Finally, we want to emphasize the importance of quantum coherence in energy and electron transfer in nanoscale materials. Relaxation of singlet excited states into same-symmetry ground state requires on the order of hundreds picoseconds to over nanoseconds. However, it would have proceeded much faster, on a picosecond or sub-picosecond timescale, if the transitions had involved fully coherent states. Curiously, the FSSH method discussed in the theory section assumes a fully coherent description of electronic excited-state dynamics. Hence, it is unlikely that the FSSH would produce correct timescales, except for ultrafast processes. Decoherence effects should be taken into account in order to obtain correct long-time dynamics. To illustrate the importance of these effects, we can consider relaxation of low-lying excited states in solid pentacene and solid C_{60} [8]. The relaxation of hot electrons occurs on the order of 500 fs in the first system, and FSSH works perfectly well. On the contrary, the timescale of nonradiative relaxation in C_{60} is greatly underestimated by plain FSSH, while introducing a decoherence correction increases the timescale by an order of magnitude, in good agreement with experiment.

Departing from the methodological consequences of decoherence, we want to emphasize

two other points. First, since decoherence is largely defined by system's environment (although some degrees of freedom of the system can also be a part of that environment), the lifetimes of excitations or separated charge carriers can be controlled by a proper choice of the environment. This type of manipulations is known and utilized in quantum optics and quantum computing. Second, the idea of controlled decoherence is already utilized by nature. In this case, light-harvesting complexes are embedded into protein environments that are capable of maintaining long-lived coherences. As a result, the dynamics of energy transfer becomes very efficient, and a nearly 100 % yield is obtained for energy transfer from site to site over long spatial distances. Proper theoretical description of nonadiabatic electron dynamics in nanoscale materials requires accurate treatment of quantum coherence [5, 9, 18].

Definition

Optical metamaterials can be understood as artificial media consisting of suitably assembled micro- or nanostructured materials such as dielectrics or metals and acquiring their essential properties from the structure rather than from the underlying material. The purpose of metamaterials is to affect the characteristics of light propagation in a manner inaccessible with natural available media. Their theoretical description evokes various concepts which are outlined in this essay.

Introduction

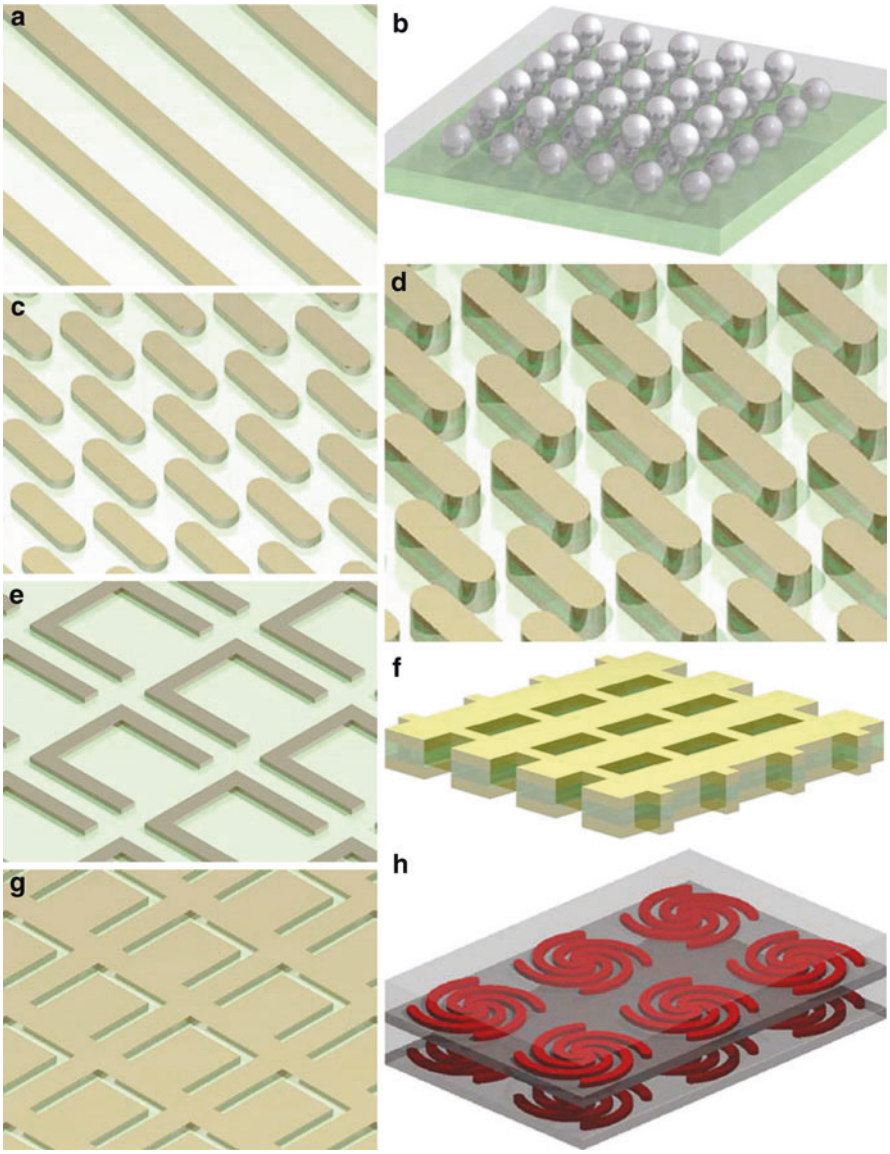
Optical metamaterials (MMs) can be understood as artificial media consisting of suitably assembled micro- or nanostructured materials such as dielectrics or metals [1–3] and acquiring their essential properties from the structure rather than from the underlying material. The purpose of MMs is to affect the characteristics of light propagation in a manner inaccessible with natural available media; hence the term material was linked with the prefix *meta*, being derived from Greek and literally meaning beyond or after. This rather generic and broad definition comprises many kinds of structured materials. Examples thereof would be photonic crystals or plasmonic structures [4, 5]. In a stricter sense, as the definition is further refined here, MMs are thought to be made from unit cells a few times or much smaller than the wavelengths in the spectral domain of interest. Here restriction is made specifically to the latter case where the propagating light does not probe for the fine details of the unit cells [6]. Its propagation can rather be fully understood by replacing the complex-shaped MM with a homogenous medium to which effective properties are assigned [7]. In the alternative case where the unit cell is only a few times less than the relevant wavelength, that is, the metamaterials represent a mesoscopic system, nonlocal effects come into play and the assignment of both an effective permittivity and permeability ceases to be meaningful. Alternative approaches for describing light propagation have to be used which are beyond the scope of this entry.

Depending on which approach is chosen to discuss MMs, the innovation comes with the deliberation from restrictions imposed by nature. The linear optical properties of natural materials at optical frequencies are entirely described by considering the permittivity function only, that is, a complex frequency-dependent function characterizing the response of matter to an electric field. The permeability function, which characterizes the response of matter to a magnetic field, can be safely disregarded since it marginally deviates from that of vacuum. For any frequency considered both permeability and permittivity represent material parameters and are linked to wave parameters, as for example, the wave vector or the refractive index, by the dispersion relation of the normal- or eigenmodes which is of pivotal importance to describe the propagation of electromagnetic fields in any structure. These eigenmodes are self-consistent solutions to Maxwell's equations in the respective medium. The propagation of an arbitrary field in this medium can then be written

as a linear superposition of such eigenmodes. The eigenmodes of a homogenous, dispersive achiral and isotropic medium are elliptically polarized plane waves characterized by wave parameters, such as impedance and refractive index. For natural materials both quantities are linked by inversion. Hence, if one parameter is determined in a given material, the other is equally fixed. Thus, independent of whether material or wave properties are considered, there is only a single degree of freedom [8, 9].

