of the chamber due to increasing pressure from osmotic regulation across the two chambers. The volumes of the chambers are designed to be 0.54 ml and 50 ml so that the larger chamber resembles a reservoir. The procedure to assemble the actuator follows the description in Sundaresan and Leo [22]. The BLM is formed from POPS and POPE lipids by painting method and the proteins are reconstituted by vesicle fusion method. In this method, 10 μl of lipids (POPS:POPE mixed in 3:1 w/w ratio and dissolved in n-decane at 40 mg/ml) is painted on

the surface and allowed to dry for 10 min under a stream of nitrogen. This is followed by the addition of 10 μl of SUT4 transporters in liposomes suspended in pH7.0 medium. The porous substrate with added components are allowed to stand in air for 15 min and assembled into the actuator.

The assembled prototype actuator is characterized by applying different concentrations of sucrose in the bottom chamber and measuring the deformation of the coverplate. As a control study, different baseline tests with a key ingredient left out is tested. The different baseline tests performed on the actuator are:

1. BLM with pH7.0 buffer on both sides of the membrane
2. BLM with pH4.0/pH7.0 gradient without sucrose dissolved in the bottom chamber
3. BLM with pH4.0/pH7.0 gradient with 5 mM sucrose dissolved in the bottom chamber



The results from baseline tests on the prototype shown in Sundaresan and Leo [22] demonstrate that there is no deformation in the coverplate for the case with pH7.0 buffer on both the sides of the membrane. Similarly, the coverplate does not show an appreciable deformation for a pH gradient applied to the membrane without sucrose. In the third baseline, pH gradient is applied across a BLM without SUT4 and 5 mM sucrose is added to the bottom chamber. It is observed that the coverplate deforms into the top chamber and is attributed to the migration of water molecules from the top chamber to the bottom chamber driven by the osmotic gradient.

The next set of experiments are performed on an actuator assembled with pH4.0/pH7.0 gradient applied across the BLM with SUT4 and different concentrations of sucrose. Representative results from these experiments are shown in Fig. 5c. From the experimental results in Fig. 5c, it is observed that the deformation in the actuator and rate of deformation increases with the initial sucrose concentration on side 1 of the membrane. The performance metrics of this actuator of this bioderived membrane-based actuator discussed in Sundaresan and Leo [22] compares well with soft polymeric electrochemomechanical actuators [27]. Thus, this demonstration follows the theoretical discussion that varying the sucrose concentration across the SUT4 cotransporter results in an osmotic gradient and leads to volumetric strain in the flexible wall of the actuator.

Hair Cell Sensors

Sensory hairs, or hair cells, are one of the most common forms of transducers found in nature. In general, a hair cell is type of sensory receptor that uses protruding structures, called cilia, to probe the surrounding environment. Sharing this basic trait, natural hair cells display tremendous diversity in their morphologies, mechanical properties, and physiological functions. As a result, animals use hair cells to detect sound, pressure, flow, vibration, chemical species, and even position (inertial tilt). Motivated by the diversity of stimuli-responsive behavior of natural hair cells, several groups have used synthetic active materials to engineer hair cell-inspired sensors. Most notably, Liu's research group [28] pioneered multiple generations of artificial cilia that used microfabricated cilia mounted on strain gauges or polymeric force-sensitive resistors (FSRs) to create an electrical response in response to flow or touch. However, living hair cells such as mammalian outer hair cells (OHCs) rely heavily on soft biological materials, namely, cell membranes and stretch-activated ion channels to sense deflections the cilia.

Building on recent advances to assemble and encapsulate an artificial cell membrane within a flexible substrate, Sarles et al. [29] demonstrated that a gel-supported lipid bilayer could be used to build a new type of membrane-based hair cell-inspired sensor. As shown in Fig. 6a, the hair cell consists of synthetic cilium (hair) that features an electrolyte-swollen polymeric gel at lower end and which is held vertically within one compartment of a nonswelling solid substrate. A second, lipid-encased aqueous volume contained in the neighboring compartment connects to the gel at the base of the hair to form a lipid bilayer. Both compartments also contain immiscible oil needed

Bioderived Smart Materials, Fig. 6 A membrane-based hair cell (**a**) uses the mechanoelectrical properties of a lipid bilayer to transduce airflow into current (**b**). (**c**) The frequency content of the measured signal correlates to the mechanical vibrations of the hair

for promoting phospholipid self-assembly at the oil–water interfaces. The performance of the hair cell sensor was characterized by measuring the current through the membrane (using conductive probes inserted into each aqueous volume) in response to the applied airflow across the hair. The results of this initial study demonstrated that the membrane-based hair cell generates an increase in the amplitude of the current through the bilayer in response to flow-induced vibration of the synthetic hair (Fig. 6b). Also, the power spectral density revealed that the frequency content of the sensing current (Fig. 6c) differs from that of the background noise evidence that the mechanical vibrations of the hair contribute to the measured current. Unlike living hair cells that use stretch-activated ion channels to provide both static and oscillatory sensing, this system only contained an Ac response (i.e., static deflection of the hair did not result in a change in the current). Yet, these initial responses did not explain the source of the current. By systematically varying the applied potential across the bilayer and holding the area of the membrane constant during the experiment, the authors discovered that the sensing current increased linearly with respect to the voltage. This result provided proof that a change in the electrical capacitance of the membrane, caused by bending in the bilayer, is the source of the measured current. In this work, the sensing currents ranged from 10 to 100 pA, depending on the speed of airflow, the length of the hair, and the transmembrane potential. Current efforts to increase the sensitivity of the sensor, provide static and directional responses, and fully encapsulate the liquid contents are underway.

Concluding Remarks

This entry presents a novel framework to develop smart materials using biomolecular components extracted from cell membranes. The bioderived smart materials use ion and fluid transport through protein transporters embedded in an impervious membrane and couple one or more of the following – chemical, electrochemical gradients across the membrane, mechanical stretch in the membrane and light energy incident on the membrane. This entry discusses a unique bioderived actuator that uses sucrose transport through a proton-sucrose transporter to generate volumetric strain. It is shown that the blocked force generated by these materials resemble soft polymeric electrochemomechanical actuators. We also present a novel electromechanical sensing concept using the BLM and demonstrate the potential of this device as a mechanical flow sensor. In the bioderived smart material systems described in this entry, two methods to fabricate the bioderived membrane are presented. Among the two methods, the first method utilizes the self-assembly of phospholipids in a pore to form a BLM with proteins. The second method, inspired by DIB, demonstrates an innovative method to fabricate a durable bilayer membrane, demonstrates the force and flow sensing, and provides a

rugged framework for future development in this field. The framework for building bioderived smart materials and their application as sensors, chemomechanical actuators, and energy harvesting devices discussed in this entry benefits from a wide variety of transporters that can be extracted from cell membranes and offers innovative approaches to couple various forms of energy.

Floccules; Microbial aggregations

Definition

Biofilms are aggregations of microbes that are encased by extracellular polymeric substances (EPS) and adhere to surfaces or interfaces. Biofilms exist in a very wide diversity of environments, and microfluidic devices are being increasingly utilized to study and understand their formation and properties.

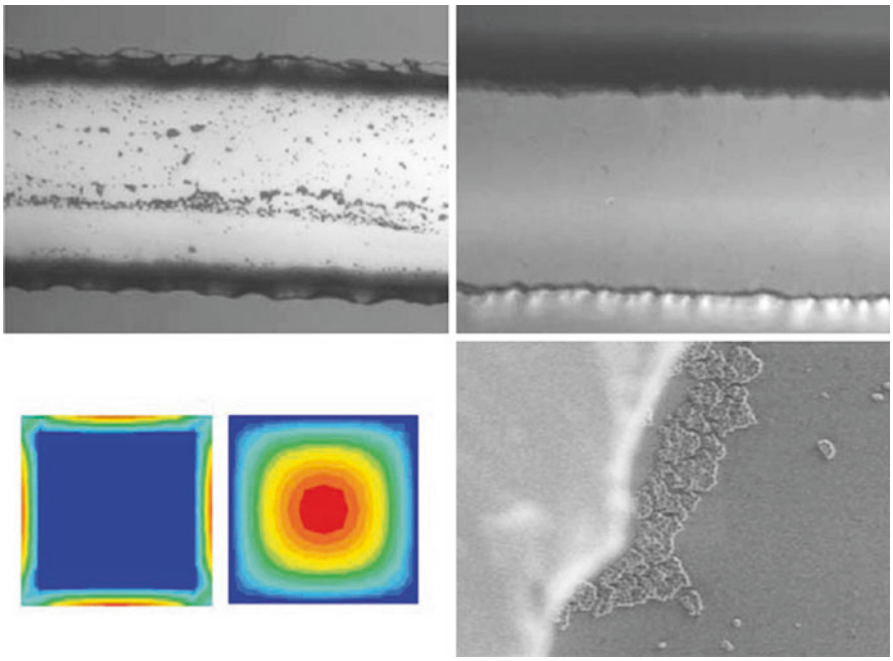
Overview

Microbes often form aggregates on interfaces, and due to a production of EPS, the aggregates become encased in a matrix [1]. Though microbes in a biofilm are physiologically distinct from bacteria growing in a free swimming state (planktonic bacteria), biofilm growth is a complex process that is typically initiated by planktonic bacteria themselves. Biofilm growth is initiated with bacterial adhesion to a surface, followed by events such as growth, EPS secretion, and morphological and physiological changes. Microbial biofilms are excellent examples of multi-scale phenomena. Cell-to-cell communication, which plays a role in biofilm formation, is molecular in nature, but occurs over a scale of several cells. Adhesion events occur at the nanometer scale and are mediated by pili or flagella, while the cells themselves are typically micron-sized. Finally the biofilms themselves typically range between 10 and 1,000 μm in thickness. These length scales are compatible with the scale of microfluidic devices, thus making such tools useful for exploring the spatiotemporal properties of biofilms. Moreover, microfluidic devices are often optimized for online optical monitoring and/or incorporation of sensors. These factors make microfluidic devices appropriate for studying biofilms. For example, the effect of miniscule changes in molecular cues (such as nanomolar concentrations) can be characterized and studied easily with microfluidic devices. Another advantage of microfluidics is that they enable the precise control of the microenvironment, thereby allowing biofilms to be subjected to controlled external stimuli. Thus, when molecular cues or signals are externally applied, minute responses in the biofilm can be

effectively studied. The use of microfluidics offers distinct advantages for fundamental studies regarding the nature, properties, and evolution of microbial biofilms. Beyond being a platform for such studies, microfluidics is being increasingly applied toward miniaturized device creation. In this entry, some of the basic methodologies involved in biofilm studies in microfluidic devices are first discussed, followed by a discussion on some of the key findings reported in this area.

Methodology

Microfluidics



Microfluidics is the precise control and manipulation of fluids contained to miniaturized channels (typical length scale <100 μm). In the microfluidics regime, fluid flow is laminar, and flow is dominated by Stokes drag and surface tension effects. The study of biofilms in microfluidic devices typically requires device design and fabrication, controlled microbial growth, and analysis. Microfluidic device fabrication by itself is a significantly evolved science. There are several different techniques for device fabrication including, but not limited to, various micromachining processes and polymer-based soft-lithography. Complex structures such as micropumps, microvalves and mixers can also be incorporated on microfluidic devices with the help of different microfabrication techniques. The techniques of microfabrication are beyond the scope of this article and interested readers can refer to one or more manuscripts on this topic [2, 3].

Biofilms

A wide range of microbial species produce biofilms. Once the appropriate device is fabricated, controlled biofilm growth in the device may be desirable. For controlled in situ biofilm growth in a microfluidic device, a dilute microbial culture may be introduced into the microfluidic device. The diluted samples are made from liquid microbial cultures once the culture achieves a specified optical density (OD). A fluid port usually provides a means for the introduction of the inoculum into the device. Depending on the microorganism and its microenvironment and the specific experimental need, proper biofilm growth can require anywhere between a few hours to several days. During this interval, it might be desirable to control environmental conditions such as temperature and humidity. In such circumstances, the device is typically housed in an incubator. Depending on the organism, aerobic or anaerobic environment may be necessary. For microfluidic devices made from PDMS or similar permeable polymers, maintaining an aerobic environment is usually not an issue. On the other hand, to maintain anaerobic conditions typically necessitates more complex device fabrication techniques. Analysis of biofilm formation may be done by various forms of microscopy. Microfluidic devices usually lend themselves to optical microscopy with considerable ease – one of the reasons why it is popular as a diagnostic setup. Use of thin-walled chambers and optically clear materials in microfluidic devices allows probing through optical means and use of high-magnification lenses. Confocal laser scanning microscopy (CLSM) has been demonstrated as a tool for integrating microfluidics in studying the evolution and structural heterogeneity of biofilms [4]. Other forms of microscopy may also be employed such as scanning electron microscopy (SEM) and atomic force microscopy (AFM). Besides microscopy, micro- and nanosensors can also be easily incorporated into a microfluidic device for in situ monitoring. For example, micro-electrodes fabricated on a glass substrate can be incorporated in a microfluidic device for electrochemical impedance spectroscopy studies.

Key Findings

Microfluidic devices, in conjunction with microscopy and other analytical techniques, enable flexible and novel approaches for probing the multiple determinants of biofilm formation. Two factors shaping the dynamics of biofilm formation are fluid dynamics and cell phenotype. Fluid dynamics determine shear forces that govern cell attachment and detachment rates, which can alter whether or not a biofilm will form, biofilm depth, biofilm

Biofilms in Microfluidic Devices, Fig. 1 Microfluidic devices can be engineered to produce well-defined flow structures and shear rates. Such devices can be used to investigate hydrodynamic influences on biofilms (From Lee et al. [5]. Reproduced with kind permission from Springer Science and Business Media)

density, and surface coverage. On the other hand, cell phenotype dictates important processes such as EPS production, growth rate, and flocculation, all of which can also have profound effects on biofilm structure and function. Cell phenotype, in turn, is a function of both environmental cues and cell-cell communication. Accordingly, recent studies have harnessed microfluidic technology to probe the effects of fluidic dynamics, cell phenotype, and cell-cell communication. Mathematical modeling efforts have integrated these findings and guided further investigations.

Influence of Fluid Dynamics on Biofilms

Several studies have examined the effects of hydrodynamics on biofilm development. For example, microfluidic devices were used by Lee et al. [5] to study the influences of hydrodynamics of local microenvironments of *Staphylococcus epidermis* biofilm formation (Fig. 1). They observed that at high flow velocity, the cells formed an elongated biofilm morphology, and at low fluid velocity clump-like multilayered biofilms were produced. The results of this study indicate that microfluidic devices with embedded microvalves can perhaps be used for screening the effects of therapeutic reagents, and as novel tools for developing predictable in vitro models of biofilm-related infections. Also, Rusconi et al. [6] studied suspended filamentous biofilms in a microfluidic device. Experiments with several bacterial strains under high flow inside the miniaturized channels demonstrated the link between the extracellular matrix and the development of biofilm structures. Secondary vertical motion from the numerical simulations of the flow in the curved channels of the microfluidic device proved that the hydrodynamic forces were key in influencing the formation of suspended biofilm filamentous structures. Another study by Richter et al. [7] examined the influence of shear stress on the growth and structure of fungal biofilms using microfluidic systems. Electrode structures were incorporated into a microfluidic device for performing cellular dielectric spectroscopy, enabling real-time, noninvasive quantification of cell morphology changes. Increase in shear stress caused a significant change in the biofilm formation patterns, and the addition of

amphotericin B resulted in distinct dynamic behavior of the biofilm.

Effect of Cell Phenotype on Attachment

In addition to hydrodynamics, cell phenotype plays an important role in biofilm formation. For example, after initial attachment, pili, flagella, and adhesins can help cells adhere to surfaces. Characterizing these determinants of cell attachment is critical for understanding the early stages of biofilm development. Using a microfluidic device, De La Fuente et al. recently examined the roles of different *Xylella fastidiosa* pili in determining cell adhesion at different flow rates [8]. To do so, they compared different genetic variants: wild-type cells, cells with only type I pili, cells with only type IV pili, and cells with no pili. They subjected these variants to different drag forces by exposing the cells to different fluid flow rates. The results enabled quantification of the role of the different pili in attachment, and the adhesion force values were within the range of adhesion forces determined by AFM and by laser tweezers for other microbes.

Cellular-Communication Inside Microfluidic Systems

Several cell processes relevant to biofilm formation, including dispersion, EPS secretion, and lipid secretion, are often regulated by cell-cell communication. Thus, several studies have focused on studying intercellular communication in biofilm contexts. Specifically, many microbes communicate through the process of quorum sensing. Quorum sensing (QS) enables a group of cells to measure their local population density through the synthesis of and response to small signal molecules that can pass from cell to cell. While quorum sensing regulates several microbial behaviors that influence biofilm formation, biofilm characteristics in turn strongly impact the efficiency of quorum sensing and signal transport, thus setting up an interplay between quorum sensing and biofilm formation. Consequently, microfluidic studies have been used to examine quorum sensing in a biofilm context.

Timp et al. [9] studied genetically engineered cells in microfluidic devices to explore the fundamental principles of quorum sensing in biofilms. Engineered cells were flowed through a microfluidic channel into a region where optical traps were used to position cells into defined patterns. The patterned cells were then enclosed in a hydrogel to mimic a biofilm. "Transmitter" cells synthesized an N-Acyl Homoserine Lactone (AHL) communication signal which was detected by "receiver" cells that fluoresced in response. Activation of the receiver cells by the transmitters was found to be heavily dependent on the hydrodynamics around the biofilm mimic. In particular, low flow rates corresponding to diffusion-dominated transport yielded efficient communication between transmitters and receivers, but this communication began to break down at high flow rates corresponding to convection-dominated transport. These results indicate that the density of bacteria necessary to constitute a "quorum" depends on the hydrodynamic properties of the environment. A similar conclusion was reached by Connell et al. [10] who studied QS in fabricated picoliter-scale microcavities. Specifically, the authors found that they could achieve a sixfold increase in QS-dependent gene expression by bacteria trapped within their microcavities when they reduced the external flow rate from 250 to 5 $\mu L\ min^{-1}$.

Another interesting aspect of QS highlighted by the Connell study was the importance of cell density, rather than total cell count as a factor governing QS behavior. In particular, because the authors were able to capture small numbers of cells in small volumes, they were able to control cell density independent of cell population size. As a result, they were able to show that as few as 150 cells are capable of exhibiting QS behavior, provided that the cells are constrained such that cell density remains relatively high. This is important, since it demonstrates the potential for small bacterial communities to exhibit some of the properties (e.g., antibiotic resistance), which are typical of biofilms. In a related study, Boedicker et al. used microfluidics to examine the QS behavior of small numbers of bacteria trapped in poly(dimethylsiloxane) (PDMS) wells [11]. In this study, the authors were able to trap as few as one to two cells in each well, and while the

majority of cells needed several rounds of cell division to initiate QS, on occasion the authors found single cells expressing QS controlled genes. Again, this result showed that it is bacterial density, rather than bacterial cell numbers, that is of fundamental importance to the onset of QS behavior. Another aspect of QS and microbial aggregation was investigated by Park et al. [12], who devised a microfluidic device resembling a maze. They investigated the growth of *Escherichia coli* cells in the device. They found that the device geometry affected aggregation of the cells. Their results led them to conclude that self-attraction in microbes could allow them to easily exceed critical QS densities.

Collectively, these studies exemplify the flexibility offered by microfluidic systems to precisely define the cell's microenvironment, including cell position, confinement geometry, and fluid flow rate. These studies have begun to shed light on fundamental questions such as when quorum sensing is truly used to sense local population as opposed to merely sensing environmental conditions such as the local diffusion rate or degree of confinement. Thus, microfluidics is enabling the study of biological principles that would otherwise not be possible using conventional approaches in biology. We next focus on how data from these unique experimental studies can be used to validate mathematical models of biofilm formation and lead to new insights.

Mathematical Biofilm Modeling and Microfluidics

Thus far several determinants of the process of biofilm formation including fluid dynamics, cell phenotype, and cell-cell communication have been discussed. The complex nature of biofilm formation makes mathematical modeling challenging, yet critical for developing a fundamental quantitative understanding of the underpinnings of the process. Proper mathematical models take into account the multistaged process with its broad range of time and length scales. Mathematical development of biofilms has been long pursued with substantial developments having taken place in the past two decades. Klapper and Dockery present a comprehensive review of mathematical model development for biofilms [13]. Today, rapid developments in the biofilm community are pushing the need for better and comprehensive models; microfluidics presents itself as an invaluable aid to the modeling community. Microfluidics not only affords researchers to explore in real time biofilm growth and dynamics, but it also allows for a controlled microenvironment that can be adjusted to suit the need of the user. A controlled microfluidic environment amenable to probing by various sensors can allow researchers to pursue valuable validation experiments for proposed models. In one such study, Janakiraman et al. [14] used a microfuidic device to study biofilm development of *Pseudomonas aeruginosa* PA14, where mass and species transport effected biofilm development and vice versa. Their use of a microfluidic device allowed assessment of biofilm growth variation with shear rates, finally leading to model validation. The validated model, which took into account mass transport and its effect on quorum sensing, allowed valuable conclusions such as that flow rate could be used to turn on and turn off quorum sensing within the biofilm. Experimentally validated models like the one presented by Janakiraman et al. [14] allow a greater understanding of biofilm kinetics. In another study, Volfson et al. [15] used microfluidic devices to investigate spatial ordering and self-organization of microbes in a microfluidic device. The authors were investigating the role of contact biomechanics in the formation of dense colonies and toward this end they used a controlled microfluidic device to monitor the two-dimensional growth of motile microbes. The experimental investigations were combined with discrete element simulations (DES), and the authors showed that biomechanical interactions could lead to highly ordered structures in a microbial colony. Such investigations can help in the complete understanding of the role of various environmental and self-generated factors that play a role in biofilm formation. Deeper quantitative understanding of biofilm formation, resulting from the interplay between modeling and experimental validation with microfluidics, will drive progress in various applications.

Other Uses of Lab-on-a-Chip Technologies

Lab-on-a-chip (LoC) technologies refer to a suite of technologies that have evolved primarily over the last decade, where complex operations such as cell culture and sensing are integrated in a miniaturized platform. Apart from sensors, LoC technologies allow microfluidic systems to be interfaced with other systems such as micro-electro-mechanical (MEMs) and opto-electric systems. MEMs devices in LoC systems have been harnessed for various studies on microbial biofilms. Several different MEMs devices have been used to pursue biofilm-related studies, thus providing key insights into fundamental phenomena such as cellular self-organization in biofilms and the role of motility [16]. Purely electrical systems have also been incorporated into LoC systems and have been employed to investigate physiological heterogeneity within microbial biofilms [17]. Emerging lab-on-a-chip technologies can also benefit biofilm research. For example, novel opto-electric techniques [18] might find a use in biofilm engineering. Rapid electro kinetic patterning (REP) is an opto-electric technique, which can be used to manipulate micro- and nanosized objects noninvasively in a microfluidic device. REP has already been used to capture an aggregation of *Shewanella oneidensis* MR-1 in a microfluidic device and place it at user-defined intervals using an infrared laser and electric fields [18]. Such an approach could be used to trigger and organize the formation of beneficial biofilms.

Other than such appeal, LoC technologies are also being employed to fabricate miniaturized devices for applications such as current production and miniaturization of assays for clinical testing.

Future Perspectives

Microfluidic systems integrated with mechanical and/or electrical transducers and sensor components open up new ways to understand biofilm formation and bacterial surface interactions. Biofilms subjected to external stimuli through molecular cues during the growth and establishment stage can be characterized for their mechanical properties more accurately using microfluidic systems. Qualitative assessment of temporal and spatial patterns of biofilm formation against antimicrobial actions (chemical method) or electric field interference [19] or a physical disruption can be effectively studied using microfluidic systems.

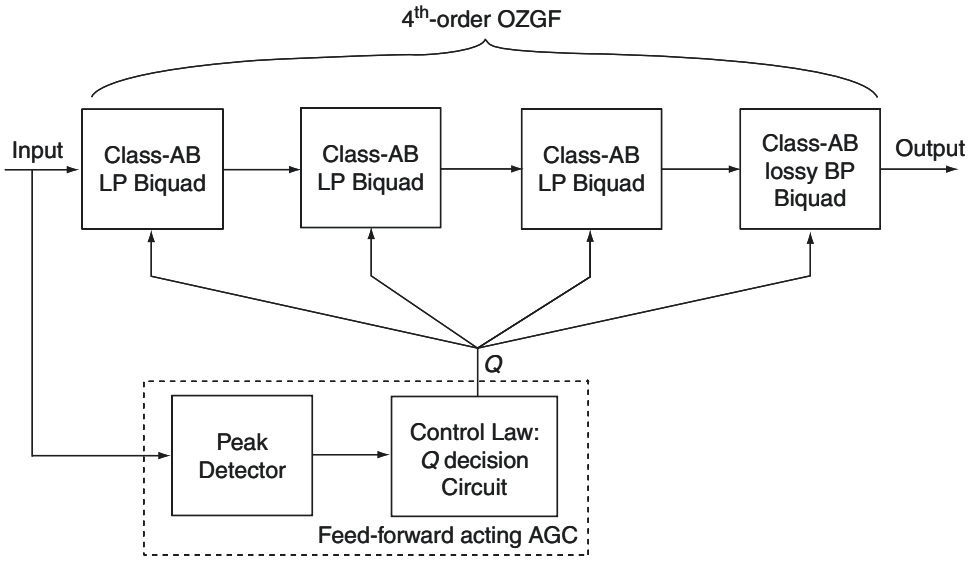
Definition

This entry deals with the design and performance evaluation of a new analogue CMOS cochlea channel of increased biorealism. The design implements a recently proposed transfer function [12], namely the One–zero Gammatone Filter (or OZGF), which provides a robust foundation for modeling a variety of auditory data such as realistic passband asymmetry, linear low-frequency tail, and level-dependent gain. Moreover, the OZGF is attractive because it can be implemented efficiently in any technological medium – analogue or digital – using standard building blocks. The channel was synthesized using novel, low-power, Class-AB, log-domain,

biquadratic filters employing MOS transistors operating in their weak inversion regime. Furthermore, the entry details the design of a new low-power automatic gain-control circuit that adapts the gain of the channel according to the input signal strength, thereby extending significantly its input dynamic range. The performance of a fourth-order OZGF channel (equivalent to an eighth-order cascaded filter structure) was evaluated through both detailed simulations and measurements from a fabricated chip using the commercially available 0.35 μm AMS CMOS process. The whole system is tuned at 3 kHz, dissipates a mere 4.46 μW of static power, accommodates 124 dB (at <5 % THD) of input dynamic range at the center frequency, and is set to provide up to 70 dB of amplification for small signals.



Introduction

The first generations of high-performance cochlea designs were synthesized using g_m-C filters and relied on power-hungry linearization techniques and/or the compressive action of the AGC for extending the input DR. However, recent advances in the field of analogue filter design have led to the development of inherently compressive systems that operate internally in the nonlinear domain while preserving overall input–output linearity. The application of *companding* in filter design resulted in the successful realization of topologies that were able to attain a wider input DR with a lower power-supply requirement compared to traditional g_m-C filters employing linearized transconductors. These companding filters or processors belong to the more general class of ELIN (Externally-Linear–Internally-Nonlinear) systems [21], and their systematic synthesis is articulated in the pioneering works of Frey [7] and Tsividis [20]. It is worth noting that the need for inherently compressive filters emerged very early in the development process of micropower, high DR cochlea designs and, in fact, a bit earlier than the first 1993 Log-domain paper by Frey [6].

Since Frey's [6] paper, Log-domain circuits progressed significantly with several contributions aiming at increasing the input DR and lowering the quiescent power dissipation. The two most thoroughly studied techniques are: (a) The use of two Class-A filters in a pseudo-differential Class-AB arrangement [8] that increases the DR without spending too much power and (b) the use of an AGC scheme that dynamically changes certain biasing levels of the filter (according to a particular measure of input signal strength) in order to optimize its output SNR and power dissipation – this technique is otherwise known as *syllabic companding* [9] and constitutes indeed a parallel engineering strategy to the one performed by the real cochlea to widen its input DR and maintain signal integrity. It is interesting to note that several mechanisms within the cochlea may include an adjustable "DC bias" in the BM caused by hair-cell interactions that affect the operating point on their detection nonlinearity and their sensitivity [15].

In the following sections, the proposed pseudo-differential, Class-AB, Log-domain implementation of a fourth-order (i.e., a cascade of four, second-order transfer functions) OZGF with the ability to automatically adapt its gain by means of a low-power, AGC circuit acting *in feed-forward* is discussed. The reason a feed-forward scheme was employed (like the one demonstrated in [17]), as opposed to a feedback (like in [5]), was in order to avoid any latency issues and to obtain faster adaptation times.

The AGC senses the strength of the input signal and according to a particular control law sets the Q values of the individual filter stages of the cascade comprising the channel. The action of the AGC helps to accommodate a wider input DR because when the input is small (say below or close to the noise floor), the OZGF adapts its gain and provides significant amplification for the output to be well above noise levels. On the other hand, when the input is large, the OZGF provides low or no amplification so that acceptable distortion levels are maintained at the output. Since, in effect, the AGC is changing the state variables or pole positions of the individual filters, the whole OZGF channel falls under the category of a *high-order, syllabically companding, ELIN, auditory (cochlea) amplifier/processor*.

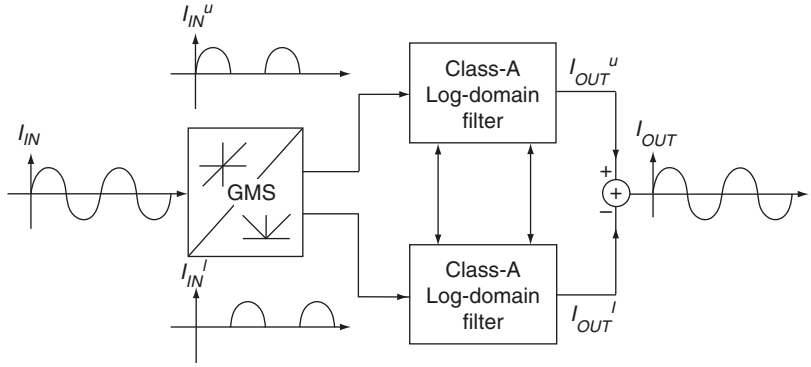
Bioinspired CMOS Cochlea, Fig. 1 Block diagram of the active fourth-order OZGF channel

Figure 1 depicts the high-level block diagram of our *active* fourth-order OZGF channel architecture.

Clarification: Please note that the term "active" we refer to the channel together with its feed-forward AGC mechanism to distinguish it from the case where the AGC is disconnected (i.e., the OZGF gain is set manually off-chip); the latter case will be simply referred to as "open loop." It should be clarified here that strictly speaking, the term "feed-forward" always refers to an open-loop controller since it does not employ feedback to determine if its input has achieved the desired goal. This means that the system does not observe the output of the processes that it is controlling. Under this strict definition, the implemented OZGF is considered open-loop *irrespective of whether the AGC is active or not*, but during the course of this entry, we shall use the terms "active" and "open loop" to refer to an OZGF channel "with-" and "without-" AGC, respectively.

The Circuits

This section deals with the design of the circuits comprising the fourth-order OZGF channel with its AGC. All device sizes, biasing currents, capacitors, and power supplies are displayed in Table 1 in section "Active OZGF Channel Measured Results."



Bioinspired CMOS Cochlea, Table 1 Electrical and device parameters

Topology	Biquads	GMS	LPF	E-cell[a]	OTA[a]
$(W/L)_{PMOS}$	300 µm/1.5 µm				20 µm/1.5 µm
$(W/L)_{NMOS}$	60 µm/8 µm				10 µm/1.5 µm
I_o	20 nA				
I_Q	2 nA–24 nA (i.e., Q between 0.834 and 10)				
I_Z	2 nA (i.e., $0.1I_o$ for a–20 dB DC gain)				
I_{LPF}	20 nA				
$I_{o_control}$	42 nA				
I_{tail}	24 nA				
V_{DD}	1.8 V				
C	20 pF				
C_{LPF}	80 pF				

[a]The reported dimensions correspond to the minimum device sizes of Fig. 13

Pseudo-Differential Class-AB Log-Domain Biquads

Class-AB designs are offered as the most efficient solution for balancing DR and low quiescent power-consumption performance requirements. This is because for small signals, a Class-AB

Bioinspired CMOS Cochlea, Fig. 2 Block diagram of a general pseudo-differential Class-AB architecture. The two vertical *arrows* between the two Class-A filters indicate coupling that ensures correct Class-AB operation

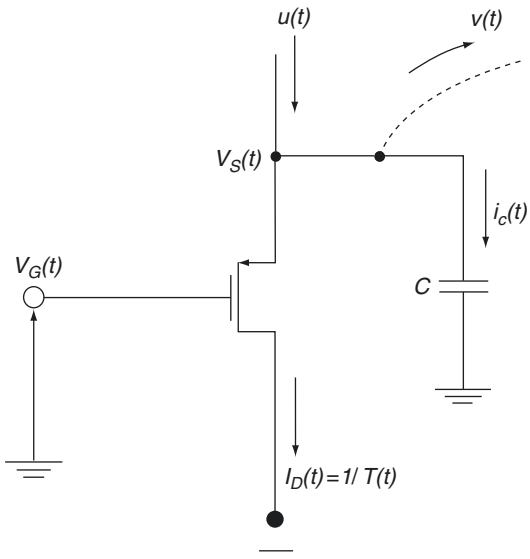
design operates with the quality of a Class-A system, whereas for large signals with the efficiency of a Class-B system.

In Log-domain, one way to design a Class-AB filter is by connecting two Class-A filters in a pseudo-differential arrangement with a signal conditioner at the input. The signal conditioner (a geometric mean splitter (GMS)) ensures that a bidirectional input signal is split into two complementary, unidirectional, positive signals, which are then processed separately by the two Class-A filters. The respective unidirectional processed outputs are subsequently subtracted to form the total bidirectional output, which is a linearly filtered version of the input (see Fig. 2). However, this is not enough to guarantee Class-AB operation unless the following two rules (implied by the vertical, two-sided arrows in Fig. 2) are obeyed [8]:

1. Firstly, a nonzero DC-operating-point solution must always exist for all the state variables (these are currents in Log-domain filter implementations) for any strictly positive, static (i.e., DC) values of the complementary inputs. This can be achieved by ensuring that the derivatives of the state-variables can become equal to zero while the state-variables themselves remain strictly positive.
2. Secondly, all state-variables must remain strictly positive provided that the complementary inputs remain strictly positive and bounded for all time. This can be achieved by enforcing the derivative of a state-variable to be strictly positive in the limit as the variable approaches zero; hence, that variable can never reach zero and thus will stay strictly positive for all time.

In short, the above two rules state that in a transistor-level implementation of a Class-AB Log-domain topology, all devices should carry nonzero and strictly positive currents at all times.

One possible Class-AB-compatible states-space (SS) description for a differential biquad is given below [8]:



$$\begin{aligned} u &= u_u - u_l \\ \dot{x}_{u1} &= \omega_o\left(-\frac{1}{Q}x_{u1} + x_{l2} + u_u - \frac{x_{u1}x_{l1}}{8}\right) \\ \dot{x}_{u2} &= \omega_o\left(x_{u1} - \frac{x_{u2}x_{l2}}{g}\right) \\ \dot{x}_{l1} &= \omega_o\left(-\frac{1}{Q}x_{li} + x_{u2} + u_1 - \frac{x_{ul}x_{l1}}{g}\right) \\ \dot{x}_{l2} &= \omega_o\left(x_{l1} - \frac{x_{u2}x_{12}}{g}\right) \\ y_{BP} &= x_{u1} - x_{l1}; y_{LP} = x_{u2} - x_{l2} \end{aligned} \tag{1}$$

where u is the differential input, y_{LP}, y_{BP} are the LP and BP differential outputs, respectively, and g is a positive factor that depends on implementation and will be defined later on. The subscripts u and l denote "upper" and "lower" referring to the two individual Class-A filter branches. The interested reader could verify that the derivatives $\dot{x}_{uj}$, $\dot{x}_{lj}$ ($j = 1, 2$) always attain a positive value whenever their respective state-variables tend to zero, or in other words to guarantee the existence of a DC operating point (condition 1). Also, nonlinear cross-coupling terms of the form $x_{ui}x_{lj}$ ($j = 1, 2$) have

been added to ensure that the derivatives can reach a zero value while the state-variables themselves remain strictly positive. Since the outputs are formed differentially, the nonlinear cross-coupling terms cancel out ensuring an overall linear characteristic.

Even though there exist various ways to synthesize Log-domain circuits, in the next section, we describe the transistor-level Log-domain implementation of Eq. 1 using the Bernoulli Cell (BC) formalism.

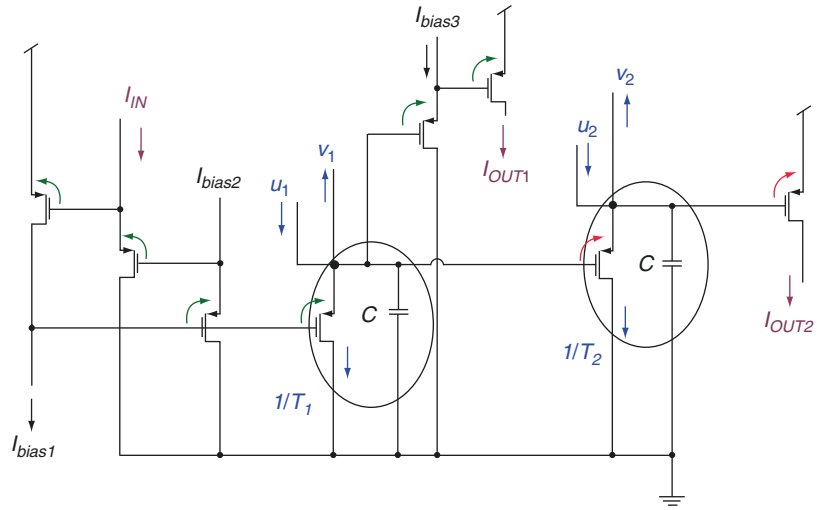
The BC was introduced in [3] as a low-level operator for synthesizing Log-domain filters. It consists of an exponential transconductor and a grounded capacitor and, through a nonlinear change of its state-variable, see Eq. 2, linearizes and electronically solves a nonlinear differential equation of the well-known Bernoulli form, see Eq. 3. A cascade of BC is known as the "Bernoulli backbone" and implements a generic set of differential equations termed the Log-Domain State-Space or LDSS. Such a "backbone" is depicted in the Log-domain biquad implementation of Fig. 6 which realizes the SS equations shown in Eq. 1. In Figs. 4, 5, and 6, the BCs are denoted by circles, each consisting of a PMOS-WI transistor and a capacitor connected between its source terminal and ground (Fig. 3).

Bioinspired CMOS Cochlea, Fig. 3 The Bernoulli cell

$$I_D(t) = I_S \exp\left(\frac{V_S(t) - V_G(t)}{nV_T}\right) = \frac{1}{T(t)} \quad (2)$$

$$\dot{T}(t) - \left[\frac{\dot{V}_G(t)}{nV_T} - \frac{u(t) - v(t)}{nCV_T}\right] T(t) - \frac{1}{nCV_T} = 0 \quad (3)$$

The synthesis of the Log-domain biquad will now be described in more detail. The transistor-level synthesis procedure is based on the direct comparison of the required dynamics of the original prototype system (i.e., Eq. 1) with those codified by the LDSS equations; the scope of this comparison is to identify the necessary time-domain relations (implemented by means of static translinear loops (TL)) that modify the LDSS dynamics in such a way so that they become identical to the desired ones [3]. Having in mind a MOS-WI implementation, the two generic LDSS equations describing a Class-A 2nd-order system (i.e., the differential equations describing two interconnected, logarithmically driven BCs [3]) are:



$$\begin{aligned} nCV_T\dot{w}_1 + (u_1 - v_1)w_1 &= I_{IN} \\ nCV_T\dot{w}_2 + (u_2 - v_2)w_2 &= w_1 \end{aligned} \quad (4)$$

with the w state variables being defined as:

$$\begin{aligned} w_1 &= T_1 I_{IN} (\text{dimensionless}) \\ w_2 &= T_2 T_1 I_{IN} = T_{2w1} (\text{units of amperes}^{-1}) \end{aligned} \quad (5)$$

and with C, n, and V_T denoting the grounded integrating capacitor, subthreshold slope parameter (usually between 1 and 2), and thermal voltage (25 mV at 300 K), respectively. At this point, the designer needs to decide on what kind of TL arrangement he/she wants to use for the interconnection of the BC. In this implementation, a used the "stacked" TL was used (as opposed to the "alternating" one), shown in Fig. 4 below. Note that the first BC is logarithmically driven because its gate voltage is essentially a level-shifted voltage arising from logarithmically compressing the input current I_{IN}.

With Fig. 4 as a reference, the w state variables can be "sensed" through two TL and extracted as the two output currents I_{OUT1} and I_{OUT2}. Note that even though w_1 is dimensionless and w_2 has

Bioinspired CMOS Cochlea, Fig. 4 Two interconnected logarithmically driven BCs representing the differential equations described in Eq. 4. The *green* TL is used to "sense" the w_1-state variable, whereas the *red* TL the w_2-state variable

dimensions of amperes^{-1}, both I_{OUT1} and I_{OUT2} have dimensions of amperes:

$$\begin{aligned} I_{OUT1} &= \left(\frac{I_{bias1}I_{bias2}}{I_{bias3}}\right)T_1 I_{IN} = \left(\frac{I_{bias1}I_{bias2}}{I_{bias3}}\right)w_1 \\ I_{OUT2} &= T_2(I_{bias1}I_{bias2})T_1 I_{IN} = T_2(I_{bias1}I_{bias2})w_1 \\ &= (I_{bias1}I_{bias2})w2 \end{aligned} \tag{6}$$

In the subsequent implementation $I_{\text{bias1}} = I_{\text{bias2}} = I_{\text{bias3}} = Io$, thus Eq. 6 becomes:

$$\begin{aligned} I_{OUT1} &= I_o w_1 \\ I_{OUT2} &= I_o w_2 \end{aligned} \tag{7}$$

By,

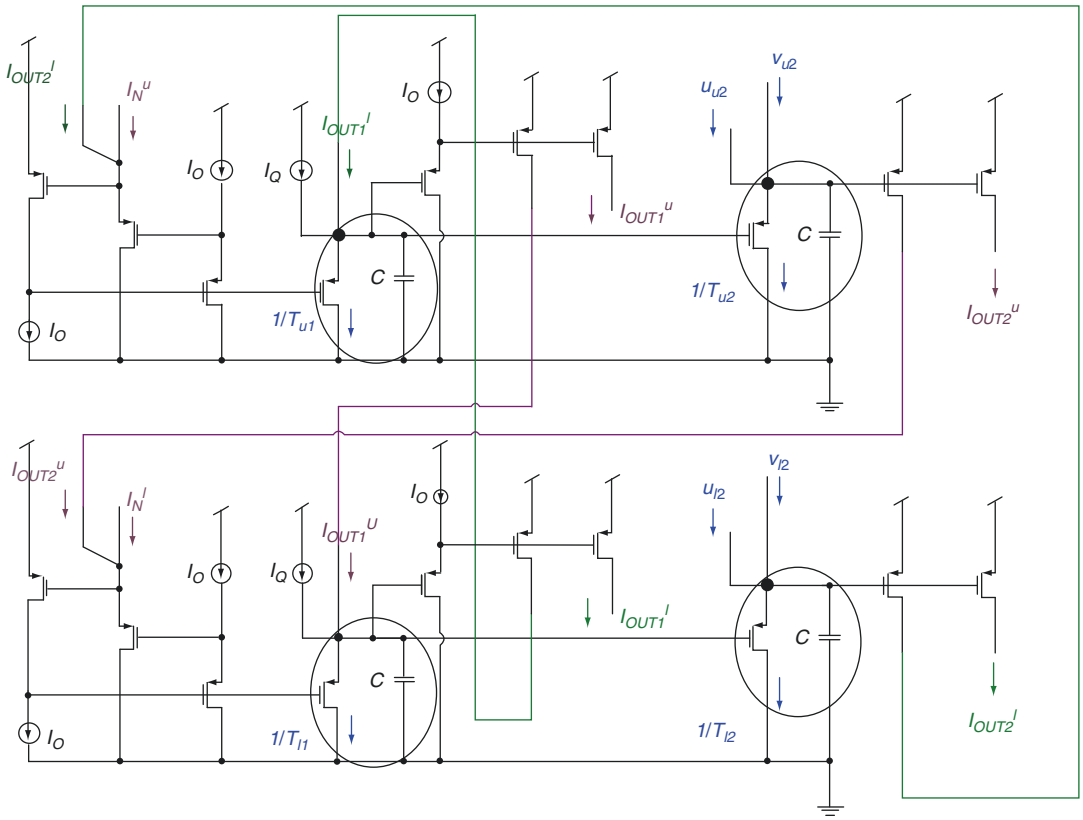
1. Splitting the input I_{IN} into two positive complementary inputs $I_{IN}{}^{u}$ and $I_{IN}{}^{l}$ (we will describe how to split I_{IN} later in section "The Input Signal Conditioner: The Geometric Mean Splitter (GMS)"
2. Duplicating the circuit topology in Fig. 4

The LDSS equations in Eq. 4 are now described in differential form as:

$$\begin{aligned} nCV_T\dot{w}_{u1} + (u_{u1} - v_{u1})w_{u1} &= I_{IN}{}^{u} \\ nCV_T\dot{w}_{u2} + (u_{u2} - v_{u2})w_{u2} &= w_{u1}n \\ CV_T\dot{w}_{l1} + (u_{l1} - v_{l1})w_{l1} &= I_{IN}{}^{l}n \\ CV_T\dot{w}_{l2} + (u_{l2} - v_{l2})w_{l2} &= w_{l1} \end{aligned} \tag{8}$$

where the subscripts u, l again indicate "upper" and "lower." Now, one needs to compare Eq. 8 with Eq. 1 and define the u, v currents via TL so that the two sets of relations become identical. As an example consider the relation of Eq. 1 and rearrange it slightly to:

$$\dot{x}_{u1} + \left(\frac{\omega_o}{Q} + \omega_o\frac{x_{l1}}{g}\right)x_{u1} = \omega_o x_{l2} + \omega_o u_u \tag{9}$$



At this point, one needs to define the u, v current of the first relation in Eq. 8 (i.e., the u, v currents of the first BC) so that it "matches" that of Eq. 9. This comparison results in:

$$\begin{aligned} nCV_T\dot{w}_{u1} + \left(I_Q + I_o w_{l1}\right)w_{u1} \\ = I_p^2 w_{l2} + I_{IN}^{u} \end{aligned} \tag{10}$$

where I_Q, I_o will be defined later on. Please check the dimensional consistency of Eq. 10, given Eq. 5. Consequently, the same comparison is performed for the lower (complementary) part of the circuit.

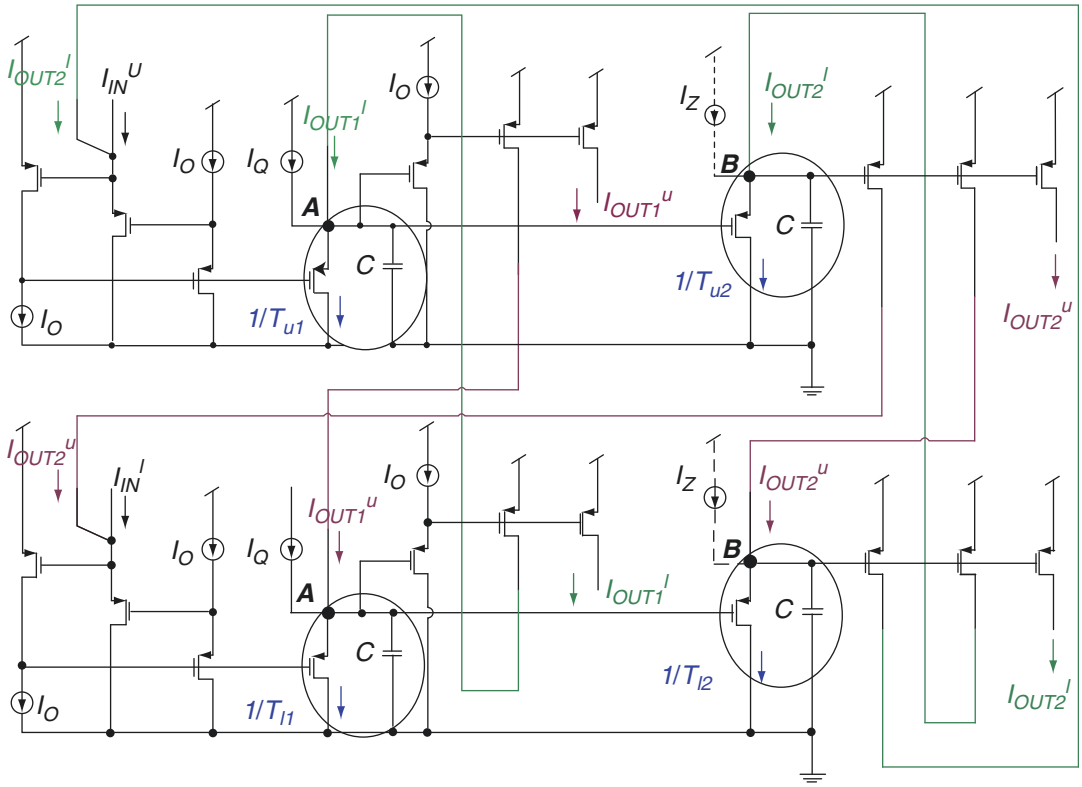
$$\begin{aligned} nCV_T\dot{w}_{l1} + \left(I_Q + I_o w_{ul}\right)w_{l1} \\ = {I_o}^2 w_{u2} + {I_{IN}}^{l} \end{aligned} \tag{11}$$

The above comparison has defined the w state variables in Eq. 6 now to be:

Bioinspired CMOS Cochlea, Fig. 5 Circuit implementation of the *upper* and *lower* u_1 and v_1 currents

$$\begin{aligned} w_{u1} &= T_1 I_{IN} = \left[T_{u1}\left(I_{IN}{}^{u} + I_o{}^{2} w_{l2}\right)\right] \\ &= \left[T_{u1}\left(I_{IN}{}^{u} + I_{OUT2}{}^{l}\right)\right] \\ w_{l1} &= T_1 I_{IN} = \left[T_{l1}\left(I_{IN}{}^{l} + I_o{}^{2} w_{u2}\right)\right] \\ &= \left[T_{l1}\left(I_{IN}{}^{l} + I_{OUT2}{}^{u}\right)\right] \end{aligned} \tag{12}$$

The circuit implementation of Eqs. 10, 11, and 12 is shown in Fig. 5. Note the feeding of the "sensed" w state variables (i.e., I_{OUT1}, 2^{u}) from the upper to the lower portion of the circuit (purple-colored connections) and vice-versa (green-colored connections) which implement the nonlinear cross-coupling terms that guarantee true Class-AB operation.



Similarly, by performing the same comparison for the other two sets of relations, the u, v currents for the second BC are defined.

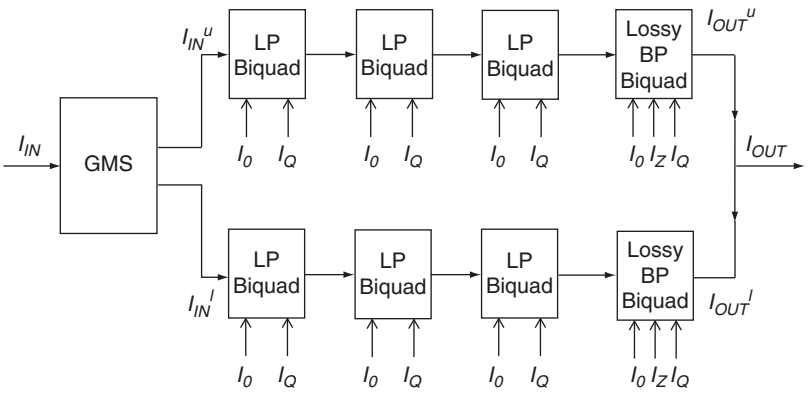
$$\begin{aligned} nCV_T \dot{w}_{u2} + \left(I_o{}^{2} w_{l2}\right) w_{u2} &= w_{u1} n \\ CV_T \dot{w}_{l2} + \left(I_o{}^{2} w_{u2}\right) w_{l2} &= w_{l1} \end{aligned} \tag{13}$$

With the w state variables defined as:

$$\begin{aligned} w_{u2} &= T_2 T_1 I_{IN} = \left[T_{u2} T_{u1}\left(I_{IN}{}^{u} + I_o{}^{2} w_{l2}\right)\right] \\ &= \left[T_{u2} T_{u1}\left(I_{IN}{}^{u} + I_{OUT2}{}^{l}\right)\right] = T_{u2} w_{u1} \\ w_{l2} &= T_2 T_1 I_{IN} = \left[T_{u2} T_{u1}\left(I_{IN}{}^{u} + I_o{}^{2} w_{u2}\right)\right] \\ &= \left[T_{l2} T_{l1}\left(I_{IN}{}^{l} + I_{OUT2}{}^{u}\right)\right] = T_{l2} w_{l1} \end{aligned} \tag{14}$$

In relations (10, 11, 12, 13, and 14), $I_{IN}{}^{u,l}$ denote the two upper and lower complementary inputs (generated from the input signal conditioner described next), $1/T_{u,lj}$ ($j = 1, 2$) are the upper and lower BC drain currents, and I_Q, I_o are biasing currents that control the quality factor Q and pole frequency ω_o, respectively. Finally, the positive factor g appearing in Eq. 1 was set equal to the biasing current I_o. The final circuit implementation is shown in Fig. 5. Finally, the outputs are formed by taking the difference of the respective

Bioinspired CMOS Cochlea, Fig. 6 The pseudo-differential Class-AB Log-domain Biquad. The design implements the state-space equations shown in Eqs. 10, 11, 12, 13, and 14. The feeding of the currents $I_{OUT1,2}{}^{u}$ ($I_{OUT1,2}{}^{l}$) to the lower (*upper*) topology (implementing the linear and nonlinear cross-coupling terms to ensure correct Class-AB operation) is shown in colored connections. All biasing current sources, as well as the subtraction of the I_{OUT} currents to form the outputs, were facilitated by means of both PMOS and NMOS cascode current mirrors not shown for clarity



"sensed" w state variables (i.e., $I_{OUT1}{}^{u} - I_{OUT1}{}^{l}$ and $I_{OUT2}{}^{u} - I_{OUT2}{}^{l}$). The LP and BP transfer functions are given by Eqs. 16 and 17, whereas Eq. 18 describes the two-pole, one–zero transfer function required for the final OZGF channel. The transfer function in Eq. 18 is obtained by adding the biasing current I_Z at points B of Fig. 6. Note also that the addition of the biasing current I_Z alters Eq. 13 in the following way:

$$\begin{aligned} nCV_T\dot{w}_{u2} + \left(I_o{}^2 w_{l2} + I_Z\right)w_{u2} &= w_{u1}n \\ CV_T\dot{w}_{l2} + \left(I_o{}^2 w_{u2} + I_Z\right)w_{l2} &= w_{l1} \end{aligned} \tag{15}$$

By inspecting Eqs. 16, 17, and 18: $\omega_o = I_o/nCV_T$, $Q = I_o/I_Q$ and the zero position is controlled by the ratio I_o/I_Z. The final fourth-order OZGF pseudo-differential Class-AB channel architecture is depicted in Fig. 7.

$$\begin{aligned} \frac{I_{OUT_{LP}}}{I_{IN}} &= \frac{I_{OUT2}{}^{u} - I_{OUT2}{}^{l}}{I_{IN}{}^{u} - I_{IN}{}^{l}} \\ &= \frac{(I_o/nCV_T)^2}{S^2 + \dfrac{(I_o/nCV_T)}{(I_o/I_Q)}S + (I_o/nCV_T)^2} \end{aligned} \tag{16}$$

$$\begin{aligned} \frac{I_{OUT_{BP}}}{I_{IN}} &= \frac{I_{OUT1}{}^{u} - I_{OUT1}{}^{l}}{I_{IN}{}^{u} - I_{IN}{}^{l}} \\ &= \frac{(I_o/nCV_T)S}{S^2 + \dfrac{(I_o/nCV_T)}{(I_o/I_Q)}S + (I_o/nCV_T)^2} \end{aligned} \tag{17}$$

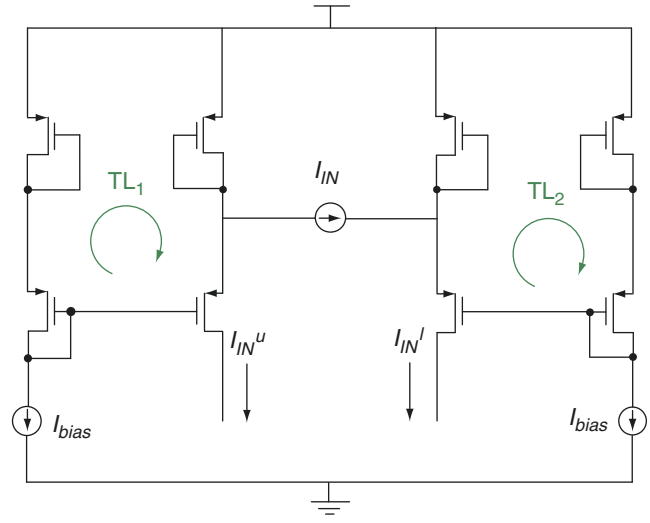
Bioinspired CMOS Cochlea, Fig. 7 The fourth-order OZGF pseudo-differential Class-AB Log-domain channel architecture

$$\frac{I_{OUT_{2PIZ}}}{I_{IN}} = \frac{{I_{OUT1}}^{u} - {I_{OUT1}}^{l}}{{I_{IN}}^{u} - {I_{IN}}^{l}} = \frac{\left(\frac{I_o}{nCV_T}\right)\left[S + \frac{I_Z}{nCV_T}\right]}{S^2 + \frac{a \times I_Q}{nCV_T}S + \frac{\beta \times {I_o}^2}{(nCV_T)^2}} \text{ with } a = \left(1 + \frac{I_Z}{I_Q}\right) \text{and } \beta = \left(1 + \frac{I_Q I_Z}{{I_o}^2}\right) \tag{18}$$

Clarification: Note that Eq. 18 has not the same denominator as Eq. 16 or 17. If one cascades Eq. 18 to a cascade of identical Eq. 16, then he/she will obtain a quasi-OZGF response which is not consistent with the transfer function discussed in [12] The choice for this discrepancy was deliberate for the following two reasons:

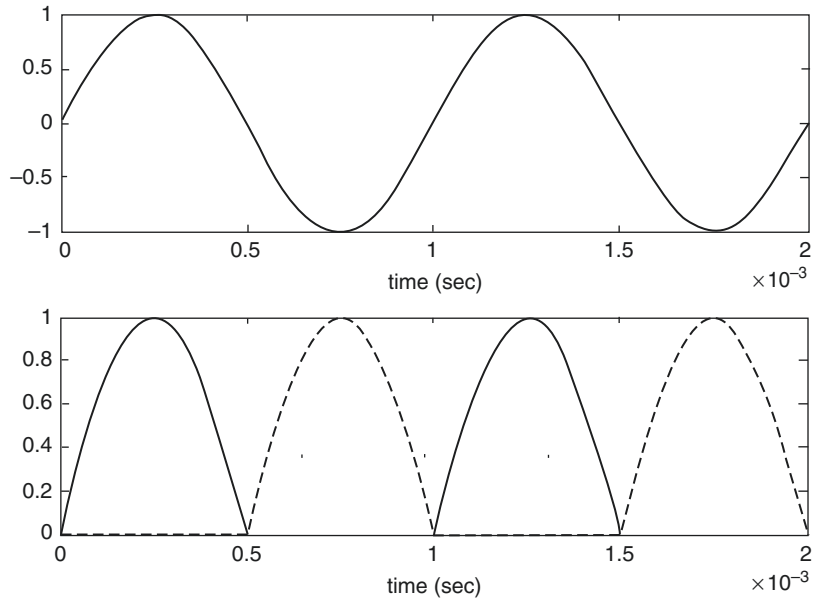
1. By adding a DC current *IZ* at point B in Fig. 6, a real zero in the transfer function is realized with the simplest possible way without adding extra circuitry. If one opts for Eq. 18 to have the same denominator as Eq. 16 or 17, then the various loops would have to be closed through exponential transconductors (E-cells) which would possibly degrade the performance of the resulting topology.
2. Since in this implementation I_Z is always fixed and 10 times smaller than I_o (in order to realize the −20 dB tail at DC), both a, β in Eq. 18 approach to unity when I_Q is maximum (i.e., for low gains – recall $Q = I_o/I_Q$). In that case, Eq. 18 approaches to a lossy BP transfer function with the same denominator as Eq. 16 or 17.

For smaller I_Q values (i.e., for higher gains) the variation in gain and pole frequency due to a and β increases but still does not affect the overall response noticeably due to the fact that in our fourth-order OZGF implementation, Eq. 18 is preceded by three identical LP biquads. This fact will become more apparent later on when we will discuss the measured frequency response of our OZGF implementation.



In other words, we chose to deviate from an ideal OZGF response due to the fact that it was easier to design Eq. 18 without sacrificing significantly any performance or modeling (like peak gain, CF, etc.) specifications.

The Input Signal Conditioner: The Geometric Mean Splitter (GMS)



For the input signal conditioner, we chose to implement the GMS for three reasons:

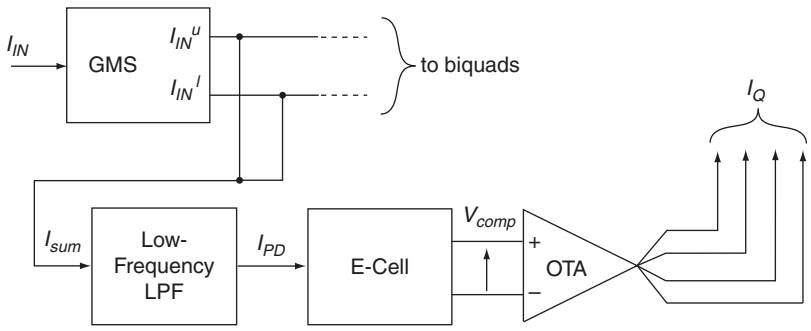
1. It exhibits a good frequency response since it contains well-defined low-impedance points.
2. It can be realized with few noncritical components.
3. And for its low DC levels, ensuring lower static power consumption and noise, relative to other splitters employing, for example, the harmonic mean law.

Figure 8 depicts the PMOS-WI GMS implementation used in this work. From the two (left and right) TL, one may deduce that:

Bioinspired CMOS Cochlea, Fig. 8 PMOS-WI implementation of the geometric mean splitter

Bioinspired CMOS Cochlea, Fig. 9 Indicative current waveforms generated by the GMS. The upper (*solid*) and lower (*dotted*) complementary inputs resemble half-wave rectified signals

$$I_{IN}{}^{u} \times I_{IN}{}^{l} = I_{bias}{}^{2} \left(= I_{o}{}^{2}\right) \tag{19}$$



$$\text{It also holds that} \ : \ \mathrm{I_{IN}} = \mathrm{I_{IN}}^{\mathrm{u}} - \mathrm{I_{IN}}^{1} \tag{20}$$

Moreover, the large-signal expressions for the two positive, complementary, upper and lower, unidirectional currents are given by:

$$I_{IN}{}^{u} = \frac{I_{IN} + \sqrt{I_{IN}{}^{2} + 4I_{o}{}^{2}}}{2} \tag{21}$$

$$I_{IN}{}^{l} = \frac{I_{IN} + \sqrt{I_{IN}{}^{2} + 4I_{o}{}^{2}}}{2} \tag{22}$$

Relations (19) and (20) together describe the splitting action and the law with which the two positive complementary inputs are defined. Figure 9 illustrates typical current waveforms generated by the GMS used in this work. The biasing current I_{bias} could in principle be set arbitrarily small to reduce the noise and static power

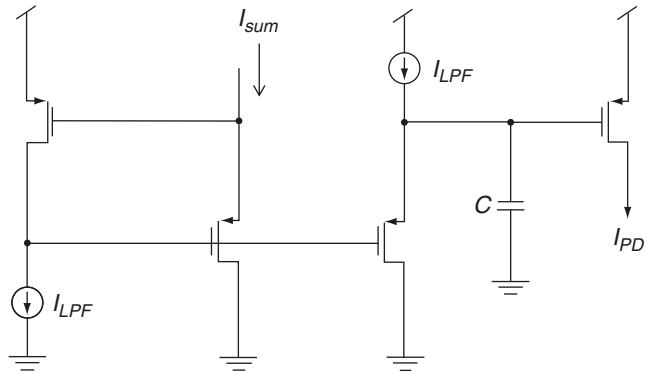
Bioinspired CMOS Cochlea, Fig. 10 Block diagram describing the processing stages of the AGC

but, in the subsequent OZGF, implementation was set equal to I_o in order to ensure similar biasing conditions (and hence impedance levels) for all the transistors comprising the OZGF channel and reduce the overall number of external pin connections.

Finally, it should be noted that one of the potential disadvantages of the GMS topology of Fig. 8 is the implementation of the floating current source I_{IN}. In practice, this current source was realized via two grounded AC-current sources at an 180° phase difference with each other. The relative matching between the two sources will play a significant role in the linearity performance of the OZGF channel since the performance of the whole system cannot exceed that of its input stage. This point will be addressed in more detail in a later section.

The Automatic Gain-Control Circuits

The AGC should be designed in such a way so that a potentially wide DR at the input of the OZGF channel (greater than six orders of magnitude in this implementation) can be compressed to a small current range (typically within one order of magnitude) for the biasing current I_Q that sets the Q of the biquads. The proposed AGC acts in feed-forward and consists of a cascade of four circuit blocks: a GMS, a low-frequency LP filter (LPF), an exponential transconductor (or E-cell) operating as a logarithmic transimpedance amplifier, and a wide linear-range OTA.



With the aid of Fig. 10, the processing stages can be summarized as follows:

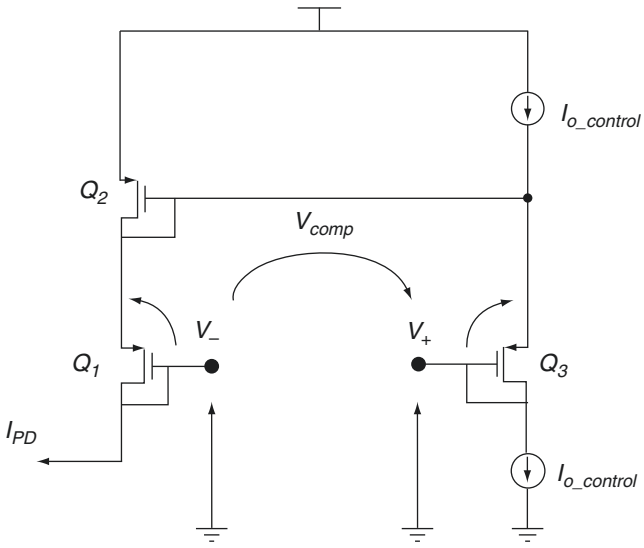
- Stage 1: The GMS ensures that for small signals, the OZGF gain does not exceed a certain value or shoot to instability (i.e., it sets the highest OZGF peak gain for zero input) and also full-wave rectifies the bidirectional input I_{IN} (I_{sum}).
- Stage 2: The low-frequency current-input current-output LPF gives a quasi-DC output (*IPD*), whose value corresponds to the peak value of the full-wave rectified current-input I_{sum}. In other words, the GMS together with the LPF implement a peak detector (i.e., full-wave rectification plus averaging).
- Stage 3: The E-cell compresses the, still-wide, current range at the output of the LPF to a differential voltage range (V_{comp}) that can be easily accommodated by the OTA that follows. The compressive *I-V* transfer characteristic is electronically controlled by a single biasing current $I_{o_control}$.
- Stage 4: The OTA converts V_{comp} to a DC current range, corresponding to the Q range of the OZGF. The tail current of the OTA (I_{tail}) together with $I_{o_control}$ of the E-cell are the two main parameters that control the law with which the Q values are determined (i.e., which input strength value corresponds to which Q).

In the subsections that follow, the AGC circuits are described in detail.

AGC Stages 1 and 2: The GMS and Low-Frequency LPF

By adding the large-signal expressions of the two splitted complementary inputs (i.e., Eqs. 21 and 22) and by defining the peak values of the input as $\hat{I}_{IN} = m \times I_o$, with m being the modulation index, we arrive at the following result:

Bioinspired CMOS Cochlea, Fig. 11 The low-frequency LPF topology – A first-order Class-A Log-domain integrator



$$\begin{aligned}\hat{I}_{sum} &= \frac{\hat{I}_{IN} + \sqrt{\hat{I}_{IN}{}^2 + 4I_o{}^2}}{2} \\ &+ \frac{-\hat{I}_{IN} + \sqrt{\hat{I}_{IN}{}^2 + 4I_o{}^2}}{2} \\ &= \sqrt{\hat{I}_{IN}{}^2 + 4I_o{}^2} = I_o\sqrt{m^2+4}\end{aligned} \tag{23}$$

with m indicating how many times larger or smaller is the input zero-to-peak amplitude relative to the biasing current I_o. The above relation states that for small m and less than 1 (i.e., when the biquads operate in their Class-A mode), $\hat{I}_{sum} \approx 2I_o$, whereas for $m \gg 1$, $\hat{I}_{sum} \approx mI_o = \hat{I}_{IN}$. In other words, for zero or small signals, the GMS outputs a current which has a minimum peak value close to $2I_o$, whereas for larger signals, it follows the input peak almost exactly. Thus, by setting the control law to map the value $2I_o$ to the minimum I_Q value (corresponding to the maximum Q, since $Q = I_o/I_Q$), the OZGF channel will always have a bounded peak gain according to the required specifications and will never shoot up to large unwanted gain values or instability. That is indeed a "hidden" and very useful operation of the GMS because it can rectify the input and set the highest bound for the OZGF peak gain in a simple and elegant manner without needing to resort to additional circuitry.

The current I_{sum} is consequently filtered by the low-frequency LPF to extract its DC component I_{PD}. However, to accurately obtain the peak value, I_{sum} needs to be multiplied by an appropriate scale factor (the crest factor). This multiplication factor, which is waveform dependent and was set here to $\pi/2$, was implemented by means of scaled current mirrors in the GMS. Since I_{sum} is a rectified positive current, the LPF does not have to operate in Class-AB mode. The LPF topology used in this work and depicted in Fig. 11 is a simple Class-A, 1st-order, Log-domain integrator which implements the transfer function in Eq. 24. All symbols have their usual meaning.

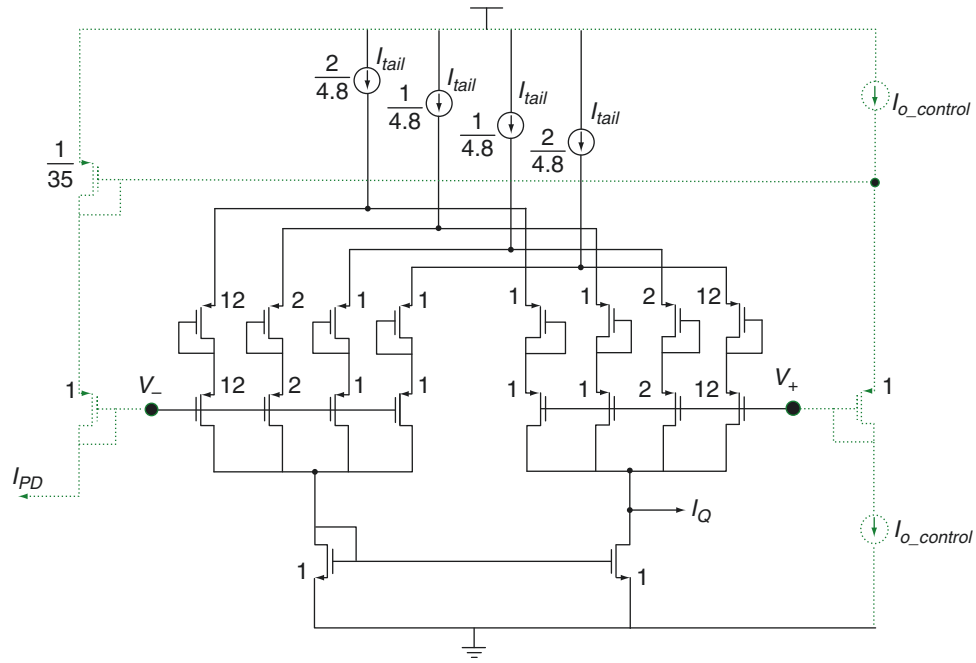
$$H_{LPF}(s) = \frac{\omega_o'}{s+\omega_o'} = \frac{(I_{LPF}/nC_{LPF}V_T)}{s+(I_{LPF}/nC_{LPF}V_T)} \tag{24}$$

Clarification: It is known from physiology that the IHC perform half-wave rectification to extract the energy of the BM vibrations. So why did we opt for a full-wave rectification in this implementation since clearly this choice is inconsistent with biology? The reason is that IHC and OHC are two separate sensors in the real cochlea. The IHC do not control the gain of the cochlea as OHC do, but through the auditory nerves create action potentials to convey information to the brain. For this reason, both the phase and frequency information of the signal they detect is important. *Half-wave rectification enhances the zero-crossings of the signal while preserving its frequency information, whereas full-wave does not (it doubles the frequency)*. In this implementation, the silicon neurons that convert the output of the OZGF channel into spikes were not designed; only a circuit that models (at least qualitatively) the function of OHC for controlling the channel's gain. The proposed AGC operates virtually at DC and so both frequency and phase information is unimportant at this point. The choice for a full-wave rectification was made since the capacitor value used in

Bioinspired CMOS Cochlea, Fig. 12 The exponential transconductor – E-cell used for AGC action

the low-frequency LPF for smoothing the full-wave rectified signal can me made smaller than in the half-wave case, thereby saving area. That is one example of a choice that is not neuromorphic in its strict sense but, given the particular chip's area requirements, serves as a viable alternative.

AGC Stages 3 and 4: The E-cell and Wide Linear-Range OTA



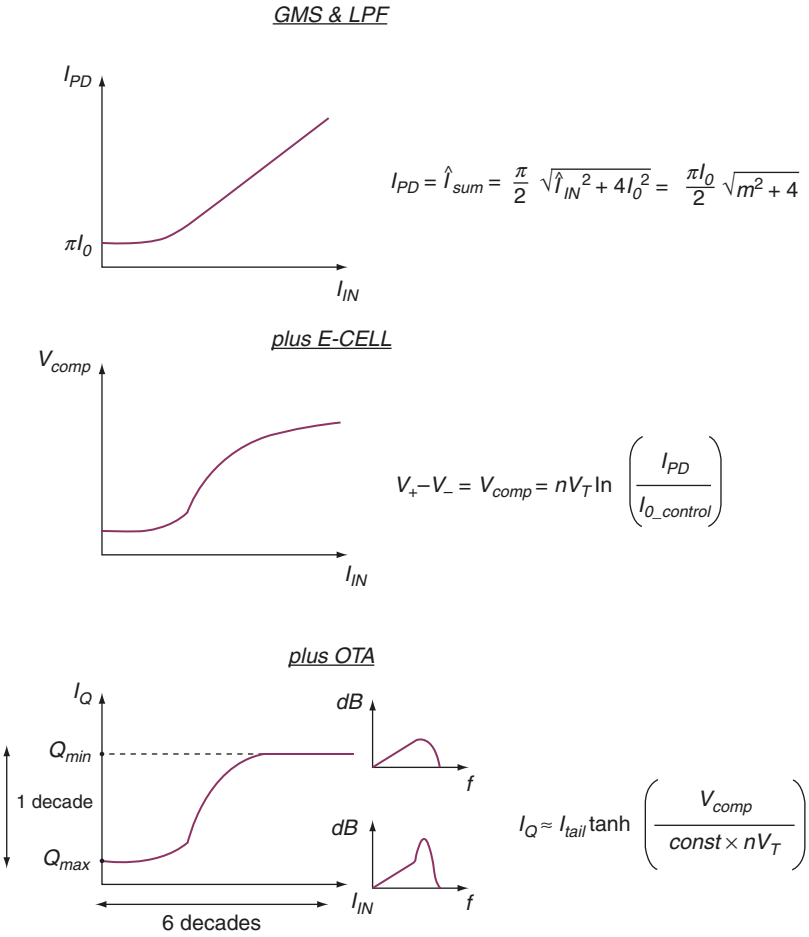
The E-cell, shown in Fig. 12, is an exponential transconductor operating as a nonlinear transimpedance amplifier. It consists of two low-impedance points (the drain-gates of devices Q_1 and Q_3), where the compressed differential voltage V_{comp} is generated when the current I_{PD} is sourced from the diode-connected drain of device Q_1. Device Q_2 serves as a degeneration (tail) resistor which, if appropriately sized, gives additional headroom for accommodating the upper biasing current source $I_{o_control}$ (implemented by means of cascoded mirrors not shown for simplicity). The reason for using an E-cell compared to a standard diode to perform the logarithmic compression is attributed to the fact that with an E-cell, the compressive *I-V* transfer characteristic can be electronically tuned by $I_{o_control}$ as described by Eq. 25. From the TL Q_1Q_3 and by assuming that $I_{Do1} = I_{Do3}$ (i.e., matched devices):

$$V+ - nV_T \ln\left(\frac{I_{PD}}{I_{Do1}}\right) + nV_T \ln\left(\frac{I_{o-control}}{I_{Do3}}\right) - V- = 0$$
$$\Rightarrow V_+ - V_- = V_{comp} = nV_T \ln\left(\frac{I_{PD}}{I_{o-control}}\right) \quad (25)$$

The compressed differential voltage V_{comp} is subsequently applied to an OTA whose linear range was widened by using two standard techniques:

1. Plurality of cross-coupled, source-coupled pairs [14, 19].
2. Source degeneration. More specifically, four OTAs, each with an appropriate offset voltage and tail current, were degenerated and connected in tandem in order to realize an overall flatter input–output slope. This was achieved by choosing the offset voltages and tail currents in such a way so that the higher-order even and odd derivatives of the total (combined) transconductance become zero.

The offset voltages were realized by scaling asymmetrically the dimensions of the devices that comprise the branches of each OTA pair (see Fig. 13). In [19], for maximally flat transconductance characteristics, these aspect ratios were calculated to be 13.4, 2.04, 1, 1 and with tail current multiplication factors of 1.83, 1, 1, 1.83.

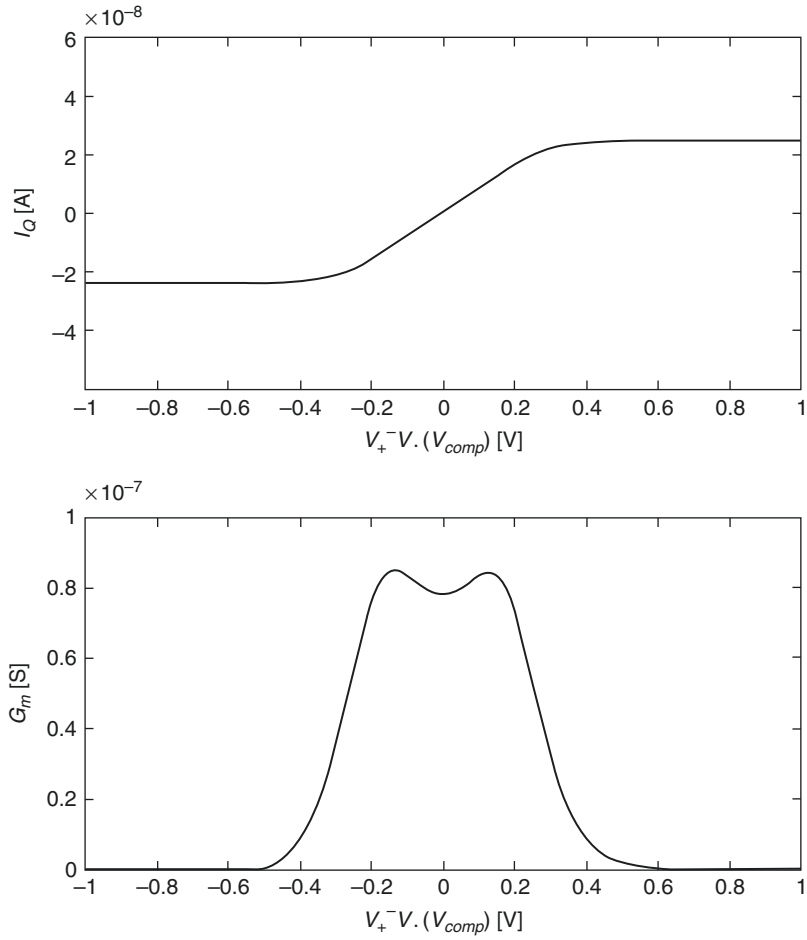


Bioinspired CMOS Cochlea, Fig. 13 The E-cell (*dotted green lines*) connected together with a wide linear-range OTA employing asymmetric cross-coupled, source-coupled pairs. The devices aspect ratios are indicated on the schematic

However, since accurate linearity is not a crucial performance requirement for the AGC, the device aspect ratios and tail current multiplication factors were set to 12, 2, 1, 1 and 2, 1, 1, 2, respectively, in order to simplify our layout matching efforts during fabrication phase. The scaling factor of 4.8, which all the tail currents are divided with, was chosen empirically so that the upper and lower saturating levels of the *V-I* tanh function coincide with the actual I_{tail} value. Figure 14 describes qualitatively the input to every AGC stage output transfer characteristics. The *x*-axes were exaggerated to indicate the various different ranges of operation. In essence, the AGC is able to compress a wide input range of 120 + dB to a much smaller range (∼20 dB) for the Q values setting effectively the peak gain of the OZGF response according to input level.

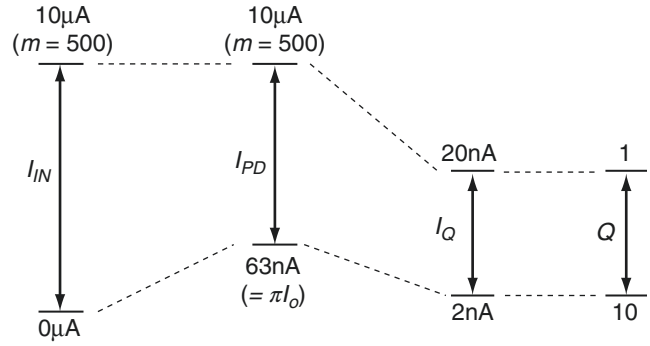
AGC Simulation and Measured Results

The simulation results presented in this section were obtained from Cadence IC Design Framework® and with the parameters presented in Table 1. Figure 15 shows the simulated *V-I* and transconductance transfer characteristics of the wide linear-range OTA for an I_{tail} of 24 nA. Strictly speaking, the achieved linear input range is around 200 mV_{peak}. However, since (a) the OTA operates in quasi-DC and (b) the overall AGC characteristic must be compressive, the practically usable range is around 400 mV_{peak}. It should be noted that since $I_Q{}^{max} \equiv I_{tail}$, the OTA sets the lowest bound of the OZGF peak gain according to $Q_{min} = I_o/I_{tail}$. The control law was calibrated (via the currents $I_{o_control}$ and I_{tail}) to map the minimum signal at the input of the OZGF (which results in a value of $2I_o \times (\pi/2)$ at the output of the LPF of the AGC) to a maximum biquad Q of 10. This corresponds to a value of 2 nA for the respective I_Q currents and a nominal OZGF peak gain of ∼80 dB. On the other hand, for a maximum allowable input of 10 μA (i.e., for $m = 500$), the AGC gives an I_Q equal to 20 nA corresponding to a Q of 1 (see Fig. 16). Since I_{tail} sets the upper level of the *V-I* transfer characteristic of the OTA, for very large input signals



Bioinspired CMOS Cochlea, Fig. 14 Input to every AGC stage output transfer characteristics. Note that the actual I_Q expression is an approximate one since a closed form expression for the transconductance of the wide linear-range OTA cannot be obtained

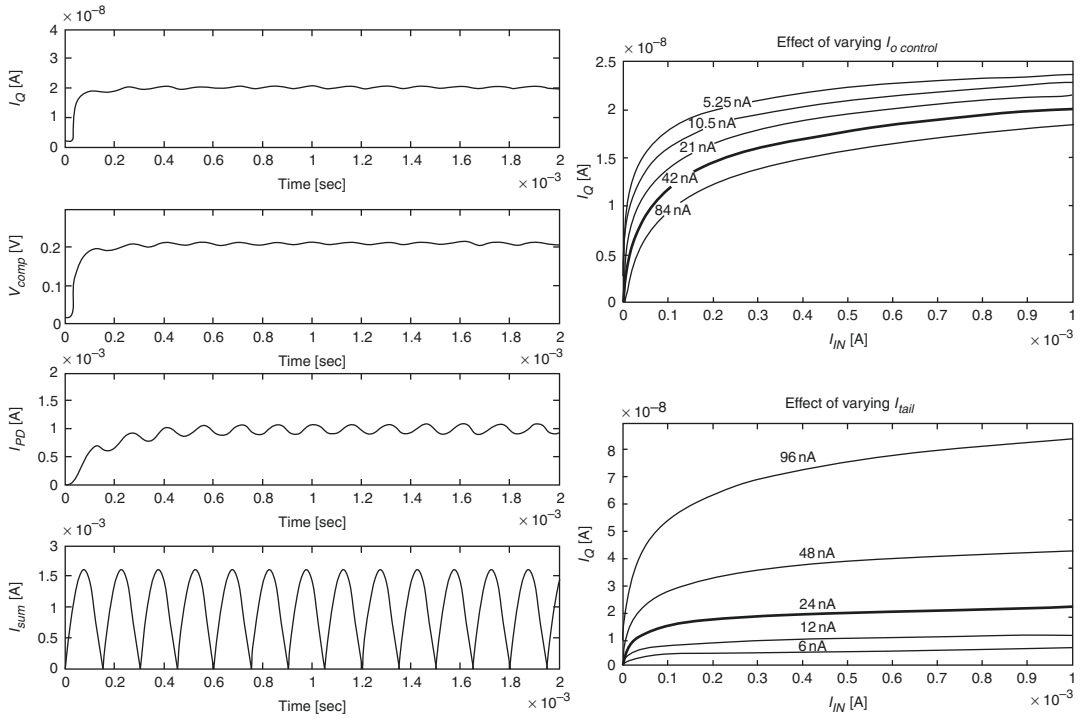
($m > 500$) the maximum I_Q value saturates at 24 nA, corresponding to a lowest Q of 0.834 and a passive OZGF peak gain of 1.43 dB. Indicative waveforms at the outputs of each AGC stage are shown in Fig. 17.



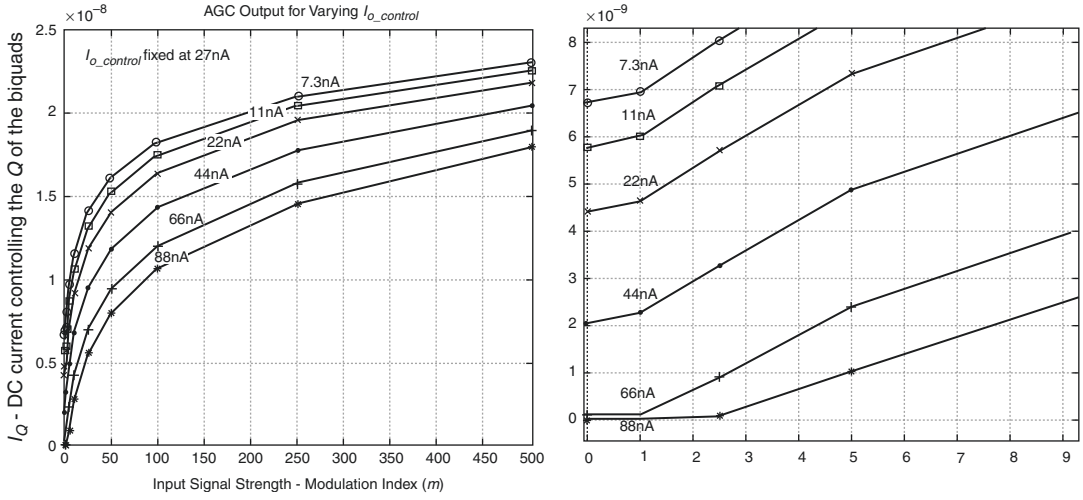
The law with which the Q values are determined was obtained by performing a DC-sweep analysis on the whole AGC system. Figure 17 depicts I_Q versus I_{IN} curves with $I_{o_control}$ and I_{tail} as the two implicit parameters. It can be observed that the overall input–output AGC transfer characteristic is logarithmically compressive in nature as suggested by Eq. 25 with $I_{o_control}$ controlling the "vertical shift" of the characteristic and with I_{tail} controlling the actual level of compression as expected from Eq. 25 and OTA operation. Also observe that a linear change in I_{tail} results in a logarithmic change on the compression level, whereas a linear change in $I_{o_control}$ results in a linear vertical shift of the whole characteristic. In conclusion, the above two electronically controllable degrees of freedom give a certain level of versatility to the AGC system because a variety of input DR values can be accommodated and mapped to a specific Q range according to the particular physiological (modelling) or design (performance) specifications (Figs. 18, 19, and 20).

Active OZGF Channel–Measured Results

The whole channel, together with its AGC, was integrated in the standard 0.35 μm AMS 2P/4 M CMOS process. The OZGF was tuned so that its

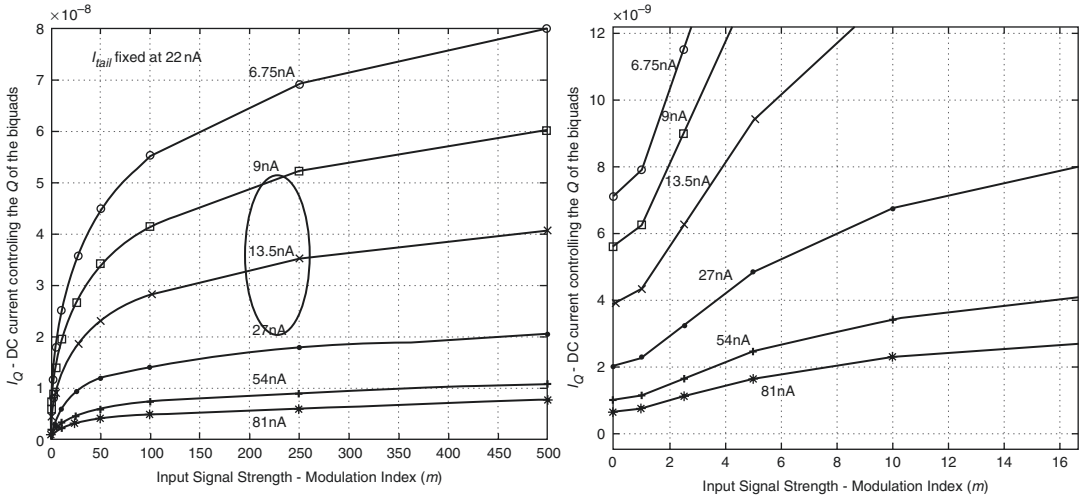


Bioinspired CMOS Cochlea, Fig. 15 *V-I-* (*upper*) and transconductance- (*lower*) simulated transfer characteristics of the wide linear-range OTA for $I_{tail} = 24$ nA

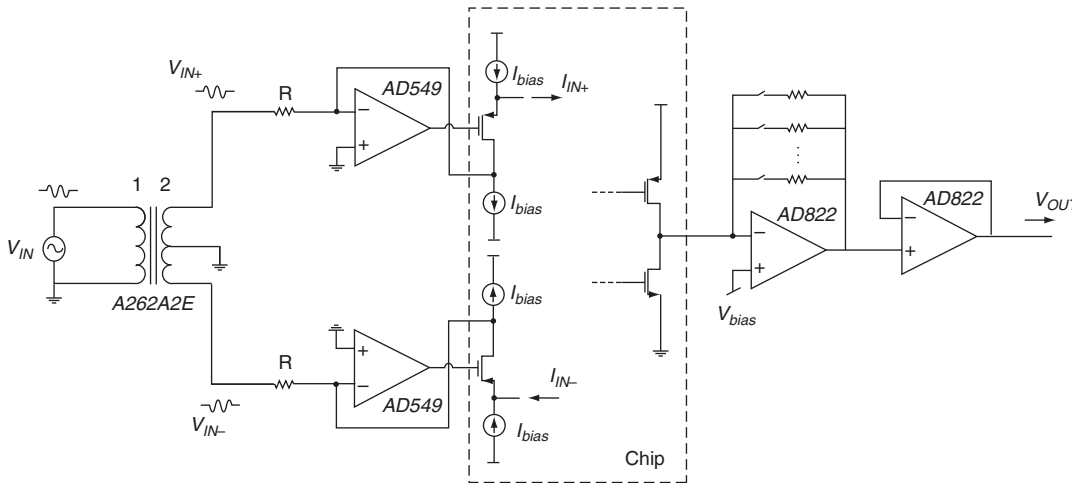


Bioinspired CMOS Cochlea, Fig. 16 Mapping of the input current range to OZGF Q values

nominal center frequency (CF) falls at 3.3 kHz for a Q of 1. This corresponds to $I_o = I_Q = 20$ nA.



Measurement Setup: In section "The Input Signal Conditioner: The Geometric Mean Splitter (GMS)" it was mentioned that one of the disadvantages of the particular GMS topology was the need to accurately realize the floating current source I_{IN} in order to minimize distortion. In this case, this was achieved by using two 6221 precision AC/DC Keithley current sources. These were programmed using MatLab™ (via their GPIB interface) and triggered externally to output two



Bioinspired CMOS Cochlea, Fig. 17 (*Left*) Current waveforms from the output of each AGC stage for an input signal of $m = 500$. Observe that the peak of I_{sum} is at ∼16 μA instead of 10 μA (due to scaling by $\pi/2$), whereas the LP-filtered version of I_{sum}, I_{PD} is at 10 μA as expected. The I_Q value is at 20 nA corresponding to a Q of 1. (*Right*) Simulated parametric DC response plots of the Q-control law with varying $I_{o_control}$ (*upper*) and I_{tail} (*lower*). The *bold curves* are the ones corresponding to the values shown in

Note that the characteristics level of for small signals (as expected from the operation of the GMS) with I_{tail} having a small effect on the *y*-intercept value (*Right*) but a much larger one on the large-signal saturating levels

Bioinspired CMOS Cochlea, Fig. 20 Experimental setup for measuring the OZGF channel

AC-current waveforms at an exact 180° phase difference with each other. Moreover, by fine-tuning their relative amplitudes and phases, we could partly overcome any mismatches between the two Class-A paths and, consequently, further optimize the linearity performance of the OZGF channel. The OZGF output current was measured via standard *I*-to-*V* converters (utilizing 100fA-leakage current AD549 Opamps) and through the 1 MΩ input resistance of a Stanford Research 1 mHz–100 kHz spectrum analyzer (the SRT785).

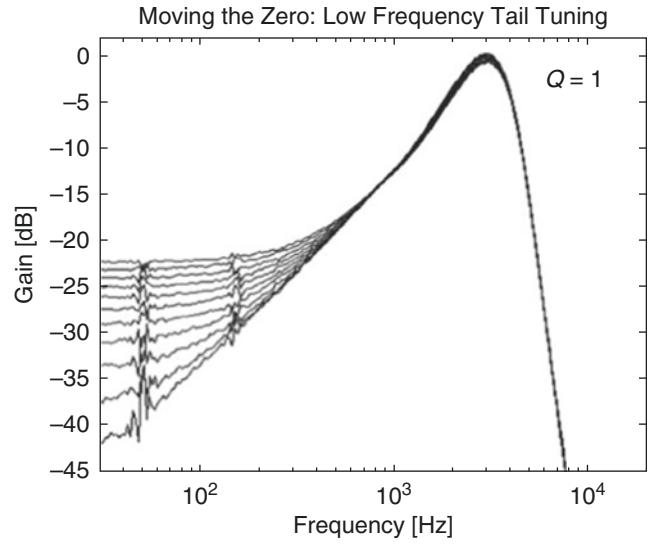

Table 1 shows the various dimensions of the devices comprising the channel and AGC. It should be emphasized that this choice occurred after careful deliberation and optimization. For the case of the Log-domain biquad (where high DR performance is of primary interest), a large *W* (such as 300 μm) shifts the $\ln I_{DS} - V_{GS}$

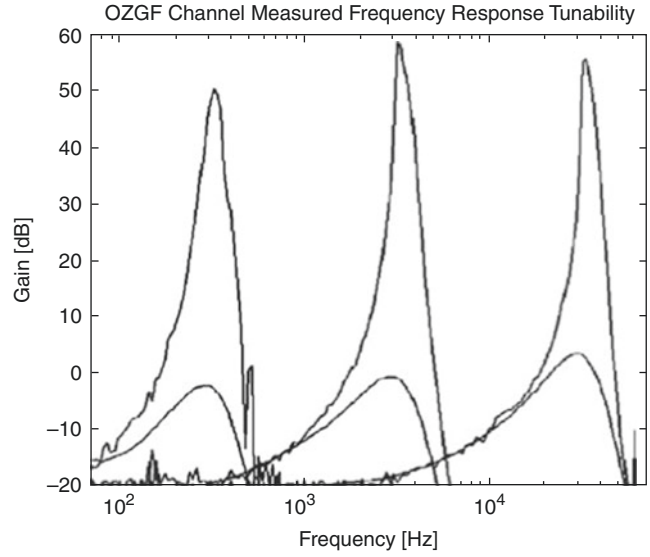
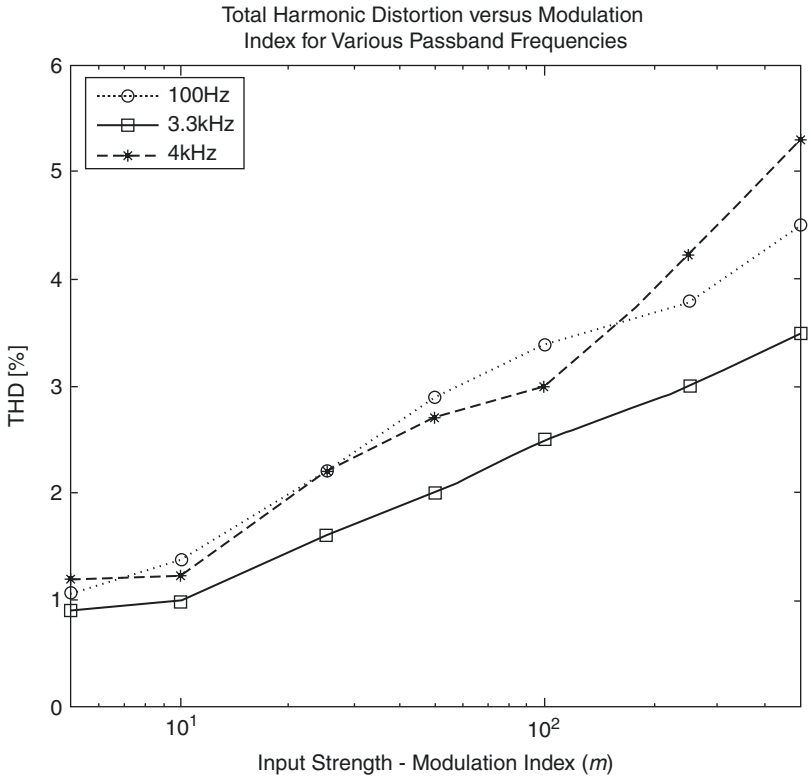


Bioinspired CMOS Cochlea, Fig. 21 Q-tunability of the active fourth-order OZGF frequency response. The maximum peak gain was measured at 70 dB

characteristic vertically so that the upper limit of the WI region extends to the μA-range, *while the leakage currents are still maintained below noise levels*. This is an important design choice to ensure that the full WI range, offered by the particular CMOS process, is exploited. In addition, the choice for L is equally important: For best THD performance, L should be made minimum since it affects the linearity of the WI slope, (i.e., the range of the flat portion of the $d(\ln I_{DS})/dV_{GS}$ versus V_{GS} curve) but a small L will give rise to channel-length modulation effects [1]. A larger L will definitely make the respective device's output impedance larger, but overall output THD will be reduced. For this reason, it was found that $L = 1.5$ μm (i.e., around four times the feature size) was a good compromise between driving capability and linearity. In addition, the device areas satisfied a 3σ-VT mismatch of about ± 2 mV which is somewhere in between moderate to precise matching.

Frequency Response: Figure 21 shows the Q-tunability of the active fourth-order OZGF frequency response. The current I_Q was changed automatically via the action of the AGC by changing accordingly the strength of the input signal from the spectrum analyzer. Observe also that a linear change in I_Q corresponds to a logarithmic change in the peak gain (or Q) due to (a) the compressive law of the AGC and (b) due to the fact that $Q = I_o/I_Q$; this is indeed another form of compressive behavior which is embedded in the frequency response and stems directly from the design equations of the Log-domain biquads. Figure 22 shows tuning of the OZGF's low-frequency tail by varying the current I_Z (note the quite small gain and pole frequency variation due to a and β terms in Eq. 18 – see again discussion at the end of section "Pseudo-Differential Class-AB Log-Domain Biquads"), whereas Fig. 23 shows the two orders of magnitude ω_o-tunability when changing the biasing current I_o to 2, 20 and 200 nA, successively. For each ω_o, two indicative Q setups are shown to demonstrate gain adaptation within the whole audio spectrum. Observe the quite stable characteristics over frequency. Also note that the low-ω_o, high-Q response is affected by input signal noise because of the low biasing current levels of the particular configuration. Finally, it should be emphasized

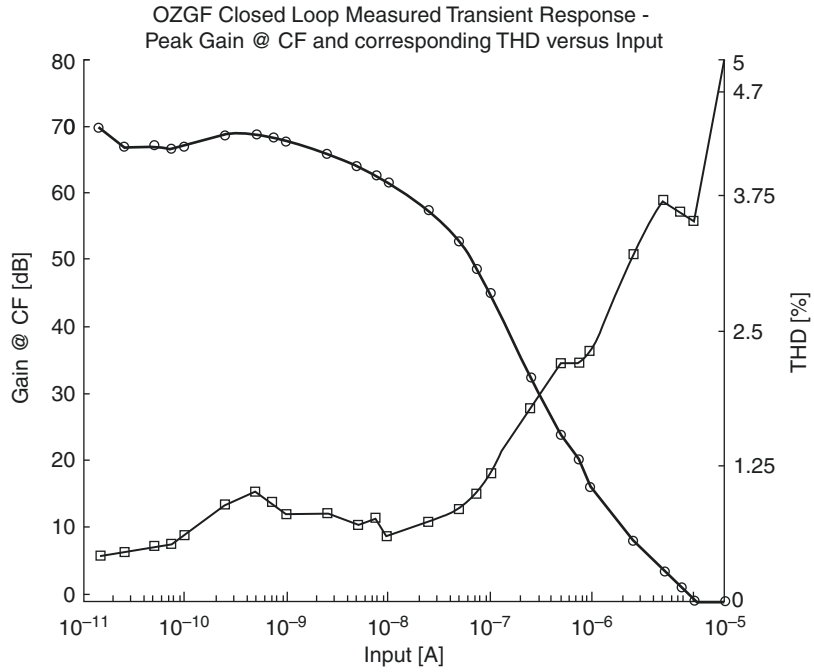


Bioinspired CMOS Cochlea, Fig. 22 Low-frequency tail tuning by means of varying the biasing current I_Z

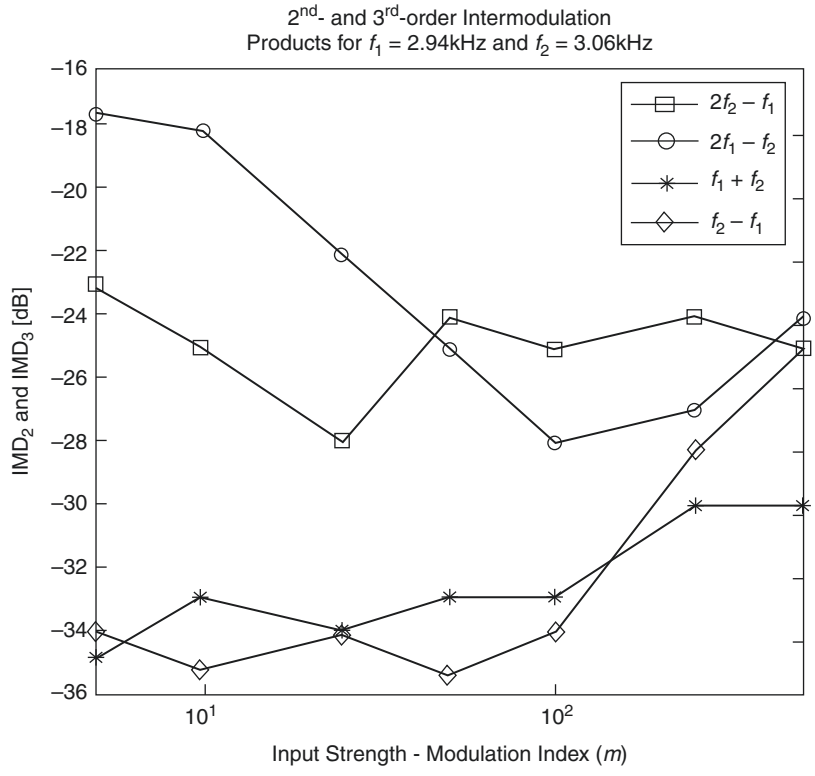
Bioinspired CMOS Cochlea, Fig. 23 Gain adaptation and ω_o-tunability (CF from 330 to 33 kHz)

that all low-to-moderate Q responses were obtained with a large m ($>>1$) in order to validate the OZGF's Class-AB operation.

Total Harmonic Distortion (THD): The THD is a common measure for assessing the linearity performance of amplifier systems. However, when talking about audio-auditory processors, its value must be appropriately judged since the "shape" of a signal's spectrum is something that affects one's hearing perception. In other words, a signal with a certain THD value might sound "aesthetically more pleasing" to our ears than another of equal or lower THD value. In commercial and academic cochlea designs, a common upper limit for THD is 4–5 % (e.g., Sarpeshkar's neuromorphic cochlea: <5 % [17, 18], MED-EL's state-of-the-art DUET EAS hearing system: <5 % @500 Hz, Phonak Super-Front PPC-4 <7 % @500 Hz, etc.). This was also justified experimentally from a recent (and one of the first) Log-domain implementations of a CMOS cochlea, where the effect of distortion started to

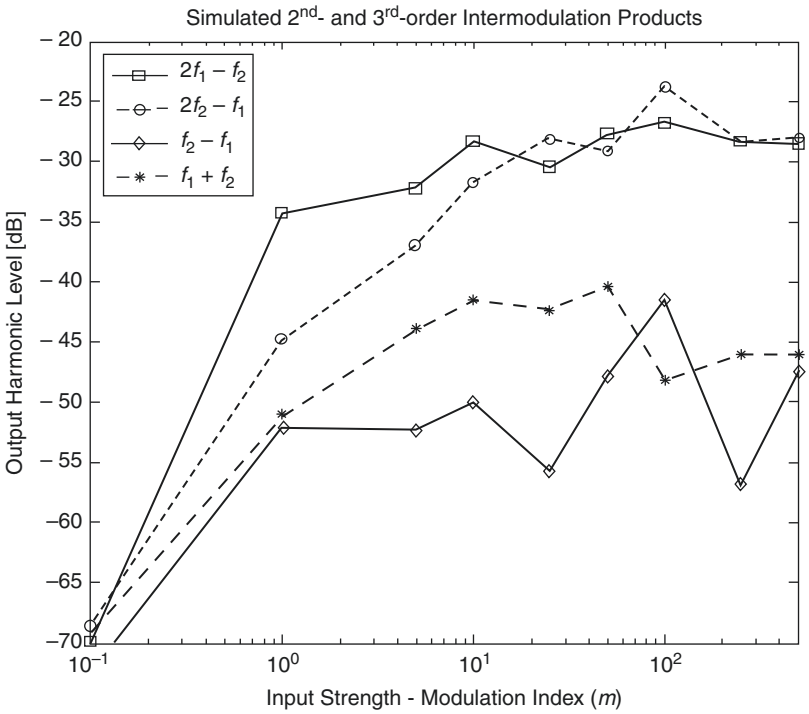


Bioinspired CMOS Cochlea, Fig. 24 Measured single-tone linearity of the fourth-order ($Q = 1$) OZGF for various passband frequencies



become evident to the ear after 5 % THD [10]. Finally, note that the 10 %@1 kHz THD value represents a desirable amount of allowable distortion for typical low-cost wide-band audio material such as FM broadcasts, CD-media or cassette tape media. For these reasons, it was decided that 5 % is a reasonable upper limit of THD for our OZGF cochlea channel.

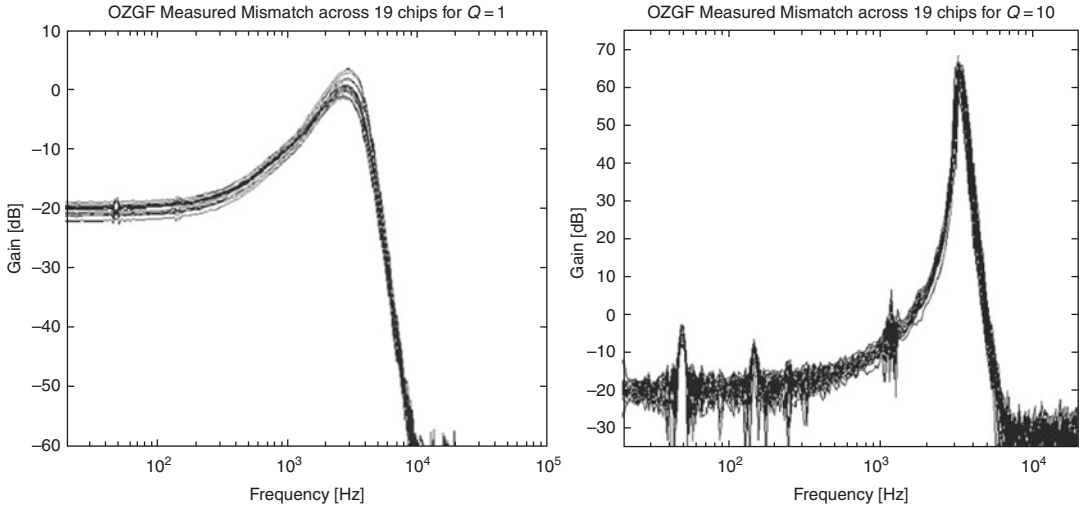
Due to their differential nature, CMOS-WI Class-AB Log-domain filters exhibit mainly odd-harmonic distortion content. Their THD (for frequencies near the pole frequency) usually reaches the 1 % value quite early (for m values as low as 1, i.e., at the border between Class-A and Class-AB operation) but grows rather slowly thereafter; this behavior renders Log-domain filters as adequate candidates for applications where moderate THD values can be tolerated. Figure 24 shows THD versus input strength (m) for various tones near-and-at the CF and deep in the passband for the open-loop $Q = 1$ OZGF response. At the CF, the THD for an input of 10 μA ($m = 500$) is at 3.5 %. Figure 25 shows how the active OZGF adapts automatically its peak gain with input level together with the corresponding output THD. For a 14 pA input tone, the OZGF provides a peak gain of 70 dB at 0.4 % output THD, whereas for an input tone of 20 μA, the peak gain is at −0.85 dB with an output THD of 5 %.



Two-Tone Intermodulation Tests: Figure 26 shows both even- and odd-order measured intermodulation distortion products (IMD) for 2 t placed at a frequency ±2 % away from the (CF) 3 kHz of the open-loop $Q = 1$ OZGF response. The IMD_2 starts at around −34 dB for small-signals and increases gradually to higher dB values with $f_2 - f_1$ increasing faster than $f_1 - f_2$. The IMD_3 is less attractive with a much unpredictable behavior toward smaller signals. These results unfortunately do not compare favorably to IMD figures reported from similar (biquadratic and not) prior CMOS-WI Log-domain efforts [11, 16] – even though those were (a) only IMD_2 (a quite unreasonable test for differential filters), (b) obtained at ±10 % of a given frequency, and (c) for lower-order filters with some gain. It is

Bioinspired CMOS Cochlea,
Fig. 25 Measured peak gain at CF and corresponding output THD versus I_{IN}

Bioinspired CMOS Cochlea,
Fig. 26 Measured two-tone third- and second-order intermodulation products of the fourth-order ($Q = 1$) OZGF for two frequencies at ±2 % away from 3 kHz

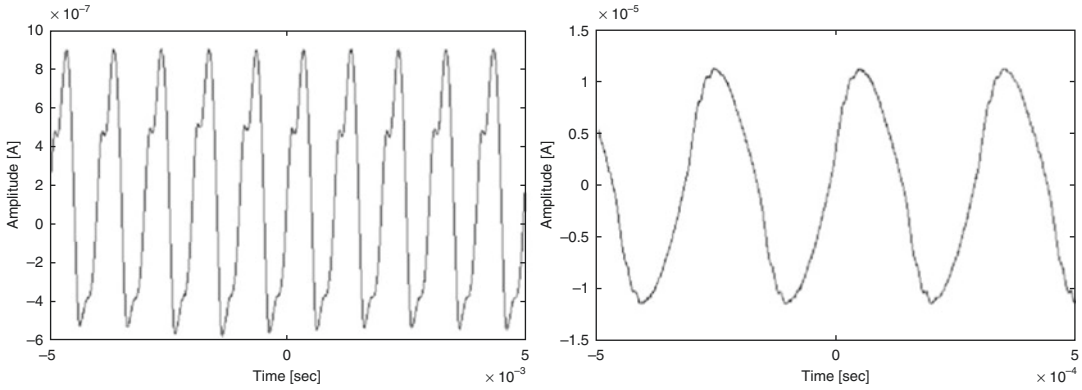


Bioinspired CMOS Cochlea, Fig. 27 Simulated two-tone third- and second-order intermodulation products of the second-generation, fourth-order ($Q = 1$) OZGF for two frequencies at ±2 % away from 3 kHz

believed that these set of results can be improved considerably in future implementations; nonetheless, one should appreciate that the real cochlea exhibits considerable intermodulation distortion, with both its $IMD_{2,3}$ levels around −20 dB for a large range of input intensities. In any case, we have managed recently to identify some potential optimization steps that may lead to an improved overall intermodulation linearity performance. A second-generation, fourth-order OZGF channel (one where its lossy BP stage is at the front of the cascade and not at the end) exhibited in simulation IMD_3 levels below −35 dB for small-signals, which also stayed below −25 dB across the whole input range (see Fig. 27).

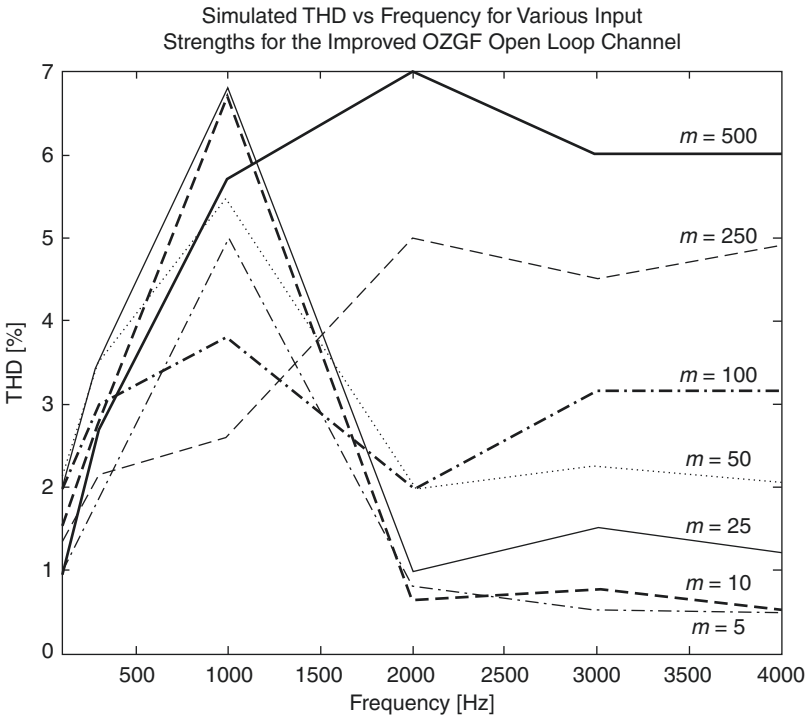
Mismatch: One potential disadvantage of all pseudo-differential Class-AB filters of the type shown in Fig. 6 is that any potential mismatch between the two signal paths translates to distortion at the output. Therefore, considerable attention was given during layout in order to try and accurately match the two Class-A branches. Specifically, the two (upper and lower) TL comprising each Class-A biquad were nested together in such a way so that every upper transistor was interdigitized with its corresponding lower counterpart. Common centroid arrangements along both axes of symmetry were also employed. Figure 28 shows $Q = 1$ (upper plot) and $Q = 10$ (lower plot) measured OZGF frequency responses across 19 chips. Observe that in both cases the relative variation between responses does not exceed 6 dB.

Input Dynamic Range (DR): In this work, by input DR, we imply the ratio of the maximum input signal for a given allowable distortion at the output (measured in % of THD) over the noise floor for zero input. The measured input DR was calculated by taking into consideration the compressive action of the AGC by dividing the maximum signal at the input of the passive ($Q = 1$) OZGF response over the measured noise floor (integrated over the 3 dB bandwidth) of the fully active ($Q = 10$) OZGF response. The maximum input DR at CF was found to be 124 dB at <5 % THD, although at different frequencies, this figure changed since the distortion is not uniform across the whole bandwidth of the OZGF. More specifically, we observed an abrupt increase in THD around 1/3 of the CF; a problem partially



Bioinspired CMOS Cochlea, Fig. 28 OZGF mismatch across 19 chips for both extreme cases of Q

attributed to the fact that at 1/3 of the CF the input tone experiences a gain of ~ -10 dB, whereas the 3rd-harmonic (which is generated and propagated across the four Log-domain biquads) a gain of ~ 2 dB. *In other words, the fundamental gets suppressed, whereas the distortion gets amplified*. Moving deeper in the passband, one would expect that this particular problem would become more severe since both the third and fifth harmonics would get amplified while the fundamental would get suppressed even further. However, this is not entirely the case because for low frequencies, the whole structure operates virtually at DC, the capacitors draw smaller currents and, hence, the exerted nonlinearities are weaker.