Metamaterials have the potential to circumvent this limitation and to provide independent control over permittivity and permeability, or refractive index and impedance. Both sets of parameters are connected by defining suitable constitutive relations. They have to be introduced into Maxwell's equations to specify the matter responses to an electric or magnetic field. Having materials at hand in which these material or wave parameters can be freely adjusted, many future applications can be envisaged which at first glance contradict the daily experience of how light propagates. Examples are the perfect lens which reconstructs an object in the image plane with unprecedented resolution or a cloaking device that allows concealing objects from external observers. It requires precise guidelines for designing MMs to achieve the necessary effective properties for bringing such applications to reality. This entry documents such approaches.

However, it has to be underlined again that any description of MMs in terms of effective material parameters is necessarily an approximation. It may serve as a model which is valid under certain constraints and where a finite number of free parameters mimic the complex structure. This greatly facilitates the description of current MMs and allows considering them in a subsequent design process for functional devices. The model is valid if the derived effective parameters are such that they do not violate the assumptions made in deriving them (for details, see Ref. [10]). A simple canonical example which illustrates the case is the retrieval of isotropic material properties for a MM whose unit cell fulfills all geometrical requirements to be considered as isotropic in the quasi-static (long wavelength) limit. Obviously, while being isotropic such material parameters must not depend on the angle of incidence. Unfortunately, this may be observed in the spectral domain where the dispersive effects of interest occur. Then, obviously, the material cannot be strictly considered as isotropic, though the deviations might be miniscule for suitably designed MMs and might be acceptable for a given application [10]. What is acceptable or not cannot be rigorously defined and it will depend on the explicit application and purpose of the effective properties, and it is moreover subject to a constantly heated debate. It is therefore not the intention of this entry to discuss the details of effective properties of various MMs but rather to explain and summarize the framework and the means to derive effective properties of optical MMs on theoretical grounds. Nevertheless, to illustrate representative unit cells for MMs and to provide an idea on how such structures look like, Fig. 1 shows examples of canonical unit cells for optical MMs along with an indication of which effective properties are affected.



The entry is structured as follows. In the second section, the idea of assigning constitutive relations to a MM is outlined. In the third section, an overview of theoretical approaches is provided that can be used to discuss the properties of optical MM on theoretical grounds. The limitations of such descriptions are finally discussed and eventually some conclusions are provided.

Constitutive Relations and Effective Properties

Any theoretical description of optical MMs has necessarily to start with Maxwell's equations which read in time domain as

$$\mathbf{rot}\,\mathbf{E}(\mathbf{r},t) = \frac{\partial \mathbf{B}(\mathbf{r},t)}{\partial t}, \qquad \mathrm{div}\,\mathbf{D}(\mathbf{r},t) = 0,$$
$$\mathbf{rot}\,\mathbf{H}(\mathbf{r},t) = \frac{\partial \mathbf{D}(\mathbf{r},t)}{\partial t} + \mathbf{j}(\mathbf{r},t), \qquad \mathrm{div}\,\mathbf{B}(\mathbf{r},t) = 0,$$

where $\mathbf{E}(\mathbf{r},t)$ and $\mathbf{H}(\mathbf{r},t)$ are the electric and magnetic fields; $\mathbf{D}(\mathbf{r},t)$ and $\mathbf{B}(\mathbf{r},t)$ are the electric displacement and the magnetic induction,

Theory of Optical Metamaterials, Fig. 1 Characteristic optical MMs consisting of different unit cells. (**a**) Metallic wire grid which acts as a diluted metal with a Drude-type effective permittivity; (**b**) and (**c**) MMs made from small metallic nanoparticles which will induce a Lorentzian-type effective permittivity around the resonance frequency of the localized plasmon polariton; (**c**) indicates that the resonance frequency can be tuned by modifying the geometry of the nanoparticles; (**d**) cut-wire pair where two metallic particles separated by a dielectric are strongly coupled, leading to a symmetric and an anti-symmetric resonance where either the permittivity or the permeability exhibits a Lorentzian resonance; (**e**) split-ring resonator supports complex resonances depending on the illumination direction and the polarization, but being best known as a unit cell possessing a magnetic resonance; (**f**) fishnet structure where a cut-wire pair is combined with a metallic wire, and the resulting medium may show both a dielectric and a magnetic resonance in the same spectral range leading to a negative refractive index; (**g**) complementary structures, as the complementary split-ring resonator, are equally important; (**h**) gammadion structure which acts as an effective chiral medium

respectively; and $\mathbf{j}(\mathbf{r},t)$ is the conductive current. The latter depend both, in general, on the electric and magnetic field in a complicated manner, specified by the respective constitutive relations. It has to be stressed that in this special form of Maxwell's equations the external charge carrier density is assumed to be zero. Assuming the realm of linear optics to be valid, it is convenient to write Maxwell's equations in temporal Fourier space by assuming a time harmonic oscillation of all fields. This leads to

$$\begin{aligned} \mathbf{rot}\,\overline{\mathbf{E}}(\mathbf{r},\omega) &= \mathbf{i\omega}\overline{\mathbf{B}}(\mathbf{r},\omega), & \operatorname{div}\overline{\mathbf{D}}(\mathbf{r},\omega) &= 0, \\ \mathbf{rot}\,\overline{\mathbf{H}}(\mathbf{r},\omega) &= -\mathbf{i\omega}\overline{\mathbf{D}}(\mathbf{r},\omega) + \overline{\mathbf{j}}(\mathbf{r},\omega), & \operatorname{div}\overline{\mathbf{H}}(\mathbf{r},\omega) &= 0, \end{aligned}$$

Arbitrary solutions to Maxwell's equations in time domain are then written as a superposition of those time harmonic solutions weighted with appropriate amplitudes. Quantum mechanical or phenomenological models allow the derivation of frequency-dependent permittivity and permeability functions or tensors, where usually the electrical conductivity is absorbed into the complex permittivity which includes contributions from bound states and free electrons. Whereas the general dependency of $\mathbf{D}(\mathbf{E},\mathbf{H})$, $\mathbf{B}(\mathbf{E},\mathbf{H})$, and $\mathbf{j}(\mathbf{E},\mathbf{H})$ can be arbitrary complex, in most cases there is a linear relationship between these quantities mediated by permittivity, permeability, and electromagnetic coupling functions. The most general constitutive relation that is yet amenable to a theoretical treatment is that of a bi-anisotropic material. Assuming from now on an infinite homogenous space and dropping the dependency on the spatial coordinate, the resulting local constitutive relations read as [11] provided that the complex conductivity is absorbed into the complex permittivity:

$$\overline{\mathbf{D}}(\omega) = \varepsilon_0\overline{\overline{\varepsilon}}(\omega)\overline{\mathrm{E}}(\omega) + \frac{1}{c}\overline{\overline{\xi}}(\omega)\overline{\mathbf{H}}(\omega)$$

$$\overline{\mathbf{B}}(\omega) = \frac{1}{c}\overline{\overline{\zeta}}(\omega)\overline{\mathrm{E}}(\omega) + \mu_0\overline{\overline{\mu}}(\omega)\overline{\mathbf{H}}(\omega).$$

The four tensorial material functions are the permittivity $\overline{\overline{\varepsilon}}(\omega)$, the permeability $\overline{\overline{\mu}}(\omega)$, and two further tensors $\overline{\overline{\xi}}(\omega)$ and $\overline{\overline{\zeta}}(\omega)$ which mediate the electromagnetic coupling. Since the magnetic (electric) field depends on the curl of the electric (magnetic) field, the equations can also be understood as a Taylor series of a more complex functional dependency of the electric (magnetic) displacement on the electric (magnetic) fields. In this expansion only the lowest order coefficients are retained. For a medium with sufficiently high symmetry, that is, unit cells composed of three mirror-symmetric orthogonal planes, electromagnetic coupling vanishes. Consequently, in this Taylor expansion a next higher order term also needs to be considered, that is, media possessing a weak nonlocal response (weak spatial dispersion). If this holds, terms would appear where the displacement fields depend on the second derivative of the fields. Under appropriate conditions, which are assumed here to be valid, this term in the electric displacement field can be transformed as to appear in the dispersive permeability $\overline{\overline{\mu}}(\omega)$ in the magnetic constitutive relation and does not need to be considered explicitly. Such transformation can be understood as a gauge transformation since physical observable fields are not affected. Moreover, such transformation is useful to explain how it is possible to observe artificial magnetism at optical frequencies for which all available materials possess usually a nondispersive permeability. An artificial medium which supports a weak nonlocal electric response, that is, a nonlocal current appearing in mesoscopic metallic structures, is hence required to observe artificial magnetism, leading to the above constitutive relations [10, 12].

At this point it has to be stressed that the constitutive relations are very general. If they can be furthermore assumed to be reciprocal, they reduce to

$$\overline{\mathbf{D}}(\omega) = \varepsilon_0\overline{\overline{\varepsilon}}(\omega)\,\overline{\mathbf{E}}(\omega) + i\frac{1}{c}\overline{\overline{k}}(\omega)\overline{\mathbf{H}}(\omega),$$

$$\overline{\mathbf{B}}(\omega) = -i\frac{1}{c}\overline{\overline{\kappa}}^{T}(\omega)\overline{\mathbf{E}}(\omega) + \mu_0\overline{\overline{\mu}}(\omega)\overline{\mathbf{H}}(\omega).$$

If, additionally, electromagnetic coupling effects may be excluded, it is possible to arrive at the relation for anisotropic crystal.

$$\overline{\mathbf{D}}(\omega) = \varepsilon_0 \overline{\overline{\varepsilon}}(\omega)\, \overline{\mathbf{E}}(\omega), \quad \overline{\mathbf{B}}(\omega) = \mu_0 \overline{\overline{\mu}}(\omega) \overline{\mathbf{H}}(\omega).$$

If isotropy holds the simplest form of the constitutive relations is achieved as

$$\begin{aligned} \overline{\mathbf{D}}(\omega) &= \varepsilon_0 \varepsilon(\omega)\, \overline{\mathbf{E}}(\omega), \\ \overline{\mathbf{B}}(\omega) &= \mu_0 \mu(\omega) \overline{\mathbf{H}}(\omega) \end{aligned}$$

It has to be noted that the introduction of more complex constitutive relations, for example, explicitly containing strong spatial dispersion, when compared to the departing point is rather pointless, though they can be written down phenomenologically. The boundary conditions that need to be imposed onto the fields at the interface between two such media are quite involved (additional boundary conditions). They have to be applied in addition to ordinary Maxwell's boundary conditions and are the subject of ongoing research in the field of MMs [13].

These material parameters can be related to wave parameters describing the propagation of an eigenmode in a MM that is characterized by any of the constitutive relations above. Assuming the simplest scenario of a homogenous isotropic medium, the wave parameters of the eigenmodes are found by plugging the ansatz for an elliptically polarized plane wave $\mathbf{E}(\mathbf{r}, t) = \tilde{\mathbf{E}}(\omega) e^{i[k(\omega) r - \omega t]}$ as the possibly simplest solution into Maxwell's equations where the propagation vector $\mathbf{k}$ is one of the wave parameters. The dispersion relation relates it to the frequency ω which appears in the material parameters

$$\mathbf{k}^2 = k_x^2 + k_y^2 + k_z^2 = \frac{\omega^2}{c^2} \varepsilon(\omega) \mu(\omega)$$

The dispersion relation defines the set of plane waves that are allowed to propagate. The second wave parameter derives from the ratio of the moduli of electric and magnetic fields and is the impedance Z

$$Z = \sqrt{\frac{\mu(\omega)}{\varepsilon(\omega)}}$$

Whereas the propagation vector describes essentially the wave evolution of the normal mode in the respective medium, the impedance determines the reflection and transmission properties at interfaces to other media. For media with more complicated constitutive relations the corresponding dispersion relations can be equally derived on analytical grounds and can be found in literature.

With these governing equations the light propagation through an arbitrary complex material can be described exploiting a set of simple quantities. The challenge to theoretically describe optical MMs is to link a MM made of mesoscopic unit cells to a homogenized medium in which the fine details of the structures may be neglected. It is therefore required that at least the fields propagating either in the actual MM or in an effectively homogeneous material possess the same wave parameters. Both materials would then be indistinguishable since their optical action is fully preserved while the complexity is significantly reduced. This link has to be established first. By assuming furthermore feasible constitutive relations, these wave parameters can be linked to effective material parameters. Established approaches for exactly this purpose are documented in the following entry.

Retrieval of Effective Properties

The retrieval of effective properties of optical MMs is usually based on an analysis of the interaction of light with the structure under investigation; therefore, it is not possible to define the properties in an absolute sense but they are rather probed for a particular illumination scenario. In theory, the interaction and the propagation of such probing fields with the MM is numerically analyzed by solving rigorously Maxwell's equations and taking into account the fine details of the spatially distributed materials forming the unit cells, usually given by $\varepsilon(\mathbf{r}, \omega)$. The spatial distribution of the permeability does not need to be considered since the intrinsic permeability of natural materials is negligible. Various numerical means exist that can be applied for this purpose such as the Finite-Difference Time-Domain (FDTD) method, Finite-Element Method (FEM),

or plane wave expansion techniques [14]. Generally, depending on whether the unit cells are periodically or randomly arranged in space, various strategies can be applied to retrieve the effective properties. In the following between these two categories will be distinguished.