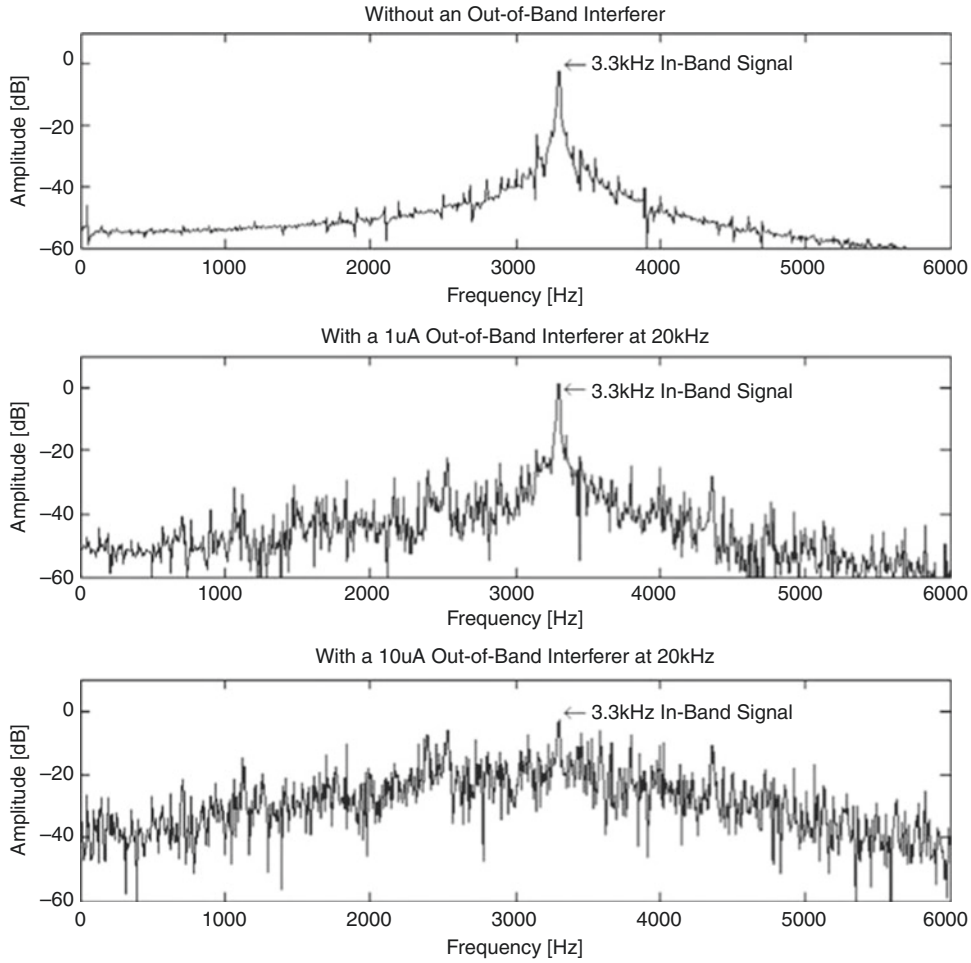


It is really interesting to notice that the aforementioned phenomenon (that of "amplified distortion" as opposed to the more common "distorted amplification") is also observed in the biological cochlea. Recent measurements in the basal and apical turns of the guinea-pig cochlea [2, 13] revealed that the real cochlea exhibits even-order harmonic content with maximum second-order harmonic distortion levels of 4 % and 28 % near and one octave below the CF, respectively. Since our implementation contains odd-harmonic content, we expect the maximum distortion to occur at 1/3 of the CF, which indeed was the case. Figure 29 illustrates large-signal transient waveforms at 1/3 of the CF and CF, respectively. Similar distortion occurred in the design of [17], where THD values of as high as 40 % were observed around one octave below the CF.

Figure 30 shows simulated results from the improved second-generation, fourth-order OZGF channel operating in open loop and with a $Q = 1$. The plot depicts THD values as a function of frequency with varying modulation index. Observe that for small m, the responses resemble HP filters, and BP filters for large m. The "sharpness" of these BP responses seem to increase with m, and their peak occurs approximately at 1/3 of the CF (around 1 kHz). Observe that for a wide range of input frequencies and strengths, the THD stays below 7 %.

Out-of-Band Interferer: A well-known problem of all ELIN topologies is that their noise floor is signal-dependent, resulting in a constant output SNR of about 60 dB for large m values. This observation was experimentally verified as well in our OZGF implementation. One manifestation of this problem is the ability of the filter to maintain good signal integrity at the presence of an out-of-bound interferer. Figure 31 shows the measured PSD of an 1 μA ($m = 50$) in-band signal at CF. An out-of-band interferer was placed at 20 kHz and for two distinct amplitudes, 1 μA

Bioinspired CMOS Cochlea, Fig. 29 Typical large-signal output waveforms from the OZGF channel at 1/3 of the CF (*upper*) and at the CF (*lower*), respectively. The THD in the *upper plot* is in excess of 20 %, whereas the distortion in the *lower plot* is less than 4 %



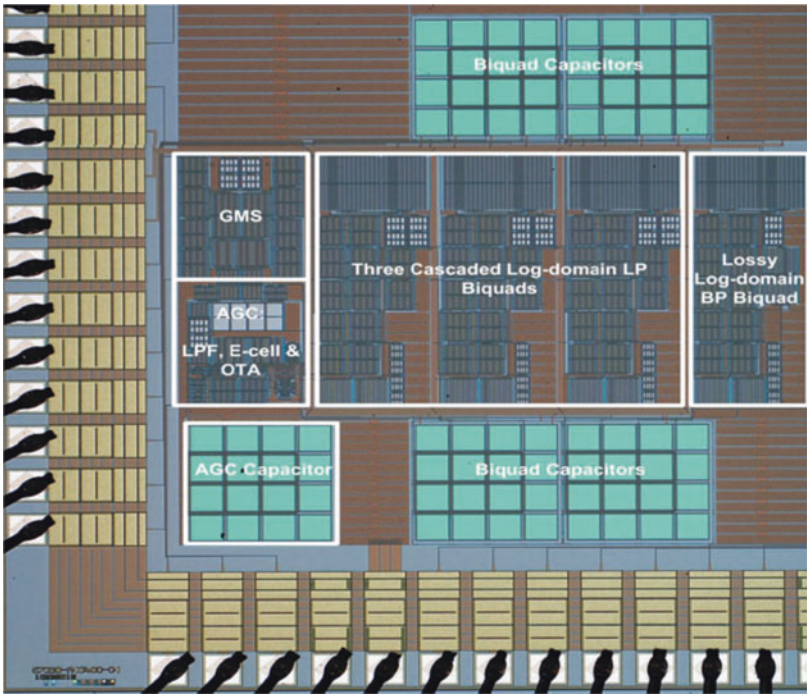
Bioinspired CMOS Cochlea, Fig. 30 Simulated THD versus frequency for varying modulation index *m*. For most of the characteristics, the maximum distortion occurs around 1 kHz (i.e., 1/3 of the CF)

and 10 μA. It was observed that the noise PSD increased from around −60 dB for the case of an absent interferer to about −40 dB for the case of the 10 μA interferer; that is about 10 dB per decade of interferer amplitude increase as predicted in [4] and experimentally verified in [16].

In conclusion, Table 2 summarizes the measured performance of the active fourth-order OZGF cochlea channel, whereas Fig. 31: Masking effect of an out-of-band interferer.

Figure 32 shows a chip micrograph of the channel's layout.

Bioinspired CMOS Cochlea, Fig. 31 Masking effect of an out-of-band interferer



Bioinspired CMOS Cochlea, Table 2 OZGF-measured performance

Power consumption	3.4 μW (no AGC), 4.46 μW (with AGC)
Noise floor	67.5pA ($Q = 1$), 14pA ($Q = 10$)
Centre frequency	3.3 kHz ($Q = 1$)–3.7 kHz ($Q = 10$)
Peak gain	70 dB with <1 % THD
Input DR at CF	124 dB with <5 % THD (with AGC)
SNR at CF	∼60 dB for $m > 10$
Total on-chip capacitance	400 pF
Chip area	1.5 mm × 1.5 mm (2.25 mm^2)

Summary, Discussion, and Conclusion

The architectural choices and measured results of this cochlea channel implementation can be summarized in the following points:

1. Instead of opting for a filter-cascade implementation, which is prone to noise and offset accumulation, gain sensitivity, and yield, this design is based on separate filter-bank channels of short-cascades. In this way, it was possible to model the propagation of distortion products; conserve on computation; and

Bioinspired CMOS Cochlea, Fig. 32 Chip micrograph of the fourth-order OZGF channel with the AGC

obtain realistic roll-off slopes, amplitude, and group-delay responses without the associate disadvantages of long-cascade models.

2. The real cochlea exhibits 120 dB of input dynamic range at 3 kHz at <5 % THD. In this work, the measured results at the exact same frequency revealed an input DR of 124 dB at <5 % THD.
3. The BM in the real cochlea has an area of approximately 70 mm^2. This is equivalent to having a filter bank employing approximately thirty fourth-order OZGF channels.
4. A linear change in Q results in a logarithmic change in the peak gain (and in the temporal resolution) of our Log-domain OZGF response (see Fig. 21). Contrary to prior cochlea implementations, this is compatible with biology.
5. The implemented fourth-order OZGF frequency response achieves 70 dB of amplification for small-signals (even though in practice, we could get gains as high as 100 dB) while maintaining a linear low-frequency tail (20 dB/Dec) with steep high-frequency roll-off slopes (−160 dB/Dec).
6. The AGC dissipates 1 μW and compresses the six orders of magnitude of input signal intensity into one decade of Q-value tuning range. Moreover, it sets the lower and upper bounds of the peak-gain response avoiding excessive distortion or instability. In addition, asymmetric attack and release time constant programmability can be easily incorporated by modifying the LPF like in [22]. Lastly, in this implementation, the AGC acts in feed-forward and takes as input the global input. The downside of such a scheme is that the AGC does not contain any frequency information. The AGC can become frequency-dependent by modifying the architecture to accept as an input the output from the last BP OZGF stage or any other stage in between (in that case the AGC regulation will be closed-loop).

All the circuits presented in this work may serve as basic building blocks for the realization of new biorealistic cochlea processors designed in any of the two commonly used architectures; filter bank, or filter-cascade. Nonetheless, the fourth-order OZGF channel presented here is a good compromise between biorealism, circuit complexity, and yield and may be suitable in filter-bank

applications were biological fidelity and/or high DR performance is of primary interest. The choice for using CMOS-WI pseudo-differential Class-AB Log-domain biquads for low-power, high DR operation has proven successful at the expense of an increased chip area since the capacitor and transistor count increases by a factor of 2.

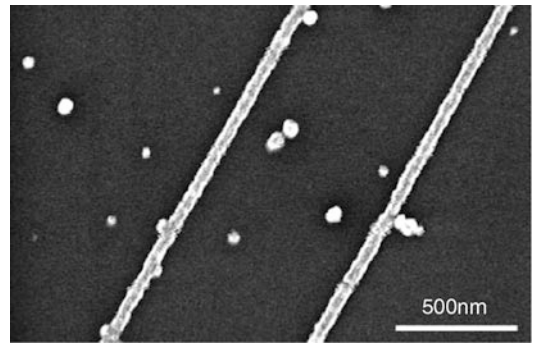
Biomimetic synthesis; Biomimetic synthesis of nanomaterials

Definition

Synthetic routes that mimic natural processes for the fabrication of nanomaterials in mild conditions and with improved control over key features such as size, shape, and hierarchical organization of the end product. These bioinspired processes frequently utilize biocatalytic templates, such as DNA, peptides, and proteins as well as cell bioreactors, whose performance can be enhanced via molecular biology tools.



The transition from the microscale to the nanoscale has been a great endeavor for mankind, which has opened a new horizon in technological applications due to the superior features of nanomaterials compared to their bulk counterparts. Although major breakthroughs in nanotechnology have been accomplished, some areas of this field remain challenging for the widespread application of these materials in everyday life. For example, the organization of nanomaterials to yield hierarchical structures with defined shapes and sizes could generate materials with novel functions derived from the spatial arrangement of the nanometric building blocks. This feature is also essential for the easy integration of nanomaterials with complex circuits and microprocessors, a crucial step for electronic applications such as sensors and solar cells. The fabrication in mild conditions such as at room temperature and in aqueous solution would greatly help disseminating the utilization of nanomaterials in real applications, since less energy would be required for the fabrication and less toxic waste generated during the manufacture process, therefore reducing costs and environmental impact related to their synthesis. To address these issues, many scientists have searched for inspiration in biological systems. Living organisms have evolved the capability of growing inorganic nanomaterials with an exquisite control over the shape, size, crystal phase, and three-dimensional arrangement. These biological processes are orchestrated by a battery of biomolecules that act as biocatalytic templates for the synthetic process. Moreover, these biological phenomena take place under mild conditions, that is, at room temperature and in aqueous solution, which are not only advantageous from an economic and ecological standpoint but can also result in the fabrication of materials with improved properties such as defect-free crystals. Usually, a bioinspired route begins from the observation of a natural process and its replication ex vivo, for example, by recreating the fabrication in the presence of biomolecules found to be crucial in the biological synthesis. Subsequently, the synthesis can be refined by generating alterations on the biocatalytic templates via expression of mutant DNA sequences in microorganisms. This approach is particularly advantageous because it allows one to create a vast array of catalytic candidates, whose appropriateness for the fabrication of the target material can be tested with high-throughput methodologies. Furthermore, once a particular template has been recognized, its production can be easily scaled up by selecting the microorganism encoding the biomolecule and making it grow in adequate conditions. Subsequently, the target biomolecule can be isolated by well-known purification protocols. The utilization of biomolecules is not only advantageous for the synthesis of nanomaterials in benign conditions and with desired shapes and sizes; the intrinsic recognition capability of certain biomolecules can be also exploited to target them at particular sites on substrates for their integration with circuits and microprocessors, which is essential for the implementation of nanomaterials in real applications. Finally, bioinspired approaches have been described that mimic the biological mechanism of formation of inorganic materials rather than utilizing biomolecules as biocatalytic templates. Among these, biomimetic approaches for the fabrication of perfectly aligned arrays of nanomaterials, also called mesocrystals, are drawing much attention since the resulting superstructures could show novel physical properties derived from the intrinsic order of the collectives.

In the following sections, the relevance of several biocatalytic templates such as DNA, peptides, and proteins will be outlined and illustrated with key examples. The utilization of cells for the synthesis of nanomaterials as well as other biomimetic approaches for the

fabrication of mesocrystals will also be covered, followed by conclusions and future directions in the field.

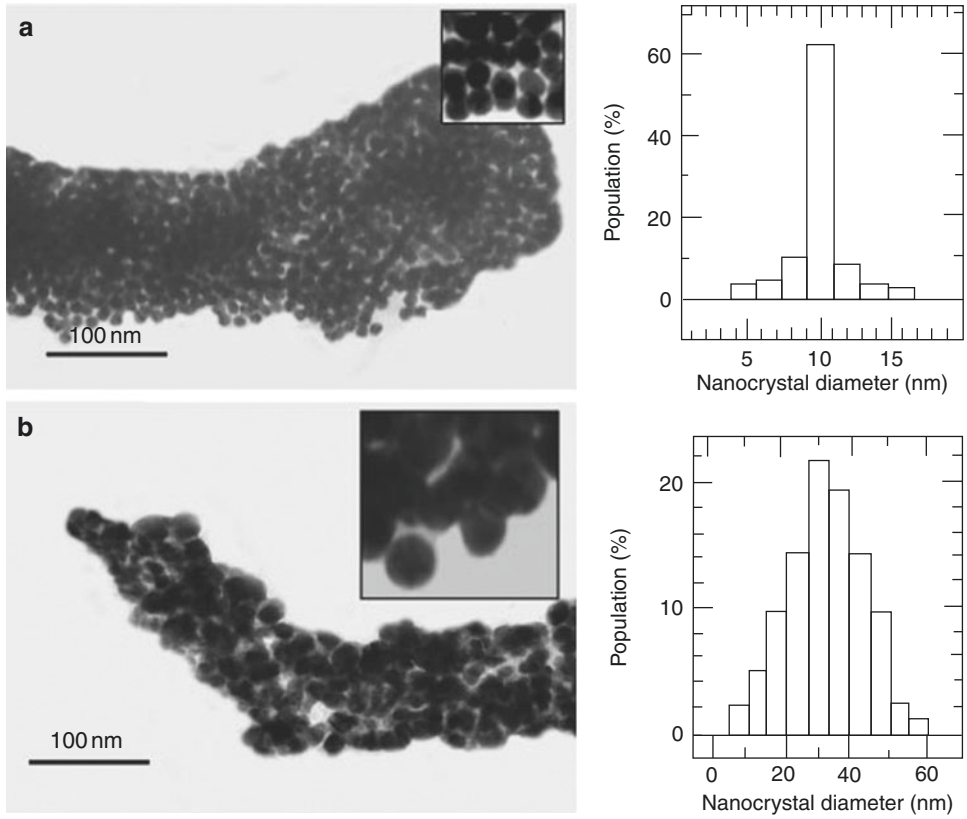
DNA

DNA molecules have been extensively used as templates for the synthesis of nanomaterials due to their inherent biorecognition capabilities and excellent chemical properties for the deposition of metallic and semiconducting materials [1]. The recognition of DNA strands bearing complementary sequences has proved to be extremely useful for the programmable assembly of DNA templates on substrates, which is an important step for the integration of nanomaterials with common technologies. Moreover, the negatively charged phosphate groups of DNA molecules can concentrate metal ion precursors in the vicinity of the template for the selective deposition of materials. In certain cases, the coordination of these metal ions to the bases of DNA can result in the formation of nanocrystals with unique properties. An early example on the advantages of using DNA molecules as templates for the fabrication of nanomaterials can be found in the work of Ben-Yoseph et al. [2]. By immobilizing oligonucleotides bearing a complementary sequence on two adjacent gold electrodes, the positioning of the DNA template was programmed to happen at the gap between the electrodes. Subsequently, silver ions were concentrated in the vicinity of the DNA bridge via electrostatic interactions, and reduction with hydroquinone yielded silver nanowires of 12 μm length that bridged the electrodes. However, the metal nanowires prepared this way showed poor conductivity mainly due to the presence of granules and defects as a consequence of the fast-growth kinetics of metallization in the aforementioned conditions. More recently it was demonstrated that the conductivity of the metal coatings on DNA templates could be greatly improved by first depositing a metal oxide such as PdO and subsequently reducing the intermediate with hydrogen gas [3]. The resulting Pd nanowires are continuous and show higher conductivities (Fig. 1).

Bioinspired Synthesis of Nanomaterials, Fig. 1 Pd nanowires templated by DNA (Reprinted from Nguyen et al. [3], copyright Wiley-VCH Verlag GmbH & Co. KGaA)

Short DNA sequences have proven to be also very useful in the formation of extremely small metal nanoparticles, the so-called metal nanoclusters. When the particle size is further reduced and approaches the Fermi wavelength of electrons, the continuous density of states breaks up into discrete energy levels leading to the observation of dramatically different optical, electrical, and chemical properties compared to larger nanoparticles. For example, Ag nanoclusters are highly fluorescent, and their reduced dimensions compared to quantum dots make them ideal candidates for bioimaging provided that they are soluble in aqueous solution. By using cytosine-rich DNA sequence as templates, Dickson et al. demonstrated the formation of Ag nanoclusters with 2–4 atoms [4]. Contrary to former approaches where the interaction between the negative-charged phosphate backbone and metal ions was the driving force for the selective growth of the material, the sequence of the DNA templates plays a crucial role in the formation of metal nanoclusters. The utilization of biotechnology tools can greatly speed up the screening of DNA sequences that are useful for the fabrication of a particular material. For example, short DNA sequences can be chemically synthesized in a random fashion and spotted on a glass substrate to generate DNA microarrays. After incubation with silver and reduction, the spots containing DNA sequences capable of growing silver nanoclusters can be detected by measuring the

fluorescence of the whole substrate with a scanner. By this methodology, blue-, green-, yellow-, and red-emitting Ag nanoclusters could be synthesized from a DNA library [5].



Peptides

Peptides have proved to be extremely useful tools for the fabrication of nanomaterials [6]. Compared to proteins, they possess shorter sequences, which facilitate their fabrication via synthetic methods. This feature also makes their 3D structure simpler and more predictable when synthesizing de novo sequences. Moreover, when carefully designed, peptides can assemble to yield supramolecular architectures with novel functions. A well-established area in nanomaterial fabrication synthesis is the application of peptides for growing nanocrystals with a particular crystalline structure, shape, and size. The selection of peptide sequences for the fabrication of nanocrystals is usually performed via molecular biology tools such as phage display. In this approach, random DNA sequences encoding peptides are inserted in bacteriophages. When the viruses replicate, they express the peptides on their capsids. Subsequently, the affinity of the peptide for a particular material is tested by applying stringent selection protocols. The peptides with the highest affinity for the target material are tested for the fabrication of nanocrystals in different conditions. Although the mechanism behind this bioinspired approach is not clear yet, it has been demonstrated that the amino acid composition and the 3D arrangement of chemical moieties dictated by the conformation of the peptides are crucial for the fabrication of nanocrystals. For example, Matsui et al. applied peptides with the sequence His-Gly-Gly-Gly-His-Gly-His-Gly-Gly-Gly-His-Gly for the fabrication of Cu nanocrystals on peptide nanotubes [7]. They found that the peptides could undergo a conformational change depending on the pH of the growing solution that could control the size and monodispersity of the resulting nanocrystals (Fig. 2). The same group demonstrated that peptides with the sequence Asn-Pro-Ser-Ser-Leu-Phe-Arg-Tyr-Leu-Pro-Ser-Asp could catalyze the growth of hexagonal Ag nanocrystals. The selectivity for growing a particular shape was provided by the high affinity of the peptide for the face (111) of Ag crystals.

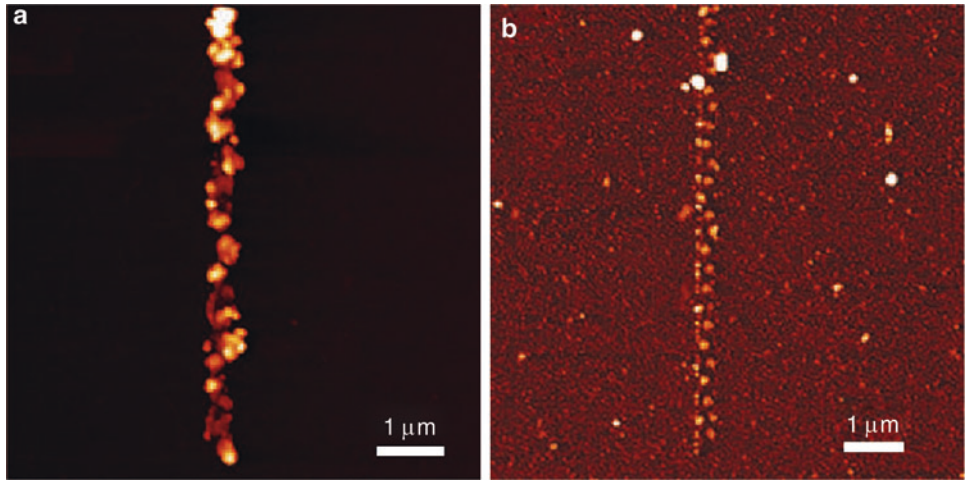
Certain peptide sequences have been reported to self-assemble and yield complex architectures with catalytic functions. For example, peptides derived from naturally occurring leucine-zipper motifs have been described to fold in a coil-coil conformation that can assemble into templates for crystal growth. By changing key amino acids of the primary sequence for thiol-rich cysteine units, the supramolecular peptide aggregates can be used as templates for the fabrication of monodisperse Ag nanoparticles [8]. In another example, the self-assembly of bolaamphiphile peptides resulted in the formation of peptide "nanodoughnuts" that could catalyze the fabrication of Ga_2O_3 [9]. Chemical residues with affinity for the metal ions preconcentrated the precursors inside the cavity of the templates and generated a gallium hydroxide intermediate. The higher hydrophobicity inside the template played a crucial role in the dehydration of the intermediate to yield crystalline Ga_2O_3, a wide bandgap semiconductor of great interest in electronics. These examples highlight the ability of peptide assemblies to work as catalytic templates for crystal growth.

Proteins

When compared to peptides, proteins show a more complex tertiary structure and can perform highly specialized tasks such as catalyzing specific chemical reactions [6]. Therefore, the adaptation of a protein for the synthesis of a nanomaterial can be a very advantageous approach provided that it can be easily purified from natural sources in large amounts. Although the higher degree of complexity seen in proteins makes it more challenging to modify their structure to gain a new function, recent advances in molecular biology have enabled the fabrication of mutants with improved features for the fabrication of nanomaterials. The rich structural variety of proteins can be exploited for the fabrication of

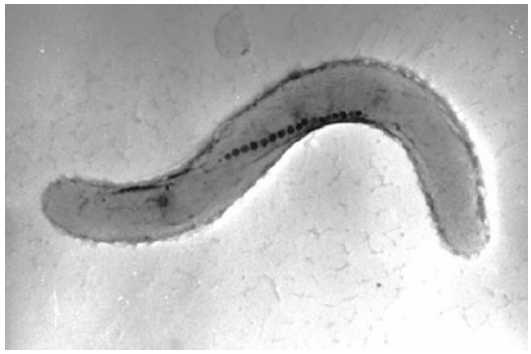
Bioinspired Synthesis of Nanomaterials, Fig. 2 Peptide-templated Cu nanocrystals. [7], copyright The National Academy of Sciences of the USA)

nanomaterials with desired shape and dimensions when these proteins act as template for the synthetic process. For example, the protein ferritin is formed by 24 subunits that generate a cavity with a diameter of 7 nm. In cells, it contains iron crystallites and hence serves as an important intracellular iron storage unit. In vitro, iron-free ferritin (apoferritin) can be loaded with metal ions to generate nanoparticles of materials such as iron and cobalt oxide, which grow inside the cavity with uniform size and shape. This feature is especially advantageous compared to classical methods for nanoparticle synthesis, since in the absence of a template it is difficult to predict the final shape and size of the nanocrystals. For instance, in the fabrication of nanoparticle-based floating gates, it is crucial that all the building blocks have a precise size, shape, and surface density. These requirements could be met by synthesizing CoO_3 nanoparticles in apoferritin and immobilizing the protein-covered nanocrystals on the device via programmed electrostatic interactions [10]. The resulting floating gate memory showed excellent charge capacity, long charge retention, and stress resistance. Moreover, it has been demonstrated that the inner cavity of the cage can be modified via genetic engineering protocols to display peptide sequences that have high affinity for a certain metal ion precursor, which paves the way for the utilization of ferritin in the fabrication of nanocrystals of diverse technologically relevant materials.



While protein cages have proved to be extremely useful for the fabrication of nanocrystals, nanostructures with a higher aspect ratio such as nanowires are required for a wide

variety of nanotechnology applications. To address this issue, a fibrillar protein such as collagen could be used as a template for the deposition of metallic or semiconducting materials. However, naturally occurring collagen may not be suitable for this application because the relatively harsh conditions for metallization can affect the conformation of the protein, therefore rendering nanomaterials of polydisperse size. This issue could be overcome by using a collagen-like triple helix protein that is genetically engineered to possess improved stability and rigidity, as well as uniform size. When used as a template for the electroless deposition of gold, the mutant protein could template the fabrication of gold nanowires of monodisperse size with a length of 40 nm and a width of 4 nm [11]. The fabrication of this protein via expression in a host microorganism such as *Escherichia coli* allows one to obtain large quantities of the biomolecular template by simply growing the bacteria and applying well-established protein purification protocols.



An emerging area in bionanotechnology is the adaptation of proteins with biocatalytic activity such as enzymes to the synthesis of nanomaterials because the mild conditions required for the biological catalysis make the manufacturing process more environmentally benign and, in some cases, with less side products. In a pioneering work by Samuelson et al., the enzyme peroxidase was utilized for the synthesis of the conductive polymer polyaniline [12]. In this approach, peroxidase catalyzed the oxidation of the monomer to trigger the polymerization in the presence of a polyelectrolyte template to yield water-soluble, high-molecular-weight polyaniline with minimal parasitic branching. The approach is particularly attractive in that it is simple (one step), uses very mild conditions, and requires minimal separation and purification. Another area that has benefited greatly from the use of enzymes for the fabrication of nanostructures is the room-temperature synthesis of oxide semiconductors. Oxide semiconductors such as ZnO are wide bandgap semiconductors with a myriad of applications in optics, electronics, solar cells, and catalysis. However, the high temperatures required for the fabrication of these materials with conventional methods increase the cost associated to the manufacturing process, which may hamper the widespread application of these materials. This issue could be solved by using the enzyme urease as biocatalytic template for the synthesis of ZnO nanoshells. In this approach, urease converted urea into ammonia and carbon dioxide, and the resulting fine-tuning of the pH at the enzyme-solution interphase could grow highly crystalline ZnO as nanoshells around the protein [13]. When immobilized on a substrate, the enzymatic production of ammonia could be harnessed to produce amorphous intermediates that could be used as ink to be patterned with an AFM tip for a pen in a procedure similar to dip-pen nanolithography [14]. By this technique called Biomimetic Crystallization Nanolithography, ZnO nanocrystals could be patterned on the surface with desired shapes and sizes, which is a crucial step for the integration of nanomaterials with electrical components of circuits and microprocessors (Fig. 3). Moreover, urease could be also applied for the fabrication of other relevant semiconductors such as metal sulfides by harnessing the production of S^{2-} via hydrolysis of thiourea. By this approach, the size, shape, and crystallinity of Ag_2S as a test material could be controlled to be as desired by fine-tuning the activity of the enzyme via inhibition with the metal ion precursor [15].

Cells

The utilization of cells such as bacteria for the fabrication of nanomaterials can be very advantageous since the fast-growth kinetics of these microorganisms in adequate conditions allows one to obtain large amounts of the target material with minimal resources. A well-known example of the application of cells in nanomaterials synthesis is the fabrication of magnetic nanoparticles by magnetotactic bacteria [16]. These microorganisms generate intracellular magnetic particles of iron oxide that allow them to migrate along oxygen gradients by acting as compass needles. Different bacterial strains have been reported to grow these bacterial magnetic particles in different shapes, which can be very advantageous for

obtaining materials with unusual nanostructures (Fig. 4). For example, the *M. magneticum* strains AMB-1 and MGT-1 synthesize cubo-octahedral nanoparticles, whereas *Desulfovibrio magneticus* RS-1 produces irregular bullet-shaped particles. Bacterial magnetic particles also have the great advantage of being synthesized surrounded by an organic membrane, whose main components are phospholipids and proteins. These biomolecules confer better solubility to the particles, which disperse well in aqueous solvents without further surface treatment. Moreover, the biomolecules present at the surface of bacterial magnetic particles show chemical moieties that can be used as anchoring points for their functionalization with a wide variety of molecules such as enzymes and antibodies. Particularly, the amino groups of the phospholipids present at the membrane can be cross-linked to antibodies and oligonucleotides with well-known covalent chemistries, which confer the particles biomolecular recognition capabilities that are useful for medical and diagnostic applications. Alternatively, the protein of interest can be generated during the biological synthesis of bacterial magnetic particles by fusing its gene to proteins known to be present on the membrane of the nanoparticles so that when the bacteria express the resulting fusion protein, it is automatically incorporated on the surface of the nanoparticles during the biosynthesis.

Mesocrystals

Biomineralizing organisms such as sea urchins and marine stars have evolved the capability to generate nanocrystals and arrange them into highly ordered mesoscopic arrangements, also known as mesocrystals [17]. The perfect alignment of the constituent nanocrystals results in similar scattering pattern and behavior in

Bioinspired Synthesis of Nanomaterials, Fig. 5 Scheme of the different mechanisms to grow nanoparticle superstructures or mesocrystals (Reprinted from Song and Colfen [17], copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim)

polarized light to those of a single crystal, although a close look into the ultrastructure reveals the presence of the small constituent nanoparticles. This phenomenon is responsible for the improved mechanical properties of the exoskeleton of crustaceans, and the replication ex vivo for the fabrication of assemblies of perfectly aligned nanocrystals of functional materials is extremely interesting to study the physical properties of nanoparticle collectives. Several mechanisms have pointed out to yield three-dimensional nanoparticle superstructures, as depicted in Fig. 5. One possibility is that crystal growth takes places inside an organic matrix such as a biopolymer, which guides the growth and alignment of the constituent nanocrystals (Fig. 5a). The presence of certain chemical groups with affinity for cationic precursors is important to initiate the nucleation of the nanoparticles inside the matrix and, in some cases, to stabilize a particular face of the crystal and direct the growth in a particular direction. Another possibility is the presence of physical fields as the driving force for nanoparticle aggregation, for example, the spontaneous alignment of dipoles (Fig. 5b). The growth of mesocrystals can also be permitted by the existence of the so-called mineral bridges, that is, the nanoparticles are held together by another inorganic structure in a "brick and mortar" fashion (Fig. 5c). Finally, when growing in a constraint reaction vessel, nanoparticles can be forced to interact and align with each other to reduce the entropy of the system (Fig. 5d). Although these basic rules for the formation of mesocrystals have been successfully replicated ex vivo by the correct choice of crystallization environment such as the presence of a polymer matrix or addition of soluble additives, the exact mechanism of this nanoparticle-mediated crystallization route remains still elusive. For example, nanospheres formed by ZnO nanocrystals oriented along the [001] direction could be obtained by using the polymer poly(vinylpyrrolidone) in a mixture of N,N-dimethylformamide (DMF) and water as a guiding matrix. The coordination of Zn^{2+} to active groups in the polymer and the stabilization of particular crystal planes play a crucial role for obtaining nanocrystal-based superstructures. The resulting porous arrangements of aligned nanocrystals are promising for photonic applications. Moreover, it is possible to fabricate composite thin films via self-assembly of the freestanding spheres by simply coating with the as-prepared suspensions, which facilitates the integration of these hybrid materials with planar devices. Recently, the biomimetic conditions for the fabrication of mesocrystals could be replicated by a novel approach in which a nanopore building block was self-assembled to yield a highly porous matrix. The macrocycle cucurbituril [7]

aggregated in the presence of Ag^+ and the ion-impregnated nanopore assemblies guided the growth of perfectly aligned Ag_2S quantum dots after the addition of S^{2-} to yield a nanoparticle superstructure with a pitch of 0.8 nm. This example represents an exquisite control over the crystallization of this material due to the extremely low solubility of Ag_2S in water, which usually results in the formation of particles of uncontrolled size and poor crystallinity. The key step of the process was to confine the metal ion precursor inside the porous matrix, which controls mass transport via diffusion of the anions through the pores of the assemblies [18]. Recently the enzyme glucose oxidase was utilized to grow mesocrystals containing gold nanoparticles under bioinspired conditions [19]. In this work the enzyme was patterned on a surface as lines separated by sub-micrometric distances. The lines were obtained by patterning the polymer polyethylene glycol with electron beam lithography. The polymer possessed carboxylic acid groups that allowed the covalent attachment of the enzyme on its surface. The enzyme generates hydrogen peroxide that tunes the kinetics of growth of gold nanoparticles. It was found that when the enzyme lines were separated by nanometric distances, the generation of hydrogen peroxide by the enzyme depended not only on the enzyme activity and mass transport but also on the nanoscale organization. This favored bioinspired nonclassical crystal growth conditions in which the nanoparticles grow by aggregation of nanometric building blocks. Clusters containing highly organized gold nanoparticles could be obtained with this method.

Conclusion and Outlook

The utilization of bioinspired approaches in the fabrication of nanomaterials is extremely useful to control key parameters such as size monodispersity, shape, and three-dimensional arrangement. These processes usually take place under mild biological conditions, which is advantageous for reducing costs and environmental impact of the manufacturing process. The utilization of microorganisms as bioreactors, whether to generate the biocatalytic template or to synthesize the target nanomaterial, facilitates the large-scale production due to the rapid growth kinetics of cells in adequate media. Moreover, in certain cases, the intrinsic recognition capabilities of the biomolecule templates can be exploited to locate the biomaterials at target places on substrates, which facilitate their integration with common technologies. While these features have been demonstrated in the last years, challenges in the field still remain. From a fundamental standpoint, it would be desirable to unravel the exact mechanism of formation of nanomaterials in biological conditions. A deeper understanding of the process would allow the formulation of rules for bioinspired synthesis so that the outcome of the manufacturing process is more predictable, and hence the fabrication of the nanomaterial requires less effort. For example, discerning the relationship between sequence and conformation in peptide and DNA templates for the fabrication of nanomaterials with specific shape, size, and polymorph could help designing de novo sequences for the synthesis of another material by applying lessons learnt from previous experiences. Another important step toward the widespread utilization of bioinspired routes would be to demonstrate the fabrication of real devices with the resulting nanomaterials. Although in the last years several key applications have been demonstrated such as the fabrication of floating memories [10] and the design of ultrasensitive sensors for the detection of heavy metal ions via target-specific bioinspired crystallization [20], the integration of nanomaterials obtained by bioinspired routes is still challenging in certain fields. For example, a common problem is that these nanomaterials are usually covered by the biological template. While this can be advantageous for their programmed assembly via biorecognition, the presence of an insulating organic layer can hamper certain applications such as in the fabrication of electronic components of circuits, in which the conductance of the nanomaterials and the electric contact with the circuitry is crucial for the performance of the device. Nevertheless, biocatalytic templates are extremely useful components of the

nanotechnology toolbox that show great potential to change classical routes for the synthesis of nanomaterials to be more environmentally benign and that offer improved control over fey features such as size, shape, and hierarchical organization.

Definition

A biological breadboard (BBB) is a platform that manipulates the adhesion and detachment of anchorage-dependent cells in a spatiotemporal

way, thus ultimately controlling a variety of cell behaviors such as cell migration, cell positioning, cell patterning, etc. The BBB is composed of an array of identical gold microelectrodes microfabricated on a Pyrex glass substrate. The gold microelectrodes are functionalized with arginine-glycine-aspartic acid (RGD)-terminated thiol (RTT) to create "cell-adhesive" surfaces; the Pyrex glass substrate is modified with polyethylene glycol (PEG) to achieve a "cell-repulsive" surface. The BBB manipulates cell adhesion and detachment by spatiotemporally controlling the reductive desorption of n-alkanethiolate self-assembled monolayers (SAMs) on gold with activation potential of -0.90 to -1.80 V. This biological platform can offer a new, versatile tool for studies of cellular dynamics, analogous to a breadboard in electronics.

Overview

Cell adhesion and detachment processes are mediated by complex biomolecules from both sides of the cell-matrix interface, fitting together like the pieces of a three-dimensional puzzle. Only biomolecules with the right shape can be involved in cell adhesion and detachment processes, and even very small changes in the shape may significantly affect cell behavior. When an anchorage-dependent cell adheres to extracellular matrix (ECM) components, integrins are activated; the activated integrins bind target ligands; the bound integrins cluster together by changing their conformation [1]. The cytoplasmic domain of the clustered integrins interacts with focal adhesion (FA) proteins (e.g., talin, focal adhesion kinase, vinculin, paxillin, etc.) to form FAs, followed by actin filament binding [2]. Likewise, cell detachment (or deadhesion) is also essential to many biological phenomena in cell biology (e.g., migration, metastasis, etc.). Cell detachment is known to result from an orchestrated process involving the molecular machinery composed of a host of extracellular, transmembrane, and cytoplasmic proteins.

Cell adhesion and detachment have profound effects on the behavior of anchorage-dependent cells. For example, cell adhesion and detachment are controlling parameters in a variety of biological phenomena such as embryonic development, cancer metastasis, wound healing, etc., and any abnormality in cell adhesion and detachment could lead to serious pathophysiological consequences [1]. The quantitative characterization of cell adhesion and detachment is therefore essential to understand a variety of pathophysiological phenomena.

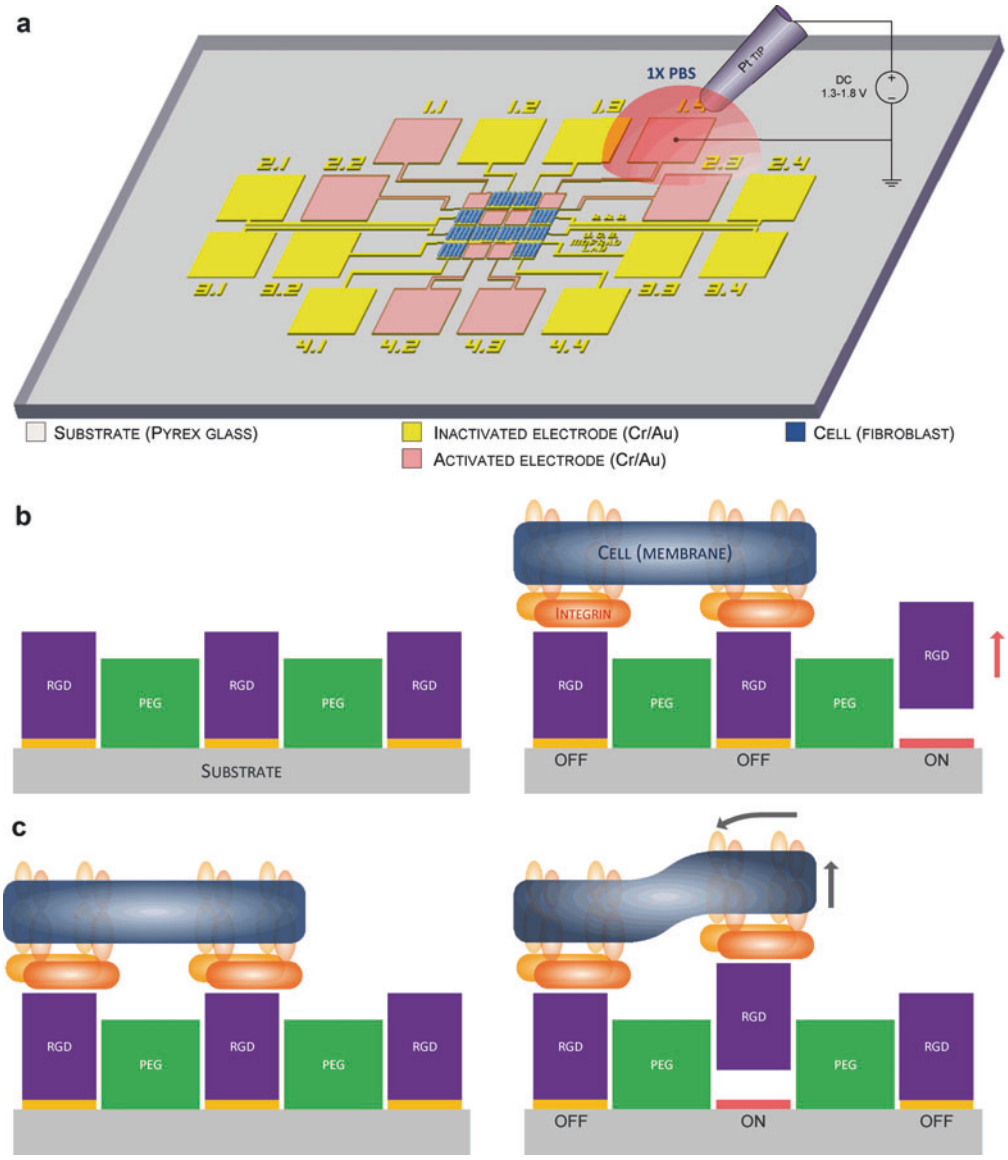
Despite significant progresses over the past decade in characterizing biomolecules and signaling pathways related to cell adhesion and detachment, the biophysical and dynamic details of cell adhesion and detachment still remain elusive and challenging. Thus, diverse experimental methods which are able to characterize cell adhesion or cell detachment have been developed. The previous techniques for cell adhesion characterization can be classified into photolithography [3], e-beam lithography [4], dip-pen lithography [5], nanoimprint lithography [6], microcontact printing [7], elastomeric stencil [8], ink-jet printing [9], optical tweezer [10], electrophoresis [11], and switchable surface [12]. Although the conventional lithography techniques (i.e., photolithography, e-beam lithography, dip-pen lithography, and nanoimprint lithography), microcontact printing, elastomer stencil, and ink-jet printing technologies successfully characterized cell adhesion using specific proteins, they manipulated not cell adhesion but cell positioning. In terms of design flexibility, they altered cell adhesion only at the beginning of microfabrication and were not involved in cell detachment characterization. The optical tweezer and electrophoresis had a possibility of protein denaturation and cell electrolysis, respectively. The biocompatibility of the switchable surface was questionable. The existing techniques for cell detachment characterization can be categorized into hydrodynamic shear force assay [13, 14], centrifugal assay [15], and micropipette aspiration [16]. The hydrodynamic shear force assay was designed to characterize cell detachment with parallel, rotational, or radial flow. Although this method was able to quantify cell detachment with a wide range of shear force, it had several inherent drawbacks of cell rupture

during experiment and considerable local deformation of the cells. The centrifugal assay provided a relatively low centrifugal force for cell detachment, thus restricting its application to anchorage-dependent cells which were either cultured for short term (i.e., less than 1 h) or coupled with weak cell-to-substrate interactions. The micropipette aspiration also resulted in rapid cytoskeletal remodeling during experiment due to the direct contact between anchorage-dependent cell and micropipette. Recently, the electrochemical techniques have been developed to solve the problems of the previous approaches such as protein denaturation, cell electrolysis, local deformation, direct contact, etc. Together with microcontact printing technique, the reductive desorption of gold-alkanethiol SAM was used to quantify cell adhesion [17]. The success of this method was, however, restricted to only cell adhesion characterization at a cellular level and was involved in complicated preparation processes. The electrochemical reaction of several polyelectrolytes was also proposed to study cell adhesion as well as cell detachment [18]. The multiple deposition of the polyelectrolytes on a substrate and even on cells of interest disturbed experimental results due to unintended changes in the cells. The shortcomings of previous approaches, described above, motivate us to develop a promising biological platform for the quantitative analysis of cellular dynamics, similar to a breadboard in electronics.

A biological breadboard is developed for spatiotemporal manipulation of cell adhesion and detachment at cellular and subcellular levels. The BBB, inspired by an electrical breadboard, has the following features in characterizing cellular dynamics related to cell adhesion and detachment: addressability, multifunctionality, reusability, and ease of use. The BBB has addressability in manipulating cell adhesion and detachment due to its exquisite structure, that is, an array of independently operated gold microelectrodes microfabricated on a Pyrex glass substrate; the BBB is used to carry out a variety of biological characterizations (e.g., cell positioning, cell patterning, cell motility control, changes in material properties, etc.) related to cell adhesion and detachment; the electrochemistry involved in the BBB (reductive desorption of gold-thiol SAM) makes the BBB reusable; the BBB is easily incorporated with other conventional instruments such as optical, fluorescent, and confocal microscopes. Moreover, the BBB provides anchorage-dependent cells with microenvironment (RGD peptide) that is as similar as possible to in vivo microenvironment. This biological platform therefore makes it possible to characterize the adhesion and detachment of *living* and *intact* cells, thus meeting with solid and reliable results in cellular dynamics.

Structure and Working Principle

The BBB consists of an array of identical gold microelectrodes patterned on a Pyrex substrate, which secures a high degree of freedom in programmably manipulating cell adhesion and detachment, as shown in Fig. 1a. The gold microelectrodes and Pyrex substrate are modified with RTT and PEG, respectively. The RTT functionalization on the gold microelectrodes is to make cell-adhesive surfaces by tethering RGD peptide to the microelectrodes via thiol compound, following the spontaneous chemisorption



$$\mathrm{R-S-H+Au \rightarrow R-S-Au+1/2H_2} \quad (1)$$

where R is a substituent [19]. The RGD-ligand provides a binding site to integrins in cell adhesion process. The PEG treatment on the Pyrex substrate is performed to achieve a cell-resistive surface where the hydrated neutral PEG chains repulse cells sterically.

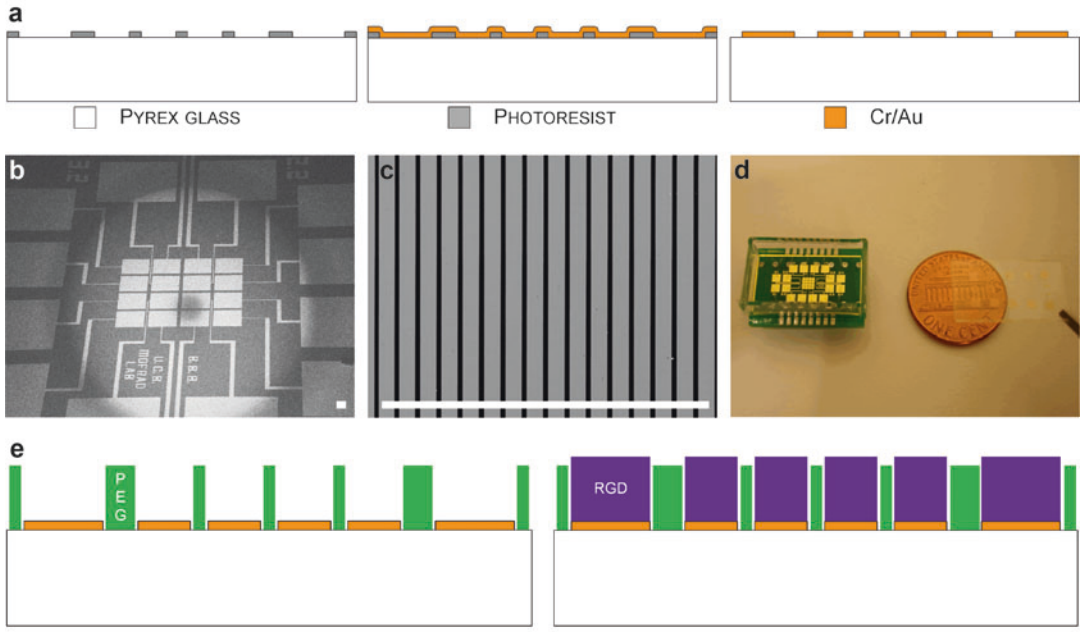
A spatiotemporal manipulation of cell adhesion is implemented by selectively detaching the RGD (and even an anchorage-dependent cell) from the gold microelectrodes with negative potential of -0.9 to -1.6 V, following the electrochemical reaction [20]

$$\mathrm{R-S-Au+H^+ + e^- \rightarrow R-S-H+Au.} \quad (2)$$

After the surface modifications, the RTT on a target area is detached by activating a

Biological Breadboard Platform for Studies of Cellular Dynamics, Fig. 1 A biological breadboard for spatiotemporal manipulation of cell adhesion and detachment at cellular and subcellular levels. (**a**) A schematic of the BBB consisting of a gold microelectrode array patterned on a Pyrex surface. The addressability, multifunctionality, reusability, and ease of use of the BBB are due to its exquisite structure and working principle. (**b**) Spatiotemporal manipulation of cell adhesion. Before cell adhesion (*left*), an RGD peptide is bound to all gold microelectrodes through RTT functionalization, whereas no cell adhesion site is formed on the Pyrex surface treated with PEG. On cell adhesion (*right*), the RGD peptide on a target microelectrode (third electrode from *left*) is detached from the target microelectrode with activation potential, followed by cell seeding. The loaded cells adhere only to inactivated microelectrodes (first and second electrodes from *left*) through RGD binding to integrin. (**c**) Spatiotemporal manipulation of cell detachment. Before cell detachment (*left*), cells adhere to the gold microelectrodes functionalized with RTT through RGD binding to integrin. On cell detachment (*right*), the cells or one part of the cell adhered to a target microelectrode (second electrode from *left*) is detached by activating the target electrode with activating potential which leads to the reductive desorption of gold-thiol SAM. The detached cells or one part of the cell retracts spontaneously

corresponding gold microelectrode with electrical potential, followed by sonication in cell culture media for 3 min and cell seeding. The loaded cells adhere only to the inactivated (still, RTT functionalized) gold microelectrodes (Fig. 1b), because the cells have substantially more affinity for cell adhesion to the RGD on the inactivated microelectrodes than to the gold of the activated microelectrodes and to the Pyrex glass substrate modified with PEG. The spatiotemporal manipulation of cell detachment is the same as that of cell adhesion except the sequential order of microelectrode activation and cell loading. For the spatiotemporal manipulation of cell detachment, the surfaces of the BBB are also modified with PEG and RTT, followed by cell seeding. The loaded cells graft and stretch to the RGD on gold microelectrodes. On cell detachment, cells or one part of the cell is detached (for subcellular detachment) from the BBB by activating a target microelectrode, and then the detached cell or cytoskeletal layer spontaneously retracts because chemical bonding between gold and thiol is broken by activation potential, as shown in Fig. 1c. When the detached cells or one part of the cell senses no external mechanical anchorage (focal adhesions), it begins to experience the liquefaction (i.e., gel–sol transition) of the cytoskeletal layer which accompanies cellular retraction by changing the length of actin filaments. This is how the BBB manipulates cell adhesion and detachment in a spatiotemporal way.



Materials and Methods

Microfabrication Process

The BBB was fabricated on a 4-in. Pyrex glass wafer with a thickness of 500 μm. After piranha cleaning with 1:1 (v:v) 96 % sulfuric acid (H_2SO_4) and 30 % hydrogen peroxide (H_2O_2) for 10 min, 1 μm-thick LOR resist (LOR 10A, MicroChem Corp.) was spin coated at 4000 rpm for 40 s, followed by soft baking at 170 °C for 5 min. A 2 μm-thick positive photoresist (S1818, Rohm and Haas Corp.) was spin coated on the LOR resist at 4000 rpm for 40 s for double-layer resist stack, followed by soft baking at 110 °C for 1 min. An optical lithography was done to micropattern the double-layer resist stack before e-beam evaporation process, as shown in Fig. 2a (left). The next was a deposition of 5 nm-thick chromium (Cr) adhesion layer and 100 nm-thick gold (Au) layer on the wafer, as shown in Fig. 2a (center). Because optical transparency in the visual spectrum is essential to make the BBB incorporate with other biological instruments (e.g., inverted optical and fluorescent microscopes), the Au layer thickness was reduced to 30 nm for experimental measurement [see Fig. 2d (right)]. Next, the Cr/Au-deposited wafer was immersed in an organic solvent mixture (BAKER PRS-3000 Stripper, Mallinckrodt Baker, Inc.) at 80 °C for 4 h to lift off the double-layer resist stack, thereby achieving two kinds of BBBs, as shown in Fig. 2a (right). One is for cell adhesion and detachment at a cellular level, each microelectrode of which is 500 μm in length and 500 μm in width, as shown in Fig. 2b. The other is for cell adhesion and detachment at a subcellular level, each gold microline of which is 10 μm in width and 3 μm in gap between two neighboring gold microlines, as shown in Fig. 2c. The microfabricated BBB was wire bonded in a chip carrier and then assembled with a cell-culture well made of polystyrene, as shown in Fig. 2d.

PEG Treatment on Pyrex Surface

Before PEG treatment, the microfabricated BBB was cleaned with an oxygen plasma chamber (PM-100 Plasma Treatment System, March Plasma Systems, Inc.) at 100 W for 30 s. The BBB was then incubated with 2 ml m-PEG silane (2 % v/v, Gelest, Inc.) and 1 ml hydrochloric acid (HCl, 1 % v/v, Fisher Scientific) dissolved in 97 ml anhydrous toluene (Fisher Scientific) for 2 h, as shown in Fig. 2e (left). This process was carried out in a nitrogen purge glove box to avoid atmospheric moisture. The incubated BBB was sequentially rinsed in fresh toluene and ethanol, dried with nitrogen, and cured at 120 °C for 2 h. The surface-modified BBB was stored in a vacuum desiccator until the next surface modification, RTT functionalization on gold surface.

Biological Breadboard Platform for Studies of Cellular Dynamics, Fig. 2 Microfabrication and surface modification of the BBB. (**a**) The BBB is fabricated by patterning an array of gold microelectrodes on a Pyrex substrate through patterning of photoresist by lithography (*left*), deposition of Cr and Au layers by e-beam evaporation (*center*), and patterning of the deposited Cr/Au layer by lift-off (*right*). (**b**) BBB for cell adhesion and detachment manipulation at a cellular level, each microelectrode of which is 500 μm in length and 500 μm in width. (**c**) BBB for cell adhesion and detachment manipulation at a subcellular level, each microelectrode of which is 10 μm in width and 3 μm in gap. (**d**) Photograph of the BBB before (*right*) and after (*left*) assembly, showing its transparency in the visual spectrum. (**e**) Surface modification process. The BBB is incubated with PEG solution to make the Pyrex surface cell repulsive (*left*), and then it is incubated with synthesized RTT solution to make gold microelectrodes cell adhesive (*right*). Scale bars of (**b**) and (**c**) are 100 μm

RTT Functionalization on Gold Surface

The gold microelectrodes of the BBB were functionalized with RTT whose solution was synthesized by chemically combining *cyclo* (Arg-Gly-Asp-D-Phe-Lys) ($C_{27}H_{41}N_9O_7$, Peptides International, Inc.) with dithiobis (succinimidyl undecanoate) ($C_{30}H_{48}N_2O_8S_2$, Dojindo Molecular Technologies, Inc.) as follows. The 3.02 mg *cyclo* (Arg-Gly-Asp-D-Phe-Lys) was dissolved in 5 ml dimethoxysulfoxide (DMSO, Sigma-Aldrich) to get 1 mM aliquot and stored at −20 °C. This reaction was made in a nitrogen purge glove box to protect the RGD peptide from exposure to atmospheric moisture. The 3.14 mg dithiobis(succinimidyl undecanoate) was also dissolved in 5 ml DMSO and then stored at −20 °C. This preparation was also done in moisture-free environment. Before a gold surface functionalization, both aliquots were warmed to room temperature in a desiccator. The 5 ml RGD peptide aliquot was mixed with 50 μl triethylamine (1 % v/v, Fisher Scientific) for 5 min to make all primary amines of a lysine amino acid unprotonated. The 5 ml dithiobis (succinimidyl undecanoate) was added to the 5 ml RGD peptide aliquot and then mixed well using a vortex mixer for 4 h to synthesize RTT solution. For the gold surface functionalization, the PEG-treated BBB was incubated with the solution for 1 h at room temperature to promote a spontaneous chemisorption between thiol and gold, followed by sonification in DMSO for 3 min, and rinsed in ethanol and phosphate-buffered saline (PBS, Sigma-Aldrich) to eliminate

all unbound RTTs from the gold surface, as shown in Fig. 2e (right). The thiol exposed to gold achieved a SAM which tethered an RGD peptide to the gold surface.

Contact Angle Measurement

The contact angles of a PEG-treated Pyrex surface and an RTT-functionalized gold surface were measured with a contact angle measurement system (KRÜSS582, KRÜSS), a goniometer. A sessile drop mode was used to estimate the wetting properties of the above two solid surfaces. The contact angle was averaged from 10 measurements. The contact angle of PEG-treated Pyrex surface was compared to that of pure Pyrex surface, and the contact angle of RTT-functionalized gold surface was compared to those of bare gold surface and thiol-treated gold surface.

X-ray Photoelectron Spectroscopy (XPS) Sample Preparation and Characterization

An XPS survey scan was used to confirm the existence of RGD peptide linked to a gold surface via thiol after RTT functionalization. An XPS sample was prepared on a 4-in. silicon wafer e-beam evaporated with 5 nm Cr adhesion layer and 50 nm Au layer. This wafer was immersed for 2 h in the prepared RTT solution for the RTT functionalization on a gold surface. A bare gold sample without RTT functionalization was run as a control experiment. The XPS analysis was carried out with a customized ESCA (Omicron NanoTechnology) at 1×10^{-8} Torr, and all measured spectra were referenced to the position of the Au 4*f* peaks. The scan was collected over a range of 20 eV around the peak of interest with pass energy of 23.5 eV.

Potentiodynamic Electrochemical Characterization of Reductive Desorption of Gold-Thiol SAM

A silicon wafer e-beam evaporated with 5 nm-thick Cr and 50 nm-thick Au was functionalized with RTT to prepare a cyclic voltammetry (CV) sample. This RTT-functionalized gold microelectrode was used as a working electrode while platinum and Ag/AgCl electrodes were used as counter and reference electrodes, respectively. A voltage supplied by a DC power source (B&K Precision Corporation, Yorba Linda, CA) was applied between the gold-thiol SAM (or Ag/AgCl electrode) and the platinum electrode. The CV was carried out in a Dubecco's phosphate-buffered saline solution [DPBS (pH 7.4), Sigma-Aldrich, St. Louis, MO] with an EG&G potentiostat model 362 (AMETEK Princeton Applied Research, Oak Ridge, TN). A scan started cathodically from 0.0 to −2.0 V, then annodically back to 0.0 V at a scan rate of 50 mV/s.

Cell Culture

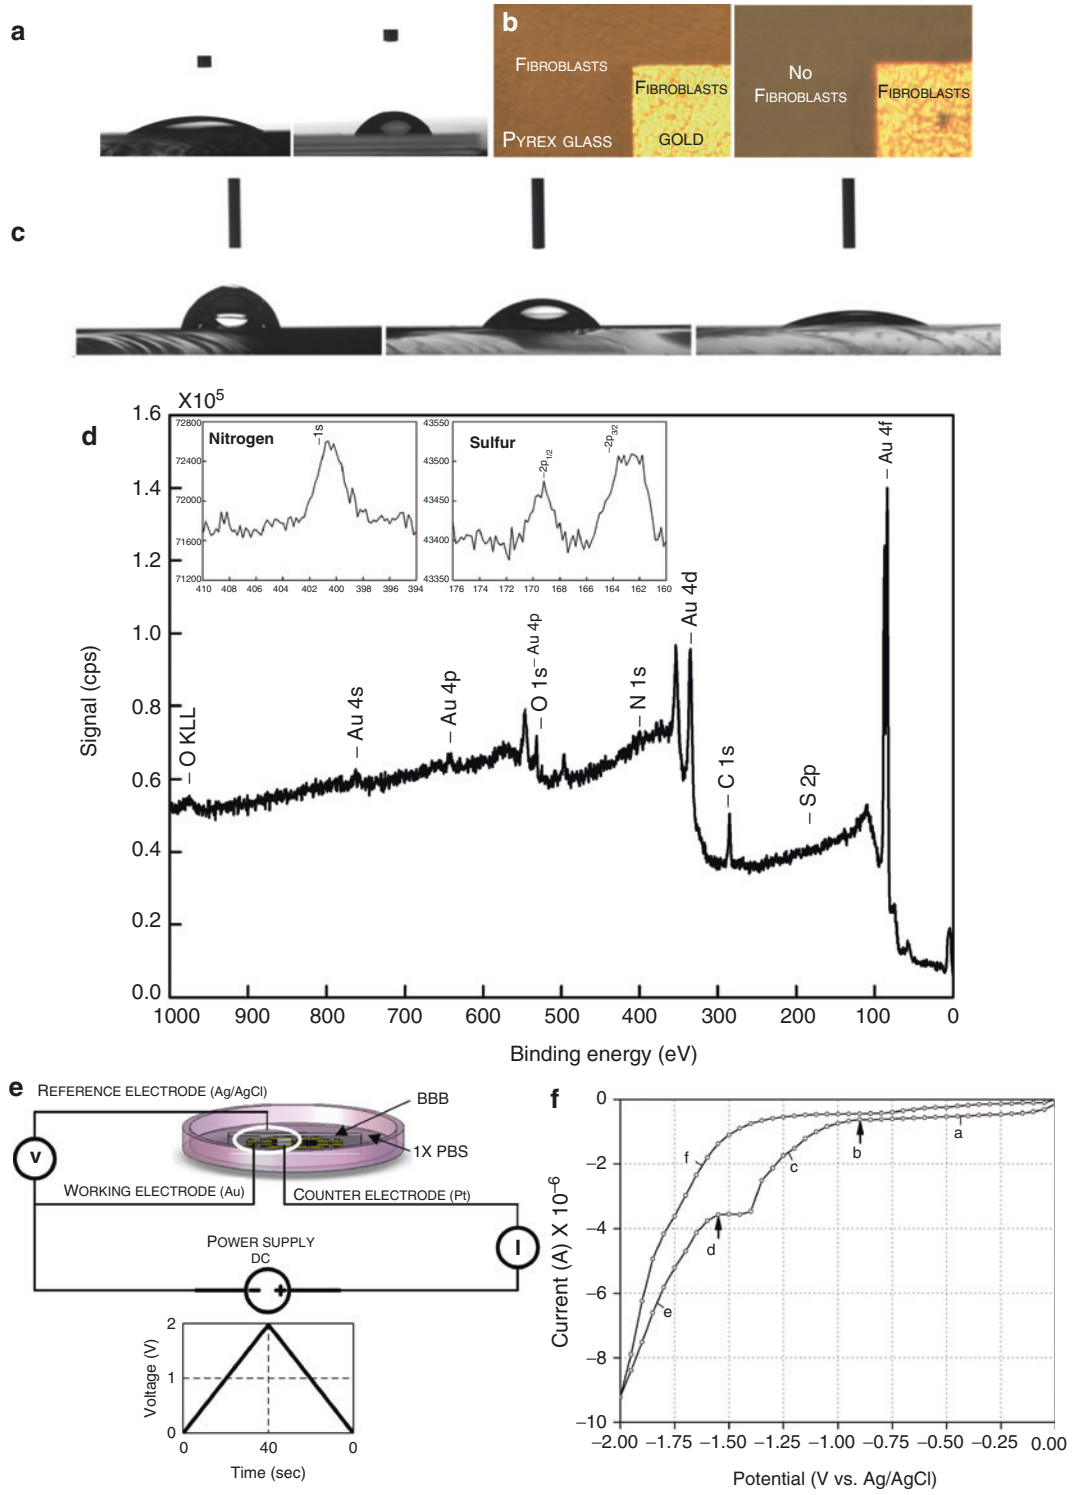
NIH 3 T3 mouse embryonic fibroblast cell (NIH 3 T3 fibroblast) was cultured in Dulbecco's modified eagle medium (DMEM, GIBCO™) supplemented with 10 % fetal bovine serum (FBS, GIBCO™) and 1 % Penicillin-Streptomycin (GIBCO™) at 37 °C in humidified 5 % CO_2 atmosphere. The cell was passaged every 4 days as follows. The cell was washed 1 time in PBS and 1X trypsinized with Trypsin-EDTA solution 0.5 %. After centrifuging the cell, it was inoculated into a new Petri dish. The NIH 3 T3 fibroblasts with a passage number of 5–20 were used in the experiments. Before experiment, the surface-modified BBB was sterilized with 70 % ethanol, washed twice with 1X PBS, and placed into a Petri dish containing 5 ml cell culture medium with a cell suspension of about 1×10^6 cells/ml. For the subcellular detachment experiments, the cell concentration was changed into 1×10^6 cells/ml. After 1 h, unattached NIH 3 T3 fibroblasts were removed by additional wash in PBS, followed by cell culture medium replacement. All experiments were carried out 24 h after cell seeding in a self-designed chamber with humidified 5 % CO_2 atmosphere and at 37 °C.

AFM Indentation

The elastic strength of the motile cytoskeletal layer (retracting after subcellular detachment) of NIH 3 T3 fibroblasts was measured with an Autoprobe CP AFM (Park Science Instruments). All measurements were made at a low indentation speed of 10 nm/s to minimize a viscous damping

effect by a dashpot of the motile cytoskeletal layer in quantifying the elastic strength with AFM. The elastic modulus of the motile cytoskeletal layer was determined from the measurement on the deflection of an AFM microcantilever (HYDRA2R-100 N, Nanoscience Instruments, Inc.) at each measurement point of interest, located on the cytoskeletal layer. Although a nominal spring constant of the AFM microcantilever was 0.011 N/m, the spring constant of the AFM microcantilever was measured as 0.016 ± 0.005 N/m, which was used in calculating the elastic modulus of the motile cytoskeletal layer with AFM.

Key Research Findings



Verification of Surface Modifications

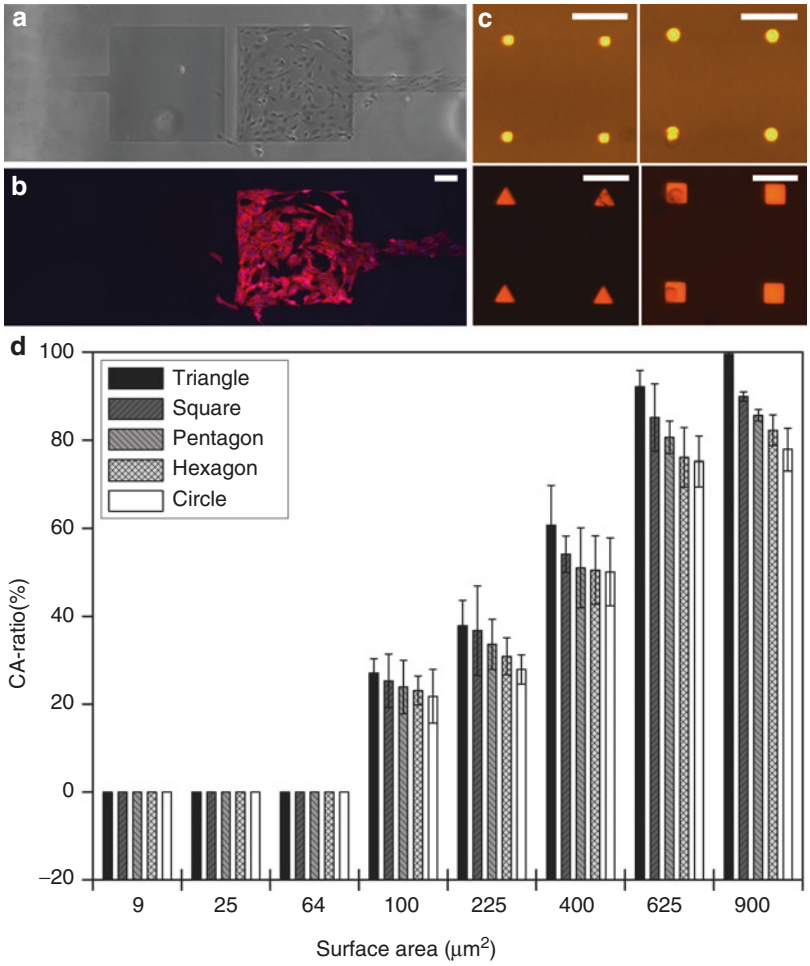
The surface modifications were verified by two methods – contact angle measurement and XPS survey. The contact angle of the PEG-treated Pyrex surface measured by a goniometer was 61.5 ± 3.8° (averaged from 10 measurements), whereas that of the untreated Pyrex surface was 25.7 ± 1.5°, as shown in Fig. 3a. This shows that a PEG-treated surface has strong hydrophobicity and consequently prevents cell adhesion and protein fouling. An NIH 3 T3 fibroblast load test was also made, as shown in Fig. 3b. The images obtained 24 h after cell seeding show the Pyrex surface is modified into cell-resistive through PEG treatment. To characterize the RTT functionalization, a contact angle was measured for bare gold, thiol-treated gold, and RTT-functionalized gold, each of which was 67.3 ± 2.5°, 53.3 ± 1.3°, and 24.6 ± 2.8°, respectively, as shown in Fig. 3c. This confirms the RTT functionalization is made as designed. The experimental results verify that our surface modifications are effective to achieve cell-repulsive and cell-adhesive surfaces in the BBB.

After RTT functionalization on gold surface, the existence of RGD linked to gold microelectrodes via thiol was also demonstrated by an XPS survey scan. A measured XPS survey spectrum of RGD/thiol/Au interface, as shown in Fig. 3d. The peaks of Au 4 *s*, Au 4*p*, Au 4*d*, and Au 4*f* indicate the presence of e-beam evaporated gold (Au(111)); the peaks of S $2p_{1/2}$ and S $2p_{3/2}$ (right inset) show that sulfur from thiol is in existence on the surface; the peaks of C 1 *s*, O 1 *s*, O *KLL*, and N 1 *s* (left inset) demonstrate that there are carbon, oxygen, and nitrogen from amine functional group ($–NH_2$) and carboxylic acid functional group (–COOH) of an RGD peptide. For reference, hydrogen was not detected due to XPS working principle. This XPS survey spectrum verifies that the RTT functionalization on the gold microelectrodes is well made as designed.

Reductive Desorption of Gold-Thiol SAM

The rapid desorption of a gold-thiol SAM under activation potential was also characterized with CV using a three-electrode system where the gold microelectrode (of the BBB), a platinum electrode, and an Ag/AgCl electrode work as a working electrode, a counter electrode, and a reference electrode, respectively, as shown in Fig. 3e. The measured CV shows the current measured at the working electrode as a function of applied voltage with respect to the Ag/AgCl electrode, as shown in Fig. 3f. At a potential range of 0.00 to −0.90 V (section a), the measured current was negligible, which means there is no reductive desorption of the SAM and consequently the SAM impedes electron transfer across an electrolyte-electrode interface. When the applied voltage increased (section c), the reductive desorption of the SAM started and finished at a potential of −0.90 V (point b) and −1.55 V (point d) respectively, breaking the chemical binding between thiol and gold. The reductive desorption of the SAM got maximized at a peak of −1.40 V. After finishing the rapid desorption of the gold-thiol SAM (sections e and f), the gold microelectrode worked as a resistor. This electrochemical result shows the activation potential needs to be larger than −0.90 V. This CV brings forward an indisputable evidence of the reductive desorption of the gold-thiol SAM and also demonstrates the negative bias potential is required to detach the RGD peptide from the gold microelectrode.

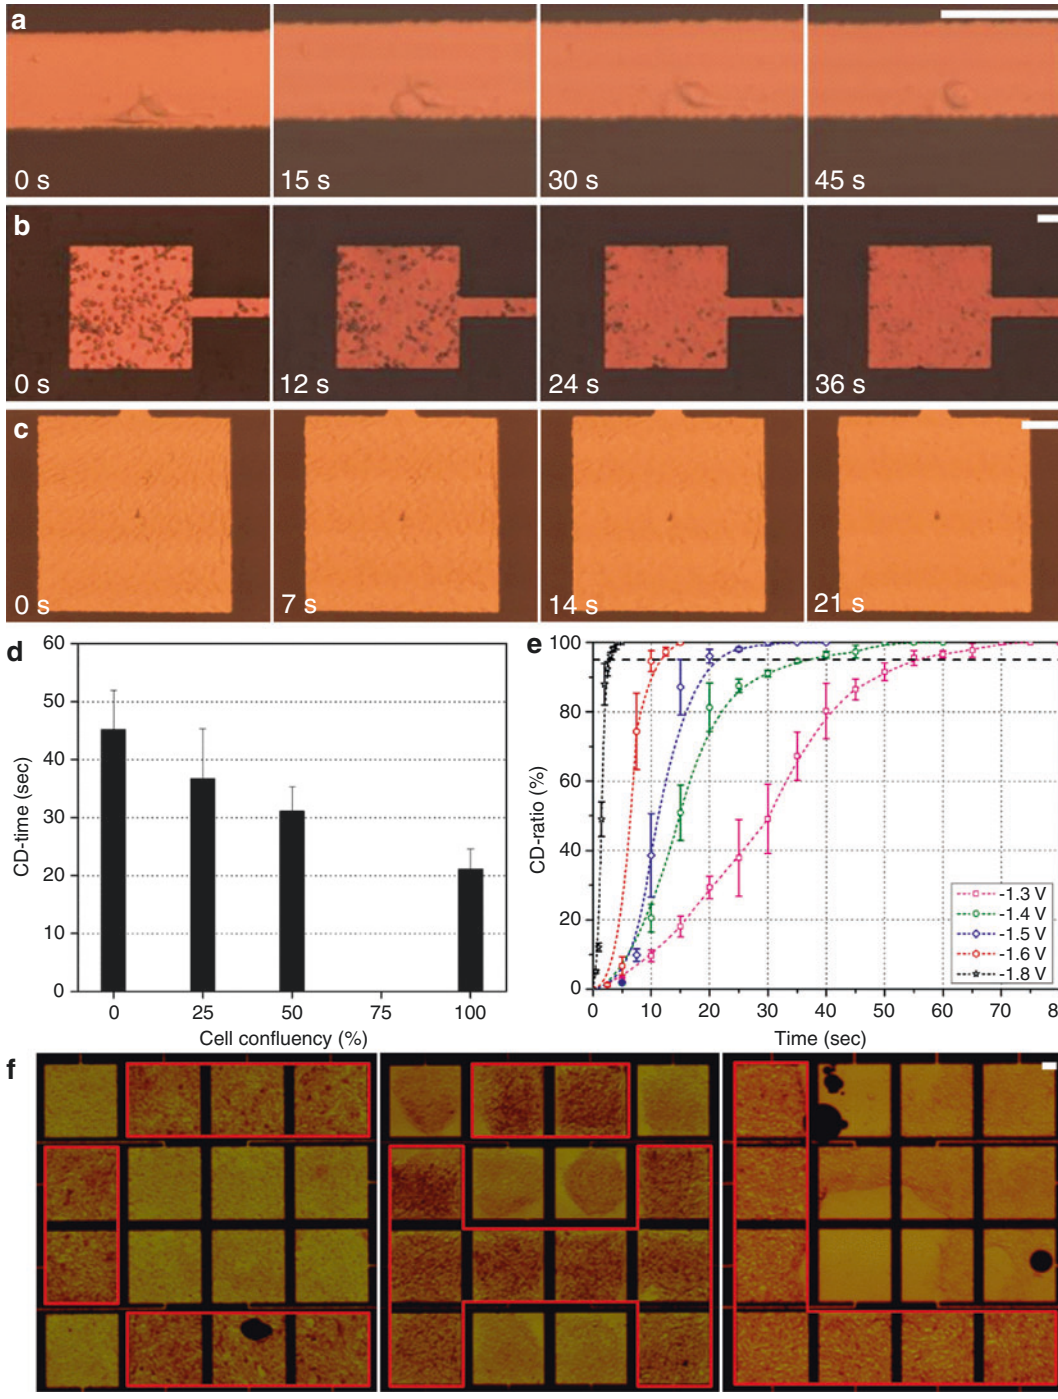
(**a**) Contact angle of the Pyrex surface before (*left*) and after (*right*) PEG treatment. The contact angle is



Cell Adhesion Manipulation

The adhesion of an anchorage-dependent cell (i.e., NIH 3 T3 fibroblast) was spatiotemporally manipulated with the surface-modified BBB composed of two-by-one gold microelectrodes where a left microelectrode was activated with activation potential of −1.20 V but a right one was inactivated. The BBB was then sonificated in a cell culture media and NIH 3 T3 fibroblasts loaded. An anchorage-dependent cell in general has much higher affinity for RGD peptide than gold and Pyrex glass when a cell makes adhesion to a substrate. The loaded cell therefore adheres only to the right electrode, as shown in optical and immunofluorescent images (Fig. 4a, b). The result demonstrates the BBB's addressability in cell adhesion manipulation. Next, the dependence of cell adhesion at a single cell level on the size and geometric shape of a gold microelectrode was studied to determine the geometry of the gold microelectrode for subcellular detachment. Forty types of gold microelectrode arrays were prepared, as shown in Fig. 4c. Each array was designed to have 25 identical gold surfaces whose size was 9 μm^2, 25 μm^2, 64 μm^2, 100 μm^2, 225 μm^2, 400 μm^2, 625 μm^2, or 900 μm^2 and their shape was an n-sided regular polygon ($n = 3,\ 4,\ 5,\ 6,\ \infty$ (circle)). NIH 3 T3 fibroblasts were loaded into the surface-modified assays at a cell suspension concentration of 1×10^6 cells/ml. As an index for quantifying cell adhesion at a single cell level, a CA-ratio which is the ratio of the number of gold microelectrodes with cell adhesion to the total number of gold microelectrodes was measured as a function of the size and geometric shape of a gold surface, as shown in Fig. 4d. The measured CA-ratio provides the following facts. First, the CA-ratio in a single cell level is proportional to the size of a gold microelectrode, and the minimum size of a gold microelectrode for single cell adhesion is the diameter of a cell in a floating state (10 μm for NIH 3 T3 fibroblast). Secondly, a cell wants to make its adhesion on the circumferential zone of a gold microelectrode rather than the central zone.

Cell Detachment Manipulation at a Cellular Level



The cell detachment dynamics at a cellular level was characterized by disconnecting an entire living cell from substrate with the BBB. The cell detachment experiments were carried out for three cases: two fibroblasts (see Fig. 5a), sparse fibroblasts with about 25 % confluence (see Fig. 5b), and confluent fibroblasts with 100 % confluence (see Fig. 5c). The experiments at cellular and subcellular levels were performed at the same experimental conditions and apparatus as those of cell adhesion experiment. As an evaluation index for cell detachment at a cellular level, a time required to detach 95 % of the adhered fibroblasts (CD-time) was measured. The three cases had the CD-times of 45.2 ± 6.8 s, 36.7 ± 8.7 s, and 21.1 ± 3.5 s (averaged from at least 10 measurements) respectively at an activation potential of −1.50 V, showing more confluent cells have shorter CD-time, as shown in Fig. 5d. This is because all cells in confluent culture are connected to each other through cell-to-cell interaction. The detachment of one cell allows the neighboring cells to be easily detached by providing an external vertical force to them. The detached cell seems to

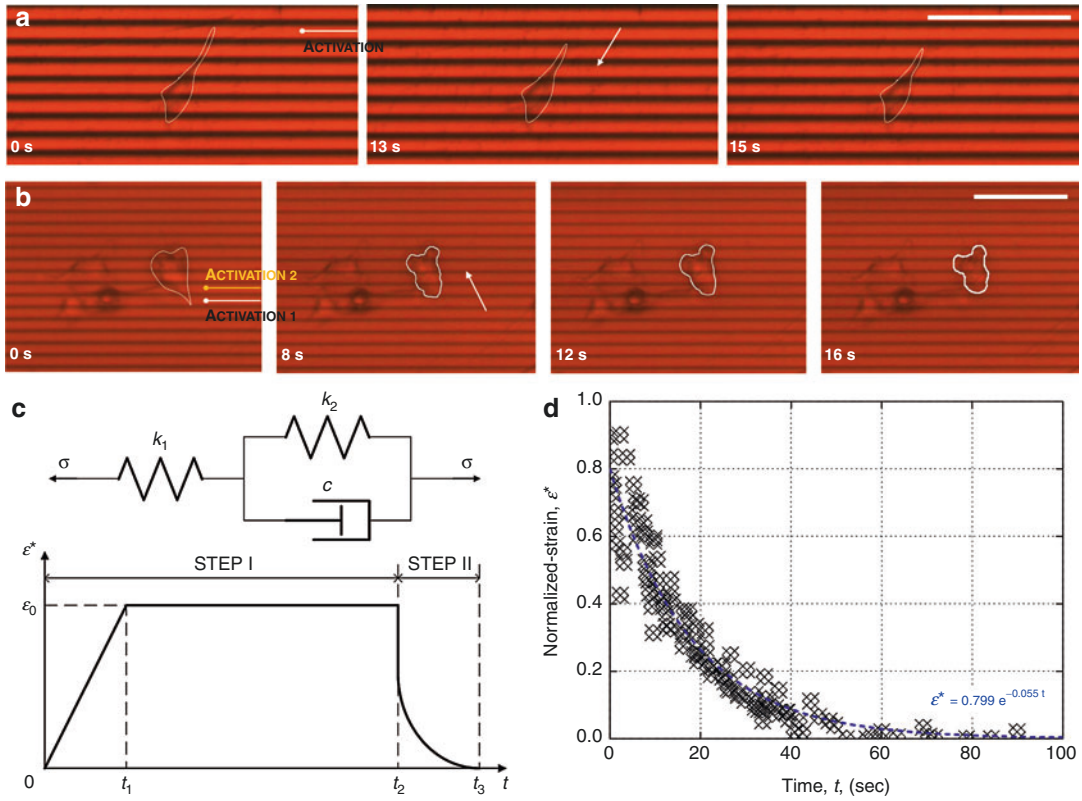
The spatiotemporal manipulation of cell adhesion is demonstrated with a two-by-one BBB where a left electrode is activated but a right one is inactivated. (**b**) Immunofluorescent image. NIH 3 T3 fibroblasts are stained for actin with rhodamine phalloidin (*red*) and for cell nucleus with DAPI (*blue*). (**c**) Cell adhesion as a function of the shape and size of gold microelectrode. No cell adhesion is made on 64 μm^2-sized square gold microelectrodes (first from *left*) with the cell suspension of 1×10^6 cells/ml; cell adhesion is made on 25 % of 100 μm^2-sized regular hexagonal gold microelectrodes (second); cell adhesion is made on 25 % of 225 μm^2-sized equilateral triangular gold microelectrodes (third); cell adhesion is made on 50 % of 400 μm^2-sized square gold microelectrodes (fourth). (**d**) CA-ratio as a function of the size and geometric shape of gold microelectrodes. Scale bar of (**b**) is 100 μm, and those of (**c**) are 50 μm

continue to communicate with the neighboring cells through cell-to-cell interaction. The effect of activation potential on cell detachment was also investigated by counting the ratio of detached cells to total cells (i.e., CD-ratio) as a function of activation time and potential, as shown in Fig. 5e. The CD-ratio gets decreased as activation potential gets increased due to the reductive desorption of gold-thiol SAM which gets faster as negative potential gets increased (see Fig. 3f). The CD-ratio monotonically increases with two inflection points, s-shape curve, which clearly demonstrates there is a large deviation in integrin binding to extracellular matrix or other cells related to cell-to-cell interaction. A programmable cell patterning of NIH 3 T3 fibroblasts was also made with a single four-by-four to demonstrate the BBB's addressability and reusability in cell detachment manipulation at a cellular

Biological Breadboard Platform for Studies of Cellular Dynamics, Fig. 5 Spatiotemporal manipulation of cell detachment at a cellular level using the BBB. (**a**) Optical sequential images showing the spatiotemporal manipulation of cell detachment for two-cell case. Two cells are detached from a gold microelectrode activated with negative potential of −1.20 V. The average CD-time for two cells is 45.2 ± 6.8 s. (**b**) Cell detachment

level, as shown in Fig. 5f. The cells were sequentially patterned in the shape of "C," "A," and "L" by using a single device. The BBB was reused through simplified organic cleaning process after each usage, experimentally verifying the addressability, multifunctionality, and reusability of the BBB at the same time. The BBB is reusable due to its reductive desorption of gold-thiol SAM which yields original gold again.

Cell Detachment Manipulation at a Subcellular Level



The cell detachment at a subcellular level was also characterized by disconnecting one part of an NIH 3 T3 fibroblast from a substrate using the BBB which consists of gold microelectrode lines with 10 μm width and 3 μm gap (see Fig. 2d). As shown in the optical sequential images (see Fig. 6a), the subcellular detachment was accomplished by retracting the detached cytoskeleton for 16 s, which is faster retraction than cell detachment at a cellular level. This is because a single cell which has no constraint in stretching itself with focal adhesions is always under higher strain than confluent cells. In the next subcellular detachment experiment, one part of NIH 3 T3 fibroblast was sequentially detached with a series of activations where the first activation (i.e., activation 1) was followed by the second one (i.e., activation 2) after 16 s. The optical sequential images reveal that repetitive activations within dozens of seconds do not have any influence on cell viability and a subcellular detachment amount is gradually increasing, as shown in Fig. 6b. These subcellular detachment experiments open a possibility for spatiotemporal manipulation of cell motility by disconnecting a part of the cell from a substrate. For example, when an anchorage-dependent cell is exposed to subcellular detachment at 3 o'clock direction, it will migrate into 9 o'clock direction.

In our biological breadboard platform, the spatiotemporal manipulation of cell adhesion and detachment is made by deliberately detaching an RGD peptide from a gold microelectrode, leading to adhere and detach an anchorage-dependent cell at cellular and subcellular levels. It is therefore necessary to check whether a detached cell is still alive rather than electrocuted. If a detached cell is electrocuted, this technology cannot be used for spatiotemporal manipulation of cell motility by disconnecting one part of the cell from a substrate and furthermore for cell adhesion and detachment manipulation for a better understanding of cellular dynamics. The viability of the detached cell was therefore characterized. In this experiment, NIH 3 T3 fibroblasts bound to the BBBs were detached by activation potential of −1.50 V. The detached cells collected with a centrifuge, and then it was loaded into a plastic Petri dish. Their viability was observed after 24 h of cell loading. This experiment shows 80 % of the detached cells are still alive. Compared to a general cell passage at which about 95 % of cells are viable, this result is comparably excellent and lays a technical foundation for spatiotemporal manipulation of cell adhesion and detachment using the BBB.

Changes in Viscoelastic Properties During Subcellular Detachment

The changes in the viscoelastic properties of a NIH 3 T3 fibroblast during its subcellular detachment were also quantified by detaching one part of the cell using the BBB. First of all, the detached cell was assumed as isotropic and viscoelastic. The retraction motion of the

(**c**) Continuum model to describe the retraction of a detached cytoskeleton where the cell is assumed as a homogeneous standard linear viscoelastic solid (*top*). Strain profile of an anchorage-dependent cell during cell adhesion and detachment (*bottom*). When a cell adheres to a substrate ($t = 0$), the cell extends its protrusion and adheres again ($0 < t \leq t_1$); the nucleus of the cell translocates ($t_1 < t \leq t_2$); one part of the cell is detached and retracts ($t_2 < t \leq t_3$). (d) Normalized strain as a function of time obtained from single cells which are detached at a subcellular level. *Arrows* of (**a**) and (**b**) indicate the retraction direction of detached cytoskeleton. Scale bars of (**a**) and (**b**) are 100 μm

detached cytoskeleton of a cell was described with a standard linear viscoelastic solid model composed of two springs, k_1 and k_2, and one dashpot, c [see Fig. 6c (top)]. From this model, a normalized strain, ε^* at retraction step [STEP II, Fig. 6c (bottom)] was mathematically expressed as

$$\varepsilon^* = \frac{\varepsilon(t - t_2)}{\varepsilon_0} = \left(1 - \frac{k_2}{k_1 + k_2}\right) e^{-\frac{k_2}{c}(t - t_2)}, \quad (3)$$

where ε_0 is the initial strain of the cell at its protrusion step (STEP I, $0 < t \leq t_1$).

The changes in the viscoelastic properties of the detached (and then retracting) cytoskeleton were measured by combining Eq. 3 with two experimental results: time-sequential images of the retraction motion of the detached cytoskeleton (obtained from 20 cells detached at a subcellular level) and AFM indentation results on the detached cytoskeleton. From the time-sequential images of subcellular detachment, the normalized strain of the detached cytoskeleton was described as $\varepsilon* = 0.799\, e^{-0.055\,t}$ (see Fig. 6d). Based on the AFM indentation results on 10 samples,

the total elastic modulus of the detached cytoskeleton ($k_{total} = k_1 k_2/(k_1 + k_2)$) was determined as 1320 ± 310 Pa. These experimental results with Eq. 3 determined the viscoelastic properties of the detached cytoskeleton ($k_1 = 6567$ Pa, $k_2 = 1652$ Pa, and $c = 30037$ Pa·sec). Compared to the previous results ($k_{total} > 4000$ Pa and $c < 100$ Pa·sec) obtained from the adhered (not detached) cytoskeleton of fibroblasts, the detached cytoskeleton showed a 3 times decrease in its elastic modulus and a 300 times increase in its damping coefficient. This measurement suggests that a detached cytoskeleton becomes softer and consequently has a remarkable increase in its damping coefficient after a few seconds of subcellular detachment. This phenomenon is likely owing to the gel–sol transition of actin filaments at cell detachment which changes the viscoelastic properties of the detached cytoskeleton. The subcellular detachment depolymerizes the cross-linked network of actin filaments. Thus, the structural strength of the detached cytoskeleton decreases, but its viscous damping capacity increases. This result shows that the BBB can be further exploited for studies of cellular rheology and for quantification of viscoelastic properties of the cytoskeleton to supplement computational modeling efforts.

Future Directions

Although we have developed the biological breadboard for spatiotemporal manipulation of cell adhesion and detachment at cellular and subcellular levels, the platforms are still at their earliest stage, i.e., there is no commercially available one. Four exquisite features of the BBB over the previous cell manipulation methods, however, make the BBB as a promising platform for studies of cellular dynamics: (i) addressability in the spatiotemporal manipulation of cell adhesion and cell detachment; (ii) multifunctionality in the characterization of cell biomechanics such as cell positioning, cell patterning, cell motility control, etc.; (iii) reusability due to the electrochemical reaction of a gold-thiol SAM; and (iv) no need for special accessories in incorporating the BBBs with other conventional instruments. Extrapolation of this technology to other anchorage-dependent cells might help us to investigate critical cellular function and behavior, thereby leading to a better understanding of cellular dynamics. Ongoing work is focusing on more in-depth control of cell motility by developing a large-scale assay to shed light on the dynamics of cell motility. Combined with molecular dynamics models, the proposed devices for programmable subcellular adhesion and detachment will offer a new platform for studies of molecular biomechanics of the cell, especially mechanotransduction at focal adhesions.

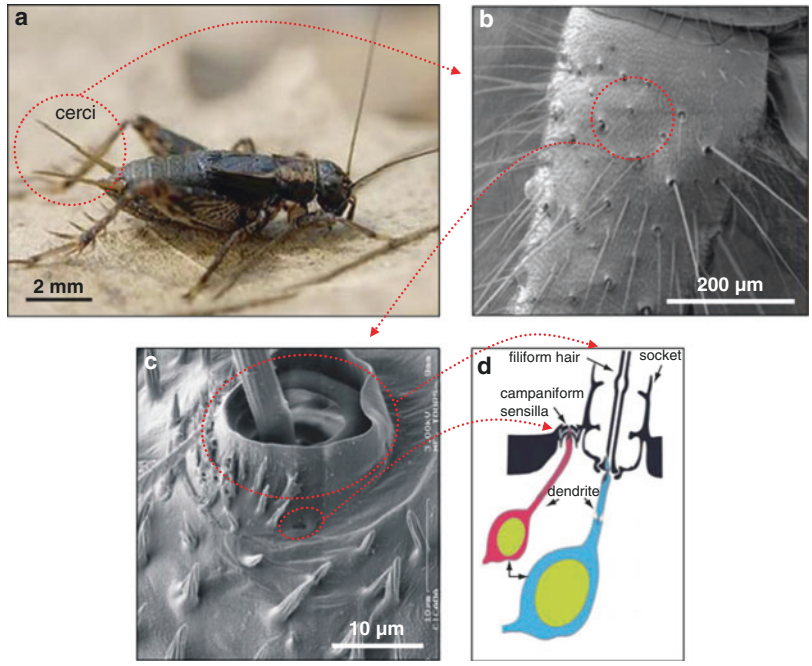
Definition

Biomimetic flow sensors are biologically inspired devices that measure the speed and direction of fluids.

Introduction

This survey starts by describing the role and functioning of airflow-sensing hairs in arthropods and in fishes, carries on with the biomimetic MEMS implementations, both for air and water flow sensing, and ends up with some perspectives for bio-inspired micro-technologies based on the latest understanding of the biological sensors.



Inspiring Biological Systems

Flow sensing systems have been mainly studied on crickets and cockroaches, and to a lesser degree on spiders. The fact that the latter are predators of the former seems to matter little so far, and this entry will concentrate on the cricket for comprehensiveness. Flow sensors in crustaceans living in water have been studied to an even lesser degree but in a similar fashion, without any relationship with biomimetics, so that these works are not mentioned here.

Arthropod Hairs

The filiform hairs of many insects, spiders, and other invertebrates are among the most delicate and sensitive flow sensing cells: they measure displacements on the order of a fraction of the hydrogen atomic diameter (sensitivity ca. 10^{-10} m = 1 Å) and react to flow speeds down to 30 μm/s. If one considers the energy needed to elicit a neuronal spike, one finds that they react with a thousandth of the energy contained in a photon, so that they surpass photoreceptors. In fact, these mechanoreceptors work at the thermal noise level [19]. These hairs pick up air motion, implying that they are measuring both the direction and speed of air particles, in contrast to pressure receivers, i.e., ears. Many insects have ears, so that the extra information available in the flow field must be useful. The biomechanics of the filiform hairs have been studied with care since several decades by several groups worldwide, based on the analogy with a single degree of freedom inverted pendulum without bending (see the latest review of hair biomechanics in [8]).

Among insects, mainly cockroaches and crickets have been studied, because their airflow-sensitive hairs are put on two antenna-like appendages, the cerci (cercus in singular, see Fig. 1). Insect hairs have usually a high aspect ratio, with a length of a few hundreds of microns up to 2 mm, and with a diameter of less than a dozen of microns (Fig. 1). Their tapered shape have been found to have an influence on the drag forces. Hairs and sockets are ellipsoidal in cross section, which leads to a movement in a preferred direction. The hairs of spiders, called trichobothria, are often curved, are innervated by several sensory cells and have an ultrastructure which is favorable to drag while minimizing weight (a feathery structure which decreases the mass and hence their inertia considerably, while increasing the friction in air). The studied airflow-sensing trichobothria are located on the legs.

Biomimetic Flow Sensors, Fig. 1 Habitus of a wood cricket (**a**), with the two cerci highlighted, on which a large number of filiform hairs, intermixed with spines and chemoreceptive hairs, can be observed (**b**). The socket of a hair is a complex system made of several membranous stoppers. It deflection is sensed through another type of mechanosensor, the campaniform sensilla, which is a strain detector (**c**). Both act as a coupled system, the cuticula being deformed once the hair touches the border of the socket. Each sensor is innervated by a single hair cell (**d**)

These two aspects regarding the exact form of cricket and spider hairs show that natural selection is acting on the tiniest details of biological organization. The base of the hairs is much more complex, and its mechanics poorly understood. In crickets, only a single sensory cell is below the hair shaft, while spiders have several (Fig. 1). At the base of the socket, another mechanoreceptor type, the campaniform sensilla, reacts to deformation of the cuticula produced by the movement of the socket. Crickets possess often two sensilla around each hair. Thus the two sensors types act as a coupled system, extending thereby the range of forces it can measure.

Arthropods are very often quite hairy, and the high density of flow sensing hairs implies that they interact with each other in order to produce a high-resolution map of flow characteristics, acting like a flow camera (Fig. 1). Up to now, only the hydrodynamic type of interaction has been studied, called viscous coupling. It was found to be highly dependent on the geometrical arrangement of hairs, of their respective lengths and preferential planes of movement, as well as on the frequency content of the input signal [4]. Hairs often interact over long distances, up to 50 times their radius, and usually negatively. Short hairs in particular "suffer" substantially from the presence of longer hairs nearby, due to a shadowing effect. Positive interactions, where the flow velocity at one hair is increased by the presence of nearby hairs, have been however observed in real animals and reproduced computationally. The biological implications of these interactions have only very recently been addressed, and hint toward a coding of incoming signals which relies strongly on the specific sequence of hairs been triggered [16]. In other words, the signature of the incoming signal is mapped into a given sequence of recruited hairs, which in turn produces a typical sequence of action potentials.

Single hairs, or groups of hairs, are not placed at random on the body. For the same reasons that the

exact shape of hairs and their relative position within a group have been most likely molded by natural selection, the position of the hairs on the sensory organ must be shaped by selection. This aspect of mechanosensory research is however badly neglected. As for the positions along the cercus, the presence of a potential acoustic fovea (i.e., a location with particularly high acuity) at the base of the cercus has been hinted already twice, not only due to the highest hair density in this region, but also because it corresponds to the region with the largest flow velocities, the cercus being the largest there. Putting hairs radially around the cercus enables crickets also to pick up transversal flows, whose peak flow velocities are larger than in the situation where the hairs would be placed on a flat surface; in the later case, hairs are submitted to longitudinal flow with lower peak velocities. In summary, where you put your sensors relative to your body geometry matters a lot.

An action potential triggered by a moving hair ends up directly in the terminal abdominal ganglion (TAG), a local neuronal processing unit. Information from all the hairs, as well as from other sensors, converges there and is processed by interneurons. The compression and convergence of information at this stage is huge: About 1,500 afferent neurons of hairs are connected to only some 20 interneurons [10]. The fact that invertebrates possess few large, singly identifiable neurons enabling comprehensive mapping and repeated recordings of activities is a unique asset which explains the interest in such exotic systems. Information coming from the central brain as well as from the higher ganglia also descends into the TAG. Once processed, the combined information moves up quickly toward higher neuronal centers, in particular the ganglia in which the hindleg movements are being decided. This local feedback loop, with little input from the main brain, enables the animal to process vital information and act accordingly very quickly. As so often with invertebrates, what can be processed locally should be done so, a distributed processing scheme which explains why biomimetics has so much to gain from this group of animals.

The last level of integration is behavior, and flow sensing is known to be of importance in predator and prey perception, sexual selection, and most likely other context, such as noticing its own speed and movement. Predator avoidance is obviously a major selection force, where speed is of paramount importance. Jumping or running away is the behavior which is elicited using appropriate stimuli. The cricket possesses in the TAG an internal map of the direction of the stimuli from the outside world and the geometric computation of the direction of incoming flow by the cercus is one of the nicest case studies of spatial representation [10]. Computing the speed of an approaching predator is also carried out by the TAG, and has been only recently established using appropriate stimuli. Where to jump is a different question, in which directing stimuli and other conditions intervene.

Natural selection therefore acts along the full chain of information transfer, from acquisition and processing, up to actuation. This is important to restate in a biomimetic context, as the extreme sensitivity on the biomechanical side of the hair shaft, which has been the exclusive focus of the engineer attention, could be otherwise lost into an inefficient sequence of information transfer. As of today, one has however very little information about the constraints acting on the different parts of the chain, and hence no idea about their optimization levels.

Fish Neuromasts

Hair cells of the lateral-line system of fish are able to detect water displacement of the order of ca. 20 nm [2]. This ability is used in various ecological contexts, such as prey and predator localization, schooling, and most likely a host of other behaviors. Fish can also detect obstacle-created flow distortions of a flow field they have generated. The blind cave fish, *Astyanax fasciatus*, is an interesting model because it is believed that this species, having lost sight and having to maneuver in darkness, possesses particularly sensitive hair cells. The spatial discrimination ability, through self-induced water movements when approaching objects, of the blind cave fishes is about 1 mm^2. The hairs of

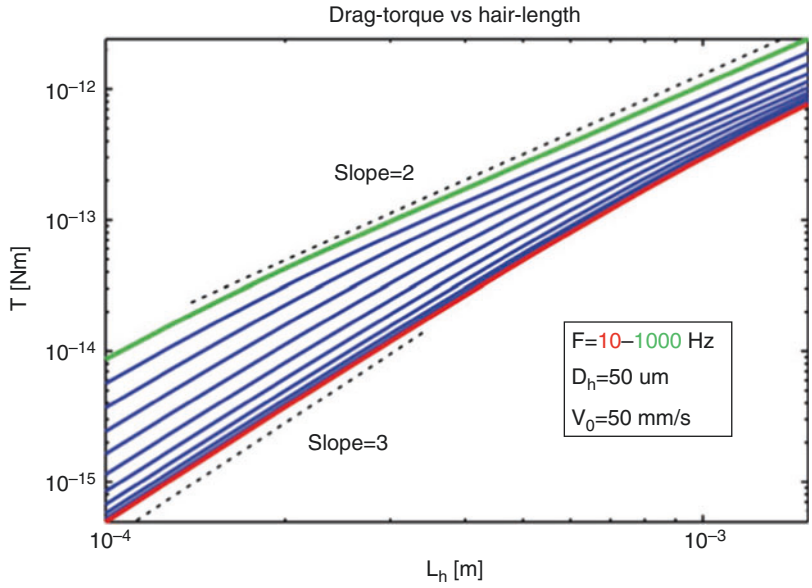
fish are located within specialized units, called neuromasts. These neuromasts, which are localized in many different parts of the body and which do not display a strong correlation with the flow structure of their environments, are located either just on the skin (called superficial neuromasts), or in specialized fluid-filled canals which produce a reticulated pattern on the head and along the body sides. A single neuromast consists of sensory cells that project into a jelly-like material, the cupula, in which several hairs (or cilia) of different lengths are embedded. The cupula is therefore the medium which connects the hairs and the external fluid.

An Engineering Perspective on Biomimetic Hairs

Hair-based flow sensing systems of arthropods and fish contain various levels, ranging from the mechanical structure, to the generation of action potentials in neurons, and signal transport, collecting and processing signals from many (hair-) sensors in the various neuronal centers. Taking inspiration from such complex systems is a non-trivial endeavor. The mechanics of these sensory systems are relatively easy to mimic in an engineering context, at least in comparison to the complexity of the neural system which requires delicate materials (e.g., membranes with ion-channels) and fluids with ion concentrations robustly and actively maintained by the organism. Consequently, up to date most of the bio-inspired flow sensors actually are defined merely by the fact that they use a hair, if needed covered by a cupula resembling cover, to capture viscous drag forces. Having no neural system in an engineering context implies that signal transduction, i.e., from the mechanical to the electrical domain, needs to be done by rather "un-bio-inspired" methods, e.g., using capacitive or piezoresistive interrogations methods. The next level up, namely the arrangement of the hair sensors into an array like structure (a cercal canopy for crickets and a lateral line for fish), is again open to engineering approaches. Mimicking the entire hair-based sensory system requires the ability to recreate dense hair-sensor arrays, including the associated electronic interfacing, asking for engineering solutions to the multiplexing problems. On the signal processing level, the biomimetic content can be high again, e.g., by exploitation of artificial neural networks to extract features and events from the multitude of array signals. The insight in the neuronal architecture of the animals needed for such exercise is however at best sketchy, with the exception of the architecture behind the directional acuity of crickets.

In view of the overall shape and sizes of the hairs in combination with the high densities and large numbers of hair sensors on the hair canopies, it is obvious that an artificial version of this kind of sensor arrays cannot be assembled but should be made monolithically. As it turns out, the range of dimensions is well attainable by micromachining techniques as used in the field of micro-electro-mechanical systems (MEMS). However, the materials generally used in MEMS are rather stiff compared to the materials found in nature, calling for some creative engineering.

Various types of hair-based flow sensors, for operation in air as well as in water, have been developed using both conventional machining and micromachining technologies. They are based on a variety of materials (including semiconductor, oxide, and polymers) and transduction principles (including electrostatic sensing, piezoresistive sensing, thermal sensing, etc.). However, artificial hair-cell (AHC) sensors represent unique challenges to microengineering design and fabrication. The high aspect ratio, vertical, hair must be fabricated using processing steps that are amenable to engineering, manufacturing and eventually scaled production. The overall process must be scalable to large areas as the AHC sensors are often used in arrays. Ideally, the sensors should be integrated with highly sensitive transduction mechanisms to couple mechanical input to electrical output. Further, it is desirable that the AHC sensors be made on a substrate that also houses the integrated electronics elements for signal conditioning and amplification.



For reasons outlined above, most of the hair-based flow sensors reported in literature are made using MEMS fabrication technology. Ironically, the fabrication of the relative large hair structures poses considerable difficulties in this technology. Two basic types of artificial hairs can be distinguished, namely, hairs fabricated in the wafer plane and hairs fabricated perpendicular to the wafer plane. The first is straightforward since surface micromachining techniques can be used. However, surface-micromachined hairs cannot easily be combined into high-density arrays. An overview of the various reports in literature on ciliar inspired actuators and sensors is found in [22].

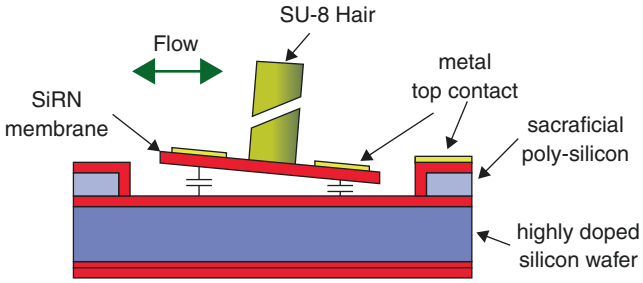
Ozaki et al. [17] were probably the first to provide flow sensors inspired by insects. Their piezoresistance-based sensors had either 400–800 μm long hairs in plane, being cantilevers exposed to flow after removing large part of the silicon substrate, or consisted of wires manually glued to a cross-shaped piezoresistive structure delivering two DOF sensitivity. Characterization by continuous flows in the m/s range proofed the functionality and directivity of the sensors. A comparable in-plane hair fabrication process was used in [12], but incorporated a stress gradient in the artificial hairs to make them curve out of plane. Readout is obtained by tracking the flow-induced vibrations of a set of dissimilar hairs resonating at different frequencies when exposed to specific flows. Argyrakis et al. [1] also use in-plane cantilevers with piezoresistive readout connected to an artificial neuronal circuit for spike generation. An alternative approach was proposed in [15] where the actual hair consisted of an optical fiber with reduced optical transmission when displaced by viscous drag. The sensor is meant for DC-flow measurements and achieves high volumetric sensitivity (μL/min range). Xueb et al. [20] more or less reverted to the structure of Ozaki using a cross-shaped frame with piezoresistors with a plastic hair of about 5 mm length. A nice twist on the hair sensor is presented in [14] by exploiting piezoelectric transduction by polyvinylidene fluoride in thermo-direct written clamped–clamped beam-type structures. Recently, interesting results have been obtained using a straightforward cantilever design in combination with appropriate electronic feedback which helped to incorporate adaptation of the sensor allowing for sharp filtering and gain [13].

Hair-Sensor Systems for Operation in Air: A Case Study

Over the course of several years, the possibilities to fabricate hair-based flow sensors and sensor arrays inspired by the hair sensors and canopies as found on the cerci of crickets have been explored. In several sensor iterations, understanding optimization criteria alongside with viable and robust fabrication technology and suitable interfacing was targeted, not only for single hair sensors but also for arrays.

The scaling of the hair sensors is clearly confined by various requirements. First of all the sensors are supposed to capture a sufficient amount of drag-force. Evidently, the longer and thicker the hairs, the larger the drag torque is (see Fig. 2). Even more so since air flowing over a substrate forms a boundary layer in which the flow-velocity transitions from zero, at the substrate, to the maximum (far-field) value. This boundary layer depends on viscosity and becomes thinner with increasing frequency. Next, for given drag torque the angular rotation will increase when the rotational stiffness decreases. Hence, a small rotational stiffness will be beneficial for the sensitivity and flow-velocity threshold. However, animals live in dynamic environments in which the amount of information derived from the flow sensors not only depends on the sensors sensitivity but also on the bandwidth in which they are sufficiently sensitive. Combining these observations one finds, unfortunately, that this bandwidth goes down with the square-root of the ratio of the spring stiffness and moment of inertia. In order for the animals to capture a large amount of drag torque while still maintaining a low spring-stiffness at a usable large bandwidth, it turns out that long and thin hairs are beneficial. Parametric studies on the drag-force as modeled by Stokes'

Biomimetic Flow Sensors, Fig. 2 Viscous drag torque on a cylinder of length L_h, diameter of 50 µm for various frequencies with flow amplitude of 10 mm/s



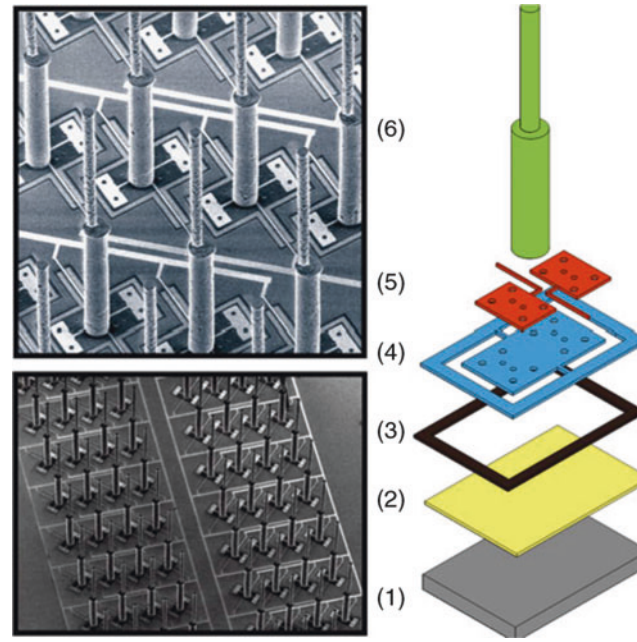
expressions showed that the dependence on hair diameter is far less than the dependence on hair length. Based on the mechanical responsivity and available bandwidth, one can propose a figure of merit (FoM) given by:

$$\frac{L^{1/2}}{\rho^{1/2} S^{1/2} D^{2/3}} \tag{1}$$

where L and D are the hair length and diameter, S is the rotational stiffness, and ρ is the specific mass density of the material from which the hairs are formed. The FoM is the product of the bandwidth of the sensors (expressed by the resonance frequency, i.e., square root of the rotational spring-stiffness S over the moment of inertia J) times their mechanical responsivity (i.e., the magnitude of angular rotation α per unit of flow-velocity V). Clearly it pays off to have long and thin hairs mounted on flexible suspensions.

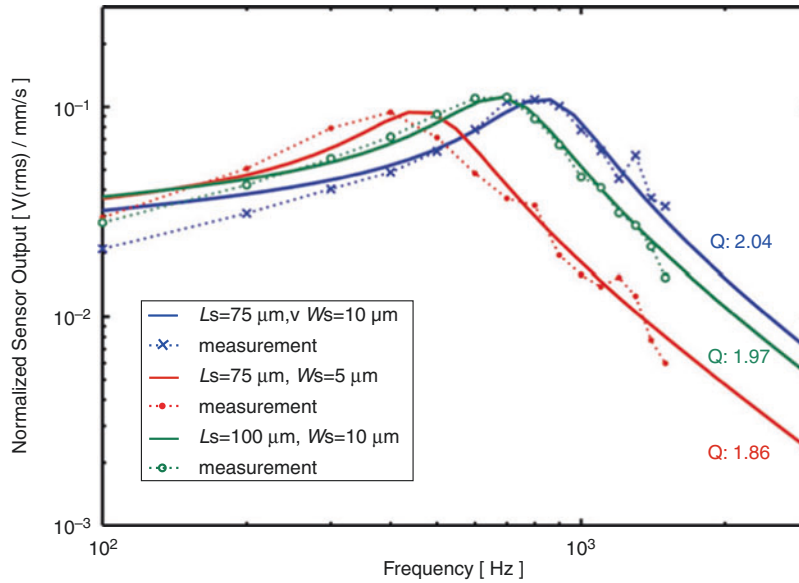
The conditions under which hair sensors have to operate are such that the Reynolds (R) and Strouhal (St) numbers are relatively low. For a hair diameter of 25–50 µm, an air-oscillation frequency of 250 Hz and a flow-velocity amplitude of 10 mm/s, R varies between 0.008 and 0.016 and St between 1.96 and 3.92 (for the flow around the hairs). The rather small Reynolds numbers and the large hair-length to hair-diameter ratio allow using the Stokes expressions for the drag torque exerted by the airflow on the hairs. Furthermore, these hair sensors are mounted on flat substrates allowing the use of the Stokes expressions for a harmonic flow along the hairs. These expressions predict a viscous flow over an infinite substrate to be harmonic in time with zero flow velocity and 45° phase advance at the substrate interface and a boundary layer thickness (δ_b) proportional to the inverse of $\beta = (\omega/2\nu)^{0.5}$ where ν is the kinematic viscosity ($1.79 \cdot 10^{-5}$ m^2/s for air at room temperature) and ω is the radial frequency. The Stokes expressions can be usefully employed for this situation [7]. As an example, for a harmonic airflow of 100 Hz, the boundary layer is roughly 0.5 mm. Note that under most conditions the artificial hairs can be assumed infinitely stiff and the rotation angles are rather small (in the order of 1–100 mrad amplitude per m/s flow-velocity amplitude).

On a basal level the simple principle of a hair sitting on a torsional mount allowing for drag-induced rotation has been the starting point for these artificial hair sensors (see Fig. 3). In the implementation, the hairs are made of SU-8. Using two deposition-exposure cycles and



Biomimetic Flow Sensors,
Fig. 3 Schematic of artificial hair-based flow sensor with differential capacitive layout

subsequent development, these hairs can be made up to 1 mm long with diameters of about 50 μm for the bottom part and 25 μm for the top part. This configuration hardly reduces the drag torque but decreases the moment of inertia of the artificial hairs by about 65 %. The rotational freedom comes from two torsion beams. These beams as well as two membranes connected to the beams are made of silicon nitride. On the membranes an Al layer is deposited which forms a capacitor together with the underlying highly doped silicon substrate. On drag-induced tilting of hair and membranes, the capacitances change in opposite fashion allowing for a differential capacitive readout scheme. The hairs sit on the membranes as well. Rotational freedom is obtained when the structure is released by sacrificial etching of the poly-silicon layer (0.5–1.0 μm thick) that sits between the membrane and a protective silicon-nitride layer on the silicon substrate.



The choice for capacitive transduction is motivated by the fact that differential capacitive readout can be very sensitive and allows for rejection of various common mode signals (e.g., those that originate from flow in the direction perpendicular to the plane in which the hair is supposed to tilt). Moreover, contrary to e.g., thermal readout, it requires little power and does not thermally pollute the air around the sensors. This may not be important for a single hair but since the interest is in larger arrays, thermal effects could be far from negligible. Additionally capacitive readout allows for interrogation of many hair sensors in an array by frequency division multiplexing. There are also some clear drawbacks: the electronics required for capacitive readout are far more complex, certainly when compared to piezoresistive transduction and the method asks for rather complex mechanical structures when applied to sensors for use in liquids, especially in water. In the latter situation, the volume between the electrodes is ideally sealed in order to prevent liquid to get between since this could lead to electrolysis and large viscous damping. Figure 4 shows an exploded view of these capacitive, artificial hair-based flow sensors. Measurements of these sensors are shown in Fig. 5. Due to a combination of the boundary layer effect (high pass) and the second-order mechanics (i.e., its behavior is described by a second-order ordinary differential equation acting as low pass), the sensors show a band-pass characteristic.

The beauty of the neural system lies in its robustness as well as its largely localized generation of signals. In contrast, the capacitive measurement method employed in these sensors is plagued by parasitic capacitances that can hardly be avoided and have a far less localized nature. Changes in temperature, humidity, wiring geometry, etc. indeed cause fluctuations of the parasitics which are large relative to the small capacitive changes that the hair sensors induce. Therefore, control of the parasitics is of paramount importance for a proper device functioning. A reduction in parasitics can be obtained using much smaller electrode areas as well as exploiting shielding. Both have been shown to be feasible using silicon-on-insulator (SOI) technology. Results of the latest generation of sensors are shown in Fig. 6.

Successive iterations led to airflow sensors delivering sensitivities of about 400 μm/s (300 Hz bandwidth) with near-perfect figure of eight directivity. In order to do this, segmented cylinders, each up to 1 mm long, were used. Large arrays of sensors (over 100) can be fabricated and,

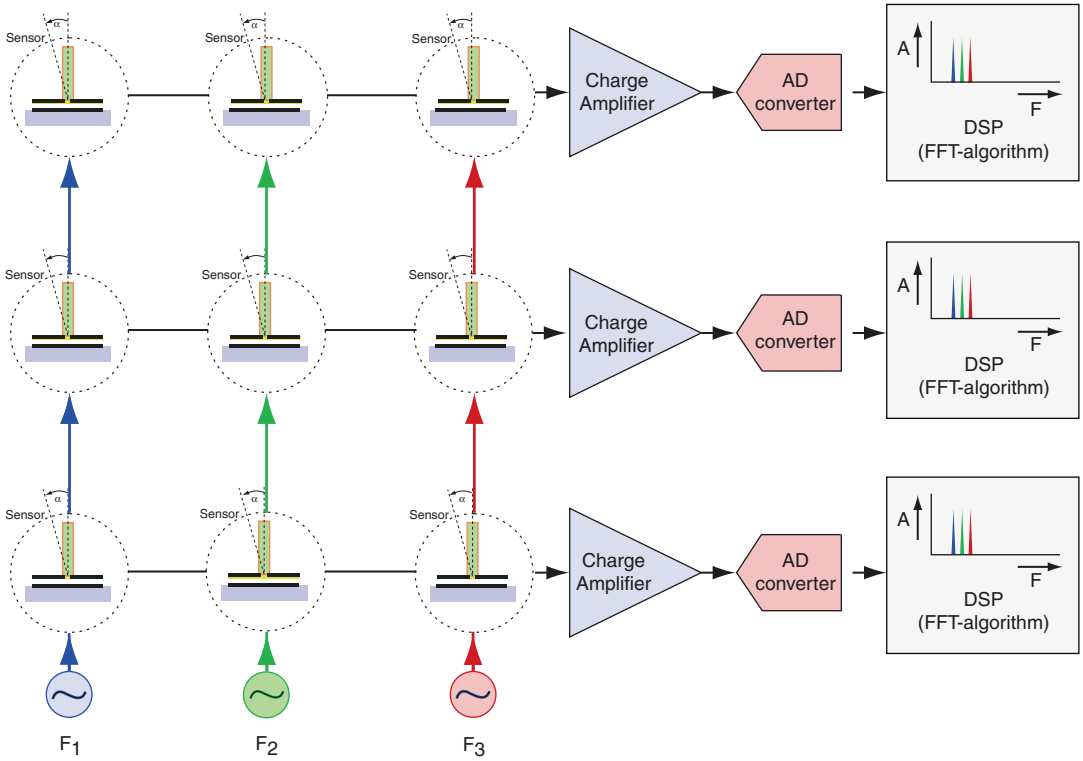
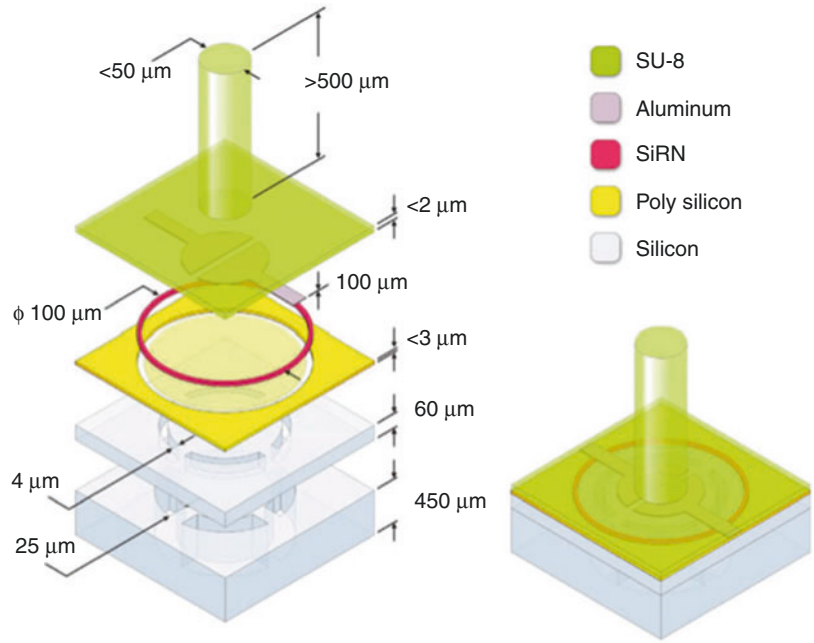
The values of the rotation beam length L_s and beam width W_s are indicated. The model predictions include fitted quality factors (Q) of 2.04 (*blue line*), 1.97 (*green line*), and 1.86 (*red line*) (Jaganatharaja et al. in preparation [11])

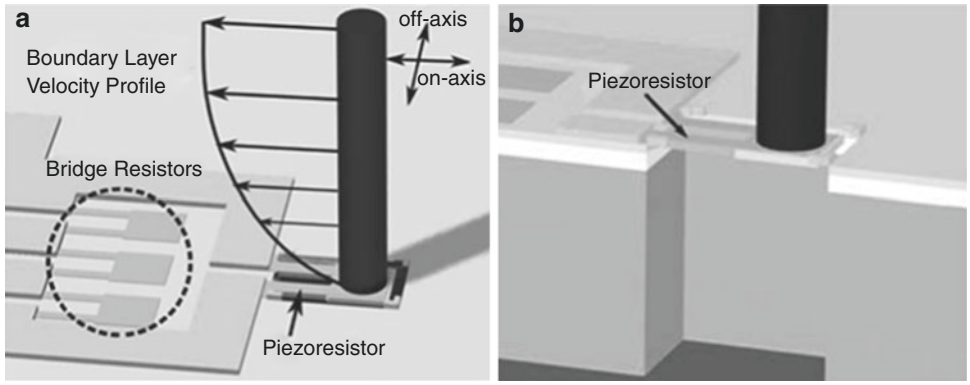


utilizing frequency division multiplexing, these sensors can be simultaneously and individually interrogated (see Fig. 7). This allows one to carry out measurements of spatiotemporal flow-patterns rather than single point measurements. Hence the aim is to develop a system delivering the functionality of a "flow camera" with sensor densities of about 25–100 sensors per mm^2 [6]. This development has largely benefitted from insights in the cricket cercal system.

Biomimetic Hairs in Water



Though functionally not necessarily different, hair-based flow sensors in water are confronted with



Biomimetic Flow Sensors, Fig. 6 *Left*: Output voltage of two generations of sensors measured in a 3 KHz bandwidth. The single hairs sensor is fabricated using a silicon on insulator substrate with a technology slightly different from the one indicated in Fig. 3. Measurements were done as a function of flow-amplitude for a 250 Hz sinusoidal flow. *Red lines* are asymptotic lines to determine the threshold flow. *Right*: directivity of the single hair sensor showing an almost ideal figure of eight (*red dashed lines*)

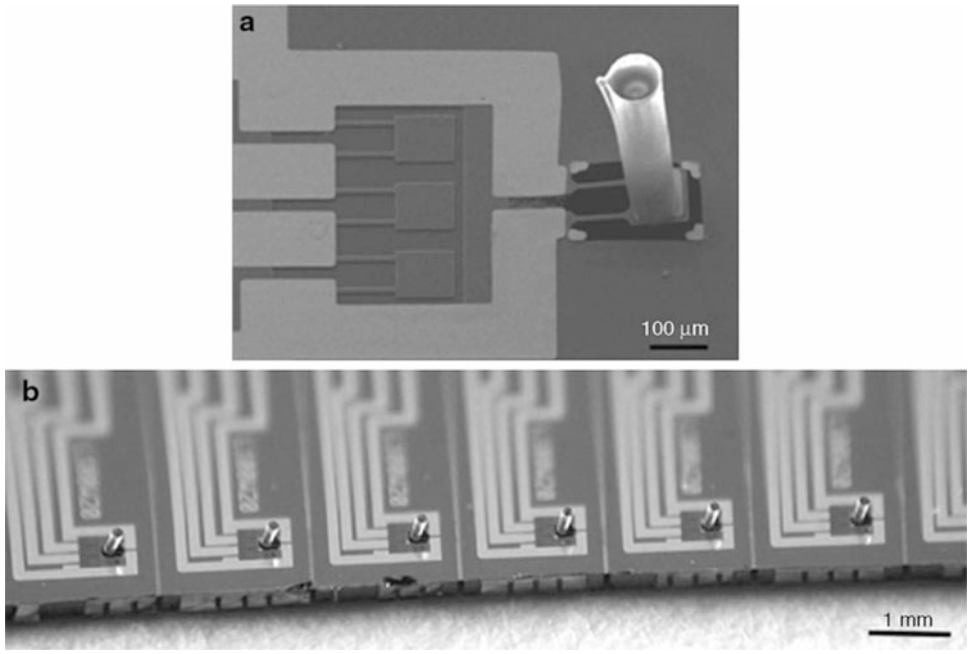
some different scaling than sensors meant for air. The differences arise due to the fact that water has a higher mass density (about 1,000 times) and a smaller kinematic viscosity (about 20 times smaller). The first means that the effects of the moment of inertia of the hairs are smaller whereas the latter translates into boundary layers about 4.5 times smaller in water than in air. Hence, hairs for use in water can be both shorter and larger in diameter.

Hair-based sensing in water may exploit arbitrary transduction principles. However, the practical problems associated with capacitive readout caused by large viscous damping and necessary prevention of electrolysis may call for rather complicated technologies [9], as indicated in Fig. 8. This may be one of the reasons that up to now not much work has been presented on capacitive aquatic hair-based sensors.

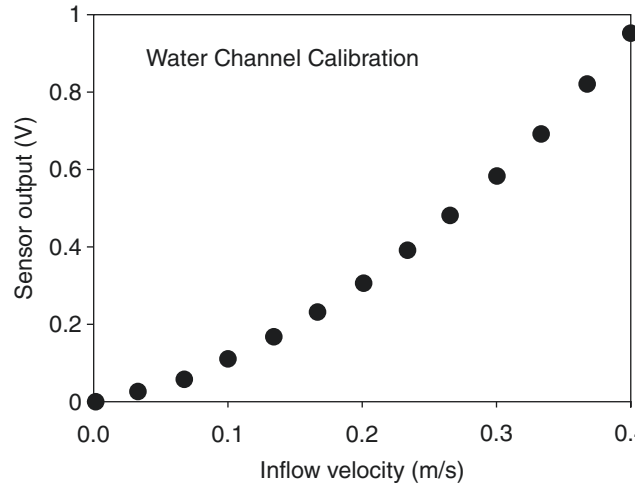
The piezoresistance-based artificial hair cell device, shown schematically in Fig. 9, consists of a cilium located at the distal end of a paddle-shaped silicon cantilever [5]. Doped silicon strain

Biomimetic Flow Sensors, Fig. 10 3-D map showing the possible combinations of cilium height, diameter, and cantilever width that satisfy the design requirements



gauges are located at the base of the cantilever. The cilium is made of photodefinable SU-8 epoxy and is considered rigid. Lateral force along the on-axis acting on the cilium will create a bending moment (M), which is translated to the silicon beam through the stiff joint. The torque introduces a longitudinal strain and can be detected by piezoresistors at the base. The relation between the induced strain (ε) and the moment is given by

$$\varepsilon = \frac{6M}{Ewt^2} \tag{2}$$



where E is the Young's modulus of silicon, w the cantilever width, and t the cantilever thickness. When used as a flow sensor, flow passing along the cilium introduces a bending moment (M) due to frictional and pressure drag. The device is primarily designed for underwater applications that require sensing of low-velocity and low-frequency flows. Structural and hydrodynamic model analyses suggest that the sensor's sensitivity is mainly determined by the following parameters: cantilever width (w), cantilever thickness (t), cilium height (h), cilium diameter (d), and sensor's distance form the leading edge (x).

For real-life underwater applications, good sensitivity in the sub-1 mm/s flow velocity range is desirable. Based on the existing signal conditioning circuitry capability, one can assume the minimum reliable voltage reading at 1,000 times signal gain as 1 mV. Taking 70 as a reasonable estimate for the gauge factor value, 1 mV output at 1,000 times signal gain translates into approximately 0.06 μ-strain using the quarter bridge model. In order to create and detect 0.06 μ-strain under 1 mm/s flow, the values of w, h, and d need to be carefully chosen. Figure 10 is a 3-D map with x, y, and z-axis being the three pertinent design variables, w, h, and d, respectively. A point within the plotted plane indicates a cantilever design that will satisfy the sensitivity requirement. The choice of w, h, and d are further narrowed down according to processing capabilities and frequency response considerations.

The cantilever thickness is chosen as 2 μm; this correlates to the thickness of the single crystal silicon epitaxial layer on the silicon-on-insulator (SOI) wafer used. For the analysis at hand, the sensor's distance from the leading edge (x) is assumed to be 2 mm, set by the die size. The devices are fabricated on SOI wafers with a 2 μm thick epitaxial silicon layer on top, 2 μm thick oxide, and 300 μm thick handle wafer. SU-8 epoxy is chosen for its ability to form rigid high aspect ratio structures. Figure 11 shows an SEM of an actual device, and an array of AHC sensors. A series of mechanical and electrical experiments were performed to characterize the sensor performance. The steady-state response to flow in water is presented in Fig. 12.

Biomimetic Flow Sensors, Fig. 11 Scanning electron micrograph of (**a**) an individual and of (**b**) an array of AHC sensors

Biomimetic Flow Sensors, Fig. 12 Experimental data of underwater steady-state flow velocity calibration of a single hair

The sensitivity of artificial hair sensors can be tailored up to some extent. However, as indicated by the FoM above there is a trade-off between bandwidth and sensitivity. There seem to be some indications that nature does not only, or not per se, maximize the mechanical response (e.g., the rotational displacement of the hairs) but also optimizes the energy captured from the environmental flow. The allometric scaling of cricket hairs seems to reflect the principle of mechanical impedance matching [19]. One may reason that capturing the maximum amount of energy will lead to the best signal-to-noise ratio whereas a high sensitivity may be obtained by proper adaptations, e.g., the lever ratio in the cricket hair-sensor system. Such systems are

found more often in nature; for example, the middle ear of the mammalian hearing system is merely an impedance transformer. It offsets the impedance difference by a factor of a few tens in order to capture maximum energy from air-borne sound waves and convert it to traveling waves in the cochlea despite a factor of a few thousand difference in acoustic impedance. Up to date little has been done in artificial hair sensors to address this aspect. Nevertheless some studies have shown the possibility to improve sensor performance by properly covering the sensory hairs by hydrogel structures, as discussed above. The high water content, reminiscent of the cupular material found in fish neuromast, alleviates the mechanical impedance difference, which together with the increased hydrodynamic surface, leads to a 40-fold improvement in responsivity [18, 21].

Perspectives

The performance of single flow detecting biomimetic MEMS hairs has steadily improved over the last two decades and the threshold flow velocity is now only about one order of magnitude higher than for the most spectacular biological sensors. This is quite an achievement, given that the signal transduction aspect of it is not carried out in a biomimetic approach. Some clever ideas might however originate from biology in this respect too. While active sensing, now found not only in humans and vertebrates but also in insects, has never been reported in these hairs yet, stochastic resonance has been already observed. This ability of biological systems to harness background or within-cell noise in order to improve signal capture needs to be seriously considered. Another as yet untapped possibility for increasing sensitivity and pattern recognition lies in the relative positioning of MEMS hairs, exploiting positive and negative viscous coupling [4]. Major challenges exist on the road until such sensors will be ready to use. They are brittle and break easily, in contrast to their natural counter parts which sustain very large deformations without harm. Furthermore, stiction problems (static friction) at the MEMS hair basis are occurring as soon as the flow velocity is too high, asking for incorporation of anti-stiction measures such as bumps and adhesion-reducing coatings. Nature is here again surprisingly resilient to extremes. Beyond potential technological applications, these hairs can now finally be turned into excellent physical models to tackle biological questions too difficult to address directly on biological materials: for example, the hydrodynamical interactions of tandem hairs moving within the same plane is nearly impossible to measure on real crickets, while MEMS of different lengths can be arranged at will.

Hair-based flow sensing is one of the few areas in which applied mathematics has been the common language of groups as diverse as field ecologists, materials scientists, aerodynamicists, theoretical physicists, computer scientists, and neurobiologists [3]. The mathematical toolbox, and its wide acceptance throughout the scientific community, is an unusual asset in biomimetics, as is the MEMS fabrication. Hair-based flow sensing is therefore *uniquely* suited for interactions among biologists and engineers working toward bio-inspired technologies.

Acknowledgments Without the many discussions we have had with our colleagues in the Cicada and Cilia projects this work would never have had the depth and breadth we have attained. These projects were the Cricket Inspired perCeption and Autonomous Decision Automata (CICADA) project (IST-2001-34718) and the Customized Intelligent Life Inspired Arrays (CILIA) project (FP6-IST-016039). Both projects were funded by the European Community under the Information Society Technologies (IST) Program, Future and Emergent Technologies (FET), Life-like Perception Systems action. We also like to acknowledge the contributions by our MSc and PhD students, PostDocs and technicians without which this paper would not exist.

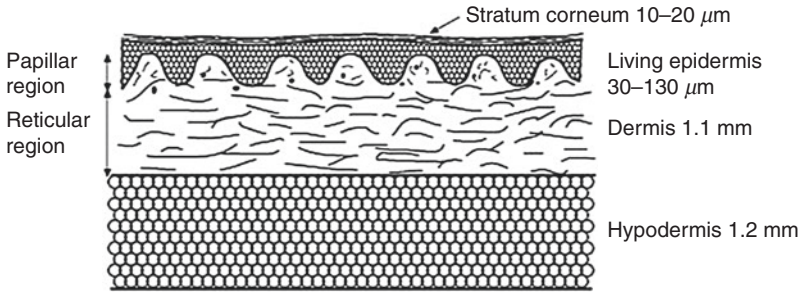
Definition

Microneedles have evolved over recent years as a replacement for traditional hypodermic needles to minimize pain during transdermal drug delivery (TDD) or during blood draw for clinical analysis. Female mosquitoes have offered scientists an excellent insight into how an organism has evolved to drive a flexible microneedle into human skin and draw blood without causing pain to the host. Microneedle designs inspired by the anatomy of a mosquito fascicle and the mechanics of feeding by female mosquitoes have been developed by several researchers.



A microneedle is able to penetrate the skin painlessly when the critical load applied by it is greater than the load required to puncture the skin and the microneedle does not buckle. Once inserted, the microneedle draws blood or delivers therapeutic agents quickly into the blood stream.

Microneedles

Microneedles are used widely as a substitute for hypodermic needles for relatively painless blood draw, drug delivery, and for precise delivery of reagents in chemical and biological systems. Contrary to hypodermic needles, microneedles do not penetrate the skin far enough to contact, pinch, or pierce nerve endings. Khumpuang et al. [1] reported that penetration between 150 and 1,500 μm is painless due to the relative absence of nerve endings at these depths. This is further illustrated by viewing the human skin anatomy as depicted in Fig. 1 [2].

As shown in Fig. 1 [2], the human skin comprises three predominant layers. The outermost skin layer (living epidermis and stratum corneum) is approximately 150 μm thick and is devoid of blood vessels and nerve endings. The next skin layer (dermis) contains blood capillaries and is about 1,100 μm thick. Although the dermis has some sensory perception, it is mostly painless to penetration. The next layer of human skin (hypodermis or subcutaneous layer) consists of fat cells, large blood vessels, and nerve endings. Hence, penetration into this layer causes pain. However, with hypodermic needles, penetration into the subcutaneous layer is necessary to deliver drug into the larger blood vessels. Generally, a microneedle penetration is limited to the dermis layer and is effective in accessing blood capillaries for drug delivery or blood draw while minimizing if not eliminating pain in the process. Microneedles diameters generally range between 40 and 100 μm and can be solid or hollow, whereas the smallest size hypodermic needles are about 320 μm in outer diameter and 160 μm in inner diameter.

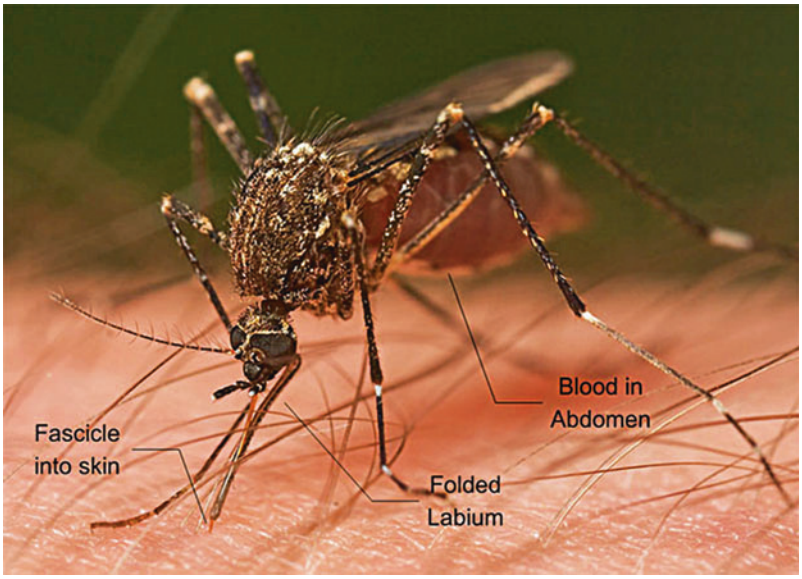
Researchers in the past have successfully created stainless steel and titanium microneedles claiming them to be painless [3–5]. Many microneedle models designed by researchers have been fabricated using silicon. Roxhed et al. [2] designed and built silicon microneedles that had side openings and ultrasharp tips. Needle tip radius has a direct bearing on the stress needed to puncture the skin. Their needles were cylindrical and tapered in shape, 400 μm long with a base diameter of 108 μm, and a tip radius below 100 nm. The bore of the needle was chosen to be

Biomimetic Mosquito-Like Microneedles, Fig. 1 Schematic representation of the anatomy of human skin [2]

eccentrically elliptic with major and minor axes dimensions of 40 and 62 μm, respectively. The side opening of the bore enables the formation of ultrasharp tips. Their needles exhibited insertion forces of 10 mN which was much smaller than previously reported data. The theoretical pressure required to penetrate human skin is given as 3.183×10^6 Pa. Silicon microneedles are generally very short, most less than 500 μm in length, and are generally painless when pushed against the skin.

Oka et al. [6] fabricated and tested silicon microneedles that were 40 μm in diameter, wall thickness of 1.6 μm, and about 1,000 μm long. They reported that their microneedle failed due to brittle fracture during insertion. Silicon microneedles which are brittle can fracture during skin penetration can be carried by blood to other parts of the body, potentially causing injury. Hence, efforts to make polymeric microneedles to prevent brittle fracture were attempted. Davis et al. [7] designed microneedles that were 720 μm long with a tip radius and thickness ranging from 30–80 to 5–58 μm, respectively. Their polymeric needles exhibited insertion forces between 0.1 and 3.0 N. Chaudhri et al. [8] fabricated high aspect ratio hollow micro needles made of SU-8 polymer based on the anatomy of a mosquito fascicle. Microneedles of about 1,600 μm in length, 100 μm in inner diameter, and about 15 μm in wall thickness were produced. The fabrication process was delineated but no results from performance studies were presented.

Reducing the diameter and wall thickness of hollow microneedles for painless insertion necessitates the use of high stiffness materials from a mechanics point of view. Although silicon microneedles are stiff, they are susceptible to fracture during penetration. On the other hand polymeric needles, although very tough, are not stiff enough to penetrate the skin painlessly at comparable dimensions without buckling. In nature, however, a mosquito uses its fascicle (the blood sucking tube) made of natural polymers and successfully penetrates the skin to draw blood. By studying the anatomy of a mosquito, the process a mosquito uses to insert its fascicle into the skin, and the process of blood draw, one can develop novel ideas leading to scientific breakthroughs in microneedle design, fabrication, and analysis.



Bioinspiration and Biomimetics

Many of nature's organisms are involved in human skin penetration and blood extraction process as part of their life cycle. Meyers et al. [9] describe sharp cutting materials from plants, insects, fish, and mammals such as razor grass, bees, mosquitoes, piranhas, shark, rabbits, and rats. They report various biomimetic devices such as scissors inspired by piranha teeth, shredder cutting blades inspired by rabbit's incisors, and syringes inspired by a mosquito.

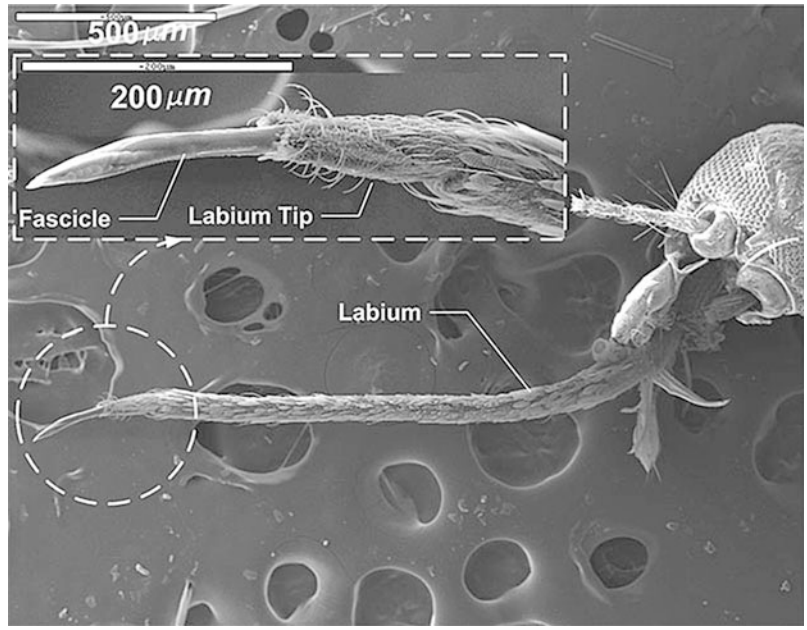
Why Mosquito?

Daniel et al. [10] compared blood feeding strategies of three common insects, mosquitoes (*Aedes aegypti*), bedbugs (*Cimex lectularis*), and body louse (*Pediculus humanus*) representing a wide range of sizes and feeding rates. Maximization of nutrient intake and minimization of blood feeding time seems to be the strategy used by all these insects given their anatomy. The results of their simulation model depicted that the mosquito fed at lower rates compared to that of a bedbug at a pressure drop that was one order of magnitude lower. The body louse on the other hand fed at one tenth the rate of a mosquito, but the pressure drop required was five times higher. The summary of their results showed that the tube radius was a critical variable that affected the feeding rate at a given pressure drop. Insects with larger food canal radius fed at faster rates at any applied pressure drop. The food canal radii for a bedbug, a mosquito, and a body louse were 8, 11, and 3.6 μm, respectively. Therefore, mosquitoes with their large syringe-like tubular food canal anatomy are an ideal model for bioinspiration and biomimetics for developing blood draw and drug delivery devices.

Figure 2 [11] depicts a mosquito that has just inserted its fascicle into the skin of a human host and has started to draw blood from the host.

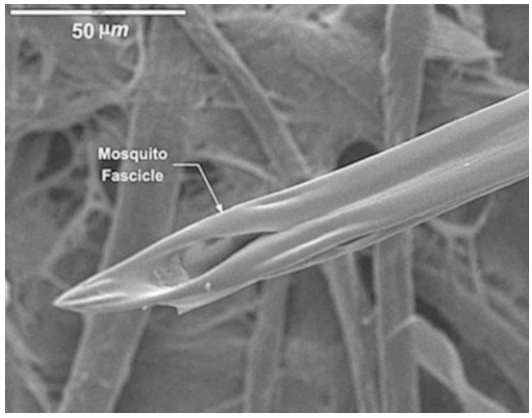
Biomimetic Mosquito-Like Microneedles, Fig. 2 Mosquito drawing blood from a human host [11]

Mosquito Anatomy



In order to understand how a mosquito draws blood from the host, it will be prudent to first introduce the anatomy of mosquito mouthparts, a compound structure, known as the proboscis.

The proboscis is 1,500–2,000 μm in length. The outer sheath is known as the labium that has a hairy structure at the end and has an inner diameter of 40 μm. The labium has a transverse slit for buckling out of the way during the insertion process. Inside the labium is the actual needle known as the fascicle with an outer diameter of 40 μm and inner diameter of 20 μm for blood draw. The fascicle of the mosquito which serves as a conduit for blood flow is generally retracted into the labium. It comprises of a labrum tube which is the main path for blood flow and hypopharynx which has a salivary duct. The fascicle has a maxilla with saw toothed tips. Figure 3 [12] depicts the tip of the fascicle of a mosquito protruding out of the labium. A fascicle extracted from the labium is shown in Fig. 4 [12]. The fascicle has a remarkable resemblance to that of a hypodermic needle. The fascicle's lateral dimension as shown in Fig. 4, decreases from about 10 μm to less than 1 μm at the tip in the last 50 μm length segment creating a very sharp tip.



Mosquito-Inspired Microneedles

Many researchers have studied the mosquito anatomy and have designed microneedles by mimicking its morphology. Xin et al. [13] observed the surface morphology of mosquito and cicada fascicles using scanning electron microscopy. They drew inspiration from the fascicle and its jagged shape to design a biomimetic painless needle. The jagged shape of the microneedle design enabled drag reduction. They proposed that their needle design was able to pierce the skin without much resistance and the surface of their needle design exhibited smaller contact area and friction. Chakraborty et al. [14] researched a female mosquito's blood extraction activity to develop and conduct a fluid mechanics analyzis of a microneedle integrated with a painless blood extraction system. They used sputtering deposition method to fabricate titanium microneedles. They reported that their theoretical transport analysis agreed well with experimental observations in terms of flow rates.

Tsuchiya et al. [4] designed a titanium microneedle inspired by the anatomy of a female mosquito fascicle. They describe a self-monitoring of blood glucose device (SMBG) triggered by a shape memory alloy (SMA) actuator.

Biomimetic Mosquito-Like Microneedles, Fig. 3 (**a**) Mosquito proboscis attached to the head (**b**) Tip of the fascicle shown protruding from the labium [12]

Biomimetic Mosquito-Like Microneedles, Fig. 4 A mosquito fascicle tip extracted from the labium [12]

The system comprised a SMA-based indentation system, microelectric pump to extract blood, and a biosensor to evaluate the level of glucose. They evaluated the performance of the insertion system which required 0.1 N force to indent the skin and the pumping system extracted 2 µl/min of blood. Kosoglu et al. [15] developed pliant microneedles for transdermal lighting. These microneedles were inspired by the anatomy of a mosquito fascicle. The usage of these microcneedles as transdermal light probes or optical fibers has the potential to illuminate tissue at a greater depth for surgery or therapeutic procedures like treatment of cancer. They used a melt-drawing process to make various tip sized silica probes with an average diameter of 73 µm. They also experimentally investigated the needle performance in piercing porcine skins. They observed that sharper probe tips had a higher success rate of penetration compared to probes with more blunt tips.

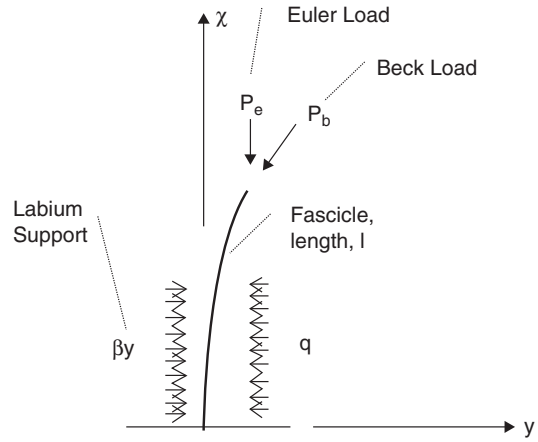
Kong et al. [16, 17] studied the structure of Aedes albopictus mosquito fascicle using scanning electron microscope (SEM). They observed and documented the entire process from skin penetration to blood feeding. They experimentally measured the insertion force using a digital balance, a glass box, and a screen cloth. The mosquito was housed within the glass box and was free to move within it. The screen cloth connected to the bottom of the glass box deflected once the mosquito extended its fascicle to penetrate and draw blood from the volunteer's hands. The force causing the deflection of the skin cloth was recorded using a digital balance connected to the system. An average force value of 1.8 µN was required for the skin penetration, which is remarkably low. Tsuchiya et al. [3] designed and fabricated a painless needle inspired by the anatomy of

a female mosquito for blood extraction. The microneedles were made using sputtering deposition method wherein a rotary substrate was used to deposit the microneedle material, subsequently etched by a chemical solution, and finally heat treated to produce the microneedle. They also reported that the titanium microneedle could be inserted into the skin without buckling.

Aoyagi et al. [18] were able to create high aspect ratio microneedles using biodegradable polymers like PMMA, polyimide, SU-8, Parylene, and polycarbonate. They successfully created 1,000 μm long microneedles that were 10 μm in diameter. The microneedle was able to collect blood plasma with high reliability using capillary suction. Aoyagi et al. [19] used mosquito-inspired microneedles to investigate the resistance force during insertion into silicone rubber. They used a static and a vibrating needle for their experiment. Chichkov [20] proposed a two-photon-polymerization process to create a hollow microneedle and other medical devices using this process. The process used a hybrid material called ormocers; needles were able to penetrate porcine tissue surfaces without fracturing. McAllister et al. [21] used microfabrication techniques to produce microneedles motivated by the anatomy of female mosquitoes. They fabricated microhypodermic needles using silicon and assembled them with heat-controlled bubble pumps. These microneedles allowed flow of water through their bores under acceptable pressures and were able to permeate skin with a greater degree of ease. Suzuki et al. [22] devised a microglucose measuring system comprising a microneedle based on the feeding anatomy of a mosquito. Their system comprised a microneedle, a micro glucose sensor, and a sampling mechanism. Yoshida et al. [23] developed a microneedle design that mimicked a mosquito fascicle. They used human hair as a starting point for manufacturing microneedles. They drilled a hollow bore into the center of a human hair using a microdrilling machine. They created a pen-shaped micro needle which was 1.1 mm long, 80 μm base diameter and, 40 μm tip diameter. Finally, they bleached the drilled human hair using a diluted bleach solution.

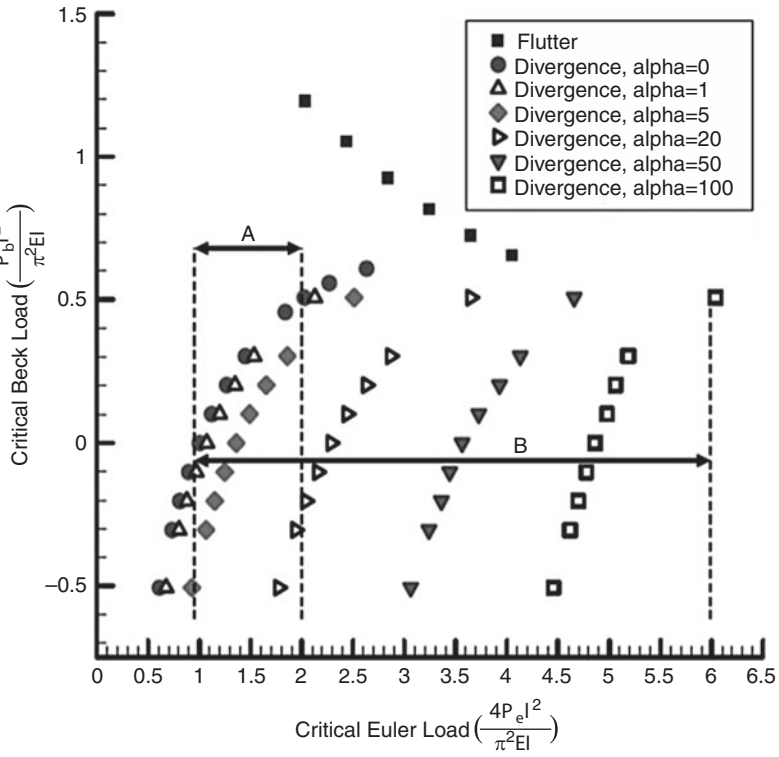
Prow et al. [24] researched and developed the Nanopatch (NP). The NP design was inspired by mosquito anatomy. The NP consisted of projections of closely packed microneedles that are smaller than other available microneedles (less than 100 μm). The NP was coated with antigen, adjuvants, and DNA payloads which were transdermally delivered to mice in the lab. The NP exhibited good results with regards to a painless and efficient vaccine delivery system. Izumi et al. [25] used isotropic dry etching process to create long silicon microneedles with three-dimensional sharp tips. Their design did not impose any limit on either the length or the shape of the microneedle. They were able to fabricate straight, jagged, and harpoon like microneedles that mimicked the anatomy of a mosquito fascicle. They also reported that their microneedles with 3-D tips penetrated artificial skins relatively easier compared to prior microneedle designs.

Roxhed [5] investigated a patch-based microneedle drug delivery system. These microneedles were inspired by mosquitoes and interfaced with small dispenser mechanisms. The dispenser mechanisms were triggered by thermal actuators and contained highly expandable microspheres. The microspheres when actuated expanded into a liquid reservoir and dispensed liquid through the reservoir outlets. These microneedles were made of monocrystalline silicon and were chemically treated by a deep reactive ion etching process. The microneedles were hollow with opening along the side to have better penetration ability. The patch was tested for insulin delivery and exhibited promising results with comparable performance to other drug delivery devices.



Mosquito Fascicle Insertion Dynamics

Almost all prior work to produce biomimetic microneedles were based on morphology as discussed in the earlier section. Very few published work exist to assess the significance of the dynamics of a mosquito penetration process in the design of bioinspired microneedles. It can be

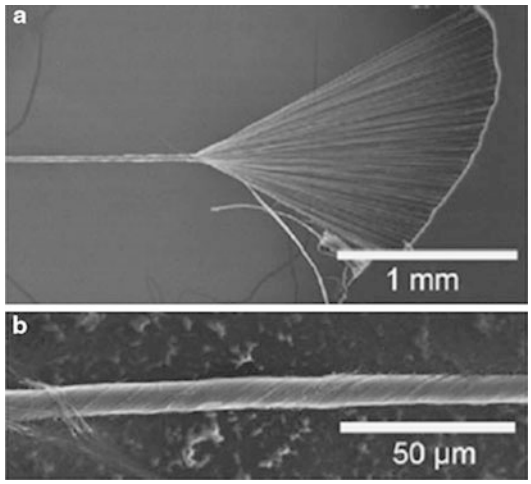


easily shown that if the morphology is reproduced without considering the material, it is possible to build a needle with high stiffness materials such as metal and silicon and penetrate the skin. If a polymeric needle is produced based on the morphology alone, the needle will not be able to penetrate the skin without bucking for comparable dimensions and material properties to that of a mosquito fascicle. Hence, studying the dynamics of the process of insertion of a fascicle into the skin by a mosquito is important. Ramasubramanian et al. [12] observed in detail how a mosquito (Aedes Aegypti) uses its fascicle to penetrate the skin, and have carried out detailed anatomical studies, and subsequently modeled the penetration process and provided insights into mosquito skin penetration process.

As observed in their research, the mosquito contacts the host to commence the feeding process. It hovers on the host from one spot to another until it is able to thrust its proboscis into the skin without bending it. Once the proboscis is thrust into the skin, the fascicle affixes itself into the epidermis of the skin with its tip and commences probing with irregular frequency. The mosquito keeps on applying axial force for some time by keeping its anatomy poised to prevent proboscis buckling and completes the penetration process by oscillating its head. The mosquito head is observed to oscillate at frequencies near 15 Hz at the commencement of the penetration process. The progressive insertion of the fascicle results in its shortening of the free length making it increasingly stable and consequently the mosquito head oscillates at relatively lower frequency, nearly 6 Hz. The labium with its axial slit is detached from the fascicle near the mouth and forms a loop that looks like a question mark (see Fig. 2). When the mosquito reaches a capillary in the dermis layer, it starts to draw blood until it is full. Figure 2 shows blood in the fascicle and collected in the abdomen.

Study of the penetration mechanics of mosquito fascicle into the skin is paramount as it is antecedent to the feeding behavior of the mosquito. Understanding the forces involved during the penetration process provides critical insights in the process of fascicle penetration as the mosquito tries to prevent the onset of buckling by keeping its posture perched appropriately. One of the movements is the forward tilt of the mosquito head between 10° and 20° with respect to vertical as shown in Fig. 2, which results in the application of a follower force which is a constituent of axial thrust. Such a feat may translate into considerable enhancement of buckling load once the fascicle is thrust into the skin. This effect of increasing the buckling load is further compounded by the labium with the labium providing lateral support during penetration. In Fig. 2, it can be seen that substantial part of the fascicle is supported by the labium and at the tip only a small part of the fascicle is visible before entering the skin. The penetration process and the mechanism of buckling force enhancement by follower force and lateral support has been described effectively by a mathematical model, quantifying their relative importance to the penetration process [12]. The fascicle (an inspiration for microneedle design described earlier) is subjected to an Euler load (P_e) and a nonconservative load known as Beck Load (P_b) supported laterally by the labium as shown in Fig. 5 [12]. The labium is treated as an elastic foundation which resists sideways motion of the fascicle. Here q is the distributed force per unit

Biomimetic Mosquito-Like Microneedles, Fig. 5 Schematic representation of fascicle-skin interaction with a mosquito applying the force components at the upper end [12]



Biomimetic Mosquito-Like Microneedles, Fig. 6 Critical load pairs plot showing the effect of lateral support by the labium and the application of Beck load [12]

length and β is the foundation modulus (force per unit deflection per unit length).

The equation of motion as obtained is given by,

$$\frac{\partial^4 y}{\partial x^4} + \left(\frac{P_e + P_b}{EI}\right)\frac{\partial^2 y}{\partial x^2} + \frac{m}{EI}\frac{\partial^2 y}{\partial t^2} + \frac{\beta}{EI}y = 0 \quad (1)$$

With appropriate boundary conditions, namely, $y(0,t) = 0$; $y'(0,t) = 0$; $y''(l,t) = 0$; and $y'''(l,t) + \left(\frac{P_e}{EI}\right)y'(l,t) = 0$ where, m is mass per unit length, E is the Young's Modulus and I is the moment of inertia, the general solution for the differential equation can be obtained [12]. As depicted in Fig. 6, the distance labeled "A" illustrates the effect of nonconservative force as an increase in Euler load from 1 to 2 is attained solely by applying a Beck load of around 0.5 without substantial increment of lateral support. The distance labeled "B" illustrates the effect of foundation stiffness as an increase of Euler load from 1 to 6 is attained by increasing the foundation stiffness value from 0 to 100 for a value of nonconservative load of 0.5, representing the maximum enhancement with both factors. Figure 6 further illustrates that in the absence of nonconservative load, an increment of Euler load by a factor of nearly 5 is still attainable for foundation stiffness values of 100. It is also observed that in the absence of foundation stiffness, the Euler load can be increased by a factor of 3.5 for a Beck load of 0.7 before the onset of flutter instability thus representing the theoretical upper bound. Therefore, the lateral support plays an important role in helping the mosquito reach a force above the limit to penetrate the skin by increasing the critical buckling load by a factor of almost 5. From the mathematical model and numerical solution, it is evident that the lateral support along with Beck load has the effect of increasing the Euler buckling load by a factor of 6 or approximately 18 mN while the lateral support by itself increases the Euler buckling load by a factor of 5. Previous research has shown that the lowest penetration force exhibited by sharpest microneedles is around 10 mN and hence it can be seen that the presence of lateral support would

Biomimetic Mosquito-Like Microneedles, Fig. 7 Ultralong carbon nanotubes spun into micro-yarns [26]

suffice in aiding the microneedle to penetrate painlessly. Taking these findings into account, a more realistic biomimetic mosquito-like microneedle can be developed.

Future Directions

Current research in this area includes constructing carbon nanotube (CNT) based reinforced polymeric microneedles with high axial stiffness along with a lateral support system. Research to construct a synthetic mosquito fascicle based on CNT yarns developed by Zhao et al. [26] is in progress. As depicted in Fig. 7 [26], CNT yarns are spun from CNT arrays. Yarns with diameters of around 40 µm coated with polymers increases the axial stiffness. The coated yarns will be supported laterally and tested for buckling behavior while penetrating porcine skin during the application of an axial force. Successful construction of a polymeric microneedle with a lateral support system should be completed in the near future.

Conclusion

A mosquito is a sophisticated biological machinery that drives a flexible microneedle painlessly into the skin and draw blood successfully. Female mosquitoes of the type *Aedes aegypti* have offered scientists an excellent peek into how a nature's organism is involved in human skin penetration and blood extraction. Microneedle designs inspired by the feeding morphology and mechanics of female mosquito offer an excellent tool for researchers and medical practitioners. Fascicles of female mosquitoes of the type *Aedes aegypti* are one of nature's pliant polymeric microneedles that penetrate human skin effectively to draw blood painlessly by remaining within the bounds of epidermis and dermis, suitably maneuvring its anatomy to avoid fascicle breakage. Significant progress has been made to develop microneedles based on mosquito morphology. Further progress is possible when the dynamics and the importance of lateral support are incorporated in the design.

Synonyms

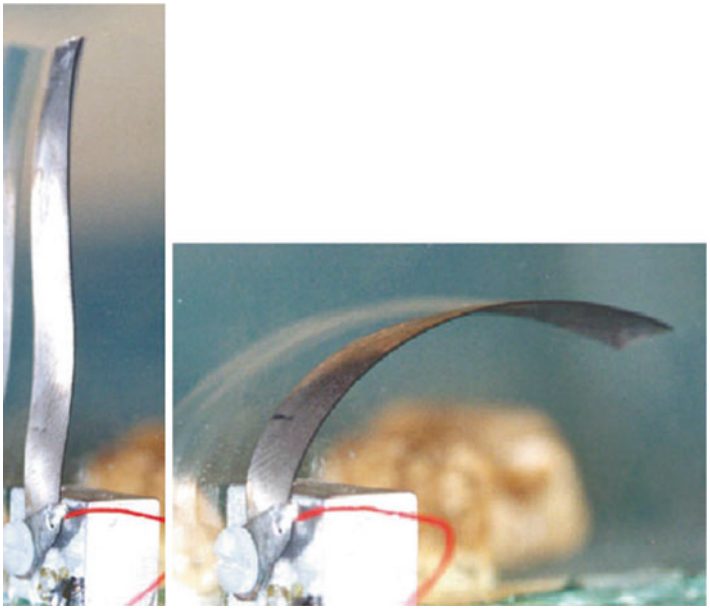
Artificial muscles; Biomimetic muscles and actuators; Electroresponsive polymers

Definition

Electroactive polymers (EAP) are also known as artificial muscles. They have the closest functional response similarity to biological muscles and therefore they gained the name artificial muscles. As such they are being considered for use to

mimic the mechanical performance of biological systems. Actuation via the use of electrical energy is an attractive activation method for causing elastic deformation in polymers and it offers great convenience and practicality.

Introduction



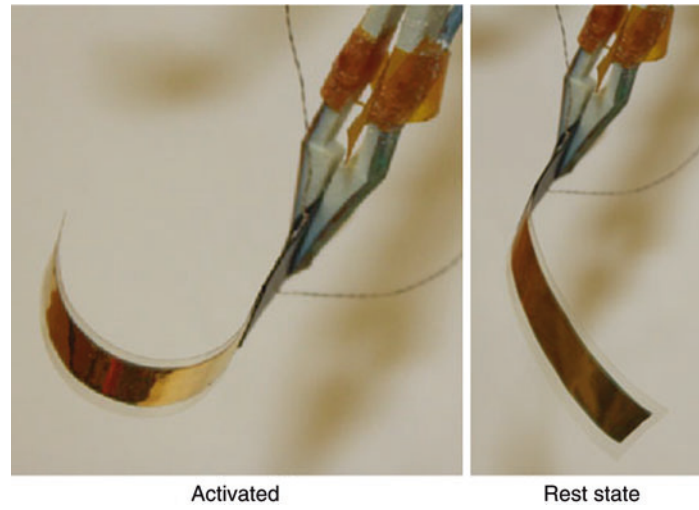
The ability to copy, adapt, and/or be inspired by nature is critically dependant on the availability of effective capabilities and tools. In most biological systems that are larger than bacteria, muscles are their actuators and they are able to lift loads as large as hundreds of kilograms with response time of milliseconds. Biological muscles are driven by a complex mechanism that is very difficult to mimic. Electroactive polymers (EAP) offer the closest functional similarity to biological muscles and therefore they gained the name artificial muscles. There are many polymers that vary their shape or size when subjected to electric, chemical, pneumatic, optical, or magnetic stimulation. However, electrical excitation is one of the most attractive activation methods for causing elastic deformation in polymers. The convenience and practicality of the electrical stimulation and the recent response improvements have made EAP materials the most preferred among the responsive polymers [1].

Polymers that respond to electrical stimulation were known for over 100 years; however, they received little attention since they responded with quite a small strain at the level of fraction of a percent. In the last 20 years, a series of EAP materials have emerged that respond with a very significant shape change. The impressive advances in improving their performance are attracting the attention of engineers and scientists from many different disciplines. Using the developed materials as actuators, many novel mechanisms and devices were already demonstrated including robot fish, fish-shaped blimp propelled by wagging its body and tail, refreshable braille displays, haptic interfaces, miniature gripper, catheter steering element, artificial eye lid, and dust-wiper.

The Available EAP Materials

The first milestone in developing EAP materials was marked by Roentgen [2] when he subjected to an electric field a rubber-band with fixed end and a mass attached to the free end. Other important steps in the development of these materials include the discoveries of the electrets by Eguchi [3] and the Polyvinylidene Fluoride (PVDF) by Kawai [4]. However, up until the 1990s, the generated strain by the known EAP materials was at the level of tenth of a percent [1]. Most of the EAP materials known today that generate large strain have emerged around 1990. One of the notable ones is the polyacrylate dielectric elastomer (VHB^{TM} 4910 from 3M^{TM}) that was reported to reach strain levels of about 380 % with a relatively short response time ($<$0.1 s) [5]. To simplify the categorization of the many EAP material types, the author divided them into two groups according to their characteristics, including the *ionic* and *electronic* (also known as the *field activated*) [1].

- *Ionic EAP*: As actuators, they consist of a polymer film with electrolyte and it is coated by two electrodes. Their activation mechanism involves mobility of ions under electrical excitation [6]. These polymers have the advantages of generating large bending displacement under activation by a relatively low voltage (1–2 V). Their disadvantages are the need to maintain electrolytes wetness, low energy conversion efficiency ($\sim$1 %), and difficulties sustaining constant displacement under activation of a DC voltage (except for conducting polymers). Since the strain in conducting polymers is proportional to charge and since they behave electrically as capacitors, they maintain a constant position under constant voltage [7]. Moreover, due to the related macroscopic motion of ions that is involved with their activation, these polymers respond relatively slow in the range of tens to a fraction of a second. Examples of ionic EAP materials include the ionomeric polymer-metal composites (IPMC), conducting polymers, carbon nanotubes, and ionic polymer gels.



Biomimetic Muscles and Actuators Using Electroactive Polymers (EAP), Fig. 1 IPMC in passive (*left*) and activated states (*right*)

Among the materials in this group, IPMC is one of the most studied EAP materials. The base polymer provides channels for mobility of positive ions in a fixed network of negative ions on interconnected clusters [6, 8]. In 1992, three different groups of researchers have reported independently the development of IPMC-based EAP, and they include: Oguro et al. [9] in Japan, as well as Shahinpoor [10] and Sadeghipour et al. [11] in the United States. The attractive characteristic of IPMC is the significant bending in response to a relatively low electrical voltage at the level of 1 V (Fig. 1). Generally, because of the fact that ions need to physically travel though the material, the response of IPMC is relatively slow (<10 Hz).

- *Electronic (also known as field-activated) EAP*: These materials are activated by Coulomb force that causes dimension change either due to direct thickness reduction (e.g., dielectric elastomers) or due to internal polarization with molecular alignment (e.g., ferroelectric EAP [12]). Generally, high electric field (>10-V/μm) is required, which may be close to the electric breakdown level that is the result of the low dielectric constant. To reduce the required high voltage two alternative approaches are used: (a) creating a stack of thin multilayers and (b) forming a composite using filler material with a high dielectric constant. Photographs of such a composite ferroelectric EAP in passive and activated states are shown in Fig. 2. The EAP material with the filler requires about an order of magnitude less voltage for its activation.

Since the materials in this group of EAP are activated by the electric field, the response is quite fast and can reach milliseconds. The advantages of the materials in this group include holding the generated displacement under a DC voltage making them attractive for robotic applications. Also, these EAP materials have a greater mechanical energy density than the ionic EAP and they can be activated in air with no major constraints. Their main disadvantage is the required high activation field that can be close to the electric breakdown level. Examples of these materials are dielectric elastomers, piezoelectric, and ferroelectric.

Currently, the dielectric elastomer EAP is considered to have the highest technology readiness with the least issues associated with the understanding of its operation. Generally,

Biomimetic Muscles and Actuators Using Electroactive Polymers (EAP), Fig. 2 Photographs of a composite ferroelectric EAP in passive (*right*) and activated states (*left*). This EAP material was provided to the author as a courtesy of Qiming Zhang, Penn State University

this EAP type is based on the use of polymers with low elastic stiffness and high dielectric breakdown strength that are subjected to an electrostatic field and they generate a large actuation strain. An actuator that is made of dielectric elastomer EAP can be represented by a parallel plate capacitor [5]. The electrodes have to be highly compliant in order to avoid impeding the generated strain and conductive carbon grease that are widely used for this purpose. The grease provides the electrodes with the required resilience and the carbon provides the required high electrical conductivity. The required very high flexibility of the conductive carbon grease and high electrical conductivity make it best fit for the task. Application of an electric field results in a strain that is proportional to the square of the electric field and to the dielectric constant while inversely proportional to the elastic modulus. The first observation of the fact that dielectric elastomers sustain large strain (23 % in silicone films) when subjected to high electric field was reported in a 1992–1993 study by Pelrine and his coinvestigators [13, 14].

Since EAP materials are still relatively new it is necessary to establish the related scientific and engineering foundations, including improvement of the understanding of the basic principles that drive them [1]. These require developing effective computational chemistry models, comprehensive material science, electromechanical analytical tools, and material processing techniques. In order to maximize the actuation capability and operation durability, effective processing techniques are being developed for their fabrication, shaping, and electroding. Methods of reliably characterizing the response of EAP materials are being developed and efforts are underway to create databases with documented material properties (http://www.actuatorweb.org/). Bringing these materials to the level of making daily used products will necessitate finding a niche application that addresses critical needs.

Applications of EAP

Significant efforts are underway to develop practical EAP actuators and commercial products are starting to emerge. Eamax, Japan, is credited for developing the first EAP-related commercial product, and at the end of 2002 it announced the marketing of a fish robot that is actuated by IPMC [1]. Mechanisms and devices applicable to many fields are being considered or developed including zoom lens of cellular phones, valves, energy harvesting, pumps, and many others. EAP actuators offer many important capabilities for devices with biomimetic characteristics [1, 15]. One may produce such devices as artificial bugs that may

Biomimetic Muscles and Actuators Using Electroactive Polymers (EAP), Fig. 3 The icon of the grand challenge for the development of EAP-actuated robotics

walk, swim, hop, crawl, and dig while reconfiguring themselves as needed. Mimicking nature would immensely expand the collection and functionality of robots allowing performance of tasks that are impossible with existing capabilities [15–17]. For example, the author and his coinvestigators constructed a miniature gripper with four IPMC-based fingers as bending actuators [1]. This gripper was demonstrated to grab rocks very similar to the human hand using hooks at the bottom emulating fingernails. Other recently reported robotic applications include a blimp with steering fins as well as a fish-shaped blimp propelled by wagging its body and tail (developed by EMPA, Switzerland).

Space applications are among the most demanding in terms of the harshness of the operating conditions (extreme temperatures, high pressure, or vacuum) and they require very high reliability and durability. Today's available materials are not applicable to handle the required actuators that need to operate down to as low as −200 °C as on Europa and Titan or +460 °C as on Venus. Another challenge is the need for large-scale EAP in the form of films, fibers, and others. The required dimensions can be as large as several meters or kilometers to produce large gossamer structures such as antennas, solar sails, and various large optical components. Making biomimetic capability using EAP material will potentially allow NASA and other space agencies to conduct missions in other planets using humanlike robots that emulate human operation before sending real humans.

Addressing the Challenges to EAP

In an effort to promote worldwide development toward the realization of the potential of EAP materials, the author posed in 1999 an arm-wrestling challenge (http://ndeaa.jpl.nasa.gov/nasa-nde/lommas/eap/EAP-armwrestling.htm). The challenge is to have an EAP-activated robotic arm win against a human in a wrestling match. The icon of this challenge is illustrated graphically in Fig. 3. The emphasis on arm wrestling with a human was chosen in order to use the intuitive comparison of our muscles as a baseline for gauging the advances in the capability of EAP actuators. Success will allow applying EAP materials to improve many aspects of our life including the development of products with unmatched capabilities and dexterity. The first arm-wrestling match was held in San Diego, California, USA, on March 7, 2005, as part of the EAP-in-Action Session of the SPIE's EAPAD Conference. Three robotic arms participated in the contest against a 17-year-old high school female student and the student won against all these arms (see Fig. 4).

The second Artificial Muscles Armwrestling Contest was held on February 27, 2006. Rather than wrestling with a human opponent the performance of the arms was measured and compared to the performance of the student (http://eap.jpl.nasa.gov). The measuring fixture (developed jointly by individuals from UCLA and the author's group at JPL) was strapped to the contest

Biomimetic Muscles and Actuators Using Electroactive Polymers (EAP), Fig. 4 An EAP-driven arm made by students from Virginia Tech and the human opponent, 17-year-old student

table and the EAP-actuated arms were tested for speed and pulling force. Each competing arm pulled on the fixture cable that has a force gauge on its other end. To simulate wrestling action, the pulling on the cable lifted a 0.5-kg weight and the speed of lifting was measured from the travel time of the weight from the bottom to the top section of the fixture. To establish a baseline for performance comparison, the capability of the student (the same student who wrestled in 2005) was measured first and then the three participating robotic arms were tested. The results have shown two orders of magnitude lower performance of the arms compared to the student.

Challenges, Trend, and Potential Development

Since the early 1990s, new EAP materials have been developed that generate large strains making them highly attractive for biomimetic and many other applications. Their operational similarity to biological muscles, including resilience, damage tolerance, and ability to induce large actuation strains (stretching, contracting, or bending) makes them unique compared to other electroactive materials. Researchers are increasingly making improvements in the various related areas including a better understanding of the operation mechanism of the various EAP material types. The processes of synthesizing, fabricating, electroding, shaping, and handling are being refined to maximize the actuation capability and durability. Methods of reliably characterizing the response of these materials are being developed and efforts are being made to establish databases with documented material properties to support engineers that are considering the use of these materials. An initiative in this area has been taken by the University of British Columbia and they formed a Web database for viewing, comparing, and submitting EAP properties [18].

Applying EAP materials as actuators of manipulation, mobility, and robotic devices involves multidiscipline including materials, chemistry, electromechanics, computers, and electronics. Even though the actuation force of the existing materials requires further improvement, there has already been a series of reported successes in the development of mechanisms that are driven by EAP actuators. However, seeing EAP replace existing actuators in commercial devices and engineering mechanisms may be a difficult challenge and would require identifying niche applications where EAP materials would not need to compete with existing technologies. It is quite encouraging to see the growing number of researchers and engineers who are pursuing careers in EAP-related disciplines. Hopefully, the growth in the research and development activity will lead to making these materials becoming the actuators of choice.

Acknowledgment Some of the research reported in this entry was conducted at the Jet Propulsion Laboratory (JPL), California Institute of Technology, under a contract with National Aeronautics and Space Administration (NASA).

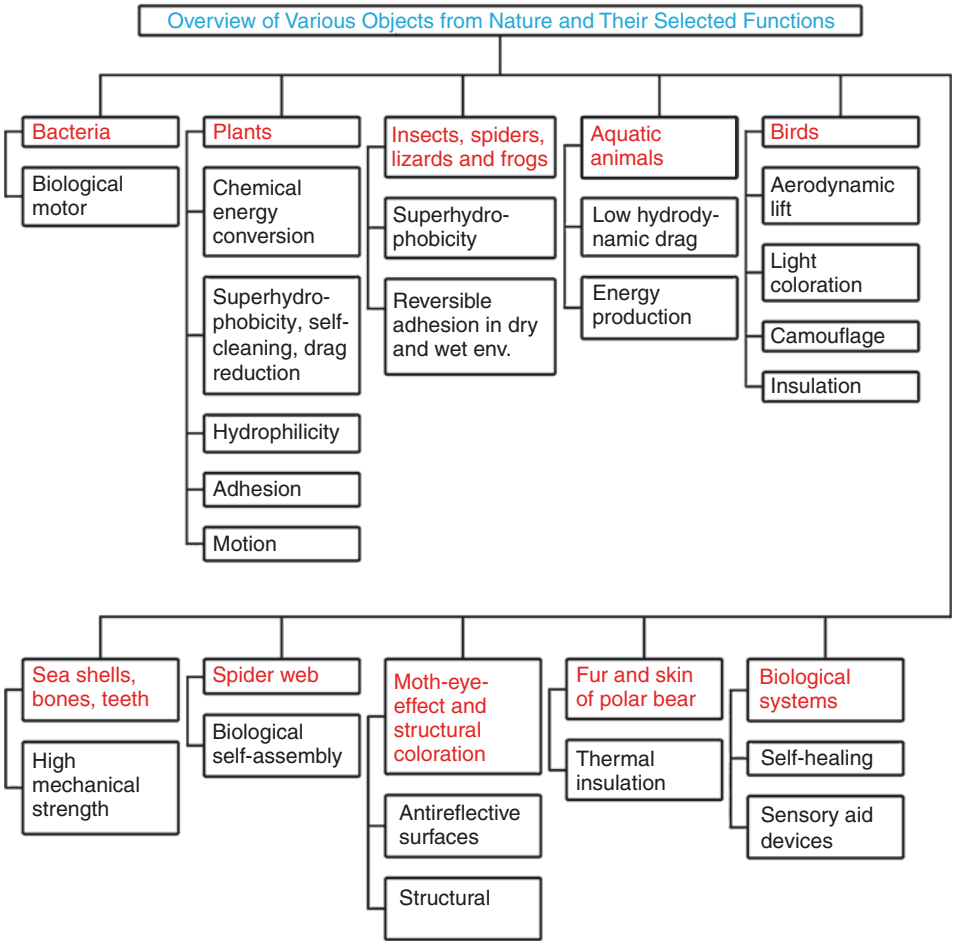
Definition

The emerging field of biomimetics allows one to mimic biology or nature to develop nanomaterials, nanodevices, and processes. Properties of biological materials and surfaces result from a complex interplay between surface morphology and physical and chemical properties. Hierarchical structures with dimensions of features ranging from macroscale to the nanoscale are extremely common in nature to provide properties of interest. Molecular scale devices, superhydrophobicity, self-cleaning, drag reduction in fluid flow, energy conversion and conservation, high adhesion, reversible adhesion, aerodynamic lift, materials and fibers with high mechanical strength, biological self-assembly, anti-reflection, structural coloration, thermal insulation, self-healing, and sensory aid mechanisms are some of the examples found in nature which are of commercial interest.

Introduction

Nature has gone through evolution over the 3.8 billion years, since life is estimated to have appeared on earth [1]. Nature has evolved objects with high performance using commonly found materials. These function on the macroscale to nanoscale. The understanding of the functions provided by objects and processes found in nature can guide researchers to imitate and produce nanomaterials, nanodevices, and processes. Biologically inspired design or adaptation or derivation from nature is referred to as "biomimetics." It means mimicking biology or nature. Biomimetics is derived from the Greek word biomimesis. The word was coined by polymath Otto Schmitt in 1957, who in his doctoral research, developed a physical device that mimicked the electrical action of a nerve. Other words used include bionics (coined in 1960 by Jack Steele of Wright-Patterson Air Force Base in Dayton, Ohio), biomimicry, and biognosis. The field of biomimetics is highly interdisciplinary. It involves the understanding of biological functions, structures, and principles of various objects found in nature by biologists, physicists, chemists, and material scientists and the design and fabrication of various materials and devices of commercial interest by engineers, material scientists, chemists, and others. The word biomimetics first appeared in Webster's dictionary in 1974 and is defined as "the study of the formation, structure or function of biologically produced substances and materials (as enzymes or silk) and biological mechanisms and processes (as protein synthesis or photosynthesis) especially for the purpose of synthesizing similar products by artificial mechanisms which mimic natural ones."

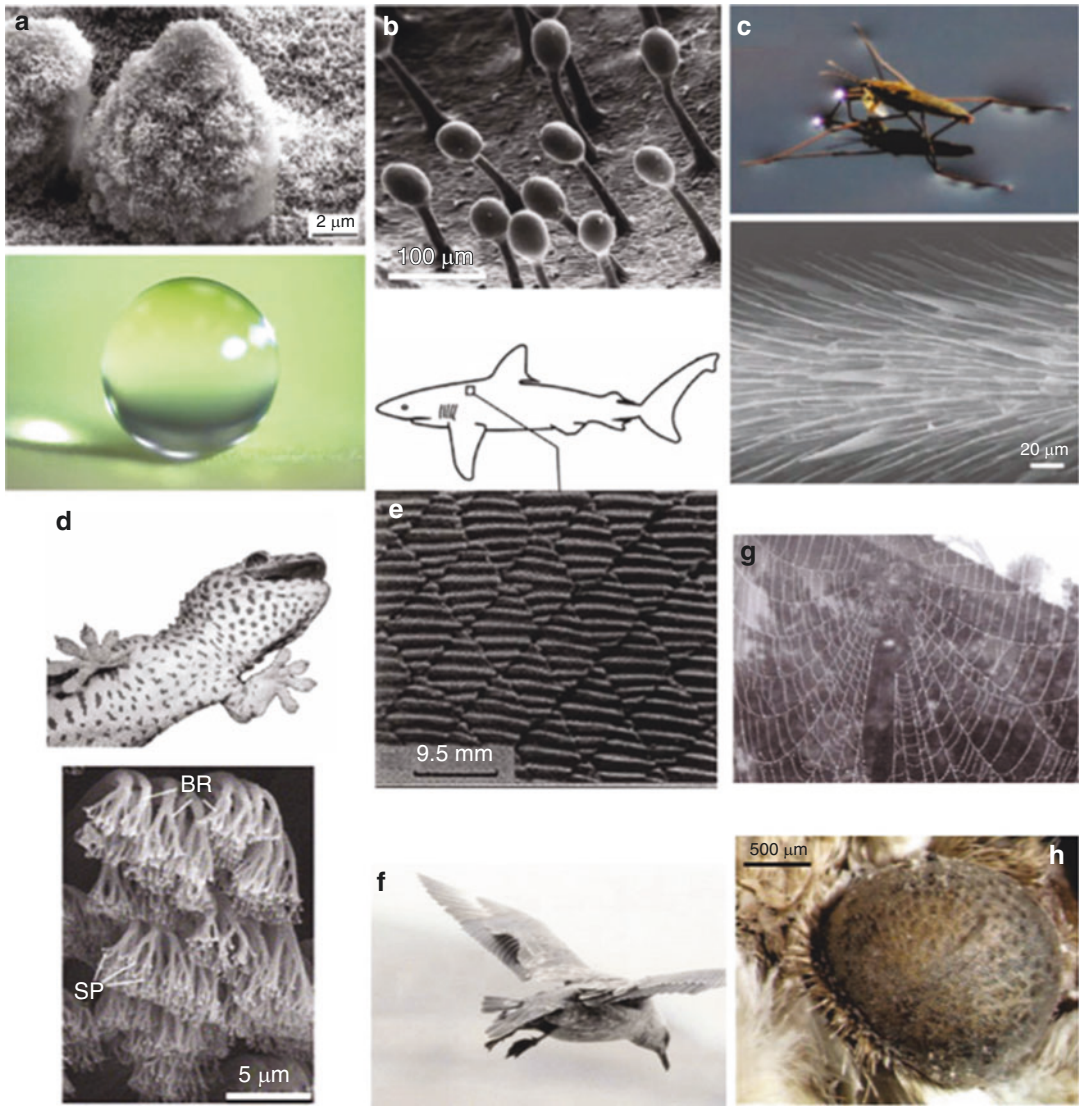


Biological materials are highly organized from the molecular to the nano-, micro-, and macroscales, often in a hierarchical manner with intricate nanoarchitecture that ultimately makes up a myriad of different functional elements [2]. Nature uses commonly found materials. Properties of materials and surfaces result from a complex interplay between surface structure and morphology and physical and chemical properties. Many materials, surfaces, and devices provide multifunctionality. Molecular scale devices, superhydrophobicity, self-cleaning, drag reduction in fluid flow, energy conversion and conservation, reversible adhesion, aerodynamic lift, materials and fibers with high mechanical strength, biological self-assembly, anti-reflection, structural coloration, thermal insulation, self-healing, and sensory aid mechanisms are some of the examples found in nature which are of commercial interest.

Various features found in nature objects are on the nanoscale. The major emphasis on nanoscience and nanotechnology since early 1990s has provided a significant impetus in mimicking nature using nanofabrication techniques for commercial applications [3]. Biomimetics has spurred interest across many disciplines.

It is estimated that the 100 largest biomimetic products had generated about US $1.5 billion over 2005–2008. The annual sales are expected to continue to increase dramatically.

Lessons from Nature and Applications



There are a large number of objects, including bacteria, plants, land and aquatic animals, and

Biomimetics, Fig. 1 An overview of various objects from nature and their selected functions [4]

sea shells, with properties of commercial interest. Figure 1 provides an overview of various objects from nature and their selected functions. Figure 2 shows a montage of some examples from nature. These serve as the inspiration for various technological developments [4].

Some leaves of water repellent plants such as *Nelumbo nucifera* (Lotus) and *Colocasia esculenta* are known to be superhydrophobic and self-cleaning due to hierarchical roughness (microbumps superimposed with nanostructure) and the presence of a hydrophobic coating [12–18]. Roughness-induced superhydrophobic and self-cleaning surfaces are of interest in various applications, including self-cleaning windows, windshields, and exterior paints for buildings, boats, ships, and aircrafts, utensils, roof tiles, textiles, solar panels, and applications requiring antifouling and a reduction of drag in fluid flow, for example, in micro/nanofluidics, boats, ships, and aircrafts. Superhydrophobic surfaces can also be used for energy conversion and conservation. Nonwetting surfaces also reduce stiction at a contacting interface in machinery [19, 20]. A model surface for superhydrophobicity and self-cleaning is provided by the leaves of the Lotus plant (*Nelumbo nucifera*) (Fig. 2a) [13–15, 21–24]. The so-called papillose epidermal cells form asperities or papillae and provide roughness on the microscale. The surface of the leaves is usually covered with a range of waxes made from a mixture of

Biomimetics, Fig. 2 Montage of some examples from nature. (**a**) Lotus effect [5], (**b**) glands of carnivorous plant secrete adhesive to trap insects [6], (**c**) pond skater walking on water [7], (**d**) gecko foot exhibiting reversible adhesion [8], (**e**) scale structure of shark reducing drag [9], (**f**) wings of a bird in landing approach, (**g**) spiderweb made of silk material [10], and (**h**) antireflective moth's eye [11]

long-chain hydrocarbon compounds that have a strong phobia of being wet. Sub-micron sized asperities composed of the 3-D epicuticular waxes are superimposed over microscale roughness, creating a hierarchical structure. The wax asperities consist of different morphologies, like tubules on Lotus or platelets on *Colocasia* [13–15]. The water droplets on these surfaces readily sit on the apex of nanostructures because air bubbles fill in the valleys of the structure under the droplet. Therefore, these leaves exhibit considerable superhydrophobicity. The water droplets on the leaves remove any contaminant particles from their surfaces when they roll off, leading to self-cleaning. A contact angle of 164° and a contact angle hysteresis of 3° have been reported for the Lotus leaf [5, 6].

Two strategies used for catching insects by plants for digestion are having sticky surfaces or sliding structures. As an example, for catching insects by using sticky surfaces, the glands of the carnivorous plants of the genus *Pinguicula* (butter-worts) and *Drosera* (sundew), shown in Fig. 2b, secrete adhesives and enzymes to trap and digest small insects like mosquitoes and fruit flies [14]. In *Pinguicula*, the stalked glands are the sticky ones which trap the insects by secreting an adhesive solution. The shorter ones are those which secrete digestive enzymes, including protease and phosphotase, and later resorb the digested material. In *Drosera*, the stalked glands can effectively enclose small flies by bringing numerous glands in contact with the prey.

Water striders (Gerris remigis) are insects which live on the surfaces of ponds, slow streams, and quiet waters. A water strider has the ability to stand and walk upon water surface without getting wet, Fig. 2c. Even the impact of rain droplets with a size greater than the strider's size does not make it immerse into water. Gao and Jiang [7] showed that the special hierarchical structure of strider legs, which are covered by large numbers of oriented tiny hairs (microsetae) with fine nanogrooves and covered with cuticle wax, makes the leg surfaces superhydrophobic and is responsible for the water resistance and enables them to stand and walk quickly on the water surface. They measured the contact angle of the insect's legs with water to be about 167°. Scanning electron microscope (SEM) micrographs revealed numerous oriented setae on the legs. The setae are needle-shaped hairs with diameters ranging from 3 μm down to several 100 nm. Most setae are roughly 50 μm in length and arranged at an inclined angle of about 20° from the surface of the leg. Many elaborate nanoscale grooves were found on each microseta, and these form a unique hierarchical structure. This hierarchical micro- and nanostructuring on the leg's surface seems to be responsible for its water resistance [16, 17] and the strong supporting force. Gao and Jiang [7] reported that a leg does not pierce the water surface until a dimple of 4.4 mm depth is formed. They found that the maximal supporting force of a single leg is 1.52 mN, or about 15 times the total body weight of the insect. The corresponding volume of water ejected is roughly 300 times that of the leg itself.

Leg attachment pads of several animals, including many insects (e.g., beetles and flies), spiders, and lizards (e.g., geckos) are capable of attaching to a variety of surfaces and are used for locomotion even on vertical walls or across ceilings [25–28]. Biological evolution over a long period of time has led to the optimization of their leg attachment systems. This dynamic attachment ability is referred to as reversible adhesion or smart adhesion [26, 27].

Attachment systems in various creatures such as insects, spiders, and lizards have similar structures. As the size (mass) of the creature increases, the radius of the terminal attachment elements decreases [29, 30]. This allows a greater number of setae to be packed into an area, hence increasing the linear dimension of contact and the adhesion strength. Based on surface energy approach, it has been reported that adhesion force is proportional to a linear dimension of the contact [19, 20]. Therefore, it increases with the division of contacts. The density of the terminal attachment elements strongly increases with increasing body mass. Flies and beetles have the largest attachment pads and the lowest density of terminal attachment elements. Spiders have highly refined attachment elements that cover their legs. Geckos have both the highest body mass and greatest density of terminal elements (spatula). Spiders and geckos can generate high dry adhesion, whereas beetles and flies increase adhesion by secreting liquids at the contacting interface.

Gecko is the largest animal that can produce high (dry) adhesion to support its weight with a high factor of safety. The gecko skin is comprised of a complex hierarchical structure of lamellae, setae, branches, and spatula [25, 26]. As shown in Fig. 2d, the gecko consists of an intricate hierarchy of structures beginning with lamellae, soft ridges that are 1–2 mm in length, that are located on the attachment pads (toes) that compress easily so that contact can be made with rough bumpy surfaces. Tiny curved hairs known as setae extend from the lamellae with a density of approximately 14,000 per square millimeter. These setae are

typically 30–130 μm in length and 5–10 μm in diameter and are composed primarily of β-keratin with some α-keratin component. At the end of each seta, 100–1,000 spatulae with a diameter of 0.1–0.2 μm branch out and form the points of contact with the surface. The tips of the spatula are approximately 0.2–0.3 μm in width, 0.5 μm in length, and 0.01 μm in thickness and get their name from their resemblance to a spatula.

The attachment pads on two feet of the Tokay gecko have an area of about 220 mm^2. About three million setae on their toes can produce a clinging ability of about 20 N (vertical force required to pull a lizard down a nearly vertical (85°) surface) and allow them to climb vertical surfaces at speeds of over 1 m/s with the capability to attach or detach their toes in milliseconds. It should be noted that a three-level hierarchical structure allows adaptability to surfaces with different magnitudes of roughness. The gecko uses peeling action to unstick itself [26, 27].

Replication of the structure of gecko feet would enable the development of a superadhesive polymer tape capable of clean, dry adhesion which is reversible (e.g., [26, 27, 31–33]). (It should be noted that common man-made adhesives such as tape or glue involve the use of wet adhesives that permanently attach two surfaces.) The reusable gecko-inspired adhesives have the potential for use in everyday objects such as tapes, fasteners, toys, and in high technology such as microelectronic and space applications. Replication of the dynamic climbing and peeling ability of geckos could find use in the treads of wall-climbing robots [34].

Many aquatic animals can move in water at high speeds with a low energy input. Drag is a major hindrance to movement. Most shark species move through water with high efficiency and maintain buoyancy. Through its ingenious design, their skin turns out to be an essential aid in this behavior by reducing drag by 5–10 % and auto-cleaning ecto-parasites from their surface [35, 36]. The very small individual tooth-like scales of shark skin, called dermal denticles (little skin teeth), are ribbed with longitudinal grooves (aligned parallel to the local flow direction of the water) which result in water moving very efficiently over their surface. An example of scale structure on the right front of a Galapagos shark (*C. Galapagensis*) is shown in Fig. 2e. The detailed structure varies from one location to another for a given shark. The scales are present over most of the shark's body. These are V-shaped, about 200–500 μm in height, and regularly spaced (100–300 μm) [37].

Due to the relatively high Reynolds number of a swimming shark, the turbulent flow occurs. The skin drag (wall shear stress) is not generally affected by the surface roughness. Longitudinal scales on the surface result in lower wall shear stresses than that on a smooth surface and control boundary layer separation. The longitudinal scales result in water moving more efficiently over their surface than it would were shark scales completely oriented differently. Over smooth surfaces, fast-moving water begins to break up into turbulent vortices, or eddies, in part because the water flowing at the surface of an object moves slower than water flowing further away from the object with so-called low boundary slip. This difference in water speed causes the faster water to get "tripped up" by the adjacent layer of slower water flowing around an object, just as upstream swirls form along riverbanks. The grooves in a shark's scales simultaneously reduce eddy formation in a surprising number of ways: (1) the grooves reinforce the direction of flow by channeling it, (2) they speed up the slower water at the shark's surface (as the same volume of water going through a narrower channel increases in speed), reducing the difference in speed of this surface flow and the water just beyond the shark's surface, (3) conversely, they pull faster water toward the shark's surface so that it mixes with the slower water, reducing this speed differential, and finally, (4) they divide up the sheet of water flowing over the shark's surface so that any turbulence created results in smaller, rather than larger, vortices [38].

It is also reported that longitudinal scales influence the fluid flow in the transverse direction by limiting the degree of momentum transfer. It is the difference in the protrusion height in the longitudinal and transverse directions which govern how much the scales impede the transverse flow.

Bechert et al. [35] reported that, based on their experimental data, thin, vertical scales result in the low transverse flow and low drag. They also reported that the ratio of the scale height to tip-to-tip spacing of 0.5 is the optimum value for low drag.

In addition to reduction of drag, the shark skin surface prevents marine organisms from being able to adhere to ("foul") it. It is not because of the Lotus effect, the shark skin is hydrophilic and wets with water. There are three factors which appear to keep the surface clean: (1) the accelerated water flow at a shark's surface reduces the contact time of fouling organisms, (2) the roughened nanotexture of shark skin reduces the available surface area for adhering organisms, and (3) the dermal scales themselves perpetually realign or flex in response to changes in internal and external pressure as the shark moves through water, creating a "moving target" for fouling organisms [38].

Speedo created the wholebody swimsuit called Fastskin bodysuit (TYR Trace Rise) in 2006 for elite swimming. The suit is made of polyurethane woven fabric with a texture based on shark scales. In the 2008 Summer Olympics, two thirds of the swimmers wore Speedo swim suits, and a large number of world records were broken. Boat, ship, and aircraft manufacturers are trying to mimic shark skin to reduce friction drag and minimize the attachment of organisms on their bodies. One can create riblets on the surface by painting or attaching a film (3 M). Skin friction contributes about half of the total drag between a solid surface and air in an aircraft. The transparent sheets with ribbed structure in the longitudinal direction have been used on the commercial Airbus 340 aircrafts. It is expected that riblet film on the body of the aircraft can reduce drag on the order of 10 % [39].

Mucus on the skin of aquatic animals, including sharks, acts as an osmotic barrier against the salinity of seawater and protects the creature from parasites and infections [36]. The mucus also operates as a drag-reducing agent on some fast predatory fishes, which allows the fish to attack more easily [40]. The artificial derivatives of fish mucus, that is, polymer additives for liquids, are used in drag reduction technology, for example, to propel crude oil in the Alaska pipeline [41].

Bird feathers perform multiple functions – make the body water repellant, create wing and tail for aerodynamic lift during flying, provide coloration for appearance as well as camouflage, and provide an insulating layer to keep the body warm. Many bird feathers exhibit hydrophobicity (an apparent contact angle of 100–140°). Bormashenko et al. [42] studied Feral Rock pigeon feathers. The morphology consists of a network formed by barbs and barbules made of keratin. It is the morphology which plays an important role in hydrophobicity. Birds consist of several consecutive rows of covering feathers on their wings which are flexible, Fig. 2f. These movable flaps develop the lift. When a bird lands, a few feathers are deployed in front of the leading edges of the wings which help to reduce the drag on the wings. Self-activated movable flaps (artificial bird feathers) have been shown to provide an increase in lift in flight experiments [36]. Birds serve as the inspiration for aircrafts and early development of wing design [43]. However, aircrafts do not flap their wings like birds to simultaneously produce lift and thrust. This is impractical in aircrafts due to limitations of scaling phenomena and the high speeds.

Spiders produce a variety of proteins, among which are major ampullate silks (MAS). MAS fibers are used by spiders as a scaffold upon which they attach other silk fibers during the formation of the web. The spider generates the silk fiber, and at the same time it is hanging on it. It has a sufficient supply of raw material for its silk to span great distances [10, 44]. Spider web is a structure built of a one-dimensional fiber, Fig. 2g. The fiber is very strong and continuous and is insoluble in water. The web can hold a significant amount of water droplets, and it is resistant to rain, wind, and sunlight [10, 45]. Spider silk is three times stronger than steel, having a tensile strength of about 1.2 GPa [46]. Some spider silks have high stiffness with a tensile modulus of about 10 GPa, while others are elastomeric with a modulus of about 1 GPa and extension to rupture of 200 %. The combination of strength and extensibility is primarily derived from the domains of crystalline β-sheets and flexible helixes within the polypeptide chain, imparting a

toughness that is greater than bone, Kevlar, and high strength steel. The web is designed to catch insects (food for the spider) that cross the net and get stuck to its stickiness and complex structure.

Optical reflection and anti-reflection is achieved in nature by using nanoscale architecture [47]. The eyes of moths are antireflective to visible light. The so-called moth-eye effect was discovered in the 1960s as a result of the study of insect eyes. For nocturnal insects, it is important not to reflect the light, since the reflection makes the insect vulnerable to predators. The eyes of moths consist of hundreds of hexagonally organized nanoscopic pillars, each about 200 nm in diameter and height, that result in a very low reflectance for visible light, Fig. 2h [11, 48]. These nanostructures' optical surfaces make the eye surface nearly antireflective in any direction.

Light reflection is avoided by a continuously increasing refractive index of the optical medium. The little protuberances upon the cornea surface increase the refractive index. These protuberances are very small microtrichia (about 200 nm in diameter). For an increase in transmission and reduced reflection, a continuous matching of the refraction index at the boundary of the adjacent materials (cornea and air) is required. If the periodicity of the surface pattern is smaller than the light wavelength, the light is not reflected [49]. If this condition is satisfied, it may be assumed that at any depth the effective refraction index is the mean of that of air and the bulk material, weighted in proportion to the amount of material present at that depth [16]. For a moth eye surface with the height of the protuberances of h and the spacing of d, it is expected that the reflectance is very low for wavelengths less than about 2.5 h and greater than d at normal incidence, and for wavelengths greater than 2d for oblique incidence. For protuberances with 220 nm depth and the same spacing (typical values for the moth eye), a very low reflectance is expected for the wavelengths between 440 and 550 nm [50].

This moth eye effect should not be confused with reduction of the specular reflectance by roughening of a surface. Roughness merely redistributes the reflected light as diffuse scattering. In the case of the moth eye there is no increase in diffuse scattering, the transmitted wavefront is not degraded, and the reduction in reflection gives rise to a corresponding increase in transmission [50].

Attempts are being made to incorporate microscopic corrugations in solar panels to reduce light reflection. Attempts are also being made to produce a glare-free computer screen by creating facets on a photosensitive lacquer using lasers. Some 25,000 dots of texture per square mm can essentially eliminate the glare on the screen [48]. Hadobás et al. [51] prepared patterned silicon surfaces with 300 nm periodicity and depth up to 190 nm. They found a significant reduction in reflectivity, partially due to the moth-eye effect. Gao et al. [52] used epoxy and resin to replicate the antireflective surface of a cicada's eye. It is also possible to create transparent surfaces using the moth-eye effect [53].

Hierarchical Organization in Biomaterials

Nature develops biological objects by means of growth or biologically controlled self-assembly adapting to the environmental condition and by using the most commonly found materials. Biological materials are developed by using the recipes contained in the genetic code. As a result, biological materials and tissues are created by hierarchical structuring at all levels in order to adapt form and structure to the function, which have the capability of adaptation to changing conditions and self-healing [16, 54]. The genetic algorithm interacts with the environmental condition, which provides flexibility. For example, a tree branch can grow differently in the direction of the wind and in the opposite direction. The only way to provide this adaptive self-assembly is a hierarchical self-organization of the material. Hierarchical structuring allows the adaptation and optimization of the material at each level.

It is apparent that nature uses hierarchical structures, consisting of nanostructures in many cases, to achieve the required performance [16–18]. Understanding the role of hierarchical structure and development of low cost and flexible fabrication techniques would facilitate commercial applications.

Outlook

The emerging field of biomimetics is already gaining a foothold in the scientific and technical arena. It is clear that nature has evolved and optimized a large number of materials and structured surfaces with rather unique characteristics. As the underlying mechanisms are understood, industry can begin to exploit them for commercial applications.

The commercial applications include new nanomaterials, nanodevices, and processes. As for devices, these include superhydrophobic self-cleaning and/or low drag surfaces, surfaces for energy conversion and conservation, superadhesives, robotics, objects which provide aerodynamic lift, materials and fibers with high mechanical strength, anti-reflective surfaces and surfaces with hues, artificial furs and textiles, various biomedical devices and implants, self-healing materials, and sensory aid devices, to name a few.

Marine bioinspired adhesives

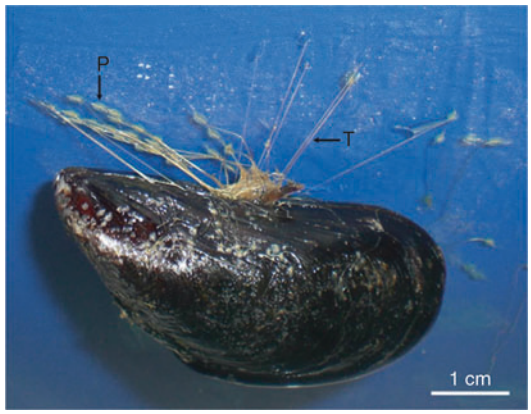
Definition

A large diversity of marine organisms possesses adhesive mechanisms allowing strong attachment to various substrata in a wet and saline

environment. This remarkable capacity raised the interest of scientists for the development of bio-inspired underwater adhesives for various applications, notably in the biomedical field. Model organisms that have been used for the development of such biomimetic adhesives include mussels, barnacles, tubeworms, and algae. All attach permanently by means of solid cements mostly made up of specialized proteins. Synthesis of biomimetic marine adhesives is performed either by the recombinant DNA technology (i.e., the production of adhesive proteins by transformed host cells such as bacteria or yeasts) or by the chemical synthesis of polymers incorporating functional groups copying key amino acids from the natural cement proteins. Other remarkable properties of natural cements, such as the capacity to form complex coacervates, to self-assemble and to cross-link, have been mimicked for the underwater delivery and in situ curing of the biomimetic adhesives.

Introduction

Of all biological phenomena that have been investigated with a view to biomimetics, adhesion in nature has perhaps received the most interest. Indeed, biological adhesives often offer impressive performance in their natural context and, therewith, the potential to inspire novel, superior industrial adhesives for an increasing variety of high-tech applications [1, 2]. Yet, because of the complexity of biological adhesion and the multidisciplinarity needed to tackle it, there has been little visible progress in the development of bio-inspired adhesives and many technological challenges remain, such as the development of adhesives which can function underwater or in aqueous environments. The marine environment is a place of choice for the search of inspiration for such adhesives. Indeed, numerous invertebrates like molluscs, worms, or sea stars produce adhesive secretions that are able to form strong attachments even when totally immersed [1, 2]. These adhesive secretions contain specialized adhesive proteins sometimes associated with other macromolecules such as polysaccharides.



Three types of adhesions can be recognized in marine organisms [3]. Permanent adhesion is characteristic of algae and animals that attach strongly to a substratum with a solid glue possessing high adhesive and cohesive strength (e.g., mussel, barnacles, tube worms, tunicates [1, 2]). Nonpermanent adhesion occurs in invertebrates that attach firmly, but only temporarily, to the substratum through viscoelastic secretions and therefore retain the capacity to move (e.g., sea anemones, gastropods, cephalopods, sea stars, sea urchins [1, 2]). Finally, instantaneous adhesion comprises adhesive systems that rely on single-use organs or cells and are used in functions requiring a very fast formation of adhesive bonds like prey capture or defense reactions (e.g., comb jellies, sea cucumbers [1, 2]). All these systems allow underwater attachment but differ by their structure, functioning, and the physicochemical characteristics of their adhesives. Among them, however, a more intense research effort has been devoted to the elucidation of the mechanisms allowing permanent adhesion of sessile invertebrates and algae [4]. These organisms are indeed involved in the economically important problem of fouling in the marine environment. Because biomimetic efforts are only possible when composition and key molecular components of biological adhesives are understood, so far only a very limited number of organisms have been used for the development of bio-inspired adhesives. The best-characterized marine bioadhesive is that from the mussel and it has inspired most of the biomimetic adhesives currently available [5]. Recently, however, other organisms such as tubeworms, brown algae, and barnacles have also been used as models. The following paragraphs will focus on these four organisms, from the features of their adhesives to the imaginative applications that have been developed for their biomimetic counterparts.

Mussels

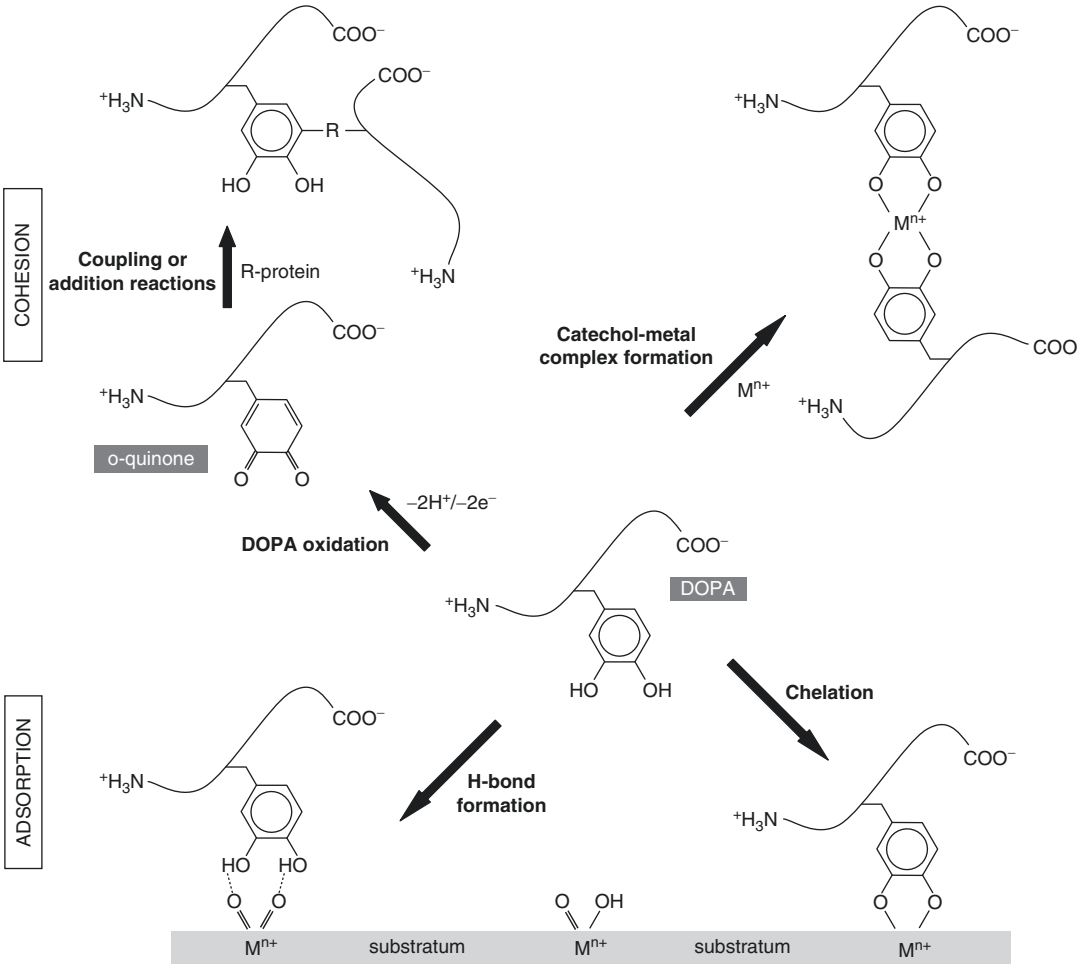
Natural Adhesive

To attach themselves to the substratum, mussels produce a byssus (Fig. 1), which consists of a

bundle of proteinaceous threads connected proximally to the base of the animal's foot, within the shell, and terminating distally with a flattened plaque which mediates adhesion to the substratum [5, 6]. These plaques are formed by the autoassembly of secretory products originating from four distinct glands enclosed in the mussel foot. These products comprise a collagenous substance, a mucous material, a mixture of polyphenolic proteins (known as foot proteins 2 to 6, abbreviated as fp-2-6) and an accessory protein (fp-1). Only the different foot proteins (fp-1-6), also known as mussel adhesive proteins (MAPs), will be considered here.

Biomimetics of Marine Adhesives, Fig. 1 A mussel of the species *Mytilus edulis* attached on a glass substratum by the mean of its byssus. The byssus consists of a bundle of threads (*T*), each terminating with a flattened plaque (*P*) which mediates adhesion to the surface

The Mussel Adhesive Proteins (MAPs)



Since the characterization of fp-1 in the early 1980s, MAPs have been the subject of a very large number of studies leading to a detailed knowledge on their structures, functions, and interactions within the byssal attachment plaque. Proteins fp-2 and fp-4 form the central core of the plaque; fp-3, fp-5, and fp-6 are located at the interface between the plaque and the substratum (primer layer); and fp-1 forms a hard cuticle protecting the core from hydrolysis, abrasion, and microbial attack [5, 6].

The 6 f. proteins (fps) constituting the attachment plaques have been mostly characterized from mussels of the genus *Mytilus*. Their characteristics are summarized in Table 1. Most MAPs exhibit repeated sequence motifs, whose number and amino acid composition vary according to the species considered. Moreover, all the proteins identified in the plaque share a common distinctive feature: the presence of 3,4-dihydroxyphenylalanine (DOPA), a residue formed by the posttranslational hydroxylation of tyrosine [5, 6] (Fig. 2). This modified amino acid fulfills two important roles in the attachment plaque (Fig. 2): it is involved in the formation of cross-links between the different fps (cohesion) and it mediates physicochemical interactions with the surface (adhesion) [5]. It is generally accepted

Biomimetics of Marine Adhesives, Table 1 Characteristics of the proteins constituting the attachment plaques in the byssus of mussels from the genus *Mytilus*

Biomimetics of Marine Adhesives, Fig. 2 Dual functionality of peptidyl DOPA groups in mussel adhesive proteins. The catechol functions of DOPA-containing proteins contribute to adhesive adsorption through hydrogen bonding of the phenolic OH groups to the oxygen atoms of the surface (*lower left*) or by forming mono-bidentate complexes with metal ions at the surface of mineral, metal oxide or metal hydroxide substrata (*lower right*). Peptidyl DOPA groups also contribute to adhesive cohesion by forming bis- or tris-catechol-metal complexes (*upper right*) or by forming intermolecular cross-links. Cross-linking follows the oxidation of DOPA to an *o*-quinone that reacts with amino acid side chains (R) of other proteins, in which R can belong to cysteine, histidine, lysine, and other DOPA residues (*upper left*)

that cross-linking reactions are related to the oxidation of DOPA to DOPA-quinone, a reaction catalyzed by a catecholoxidase in the byssus. DOPA-quinones may also result from redox reactions involving transition metal ions or may form spontaneously at alkaline pH. Once formed, DOPA-quinone is capable of participating in a number of different reaction pathways leading to intermolecular cross-link formation [6]. DOPA also confers to proteins a capacity for intermolecular metal complexation through the formation of tris- and/or bis-catechol-metal complexes. On the other hand, DOPA is also involved in surface coupling, either through hydrogen bonds or by forming complexes with metal ions and metal oxides present in mineral surfaces [5, 6]. These complexes possess some of the highest known stability constants of metal-ligand chelates. Some of the MAPs also contain other posttranslationally modified amino

acids such as O-phosphoserine (fp-5 and fp-6), which could mediate adhesion to calcareous substrata, or 4-hydroxyproline (fp-1), 3,4 dihydroxyproline (fp-1) and 4-hydroxyarginine (fp-3) which could make hydrogen bonds with surfaces [5, 6].

MAP Extraction and Purification

The extraction and purification of MAPs directly from mussel tissues for purposes is feasible but is economically and ecologically problematic. Indeed, several thousands mussels are needed to obtain 1 g of proteins [4, 7, 8]. Harvesting the natural adhesive is therefore an unrealistic solution for most industrial applications. A commercial MAP extract is however commercially available under the name Cell-Tak™ (BD Biosciences, Franklin Lakes, NJ USA) and consists of a mixture of fp-1 and fp-2. It is sold as an adhesive for the in vitro immobilization of cells and tissue sections on various surfaces, including plastic, glass, metal, and biological materials [4]. In vivo transplantation experiments (e.g., corneal transplantation in rabbit) also showed that Cell-Tak appeared to be nontoxic and well tolerated by biological systems. In the laboratory, the adhesive properties of an extracted MAP mixture similar to Cell-Tak (i.e., containing ∼80 % fp-1 and ∼20 % fp-2) were investigated by bonding together strips of porcine tissues, either skin or small intestinal submucosa [8]. With skin, a satisfactory joint strength of about 1 MPa, similar to the commercial fibrin glue Tisseel™ (Baxter, Deerfield, IL USA) was obtained, but only for long curing time exceeding 12 h. With small intestine, an adhesive strength of almost 0.5 MPa was reported and the curing was reduced to 1 h by the addition of oxidizing transition metal ions such as Fe^{3+} and V^{5+}. It is usually admitted that adhesives suitable for medical applications should possess an adhesive and cohesive strength ranging from 0.01 to 6 MPa, depending on the particular bonding site (e.g., relatively unstressed soft tissues versus bones or tendons) [2]. In addition, the properties of the adhesive should be adapted to the "dry" (topical tissues such as teeth or skin) or "wet" (internal organs bathed in body fluids) state of the bonding site.

Production of Mussel Mimetic Adhesives and Their Applications

To bypass the problem of obtaining MAPs directly from mussels, biomimetic adhesives have been developed. These bio-inspired molecules are produced either in the form of recombinant preparations of the adhesive proteins or in the form of chemically synthesized polymers incorporating DOPA or catechol groups.

Production of Recombinant MAPs

Recombinant DNA technology has been used in order to obtain larger quantities of mussel adhesive proteins [6–9]. Attempts to produce recombinant forms of MAPs started in the early 1990s with the expression, production, and purification of complete fp-1 and of synthetic fp-1 protein analogs consisting of 6–20 repeats of the consensus fp-1 decapeptide (Ala-Lys-Pro-Ser-Tyr-Pro-Pro-Thr-Tyr-Lys) in the yeast or in the bacterium *Escherichia coli* [6, 9]. However, these first attempts failed to obtain large amounts of recombinant proteins (Table 2) for different reasons including the highly biased amino acid composition of fp-1 and differences in codon usage between mussels and the heterologous expression systems [6, 9]. Bacterial expression of recombinant fp-1 was enhanced by the fusion of fp-1 with an *E. coli* signal peptide (OmpASP), which boosts secretion by directing the expressed protein to the periplasm. Another problem with the heterologous expression of fp-1 and MAPs in general is that the recombinant proteins lack the posttranslational modifications such as the hydroxylation of proline, arginine, or most importantly, tyrosine residues. The production of functional recombinant MAPs therefore requires an additional in vitro modification step: the enzyme-catalyzed modification of tyrosine residues into DOPA [6]. This is usually done using a commercially available mushroom tyrosinase.

Fp-3 and fp-5 are other interesting adhesive proteins as they have a high DOPA content and are present at the interface between the byssus attachment plaques and the substratum. Both were cloned in expression vectors containing a histidine tag sequence which allows purification of the protein using metal affinity

Biomimetics of Marine Adhesives, Table 2 Comparison of several recombinant mussel adhesive proteins

Recombinant protein	Host	Production yield (mg/L) after purification	Solubility (g/L)
fp-1	*Saccharomyces cerevisiae* (Y)	nd	nd

fp-353	*Escherichia coli* (B)	39	90

B bacterium, *Y* yeast, *nd* not determined

chromatography [9]. The vectors were expressed in *E. coli* with subsequent in vitro treatment by mushroom tyrosinase for DOPA formation. Recombinant fp-5 presented a low purification yield (Table 2) but remarkable adsorption and adhesive abilities on various surfaces [6, 9]. Indeed adsorption and adhesion forces were comparable to – and sometimes exceeded – those of Cell-Tak. A better purification yield was achieved for recombinant fp-3 (Table 2). The adhesion capabilities of this protein were, however, lower than those of recombinant fp-5, but still comparable to those of Cell-Tak. Recombinant fp-5 was also tested successfully as a cell-adhesion material for in vitro cell culture [6, 9].

The successful production of recombinant MAPs and their good performance in microscale adhesion tests were encouraging. However, macroscale testing and large-scale applications were still prevented by poor production due to post-induction bacterial cell growth inhibition and by the low solubility of purified proteins in aqueous buffers (Table 2). To overcome these limitations, recombinant hybrid adhesive proteins were designed, the so-called fp-353, fp-151, and fp-131 [7, 9]. The former is a fusion protein with fp-3 at each terminus of fp-5. Because fp-353 formed inclusion bodies, host cell growth inhibition did not occur. In addition, the solubility of fp-353 was better than that of fp-3 or fp-5 alone, permitting the preparation of a viscous concentrated glue solution for large-scale adhesion strength measurements. The fp-151 and fp-131 hybrids resulted from the fusion of six fp-1 decapeptide repeats at each terminus of fp-5 and fp-3, respectively [6, 7, 9]. Recombinant fp-151 displayed the highest production yield reaching 1 g/L of batch-type flask culture (Table 2). In fed-batch-type bioreactor cultures, similar high production levels were maintained through a co-expression of fp-151 with bacterial hemoglobin that facilitates the utilization of cellular oxygen [6]. Of all recombinant MAPs, fp-151 possesses the highest solubility (up to 330 g/L), allowing the concentration of the protein solution into a sufficiently viscous liquid for practical adhesive application. Additionally, fp-151 showed a better adsorption and a similar adhesion force, compared to recombinant fp-5, and its adhesive strength (∼0.8 MPa on cowhide, ∼1.1 MPa on aluminum, and ∼1.8 MPa on poly (methyl methacrylate [Plexiglas])) is always largely in excess to that of fibrin glue. The recombinant fusion proteins, marketed in milligram quantities (Kollodis, Inc), are less expensive than extracted MAPs (Cell-Tak) [7].

Fp-151 proved to be biocompatible for the in vitro culture of various cell types including both anchorage-dependent and anchorage-independent cells [6, 9]. In this context, fp-151 was also fused to a RGD peptide, a sequence identified as a cell-adhesion recognition motif by integrins, and used in culture plates coating. The resulting hybrid, fp-151-RGD, maintained the high production yield of fp-151, but also presented superior spreading and cell-adhesion abilities compared to the commercially produced cell-adhesion materials poly-L-lysine (PLL) and

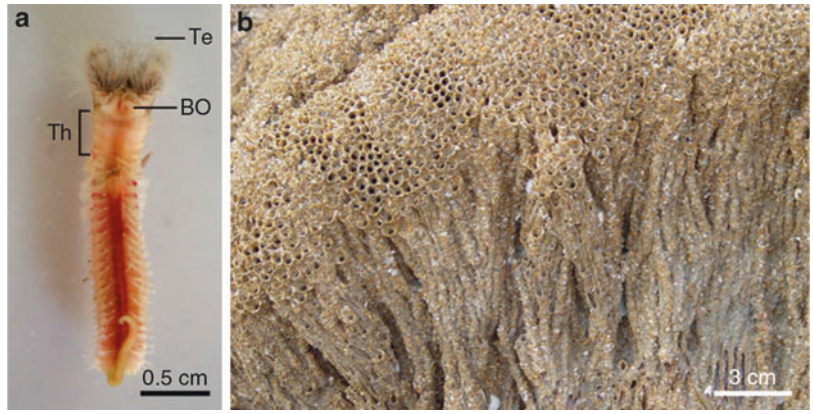
Cell-Tak, and this regardless of mammalian cell line used [6]. The excellent adhesion and spreading abilities of fp-151-RGD might be due to the fact that it combines three types of cell-binding mechanisms: DOPA adhesion of Cell-Tak, cationic binding force of PLL, and RGD sequence-mediated adhesion of fibronectin. These characteristics make the two hybrid proteins fp-151 and fp-151-RGD suitable for use as cell-adhesion material in cell culture or tissue engineering. In a totally different context, fp-151 has been proposed as a potential gene delivery material in view of its similar amino acid composition to histone proteins, which are known as effective mediators of transfection. The fusion protein displayed comparable transfection efficiency in human and mouse cells compared to the widely used transfection agent Lipofectamine™ (Invitrogen).

Production of MAP Mimetic Adhesive Polymers

Another way to mimic mussel adhesive proteins is by the chemical synthesis of important functional parts of these adhesives. This has been done either by peptide synthesis or by the functionalization of various other polymers with MAP reactive groups, mostly DOPA or catechol groups.

Various synthetic polypeptides inspired by MAPs were studied for adhesion strength [7, 8, 10]. This approach was used to experimentally identify the exact functions of the amino acids that are active in the chemistry of the adhesive proteins. The importance of particular MAP over-expressed amino acids, mainly Lys and Tyr/DOPA, was therefore tested through different polytripeptides and polydipeptides such as poly (X-Tyr-Lys), poly(Gly-Lys), poly(Tyr-Lys), and poly(Gly-Tyr), each peptide being subsequently incubated with tyrosinase for the enzymatic hydroxylation of tyrosines into DOPA. The adhesive strength of poly(X-Tyr-Lys) peptides, irrespective of whether X was Gly, Ala, Pro, Ser, Leu, Ile, or Phe, measured on pig skin (i.e., 0.01 MPa) was higher than that of poly(Gly-Lys) peptides but similar to the one of poly(Tyr-Lys) peptides and of a poly(fp-1 decapeptide) [10]. Tyrosine (DOPA) and lysine thus appears as key amino acids for adhesion efficiency, with little importance of the other residues and of the primary structure of the MAPs. A poly(Gly-Tyr-Lys) peptide was also used as a surgical glue to close a skin incision in a living pig. Good incision adhesion and reduced immunological response after 1 week were observed.

Peptide synthesis also allows the direct incorporation of DOPA into the polymers, thus avoiding the complications associated with the oxidation of precursor tyrosine residues [7, 8, 10]. Water soluble copolypeptides containing DOPA and Lys residues were prepared by polymerization of α-amino acid N-carboxyanhydride monomers. Using lap shear tensile adhesive measurements, these copolymers were found to form moisture-resistant adhesive bonds to a variety of substrata after cross-linking with different oxidizing agents. Adhesion was strongest to metals and polar surfaces such as glass (3–5 MPa) [10]. Adhesive strength of about 0.2 MPa was also measured on porcine skin and bone in vitro. Furthermore, outcomes of endothelial cell cultures demonstrated that the copolypeptide presented a good cell affinity, which would provide basic data for its application in the biomaterial field [10].



DOPA being considered as a key component of MAPs for adhesion, functionalization of synthetic polymers other than polypeptides with catechol groups has emerged as a promising strategy for the development of new biomimetic adhesives [1, 7, 11]. Following this approach, simplified polymer mimics of MAPs have been designed in which a polystyrene backbone is used to take the place of the protein polyamide chain. Hardening of this poly[(3,4-dihydroxystyrene)-*co*-styrene] by treatments with various oxidizing agents including dichromate and Fe^{3+} yielded adhesive strength of up to 1.2 MPa on aluminum [7]. Linear and branched poly(ethyleneglycol) (PEG) molecules were also chemically coupled to one to four DOPA endgroups. PEG has a low toxicity and is considered to be nonallergenic, therefore allowing its utilization as a convenient platform in medicine [1]. The addition of oxidizing agents resulted in the polymerization of PEG-DOPA via DOPA-quinone cross-links, forming polymer networks and rapid gelation. Although these gels were not

adhesive, it has been shown that unoxidized four-armed PEG polymers functionalized with a single DOPA residue at the extremity of each arm (PEG-$DOPA_4$) adsorbed strongly on mucin, this mucoadsorption being largely due to the presence of DOPA [11]. A tissue adhesive was investigated by using liposomes in order to compartmentalize an oxidizing reagent ($NaIO_4$) in a solution containing PEG-$DOPA_4$ [11]. While sodium periodate is sequestered in these vesicles at room temperature, it is released in the polymer solution when liposomes melted at wound site (37 °C). Oxidation of PEG-$DOPA_4$ resulted in hydrogel formation with interesting adhesive properties. Indeed, lap shear strength between two porcine dermal tissues was five times higher than that of fibrin glue [11]. A similar strategy was used for efficient immobilization of transplanted pancreatic islets in mice, with minimal inflammatory response. Polymers made up of PEG-DOPA coupled to polycaprolactone (PCL) were also used to coat the biologic meshes used for hernia repair.

Paradoxically, PEG-DOPA polymers can also be used for antifouling applications. In this last case, DOPA or DOPA-containing peptides are conjugated to PEG polymers to allow their adsorption to Au and Ti surfaces [1]. The surfaces modified with these polymers were shown to be resistant to cell attachment and protein adsorption suggesting that they might be used to design cell and protein-resistant surfaces for medical implants, anti-icing coating on aircraft wings and nonfouling marine structures (Kensey Nash Corporation, Exton, PA USA).

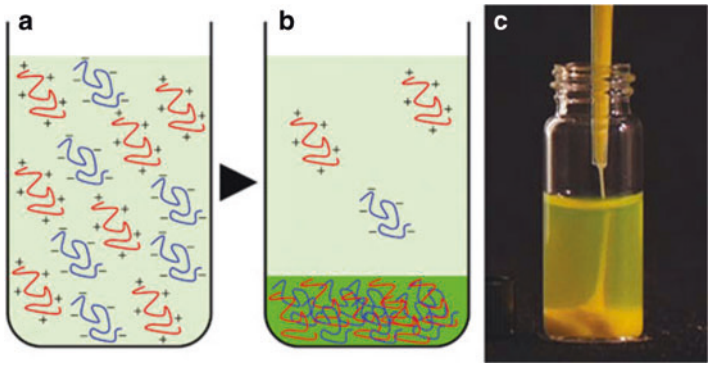
The use of toxic oxidizing reagents for solidification of hydrogels represents a medical concern for in vivo applications [1, 2, 7, 11]. To avoid such reagents, DOPA was then conjugated to poly(ethyleneoxide)-poly(propyleneoxide)-poly(ethyleneoxide) (PEO-PPO-PEO) block copolymers. These DOPA-modified block copolymers were soluble in cold water but self-aggregated into micelles at a higher temperature that was dependent on the block copolymer concentration. For instance, a 20 wt% solution formed gels when heated to body temperature. Photopolymerization is another approach to achieve oxidation-free cross-linking and monomers combining DOPA and a UV (or visible light)-polymerizable methacrylate group were therefore copolymerized with PEG diacrylate. In both heat and light-triggered polymerization, gelation did not result from DOPA-quinones cross-links. DOPA groups were thus available for adhesion but the adhesive strength of these hydrogels was not investigated. Self-assembly of amphiphilic triblock copolymers is also an alternative strategy to obtain oxidation-free polymerization. Triblock copolymers were made up of hydrophobic endblocks consisting of poly(methylmethacrylate) (PMMA) and of a poly(methacrylic acid) (PMAA) water-soluble midbl ock. DOPA was incorporated into the hydrophilic PMAA. Hydrogels were then obtained by exposing triblock copolymers solution in DMSO to water vapor. As water diffused into the solution, the hydrophobic endblocks formed aggregates that were bridged by water-soluble midblocks. Underwater adhesive properties of a DOPA-modified PMMA-PMAA-PMMA membrane on titanium and pig skin were assessed and showed strong adhesion in both cases.

The strategy centered on the functionality of the catechol group reaches its highest point with the report of a method to form multifunctional polymer coatings through simple dip-coating of objects in an aqueous solution of dopamine, a DOPA analog [12]. Indeed, dopamine self-polymerization forms thin, surface-adherent polydopamine films onto a wide range of inorganic and organic materials including metals, oxides, polymers, semiconductors, and ceramics. Secondary reactions can then be used to create a variety of ad-layers [12, 13]. On metals, these polydopamine films can provide corrosion protection properties. They can also promote cell adhesion on any type of material surfaces including the well-known anti-adhesive substrate, poly(tetrafluoroethylene), and therefore convert a variety of bioinert substrates into bioactive ones [12, 13]. Another important application of this method is the improvement of interfacial properties in composites. The macroscale properties of polymer-matrix composites depend immensely on the quality of the interaction between the reinforcement phase and the bulk polymer, and

Biomimetics of Marine Adhesives, Fig. 3 A polychaete of the species *Sabellaria alveolata* (**a**) and a reef fragment made of the imbricated tubes built by individuals of this species (**b**). *BO* building organ, *Te* tentacles, *Th* thorax

polydopamine films deposited on the reinforcement phase have been demonstrated to increase interfacial shear stress. For solar cell applications, binding photosensitizer onto semiconductor surfaces, especially TiO_2 surfaces, via catechol groups is a very promising method for creating stable interfaces [13].

Tubeworms



Some polychaete worms of the family Sabellariidae are tube-dwelling and live in the intertidal zone. They are commonly called honeycomb worms or sandcastle worms because they are gregarious and the tubes of all individuals are closely imbricated to form large reef-like mounds (Fig. 3). To build the tube in which they live, they collect particles such as sand grains or shell fragments with their tentacles from the water column and sea bottom. These particles are then conveyed to the building organ which is a crescent-shaped structure near the mouth. There, the particles are dabbed with spots of cement secreted by two types of unicellular glands located in the worm's thorax, and then added to the end of the preexisting tube by the building organ [2, 7, 14].

Cement composition has been investigated in the species *Phragmatopoma californica*. The adhesive consists mostly of three proteins (known as *Phragmatopoma* cement proteins 1–3, abbreviated as Pc-1, 2, and 3) and large amounts of Mg^{2+} and Ca^{2+} ions [7, 14]. The three cement proteins have highly repetitive primary structures with limited amino acid diversity (Table 3). As it is the case for plaque proteins in mussels, Pc-1 and 3 are present in the form of several variants. Pc-1 and 2 contain basic residues with amine side chains and DOPA residues, some of which are halogenated into 2-chloro-DOPA residues [14, 15]. DOPA residues presumably play the same functions as in MAPs (Fig. 2), contributing to both adsorptive interactions with the surface (adhesion) and cross-link formation (cohesion). Regarding the chloro-DOPA residues, they could be involved in the protection of the cement from microbial fouling and degradation. Pc-3 is particularly rich in serine (72.9 mol%) and careful calculations indicated that up to 90 % of

Biomimetics of Marine Adhesives, Fig. 4 Complex coacervation is the associative phase separation in a solution of positively and negatively charged macroions. From a stable colloidal solution of polyelectrolyte complexes (**a**), a trigger such as a pH change leads to the formation of two immiscible aqueous phases, a dilute equilibrium phase and a denser solute-rich phase (**b**). The latter, called the coacervate phase, is an isotropic liquid containing amorphous associative particles that move freely relative to one another ((**c**) Courtesy of R. Stewart, University of Utah, USA)

these serine residues are posttranslationally phosphorylated [14, 15]. Pc-3 is therefore a remarkably acidic protein (pI ∼ 1). Phosphorylation is thought to impart a potential for both cohesive (by Ca^{2+} or Mg^{2+} bridging) and adhesive contributions to the cement [14].

The co-occurrence of the positively charged Pc-1 and Pc-2 proteins and the negatively charged Pc-3 protein in the tube worm cement led to the hypothesis that a phenomenon called complex coacervation could play a role in the condensation of the adhesive in the form of a dense water-immiscible fluid [14, 15]. Complex coacervation is the spontaneous separation of an aqueous solution of two oppositely charged polyelectrolytes into two immiscible aqueous phases, a dilute equilibrium phase and a denser solute-rich phase (Fig. 4). Coacervation occurs when the charges of the polyelectrolytes are balanced. This phenomenon is therefore pH dependent, occurring to the maximum extent at the pH where the solution is electrically neutral; ionic strength dependent, since shielding of charges can change the charge balance of the system [15]; and dependent on the ratio of polyelectrolyte concentrations. Whether complex coacervation is really involved in the formation of the natural cement or not is still under debate. However, the ideal material and rheological properties of complex coacervates provided a valuable blueprint for the synthesis of a biomimetic, water-borne, underwater adhesive [15]. Based on the tubeworm model, poly(meth) acrylate polymers with phosphate, amine, and catechol side chains in the same molar ratios as the natural adhesive proteins Pc1-3 were synthesized [7, 15]. Analogs of Pc-1 and 2 were created by copolymerization of *N*-(3-aminopropyl) methacrylamide hydrochloride (APMA) and acrylamide. Mimics of Pc-3 were synthesized by free radical copolymerization of monoacryloxyethyl phosphate (MAEP), acrylamide, and dopamine methacrylate (DMA), the latter being a DOPA analog monomer [15]. Both copolymers were mixed, with divalent cations, in similar proportions as the natural proteins. Around neutral pH, they condensed into a liquid complex coacervate (Fig. 4c) while at pH 10, they formed a hydrogel through cross-links between dopaquinone and amine side chains [7, 15]. The underwater bond strength of the biomimetic adhesive on aluminum was ∼0.8 MPa, about twice the value estimated for the natural glue [15]. Moreover, a biodegradable, temperature-triggered version of the adhesive coacervate was designed by replacing the APMA/acrylamide copolymer by an amine-modified collagen hydrolysate. This adhesive coacervate was used to repair rat calvarial bone defect and was capable of maintaining three-dimensional bone alignment in freely moving rats over a 12-week indwelling period

Biomimetics of Marine Adhesives, Fig. 5 The brown alga *Fucus serratus* ((**a**) Courtesy of H. Bianco-Peled, Technion – Israel Institute of Technology) and the chemical structure of brown algal polyphenol (**b**) and phloroglucinol monomer (**c**)

[15]. Histological evaluation demonstrated that the adhesive was gradually resorbed and replaced by new bone with an inflammatory response commensurate with normal wound healing. This noncytotoxic degradable coacervate therefore appears to be suitable for use in the reconstruction of craniofacial features [15].

The tubeworm cement-inspired complex coacervates prompted efforts to form complex coacervates with other biomimetic adhesives such as the mussel hybrid fusion proteins fp-151 and fp-131 [15]. The MAP hybrids are insoluble at physiological pH so coacervation was done at pH 3.8 with hyaluronic acid (HA) at HA:fp-151 (or fp-131) ratios of 3:7. Importantly, it was found that the highly condensed complex coacervates significantly increased the bulk adhesive strength of MAPs in both dry and wet environments (up to ~4 MPa on aluminum) [15]. In addition, oil droplets were successfully incorporated in the coacervate, forming a microencapsulation system that could be useful in the development of self-adhesive microencapsulated drug carriers, for use in biotechnological and biomedical applications. Coacervates were also prepared using HA and fp-151-RGD [15]. The low interfacial energy of the coacervate was exploited to coat titanium (Ti), a metal widely used in implant materials. The coacervate effectively distributed both HA and fp-151-RGD over the Ti surfaces and enhanced osteoblast proliferation.