Periodic Structures

Most of current MMs are fabricated by top-down technologies such as electron beam lithography or direct laser beam writing. These technologies allow fabricating unit cells with critical dimensions in the order of a few tenths of nanometers, in most cases as planar nanostructured thin films on substrates. Repeating these techniques in a sequential or parallel process allows manufacturing MMs made of periodically arranged unit cells in all spatial dimensions. To eventually observe effective properties beyond those achievable by a mere spatial average of the intrinsic material properties of the involved constituents, resonances in the unit cells are often exploited. The required sub-wavelength size of the unit cells usually requires the coupling of the electromagnetic field to the free electrons in metals; hence plasmonic materials are often used in the design of optical MMs. In most cases gold is preferred since it is chemically stable, but also silver or aluminum can be used. Such MMs are therefore comparable to metallic photonic crystals, however, with much smaller periods, and consequently the language used to discuss their properties is intimately linked to it. Most notably, light propagation in bulk MMs is characterized by a dispersion relation as it will be discussed at first. The dispersion relation only allows determining the wave vector $\mathbf{k}$ that characterizes the evolution of a Bloch mode (for a definition see below), from which an effective index can be derived. As argued below, from the dispersion relation further quantities can be derived that are important to describe the propagation of finite beams (either spatially or temporally confined) through the bulk MM. From the tangential fields of an eigenmode the impedance linked to it can be derived. With these two quantities the entire set of wave parameters would be at hand. Moreover, for a deviating geometry and by relying on simulated reflection and transmission coefficients of an incident plane wave at a MM slab with finite thickness, both wave parameters can be equally retrieved. Such a procedure is part of a second succeeding section. Eventually, only if the wave parameters as retrieved by both approaches are identical the MM can be considered homogenous.

Retrieval Using the Dispersion Relation

An appropriate description of bulk properties of MMs made of periodically arranged unit cells is based on the dispersion relation. The periodic structure is characterized by the dielectric function

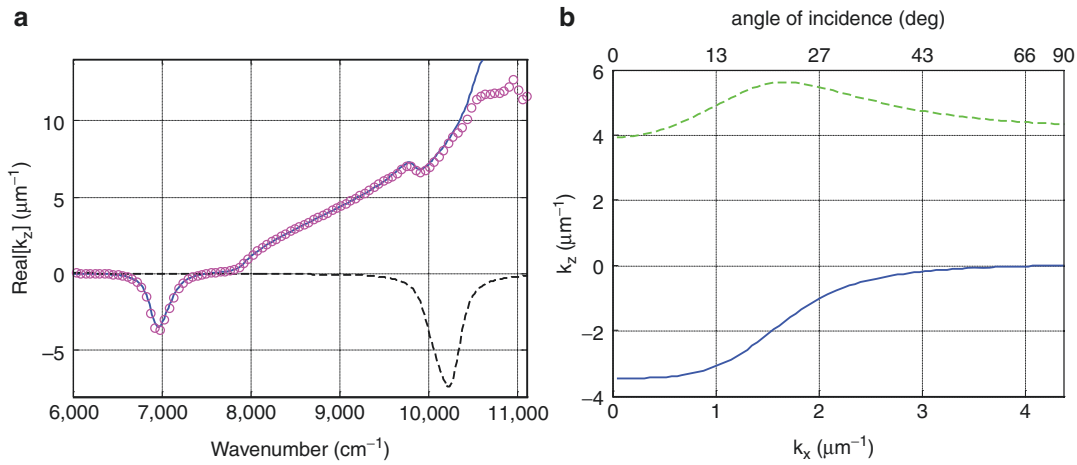
$$\varepsilon(\mathbf{r},\omega) = \varepsilon(\mathbf{r} + m\Lambda,\omega)$$

with Λ and m being the period of the structure and an integer, respectively. For simplicity it has been assumed that the MM's unit cells are made from isotropic materials. Since in the infinite medium two points displaced by one period in space are indistinguishable, the eigenmodes have to feature identical properties, that is, it is said they are Bloch periodic

$$\mathbf{u}_\mathrm{k}(\mathbf{r},\omega) = \mathbf{u}_\mathrm{k}(\mathbf{r} + m\Lambda,\omega)$$

The Bloch modes amplitude is periodic with the lattice and its phase evolves like a plane wave

$$\mathbf{E}_\mathrm{k}(\mathbf{r},\omega) = \mathbf{u}_\mathrm{k}(\mathbf{r},\omega)\mathrm{e}^{i[\mathrm{k}(\omega)\mathrm{r}-\omega t]}$$



As for any normal mode the Bloch wave vector $\mathbf{k}$ and the frequency ω are interrelated, that is, they have to obey a specific dispersion relation. This dispersion relation to be solved requires in general numerical means. There are a discrete number of Bloch modes which can be excited in the bulk MM. Nevertheless, from a conceptual point of view the approach is identical to that of a homogeneous, dispersive medium, that is, the governing dispersion relation is a single equation with four interrelated parameters. It suggests that three of them can be chosen freely. Alternatively, fixing three parameters by external constraints only excites Bloch modes with a given fourth

parameter. In dealing with photonic crystals it is common to fix all components of the wave vector and then solve for the frequency at which the solutions are allowed to oscillate. However, a more rational approach is preferred here that is linked to an experiment. Therefore, the frequency ω (imposed by selecting a light source) and the tangential wave vector components at interfaces *kx* and *ky* are fixed. This is regarded as the referential plane where the evolution of the Bloch modes in the bulk starts (imposed by selecting the angle of incidence for an external plane wave since the tangential wave vector components are conserved). The dispersion relation is solved for the longitudinal wave vector component k_z. This allows to reveal by numerical means the entire functional dependency of k_z on all parameters and allows to disclose the entire dispersion relation $k_z = k_z(k_x, k_y, \omega)$ [15].

The number of modes that can be solved for is generally infinite. For an empty sub-wavelength lattice, however, only a single mode has a real valued propagation constant whereas all the others are evanescent. The same holds for a MM which is expected to be homogenizable, that is, there is a single mode with an imaginary part much less than those of all higher order modes. The imaginary part of this dominating mode is not strictly zero as soon as materials are incorporated into the unit cells that are intrinsically absorptive (e.g., metals). It furthermore has to be said that the eigenmodes appear always pairwise with opposite sign corresponding to forward and backward propagating modes, respectively. The proper branch has to be chosen in accordance with considerations imposed by the finiteness of the amplitudes, that is, by considering as the principal propagation the positive *z*-axis, only those eigenmodes can be excited which decay exponentially upon propagation. The corresponding eigenmode with the negative propagation constant has to be taken into account for opposite propagation direction. A MM supporting a backward wave is easily identified in such analysis by unraveling the parameter space where the imaginary part of the propagation constant is opposite to the real part. In this spectral domain the MM is said to have a negative index, since the index is defined as the length of the wave vector in the MM normalized to the length of the wave vector in vacuum.

From the dispersion relation of the modes in the center of the Brillouin zone, that is, $k_x = k_y = 0$, and while considering additionally the symmetry of the unit cell, many conclusions can be already drawn on the polarization properties of the MM. For example, a C_4 symmetric unit cell (identical under rotation by 90° with respect to the z-axis) leading to a pair of identical propagation constants will show a polarization independent response. The field of the two modes will then be dominated by a component either polarized in the *x*- or in the *y*-direction and an arbitrary superposition of both modes is an eigenmode, in particular, also circularly polarized light. If the two propagation constants are different while still being C_4 symmetric, the medium is chiral and the chirality constant κ can be extracted from the difference of both propagation constants. A complete discussion of such properties is beyond the scope of this entry but can be found in literature.