Brown Algae

Brown algae live firmly attached on substrata in the subtidal and intertidal rocky shores where they are often exposed to high gradients of turbulence [1]. They have therefore developed adhesive strategies to attach themselves strongly and durably throughout their life cycle, from the microscopic reproductive cell stages to the large thalli of mature algae (Fig. 5a). Enzymatic extractions and cytochemical studies indicated that the adhesive mucilage produced by these algae contain polysaccharides and glycoproteins [1, 16]. Phenolic polymers also play a role in brown algae adhesion. They appear to be secreted a few hours after fertilization, allowing initial substratum adhesion and, after germination, are localized at the site of adhesive mucilage formation, the rhizoid tip in the case of *Fucus*. These polyphenols are composed of phloroglucinol units linked by carbon–carbon and ether bonds (Fig. 5b). They are reminiscent of the DOPA-containing proteins of mussels and tubeworms in that they can be oxidized and form

cross-links. The proposed mechanism of algal adhesion indeed postulates that the polyphenols are oxidized by an extracellular vanadium bromoperoxidase to enable their cross-linking with the polysaccharide components of the adhesive such as alginate [16].

The adhesive of the species *Fucus serratus* inspired a biomimetic glue composed of synthetic phloroglucinol units (Fig. 5c), alginate, and calcium for medical applications [17]. This synthetic adhesive was shown to be capable of adhering to a variety of both hydrophilic and hydrophobic surfaces, with strength similar to that of the algal-born natural adhesive (0.017–0.025 MPa). It also adhered well to porcine tissue and was shown to be safe for living cells. The biomimetic adhesive was also tested on porcine muscle tissue and presented a tensile strength similar to that of the commercially available fibrin glue Tisseel™. It is marketed as a vascular sealant for surgical adjunctive leakage control (SEAlantis Ltd., Haifa, Israel).

Barnacles

Barnacles are sessile crustaceans that attach firmly and massively not only to a large variety of underwater natural substrata such as rocks (Fig. 6), but also to man-made substrata such as ship hulls therefore causing major economical losses [2].

Biomimetics of Marine Adhesives, Fig. 6 Group of barnacles of the species *Elminius modestus* attached on a rock (Picture courtesy of N. Aldred, Newcastle University, UK)

In these organisms, attachment is mediated by the release of a permanent adhesive called cement [1, 2, 18]. In acorn barnacles, this cement is produced by large isolated secretory cells (the cement cells) joined together by ducts which open onto the base of the animal [18]. The cement is composed of approximately 90 % proteins with the remainder as carbohydrates (1 %), lipids (1 %), and inorganic ash (4 %, of which calcium accounts for 30 %). More than ten proteins have been found in the cement (cement proteins abbreviated as cp) [1, 19], of which six have been purified and characterized, originally from the species *Megabalanus rosa* and later from other species from the genera *Amphibalanus*, *Balanus*, *Fistulobalanus* and *Semibalanus* [1]. Their features are summarized in Table 4. Among these proteins, three (cp-19 k, cp-20 k, and cp-68 k) have a surface coupling function, two (cp-52 k and cp-100 k) have a bulk function, and the last one (cp-16 k) is an enzyme whose possible function is the protection of the cement from microbial degradation [18, 19]. Evidence to date suggests that barnacles display a contrasting adhesive system compared to mussels and tubeworms, two animals characterized by their reliance on post-translational modification of adhesive proteins, especially the formation of DOPA residues. On the other hand, little or no posttranslational modifications have been found so far in individual barnacle cement proteins [18]. Their strong attachment to surfaces does not involve therefore the "DOPA-system." Only one of the cement proteins, cp-68 k, appears to be posttranslationally modified. This protein is indeed glycosylated, although the glycosyl moiety is limited in amount.

As in mussels, the first attempts to exploit the potentialities of barnacle glue were undertaken in the early 1980s. Native cement was shown to be effective in tests of rabbit bone repair. However, the difficulty to collect sufficient quantities of adhesive material prevented further use of this material in concrete medical procedures [7]. Recently, the proteins cp-19 k and cp-20 k, have been produced in bacteria in the form of recombinant proteins at the laboratory scale. Both recombinant cps were demonstrated to present underwater irreversible adsorption activity to

Biomimetics of Marine Adhesives, Table 4 Characteristics of the cement proteins of the barnacle *Megabalanus rosa*

Protein[a]	Repeated unit	Feature	Proposed function
cp-16 k	None	Similar to lysozyme	Antimicrobial
cp-19 k	None	Bias toward Ser, Thr, Gly, Ala, Lys, Val (these residues amount for 67 % of the total amino acids)	Surface coupling
cp-20 k	Six Cys-rich repeated sequences	Cys, charged amino acids	Surface coupling
cp-52 k	Repetitive sequence	Hydrophobic	Cement structural framework
cp-68 k	None	Bias toward Ser, Thr, Ala, Gly (these residues amount for 60 % of the total amino acids); glycosylated	Surface coupling
cp-100 k	None	Hydrophobic	Cement structural framework

Ala alanine, *Cys* cysteine, *Gly* glycine, *Lys* lysine, *Ser* serine, *Thr* threonine, *Val* valine

[a]Denotes cement protein with its apparent molecular weight (kDa)

a variety of surface materials, including positively charged, negatively charged, and hydrophobic ones [19].

The protein cp-20 k was used for the design of self-assembling peptides [18]. This protein is characterized by its high content of charged amino acids and cysteines, and by the presence of six repetitive sequences deduced from the alignment of cysteines (Cys) [1]. A single repetitive sequence, containing four Cys, has been chemically synthesized to obtain a water-soluble peptide solution. The addition of salt at a final concentration of 1 M triggered an irreversible self-assembly into a macroscopic membrane made up of interwoven nanofilaments [18]. Treatment with dithiothreitol (DTT), a reducing agent, and the replacement of cysteines by serines in the peptide did not affect self-assembly. This means that the latter is not dependent on the formation of disulfide bonds but rather on noncovalent molecular interactions. However, extended incubation of the peptide solution in buffers at alkaline pH caused a conformational change and the formation of a three-dimensional mesh-like structure stabilized by disulfide bonds. It was proposed that this self-assembling peptide may present a novel source of inspiration for the design of new materials [18].

Perspectives

From the biologist's perspective, marine adhesives may serve one or more of the following functions: (a) the temporary or permanent attachment of an organism to a surface, including dynamic attachment during locomotion and maintenance of position; (b) the collection or capture of food items; or (c) the building of tubes or burrows. The evolutionary background and biology of the species, on one hand, and environmental constraints on the other hand, both influence the specific composition and properties of adhesive secretions in a particular organism. The diversity of marine adhesives is therefore huge and daunting for researchers but, in return, it will also allow a great deal of flexibility in applications. To date, only a very limited number of marine organisms have been used as models for the development of biomimetic adhesives and most of this diversity remains unexploited. The study of new model organisms representative of the three different types of adhesion is therefore required in order to extract essential structural, mechanical, and chemical principles from their adhesives. Simplification of natural systems while retaining the desired efficacy is, indeed, one of the foundation stones of biomimetics. As quoted by Herbert Waite [2], it is no longer absurd to predict that a compilation of bio-inspired adhesive designs will someday fill a textbook with recipes for a whole range of applications, from technical to medical.

Definition

The study and industrial application of structural colour and antireflective devices in nature.

Introduction

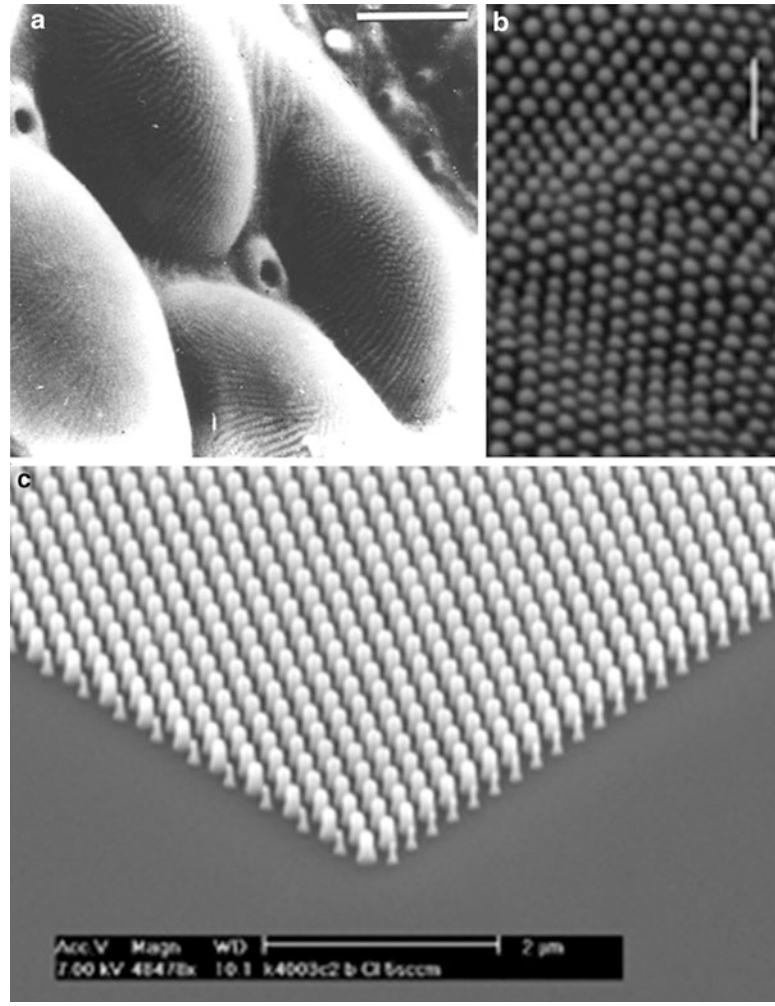
Three centuries of research, beginning with Hooke and Newton, have revealed a diversity of optical devices at the nanoscale (or at least the submicron scale) in nature [1]. These include structures that cause random scattering, 2D diffraction gratings, 1D multilayer reflectors, and 3D liquid crystals (Fig. 1a–d). In 2001 the first photonic crystal was identified as such in animals [2], and since then, the scientific effort in this subject has accelerated. Now we know of a variety of 2D and 3D photonic crystals in nature (e.g., Fig. 1e, f), including some designs not encountered previously in physics.

Biomimetics of Optical Nanostructures, Fig. 1 Summary of the main types of optical reflectors found in nature: (**a**–**d**) where a light ray is (generally) reflected only once within the system (i.e., they adhere to the single scattering, or first Born approximation) and (**e**, **f**) where each light ray is (generally) reflected multiple times within the system. (**a**) An irregular array of elements that scatter incident light into random directions. The scattered (or reflected) rays do not interfere. (**b**) A diffraction grating, a surface structure, from which incident light is diffracted into specific angular directions resulting in a spatial separation of its angular wavelength/color

Biomimetics is the extraction of good design from nature. Some optical biomimetic successes have resulted from the use of conventional (and constantly advancing) engineering methods to make direct analogues of the reflectors and antireflectors found in nature. However, recent collaborations between biologists, physicists, engineers, chemists, and materials scientists have ventured beyond merely mimicking in the laboratory what happens in nature, leading to a thriving new area of research involving biomimetics via cell culture. Here, the nanoengineering efficiency of living cells is harnessed, and nanostructures such as diatom "shells" can be made for commercial applications via culturing the cells themselves.

Engineering of Antireflectors

Some insects benefit from antireflective surfaces, either on their eyes to see under low-light conditions or on their wings to reduce surface reflections in transparent (camouflaged) areas. Antireflective surfaces, therefore, occur on the corneas of moth and butterfly eyes [3] and on the transparent wings of hawkmoths [4]. These consist of nodules, with rounded tips, arranged in a hexagonal array with a periodicity of around 240 nm (Fig. 2b). Effectively, they introduce a gradual refractive index profile at an interface between chitin (a polysaccharide, often embedded in a proteinaceous matrix; r.i. 1.54) and air and hence reduce reflectivity by a factor of ten.



This "moth-eye structure" was first reproduced at its correct scale by crossing three gratings at 120° using lithographic techniques and employed as antireflective surfaces on glass windows in Scandinavia [5]. Here, plastic sheets bearing the antireflector were attached to each interior surface of triple-glazed windows using refractive-index-matching glue to provide a significant difference in reflectivity. Today, the moth-eye structure can be made extremely accurately using e-beam etching [6] and is also employed commercially on solid plastic and other lenses.

A different form of antireflective device, in the form of a sinusoidal grating of 250 nm periodicity, was discovered on the cornea of a 45 million-year-old fly preserved in amber [7] (Fig. 2a). This is particularly useful where light is incident at a range of angles (within a single plane, perpendicular to the grating grooves), as demonstrated by a model made in photoresist using lithographic methods [7]. Consequently, it has been employed on the surfaces of solar panels, providing a 10 % increase in energy capture through reducing the reflected portion of sunlight [8]. Again, this device is embossed onto plastic sheets using holographic techniques.

Engineering of Iridescent Devices

Many birds, insects (particularly butterflies and beetles), fishes, and lesser-known marine animals display iridescent (changing color with angle) and/or "metallic" colored effects resulting from photonic nanostructures. These appear comparatively brighter than the effects of pigments and often function in animals to attract the attention of a potential mate or to startle a predator. An obvious application for such visually attractive and optically sophisticated devices is within the anti-

Biomimetics of Optical Nanostructures, Fig. 1 (continued) components. Each corrugation is about 500 nm wide. Diffracted rays superimpose either constructively or destructively. (**c**) A multilayer reflector, composed of thin (ca. 100 nm thick) layers of alternating refractive index, where light rays reflected from each interface in the system superimpose either constructively or destructively. (**d**) A "liquid crystal" composed of nano-fibers arranged in layers, where the nano-fibers of one layer lie parallel to each other yet are orientated slightly differently to those of adjacent layers. Hence, spiral patterns can be distinguished within the structure. The height of the section shown here – one "period" of the system – is around 200 nm. (**e**) Scanning electron micrograph of the "opal" structure – a close-packed array of submicron spheres (a "3D photonic crystal") – found within a single scale of the weevil *Metapocyrtus* sp.; scale bar = 1 μm. counterfeiting industry. For secrecy reasons, work in this area cannot be described, although devices are sought at different levels of sophistication, from effects that are discernable by the eye to fine-scale optical characteristics (e.g., polarization and angular properties) that can be read only by specialized detectors. However, new research aims to exploit these devices in the cosmetics, paint, printing/ink, and clothing industries. They are even being tested in art to provide a sophisticated color change effect.

Original work on exploiting nature's reflectors involved copying the design but not the size, where reflectors were scaled up to target longer wavelengths. For example, rapid prototyping was employed to manufacture a microwave analogue of a *Morpho* butterfly scale that is suitable for reflection in the 10–30 GHz region. Here layer thicknesses would be in the order of 1 mm rather than 100 nm as in the butterfly, but the device could be employed as an antenna with broad radiation characteristics or as an antireflection coating for radar. However, today, techniques are available to manufacture nature's reflectors at their true size.

Nanostructures causing iridescence include photonic crystal fibers, opal and inverse opal, and unusually sculpted 3D architectures. Photonic crystals are ordered, often complex, sub-wavelength (nano)lattices that can control the propagation of light at the single wave scale in the manner that atomic crystals control

Biomimetics of Optical Nanostructures, Fig. 3 (**a**) A manuka (scarab) beetle with (**b**) titania mimetic films of slightly different pitches. (**c**) Scanning electron micrograph of the chiral reflector in the beetle's cuticle. Scale bar = 500 nm. (**d**) Scanning electron micrograph of the titania mimetic film. electrons [9]. Examples include opal (a hexagonal or cubic close-packed array of 250 nm spheres) and inverse opal (a hexagonal array of similar-sized holes in a solid matrix). Hummingbird feather barbs contain ultrathin layers with variations in porosity that cause their iridescent effects, due to the alternating nanoporous/fully dense ultrastructure [10]. Such layers have been mimicked using aqueous-based layering techniques [10]. The greatest diversity of 3D architectures can be found in butterfly scales, which can include micro-ribs with nano-ridges, concave multilayered pits, blazed gratings, and randomly punctate nano-layers [11, 12]. The cuticle of many beetles contains structurally chiral films that produce iridescent effects with circular or elliptical polarization properties [13]. These have been replicated in titania for specialized coatings [13], where a mimetic sample can be compared with the model beetle and an accurate variation in spectra with angle is observed (Fig. 3). The titania mimic can be nanoengineered for a wide range of resonant wavelengths; the lowest so far is a pitch of 60 nm for a circular Bragg resonance at 220 nm in a Sc_2O_3 film (Ian Hodgkinson, pers. comm.).

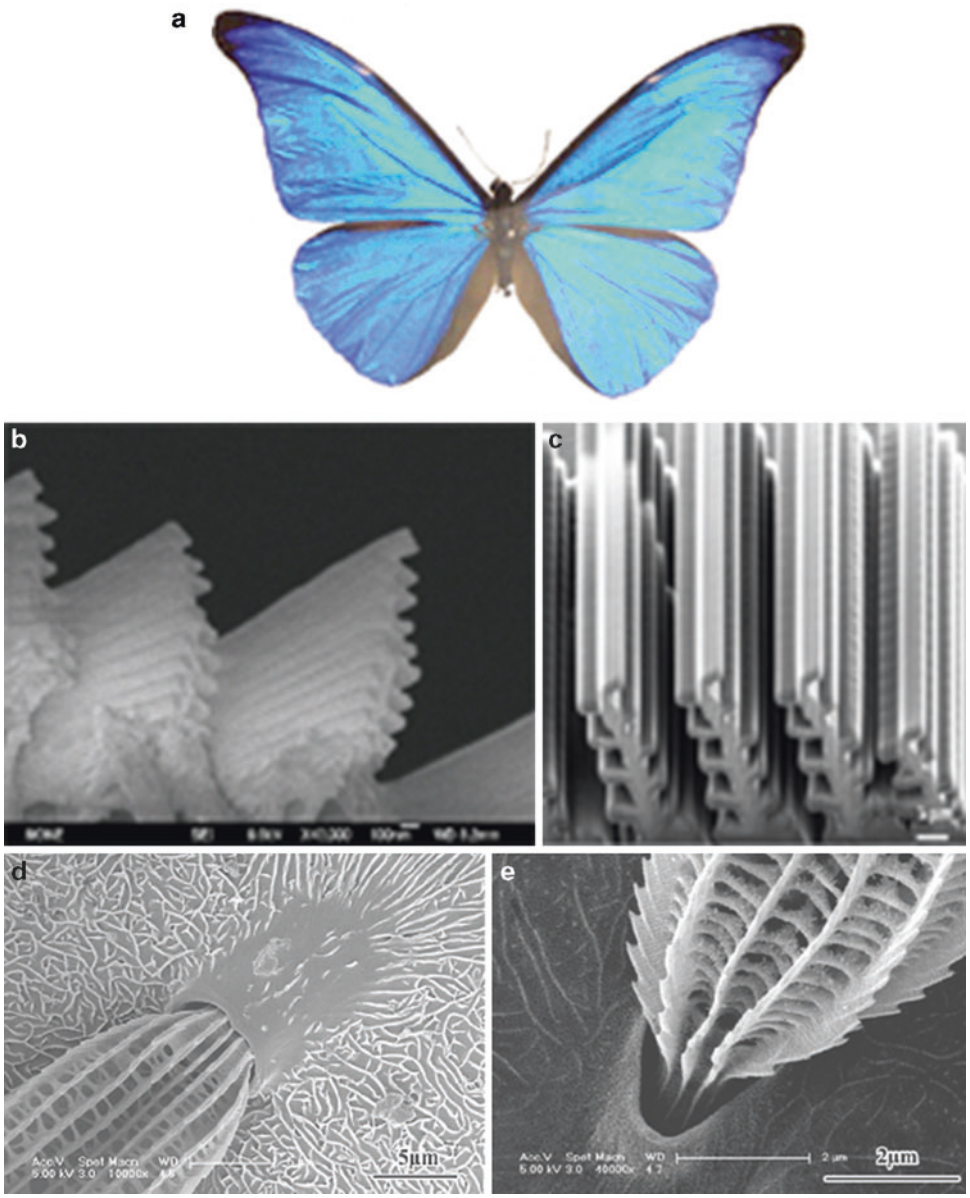
Biomimetic work on the photonic crystal fibers of the *Aphrodita* sea mouse is underway. The sea mouse contains spines (tubes) with walls packed with smaller tubes of 500 nm, with varying internal diameters (400–450 nm). These provide a bandgap in the red region and are to be manufactured via an extrusion technique. Larger glass tubes packed together in the proportion of the spine's nanotubes will be heated and pulled

through a drawing tower until they reach the correct dimensions. The sea mouse fiber mimics will be tested for standard PCF applications (e.g., in telecommunications) but also for anti-counterfeiting structures readable by a detector.

Analogues of the famous blue *Morpho* butterfly (Fig. 4a) scales have been manufactured [14, 15]. Originally, corners were cut. Where the *Morpho* wing contained two layers of scales – one to generate color (a quarter-wave stack) and another above it to scatter the light – the model copied only the principle [14]. The substrate was roughened at the nanoscale and coated with 80 nm thick layers alternating in refractive index [14]. Therefore, the device retained a quarter-wave stack centered in the blue region, but incorporated a degree of randomness to generate scattering. The engineered device closely matched the butterfly wing – the color observed changed only slightly with changing angle over 180°, an effect difficult to achieve and useful for a broad-angle optical filter without dyes.

A new approach to making the 2D "Christmas tree" structure (a vertical, elongated ridge with several layers of 70 nm thick side branches; Fig. 4b) has been achieved using focused-ion-beam chemical-vapor-deposition (FIB-CVD) [15]. By combining the lateral growth mode with ion beam scanning, the Christmas tree structures were made accurately (Fig. 4c). However, this method is not ideal for low-cost mass production of 2D and 3D nanostructures, and therefore, the ion-beam-etched Christmas trees are currently limited to high-cost items including nano- or micron-sized filters (such as "pixels" in a display screen or a filter). Recently, further corners have been cut in manufacturing the complex nanostructures found in many butterfly scales, involving the replication of the scales in ZnO, using the scales themselves as templates [16] (Fig. 4d, e).

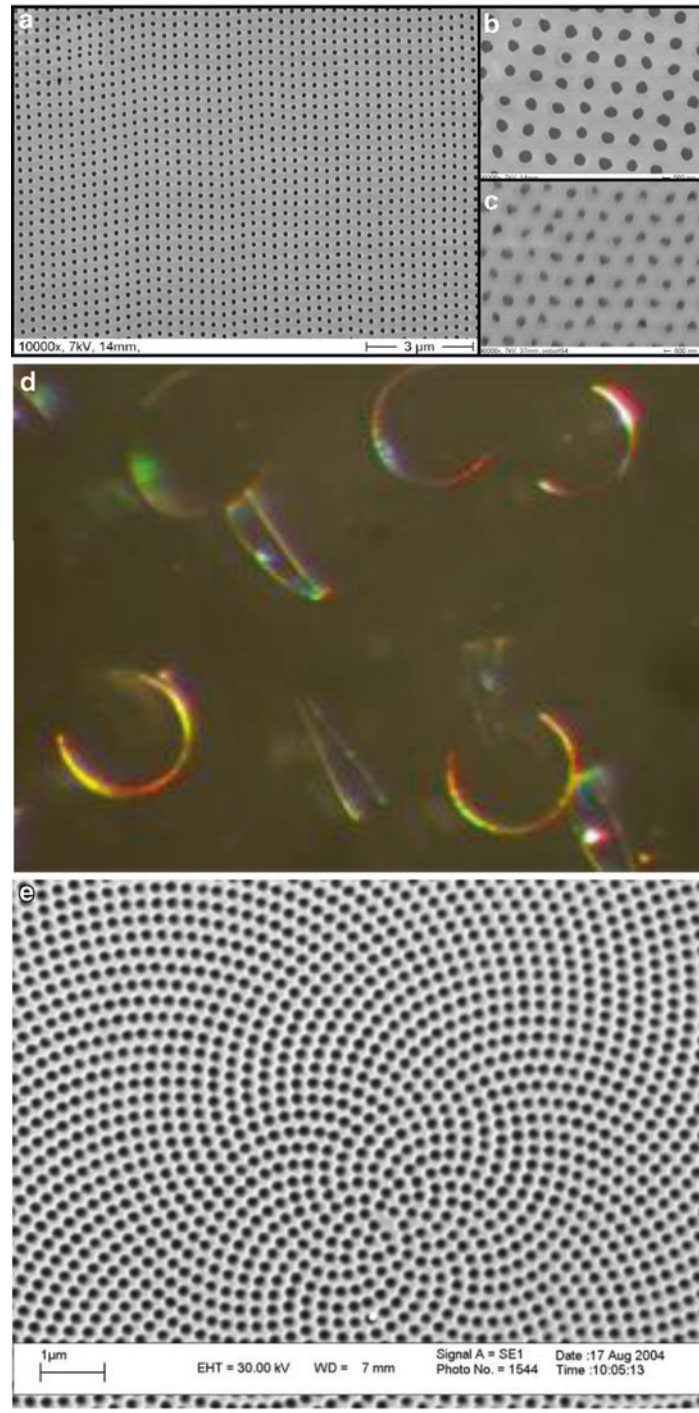
Cell Culture



Sometimes nature's optical nanostructures have such an elaborate architecture at such a small (nano)scale that we simply cannot copy them using current engineering techniques. Additionally, sometimes they can be made as individual reflectors (as for the *Morpho* structure), but the effort is so great that commercial-scale manufacture would never be cost effective.

An alternative approach to making nature's reflectors is to exploit an aspect other than design – that the animals or plants can make them efficiently. Therefore, we can let nature manufacture the devices for us via cell culture techniques. Animal cells are in the order of 10 μm in size and plant cells up to about 100 μm and hence suitable for nanostructure production. The success of cell culture depends on the species and on the type of cell from that species. Insect cells, for instance, can be cultured at room temperature, whereas an incubator is required for mammalian cells. Cell culture is not a straightforward method, however, since a culture medium must be established to which the cells adhere, before they can be induced to develop to the stage where they make their photonic devices.

Current work in this area centers on butterfly scales. The cells that make the scales are identified in chrysalises, dissected, and plated out. Then the individual cells are separated, kept alive in culture, and prompted to manufacture scales through the addition of growth hormones. Currently, we have cultured blue *Morpho* butterfly scales in the lab that have identical optical and structural characteristics to natural scales. The cultured scales could be embedded in a polymer or mixed into a paint, where they may float to the surface and self-align. Further work, however, is required to increase the level of scale production and to harvest the scales from laboratory equipment in appropriate ways. A far simpler task emerges where the iridescent organism is single celled.



Diatoms and Coccolithophores

Diatoms are unicellular photosynthetic microorganisms. The cell wall is called the frustule and is made of the polysaccharide pectin impregnated with silica. The frustule contains pores

Biomimetics of Optical Nanostructures, Fig. 4 (**a**) A *Morpho* butterfly with (**b**) a scanning electron micrograph of the structure causing the blue reflector in its scales. (**c**) A scanning electron micrograph of the FIB-CVD-fabricated mimic. A Ga^+ ion beam (beam diameter 7 nm at 0.4 pA, 30 kV), held perpendicular to the surface, was used to etch a precursor of phenanthrene ($C_{14}H_{10}$). Both give a wavelength peak at around 440 nm and at the same angle (30°). (**d**) Scanning electron micrograph of the base of a scale of the butterfly *Ideopsis similis*. (**e**) Scanning electron micrograph of a ZnO replica of the same part of the scale in (**d**) ((**a**–**c**) by K. Watanabe and (**d**) and (**e**) by W. Zhang, all reproduced with permission of the authors. Scale bars: (**b**) and (**c**) = 100 nm, (**d**) = 5 μm, (**e**) = 2 μm)

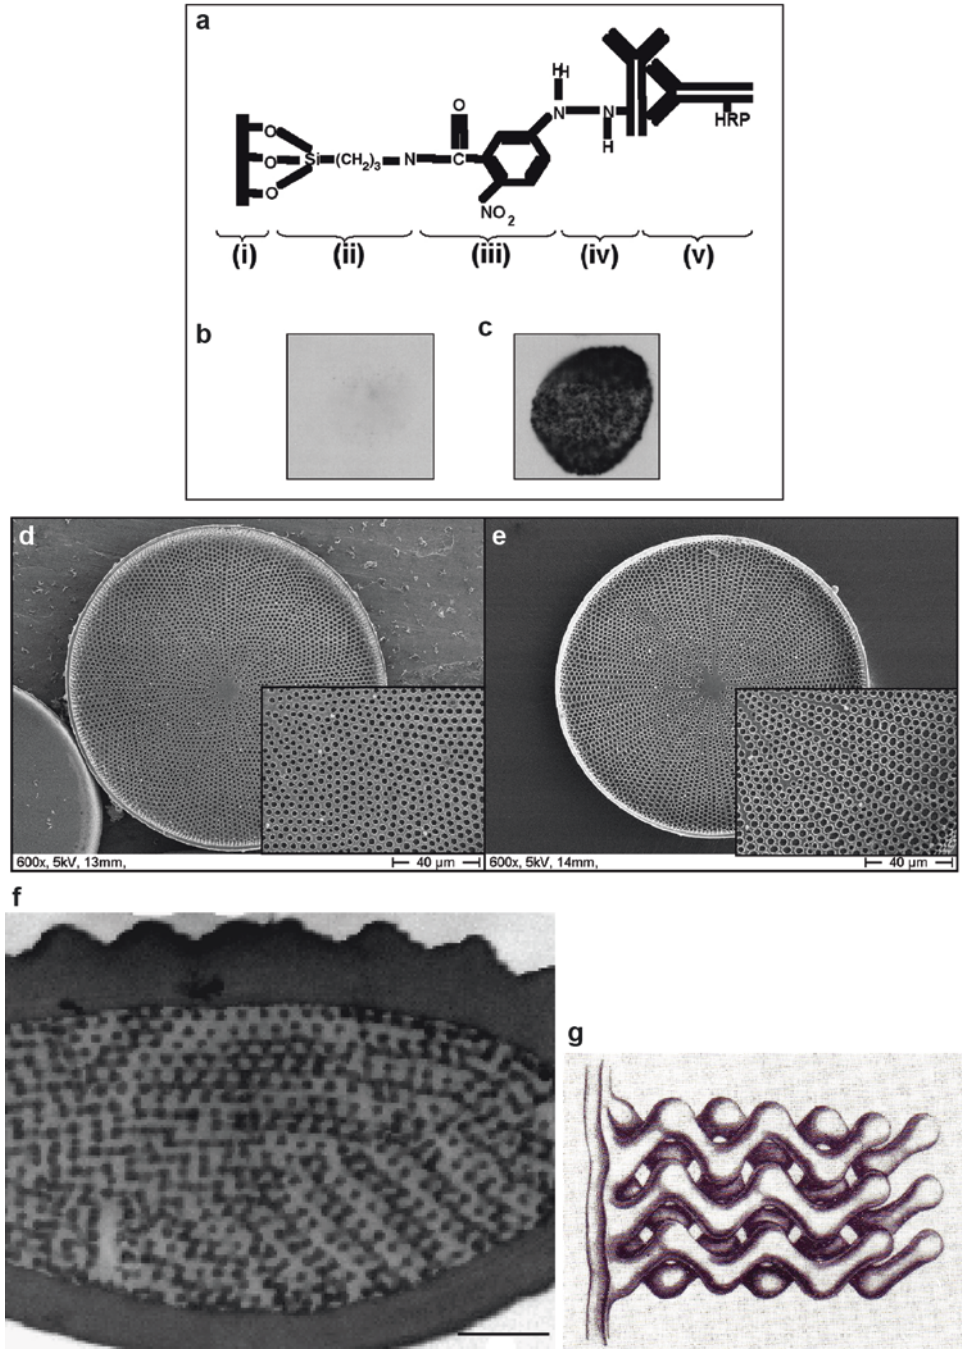
(Fig. 5a–c) and slits which give the protoplasm access to the external environment. There are more than 100,000 different species of diatoms, generally 20–200 μm in diameter or length, but some can be up to 2 mm long. Diatoms have been proposed to build photonic devices directly in 3D [17]. The biological function of the optical property (Fig. 5d) is at present unknown, but may

Biomimetics of Optical Nanostructures, Fig. 5 (**a**–**c**) Scanning electron micrographs of the intercalary band of the frustule from two species of diatoms, showing the square array of pores from *Coscinodiscus granii* (**a**, **b**) and the hexagonal arrays of pores from *C. wailesii* (**c**). These periodic arrays are proposed to act as photonic crystal waveguides. (**d**) Iridescence of the *C. granii* girdle bands. (**e**) Southampton University mimic of a diatom frustule (patented for photonic crystal applications), scanning electron micrograph (By G. Parker, reproduced with permission)

affect light collection by the diatom. This type of photonic device can be made in silicon using a deep photochemical etching technique (initially developed by Lehmann [18]) (e.g., Fig. 5e). However, there is a new potential here since diatoms carry the added advantage of exponential growth in numbers – each individual can give rise to 100 million descendents in a month.

Unlike most manufacturing processes, diatoms achieve a high degree of complexity and hierarchical structure under mild physiological conditions. Importantly, the size of the pores does not scale with the size of the cell, thus maintaining the pattern. Fuhrmann et al. [17] showed that the presence of these pores in the silica cell wall of the diatom *Coscinodiscus granii* means that the frustule can be regarded as a photonic crystal slab waveguide. Furthermore, they present models to show that light may be coupled into the waveguide and give photonic resonances in the visible spectral range.

The silica surface of the diatom is amenable to simple chemical functionalization (e.g., Fig. 6a–c). An interesting example of this uses a DNA-modified diatom template for the control of nanoparticle assembly [19]. Gold particles were coated with DNA complementary to that bound to the surface of the diatom. Subsequently, the gold particles were bound to the diatom surface via the sequence-specific DNA interaction. Using this method, up to seven layers were added showing how a hierarchical structure could be built onto the template.



Porous silicon is known to luminesce in the visible region of the spectrum when irradiated with ultraviolet light [20]. This photoluminescence (PL) emission from the silica skeleton of diatoms was exploited by De Stefano [21] in the production of an optical gas sensor. It was shown that the PL of *Thalassiosira rotula* is strongly dependent on the surrounding environment. Both the optical intensity and peaks are affected by gases and organic vapors. Depending on the electronegativity and polarizing ability, some substances quench the luminescence, while others effectively enhance it. In the presence of the gaseous substances NO_2, acetone, and ethanol, the photoluminescence was quenched. This was because these substances attract electrons from the silica skeleton of the diatoms and hence quench the PL. Nucleophiles, such as xylene and pyridine, which donate electrons, had the opposite effect and increased PL intensity almost ten times. Both quenching and enhancements were reversible as soon as the atmosphere was replaced by air.

The silica inherent to diatoms does not provide the optimum chemistry/refractive index for many applications. Sandhage et al. [22] have devised an inorganic molecular conversion reaction that preserves the size, shape, and morphology of the diatom while changing its composition. They perfected a gas/silica displacement reaction to convert biologically derived silica structures such as frustules into new compositions. Magnesium was shown to convert SiO_2 diatoms by a vapor-phase reaction at 900 °C to MgO of identical shape and structure, with a liquid Mg_2Si by-product. Similarly, when diatoms were exposed to titanium fluoride gas, the titanium displaced the silicon, yielding a diatom structure made up entirely of titanium dioxide, a material used in some commercial solar cells.

An alternative route to silica replacement hijacks that native route for silica deposition in vivo. Rorrer et al. [23] sought to incorporate elements such as germanium into the frustule, a semiconductor material that has interesting properties that could be of value in optoelectronics, photonics, thin-film displays, solar cells, and a wide range of electronic devices. Using a two-stage cultivation process, the photosynthetic marine diatom *Nitzschia frustulum* was shown to assimilate soluble germanium and fabricate Si-Ge oxide nanostructured composite materials.

Porous glasses impregnated with organic dye molecules are promising solid media for tunable lasers and nonlinear optical devices, luminescent solar concentrators, gas sensors, and active waveguides. Biogenic porous silica has an open spongelike structure, and its surface is naturally OH terminated. Hildebrand and Palenik [24] have shown that rhodamine B and 6G are able to stain diatom silica in vivo and determined that the dye treatment could survive the harsh acid treatment needed to remove the surface organic layer from the silica frustule.

Now attention is beginning to turn additionally to coccolithophores – single-celled marine algae, also abundant in marine environments. Here, the cell secretes calcitic photonic crystal frustules which, like diatoms, can take a diversity of forms, including complex 3D architectures at the nano- and microscales.

Iridoviruses

Viruses are infectious particles made up of the viral genome packaged inside a protein capsid. The iridovirus family comprises a diverse array of large (120–300 nm in diameter) viruses with icosahedral symmetry. The viruses replicate in the cytoplasm of insect cells. Within the infected cell, the virus particles produce a paracrystalline array that causes Bragg refraction of light. This property has largely been considered aesthetic to date, but the research group of Vernon Ward (New Zealand), in collaboration with the Biomaterials Laboratory at Wright-Patterson Air Force Base, are using iridoviruses to create biophotonic crystals. These can be used for the control of light, with this laboratory undertaking large-scale virus production and purification as well as targeting manipulation of the surface of iridoviruses for altered crystal properties. These can provide a structural platform for a broad range of optical technologies, ranging from sensors to waveguides.

Virus nanoparticles, specifically *Chilo* and *Wiseana* invertebrate iridoviruses, have been used as building blocks for iridescent nanoparticle assemblies. Here, virus particles were assembled in vitro, yielding films and monoliths with optical iridescence arising from multiple Bragg scattering from close-packed crystalline structures of the iridovirus. Bulk viral assemblies were prepared by centrifugation followed by the addition of glutaraldehyde, a cross-linking agent. Long-range assemblies were prepared by employing a cell design that forced virus assembly within a confined geometry followed by cross-linking. In addition, virus particles were used as core substrates in the fabrication of metallodielectric nanostructures. These comprise a dielectric core surrounded by a metallic shell. More specifically, a gold shell was assembled around the viral core by attaching small gold nanoparticles to the virus surface using inherent chemical functionality of the protein capsid [25]. These gold nanoparticles then acted as nucleation sites for electroless deposition of gold ions from solution. Such nano-shells could be manufactured in large quantities and provide cores with a narrower size distribution and smaller diameters (below 80 nm) than currently used for silica. These investigations demonstrated that direct harvesting of biological structures, rather than biochemical modification of protein sequences, is a viable route to create unique, optically active materials.

The Mechanisms of Natural Engineering and Future Research

Where cell culture is concerned, it is enough to know that cells *do* make optical nanostructures, which can be farmed appropriately. However, in the future an alternative may be to emulate the natural engineering processes ourselves, through reacting the same concentrations of chemicals under the same environmental conditions and possibly substituting analogous nano- or macro-machinery.

To date, the process best studied is the silica cell wall formation in diatoms. The valves are formed by the controlled precipitation of silica within a specialized membrane vesicle called the silica deposition vesicle (SDV). Once inside the SDV, silicic acid is converted into silica particles, each measuring approximately 50 nm in diameter. These then aggregate to form larger blocks of material. Silica deposition is molded into a pattern by the presence of organelles such as mitochondria spaced at regular intervals along the cytoplasmic side of the SDV [26]. These organelles are

Biomimetics of Optical Nanostructures, Fig. 6 (continued) in the presence of nickel sulfate (**e**). Note the enlargement of pores, and hence change in optical properties, in (**e**). (**f**) "Photonic crystal" of the weevil *Metapocyrtus* sp., section through a scale, transmission electron micrograph; scale bar = 1 μm (see Parker [33]). (**g**) A comparatively enlarged diagrammatic example of cell membrane architecture: tubular cristae in mitochondria from the chloride cell of sardine larvae (From Threadgold [37]). Evidence suggests that preexisting internal cell structures play a role in the manufacture of natural nanostructures; if these can be altered then so will the nanostructure made by the cell

thought to physically restrict the targeting of silica from the cytoplasm, to ensure laying down of a correctly patterned structure. This process is very fast, presumably due to optimal reaction conditions for the synthesis of amorphous solid silica. Tight structural control results in the final species-specific, intricate exoskeleton morphology.

The mechanism whereby diatoms use intracellular components to dictate the final pattern of the frustule may provide a route for directed evolution. Alterations in the cytoplasmic morphology of *Skeletonema costatum* have been observed in cells grown in sublethal concentrations of mercury and zinc [27], resulting in swollen organelles, dilated membranes, and vacuolated cytoplasm. Frustule abnormalities have also been reported in *Nitzschia liebethrutti* grown in the presence of mercury and tin [28]. Both metals resulted in a reduction in the length to width ratios of the diatoms and fused pores and a reduction in the number of pores per frustule. These abnormalities were thought to arise from enzyme disruption either at the silica deposition site or at the nuclear level. We grew *Coscinodiscus wailesii* in sublethal concentrations of nickel and observed an increase in the size of the pores (Fig. 6d, e) and a change in the phospholuminescent properties of the frustule. Here, the diatom can be "made to measure" for distinct applications such as stimuli-specific sensors.

Further, *trans*-Golgi-derived vesicles are known to manufacture the coccolithophore 3D "photonic crystals" [29]. So the organelles within the cell appear to have exact control of (photonic) crystal growth ($CaCO_2$ in the coccolithophores) and packing (SiO_3 in the diatoms) [30, 31]. Indeed, Ghiradella [9] suggested that the employment of preexisting, intracellular structures lies behind the development of some butterfly scales, and Overton [32] reported the action of microtubules and microfibrils during butterfly scale morphogenesis. Further evidence has been found to suggest that these mechanisms, involving the use of molds and nanomachinery (e.g., Fig. 6f, g), reoccur with unrelated species, indicating that the basic "eukaryote" (containing a nucleus) cell can make complex photonic nanostructures with minimal genetic mutation [33]. The ultimate goal in the field of optical biomimetics, therefore, could be to replicate such machinery and provide conditions under which, if the correct ingredients are supplied, the optical nanostructures will self-assemble with precision.

For further information on the evolution of optical devices in nature, including those found in fossils, or when they first appeared on earth, see references [34, 35], and for information on cell culture in a *Morpho* butterfly, see reference [36].

Definition

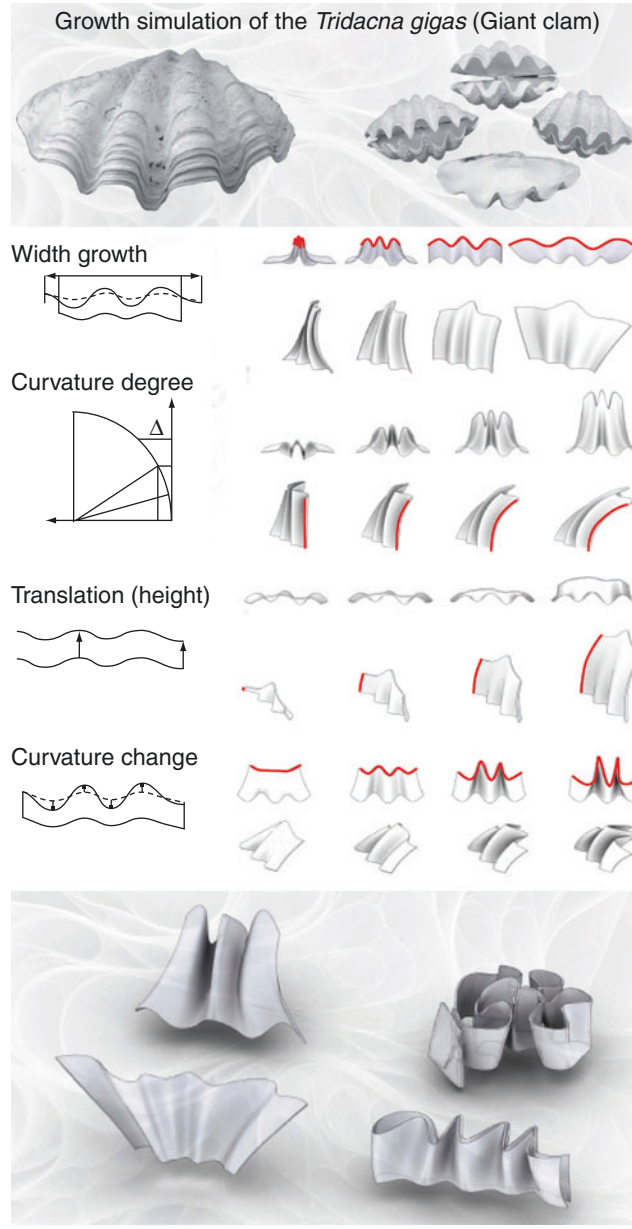
Biornametics – Architecture Defined by Natural Patterns – is an emerging contemporary design practice that explores a new methodology to interconnect scientific evidence with creative design in the field of architecture. The word biornametics is generated from "ornament," referring to the famous Austrian architect Adolf Loos, and "biomimetics," the abstraction of good design from living nature (see "▶ Biomimetics").

Overview

In biornametics research, role models from nature, static and dynamic patterns (e.g., nanostructured surfaces or materials with functional hierarchy

from the nano- to the macroscale), are investigated, and the findings are applied to design strategies. The emergence of patterns in nature at all scales of existence of organisms as one of the most important signs of life – order – is not arbitrary but highly interconnected with boundary conditions, functional requirements, systems requirements, material, and structure. The three main areas of investigation for role models in biornametics are, firstly, **surface patterns, nanotextured surfaces, and nanostructured materials**; secondly, **shape, growth, and deployable structures;** and, thirdly, **adaptation and reorganization**. Biological building strategies rely basically on repetition, variation, and self-similarity. Often simple building blocks are arranged with molecular precision and thus achieve diverse and highly specialized material properties.

Biornametics research aims at understanding the functionality of these natural patterns by extracting the principles found in current nanotechnology research and transferring these principles to an architectural interpretation. Colors are just one very important example. In contrast to pigment colors, structural colors that are found on some butterfly wings and beetles and even on plants [1–3] are primarily determined by the geometry of the underlying material. Interesting is also the generation of these surfaces and materials, as well as multifunctional properties such as durability, degradation, or self-repair. Further examples include plant-environment interactions such as the pitcher plant that lures animals onto a super-sliding surface or the lotus leaf's self-cleaning properties and nanostructured composite materials with high toughness such as the abalone shell. The patterns in these role models from living nature fulfill their purpose and are surprisingly elegant and appeal to the aesthetic dimension of the human perception (Fig. 1). The transfer of surface patterning to architectural elements may deliver added or integrated functionality or reinterpret specific functions on another scale.



Summary

Biornametics – Architecture Defined by Natural Patterns – is a transdisciplinary arts-based design practice that explores different approaches to a new design methodology to interconnect scientific evidence from the life sciences with creative design in the field of architecture. The starting point of *biornametics* takes on the history of one of the composed parts of the word "ornament" referring to Adolf Loos [4] and extends into another "biomimetics [bionik in German]" [5–7].

Biornametics especially refers to the more recent terminology where the "New Ornament" as an emerging contemporary design practice is based on digital techniques. It is less concerned with serial rationality but with algorithmic, digital operations and connecting the processes of planning and production. The second part of the artificial word biornametics stems from biomimetics and means the strategic search for nature's solutions. The hypothesis underlying this strategy is that living nature has evolved in a process of continuing adaptation to become a complex changing environment and that the exploitation of highly optimized solutions is likely to deliver innovations that provide more intelligence and higher efficiency than our standard methods.

Biornametics research and the simulation of role models from nature, static and dynamic patterns (e.g., growth principles, movement patterns, adaptation and differentiation as key for emergence of patterns, etc.), provide the basics for subsequent applications in art. The emergence of patterns in nature at all scales of existence of organisms as one of the most important signs of life – order – is not arbitrary but highly interconnected with boundary conditions, functional and systems requirements, materials, and structure. The findings from role models and their simulation are applied to design strategies and translated into prototypical architectural concepts.

As a result of the first ever biornametics research cycle, performed between 2010 and 2013, a physical installation was set up temporarily in the Silver Gallery of the University of Applied Arts in Vienna, Austria, demonstrated one of the unlimited possibilities of interpretation of a single principle, and was thus closely related to the perception of the executing team. The goal was to build a lightweight and cost-efficient

Biornametics: Architecture Defined by Natural Patterns, Fig. 1 Ornaments for architecture inspired by a growth simulation of the giant clam, starting from the initial nanocrystalline composite, followed by the formation of a two-dimensional disk protrusion and the formation of crystalline curls

spatial structure with an inherent potential to move, or to be moved, by stimuli from the external environment.

A paramount step in biornametics research is panel discussions with panelists from different backgrounds (such as architecture, mathematics, engineering, physics, and biomimetics) to produce more aspects of methodology and scientific input with feedback from the interested general public. The aim of such explorative debates is to present different approaches to science-based design and to reason about the value of incorporating findings from the life sciences into architectural design methodologies. Springer Scientific Publishing published results from the first biornametics research cycles in a book that takes this approach further and creates the context of the current discussion of arts-based research [8].

Future continuous research can be deducted from the potential that was discovered and lies in the theme of growth and how one can make use of the functions the growing element offers during different phases and the topic of nanotechnology in building and creating in a yet rather unknown scale.

Background

The first biornametics research cycle started in 2010. The Austrian Science Fund installed in the year 2009 a funding program for arts-based research, called PEEK. In this program any person engaged in arts-based research who has the necessary qualifications can apply for funding for up to 36 months. PEEK goals are to support high-quality and innovative arts-based research in which artistic practice is integral to the inquiry. In this way, research capacity, quality, and international standing of arts-based researchers in Austria shall be increased. Further benefits are an increase of both public awareness and awareness within the academic and the arts communities of arts-based research and its potential applications.

The team around architect and artist Barbara Imhof was one of the first to secure PEEK funding: for the first ever cycle of biornametics research, architecture defined by natural patterns. Biornametics research combines scientists, architects, and artists in a highly creative, innovative team.

Host research institution of this first cycle of biornametics research was the University of Applied Arts, Vienna, Austria; key people were Barbara Imhof and Petra Gruber. Collaborating institutions were located in Austria, Germany, Italy, the United Kingdom, and Malaysia. The duration of this first cycle of biornametics research was from May 2010 until March 2013.

Aims of Biornametics Research

The intellectual aim of biornametics arts-based research is the exploration of an aesthetic and functional interpretation together with utilization of new manufacturing technologies and elaboration of biomimetic design methods and the New Ornament.

1:1 implementation is used to communicate the approach and its theme as test bed experimenting the physical translation process and experience the implications arising from unexpected solutions or developments.

Aims of biornametics arts-based research:

- Research, analysis, and simulation of dynamic patterns from nature.
- Patterns from nature are investigated and deep principles behind morphogenesis defined. Analogies in architectural design are identified to clarify application possibilities.
- Successful transfer of found principles to architectural application shall deliver intelligent, efficient, and ecological designs which also will create new forms and new aesthetics.
- Deliver visualization and prototypes of the architectural interpretation.
- Application to an architectural scenario is crucial for the success of transfer. The development of a real project manifests the validity of the approach.
- Further development and refinement of the biornametics methodology to transfer nature's patterns to architectural application.
- The development of a methodology for the transfer of information into the architectural discipline is important as a pathway for follow-up studies. The biomimetic method goes beyond superficial interpretations of findings from nature.
- Serve as a role model for interdisciplinary architectural design work.

Integration of findings from other disciplines such as the life sciences is not an easy task. The new design approach needs a formal framework that allows dynamic exchange of information. Preconditions for this exchange are the willingness to cross the borders between disciplines and to deal with other "languages" (terminologies) and cultures [9]. By involving different researchers and consultants with various backgrounds such as nanotechnology, biomimetics,

informatics, mathematics, structural engineering, architecture, and design, a multidisciplinary team is created that investigates and develops novel design strategies for architecture with an exemplary application structure.

Limitations

The integration of new production technologies to the research approach can only be achieved in follow-up attempts (e.g., subsequent projects together with industry). The main reason for this is to keep the simulations and computational results as broad and systemic as possible, to allow for potential application developments in a wide variety of fields. Collaboration with industry will supply the necessary production workspaces and machines.

Effects of the Design Practice Outside the Core Field of Research

Biornametics research is cross-disciplinary work based on a scientific approach to architectural design; it is a new teaching method with high potential to strengthen innovation in architecture. A continuously growing database of potential role models and principles provides the basis for further more specific follow-up arts-based research approaches that explore the applicability in the field of architecture. One more general aspect that shows great potential to be developed further is the integration of new production technologies into the process.

Research Areas

The research areas for biornametics research refer to a main issue in biomimetics: the relation between structure and function. Three initial main areas of investigation for role models from nature were defined in the first research cycle:

1. Surface patterns, nanotextured surfaces, and nanostructured materials
2. Shape, growth, and deployable structures
3. Adaptation and reorganization

These three areas reflect the specific scientific expertise in the scientific team of the first biornametics research cycle: expert consultant George Jeronimidis is versatile in biomimetics and fiber structures, and therefore the role models focus rather on plants than on animals, and Ille C. Gebeshuber is an expert in nanotextured surfaces and structural colors.

In biornametics research the sample role models from nature to be investigated need to be chosen with regard to:

- Availability of reliable information
- Tangibility of scales and processes
- Exclusion of biochemistry and metabolic processes
- Expected innovative potential for spatial and architectural applications

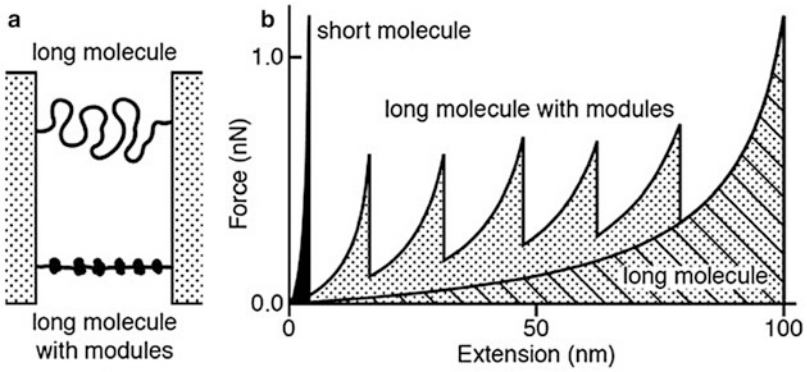
The methodology starts with a selection of role models from nature ("scientific input"). At the same time a primary investigation in successful transfers, architectural applications, and outcome scenarios delivers exemplary knowledge and guarantees novelty of the selected approach.

The base of biornametics research, patterns and their scientific exploration, partly finds a feedback in the architectural theory of the ornament. After the first phase of data collection starts the computation of models, followed by concept development and design.

The first transfer generally takes place when the selected role model patterns are analyzed regarding their potential application and their abstracted principles. Digital simulations are used to investigate the principles. In the second transfer analogy is established by exploring applications where the abstracted principles could be applied.

The final step is the proto-architectural implementation of showcase applications to be exhibited and communicated to the scientific and architectural community by means of publications and scientific papers in journals and conference proceedings.

Surface Patterns, Nanotextured Surfaces, and Nanostructured Materials



Biological systems exhibit a wealth of functional units highly optimized for a range of parameters, also on the nanoscale, by only combining a handful of starting materials. Biological building strategies rely basically on repetition, variation, and self-similarity. Often simple building blocks are arranged with molecular precision and thus achieve diverse and highly specialized material properties.

Colors are just one very important example. In contrast to pigment colors, physical colors that are found on some butterfly wings and beetles are primarily determined by the geometry of the underlying material. The process of generation of these surfaces and materials is also interesting, as well as their properties such as durability, degradation, or self-repair.

Further examples include plant-environment interaction, for example, the pitcher plant that lures animals onto a super-sliding surface or the well-known self-cleaning principle that was discovered in the lotus leaf. Patterning on the nanoscale also produces materials that have unequaled properties, for example, the abalone shell ([10]; Fig. 2).

The patterns found do not only fulfill their purpose but are surprisingly elegant and appeal to the aesthetic dimension of the human perception. The transfer of surface patterning to architectural elements may deliver added or integrated functionality or reinterpret specific functions on another scale.

Biornametics research role models with relevance to surface patterns, nanotextured surfaces, and nanostructured materials are photonic crystals in the jewel beetle (Fig. 3); super-sliding nanostructure-based slippery surfaces of the yellow pitcher plant (Fig. 4); multifunctional nanostructures on the *Morpho* butterfly (Fig. 5), providing coloration, tuned wettability, unidirectional water runoff, and further nanoscale-based properties; superhydrophobic surfaces of the giant Amazon water lily (Fig. 6); complex nanocomposite of the abalone shell (Fig. 7), with high fracture resistance and iridescent colorations (abalone parts are used in jewelry, for their color play and durability); opal-like photonic crystals of the peacock feather (with exquisite control of the color-generating nanostructures for the various colors, Fig. 8); the octopus (Fig. 9), who can quickly and reversibly change color; the *Strelitzia* plant (Fig. 10) with impressive superhydrophobic properties; and, last but not least, insect wings (Fig. 11) and more generally surfaces of insects with various functionalities based on nanoscale organization of the material.

Biornametics: Architecture Defined by Natural Patterns, Fig. 2 Concept for an adhesive [10]. (**a**) Two ways to attach two particles: with a long molecule or with a long molecule with nodules. (**b**) When stretched, a short molecule can only be extended a little and would then break. A long molecule would be stretched much more and finally break. However, a long molecule with nodules, with sacrificial bonds that break before the backbone of the molecule breaks, increases the toughness of the adhesive. Such a strategy is applied in the abalone shell and also in diatom adhesives (Reprinted by permission from Macmillan Publishers Ltd: Nature, Smith et al. [10], copyright (1999)

Shape, Growth, and Deployable Structures

The topic of morphogenesis in nature is about the development of shapes in general. In the context of biornametics research, the interest lies in the dynamics of shapes and shape change. The topic focuses on the ontogenetic development of three-dimensional complex shapes (in contrast to an evolutionary perspective) and on other phenomena related to shape change in organisms.

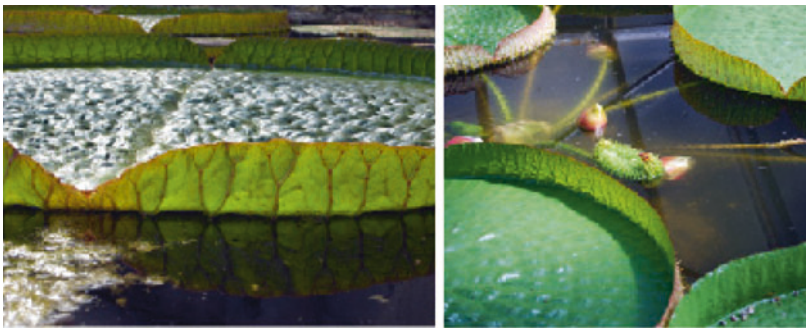
Biornametics: Architecture Defined by Natural Patterns, Fig. 3 Jewel beetles are living jewels. Their cuticle is organized similar to precious opal, a highly prized iridescent gemstone. The brilliant coloration originates from photonic crystals, composed of spheres of a couple of hundreds of nanometers in diameter, arranged in hexagonal densest packing, acting as a Bragg reflector for visible light

The development of organisms is based on cell division, the basis for the generation of tissues and organs. The principles of cell growth as investigated in microbiology can be included, but the focus of the topic lies on the research findings in developmental biology.

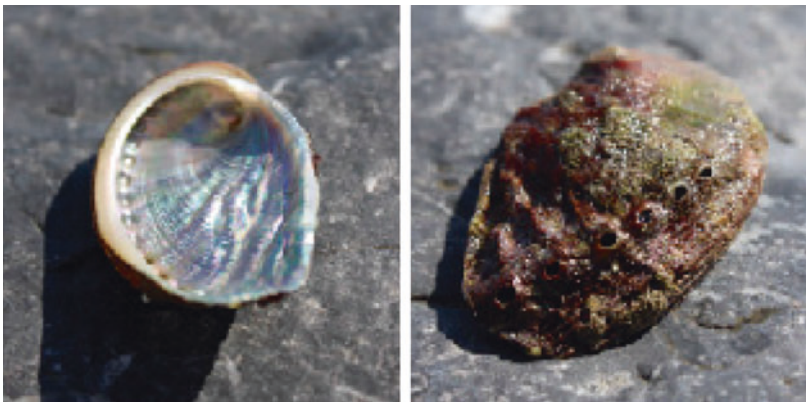
Interesting issues are the principles of growth in organisms and the differentiation of tissues and materials [11]. The time-based rules of growth and the spatial geometric definition of growth principles (growth patterns) are of specific importance. Specific topics, for example, branching, should be included.

Especially in the plant realm, the relation between growth and deployment is of interest. On a shorter timescale, fast deployment promises to yield significant biornametics research results or, more general, fast shape change in organisms, which aims at, for example, defense or attraction purposes.

The research of mechanisms leading to shapes and shape change in nature shall go beyond the generation and control of complex geometries by establishing a strong link to efficiencies and functionality. This is also a focus in current architectural research and development.



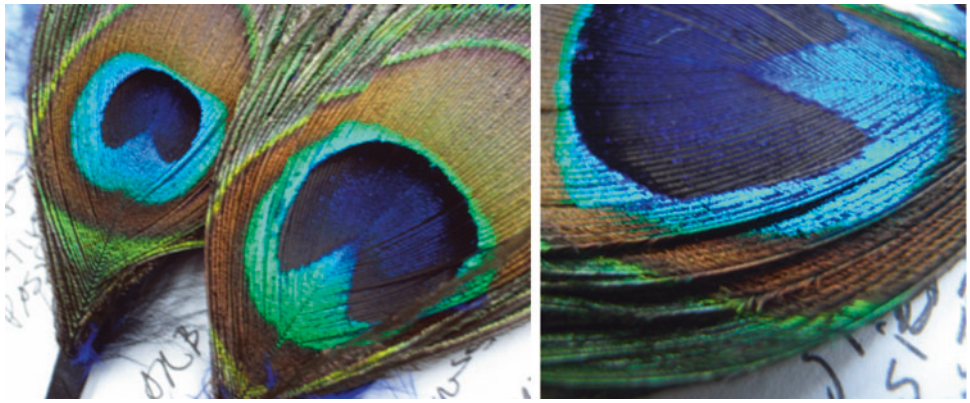
Biornametics research role models with relevance to shape, growth, and deployable structures are the *Morpho* butterfly (Fig. 5) with



Biornametics: Architecture Defined by Natural Patterns, Fig. 4 Nanoscale structures are the physical basis for the super-slippery inner surfaces of pitcher plants

Biornametics: Architecture Defined by Natural Patterns, Fig. 5 Multifunctional nanostructures on the *Morpho* butterfly and on various other butterflies provide brilliant coloration, temperature regulation, water runoff paths (unidirectional), and much more

Biornametics: Architecture Defined by Natural Patterns, Fig. 6 The giant Amazon water lily grows up to 2.5 m in diameter. Hierarchical micro- and nanostructures provide exquisite self-cleaning properties



Biornametics: Architecture Defined by Natural Patterns, Fig. 7 The abalone shell is a fascinating natural nanocomposite made from calcite and some % of adhesive protein matrix. The fracture toughness of the composite is 1000 times larger than the one of a single calcite crystal

interesting nanoscale-based biomechanics; the giant Amazon water lily (Fig. 6) which can grow up to 2.5 m in diameter, supported by functionalities based on nanostructures, nanomechanics, and nanochemistry; the abalone shell (Fig. 7), in which the self-assembly of its toughness-providing complex nanocomposite of protein matrix and calcite bricks can inspire in situ growth of building materials, using, for example, CO_2 from the air and water, similar to various further biomineralizing organisms [12]; and spider silk (Fig. 12), forming strong, tough, large, mechanically stable lightweight constructions.

Adaptation and Reorganization

The topic Adaptation and Reorganization treats the stabilization capacity in dynamic and living systems. The adaptive capacities include

Biornametics: Architecture Defined by Natural Patterns, Fig. 8 The brilliant colors of the peacock originate from nanostructures, not from pigments. In the *blue*, *green*, and *light blue* regions, the size of the color-generating nanostructures only differs by some nanometers – an exquisite example of control on the nanoscale by animals

Biornametics: Architecture Defined by Natural Patterns, Fig. 9 The color change abilities of the octopus are legendary. Just recently researchers found the nanoscale reason behind the fast and reversible color change: photonic crystals with tunable size

Biornametics: Architecture Defined by Natural Patterns, Fig. 10 The beautiful shape of *Strelitzia* flowers has inspired the shape of quite a few houses. And also on the nanoscale, *Strelitzia* is inspiring: unidirectional water runoff properties on the plant, as if painted by the brush of an artist

structural change that might affect physical properties such as strength, stiffness, or mass/surface ratio. Also deformation relates to the topic Adaptation and Reorganization; it is about form change due to disturbances. Adaptation can also refer to organizational aspects, for example, the implementation of failure-tolerant systems or mass management tools in case of circulation.

Adaptation and reorganization in biological systems are triggered by a change in environment that the organism or system is either subjected to or actively looking for. Therefore methods of adaptation comprise active, explorative strategies and passive, responsive methods to environmental changes. Examples for both explorative strategies and response can be found in climbing plants, lianas, and vines that actively look for a suitable environment and react to change in structural support with reorganization of tissue. Hierarchical vine-tree-like carbon nanotube architecture inspired by the natural role model shows interesting properties of self-assembly into scaffolds with extraordinary material properties that can yield completely new building materials, for architecture and artistic applications, as well as devices that have to withstand specific conditions

(parameters in tunable materials are responsive to environmental conditions).

In these cases, adaptation is often achieved by local decision-making and local differentiation. The topic focuses on long-term processes that aim at creating or reestablishing equilibrium in a dynamic system that can deliver valuable strategies for the creation of built environment.

Biornametics research role models with relevance to adaptation and reorganization are spider silk, which can mechanically adapt to changing mechanical conditions by unfolding extra units (such as the need when an insect is trapped, preventing rupture of the net, Fig. 12); the octopus (Fig. 9), with amazing adaptation and reorganization properties on all length scales, of high importance for adaptive buildings and reorganizing structures depending on external needs (e.g., deployable guest rooms); the *Strelitzia* flower (the physics of unfolding flowers is complex and has only recently been treated in detail, Fig. 10); and insect wings (Fig. 11), with their amazing transparent, tough, and strong lightweight deployable structures that serve for a lifetime.

Biornametics: Architecture Defined by Natural Patterns, Fig. 11 Insects can deploy their wings without anybody from the outside pulling. This makes them interesting for space applications. And on the nanoscale, insect eyes and wings exhibit various structures responsible for functionalities such as antireflectivity, increased reflectivity, and self-cleaning

Role Model Research

Role model research is an integral part of the biornametics approach. Being together in a botanic park (or, even better, in a virgin rainforest) with high species diversity, with scientists, architects, biologists, artists, and people from further fields, inspires interdisciplinary and lateral thinking, transdisciplinary discussions, and cross-fertilization of ideas. The first round of biornametics research established 37 role models, 10 of them with functionalities based on nanoscale properties (see Figs. 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12). This collection shall be extended with each cycle, resulting in a "treasure chest" for

Biornametics: Architecture Defined by Natural Patterns, Fig. 12 Spider silk is a strong and lightweight material. Its functionality is based on properties emerging from smart arrangement of perfect nanocrystals within a soft matrix and further levels of hierarchy at various length scales

biornametics researchers and further interesting audience aiming at inspiration from living nature.

Research in the areas of surface patterns, nanotextured surfaces, and nanostructured materials; shape, growth, and deployable structures; as well as adaptation and reorganization yields:

- Relevant new and established literature that is new to the team
- Finding of new interesting phenomena fitting to the three topics
- Good photographs/videos of phenomena (for use in websites, publications, talks, outreach work, etc.)
- Establishing and outfitting of the website with first information

Role Model Search

Starting with the three main research areas, the team applies a solution-based methodology to extract information from living nature and investigates the three areas and the role models through scientific papers. In this bottom-up process, biology delivers the input, with basic topics and specific examples. From these inputs, deep principles are extracted, in an abstraction step, which are subsequently realized in an artificial material, and implemented to architecture, taking into consideration respective boundary conditions and target aims.

Role Model Data Sheets

The role models need to be investigated further regarding their value for the specific arts-based research approach. A datasheet needs to be developed for each role model. These serve as working draft of the observed role model phenomena and present the underlying scientific information for the arts-based research approach.

The datasheets are organized in two sheets per role model containing an image, the Latin name, the area of defined research, an abstract with a selection of the most interesting features, references, first application ideas, and a functional diagram of the feature to be explored in the further process.

There are ten role models from the first cycle of biornametics research that are based on nanoscale effects; they are introduced in more detail below.

Role Model 01: Jewel Beetle, Coleoptera

Jewel beetles (Fig. 3) are tropical beetles. Their brilliant, iridescent, metallic-looking coloration is highly durable – million-year-old fossil jewel beetles still show magnificent coloration. The color is generated by periodic nanostructures that interact with light. For the coloration, the size of the structures is important, and far less important is the material of the structures (at this size, all is transparent) – which makes this role model very interesting for transfer to technological applications. In some cases, these nanostructures are reactive, i.e., they swell or shrink with certain stimuli, simultaneously changing color. The principle of structural coloration is an example of the deep principle *structure rather than material* and is often applied in living systems.

Role Model 02: *Sarracenia flava*, Pitcher Plant

The yellow pitcher plant (Fig. 4) is a carnivorous plant. Its insides are covered with nanostructures that result in a highly slippery surface for prey insects, yet some symbionts such as pitcher plant spiders can perfectly manage the slippery surfaces and walk on it. Tunable surfaces, which are slippery for certain materials and sticky for others, promise high application potential in architecture.

Role Model 03: *Morpho peleides*, Blue *Morpho* Butterfly

The *Morpho* butterfly (Fig. 5) has such strong, brilliant colors that it can be seen from kilometers away – flashes of blue light in the Costa Rica rainforest. The scales of certain butterflies are covered with multifunctional periodic nanostructures that control wettability, cause coloration, tune water runoff directions, control temperature, etc. Transfer potential to architecture is high, especially for walls and skins of buildings.

Role Model 04: *Victoria amazonica*, Giant Water Lily

The giant Amazon water lily (Fig. 6) can have up to 2.5 m in diameter. Similar to the lotus leaf, its leaves show self-cleaning abilities that are not based on ultrasmooth surfaces but on hierarchical structures, bridging from the nano- via the micro- and meso- to the macroscale. Self-cleaning

surfaces are of high interest in human applications (buildings, cars, dishes, clothes, etc.), and also this effect is based on *structure rather than material* and can easily be transferred to art and architecture applications, by using different materials. The size of the structures is crucial though, in combination with the surface tension of the fluids that will come in contact with the surface.

Role Model 05: *Haliotis*, Red Abalone Shell

The abalone shell (Figs. 2 and 7) mainly consists of calcium carbonate, a rather brittle material. Nevertheless its fracture toughness is 1000 times higher than a crystal of the pure material. The secret is in the few % of protein in the material and in the structure of the arrangement. Little bricks of calcium carbonate, a couple of hundreds of nanometers in size, are glued together with proteins as mortar. The protein is soft, and an attempt to break the abalone shell results in some little brick breaking, but most of the energy being dissipated in the soft protein matrix. Furthermore, the glue between the calcium carbonate bricks shows highly interesting nanomechanical properties (Fig. 2) that majorly contributes to the fracture toughness of the material: it is a self-healing adhesive. The transfer of properties of the complex nanocomposite of the abalone shell can yield the development of fracture-resistant building materials, which is interesting for earthquake-prone regions, and strong, tough, self-repairing adhesives that are needed in various architecture applications.

Role Model 06: *Pavo cristatus*, Peacock

The peacock (Fig. 8) is a beautiful bird. Its feathers have already been mentioned by Sir Isaac Newton in his classic book *Opticks* as an example for structural colors. When watched with high-resolution microscopes, the physical basis of the brilliant colors of the peacock becomes obvious: feather material is arranged as photonic crystals, with little spheres of similar size in hexagonal densest packing. Regions with different colors on the peacock feather refer to different sizes of the spheres in the natural opal. These size differences are on the order of just some tens of nanometers. The order of this arrangement is amazing.

Role Model 23: Spider Silk

Spider silk (Fig. 11) is one of the toughest materials in living nature. Cloth woven from spider silk is stronger than similar materials woven from Kevlar fibers. On the nanoscale, spider silk is a complex nanocomposite, with beta sheet nanocrystals embedded in semi-amorphous protein phase.

Role Model 34: *Octopus vulgaris*, Common Octopus

In octopus (Fig. 9), part of the impressive and rapid color change is based on nanostructures and their interaction with light. The size of the photonic crystal changes, by smart rearrangement of the matrix between the single optically relevant particles, and this causes the color change – this effect is physically similar to the color change in soap bubbles when they become thinner with time.

Role Model 36: *Strelitzia reginae*, Crane Flower or Bird of Paradise

There are various houses with shapes inspired by the extraordinary form of *Strelitzia* flowers (Fig. 10). *Strelitzia* leaves exhibit unidirectional water runoff characteristics and superhydrophobic properties that are based on minuscule surface structures. Transfer of these properties to surfaces of buildings can result in unique, beautiful patterns for water runoff, in the case of rain, for example, and even the appearance of messages and other text on windows, invisible on sunny days. They can also inspire bird-protective coatings, if their reflective properties are in the UV range, a wavelength portion of light that cannot be seen by people but can very well be detected by birds, who can see in the UV range. In this way, the huge number of birds that die every year from collisions with buildings (this number is in the billions!) can be drastically reduced, without compromising the visual appearance of the building to the human eye. A further property worthwhile of being transferred to architecture and art, and technology in general, is self-cleaning abilities based not on toxic chemical coatings but on structural coatings, which can in principle be obtained by structuring the most outer

material of the building, without adding another layer (biomimetic principle: *integration instead of additive construction*).

Role Model 37: Insect Wings

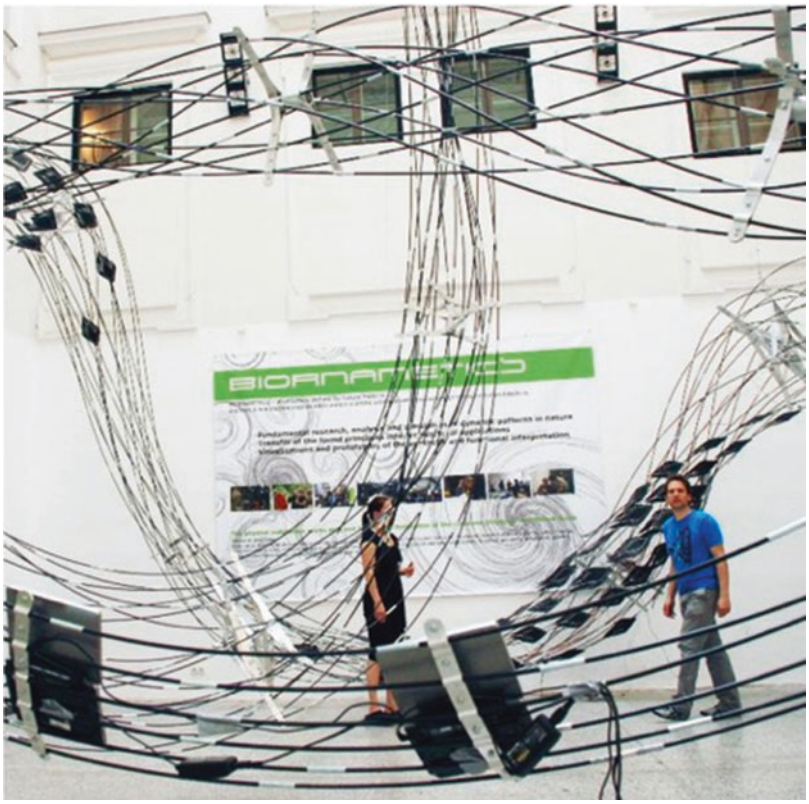
Insect wings (Fig. 11), such as the self-deployable wings of ladybirds, have been inspiring self-deployable structures for space applications and further uses in territories that are unfriendly to people for various decades. With the arrival of the age of nanotechnology, further amazing inspiring properties of insect wings and more generally surfaces of insects have been identified. The nanostructures in these organisms are multifunctional and serve various purposes depending on the environment, current situation, and further parameters. Self-cleaning, beautiful non-bleaching coloration, temperature regulation, control of wetting behavior, self-repair, and various optical properties (e.g., reflective, antireflective) have been identified and are starting to be used in applications such as antireflective surfaces of optical lenses and glasses (inspired by the moth eye).

Role Model Categories Diagram

In the following step of the biornametics research methodology, the role models are categorized into the three main established groups. Due to the multifunctionality of biological materials, there will be many overlaps, so some role models fit into several groups, and the aspects that are interesting to investigate are ambiguous.

For example, spider silk (Fig. 11) fits into the category *shape, growth, and deployable structures* and into the category *reorganization and adaptation*.

> Some spiders use glues while others deploy strands of fine filaments for fixing flies. Recent work has provided new insights into the mechanical properties of these nanoscale ropes.
>
> A spider's web, typically in combination with a powerful poison, is its principal tool in the struggle for survival. It is a highly tuned, lightweight net-structure that relies heavily on skillful engineering and the fitting deployment of a most versatile material: the spider's famous silk. A typical web spider makes up to seven different types of silk, some of which can be tuned to suit environmental circumstances by adjustment of the spider's spinning physiology. Individual silk threads, each around a micrometer in diameter, are actively drawn from microscopic spinning spigots perched on motile spinneret mounds, resembling miniature batteries of battle-ship gun-turrets. . . . The resulting filamentous tangle clings to, and often totally covers, a pair of much thicker support fibers issuing from spigots on the main spinnerets. This multiple-fiber rope can be further reinforced by crimped, spring-like fibers from yet another set of spigots, which pull up tight the by now rather complex, composite fiber. ([13], text slightly adapted)



Thus the spider silk follows interesting growth principles during its "spiderfacturing." In this way it also adapts to the neighboring environment so well that it can provide the framework of catching food for its producer.

Art Installation

A physical installation shall be the result of the translation of specific principles encountered, analyzed, and discussed during the research work of the biornametics research approach. The installation shall demonstrate one of the unlimited possibilities of interpretation of a single principle and thus be closely related to the perception of the executing team. The goal in the first round of biornametics research was to build a lightweight and cost-efficient spatial structure with an inherent potential to move, or to be moved, by stimuli from the external environment (Fig. 13).

The primary structural system of the installation reflects a specific organization of fibers arranged in concentric layers twisted clockwise and counterclockwise around a virtual axis. This organization of fibers can be found as a structural principle in several role models investigated during the research, displaying a high capacity to resist and adapt at the same time. This capacity depends on the geometry of the arrangement and the material properties of the fibers. Possible deformations can only happen within certain limits relative to the stiffness of the material and structure. The adaptive capacities of the structure exceeded by far those of conventional structural building elements.

Glass fiber tent poles were chosen for the fibers because of their structural properties, the

Biornametics: Architecture Defined by Natural Patterns, Fig. 13 Art installation in the Silver Gallery at the Vienna University of Applied Arts, Austria. The single parts of the installation were developed in the biornametics research approach

modularity of the system, and the easy availability at appropriate costs. A few reversible and numerous irreversible joints had to be defined. The so-called spacers kept the elements at specified distances and positions in order to maintain the spatial arrangement of the overall system.

The joints between the spacers and the fibers were designed to produce as little friction as possible and so allow easy movement by gliding along the fiber's axis. On the other hand, fixing of the connection points was necessary to ensure that the system would lock temporarily in a chosen position.

The use of a test setup with sensors and movement control would have exceeded the given budget and time restrictions, so the installation was fixed in space, but change in shape was enabled by a controlled and synchronized setup process, specifically by altering unlocked joints in specified places. The whole construction was suspended from the ceiling, and its performance demonstrated a resistance sufficient to maintain its shape.

Adaptable stiffness of the structure (not necessarily of the material involved) could be a point of departure for future development of more flexible and even reversible building systems (e.g., structures exerting increasing resistance under increasing external forces). On a second level of hierarchy, the installation demonstrated another adaptive process often found in nature: speeds of transformation varying in reaction to specific environmental changes. The system consisted of reactive leaflike structures that were partially fixed to the primary fiber structure together with sensory, control, and actuation equipment. The elements were added in a cantilevering mode and therefore reached a higher level of flexibility and of visible change.

Future Directions of the Field

In the fourth round of the PEEK funding scheme, *GrAB*, *Growing as Building*, the sequel arts-based

research approach to biornametics, was funded by the Austrian Science Fund FWF in the frame of PEEK 2011. *GrAB – Growing As Building* – runs from 2013 until the end of 2015. GrAB takes growth patterns and dynamics from nature and applies them to architecture with the goal of creating a new living architecture. The aim of GrAB is to develop architectural concepts for growing structures. Three main directions are investigated: transfer of abstracted growth principles from nature to architecture, integration of biology into material systems, and intervention of biological organisms and concepts with existing architecture. Key issues of investigation are mechanisms of genetically controlled and environmentally informed, self-organized growth in organisms and the differentiation of tissues and materials.

Research parameters include, for example, size, height, speed, and properties such as the stiffness or flexibility of structures, which are equally important in living systems and in architecture [14].

The methodology of biomimetic information transfer used is based on refined methods from biornametics research. Computer simulations remodeling relevant principles and physical models are used to understand selected natural phenomena and inform the translation process. Artistic and architectural tools and methods are jointly used with practices from the natural sciences. A Biolab provides hands-on experience with growth of organisms.

The architectural interest lies in the development of structures in a specific environment following an interaction of elements derived from natural pattern formation. To support the transfer of dynamic, growing structures, recent advancements in processing technologies such as additive manufacturing systems are investigated and possibly integrated into design concepts and both analogue and digital models. Scales tackled can include materials (also nanoscale), built elements and structures, as well as urban systems.

Along with architects and artists, scientists from the field of biology, biomimetics, and engineering including students collaborate to develop this arts-based research approach in a holistic way and to supply all the necessary expertise.

The work on GrAB commenced in June 2013 and will run for 2.5 years until the end of November 2015. The host research institution is the University of Applied Arts, Vienna; key people are Barbara Imhof and Petra Gruber. Collaborating institutions are located in Austria, the United Kingdom, Germany, the Netherlands, and Ethiopia.

Nanoscience and nanotechnologies are important for various aspects of GrAB, with the language of life being spoken and programmed on the nanoscale, with evident effects on the micro- and mesoscale, and finally on the macroscale of the built environment and urban systems.

Synonyms

Bioprobes; Biosensing; Nanobiosensors

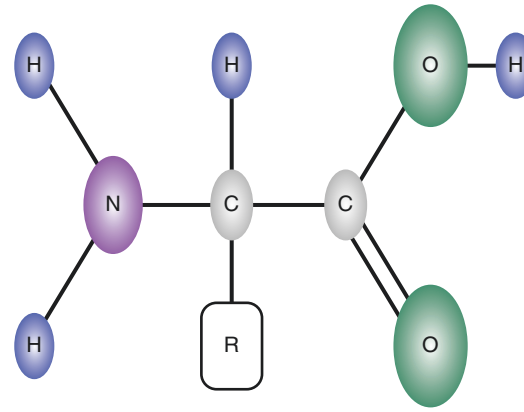
Definition

A biosensor is a system or device which incorporates a biologically active material in intimate contact with an appropriate transduction element for the purpose of detecting the concentration or activity of chemical species in any type of sample.

Overview

The important components of a biosensor are (1) a bioreceptor (e.g., enzymes, antibody, microorganism, or cells); (2) a transducer of the physicochemical signal, and (3) a signal processor to interpret the information that has been converted. Depending on the type of physicochemical signal produced, i.e., electrochemical, mass, thermal, or optical, the transduction element can come in various forms, such as electrodes for amperometric and potentiometric detection, field effect transistors (FET), piezoelectric quartz (TSM, QCM), thermistors, and optical fibers/optoelectronic systems. Biosensors have found many applications in a range of industries including defense, medicine, food, pharmaceutical, and healthcare owing to their rapid response time in detection, coupled with the emergence of complementary technologies. As fabrication technologies become more sophisticated, research and development has continually reduced the size of biosensing devices, giving rise to submicron detection systems known collectively as *nanobiosensors*.

One of the first descriptions of a man-made biosensor was the e*nzyme electrode*, coined by Clark and Lyons in 1962 [1]. In this system an oxidoreductase enzyme was held next to a platinum electrode in a membrane sandwich. Holding the platinum anode to a positive potential (0.6 V) relative to an Ag/AgCl reference electrode, an enzymatic catalyzed oxidation reaction of glucose produced hydrogen peroxide detected by the platinum electrode. It was not until 1967 that Updike and Hicks gave the necessary details required to build a functional enzyme electrode for glucose monitoring [2], paving the way for the first commercial biosensor for measurement of glucose in whole blood to come on to the market in 1974. The biological entity (i.e., enzyme) catalyzing this reaction produced a physicochemical signal, which was converted to an electrical signal, similar in process to the different sensory systems found in the human body.



Biosensors which incorporate an electrochemical (EC) transduction element monitor an electroactive species which is produced or consumed by the action of the biological element. These include amperometric, potentiometric, conductimetric, and field effect transistor (FET)-based detection [3, 4]. Enzyme-based electrodes are the most

commonly used biosensors associated with electrochemical transduction elements (i.e., amperometric and potentiometric). The basic principle behind amperometric detection (e.g., glucose electrode) works by holding the voltage potential between a working and reference electrode constant, while measuring the variation in current in relation to the concentration of the active species. In contrast, potentiometric detection (e.g., pH electrode) is based on holding the current constant or at zero and measuring the variation in voltage as a logarithmic proportion of the reactive species. Oxidoreductases and hydrolases are commonly used enzymes in these systems, and can be immobilized on to the electrode in a variety of ways. To improve these sensor characteristics, high porosity membrane structures (e.g., polycarbonate) allow a more controlled substrate flux to the immobilized enzyme layer, situated just above the detection electrode. Both potentiometric and amperometric biosensing systems receive considerable amounts of attention as they have the advantages of being low cost, single-use devices with a high degree of reproducibility. The associated instrumentation is also very inexpensive and compact, lending these biosensors to on-site measurements in fields as varied as environmental monitoring to bioprocess monitoring.

Classification of Bioreceptors

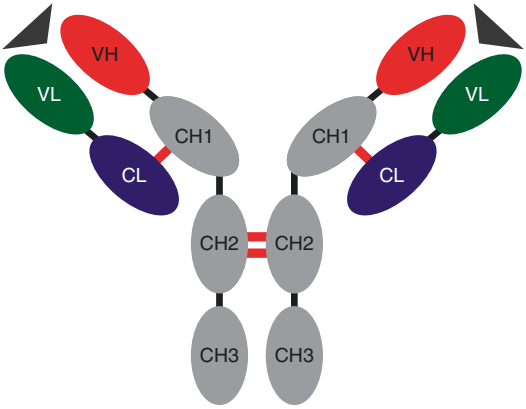
Enzymes and Antibodies

The vast majority of biochemical reactions taking place in a cell are permitted through the catalytic ability of enzymes. Enzymes are globular proteins; their primary structure consists of sequences of L-amino acids linked via condensation reactions to form polypeptide chains. The basic generic structure of an amino acid can be seen in Fig. 1, where the letter R denotes the side chain of the peptide. These peptides can be classified as polar neutral (cysteine and tyrosine being the most hydrophilic amino acids), nonpolar neutral (hydrophobic), basic (negatively charged), or acidic (positively charged) depending on the attached groups. There are 20 different types of L-amino acids, and with variations in size from

Biosensors, Fig. 1 Generic structure of an amino acid residue. The R-side group denotes the amino group

62 to 2,500 amino acid residues an enormous combination of polypeptides can be created. The primary structured polypeptide is the starting point for the final globular protein. As the amino acids begin to interact with each other through ionic interactions, van der Waals forces, hydrogen bonding, and hydrophobic bonding, complex folding arrangements begin to occur. This secondary structure, commonly termed α-helix or β-pleated sheet, may contain regions of regular folding patterns, stabilized by weak interactions of neighboring carboxylic (–COOH) and amine ($–NH_2$) side groups. Neighboring interactions of the R-side groups determine the 3D conformational shape of the protein, referred to as the tertiary structure. Quaternary structures are formed when separate macromolecules (e.g., cofactors) get linked in a specific order forming enzymes of high stereospecificity, regiospecificity, and chemoselectivity.

Enzymes are classified into six major groups: (1) oxidoreductases, (2) transferases, (3) hydrolases, (4) lyases, (5) isomerases, and (6) ligases (Table 1). They are able to retain their catalytic activity within a limited range of parameters (i.e., pH, temperature, fluid forces, and chemical agents), but are well suited for amperometric and potentiometric biosensors due to their high turnover numbers, defined by the net number of substrate molecules reacted per catalyst active site per unit time. The dependence of the speed of reaction to the concentration of substrate can be described



Biosensors, Table 1 Class of enzymes and examples within each class

Enzyme definition	Examples
Oxidoreductases: catalyze oxidation and reduction reactions	*Glucose oxidase*, *Alcohol dehydrogenase, Lactate dehydrogenase, Diacetyl reductase*
Transferases: transfer functional groups	*Thiaminase, DNA methyltransferase, Choline acetyltransferase*
Hydrolases: catalyze the hydrolysis of bonds	*Phospholipase, Lipoprotein lipase, Phosphatase, Dexyribonuclease, RNase, Lysozyme*
Lyases: cleaves bonds, not via hydrolysis or oxidation	*Carbonic anhydrase, Tryptophan synthase, Adenylate cyclise*
Isomerases: catalyzes isomerization change of molecules	*Protein disulfide isomerise, Topoisomerase, Phosphoglucomutase*
Ligases: links two molecules via covalent bonds	*DNA ligase, CTP synthase, Acetyl-CoA carboxylase*

using the equation derived by Michaelis–Menten in Eq. 1, where V is the reaction rate, [S] is the substrate concentration, and K_m is the Michaelis–Menten constant at which the substrate concentration gives the reaction rate which is half of V_{max} (maximum rate at substrate saturation). Although enzymes are most widely used in biosensing systems, they have a high cost factor in terms of production and purification as they have to be derived from biological sources:

$$V = \frac{V_{\max}[S]}{K_m + [S]} \quad (1)$$

Antibodies, also known as immunoglobulins (Ig), are a class of globular proteins (~150 kDa) which bind to specific antigenic structures forming an antibody-antigen complex, and they have widespread applications in clinical diagnostics and biotechnology. Their basic structure comprises of four polypeptide chains arranged in a Y configuration (Fig. 2). There are two heavy chains and two light chains connected by disulfide bonds. The base of the Y-structure is known as the

Biosensors, Fig. 2 Representative structure of an IgG antibody consisting of four polypeptide chains, interlinked with disulfide bridges (CH2–CH2; CH1–CL). CH1–CH3 represents the constant heavy chains; CL represents the constant light chains; VL and VH are the variable light and heavy molecules, respectively, which form the paratope regions for antigenic binding (*triangle*)

Fc (fragment crystallizable) region and is found in the constant domain containing the heavy chains which define the class or isotype of antibody in mammals (i.e., IgA, IgM, IgG, IgD, and IgE). The Fab (fragment-antigen binding) region is found in the variable domain and contains the light chains and heavy chains which make up the amino terminal–shaped antigen binding site, known as the paratope, the most important region for antigen binding on the antibody. The two binding sites on the arms of the antibody can be extremely variable, allowing millions of different antibodies with slightly varying paratopes to exist. This lends antibodies to be widely applied in immunoassays for molecule detection across cells, large proteins, and even amino acids.

Nucleic Acids

Nucleic acids are a group of linear polymers made up of nucleotides. Nucleotides comprise a purine or pyrimidine nucleobase, a pentose sugar, and a phosphate group. The five known nucleotides or bases are (1) Adenine (A), (2) Guanine (G), (3) Cytosine (C), (4) Thymine (T), and (5) Uracil (U). The base pairing (b.p) of these nucleotides in the biopolymer molecule DNA takes the form of A-T and G-C. Deoxy-ribonucleic acid (DNA) and ribonucleic acid (RNA) are double-stranded helix

and single-stranded polynucleotides, respectively, though this is more of a generalization rather than a rule. DNA and RNA have very similar chemical structures, apart from two distinct differences: (1) DNA contains 2-deoxyribose, a sugar lacking one oxygen atom compared to the ribose sugar of RNA; (2) RNA uses the nucleobase Uracil as a base, while DNA uses Thymine. The main role of DNA is the long-term storage of the genetic code of living organisms, containing instructions for the construction of macromolecules needed in cells such as proteins and RNA. The genetic information is coded into groups of three adjacent nucleotides termed codons, which represent the 20 different amino acids, the start codon, and the stop codon encoded by RNA. RNA can be considered as the workhorse for protein synthesis, copying the genetic information through transcription (messenger RNA) and translation (transfer RNA and ribosomal RNA) providing information to synthesize all the proteins needed by cells in the body. Development of microarrays has led to a new generation of biochips capable of multiplexing for rapid drug discovery and environmental analysis as will be discussed later.

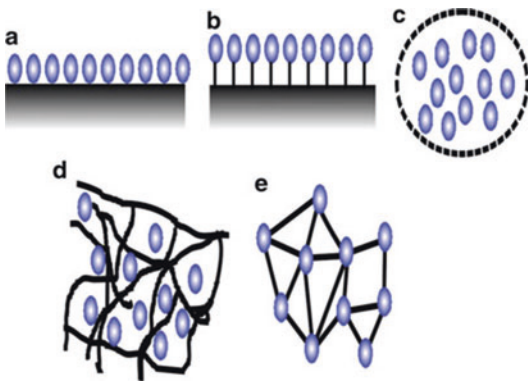
Cells and Microorganisms

A vast range of microbes (i.e., yeast, algae, bacteria) have been utilized in biosensor systems, having the advantage of being massively produced through cell culturing. They are classified into two major groups based on the sensing technique employed: electrochemical microbial biosensors and optical microbial biosensors [5]. The basic principle is that certain strains of microorganisms preferentially metabolize certain compounds, with the metabolic waste being excreted detected by a transduction system. Although microbial biosensors are less sensitive than enzymatic biosensors, and the overall detection period can be longer, they are well suited to environmental analysis (e.g., Biological Oxygen Demand (BOD)) where the global effect of some toxin is detected rather than a specific toxin or compound. An interesting and growing area of research which uses this principle is that of *synthetic biology*, where a commonly used microbial chassis (e.g., *E. coli*, *S. cerevisiae*) is transfected with a gene that is turned on in the presence of a specific substrate. This has rapid sensing applications in healthcare monitoring of viruses and toxins.

Artificial Bioreceptors

The application of artificial bioreceptors is based on the naturally occurring structures of catalytic antibodies (abzymes), where these antibodies have been produced artificially by directing them against an analogue compound of the transition state for a given reaction. These abzymes have the same specific recognition of natural antibodies and the catalytic activity of enzymes reacting to substrates (antigen) to form an end product with comparable kinetics.

Molecular-imprinted polymers (MIPS) are another form of artificial bioreceptors. They are created by mixing functionalized monomers with an analogue or target molecule which binds to the monomers through hydrogen bonds, hydrophobic bonds, or ionic interactions, thus creating a template around which the polymer will form [6]. Through polymerization reactions (i.e., UV irradiation) in the presence of a cross-linking agent a 3D rigid structure is created with complementary sites for the target molecule. Removal of the template target leaves a molecularly imprinted polymer designed for specific recognition of target molecules. Although this method for creating receptors is useful for hard to obtain natural bioreceptors, there are issues regarding the polymerization stage which can often lead to wrong structure formations.



Unlike enzymes, antibodies and MIPS form ligand-receptor complexes which do not produce physicochemical signal, so quantitative or qualitative detection must be made via indirect or direct methods. Indirect methods use a secondary biological system label (bioconjugate) which emits a physicochemical signal, such as a light-emitting probe (e.g., Horseradish peroxidase) or a radioactive element, commonly used in immunosensor applications. Direct methods do not require labeling, and involve measurement changes in mass, electrical properties, or optical properties as the ligand-receptor complex is formed. The non-catalytic activity of these receptors means that once the complex has been formed reuse of

the receptor in the biosensor can only be achieved through device washing to dissociate the complex.

Immobilization Techniques

Attachment of bioreceptors to the surface or in very close proximity of a signal transduction element is usually a prerequisite for biosensors to operate efficiently. A range of immobilization methods have been developed for immobilizing cells and nanoscale bioparticles (enzymes, antibodies, etc.) on and within a variety of substrates including microscope glass slides, micro- and nano-electrodes (i.e., gold, metal oxides, platinum, silver, etc.), SiO_2, polymers, and hydrogels. The technique employed is very much dependent on the bioreceptor and the substrate to which it has to be immobilized for subsequent signal transduction. Originally developed for enzyme immobilization, techniques can be classified into five broad areas which are adsorption, inclusion, covalent coupling on activated surfaces, cross-linking, and confinement (Fig. 3).

Inclusion uses polymerization reactions to embed or encapsulate the bioreceptor within a cross-linked system such as a hydrogel. Mainly used to immobilize whole cells or subcellular fractions, it provides a homogeneous distribution of bioreceptor within the gel but the reagents used for cross-linking (i.e., photo-initiators) can produce free radicals on UV-activated polymerization which can be detrimental to the biological structures present. A well-developed technology, widely used in fiber-optic biosensors is that of the *sol-gel* technology. Initially centered on metalloproteins it has been extended to encapsulate proteins, enzymes, antibodies, and whole cells with the biomolecules retaining their structural integrity and biological function [7].

Biosensors, Fig. 3 Representation of techniques employed for bioreceptor (*sphere*) immobilization on and within substrates for biosensor. (**a**) Adsorption; (**b**) covalent attachment to functionalized surfaces; (**c**) encapsulation in a semipermeable membrane; (**d**) inclusion in gels; (**e**) cross-linking using cross-linking agents, i.e., glutaraldehyde

Adsorption processes occur due to simple interactions of the bioreceptor and the substrate. The substrate can be either charged, leading to ionic bonds being created, or uncharged leading to weaker bonds (hydrogen, hydrophilic, and van der Waals effects). Due to varying environmental factors which may occur at the interface, desorption of the bioreceptors is common when change in pH or ionic strength is present, making this technique less widely used for immobilization.

Entrapment involves the bioreceptor remaining in solution, compartmentalized by a semipermeable membrane, allowing small molecules through. This technique is particularly useful in hydrogel biosensing applications where control is of huge importance such as in drug delivery systems which rely upon the slow release of drugs into a system based on the target analyte concentration.

Cross-linking is a technique whereby a bifunctional agent such as glutaraldehyde encourages attachment of polypeptide structures to each other or on to substrate surfaces to make the complex more stable. This technique is particularly useful in the processes involving adsorption or inclusion.

Covalent binding of proteins on activated surfaces can be achieved through the covalent bonds developed between functional groups not required in the biorecognition process. The surface activation process prior to immobilization can be achieved either via a direct method whereby amine ($–NH_2$), carboxylic (–COOH), hydroxyl (–OH), or sulfhydryl (–SH) groups on the substrate surface are functionalized through a range of reagents before covalent binding can occur

with the functional group of the bioreceptor. Another common method is silanization of glass surfaces with an organosilane containing an organic functional group at one end and an alkoxysilyl group at the other end of the molecule.

Carboxylic groups can be activated using the acyl nitride method or carbodiimide method. The acyl nitride method transforms the carboxylic acid group to hydrazides through esterification by methanol in acidic solution, then treatment with hydrazine. A final treatment step with sodium nitrite gives acyl nitride which forms an amide bond with the amine groups of the bioreceptor. The carbodiimide method reacts in acidic solution with the carboxylic group forming a key intermediate, *O*-acylisourea a carboxylic ester, subsequently forming an amide bond with the amine group of the bioreceptor. Hydroxyl groups are activated using cyanogen bromide forming an intermediate which reacts with the amine group of the bioreceptor. Amine groups can be activated using diazonium salts, while sulfhydryl groups are activated through the formation of disulfide bridges between thiol groups of the bioreceptor and the substrate, after surface treatment with 2,2′-dipyridyldisulfide. Although most of these techniques are straightforward to perform, ready to use activated surfaces are commercially available (e.g., Sigma Aldrich). As nanostructures, nanoparticles (NP), and thin films become increasingly incorporated into biosensors, variations to these immobilization techniques for biomolecule attachment have been applied such as layer by layer (LbL) and Langmuir–Blodgett (LB) films for better molecular architectures and ultimately enhanced performances in biosensing systems [8].

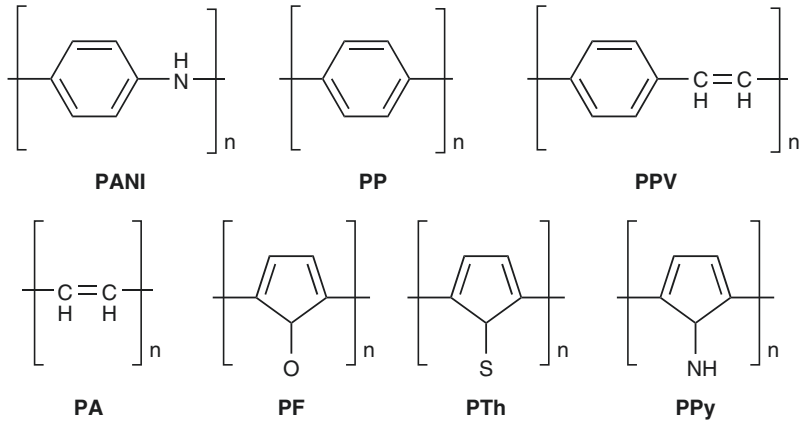
Detection Technologies for Nanobiosensors

A wide range of biosensor technologies have been developed since the electrode enzyme of 1962. In recent decades nanomaterials have made significant headway in to biosensor systems for improving the limit of detection (LOD) in a host of complex sample solutions. These new nanobiosensors (or bionanosensors) typically use traditional detection techniques with nanotechnology to develop a host of enhanced bioelectronic devices for a variety of biomedical research and industrial applications. Along with optical, electrochemical, and mass transduction systems, biosensors have also utilized thermistors and magnetic beads as transduction elements. The state of art for current nanotechnologies involved in biosensing is extremely large and intertwined between detection technologies; hence for simplification the following section serves as an illustrative description of novel, and by no means exhaustive, approaches in the most common biosensing techniques.

Electrochemical-Based Detection

Carbon Nanotube Biosensors

An emerging building block of novel nanostructures and devices used in electrochemical biosensing applications are *carbon nanotubes* (CNT). Synthesized in various forms (e.g., single walled (SWCNTs), multi-walled (MWCNTs)), CNTs possess a large surface per unit mass and excellent mechanical and electrical properties making them extremely powerful in electronic detection of biomolecules, viruses, and cells. Functionalization of CNTs with different chemical groups has been achieved using both covalent and non-covalent methods [9]. At low potentials, various analytes can be oxidized with little surface fouling, making them ideal for high selectivity and reusability. Commonly used is the –COOH group for covalent bonding on CNTs via oxidizing treatment, which may also create other functional groups (e.g., hydroxyl, carbonyl, etc.) at defect sites of the graphene sheet. These other functional groups can be easily converted to carboxylic acids through perchloric acid ($HClO_4$) treatment or potassium permanganate ($KMnO_4$), which sets the surface for immobilization of bioreceptors through the carbodiimide method. CNT electrochemical (CNT-EC) biosensing has been reported for detecting glucose and neurotransmitters and a range of other biological entities, including nucleic acids and viruses. Immobilization of single-stranded DNA



(ssDNA) molecules, mainly through covalent attachment, on CNTs has led to the development of electrochemical DNA biosensors which have been used to sense nucleic acids, genes, and DNA molecules. In addition, the enhanced amplification in signal transduction has seen their use in detecting DNA hybridization reactions. There are a host of doped and nanocomposite CNT electrodes developed for a variety of DNA detection applications, with sensing techniques that include impedance spectroscopy, surface conductance, and differential pulse voltammetry. Studies into the characteristics of immobilized ssDNA and hybridization of DNA have also been conducted using techniques such as cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS).

Since about 85 % of the biosensor market, worth approximately US$ 8.5 billion, belongs to glucose sensors, a large amount of novel biosensing ideas are based around blood glucose monitoring [9]. Strategies based on the presence or absence of enzymes as the bioreceptor element has been applied to CNTs for glucose monitoring. The enzyme glucose oxidase (GOD), which catalyzes the oxidation of glucose, has been immobilized on an Ag-NP/CNT/Chitosan composite giving a rapid and steady response to the substrate. This was also demonstrated on MWCNTs/ZnO-NPs, where GOD was electrostatically bound to ZnO-NPs based on isoelectric point differences. Incorporation of GOD into a colloidal Au-CNT composite showed that the apparent Michaelis–Menten constant showed a high affinity of the enzyme to the substrate under the microenvironment of the AuNPs. MWCNTs modified with ferrocene electrodes have been immobilized with GOD, and gave an improved response to glucose oxidation as the ferrocene acted as an electron transfer mediator while the MWCNT acted as the conductor. Though doped-CNT electrodes can promote electron transfer in redox reactions interference could result as endogenous O_2, unless extracted, may react with GOD producing H_2O_2, thus underestimating the glucose level. CNT-based biosensors not employing enzymes for glucose monitoring tend to be low in cost and can be achieved through, for instance, the direct growth of CuNPs on CNTs through self-assembly or via the use of immobilized microbes on CNT-modified carbon paste electrodes [10].

CNT-EC biosensors largely tend to be based upon amperometric sensing, with the CNT either surface modified with an oxide or chemically doped with a variety of NPs for label-free detection of biomolecules such as immunoglobulins and insulin. A wide range of CNT-bioreceptor bioconjugate-based biosensors have also recently been developed for real-time detection with detection limits down to a zeptomole (10^{-21}) based on double-step amplification. For example, immunoaffinity reactions (i.e., formation of antibody-antigen complexes) have been detected on CNTs as a function of mechanical and electrical properties of the CNT; CNT-FET (field effect transistors) have been used to detect mismatches of dsDNA sequences through decreases in conductance; viral antibodies have been immobilized on to CNTs through the use of polymers to detect viruses; and metal-NPs have been used for DNA attachment to CNTs for enhanced detection of sequence-specific target DNA and human hepatitis B virus ssDNA with LOD as low as 0.035 pM [10].

Conducting Polymer Biosensors

Another class of nanomaterial which has recently received widespread interest for biosensor applications are a class of functional polymers known as *conducting polymers* (CP). Their attractiveness as electrochemical transducers in sensing stems from their highly conjugated polymer chain composed of alternating single and double carbon–carbon bonds, which can be doped or de-doped in a controllable manner. When used as nanostructures, these unique properties are further enhanced with large surface area, nanoscale size, and the exhibition of quantum effects making response times significantly faster than bulk polymers. The primary principle behind CPs as sensing devices is based on the "before and after" sensing of a target molecule on the surface on the CP, meaning that the sensitivity of the CP is highly dependent on its surface area where target molecules have the ability to increase or decrease

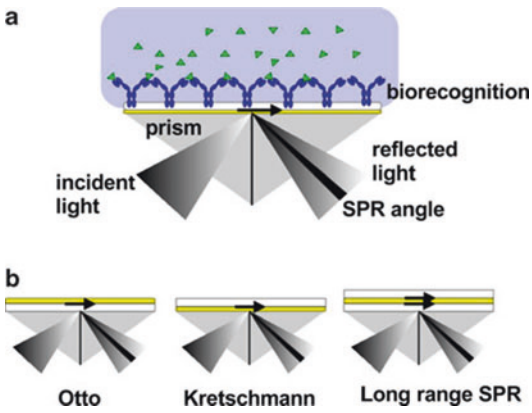
Biosensors, Fig. 4 Chemical structures of common conductive polymer units: polyaniline *PANI*), poly(para-phenylene) *PP*, poly (phenylenevinylene) *PPV*, polyacetylene *PA*, polyfuran *PF*, polythiophene *PTh*, polypyrrole *PPy*

mobile charge carriers, thus affecting the conductivity of the CP. Figure 4 shows the typical molecular structures of CPs for biosensing applications. Techniques used to synthesize CP nanostructures include hard- and soft-template methods and electrospinning. In the hard-template method, which is most commonly used, a template membrane is required to guide the growth of the nanost ructures within the pores leading to a completely controlled nano-morphology dictated by pores and channels, which can give CP nanowires of 3 nm in diameter. As the template needs removing post-process, the technique has some limitations in that the nanostructures can be destroyed or deformed. Various preparation protocols using the hard-template method have been described using either chemical or electrochemical polymerization, but the important variable in these processes is the actual template which can take the form of porous alumina membranes (Al_2O_3), polycarbonate membranes, or nanofibers [11]. In contrast, the soft-template method sometimes referred to as a self-assembled method requires no template. It is a cheap and fairly simple technique based on non-covalent interactions driving the self-assembly (e.g., π–π stacking interactions, hydrogen bonding, and dispersive forces), and can use oligomers, DNA, surfactants, colloidal particles, or colloids to synthesize CP nanostructures, also via both electrochemical and chemical methods [11].

Conducting polymers are extremely versatile when used in biosensing devices and have been used as immobilization matrices, artificial bioreceptors, and transducers for electrical charge from redox reactions [12]. Based on conductometric detection, a change of electrical conductivity of the CP nanostructure upon interaction with target analytes can be measured. The basis of potentiometric detection is the detection of changes to the chemical potential of the CP due to internal shifts in the anion equilibrium. Using these two detection techniques, CP-based biosensors have been developed based on nanothin films and nanostructures. Nanothin CP films, produced by electrochemical polymerization, spin coating, or layer by layer techniques, tend to have bio-active molecules embedded allowing target analytes adsorbing on to the film diffuse into the film for interaction with the receptor. As examples, an ultra thin film of PPy-GOD composite was fabricated for potentiometric sensing of glucose, showing a high sensitivity to glucose at low current. An organic thin film transistor (OTFT) for glucose monitoring had a channel of immobilized GOD on poly (3,4-ethylenedioxythiophene)-polystyrene sulfonate (PEDOT-PSS) CP film, giving rapid response times (∼20 s) and high selectivity between drain current and glucose concentration in test conditions. Using layer by layer self-assembly, an ion-sensitive field effect transistor (ISFET) was fabricated with polyaniline (PANI) as the thin film channel giving glucose sensitivity of <0.8 μA/mM, further indicating the potential of nanothin film CP as low cost biosensor materials. Other defining factors which influence the performance of these nanothin films include the thickness of the film, the roughness of

the film, and the nanoporosity of the film. CP nanostructures include CP-nanoparticles (CP-NP) which tend to be dispersed on electrode surfaces to increase area/volume ratio for favorable adsorption of biomolecules; nanoarrays of nanotubes/nanowires in highly ordered alignment have shown increased sensitivity in hybridization, mass transport, and kinetic studies; and individually addressable 1D nanostructures (nanowires/nanotubes) which have shown extremely powerful transduction capabilities due to the high contact area of the analyte on the nanostructure which produces polarons and bipolarons along the backbone of the CP [11]. This effectively affects the electrical conductivity of the CP nanotube or nanowire which subsequently results in an enhanced and amplified signal based on nanosurface interactions.

Nanobiosensing has evolved even further through the development of ultrasensitive, electrical biosensors known as *nanowire biosensors* (inorganic or semiconductor), which tend to be comparable in size of the biological or chemical species being sensed. This enables excellent primary transduction of signals to interfacing macroscopic instrumentation, through direct integration of nanodevices (e.g., nano-FET) with miniaturized systems.



Optical-Based Biosensors

Variations in optical phenomena based on the resultant interactions of target analyte and bioreceptor form the basis of optical transducer technologies. Fiber-optic technology has been a key driving force in the development of many of these optical techniques for biosensor applications. As such the term *optrodes* has come to define devices which incorporate optic fibers as transduction elements in sensors. A fiber-optic biosensor is a device in which a reaction phase is associated with a transduction system made from optical fibers or bundles of optical fibers directly coupled to some form of light detector. The reaction phase (e.g., sol-gel film) contains immobilized bioreceptors which generates an optical signal upon biorecognition with target analytes, transmitting the signal through the optic fiber to the detector.

Covering different regions of the electromagnetic spectrum (UV, visible, IR, NIR), optical sensors are based on various optical principles (absorbance, fluorescence, luminescence, reflectance), which allow the measurement of a range of properties including light intensity, refractive index, scattering, diffraction, and polarization. Nanotechnology has played an important part in enhancing optical sensing techniques as will be highlighted.

Surface-Plasmon Resonance (SPR)

The most common technology used in optical biosensing is surface-plasmon resonance (SPR). Belonging to the class of refractometric sensing it exploits *surface-plasmon polaritons* (electromagnetic waves) to probe interactions of analytes in solution forming complexes with bioreceptors immobilized on the SPR sensor surface through adsorption. This highly sensitive method is based on the collective oscillatory excitement of electrons propagating between a metal film and dielectric interface, leading to a total absorption of light at a particular angle of incidence (Fig. 5). Surface plasmons are optically excited if the projection of the incident light wave vector along the x-axis matches the propagation constant of the surface plasmon (k_{sp}), described as:

Biosensors, Fig. 5 (**a**) Typical setup of a SPR biosensor, with the *black arrow* showing the direction of the SPP wave at the interface of the metallic surface and the dielectric (*white*); (**b**) typical configurations used in SPR biosensors

$$k_{sp} = \frac{\omega}{c}\left[\frac{\varepsilon_m \varepsilon_d}{\varepsilon_m + \varepsilon_d}\right]^{0.5} \quad (2)$$

where ε_m and ε_d are the dielectric constants of metal and dielectric, respectively, ω is the angular frequency of light, and c is the speed of light in vacuum.

A change to k_{sp} resulting from a change to the refractive index of the sensed medium, i.e., the dielectric, subsequently alters the resonance conditions of the surface plasmons interacting with the optical wave. Three relevant characteristics are critical to sensor design and performance, which are:

1. *Enhancement of electric field*: at the resonance angle, the intensity of the electric field at metal-dielectric interface is significantly enhanced due to the smaller complex permittivity in the dielectric compared to the metal.
2. *Propagation length*: the propagation constant, *ksp*, contains complex permittivity quantities for both metal and dielectric (Eq. 2) resulting in a complex wave vector. The imaginary component of the propagation constant (k_{sp}") represents the attenuation by metal absorption and radiative losses, implying the field intensity decays by a characteristic length of $1/2k_{sp}$". The surface plasmon decay length (δ_{sp}) is thus defined in Eq. 3, where λ_0 is the optical wavelength:

$$\delta_{sp} = \lambda_0 \frac{\left(\varepsilon'_m\right)^2}{2\pi\varepsilon''_m}\sqrt{\left(\frac{\varepsilon'_m + \varepsilon_d}{\varepsilon'_m \varepsilon_d}\right)^3} \quad (3)$$

3. *Penetration depth*: the other component of the parallel wave vector is the perpendicular wave vector to the interface which is an imaginary amplitude wave vector that decays in the z-direction. The penetration depth (δi), a couple of hundred nanometers in water, is defined as the distance in the perpendicular direction to the interface where the electromagnetic field inside the medium (i) falls to *1/e* (~37 %) and can be expressed by Eq. 4:

$$\delta_i = \frac{\lambda_0}{2\pi}\sqrt{\left|\frac{\varepsilon'_m + \varepsilon_d}{\varepsilon_i^2}\right|} \quad (4)$$

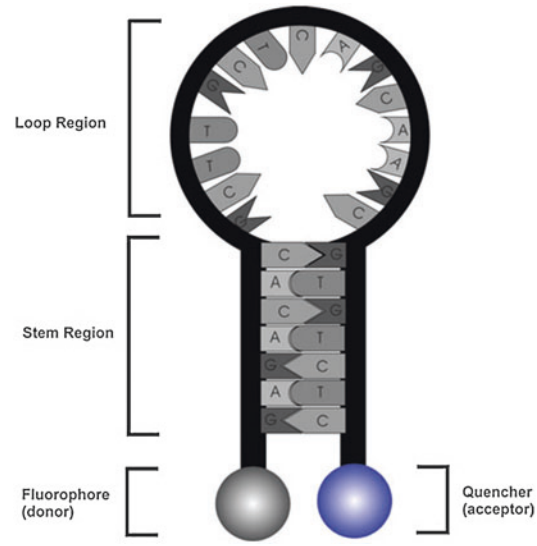
Optical excitation methods for surface plasmons include prism, grating, and waveguide coupling. The characteristic measurement of the resonance has lead to SPR sensors to be categorized into angular (monochromatic light), wavelength (polychromatic light), intensity, or phase modulation [13].

SPR-based biosensors work on the basis of an alteration to the refractive index near the surface of the functionalized sensor when a biomolecular interaction occurs. The performance of the SPR-based biosensor is highly dependent on the intrinsic optical performance of SPR sensor (sensitivity and resolution) and the characteristics of the functionalized surface. Advances in SPR sensor performance has led to increased sensitivity of systems containing immobilized biorecognition elements, with commercial systems having refractive index resolution (LOD equivalent) as low as 1×10^{-7} RIU (Refractive Index Unit). Researchers worldwide are continuing to construct novel coupling approaches, mainly based on Kretschmann's configuration (as depicted in Fig. 5b), for greater sensitivity such as the multilayer structure long range surface plasmons (LRSPs) which offer greater optical field enhancement, lower propagation loss, and longer field penetration (for virus and bacteria detection) over conventional surface plasmons. Optical fiber-based sensors and integrated optical waveguide SPR sensors offer the development of miniaturized systems for in vivo applications and multichannel sensing on a single chip [13].

Functionalization of the metallic surface (typically Au film) is commonly achieved through covalent attachment as this creates a stable and strong binding to the surface and allows regeneration of the sensor interface after removing analytes from the surface but not the attached bioreceptor. The functional self-assembled monolayers (SAMs) of thiolated organic compounds is a routine approach for covalent attachment of thiol groups of the bioreceptors, while polymeric layers such as carboxymethylated dextran (CM-dextran) thin films offer advantages of reduced binding interference, reduction in nonspecific binding by acting as a buffer, and increased attachment points over SAMs. Although gold thin films are commonly used

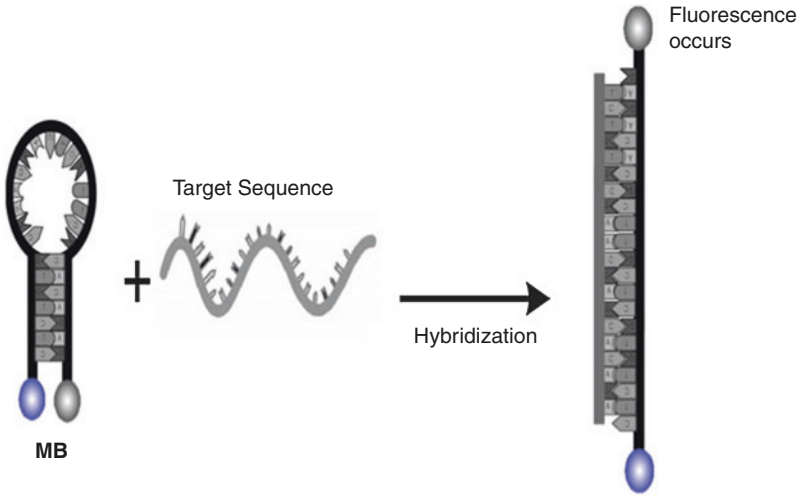
substrates for SPR biosensors because of their stability in aqueous environments and easy functionalization through alkanethiol SAMs, they have been found not to be the best candidates for high sensitivity SPR sensing. Indium tin oxide (ITO) has been reported to be a better candidate, though excitation and detection would occur in the infrared range. For conventional visible range excitation and detection, silver/gold layers have been used and lamellar overcoat structures, where a thin layer of a dielectric (oxide based) is deposited over silver metal thin film providing efficient protection from the aqueous solution which could damage the silver film [14]. There has also been a large focus on polymeric thin-film electrodeposition of oligomeric and conducting polymers on to gold surfaces for SPR biosensing. They have been used as they possess properties (hydrophobicity, pH, surface charge) which reduce nonspecific adsorption, which in turn increases the sensitivity and specificity of a biosensor. The conductive polymer polypyrrole has been intensively used in biosensors due to its biocompatibility, stability, and conductivity. Entrapment of bioreceptors in polypyrrole has been shown to be less attractive as the hydrophobicity of the substrate makes target molecule diffusion difficult. A more promising approach is the functionalization of the conducting polymer through covalent binding of the bioreceptor on the carboxyl groups. This method of functionalization has become a routine technique, based on electrospotting, for DNA array SPR chip fabrication.

The most common bioreceptor used on SPR-based biosensors are antibodies and commercial SPR systems (BIAcore^{TM}, real-time biospecific interaction analysis) have been developed for pharmaceutical drug discovery, antibody characterization, proteomics, immunogenicity, and much more in life science research. Essentially, SPR-based biosensing is a label-free detection method, but for signal amplification and enhanced surface chemistry new approaches which involve nanomaterials (e.g., CNTs, NP, nanowires) have been developed [13]. The effect of nanostructures on surface plasmons has led to a growing area of photonic studies known as nanoplasmonics. Metal-NPs are incorporated into SPR-based biosensors due to the lack of small molecule detection with conventional systems. As low molecular weight compounds produce a negligible change in the refractive index of the sensing surface, metal-NPs overcome this due to their localized SPR (LSPR) frequency (refer to ▶ Optical Properties of Metal Nanoparticles). This occurs as a result of the incident light interacting with particles much smaller than the incident wavelength, and the presence of metal-NPs is characterized by intense adsorption and light scattering. The enhanced electric field has shown to give an order of magnitude increase in sensitivity (5×10^{-8} RIU) and has enhanced other spectroscopic methods such as surface-enhanced Raman spectroscopy (SERS). For instance, SPR signal output has been increased through mass or enzymatic processes at the bioreceptor-ligand complex. Immobilized peptide nucleic acids (PNA) for point mutation detection were hybridized with DNA-modified nanoparticles. The LOD for this ultrasensitive mismatch was as low as 1 fM using this technique [15]. A similar approach was applied to Poly-T modified nanoparticles, which bind to surface-immobilized Poly-A tails forming a ternary surface complex, with LOD for 19–23 mer as low as 10 fM.



Experimental measurements based on labeling may be problematic due to metal-NP influences on binding kinetics and biomolecular interactions. A different approach toward incorporating nanotechnology into SPR-based systems focuses on the sensing matrices, which alleviate problems associated with biomolecular labeling. SPR-based immunosensors had immobilized AuNPs encapsulated in dendrimers on SAM-modified gold surfaces providing an enhanced surface density for analyzing insulin, while the sensitivity of SPR-based hormone assays were significantly enhanced using AuNPs [14]. A sensing medium which had gold embedded in a hydrogel and functionalized for small molecule detection swelled upon biorecognition, which increased the distance between AuNPs in the hydrogel. A shift in the SPR curve to higher angles was a result of the intercorrelation of both SPR and LSPR.

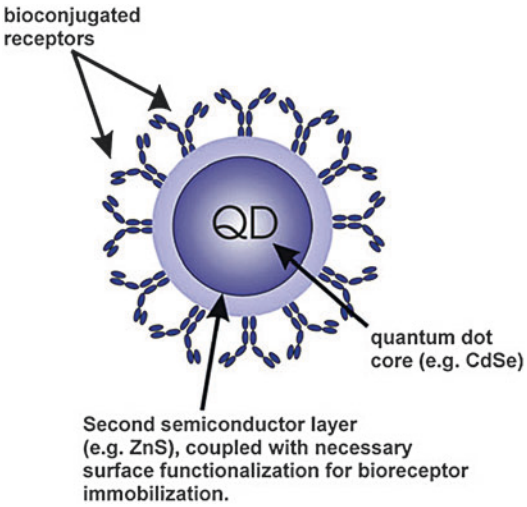
Molecular Beacons and Quantum Dots



Luminescence is the emission of electromagnetic radiation in the ultraviolet, visible, and infrared spectra from atoms or molecules as a result of the transition of electronically excited states to a lower energy state, usually the ground state. There are various forms of luminescence (e.g., phosphorescence, bioluminescence, chemiluminescence, and fluorescence) which have been applied to biosensors and fiber-optic biosensing for a diverse range of activities ranging from glucose monitoring and genosensors to environmental monitoring and biopharmaceutical process monitoring.

Fluorescence is a widely used optical technique in biosensing, and there are three types of sensing employed. First is direct sensing when a specific target molecule is detected before and after a reaction or change takes place. The second form involves an indirect detection by the addition of a dye (e.g., FITC, GFP) which will tag the presence of the target molecule. The final form is known as fluorescence resonance energy transfer (FRET), which generates a unique fluorescence signal. Developed by Förster and Weber, FRET requires two probes: a donor (fluorophore) and an acceptor (chromophore) [10, 16]. Irradiating the donor with light of an appropriate wavelength produces an oscillating dipole which resonates with the dipole of the acceptor in close proximity. This dipole–dipole interaction is a radiationless transfer of energy between the donor and acceptor. As such if the acceptor is another fluorophore with an excitation wavelength that overlaps with emission wavelength of the donor, the transfer of energy from the donor to the acceptor will stimulate fluorescence of the acceptor. The two major strategies used to develop FRET biosensors are: (1) two chain probes in which the fluorophores are on two different molecules resulting in intermolecular FRET when two molecules come into close proximity to each other, or (2) FRET due to intramolecular conformational change based on single-chain probes with fluorophores attached to different regions of a single molecule.

Optical DNA nanobiosensors have been developed through the use of molecular beacons (MB) and quantum dots (QD) in optical nano-imaging systems. MBs are single-stranded nucleic acid probes consisting of a stem, a loop, and a fluorophore/quencher pair (Fig. 6). The close proximity (~10 nm) of the donor fluorophore and acceptor quencher in the hairpin, made possible by the "locking" mechanism of the stem region (~4–7 nucleobase pairs), effectively turns off the fluorescence via FRET. They are widely used in fluorometric analysis of nucleic acids. A conformational change of the MB occurs upon hybridization with the complementary target (ssDNA or RNA) which increases the physical separation distance between the fluorophore and quencher, thus providing a fluorescence signal (Fig. 7). Different color fluorophores can be used simultaneously for detection of multiple targets in the same solution. This label-free detection tool is sensitive and its importance in biosensor technology offers high selectivity with real-time monitoring of hybridization for analysis of gene polymorphism in genetically modified organisms, polymerase chain reaction (PCR), and ligase reactions. They have been used to detect bacteria, viruses, and other microorganisms in a variety of conditions; studies of genotyping, genetic disorders associated with point mutations, and drug discovery have been conducted with various



Biosensors, Fig. 6 A molecular beacon consisting of a loop region, stem region, and a fluorophore/quencher pair separated by ~10 nm, inhibiting fluorescence

Biosensors, Fig. 7 Hybridization reaction of a molecular beacon with a target sequence oligomer. The increased separation distance between the fluorophore and the quencher allows fluorescence to occur

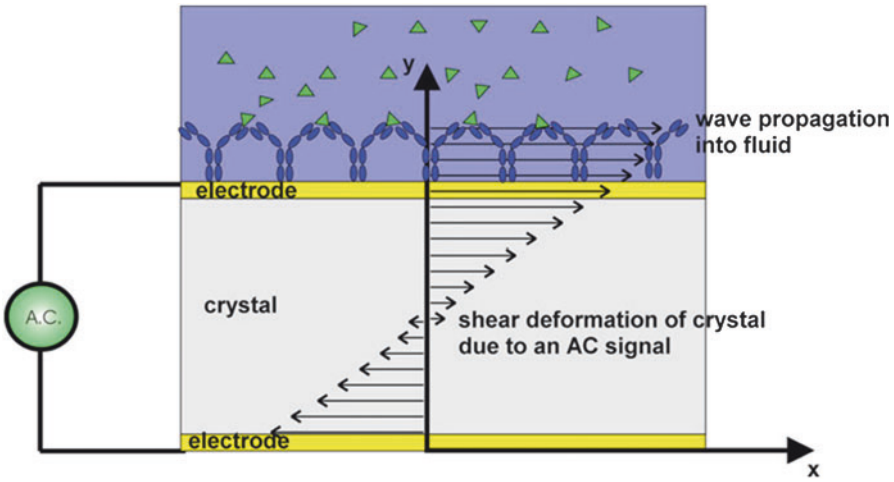
aspects of MBs. Other innovative approaches for using MBs as nanobiosensors have included visualizing the transport and distribution of mRNA; incorporating MBs in flow cytometry studies for oxidative stress analysis; detecting mutations in the *rpoB* of *Mycobacterium tuberculosis* (TB) via MB-qPCR as a screening tool for multidrug-resistant tuberculosis; real-time detection of dsDNA; and linking MBs to the fuse silica surface for drug delivery. These applications highlight the importance of MBs as a powerful tool in intracellular monitoring of nucleic acids and in the ongoing development of highly selective optical biosensors.

QDs are nanoscale semiconductor structures grown by epitaxial techniques in nanocrystals by chemical methods. They consist of a colloidal core (e.g., cadmium selenide, cadmium sulfide, and indium arsenide) covered with surface coatings which decrease leaching of the metal from the core (Fig. 8). Based on the reduced size of QDs, they possess discrete electronic energy which gives rise to their unique optical properties and their use as a fluorescent probe for biomolecular imaging or even as a donor in molecular beacons [17]. In comparison to organic dyes, and fluorescent proteins, QDs are controllable in many ways including their size-oriented optical and electronic properties, tunable light emission, resistance against photobleaching, and simultaneous excitation of multiple fluorescence

Biosensors, Fig. 8 Quantum dot for nanobiosensing applications conjugated with antibodies on the outer surface

colors [10]. More recently, development of heavy metal-free QDs with similar optical properties has overcome issues regarding cytotoxicity presented by heavy metals such as cadmium. Their photo-stable fluorescence and water solubility upon coating with amphiphilic polymers has seen QDs being used in biodetection systems, biosensing and high-throughput bio-analytical systems, quantitative cellular investigative studies, and nanobiomedicine.

Surface immobilization of antibodies, DNA, proteins, biopolymers, peptides, and nucleic acid on QDs has significantly advanced bio-imaging and biosensing over the past decade. Bioreceptor attachment via cross-link molecules with diverse reactive groups, e.g., –SH, NH_2, or –COOH, is attained through covalent or electrostatic interactions. A broad absorption spectra with high extinction coefficients and a full width at half maximum (FWHM) of 20–30 nm is afforded by QDs. Emissions of QDs can be quenched by gold nanoparticles (AuNPs), and this has been exploited in fluorescent assays for DNA detection where QDs and AuNPs were used as a FRET donor-acceptor couple based on cadmium selenide QDs bioconjugated with a short DNA strand and hybridized with a AuNP-DNA strand. The development of a single-QD-based nanobiosensor for detection of multiple DNA of HIV-1 and HIV-2 has been developed [10] using the nanobiosensor as a local nanoconcentrator, capable of significantly amplifying both fluorescence signal and FRET signals, with potential use for point of care diagnostics and high-throughput screening. QDs have also been applied in chip-based DNA microarrays for analyzing single nucleotide polymorphism and multi-marker discovery, with anticipated LODs as low as 2 nM concentrations of DNA-NP probes. Interestingly, the use of QDs has been discovered in gene technology, where QD-FRET has been utilized in labeling and recognizing target sequences of DNA with red, blue, and green QDs in different combinations. Discrimination and detection of a single base pair mismatch has been reported using a QD-DNA nanobiosensor, potentially leading to very advanced applications in clinical diagnostics of DNA mutants with drug resistance. Chemiluminescence and bioluminescence resonant energy transfer (CRET and BRET, respectively) generate an excited state donor through chemical and biochemical reactions and are believed to be more advantageous than FRET due to lower background from optical excitations [17].



Mass Sensitive Biosensors

Piezoelectric crystals, more commonly referred to as quartz crystal microbalances (QCM) are mass sensitive devices which transform a mass loading at the gold electrode sensor surface, due to adsorbing analytes, into a change in the intrinsic resonance frequency of the QCM. When a low voltage AC signal is applied to thin layer electrodes sandwiching a quartz crystal, the piezoelectric nature of the crystal produces a shear (tangential) deformation causing both surfaces to move in parallel, but in opposite directions, thereby producing acoustic waves which propagate through the bulk of the crystal perpendicular to the surface (Fig. 9). The resonance frequency of the crystal depends on the shear acoustic wave velocity and the thickness of the crystal substrate. The fundamental resonance frequency and odd overtones are the only harmonics which can be excited as predicted using the shear acoustic wave (ν) propagation equation. Also, as ν is very dependent on the properties of the propagating material, i.e., Young's Modulus and density, thickness shear mode (TSM) resonators are well suited for determination of material-specific parameters, which are difficult to obtain using other biosensing techniques such as SPR.

Able to operate in three modes (i.e., flexural, extensional, and thickness shear), thickness shear mode is the most sensitive with the resonant frequency change being a measure of the thin layer mass attached to the crystal surface. It is also the only mode which can be electrically excited with a low voltage, as the other modes have a coupling factor of zero. In a vacuum, the relation between mass and resonant frequency is considered to be proportional to the added thin layer solid mass on the device surface as described by the Sauerbrey equation (Eq. 5), where f_0 is the resonance frequency of the unperturbed quartz resonator, F_q is the frequency constant of the crystal, ρ_q is the quartz density, and A_{el} is the electrode area:

$$\Delta f_m = -\frac{f_0^2}{F_q \rho_q} \frac{\Delta m_s}{A_{el}} \tag{5}$$

To take into consideration a QCM in contact with fluids, Kanazawa and Gordon proposed a theoretical relationship which factors in the material properties of both quartz and a Newtonian

Biosensors, Fig. 9 Illustration of a quartz crystal microbalance biosensor depicting the shear acoustic wave propagating in the bulk of the crystal and into the fluid in contact with one surface. Typical decay lengths of the wave into the fluid are of the order of nanometers, making ligand-complex interactions with surface-immobilized nanoscale bioreceptors and thin film deposition of materials on the surface detectable due to a change in resonance frequency

fluid as defined in Eq. 6, where μ_q is the shear module in the x-direction, ρ_l is the density of the liquid, and η is the liquid viscosity:

$$\Delta f_1 = -\sqrt{f_0^3 \frac{\eta_l \rho_l}{\pi \mu_q \rho_q}} \tag{6}$$

Suitable oscillator circuits have been designed for the application of these sensors to biological detection in liquid samples, combined with modified surface chemistries of the sensing surface for the immobilization of bioreceptors. QCMs typically operate at frequencies between 1 MHz and 10 MHz, with a frequency-determination limit of 0.1 Hz and a LOD of mass bound to the electrode surface of 10^{-10}–10^{-11} g, subject to calibration of the instrumentation. QCM-based biosensors have been used extensively by researchers for detection of micron-sized bacteria such as *Escherichia coli* and to study the mechanisms involved in surface adhesion and formation of microbial biofilms [18]. The sensitivity of QCMs has been shown to increase with the incorporation of NPs.

It is appropriate to mention here that DNA biosensors, generically known as genosensors, have also been applied to QCMs. These genosensors monitor and detect in real-time DNA hybridization events, through immobilized macromolecules. An AuNP-amplified QCM DNA biosensor for *E. coli* detection had AuNPs immobilized on the surface of the QCM, increasing the surface area of the sensor and allowing more ssDNA probes to be absorbed on to the surface which then captured the biotinylated *E. coli* DNA. Amplification has been enhanced further using outer-avidin-coated AuNPs giving an LOD as low as 2×10^3 CFU/mL. A similar technique has recently been applied for the specific and rapid detection of avian influenza virus H5N1. A magnetic nanobead amplification-based QCM immunosensor was fabricated, whereby polyclonal antibodies against the AI H5N1 virus surface antigen hemagglutinin were immobilized on the gold surface through SAMs of 16-mercaptohexadecanoic acid. Capture of the virus on the immobilized antibodies resulted in a decrease in resonant frequency of the QCM, which was further amplified by the magnetic nanobeads coated with anti-H5 antibodies bound between antibody and antigen.

The real-time detection of lysozymes on a QCM nanosensor has been achieved using immobilized molecular-imprinted polymers (MIPs) giving a detection limit of 1.2 ng/mL and

a high selectivity and sensitivity in a concentration range of 0.2–1,500 μg/mL. They include the use of QCMs in bacteria detection, hemostasis studies; immunoassay studies; carbohydrate binding; oligonucleotide interactions; protein, enzyme kinetic, and cellular studies; and small molecule interactions via MIP and small molecule surface immobilization [18]. The vast majority of these applications had the gold surface of the QCM chemically functionalized through SAMs of both natural and artificial bioreceptor elements which aided in the detection of specific entities, thereby increasing the limit of detection and quantification significantly in comparison to some optical techniques.

Microarray Biosensors

Microarrays, also known as biochips, are 2D or 3D molecular receptor arrays which allow for the simultaneous detection of a large number of substances through the interaction of target analytes with substrate-bound bioreceptors. There are several categories of microarrays (e.g., DNA, proteins, aptamers, whole-cell) which typically comprise several hundred to several thousand "spots" or "zones" on which the bioreceptor (s) can be immobilized. The applications of these microarray biosensors are far-reaching and have been used in gene expression, protein-expression profiling, point mutation analysis, immunodiagnostics, drug screening, cell analysis, and DNA sequencing to name a few. A brief description of the most common microarray technologies to date is provided.

DNA microarrays consist of immobilized cDNA (<5,000 b.p) or oligonucleotides (<80 b.p) which interrogate target analytes (e.g., DNA) in sample solutions. In principle, the assays developed largely depend on the specific molecular recognition between complementary sequences of nucleobases. Depending on the method of detection or "microarray reading," bioreceptors have usually been immobilized on glass/silicon substrates, metal-coated (i.e., ITO, gold) glass substrates, or polymeric substrates. Companies (i.e., Affymetrix) have developed precision equipment for high-density "spotting" of bioreceptors on functionalized substrates for rapid screening studies, along with appropriate microarray reading software. The most widely used detection method for DNA microarrays is fluorescence detection. Target molecules are tagged with a fluorophore and upon hybridization with the bioprobe, the spot or zone will fluoresce. Other forms of detection for DNA microarrays include chemiluminescence/electrochemiluminescence. DNA microarray technologies have been used to map the genome sequence of multiple organisms including humans and yeast.

Protein microarrays can generally be classed as either analytical/diagnostic or functional microarrays. They were developed upon completion of genome mapping, leading to the prediction of open reading frames (ORF) from genomes making it possible to express the full or partial proteome with large-scale cloning and gene expression methods. An analytical form of these microarrays is the antibody microarray which forms complexes with the target protein or antigen, and offers tremendous potential in clinical research and diagnosis. The functional form of protein microarrays which possess high-density proteins or peptides can represent complete or partial proteome of an organism. They are mainly used in studies involving protein–protein, protein–DNA, and protein–small molecule interactions, also offering wide-ranging applications in clinical cancer studies, viral infections, and autoimmune disease studies [19].

A modified analogue to DNA is peptide nucleic acids (PNA), which possesses a neutral peptide backbone (polyamide) instead of a negatively charged phosphate-sugar backbone. In comparison to DNA, PNA exhibits high chemical stability, resistance to enzymatic degradation, the ability to recognize specific nucleic acid sequences, strand invasion capabilities, high thermal stability, and ionic strength and the ability to hybridize with nucleic acids. Since their discovery in 1991, researchers have shown PNA-based biosensors to be extremely versatile in a range of systems including electrochemical, mass, and SPR-based on its unique biophysical properties. For example, μ-patterning of DNA on to microarrays has been achieved using electrohydrodynamics (EHD). DNA was found to be

affected by thermal and electrical properties upon immobilization, but the use of PNA in the patterning process did not affect its function or structural integrity.

Future Trends

Biosensors have undergone a rapid transformation over the past half century. It continually remains in a state of flux with innovative applications of nanotechnology for even faster, cheaper, and smaller biosensing systems for areas as diverse as personalized healthcare, point of care (POC) diagnostics, and rapid biodetection of pathogens in bioterrorism. These are being realized as microfabrication and miniaturization of electronic and transduction elements become incorporated into systems known collectively as lab-on-a-chip (LOC) systems or micro-total analysis systems (μ-TAS). These systems rely on the complete processing and transportation of biological samples on a single microchip through micro- and nanofluidic channels, from sample preparation to sample analysis through advanced biosensing techniques. Novel material properties, the development and integration of particle manipulation techniques, and increasing processing power will drive the next generation of biosensing nanosystems.

Graphene, a carbon allotrope isolated from graphite, has been reported as a new alternative to CNTs and metal alloy NPs ever since its discovery in 2004 [20]. Advances in graphene-based biosensors show significant advantages over CNT and metal-NPs. Purported problems associated with CNTs and metal-NPs, such as inconsistent signal amplification and metal impurities interfering with redox reaction with the biomolecules are thought to be avoided with the use of graphene in electrochemical nanobiosensor research. There is still a need of bioconjugation protocol development for bioreceptor immobilization on graphene before the uptake of electrochemical graphene-based biosensors becomes more commonplace.

Particle manipulation through AC electrokinetic phenomena, including electrowetting deposition (EWOD), *dielectrophoresis* (DEP), and *AC electro-osmosis* (ACEO) have shown tremendous potential in bionanotechnology. They have shown simplicity in integration with various biosensing transducers, and coupled with high specificity and sensitivity for particle manipulation in a range of media solutions, the rate of detection in biosensor systems is significantly greater than conventional methods (i.e., adsorption and electrostatic attraction) which rely heavily on bringing the target analyte in contact to the bioreceptor for high-quality sensing.

Bone turnover

Definition

Bone remodeling is a dynamic physiological process in which the combined effect of bone formation and bone resorption occurs at a specific location of the bone architecture to enable bones to adapt to mechanical stresses, to repair its microstructure and thus maintain the mechanical integrity of the skeleton, and to maintain mineral homeostasis. Bone remodeling consists of two main subprocesses, bone resorption by osteclasts followed by bone formation by osteoblasts without causing large changes in bone quantity, geometry, or size. An imbalance in the regulation of bone remodeling's two subprocesses results in many metabolic bone diseases, such as osteoporosis.

Overview

Bone is a metabolically active tissue capable of adapting its structure to mechanical stimuli and repairing structural damage. It has the capability of forming new osseous tissue at locations that are damaged or missing, such as in fracture healing, distraction osteogenesis or bone implants interface, or removing bone matrix in case of disuse. (Distraction osteogenesis: surgical process in which new bone formation is induced through gradual traction in an osteotomy site to reconstruct skeletal deformities or lengthen bones.) This calcified, vascular, connective tissue has many functions, including support, protection, mineral storage, blood cell production,

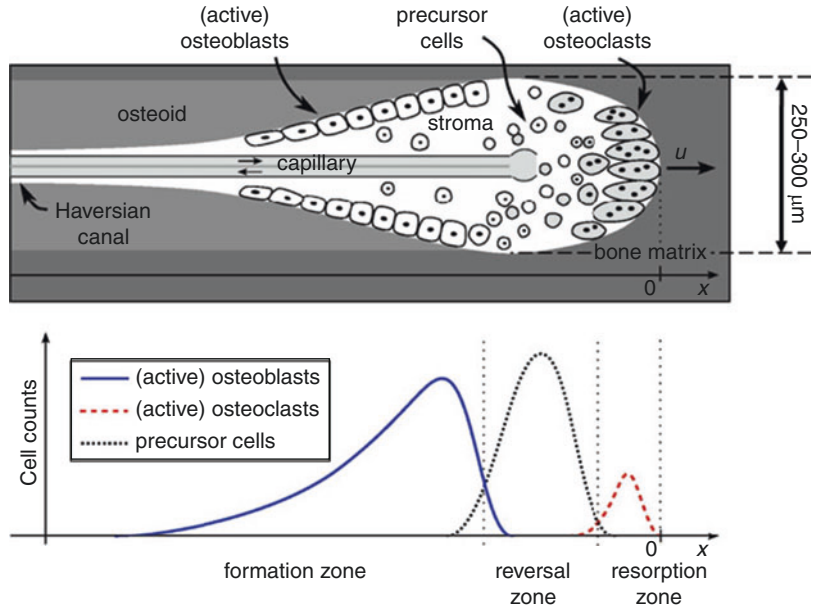
hematopoiesis, and locomotion through the attachment of muscles.

There are three basic mechanisms involved in the turnover and development of bone: the longitudinal growth, modeling, and remodeling. The former, the longitudinal growth, ceases with closure of the epiphyseal plates after the growing period. The second, modeling, serves to alter the bone that is present and to determine its geometry and size [1]. Bone modeling at any surface involves an uncoupled activity of osteoclast activation (A) followed either by formation (A-F) or resorption (A-R). (Osteoclast: specialized cells capable of bone resorption.) The latter, bone remodeling, starts with fetal osteogenesis and continues throughout life. It involves the coupled action of the osteoclastic and osteoblastic activities at localized areas on the bone surface (A-R-F) and differs from bone modeling, in which these processes occur independently at distinct anatomical locations (Osteoblast: bone forming cells). By the process of remodeling, bone is continuously resorbed and rebuilt at about one to two million microscopic sites per adult skeleton by teams of cells or remodeling units. These remodeling units are structures which persist for a variable but unknown period of time, traveling through the bone structure to carry out the functions of bone turnover in an ordered and predictable manner. Osteoclast–osteoblast interaction is needed for coupling bone resorption and formation both temporarily and spatially [1, 2]. Temporarily, since in each remodeling cycle, there occurs a succession of cellular events in the same place but at different times. Spatially, since in each remodeling unit, the same events are occurring in different places but at the same time.

Biological Principles

Bone Structure

At the structural level, mature bone can be classified into compact/cortical bone and cancellous/trabecular bone. *Cancellous bone* has large, open spaces surrounded by thin, interconnected plates of bone. The large spaces contain red bone marrow where hematopoiesis occurs and the plates of bone are trabeculae composed of several layers of lamellae. By contrast, *compact bone* is much denser than cancellous bone, with spaces reduced in size and lamellar organization more precise and thicker. The typical range of apparent density of cancellous bone is 1.0–1.4 g/cm^3 compared to about 1.8–2.0 g/cm^3 for compact bone [3]. (Apparent density: mass per unit volume of a region of bulk bone, which includes Haversian canals, marrow spaces, and other soft tissue spaces.) Cancellous bone can be found in the epiphysis or heads of long bones while cortical bone is found in the diaphysis or shaft of the bone and the outer layer of the trabecular bone. In the entire skeleton around 80 % of the total skeletal mass is composed of cortical bone and only 20 % is cancellous bone and the volume fraction (including internal pores like lacunae and canaliculi) is 0.8 mm^3/mm^3 and 0.2 mm^3/mm^3, respectively.



At the tissue level, bone may be divided into two wide categories:

- *Woven bone/primary bone*: This type of bone is laid down rapidly as a disorganized arrangement of collagen fibers and osteocytes. In adult skeleton, this young regenerated bone can be found in a fracture callus, during distraction osteogenesis and in areas undergoing active endochondral ossification.
- *Lamellar bone/secondary bone*. This mature bone can exist in cortical and trabecular bone. Unlike woven bone, this tissue is well organized and regular.

The Remodeling Cells

The remodeling process requires the synchronized activities of molecular mechanisms and multiple cellular participants, such as osteoblasts, osteoclasts and osteocytes to ensure that bone formation and bone resorption occur sequentially.

- *Osteoclasts*: Are multinucleated cells derived from hematopoietic cells formed by the fusion of mononuclear progenitors of the monocyte/macrophage family. They are the principal resorptive cells of bone by secretion of acid and proteases.

Bone Remodeling, Fig. 1 Cross-sectional diagram of a BMU in cortical bone. Osteoclasts resorb the bone matrix at the front while osteoblasts lay down osteoid toward the back to refill the cavity. The central capillary provides a supply of precursor cells, as well as various nutrients [5]

- *Osteoblasts*: Are mononuclear bone cells of mesenchymal origin that have several important roles in bone remodeling: expression of osteoclastogenic factors, production of bone matrix proteins (osteoid) and bone mineralization. It represents a heterogeneous family of cells, including immature osteoblast lineage cells, and differentiating and mature matrix-producing osteoblasts.
- *Osteocytes*: Terminally differentiated osteoblasts embedded in the mineralized collagen matrix that are likely to determine which bone surface osteoclasts will resorb. These cells are the most abundant cells in bone, accounting for 90–95 % of all bone cells. They may act as sensors for the chemical and mechanical signals, such as microcracks and loss of mechanical loading. Osteocytes communicate with each other and with cells on the bone surface, via the dendritic processes encased in canaliculi (Canaliculi: microscopic canals between the various lacunae of ossified bone).

The Remodeling Unit

The remodeling process is not performed individually by each cell but by groups of cells acting as organized units. Clusters of osteoclasts and osteoblasts are arranged within temporary anatomical structures known as "basic multicellular units" (BMUs). A BMU consists of around 20 osteoclasts and several hundred osteoblasts. Active BMUs consists of a leading front or "head" of bone resorbing osteoclasts and a tail portion occupied by osteoblasts (Fig. 1). The "head" contains a capillary bud to supply nutrients and probably to supply the progenitor cells for osteoclasts and osteoblasts. BMUs are not permanent structures since they form in response to a specific signal, perform their function and die, leaving a few residual lining cells and osteocytes. The number of BMUs working in a specified volume of tissue depends on the "activation frequency" and the "sigma period" [4]. The former refers to the frequency with which new remodeling cycles are created per unit cross-sectional area of arbitrary thickness and thus is a measure of the rate of bone turnover. The latter refers to the speed with which the BMU travels through the tissue space. It quantifies the time of completion of one remodeling cycle at a given location in the bone. Sigma periods are frequently subdivided into resorption and formation periods. Formation is much slower than resorption. In humans, the total remodeling cycle is about 4 months, about 3 weeks for resorption, and about 3 months for rebuilding the lost bone.

The Remodeling Cycle

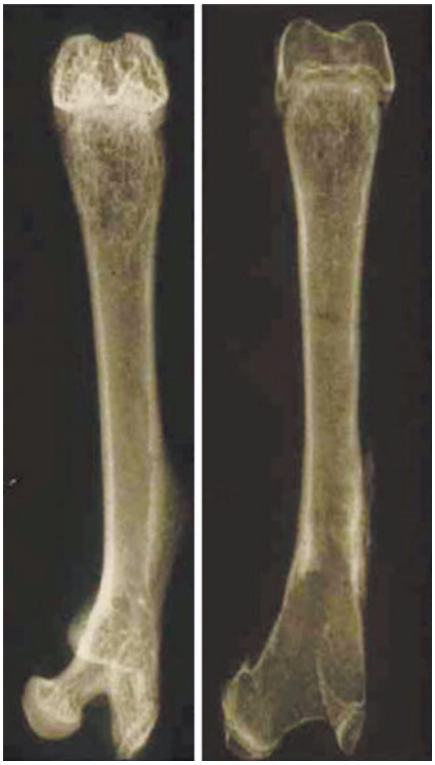
There are three principal stages in the BMU lifetime: activation of osteoclasts, resorption of the old bone, and formation of new bone matrix (A-R-F) (Fig. 1). The spatial and temporal arrangements of the cells within the BMUs ensure a coordination between the different phases of the remodeling process. The A-R-F process may be further divided into six separated phases: activation, resorption, reversal, formation, mineralization, and quiescence (see Fig. 1):

- *Activation phase*: Activation takes place when an activation signal or stimulus, including chemical, mechanical, and electrical signals, converts a previously inactive bone surface into a remodeling one. It is important to distinguish between origination and activation. The former occurs only once for each BMU at a quiescent surface while the latter is a continuous process that occurs at the cutting edge of the BMU. As the lifespan of the individual cells in a BMU is much shorter than that of the BMU, activation involves gathering of the cells that will form the BMU. In both cortical and cancellous bones, osteoclasts participate in activation or recruitment. In addition, bone lining cells of osteoblastic nature are available on the cancellous surfaces. Systemic hormones, growth factors, and interleukins play a role at this step, helping to recruit new osteoclasts by enlarging the precursor pool.
- *Resorption phase*: Bone resorption is a multistep process initiated by the proliferation of immature osteoclast precursors, the commitment of these cells to the osteoclast phenotype, and finally the degradation of the organic and inorganic phases of bone by the mature resorptive cells. It involves the following steps:
  - Attachment of the osteoclasts to the target matrix: Newly created osteoclasts attach themselves to a bone surface and form a ruffled membrane.
  - Acidification of resorption lacunae. Osteoclasts acidify the extracellular microenvironment. For instance, they secrete both hydrochloric acid, to resorb hydroxyapatite, and proteases like cathepsin K to degrade collagen and other bone matrix proteins.
  - Bone demineralization. The acidic milieu mobilizes the mineral phase of bone and provides an optimal environment for organic matrix degradation.
  - Dissolution of the bone tissue forming a resorption lacuna.
  - The products of bone degradation are endocytosed by the osteoclast, transported, and finally released to the extracellular space.
  - Detachment of osteoclasts and movement to a new site of bone degradation.
- *Reversal phase*: The transition from osteoclastic to osteoblastic activity takes several days (around 9 days) and results in a cylindrical space lying between the resorptive region and the refilling region [1]. The length of this region may vary considerably, depending on the lag between the resorptive and formative phases.
- *Formation phase*: In this step, the osteoblasts initially synthesize the organic matrix called osteoid to restore the previously resorbed bone. The apposition rate of matrix and of mineral is more rapid initially, with an initial rate of 1–2 μm/day which gradually decreases to zero as the cavity is filled. As an individual ages, the amount of bone deposited in the resorption lacunae by osteoblasts is less than that previously removed by osteoclasts. This negative balance of osteoblastic relative to osteoclastic activity is responsible for the loss of bone that occurs with age and that when pronounced leads to osteoporosis.
- *Mineralization phase*: Following deposition of the unmineralized bone matrix, called osteoid, mineral is deposited within and between the collagen fibers. This process is delayed by a period of time known as the mineralization lag time, which is normally about 15 days. Once begun, approximately 60 % of the mineralization of the osteoid occurs during the first few days [4]. This is called primary mineralization. The remainder of the mineral is added at a decreasing rate for around 6 months during the secondary mineralization.

- *Quiescence*: Once the resorption and formation processes are completed, the osteoclasts disappear, and the osteoblasts become osteocytes or Haversian canal lining cells, or they disappear.

Cortical Versus Trabecular Remodeling

Bone remodeling has been well described in cortical [1] and cancellous bone [6]. Current evidence indicates that the differences in the remodeling activities of these two types of bone reside in the different mechanical environments of the bone cells in cortical or cancellous bone.



For instance, in *cortical remodeling*, since BMUs become isolated within the cortex and osteoclasts and osteoblasts need nourishment, the tunnel cannot be entirely refilled during the formation phase. Each BMU leaves a central passageway in the bone to support the metabolism of the BMU and bone matrix osteocytes, and to carry calcium and phosphorous to and from the bone when necessary. This passageway is called Haversian canal and is typically 40–50 μm in diameter in humans and contains two capillaries: a "supply" and a "return" vessel. In human adults, osteonal BMUs replace about 5 % of compact bone each year [3].

In *trabecular and endocortical surfaces* since BMUs work on trabeculae surfaces, the cells do not dig and refill tunnels but trenches (half-tunnels). Because a BMU is about the same diameter as a trabecula, the remodeling unit in cancellous bone is equivalent to half of a cortical remodeling unit. BMUs replace human adult trabeculae bone at a higher rate than cortical bone, about 25 % each year [3] since the surface/volume relationships are much greater in the cancellous bone. Another difference is that cancellous bone BMUs proceed along a surface lined with lining cells, which could participate in remodeling, whereas there are no lining bone cells within the cortex. Cancellous bone has also more ready access to marrow cells than cortical bone.

Key Research Findings

Bone remodeling is the final phenomenological consequence, observable at the bone microarchitectural level, of a cascade of biological events which take place at different spatial scales ranging from molecular to cell/tissue levels. The nature of the phenomena involved in the process of bone remodeling is diverse including molecular mechanisms due to genetic factors or interaction between cells, where mechanics plays an important role. The importance of the former (genetics) versus the latter (mechanics) has been widely discussed during the last decades. Specifically, a number of cytokines, receptors, and proteins have been reported to have an important role in bone remodeling. On the other hand, it has been evidenced that mechanical factors such as the interstitial fluid flow, dynamic loading, or the presence of microcracks influence bone remodeling. Both mechanics and genetics are coupled effects, such that mechanics or genetics themselves cannot explain the phenomenon of bone remodeling [7]. In fact, it may be assumed that mechanical forces acting at the tissue level induce a cascade of molecular mechanisms activated at a lower observation (protein) scale. Then, molecular mechanisms provide a cue transcripted at the cell level which develops a specific function. This hypothesis is termed *mechanotransduction*.

The effect of genetics in contrast to mechanics was highlighted in an animal experiment presented in Ref. [8]. The experiment analyzed bone growth rather than bone remodeling and proceeded as follows. The cartilaginous primordia of the femur (the cartilage anlage where femur develops from) of a developing mouse was isolated to analyze the effect of the mechanical loading during growth. It was carried out transplanting this tissue into the mouse's spleen site, where mechanical loads are absent, during growth. As a result, the transplanted femur in the spleen, where no mechanical loading was developed, was compared after growth to a normal physiological one, which was subjected to a normal mechanical environment. Figure 2 shows the appearance of both femurs with and without a normal loading environment during growth. It can be observed the lack of bone tissue of the unloaded femur in terms of lower bone mass distribution and organization, thinner cortical wall, undeveloped femoral

Bone Remodeling, Fig. 2 Two mouse femurs showing the isolated effect of genetics (*right*) and the combined effect of genetics and mechanics (*left*) during growth (From Chalmers and Ray [8])

neck, and curvature of the femoral diaphysis [9]. Even though bone growth during development is a different process than bone remodeling, this experiment illustrates the importance of both genetics and mechanics, and genetics itself, in bone tissue function and form.

In the following sections, some key research findings related to the cellular and molecular mechanisms as well as the mechanical factors involved in bone remodeling are discussed.

Cellular and Molecular Mechanisms Involved in Bone Remodeling

Bone remodeling is the coordinated action of BMUs, as previously introduced. First, a signal, probably coming from a mechanical cue or hormone, activates bone cells in the so-called activation phase. It is thought that osteocytes are the cells involved in the transduction of the above-mentioned mechanical stimulus into a biological signal. In this phase, PTH, a calciotropic hormone secreted by the parathyroid glands, binds to the seven-transmembrane G-protein-coupled receptor (called the PTH receptor) of osteoblastic cells. It activates protein kinase A, protein kinase C, and calcium intracellular signaling pathways of osteoblastic cells, which induces a wave of transcriptional response that produces a secretion of molecules that recruit osteoclast precursors, induce osteoclast differentiation and activation, and establish *bone resorption* [10]. Then, in response to PTH, osteoblasts produce the chemokine MCP-1 (monocyte chemoattractant protein-1), which is a chemoattractant for osteoblasts precursors [10]. In addition, during the resorption phase, cytokines CSF-1, RANKL, and OPG are modulated in response to PTH to activate and maintain osteoclasts activity. Specifically, these cytokines promote osteoclasts proliferation, spreading, motility, cytoskeletal organization, and coordinate differentiation from osteoclasts precursors to multinucleated osteoclasts. Then, bone organic matrix is degraded and dissolved by matrix metalloproteinases and a collection of collagenolytic enzymes with a low pH [10]. At the *reversal phase*, a cell from the osteoblast lineage removes collagen remnants from the bone surface and prepares it for subsequent osteoblast-mediated bone formation. In the *formation phase*, mechanical strain on bone and PTH signaling, via PTH receptors on osteocytes, activate a signaling pathway which determines the early stage of bone deposition. Moreover, mesenchymal stem cells or early osteoblast progenitors differentiate and secrete molecules that ultimately form replacement bone [10]. The molecules include collagen I proteins and non-collagenous ones, such as proteoclycans, glycosylated proteins, and lipids. During the *mineralization phase*, once an equal quantity of resorbed bone has been formed, an activation signal informs the remodeling cycle to cease.

Many of the above summarized processes which take place during different phases of bone remodeling are under research and some of them are still poorly understood. However, it has been briefly evidenced that many times a mechanical

signal is involved in the related molecular and cellular mechanisms present in bone remodeling. In the next section, a discussion of the effects of mechanical signals on bone remodeling is introduced from a cell/tissue perspective.

Mechanics in Bone Remodeling

The important role that different mechanical signals have in the process of bone remodeling has been evidenced in recent years. It is thought that mechanical forces, transferred by muscle and bones, interact at the protein level allowing a transcription into biochemical signals which influences cell function. Some of the mechanisms of the transcription of a mechanical cue into a biochemical signal involved at the molecular level in bone remodeling have been exposed in the previous section. This process, termed mechanotransduction, remains to be elucidated.

A phenomenological consideration of the effect of mechanics in bone remodeling aims to establish a cause-effect statement of the problem. In this sense, "cause" would be a certain mechanical factor and "effect" would be its specific consequence on the continuous formation/resorption of bone, i.e., bone remodeling, observable at the macroscopic level of the bone architecture. In bone remodeling, osteocytes have been traditionally considered as a candidate for bone mechanosensing [7]. Cowin and coworkers have reported that osteocytes sense a range of strain levels exerted at different frequencies at the bone tissue, by means of the fluid flow pressure in the lacunar-canalicular porosity system [11]. Specifically, it has been suggested that strain, shear stress, or fluid flow give rise to changes in the ion channel conductance in the osteocytic membrane, which releases intracellular Ca^{2+} that regulates the opening and closing of membrane ion channels in the communicating junctions. Therefore, the gap junctions modulate the intracellular potential and current that passes through the network of interconnected osteocytes and surface osteoblasts which induce their function [11].

As discussed above, both mechanical load (strain), frequency and fluid flow within the bone pores are essential stimulus for bone adaptation. On one hand, it has been shown that application of load frequency stimulates bone formation when load is applied over 0.5 Hz. Specifically, Hsieh and Turner [12] reported more bone formation in a rat forelimb when application load was 10 cycle/s versus 1 cycle/s. Moreover, small loads were applied to the sheep hindlimbs at 30 cycle/s [13] showing encouraging results. As a conclusion, experimental results suggest that bone formation is proportional to the product of frequency times strain amplitude [11, 14]. It has been proved that a certain strain level at a given frequency may lay down within the physiological regime which stimulates osteocytes' mechanosensory system [11]. On the other hand, interstitial fluid flow circulates through the bone pores, canaliculi, and canals associated to the different porosity levels of bone. Interstitial fluid flow has been postulated as another important stimulus for bone formation due to the transport of nutrients to individual cells buried within the matrix. Moreover, the indirect shear stress and hydrostatic pressure produced by the fluid circulation may induce the necessary stimulus to activate the process of bone remodeling. Different sources to induce fluid movement are gravity forces, capillary forces (i.e., vasculature), hydrostatic pressure-induced flow of blood through vasculature, or forces exerted by muscles and bones and transmitted to the bone fluid due to the poroelastic architecture of the bone tissue.

A consequence of the effect of mechanics on bone formation and remodeling is the loss of bone mass in the absence of activity or bone disuse. It has been widely reported that astronauts, under the effect of microgravity and hence low mechanical stimulation of bones, undergo a rate of bone mass loss of the skeleton approximately of 1 % per month. In this context, LeBlanc et al. [15] reported the measurements made from 1990 to 1995 on 18 cosmonauts involving 12 space missions measured before and after missions lasting from 4 to 14.4 months. Eighteen crew members received a lumbar spine and hip scan before and after flight; 17 crew members received an additional whole body scan. Results, shown in Table 1, were expressed as percent change from baseline per month of flight in order to account for the different flight times.

Bone Remodeling, Table 1 Bone mineral density and body composition changes ($p < 0.01$) significantly different from baseline, after 4–14.4 months of space flight

Variable	N	%/Month change	SD
Lumbar spine	18	−1.06	0.63
Femoral neck	18	−1.15	0.84
Trochanter	18	−1.56	0.99
Total body	17	−0.35	0.25
Pelvis	17	−1.35	0.54
Arm	17	−0.04	0.88
Leg	16	−0.34	0.33

Moreover, another evidence of the importance of the mechanical forces in bone remodeling is the fact that the skull may actually gain bone due to the increased fluid pressure owing to the caudal shift of fluids in microgravity [7].

Another interesting mechanical cue for bone remodeling is the presence of microcracks along the bone tissue. Microcracks appear as a consequence of accumulated microdamage due to repetitive loading. Microdamage is even produced at physiological levels of strain and has been reported to be a mechanical signal to initiate the process of tissue repair during bone remodeling [16]. On the other hand, under severe or extreme amplitude of the loading, for example athletes during competition, microcracks may eventually produce failure or breaking of the bone organ.

Future Directions

Understanding bone remodeling as well as the implicated mechanisms in such a process may provide insight in bone function and related bone diseases. Specifically, once the mechanical and molecular mechanisms involved are elucidated, one may control bone formation or resorption by the design of drugs, biomaterials or actuators which interact with the bone tissue. To this end, how forces are transferred from muscles and skeleton to the protein level, and how these forces induce a cascade of biochemical signals, i.e., mechanotransduction, is a keystone which remains to be investigated.

A proper knowledge of bone remodeling mechanisms may add some light for the explanation of the process, and hopefully may provide a clinical solution for diseases involving abnormalities in bone remodeling such as osteoporosis and osteosclerosis. In one hand, osteoporosis, the most common bone disease, is a remodeling disease in which patients have a low bone mass condition with a high risk of fracture. This disease reflects an imbalance in the skeletal turnover so that bone resorption exceeds bone formation. On the other hand, patients with osteosclerosis have an increased bone mass due to stimulated osteoblast activity. These bone diseases and their consequences are major public health problems. Their study may benefit advances in the field of bone remodeling such as bone healing, distraction osteogenesis, or osteointegration processes around implants, among many other orthopedic protocols and techniques. Mathematical models have been developed for the analysis of bone remodeling. Currently, this is an intense area of research carried out by engineers, mathematicians, and physicists. The main objective of mathematical modeling is to predict information for a number of applications with a clinical or research interest to reduce animal experimentation, reduce cost and time, improve protocols, and aid the clinician to take decisions related to diseases in bone remodeling. Specially, many models have focused on the analysis of mechanics in bone remodeling from a continuum approach. The input of these models is normally a so-called mechanical stimulus, namely, fluid flow velocity, shear stress, pressure, or a certain combination of the components of the stress or strain tensors. Normally, models assume a higher amount of deposited bone in places where the mechanical stimulus is higher. Continuum models may be classified into phenomenological and mechanistic ones. In one hand, phenomenological models aim at predicting how macroscopic forces induce bone function and form during bone remodeling [17–21]. Many phenomenological parameters have to be calibrated in this kind of models whereas results should be analyzed in qualitative terms. Figure 3 shows a numerical simulation of bone remodeling and how it compares to actual

clinical results [22]. Mechanistic models establish a link between mechanical forces and the implicated biological functions to explain certain features of bone remodeling [23–25]. Mechanistic approaches are usually more complex since they analyze the coupled effect of mechanics and biology in bone remodeling. In the recent years, the term in silico approach has been coined to classify mathematical models into the different scientific methodologies present in the clinical practice such as bone remodeling.

Recently, the use of biomaterials to enhance or improve the function of a damaged tissue, or to promote tissue growth, has been proposed. This new discipline is named *Tissue Engineering* and offers many applications in the case of bone tissue. Specifically, new biomaterials (ceramic-based, bioactive glasses, polymers) are used as a scaffold which interacts with the bone tissue, with the purpose that cells colonize the scaffold biomaterial, attach, and develop their specific function finally leading to the growth of new bone tissue. Several requirements must be fulfilled by the scaffold biomaterial to develop its proper function. First, it must be a biocompatible biomaterial which interacts with the bone tissue. Moreover, it must be strong enough to support physiological loads at its specific location allowing cell attachment and fluid circulation in the interior. Mechanics is also an important factor in bone tissue engineering, as the signaling pathways are similar to the bone tissue but here the extracellular matrix is the biomaterial itself. The gold standard in bone tissue engineering is to promote the growth of functional bone tissue in circumstances where nature has lost its ability to develop new tissue under a disease or age-related complications.

Definition

Lubricants are commonly used for reduction in friction and wear of interfaces. In some applications, the solid surfaces are so close together that some asperities come in contact and others are mitigated by a thin film of lubricant, Fig. 1. Under these conditions, the lubricant viscosity is relatively unimportant and the physical and chemical interactions of the lubricant with the solid bodies controls friction and wear. Even a monolayer of adsorbed molecules may provide some protection against wear. Lubrication in some situations can be achieved by the use of multimolecular lubricant films. Monolayer lubrication is referred to as boundary lubrication and multimolecular lubrication is referred to as mixed lubrication. Boundary lubrication usually occurs under high-load and low-speed conditions in machine components such as bearings, gears, cam and tappet interfaces, and piston ring and liner interfaces. Boundary lubrication forms a last line of defense. In many cases, it is the regime which controls the component life [1–12].

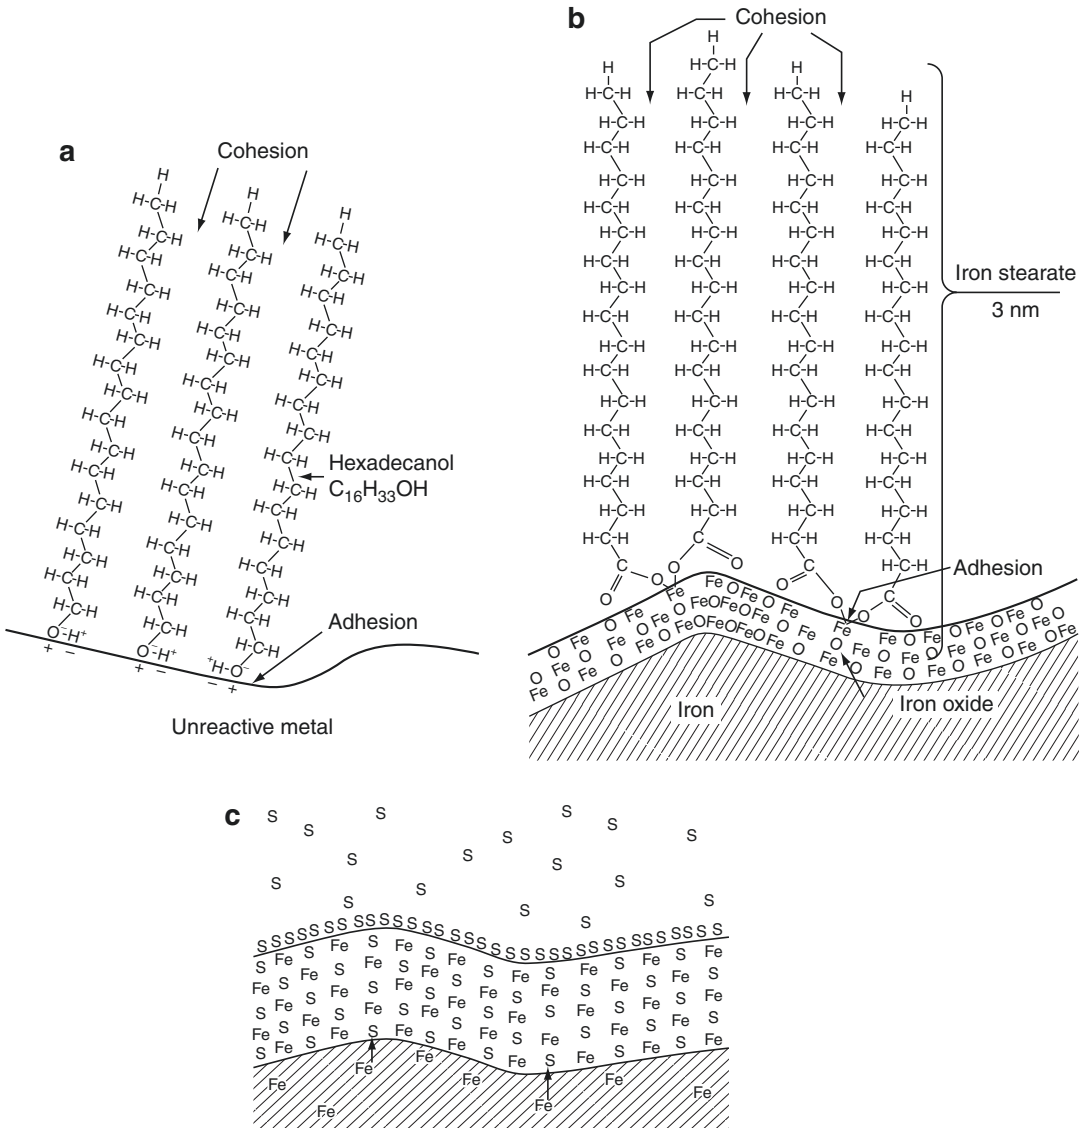
Various lubricants and greases are used for lubrication of machine components operating in various lubrication regimes [3–7, 12–21]. Additives are commonly used to provide the desirable properties and interaction with the interface.

Overview

For the case of two contacting bodies coated with a continuous solid monolayer of lubricant with a load too small to cause plastic deformation, the interface is in equilibrium under load for some time since the films prevent contact between the substrates. The films do not allow any state of lower free surface energy than the initial state. The films will thus lubricate over a considerable sliding distance if the bodies are subjected to low-speed sliding, although they will eventually be worn away. Alternatively, if the temperature is raised slightly above the melting point of the films, the admolecules will acquire some mobility and no state involving more than one complete monolayer can be stable. Activation energy for migrating away from the loaded region is provided thermally – and mechanically also, if a low-speed sliding is imposed. The two layers initially present thus penetrate each other and

Boundary Lubrication, Fig. 1 Schematic of two surfaces separated by a boundary layer of lubricant

adsorbed molecules tend to move away from the loaded interface. An equilibrium between a partial monolayer at the loaded interface and a surrounding vapor, if it exists, is generally metastable since the state for which the bodies are in direct contact usually has lower energy than any lubricated one.



The boundary films are formed by physical adsorption, chemical adsorption, and chemical reaction; for typical examples, see Fig. 2. The physisorbed film can be of either monomolecular (typically <3 nm) or polymolecular thickness. The chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can have a large film thickness. In general, the stability and durability of surface films decrease in the following order: chemical reaction films, chemisorbed films, and physisorbed films.

A good boundary lubricant should have a high degree of interaction between its molecules and the sliding surface. As a general rule, liquids are good lubricants when they are polar and thus able to grip solid surfaces (or be adsorbed) [3–6, 14]. Polar lubricants contain reactive functional groups with low ionization potential or groups having high polarizability. Boundary-lubrication properties of lubricants are also dependent upon the molecular conformation and lubricant spreading. Examples of nonpolar and polar molecules are shown in Fig. 3. In the case of Z-DOL, a hydrogen atom, covalently bonded with oxygen atom in the O–H bond, exposes a bare proton on the end of the bond. This proton can be easily attracted to the negative charge of other molecules because the proton is not shielded by electrons, and this is responsible for the polarity of the O–H ends. Likewise, the lone pairs of electrons in the oxygen and fluorine atoms in both molecules are unshielded, and can be attracted to positive charges of other molecules, and thus exhibit electronegativity which is responsible for some polarity. The CF_3 end in Z-15 is symmetric, and its polarity is low.

In addition to the polarity of liquids, the shape of their molecules governs the effectiveness, which determines whether they can form a dense, thick layer on the solid surface. Ring molecules or branch chain molecules tend to be poorer than straight chain molecules because there is no way in which they can achieve a high packing density. Straight chain molecules with one polar end, such as alcohols and soaps of fatty acids, are highly desirable because they enable a thick film to be formed with the polar end tightly held on the surface and the rest of the molecule normal to the surface. If the sliding surface has to operate under humid conditions, the lubricant should be hydrophobic (i.e., it should not absorb water or be displaced by water).

The most readily observed cause of breakdown of thin-film lubrication is the melting of a solid film and degradation of liquid films, but some degree of lubrication may persist to a higher temperature. Sliding speed and load influence the performance of multilayers.

The properties of the solid surface that are desirable for good lubrication are discussed.

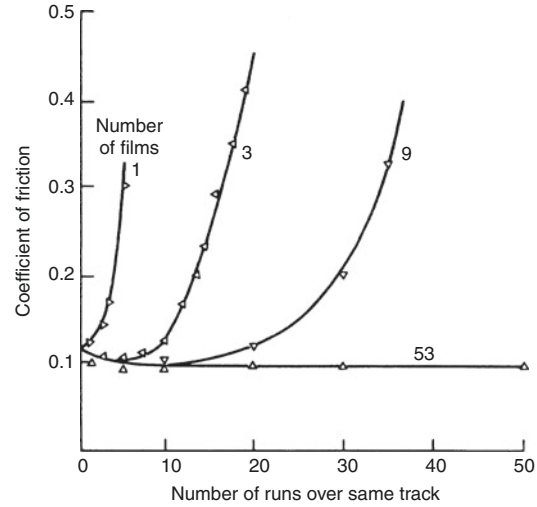
A solid should have a high surface energy so that there will be a strong tendency for molecules to adsorb on the surface. Consequently, metals tend to be the easiest surfaces to be lubricated. The solid surface should have a high wetting (or low contact angle) so that the liquid lubricant wets the solid easily. For better lubrication, the surface should be reactive to the lubricant under test conditions so that durable, chemically reacted films can form. Another property of solid surfaces is hydrophobicity. The surfaces should be highly functional with polar groups and dangling bonds (unpaired electrons) so that they can react with lubricant molecules and adsorb them. Examples of hydrophilic silicon oxide surface and its reactivity to ambient water and amorphous carbon surface with polar groups and dangling bonds which promote adsorption of perfluoropolyether molecules are shown in Fig. 4 [14]. Additives to the lubricants can also enhance the formation of chemically reacted films.

Data showing the effect of environment and types of lubricants and their interaction with solid surfaces on boundary lubrication behavior are now presented.

Effect of Adsorbed Gases

Boundary films occur on almost all surfaces because they reduce the surface energy and are thus thermodynamically favored. Normally, air covers any surface with an oxidized film plus adsorbed moisture and organic material. Inadvertent lubrication by air is the most common boundary lubrication. Figure 5a shows the reduction in the coefficient of friction that is obtained by the adsorption and/or chemical reaction of oxygen on clean iron surfaces outgassed in a vacuum (roughly 10^{-6} torr or mmHg). The coefficient of friction is markedly reduced by admission of oxygen gas, though the oxygen pressure is very low (roughly 10^{-4} torr). As oxygen pressure is allowed to increase, the friction is reduced still more. Finally, if the surfaces are allowed to stand for some period of time, the adsorbed oxygen film becomes more complete and the friction drops still further. Note that the seizure of clean metals is prevented by even a trace of oxygen, as obtained at 10^{-4} torr [22].

Figure 5b shows the effect of the addition of hydrogen sulfide on the coefficient of friction of outgassed (clean) iron surfaces; the friction reduced abruptly and appreciably. It is necessary to heat the surface over 790 °C before the decomposition of the film takes place and friction rises. It is probable that hydrogen sulfide reacts with the clean iron surfaces to form an iron sulfide (FeS) film.



Boundary Lubrication, Fig. 5 (**a**) Effect of oxygen on the coefficient of friction of outgassed iron surfaces and (**b**) effect of hydrogen sulfide on the coefficient of friction of outgassed iron surfaces [22]

Effect of Monolayers and Multilayers

It is possible to show by use of monomolecular layers and multimolecular layers that a very thin film of lubricant at the surface can be effective in reducing friction. In studying the effects of monolayers or multilayers, it is convenient to use the well-known Langmuir–Blodgett (L–B) technique. This technique involves floating an insoluble monolayer on the surface of water and then transferring it from the surface of the water to the surface of the solid (by successive dippings) to which the monolayer or multilayer is to be applied. This technique is convenient for deposition of films of known and controllable thicknesses.

Bowden and Tabor [23] deposited the films of a long-chain fatty acid (stearic acid) on a stainless-steel surface. The lubricated surface was slid against an unlubricated surface at 10 mm/s, and the coefficient of friction was recorded from the beginning of sliding. Data shown in Fig. 6 for a monolayer and with multilayers of 3, 9, or 53 films show that the greater the number of films, the longer it takes to wear off or displace this protective film and, consequently, the longer the time in which the film is an effective boundary lubricant. The films deposited by the L–B technique are not entirely equivalent to the type of protective film developed from lubricants in practice with respect to either molecular packing or composition. The stearic acid films, however, were close packed and regularly oriented with the polar group in the water surface.

Boundary Lubrication, Fig. 6 Wear behavior of a number of stearic acid films deposited on stainless-steel sliding against unlubricated stainless-steel surface [23]

Israelachvili et al. [24] have elegantly measured the frictional force or shear stress (frictional force divided by the apparent area of contact) required to sustain sliding (shearing) of two molecularly smooth mica surfaces with various molecular layers(s) of a liquid film in between. The two liquids used were octamethylcyclotetrasiloxane (OMCTS) and cyclohexane, and have mean molecular diameters of 0.85 and 0.5 nm, respectively. Measurements were made at sliding velocities ranging from 0.25 to 2 μm/s after steady-state sliding was attained. They found that the shear stress depended on the

number of boundary liquid layers, Table 1; in cyclohexane, for example, shear stress fell by about an order of magnitude per additional layer. In other words, the friction is quantized depending on the number of molecular layers separating the surfaces. By extrapolation, one may infer that when seven to ten layers are present, the shear stress of the liquid film would have fallen to the value expected for bulk continuum Newtonian flow. It is noteworthy that this is about the same number of layers as when the forces across a thin film and the whole concept of viscosity begin to be described by continuum theories [25].

Boundary Lubrication, Table 1 Shear stress as a function of number of boundary layers trapped between two mica surfaces for octamethylcyclotetrasiloxane (OMCTS)[a] and cyclohexane[b]

	Shear stress (MPa)	
Number of layers	OMCTS	Cyclohexane
1	8.0 ± 0.5	$2.3 \pm 0.6 \times 10$
2	6.0 ± 1.0	1.0 ± 0.2
3	3.0 ± 1.0	$4.3 \pm 1.5 \times 10^{-1}$
4	Not measured	$2.0 \pm 1.0 \times 10^{-2}$

[a]Molecular diameter ~ 0.85 nm
[b]Molecular diameter ~ 0.5 nm

Effect of Chemical Films

The addition of a small trace of a fatty acid (polar lubricant) to a nonpolar mineral oil or to a pure hydrocarbon can bring about a considerable reduction in the friction and wear of chemically reactive surfaces. Typical results taken from [23] are given in Table 2. In these experiments, friction was measured using identical materials sliding against each other and lubricated with a (nonpolar) paraffin oil or with 1 % (polar) lauric acid added to the paraffinic oil. They found that with unreactive metals (such as Pt, Ag, Ni, and Cr) and glass-the fatty acid is no more effective than a paraffin oil. In contrast, the results for lubrication of reactive metals (such as Zn, Cd, Cu, Mg, and Fe) show that very effective lubrication can be obtained with a 1 % solution of lauric acid in paraffin oil. Bowden and Tabor [23] have further shown that a 0.01 % solution of lauric acid in paraffin oil reduces the coefficient of friction of chemically reactive cadium surfaces from 0.45 to 0.10. Even smaller concentrations (0.001 %) of lauric acid can reduce friction slowly with time (after a few hours). In the case of the less-reactive metals, such as iron, which cannot be lubricated by a 1 % solution of fatty acid, they are well lubricated by a more concentrated solution. These results indicate the strong effects of films formed by chemical reaction on friction and wear.

Boundary Lubrication, Table 2 Efficiency of lubrication by paraffin oils or 1 % lauric acid in paraffin oil compared with reactivity of metal to lauric acid [23]

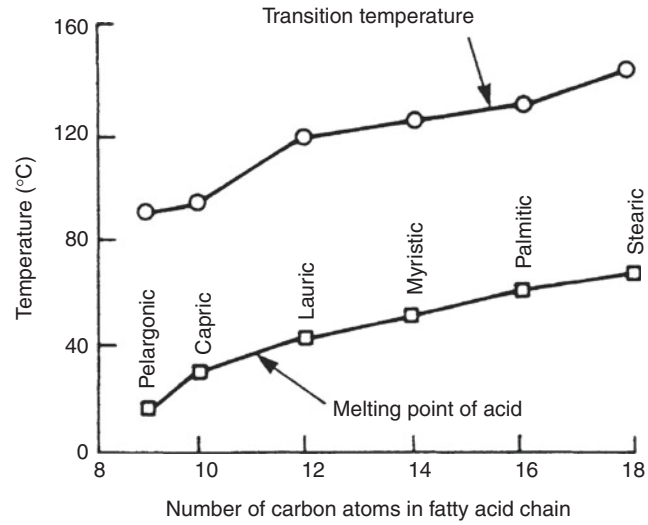
[a]Estimated amount of acid involved in the reaction assuming formation of a normal salt



Friction and wear measurements on monolayers of various substances show that whereas a single monolayer of a given polar compound on a reactive surface provides low friction and wear, on unreactive surfaces it may be completely ineffective, and as many as ten or more layers may be needed. Bowden and Tabor [23] deposited multilayers of stearic acid and metal soaps (believed to be responsible for good lubrication behavior when stearic acid is used as a lubricant on a metal surface) on unreactive and reactive metal surfaces and made the friction measurements. Table 3 shows the number of layers required for effective lubrication. It is found that a larger number of films are needed for unreactive surfaces (see also Ling et al. [11]).

Boundary Lubrication, Table 3 Lubrication of various metal surfaces by layers of stearic acid and metal stearates deposited by the Langmuir–Blodgett technique [23]

	Number of layers for effective lubrication	
Metal	Stearic acid	Metal soap (Cu or Ag stearates)
Unreactive

Silver	7	3
Nickel	3	3
Reactive		
Copper	3	3
Stainless steel	3	1

Parraffins, alcohols, ketones, and amides become ineffective lubricants at the bulk melting point of the lubricant. When the melting occurs, the adhesion between the molecules in the boundary film is diminished and breakdown of the film takes place. The increased metallic contact through the lubricant film leads to increased friction and wear. With saturated fatty acids on reactive metals, however, the breakdown does not occur at their melting points but at considerably higher temperatures. This is shown in Fig. 7 for a series of fatty acids on steel surfaces, and it is seen that breakdown (transition temperature) occurs at 50–70 °C above the melting point. The transition temperature corresponds approximately to the melting point of the metallic soaps formed by chemical reaction [23]. The actual value of the breakdown temperature depends on the nature of the metals and on the load and speed of sliding. The esters of saturated fatty acids also behave like acids, except that the difference between the transition and melting temperatures (T_t–T_m) decreases with increasing ester group length, approaching zero at 26 carbon atoms.

Thus, lubrication is affected not by the fatty acid itself but by the metallic soap formed as a result of the chemical reaction between the metal and the fatty acid. Also, T_t–T_m is a measure of the

Boundary Lubrication, Fig. 7 Breakdown or transition temperature of fatty acids on steel surfaces and their melting points as a function of chain length [23]

Boundary Lubrication, Fig. 8 Effect of chain length (or molecular weight) on coefficient of friction (of stainless-steel sliding on glass lubricated with a monolayer of fatty acid) and contact angle (of methyl iodide on condensed monolayers of fatty acids on glass) [26]

strength of adsorption that is due to a dipole–metal interaction.

Effect of Chain Length (or Molecular Weight)

The effect of chain length of the carbon atoms of paraffins (nonpolar), alcohols (nonpolar), and fatty acids (polar) on the coefficient of friction was studied by Bowden and Tabor [23] and Zisman [26]. Figure 8 shows the coefficient of friction of a stainless-steel surface sliding against a glass surface lubricated with a monolayer of fatty acid. It is seen that there is a steady decrease in friction with increasing chain length. At a sufficiently long chain length, the coefficient of friction reaches a lower limit of above 0.07. Similar trends were found for other lubricant films (paraffins and alcohols). Zisman [26] also found that the contact angle of methylene iodide on a monolayer rises to a high constant value for polar, long-chain molecules of paraffins, alcohols, and fatty acids, indicating an increase in packing to an optimum condition with an increase in the number of carbon atoms in the chain. Owens [27] has confirmed that in polymer lubrication a complete surface coverage occurs with fatty acids having long chain lengths.

Zisman [26] and Owens [27] have shown that the durability of the lubricant film also increases with an increase in the film chain length. These results suggest that monolayers having a chain length below 12 carbon atoms behave as liquids (poor durability), those with chain lengths of 12–15 carbon atoms behave like a plastic solid (medium durability), whereas those with chain lengths above 15 carbon atoms behave like a crystalline solid (high durability).

Principal Classes of Lubricants

Liquid lubricants (oils) include natural organics consisting of animal fat, vegetable oils, mineral (or petroleum) fractions, synthetic organics, and mixtures of two or more of these materials. Various additives are used to improve the specific properties [3–7, 12, 15, 17–20]. A partial list of the lubricant types is shown in Table 4.

Closure

Boundary lubrication is accomplished by mono- or multimolecular films. The films are so thin that their behavior is controlled by interaction with the substrates. Molecular structure of the lubricants and functionality of the substrate affect the type and degree of bonding of the lubricant to the substrate.

Liquid lubricants include mineral (or petroleum) and synthetic organics. Various additives are used to improve specific properties. Mineral oils are excellent boundary lubricants and by far the most used lubricants. Synthetic lubricants can be used at greater extremes of

Boundary Lubrication, Table 4 Types of liquid lubricants (oils)

Natural organics	Synthetic organics
Animal fat	Synthetic hydrocarbons (polybutene)
Shark oil	Chlorinated hydrocarbons
Whale oil	Chlorofluorocarbons
Vegetable oils	Esters
Mineral (petroleum) oils	Organic acid
Paraffinic	Fatty acid
Naphthenic	Dibasic acid (di)
Aromatic	Neopentyl polyol
	Polyglycol ethers
	Fluoro
	Phosphate
	Silicate
	Disiloxane
	Silicones
	Dimethyl
	Phenyl methyl
	Chlorophenyl methyl
	Alkyl methyl
	Fluoro
	Silanes
	Polyphenyl ethers
	Perfluoropolyethers

environment, including temperature, humidity, and vapor pressure. Mineral oils are typically used up to a maximum temperature of about 130 °C and some synthetic oils up to about 370 °C. However, synthetic lubricants are more expensive than mineral oils. There are several properties of lubricants which are important for lubrication; their relative importance depends upon the industrial application. Additives are commonly used to modify friction and wear of lubricants and greases. These are classified as friction modifier, antiwear, and extreme pressure.

Greases are used where circulating liquid lubricant cannot be contained because of space and cost and where cooling by the oil is not required or the application of a liquid lubricant is not feasible.

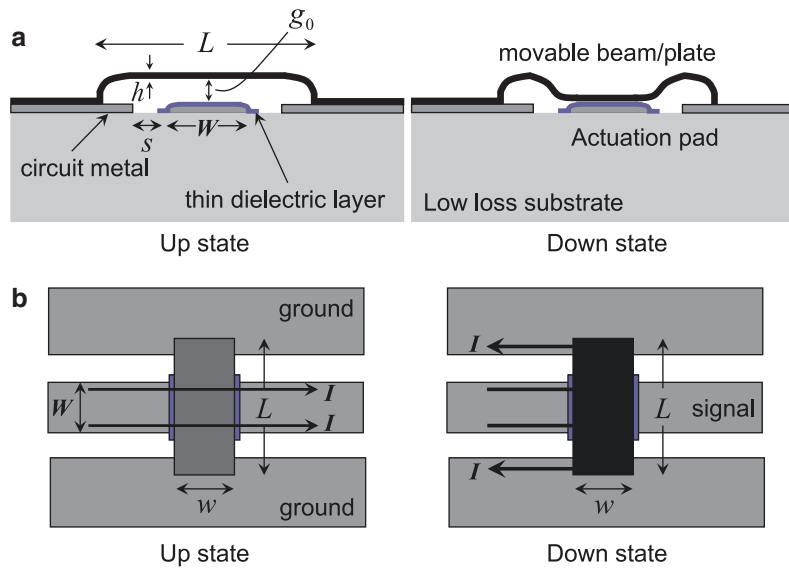
Electrostatic RF MEMS switches; Micromechanical switches; RF MEMS switches



Definition

Capacitive micro-electro-mechanical systems (MEMS) switches are a special type of micromachined switches that control radio frequency (RF) signal paths in microwave and millimeter-wave circuits through mechanical motion and contact.

Overview

Capacitive and direct current (dc)-contact MEMS switches are among the most important micromachined devices for high-frequency applications due to their near-ideal RF performance. Dc-contact switches function similarly to conventional relays: micromachined beams or plates move under the influence of an appropriately applied force (e.g., electrostatic force) to open or close a metal-to-metal contact. While micromachined beams or plates are also utilized in capacitive switches, these switches rely on metal-to-dielectric contacts to implement their on and off states. Capacitive switches are particularly attractive for demanding high-frequency communications, electronic warfare, and radar systems due to their ultralow loss (<0.1–0.2 dB up to 40 GHz), high isolation (>20–50 dB for frequencies beyond 10 GHz), very high linearity (>66 dBm third-order intercept point), and near-zero power consumption (∼tens of nJ per

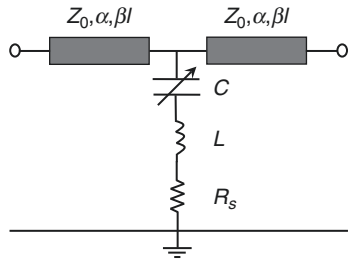
switching cycle and zero quiescent power for electrostatically actuated switches). When compared to solid-state switches, capacitive switches are relatively slow devices with speeds ranging in the tens to hundreds of microseconds range. This speed is primarily limited by switch inertia and squeeze film damping. Their relatively large lateral dimensions of tens or hundreds of μm allow capacitive switches to handle several 100 mW of RF power. Long-term operation, however, can only be achieved if they are hermetically sealed in order to avoid contamination- and humidity-induced failure. Hermetically sealed capacitive switches have successfully switched over 100 billion cycles at room temperature and under low RF power conditions (20 dBm). Despite the aforementioned RF advantages, capacitive switches are currently not available commercially and are not widely utilized in defense or communication systems. This is primarily due to the facts that (1) high-yield manufacturing processes are not widely available yet and (2) their main failure modes such as dielectric charging, dc/RF gas discharge and metal creep and the physics behind them have not been adequately understood and addressed today.

Switch Structure and Actuation Mechanisms

Figure 1 shows a typical capacitive MEMS switch [1]. This is a shunt switch configuration, and is the dominant capacitive switch configuration in the literature today. The signal travels down the center conductor, and if the switch closes, will return along the outside conductors. It is, however, possible to design geometries for series configurations. Their characteristics, nevertheless, are very similar to the ones found in shunt switches. Consequently, this entry focuses primarily on shunt capacitive switches.

The switch in Fig. 1 consists of a movable beam or plate that is anchored to the switch substrate. While typically the term "plate" may better characterize the geometry of Fig. 1 for typical lateral switch dimensions, it is common in the RF MEMS literature to refer to this geometry as a fixed-fixed beam. Hence the term "beam" is adopted here to describe such capacitive switch geometries. Cantilever beams are also possible particularly for series switch configurations. The fixed-fixed beam anchors are typically metallic and are connected to the RF line. For example, they can be connected to the ground planes of a



coplanar waveguide line as shown in Fig. 1b. The movable beam is typically composed of a thin-film (thickness h of 0.5–2 μm) metal such as gold, aluminum, nickel, or molybdenum. It is also possible that the beam is comprised of multiple layers including thin-film dielectrics such as silicon nitride or silicon dioxide and metals. One or more metallic pads are placed underneath the beam. In the simplest case, a single metallic pad is placed under the beam as shown in Fig. 1b. In this case, this pad is the center conductor of the coplanar waveguide line. This pad is usually covered by a thin (0.1–0.3 μm) dielectric layer such as silicon nitride, silicon dioxide, or more recently amorphous [2] or ultrananocrystalline [3] diamond.

The beam's length and width are determined by the required down-state switch capacitance as explained in the following section. This results in length and width in the tens to hundreds of μm for 5–40 GHz capacitive switches. The thickness of the dielectric layer also impacts the down-state capacitance. While high capacitance is in general required, thicknesses lower than 0.1 μm are hard to achieve in practice due to the need to handle high electric fields (dc and/or RF) across this dielectric. The gap (g_0) between the bottom surface of the movable beam and the top surface of the dielectric layer is determined by the need to minimize the up-state capacitance. A low up-state capacitance is necessary for low insertion loss. Capacitive switches in the 5–40 GHz range typically have gaps in the 2–5 μm range.

The switch has two states of operation. In the up state, the RF signal goes through the signal line almost unaffected by the movable beam. The up state is also called "zero biased" or "on state". In the down state the RF signal does not go through the RF line because it is reflected (see following section). The down state is also called the "biased" or "off state." An actuation mechanism is required to move the switch beam between these two states. Several possible actuation schemes exist, including electrostatic, electrothermal, magnetostatic, and piezoelectric. Table 1 summarizes the main advantages and drawbacks of each actuation scheme. The vast majority of reported capacitive switches are electrostatically actuated. They use the same actuation principle as the one originally proposed when the first capacitive switch was invented and reduced to practice in 1994 [4, 5]. In this original scheme a dc actuation voltage is applied between the movable beam and the actuation pad underneath it (Fig. 1). The beam is attracted due to the generated electrostatic field and collapses on the switch dielectric layer. Despite the need to generate a high dc voltage (30–100 V), which can be readily accomplished using a dc-dc converter, electrostatic switches exhibit the most desirable electromechanical characteristics, including the fastest possible response,

Capacitive MEMS Switches, Table 1 Main advantages and drawbacks of common actuation schemes for capacitive RF MEMS switches

Actuation mechanism	Advantages	Drawbacks
Electrostatic	Zero quiescent power consumption, easy biasing circuit, fast transient response (tens of microseconds)	Need to generate high voltage, high voltage may lead to charging and breakdown issues
Magnetostatic	Low voltage, high contact pressure, potentially low power with latching mechanism	Low quiescent power consumption requires latching, slower than electrostatic due to increased switch size
Electrothermal	Low voltage, high contact pressure, size comparable to electrostatic schemes	High quiescent power consumption (mW), slow response time (tens to hundreds of milliseconds)
Piezoelectric	Same as electrostatic by with low voltage	Difficult to achieve high-quality piezoelectric layer and integrate it with RF circuit at low temperatures

Switch Impedance

$$Z_s = R_s + j\omega L + \frac{1}{j\omega C},\ C = \begin{cases} C_{UP} \\ C_{DOWN} \end{cases}$$

$$f_0 = \frac{1}{2\pi\sqrt{LC}}$$

Typical Values		
	X-band	K-band
C_{UP}/C_{DOWN}	0.1/6 pF	0.04/3 pF
L	4–80 pH	6–50 pH
R_s	0.1–0.3 Ω	0.1–0.3 Ω

$$Z_s = \begin{cases} 1/j\omega C & for \quad f << f_0 \\ R_s & for \quad f = f_0 \\ j\omega L & for \quad f >> f_0 \end{cases}$$

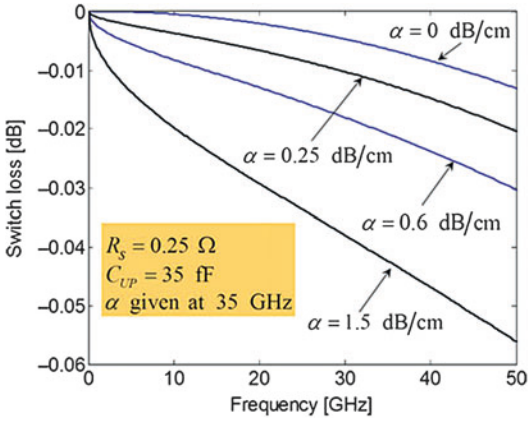
Capacitive MEMS Switches, Fig. 2 Lumped-element equivalent circuit of the capacitive switch shown in Fig. 1. Typical values are provided for the lumped components of this circuit

zero quiescent power consumption, and the easiest possible biasing circuits. The resulting high fields though may lead to (gas and solid) dielectric charging and their associated reliability issues. More detailed discussion can be found in the last section.

RF Performance

Figure 2 shows a simple but physically meaningful and accurate lumped-element equivalent circuit of the switch shown in Fig. 1. It also includes typical values for all the equivalent circuit components [1]. The parameters α and β in this figure represent the attenuation constant and propagation constant of the transmission line respectively. The up- and down-state capacitance values are the most critical ones in this equivalent circuit. The up-state capacitance can often be accurately calculated by a typical quasi-static expression

$$C_{UP} = C_{PP} + C_{ff} = \frac{\varepsilon_0 A}{g_0 + \frac{t_d}{\varepsilon_r}} + C_{ff}$$



where C_{PP} and C_{ff} are the parallel-plate and fringing-field capacitances, respectively, A is the RF area of the switch ($A = Ww$ in Fig. 1), g_0 is the initial switch height, t_d is the dielectric layer thickness, and ε_r is this layer's dielectric constant. For typical switch geometries, the fringing-field capacitance could reach 25–50 % of the parallel plate capacitance. If improved accuracy is needed, a full-wave simulation is performed to estimate the switch up-state capacitance. The up-state capacitance must be sufficiently small to minimize the up-state insertion loss. Assuming a well-designed switch where the contributions from L and R_s can be ignored in the up state, the switch up-state reflection coefficient can be calculated from

$$S_{11} = \frac{-j\omega C_{UP} Z_0}{2 + j\omega C_{UP} Z_0}$$

where Z_0 is the characteristic impedance of the transmission line (typically 50 Ω). For example, an up-state capacitance of 70 fF results in $S_{11} < -10$ dB up to approximately 30 GHz. The up-state switch ohmic loss is the other critical up-state characteristic. The total ohmic loss of the switch can be calculated as

$$Loss = 1 - |S_{11}|^2 - |S_{21}|^2$$

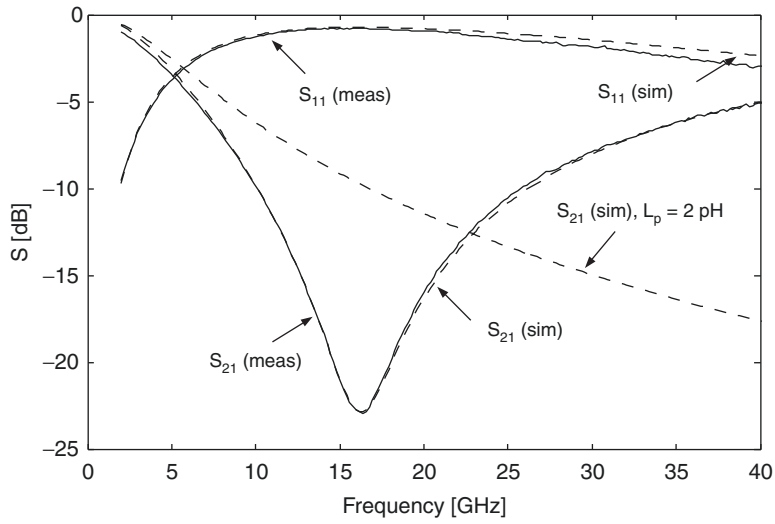
This depends on (a) the attenuation α (dB/cm) of the transmission line underneath the movable beam and (b) on the switch series resistance R_s.

Capacitive MEMS Switches, Fig. 3 Simulated ohmic loss for a typical shunt capacitive switch. The attenuation *a* (dB/cm) depends on the transmission line characteristics

Well-designed capacitive switches can exhibit a total loss of less than 0.1 dB up to 40 GHz. Figure 3 shows numerical values for this loss for typical switch characteristics.

The switch down-state capacitance is more complicated to calculate because the switch beam may not be perfectly flat against the dielectric layer. Even in good designs this may not be possible due to the roughness of the layers involved. A model that is often used to capture the nonideal down-state switch capacitance is [1]

$$C_{DN} = \frac{\varepsilon_0 A}{2}\left(\frac{1}{r + \frac{t_d}{\varepsilon_r}} + \frac{\varepsilon_r}{t_d}\right)$$



where r is the roughness amplitude. The down-state fringing-field capacitance is not included in this equation because it is typically not significant (<5 % of the parallel-plate capacitance) due to the small dielectric layer thickness. As shown by the equation above, the experimentally achieved down-state capacitance can vary greatly depending on the true contact area and the dielectric layer characteristics including its roughness. In practice, it is difficult to avoid a 30–50 % degradation of the down-state capacitance compared to the theoretical parallel-plate value. A high down-state capacitance (2–5 pF) is typically required in order to achieve an acceptable isolation (>20–50 dB) level at the desired frequency. One way to achieve this is to decrease the dielectric layer thickness. However, this dielectric layer needs to sustain very high electric fields (50–150 V/μm) across its thickness. Given typical fabrication process limitations that prohibit high-temperature growth processes for the dielectric layer (please see fabrication section), dielectric layers thinner than 0.1–0.2 μm become impractical. A second way to increase the down-state capacitance is to increase the dielectric constant. For instance, barium-strontium-titanate (BST) or strontium-titanate-oxide (STO) films with dielectric constants up to 400 can be employed. Besides additional fabrication complexities, these films have not been thoroughly studied in MEMS switches and may exhibit unacceptably high dielectric charging. Most switches typically employ some form of silicon dioxide or silicon nitride dielectric with dielectric constant in the 3.9–7.5 range. For switches with very low inductances (L < 1–2 pH), the switch isolation can be approximately calculated as

$$S_{21} = \frac{2}{2 + j\omega C_{DN} Z_0}$$

A more accurate calculation reveals that the switch inductance and series resistance also determine the total down-state isolation. In particular, its inductance cancels the down-state capacitance at the switch resonant frequency

$$f_0 = \frac{1}{2\pi\sqrt{LC_{DN}}}$$

This frequency can be adjusted by controlling the switch physical geometries. Switch inductances in the range of 1–100 pH can be readily achieved [1]. However, higher switch inductance typically results in a higher switch series resistance. Typical switch resistance values range in the 0.1–2 Ω range. The series resistance is the primary limiting factor of the switch isolation at its resonant frequency. At that frequency the switch isolation can be calculated as

Capacitive MEMS Switches, Fig. 4 Simulated and measured down-state scattering parameters of a capacitive MEMS switch (After Ref. [6] with permission)

$$S_{21} = \frac{2R_S}{2R_S + Z_0} \approx \frac{2R_S}{Z_0} \text{ at } f = f_0$$

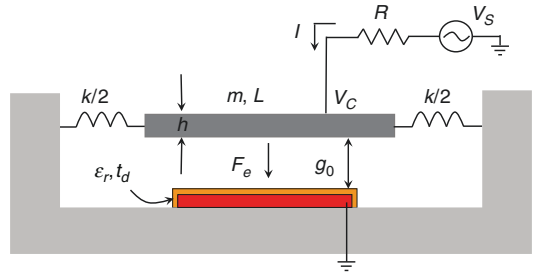


Figure 4 shows measured and simulated results of a typical capacitive switch [6] with $C_{DN} = 1.1\,\text{pF}$, $L = 87\,\text{pH}$, $R_s = 1.95\,\Omega$. This figure also shows the expected performance when the inductance is reduced to $L = 2\,\text{pH}$.

Electromechanical Considerations: Static Behavior

Figure 5 shows a simple but physically meaningful one-dimensional electromechanical model of the switch geometry of Fig. 1. The beam is modeled as a spring-mass system with a spring constant k. This spring constant depends on (a) the beam geometry, (b) the electrostatic force distribution on the beam, and (c) the residual stress of its structural film. The residual stress σ (MPa) is due to the fabrication process and depends on the exact deposition conditions. Typically a tensile stress (σ(MPa)) is needed in order to avoid buckling. The spring constant can be expressed as

$$k = k_1 + k_2$$

where k_1 depends on the first two factors and k_2 depends on the residual stress. The exact values

Capacitive MEMS Switches, Fig. 5 One-dimensional electromechanical model of a capacitive RF MEMS switch

can be calculated based on the specific switch design. For example, for the fixed-fixed beam of Fig. 1 and assuming that $W = L/3$ and that the electrostatic attractive force is uniformly distributed along the beam section directly above the coplanar waveguide center conductor, the spring constant can be calculated as [1]

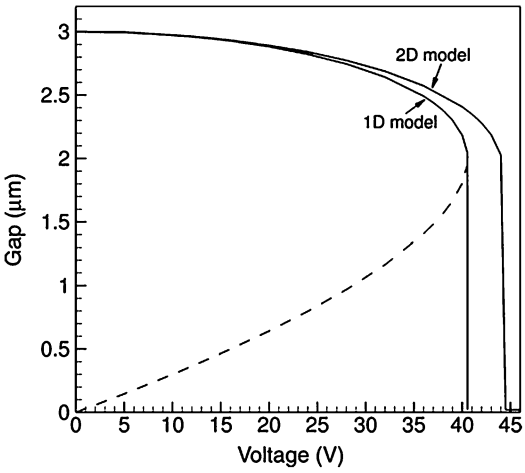
$$\begin{aligned} k &= k_1 + k_2 \\ &= 32Ew\left(\tfrac{h}{L}\right)^3\left(\frac{27}{49}\right) + 8\sigma(1-\nu)w\left(\frac{h}{L}\right)\left(\frac{3}{5}\right) \end{aligned}$$

where ν is the beam's Poisson's ratio. For usual beam geometries and fabrication processes with residual stress in the order of 10–50 MPa, the second term dominates the spring constant. Typical spring constant values range from 10 to 50 N/m in order to provide sufficiently high restoring

force and avoid stiction issues. While low spring-constant designs have been successfully demonstrated [7], special care needs to be taken in avoiding stiction and self-actuation due to high RF power [8]. It is also important to mention that the above spring constant calculations are based on small-deflection theory. A nonlinear spring constant may need to be derived if this condition is not satisfied.

The electrostatic force F_e on the switch beam can be calculated as

$$F_e = \frac{\partial W_e}{\partial g} = \frac{1}{2} V^2 \frac{\partial C(g)}{\partial g} \approx \frac{1}{2} \frac{\varepsilon_0 A V^2}{g^2}$$



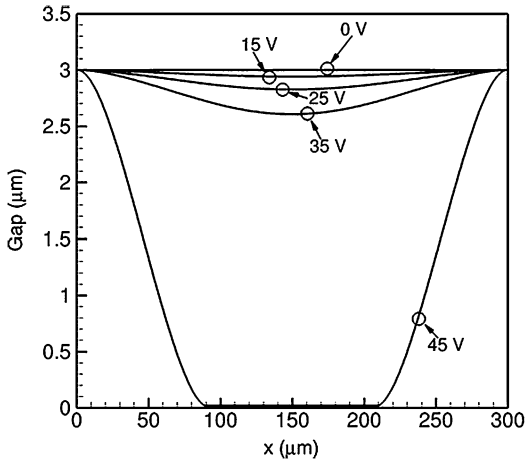
where W_e is the stored electrostatic energy, g is the switch gap between the beam and the actuation pad, and V is the applied electrostatic voltage. The last approximation is based on assuming a parallel-plate capacitance approximation and by ignoring the dielectric contribution. The static switch gap can be calculated by taking into account the static equilibrium of the forces applied on the beam

$$\frac{1}{2} \frac{\varepsilon_0 A V^2}{g^2} k(g_0 - g)$$

The above equation can be solved for the applied voltage as

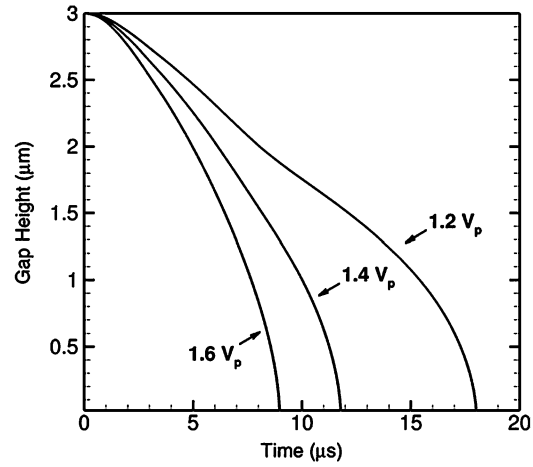
$$V = \sqrt{\frac{2k}{\varepsilon_0 A} g^2 (g_0 - g)}$$

This equation is plotted in Fig. 6 for typical switch parameters. As Fig. 6 shows, there are two possible gaps for any given actuation voltage. This is not observed in practice and is a result of the unstable behavior of the beam. In particular, for small actuation voltages, the electrostatic force is increased proportionally to $\frac{1}{g^2}$. However, the restoring force is only increased proportionally to g. Hence, there is a critical gap beyond which the restoring force cannot hold the beam and the beam collapses on the dielectric surface. This critical gap can be found from the previous equation by taking its derivative and setting it up to zero



Capacitive MEMS Switches, Fig. 6 Simulated gap-voltage relationship for a capacitive MEMS switch with the following characteristics: $L = 300$ μm, $w = 100$ μm, $W = 120$ μm, $h = 1$ μm, $g_0 = 3$ μm, (Young's modulus) = 79 GPa, $\sigma = 10$ MPa. These results have been o btained with the PRISM center online simulation tool in MEMShub [13]

$$\frac{\partial V}{\partial g} = 0 \overset{g_c = \frac{2}{3} g_0}{\rightarrow}$$



The voltage, therefore, required for actuating the beam, called the pull-in or pull-down voltage V_p, is given by

$$V_p = V(g_c) = \sqrt{\frac{8 k g_0^3}{27 \varepsilon_0 A}}$$

Figure 6 also shows the voltage-gap relationship as obtained by a two-dimensional beam model [13]. The gap plotted is between the center of the beam and the actuation pad. This curve is slightly different because the beam is not deformed as a perfectly flat object as assumed by the one-dimensional model. Figure 7 shows the actual deformed shape of the movable beam for voltages up to the pull-down voltage. Actuation voltages in the range of 30–100 V are typical in RF MEMS switches. Notice, however, that once the beam is actuated, the voltage required to hold the beam down (hold-down voltage V_h) is much lower because the gap between the beam and the actuation pad is much lower than g_0. It is hard to

Capacitive MEMS Switches, Fig. 7 Simulated shape of the movable beam of a capacitive MEMS switch for different bias voltages. The characteristics of the switch geometry are the same as in Fig. 6. These results have been obtained with the PRISM center online simulation tool in MEMShub [13]

Capacitive MEMS Switches, Fig. 8 Simulated switching time (pull-down) of a capacitive MEMS switch for different bias voltages. The characteristics of the switch geometry are the same as in Fig. 6. These results have been obtained with the PRISM center online simulation tool in MEMShub [13]

analytically calculate the hold-down voltage because it depends on many fabrication-dependent conditions such as the adhesion force between the beam and the dielectric layer. Typical hold-down voltages are in the range of 5–15 V [1]. Consequently, the gap-voltage relationship is strongly hysteretic. It is also worth mentioning that nonideal conditions such as an initial beam curvature and nonlinear bending are not included in this model. These effects can be captured by more complicated nonlinear beam models such as the ones presented in [9, 10].

Electromechanical Considerations: Dynamic Behavior

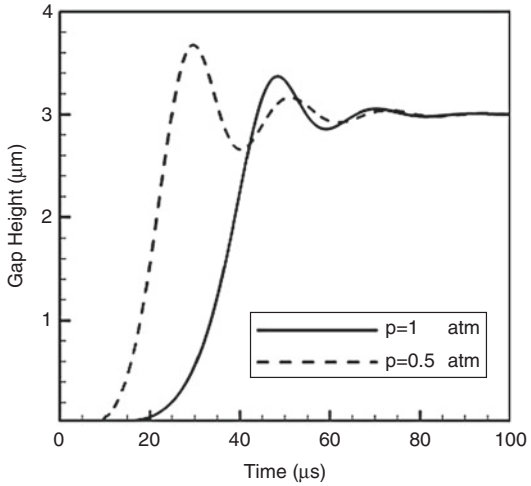
The dynamic behavior of the capacitive MEMS switch of Fig. 1 can be approximately captured by a one-dimensional model as described by the following equation

$$mg''(t) + bg(t) + kg(t) = F$$

where m is the switch mass, b is the damping coefficient, and f is the externally applied force. RF MEMS switches are typically packaged in an environment of 1 atm in order to avoid excessive ringing due to an underdamped response. As a result, the switch damping is dominated by squeeze-film damping as the gas under the beam is displaced during the switch motion. Due to the small gap g_0, it is in general difficult to accurately calculate the damping coefficient particularly in the near-contact region. This is further complicated by the possible existence of holes in the beam that aid its fabrication and substantially improve its switching speed. While there are several published approximations that can yield a reasonable approximation to the damping coefficient [1], accurate macro-models based primarily on rarefied gas dynamics only recently started becoming available [11, 12]. An equivalent way to characterize the switch damping is by its mechanical quality factor defined as

$$Q = \frac{k}{\omega_0 b}$$

where $\omega_0 = \sqrt{\frac{k}{m}}$ is the switch mechanical frequency. Typical switches show mechanical frequencies in the 20–100 kHz range and quality factors in the 0.5–2 range. Figures 8 (switch closure) and 9 (switch opening) illustrate dynamic



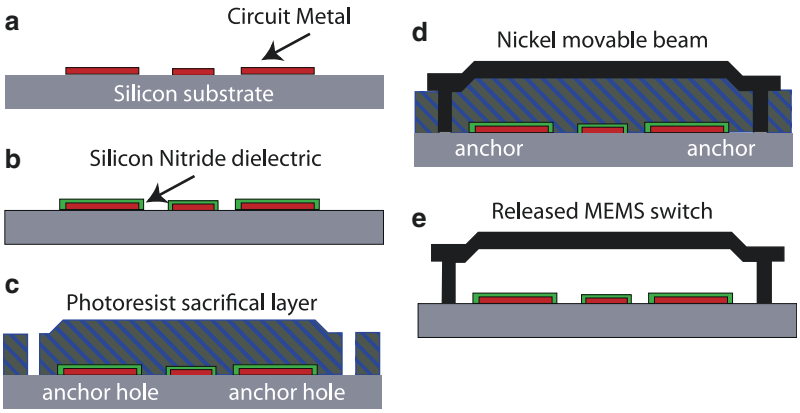
responses as calculated by two-dimensional beam models that accurately capture squeeze-film damping [13]. Notice that the displacement at the center of the beam is plotted in these graphs.

The switching speed can also be estimated based on the simple one-dimensional model. While it is difficult, in general, to derive an exact analytical solution, this model can provide reasonable approximations for common cases. For example, for $Q > 2$, the closing time can be estimated by [1]

$$t_s \approx 3.67 \frac{V_p}{V_s \omega_0}$$

where V_s is the applied voltage. Other limiting cases can be found in [1]. In general, closing times in the 5–50 μs range can be achieved. A similar range is typically possible for the release times.

The one-dimensional model can also be used to estimate the velocity and acceleration of the switch. Switching velocity in the 1–10 m/s range can be observed in the near-contact region. Due to its small mass, the switch acceleration can exceed 10^6 m/s^2 in the same region.



Capacitive MEMS Switches, Fig. 9 Simulated switching time (release) of a capacitive MEMS switch for different pressure levels. The characteristics of the switch geometry are the same as in Fig. 6. These results have been obtained with the PRISM center online simulation tool in MEMShub [13]

Fabrication Methods

Capacitive switches can be fabricated with conventional micromachining processes and require a small number of masks. Figure 10 illustrates the masks of a typical fabrication process.

- Step (a): The first mask defines the circuit metal of Fig. 1 after this metal layer is deposited on the substrate through evaporation, sputtering, or electroplating. Gold, aluminum, and copper are common metal choices. A smooth metal surface is particularly important directly underneath the switch beam in order to minimize local electric field enhancement.
- Step (b): The second mask defines the dielectric layer to cover the portion of the metal that

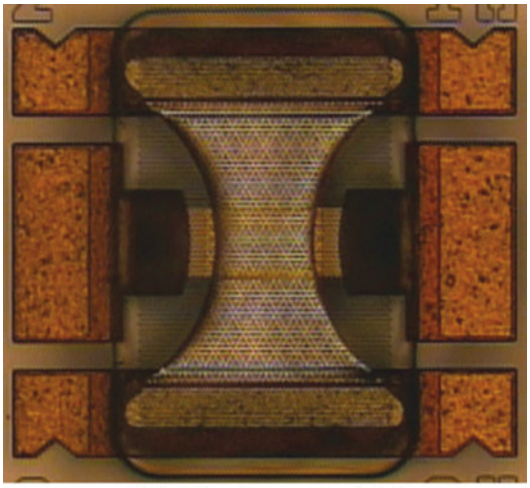
Capacitive MEMS Switches, Fig. 10 Simplified typical fabrication process for a capacitive MEMS switch

will be under the beam. Unless a high melting temperature metal has been deposited (e.g., tungsten), a relatively low-temperature process is required for the deposition and patterning of the dielectric layer in order to avoid damaging the circuit metal. Plasma-enhanced chemical vapor deposition (PECVD) is the most common process for depositing silicon nitride/oxide films. This is usually followed by a reactive ion etching (RIE) step that helps etching the unwanted dielectric layer parts.

- Step (c): The third mask is used to define the sacrificial layer of the switch. The sacrificial layer is the layer upon which the beam will be deposited, and this material needs to be removed at the end of the process to release the beam. The beam anchor points are defined in this step by selectively etching the sacrificial layer. This can be a dry- or a wet-etch step. More complicated processes may involve an additional planarization step before the next mask. The choice of the sacrificial layer material is critical as it controls many important parameters of the switch design, including the residual stress of the beam. Common material choices include photoresists, other photoconductive polymers, and polyimides. There is no sufficient understanding in the open literature of the exact processes that are involved in controlling the beam layer residual stress in the presence of a sacrificial layer. Important parameters though include, among others, the atomic structures of each film and the deposition temperatures of each film.
- Step (d): The fourth mask defines the actual beam layer. A variety of processes can be utilized including evaporation, sputtering, and electroplating of the beam layer(s). This step is also critical in determining the final residual stress of the beam.
- Step (e): The beam is finally released by etching (wet or dry) the sacrificial layer and by drying (if needed) the switch wafer. Etching of the sacrificial layer can also influence the beam residual stress particularly if a high-temperature process is necessary. If wafer drying is needed, this needs to be done carefully in order to avoid damage to the beam or causing stiction to the substrate. Stiction may occur if drying involves removing a liquid with high surface tension (e.g., water) underneath the beam. Such a liquid will pull the beam down as it evaporates. Special drying processes and equipment based on supercritical carbon dioxide have been successfully developed [14] and followed by many MEMS researchers.

The last step in the fabrication process is packaging, which is discussed in the following section.

Packaging



Hermetic packaging is required for capacitive RF MEMS switches to avoid any contamination- or humidity-induced early failure. While conventional hermetic packages exist, they are not well suited for capacitive RF MEMS switches or circuits. First, if switches need to be inserted in conventional hermetic packages, these switches will have to be diced first since several thousands of them can be simultaneously fabricated on a wafer. Dicing released switches is particularly dangerous for the switches and may considerably reduce the process yield. Second, conventional hermetic packages are expensive (∼tens of dollars/package) and not well-suited for cost-driven consumer applications. Third, they typically exhibit a relatively high insertion loss, which is often much higher than the switch itself (e.g., a DC-40 GHz package could exhibit 0.6 dB at 20 GHz [1]).

As a result, it is important to follow a cost-effective on-wafer hermetic packaging scheme. In this case, a wafer-scale package is first completed and then dicing follows. A wide variety of approaches have been developed so far to accomplish this. These approaches can be divided into three main categories:

- Two-wafer hermetic packages completed by fusion, glass-frit, thermocompression, eutectic, or anodic bonding. These packages are created by bonding two wafers together using one of the aforementioned approaches. The main advantage of these techniques is that they

result in excellent hermetic bonds. Their main drawback is that they may require high temperatures (300–1,000 °C depending on the technique) with the exception of low-temperature eutectic bonds (e.g., indium–gold bonds). In addition, these techniques tend to be relatively expensive since packaging cost usually accounts for 60–80 % of the total cost.

- Two-wafer quasi-hermetic packages completed by low-temperature polymer or solder-bump bonding. This technique is similar to the previous one, except that sealing is achieved by low-temperature bonding (room temperature −150 °C). A wide variety of polymers can be used for this. While low temperatures can be achieved, packages fabricated with such bonding typically exhibit very low but nonzero leak rates [1].
- Hermetic packages fabricated by on-wafer microencapsulation using micromachining techniques [15]. These techniques do not require a second wafer cap. Instead, every switch or switching circuit is encapsulated in a tiny package on its own wafer by a microfabricated technique. Typical temperatures in this process are in the 200–250 °C range. These techniques are ideally suited for the small size and high RF bandwidth of MEMS devices and typically result in low-cost fabrication. Particular attention needs to be paid though to ensure compatibility between the switch and package fabrication processes. Figure 11 shows a switch packaged with this technique.

Circuits and Applications

Capacitive MEMS switches may be employed in a number of circuits mostly for communication, radar, and electronic warfare systems [1]. Variable capacitors and impedance tuners for cell phones and other radios in mobile form factors constitute the most important applications in the commercial sector. MEMS variable capacitors (varactors) can be formed by connecting in parallel several capacitive MEMS switches and selectively activating them. Several companies including WiSpry and Cavendish Kinetics are pursuing this particularly due to the large cell phone market size.

The most important of the high-frequency circuit applications (>10 GHz) are high-isolation switching packets, true-time delay networks and phase shifters, reconfigurable impedance tuners for amplifiers and antennas, high-quality-factor reconfigurable filters, and tunable oscillators. Many of these circuits exploit the near-ideal RF performance of capacitive switches. Consequently, optimal performance can be usually achieved by employing a circuit- or sub-system-level package instead of a device-level package. Examples of several of these circuits can be found in [1].

Failure Mechanisms and Reliability

Capacitive MEMS switches suffer from high electric dc and/or RF fields through narrow gaps and dielectric layers. These fields can readily reach 5–50 V/μm in the up state and may increase further during actuation. Such fields may cause field emission and ionize the gas in the switch gap [16]. The long-term effects of field emission and

gas discharge are not known at this point. In addition, when such fields are applied across a thin-film solid dielectric, charges may get trapped in the dielectric layer leading to dielectric charging. A number of studies have been completed (see for example [17, 18]) focusing mostly on charges trapped in the bulk of the dielectric. However, surface charging of the solid dielectric that is also influenced by gas ionization is potentially more detrimental to the switch performance and is not well understood today. Charging phenomena are the leading cause of failure in capacitive switches today. Long-term drift of actuation voltage, stiction, and breakdown can be observed as a result of these charging issues.

Besides solid and gas dielectric charging, metal creep is another potential failure mechanism. Creep may be developed in the movable beam material if a switch is subjected to a constant stress. For example, if a switch is left in its down state for a long time (typically tens to thousands of hours), the beam material may creep resulting in a temporary or permanent change of the switch spring constant. Several recent papers show it is potentially an area of concern for capacitive MEMS switches [19, 20]. Creep at high temperature may be even a more significant area of concern.

Other possible failure modes include

- Beam buckling due to high temperatures. This may be caused during release process, normal high-temperature operation, or due to high RF currents through the movable beam under high RF power conditions.
- Self-actuation of the switch movable beam due to high RF power [8]. A high RF voltage may result in self-actuation because the attractive electrostatic force is proportional to the square of the switch voltage. This limits the switch power handling.
- Hot switching failure. When a capacitive switch needs to interrupt high RF currents or sustain high transient RF voltages, abrupt chemical changes may occur at its surfaces leading to premature wear and failure. This is related to the dielectric charging phenomena.
- Shock-induced failure. High shocks (>30,000–100,000 g) may result in beam fracture particularly if contact is achieved. Such events are rare in most applications.

Failures related to cycling-induced fatigue, crack generation, and fracture are not typically observed under normal operating conditions. However, they may become important at extreme temperatures particularly for movable beams based on thin-film metals. Despite the aforementioned failure modes, the best switches today have achieved over 100 billion cycles under typical laboratory conditions when driven by 30 kHz bipolar bias waveforms with approximately 35 V peak amplitude. These devices were hot-switched at a power level of 20 dBm at 35 GHz [21]. However, these cannot be considered typical results. Early failures are found in several wafer samples. Additional research is required to increase the observed reliability and limit early failures that are commonly due to poor fabrication process control.

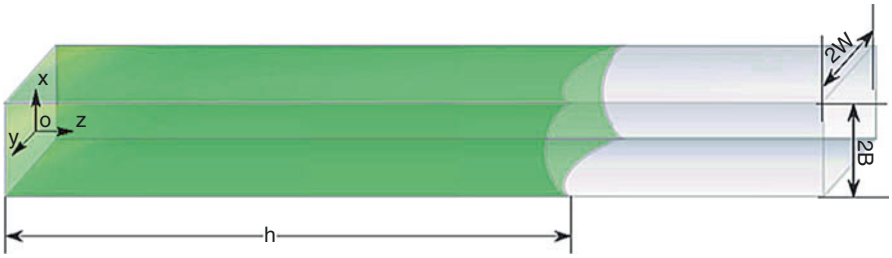
Definition

The fluid flow in an enclosed conduit due to simultaneous changes in the inherent surface energies of fluid and solid surface of the conduit.



Introduction

Everything in the universe has its own state of energy, which is represented by possible combinations of 132 elements of periodic table. The simplest form of each element is an atom and each atom has three different components: proton, electron, and neutron. Further, each element has a fixed number of electrons, which arrange themselves in different shells, and the number of electrons in each shell can be determined by Bohr's theory. Several individual elements or atoms do not have sufficient number of electrons

in their outer shell and this makes it unstable and further the element tries to become stable by searching for required electrons. The finding of sufficient electrons at the outer shell results in the formation of a molecule or in bulk cluster of molecules. The surface or interface formation with this cluster of molecules creates an imbalance in the arrangement and orientation of the molecules in the cluster, mainly across the interface. This imbalance represents the energy of system. Every system in the universe tries to attain the minimum state of energy and, therefore, in the case of liquid in the air, it has been observed that the raindrops always attain the spherical shape. Liquid molecules have capability to orient themselves. Hence, they can form the shape of minimum energy but in the case of solid molecules, they try to minimize the state of energy by covering up the liquid if it comes in contact. In this case, the solid surfaces are not in equilibrium with the saturated vapor, i.e., they are not in a state of minimum energy. The moment at which conduit or channel with high energy level surfaces comes in contact with lower energy level liquid interface, the solid surface tries to envelope itself with the liquid to attain the minimum energy. In the case of the higher energy liquid in comparison with the solid surfaces, the liquid interface tries to minimize its surface. The prior case can be illustrated with the water (72 dyn/cm) in glass channel (~200–300 dyn/cm) and the mercury (~700–735 dyn/cm) with the same glass channel is an example of the latter case.

The recent developments in the microfabrication technologies allowed to fabricate features of sizes from micro- to nanoscales. The surface to volume ratio of the feature increases as the scale of the feature decreases which in turn makes surface forces dominant over other forces. Because of high surface forces, very high pressure is required to pump the fluid in microchannels. Hence, researchers have developed different nonmechanical pumping mechanism with the help of electrokinetic and/or megnetohydrodynamic approaches. Generation and actuation of electric and/or magnetic field are an additional burden on the system which increases both the fabrication process and cost of the device. Therefore, attempts are being made to develop a flow without any external means. The fluid flow can be achieved by controlling surface chemistry, fluid properties like surface tension, or by changing the geometries. Such transport of fluid is called autonomous flow or autonomous pumping which is an ideal transport mechanism for microfluidic applications. The dominance of surface forces at microscale plays a significant role in deciding the pumping approach in microfluidic devices. Hence, nowadays surface tension–driven flow in microfluidic devices has widely attracted the attention of researchers. As explained earlier, the capillary action is the interplay between the surface energies or surface tension between the fluid and solid surface in contact. Moreover, at microscale, due to very high surface to volume ratio, the possibility of available surface area is very high. One can easily pump the fluid with capillarity provided the fluid has lower surface energy than the solid surfaces. For optimum design and function of any microfluidic device which works on capillary flow principle, it is essential to predict its behavior in advance and it is therefore necessary to perform the theoretical analysis of capillary flow within the microchannels. The prediction of the temporal variations in the flow front position along capillary length is the ultimate goal of the theoretical analysis. Therefore, generally the analysis is performed to predict the flow front position, i.e., penetration depth for given working and operating conditions.

Over the last century, the capillary phenomenon has become a topic of interest due to its importance in several areas. First time in literature, Washburn proposed a closed form solution for the penetration depth in a channel of millimeter dimension. The closed form solution is derived by balancing the surface tension force to viscous force and it is observed that the penetration depth is proportional to the square root of the time. As explained earlier, capillary phenomenon is the change in the surface energy process and to encompass the concept of change in the surface energy, one can use the thermodynamic approach for analysis. The surface energy of solid is the

Capillary Flow, Fig. 1 Schematic of the microchannel of width 2B, depth 2 W considered for theoretical modeling [6]

topic of ongoing debate. Moreover, there are several effects like dynamic contact angle, inlet effects, reservoir effects, suspension flow, etc., which require tedious and cumbersome analysis. Attempts are also being made to present analysis with microscopic energy balance approach where different forces are accounted in terms of different forms of energy. On the other hand, hydrodynamic models, based on the conventional fluid mechanics principle, are easy to implement. Such models are mainly developed by two distinct approaches in the literature, namely, differential and integral approach. The moving fluid-air interface with the differential approach becomes computationally costly, whereas the integral approach with moving control volume provides a simple form of ordinary differential equation. In such modeling or analysis, the governing equation for flow front transport is obtained by balancing different forces like viscous, inertial, gravity, pressure forces, etc. The velocity-dependent terms like inertial and viscous terms of the governing equation are determined with the velocity profile across the channel. In the literature, the steady state assumption is applied from the very entrance of the channel neglecting the entrance length effect. This assumption has been widely adopted till date as done by Washburn where the time and length scale used for the validation of the theoretical model was big. Hence, the assumption of a steady state velocity profile holds true. Whereas, in the case of microfluidic channels the length and timescale is very small; hence, the Washburn prediction does not follow the observation as demonstrated by Saha and Mitra [1, 2]. The later part of this entry is dedicated to emphasize the importance of such microscale effects in the analysis. Main emphasis is given to the integral approach based on modeling due to the ease of its adaptability. Therefore, in the next section, the overview of the modeling of the capillary transport is discussed in brief.

Mathematical Modeling

Figure 1 shows the microchannel of width 2B and depth of 2 W is considered for the theoretical modeling. The momentum equation in integral form for homogeneous, incompressible, and Newtonian fluid can be written as [3]:

$$\sum F_z = \frac{\partial}{\partial t}\int_0^h \int_{-W}^{W} \int_{-B}^{B} \rho v_z dx dy dz + \int_{-W}^{W} \times \int_{-B}^{B} v_z(-\rho v_z) dx dy \tag{1}$$

where $\sum F_z$ refers to all forces present during the development of the fluid-air interface, ρ is the fluid density. Generally, forces present during the capillary transport are viscous (F_v), gravity $\left(F_g = 4\rho g h B W\right)$, pressure forces at the flow front (F_{pf}), and at the inlet (F_{pi}).

$$\sum F_z = \underbrace{F_v}_{\text{velocity dependent}} + \underbrace{F_g + F_{pf} + F_{pi}}_{\text{velovity independent}} \tag{2}$$

The Eq. 1 contains three velocity-dependent terms, namely, transient, convective, and viscous force which is generally determined as velocity profile, v_z, across the channel. The fully developed

flow assumption, i.e., Poiseuille flow assumption, is widely used in the literature neglecting the transience in the velocity profile [4, 5]. The consequence of such assumptions particularly at microscales will be discussed in detail in the later part.

The steady state velocity profile can be used to determine the velocity-dependent terms of the momentum equation. Moreover, remaining pressure force terms are calculated with available expressions (from the literature) for pressure fields at respective locations. The pressure force at the fluid-air interface can be determined by well-known Young-Laplace equation with fluid surface tension (σ) and equilibrium contact angle (θe). The approximated pressure field expression at the entrance of the microchannel is used widely to determine the pressure force at the entrance of the microchannel. Levin et al. [7], for the first time in the literature, claimed that atmospheric pressure cannot be used as entrance pressure at the inlet of the microchannel. The pressure field expression for circular capillary is derived by assuming a separate hemispherical control volume as fluid source other than the control volume considered within the microchannel. Further several researchers have used same expression for rectangular microchannels with an assumption of equivalent radius. In such analysis, with an equivalent radius assumption, the hemispherical control volume of equivalent radius of projected area of rectangular microchannel entrance is presented in Eq. 3.

$$p(o,t) = p_{atm} - \left\{ 1.11\rho\sqrt{BW}\frac{d^2h}{dt^2} + 1.58\rho\left(\frac{dh}{dt}\right)^2 + \frac{1.772\mu\, dh}{\sqrt{BW}\, dt} \right\} \tag{3}$$

The importance of an appropriate entrance pressure field expression for rectangular microchannel is also discussed in detail in later part of the study. Finally, determining all terms of Eq. 1 and rearranging as per order of differential operator, one can obtain the dimension form of the ordinary differential equation which governs the capillary transport in the microchannels. Further, nondimensional governing equation as shown in Eq. 4 can be obtained by performing nondimensional analysis with characteristic time, $t_0 = \frac{\rho(2B)^2}{12\mu}$ and characteristic length $h_0 = 2B$.

Capillary Flow, Table 1 Constants of the generalized nondimensional governing equation for a capillary flow in a microchannel with fully developed velocity profile [3]

Constants	Expressions
C_1	$\frac{0.55}{\sqrt{\gamma}}$
C_2	0.958
C_3	1
C_4	$0.295\sqrt{\gamma}$
C_5	$\frac{B_o}{144Oh^2}$
C_6	$\frac{\gamma - cos\,\theta_e}{72Oh^2}$

$$(h^* + C_1)\frac{d^2h^*}{dt^{*2}} + C_2\left(\frac{dh^*}{dt^*}\right)^2 + (C_3 + C_4h^*)\frac{dh^*}{dt^*} + C_5h^* + C_6 = 0 \tag{4}$$

The coefficients of Eq. 4 are tabulated in Table 1. Two nondimensional numbers are obtained, i.e., Bond number (Bo) and Ohnesorge number (Oh). The constants of this equation are functions of different nondimensional groups like Ohnesorge number (Oh), Bond number (Bo), and aspect ratio (γ). The Ohnesorge number represents the ratio of viscous to surface tension force, i.e., $Oh = \frac{\mu}{\sqrt{2B_{\rho\sigma}}}$, the Bond number dictates the ratio of gravity to surface tension force, i.e., $\left(B_O = \frac{\rho g(2B^2)}{\sigma}\right)$.

The solution of Eq. 4 predicts the penetration depth with capillary flow. The numerical [8] and analytical [3] solutions of Eq. 4 are available in the literature.

Revisiting the Assumptions for Microscale Applications

As mentioned earlier, the velocity-dependent terms of momentum equation are determined with an assumption of a steady state. It is assumed that at the very entrance of the microchannel the flow is fully developed. However, in reality, three different flow regimes can be observed in the capillary flow: entry regime, Poiseuille regime,

where the flow is fully developed, and the regime behind the fluid-air interface, i.e., surface tension regime. The steady state assumption, i.e., parabolic velocity profile assumption, is valid for steady state flow, whereas capillary flow is inherently a transient phenomenon. The parabolic velocity profile assumption is a reasonably good assumption for macroscale capillaries as shown by several researches [5, 7, 9]. Moreover, such assumptions are only valid in the case of a very high viscous fluid or very low Reynolds number flow which may not be true in every case [10]. Hence, it is important to consider and analyze such transience in the analysis at microscale. This can be tackled by considering the transient or developing velocity profile instead of the steady state velocity profile as explained in the following section.