The question on whether the medium is isotropic or anisotropic (biaxial or arbitrary) can only be answered while disclosing the functional dependency of k_z on k_x and k_y at a fixed frequency of interest. As argued before, this iso-frequency curve has a fixed shape for a given medium, that is, it is spherical for an isotropic medium, ellipsoidal for a biaxial anisotropic medium, but in most cases it possesses a complexity beyond those simple shapes and the medium is anisotropic in the literal sense, that it is just said to be non-isotropic. An example of such a dispersion relation depending on the frequency for a fixed tangential wave vector and another one depending on a tangential wave vector for a fixed frequency are shown in Fig. 2 for the fishnet MM. As can be seen in Fig. 2, the fishnet MM is neither isotropic nor biaxial anisotropic, but the iso-frequency curve shows a much more complicated functional dependency on the frequency where the relevant dispersive effects occur, that is, where the effective index takes negative values for the real part. This has dramatic consequences on the ability of the structure to refract or diffract light. While the direction into which light is refracted is linked to the refractive index only for an isotropic material,

Theory of Optical Metamaterials, Fig. 2 Dispersion relation of a referential optical metamaterial, i.e., the fishnet as shown in Fig. 1f. (**a**) Shows the real part of the propagation constant of the two lowest order modes (*blue solid line* and *black dashed line*) as a function of the frequency at $k_x = k_y = 0$. The *dotted points* show for comparison results as retrieved from the finite structure which requires a retrieval using the complex reflection and transmission coefficient as discussed in the entry further below. (**b**) Shows the real (*blue solid line*) and the imaginary part (*green dashed line*) of the lowest order mode as a function of the tangential wavevector component k_x at $k_y = 0$. The frequency was fixed as to correspond to the spectral domain where the propagation constant is the largest negative, i.e., 7,000 cm^{-1}

it is given in such more complicated mesoscopic structures by the normal vector of the iso-frequency curve. This is an extension of a well-known concept for biaxial anisotropic materials, where the direction of the Poynting vector, that is, the direction into which energy flows or a bundle of rays is refracted, is no more parallel to the wave vector but normal of the iso-frequency curve for the respective wave vector.

Similarly, the next higher order derivative is linked to the diffraction coefficient, being a measure how strong a finite bundle spreads upon propagation (normal diffraction – positive curvature of the iso-frequency curve) or whether the opposite holds and a diffractively broadened beam can be re-focused while propagating through a suitably designed MM (anomalous diffraction – negative curvature of the iso-frequency curve). Such compensation of the normal diffraction of free space with a suitable anomalous diffraction explains how it is possible to use a MM slab as an imaging device.

The conclusion can be drawn that in order to describe the propagation of pulsed beams in an arbitrarily structured bulk medium it suffices to know the dispersion relation of the normal modes. Effects like diffraction and dispersive spreading have their physical origin in the different phase evolution in propagation direction for different frequencies and transverse wave vector components. A simple example for this statement is pulse propagation in optical fibers. There diffraction is arrested (only one transverse wave component) and the first term of the Taylor expansion of the dispersion relation provides the group velocity whereas the second one provides group velocity dispersion (dispersive spreading). And similarly, just as dispersion managed fiber (alternating segments of normal and anomalous group velocity dispersion) allows for a complete pulse restoration, a MM slab that compensates the diffraction in a homogeneous medium may act as a perfect lens that enables to restore a spatially confined input field in some output plane.

However, the dispersion holds only in an infinite bulk medium. It contains no information on the transition between different media (conventional medium-MM, MM-MM). The missing link is the field impedance which is a measure for the coupling strength of normal

modes propagating in different media. Various definitions with different complexity are feasible. Here a definition that is based on the coupling efficiency of an input to a homogenizable MM (field propagation may be described by only one Bloch mode) at a certain interface is used. This is the so-called tangential impedance which is defined as the ratio of the spatial average of the tangential electric to the tangential magnetic fields across a given interface. Assuming a mirror-symmetric unit cell the average of the x-component of the electric field vanishes and the MM impedance reads as (the superscript hints to a Bloch mode)

$$Z = \frac{\left\langle E_y^B \right\rangle}{\left\langle H_x^B \right\rangle}.$$

To sum up to only describe light transition between media and light propagation in an arbitrary, but homogenizable, MM it suffices to know the dispersion relation and the impedance of the normal modes, which represent so-called wave parameters. In general, it is impossible, but also not required, to assign effective material parameters to MMs. However, if this is desired the consistent validity of the respective constitutive relations is required. This aspect will be discussed in the succeeding section when the parameter retrieval is performed using the reflection and transmission coefficients of a plane wave at a MM slab. This method, known as NRW-method, is particularly popular since it allows for exploiting measured reflection/transmission data for the retrieval thus not requiring propagation simulations [16]. But, since both complex coefficients need to be known with high precision, most notably in the measured phase, the retrieval using solely experimental results still constitutes a major challenge.

Retrieval Using Reflection and Transmission Data from a Slab

The appealing aspect of the parameter retrieval using reflection/transmission data relies on its simplicity. For a MM characterized by two parameters (propagation constant and impedance), two independent sets of measurements are required. Since most MMs are fabricated as slabs with a finite thickness, their explicit consideration is attractive. To render such simple approach to be applicable, it has to be assumed that the MM does not generate depolarized light, that is, electromagnetic coupling should not occur, and the light propagating through the slab has to remain in the plane of incident while traversing the structure. If both conditions are valid, the complex reflection and transmission coefficients can be computed under the assumption that the field propagating in the MM is characterized by a single Bloch mode (homogenization), that has a characteristic dispersion relation, and the coupling from a surrounding media occurs equally only to that single eigenmode, that can be expressed using the tangential impedance. Then reflection and transmission coefficients of a MM slab (labeled by F) with thickness d, sandwiched between a substrate (labeled by S) and a cladding (labeled by C) material where the dispersion relation for isotropic media holds, read as

$$T = \frac{2k_S\xi A}{\xi(k_S + k_C)\cos(kd) - i\left(\xi^2 + k_S k_C\right)\sin(kd)},$$
$$R = \frac{\xi(k_S + k_C)\cos(kd) - i\left(\xi^2 + k_S k_C\right)\sin(kd)}{\xi(k_S + k_C)\cos(kd) - i\left(\xi^2 + k_S k_C\right)\sin(kd)}.$$

Here it has been assumed that the z-coordinate is normal to the slab and that only the x-component of the tangential wave vector is nonzero. Moreover, some abbreviations have been introduced to facilitate the notation, that is (for details, see Ref. [10]),

$$k_{S,C} = \alpha^{S,C}k_z^{S,C}, k = k_z^F, \xi = \alpha^F k_z^F, \alpha_{TE}^i = 1/\mu^i, \alpha_{TM}^i = 1/\varepsilon^i A_{TE} = 1, A_{TM} = \sqrt{\frac{\mu^C\varepsilon^S}{\varepsilon^C\mu^S}}$$

Here a TE and TM polarization is introduced where the electric field is normal to or in the plane of incidence, respectively. Here a restriction is imposed to the TE case. The equations can be uniquely inverted as to provide the desired wave vector component k in longitudinal direction

inside the MM slab and the tangential impedance ξ. These equations read as

$$k(k_x,\omega) = \pm\cos^{-1}\left\{\frac{k_z^S(1-R^2)+k_z^C T^2}{T\left[k_z^S(1-R)+k_z^C(1+R)\right]}\right\}+2m\pi,$$

$$\xi(k_x,\omega) = \pm\sqrt{\frac{\left(k_z^S\right)^2(1-R)^2-k_z^C T^2}{\left[(1+R)^2-T^2\right]}}$$

The different signs account for forward and backward propagation. They have to be chosen such that the waves decay upon propagation (imaginary part of k) and the tangential impedance takes positive values at normal incidence where it is linked to the impedance via $\xi_{TE} = \frac{\omega}{c}\frac{1}{Z}$ and $\xi_{TM} = Z\frac{\omega}{c}$. The branch number m occurring in the expression for the longitudinal wave number reflects that the field may exhibit a different number of nodes in a finite slab. The correct determination of the proper branch number can be achieved by various means. For example, it is possible to solve for the longitudinal wave number at marginally small frequencies where independent of the absolute thickness of the slab a field node does not appear because of the long wavelength. An alternative approach is to solve for the longitudinal wave for varying thickness. A consistent solution must not depend on the thickness. Another popular approach, the authors prefer too, is to solve the problem at the frequency of interest where all geometrical MM dimensions are scaled sufficiently down and the branch number can then be unambiguously fixed as to be $m = 0$. Up-scaling the geometry hitherto and requiring continuity of the longitudinal wave number while the scaling is performed requires the permanent adjustment of the branch number. The process is repeated until the geometry of interest is finally reached.

The wave parameters as retrieved by considering the reflection and transmission data are only comparable to those retrieved from the dispersion relation if the light propagation in the MM is dominated by a single, dominating Bloch mode and if the external illumination excites only this mode. If both conditions are met, the MM is said to be homogenizable since all the complex details are projected on two quantities, the wave number and the tangential impedance. If MMs are homogenizable their properties will be independent of the MM thickness. Since the tangential impedance is linked to the field distributions in a particular plane of the unit cell, it is furthermore required that the unit cell is symmetric for both propagation directions. Extensions of the parameter retrieval taking other properties into account, for example, electromagnetic coupling, are reported in literature and shall be not discussed here [17].

Crucial to an effective description of MMs is the fact that the tangential impedance and the longitudinal wave vector component will depend explicitly on the tangential wave vectors and the frequency. The frequency dependence is usually not an issue since any known material possesses a frequency dependent response, that is, it is said to be dispersive. To further reduce the complexity of the wave parameters and to remove the dependency on the tangential wave vectors, the wave parameters as retrieved can be linked in some cases to material parameters. This requires, however, the strict validity of the constitutive relations. For example, if the material is assumed to be isotropic, the scalar and only frequency dependent material properties are linked to the wave number and the impedance for the scenario above for TE polarization as

$$\mu(\omega) = \frac{k(k_x,\omega)}{\xi(k_x,\omega)} \text{ and } \varepsilon(\omega) = \frac{n^2(\omega)}{\mu(\omega)}$$

and for TM polarization as

$$\varepsilon(\omega) = \frac{k(k_x,\omega)}{\xi(k_x,\omega)} \text{ and } \mu(\omega) = \frac{n^2(\omega)}{\varepsilon(\omega)}$$

Here the effective index of the MM defined as $n^2(\omega) = \frac{k_x^2+k^2}{(\omega/c)^2}$ has been introduced.

Please note, the assumption on the validity of the isotropy enters this framework of equation by assuming that the iso-frequency curve derived from the dispersion relation is a circle in the 2D case and the index will not depend explicitly on the tangential wave vector. Moreover, the functional dependency of k and ξ on k_x is also

intimately linked and it will cancel out for an isotropic MM, that is, it will provide always the same material parameter independent of the tangential wave vector component. Of course, this does not necessarily need to be valid and deviations can be taken as a clear signature that the MM does not act as an isotropic material.

Similar procedures exist for biaxial materials, though then the response of the matter at two tangential wave vector components needs to be considered to disclose some selected entries of the material tensors. Other illumination scenarios are then furthermore required (i.e., modifying k_y or the considered polarization) to disclose all entries. Also, retrieval procedures that reveal the entire tensors taking into account also electromagnetic coupling effects exist in literature [16]. More complicated constitutive relations cannot be considered in most cases and in the case of contradictions, that is, different material properties are revealed while considering waves with different tangential wave vector components, a description in terms of material properties is not suggested and instead considerations should be restricted to the wave parameters.

Amorphous Structures

Whereas in the approach discussed in the previous section it was assumed that the unit cells are periodically arranged and a discussion in terms of Bloch modes could be performed, MMs can be also fabricated using bottom-up technologies that rely on self-organization mechanisms, for example, based on colloidal nanochemistry. Then, control over the geometry of the individual unit cell might be possible but not over the way they arrange. Likely, the structures will be randomly or amorphously arranged. For MMs of such geometry various mixing rules have been established in the past that allow to assign effective properties while considering only the scattering properties of the individual unit cells and their volume filling fraction. Such approaches are discussed in this section. Since the importance of such bottom-up MMs is still less when compared to MMs fabricated with top-down technologies, this section is kept rather concise to reflect its weight.

Retrieving Properties of Individual Meta-atoms

The properties of individual meta-atoms that eventually form a bulk MM are best accessed by investigating the scattered field generated by these meta-atoms. This scattered field can be expanded into multipoles which can be written either in a Cartesian or a spherical base. The idea of such an expansion is best understood in analogy to a Fourier series, where an arbitrary wave field can be written as a superposition of plane waves. Here the fields are decomposed into terms that are not spatially delocalized as plane waves, but they are linked to a definite origin where the scattered field emanates from. Since the multipoles are orthonormal functions, the expansion is unique and characteristic for a certain meta-atom. An expansion in spherical coordinates is well established in other fields of photonics, that is, in Mie theory. There the field scattered by a sphere is decomposed into spherical harmonics [18]. The expansion of a field scattered from an arbitrary object using such spherical harmonics reads as

$$\mathbf{E}_{\mathrm{Sca}}(r,\theta,\varphi) = \sum_{n=1}^{\infty}\sum_{m=-n}^{n} k^2 E_{nm}[a_{nm}\mathbf{N}_{nm}(r,\theta,\varphi) + b_{nm}\mathbf{M}_{nm}(r,\theta,\varphi)]$$