The transient momentum equation in the direction of the flow for pressure-driven flow is:

$$\rho \frac{\partial v_z}{\partial t} = \mu \frac{\partial^2 v_z}{\partial x^2} + \frac{dp}{dz} \tag{5}$$

The velocity in Eq. 5 is a combination of steady and transient part of velocity as depicted in Eq. 6 [11]:

$$v_z(x,t) = v_{z\infty}(x) + v_{zt}(x,t) \tag{6}$$

where $v_{z\infty}(x)$ is the fully developed or steady state velocity, i.e.,

$$v_{z\infty}(x) = \frac{B^2}{2\mu}\frac{dp}{dz}\left[1 - \left(\frac{x}{B}\right)^2\right] \tag{7}$$

The transient part of the velocity can be obtained by separation of the variable method which can be given as [6]:

$$v_{zt}(x,t) = 2\sum_{n=1}^{\infty}(-1)^n\left[\frac{1}{B\mu\lambda_n^3}\frac{dp}{dz}\right]cos\,(\lambda_n x)exp \times \left(-v\lambda_n^2 t\right) \tag{8}$$

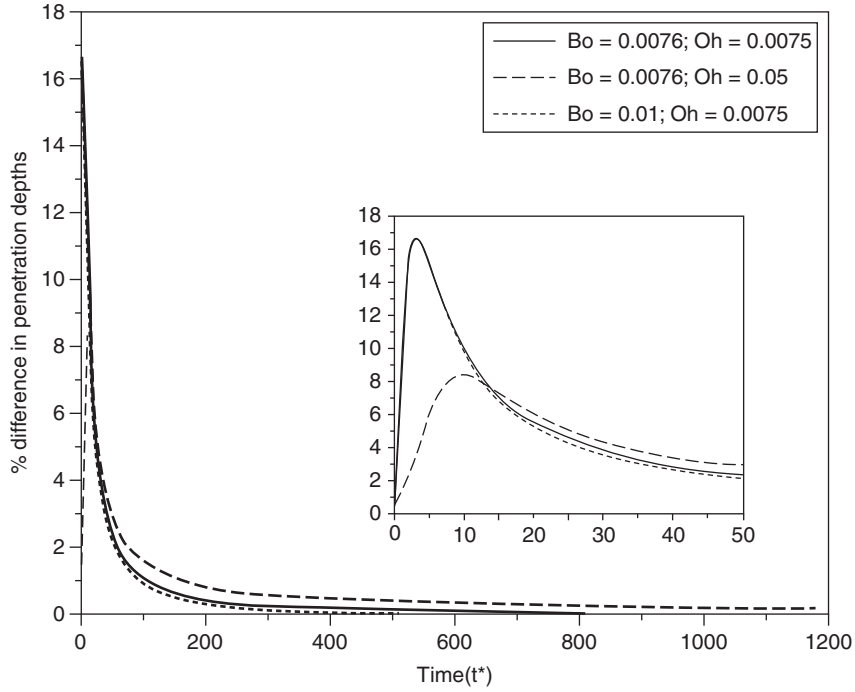
where v is the kinematic viscosity of the fluid and $\lambda_n = \frac{(2n-1)\pi}{2B}$. By combining Eqs. 5 and 7 the transient velocity profile $v_z(x, t)$ can be obtained by:

$$v_z(x,t) = \left\{\sum_{n=1}^{\infty}(-1)^n\frac{1}{B\mu}\left(\frac{2}{\lambda_n^3}\right)cos\,(\lambda_n x)exp \times \left(-v\lambda_n^2 t\right) + \frac{1}{2\mu}\left(B^2 - x^2\right)\right\}\frac{dp}{dz} \tag{9}$$

Further, the average velocity across the channel can be represented as:

$$v_z(t)_{avg} = \frac{B^2}{3\mu}\left[1 - \sum_{n=1}^{\infty}\frac{96}{(2n-1)^4\pi^2}exp \times \left(-\frac{(2n-1)^2\pi^2 vt}{4B^2}\right)\right]\frac{dp}{dz} \tag{10}$$

Finally, the velocity profile in terms of the penetration with transient velocity is:



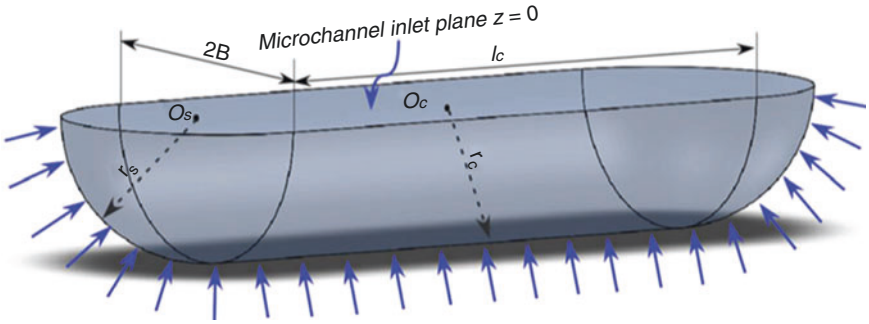
$$v_z(x,t) = \frac{B^2}{2\mu}\alpha_1\left\{\sum_{n=1}^{\infty}(-1)^n\left[-\frac{4}{(B\lambda_n)^3}\right]cos\,(\lambda_n x)exp\left(-v\lambda_n^2 t\right) + \left(1 - \frac{x^2}{B^2}\right) \times \left\{\frac{1}{\alpha_1\left[1 - \sum_{n=1}^{\infty}\beta_1 exp\left(-\lambda_n^2 vt\right)\right]}\right\}\frac{dh}{dt} \tag{11}$$

where

$$\alpha_1 = \frac{\left[(\phi)^4 - 4exp - \frac{\phi^2 t}{3}\right]}{\left[(\phi)^4 - 6exp - \frac{\phi^2 t}{3}\right]}$$

and $\phi = \lambda_n B$.

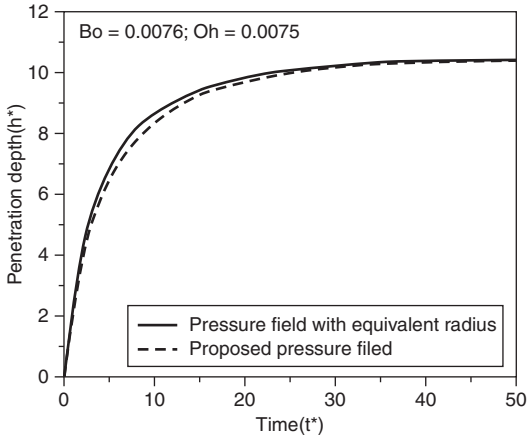
A similar approach can be followed as explained in the previous section and further the governing equation for capillary transport can be derived with the transient velocity profile provided in Eq. 11. Moreover, the difference in the penetration depth with both approaches, i.e., with the steady state and transient velocity profile, under different operating conditions can be compared. Figure 2 shows the difference in the penetration depth in such cases where the difference in the penetration depth is more at the beginning of



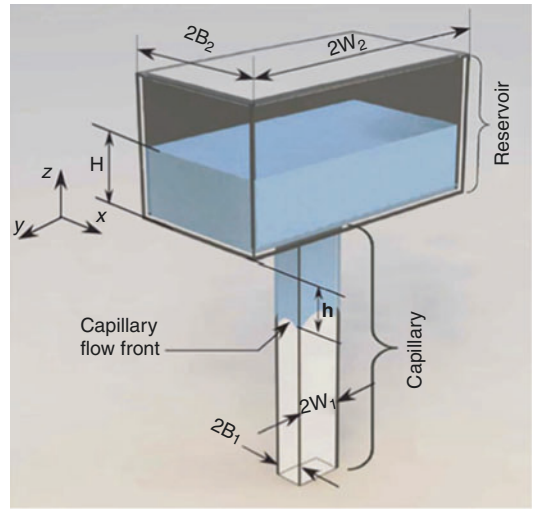
Capillary Flow, Fig. 2 Transient response in the difference in the penetration depths with the fully developed (steady state) and developing (unsteady) velocity profile under different conditions [6]

the filling process, as shown in the inset of Fig. 2. This difference in the penetration depth decreases as the flow progresses along the microchannel where the flow becomes a fully developed flow. This can also be explained with the help of boundary layer theory which is the effect of fluid viscosity. The boundary layer thickness increases as the viscosity of fluid increases because of the retardation of flow due to increase in the viscosity, whereas in the case of the fluid density, the effect is opposite to viscosity. Therefore, the difference in penetration depth with the high density fluid (Bo $= 0.01$) is higher than the difference with the high viscous fluid. It is evident from the analysis that the transience effect in the analysis has a significant impact on the filling process prediction, particularly at the beginning of the filling process. At microscale, such difference needs to be accounted prior to the design.

As discussed earlier, the pressure force at the entrance of the microchannel is determined with the help of the pressure field at the microchannel entrance. Several researchers [3–8] have adopted the pressure field expression with an equivalent radius assumption. Levin et al. [6] developed an entrance pressure field expression for circular capillary, assuming a hemispherical control volume as a separate control volume at the entrance which is responsible for a sink flow at the entrance of capillary and the pressure field. Moreover, a similar expression for rectangular capillaries is extended with an equivalent radius assumption. In such cases, the radius of circular capillary is replaced by the equivalent radius of projected area at the entrance of the channel. This is not a realistic representation for noncircular capillaries particularly for high aspect ratio microchannels where it is not appropriate to consider the hemispherical control volume for the sink flow or pressure field at the microchannel entrance. In the case of such geometries, the control volume needs to be considered as a combination of semicylinder and hemisphere as shown in Fig. 3.



The detailed derivation of the pressure field expression with this control volume can be seen in [6] which is:

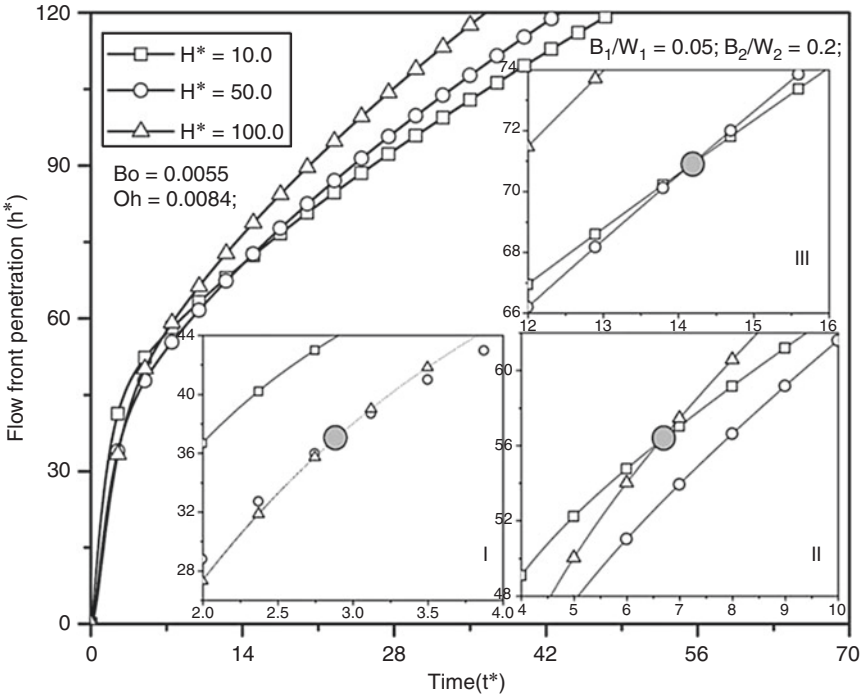


Capillary Flow, Fig. 3 The fluid volume from infinite reservoir considered as control volume for pressure field expression analysis in the case of rectangular microchannel. The *arrow* shows the direction of the fluid flow from the reservoir into the microchannel [6]

$$p(0,t) = p_{atm} - \rho B\left\{\left[\frac{4\gamma + 3(1-\gamma)}{24}\right]\left\{\pi\left[\frac{1}{2\pi} + \frac{2}{\pi^2} + \frac{6}{10}\right]\right\} + \left[1 - \frac{2}{\pi} ln\frac{R_\infty}{B}\right]\right\}\frac{d^2h}{dt^2}$$
$$+\rho\left\{\left[\frac{1(1-\gamma)}{\pi^2} - \frac{6}{5}\right] - \left[\frac{4\gamma + 3(1-\gamma)}{6}\right] \times \left[\frac{(2-\gamma)}{2\pi} - \frac{(1-\gamma)}{\pi^2}\right]\right\}\left(\frac{dh}{dt}\right)^2 - \frac{4\mu}{B} \times \left[(2-\gamma) + \frac{(1-\gamma)}{\pi}\right]\frac{dh}{dt} \quad (12)$$

where R_∞ represents the radial distance far away from the control volume in the reservoir, where the sink action, i.e., entrance pressure force, disappears. One can re-derive the governing Eq. 4, using pressure field expression presented in the Eq. 12, and determine the effect of such a pressure field on the analysis. Figure 4 shows the comparison of variations in the penetration depth with recently proposed pressure and with equivalent radius field expressions. The approximated pressure field overpredicts the penetration depth. The difference in the penetration depth with the proposed pressure field is significant, which shows that it is important to consider the proposed pressure field for a rectangular microchannel rather than an approximated pressure field. The transport with a capillary action is the balance among surface, viscous, and other body forces which retard the flow as it progresses. Hence, the capillary flow always attains a steady state which is generally termed as an equilibrium penetration depth in the literature. If the length of the channel is longer than that of the equilibrium penetration depth, then flow front cannot reach the outlet and, therefore, the assistance to the capillary flow is attempted in such cases. Passive or nonmechanical pumping approaches combined with the capillary flow serve this enhancement. The scaling analysis suggests that the gravity force is less dominant at microscale [12], but several researchers have demonstrated that gravity can be used as an assistance to the capillary flow [13–15]. Generally, the capillary flow analysis is performed with an assumption of infinite reservoir. Hence, the reservoir effect and the gravitational force from the reservoir are generally neglected in the analysis. To accommodate the entrance effect of finite size reservoir at the inlet of the microchannel in the theoretical modeling, the entrance pressure field is developed for the arrangements shown in Fig. 5. The rectangular microchannel with rectangular reservoir on the top of the microchannel is considered and the pressure field with the gravity and reservoir effect is developed in the flow [16]. Moreover, this pressure field is used to obtain the governing equation for capillary flow under the influence of gravity head from the reservoir.

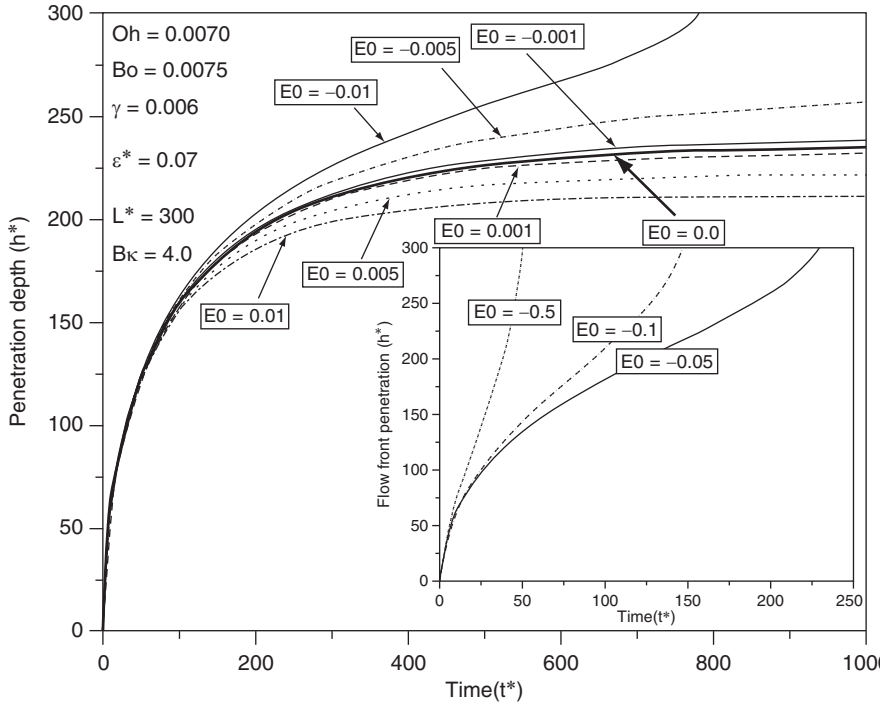
Capillary Flow, Fig. 4 The comparison of variations in the penetration depth with equivalent radius and recently proposed pressure field expressions. Figure 4 shows the comparison of penetration depth for $\gamma = 0.9$ with the corresponding difference in the penetration depth [6]



Capillary Flow, Fig. 5 Schematic of a gravity-assisted capillary flow in a vertically oriented capillary of width $2B_1$ and depth $2\ W_1$. The additional gravitational head from the fluid in a finite reservoir of size ($2B_2 \times 2\ W_2$) is assisting the capillary flow [16]

The reservoir with three different levels of fluid in the reservoirs (H^*), namely, 10, 50, and 100, is considered for the analysis. Figure 6 shows the variations in the penetration depth (h^*) with different operating conditions. This analysis represents the interplay between the surface tension force and gravity head from the reservoir. The capillary flow takes place in the channel which remains same for all three cases, whereas the level of the fluid from the reservoir increases from case I to case III. Thus, for three cases, the capillary effect is the same but the gravity head is different. At the beginning of the transport, the fluid from the reservoir offers less inertia to the fluid transport and the capillary force dominates over the gravity from the reservoir. Therefore, at the beginning of the transport, the penetration depth with a lower reservoir fluid level ($H^* = 10.0$) is higher than the other two penetration depths as shown in the inset I. Similarly, the penetration depth with the highest reservoir fluid level ($H^* = 100.0$) has the lowest penetration depth as compared to others.

Moreover, as the fluid progresses in the microchannel, the momentum from the reservoir fluid assists the capillary flow and the gravitational force, due to which the fluid from the reservoir becomes dominant over the capillary force within the microchannel. This results in transcendence among the penetration depths with a different gravity head. The penetration depth with the highest gravity head ($H^* = 100$) surpasses the penetration depth with gravity head $H^* = 50$ and $H = 10^*$ in inset I and II two, respectively. This can be attributed to as an interplay between the surface tension force, i.e., the capillarity and gravitational force from reservoir. In the case of microfluidic applications, the sizes of reservoir and microchannel are comparable to each other. Hence one cannot neglect the effect of the reservoir in such cases, particularly if it is surface tension–driven pumping. Further, one can assist the capillary flow with an appropriate arrangement of reservoir.



There are always certain limitations to the autonomous pumping which make them inadequate in long microchannels. Hence, it is important to enhance the pumping ability by other means. Further enhancement in the capillary flow can be achieved by coupling the capillary flow with the electroosmotic flow which is one of the electrokinetic pumping mechanisms. In most of the cases, the inner wall of a microchannel always has surface charges due to different

Capillary Flow, Fig. 6 Transient response of a flow front transport for different gravitational heads in the reservoir with Bo = 0.0055, Oh = 0.0084, $B_1/W_1 = 0.05$ $B_2/W_2 = 0.2$. (**I**) Flow front penetration rate for $H^* = 100$ surpasses the penetration rate for $H^* = 50$. (**II**) Flow front penetration rate for $H^* = 100$ surpasses the penetration rate for $H^* = 10$. (**III**) Flow front penetration rate for H = 50 surpasses the penetration rate for $H^* = 10$ [16]

mechanisms like ionization, dissociation of ions, isomorphic substitution, etc., [17]. These surface charges distribute ions of the electrolytes in a specific pattern when brought into contact with an electrolyte which is generally termed as the formation of electrical double layer (EDL). After applying the electric field across the channel, the movement of the ions takes place, which results in the movement of the fluid due to an electric field [18]. The electrolyte solution is transported with the capillary action; one can further assist the capillary flow. An additional body force due to electroosmotism is added to Eq. 2, which accommodates the additional effect of electroosmosis. Further one can analyze the interplay between the capillarity and electroosmotisms as presented in the recent studies [19]. Figure 7 shows the variation in the penetration depth of the capillary flow under the influence of electroosmotism. Through a nondimensional analysis, a new nondimensional number is proposed, i.e., Eo which represents the ratio between the surface tension force and electroosmotic force. The direction of the electroosmotic flow can be reversed by changing the electric field direction. Hence, negative and positive Eo numbers are observed in the analysis. The negative Eo numbers represent the change in the direction of the electric field as compared to positive Eo numbers. The pure capillary flow can be seen as Eo = 0.

The variation in the penetration depth under three different operating conditions is shown in Fig. 7. As observed in the pure capillary case (Eo = 0), the penetration depth attains the equilibrium penetration depth, whereas in the case of − Eo numbers, the equilibrium penetration depth increases with increment in the magnitude of − Eo numbers. This represents that in the case of electroosmotic flow with − Eo number, the capillary flow is assisted by electroosmotism. In this analysis, the nondimensional length of the

Capillary Flow, Fig. 7 Variation in the penetration depth for vertically oriented channel with water as electrolyte, where B = 100 μm, W = 400 μm, L = 75 mm, $\zeta = -75$ mV and constant contact angle is 27°. The inset shows the variation in the electric field within the electrolyte as the flow front progresses under different applied voltages [19]

microchannel (L^*) is considered as 300 and with –Eo = −0.01 the entire filling of the microchannel is observed. In the case of positive Eo numbers, it is observed that the electroosmotism acts in a opposite direction of the capillary flow. Hence, it retards the flow and this can be observed by the decrement in the equilibrium penetration depth with the increment in the positive Eo numbers.

For the enhancement in the capillary flow, a transport with additional gravity head and electroosmotic forces are considered. A generalized theoretical modeling for a gravity-assisted capillary flow with reservoir effects and electroosmotically assisted capillary flow is reported in brief. It is observed that even though the scaling among forces suggests that the gravitation force is negligible at microscale, the reported analysis infers that with a finite reservoir, an added advantage due to gravity can be a useful tool to transport the fluid at microscale. This added force for the capillary transport can be utilized without any additional burden in the design of the LOC device. The electroosmotically assisted capillary flow model suggests that in a combined flow the electrokinetic parameters have an important influence on the capillary flow. Such electrokinetic flow approaches can be coupled to enhance the capillary flow transport in the microchannel.

The wetting properties of the fluid decide the capability of pumping with a capillary flow. Therefore, it is important to know the precise magnitude of wetting properties like contact angle and surface tension of the working fluid. The microfluidics has become a promising option for biomedical application and inclusion of biomolecules is an unavoidable part in such applications. In most cases, the biomolecules are attached with the microbeads and transported to the desired locations. It is evident from the experimental analysis that the inclusion of microbeads changes the wetting behavior drastically [20]. Therefore, it is

necessary to consider the effect of microbeads in the fluid for the analysis. This can be done by considering the following expressions for surface tension and contact angle: density and viscosity which are functions of volume fraction of microbeads. Such correlations of the surface tension and contact angle are provided in [20]. Such expressions for the variation in the contact angle and surface tension with the volume fraction can be readily used in modeling transport processes of microbead suspensions in micro-capillaries, used in the microfluidic devices.

In passive pumping, particularly with the capillary flow, different aspects due to microscale effects like aspect ratio–dependent velocity profile, contact angle at four walls, fluid-air interface dynamics in the case of suspension flow, etc., need to be investigated in detail. Theoretically the concept of electroosmotically assisted capillary flow has been presented but the experimental demonstration of such phenomena is also an interesting area of research. Moreover, wetting of biomolecule suspensions under transient effects instead of the steady state is also needed to be studied. The experimental study of the flow behind the front and at the entrance of the microchannels is also an interesting study to perform.

Definition

Capillary origami is the folding of an elastic planar structure into a three-dimensional (3D) structure by capillary action between a liquid droplet/bubble and a structure surface.

Why Capillary Origami?

The fabrication of 3D structures is one of the major challenges for micro- and nano-fabrication. Folding of an elastic planar structure after patterning and release is one technique to fabricate a 3D structure using self-assembly. The term *origami* is taken from the Japanese art of paper folding; while the actuation of the folding is accomplished by using capillary forces of a fluid droplet, hence, the technique has been termed *capillary origami*. The combination of the folding process with capillary forces has resulted in a new technique for micro- and nano-fabrication.

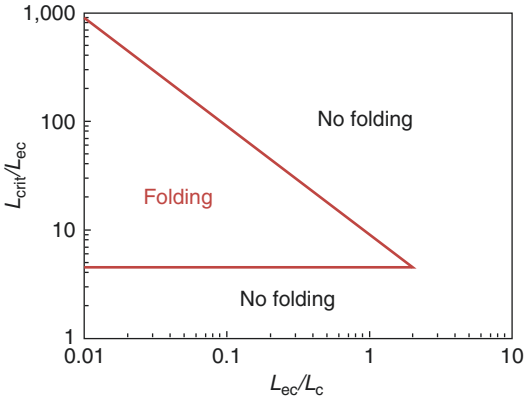
History

The term *capillary origami* was first introduced in 2007 by Charlotte Py et al. to describe the folding of a polydimethylsiloxane (PDMS) sheet into a 3D structure by using capillary forces created by a water droplet [1]. As early as 1993, Syms and Yeatman demonstrated that 3D structures could be fabricated by folding surfaces using capillary forces produced by molten solder [2]. Later Richard R. A. Syms introduced the term *surface tension-powered self-assembly* to describe the technique [3, 4]. Both of these techniques are quite similar in that 3D structures can be produced by folding elastic thin films. Both use capillary forces for self-assembly. In the first example, various liquids such as water are used, while for the second study, molten metals such as solder were used, which then solidified fixing the 3D microstructures.

Principles

At the macroscale level, the influence of capillary forces is negligible compared to other forces such as gravity, electrostatic, or magnetic. Because capillary forces scale linearly with the characteristic size of the system, at submillimeter dimensions, capillary forces begin to dominate since the majority of other forces decrease much more rapidly than the first power of the length. For example, a human cannot walk on water because capillary forces produced at the water surface are much smaller than the gravitational force acting on a human, which scales as the cube of the length. On the other hand, the much smaller water strider can easily walk on water because capillary forces are large enough to balance the gravitational force produced by the water strider. For capillary origami, capillary forces need to be large enough to counteract the weight of the liquid droplet and the structural forces of the planar layer.

In terms of energy, for capillary origami, one needs to consider the interplay of three different energies: capillary energy, bending energy, and gravitational potential energy. For a two-dimensional (2D) model, the capillary energy per unit length of the interface (2D analog of the surface energy) is defined as $E_c = L'\gamma$, where L' is the length of the interfacial surface of the fluid and γ is the surface tension [5]. The bending energy per unit length is approximately $E_b = \frac{LB}{2R^2}$, where

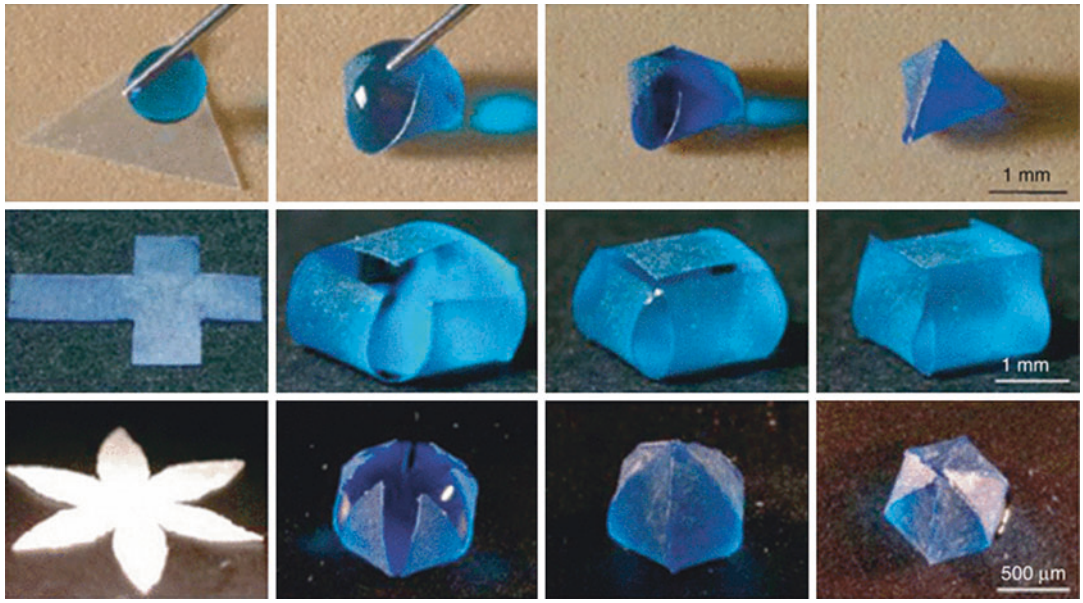


L is the length of the structure and R is the radius of curvature [6]. $B = \frac{Eh^3}{12(1-\nu^2)}$ is the bending rigidity of the structure, where E is Young's modulus, h is thickness of the layer, and ν is Poisson's ratio. If one only considers the mass of the fluid, assuming that it is much larger than the mass of the structure, then the gravitational potential energy per unit length is $E_g = \rho S g z$, where ρ is the density, S is the surface area, g is the constant of gravity, and z is the height of the center of mass. By neglecting the effect of gravity and assuming complete circular folding, [7] derived simplified criteria for folding considering the interplay between capillary and bending energies, which are expressed as

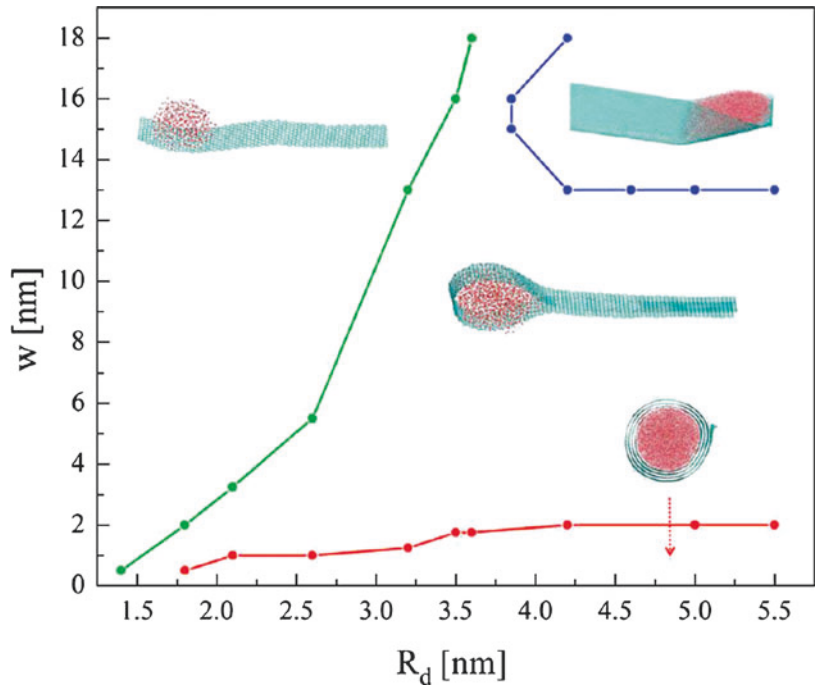
$$\sqrt{2\pi} < \frac{L_{\text{crit}}}{L_{\text{ec}}} < 2\sqrt{2\pi}\frac{L_{\text{c}}}{L_{\text{ec}}} \qquad (1)$$

where L_{crit} is the critical length of a structure for folding to occur, $L_{\text{c}} = \sqrt{\frac{\gamma}{\rho g}}$ is the capillary length [5], and $L_{\text{ec}} = \sqrt{\frac{B}{\gamma}}$ is the elasto-capillary length [8].

The simplified criteria for folding derived from Eq. 1 can be plotted as shown in Fig. 1. To fold a structure requires $\frac{L_{\text{ec}}}{L_{\text{c}}} < 2$ or $L_{\text{c}} > \frac{L_{\text{ec}}}{2}$ or $\gamma > \frac{\sqrt{B\rho g}}{2}$ indicating that the capillary length must be larger than half of the elasto-capillary length so that the capillary effect can overcome bending rigidity of the structure. The other requirement for folding is $\frac{L_{\text{crit}}}{L_{\text{ec}}} > \sqrt{2\pi} \cong 4.44$ or $L_{\text{crit}} > 4.44 L_{\text{ec}}$ confirming that the length of the structure should also be long enough for a liquid droplet to wet the surface to produce sufficient capillary forces to fold the structure. For the 3D structures, the folding criteria become more complex. In particular in 3D, the critical length also depends on the shape of the initial template such that $L_{\text{crit}} \cong 7L_{\text{ec}}$ for squares and $L_{\text{crit}} \cong 12L_{\text{ec}}$ for triangles [9]. Figure 2 shows examples of capillary origami structures of a pyramid, a cube, and a quasi-sphere obtained from folding triangle-, cross-, and flower-shaped PDMS sheets, respectively [10].

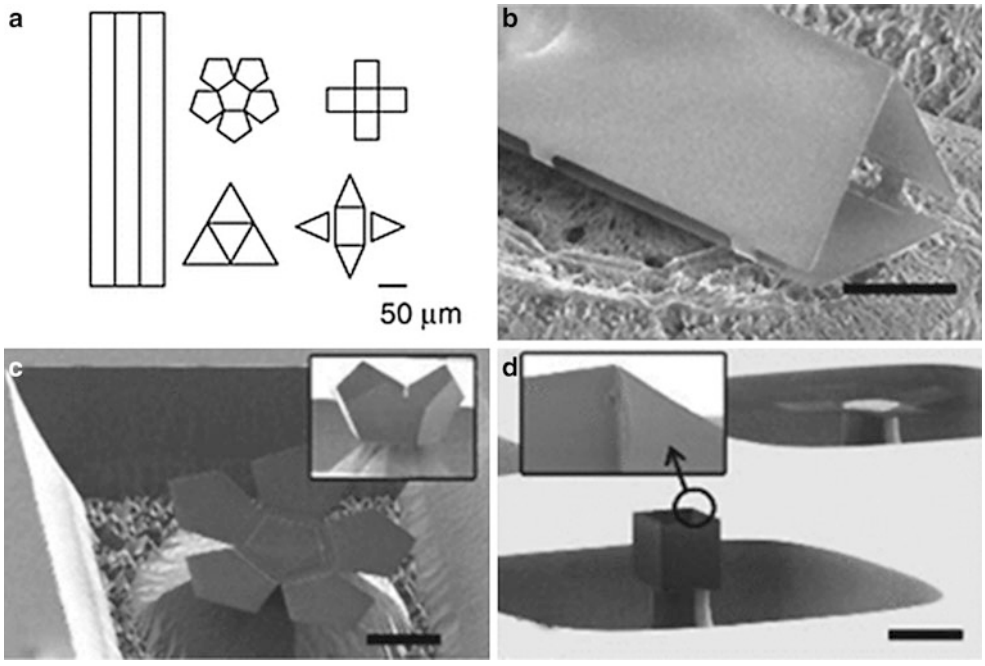


The concept of capillary origami has also been modeled at the nanoscale. Molecular dynamics simulations show the folding of planar graphene nanostructures by water nanodroplets [11]. Figure 3 summarizes the folding by presenting a phase-like diagram by plotting droplet radius (R_d) versus the ribbon width (w). From the graph, four different areas or phases can be identified corresponding to four different bending modes: nonfolding, sliding, zipping, and rolling. Figure 3 (left) shows the nonfolding phase where the nanoribbon end does not fold around the nanodroplet. The nonfolding phase is adjacent to the sliding phase where the nanoribbon end folds around the nanodroplet and then slides on the nanoribbon surface. The right top of the figure shows the zipping phase where the width of ribbon is several times greater than the droplet radius allowing the ribbon to fold around the droplet in the orthogonal direction. In the rolling phase ($w \leq \frac{1}{2}R_d$), the ribbon folds around the droplet and then continues wrapping in a scroll-like manner.



Capillary Origami, Fig. 1 Folding criteria plotted from Eq. 1 assuming complete circular folding and neglecting the effect of gravity

Applications



Capillary origami has been used to fabricate a number of 3D microstructures. Figure 4 illustrates the self-assembly of structures with various geometries. The initial planar templates are shown in Fig. 4a, and the folded final 3D microstructures are shown in Fig. 4b–d. The initial planar templates with lengths ranging from 50 to 100 μm and

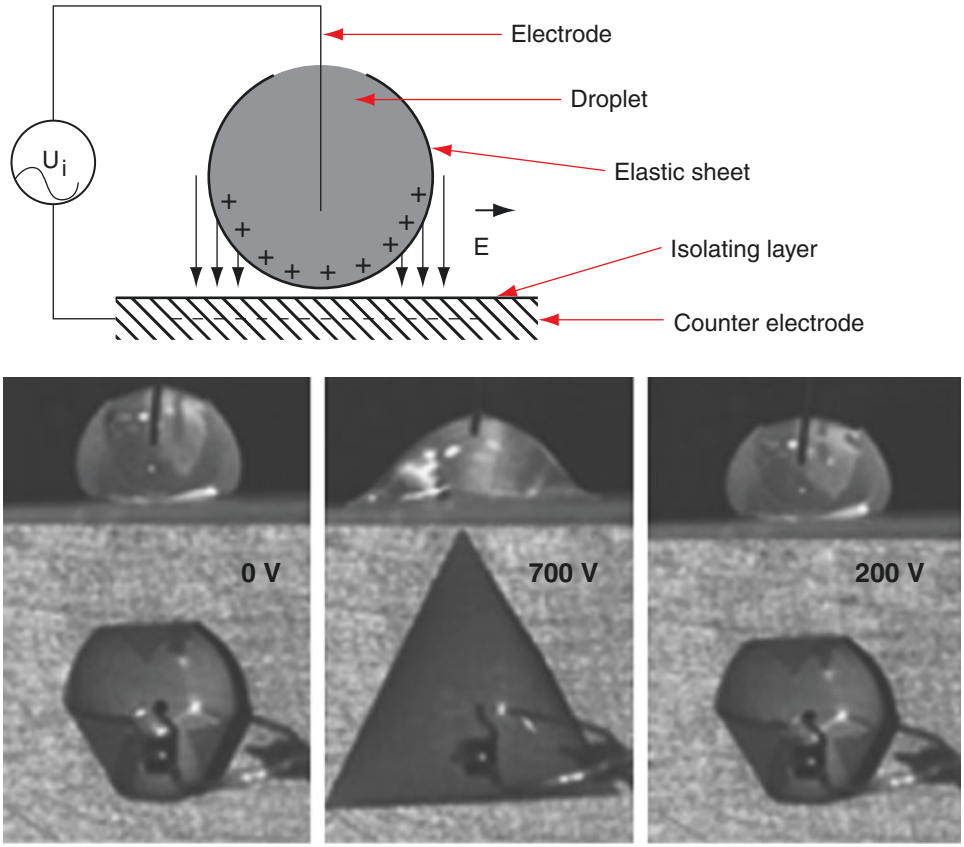
a thickness of 1 µm were fabricated from silicon nitride thin films deposited and patterned by using standard micromachining processing typically used for integrated circuit and MEMS fabrication. Water droplets then were deposited on the templates to fold 3D microstructures [12]. Figure 5 shows another example of microfabrication of a quasi-spherical silicon solar cell based on capillary origami. After fabrication by conventional micromachining processing, the initial flower-shaped silicon template was folded into a sphere using a water droplet. Unlike conventional flat solar cells, this spherical solar cell enhanced light trapping and served as a passive tracking optical device, absorbing light from a wide range of incident angles [13].

Besides using liquid droplets, capillary origami structures can be constructed by using soap

Capillary Origami, Fig. 6 Capillary origami 3D structures formed from triangle- and flower-shaped templates using soap bubbles (scale bar: 2 cm) (Images reprinted from Ref. [14] with permission)

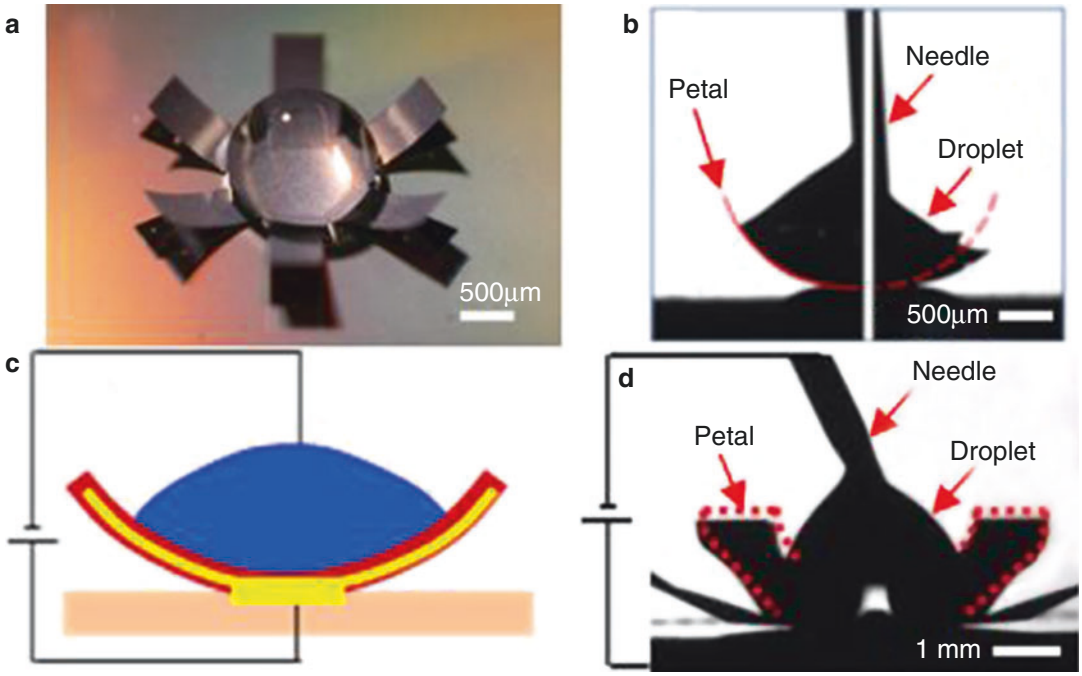


Capillary Origami, Fig. 7 The folding of an artificial flower when submerged in water (Reprinted with permission from Ref. [15]. Copyright 2009, American Institute of Physics)

bubbles as shown in Fig. 6. The weight of a soap bubble is much less than that of a liquid droplet especially for large droplets capable of covering centimeter-size structures when gravitational forces become significant. A soap bubble was shown to fold a centimeter-size elastic structure, which cannot be accomplished using a liquid droplet [14].

Petals of a flower also can be folded into a structure similar to capillary origami when submerged in water as shown in Fig. 7. The folding of the flower in water is accomplished by the interplay of elastic, capillary, and hydrostatic forces. During submersion, hydrostatic pressure pushes against the back of petals, and surface tension prevents water from penetrating through the spacing between petals resulting in trapping an air bubble inside a flower. The inside of the folded flower remains dry protected by the air bubble [15].

Structures formed by capillary origami also can be actuated by using electrostatic fields to reversibly fold and unfold then. For this application, we need to take into account the interplay of capillary, elastic, and electrostatic forces. As shown in Fig. 8, an electric field was applied between the droplet and the substrate. When the voltage was increased, the electrostatic force increased eventually overcoming capillary forces resulting in unfolding of the PDMS sheet. When the voltage was decreased below a certain threshold, the electrostatic force was no longer strong enough to prevent capillary forces from again folding the elastic sheet [16].



For flower-shaped polycrystalline silicon microstructures (called microflowers), the degree

Capillary Origami, Fig. 8 Capillary origami controlled by an electric field. The schematic of the experimental setup is shown at the far left, and three images to the right show the results of increasing voltage from 0 V to 700 V and decreasing voltage from 700 V to 200 V (Images from Ref. [16] – reproduced by permission of The Royal Society of Chemistry)

of folding was dynamically controlled by two different methods as shown in Fig. 9 [17]. The change in the bending angle was achieved by changing the volume of a liquid droplet by using an automated syringe pump. The petals reversibly bent and relaxed as the liquid was added and withdrawn. The electrowetting process (Fig. 9c) was also used to control bending. Capillary forces exerted by the liquid droplet on the petals can be changed by changing its contact angle by applying a voltage to the conducting liquid droplet placed on the petals. A thin dielectric layer of SiO_2 was thermally grown on the conductive Si petals to fabricate the electrowetting device. Both methods were used to reversibly actuate the petals without completely wrapping around the droplet, leaving part of the petal surface free to reflect incident light. The direction of the incoming light can then be dynamically controlled by the bending of the petal demonstrating an example of an optofluidic device.

Capillary origami is a simple and inexpensive method to fabricate 3D structures at the submillimeter scale. By using capillary forces, intricate and delicate 3D thin-film structures can easily be fabricated, which would be difficult to obtain by other methods. More applications exploiting the advantages of capillary origami itself or in combination with electric fields can readily be envisioned. Ultimately one expects to see more commercial products based on this versatile technique.

Carbon MEMS

Rodrigo Martinez-Duarte, Monsur Islam and Rucha Natu
Multiscale Manufacturing Laboratory, Department of Mechanical Engineering, Clemson University, Clemson, SC, USA

Synonyms

C-MEMS; Carbon microelectromechanical systems

Definition

A process used to fabricate miniaturized glass-like carbon structures through the carbonization of previously shaped organic precursors.

Overview

Carbon MEMS combines different patterning techniques with carbonization to derive miniaturized glass-like carbon features from an organic precursor. Since glass-like carbon is a brittle material, the carbonization of an already patterned precursor compares advantageously against subtractive manufacturing of glass-like carbon bulk. To date, the most common precursor patterning technique used in C-MEMS has been conventional photolithography, but many other techniques could be used. These cover a wide range: from relatively inexpensive like electrospinning, stamping, molding, polymer machining, and casting to next-generation lithography (NGL) techniques such as nanoimprint lithography (NIL) and electron beam lithography. The choice of precursor patterning technique is dictated by the quality, complexity, and final dimensions of the desired carbon part. Shrinkage of the precursor structure occurs during carbonization and must be accounted for. However, the existence of commercial high-quality precursors, like the negative photoresist SU-8, and availability of standardized fabrication tools make the fabrication process and the dimensional control highly reproducible.

Historical Background

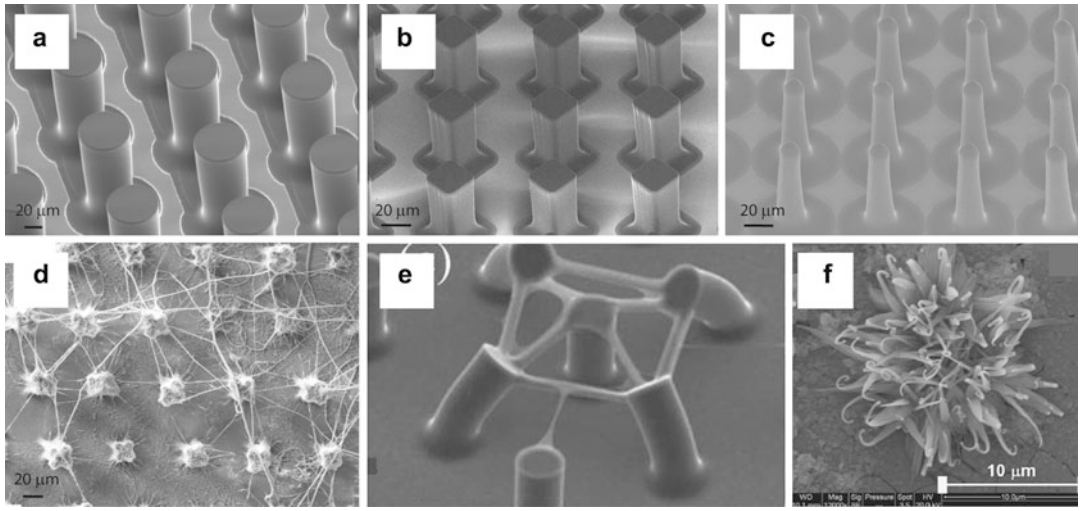
Carbon can be found as a number of allotropes including diamond, lonsdaleite, buckminsterfullerenes, graphene, carbyne, graphite, carbon nanofoams, diamond-like carbon, amorphous carbon, and those carbons derived from the pyrolysis of organic materials, better known as glass-like carbons. Different precursors to obtain glass-like carbon may be used, including phenolic resins, polyfurfuryl alcohols, cellulose, polyvinyl chloride, and polyimides.

The first documented modern derivation of glass-like carbon from an organic resin (phenolic in this case) appears to be from 1915, when Weintraub and Miller in Massachusetts, USA, derived disks of a "very bright, shiny looking carbon with hardness equal or greater than 6 on the Mohs mineral scale." These disks were then used for better microphones in telephone transmitters. Their fabrication protocol featured slow heating of a hardened resin to a temperature close to 700 °C in about 1 week, followed by firing at temperatures from 800 to 1100 °C in just a few hours. The advantage of patterning an organic precursor, rather than carbon bulk, was realized

since then [1]. A sustained flow of publications on glass-like carbon did not begin until 1962, when Davidson, at the General Electric Co. in Kent, England, derived glass-like carbon from cellulose [2], and Yamada and Sato, at the Tokai Electrode Manufacturing Co. in Nagoya, Japan, published preliminary characterization results of carbon derived from organic polymers [3]. They named such carbon "glassy carbon," a term that was later registered as a trademark. Around the same time, in 1963, Lewis, Redfern, and Cowlard at the Plessey Company in the UK postulated the use of glass-like carbon, named "vitreous carbon" by the authors and later registered as trademark as well, as an ideal crucible material for semiconductors. Later that year, Redfern and Greens disclosed several production processes to derive this "vitreous carbon" in a patent [4]. In 1965, the advantages of glass-like carbon electrodes for voltammetry and analytical chemistry were characterized by Zittel and Miller, from Oak Ridge National Laboratory in the USA, using "glassy carbon" from the Tokai Electrode Manufacturing Co. [5]. In 1967, Cowlard and Lewis published a detailed description of the properties of "vitreous carbon," the fabrication process and its potential applications [6]. The decade of 1970 brought a significant interest on the use of glassy carbon as a material for different implants and biomedical instrumentation and also witnessed an explosion of the interest on glassy carbon by the analytical and electrochemistry communities, which still remains strong. In 1971, a structural model for glass-like carbon was postulated by Jenkins and Kawamura [7]. This model is up to this date the only one capable of explaining most of the experimental results obtained with glass-like carbon.

Carbon derived from organic polymers by pyrolysis in inert atmosphere has been historically known by three different names: "vitreous carbon," "glassy carbon," and glass-like carbon. Although highly referenced in implant-related publications during the 1970s, the term "vitreous carbon" started to fall in disuse by the end of that decade. "Vitreous carbon" is now better identified with reticulated vitreous carbon (RVC), a material introduced in the late 1970s by Chemotronics International Inc. from Ann Arbor, Michigan. The commercialization of Tokai's "glassy carbon" electrodes targeting the electrochemistry market made "glassy carbon" the term of preference for the electroanalytical chemistry community to refer to glass-like carbon. In 1995, the IUPAC (International Union of Pure and Applied Chemistry) defined glass-like carbon as the material derived by the pyrolysis of organic polymers and recommended that the terms "glassy carbon" and "vitreous carbon," which had been introduced as trademarks, should not be used as synonymous for glass-like carbon.

From the microfabrication standpoint, in 1983 Lyons et al. at AT&T Bell Laboratories published their work on the use of photodefined novolac resist patterns as precursors for carbon microstructures [8]. The drive behind this effort was finding an alternative to carbon films deposited by chemical vapor deposition. Miniaturized glass-like carbon 3D structures were not reported until the late 1990s by Schueller and coworkers at Harvard University. In their process, polydimethylsiloxane (PDMS) molds were fabricated using soft lithography and then used to pattern furfuryl alcohol-modified phenolic resins and phenol-formaldehyde resins, which were subsequently carbonized [9]. By 2000, Kostecki and colleagues were obtaining further results on the fabrication of planar carbon microelectrodes from positive photoresists to study the influence of their geometry in their electrochemical response [10]. Such work ignited the use of pyrolyzed photoresist films, or PPF, in fields such as electrochemistry. In 2002, the derivation of carbon from negative photoresists was reported by Singh et al. [11]. The obtained carbon showed higher electrical resistivity and vertical shrinkage than the one synthesized from positive resists. In 2004, structures with aspect ratios higher than 10 were reported by Wang et al. at the University of California, Irvine (UCI) [12, 13]. These authors coined the term Carbon MEMS. Since then, most of the work identified as Carbon MEMS has used SU-8 as carbon precursors and photolithography to shape 3D structures. Other precursors include resorcinol–formaldehyde gels [14] and cellulose. Starting in 2009, electrospinning of SU-8 and PAN (polyacrylonitrile) has been developed toward obtaining carbon fibers in the nanoscale [15, 16].



Material Properties of Carbon MEMS

The carbon obtained in a Carbon MEMS process resembles glass-like carbon. Although the choice of precursor and patterning technique has an impact on the properties of the resultant carbon, the following properties can serve as a starting reference. Although a consensus on the crystalline structure of glass-like carbon has not been reached to this date, the most widely accepted model [7] is the one that considers this type of carbon as made up of tangled and wrinkled aromatic ribbon molecules that are randomly cross-linked by carbon–carbon covalent bonds. The ribbon molecules form a networked structure, the unit of which is a stack of high strained aromatic ribbon molecules. Such structure of crystallites reflects the features of thermosetting resins structure which are commonly used as precursors for glass-like carbons. Glass-like carbon is widely considered as impermeable to gases and extremely inert, with a remarkable resistance to chemical attack from strong acids and other corrosive agents such as bromine. The material will react with oxygen at temperatures above few hundred degrees centigrade, making oxygen plasma a favored etching process. Glass-like carbon has a hardness of 6–7 on Mohs scale, a value comparable to that of quartz. Its density ranges from 1.4 to about 1.5 g cm^{-3}, compared to 2.3 g cm^{-3} for graphite. X-ray diffraction studies have shown that glass-like carbon presents an extremely small pore size, ~50 Å, of a closed nature, and that has an amorphous structure [31–38]. Glass-like carbon features a coefficient of thermal expansion of 2.2–3.2 × 10^{-6} K^{-1} which is similar to some borosilicate glasses. Its Young's modulus can vary between 10 and 40 GPa. An indicative electrical resistivity of glass-like carbon is 1 × 10^{-4} Ω m when the carbonization temperature is as high as 900 °C. The electrical resistivity drops further as the temperature increases over this value or the dwell time at temperatures below it increase [17, 18]. One of the reasons glass-like carbon is preferred by electrochemists is the fact that it has a wider electrochemical stability window than platinum and gold.

Photolithography as Toolbox for Carbon MEMS

The embracing of photolithography to fabricate the precursor photoresist structure has brought significant advantages and enabled rapid and notable developments. Photolithography refers to patterning with light, since the chemical composition of the photoresist changes upon being exposed to light of specific wavelengths, usually 365 nm for SU-8. In SU-8, light starts a cross-linking reaction in the matrix that makes the exposed section less soluble in a developer. The photolithography mask, a patterned stencil that enables the selective pass of light, must then be designed accordingly to the desired final topography: transparent areas in the mask must correspond to the topography to be fabricated. Traditional photolithography of a negative-tone photoresist involves a set of basic processing steps: spin coating a photoresist on a substrate, soft bake to evaporate the casting solvent, exposure through the mask to initiate cross-linking, postexposure bake to finalize cross-linking, and developing to obtain the exposed topography. Optimization of specific steps in traditional photolithography protocols has enabled the fabrication of a number of structures detailed below. The use of electrospinning has also emerged as an alternative to spin coating to deposit nanoscaled polymer fibers on a substrate, either as bulk or as single fibers (Fig. 1).

The fabrication of high-aspect ratio carbon structures, like those shown in Fig. 1a, b, was the first milestone of Carbon MEMS technology. SU-8 was an ideal choice of precursor to achieve this, given its low absorbance of light at wavelengths above 360 nm and the possibility to implement very thick layers in a single spin-coating step. Multistep photolithography has been used to fabricate dense arrays of carbon electrodes of different shapes to be used for capacitors [20, 21], heaters [22], glucose sensors [23], batteries [24–27], bioparticle manipulation using electrokinetics [28–36], and cell scaffolding [37]. By varying the exposure setup and dose, wires and suspended plates can also

Carbon MEMS, Fig. 1 (**a**) High-aspect ratio carbon electrodes on planar connecting leads. SU-8 precursor structure was fabricated using two-layer photolithography. (**b**) Further example of high-aspect ratio carbon structures. (**c**) Tapered carbon structures fabricated using backexposure during photolithography. (**d**) Example of SU-8 wires suspended between carbon posts. The fibers were made with electrospinning and later carbonized (Reprinted from [16] with permission from Elsevier). (**e**) Wire arrays made using electron beam lithography. Reprinted from [19] with permission from Elsevier. (**f**) Example of a fractal structure after carbonizing a sol–gel polycondensation of resorcinol and formaldehyde (Reprinted from [14], with permission from Elsevier)

be manufactured. The implementation of a photolithography process on a releasable substrate or on a sacrificial layer leads to free-standing SU-8 structures which were used as micromolds after carbonization [38]. Only the carbonization of free-standing SU-8 structures leads to a true isometric shrinkage. Carbonization of precursor structures anchored to a substrate yields carbon structures with a slight distortion on their base. UV backexposure of an SU-8 layer through a transparent substrate, fused silica, for example, leads to the development of tapered structures resembling cones (Fig. 1). Exposure dose can be tailored to specify the taper of the angle [39]. SU-8 wires suspended between two posts were made in 2006 using electron beam lithography. After carbonization, a number of carbon wire arrays were obtained (Fig. 1e) [19]. Suspended carbon wires like those shown in Fig. 1d have also been made using electrospinning in recent years [16, 40–42]. Electrospinning was also used to deposit a fiber mat on a substrate which was then patterned using photolithography. The fibrous structures were then carbonized to obtain highly porous carbon structures [15].

Other methods to shape the precursor exist. For example, in 2009, carbon fractals and microspheres were obtained by pyrolyzing a sol–gel polycondensation of resorcinol with formaldehyde [14]. The amount of surfactant during sol–gel synthesis determined the size of the spheres and the eventual switch to fabricating fractal structures (Fig. 1f). Micromolding of parylene has also been used to fabricate high-aspect ratio carbon posts [43].

Shrinkage

Carbonization is the process by which solid residues with a high content of carbon are obtained from organic materials, usually by pyrolyzing them in an inert atmosphere. The degree of shrinkage and carbon yield, the ratio of the weight of carbon to the weight of the original polymer sample, varies depending on the choice

of carbon precursor, its degree of cross-linkage, and its shape. For example, SU-8 features a carbon yield of 35–60 % [39]. The variability seems to depend on the shape of the precursor micro- or nanostructure.

In the case of Carbon MEMS, carbonization usually takes place in a furnace under a nitrogen, vacuum of forming gas atmosphere under a flow around 2000 ml/min. The carbonization protocol features three stages: (1) a temperature ramp from room temperature to 200–300 °C at 10 °C/min, followed by a 30 min dwell (this step is to completely eliminate the solvent and allow for any residual oxygen to be evacuated from the chamber and prevent combustion of the polymer as the temperature is raised further), (2) a temperature ramp to 900–1000 °C at 10 °C/min with a 1–4 h dwell, and (3) a natural cooldown to room temperature by turning the furnace off. Carbonization is a complex process with many reactions taking place concurrently, including dehydrogenation, condensation, hydrogen transfer, and isomerization. The pyrolysis process of organic compounds can be divided into three major steps: (1) pre-carbonization, (2) carbonization, and (3) annealing. During pre-carbonization ($T < 300$ °C), molecules of solvent and unreacted monomer are eliminated from the polymeric precursor. The next step, carbonization, can be further divided into two substages: (a) from 300 to 500 °C, when heteroatoms such as oxygen and halogens are eliminated causing a rapid loss of mass while a network of conjugated carbon systems is formed and hydrogen atoms start being eliminated, and (b) from 500 to 1200 °C, where hydrogen, oxygen, and nitrogen atoms are almost completely eliminated and the aromatic network is forced to become interconnected. At this point, permeability decreases and density, hardness, Young's modulus, and electrical conductivity increase. The carbon content of the structures carbonized at 900 °C is expected to exceed a mass fraction of 90 % in weight. At $T \sim 1300$ °C, more than 99 % carbon can be found. Annealing is usually carried out at temperatures above 1200 °C to allow for the gradual elimination of any structural defects and evolution of any further impurities.

Applications

Several applications have been demonstrated using Carbon MEMS. Some examples include the development of 3D architectures for lithium-ion batteries [24, 25], carbon plates in PEM fuel cells derived from machined polyimide [44, 45], post arrays which were electrochemically activated or decorated with carbon nanotubes to achieve supercapacitors [20, 21], and the development of carbon microspheres and fractal-like structures for sensors and batteries [14]. Other sensor applications include post arrays for rapid quantification of glucose in low concentrations [23] and interdigitated arrays with very narrow gaps to implement redox-based detection of dopamine with an amplification factor up to 25 [46]. C-MEMS devices have also been used as substratum for cell growth [47] and as carbon scaffolds to induce stem cell differentiation [37]. Extended arrays of carbon posts have been integrated in flow-through microfluidic devices to implement high-throughput cell separation and manipulation using electric fields in a technique now known as carbon-electrode dielectrophoresis [28, 29, 48]. This technique has been used to purify viable bacteria from an antibiotic-treated sample [31], to implement a sample preparation step that increases the sensitivity of traditional PCR protocols [34], and to extract DNA from a sample [32]. The combination between centrifugal microfluidics and carbon-electrode DEP marked an important step toward a sample-to-answer diagnostic platform [30]. Particle transport using electric fields has also been implemented [36], as well as high-throughput electrical lysis of different cells [33]. Other applications include the use of Carbon MEMS techniques to fabricate robust, inexpensive carbon shapes for the micromolding of bulk metallic glasses [38, 49].

Future Directions of the Field

Although most of the Carbon MEMS work has been done using SU-8 photoresist and photolithography, there is a strong interest on using different precursors, including biopolymers [50].

Development of techniques for shaping these precursors in the micro- and nanoscale will be needed, i.e., extrusion-based additive manufacturing. Electrospinning has been gaining importance as a technique to fabricate precursor nanostructures and is expected to be developed further. A broader use of composites is also expected: the patterning of SU-8-CNTs composites has been published [21] and preliminary work has also been disclosed using SU-8- silver and SU-8-silica composites. The use of catalysts to lower the energy required for carbonization is also of high interest, as well as understanding the shrinking process.

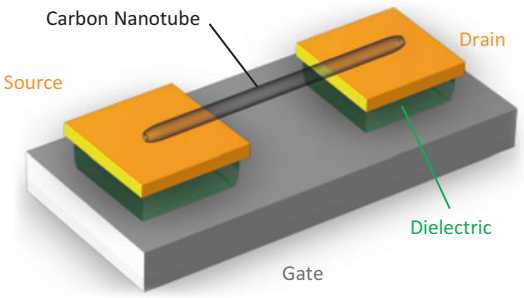
Definition

Carbon nanotube nanoelectromechanical systems (NEMS) are devices that combine the electrical and mechanical degrees of freedom in carbon nanotubes, the one-dimensional (1D) form of crystalline nanocarbon. It holds the record of the smallest NEMS made to date, with the part in motion being a single molecule – an individual carbon nanotube. The most common type of carbon nanotube NEMS device is carbon nanotube resonator, which generally assumes the geometry of a suspended carbon nanotube field-effect transistor (FET), with source and drain electrodes connecting both ends of the nanotube and a third nearby gate electrode forming a capacitor with the nanotube. The suspended segment of the nanotube can be actuated electrostatically by applying a bias voltage (DC, AC, or both) between the nanotube and the gate electrode, and the mechanical motion of the device can in turn be detected electrically by monitoring the electronic transport through the nanotube FET. Combining the outstanding electrical and mechanical properties of its building material, carbon nanotube NEMS devices exhibit, in several aspects, superior performance currently unavailable in NEMS based on other nanomaterials. In particular, leveraging the ultrasmall mass in motion, NEMS resonators based on carbon nanotubes have demonstrated extreme sensitivity to external stimuli (e.g., mass, force). In addition, the atomically perfect crystalline surface of carbon nanotube makes it a unique platform for studying surface physics processes. Together with the ultrahigh sensitivity to adsorbed mass, exotic phenomena have been observed using carbon nanotube NEMS, such as phase transitions in the pseudo-1D system formed by the adsorbed gas atomic layer on the surface of an individual carbon nanotube.



Introduction

Since its discovery, carbon nanotube (CNT) has been extensively studied for its outstanding physical properties. Structurally, CNT can be categorized into single-walled carbon nanotubes (SWCNT) and multi-walled carbon nanotubes (MWCNT). A SWCNT is a hollow cylinder whose entire surface (except the ends) is made of carbon atoms arranged in the graphitic hexagonal honeycomb lattice. It can be conceptually constructed by rolling a piece of graphene (a single layer of graphite) along one of the directions that allow the carbon atoms to seamlessly stitch to their counterparts on the opposite edge of the graphene sheet. Typical SWCNTs have diameter on the order of 1 nm. A MWCNT consists of multiple coaxial layers, with each layer being an individual SWCNT. Consequently, MWCNT generally has greater diameter and larger mass than SWCNT. Most carbon nanotube NEMS devices are constructed based on SWCNTs to take advantage of their small mass and diameter.

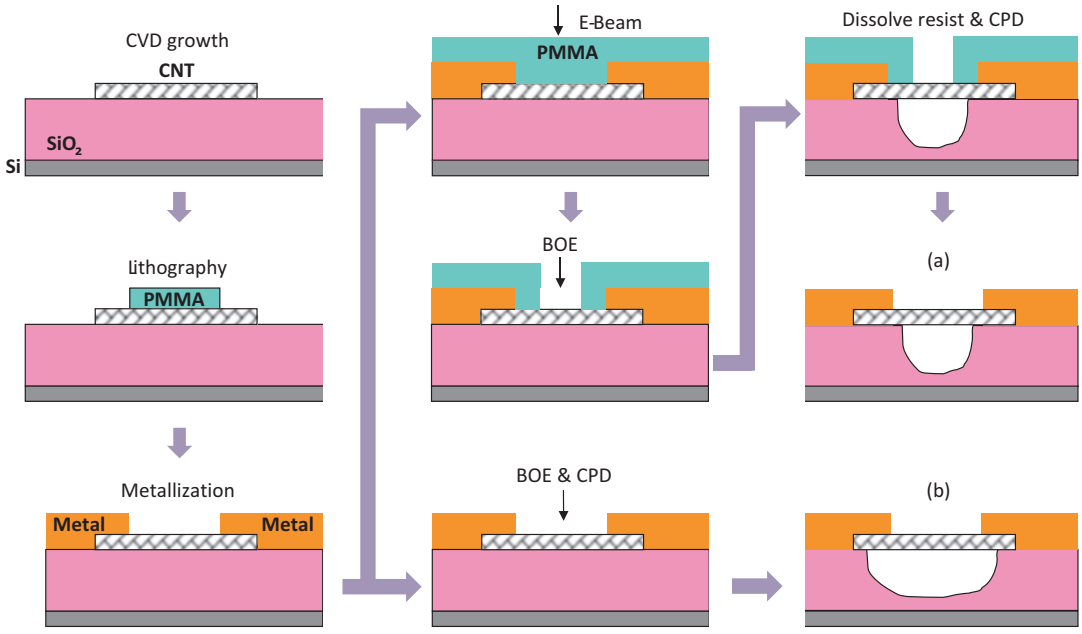
Nanoelectromechanical systems are devices that have both electronic and mechanical degrees of freedom, with one or more dimensions of the motional part being on the scale of 100 nm or less. The scaling down of the device dimensions can give rise to new physical phenomena and enhanced

functionalities. NEMS devices are often used for sensing, signal processing, and actuation at the nanoscale.

By having an individual carbon nanotube as the part in motion, CNT NEMS devices leverage the ultrasmall diameter/ultrahigh aspect ratio and ultralow mass of nanotubes, as well as their electronic properties (high current density, quantized and ballistic electronic transport, etc.) and mechanical (high flexibility, high elastic modulus, etc.) properties. While several NEMS based on multi-walled nanotubes utilize the interlayer motion to build linear [1] and rotational [2] bearings, the great majority of carbon nanotube NEMS devices are resonators [3–20] with the resonator body made entirely by a nanotube, with the first one [3] demonstrated in 2004. The rest of the article thus focuses on CNT NEMS resonators.

Carbon Nanotube NEMS, Fig. 1 Schematic of a carbon nanotube NEMS resonator/suspended-channel FET

Geometries/Structures

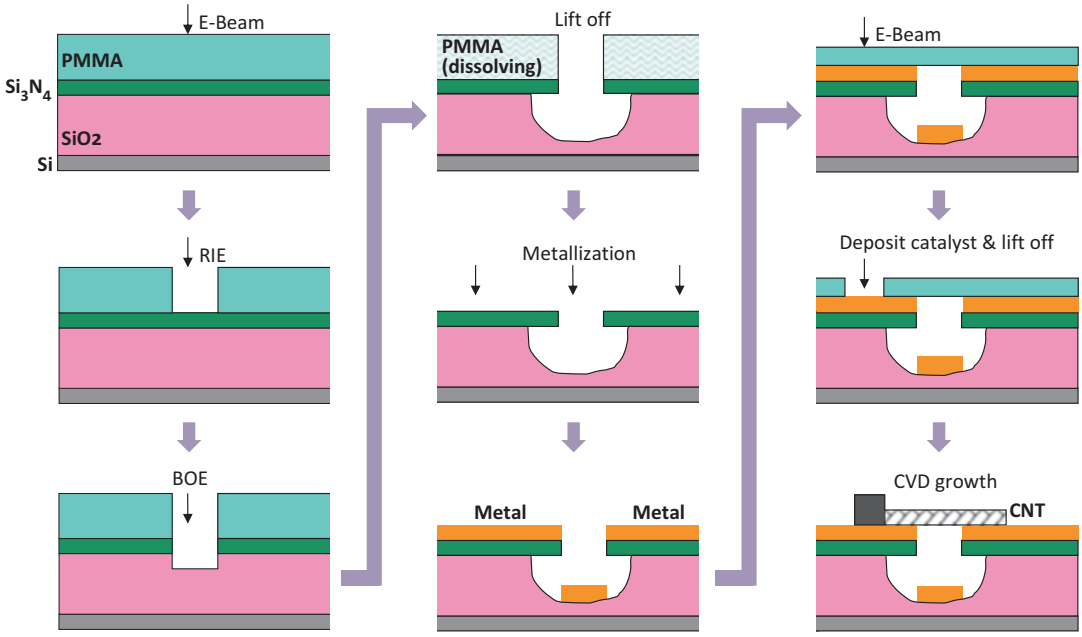


Most carbon nanotube NEMS resonators assume the geometries of a doubly clamped beam/string [3–18] and function as suspended-channel FETs (Fig. 1). The carbon nanotube is suspended over a microtrench and is mechanically anchored at both ends and electrically connected to the source and drain electrodes. In some cases, the electrodes themselves serve as the mechanical anchors for the nanotube (i.e., the nanotube is directly suspended between the two electrodes). The gate electrode is typically located underneath the nanotube (toward the bottom of the trench): a common configuration is to use the heavily doped Si back gate that extends the entire device die; alternatively, local gate at the bottom of the trench (through aligned deposition of metal layers) can also be used. Specially designed gate (e.g., side gate) has also been demonstrated in carbon nanotube NEMS [4].

A less common type of carbon nanotube NEMS takes the form of a singly clamped beam [19, 20]. To date, such structure has been realized using multi-walled carbon nanotubes (with the thinnest being double walled). Electrically, the nanotube is directly connected to one electrode (the clamp) and faces an opposing electrode which is not in contact with the nanotube. Additional gate electrodes along the length of the nanotube can also be used, even though they generally do not provide the canonical gating effect as in the FET structure (as the singly clamped structure does not facilitate electronic transport measurements). Compared with the doubly anchored suspended FET structure, the singly clamped beam structure presents some unique opportunities such as utilization of the field-emission properties of carbon nanotube, at the cost of forfeiting the access to carbon nanotube's electronic transport properties and the capability of electrostatically tuning the mechanical motion through gating, which are detailed in following sections.

Making Carbon Nanotube NEMS

There are a number of ways to fabricate doubly clamped carbon nanotube NEMS, which can be categorized into two main schemes: (i) grow/deposit carbon nanotube on the substrate first and then fabricate the suspended structure and (ii) fabricate the device structure first without carbon nanotube and then grow/transfer the nanotube onto the prefabricated structure.



Typical process flow for making doubly clamped carbon nanotube NEMS resonator using scheme (i) is illustrated in Fig. 2. First, carbon nanotube is grown on a SiO_2-covered Si wafer using chemical vapor deposition (CVD). Metal electrodes are then patterned on the carbon nanotube (either aligned to a selective nanotube or

Carbon Nanotube NEMS, Fig. 2 Schematic of fabricating doubly clamped carbon nanotube NEMS resonator using scheme (i), with two major categories of resulting device geometry (**a**) and (**b**) shown

patterned randomly but in a large array) through photolithography, electron-beam lithography, or contact (stencil) mask followed by electron-beam or thermal evaporation. Non-suspended carbon nanotube FET is obtained upon completion of the above steps. To suspend the electrically contacted nanotubes, often a second layer of aligned lithography is performed to open etch windows at locations where suspended segment of carbon nanotube is desired. Such etch window may or may not enclose part of the electrodes (i.e., the inner edges of the electrodes may or may not be exposed in the etch window). In some cases, the metal contacts themselves are used as etch masks, and the second lithography step (for open etch windows) is omitted. Once the etch window is defined, an etch step is performed to remove the underlying oxide in the exposed area to suspend the carbon nanotube. Buffered oxide etch (BOE) is most commonly used, often followed by critical point drying (CPD) to prevent the nanotube from collapsing and sticking to the bottom of the etching-formed microtrench (due to the capillary force during the drying process), while vapor HF etch is a practical alternative.

Depending on the size and geometry of the etch window, two major categories of device geometry can result from this fabrication scheme: (a) the nanotube segment between the metal electrodes is partially suspended in the middle section and clamped to the SiO_2 substrate on both sides and (b) the entire nanotube segment between the metal electrodes is suspended, and the electrodes themselves, while also serving as mechanical clamps for the suspended nanotube, are also partially suspended. Each geometry has its own unique attributes. In the former case (a), the mechanical clamp through van der Waals interaction with the SiO_2 is often sufficiently strong and provides good mechanical clamping, but the electronic properties measured between the electrodes contain information from both suspended and unsuspended segments. In the latter case (b), the entire electronic signal comes from suspended nanotube, but the suspended metal layer can be floppy and exhibit its own resonances during measurement. Note that due to the nondirectional nature of the etch processes (BOE or vapor HF), it is not practical to obtain devices where the boundary of the etched microtrench exactly aligns

Carbon Nanotube NEMS, Fig. 3 Schematic of fabricating doubly clamped carbon nanotube NEMS resonator using scheme (ii)

with the edge of metal electrodes, a third geometry which presumably possesses the advantages of both geometries (a and b) mentioned above.

Typical fabrication process for building carbon nanotube NEMS using scheme (ii) is shown in Fig. 3. The first part is to fabricate the device structure without the nanotube. It can be generally considered as the procedure as in scheme (i) without the nanotube growth at the beginning. Nevertheless, due to the absence of carbon nanotube, a number of things can be done differently. First, directional etch (such as RIE) of SiO_2 can be used instead of BOE or vapor HF, which can result in vertical sidewalls of the microtrench which can be aligned to the edges of the metal electrodes (e.g., using the metal as an etch mask). Second, the choice of supporting material for the carbon nanotube is expanded. For example, a Si_3N_4 can be added on top of the SiO_2 to facilitate undercutting of SiO_2 (which can result in substantially high aspect ratio structures) while providing strong mechanical support to the otherwise floppy metal electrodes [5]. These features are desirable for creating suspended carbon nanotube NEMS in the following step. For example, the undercut will prevent the nanotube from sticking to the SiO_2 microtrench sidewall during growth, yielding a higher suspension rate; and the nitride support will prevent metal from collapsing during the high-temperature growth process while also serving as a stiff clamp once the nanotube is suspended between electrodes. Once the device structure is prepared, a final step is performed to deposit carbon nanotube across the microtrench (and between the electrodes), often through CVD growth [5, 6]. Other techniques, such as stamp transfer, can also be used [7].

Both fabrication schemes have their advantages and limitations. In scheme (i), individual nanotubes can be identified, even characterized (such as using electronic transport and AFM), before additional effort is invested to turn it into a NEMS device by suspending the nanotube. In addition, with proper procedures (such as CPD), the success rate for achieving individual suspended devices is reasonably high, while the effort in making each device is substantial (as devices are fabricated on individual bases). In contrast, in scheme (ii), the device structures can be prefabricated at wafer scale, but for CVD growth, it requires an additional lithography

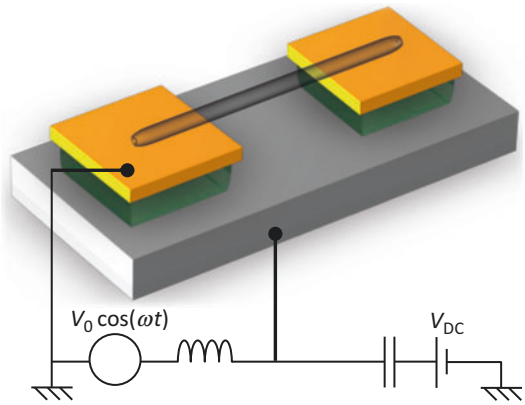
step to pattern the catalyst (otherwise, the randomly grown nanotubes could electrically short the electrodes), and the yield of the growth step (chances of obtaining an individual suspended carbon nanotube across a microtrench and bridging a pair of electrodes) is far from unity. Nevertheless, the large-scale processes (patterning and growth) largely make up for the total device yield. While the CVD growth may impose limitations on the material choice for metal electrodes (to sustain during the high-temperature growth), the nanotube transfer technique [7] offers a versatile alternative, as long as the nanotube-metal contacts are properly treated (such as annealing or use freshly deposited metal) to ensure good electronic performance.

Besides the abovementioned differences in device structures and materials between the two fabrication schemes, another important contrast is the cleanness of the carbon nanotube. In scheme (i), the nanotube undergoes a number of wet processes and is directly exposed to various chemicals (resist, polymer, etchant, solvent, etc.), which could lead to contaminants and defects on the nanotube surface. However, this does not necessarily preclude the resulting carbon nanotube NEMS device to exhibit certain desired performances, such as ultrahigh sensitivity to admass. Consequently, atomic-level mass sensing has been demonstrated on carbon nanotube NEMS resonators fabricated using this scheme [8–10]. In contrast, in scheme (ii), the carbon nanotube does not undergo any additional processing and thus can maintain its as-grown atomically perfect surface. Therefore, devices fabricated using this scheme are used in applications where pristine nanotube surface is required, such as studying transport in ultraclean suspended nanotubes or using nanotube as a substrate for investigating monolayer gas adsorption on low-dimensional surfaces [5, 11].

Singly clamped nanotube NEMS structures are often made by mounting the carbon nanotube onto a predefined structure, which often involves steps that are not compatible with standard nanofabrication processes, such as attachment of nanotube inside SEM/TEM. The fabrication is often performed at the level of individual devices and is thus highly labor intensive.

Actuation of Device Motion

To date, most nanotube NEMS resonators are operated in vacuum (mTorr or below), with a few measured in low pressure (a few Torr). The most common actuation scheme for carbon nanotube NEMS is electrostatic actuation through a gate electrode, which prevails in the doubly clamped device structure. In this configuration, the nanotube and its gate form the two electrodes of a capacitor. When a voltage is applied across the capacitor (with 0 net electric charge), an attractive electrostatic force is generated between the two electrodes, with its magnitude equal to



$$F = \frac{1}{2} C' V^2, \tag{1}$$

where C' is a derivative of the capacitance with respect to the distance between its two electrodes and V is applied voltage. Accordingly, the nanotube is attracted toward the gate when a finite gate voltage exists and is driven into oscillation when an AC voltage is applied. For carbon nanotube NEMS resonators, when the driving signal is at the frequency of the device's natural frequency, mechanical resonance with enhanced amplitude ensues.

It is worth noting that in most cases, a DC voltage is applied in addition to an AC voltage (Fig. 4), and there are two main reasons. First, Eq. 1 shows that the driving force is proportional to V^2. If a pure AC voltage $V = V_0\cos(\omega t)$ is applied, $F \propto V^2 \propto \cos^2(\omega t) = (1 + \cos(2\omega t))/2$, which has no $\cos(\omega t)$ term. This suggests that the device will be driven at 2ω instead; thus, the response will be more complicated than that of a simple harmonic resonator. Instead, when a DC component V_{DC} is included, $V = V_0\cos(\omega t) + V_{\mathrm{DC}}$, then

$$\begin{aligned} F \propto V^2 &= (V_0 \cos(\omega t) + V_{DC})^2 \\ &= V_{DC}^2 + 2V_{DC}V_0 \cos(\omega t) \\ &\quad + V_0^2 \cos^2(\omega t), \end{aligned} \tag{2}$$

which, in the case of $V_{\mathrm{DC}} \gg V_0$ (which is often the case), the driving force is mostly at 1ω. Second, Eq. 2 shows that there will be a static term ${V_{\mathrm{DC}}}^2$ in the force applied. Due to the ultra-flexibility of

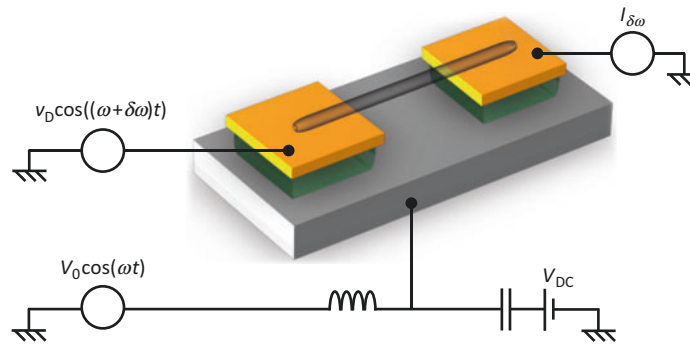
Carbon Nanotube NEMS, Fig. 4 Electrostatic actuation of doubly clamped carbon nanotube NEMS resonators

carbon nanotube (in comparison with thicker devices with similar geometry, such as lithography-defined nanowires), this static force is capable of generating sufficient tension in the nanotube and significantly tuning its resonance frequency. It is not atypical for a resonance to be tuned by more than 200 % with just a few volts of DC gate voltage.

For singly clamped devices, a nearby electrode (similar to the gate electrode in the doubly clamped case) can be used to capacitively actuate the vibratory motion [19]. Resonant motion driven using electromagnetic wave has also been demonstrated [20]. Additionally, due to the ultrasmall mass of carbon nanotubes, it is possible to directly visualize their completely undriven thermomechanical resonances in electron microscopes as a position-dependent blurring of the nanotube image. This has been observed for both singly and doubly clamped devices.

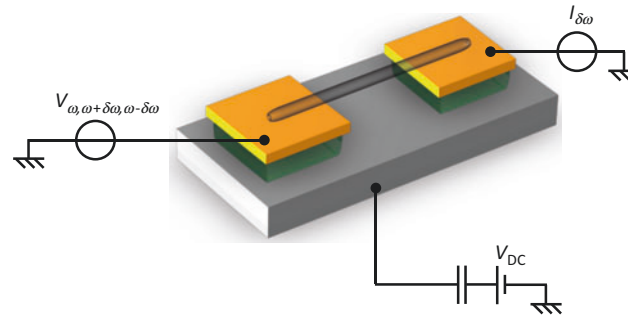
Readout of Device Motion

Electronic readout prevails in doubly clamped carbon nanotube NEMS resonators. This readout scheme utilizes the fact that motion-induced on-tube charge fluctuation modulates the conductance of the CNT FET and thus generates an oscillation in the amplitude of the electronic current through the device. Specifically, the device displacement δz induces a change in the nanotube-gate capacitance $\delta C = C'\delta z$, which leads to an additional on-tube electric charge δQ, which further leads to a modulation in the device conductance δG. Specifically, the charge variation can be expressed as



$$\delta Q = V_g \delta C + C \delta V_g. \quad (3)$$

The first term in Eq. 3 accounts for the motion-induced change in capacitance. When the device is mechanically on resonance, the motion amplitude increases substantially from the off-resonance background. Consequently, the first term surges at the device's resonance frequency. The second term represents the conventional gating effect in CNT FET devices and is present even in non-suspended devices. When the device is on resonance, the motion amplitude can be as large as several nm, while the vacuum gap to the gate is typically 100 s of nm. The change in gate capacitance (δC) is therefore only $2 \sim 3$ orders of magnitude smaller than the static gate capacitance of the nanotube, which is sometimes on the same order of magnitude as the $\delta V_g / V_g$ ratio. Consequently, the contribution of both terms in Eq. 3 ($V_g \delta C$ and $C \delta V_g$) can be on the same order of magnitude when the device is on resonance, and the mechanical resonance is often manifested as a sharp feature on top of a slowly varying background.



However, such current fluctuation – which is at the same frequency as the device motion – is often masked by the capacitive current generated by the electrostatic driving signal on the gate, which is also at the same frequency, but at a much larger amplitude, due to the large parasitic capacitance from the electrodes (including the wire bonding pads), which is typically several orders of magnitude larger than the nanotube's capacitance.

To overcome this challenge, frequency downmixing technique is often used to extract the motion-induced signal from the large capacitive background. There are two types of mixing techniques: one uses amplitude modulated (AM) signal and the other one uses frequency modulation (FM).

The basic operation principle of AM downmixing roots from a two-source mixing technique [3], which is illustrated in Fig. 5. In this setup, two

Carbon Nanotube NEMS, Fig. 5 Schematic of the two-source mixing setup for resonant motion readout

Carbon Nanotube NEMS, Fig. 6 Schematic of the one-source (*AM*) mixing setup for resonant motion readout

radio-frequency (RF) signals offset by a small frequency difference $\delta\omega$ (typically in the kHz range) are applied to the gate and drain of the CNT FET, respectively. The RF signal at frequency ω generates a nanotube motion at the same frequency and thus the modulation of device conductance: $\delta G = \delta G_0 \cos(\omega t)$. The drain bias applied is at a slightly different frequency: $V_{\text{Drain}} = V_{\text{D}} \cos((\omega + \delta\omega)t)$. The modulation in the current through the nanotube FET is therefore

$$\begin{aligned}\delta I &= V_{\text{Drain}} \times \delta G \\ &= \delta G_0 V_{\text{D}} \cos\left((\omega + \delta\omega)t\right) \cos\left(\omega t\right) \\ &= \delta G_0 V_{\text{D}} (\cos\left((2\omega + \delta\omega)t\right) + \cos\left(\delta\omega t\right))/2\,,\end{aligned} \tag{4}$$

which has a term at the difference frequency $\delta\omega$ and still carries the information of the device motion (through the term δG). In contrast, the capacitive current, though still much larger in amplitude, remains purely at frequency ω. Using a lock-in amplifier referenced at the difference frequency $\delta\omega$, it is possible to reject the electronic signal from all other frequencies and detect the device motion (at ω) by examining the down-mixed FET current at $\delta\omega$.

The AM mixing technique simplifies the two-source scheme by requiring only one RF signal source (Fig. 6). The output of the RF source is AM modulated at the lock-in reference frequency $\delta\omega$ and is applied to the drain electrode

$$V_D = (1 + A\cos\left(\delta\omega t\right))V_0 \cos\left(\omega t\right), \tag{5}$$

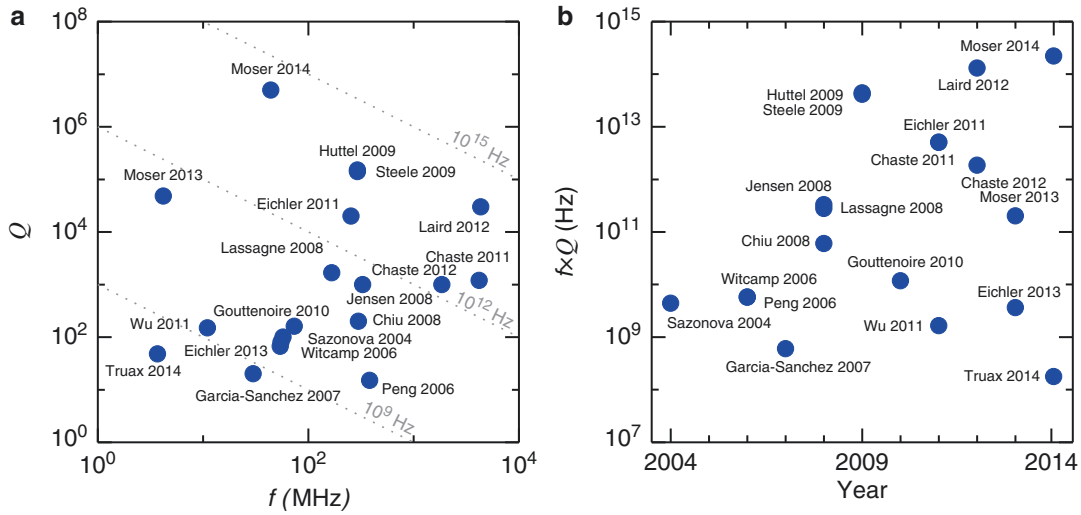
which has components at the frequencies ω, $\omega + \delta\omega$, and ω-$\delta\omega$. A is the modulation depth and ranges between 0 and 100 % (values close to 100 % are often used). The gate voltage only carries a DC component in this case. The AC component on the drain effectively creates an alternating bias voltage between the nanotube and the gate and drives the vibration of the nanotube. When considering the motion of the nanotube resonator, this is equivalent to applying these three AC components at the gate. Thus, the AM

scheme is equivalent to the two-source setup, with both the conductance modulation and the drain bias having components in ω, $\omega + \delta\omega$, and ω-$\delta\omega$. Consequently, the mixing current has low frequency components at DC, $\delta\omega$, and $2\delta\omega$. Typically, the $\delta\omega$ component is being measured by the lock-in amplifier.

In the AM readout scheme, even though the capacitive current from the contacts are removed through frequency down-mixing, the non-motional current (the second term in Eq. 3) has a finite term at $\delta\omega$, which presents a frequency-dependent background, and can sometimes hinder the observation of mechanical resonance. The FM readout scheme [12], a later-developed technique, removes this non-motional mixing current in addition to the capacitive current, allowing more efficient detection of mechanical resonance.

For singly clamped devices, direct electronic readout is unavailable as the nanotube itself does not typically form a closed path in the circuit. One can force the open circuit to close by using the nanotube as a field emitter by applying a high voltage across the tube and an opposing cathode and monitor the field-emission current as the nanotube vibrates. Such readout scheme can be destructive, and irreversible shortening of the nanotube due to the large current has been observed [20]. Alternatively, the vibrational amplitude can be estimated directly through imaging in electron microscope. While in such scheme quantitative measurement remains very challenging, imaging offers the opportunity of directly observing the mode shape of the individual resonances, similar to AFM measurements [13].

Frequency Tuning



The resonance frequency of carbon nanotube NEMS resonator can often be effectively tuned via adjusting the DC gate voltage. There are two main effects involved: electrostatic tensioning, which leads to an increase in resonance frequency as V_g is increased, and capacitive softening, which has the opposite effect.

For doubly clamped devices, the attractive force resulting from the application of gate bias induces tension in the nanotube and thus increases its resonance frequency. The magnitude of the gate voltage affects the elastic regime in which the nanotube NEMS resonator operates [3]. At small gate bias, the flexural rigidity dominates, and the nanotube vibrates as a bending beam. As V_g increases, the flexural rigidity is overcome by the electrostatic force from the gate, and the nanotube operates as a hanging chain that cannot be elongated (i.e., the chain has negligible flexural rigidity but infinite extensional rigidity). As the gate voltage further increases, the extensional modulus becomes important, and the nanotube behaves like an elastic string. In these different regimes, the frequency has different dependences on the gate voltage.

Due to the large aspect ratio of carbon nanotube, it is common for the suspended segment in a doubly clamped device to exhibit finite slack (i.e., the length of the nanotube is longer than the distance between its two clamping points). It is worth noting that the amount of initial slack affects how the frequency increases with V_g in the different regimes, and such effect further depends on individual resonant modes [3, 14].

Capacitive softening roots from the fact that the nanotube is vibrating in a nonuniform electric field, and the finite field gradient reduces the restoring force toward the equilibrium position (a negative effective spring constant). With finite slack, the nanotube can thus have both in-plane and out-of-plane resonant motion, which exhibit different responses to the capacitive softening effect [4], as the observation of such effect requires the device motion be in the direction of the electric field gradient.

Unlike in doubly clamped devices, tension cannot be easily introduced in singly clamped nanotube NEMS resonators. Thus, such device typically operates in the bending regime, and the use of multi-walled nanotubes (with greater bending rigidity) can help achieve higher resonance frequencies. Further, the gate tuning effect, though it exists, is much smaller than in doubly clamped devices in which tension can be effectively introduced.

Carbon Nanotube NEMS, Fig. 7 Partial summary of (**a**) f_{res}, Q and (**b**) $f_{res} \times Q$ for carbon nanotube NEMS resonators studied between 2004 and 2014. *Dashed lines* in (**a**) represent contours of constant $f_{res} \times Q$

Device Performances

For NEMS resonators, two important device parameters are the resonance frequency f_{res} and quality factor Q. While f_{res} can be effectively turned by gate voltage, within the commonly used V_g range (on the order of ± 10 V), the f_{res} variation is generally within one order of magnitude. In contrast, other device parameters, such as dimension and initial tension, have much larger effects on f_{res}. Specifically, shorter devices have higher f_{res} (e.g., $f_{res} = 4.2$GHz for an 110-nm-long nanotube resonator [15], while $f_{res} = 4.2$ MHz for a 4-μm-long device made by the same group of researchers [16]), and devices with lower tension can have very low f_{res} (e.g., $f_{res} = 3.7$ MHz for a 1.89-μm-long nanotube suspended over a MEMS structure which can introduce slack/reduce tension in the nanotube in a controlled way [17]).

The quality factor of carbon nanotube resonators typically increases as temperature decreases: Q ranges between $10^1 \sim 10^3$ at room temperature, and increases to $10^1 \sim 10^6$ at cryogenic temperatures, due to reduction of phonon-phonon scattering and suppression of electron motion (in the Coulomb blockade regime), two mechanisms that dissipate energy during the nanotube motion. Advancement in transduction techniques has further enabled electronic readout of the completely undriven thermomechanical motion of carbon nanotube NEMS resonators, and by removing external driving and electrostatic noise from the gate electrode, researchers have observed mechanical resonance with intrinsic Q up to 5×10^6 [18]. Figure 7a provides a partial list of f_{res} and Q for some of the nanotube resonators demonstrated between 2004 and 2014, and Fig. 7b shows how $f_{res} \times Q$, one of the most important figures of merit for NEMS devices, evolves throughout the decade.

Applications

Carbon nanotube NEMS resonators are highly sensitive to external stimuli due to the small mass and high flexibility of carbon nanotubes and are thus used in a number of sensing applications.

The resonance frequency of a NEMS resonator is sensitive to any adsorption on its surface, which increases the mass in motion (and thus decreases f_{res}). On the first order (not considering the mode shape of individual resonance modes and the detailed location of adsorbed mass), the frequency

shift δf due to adsorption of additional mass δm for a resonator with mass m is

$$\delta f = \frac{\delta m}{2m} f_{\text{res}}. \tag{6}$$

Given the same frequency resolution, a smaller resonator mass m leads to a finer adsorption mass resolution δm. Given the ultrasmall mass of an individual carbon nanotube (especially single-walled carbon nanotube), it is natural that CNT NEMS resonators are used for ultimate mass sensing. Initial works have achieved mass sensitivity of $10^{-21} \sim 10^{-22}$g [8, 9, 19], sufficient for resolving individual Argon atoms. From Eq. 6, it is also clear that a higher f_{res} leads to a higher frequency-to-mass responsivity (f_{res} shift per adsorbed mass). Consequently, years after the initial experiments, with improvement in device fabrication and transduction scheme, and very importantly, by using a carbon nanotube resonator with a much higher resonance frequency (f_{res} ~2GHz, one order of magnitude higher than in previous works), mass sensing at single proton level (10^{-24}g) has been demonstrated [10].

In addition to mass sensing, carbon nanotube NEMS resonators have also been used for ultrasensitive force detection. In contrast to mass sensing, where high f_{res} (which means short nanotube with high tension) is desirable, to achieve more sensitive force detection, the opposite is preferred. This is because long nanotubes with little initial tension have ultralow spring constant, and thus, its frequency can be highly sensitive to external forces which modify the spring constant of the resonator system. Using a 4-μm-long nanotube resonator with f_{res} as low as 4.2 MHz, researchers have demonstrated force sensitivity of $10^{-20}\text{N/Hz}^{-1/2}$ at cryogenic temperatures [16].

Compared with other NEMS structures fabricated using top-down techniques (such as lithography and etching), carbon nanotube resonator is unique in that the surface of the motional part (the nanotube) can be atomically well defined, especially for CNT NEMS fabricated using the growth-on-prefabricated-structure scheme. This offers the opportunity of exploring surface phenomena on a highly curved and atomically perfect surface, such as phase transition in the adsorbed monolayer on the nanotube surface. Historically, graphite surface has been the canonical platform for studying surface adsorption and phase behavior in two-dimensional adsorption systems, thanks to its simple and well-defined surface structure (the honeycomb pattern formed by carbon atoms). The surface of a single-walled carbon nanotube inherits the advantages of the graphite surface and offers a few additional properties unavailable in conventional two-dimensional (2D) graphitic surfaces: first, it is highly curved and thus imposes an additional boundary condition for the adsorbed layer (along the circumferential direction), and due to this strong confinement, the resulting adsorption system approaches the 1D limit; second, the significant reduction of carbon atoms (compared with those on and under conventional 2D graphitic surface) leads to decreased adsorption potential energy and thus can shift the equilibria of phase transitions in the adsorption system. When a phase transition takes place in the adsorbed atomic layer (which is accompanied by a sudden change in its density, as in 3D phase transitions), the mass of the resonator undergoes an abrupt change, which is reflected in a sudden shift in resonance frequency. Experimentally, phase transitions have been observed for Ar, Kr, and ^{4}He, with several low-dimensional phases, including commensurate phase – a phase specific to adsorption systems, in which the arrangement of adsorbate atoms conforms to the underlying substrate atoms – being identified [5, 11].

Besides sensing applications, carbon nanotube NEMS resonators have also been demonstrated as active components in RF circuits. Both singly clamped [20] and doubly clamped [12] structures have been used. In one example, researchers utilize the field-emission current from a singly clamped nanotube resonator to function the NEMS device as the antenna, tuner, amplifier, and demodulator in a radio. In another case, using the FM mixing technique, researchers demonstrate digital demodulation function with a doubly clamped carbon nanotube NEMS resonator, with data transfer rate meeting the GSM specifications.

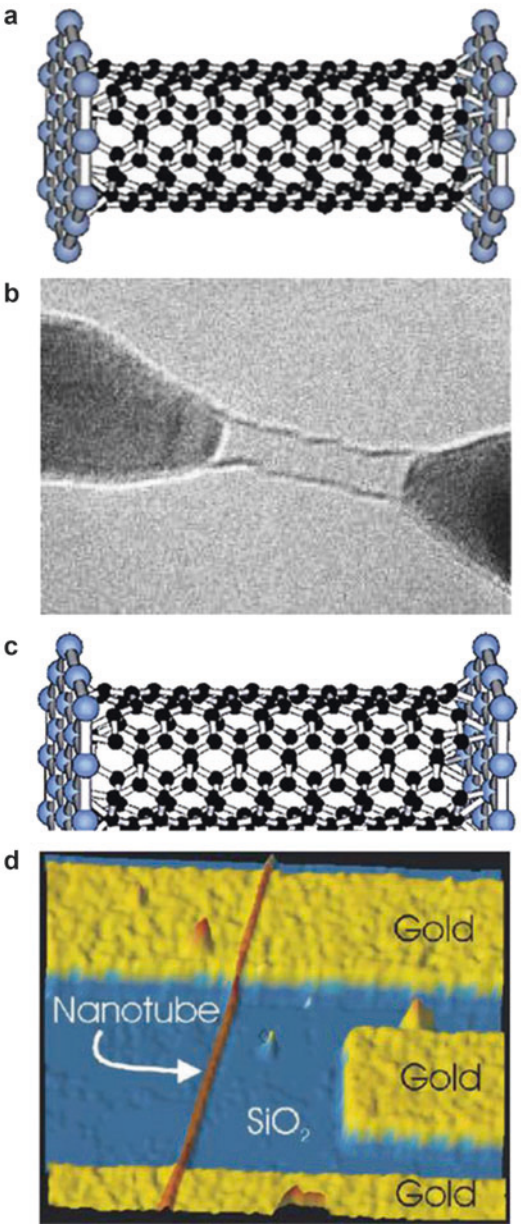
Carbon nanotube-metal interface

Definition

Carbon nanotube-metal contacts are widely present in many carbon nanotube-based nanodevices, and their electronic structures may significantly



influence the operation and performance of carbon nanotube-based nanodevices.

Overview

Carbon nanotubes (CNTs) are quasi-one-dimensional materials with remarkable mechanical and electronic properties promising a wide range of applications from field-effect transistors (FETs) and chemical sensors to photodetectors and electroluminescent light emitters. In most of these CNT-based nanodevices, metals are present as electrodes in contact with the CNTs. Many factors including the CNT-metal contact geometry, microscopic atomic details at the interface, and the resulting electronic structure can play a significant role in determining the functionality and performance of the devices. For instance, it has been demonstrated that an individual semiconducting CNT can operate either as a conventional FET or an unconventional Schottky barrier transistor, depending on the properties of the metal-CNT contact. In general, the electrical transport characteristics of the CNT-metal systems are sensitive to the choice of metal element as the electrode.

CNT-Metal Contact Geometry

There are two types of interface geometries of CNT-metal contacts, i.e., end contact and side contact [1, 2]. The end-contact geometry refers to the cases where metals are merely in contact with the open ends of one-dimensional CNTs, as illustrated in Fig. 1a. This contact geometry can be naturally achieved in the catalytic CVD growth of CNTs, where CNTs sprout from catalytic metal particles with the CNT axis normal to the metal surface. Figure 1b shows a sample experimental image of an end contact between a single-wall CNT and two Co tips in an in situ electron microscopy setup. The side-contact geometry refers to the cases where metals are in contact with the sidewall of CNTs, as illustrated in Fig. 1c. This contact geometry occurs when a CNT lays on the surface of a flat metal substrate. In most of CNT-based nanodevices, such as CNT FETs, metal strips are deposited from above to cover the CNTs laying on the surface as to build

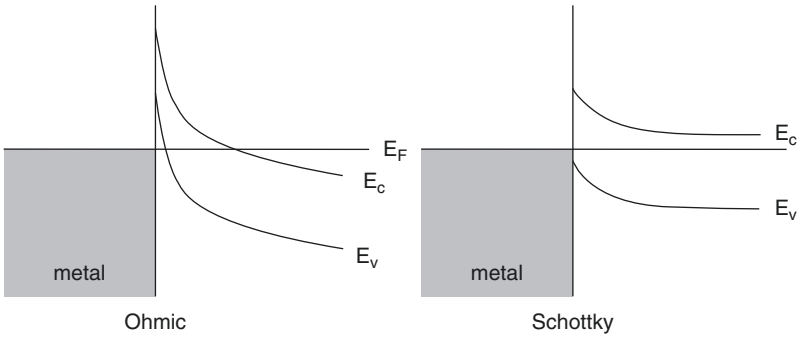
electrodes, fully covering sections of the CNTs, as shown in Fig. 1d. Among these two contact geometries, the side-contact geometry is more technologically relevant to CNT-based nanodevices.

Bonding and Wetting Properties of Metals on CNTs



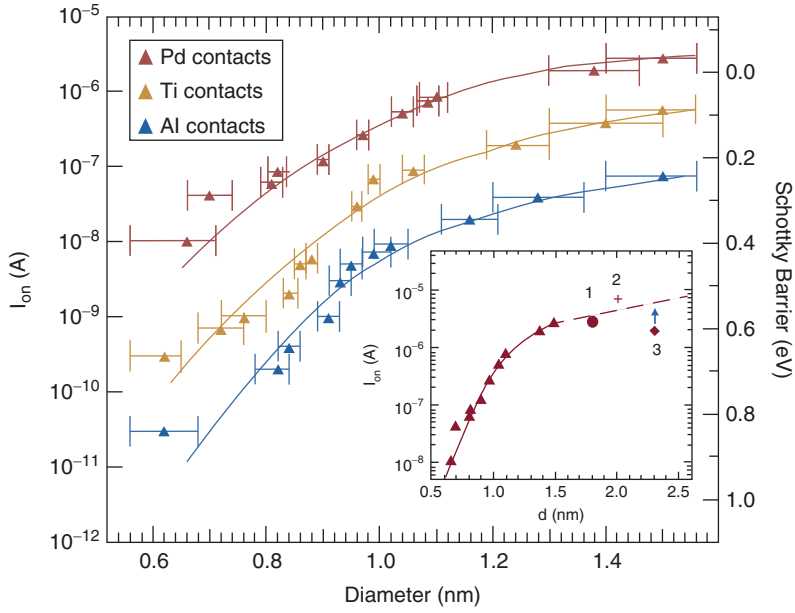
In the end-contact geometry, metals form strong covalent bonds with carbon atoms at the open ends of CNTs [5]. The bonding energy can be as high as, e.g., 7.6 eV for a single bond at a CNT–Co contact, according to density functional calculations. Due to the strong covalent nature of the bonding, large mismatch-induced strains or high tensile strength can be built up at the interface.

In the side-contact geometry, metals and CNTs form much weaker bonds due to the nearly chemically inert side walls of CNTs [5]. Single-wall CNTs are built up of a cylindrically closed sheet of graphene, in which carbon atoms arranged in a honeycomb structure form very stable *sp2*-hybridized covalent bonds with the *pz*-orbitals of carbon extending normal to the sidewalls. The interaction between metals and CNTs in the side-contact geometry is determined by the hybridization between the carbon *pz*-orbitals and the unbonded orbitals of the metals. Alkali and simple metals have binding energy around 1.5 eV per atom. Some transition metal atoms with unpaired *d* electrons, such as Sc, Ti, Co, Ni, Pd, Pt, form strong bonds with a binding energy around 2.0 eV per atom, whereas the transition metals with fully occupied *d* orbitals such as Cu, Au, Ag, and Zn have relatively weak binding with a binding energy less than 1.0 eV per atom. On the other hand, the binding energy of metal on CNTs also depends on the radius of CNTs. In general, the larger is the radius, the weaker the binding energy.

The wettability of metals on CNTs is critical to the electrical transport properties at CNT-metal contacts. In addition, CNTs can be used as templates to produce metallic nanowires with controllable radius by continuously coating the sidewalls of CNTs with metals. Experiments using different techniques such as electron beam evaporation, sputtering, and electrochemical approaches have achieved continuous coating of Ti and quasi-continuous coating of Ni and Pd on CNTs [5, 6]. Such metallic nanowires are ideal to be used as conducting interconnects in nanodevices. Metals such as Au, Al, Fe, Pb form isolated discrete clusters rather than a uniform coating layer on the surface of CNTs. Figure 2 shows sample TEM images of Ti, Ni, Pd, Au, and Fe coatings on CNTs [6]. The correlation between the wettability

Carbon Nanotube-Metal Contact, Fig. 2 TEM images of (**a**) Ti, (**b**) Ni, (**c**) Pd, (**d**) Au, (**e**) Al, and (**f**) Fe coatings on carbon nanotubes

Carbon Nanotube-Metal Contact, Fig. 3 A schematic illustration of the energy levels for an ohmic and a Schottky contact between a metal and a semiconducting CNT



of these metals and their binding energies on CNTs is clear, i.e., metals with relatively strong binding energies with CNTs tend to form uniform coatings.

Electronic Structures of CNT-Metal Contacts

The electronic structure of CNT-metal contacts has a significant impact on the operation and performance of CNT-based nanodevices [2]. Due to the one-dimensional nature of CNTs and their special contact geometries, CNT-metal contacts exhibit some unusual features when compared to traditional planar contacts.

For metallic CNTs, as in contact with metals, ohmic contacts are normally formed at the interface, where no interface potential barrier exists, and the contact resistance is primarily determined by the wettability of the metal and the local atomic bonding and orbital hybridization at the interface [2]. Palladium is found to be optimal as electrodes to make ohmic contacts with metallic CNTs.

Semiconducting CNTs form either ohmic contacts or Schottky barriers at the interface with metals [2]. Figure 3 schematically illustrates the energy levels for an ohmic and a Schottky contact between a metal and a semiconducting CNT. A distinctive feature of CNT-metal contacts from traditional planar metal/semiconductor interfaces is that the height of the Schottky barrier formed at CNT-metal contacts strongly depends on the work function of the metal for a given semiconducting CNT [7, 8]. In general, at traditional planar metal/semiconductor interfaces, the Schottky barrier height shows very weak dependence on the metal work function due to the so-called Fermi-level pinning effect [9]. The strong dependence of the Schottky barrier on the metal work function in CNT-metal contacts is attributed to the reduced dimensionality of CNTs, which entirely changes the scaling of charge screening at the interface, making the depletion region decay rapidly in a direction normal to the interface and thus significantly weakening the Fermi-level pinning effect [7]. Experimental and theoretical work has shown that the interface Schottky barrier regions are much thinner in one dimension than those in three dimensions. In this case, charge carrier tunneling through the Schottky barriers becomes important. Because of the involvement of tunneling and thermionic emission in the carrier transport at the interfaces, the dependence of the on-current of CNT transistors on the Schottky barrier becomes very strong. Figure 4 shows experimental CNT-FET on-current and Schottky barrier height as a function of the CNT diameter for three different metal electrodes, Pd, Ti, and Al [8]. When the metal work functions are in the valence or conduction band of the semiconducting CNTs, ohmic contacts will likely be formed at the interface. Experimental measurements have shown that certain metals with high work functions, such as Pd, can produce nearly ohmic contacts with semiconducting CNTs. Ohmic contacts are more desirable in devices where contact resistance needs to be minimized. In addition to the metal work function, other factors, such as the

Carbon Nanotube-Metal Contact,
Fig. 4 Experimental CNT-FET on-current (*left axis*) and computed Schottky barrier height (*right axis*) as a function of the CNT diameter for three different metal electrodes, Pd, Ti, and Al

contact geometry and the chemical bonding at the interface also play important roles in the transport properties of CNT-metal contacts.

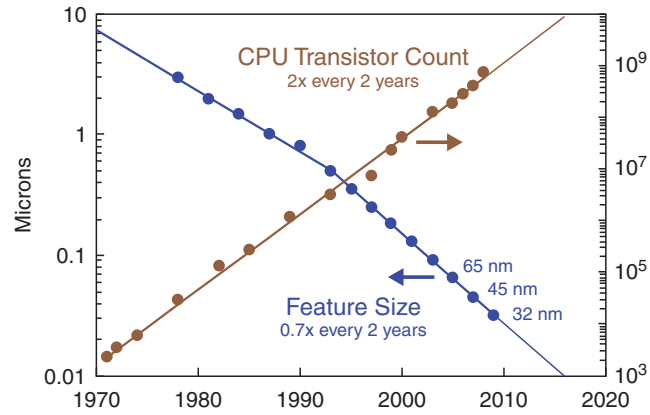
Carbon nanotubes for interconnects in integrated circuits; Carbon nanotubes for interconnects in microprocessors

Definition

Chip interconnections electrically connect various devices in a microprocessor. Today's established technology for interconnects is based on copper. However, it may be technically challenging to extend copper use to future interconnects in microprocessors with smaller lithographic dimensions due to materials properties limitations. Carbon nanotubes are currently investigated as a potential replacement for future integrated circuits (microprocessors). Although carbon nanotubes are a clear winner against copper in terms of materials properties, multiple fabrication challenges need to be overcome for carbon nanotubes to enter the semiconductor fab and replace copper for chip interconnections.

Motivation



Following over 40 years of successful fulfillment of Moore's law, stating that the number of transistors in a chip doubles every 2 years, we have already moved from microelectronics to nanoelectronics [1]. Although the *"end of scaling"* has been predicted many times in the past, enormous technical challenges, especially quantum mechanical issues and billion-dollar lithography investments, are a serious threat to further miniaturization (Fig. 1).

Today's latest processors are manufactured using the 32-nm technology. To move toward the 22-nm node and beyond, issues such as lithographic limitations, leaking currents in ultra-thin dielectrics (only a few monolayers thick), insufficient power and thermal dissipation, and interconnect reliability must be resolved [1]. At the transistor level, the performance is negatively affected by increased off-state currents due to short channel effects, increased gate leakage due to tunneling through nanometer-thin dielectric layers, and increased overall gate capacitance due to decreasing gate pitch.

Although quantum mechanical tunneling and leakage currents may eventually stop further scaling, efficient heat removal from a chip is currently the biggest obstacle. In this respect, the many kilometers of copper interconnects present in today's chips are the main culprit for heat generation. For instance, in 2004, Magen et al. [2] showed that for a microprocessor fabricated with the 0.13-μm-node technology consisting of 77 million transistors, interconnects consumed more than 50 % of the total dynamic power. Given the increased length of interconnects, their reduced cross section, and the increased current densities circulating into the interconnects of our latest chips, the problem has been further exacerbated.

Additionally, copper interconnects are a major contributor to the total resistance-capacitance (RC) delay of the chip, can fail by electromigration, and need a liner to avoid diffusion into the silicon. Bottom line, the interconnect issue is so serious that the International Semiconductor Roadmap [3] (ITRS, an expert team assessing the semiconductor industry's future technology requirements for the next 15 years) indicates copper interconnects as a possible dealbreaker to further miniaturization for IC nodes beyond 22 nm.

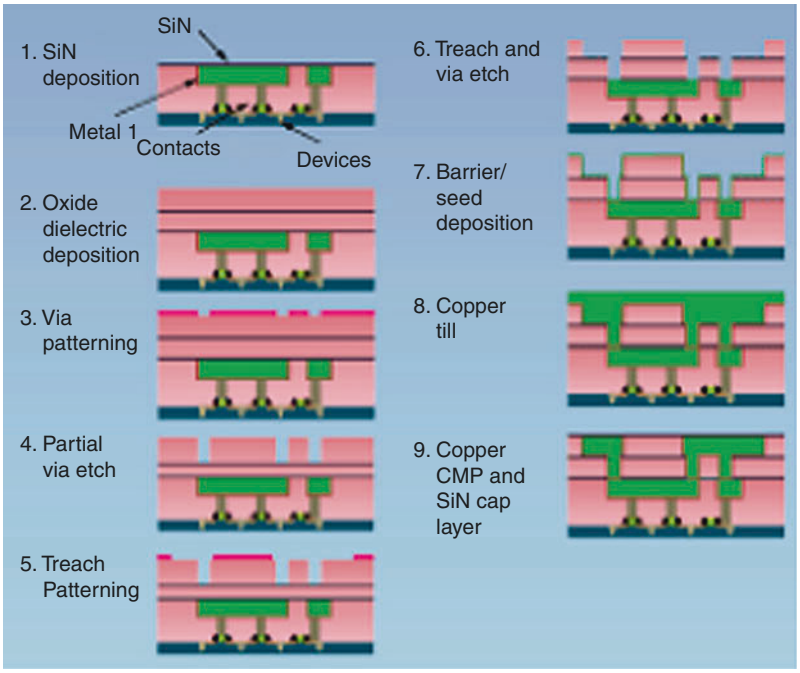
Many technology options are currently under investigation to replace copper for interconnects. Among them, we can mention other metals (mainly silicides), wireless, plasmonics, and optical interconnects. Most notably, there has been an intense research effort on new nanotechnology materials such as carbon nanotubes, which, at

Carbon Nanotubes for Chip Interconnections, Fig. 1 Moore's Law: Transistor count has doubled while feature size has decreased by 0.7X every 2 years (Figure reprinted with permission from Kuhn [1])

the theoretical level, could solve all the above technical issues suffered by copper.

The plan of this section is to first introduce the reader to copper interconnects' fabrication and limitations. Next, we will compare copper to carbon nanotubes (CNTs) and detail possible models for implementation. An important paragraph will focus on the state-of-the-art of CNT fabrication, prior to concluding on the outstanding issues and outlook for future CNT-based chip interconnections.

Background on Copper Interconnects and Dual-Damascene Process



In 1997, IBM introduced the revolutionary *"dual-damascene"* process to fabricate copper interconnects and to replace aluminum interconnects, the industry standard at the time. Compared to aluminum, copper presents two major advantages: (1) 50 % lower resistivity (Cu ≈ 1.75 μm cm vs. Al ≈ 3.3 μm cm) and (2) higher current densities before failure by electromigration (up to 5×10^6 A/cm^2) [4, 5]. Although, as a material, copper was a clear winner against aluminum, fabrication challenges delayed its introduction. Historically, we may be at a similar juncture with carbon nanotubes compared to copper as we were with copper compared to aluminum in 1997: in spite of their superior materials properties, mainly fabrication issues are now preventing the introduction of nanotubes in the semiconductor industry to replace copper interconnects.

Copper diffuses into silicon, generating mid-gap states that significantly lower the minority carrier lifetime and which lead to leakage in diodes and bipolar transistors. Copper also diffuses through SiO_2 and low-k dielectrics, and therefore requires complete encapsulation in diffusion barriers. Since no dry etches were known for copper, IBM's bold innovation of polishing using chemical mechanical polishing (CMP), after electroplating the copper, was significantly at odds with the technological processes at that time in semiconductor fabrication.

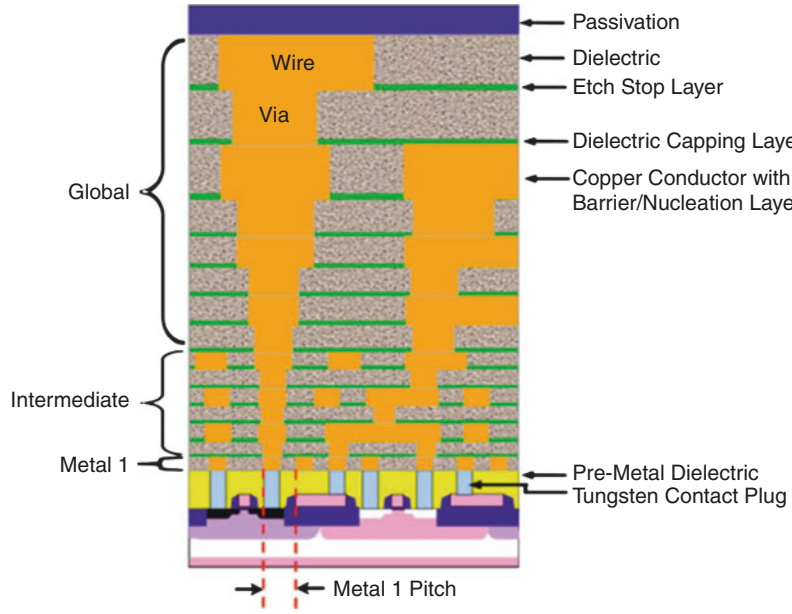
The copper dual-damascene process consists of the following steps:

- Develop a pattern for wires or vias by patterned etching of the dielectric.
- Deposit a barrier layer (usually Ta) to prevent copper diffusion into silicon.
- Deposit a copper seed layer.
- Fill the vias with copper using electrodeposition.
- Remove excess copper using CMP.
- Repeat the process to lay the alternating layers of wires and vias which will form the complete wiring system of the chip (Fig. 2).

Typical microprocessor design follows a *"reverse scaling"* metallization scheme with multiple layers of interconnects labeled as local, intermediate, and global interconnects, with increasing width. Very thin local interconnects locally connect gates and transistors within a functional block and are usually found in the lower two

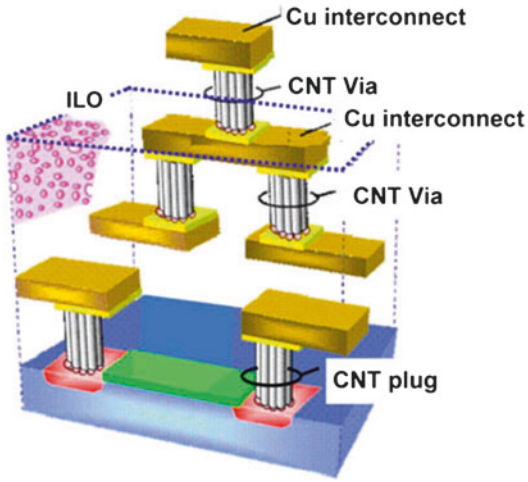
Carbon Nanotubes for Chip Interconnections, Fig. 2 Dual-damascene process of copper filling an interconnect via (Figure reprinted with permission from Jackson et al. [21])

metal layers. The wider and taller intermediate interconnects have lower resistance and provide clock and signal within a functional block up to 4 μm. Global interconnects are found at the top metal layers and provide power to all functions in addition to connecting functional blocks through clock and signal. They are usually longer than 4 μm (up to half of the chip perimeter) and exhibit very low resistance to minimize RC delay and voltage drop. Below are a typical cross section of an I.C. chip and a possible implementation using CNTs (Figs. 3 and 4).



Limitations of Copper Interconnections

Copper interconnects have efficiently scaled down to the current 32-nm-node microprocessors, although this has required many technological advances to allow ever-shrinking copper cross sections to carry increasing currents without failure. However, we may be very close to smashing against a technical wall because of materials failure and related fabrication issues.



Alternative materials or technologies would require many changes in semiconductor fabrication and massive investments; thus the large semiconductor companies are doing the impossible to extend copper application to future nodes. It is clear that only when up against an insurmountable technical wall will the semiconductor industry switch to a new technology.

Electrical resistance is a major issue now that copper interconnect cross sections are comparable to the mean free path of electrons in copper (~40 nm in Cu at room temperature). Grain boundary and surface scattering are significant contributors to the increased resistance, especially now that we have reached nanoscale dimensions. At the microstructural level, the grain boundaries play an important role, hence, among other fabrication concerns, controlling the copper grain size during electrodeposition has allowed to limit the grain boundary scattering impact thus far.

The steep rise in interconnect resistance for smaller IC nodes is a major source of RC delays and directly affects the chip reliability by increasing the risk of electromigration failure, a major issue for further downscaling. Electromigration is the transport of material caused by the gradual movement of the copper ions due to the momentum transfer between conducting electrons and

Carbon Nanotubes for Chip Interconnections, Fig. 3 Typical cross sections of hierarchical scaling in current microprocessor (Figure reprinted with permission from the Semiconductor Industry Association [22])

Carbon Nanotubes for Chip Interconnections, Fig. 4 Schematic view of possible implementation of carbon nanotube via interconnects in lieu of copper (Figure reprinted with permission from Awano et al. [7])

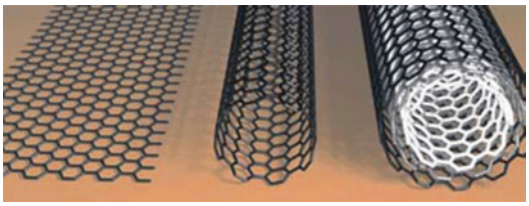
diffusing metal atoms, which occurs for high current densities, which can create voids leading to open circuits. Given that downscaling leads to a reduction of the interconnects' cross section, the problem is amplified at subsequently smaller nodes. To compound the issue, the need for a resistive diffusion barrier layer, also called a liner (usually Ta), to avoid copper diffusion into silicon, further reduces the available conductive copper cross section, thus increasing the risk of electromigration failure, especially as the operating temperature rises.

In addition to the increased resistance and the electromigration failure risk, many other aspects of the dual-damascene process are becoming potential sources of failure as the node shrinks. Among the many integration concerns, we can mention materials issues such as interface adhesion between the different materials (copper, low-k dielectrics, etc.), liner effectiveness, metal voids, CMP interface defects, etc. Concurrently, there is a long list of process-related issues such as the need for etch/strip/clean processes (to avoid damage to low-k dielectric materials), atomic layer deposition (ALD) processes to deposit liners, copper plating and CMP techniques, etc.

A few interesting numerical estimates taken from the 2009 projections from ITRS, [3] provide the reader with the magnitude of the technical challenge to extend copper interconnect technology (Table 1).

As already mentioned, many alternative technologies are currently being investigated for replacement of copper as interconnect material that would require significant chip redesigns and

Carbon Nanotubes for Chip Interconnections, Table 1 Selected critical parameters for copper use as interconnects in future IC nodes (Data from the Semiconductor Industry Association [22])



Year of production (estimated)	2010	2015	2020
MPU/ASIC metal 1½ pitch (nm) (contacted)	45	25	14
Total interconnect length (m/cm^2) – metal 1 and 5 intermediate levels, active wiring only	2,222	4,000	7,143
Barrier/cladding thickness (for Cu intermediate wiring) (nm)	3.3	1.9	1.1
Interconnect RC delay [ps] for a 1-mm Cu intermediate wire, assumes no scattering and an effective ρ of 2.2 μΩ-cm	1,132	3,128	9,206

new fabrication technologies. Some examples include optical interconnects, radio frequency (RF) interconnects, plasmonics, and 3-D interconnects (probably still copper). The interested reader can find more details on these alternative technologies in the review paper from Havemann et al. [6] (now a little dated) or in the latest ITRS report on interconnects [3].

The Case for Carbon Nanotube Interconnects

An interesting solution, which has been the subject of intense research in recent years, is to replace copper with carbon nanotubes. If a reliable and repeatable fabrication process consistent with Complementary Metal Oxide Semiconductor (CMOS) technology requirements could be developed, integration into existing chip architectures may not require significant process redesign (Fig. 5).

Carbon nanotubes, which can be visualized as rolled sheets of graphene, have been widely investigated as a promising new material for many electrical device applications [5, 7] (e.g., transistor (CNT-FET), interconnects) as they exhibit exceptional electrical, thermal, and mechanical

Carbon Nanotubes for Chip Interconnections, Fig. 5 Graphical representations of ideal graphene sheet, SWCNT, MWCNT (Figure reprinted with permission from Graham et al. [22])

properties [8]. When comparing materials properties, CNTs are a clear winner against copper. Studies show that CNTs are stable for current densities up to 10^9 A/cm^2, two orders of magnitude higher than copper. CNTs can exhibit multichannel ballistic conduction over distances of microns. Because of their higher chemical stability relative to copper, diffusion barriers (liners) are not needed for CNTs, thus allowing a larger conductive cross section compared to copper for the same technology node. Additionally, their mechanical tensile strength (100 times that of steel) and their high thermal conductivity (comparable to diamond) give CNTs an edge compared to copper. Finally, growing CNTs in high aspect ratio vias could allow the design of chips with higher interlayer spacing to reduce overall RC losses and to decrease chip-layer energy dissipation [9].

Before examining possible models of CNT-based interconnect architectures, it is important to clearly understand CNTs' electrical properties, which represent the most critical material limitation to resolve with respect to copper. The electronic band structures of single-wall CNTs (SWCNTs) and of graphene are very similar. For graphene and metallic SWCNTs, the valence band and the conduction band touch at specific points in the reciprocal space. For semiconducting SWCNTs, the conduction band and the valence band do not touch. Semiconducting SWCNTs have been extensively studied as channels in transistor devices while metallic SWCNTs have been considered for applications such as IC interconnects and field emission.

The resistance of a CNT contacted at both ends is the sum of three resistances [5, 10]:

$$R_{CNT} = R_Q + R_L + R_{CONTACT}$$

where R_Q is the quantum resistance, R_L is the scattering resistance, and $R_{CONTACT}$ is the contact resistance. We will now discuss these three resistances.

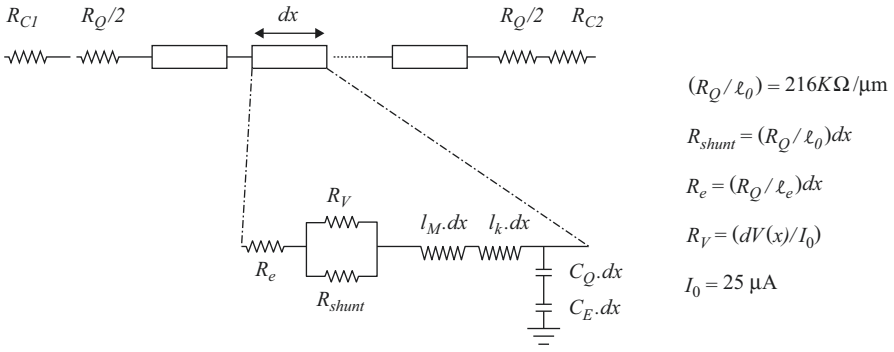
An ideal (defect-free) metallic SWCNT electrically contacted at both ends, in the absence of scattering or contact resistance, exhibits a resistance $R = 2R_Q \approx 13\,\text{k}\Omega$ as a SWCNT has two conduction channels. The quantum resistance $R_Q = 6.5\,\text{k}\Omega$ is due to the mismatch between the number of conduction channels in the nanotube and the macroscopic metallic contacts. The one-dimensional confinement of electrons, combined with the requirement for energy and momentum conservation, leads to ballistic conduction over distances in the order of a micron.

The scattering resistance is due to impurities or nanotube defects that reduce the electron mean free path, and depends on the length l of the SWCNT:

$$R_L = \frac{1}{2R_Q}\left(\frac{l}{l_0}\right)$$

For defect-free SWCNT lengths below a micron, we can neglect the scattering resistance.

The contact resistance, which results from connecting the SWCNT to a contact (usually metallic), depends strongly on the material in contact with the nanotube, and on the difference between their work functions. The work functions of multiwall CNTs (MWCNTs) and SWCNTs have been estimated to be 4.95 and 5.10 eV, respectively [10]. Palladium has been found to be one of the materials minimizing the contact resistance, better than titanium or platinum contacts (which exhibited nonohmic behavior when in contact with CNTs) [10].



For interconnect applications, most often bundles of SWCNTs are considered. It is important to note that the coupling between adjacent SWCNTs is negligible since, for defect-free SWCNTs, the electrons would rather travel along the SWCNT axis (ballistic path) than across SWCNTs because of the large inter-CNT tunneling resistance (2–140 MΩ) [10]. Thus, the resistance of a bundle of SWCNTs can be viewed as a parallel circuit of the resistances of the individual SWCNTs. If we have n SWCNTs, the resistance of the bundle will be:

$$R_{SCWNT\ bundle} = \frac{R_{SCWNT}}{n}$$

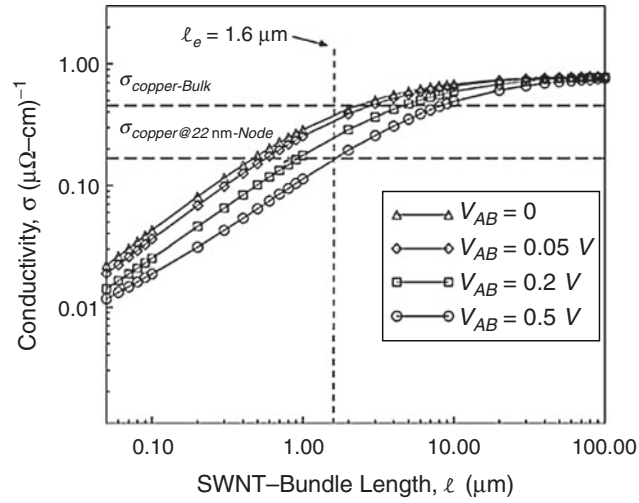
The above overview related to SWCNTs. The electrical properties of MWCNTs have not been as extensively studied because of the additional complexities arising from their structure, as every shell has different electronic characteristics and chirality, in addition to interactions between the shells [11]. Geometrically, the interwall distance in a MWCNT is 0.34 nm, the same as the spacing between graphene sheets in graphite. What still has to be clarified is how the conductivity of a MWCNT varies with the number of walls.

Initially, it was thought that the conductance of a MWCNT occurred only through the most external wall, which seems to be the case at low bias and temperatures, where electronic transport is dominated by outer-shell conduction. However, theoretical models and experimental results indicate that shell-to-shell interactions can significantly lower the resistance of MWCNTs with many walls [5, 10].

One view is that the conductivity of a MWCNT with n walls is simply n times the conductivity of a SWCNT. Li et al. [12] experimentally measured an electrical resistance of only 34.4 Ω for a large MWCNT with outer diameter of 100 nm and inner diameter of 50 nm (= > 74 walls). This value was much lower than the one that could be calculated assuming all walls participated separately in the electrical conduction (i.e., calculated as the parallel of the resistances for each wall) showing that interwall coupling contributes to additional channels of conductance. Naeemi et al. [13] also assumed intercoupling between CNT walls in their models to increase the channels of conduction with increasing number of walls. However, their conductance was lower compared to that measured experimentally by Li's team.

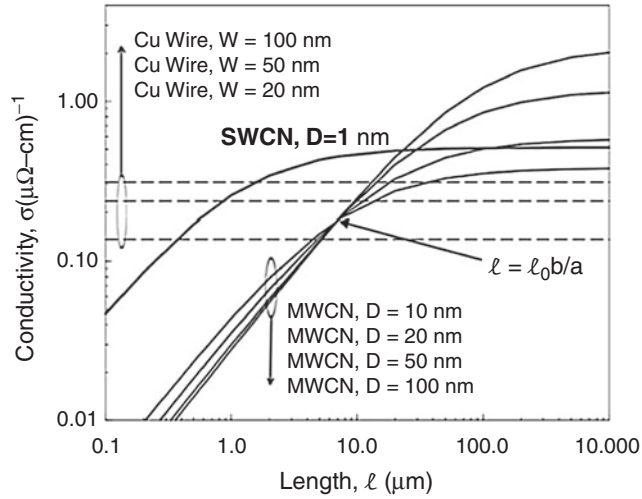
Carbon Nanotubes for Chip Interconnections, Fig. 6 Equivalent circuit model of metallic SWCNT used in HSPICE simulations (Figure reprinted with permission from Naeemi and Meindl [14])

Bottom line: The conductivity of MWCNTs increases with the number of walls but the exact relationship has not yet been exactly clarified.



Models of CNTs as Interconnects

Various studies investigated replacing copper interconnects with bundles of CNTs (SWCNTs or MWCNTs) or with one large MWCNT. A first approach consists of using densely packed SWCNTs. Modeling SWCNTs as equivalent electrical circuits and using SPICE simulations, Naeemi et al. [14] showed that a target density of SWCNTs of at least 3.3×10^{13} CNTs/cm^2 was required. Currently achieved maximum densities for CNTs in vias barely reach 10^{12} CNTs/cm^2, which is still an order of magnitude smaller than required. Furthermore, since statistically only one-third of the SWCNTs grown are metallic (the other two-third are semiconducting), the conduction of the bundle will only occur in the metallic SWCNTs (Fig. 6).

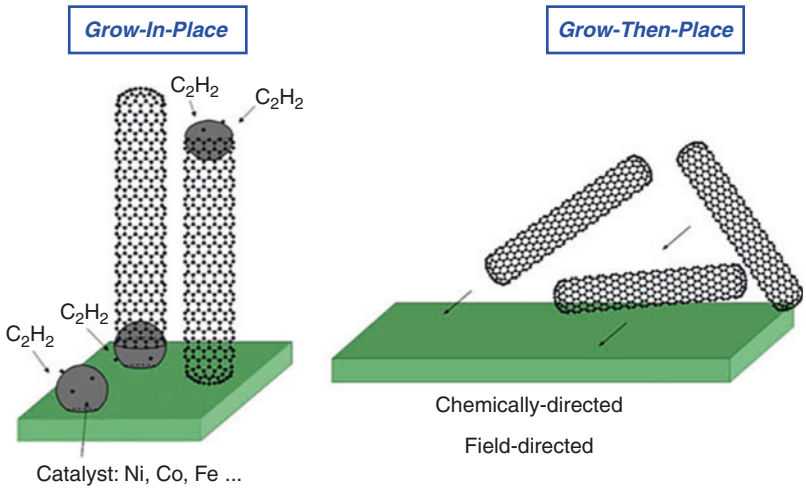


Naeemi et al. [14] also compared SWCNT bundles to copper as local, intermediate, and global interconnects. They showed that, in SWCNT bundles, resistance and kinetic inductance decreased linearly with the number of nanotubes in the bundle, while magnetic inductance changed very slowly. The resistance of a bundle of SWCNTs with sufficient metallic nanotubes was smaller than the resistance of copper wires, while capacitance was comparable. SWCNT bundles also fared better compared to copper in reducing power dissipation, delay, and crosstalk. For local interconnects, they quantified the improvements as 50 % reduction in capacitance, 48 % reduction of capacitance coupling between adjacent lines, and 20 % reduction in delay. For intermediate interconnects, the improvements were more marked, especially in terms of improved conductivities. For global interconnects, dense SWCNT bundles proved critical to improve bandwidth density (Fig. 7).

Using MWCNTs, which are all electrically conductive as they exhibit multiple channels of conduction (compared to only one-third metallic SWCNTs), could lower the resistivity of the bundle, although fewer of them can be packed in the same space because they usually have larger diameters (but also require a lower packing density compared to SWCNTs). In a different modeling study, Naeemi et al. [13] explored the suitability of MWCNTs as replacement for copper interconnects. They concluded that for long lengths (over 100 μm), MWCNTs have conductivities many times that of copper and even of SWCNT bundles. However, for short lengths (less than 10 μm), dense SWCNT bundles can exhibit a conductivity that is twice that of MWCNT bundles. Thus, for via applications, they recommended using dense bundles of SWCNTs or, alternatively, bundles of MWCNTs with small diameter (i.e., with few walls) (Fig. 8).

Using an individual MWCNT with large diameter could offer high conductivity due to the participation of multiple walls to significantly

Carbon Nanotubes for Chip Interconnections, Fig. 7 Conductivity of densely packed SWCNT bundles versus length for various bias voltages (Figure reproduced with permission from Naeemi and Meindl [14])



Carbon Nanotubes for Chip Interconnections, Fig. 8 Conductivity of MWCNTs with various diameters compared to Cu wires and dense bundles of SWCNTs (Figure reproduced with permission from Naeemi and Meindl [13])

increase the channels for conduction. However, as previously mentioned, the exact relationship between the number of walls and the conductance has yet to be clarified.

In conclusion, the choice of nanotubes may differ depending on the type of interconnect. For instance, dense bundles of SWCNTs or MWCNTs with few walls may be more suitable for small-section vertical vias, while dense bundles of larger MWCNTs may be more appropriate for long-range interconnects. The option of using a large MWCNT which fills all the space available needs to be further investigated. It is also plausible that hybrid systems of copper/SWCNTs/MWCNTs may be the best solution; for instance, small-section vertical vias may be replaced by dense SWCNT bundles, while larger long-range horizontal interconnects may still use copper, dense bundles of MWCNTs, or even metal-CNT composites.

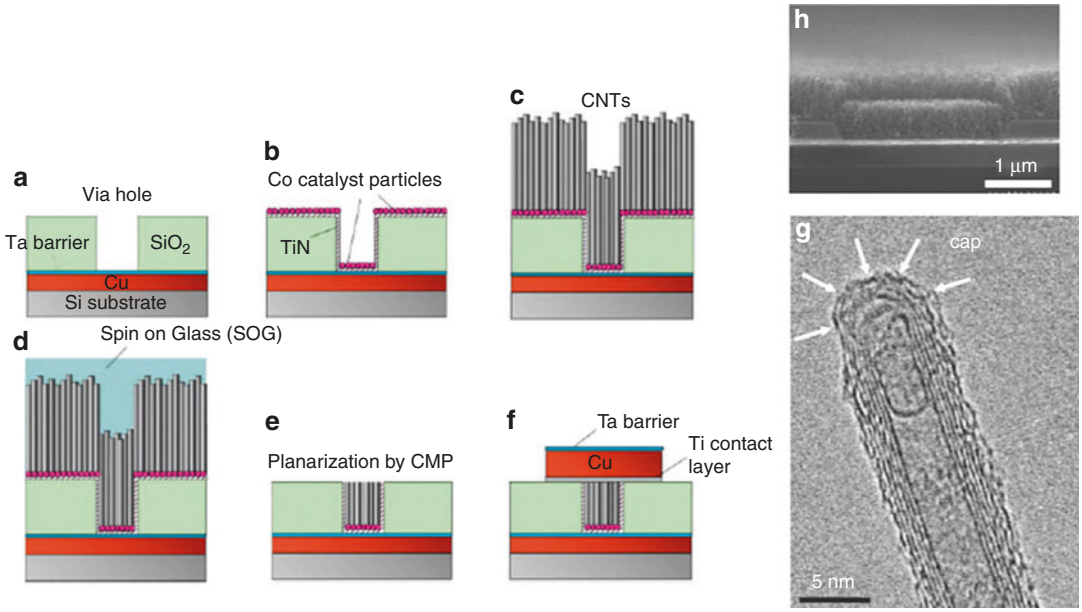
Practical Implementation: Fabrication State of the Art and Outstanding Issues

Reliable and repeatable high-yield CNT fabrication compatible with CMOS standards is the main bottleneck in replacing copper in chip interconnections. Although hundreds of research teams have focused their efforts on nanotube growth and thousands of papers detailing growth recipes have been

Carbon Nanotubes for Chip Interconnections, Fig. 9 Pictorials comparing the "grow-in-place" and "grow-then-place" techniques (Reproduced with permission from Professor Carl V. Thompson [18])

published, surprisingly, very few have focused on the growth on conductive substrates at CMOS-compatible processing temperature [7, 10, 15, 16]. It is still a challenge to reliably and consistently synthesize CNTs on conductive layers at temperatures below 400–450 °C, the maximum temperature allowed in CMOS fabrication to avoid disrupting previous diffusion patterns. Furthermore, it is still difficult to precisely control CNT diameter and height, although chemical vapor deposition (CVD) from thin films of controlled thickness [17] or from nanoparticles [16] of controlled size has shown encouraging results.

To utilize carbon nanotubes in industrial applications, two main approaches have been considered: *"grow-in-place"* and *"grow-then-place"* [18] (Fig. 9).



Grow-then-place: This technique consists of first preparing nanotubes and subsequently transferring them to a substrate. Arc discharge and laser ablation are the main techniques used to synthesize free-standing nanotubes. The nanotubes may be subsequently selected (e.g., separating SWCNTs or metallic SWCNTs) and purified prior to use. To transfer them to another substrate, CNTs are usually functionalized in a way that they will attach to pre-patterned areas of the substrate which will attract functionalized CNTs. An interesting technique for interconnect vias is based on using electrophoresis to push CNTs dispersed in a liquid solution into a matrix with pits (e.g., porous alumina matrix).

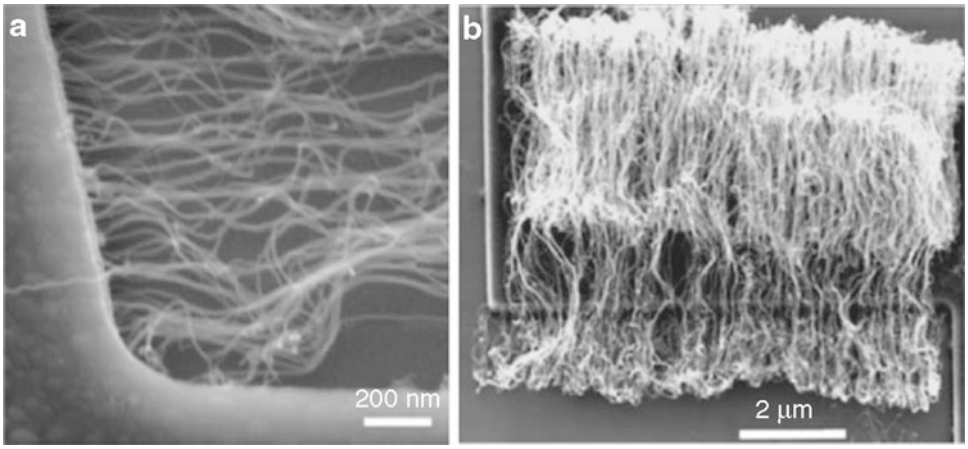
The advantages of this method are that it places no restrictions on the process or temperature used for CNT synthesis and allows to pretreat the CNTs (e.g., select, purify, functionalize). The major drawback is that no successful and repeatable technique to transfer the CNTs to the substrate has been developed to date. The challenge of resolving this issue appears too high to make this technique a candidate for the CMOS industry. However, free-standing, purified, CNTs are manufactured by many companies and sold for other applications (e.g., CNT-polymer composites).

Grow-in-place: this technique usually consists of preparing the sample with a catalyst present in the locations where the nanotubes will be synthesized. For instance, a thin catalyst film can be deposited using e-beam evaporation or sputtering; alternatively, nanoparticles can be deposited on a substrate. Synthesis is usually performed using thermal or assisted (e.g., plasma) CVD.

This method has several advantages: (1) good control of nanotube position (CNTs will grow where there are catalysts), (2) proven recipes to obtain crystalline CNTs (at least on insulating substrates), (3) proven capabilities to obtain carpets of vertically aligned CNTs, (4) physical contact with the substrate, (5) electrical contact with the substrate, and (6) CVD techniques are commonplace in the CMOS industry.

The major drawbacks are that (1) the processing temperature should be below 400–450 °C (CMOS-compatibility), thus putting

Carbon Nanotubes for Chip Interconnections, Fig. 10 Process to synthesize CNTs into pits, SEM cross section, and TEM showing crystalline MWCNT (Reprinted with permission from Yokoyama et al. [23])



serious limits on the synthesis method and (2) the CNTs should be directly synthesized on the substrate of choice, usually a metallic layer to provide electrical contact. Although growing dense carpets of crystalline CNTs on insulating substrates such as alumina or silicon oxide has been achieved by many, CNT growth on metallic layers still remains a serious challenge. Interactions between the catalyst and the metallic substrate (e.g., alloying) are the major impediments for the successful growth of dense carpets of CNTs on metallic layers.

In addition to interesting results obtained from university research, good progress on the growth and characterization of carbon nanotubes for interconnects has been achieved by industrial laboratories, initially by Infineon and now by the Fujitsu laboratories. In 2002, Kreupl et al. [19] of Infineon showed that bundles of CNTs could be grown in pits of defined geometry.

More recently, Awano et al. [7] of Fujitsu grew bundles of MWCNTs in a 160 nm via at 450 °C and measured an electrical resistance of 34Ω (the CNT density observed was 3×10^{11} CNTs/cm^2). This follows a previous result obtained earlier by the same team where they grew MWCNTs into a 2 μm via at temperatures close to 400 °C with the lowest resistance measured of 0.6Ω after CMP and annealing in a hydrogen atmosphere [5] (Fig. 10).

Kreupl et al. [19] succeeded in growing a single MWCNT into a 25-nm hole and measured a high resistance of 20–30 kΩ. Given the difficulty of growing a single large MWCNT and the difficult task of making a precise electrical measurement, there may be room for further improvement if we could grow an individual, crystalline (defect-free) MWCNT with the maximum number of walls for a given external diameter, thus maximizing the number of channels of conduction.

Most of the effort on CNT synthesis to replace copper interconnects has focused on vertical growth of dense carpets of CNTs, which can be achieved by a high density of active catalyst dots. In contrast there have been fewer successful reports of horizontal growth, with less spectacular results. Many techniques have been used to achieve horizontal alignment among which we can mention high gas flow rates, electric fields, and epitaxial techniques to guide horizontal alignment of the nanotubes [10]. In 2010, Yan et al. [20] obtained an interesting horizontal

Carbon Nanotubes for Chip Interconnections, Fig. 11 Scanning electron microscope images of dense carpets of horizontally aligned CNTs grown using CVD (Figure reproduced from Yan et al. [20])

growth of bundled CNTs with a density of 5×10^{10} CNTs/cm^2, which is approaching what has been achieved for vertical CNT growth (although still over an order of magnitude lower compared to the best result for vertical CNT growth) (Fig. 11).

Although the experimental results obtained are encouraging, there are still numerous challenges that need to be resolved for CNTs to enter the semiconductor fab:

1. Increase the CNT areal density by one or two orders of magnitude. For SWCNTs, assuming all of them are metallic, a packing density of 10^{13}–10^{14} CNTs/cm^2 is required to compete with copper in terms of resistance, while for MWCNTs, the required packing density is lower and depends on the number of channels of conduction (i.e., number of walls). This will require, among other considerations, adequate catalyst and underlayer materials choice and deposition, possible surface pretreatment (e.g., plasma, reduction, and etching), maximum nucleation of active catalyst dots, and optimizing the CNT growth process. Although CNT areal density is an important issue, it may not be the dealbreaker.
2. Minimize the contact resistance between the CNTs and the substrate. To achieve maximum conductivity, the choice of the appropriate underlayer is critical; specific metals (e.g., Pd) and possibly silicides are good candidates. For MWCNTs, it is also important to ensure electrical contact with all the walls.
3. When using SWCNTs, synthesize only metallic SWCNTs (on average one-third of the SWCNTs grown) which are the ones participating in the electrical conduction. This is closely linked to the issue of chirality control, for which no solution has been proposed to date. Selective catalyst choice may provide an alternative avenue to synthesize a higher fraction of metallic SWCNTs.
4. Control growth direction of CNTs. This is especially challenging for horizontal interconnects where the directionality and the packing density achieved are still lagging compared to vertical growth of CNTs, despite some interesting progress in this area [10, 20].
5. Synthesize crystalline, defect-free CNTs to ensure maximum electrical conductivity in the nanotube. This is challenging, especially when combined with the requirement of growing CNTs at low temperature to achieve CMOS compatibility.
6. Synthesize CNTs at temperatures below 400–450 °C to ensure CMOS compatibility.
7. Repeatably yield the same CNT structures when the same process conditions are applied. This is a major issue since important variations in the structure and shape of the CNTs grown have been experimentally observed.

Conclusions and Outlook for CNTs as Chip Interconnections

In the past decade, the synthesis of CNTs and the understanding of their growth mechanisms have massively improved. However, for CNTs to enter the CMOS fab and replace copper, significant challenges still need to be resolved. In my opinion, the most significant challenge to overcome is developing a reliable and repeatable fabrication process consistent with CMOS conditions. To achieve that tall order, we need to improve our understanding of the CNT growth mechanisms. Although many simulation models and many experimentally-based insights have been achieved [10], there are still many questions related to CNT growth mechanisms that have not been fully answered. For instance:

- Which precursor gases favor CNT growth and which gases hinder CNT growth? What is the role of the gases in the resulting level of crystallinity of the CNTs grown? Could we pretreat the gases to improve the CNT yield or structure?
- What is the exact role of the catalyst? How does its materials properties and its lattice structure influence the resulting CNTs grown (in shape and structure)?
- What is the role of the underlayer (layer below the catalyst) and its interactions with the catalyst? Why is it so challenging to grow CNTs on metallic layers?

In addition to improving our mechanistic understanding of CNT growth, I believe that a parallel effort focused on developing better reactors is needed. Most researchers use standard CVD-based systems that were designed for a general purpose. A customized reactor, where the same growth conditions can be repeatably achieved with very small variations could provide the repeatability in results (CNT structures) that has eluded us so far.

Carbon nanotubes are already becoming a manufacturing reality in mechanical engineering applications (e.g., CNT-based composites) and many interesting results have been obtained to develop novel CNT structures for electrical applications. Although the jury is still out, if process repeatability could be achieved, we could hope, not only that CNTs will enter the CMOS fabs and replace copper for chip interconnections, but also that they will lead to innovative ventures requiring lower investments to develop integrated circuits with radically new architectural designs using carbon nanotubes as new building blocks.

Definition

The Car–Parrinello molecular dynamics (CPMD) is an extension of the Lagrangian formalism of

classical molecular dynamics in which the model potential describing the interaction among atoms is replaced by the total energy functional of the system as provided by the Density Functional Theory (DFT). The electronic wavefunctions are explicitly introduced as new dynamical variables. The simultaneous Euler-Lagrange equations of motion for both sets of dynamical variables, atomic coordinates and electronic wavefunctions, avoid the explicit minimization of the DFT total energy at each step of the dynamics. Instead, they introduce a fictitious dynamics of the wavefunctions representing an adiabatic updating on-the-fly of the electronic structure along the atomic dynamics.

Introduction

The main target in atomic-scale simulations is to reproduce in a realistic way physical and chemical events occurring in materials. Specifically, the scope of First Principles Molecular Dynamics (FPMD) is to study a system of *interacting* nuclei and electrons by recreating it on a computer in a way as close as possible to nature and by simulating its dynamics over a *physical length of time* relevant to the properties of interest. The inherent complexity of the simulated systems, from solids to biological macromolecules, calls for methods able to go beyond the simple calculation of the electronic structure of a given set of coordinates $\mathbf{R}_I$ representing the positions of atoms. This is exactly the idea that started the entire field of Molecular Dynamics (MD).

From an historical point of view, the MD approach was introduced by Alder and Wainwright [1] in the late 1950s to study the interactions of hard spheres. Many important insights concerning the behavior of simple liquids emerged from their studies, but due to the limitations of the computational facilities and the pioneering stage of the MD, it was only in 1964 that the first dynamical simulation could be done. That milestone case focused on liquid Ar with the interatomic interaction modeled by a truncated Lennard-Jones potential [2]. In a nutshell, any MD method is an iterative numerical scheme for solving some equations of motion (EOM), representing the physical evolution of the system under study. Modeling the interaction of atoms with an analytic potential $V(\mathbf{R}_I)$, especially when chemical bonds evolve in time and they are broken or formed is a hard task not yet solved apart from a very limited class of chemical species. On the other hand, the electronic structure for a general many-body system can be determined with a computationally reasonable workload by means of the density functional theory (DFT), originally proposed in the early 1960s by Kohn, Hohenberg, and Sham [3, 4]. Its importance in the advancement of computational quantum chemistry and related fields was acknowledged by the Nobel Prize in Chemistry in 1998 awarded jointly to Walter Kohn and John A. Pople. Joining the two fields, MD and DFT, is exactly what the Car–Parrinello method is about, extending the range of both concepts [5, 6].

A Brief Overview of Density Functional Theory: The CPMD Potential

The DFT is a formulation of the many-body quantum mechanics in terms of an electron density distribution, $\rho(\mathbf{x})$, which describes the ground state of a system composed of interacting electrons and point-like nuclei having positions $\{\mathbf{R}_I\}$ [7]. All along the text, atomic units will be used for simplicity. In practice, single-particle wavefunctions $\psi_i(\mathbf{x})$ are used to express the many-body mathematical function ρ $(\mathbf{x})$. The dramatic simplification, is the fact that not even the specific analytic form of the complex function $\psi_i(\mathbf{x})$ matters, but only its square modulus, so that the electron density reads

$$\rho(\mathbf{x}) = \sum_{i=1}^{N^{occ}} f_i |\psi_i(\mathbf{x})|^2 \qquad (1)$$

This expression is clearly a single Slater determinant constructed from wavefunctions representing all the N^{occ} occupied orbitals. The coefficients f_i are the (integer) occupation numbers, and they are equal to 1 in the case in which the spin is explicitly

considered (spin-unrestricted) or equal to 2 if the spin is neglected and energy levels are considered as doubly-occupied (spin-restricted). Furthermore, the wavefunctions $\psi_i(\mathbf{x})$ are subject to the orthonormality constraint

$$\int \psi_i^*(\mathrm{x})\psi_j(\mathrm{x})\, d^3x = \delta_{ij} \tag{2}$$

as in any quantum mechanics approach. The Kohn-Sham (KS) DFT total energy of the system in its ground state is then written as

$$E^{KS}[\{\psi_i\}] = E_k[\{\psi_i\}] + E_H[\rho] + E_{xc}[\rho] + E_{eI}[\rho] + E_{II} \tag{3}$$

In Eq. 3, the first three terms on the right-hand side (E_k, E_H, E_{xc}) describe all the electron–electron interactions, the fourth term (E_{eI}) refers to the electron–nucleus interaction, and the fifth one (E_{II}) corresponds to the nucleus–nucleus interaction. More explicitly, E_k is the Schrödinger-like kinetic energy expressed in terms of the single-particle wavefunctions $\psi_i(\mathbf{x})$ as

$$E_k[\{\psi_i\}] = \sum_{i=1}^{N^{occ}} f_i \int \psi_i^*(\mathbf{x}) \left(-\frac{1}{2}\nabla^2\right) \psi_i(\mathbf{x})\, d^3x \tag{4}$$

It must be remarked that this expression for the kinetic energy does not depend on the density $\rho(\mathbf{x})$ but directly on the wavefunctions. The second term, E_H, is the Hartree energy, i.e., the Coulomb electrostatic interaction between two charge distributions

$$E_H[\rho] = \frac{1}{2}\int\int \frac{\rho(\mathbf{x})\rho(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} d^3x\, d^3y \tag{5}$$

The exchange interaction and the electron correlations due to many-body effects are represented by the term $E_{xc}[\rho]$, whose exact analytical expression is unknown. There are good approximations derived from the homogeneous electron gas limit for the exchange interaction [7], the so-called local density approximation (LDA), whose name comes from the fact that a homogeneous distribution of interacting electrons is assumed, in which $\rho(\mathbf{x})$ depends just on the local point $\mathbf{x}$. Similarly, in the LDA version of the correlation energy [7], the explicit analytic form of the functional comes from a parameterization of the results of quantum Monte Carlo calculations. Due to the insufficiency of a simple LDA approximation for many real systems, nonlocal approximations, including the gradient of the density, are often adopted and the exchange-correlation functional becomes $E_{xc}[\rho,\ \nabla\rho]$. In practical applications, however, the gradient enters only with its modulus, thus adding only a modest computational cost. The electrostatic interaction between electrons and nuclei, is then

$$E_{eI}[\rho] = -\int \sum_{I=1}^{M} \frac{Z_I \rho(\mathbf{x})}{|\mathbf{x}\text{-}\mathbf{R}_I|} d^3x \tag{6}$$

where Z_I is the charge of the Ith nucleus. However, in practice, this expression "as is" is computationally expensive. In fact, two different length scales come into play: a small one for the core electrons, characterized by rapidly varying wavefunctions, especially in the region very close to the nucleus, and a longer one for the valence electrons that form chemical bonds and vary more smoothly. Clearly, the first one would dominate and add a computational workload that would make impractical simulations of large systems. To overcome this problem, one can observe that core electrons are generally inert and do not participate to chemical bonds. This crucial observation led to the use of pseudopotentials [6]. Namely, core electrons are eliminated and a potential describing the core–valence interaction is built by fitting to the all-electron solutions of the Schrödinger or Dirac equation for the single atom of the chemical species considered. In a pseudopotential (PP) approach, the electron–nucleus interaction is rewritten as

$$E_{eI}[\rho] = \int d^3x V_{ps}(\mathbf{x} - \mathrm{R}_I) \cdot \rho(\mathbf{x}) \tag{7}$$

Finally, the fifth and last term in right-hand side of Eq. 3 is simply the Coulomb interaction between two classical nuclei I and J and is written as

$$E_{II} = \sum_{I<J}^{M} \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} \tag{8}$$

where Z_I and Z_J are the net valence charge in a PP approach. The total energy E^{KS} of the ground state of such a system of interacting electrons and nuclei is obtained by minimizing the KS functional with respect to the single-particle orbitals $\psi_i(\mathbf{x})$, which, in practice, means solving the KS Schrödinger-like equations

$$\frac{\delta E^{KS}}{\delta \psi_i^*} \equiv H^{KS}\psi_i(\mathbf{x}) = \varepsilon_i \psi_i(\mathbf{x}) \tag{9}$$

The Basis Set Issue

A somehow arbitrary issue is the proper definition of $\psi_i(\mathbf{x})$. The answer is the selection of a proper basis set on which orbitals can be expanded. One possible choice is a localized basis set expressing the one-electron wavefunctions as

$$\psi_i(\mathbf{x}) = \sum_{k=1}^{M} c_i^k \phi_k(\mathbf{x}; \{\mathbf{R}_I\}) \tag{10}$$

and the number of analytic functions used, M, is also an indicator of the computational cost of the quantum calculation, in the obvious sense that the larger the basis set, the higher the computational workload. One of the most popular basis sets is represented by Gaussian-type orbitals (GTO)

$$\phi_k(\mathbf{x} - \mathbf{R}_I) = \phi_k(\mathbf{r}) = N_k \cdot r_x^{k_x} r_y^{k_y} r_z^{k_z} \cdot \exp\left(-\alpha_k \cdot r^2\right) \tag{11}$$

where $\mathbf{r} = \mathbf{x} - \mathbf{R}_I$. When such a basis set is used, the constants $N_\mathbf{k}$, and $\alpha_\mathbf{k}$ are kept fixed during the electronic structure calculation, whereas the coefficients c_i^k are allowed to vary until they are fully optimized [8]. It must be remarked that orbitals expanded in a localized basis set depend on the atomic positions $\mathbf{R}_I$. As a consequence, in any calculation in which the forces acting on the ions are required, the explicit derivatives of these wavefunctions with respect to $\mathbf{R}_I$ must be computed, leading to non-Hellmann-Feynman force components known in the literature as Pulay forces [6, 8]. An alternative basis set rather popular in physics is represented by plane waves (PW)

$$\psi_i(\mathbf{x}) = \sum_{\mathrm{G}=0}^{\mathrm{G}^{\max}} c_i(\mathbf{G})\, e^{i\mathbf{G}\cdot\mathbf{x}} \tag{12}$$

where the sum is truncated at a suitable cut-off $\mathbf{G}^{\max}$. In this case, no dependence on the atomic coordinates and no arbitrariness in the increase in the number of basis functions exist.

First Principles Molecular Dynamics

Until the early 1980s, few applications of DFT went beyond the static calculations of the electronic structure. Nonetheless, finite temperature and entropy effects are two of the dominant features in matter and their role is often far from negligible. In this respect, the FPMD has represented a huge step forward. In this particular combination of DFT and MD, the interactions among atoms, instead of being described by an analytical function $V(\{\mathbf{R}_I\})$ of the atomic coordinates $\mathbf{R}_I$, is directly computed from the DFT total energy E^{KS}, which is simultaneously a function of the electron wavefunctions and the atomic coordinates. The Born–Oppenheimer (BO) approximation [9] allows to disentangle the motions of the electrons and the nuclei, and each time the nuclei $\mathbf{R}_I(t)$ are displaced from given positions at time t to new positions $\mathbf{R}_I(t + \Delta t)$ at a subsequent time $t + \Delta t$, an optimization of the electronic structure has to be performed. Then the forces acting on the nuclei are estimated from the gradient of E^{KS} with respect to the ionic position and the variables $\mathbf{R}_I(t)$ are updated to $\mathbf{R}_I(t + \Delta t)$ by solving via finite differences the Newton-like EOM

$$M_I \ddot{\mathbf{R}}_I = -\nabla_{\mathbf{R}_I} \min_{\{\psi_i\}} E^{KS}[\{\psi_i\}, \{\mathbf{R}_I\}] \tag{13}$$

This iterative procedure assumes that the electronic structure is recomputed and the full diagonalization of the Hamiltonian is performed at each time step t along the discrete trajectory $\{\mathbf{R}_I(t)\}$.

Car–Parrinello Molecular Dynamics

An alternative to this scheme, which has represented a real breakthrough in first principles dynamical simulations, was proposed in 1985 by R. Car and M. Parrinello [5]. The scope (and driving force) was to overcome the two major efforts arising in FPMD: On one hand one has to integrate the equations of motion for the nuclear positions as in Eq. 13, which represent the long timescale part to the problem. On the other hand, one has to propagate dynamically the smooth time-evolving (ground state) electronic subsystem. The Car–Parrinello molecular dynamics (CPMD) is able to satisfy this second requirement in a numerically stable way and makes an acceptable compromise for the time step length of the nuclear motion. The formulation is an extension of a classical molecular dynamics Lagrangian in which the electronic degrees of freedom (wavefunctions) are added to the system, along with any other dynamical variable $q_\alpha(t)$, i.e., thermostats, barostats, reaction coordinates, etc.

$$\mathcal{L}^{CP} = \frac{1}{2}\sum_I M_I \dot{\mathbf{R}}_I^{\,2} + \sum_i \mu \int \left|\dot{\psi}_i(\mathbf{x})\right|^2 d^3x + \frac{1}{2}\sum_\alpha \eta_\alpha \dot{q}_\alpha^2 - E^{KS}[\rho, \{\mathbf{R}_I\}, q_\alpha] + \sum_{ij}\lambda_{ij}\left(\int d^3x \psi_i^*(\mathrm{x})\psi_j(\mathrm{x}) - \delta_{ij}\right) \quad (14)$$

The first term on the right-hand side of Eq. 14 is the kinetic energy of the nuclei, the second one the fictitious kinetic energy of the electrons representing the update of the wavefunctions during the dynamics, the third one the kinetic term of any further dynamical variable used in the sense specified above, the fourth one is the DFT total energy, and the last addendum is the orthonormality constraint for the wavefunctions. The kinetic energy for the electronic degrees of freedom is the main novelty of the CPMD approach: A strategy to update on-the-fly the wavefunctions when ions undergo a dynamical displacement, avoiding expensive iterative diagonalization required by the BO approach at each time step. The Euler–Lagrange EOM are as follows:

$$\mu\ddot{\psi}_i(\mathbf{x}) = -\frac{\delta E^{KS}}{\delta \psi_i^*} + \sum_j \lambda_{ij}\psi_j(\mathbf{x}) \quad (15)$$

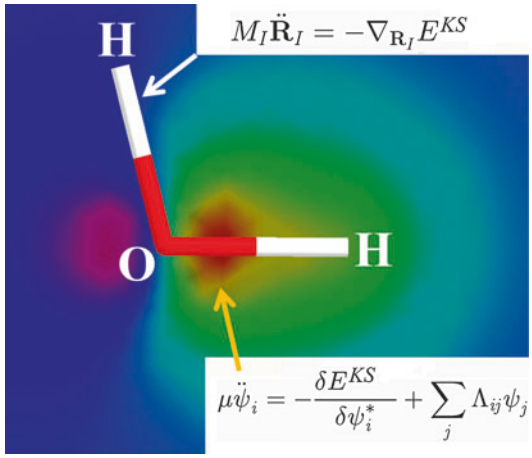
$$M_I\ddot{\mathbf{R}}_I = -\nabla_{\mathbf{R}_I} E^{KS} \quad (16)$$

$$\eta_\alpha \ddot{q}_\alpha = -\frac{\partial E^{KS}}{\partial q_\alpha} \quad (17)$$

The fictitious mass μ assigned to the orbitals $\psi_i(\mathbf{x})$ is the parameter that controls the speed of the updating of the wavefunctions with respect to the nuclear positions. For this reason, it determines the degree of adiabaticity of the two subsystems, electrons and nuclei.

It is straightforward to give a Hamiltonian, instead of a Lagrangian, formulation of the CPMD method, via a simple Legendre transform after defining the momenta

$$\pi_i(\mathbf{x}) = \frac{\delta \mathcal{L}^{CP}}{\delta \dot{\psi}_i}(\mathbf{x}) = \mu\dot{\psi}_i(\mathbf{x})$$



$$\pi_i^*(\mathbf{x}) = \frac{\delta \mathcal{L}^{CP}}{\delta \dot{\psi}_i(\mathbf{x})} = \mu\dot{\psi}_i^*(\mathbf{x}) \quad (18)$$

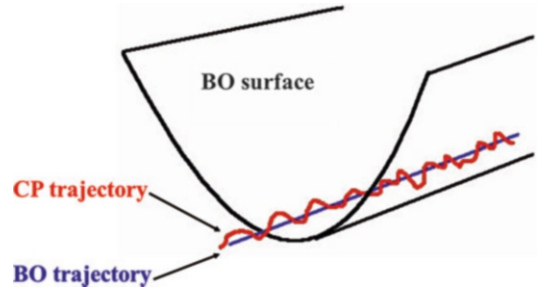
$$\mathbf{p}_i = \nabla_{\dot{\mathbf{R}}_I}\mathcal{L}^{CP} = M_I\dot{\mathbf{R}}_I \quad (19)$$

$$\dot{\zeta}_\alpha = \frac{\partial \mathcal{L}^{CP}}{\partial \dot{q}_\alpha} = \eta_\alpha \dot{q}_a \quad (20)$$

so that the Hamiltonian reads

$$H^{CP} = \sum_I \frac{\dot{\mathbf{p}}_I^{\,2}}{2M_I} + \sum_i \int \frac{\pi_i^*(\mathbf{x})\,\pi_i(\mathbf{x})}{\mu} d^3x + \sum_\alpha \frac{\dot{\zeta}_\alpha^2}{2\eta_\alpha} - E^{KS}[\rho, \{\mathbf{R}_I\}, q_\alpha] - \sum_{ij}\lambda_{ij}\left(\int \psi_i^*(\mathbf{x})\psi_{\mathrm{j}}(\mathbf{x})\, d^3x - \delta_{ij}\right) \quad (21)$$

Car–Parrinello Molecular Dynamics, Fig. 1 Atomic structure (sticks; *red* = O, *white* = H) of a water molecule and electronic wavefunction of an O–Hs-bond in terms of density map (*blue*: $|\psi_i(\mathbf{x})|^2 = 0$, *red*: $|\psi_i(\mathbf{x})|^2 =$ maximum). The two sets of dynamical variable evolve in time according to the equations of motions indicated, coupled via E^{KS}



and the CPMD equations of motion (Fig. 1) will be given by the corresponding Hamilton EOMs.

A rigorous mathematical proof of this scheme has been given by Bornemann and Schütte [10], showing that the CPMD trajectory $\{\mathbf{R}^{\mathrm{CP}}(t)\}$ stays close to the BO one $\{\mathbf{R}^{\mathrm{BO}}(t)\}$ and the upper bound is proportional to the square root of the fictitious mass μ

$$\left|\mathrm{R}^{CP}(t) - \mathrm{R}^{BO}(t)\right| < C \cdot \sqrt{\mu} \qquad (22)$$

where C is a positive constant (Fig. 2).

The fact that the CPMD was a milestone step forward in realistic simulations of materials at various thermodynamics conditions can be easily seen by the number of publications in first principles molecular dynamics (FPMD) before and after 1985. Indeed, the original Car–Parrinello publication has more than 7,000 citations in 2014 (source: ISI Web of Science), and, to acknowledge the importance of the method, the international Physics and Astronomy Classification Scheme (PACS) introduced in 1996 a new identification number, 71.15.Pd, to classify Car–Parrinello related publications. Since then, the method has been applied to a wide variety of materials, ranging from solids, to liquids, and to biological systems [11, 12].

Numerical Details

Although it is not restriction neither of DFT [13] nor of CPMD [14], PWs are often used as a convenient basis set for the coding of CPMD, since they have several good properties: (i) Accuracy can be systematically improved in a fully variational way, (ii) PWs are independent from atomic positions (i.e., no Pulay forces [6]), (iii) PWs can be easily distributed in parallel processing. However, it must be observed that the fact that PWs are not localized can lead to inefficiencies for small clusters or surfaces placed in a large simulation cell. The equations of motion are discretized by finite differences, via a Verlet or velocity-Verlet algorithm [15]. The ionic variables $\mathbf{R}_I$(t) are updated at a rate Δt, while the electronic degrees of freedom are updated at a rate $\Delta t/\mu^{1/2}$, i.e.,

$$\begin{aligned}\frac{\mu}{\Delta t^2}\left[c_i(\mathbf{G}, t+\Delta t) + (\mathbf{G}, t-\Delta t) - (\mathbf{G}, t)\right] \\ = -\sum_{G'} \left\langle \mathbf{G}\middle| H^{CP} \middle|\mathbf{G}'\right\rangle c_i(\mathbf{G}') \\ + \sum_j \Lambda_{ij} c_j(\mathbf{G})\end{aligned} \qquad (23)$$

For most of the applications, Δt and μ fall in the range 3–5 au and 300–600 au, respectively. Of course, the (quantum) time scale of electrons is dominating in this kind of approaches and simulations times are of the order of few tens or, at very best, hundreds of ps. As far as the system size is

concerned, with N electrons and $\mathbf{G}^{\max}$ PWs, $\mathbf{G}^{\max}$ being integer, the scaling of the various parts composing the CPMD algorithm is $O(N\ \mathbf{G}^{\max})$ for the kinetic term, $O(N\ \mathbf{G}^{\max}\ \log\ \mathbf{G}^{\max})$ for the local potential and $O(N^2\ \mathbf{G}^{\max})$ for both the nonlocal term and wavefunctions orthogonalization procedure.

Second-Generation Car–Parrinello Molecular Dynamics

The inherent high computational cost associated to the electronic structure calculations has limited the affordable timescales for several years. Only the most advanced high performing computer platforms recently available have allowed to increase the system size to about a thousand of atoms and simulation times towards hundreds of picosecond. Yet, many phenomena still call for a substantial boost. These are, for instance, diffusion in solids or, in the case of glasses generation from the melt, a less rapid cooling rate suitable to avoid numerically induced structural problems. While linear scaling methods can be a viable way to access larger system sizes, they still have to face the problem of the simulation timescale. Moreover, the crossover point at which linear scaling methods become advantageous has remained fairly large, especially if high accuracy is needed. An interesting attempt at overcoming these limitations has been proposed in 2007 [16]. The basic idea is to join the advantages of both the BO approach and the CPMD; in a "nutshell"

	CPMD	BO
Conservation of constants of motion	**Good**	Convergence dependent
Electronic optimization	**Not needed**	Needed
Hamiltonian diagonalization	**Not needed**	Needed
Integration step Δt	Small	**Large**
Minimum of the BO surface	Approximate	**Exact**

These two approaches have nearly complementary features as sketched above. Following the CPMD formulation, it can be remarked that the Lagrangian formulation for the propagation of the wavefunctions is stable by construction, thus providing a reliable integration. This *stability* feature must then be preserved. Concerning the *efficiency*, large integration steps Δt are desirable and possibly a small, or better zero, deviation from the BO surface should be kept all along the dynamics to get a high *accuracy*. The mathematical result of this list of requirement resumes into a modified ionic EOM

$$M_I\ddot{\mathbf{R}}_I = -\frac{\partial \mathrm{E}_{NSC}}{\partial \mathbf{R}_I} + \sum_{i,j}\Lambda_{ij}\frac{\partial}{\partial \mathbf{R}_I}\left\langle \psi_i \middle| \psi_j \right\rangle - 2\frac{\partial \langle \psi_i|}{\partial \mathbf{R}_I}\left(\frac{\delta \mathrm{E}_{NSC}}{\delta \langle \psi_i|} - \sum_j \Lambda_{ij}|\psi_j\rangle\right) \tag{24}$$

While the first term in the right hand of the equation is clear, the rest seems a bit puzzling at a first glance. Indeed, in the original formulation [16], the selected basis set is not PW, but a localized basis set as in Eq. 10. Hence, the electronic wavefunctions depend also on the atomic coordinates $\mathbf{R}_I$ and the request of orthogonality at each step is released to save time, meaning that the scalar product $<\psi_i|\psi_j>$ is no longer vanishing. Analogously, the total energy E^{DFT} is not reoptimized as in full self-consistent BO procedures and for this reason is indicated as non-self-consistent energy E_{NSC}. Wavefunctions are propagated according to an algorithm which resembles the original CPMD formulation in the sense that second order EOMs are used, but a damping term (first-order derivative) is present which reminds a sort of steepest-descent algorithm typical of the BO dynamics. The net result is the electron dynamics,

$$\mu\frac{d^2}{dt^2}|\psi_i\rangle + \gamma\frac{d}{dt}|\psi_i\rangle = -\frac{\delta E_{NSC}}{\delta\langle\psi_i|} + \sum_j \Lambda_{ij}|\psi_i\rangle \tag{25}$$

which is then solved via a predictor–corrector scheme. With no pretention of completeness, the procedure can be summarized as follows. On a

first instance, in a localized basis set $\{|q>\}$, the electronic wavefunctions are expanded as

$$|\psi_i\rangle = \sum_{q=1}^{M} C_{iq}|q\rangle \tag{26}$$

on the M functions composing the localized basis. Then the NxM matrix of the expansion coefficient is written as

$$\mathbf{C} = [C_{iq}] = \begin{pmatrix} C_{11} & . & . & C_{1M} \\ . & . & & . \\ . & & . & . \\ C_{N1} & . & . & C_{NM} \end{pmatrix} \tag{27}$$

and the density matrix becomes $\mathbf{P} = \mathbf{C}\mathbf{C}^T = \mathbf{PSP}$. The MxM matrix indicated as $\mathbf{S}$ is just given by the expansion coefficient and its matrix elements have the usual form

$$S_{qq'} = \sum_{i=1}^{N} C_{iq}^{*} C_{iq} \tag{28}$$

Hence, the (DFT) total energy can be rewritten as $E^{\text{tot}}[\mathbf{C},\mathbf{R}_I]$ which can be used in a straightforward way to write a BO dynamics

$$M\ddot{\mathbf{R}}_I = -\nabla_{\mathbf{R}_I} \min\{E^{\text{tot}}[\mathbf{C},\mathbf{R}_I]\} \quad \forall \mathbf{C}^T \cdot \mathbf{S} \cdot \mathbf{C} = \mathbf{1} \tag{29}$$

under the given constraint on C which resumes in an implicit orthogonality condition. However it must be kept into account that: (i) Diagonalization and minimization of E^{tot} are required in BO; (ii) Hellman-Feynman forces are just one component since Pulay forces due to the local basis set are present. Residual force components appear due to non-self-consistency (NSC) of the approach. To take into account all the points above, the basic strategy can be summarized in four major points:

1. Propagate the electronic variables in time according to the CP original idea of updating on-the-fly to avoid expensive full diagonalization operations
2. Use a good propagation algorithm $\mathbf{C}(t_n) = f(\mathbf{C}(t_{n\text{-}1}),\ldots,\mathbf{C}(t_{n\text{-}m}))$ depending on previous time steps $m \in [1,K]$ time steps
3. Select the appropriate number of steps K to keep $\mathbf{C}(t_n)$ as close as possible to the (electronic) ground state
4. Enforce convergence on the BO surface, correct this propagation CPMD-like afterwards

Point 3 corresponds to the first move in the numerical integration procedure and it can be identified as the "predictor" part directly deriving from a standard numerical integration of the CPMD type equations of motion. Point 5, instead, is the "corrector" needed afterwards to better converge the wavefunctions and to restore the neglected self-consistent loop. The use of not necessarily fully converged wavefunctions at the predictor propagation stage allows for large integration steps, thus resulting in a remarkable boost in the dynamics.

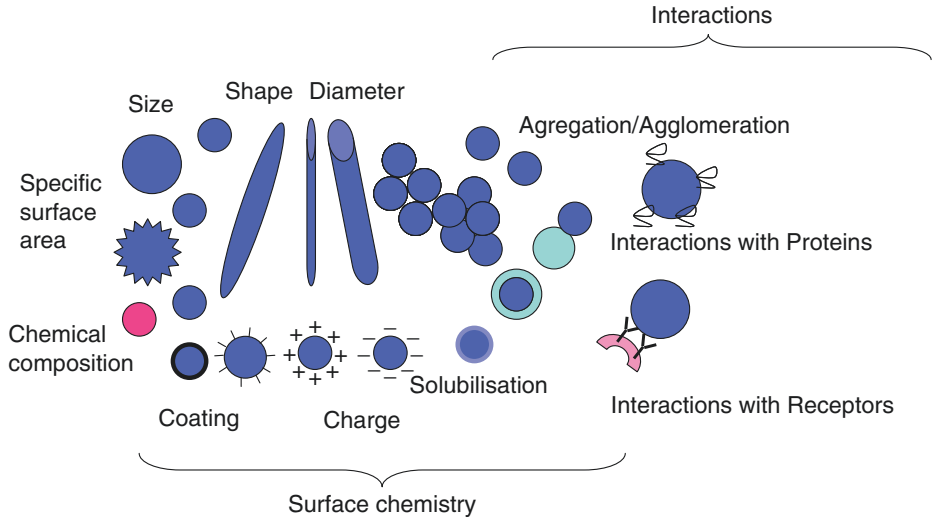
Cellular and molecular toxicity of nanoparticles

Definition

The interaction between nanoparticles and cell triggers a cascade of molecular events which could induce a toxicity and cell death. They are associated with the uptake of nanoparticles, their persistence at cellular level, and their ability to release free radicals and to induce an oxidative stress. The resulting activation of molecular pathways and transcription factors could lead to a pro-inflammatory response or, depending on the level of free radicals, apoptosis.

Background



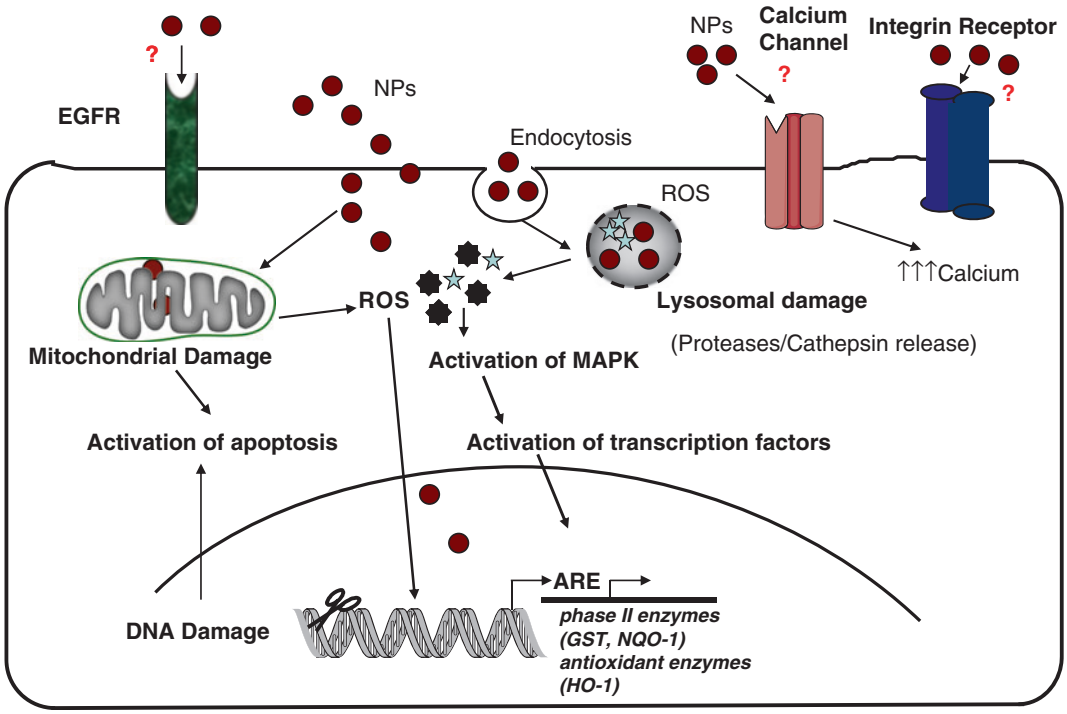
The last 5 years have shown an increasing number of papers on the mechanisms of nanoparticle (NP) cytotoxicity. What are the reasons? It is likely that the specific useful properties which appear at nanoscale can also lead to adverse effects. This hypothesis is strongly supported by in vivo and in vitro studies to compare the toxicity of NPs with their fine counterparts of the same chemical composition. These results have clearly demonstrated a higher toxicity of particles at nanoscale than at microscale. Moreover, it appears from experimental studies that solid nano-sized particles could be translocated beyond the respiratory tract and could induce a systemic response. The interstitial translocation of a same mass of particles is higher for ultrafine than fine particles after intratracheal instillation in rats [1]. Surface area, which is strongly increased for NPs compared to micro-particles of same chemical composition, and surface reactivity are considered as the principal indicators of NP reactivity. It was shown that a toxic response could be observed even to apparently nontoxic substances when the exposure occurred in the nanometer size range. All these observations have led to the development of a new field of toxicology, nanotoxicology [2]. However, the toxicological mechanisms which sustained the biological response are not yet clear and a matter of debates.

The concerns about the toxicity of engineered nanoparticles, which are increasingly used for industrial and medical applications, came also

from the knowledge on the toxicity of non-intentional atmospheric particles. Short-term epidemiological studies in Europe and North America have showed an association between cardiorespiratory morbidity and mortality and an increased concentration of atmospheric fine particles [3]. Moreover, the long-term epidemiological studies have also demonstrated an association between exposure to atmospheric particles (particulate matter or PM10 and 2.5) and increased cancer risk [3]. In parallel, in vitro and in vivo studies on fine and ultrafine airborne particles such as diesel exhaust particles, PM2.5, gave causal explanations to these adverse health effects (reviewed in Ref. [1]). They allow defining the molecular events induced by these particles in lung cells. The major event is a pro-inflammatory response which is characterized by the release of various cytokines (pro-inflammatory mediators), associated with the activation of transcription factors and signaling pathways. This was especially demonstrated for diesel exhaust particles (DEP), a major component of urban PM in Europe. These events are mostly induced by organic components of the DEP and are probably mediated by the generation of reactive oxygen species (ROS) during the metabolism of organic compounds (for a review, see Ref. [4]). These findings were used as a background for the researches on biological mechanisms induced by NPs considering that fine and ultrafine atmospheric particles have great similarities with NPs, especially diesel exhaust particles which are of nano size and aggregate after their release in the atmosphere.

It became rapidly obvious that the understanding of the cellular and molecular mechanisms leading to the biological effects of NPs was essential for the development of safe materials and accurate assays for risk assessment of engineered NPs [2], and several recent reviews were focused on demonstrated or hypothetic cellular mechanisms of these responses [4–6].

The first event, when NPs enter in contact with the human body by inhalation, oral and dermal exposure, or intravenous application, is their interaction in the biological fluids and the cellular microenvironment with biological molecules such as proteins thus forming a protein corona [7]. Consequently, NPs do not directly interact with the cell membrane but through the protein and/or lipids of the corona. NP-bound proteins may recognize and interact with membrane receptors or could bind nonspecifically to cellular membranes. Whatever these interactions, they seem to play a central role which could determine further biological responses. In particular, these interactions may drive the uptake of NPs by the first target cells at the level of the biological barriers such as immune cells (macrophages, dendritic cells, and neutrophils) or epithelial and endothelial cells. This uptake seems to be general for many NPs which are able to bind proteins at their surface, and the paradigm of "Trojan horse" was developed to explain this uptake and the further biological responses. One of the first responses is the direct or indirect production of ROS which is associated with the size, the chemical composition, and the surface reactivity of the NPs. This common response occurs for a large number of NPs even with different chemical patterns and different abilities to form agglomerates, and thus the paradigm of the central role of oxidative stress was developed [5]. These authors suggested that "although not all materials have electronic configurations or surface properties to allow spontaneous ROS generation, particle interactions with cellular components are capable of generating oxidative stress." Further activation of nuclear factors and specific genetic programs are associated with the level of ROS production leading to cell death by necrosis and apoptosis or adaptive responses such as pro-inflammatory responses, antioxidant enzyme activation, repair processes, effects on cell cycle control, and proliferation. Over the last years, numerous in vitro studies have confirmed this hypothesis leading to the development of assays using the detection of ROS or oxidative stress for the screening of NPs. However, new data during the last year have pointed out other specific effects of NPs which are not related to oxidative stress. For example, NPs can interact with membrane receptors, induce their aggregation, and mimic sustained physiological responses through specific signaling pathways in the target cells. This type of mechanism may contribute to the development of diseases but



Cellular Mechanisms of Nanoparticle Toxicity, Fig. 1 Different physicochemical characteristics of the nanomaterials involved in their biological activity: size, surface area, shape, bulk chemical composition, surface chemistry including solubility as well as surface charge or coatings, and interactions between particles leading to agglomeration and aggregation as well as with proteins leading to "corona" or with receptors in the cell membrane

could also be of use to develop therapeutic strategies whereby NPs activate or block specific receptors.

Cellular Uptake of Nanoparticles and Their Fate at Cellular Level

The uptake of particles by specialized immune cells in human is a normal process which leads to their removal and contributes to the integrity of the body. However, depending on the level of the uptake, this process could induce an increasing release of inflammatory mediators and disturbance of the normal functions of phagocytes such as the clearance and the destruction of pathogens. One of the knowledge of the last fifty years on the effects of a sustained exposure to airborne particles, especially at occupational level, is the concept of overloading. If the mechanisms of clearance are not sufficient to eliminate the particles and if they are persistent, the particles could accumulate in the tissues, leading to a sustained inflammation and chronic pathologies. This was demonstrated not only for exposure to quartz, asbestos, coal, and mineral dusts but also for longtime exposure to heavy PM-polluted atmospheres such as in Mexico City [1]. These questions of uptake and persistence are fundamental for risk assessment evaluation of NPs. This may explain the number of papers published recently that analyze the mechanisms of uptake, the behavior, and the translocation of various NPs. So far, it appears that the response depends on several different parameters: the NP surface and its specific chemical composition resulting from the engineering processes; the capacity of NPs to form aggregates (strongly bonded or fused NPs) or agglomerates (collection of weakly bound NPs); and the methods used for dispersion and experimental preparation, which determine the ability of NPs to adsorb or not specific biological compounds such as proteins, to form the "corona" and to interact with biological membranes [7]. The amount and the structural/functional properties of the adsorbed proteins drive the interactions of these nanomaterials with the membranes and their uptake (Fig. 1). Recent studies have clearly identified a number of serum proteins such as albumin, IgG, IgM, IgA, apolipoprotein E, cytokines, or transferrin that bind to carbon black, titanium dioxide, acrylamide,

Cellular Mechanisms of Nanoparticle Toxicity, Fig. 2 A schematic representation of NP-triggered cellular pathways through membrane receptors, ROS production, and implication of oxidative stress in these responses. NPs could induce activation of EGF or integrin receptors can lead to apoptosis, inflammation, or proliferation. ROS produced by NPs in immediate cellular environment or inside the cells lead to activation of redox-dependent signaling pathways like MAPK and the activation of transcription factors, e.g., AP-1, NF-kB, or Nrf2. They migrate to the nucleus and modify gene expression of cytokines, phase 2 enzymes (glutathione S transferase or GST, quinone oxidoreductase 1 or NQO-1), and antioxidant enzymes (heme oxygenase 1 or HO-1). Oxidative stress could also result in the damage of different organelles like the mitochondria, lysosomes, and nucleus resulting to apoptosis. Accumulation of high intracellular calcium levels through a direct effect on calcium channel might also act as an alternative mechanism for the induction of these mechanisms (Adapted from Marano et al. [11])

or polystyrene NPs [8]. Among the identified proteins, several are ligands for cellular receptors and may contribute to the biological effects of NPs. For example, receptor aggregation induced by NPs could lead to cell signaling: coated gold NPs were able to bind and cross-link IgE-Fc epsilon receptors leading to degranulation and consequent release of chemical mediators [9].

On another hand, integrins such as $\alpha_5\beta_3$ are known to play a key role in cell signaling, and their activation by extracellular ligands can modulate biological processes such as matrix remodeling, angiogenesis, tissue differentiation, and cell migration. These receptors were recently demonstrated as important membrane targets for carbon NPs, and their activation induced lung epithelial cell proliferation which was due at least in part to β1-integrin activation [6].

As far as uptake process is concerned, it is likely that different cell types might have different uptake mechanisms, even for the same NPs. The possible pathways of cellular uptake were previously described by several authors (see Ref. [10]). It could occur through phagocytosis, macropinocytosis, clathrin-mediated endocytosis, non-clathrin- and non-caveolae-mediated endocytosis, caveolae-mediated endocytosis, or diffusion (Fig. 2). These mechanisms have been described for different NPs and may occur for the same NP depending on the cell type, the medium, and the level of aggregation. Therefore, uptake processes are considered as very complex and not

easy to measure. Dawson et al. [12] have postulated that the uptake depends mostly on the size: NPs less than 100 nm can enter the cells and less than 40 nm in the nucleus. It was also suggested that the size of the NPs determine caveolin- versus clathrin-dependent uptakes [13]. However, these oversimplified scenarios are refuted by obvious discrepancies in the recent literature about the optimal size, shape, and mechanisms of internalization of NPs.

The surface charge of the NPs could be an important factor for uptake since the negatively charged surface membrane could favor the positively charged NPs for higher internalization. However, negatively charged NPs were also shown to have enhanced uptake as compared to unfunctionalized NPs, perhaps by their possible interactions with proteins. Endocytosis of small NPs is energy dependent and associated with lipid rafts, dynamin, and F-actin mechanisms. Phagocytosis and macropinocytosis are mostly involved in the endocytosis of large particles (more than 500 nm) and also in the uptake of the aggregates or agglomerates of NPs which could be promoted by their opsonization in the biological fluids. Macropinocytosis (which is one kind of pinocytosis) is also an important mechanism for positively charged NPs and TiO_2 or carbon black aggregate internalization [14].

The behavior of the NPs after their uptake is another important question, but, surprisingly, as far as now, little is known about the intracellular fate of NPs. Most of the transmission electron microscopy (TEM) observations have shown the NPs in cytoplasmic vesicles limited by membranes. These vesicles could further be transported in the cytoplasm through the microtubule network. The bio-persistence of nanomaterials which are resistant to degradation in the endosomal compartment could be one of the factors of further toxicity and accumulation. However, several metal oxide NPs are toxic after dissolution in the cell. Indeed, the uptake of ZnO NPs into the lysosomal acidic medium accelerates their dissolution and the release of Zn^{2+} ions in the cytoplasm. Their excess could induce cytokine production and cytotoxicity and the initiation of acute inflammation at the level of the target organ such as the lung.

NPs such as TiO_2 or carbon black NPs were also observed free in the cytoplasm of cells [14]. Two explanations may be put forward. The first one is that NPs could directly enter by diffusion through the lipid bilayer. It has been shown that cationic NPs could pass though cell membranes by generating transient holes without membrane disruption [15]. Another possible explanation could be the release of NPs after rupture of endosomal compartment. It was described that cationic NPs, after binding to lipid groups on the cell surface membrane, could be endocytosed in vesicles and accumulated in the lysosomal compartment. Within, they are able to sequestrate protons which could lead to the activation of proton pumps and further rupture of the ion homeostasis and lysosomal accumulation of water. The subsequent lysosomal swelling and membrane rupture lead to the cytoplasmic release of NPs [16]. In proliferating cells, these cytoplasmic NPs, associated or not with microtubules, could enter in the nucleus during the mitosis, which could explain that nonsoluble NPs were observed in the nucleus [14]. More rarely, NPs were also observed within the mitochondrial matrix but, so far, no explanation was given to explain this organelle localization.

The Cellular Stress Induced by Nanoparticles and Its Biological Consequences

The last 10 years of research conducted on the mechanisms of toxicity of non-intentional as well as engineered NPs has led to the establishment of a consensus within the scientific community of toxicologists to consider the central role of oxidative stress in cellular responses to NPs leading to inflammation or apoptosis [5, 17] (Fig. 2). The concept of oxidative stress was developed for many years to explain dysfunctions leading to pathologies. Oxidative stress could occur when reactive oxygen species (ROS) are overproduced leading to an imbalance between ROS production and antioxidant defense capacity. Oxidative stress could also occur when the organism shows a deficiency in antioxidant systems and, especially,

in antioxidant enzymatic systems (superoxide dismutase, catalase, glutathione peroxidase). An increased concentration of ROS, exceeding the antioxidant capacity of the cells, can lead to oxidative damage at molecular or cellular level.

ROS have important cellular roles either by acting as second messengers for the activation of specific pathways and gene expressions or by causing cell death. In the hierarchical oxidative stress model in response to NPs, Nel et al. [5] propose that a minor level of oxidative stress leads to the activation of the antioxidant protection, whereas, at a higher level, cell membrane and organelle injuries could lead to cell death by apoptosis or necrosis, but specific signaling pathways and gene expression are involved at each step. The induction of oxidative stress by several NPs is due to their ability to produce ROS (e.g., TiO_2) or to lead to their production. The surface properties of NPs modulate the production of ROS, and the smaller they are, the higher is their surface area and their ability to react with biological components and to produce ROS. However, if this cellular induction appears to be general, all the NPs are not able to produce ROS, and the cellular increase of the latter could be an indirect effect of the uptake.

ROS interact nonspecifically with biological compounds, yet some macromolecules are more sensitive such as the unsaturated lipids, amino acids with a sulfhydril group (SH), and guanine sites in nucleic acids. When lipid bilayer is attacked by ROS, cascade peroxidation occurs leading to the disorganization of the membranes and of their functions (exchange, barriers, information). The most sensitive proteins contain methionine or cysteine residues, especially in their active site, and their oxidation could lead to modifications of their activity and even to their inactivation.

The adaptive cellular responses to NPs are associated with the modulation of different redox-sensitive cellular pathways. Tyrosine kinases and serine/threonine kinase such as mitogen-activated protein kinases or MAP kinases were especially studied (ERK, p38, and JNK) in association with several transcription factors such as NFκB. The free radical can degrade the NFκB inhibitor IκB by the activation of the cascades leading to its proteolysis. The activation of NFκB induces its translocation within the nucleus and its link to consensus sequences in the promoter of numerous genes leading to their transcription. This is also the case for other transcriptions factors such as AP1 and NrF2. The latter plays an essential role in the antioxidant response element (ARE)-mediated expression of phase 2 enzymes such as NQO1 (NADPH quinone oxidoreductase-1) and antioxidant enzymes such as heme oxygenase-1 (HO-1). Indeed, HO-1 was found to be activated by CeO_2 NP exposure of human bronchial cells via the p38-Nrf-2 signaling pathway. The ability of NPs to interact with these signaling pathways could partially explain their cytotoxicity. Recently, TiO_2 and SiO_2 NPs were demonstrated in vitro and in vivo to induce the release of IL1β and IL1α, two potent mediators of innate immunity, via the activation of the inflammasome, a large multiprotein complex containing caspase 1 which cleaves pro IL1-β in its active form. These results lead to consider that these NPs could induce a potent inflammatory response. However, the mechanisms leading to this activation are not yet clear.

Another important target of ROS produced by NPs is DNA. Oxidative damage of DNA could generate intrachain adducts and strand breakage. The bond between the base and deoxyribose could also be attacked leading to an abasic site, and the attack on the sugar could create a single-strand break. The genotoxicity of NPs begins to be studied and recent reviews pointed out the possible genotoxic mechanisms.

However, oxidative stress appears now not sufficient to explain all the biological effects of NPs. The role of epidermal growth factor receptor (EGFR) was investigated by the group of K. Unfried with the demonstration that carbon black NPs induce apoptosis and proliferation via specific signaling pathways both using EGFR [18]. Carbon black NPs could also impair phagosome transport and cause cytoskeletal dysfunctions with a transient increase of intracellular calcium not associated with the induction of ROS since antioxidants did not suppress the response,

which could be due to a direct effect on ion channels that control the calcium homeostasis in the cell [19]. Even if all the mechanisms are not completely demonstrated, it appears now that transmembrane receptors are implicated in NP-induced cell signaling and could lead to specific biological responses to NPs.

Nanoparticles and Cell Death

NPs have also been shown to induce either apoptotic or necrotic cell death in a variety of in vitro systems depending on the concentration and duration of exposure. This induction of cell death mechanism by NPs might act as a basis of different pathologies, and consequently it is important to understand NP-induced apoptosis pathways. Cells are able to undergo apoptosis through two major pathways, the extrinsic pathway with the activation of death receptors and the intrinsic pathway with the central role of mitochondria, its permeabilization, and the release of cytochrome *c* leading to the activation of apoptosome. Recently, the permeabilization of lysosomal membrane was also shown to initiate apoptosis with the release of catepsins and other hydrolases from the lysosomal lumen. The molecular pathways of apoptosis induction by carbon black and titanium dioxide NPs in human bronchial epithelial cells were recently studied. It was shown that the initial phase of apoptosis induction depends upon the chemical nature of the NPs. Carbon black NPs triggered the mitochondrial pathway, with the decrease of mitochondrial potential, the activation of bax (a proapoptotic protein of the Bcl2 family), and the release of cytochrome *c*, and the production of ROS is implicated in the downstream mitochondrial events. TiO_2 NPs induced lysosomal pathway with lipid peroxidation, lysosomal membrane destabilization, and cathepsin B release [20]. Lysosomal permeabilization has also been shown to be important in silica NP-induced apoptosis. These results point out the necessity of a careful characterization of the molecular mechanisms involved by NPs and not just describing at the final outcome.

Future Directions of Research

The interactions between nanomaterials and their biological target are essential to explain their biological effect, and the interest of the recent researches on the cellular mechanisms induced by NPs is to take into account the specificity of the cells and their microenvironment. The first step is the formation of the corona in biological fluids whose composition and affinity kinetics strongly depend on the characteristics of NPs and, especially, their size and surface reactivity. This coating of proteins influences the aggregation, the final size, and, finally, the uptake of NPs via the interaction with the membranes, their specific receptors, or lipid rafts. This could determine if the nanomaterial is bioavailable and if NPs induce or not adverse interactions. The central mechanism proposed to explain the biological response is the oxidative stress. However, this paradigm is debated because very similar oxidative stress effects observed in cellular models and induced by different particles could lead in vivo to different pathological effects. It is now obvious that oxidative stress is a common and nonspecific mechanism in toxicology and that the responses at the level of the cell depend on the perturbation of the redox balance with a few number of induced signaling pathways. The different biological responses could depend on the tissue specificity which could lead to different diseases observed after occupational or environmental exposure to well-known particles or fibers.

Recent studies have also shown that NPs could develop a response without a direct contact with the cells but after an induction of secreted factors, which is the "bystander effect." Small molecules such as purines could be increased at cytoplasmic level in response to NPs, transferred through the gap junctions within a tissue to activate specific receptors [10]. Moreover, NP-induced apoptosis was also demonstrated to be propagated through hydrogen peroxide-mediated bystander killing in an in vitro model of human intestinal epithelium. These specific responses could explain the differences observed in vivo. Finally, the

interactions of NPs with proteins, enzymes, cytokines, and growth factors, outside or inside the cell, lead to modifications of the functions of these proteins with a possible indirect pathological effect.

The large variety of engineered NPs on the market and under development makes these studies very complex. However, the development of safe nanomaterials depends on better knowledge of these specific interactions.

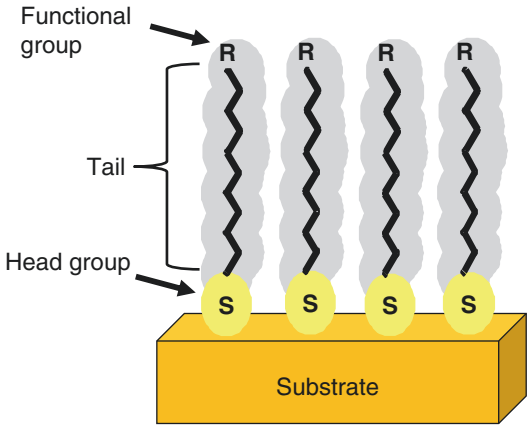
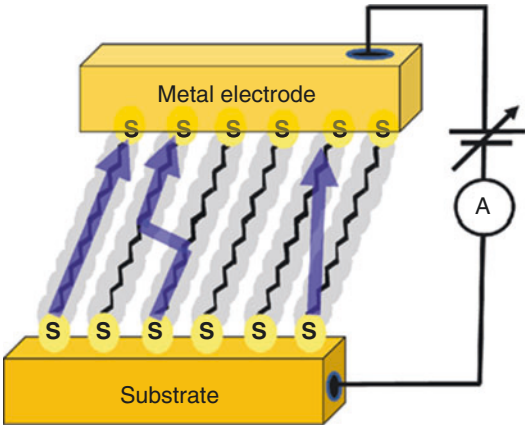
Charge transfer on self-assembled monolayer molecules

Definition



Charge transport in self-assembled monolayers (SAMs) is the transport of an electron or a hole through an organized molecule layer which is bound to a substrate.

Overview



Charge Transport Through Organic Molecules

Significant studies on charge transport properties through organic molecules have been carried out in the general area of molecule-based and molecule-controlled electronic devices, often termed "molecular electronics" [1, 2]. Self-assembled monolayers (SAMs) are composed of an organized layer of amphiphilic molecules in which one end of the molecule, the "head group," shows a special affinity for a substrate [3]. SAMs also consist of a tail with a functional group at the terminal end, as seen in Fig. 1.

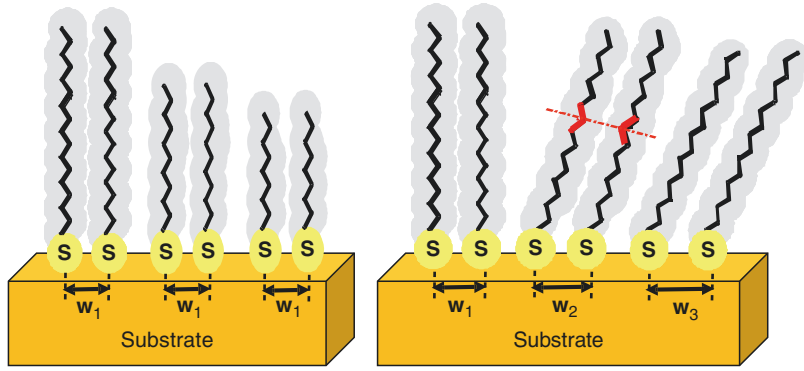
Charge transport of organic molecules is usually limited by hopping processes and is therefore dominated by surface ordering. Self-assembled monolayers are a good model system of molecular electronics due to the ordered surface structure. In order to measure charge transport in a self-assembled monolayer, the substrate surface should be metallic. For example, a gold surface

Charge Transport in Self-Assembled Monolayers, Fig. 1 Schematic of a self-assembled monolayer (*SAMs*) showing the head group that is bound to the substrate. SAMs consist of a tail with a functional group at the terminal

Charge Transport in Self-Assembled Monolayers, Fig. 2 Scheme of charge transport mechanisms through self-assembled monolayers. The dominant charge transport mechanism in a molecular junction involves "through-bond" (*TB*) tunneling, and "through space" (*TS*) as illustrated in the left and right transport channel, respectively

exhibits strong bonds with alkanethiol through S–H bonds. The other electrode should also be metallic for charge transport through the self-assembled monolayer. The measurement scheme of charge transport through a self-assembled monolayer that represents a conductor-molecule-conductor junction is shown in Fig. 2.

Charge Transport Mechanism



For insulating molecules, such as alkane chains, electron transport occurs via tunneling mechanisms. When such molecules are placed between electrodes, the junction resistance changes exponentially: $R = R_0 \exp(\beta s)$, with electrode separation s, where R_0 is the contact resistance and β a decay parameter. In most experiments, the separation s is the length of the alkane chain. However, length is not the only important parameter. Conformation and molecular orientation relative to the electrodes are also important. Other factors need to be considered as well, including energy positions of the highest occupied and lowest unoccupied molecular orbitals (HOMO, LUMO), electrode work function, and nature of the bonding to the electrodes.

Charge transport mechanisms through self-assembled monolayers consist mainly of three processes [4]. The dominant charge transport mechanism in a molecular junction is "through-bond" (TB) tunneling, where the current follows the bond overlaps along the molecules (as illustrated in the left transport channel of Fig. 2). Another contribution involves the charge transport from electrode to electrode, in which the molecule plays the role of a dielectric medium that is called "through space" (TS), as illustrated in the right transport channel of Fig. 2. The last contribution of charge transport pathway involves a chain-to-chain coupling as illustrated in the middle of Fig. 2. As the molecular chains tilt, the decrease of the electron tunneling distance leads to a lateral hop between the neighboring molecular chains.

Two Pathway Models

If electron transport was determined purely by tunneling through the alkane chains, one would expect the value of β to equal zero, since the tunneling distance is the same for all tilt angles. The nonzero value of β indicates the existence of either intermolecular charge transfer or variations in the S-Au bonding as a function of tilt that affect the conductivity in an exponential way with angle.

Slowinski et al. [4] proposed a two-pathway conductance model involving "through-bond" tunneling, and the "chain-to-chain" coupling.

Charge Transport in Self-Assembled Monolayers, Fig. 3 Scheme of the measurement of the junction resistance for two different situations: (*1*) decreasing of the alkane chain (*left* part), and (*2*) the tilting of the alkane chain while maintaining the same number of carbon atoms (*right* part), which will yield the resistance (*1*) per unit length of molecule or (*2*) tilting angle of the molecules, respectively

Assuming no effects due to changes in S-Au bonding, the first pathway is independent of tilt, while the second depends on the tilt angle. The tunneling current, thus, is given by

$$I_t = I_0 \exp(-\beta_{TB} d) + I_0 n_s \exp[-\beta_{TB}(d - d_{CC} \tan \Theta)] \times \exp(-\beta_{TS} d_{CC})$$

where I_t is the current at a specific tilt angle Θ, d is the length of the molecule, n_s is a statistical factor accounting for the number of pathways containing a single lateral hop as compared to those containing only through-bond hops, d is the diameter of the molecule chains, β_{TB} and β_{TS} are respectively through-bond and through-space decay constants. For example, in case of C16 alkanethiol molecule chains, $d_{CC} = 4.3$ Å, $d = 24$ Å, and $n_s = 16$, i.e., the number of carbon atoms in the molecule.

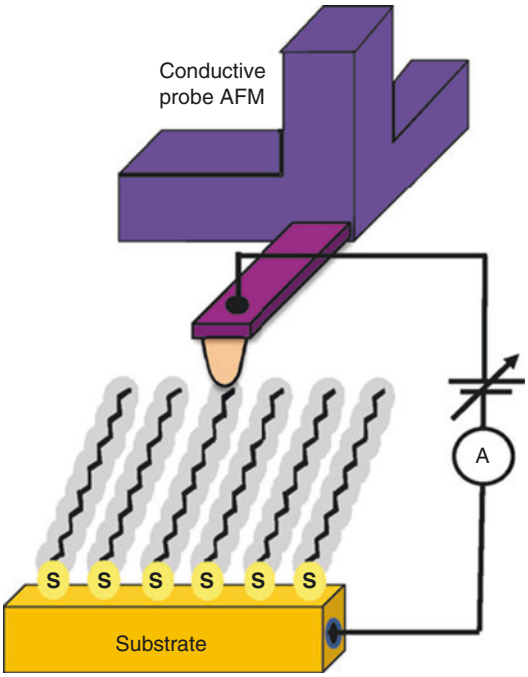
Decay Constant upon Shortening and Tilting of Molecules

The junction resistance is dependent on electrode spacing for two different situations: (1) shortening of the alkane chain [5] and maintaining the same width (w) between chains and (2) tilting of the alkane chain but changing w [6, 7]. These measurements will yield the resistance per unit length of molecule or tilting angle of the molecules, respectively. The conductance decay constant β has already been measured using SAMs with different chain lengths when the separation between electrodes decreases as a function of the alkane chain length (the left image of Fig. 3). The decay constant, β, upon tilting of molecules can be measured using deformation with an AFM tip and simultaneous measurement of current (the right image of Fig. 3). This methodology will be described in the next section.

Basic Methodology

Preparation of Self-Assembled Monolayer

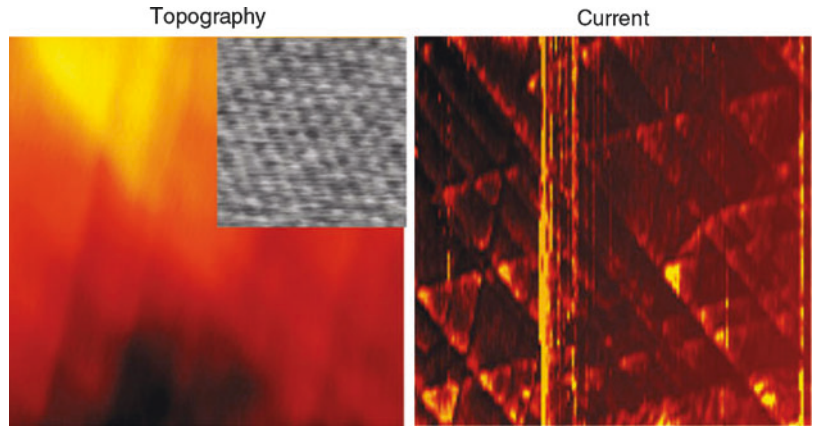
The organic molecular films on various types of substrates (conducting, semiconducting, or insulating substrates) have been prepared using techniques such as the Langmuir-Blodgett technique, dipping the substrates into solution with molecules, drop casting, or spin-coating [8].



As one example, details on the preparation of an alkanethiol SAM will be described below. Gold substrates (200–300 nm of gold coating over 1–4 nm of chromium layer n glass) are prepared by butane flame annealing in air after cleaning in acetone, chloroform, methanol, and a piranha solution (1:3; H_2O_2:H_2SO_4). The resulting surface consisted of large grains with flat terraces of (111) orientation (sizes up to 400 nm) separated by monatomic steps. Flatness and cleanness were tested by the quality of the lattice-resolved images of the gold substrate.

Two types of hexadecanethiol (C16) self-assembled monolayer can be formed on Au (111): complete monolayers of the molecules and islands of molecules covering only a fraction of the substrate. In the first case, the film was produced by immersing the substrate in 1 mM ethanolic solution of C16 for about 24 h, followed by rinsing with absolute ethanol and drying in a stream of nitrogen to remove weakly bound molecules. Incomplete monolayers in the form of islands were prepared by immersing the substrate in a 5 μM ethanolic solution of C16 for approximately 60 s, followed by rinsing. Samples consisting of islands facilitate the determination of the thickness of the molecular film relative to the surrounding exposed gold substrate. The molecular order of the islands improves with storage time at ambient conditions.

Techniques to Measure Charge Transport in Self-Assembled Monolayers



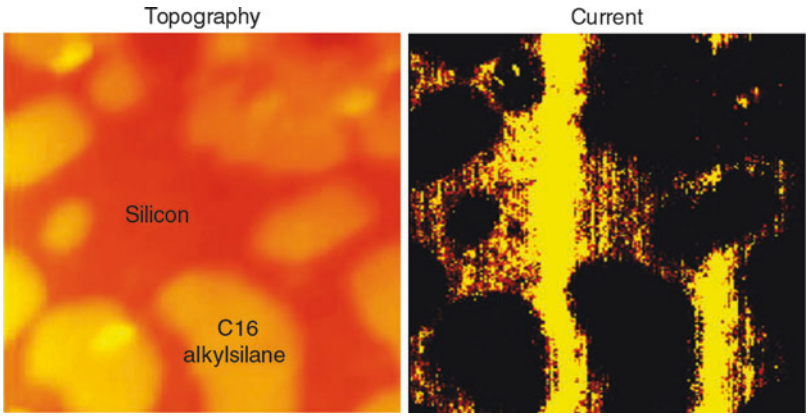
The current through a thiol SAM on a hanging Hg drop electrode can be measured in an electrochemical solution. The current was measured as a function of the monolayer thickness that can be tuned by two methods: by changing the number of carbons in the alkane chain and therefore its length; or, expansion of the Hg drop such that the monolayer surface coverage was reduced and the molecules increased their tilt angle with respect to the surface. Slowinski et al. determined the decay constants $\beta_{TB} = 0.91/Å$ and $\beta_{TS} = 1.31/Å$ by both a fit to their experimental data and by independent ab initio calculations. Mercury drop expansion experiments by Slowinsky et al. have shown a dependence of the current through the alkanethiol monolayers on surface concentration, prompting the authors to suggest the existence of additional pathways for charge transfer, like chain-to-chain tunneling.

Scanning tunneling microscopy and scanning tunneling spectroscopy have been used to reveal the atomic scale surface structure and charge transport properties of SAM layers [9, 10]. STM has been used to reveal various phases of surface structure and atomic scale defects, which could play a crucial role in the electrical transport.

Charge Transport in Self-Assembled Monolayers, Fig. 4 Scheme of conductance measurements of SAM with a conductive-probe atomic force microscopy (*CP-AFM*) system

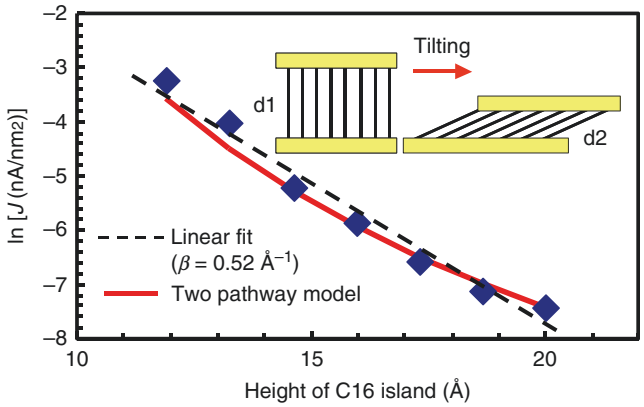
Conductance measurements were performed with a conductive-probe atomic force microscopy (CP-AFM) system. The use of AFM with conducting tips provides the ability to vary the load on the nanocontact and also opens the way for exploring electron transfer as a function of molecular deformation. A junction is fabricated by placing a conducting AFM tip in contact with a metal-supported molecular film, such as a self-assembled monolayer (SAM) on Au, as shown in Fig. 4. The normal force feedback circuit of the AFM controls the mechanical load on the nanocontact while the current–voltage (*I–V*) characteristics are recorded. The possibility to control the load on the contact is an unusual characteristic of this kind of junction and provides the opportunity to establish a correlation between the mechanical deformation and electronic properties of organic molecules. The normal force exerted by the cantilever was kept constant during AFM imaging, while the current between tip and sample was recorded. It is crucial to carry out the experiment in

Charge Transport in Self-Assembled Monolayers, Fig. 5 AFM images (200 × 200 nm) of topography, and current images obtained simultaneously for a full monolayer of C16 on Au (111) surface. Lattice-resolved images of the film (*inset* in the *left* figure) reveal a lattice image of SAM (size: 2 × 2 nm)



the low load regime so that there is no damage to the surface. This can be confirmed by inspection of the images with Ångstrom depth sensitivity as well as by the reproducibility of the current and adhesion measurements. If the measured conductance did not change at constant load and did not show time-dependent behavior in the elastic regime, the tip experiences minimal changes during subsequent contact measurements.

Key Research Findings



The molecular tilt induced by the pressure applied by the tip is one major factor that leads to increased film conductivity. By measuring the current between the conductive AFM tip and SAM as a function of the height of the molecules, the decay parameter (β) can be obtained [11]. Wold et al. studied the junction resistance as a function of load using AFM. The resistance was found to decrease with increasing load within two distinct power law scaling regimes [12]. Song et al. examined the dependence of the tunneling current through Au-alkanethiol-Au junctions on the tip-loading force [13]. It is found that the two-pathway model proposed by Slowinsky et al. can reasonably fit with the results, leading the authors to conclude that the tilt configuration of alkanethiol SAMs enhances the intermolecular charge transfer.

Figure 5 shows topography and current images obtained simultaneously for a full monolayer of C16 on an Au (111) surface. The topographic image reveals the commonly found structure of the gold film substrate, composed of triangular-shaped terraces separated by atomic steps. Lattice-resolved images of the film (inset in the left figure) reveal a ($\sqrt{3} \times \sqrt{3}$)-R30° periodicity of the molecules relative to the gold substrate. Qi et al. measured current–voltage (I–V) characteristics on the C16 alkanethiol sample for loads varying between −20 and 120 nN, and found that the current changes in a stepwise manner and the plateaus are associated with the discrete tilt angle of the molecules. A stepwise response of the SAM film to pressure has been observed previously in other properties such as film height and friction of alkanesilanes on mica and alkanethiols on gold.

In order to measure the thickness of the self-assembled monolayer upon molecular deformation, the SAM islands that partially cover the substrate can be used. The heights of the islands can be obtained from topographical AFM images, while charge transport properties of alkanesilane SAMs on silicon surface are measured using AFM with a conducting tip. In this manner, the load applied to the tip-sample contact can be varied while simultaneously measuring electric conductance. Figure 6 shows the topographic and current images, respectively, that were acquired simultaneously on hexadecylsilane islands on a silicon surface. The image size is 500 × 500 nm. The hexadecylsilane islands are 100–200 nm in diameter and have a height of 1.6 nm at the applied load of 0 nN (or effective total load of 20 nN). It is also

Charge Transport in Self-Assembled Monolayers, Fig. 6 AFM images (500 × 500 nm) of topographic, and current images, respectively, that were acquired simultaneously on hexadecylsilane SAM islands on silicon surface

Charge Transport in Self-Assembled Monolayers, Fig. 7 Semilog plot of current density (nA/nm^2) as a function of the height of the hexadecylsilane SAM islands on a silicon surface. A decay constant (β) = 0.52 ± 0.04 Å^{-1} was found for the current passing through the film as a function of tip-substrate separation

clear that the current measured on the alkanesilane island is much smaller than that measured on the silicon surface.

These changes were shown to correspond to the molecules adopting specific values of tilt angle relative to the surface, and explained as the result of methylene groups interlocking with neighboring alkane chains. In the case of complete monolayers of alkanethiol SAM, the junction resistance (R) was measured as a function of the applied load [6]. These data were converted to current versus electrode separation by assigning each step in the current to a specific molecular tilt angle, following the sequence established in previous experiments. It was found that ln(R) increases approximately linearly with tip-surface separation, with an average slope β = 0.57 (±0.03) Å^{-1}. Similar measurement of the decay parameter upon the molecular tilts was carried out with a scanning tunneling microscope and simultaneous sensing of forces. By measuring the current as a function of applied load, a tunneling decay constant β = 0.53 (±0.02) Å^{-1} was obtained [14].

In the case of hexadecylsilane molecules, the local conductance of hexadecylsilane SAM islands on a silicon surface was measured with conductive-probe AFM. A semilog plot of current density (nA/nm^2) was obtained as a function of the height of the hexadecylsilane SAM islands on a silicon surface, as shown in Fig. 7. A decay constant (β) = 0.52 ± 0.04 Å^{-1} was found for the current passing through the film as a function of tip-substrate separation [7]. Figure 7 shows the best fit of the two-pathway model with the experimental current measurement as a function of the heights of molecule islands by using the fitting parameters of β_{TB} and β_{TS} that are 0.9 and 1.1 Å^{-1}, respectively. The good fit indicates that

the two-path tunneling model is a valid model to describe this observation.

While saturated hydrocarbon chains mainly interact with each other via weak van der Waals forces, much stronger intermolecular π-π interactions can be present in organic films comprised of conjugated/hybrid molecules. This influences charge transport significantly [5, 15]. In a conductance AFM study of two SAM systems, Fang et al. revealed the role of π-π stacking on charge transport and nanotribological properties of SAM consisting of aromatic molecules [16]. The two model molecules chosen in this study are (4-mercaptophenyl) anthrylacetylene (MPAA) and (4-mercaptophenyl)-phenylacetylene (MPPA). In MPPA, the end group is a single benzene ring, while in MPAA it is changed to a three fused benzene ring structure. This structural difference induces different degrees of lattice ordering in these two molecular SAM systems. Lattice resolution is readily achieved in the MPAA SAM, but it is not possible for the MPPA SAM under the same imaging conditions, indicating the MPAA is lacking long-range order. However, it is important to note that even without long-range order, the stronger intermolecular π-π stacking in the MPAA SAM greatly facilitates charge transport, resulting in approximately one order of magnitude higher conductivity than in the MPPA SAM.

Future Directions for Research

In this contribution, the basic concept of and recent progress on charge transport studies of organic SAM films formed by saturated hydrocarbon molecules and conjugated molecules has been outlined. Several techniques, including AFM, STM, and hanging Hg drop electrode, are used to elucidate the charge transport properties of SAM layers. A number of molecular scale factors such as packing density, lattice ordering, molecular deformation, grain boundaries, annealing induced morphological evolution, and phase separation play important roles in determining charge transport through SAM films. High resolution offered by scanning probe microscopy (SPM) is a key element in identifying and studying microstructures (e.g., molecular tilt, lattice ordering, defects, vacancies, grain boundaries) in organic films and their effects on electronic properties. Other advanced surface characterization techniques, such as SAM with nano-electrodes, in combination with conductive-probe atomic force microscopy, and spectroscopic techniques such as ultraviolet photoemission spectroscopy (UPS) and inverse photoemission spectroscopy (IPES), could be promising venues to explore the correlation between microstructures and electronic properties of organic films.

Definition

Photochemical milling (PCM), also known as photochemical machining, is the process of fabricating high precision metal workpieces using photographically produced masks and etchants to corrosively remove unwanted parts. This process is called wet etching in MEMS fabrication techniques and can be also applied to nonmetal materials. Wet etching, when combined with nanolithography, is a useful process to fabricate detailed nanostructures by extremely controlled removal (Fig. 1).

Overview

Photochemical machining (PCM) produces three-dimensional features by wet chemical etching (Fig. 2). PCM yields burr-free and stress-free metal products and allows for the machining of a wide range of materials which would not be suitable for traditional metal working techniques. PCM is also known as photoetching,

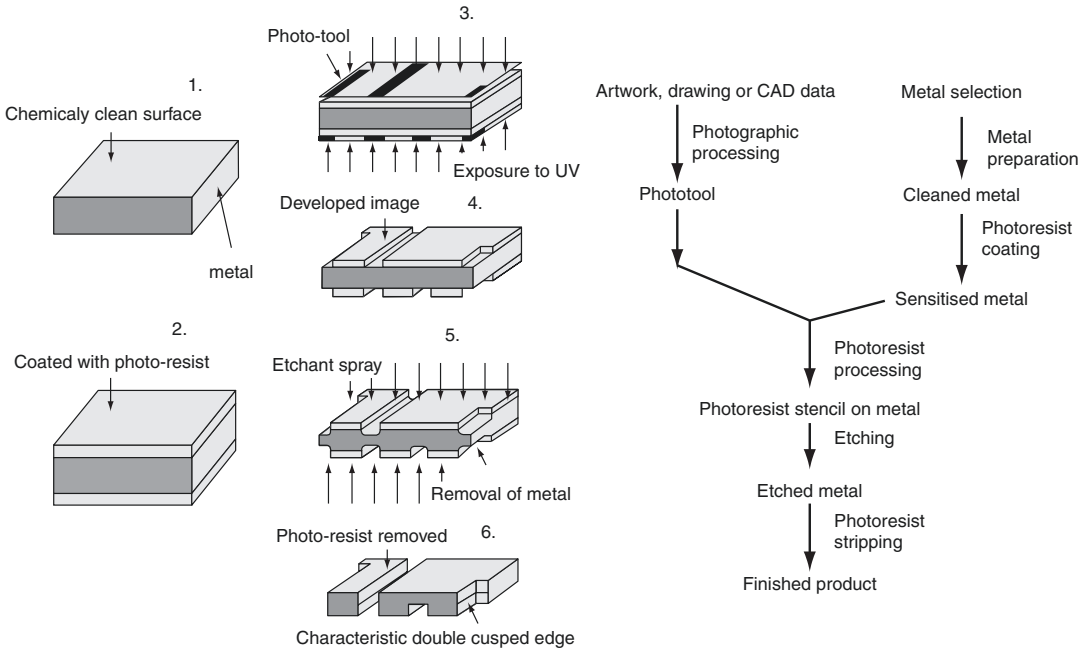
Chemical Milling and Photochemical Milling, Fig. 1 (**a**) Schematic illustration of photochemical milling process

photomilling, photofabrication, or chemical blankening [1]. There is a special type of photochemical milling that uses light for initiating or accelerating the wet etching process in metal or semiconductor materials.

The combination of photoresists and wet etching enables the fabrication of very detailed structures with complex geometry or large arrays of variable etching profiles in thin (<2 mm) flat metal sheets. Photoresists are made of synthetic polymers having consistent properties. Liquid photoresist coats a thin film by dipping or spin casting which enables the production of detailed patterns, but often creates pinholes in the thin layer. Thick dry photoresist films applied by hot lamination have advantages of process simplicity and reliability although the materials are expensive.

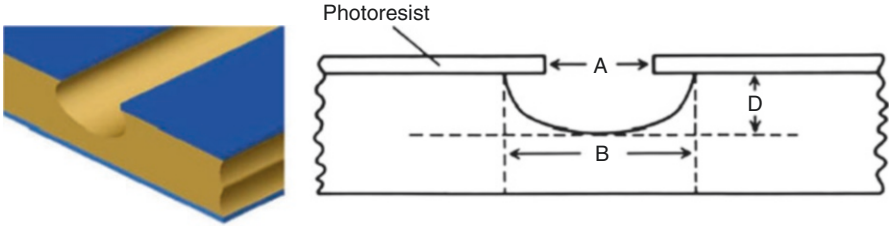
The process of wet etching is based on the redox chemistry of etchant reduction and metal oxidation, which results in the formation of soluble metal-containing ions that diffuse away from the reaction metal surface. Many metals commonly used in manufacturing industry are etched readily in aqueous solutions comprising etchant (e.g., ferric chloride). Metal oxides and virtually all materials can be etched with a proper selection of etchant regardless of different etching rates.

Wet etching in the PCM process is isotropic where the etchant attacks both downward into the material and sideways under the edge of the resist layer and the ratio of the depth to the undercut is termed the etch factor (Fig. 3). In MEMS device fabrication, the undercut plays a key role in fabricating free-standing microstructure patterns (e.g., beams and cantilevers) that are necessary where microstructures have to be flexible, thermally isolated, small mass, double-sided contacts with gases or liquid surroundings. In most cases, the free-standing material is deposited as a film on a substrate surface, termed a sacrificial material. The etchant, possessing a lateral etching component, must be sufficiently selective not to attach the free-standing material. Further, novel nanolithography techniques enable to create submicrometer-scaled features.



Basic Methodology

Photolithography



An image of the profile of the flat feature is generated by computer-aided design (CAD) and electronically transferred onto a photographic film to produce a phototool, a photolithographic mask as known in MEMS. The photoresist is exposed through the phototool from ultraviolet source. There are two types of photoresist – negative and positive. UV lights soften the positive film, and the exposed area is released in the developing solution. The negative photoresist film has reversed pattern developing characteristics. Wet resist is applied to a metal sheet by a dipping process while spin coating is commonly used in micromachining (Fig. 4).

Wet Etching

In wet chemical etching, the components of the solid are changed into soluble chemical components which are transported by diffusion or convection away from the surface into the bulk of the solution. The solvent molecules form a shell around the dissolved solid particles that are mobile in the liquid phase. The specific interactions of the components of the liquid with the solid determine the reaction rate, which is attributed to a greater etching selectivity of the solid

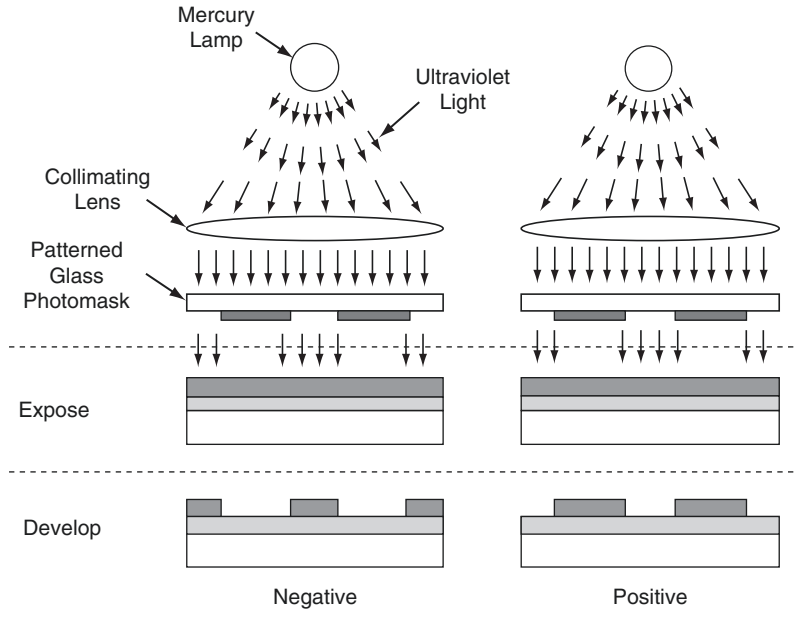
than dry etching methods. Water is used as the solvent in most wet etching processes [3].

1. In a metal or a semiconductor, the dissolution of metal or semiconductor is accompanied by an electron transfer and obeys the laws of electrochemistry. The oxidation reaction of metal or semiconductor M releases metal ions into solution and produce electrons.



$$M = M^{n+} + ne^{-} \quad (\text{anodic partial process})$$

A secondary chemical redox process takes place to transfer the liberated electrons to an oxidizing agent OM in the solution.

$$OM + ne^{-} = OM^{n-} \quad (\text{cathodic partial process})$$

The anodic and cathodic partial processes results in etching metal.

$$M_{\text{in solid}} + OM_{\text{in solution}} = M^{n+} + OM^{n-}$$

Chemical Milling and Photochemical Milling, Fig. 4 Positive and negative photoresist Ref.[2]

The etch rate corresponds to the number of metal ions produced at the solid surface per time unit, which is proportional to the interchanged anodic partial current I over the surface A, I/A. Metals and semiconductors often dissolve as complexes (e.g., $[MY_x]^+$) where smaller molecules or ions (ligands) form a chemically bound primary shell around the central atom. The etch rate can be changed by varying the concentration of reactants, temperature, viscosity, and convection of the solution.

2. In dielectric materials, acid–base reactions take place if the material to be etched reacts with hydrogen or hydroxyl ions. The cations are solvated by water as a strong polar solvent and they can diffuse rapidly into the bulk of the solution. Etching processes are applicable with oxides and hydroxides of metals and semiconductors at low pH-values,

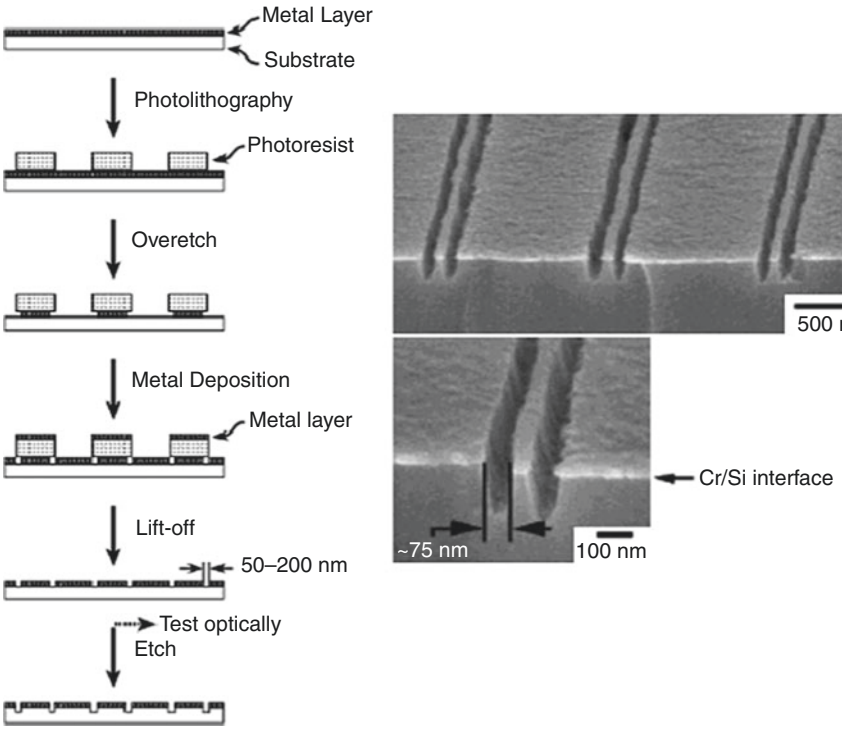
$$M_xO_y + 2yH^+ = xM^{2y/x+} + yH_2O$$
$$M(OH)_x + xH^+ = M^{x+} + xH_2O$$

M = metal or semiconductor (e.g., Cu, Si)

Similarly, at very high pH-values some metals and semiconductors form stable water dissolvable complexes that are easily solvated by water.

Acidic anions, such as chloride and fluoride, or neutral molecules react as ligands, a typical example of which is the etching of SiO_2 in HF-containing etchants.

$$SiO_2 + 6HF = H_2SiF_6 + H_2O$$



Salt-like film is also dissolved by complexing agents. For example, copper chloride is etchable in neutral KCl solutions.

$$CuCl + 2Cl- = [CuCl_3]^{2-}$$

Key Research Findings for Nanotechnology

Edge Lithography

Undercutting by isotropic wet etching is applied to transfer the edges of a photoresist pattern into a feature of the final pattern, as illustrated in Fig. 5. The process generates 50 nm scale trenches by controlled undercutting. Currently, patterning features <100 nm are possible by advanced lithography techniques – deep ultraviolet, electron beam writing, extreme ultraviolet, and x-ray photolithography – but are prohibitively

Chemical Milling and Photochemical Milling, Fig. 5 (*Left*) Schematic illustration of the process generating nanometer-scale lines by controlled undercutting. A pattern is produced in the photoresist by photolithography or soft lithography. An isotropic etch is applied to the substrate beneath the photoresist. Shallow undercutting of the base layer, followed by evaporation into the exposed areas, and lift-off generates ~50 ± 200 nm gaps in the thin film at the edges of the photoresist pattern. The pattern is then used as an optical filter. (*Right*) SEM image of a cross section of linear trenches at the edges of a 100 nm line transferred into a Si <100 > substrate. The trenches are 250 nm deep Ref. [4]

expensive. In contrast, edge lithography is a convenient, inexpensive technique for patterning features with nanometer-scale dimensions.

Wet Etching for Maskless Patterning

In the photochemical etching process, light exposure can increase the charge carrier density in near surface areas which enhances the anodical as well as the cathodical partial processes in wet etching. For example, defect electrons in the lower band left by light exposure support the release of cations and at the same time the released electrons in the conduction band are readily accepted by an oxidizing agent in the solution. In the same process, the intensive exposure with a focused beam enables direct pattern generation without a lithographic mask. This method is specified preferentially for patterning semiconductors deposited on a nonconducting substrate (e.g., GaN on sapphire) [5].

Future Directions for Research

Wet chemical etching is a simple, inexpensive, and well-understood process. The process plays a key role in the field of MEMS and nanotechnology. Continuous effort is being made to provide controllability, repeatability, and, most importantly, detail in fabricating microstructures. New etchant compositions have been developed to apply wet chemical etching to the materials constituting new devices. A representative example is selective removal of metal nitride films on sapphire for a

new version of a light-emitting diode. At the same time, great efforts have been made to develop new lithography techniques for nanoscale patterns such as proximal probe lithography, very thin to monolayer lithography, and soft lithography. PCM equipped with the emerging lithography techniques can cause the paradigm shift in the creation of nanoscaled features [6].

Definition

Chemical vapor deposition (CVD) is referred to deposition process of thin films and nanostructures through chemical reactions of vapor-phase precursors. Since CVD can be conducted using high purity precursors, it likely leads to thin film and nanostructures with high purity. The use of vapor-phase precursors also enables better control on the composition and

doping of thin films and nanostructures. For example, Si thin films can be deposited by decomposition of silane gas (SiH_4) by plasma or heat as follows: SiH_4 (g) → Si (s) + $2H_2$ (g). Doping of Si films with boron will lead to p-type Si films and can be achieved by the addition of B_2H_6 gas.