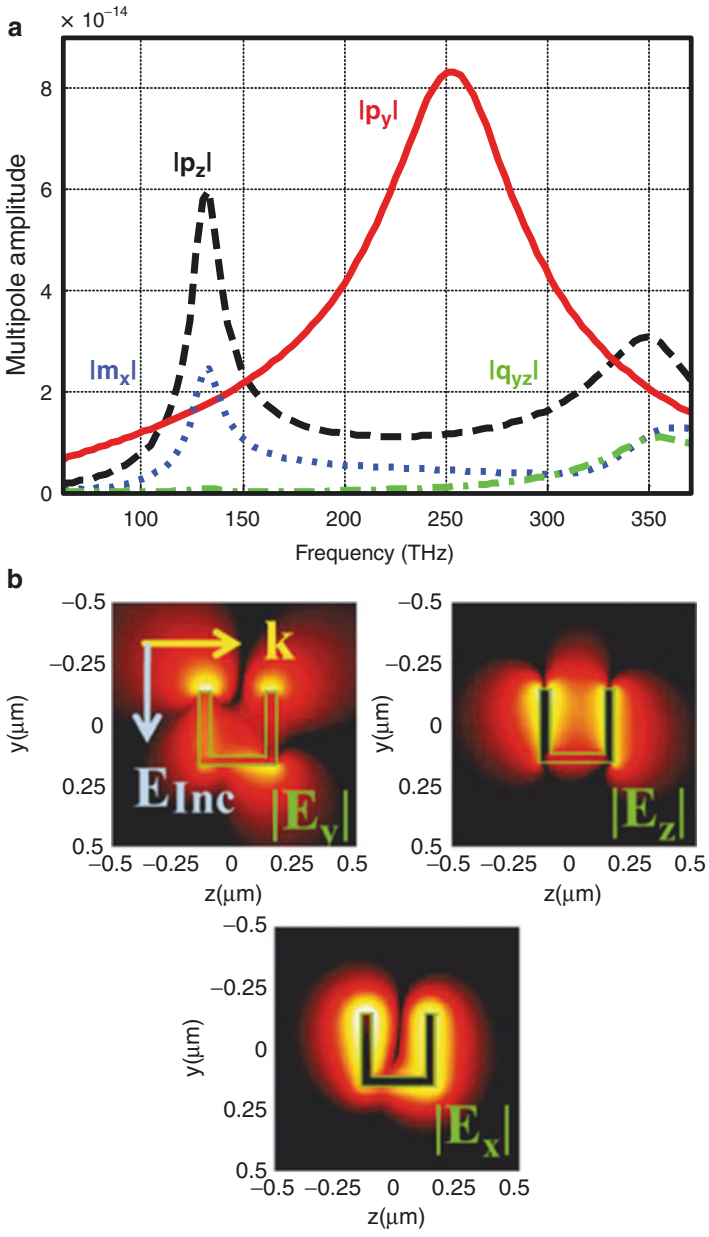
where k is the free space wave number of the surrounding medium, E_{nm} are some normalizing amplitudes, $\mathbf{N}_{nm}$ and $\mathbf{M}_{nm}$ are the vector spherical harmonics which are defined in literature, and a_{nm} and b_{nm} are the complex amplitudes at which they are excited to generate a particular scattered field. It has to be stressed that any scattered field can be expanded around a chosen origin in this way. Occasionally, the center of the coordinate system might be chosen inappropriate, leading to some ambiguity in the expansion. Therefore, the coordinate system should be appropriately chosen such that the smallest number of scattering coefficients attains nonzero values. In most practical cases this is either the geometrical center of the meta-atom or the center of gravity. Moreover, the vector spherical harmonics have a physical meaning. Roughly speaking, the vector spherical harmonics $\mathbf{N}_{nm}$ describe the scattered electric field in terms of contributions evoked by electric

multipole situated in the origin [19]. The first index n designates the respective Cartesian multipole. The electric field generated by their magnetic counterparts is associated to the coefficients $\mathbf{M}_{nm}$, respectively. Assembling the scattering properties of a single meta-atom is best performed by establishing the so-called *T*-matrix. The entries of this T-matrix suggest that illuminating the meta-atom with an incident field corresponding to a purely spherical harmonic of the order *n'm'* will generate scattered multipoles of all the orders with the index *nm* and their respective amplitude strengths are the entries of one column of the T-matrix.

The retrieval of the contributions to the scattered field generated by a given meta-atom is performed by computing its scattered field $\mathbf{E}(\mathbf{r}, \omega)$ with a rigorous method of choice (e.g., FDTD or FEM) upon illumination with a suitably chosen illumination and solving for the mode contents of the scattered field. Computing the overlap integral over a sphere at a certain radius a yields all coefficients of the multipole expansion

$$a_{nm} = \frac{\int_0^{2\pi}\int_0^{\pi} \mathbf{E}(r=a)\mathbf{N}^*_{nm}(r=a)\sin\theta d\theta d\varphi}{\int_0^{2\pi}\int_0^{\pi} \mathbf{N}_{nm}(r=a)\mathbf{N}^*_{nm}(r=a)\sin\theta d\theta d\varphi},$$

$$b_{nm} = \frac{\int_0^{2\pi}\int_0^{\pi} \mathbf{E}(r=a)\mathbf{M}^*_{nm}(r=a)\sin\theta d\theta d\varphi}{\int_0^{2\pi}\int_0^{\pi} \mathbf{M}_{nm}(r=a)\mathbf{M}^*_{nm}(r=a)\sin\theta d\theta d\varphi},$$



where the asterisks designate complex conjugated fields.

From these coefficients it can be seen whether the structure indeed causes a magnetic response, which likely will induce a resonance in the magnetic dipole coefficients linked to b_{1m}, or to an electric dipole coefficient linked to a_{1m}. It also allows revealing the possible contribution of higher order multipoles, the appearance of which prevents the assignment of effective material parameters. Nevertheless, with such an analysis all properties of interest can be evaluated.

An example where the scattered field of a split-ring resonator is expanded into multipoles at optical frequencies can be seen in Fig. 3. Since the symmetry of the split-ring resonator suggests the usage of a Cartesian coordinate system, the spherical multipoles are transferred into Cartesian ones. Only multipoles with significant nonzero amplitude are shown. It can be seen that the lowest order resonance is linked to a magnetic dipole oriented normal to the plane of the split-ring resonator and to an electric dipole oriented in this plane. The second order resonance is linked entirely to an electric dipole where currents oscillate in the two arms of the split-ring resonator in phase.

Mixing Rules

By assuming that the MM is finally composed of complex meta-atoms which generate upon the excitation by an external field secondary electric or magnetic dipole, effective properties can be assigned to such materials on the base of suitably chosen mixing rules [20]. Then, the meta-atoms attain the position of artificial polarizable entities and an averaging procedure can be applied, similar to the transition of microscopic to macroscopic Maxwell's equations, just with the only noticeable distinction that the transition is now made from mesoscopic to macroscopic Maxwell's equations where this mesoscopic system is now man-made. Many of such mixing rules exist and usually they have been developed for a particular MM geometry. For example, for MMs made of interleaved domains the Bruggemann formula was used; a MM made of a sequence of slabs requires for the introduction of an effective property either to take the geometrical mean of the intrinsic material properties (in the direction where the electric field is parallel to the slab, i.e., TE polarization) or the reciprocal of the geometrical mean of the reciprocal material properties (in the direction where the electric field is perpendicular to the slab, i.e., TM polarization). However, all these approaches represent approximations which have to be verified by suitable experiments. Thus, the application of

Theory of Optical Metamaterials, Fig. 3 (**a**) Amplitude of the dominant electromagnetic multipole contributions to the scattered field if a split ring is illuminated with a plane wave propagating in the plane of the split-ring resonator and the electric field is also polarized in the plane of the split-ring resonator, as shown in the *top* of (**b**). (**b**) Amplitude of the scattered electric field from an individual meta-atom in the y–z plane at 130 THz

particular mixing rules might be suitable but occasionally it might also be inappropriate. An exhaustive overview over such mixing rules can be found in the respective literature.