Classification

Classification by Operating Pressures

Chemical reactions involved in a CVD technique can be initiated by many ways leading to the classification of various types of CVD approaches. For example, CVD can be classified according to the operating pressures as follows:

- *Atmospheric pressure CVD* (APCVD) is referred to CVD processes that are conducted at atmospheric pressure. The advantage of APCVD is a simple experimental setup without the need of a vacuum system. The potential drawback will be the undesired contamination.
- *Low-pressure CVD* (LPCVD) is referred to CVD processes at pressures below and close to atmospheric pressure. One of the purposes of reducing the operation pressure is to avoid undesired reactions between precursors. LPCVD can also improve film uniformity.
- *Ultrahigh vacuum CVD* (UHVCVD) is referred to LPCVD processes at a very low pressure, typically below ~10^{-8} torr.

There are *CVD* processes that operate at high pressures. See details in section "Classification by Excitation Techniques."

Classification by Excitation Techniques

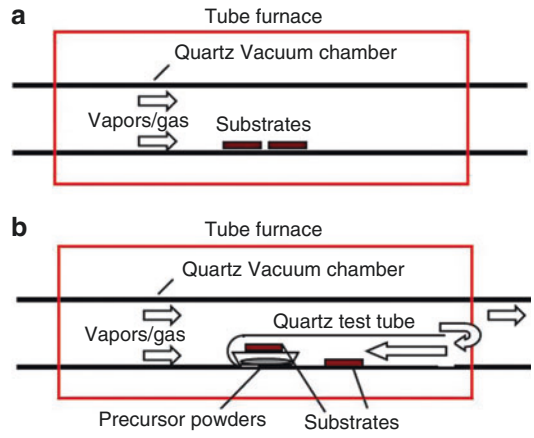
In addition, CVD can be classified by the excitation techniques that initiate the chemical reactions. For example:

- *Plasma-enhanced CVD* (PECVD) is referred to CVD processes that employed plasmas to initiate the needed chemical reactions. In general, PECVD could reduce the growth temperatures as the chemical reactions in PECVD are not ignited by heat. There are many subclassification of PECVD depending on the type of AC potential used for plasma generation. For example, RF-PECVD and MW-PECVD employed radio frequency (RF, typically at 13.56 MHz) and microwave (MW, 2.45 GHz) potential to dissociate gases and produce the needed chemical reactions. Some PECVD are classified by the configuration of plasma generation. For instance, inductively coupled-plasma CVD (ICP-CVD) is actually RF-PECVD that uses an induction coil as the RF electrode outside the vacuum chamber and is sometimes called remote plasma CVD [1]. On the other hand, two RF plasmas can be used in a CVD system. For example, a dual RF-PECVD approach was demonstrated for the growth of vertically aligned carbon nanofoils/nanowalls and carbon nanotubes (CNTs) [2, 3].
- *Thermal CVD* is referred to CVD processes that employed heat to initiate the needed chemical reactions. The most common thermal CVD technique employed external furnace to control the growth temperatures of the entire reaction zone (e.g., vacuum quarts/glass chambers). This is sometimes called *hot-wall thermal CVD*. The advantages of this approach are including the potential of large-scale synthesis. In contract, there are several approaches to achieve the so-called *cold-wall thermal CVD*. For example, hot filaments (HF) are used to heat up the temperatures of the adjacent substrates while the needed chemical reactions are ignited with higher temperatures on the filaments. This approach is called *hot filament CVD* (HFCVD). Other heating approaches can also be used including IR lamps, laser beams, and passing current flows through a suspended Si chip [4].

Classification by the Precursor Type and Feeding Procedure

CVD can also be classified by the type of precursors or the procedures where precursors are introduced into the reaction chamber. Some of the examples are described as follows:

- *Aerosol-assisted CVD (AACVD)* involves the use of carrier gases (usually inert gases such as

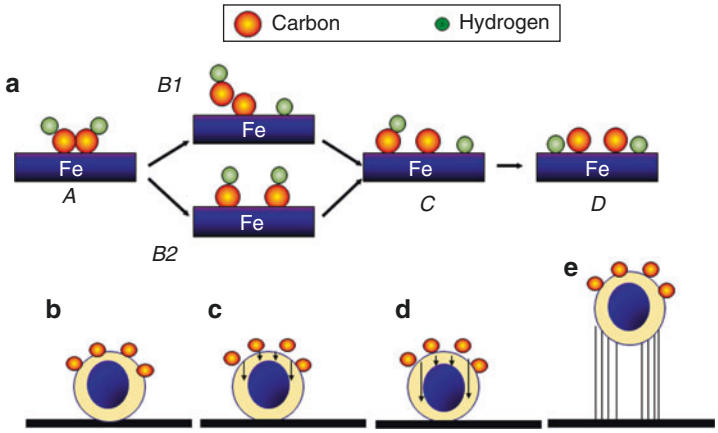


Ar, He, etc.) to transfer vapors of liquid-phase precursor into the reaction chamber in the form of aerosol. This approach enables the use of liquid precursors for the CVD process. The most well-known AACVD is *metalorganic CVD* (*MOCVD*) where metal organic solids are dissolved in organic solvents. For example, trimethylgallium [TMGa, $Ga(CH_3)_3$] is often used as the source of Ga to form GaN when it reacts with ammonia (NH_3) at high temperatures. Thus *AACVD* can be viewed as a subclassification of *thermal CVD*.

- *Atomic layer CVD* (*ALCVD*) is better known as *atomic layer deposition* (*ALD*) or *atomic layer epitaxial* (*ALE*) [5]. ALD allows conformal deposition of monolayer of binary (or ternary) compounds by introducing the two (or three) reacting precursors in a pulsed mode one after another. For example, monolayers of zinc sulfide (ZnS) can be deposited by first exposing the growth surface with $ZnCl_2$. Once chemisorption of $ZnCl_2$ is completed, the reaction chamber will be purged with an inert gas. Thereafter, hydrogen sulfide (H_2S) will be introduced to the chamber so that the following reaction will take place on the growth surface: $ZnCl_2$ (g) + H_2S (g) → ZnS (s) + HCl (g). Since the chemical process is self-limiting, only one monolayer (or less) of ZnS will be formed in each cycle. The advantage of *ALD* is conformal coating on the full surface of the sample and the precision of film thickness control. The major drawback is the extreme low deposition rate. *ALD* is usually conducted at low temperatures (200–400 °C) and may be viewed as a subclassification of *thermal CVD*. However, plasma and metal organic precursors are sometimes used in *ALD*.

Examples of CVD Approaches for Nanotechnology

Catalytic Chemical Vapor Deposition (CCVD)

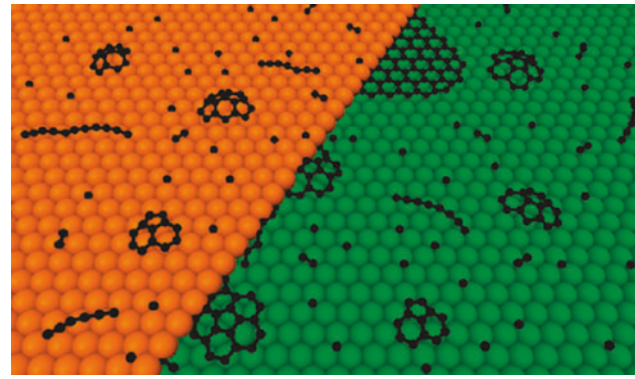


Catalytic chemical vapor deposition (*CCVD*) is the simplest and most popular technique for the synthesis of carbon nanotubes (CNTs), graphene, and nanowires (NWs). *CCVD* is simply a *thermal CVD* approach with the use of catalyst that induces the formation of nanomaterials. A typical experimental layout for *CCVD* is shown in Fig. 1. As shown, the *CCVD* system consists of a tube furnace and a quartz tube chamber where chemical reactions are taking place.

Chemical Vapor Deposition (CVD), Fig. 1 (**a**) Typical setup for CCVD. (**b**) Modified double-tube configuration

Synthesis of Vertically Aligned Carbon Nanotubes by CCVD

A typical experimental setup of *CCVD* for the synthesis of carbon nanotubes (CNTs) is shown in Fig. 1a. In this case, the substrates (usually oxidized Si) are first deposited with catalyst films such as Fe, Ni, or Co by electron beam evaporation, sputtering, pulsed laser deposition, etc. [6–8]. Then, these samples were then annealed at 600 °C in Ar, N_2, or H_2 for about 30 min. During the annealing process, these catalyst films will be converted into nanoparticles that will serve as the growth sites for CNTs. After the annealing, the growth temperatures (~600–800 °C) and growth ambient (usually Ar, H_2, or their mixtures) will be set prior to the introduction of hydrocarbon source gas (methane, CH_4; ethylene C_2H_4, acetylene, C_2H_2). These hydrocarbon gases will be decomposed on the surface of the catalyst nanoparticles through the chemical process of dissociative adsorption [6].



Chemical Vapor Deposition (CVD), Fig. 2 (**a**) Sequences of dissociative adsorption of C_2H_2 on Fe surface (see text for detailed description). The (**b**) decomposed carbon atoms (**c**) diffused into the subsurface of the solid-core Fe nanoparticle until (**d**) supersaturation and then (**e**) segregate as nanotubes

For example, dissociated adsorption of C_2H_2 is summarized in Fig. 2 [6]. Figure 2a shows the adsorption of a C_2H_2 molecule (step *A*) on the surface of the Fe nanoparticle. This will lead to either the breaking of C–H bond (step *B1*) to form C_2H and H fragments or the breaking of C=C bond (step *B2*) to form two C–H fragments. The catalytic function of the Fe nanoparticle is to reduce the energy required for decomposition by a charge transfer from hydrocarbon molecules to Fe. According to a first principle calculation, the dissociation energy of the first hydrogen atom from an isolated C_2H_2 (step *A* to *B1*) in vacuum can be reduced from 5.58 to 0.96 eV. On the other hand, the energy barrier between *A* and *B2* is 1.25 eV. The C–H bond breaking (step *B1*) is followed by C–C bond breaking (step *C*) with a potential barrier of 1.02 eV, whereas C=C bond breaking (step *B2*) is followed by C–H bond breaking (step *C*) with an energy barrier of 0.61 eV. Both modes (*A* to *B1* to *C or A* to *B2* to *C*) are possible and give one C–H fragment, one C, and one H. The decomposition of C_2H_2 is completed after the breaking of the last C–H bond (step *D*) with the need of a potential energy of 0.61 eV.

The decomposed carbon atoms (Fig. 2b) will then diffuse into the subsurface of the Fe nanoparticle (Fig. 1c). At typical growth temperature (650–800 °C), these nanoparticles are not melted even after considering the eutectic point of Fe-C phase. Since dissociative adsorption is an exothermic process, the near surface temperatures of the catalytic nanoparticles will be higher than the growth temperatures. Since the melting of nanoparticles starts from their surfaces, it is possible that the near surface region of the particles is melted. This will form the gas-liquid interface between carbon and Fe solid-core nanoparticles. Due to the high diffusion, rate of carbon in Fe melts; a Fe-C alloy will start to form. When these nanoparticles become supersaturated with carbon (Fig. 2d) to a value critical for growth at the solid-liquid interface, the excess carbon will segregate as carbon nanotubes (Fig. 2e). A tip-growth mode is illustrated in this figure where the nanoparticles remained at the tips of CNTs. A base-growth mode is also possible where the nanoparticles remained at the bases of CNTs. Thus, the diameters of CNTs depend to certain extent on the diameters of the nanoparticles. By controlling the thickness of the catalyst films and other parameters, *CCVD* enables the growth of vertically aligned (VA) single-, double-, and multi-walled CNTs [8].

In fact, one of the most impressive achievements in the growth of vertically aligned single-walled CNTs (VA-SWCNTs) is the so-called super growth [9]. This water-assisted approach was based on *CCVD* with the addition of 20–500 ppm of water vapors. These water vapors were introduced into the growth chamber by flowing carrier gas (Ar, or He with 40 % H_2) through a water bubbler. Ethylene was used as the carbon source along with various catalysts

Chemical Vapor Deposition (CVD), Fig. 3 Nucleation of graphene on Ni (111) surface (Reprinted with permission from J. Gao et al., J. Am. Chem. Soc. C **133**, 5009 (2011). Copyright (2011) American Chemical Society)

[Fe (1 nm), Al (10 nm)/Fe (1 nm), Al_2O_3 (10 nm)/Fe (1 nm), to Al_2O_3 (10 nm)/Co (1 nm)]. VA-SWCNTs with the length of several mm and diameter of 1–3 nm were reported. This approach also enabled the growth of double- and multi-walled CNTs [10] (Fig. 3).

The abovementioned *CCVD* approaches are achievable at relatively low temperatures and lead to VA-SWCNTs. Historically SWCNTs were grown by *CCVD* at higher temperatures in a powder form. In 1996, Dai et al. demonstrated the growth of SWCNTs at 1200 °C by using carbon monoxide (CO) as the carbon source gas and supported MoO_x powder as the catalyst [11]. In this case, powder form of SWCNTs was grown on the catalyst that was loaded on a quartz boat. Later, the growth temperature was being able to reduce to 1000 °C by using CH_4 as the source gas, resulting in the growth of randomly distributed SWCNTs on powders of supported metal-oxide catalysts [12]. The diameters of these SWCNTs are 1–6 nm. In addition, *CCVD* could also be modified into a high-pressure mode for large-scale synthesis of SWCNTs [13]. In this approach, liquid iron pentacarbonyl, $Fe(CO)_5$, was used as the catalyst and was introduced into the CVD chamber by CO gas. At operational pressures of 1–10 atm and temperatures of 800–1200 °C, $Fe(CO)_5$ will thermally be decomposed into iron clusters in gas phase and react with CO gas to produce SWCNTs. The yield of SWCNTs was found to increase with temperature and pressure. The average diameter of SWCNTs was decreased from ~1.0 nm at 1 atm to 0.8 nm at 10 atm. This approach is now known as high-pressure carbon monoxide (HiPCO) technique, one of the major techniques for large-scale synthesis of SWCNTs with small diameters. Finally, alcohol was also used as the carbon source for the synthesis of SWCNTs by *CCVD* [14]. In this case, ethanol vapors (5 torr) were supplied to the reaction chamber that contained Fe/Co catalyst supported with zeolite at 700–800 °C.

Synthesis of Graphene by CCVD

CCVD is also applicable for the synthesis of two-dimensional (2D) materials. For example, the growth of graphene by CCVD has been demonstrated using Ni [15, 16] and Cu plates [17]. Theory suggests that the decomposition of hydrocarbon gases on Ni or Cu are similar to the dissociative adsorption discussed for the growth of CNTs discussed earlier with differences on the atomic configuration [18]. The major differences are (1) carbon atoms dissolve into the bulk / sub-surface of the Ni plate and led to the formation of few layered graphene (FLG); (2) contrarily, the growth process is limited on the surface in the Cu case and result in the formation of mono layered graphene (MLG) [17]. Theory also suggests that the growth of graphene on Cu surface by methane (CH4) gas could happened with hydrocarbon radical instead of free carbon atoms [18].

The nucleation of 2D materials such as graphene is also different from that in 1D CNTs. for the case of CNTs, nucleation is confined on

the surface and subsurface regions of the zero dimensional metal particles. The nucleation of graphene involves a lot more surface diffusion processes [19]. As shown in Fig. 3, the process involves the transformation of 1D carbon chain to 2d sp2 carbon clusters/networks. Furthermore, it was suggested that graphene nucleation near a step edge is more preference to that on a terrace.

Synthesis of ZnO Nanostructures by CCVD

On the other hand, *CCVD* can be modified into a *double-tube* configuration as shown in Fig. 1b. This approach will enable the use of solid precursors to generate the needed growth vapors. For example, various ZnO nanostructures can be grown by such a setup by using ZnO and graphite powders as the precursors [20, 21]. As shown, these powders were loaded on a ceramic combustion boat which is contained at the end of a closed-end quartz tube. The substrates can be placed a distance away from the boat. The following reactions will occur at 1100 °C when oxygen gas (O_2) is introduced:

$$\mathrm{ZnO\,(s)\ +\ C\,(s)\ \rightarrow\ Zn\,(g)\ +\ CO\,(g)}$$

$$\mathrm{2Zn\,(g)\ +\ O_2(g)\ \rightarrow\ 2ZnO\,(s)}$$

Based on this approach, various ZnO nanostructures can be grown with and without the use of catalyst (gold films, Au), including nanotubes [20], nanowires, nanobelts, nanocombs [21], and nanosquids [22].

Synthesis of Boron Nitride Nanotubes by CCVD

The double-tube *CCVD* configuration in Fig. 1b was also used for the growth of boron nitride nanotubes (BNNTs) [23–25]. In this case, boron, magnesium oxide, and iron oxide were used as the precursors and were loaded on the ceramic boat. The possible chemical reaction at 1100–1200 °C is 4B (s) + MgO (s) + FeO (s) → $2B_2O_x$ (g) + MgO_y (s) + FeO_z (s), where x, y, and z are yet to be determined. When ammonia gas (NH_3) is introduced into the chamber, the generated boron oxide vapors (B_2O_x) will react with NH_3 to form BNNTs. The partially reduced MgO_y and FeO_z are the possible catalysts for the formation of BNNTs [23]. It is noted that the synthesis of BNNTs by these chemical processes usually requires temperatures above 1350 °C. The key success for the low-temperature growth discussed here is due to the so-called "growth vapor trapping" approach obtained by placing the bare substrates directly on the ceramic boat. These substrates trapped the growth vapors from the precursors and enhanced the nucleation rate of BNNTs at low temperatures. In recent experiments, Fe, Ni, or MgO films were coated on the substrates used as the catalysts [24, 25]. Such an approach leads to patterned growth of BNNTs. The possible chemical reactions are

$$\mathrm{B_2O_2(g)\ +\ MgO\,(s)\ +\ 2NH_3(g)\ \rightarrow\ 2BN\,(s,\ BNNTs)\ +\ MgO(s)\ +\ 2H_2O(g)\ +\ H_2(g),\ or}$$

$$\mathrm{B_2O_2(g)\ +\ Ni\ (s)\ or\ Fe\ (s)\ +\ 2NH_3(g)\ \rightarrow\ 2BN\ (s,\ BNNTs)\ +\ Ni\ (s)\ or\ Fe\ (s)\ +\ 2H_2O\ (g)\ +\ H_2(g)}$$

Definition

Chitosan nanoparticles are biodegradable, nontoxic carriers for nucleotides and drugs with the potential for broad applications in human disease.

Overview

Characteristics of Chitosan

Chitosan is a natural cationic polysaccharide composed of randomly distributed *N*-acetyl-D-glucosamine and β-(1,4)-linked D-glucosamine. Chitosan can be chemically synthesized via alkaline deacetylation from chitin, which is the principal component of the protective cuticles of crustaceans [1]. Chitosan is biodegradable in vivo by enzymes such as lysozyme, which is endogenous and nontoxic [2]. In addition, biodegradation of chitosan is highly associated with the degree of deacetylation. These properties render chitosan particularly attractive for clinical and biological applications as a highly biocompatible material with low toxicity and immunogenicity.

Several techniques have been designed to assemble chitosan nanoparticles (CH-NPs) as a drug delivery system including emulsions, ionotropic gelation, micelles, and spray drying. A variety of therapeutic agents can be loaded into CH-NPs with high efficiency, which can then be injected intravenously, intraperitoneally, or intrathecally.

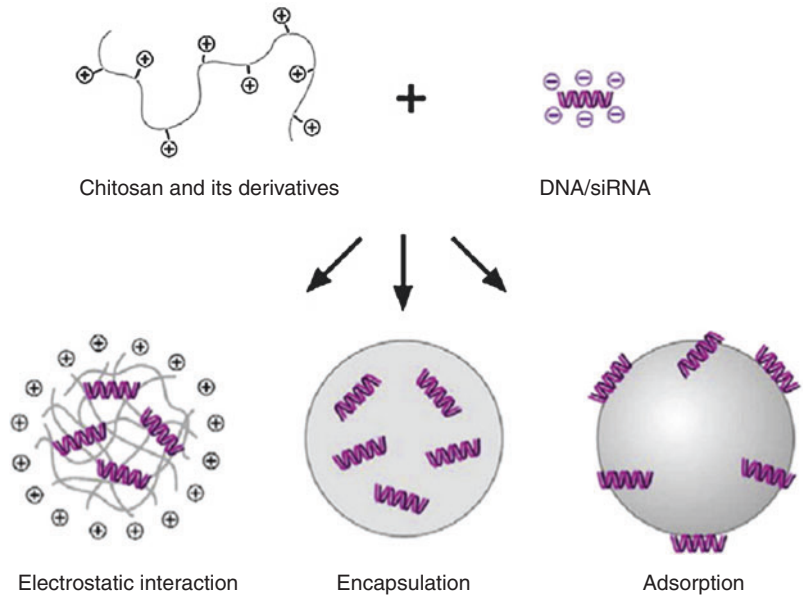
Chemical Modification of Chitosan

The abundant amine and hydroxyl groups present in chitosan offer a unique opportunity to attach targeting ligands or imaging agents. Numerous derivatives of chitosan have been designed and tailored to improve the physicochemical and adhesive properties of nanoparticles such as size, shape, charge, density, and solubility. Quaternized chitosan, *N*,*N*,*N*-trimethyl chitosan, thiolated chitosan, carboxyalkyl chitosan, sugar-bearing chitosan, bile acid-modified chitosan, and cyclodextrin-linked chitosan are among the modifications frequently utilized in chitosan-based drug delivery systems. Each modification offers unique properties and characteristics. For instance, trimethyl chitosan is soluble over a wide pH range and enhances the condensation capacity of plasmid DNA at neutral pH due to fixed positive charges on its backbone. Thiolation of chitosan provides free sulphydryl groups on its side chains and forms disulfide bonds with cysteine-rich subdomains of mucoglycoproteins on cell membranes and increases cellular uptake. In addition, both modifications have been used as nonviral carrier systems to combine the advantages of trimethyl chitosan and thiolated chitosan while minimizing their shortcomings [3].

Hydrophobic moieties can also be attached to chitosan to facilitate the incorporation of insoluble drugs, i.e., hydrophobic glycol chitosan nanoparticles. Chemical conjugation of hydrophobic 5β-cholanic acid to the hydrophilic glycol chitosan backbone allows for the incorporation of the water-insoluble drug camptothecin [4].

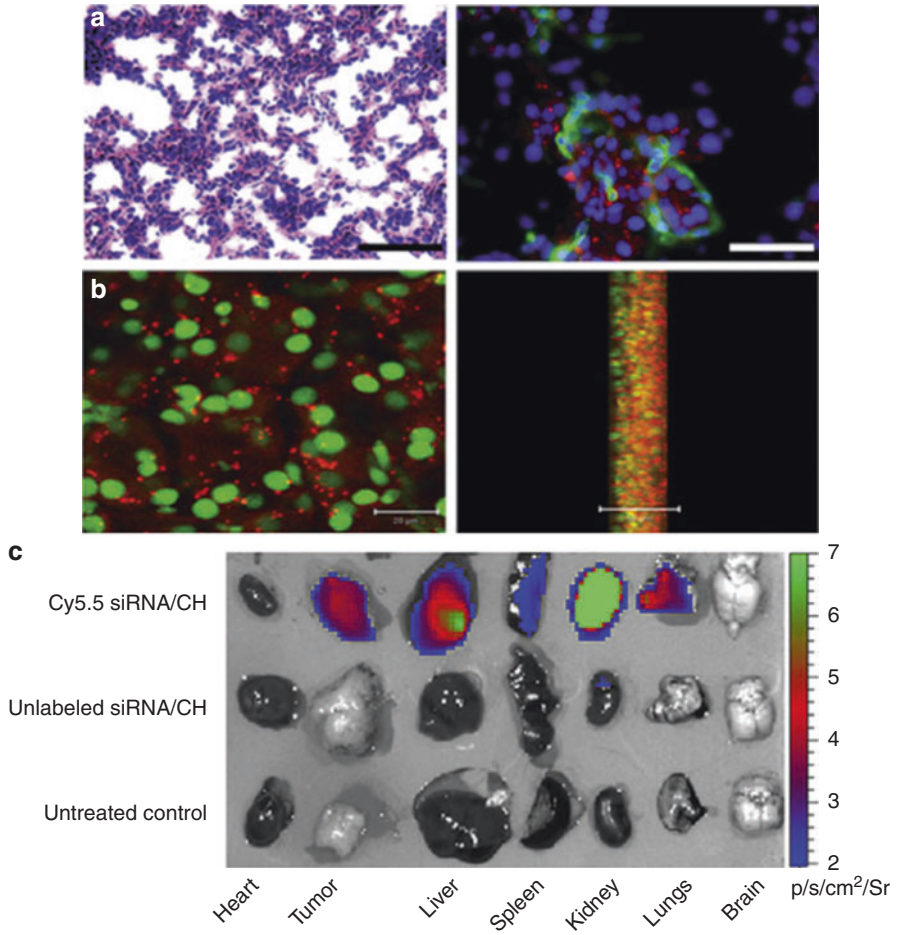
Key Research Findings

Preparation of Chitosan Nanoparticles



The amino groups of chitosan backbone can interact with anionic molecules such as tripolyphosphate (TPP). The ionic cross-linking of chitosan is advantageous since the method is easy and mostly performed under mild conditions without using organic solvents. Ionotropic gelation of chitosan using TPP for the incorporation of low molecular drugs, proteins, DNA/siRNA have been demonstrated [5]. CH-NPs are rapidly formed through ionic interactions between the negatively charged phosphates of TPP and positively charged amino groups of chitosan.

Drug Delivery



Ringsdorf first reported the concept of polymer–drug conjugates for delivering small molecule drugs [6]. The concept of polymer–drug conjugates allows chemical conjugation of a drug using a biodegradable spacer. The spacer is usually stable in the bloodstream, but cleaved at the target site by hydrolysis or enzymatic degradation. Based on this concept, several polymer–drug conjugates have been developed such as glycol chitosan conjugated with doxorubicin, which forms self-assembled nanoparticles in an aqueous condition. A paclitaxel-chitosan conjugate that can be cleaved at physiological conditions was developed for oral delivery of paclitaxel. *N*-succinyl-chitosan-mitomycin conjugates demonstrated high antitumor efficacy against a variety of murine tumor models of leukemia, melanoma, and primary and metastatic liver tumors.

Gene Delivery

Recently, plasmid DNA, siRNA, and oligonucleotide-loaded CH-NPs have been used for targeted gene silencing. Positively charged chitosan can easily form polyelectrolyte complexes with negatively charged nucleotides based on electrostatic interaction, incorporation, or adsorption, as illustrated in Fig. 1 [7]. The positive charge on the surface of CH-NPs is desirable to prevent aggregation due to electrostatic repulsion and increase binding efficiency with the negatively charged cell membrane by enhancing electrostatic interactions. However, other cellular uptake mechanisms such as clathrin-mediated endocytosis, caveolae-mediated endocytosis, and macropinocytosis may also be involved [8]. Moreover, the configuration of chitosan is modified under acidic pH by triggering the opening of tight junctions. Acidic pH results in an increase in the number

Hematoxylin and eosin, original magnification 2003 (*left*); tumor tissues were stained with anti-CD31 (*green*) antibody to detect endothelial cells (*right*). The scale bar represents 50 mm. (**b**) Fluorescent siRNA distribution in tumor tissue. Sections (8 mm thick) were stained with Sytox green and examined with confocal microscopy (scale bar represents 20 mm) (*left*); lateral view (*right*). Photographs taken every 1 mm were stacked and examined from the lateral view. Nuclei were labeled with Sytox green and fluorescent siRNA (*red*) was seen throughout the section. At all time points, punctated emissions of the siRNA were noted in the perinuclear regions of individual cells, and siRNA was seen in >80 % of fields examined. (**c**) Shows fluorescence intensity overlaid on white light images of different mouse organs and tumor

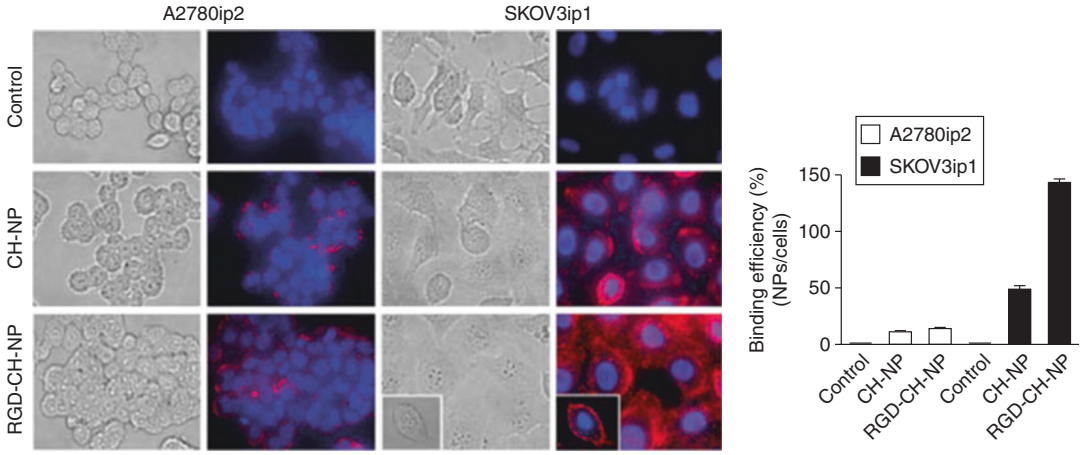
of protonated amines on the chitosan leading to a further disruption on membrane organization. It has also been reported that chitosan can swirl across the membrane lipid bilayer and facilitate the cellular uptake of the polyplex due to increase in mole fraction of chitosan, leading to reduction in the polymeric chains which results in decreased molecular weight [7]. In addition, Lu et al. have recently reported the biodistribution of intravenously administered siRNA-CH-NPs in tumor-bearing mice. They demonstrated that CH-NPs allowed for a higher localization of siRNA in tumor tissues compared to other organs (Fig. 2) [9].

Electrostatic interactions between protonated amines of chitosan and negative charge of DNA or siRNA leads to spontaneous formation of highly compact encapsulation of either DNA or siRNA into CH-NPs [10]. Gel electrophoresis has been used to assess hydrogen bonding and hydrophobic interactions between chitosan and DNA [11]. However, a major limitation of siRNA

delivery is its rapid degradation in plasma and cytoplasm. It has been reported that stable chitosan/siRNA complexes can protect siRNA degradation in circulation of CH-NPs in bloodstream to overcome extracellular and intracellular barriers. On the other hand, disassembly is also needed to allow release of siRNA. This emphasizes the importance of an appropriate balance between protection and release of siRNA for biological functionality [12].

Positively charged CH-NPs can bind to negatively charged cell surfaces with high affinity. CH-NPs are known to overcome endosomal escape via its "proton sponge effect." Once these nanoparticles penetrate into an acidifying lysosomal compartment, the unsaturated amino groups of chitosan distrain protons that are delivered by proton pumps (vATPase) which is called the "proton sponge mechanism." Subsequent lysosomal swelling and rupture leads to endolysosomal escape of nanoparticles [13].

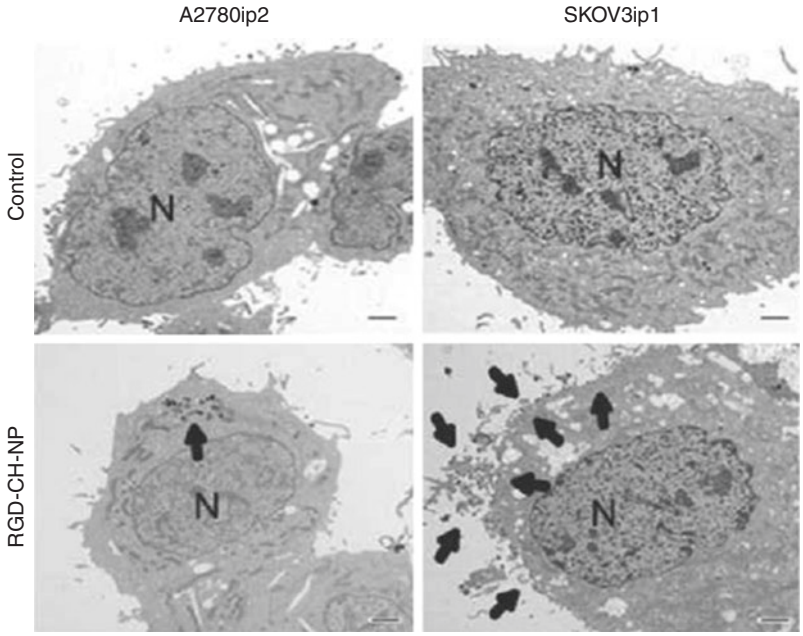
Targeted Delivery



An ideal delivery system should lead to enhanced concentrations of therapeutic payloads at disease sites, and minimize potential non-desirable off-target effects, and ultimately raise the therapeutic index. Differences between tumor and normal tissue microenvironment and architecture, such as vascularization, overexpressed receptors, pH, temperature, ionic strength, and metabolites, can be exploited for selective targeting.

Targeted delivery systems have been designed to increase and/or facilitate uptake into target cells, and to protect therapeutic payloads. Recent work comparing non-targeted and targeted nanoparticles have shown that the primary role of the targeting ligands is to enhance selective binding efficiency to receptor in cell surface and cellular uptake into target cells, and to minimize accumulation in normal tissues. The addition of targeting ligands that provide specific ligand-receptor binding on nanoparticle-cell surface interactions can play a vital role in the ultimate location of nanoparticles. For example, nanoparticles decorated with specific moieties such as peptides, proteins, or antibodies can be targeted to cancer cells via cell-surface receptor proteins such as transferrin or folate receptors (known to be increased on a wide range of cancer cells). These targeting ligands enable nanoparticles to bind on to cell-surface receptors and penetrate cells by receptor-mediated endocytosis.

Target selective ligand-labeled CH-NPs can enhance receptor-mediated endocytosis. Various receptors on the tumor cell surface have been established as a target-binding site to achieve selective delivery. The overexpression of transferrin and folate in certain tumors has been exploited to deliver CH-NPs conjugated with these receptor's ligands [14, 15]. Another example is the $\alpha v\beta 3$ integrin, which is overexpressed in a wide range of tumors, and is largely absent in normal tissues. Han et al. [16] have recently reported that the administration of RGD peptide-labeled CH-NPs led to increased tumor delivery of siRNA-CH-NP and enhanced antitumor activity in ovarian carcinoma models (Figs. 3 and 4).



Chitosan-Based Environmental-Responsive Particles

Physiological alterations such as pH, temperature, ionic strength, and metabolites in the microenvironment of tumor have gained increased interest in terms of targeted therapy. Potential differences in these parameters between tumor and normal tissue can be used for enhanced targeting. A novel, pH responsive NIPAAm/CH-NPs containing camptothecin and paclitaxel was successfully used to enhance tumor uptake and antitumor activity [17]. On the other hand, thermosensitive CH-g-poly(*N*-vinylcaprolactam) composite has been developed by an ionic cross-linking method and incorporated with 5-FU (5-fluorouracil). This study showed that 40 % of drug is released from the particles when the temperature is above a lower critical solution temperature of 38 °C while only 5 % of drug is released below 38 °C, which confirms the drug release mechanism of this polymeric carrier system is based on temperature. These nanoparticles were more toxic to cancer cells while devoid of toxicity to normal cells, leading to enhance antitumor efficacy [18].

Chitosan-Based Magnetic Nanoparticles

Chitosan-based magnetic nanoparticles have been developed for magnetic resonance (MR) imaging via passive and tissue-specific targeting. The low-oxidizing ferromagnetic materials are the most commonly used compounds for nanoparticle formulations and provide a stable magnetic response. The accumulation of magnetic nanoparticles when injected intravenously can be induced when the tissue or organ is subjected to an external high-gradient magnetic field [19]. Drugs, DNA plasmids, or bioactive molecules are released into target tissues and effectively taken up by tumor cells after accumulation of these carriers. On the other hand, magnetic nanoparticles such as iron oxide nanoparticles

(Fe_3O_4) are applied to oscillating magnetic fields, which results in the generation of heat and holds potential for rapid heating of tumor tissue.

When magnetic nanoparticles are administered systemically, they are rapidly coated with plasma proteins. These particles are taken up by the reticuloendothelial system, leading to decreased circulation time. Magnetic nanoparticles coated with hydrophilic materials such as chitosan could provide longer circulation time. In addition, chitosan-coated magnetic nanoparticles, which are used in magnetic resonance imaging, can also be functionalized and used as theranostic carriers due to amino and hydroxyl groups of chitosan.

Application of Chitosan Nanoparticles for SiRNA Delivery

Recently, siRNA targeted to EZH2 (a critical component of the polycomb repressive complex 2 [PRC2]), loaded CH-NPs were shown to enhance the delivery of siRNA to tumors, leading to downregulation of the target protein and subsequently enhanced antitumor activity. Lu et al. demonstrated target gene silencing using EZH2 siRNA loaded CH-NPs, leading to increased antitumor efficacy in animal tumor models. Moreover, Zhang et al. reported the use of intrathecal administration of siRNA targeted against specific muscarinic receptor subtypes loaded in CH-NPs in a rat model of pain. CH-NP/siRNA was distributed to the spinal cord and the dorsal root ganglion [20]. The administration of Chitosan-M_2-siRNA caused a large reduction in the inhibitory effect of muscarine on the rat paw withdrawal threshold from a heat stimulus. These studies support the use of CH-NPs as a delivery system for siRNA into neuronal tissues in vivo.

Future Directions for Research

Chitosan nanoparticles offer a unique potential for clinical and biological applications due to low immunogenicity, low toxicity, and high biocompatibility. In addition to its advantages such as protonated amine groups, chitosan can increase binding efficiency with cells because of electrostatic interactions. Therefore, CH-NPs may be used for broad applications in human disease. Moreover, chitosan allow modifications that will exploit the inherent physicochemical properties by conjugation of selective ligands. The highly desirable specific targeting of drugs has been elusive to date; however, CH-NPs can bring us closer to this goal.

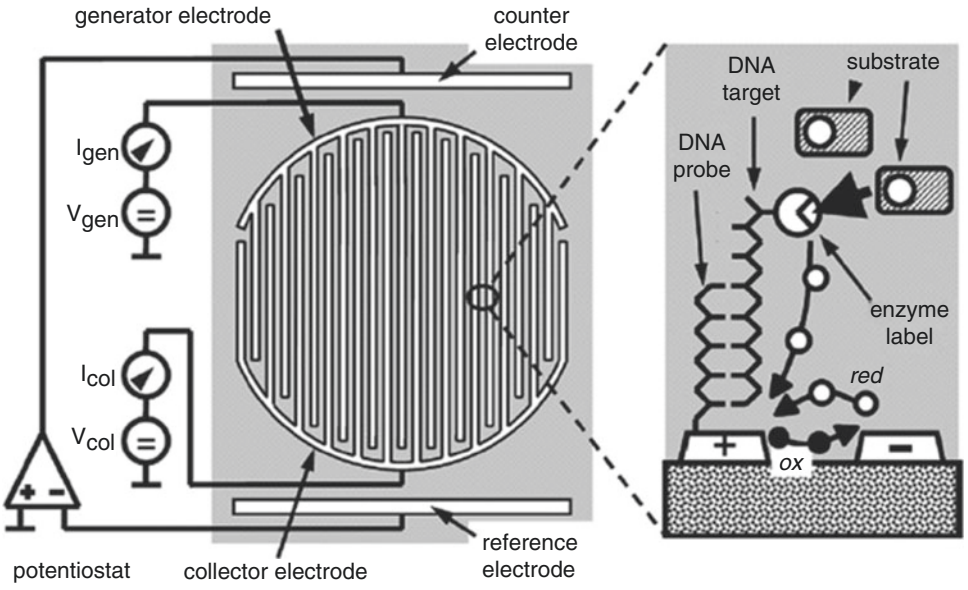
Definition

CMOS MEMS biosensors are miniaturized biosensors fabricated on CMOS (complementary metal-oxide semiconductor) chips by the MEMS (microelectromechanical systems) technology.

Overview

A biosensor is a device designed to detect a biochemical molecule such as a particular deoxyribonucleic acid (DNA) sequence or particular protein. Many biosensors are affinity-based, meaning that they use an immobilized capture probe that selectively binds to the target molecule being sensed. Most biosensors require a label attached to the target, and the amount of detected label is assumed to correspond to the number of bound targets. Labels can be fluorophores, magnetic beads, gold nanoparticles, enzymes, or anything else allowing convenient binding and detection; however, labeling a biomolecule can change the associated binding properties, especially for protein targets.



An electrical biosensor is capable of detecting a binding event by producing an electrical current and/or a voltage. Conventional optical detection methods require external instruments that are expensive and not amenable to miniaturization. Electrical bioassays hold great promise for numerous decentralized clinical applications ranging from emergency-room screening to point-of-care diagnostics due to their low cost, high sensitivity, specificity, speed, and portability. Miniaturization of an electrical biosensor can be achieved through microfabrication – widely known as the MEMS technology; in addition, the sensing circuits can be embedded on the same chip through integrated-circuit (IC) processes, among which the CMOS technology is the most popular choice for implementing various analog and digital circuits. A fully integrated CMOS MEMS biosensor array is capable of providing real-time high-throughput detection of multiple samples. CMOS biosensors can be implemented based on the electrochemical, impedimetric, ion-sensitive, magnetic, optical, and micromechanical approaches, which require different MEMS processes to construct the sensing interfaces. Some of the methods require labeling and some are label-free for bio-signal transduction. More details are provided in the following sections.

Sensing Principles and Key Research Findings

Electrochemical Biosensors

Electrochemical biosensors have been the subject of basic as well as applied research for many years. In 1970, Dr. Leland C. Clark demonstrated that glucose could be measured in whole blood with the presence of the glucose oxidase enzyme. Commercial glucose sensors based on electrochemical detection have been developed since then. Electrochemical biosensors typically depend on the presence of a suitable enzyme in the biorecognition layer to catalyze reaction of electroactive substances. Affinity-based electrochemical sensors use enzymes as labels that bind to antibodies, antigens, or oligonucleotides with a specific sequence.

Electrochemical biosensors can employ potentiometric, amperometric, and impedimetric sensing principles to convert the chemical information into a measurable electrical signal. In potentiometric devices, ion selective electrodes (ISE) are commonly used to transduce a biorecognition event into a potential signal between the working and the reference electrodes whose value, depending on the concentration of the analyte,

CMOS MEMS Biosensors, Fig. 1 Schematic of the CMOS interdigitated microelectrode for electrochemical DNA detection. On the *right*: schematic illustration of the redox-cycling process (Schienle et al. © 2004 IEEE)

can be predicted by the Nernst equation. The current flowing through the electrode is equal to or near zero.

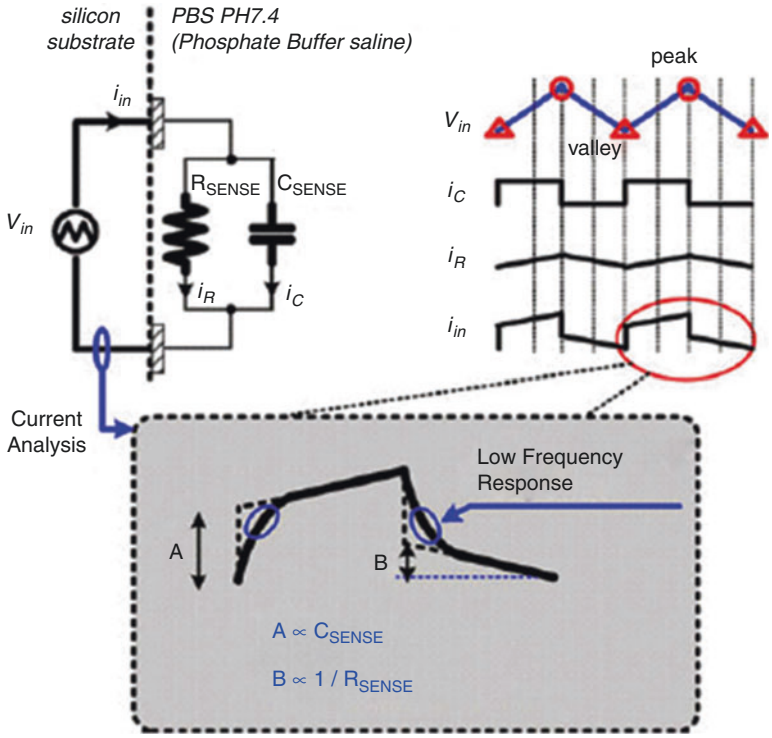
Amperometric biosensors operate by applying a constant potential and monitoring the current associated with the reduction or oxidation of an electroactive species. The sensors can work in three- or four-electrode configurations. The former case consists of a reference, a working, and a counter electrode. The four-electrode setup has an additional working electrode such that oxidation and reduction take place at anode and cathode simultaneously. Working electrodes are normally made of noble metals which are critical to the operation of a sensor. Since these metals are not CMOS compatible, the electrodes must be formed after fabrication of CMOS circuits. Silver/silver chloride (Ag/AgCl) is commonly used as the reference electrode in many electrochemical biosensors. Since not all particles oxidized at the anode reach the cathode, a potentiostat, whose input and output are connected to a reference and to a counter electrode, respectively, is required to provide the difference current to the electrolyte and regulate the potential of the electrolyte to a constant value.

Interdigitated microelectrodes have been adopted in many electrochemical biosensors for quantitative analysis. The width and spacing of microelectrodes are reduced by microfabrication. The main advantage is the enhanced redox current due to fast redox recycling, as the chemical products produced at one side of the electrodes are readily collected at the other side of adjacent electrodes and regenerated to the original states. The relationship between the produced redox current and the analyte concentration has been derived by Aoki et al. [1].

Electrochemical DNA hybridization biosensors rely on the conversion of the DNA base-pair recognition event into an electrical signal. Schienle et al. [2] reported a CMOS electrochemical DNA sensor array with each sensing element consisting of interdigitated gold electrodes separated by 1 μm. As depicted in Fig. 1, probe molecules were immobilized on the gold surface through thiol coupling and the target molecules were tagged by an enzyme label (alkaline phosphatase). A chemical substrate (para-aminophenyl phosphate) was applied to the chip after hybridization. The enzyme label on the matched DNA strands cleaved the phosphate group and

generated an electroactive compound (para-aminophenol), which was subsequently oxidized and reduced as the indicator of successful DNA hybridization. Levine et al. [3] also reported a CMOS electrochemical DNA sensor array which was operated based on conventional cyclic voltammetry (CV). During the measurement the electrode potential was scanned up and down in order to produce the redox reactions associated with the ferrocene labels attached to DNA strands. In addition to DNA detection, CMOS electrochemical sensors have been realized to allow high-throughput detection of dopamine and catecholamine release from adrenal chromaffin cells [4], since the release of neurotransmitters from secretory vesicles of biological cells is closely related to the function of a nervous system.

Impedimetric Biosensors



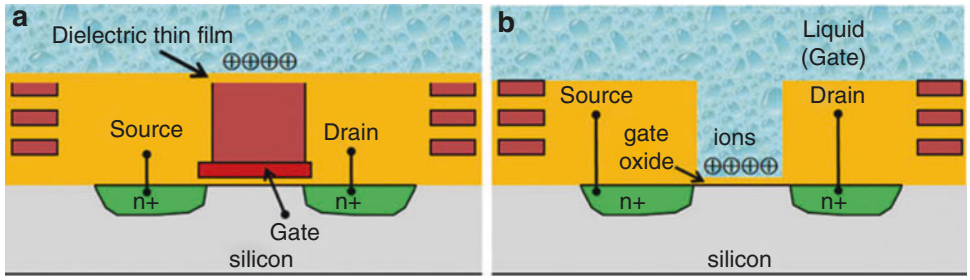
Changes in the electrical properties of a sensing interface (e.g., capacitance, resistance) can occur when a target biomolecule interacts with a probe-functionalized surface. A conventional impedimetric biosensor measures the electrical impedance of an electrode-solution interface in a.c. steady state with constant d.c. bias conditions. This approach, known as electrochemical impedance spectroscopy (EIS), is accomplished by imposing a small sinusoidal voltage over a range of frequencies and measuring the resulting current. The current–voltage ratio gives the impedance, which consists of both energy dissipation (resistor) and energy storage (capacitor) elements. Results obtained by EIS are often graphically represented by a Bode plot or a Nyquist plot. EIS reveals information about the reaction mechanism of an electrochemical process since different reaction steps can dominate at certain frequencies. Impedimetric biosensors can detect a variety of target analytes by simply varying the probe used. Changes in the impedance can be correlated to DNA hybridization, antigen–antibody reaction, or be used to detect biological cells.

The interface impedance is commonly represented by an equivalent circuit model for analysis. E. Warburg [5] first proposed that the interface impedance can be represented by a polarization resistance in series with a polarization capacitor. The interface capacitance possesses a frequency dependency and is commonly represented by the Gouy-Chapman-Stern model as the series combination of the double-layer capacitance (Helmholtz capacitance) and the diffuse layer capacitance (Gouy-Chapman capacitance).

In addition to the frequency-domain measuring method, interface impedance changes can be measured by the potentiostatic step method where small potential steps are applied to the working electrode and the transient current responses, as determined by the time constant of the interface resistance and capacitance, are measured accordingly. Lee et al. [6] reported a fully integrated CMOS impedimetric sensor array for label-free detection of DNA hybridization. The changes in the reactive capacitance and the charge-transfer resistance on the gold sensing electrodes were extracted by applying a triangular voltage waveform and monitoring the produced currents. As illustrated in Fig. 2, the current flowing through the capacitor is associated with the slope of the applied triangular wave, while the current flowing through the resistor is in proportion to the magnitude of the triangular wave. The reported detection limit was 10 nanomolar (nM).

It is important to distinguish the differences between faradaic and non-faradaic biosensors for impedance detection. In electrochemical terminology, a faradaic process involves charge transfer across an interface, while a transient current can flow without charge transfer in a non-faradaic process by charging a capacitor. The faradaic EIS requires the addition of a redox species which is alternately oxidized and reduced by the transfer of charges to and from the metal electrode. In contrast, no additional reagent is required for non-faradaic impedance spectroscopy. The associated impedance change is predominantly capacitive with the charge transfer resistance being omitted.

Miniaturized CMOS capacitive sensors have been developed for numerous biosensing applications. As the sensor size is small, monolithic integration provides the benefit of enhancing the signal-to-noise ratio by reducing the parasitic capacitance observed at the sensing node, which



CMOS MEMS Biosensors, Fig. 2 Schematic of the impedance extraction method (Adopted by Lee et al. © 2010 Elsevier)

would otherwise negatively impact the detection limit during direct capacitance measurement. Stagni et al. [7] reported an 8 × 16 CMOS DNA sensor array where the bindings of complementary DNA strands on gold microelectrodes reduced the dielectric constant of the electrode-analyte impedance and the associated change was used to modify the charging and discharging transients of the detection circuit. Capacitive sensitivity can be enhanced by use of interdigitated microelectrodes with the minimum gap defined by the adopted CMOS process. Lu et al. [8] reported very sensitive detection of the neurotransmitter dopamine in the sub-femtomolar (fM) range. CMOS capacitive sensors have also been used for monitoring cellular activity since the morphological and physiological states of biological cells have correlations with their electrical properties [9].

The impedance change of a biosensing event can be made purely resistive with additional chemical modifications. Li et al. [10] reported a DNA array detection method in which the binding of immobilized DNA probes functionalized with gold nanoparticles produced a conductivity change between adjacent metal electrodes, which were made of gold metal in order to withstand the chemical in the clean processing. The detected signal can be further enhanced by additional silver deposition. Silicon dioxide was used as the underlying material under the gap for immobilization of the DNA probes. Detection limit of the target DNA concentration was 1 picomolar (pM).

Ion-Sensitive Field Effect Transistors (ISFET)

ISFETs were first developed in the early 1970s and have been utilized in various biosensing applications which depend on the type of receptor used for analyte recognition or how a signal is generated. Immunologically modified FETs and DNA-modified FETs detect the change of surface charges by monitoring the associated current–voltage relationship. Cell-based FETs detect the potential changes produced by biological cells due to the flow of ions across the cell membranes upon stimulations. For applications where it is required to build an ISFET array to provide detection of multiple samples at different locations,

CMOS MEMS Biosensors, Fig. 3 (**a**) Schematic of the floating-gate ISFET structure. (**b**) Schematic of the open-gate ISFET structure

monolithic integration is then preferred in order to reduce wiring complexity and noise interference.

CMOS ISFET sensors can be built by using a floating-gate or an open-gate structure as depicted in Fig. 3. The floating-gate structure is easier to fabricate as it requires minimal post-processing after completion of a conventional CMOS process. Silicon dioxide or silicon nitride in the CMOS passivation thin films can be used as the material for surface functionalization. The produced signal due to charges on sensor surface is capacitively coupled to the floating gate through a relatively thick dielectric layer which reduces the signal-coupling efficiency. The gate in an open-gate ISFET is removed and replaced by the aqueous solution whose potential is commonly set via a reference electrode. The exposed gate oxide is used for surface functionalization. Since the gate oxide thickness is only tens of angstroms in a conventional sub-μm CMOS process, sensitivity is thus significantly enhanced as compared to a floating-gate ISFET.

Accumulated charges on the ISFET surface modulate the threshold voltage of a MOS transistor, leading to a channel current change under fixed voltage biases of the drain, source, and gate terminals. The threshold voltage of an open-gate ISFET is expressed as:

$$V_{th} = E_{ref} - \Psi + \chi_{sol} - \frac{\phi_{si}}{q} - \frac{Q_{ox} + Q_{ss} + Q_B}{C_{ox}} + 2\phi_F$$

where E_{ref} is the reference electrode potential, Ψ is a chemical input parameter as a function of solution pH value, χ_{sol} is the surface dipole potential of the solvent, ϕsi is the work function of silicon, q is the electron charge, C_{ox} is the gate oxide capacitance per unit area, Q_{ox} and Q_{ss} are the charges in the oxide and at the oxide-silicon interface, Q_B is the depletion charges in silicon and ϕ_F is the difference between the Fermi potential of the substrate and intrinsic silicon.

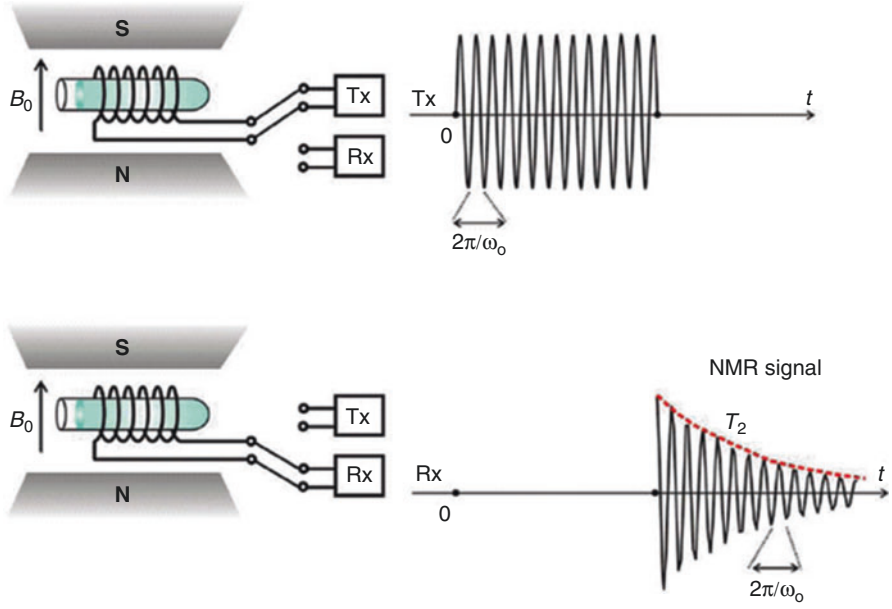
Kim et al. [11] reported the use of p-type ISFET fabricated in a standard CMOS process for detection of DNA immobilization and hybridization. Gold was deposited by post-processing as the gate material for immobilizing DNA due to its chemical affinity with thiols. The channel current increased during hybridization due to the negative charges present in the phosphate groups of DNA strands. Li et al. [12] presented a post-CMOS fabrication method to make open-gate ISFETs and demonstrated ultrasensitive dopamine detection in the fM range.

Magnetic Biosensors

Some of the magnetic biosensors require the use of magnetic beads as labels attached to the samples in order to induce a measurable electrical signal when specific binding on sensor surface occurs. Magnetic beads are made of small ferromagnetic or ferrimagnetic nanoparticles that exhibit a unique quality referred to as superparamagnetism in the presence of an externally applied magnetic field. This phenomenon, as discovered by Louis Néel (Nobel Physics Prize winner in 1970), has been used in numerous applications such as magnetic data storage and magnetic resonance imaging (MRI).

Several methods can be used to electronically detect the existence of magnetic beads, such as the GMR (giant magnetoresistance) effect discovered by the 2007 Nobel Physics Prize winners Albert Fert and Peter Grünberg. The effect appears in thin film structures composed of alternating ferromagnetic and nonmagnetic layers. A significant change in the electrical resistance is observed depending on whether the magnetization of adjacent ferromagnetic layers is in a parallel alignment (the low-resistance state) due to the applied magnetic field or an anti-parallel alignment (the high-resistance state) in the absence of the magnetic field.

Han et al. [13] reported a CMOS DNA sensor array that adopted the spin valve structure to observe the GMR effect. Magnetic thin films of nanometers in thickness were deposited and patterned after the conventional CMOS process. The biotinylated analyte DNA was captured by complementary probes immobilized on the sensor surface. Then streptavidin-coated magnetic labels were added and produced specific binding to the hybridized DNA. The stray magnetic field of the magnetic labels was detected as a resistance change in the sensor. In general, signal modulation is required in the sensing scheme in order to separate the true bio-signals from the false ones caused by drifts or ionic solution interference. Other than the GMR principle, detection of magnetic beads can be achieved based on the Hall effect of a CMOS sensor. As discovered by Edwin Hall in 1879, the effect produces an electric field perpendicular to the magnetic induction vector and the original current direction. Detection of a single magnetic bead has been demonstrated [14].



To eliminate the needs of externally applied magnetic fields and post-CMOS fabrication for a magnetoresistive biosensor, Wang et al. [15] presented an inductive approach that can detect existence of a single magnetic bead on a CMOS chip. The sensing scheme used a highly stable integrated oscillator with an on-chip LC resonator. An a.c. electrical current through the on-chip inductor produced a magnetic field that polarized the magnetic particles present in its vicinity, leading to an increased effective inductance and therefore a reduced oscillation frequency. As the frequency shift due to a single micron-size magnetic bead is typically a few parts per million (ppm) of the resonant frequency, the sensing oscillator needs to have small phase noises at small offset frequencies to achieve a stable frequency behavior.

A miniaturized CMOS NMR (nuclear magnetic resonance) system has been reported by Sun et al. [16] for applications in biomolecular sensing. NMR was first discovered by Isidor Rabi who was awarded Nobel Prize in Physics in 1944. Magnetic nuclei, like ^{1}H and ^{31}P, could absorb radio frequency (RF) energy when placed in a magnetic field of a strength specific to the identity of the nuclei. The nucleus is described as being in resonance when the absorption occurs. Different atomic nuclei within a molecule exhibit different resonant frequencies for the same magnetic field strength. Essential chemical and structural information about a molecule can thus be studied by observing such magnetic resonant frequencies.

The reported CMOS NMR system consists of a magnet (static magnetic field), an RF coil surrounding a sample, and an RF transceiver linked to the coil as shown in Fig. 4. The RF magnetic field produced through the coil at the right frequency ω_o can excite nuclei spins within the sample. Once the RF excitation is stopped and the receiver is connected to the coil, the detected NMR signal displays an exponential relaxation in the precession of the net magnetic moment. Both the resonant frequency and the relaxation's characteristic time are specific for the sample to be studied.

Optical Biosensors

Optical detection methods such as luminometry and fluorometry can be utilized to make CMOS-based biosensors. Luminometric methods, such as luciferase-based assays, involve the detection and quantification of light emission as a result of a chemical reaction. Luciferase is a generic term for the class of oxidative enzymes used in bioluminescence. Such methods have been used to detect pathogens and proteins, perform gene expression and regulation studies, and sequence DNA. Fluorometric methods require an excitation source to stimulate photoemission of the fluorescent-tagged species and optical filters to separate the generated photoemission from the

CMOS MEMS Biosensors, Fig. 4 Operation of the CMOS NMR system (Sun et al. © 2009 IEEE)

high background interference. Luminometry is more amenable to miniaturization and integration than the fluorometric methods since no filters or excitation sources are required.

Eltoukhy et al. [17] reported a CMOS photodetector array which was directly integrated with a fiber-optic faceplate with immobilized luminescent reporters/probes for DNA synthesis by pyrosequencing. Pyrosequencing is a "sequencing by synthesis" technique which involves taking a single strand of the DNA to be sequenced and then synthesizing its complementary strand enzymatically. Synthesis of the complementary strand is achieved with one base pair at a time by monitoring the activity of the DNA synthesizing enzyme with another chemiluminescent enzyme. The challenge of such a detection system is to achieve high sensitivity despite the presence of relatively high dark currents. The reported sensor array was able to detect emission rates below 10^{-6} lux over a long integration time (30 s).

Huang et al. [18] reported a CMOS microarray chip that leveraged low-cost integration of solid-state circuits for fluorescence-based diagnostics. The featured time-gated fluorescence detection was able to significantly reduce interferences from the external excitation source, eliminating the need for additional optical filters. Direct immobilization of DNA capture strands on the CMOS chip allows placement of optical detectors in close vicinity to the fluorescent labels, leading to improved collection efficiency and providing imaging resolution limited by pixel dimensions rather than diffraction optics.

In addition to the aforementioned approaches, a method based on detection of the incident light intensity using a normal light source has been developed [19]. The technique uses gold nanoparticles with silver enhancement to induce opacity on top of CMOS photodetectors when specific bindings occur. It does not require an external optical scanner and a specific light source as needed in the fluorescence-based method.

Micromechanical Cantilevers

Microcantilever-based biosensors have attracted considerable attention as a means of label-free detection of biomolecules. Intermolecular forces arising from adsorption of small molecules are known to induce surface stress. The specific binding between ligands and receptors on the surface of a microcantilever beam thus produces physical

bending of the beam. Optical detection of the beam deflection due to hybridization of complementary oligonucleotides has been demonstrated [20]; however, the method requires external instruments that are not amenable to monolithic integration.

Piezoresistive detection is a viable alternative for CMOS integration because it is compatible with aqueous media. The piezoresistive effect is associated with the resistivity change of a semiconductor subject to a mechanical strain. By placing a MOS transistor into the base of a cantilever, modulation of the channel current underneath the gate region can be measured as a result of adsorption-induced surface stress [21]. Sensing resolution of the static beam deflection is limited by the flicker noise – the dominant source of noise in MOS transistors at low frequencies.

Summary

A miniaturized biosensing platform can be achieved through monolithic integration of sensing devices and detection circuits by the CMOS MEMS technology. Sensing devices that can be directly fabricated on a CMOS chip are introduced, including those based on electrochemical, impedimetric, ion-sensitive, magnetic, optical, and micromechanical approaches. Some of the methods require labeling (e.g., magnetic beads, nanoparticles) and some are label-free for bio-signal transduction. Some approaches use the devices (e.g., transistors) or the materials (e.g., metal electrodes) in a CMOS process for sensing, such that sensor performances can be enhanced in accordance with the scaling of CMOS technologies. Arrays of sensors can be conveniently fabricated on a CMOS chip such that sensing resolution and accuracy can be enhanced through statistical analysis of the collected data.

Definition

CMOS-MEMS are micromachined systems in which MEMS devices are integrated with CMOS circuitry on a single chip to enable miniaturization and performance improvement. CMOS-MEMS also refers to microfabrication technologies that are compatible with CMOS fabrication processes.

Overview

Microelectromechanical systems (MEMS) leverage semiconductor fabrication technologies to manufacture various miniature sensors and actuators. Due to their low cost and small size as well as their much improved reliability, MEMS devices have been widely used even in our daily life, e.g., MEMS accelerometers for automobiles' airbags, MEMS gyroscopes for electronic stability program (ESP) in automobile braking systems, MEMS tire pressure sensors; digital micromirror device (DMD)-enabled portable projectors, MEMS inkjet printers, MEMS resonators as frequency references, etc. Moreover, smart cell phones are now equipped with MEMS gyroscopes and accelerometers for motion actuated functions. They are also installed with surface-mounted MEMS microphones for even smaller size. The worldwide MEMS market reached 6.5 billion US dollars in 2010 [1].

Continuous miniaturization, expanded functionalities, lower cost, and improved performance are the ultimate goals of MEMS. The nature of MEMS strongly suggests direct integration of mechanical structures with electronics whose fabrication is dominated by CMOS technologies. In the last couple of decades, great efforts have been made in the integration of MEMS structures with ICs on a single CMOS substrate. The pioneering work for CMOS-MEMS transducers was done by H. Baltes and his coworkers at the Swiss Federal Institute of Technology Zurich (ETH) [2]. They employed both wet bulk silicon micromachining and surface micromachining techniques in the fabrication of integrated CMOS-MEMS devices. With the great advances in IC and MEMS

technologies, the current focus of CMOS-MEMS integration technology is on the modification and standardization of CMOS technology to accommodate MEMS technology. One of the best-known commercial CMOS-MEMS devices is the digital micromirror device (DMD) manufactured by Texas Instruments. Recently, some CMOS foundries, such as TSMC, X-Fab and Global Foundries, have begun to offer CMOS-MEMS services for research and product developments.

This entry summarizes a variety of CMOS-MEMS technologies and devices that have been developed. Particular materials needed in associated CMOS-MEMS will also be introduced. Typical MEMS devices, including inertial sensors, resonators, and actuators, are exemplified in featuring the respective technologies.

Classification of CMOS-MEMS Technologies

MEMS can be integrated with CMOS electronics in many different ways. One common way to categorize CMOS-MEMS technologies is from the perspective of manufacturing processes. Based on the process sequence, CMOS-MEMS technologies can be classified into three categories: Pre-CMOS, Intra-CMOS, and Post-CMOS [3]. Due to its popularity and accessibility, post-CMOS will be described in more detail in this entry.

Pre-CMOS

It is widely accepted that pre-CMOS technologies are represented by the modular integration process originally developed at Sandia National Laboratories. As suggested by the name, in pre-CMOS technology, MEMS structures are pre-defined and embedded in a recess in silicon wafer; and the recess is then filled with oxide or other dielectrics. The wafer is then planarized prior to the following process steps for CMOS electronics [4]. In this "MEMS first" process, although MEMS structures are pre-defined, a wet etch after the completion of the standard CMOS processes is required to release the pre-defined MEMS structures. Due to the involvement of photolithography process needed for patterning the MEMS in the recess, the thickness of the MEMS structures is constrained by the lithographical limit.

Other methods for the formation of MEMS structures in pre-CMOS technologies, including wafer bonding and thinning for epitaxial and SOI wafers in which MEMS are prefabricated, have also been reported in the fabrication of a variety of MEMS devices.

Inter-CMOS

In early 1990s, Analog Devices, Inc (ADI) specifically developed a MEMS technology based on its BiCMOS process. This "iMEMS" technology, originally dedicated to manufacturing CMOS-MEMS accelerometers and gyroscopes, is an intermediate-CMOS-MEMS, or Inter-CMOS-MEMS technology in which the CMOS process steps are mixed with additional polysilicon thin-film deposition and micromachining steps to form the sensor structures [5]. Infinion's pressure sensors are also fabricated using this kind of Inter-CMOS-MEMS technology. To reduce the residual stress in structural polysilicon, high temperature annealing is normally required in the Inter-CMOS-MEMS, which could pose a potential risk to CMOS interconnect and active layers. Thus, the thermal budget should be carefully designed. Moreover, it is almost impractical to perform intermediate CMOS and MEMS processed in separate foundries due to possible contaminations in the wafer transfer and processes. Therefore, a dedicated foundry used for both CMOS and MEMS is necessary for Inter-CMOS-MEMS technology, which may not take full advantages of mainstream technologies in either area.

Limitations of Pre- and Inter-CMOS-MEMS

Since surface micromachining and polysilicon are typically used, most of the Pre- and

Inter-CMOS-MEMS technologies suffer from the limitations of thin-film structural materials. (1) Structural curling and cost associated with stress compensation: Due to the residual stress in the deposited thin films in the device, polysilicon structures often exhibit curling after release, resulting in reduced sensitivity, lower mechanical robustness, and increased temperature dependence. Although stress compensation can be realized via multiple controlled process steps, the associated cost is quite high. (2) Small size and/or mass: The curling of thin-film structures in turn limits the size of the overall microstructure. The mass is further reduced due to the small thickness of thin-film polysilicon. For inertial sensors, the smaller the structure mass, the lower performance of the device. (3) Parasitics: In a surface micromachined polysilicon accelerometer, depending on polysilicon wiring path, the parasitic impedance may considerably lower the static and dynamic performance of the device. (4) Cost and suboptimal processes of the dedicated foundry needed: The dedicated foundry combining CMOS and MEMS fabrications needed for pre- and inter-CMOS-MEMS is normally expensive and suboptimal for either fabrication. It is against the modern trends in which flexible accessibility of optimal and cost-effective processes are preferable.

Post-CMOS

Post-CMOS-MEMS refer to the CMOS-MEMS processes in which all MEMS process steps are performed after the completion of the CMOS fabrication. The advantages of post-CMOS-MEMS over Pre- and Inter-CMOS-MEMS include process flexibility and accessibility and low cost. In contrast to both Pre-CMOS-MEMS and Inter-CMOS-MEMS, for Post-CMOS-MEMS technology, the fabrications of CMOS circuitry and MEMS structures are performed independently. The flexibility of foundry access makes it possible to take advantages of both advanced CMOS technologies and optimal MEMS fabrication. This is particularly attractive to research community in exploration of state-of-the-art in MEMS. Some design rules may need to be changed to accommodate MEMS structure design in the CMOS design stage. Meanwhile, post-CMOS microfabrication should be carefully designed, particularly considering the thermal budget, so as not to affect the on-chip CMOS electronics.

According to how MEMS structures are formed, post-CMOS-MEMS technologies fall into two categories: additive and subtractive. In additive post-CMOS-MEMS, structural materials are deposited on a CMOS substrate. In subtractive post-CMOS-MEMS, MEMS structures are created by selectively etching CMOS layers. Apparently, additive post-CMOS-MEMS methods require more stringent material compatibility with the CMOS technologies used. Thus, they are less utilized than subtractive post-CMOS-MEMS. The following introduction will focus more on subtractive post-CMOS-MEMS.

Additive MEMS Structures on CMOS Substrate

In additive post-CMOS-MEMS, metals, dielectrics, or polymers are deposited and patterned to form MEMS structures normally on top of the CMOS layers. Some commercial MEMS products are fabricated using additive post-CMOS-MEMS approaches. In this category, the best-known product is probably the digital mirror device (DMD), the core of the digital light processing (DLP) technology developed by Texas Instruments. In a DMD, tilting mirror plates and their driving electrodes are fabricated directly on top of CMOS circuits. Three sputtered aluminum layers are used to form the top mirror plate and the two parallel-plate electrodes for electrostatic actuation, respectively. The driving electrodes are addressed via CMOS memory cell. To release the mirror plate and top electrodes in the post-CMOS-MEMS fabrication of the mirrors, deep-UV hardened photoresist is used as the sacrificial layer.

In some circumstances where CMOS protection is well designed, electroplating can also be used to grow microstructures on top of CMOS electronics. Other structural and sacrificial materials, such as polycrystalline SiGe and Ge, have

been used to create CMOS-MEMS as well [6]. Additive post-CMOS-MEMS processes, along with their respective materials, are summarized in the following table (Table 1).

In addition to the approaches of forming MEMS structures on top of the CMOS substrate by thin-film deposition, wafer bonding provides another method to directly integrate MEMS structures on CMOS substrate [11]. For instance, a prefabricated polysilicon capacitive acceleration sensor wafer is bonded to a CMOS wafer with read-out electronics. In a wafer-bonded piezoresistive accelerometer, the micromachined bulk silicon proof mass was sandwiched by a bottom glass cap and a top CMOS chip on which the conditioning circuit was integrated. SOI-CMOS-MEMS has also been attempted for monolithic integration of electronics with bulk MEMS structures. With 3-dimensional packaging enabled by technological breakthroughs such as through-silicon vias (TSVs), this integration method promises to be further developed in manufacturing complex microsystems. MEMS suppliers, including STMicroelectronics and InvenSense, have adopted wafer-to-wafer or chip-to-wafer bonding CMOS-MEMS integration.

Subtractive Post-CMOS-MEMS

In these devices, MEMS structures are formed from built-in CMOS thin-film stacks including metals and SiO_2, or from the silicon substrate. These materials are patterned and removed partially by wet or dry etching to release the MEMS structures. This section describes the thin-film and bulk CMOS-MEMS formed by such subtractive processes.

Subtractive CMOS-MEMS by Wet Etching

The first generation of CMOS-MEMS sensors was fabricated using a post-CMOS subtractive process in which silicon substrate was completely or partially removed using a wet etching method, leaving behind thin-film or bulk MEMS structures [2]. For thermal sensors in which beams or membranes consisting of dielectric layers, the substrate silicon is normally etched away completely to obtain thermally isolated structures. The silicon dioxide membrane can act as an intrinsic etch stop layer in backside silicon anisotropic wet etch using KOH, ethylene diamine-pyrocatechol (EDP), or Tetramethylammonium hydroxide (TMAH). A high-Q RF MEMS filter with an inter-metal dielectric layer as structural material was reported by IBM. A medical tactile sensor array was also reported in which the aluminum sacrificial layer was etched from the backside of the wafer after the CMOS substrate was etched through [12].

The silicon substrate can also be included in the MEMS structures using a wet etch process. The first method is to perform a time-controlled backside etch with a well-calibrated etching rate. A uniform single crystal silicon membrane with a desired thickness can be created. This method has been widely used in industry for fabrication of large volume products such as integrated pressure sensors. In cases where the silicon membrane thickness is not critical, even mechanical processing such as grinding can be used to create the backside cavity.

The second method involves the utilization of an automatic etch stop technique to create silicon membranes or MEMS structures. In this case, an anisotropic etch stops at the electrochemically

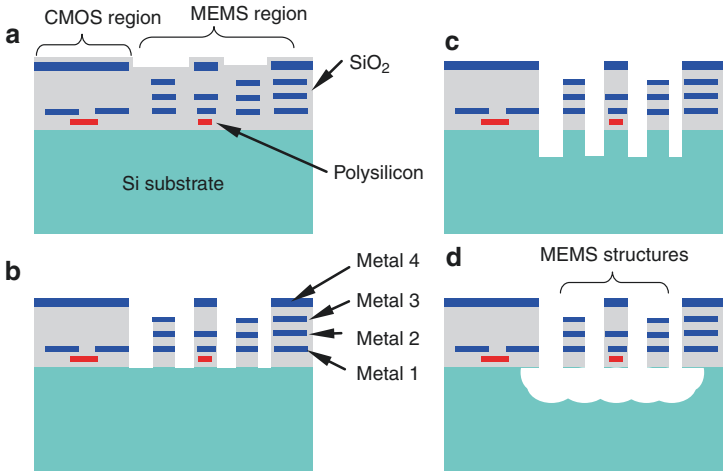
biased p-n junction formed between the n-well and p-type substrate in CMOS [13]. Although the electrochemical electrode design and implementation are complicated, this process can be specifically used in the fabrication of highly sensitive pressure/force and thermal sensors. The anisotropic etch stop can also occur at highly doped ***p*** regions in the substrate. This method has been used in fabrication of many suspended structures including neural probes [14]. Note that the p++ doping process may not be available in a standard CMOS process. In the case where only a small portion of the silicon substrate needs to be removed to reduce the circuit-substrate coupling, a wet silicon etch can be performed from the front side. In wet silicon etching, either silicon nitride or additional polymers or both can be used to protect the front CMOS and pads.



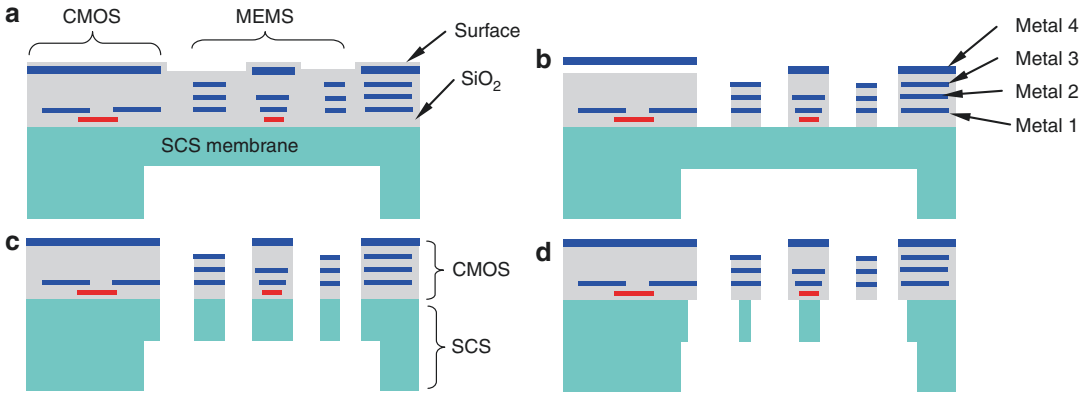
Polymers sensitive to analytes can be coated on finished CMOS-MEMS structures for chemical and biological sensing. For example, the first CMOS-MEMS electronic nose was demonstrated by forming polymer-coated CMOS thin-film cantilevers on a CMOS chip [15].

Table 2 summarizes some representative devices that were fabricated using wet etching when this technology was dominant in post-CMOS micromachining. Bibliographies of these efforts can be found in the above citations in this section.

Subtractive Post-CMOS-MEMS by Dry Etching

Dry etching processes have quickly become popular in microfabrication for both MEMS research and industry. Particularly, the deep reactive ion etching (DRIE) technology, or Bosch process, has revolutionized subtractive post-CMOS microfabrication [23]. This section describes thin-film and bulk CMOS-MEMS devices fabricated using dry etching processes.

Most dry etching processes are based on plasma processes, such as reactive ion etch (RIE) and DRIE, while etchants in the vapor phase can also be used for dry etching. For example, vapor XeF_2 provides good isotropic etching of silicon, which has been used for releasing CMOS thin-film MEMS structures [24]. The combination of RIE and DRIE, performed from the front or back side, or both sides, has been used to fabricate a large variety of CMOS-MEMS devices. Depending on the structural materials and etching methods employed, subtractive post-CMOS can be divided into two types: thin-film processes and bulk processes.



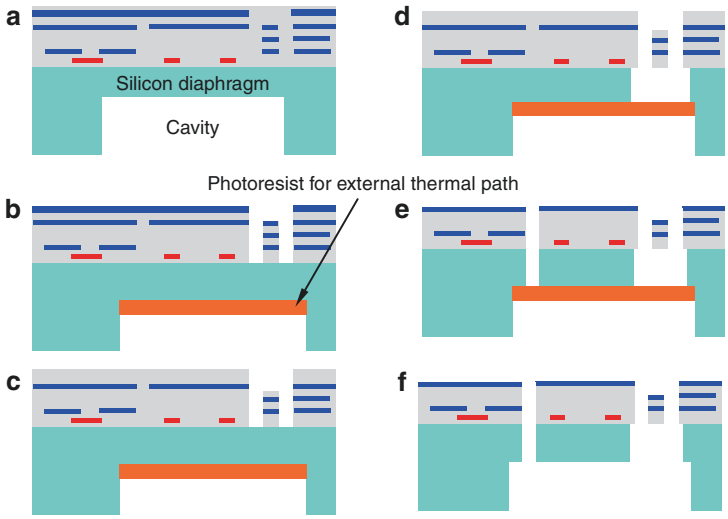
CMOS MEMS Fabrication Technologies,
Fig. 1 CMU post-CMOS fabrication process for MEMS structures made of CMOS thin films

Thin-Film Post-CMOS-MEMS Dry Processes In thin-film processes, structural materials are composed of CMOS thin films. Figure 1 depicts the process flow of a thin-film post-CMOS-MEMS process, which was originally developed at Carnegie Mellon University [25]. A sequenced process consisting of an isotropic SiO_2 etching, a silicon DRIE and an isotropic Si RIE releases the MEMS structure. In these process steps, the top metal layer acts as a mask to form the MEMS structures and to protect the CMOS circuitry, as seen in Fig. 1a, b. Anisotropic and isotropic silicon etching complete the process flow, as seen in Fig. 1c, d. Various inertial sensors have been fabricated using this thin-film technology. In all these inertial sensors, mechanical springs and proof masses are formed by the multiple-layer CMOS stacks consisting of SiO_2 and metals. The sensing capacitance is formed from sidewall capacitance between comb fingers. The multiple CMOS metal layers inside the comb fingers and other mechanical structures allow very flexible electrical wiring, facilitating different sensing schemes including vertical comb-drive sensing. Akustica, Inc. has commercialized digital microphones using a modified version of this process. Other sensors have also been demonstrated using similar thin-film technology, such as humidity sensors and chemical sensors.

All these thin-film post-CMOS dry etching processes have excellent CMOS compatibility and accessibility as well as design flexibility. However, a major issue is the large vertical curling and lateral buckling of suspended MEMS structures, which is caused by the residual stress in the stacked thin-film CMOS layers. Although structural curling can be tolerated for some small devices such as RF MEMS, for devices such as inertial sensors that need relatively large size, the impact of structural curling can be severe.

Bulk CMOS-MEMS Dry Process In order to overcome the structural curling and to increase the mass, flatness, and robustness of MEMS structures, single crystal silicon (SCS) may be included underneath the CMOS thin-film stacks. The SCS silicon structures are formed directly from the silicon substrate using DRIE. Figure 2 illustrates the process flow [26]. The process starts with the backside silicon DRIE to define the MEMS structure thickness by leaving a 10–100 μm-thick SCS membrane (Fig. 2a). Next, the same anisotropic SiO_2 etch as in the thin-film process is performed on the front side of wafer (chip) to expose the SCS to be removed (Fig. 2b). The following step differs from the thin-film process in that an anisotropic DRIE, instead of isotropic etch, finalizes the structure release by etching through the remaining SCS diaphragm, as shown in Fig. 2c. With the SCS underneath the CMOS interconnect layers included, large and flat MEMS microstructures can be obtained. If necessary, an optional time-controlled isotropic silicon etch can be added. This step will undercut the SCS

CMOS MEMS Fabrication Technologies, Fig. 2 DRIE bulk CMOS-MEMS process flow



underneath the designed narrow CMOS stacks to create thin-film structures (Fig. 2d). This step is particularly useful for fabricating capacitive inertial sensors. It can be used to form the electrical isolation structures between sensing fingers and silicon substrate.

The DRIE CMOS-MEMS technology has shown great advantages in the fabrication of relatively large MEMS devices such as micromirrors. Large flat mirror can be obtained by including portion of silicon substrate underneath the aluminum mirror surface. A CMOS-MEMS gyroscope with a low noise floor of 0.02°/s/sqrtHZ has also been demonstrated using this technology [27].

By attaching SCS underneath the CMOS stack comb fingers, the sensing capacitance can be considerably increased for larger signal-to-noise ratio (SNR). Although CMOS thin films are still used in some microstructures for electrical isolation, the length of the thin-film portion is minimal to reduce the temperature effect. Compared to the thin-film dry CMOS-MEMS process, a backside silicon DRIE step is added. This requires an additional backside lithography step to define the region for MEMS structures. The maximum thickness of the MEMS structures is limited by the aspect ratio that the silicon DRIE can achieve.

An Improved Bulk CMOS-MEMS Process The bulk CMOS-MEMS process depicted in Fig. 2 is useful in fabrication of many devices where SCS structures are desired to improve both mechanical and electrical performance of the devices. However, for some devices, very fine structures are formed in step (c) in Fig. 2; so the damage caused by the step (d) to these fine structures may be severe. This is particularly true for the fabrication of capacitive inertial sensors where narrow-gap sensing comb fingers are needed. For instance, in performing the isotropic silicon undercut to form the narrow CMOS beams for electrical isolation, the SCS in the comb fingers is also undercut. The sensing gap increases due to the undesired undercut greatly reduce sensitivity and signal-to-noise ratio (SNR). If the undercut occurs in mechanical structures such as suspension springs, the characteristics of the device will also be affected. Another issue is related to the thermal effect in the plasma etch for the SCS undercut. Upon completion of the silicon undercut, the greatly reduced thermal conductance from the isolated structure to the substrate can cause a temperature rise on the released structures. Slight over-etch is often necessary to accommodate process variations, but this will generate a large temperature rise on the suspended structures which in turn dramatically increases the SCS etching rate, resulting in uncontrollable and damaging results [28].

A modified dry bulk CMOS-MEMS process has been demonstrated to effectively address the issues caused by the undesired SCS

CMOS MEMS Fabrication Technologies, Fig. 3 The modified bulk CMOS-MEMS process for separate etching of CMOS beams and SCS microstructures. Backside photoresist coating effectively reduces temperature in the device release, reducing deleterious non-uniform etching

undercut [28]. In the refined process illustrated in Fig. 3, the etching of the CMOS connection beams is performed separately from the etching of the microstructures where SCS is needed. The top metal layer is specifically used to define the connection beams. After their formation, the top metal layer is removed using a plasma or a wet etch. Then other microstructures are exposed after a SiO_2 etch. The direct etch-through of the remaining silicon on the microstructures will complete the release process. To reduce the thermal effect described above, a thick photoresist layer is patterned on the backside of the cavity. In the release step, the applied photoresist provides a thermal path that reduces the temperature rise on the etched-through structures. The removal of the photoresist using O_2 plasma etching completes the entire microfabrication process. Owing to the monolithic integration and large proof mass enabled by the inclusion of SCS, bulk CMOS-MEMS inertial sensors have demonstrated better performance than their thin-film counterparts [29]. The photoresist coating can also be replaced by sputtering a layer of metal such as aluminum.

Combined Wet/Dry Processes

In addition to the integration methods described above, efforts have been continuously made to integrate CMOS with MEMS using the combination of different microfabrication technologies. By combing silicon anisotropic wet etch with DRIE, some sophisticated surface and bulk MEMS structures such as bridges and cantilever arrays can be created. A multi-sensor system was demonstrated using a combined etch process [30]. In the accelerometers reported in [31], isotropic wet etching is used to remove metal layers in CMOS thin stacks to create parallel-plate-like vertical capacitors for gap-closing sensing. A silicon RIE follows to release the MEMS devices and break the coupling between the sensing thin films and the substrate. Sensitivities are largely increased with the gap-closing sensing compared to comb-finger sensing.

Summary

CMOS-MEMS technologies have been placed in pre-CMOS, intra-CMOS, and post-CMOS categories. Both pre-CMOS and intra-CMOS have issues such as dedicated foundries with suboptimal and less cost-effective processes. So it is normally impractical for academic research community to access these dedicated facilities. Post-CMOS provides excellent CMOS compatibility, foundry accessibility, and design flexibility, and the cost is also relatively low. While the

process standardization and industrialization of CMOS-MEMS technologies are in continuous progress, innovative processing technologies have opened up new pathways for integration. Wafer bonding–based integration has blurred the boundary between pre- and post-CMOS-MEMS integrations. SOI-CMOS-MEMS have also been aggressively explored. The technologies involved in this new exploration have emerged as enabling means for three-dimensional and systems-in-package integrations. More recently, technologies to co-fabricate many subsystems including nano-systems are being pursued enthusiastically.

CMOS-MEMS integration will continually evolve with the emergence of new fabrication technologies and new materials. While some companies have demonstrated promising CMOS-MEMS products, more joint efforts from research community and industries are needed for new process transfer and standardization to allow large volume fabrication of new products.

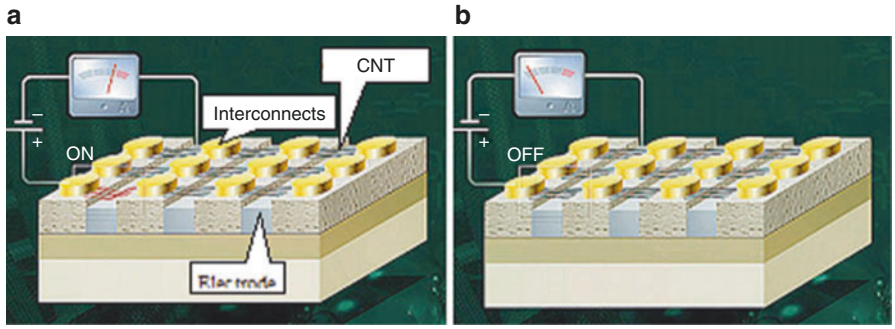
Monolithic integration of carbon nanotubes



Definition

Carbon nanotubes can be directly grown on CMOS substrate without degrading the performance of CMOS electronics.

Introduction

With numerous outstanding electrical, mechanical, and chemical properties, carbon nanotubes (CNTs) have been explored for various applications with great success. As CMOS circuits possess powerful interfacing, signal amplification, conditioning, and processing capabilities, it is also highly desired to integrate CNTs with CMOS. CNTs may be either used as part of CMOS electronics or as sensing elements to form functioning nano-electromechanical systems (NEMS). Figure 1 shows a nanotube random-access memory (NRAM) which uses CNT ribbons as switches [1].

Many sensors based on CMOS-CNT hybrid systems have also been demonstrated, including mechanical, thermal, and chemical sensors [3, 4]. The integration of CMOS circuits with CNT sensors can increase signal-to-noise ratio and dynamic range, lower power consumption, and provide various controls and automations. Other efforts have been made to use multiwall carbon nanotubes (MWNTs) as CMOS interconnect for high frequency applications [5], or to apply CNT-based nano-electromechanical

CMOS-CNT Integration, Fig. 1 The structure of NRAM at (**a**) on and (**b**) off states [2]

switches for leakage reduction in CMOS logic and memory circuits [6].

However, monolithic integration of CMOS and CNTs is still very challenging. Most CMOS-CNT systems have been realized either by a two-chip solution or low-throughput CNT manipulations. In this entry, CMOS-CNT integration approaches are reviewed, with a particular focus on a localized heating CNT synthesis method that can grow CNTs on foundry CMOS.

CNT Synthesis

There are three main methods for carbon nanotube synthesis: arc-discharge [7], laser ablation [8], and chemical vapor deposition (CVD) [9]. The first two methods involve evaporation of solid-state carbon precursors and condensation of carbon atoms to form nanotubes, where high annealing temperature, typically over 1000 °C, is required to remove defects and thus produce high-quality nanotubes. However, they tend to produce a mixture of nanotubes and other by-products such as catalytic metals, so the nanotubes must be selectively separated from the by-products. This requires post-growth purification and manipulation.

In contrast, the CVD method employs a hydrocarbon gas as the carbon source and involves heating metal catalysts in a tube furnace to synthesize nanotubes. Nanotubes can grow either on the top (tip growth) or from the bottom (base growth). The diameters and locations of the grown CNTs can be controlled via catalyst size and catalyst patterning, and the orientation can be guided by an external electric field. Suitable catalysts that have been reported include Fe, Co, Mo, and Ni [10]. Compared to the arc-discharge and laser ablation methods, CVD uses much lower growth temperature, but it is still too high for direct CNT growth on CMOS substrates.

In addition, during or after CNT growth, electrical contacts need to be formed for functional CNT-based devices. It is reported that Mo provides good ohmic contacts with nanotubes and shows excellent conductivity after growth, with resistance ranging from 20 kΩ to 1 MΩ per tube [11]. Several other metals, such as palladium, gold, titanium, tantalum, and tungsten, have also been investigated as possible electrode materials.

CMOS-CNT Integration

To integrate CNT on CMOS, there are several factors that must be taken into account: temperature budget, material compatibility, CNT type, CNT quality, and contamination. Depending on when CNTs are made, CMOS-CNT integration technology can be categorized as follows:

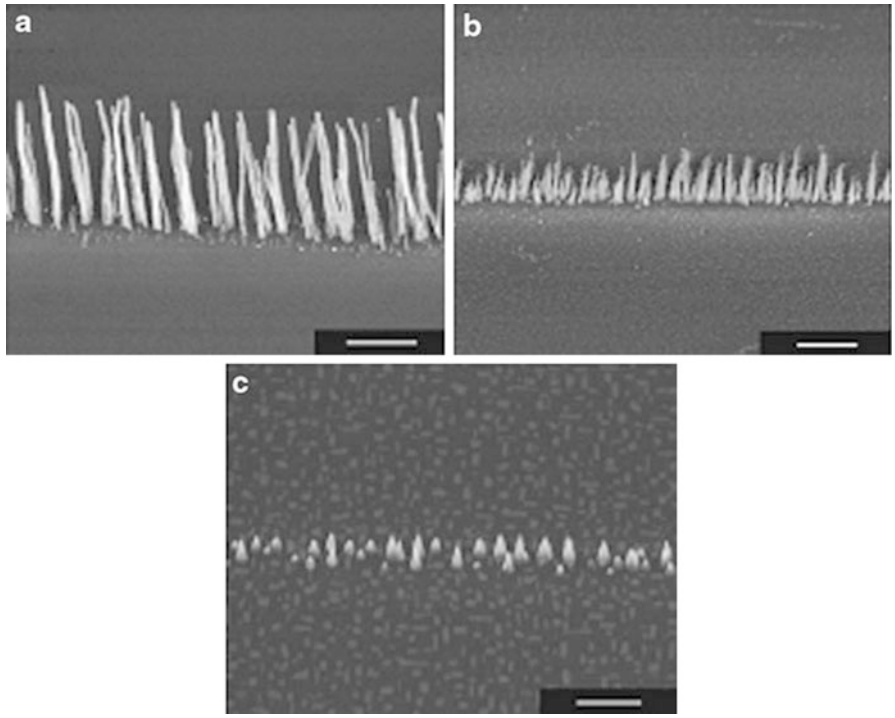
- Pre-CMOS: CMOS processes will be performed after CNTs are synthesized in place
- Intra-CMOS: CNT growth steps are inserted into CMOS fabrication steps
- Post-CMOS: CNTs are introduced after all CMOS processes have been done

For pre-CMOS, CNTs must go through standard CMOS process steps. This is very difficult to realize. There are temperature constraints, material compatibility, and contamination issues. There is no report about pre-CMOS CNT integration yet. For intra-CMOS, CNTs will be introduced at a later stage in the CMOS fabrication sequence, so it is easier to protect CNTs than in the pre-CMOS case. But temperature and contamination issues still must be considered. Post-CMOS, on the hand, completely eliminates CMOS contamination issues. It has potential to achieve mass production and low cost, but the temperature remains a limiting factor.

Intra-CMOS CNT Integration

Intra-CMOS (High Temperature CNTs)

Thermal CVD has been used to grow CNTs directly on CMOS substrate. For example, Tseng et al. demonstrated, for the first time, a process that monolithically integrates SWNTs with n-channel metal oxide semiconductor (NMOS) FET in a CVD furnace at 875 °C [12]. However, the high synthesis temperature (typically 800–1000 °C for SWNT growth) may damage the aluminum metallization layers and change the characteristics of the on-chip transistors as well. Ghavanini et al. assessed the deterioration level of CMOS transistors with certain CNT CVD synthesis conditions applied, and they reported that one PMOS transistor lost its functions after the thermal CVD treatment (610 °C, 22 min) [13]. As a result, the integrated circuits in Tseng's thermal CVD CNT synthesis can only consist of NMOS and use n+ polysilicon and molybdenum as interconnects, which make it incompatible with foundry CMOS processes.



Intra-CMOS (Low Temperature CNTs)

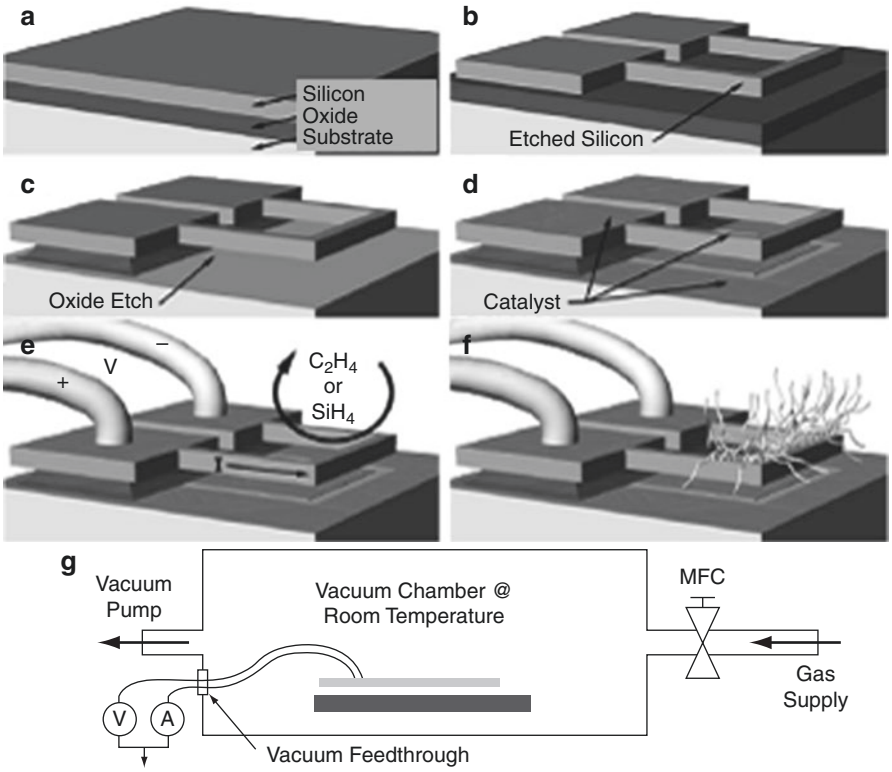
Some other attempts have been made to develop low temperature growth using various CVD methods. Hofmann et al. reported vertically aligned carbon nanotubes grown at temperature as low as 120 °C by plasma-enhanced chemical vapor deposition (PECVD) [14]. However, the decrease in growth temperature jeopardizes both the quality and yield of the CNTs, as shown in Fig. 2. The synthesized products are actually defect-rich carbon nanofibers rather than MWNTs or SWNTs.

Intra-CMOS (Localized Heating)

Localized heating: To accommodate both the high temperature requirement (800–1000 °C) for high-quality SWNT synthesis and the temperature limitation of CMOS processing (<450 °C), CNT synthesis based on localized heating has drawn great interest recently. Englander et al. demonstrated, for the first time, the localized synthesis of silicon nanowires and carbon nanotubes based on resistive heating [15]. The fabrication processes are shown in Fig. 3. Operated inside a room temperature chamber, the suspended micro-electromechanical system (MEMS) structures serve as resistive heaters to provide high temperature at predefined regions for optimal nanotube growth, leaving the rest of the chip area at low temperature. Using the localized heating concept, direct integration of nanotubes at specific areas can be potentially achieved in a CMOS compatible manner, and there is no need for additional assembly steps. However, the devices typically have large sizes and their fabrication processes are not fully compatible with the standard foundry CMOS processes. Although this concept has solved the temperature incompatibility problem between CNT synthesis and CMOS circuit protection, the fabrication processes of microheater structures still have to be well designed to fit into standard CMOS foundry processes and the resistor materials must be selected to meet the CMOS compatibility criteria.

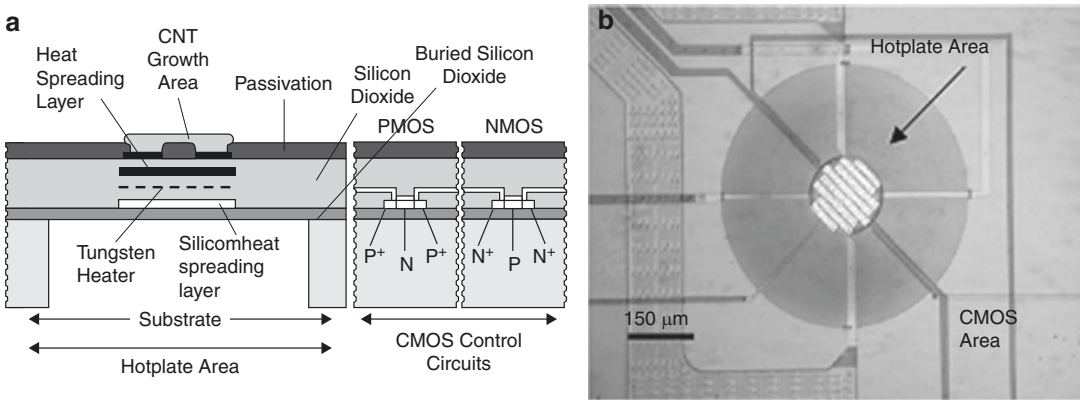
Using the localized heating technique described above, on-chip growth using CMOS micro-hotplates was demonstrated by Haque et al. [16]. As shown in Fig. 4, tungsten was used for both the micro-hotplates (as the heating source) and interdigitated electrodes for nanotubes contacts. MWNTs have been successfully synthesized on the membrane, and simultaneously connected to CMOS circuits through tungsten metallization. Although tungsten can survive the high temperature growth process, and has high connectivity and conductivity, Franklin et al. reported that no SWMTs were found to grow from catalyst particles on the

CMOS-CNT Integration, Fig. 2 SEM images of vertically aligned CNFs grown by PECVD deposition at (**a**) 500 °C, (**b**) 270 °C, and (**c**) 120 °C (scale bars: (**a**) and (**b**) 1 μm and (**c**) 500 nm) [14]



tungsten electrodes, presumably due to the high catalytic activity of tungsten toward hydrocarbons [11]. Further, although the monolithic integration has been achieved, the utilization of tungsten, a refractory metal, as interconnect metal is limited in foundry CMOS, especially for mixed-signal CMOS processes. Moreover, this approach requires a backside bulk micromachining process and is limited to SOI CMOS substrates.

Post-CMOS CNT Integration

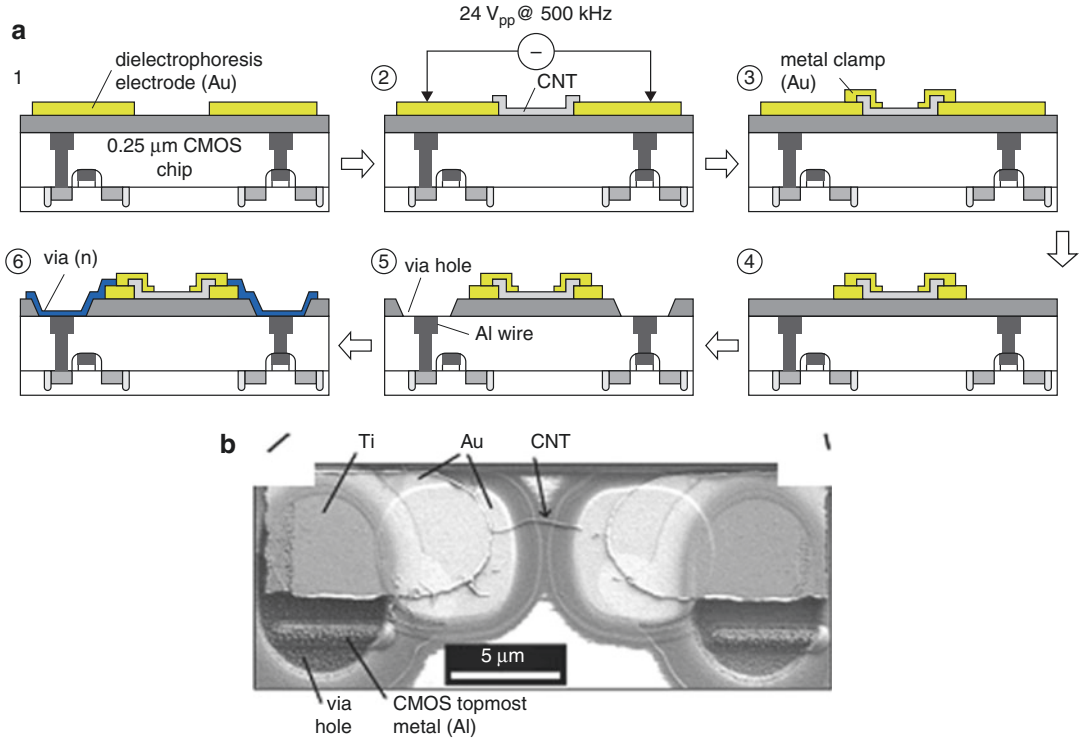


Post-CMOS (CNT Transfer and Assembly)

To overcome the temperature limitation, one possible solution is to grow nanotubes at high temperature first and then transfer them to the desired locations on CMOS substrates at low temperature. However, handling, maneuvering, and integrating these nanostructures with CMOS chips/wafers to form a complete system are very challenging. In the early stage, an atomic force microscope (AFM) tip was used to manipulate and position nanotubes into a predetermined location under the guide of scanning electron microscope (SEM) imaging [17]. Although this nanorobotic manipulation realized precise control over both the type and location of CNTs, its low throughput makes large scale assembly prohibitive.

Other post-growth CNT assembly methods include surface functionalization [18], liquid-crystalline processing [19], dielectrophoresis (DEP) [20], and large scale transfer of aligned nanotubes grown on quartz [21]. A 1 GHz CMOS circuit with CNT interconnects has been demonstrated using a DEP-assisted assembly technique [5]. The fabrication process flow and the assembled MWNT interconnect are shown in Fig. 5. The DEP process provides the capability of precisely positioning the nanotubes in a noncontact manner, which minimizes the parasitic capacitances and allows the circuits to operate at more than 1 GHz. However, to immobilize the DEP-trapped CNTs in place and to improve the electrical contact between CNTs and the

CMOS-CNT Integration, Fig. 3 Fabrication process and localized heating concept [15]

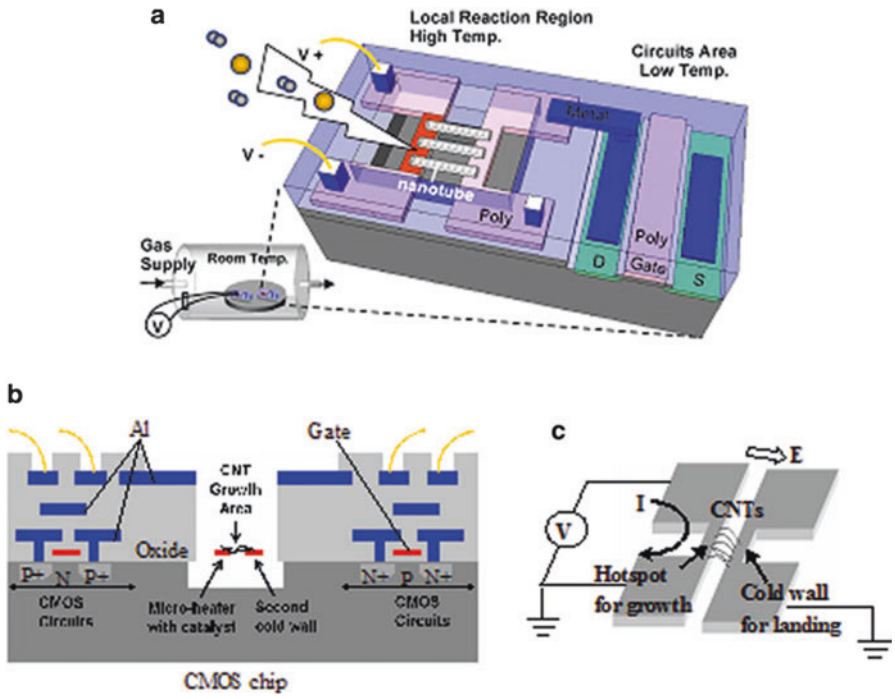


CMOS-CNT Integration, Fig. 4 (**a**) Schematic of the cross-sectional layout of the chip. (**b**) Optical image of the device top view showing the tungsten interdigitated electrodes on top of the membranes, heater radius = 75 µm, membrane radius = 280 µm [16]

electrodes, metal clamps must be selectively deposited at both ends of the CNTs (Fig. 5a, step 3). The process complexity and low yield (~8 %, due to the MWNT DEP assembly limitation) are still the major concerns.

Post-CMOS (Localized Heating)

Monolithic CMOS-CNT integration is desirable to fully utilize the potentials of nanotubes for emerging nanotechnology applications, but the approaches introduced above still cannot



CMOS-CNT Integration, Fig. 5 (**a**) Process flow to integrate MWNT interconnects on CMOS substrate. (**b**) SEM image of one MWNT interconnect (wire and via) [5]

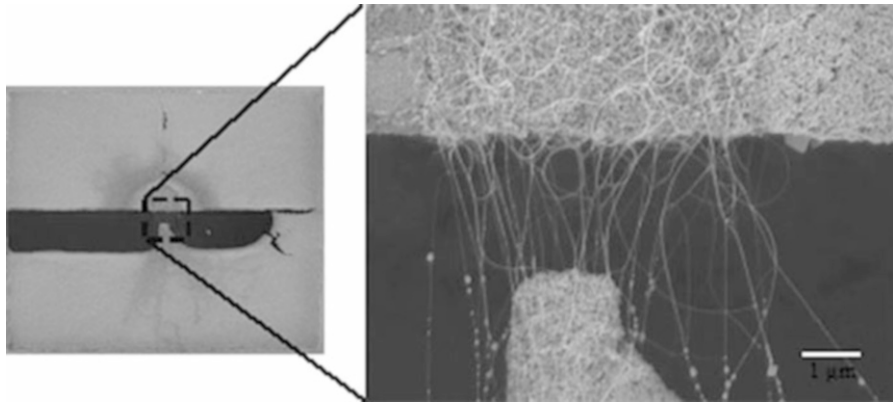
meet all the requirements and realize complete compatibility with CMOS processes. To solve the problem, a simple and scalable monolithic CMOS-CNT integration technique using a novel maskless post-CMOS surface micromachining processing has been proposed. This approach is fully compatible with commercial foundry CMOS processes and has no specific requirements on the type of metallization layers and substrates.

As illustrated in Fig. 6, the basic idea of the monolithic integration approach is to use maskless post-CMOS MEMS processing to form micro-cavities for thermal isolation and use the gate polysilicon to form resistors for localized heating as well as the nanotube-to-CMOS interconnect. The microheaters, made of the gate polysilicon, are deposited and patterned along with the gates of the transistors in the standard CMOS foundry processes. One of the top metal layers (i.e., the metal-3 layer as shown in Fig. 6b) is also patterned during the CMOS fabrication. It is used as an etching mask in the following post-CMOS microfabrication process for creating the micro-cavities. Finally, the polysilicon microheaters are exposed and suspended in a micro-cavity on a CMOS substrate. The circuits are covered under the metallization and passivation layers, as illustrated in Fig. 6b. Unlike the traditional thermal CVD synthesis in which the whole chamber is heated to above 800 °C, the CVD chamber is kept at room temperature all the time, with only the microheaters activated to provide the local high temperature for CNT growth (Fig. 6a, the red part represents the hot microheater).

The top view of a microheater design is shown in Fig. 6c. There are two polysilicon bridges: one as the microheater for generating high temperature to initiate CNT growth and the other for CNT landing. With the cold wall grounded, an E-field perpendicular to the surface of the two bridges will be induced during CNT growth. Activated by localized heating, the nanotubes will start to grow from the hotspot

The *red* part represents the hot microheater that has been activated for high temperature nanotube synthesis. (**b**) Cross-sectional view of the device. (**c**) The schematic 3D microheater showing the local synthesis from the hotspot and self-assembly on the cold landing wall under the local electric field

(i.e., the center of the microheater) and will eventually reach the secondary cold bridge under the guide of the local E-field. Since both the microheater bridge and the landing bridge are made of the gate polysilicon layer and have been interconnected with the metal layers in CMOS foundry process, the as-grown CNTs can be electrically connected to the CMOS circuitry on the same chip without any post-growth clamping or connection steps.



This technology has been verified at the chip level. The CMOS chips were fabricated in the AMI 0.5 μm 3-metal CMOS process. Optical microscope images of a CMOS chip before and after MEMs fabrication are shown in Fig. 7a, b. The total chip area is 1.5 × 1.5 mm^2, including test circuits and 13 embedded microheaters. SEMs of two microheaters are shown in Fig. 7d, e, with resistances of 97 and 117 Ω, respectively. At about 2.5 V, red glowing was observed for the design in Fig. 7e. This voltage was also used for the CNT growth.

Figure 8 shows one device with successful CNT growth, where individual suspended carbon nanotubes were grown from the 3 × 3 μm microheater shown in Fig. 7e and landed on the near polysilicon tip. The overall resistance of the CNTs is measured between the microheater and the cold polysilicon wall at room temperature. The typical resistances of in situ synthesized CNTs range from 5 to15 MΩ. The resistance variation from device to device is mainly due to the variation of the CNT quantity grown on each microheater. Junction effects of Schottky contacts were observed for self-assembled polysilicon/CNTs/polysilicon heterojunctions.

After successful synthesis of carbon nanotubes, the influence of the localized heating on nearby CMOS circuits was evaluated. Simple circuits, such as inverters, were tested and proved working properly. There was no change to the rising and falling time after the CNT growth. The dc electrical characteristics of individual

transistors had no considerable change after CNT growth, demonstrating the CMOS compatibility of this integration approach.

Summary

CMOS-CNT integration has been demonstrated by using both intra- and post- CMOS processes. Several methods have been developed to overcome the temperature conflict between CNT growth and CMOS, including using high temperature refractory metals for interconnect, low temperature CVD, transferring/assembling CNTs prepared off site, and localized heating. Among these techniques, localized heating is very promising. Truly monolithic CNT-CMOS integration has been demonstrated on foundry CMOS substrate by employing MEMS and localized heating. This post-CMOS microfabrication is maskless, and the CNT growth does not affect the characteristics of the transistors on the same chip.

MEMS resonators integrated with circuits; MEMS/IC integrated resonator circuits; Micromechanical resonators fabricated using CMOS-MEMS technologies

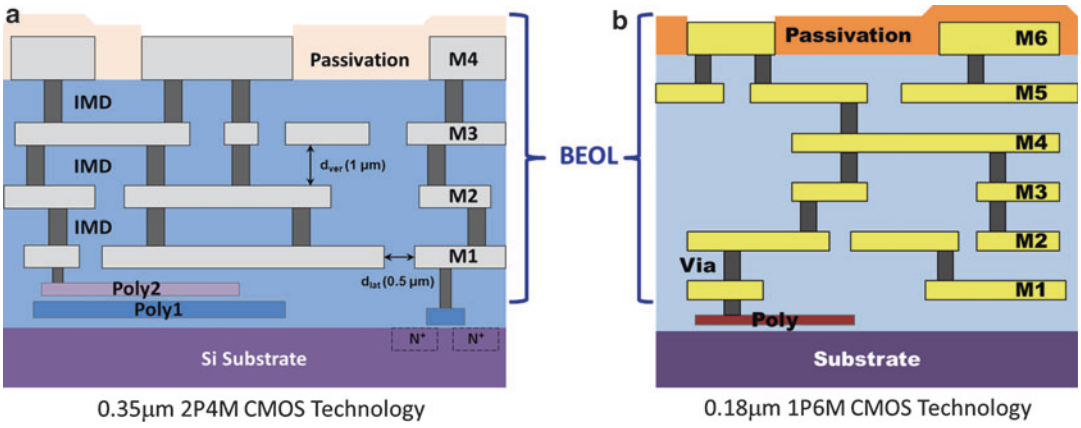
Definition

Based upon a strict definition, a CMOS-MEMS resonator is fabricated using a CMOS foundry orientated process to realize MEMS/IC integration for resonator applications, such as oscillators and filters. The integrated CMOS-MEMS fabrication platform is a key technology to reduce the form factor, enhance the performance, increase the functionality, and facilitate circuit integration for portable sensing devices and Internet of Things (IoTs). The integrated CMOS-MEMS circuits greatly reduce the parasitic stray capacitances at the MEMS-circuit interface so that it not only improves the system responses at high frequencies but also reduces the power consumption of the electronic circuits. This platform benefits the future portable/wearable electronic products for smaller size and longer standby time.

Principle of Operation

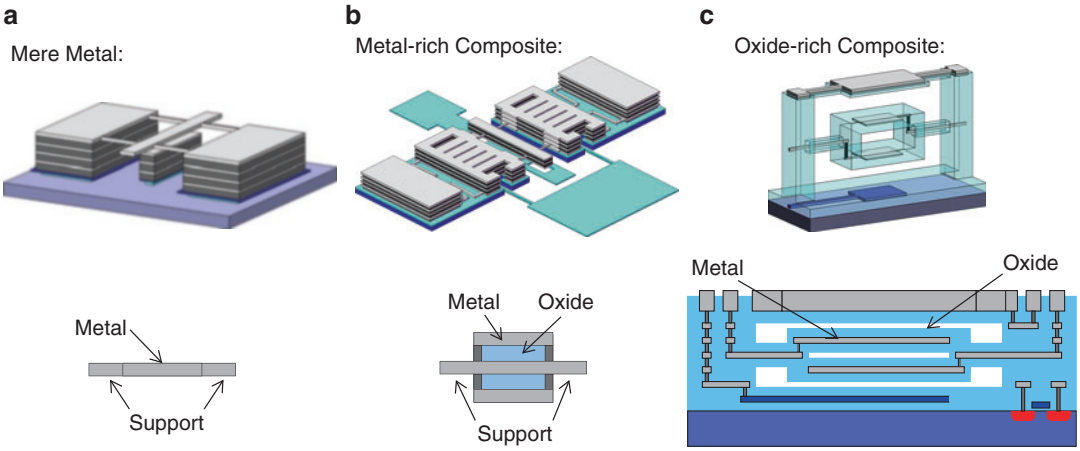
CMOS-MEMS resonators are mainly formed by the CMOS back-end-of-line (BEOL) materials, including interlayer dielectrics (ILD), e.g., SiO_2, and conductive metals, e.g., AlCu or Cu [1]. The target of this technology is to facilitate MEMS/IC monolithic integration without the need of additionally complex processes, such as heterogeneous integration using wafer bonding or 3D IC. Figure 1 presents two configurations of CMOS technology where the BEOL is highlighted. As can be seen, the BEOL materials will be used as MEMS structures of resonators, while the transistor circuits are naturally integrated with the resonators, thus leading to a much smaller form factor and less parasitics as compared to the current technologies (e.g., two-chip or heterogeneous integration solution). Since the capacitive transducers inherently exist, they are used as the major driving and sensing mechanism for CMOS-MEMS resonators [1–4] although the piezoresistive readout [5] can also be implemented once the polysilicon material (cf. Fig. 1) serves as the piezoresistors for motion detection. In this entry, only the pure capacitively transduced CMOS-MEMS resonator technology, i.e., the mainstream transduction in CMOS-MEMS, is introduced.

Resonator Structure



Based on various maskless post-CMOS release processes (i.e., no additional lithography step is required), the CMOS-MEMS resonator structures can be categorized into (a) mere-metal, (b) metal-rich composite, (c) and oxide-rich composite configurations, as shown in Fig. 2. The implemented processes resulting in structures in Fig. 2 will be discussed in the next section. With these structures, the CMOS-MEMS resonators exhibit different performance in terms of quality factor (Q) and thermal stability (i.e., temperature coefficient of frequency, TC_f).

Resonance Frequency



To determine the resonance frequency of the CMOS-MEMS composite beam resonators indicated in Fig. 2b and c, the Euler-Bernoulli approach can be used to attain a first-order approximation of the resonance frequency (f_{nom}) using a formula given by

$$f_{nom} = \frac{1}{2\pi}\sqrt{\frac{k_m}{m_{re}}} = \frac{1}{2\pi}(\beta_1 L_r)^2\sqrt{\frac{\sum(E_i I_i)}{\sum(\rho_i A_i)}}\frac{1}{L_r^2} \quad (1)$$