In the context of effective properties as discussed here where it is assumed that the MM is made of strongly scattering localized meta-atoms for which the scattered field can be expanded in terms of electromagnetic multipoles, the introduction of effective properties using the Clausius-Mossotti formula is most appropriate. In its simplest formulation it assumes that the MM consists of scattering entities characterized by both an electric and magnetic polarizability $\alpha_{E,M}$ which can be obtained by normalizing the electric and magnetic dipole moments to the dipole coefficients of the incident fields. By assuming that all meta-atoms are arranged in the same direction, the

T

Cartesian polarizabilities can be used to retrieve the particular entries of the respective material tensors which are valid by assuming the constitutive relations of an anisotropic crystal. If the surrounding medium is vacuum the effective parameters are given by

$$\varepsilon_{ii,\,\mathrm{Eff}}(\omega) = \frac{3 + 2V\alpha_{ii,\,\mathrm{E}}(\omega)}{3 - V_{\alpha ii,\,\mathrm{E}}(\omega)} \quad \text{and}$$
$$\mu_{ii,\,\mathrm{Eff}}(\omega) = \frac{3 + 2V\alpha_{ii,\,\mathrm{M}}(\omega)}{3 - V_{\alpha ii,\,\mathrm{M}}(\omega)}$$

Here V enters the equation as the volume filling fraction which is required to smaller, or even significantly smaller, than the percolation limit. For a completely statistical orientation of meta-atoms, an appropriate averaging procedure over the polarizability for all possible configurations has to be performed at first to extract the isotropic material properties emerging in this case. By this final step, effective material properties can eventually be assigned to a medium made from such strongly scattering entities.

However, the aspects last discussed here are not yet fully explored since the availability of suitable MMs made from strongly scattering elements is currently the subject of ongoing research. The approach discussed above has been extensively verified for MMs made from small metallic nanoparticles where all the assumptions imposed here are valid. But in any case the outlined procedure can be used to assign effective properties to such MM once sufficient information concerning their structure and scattering properties is available.

Conclusion

In conclusion, an introduction has been presented here that will facilitate the understanding of optical metamaterials. The entry is written from a perspective of a theoretician who may basically pursue two different aims. On the one hand he starts from a medium at hand that exhibits particular constitutive relations. Whereas for most optical materials available in nature, the complexity is limited by a dispersive tensorial permittivity, metamaterials may provide more complex relations which include dispersive tensorial permittivity and permeability as well as electromagnetic coupling. Then a genuine theoretical goal consists in the investigation of exciting implications for light propagation. Optics investigated under such assumption with the addition of a spatial dependent material is now frequently termed transformation optics and bears a great potential for innovative applications in optical systems.

On the other hand, at present it is feasible to fabricate almost arbitrarily nanostructured unit cells with an ever increasing complexity. The complex details tend to be important if light interacts resonantly with the unit cells, leading to unusual and extraordinary effects which allow for the control of light propagation in MMs formed from these unit cells. In this respect it is required that the transition from/to the environment and the propagation within the MM may be described by a simple set of wave parameters as the propagation vector and the impedance of the respective normal modes. Under certain conditions it might be possible to relate these parameters to effective material parameters the introduction of which facilitates appreciably the description of optical effect in MMs. In this case a very close connection to the first issue can be established. The complete understanding of the second issue is currently an important aim in theoretical optics.

The entry is actually devoted to shed some light on these issues and to provide a first guide of orientation to discuss them. Many more questions could likely be raised and many aspects necessarily had to be kept quite concise. Many details just mentioned can be found in the literature referred to here. The more detailed references that have been included hopefully will serve the valuable reader as a valuable source for further information beyond the basic ideas discussed in here.

Electrothermal actuators; Electrothermomechanical actuators; Heatuators; Thermomechanical actuators

Definition

Thermal actuators are mechanical systems that use the thermally induced expansion and contraction of materials as a mechanism for the creation of motion. These devices are compliant structures, using elastic deformation and mechanical constraints, that frequently are designed to amplify the motion generated by thermal expansion or contraction. Temperature changes that result in thermal actuation are most commonly provided by environmental changes or by Joule heating from electrical current flow. In the context of nanotechnology, thermal actuators refer to microscale and nanoscale devices used to mechanically interact with nanoscale structures, with motion generated by the thermally induced expansion and contraction of materials.

Key Principles, Concepts, and Phenomena

Thermal actuators are useful for applications where low voltage, small footprint, and high force output are desirable device characteristics.

In the context of microscale and nanoscale engineering, thermal actuators can be used as microelectromechanical systems (MEMS) capable of translating electrical signals into controllable displacements with resolution smaller than 1 μm. Displacement for thermal actuators can be designed as small as several nanometers [1]. For the discussions below, it should be noted that simple calculations discussed in this essay have been provided in order to enable quick initial evaluation of possible actuator designs. For more accurate understanding and operation of these actuators, multiphysics simulations and calculations, and experimental characterization of constructed devices are recommended.

Surface Contact and Connections in MEMS/NEMS Design

At size scales of hundreds of microns or smaller, contacting surfaces can have significant friction and stiction capable of inhibiting device motion. Stiction is the phenomenon where static surfaces contact each other, preventing motion and separation of the surfaces. Stiction may be caused by electrostatic and van der Waals forces. This can cause devices to pull into contact with underlying surfaces and substrates. In contact, these surfaces experience friction, the resistance of contacted surfaces to sliding motion, and can be strong enough to impede all motion. In pinned joints, contact surfaces are smaller, but friction can lead to significant wear, resulting in eventual failure of a device. For design of solid microscale and nanoscale actuators, contact surfaces are minimized to only those surfaces where contact is absolutely necessary for device function. For maximum reliability, actuators themselves are typically designed as suspended structures with clamped end conditions. The fabrication of pinned beam connections is typically imprecise using common microfabrication techniques. Additionally, they present regions subject to wear and friction which may decrease the reliability of actuator motion.

Compliant Structures

Compliant structures are arrangements of elastic bodies with constrained joints that generate or transmit motion. Because pinned joints are not optimal for microscale and most nanoscale thermal actuator designs, these designs employ elastic deformation to allow motion. As such, thermal actuators are a subset of compliant mechanisms used for the generation of motion. Compliant structures and compliant mechanisms are a significant area of study and are frequently used in conjunction with thermal actuators to achieve additional displacement amplification or other effects such as motion sensing, thermal management of moving parts, or motion stabilization [2–11]. Repeatable operation of the thermal actuator requires operation within the elastic limits of the actuator material. Excessive heating and mechanical strain can ultimately lead to failure of the thermal actuator mechanism. In particular, it is possible to "burn out" the thermal actuator due to excessive input power, which leads to creep, softening, and eventual melting of the actuator material.

Thermal Expansion

Thermal expansion and contraction of materials is the fundamental mechanism by which motion is generated in thermal actuators. Thermal expansion in solids originates from the nature of atomic or molecular bonding within solids. A rise in temperature increases the bond lengths between atoms or molecules in a solid due to increased energy of the populations of phonons and electrons within the solid.

Thermal expansion can be treated as a continuum behavior in classical solid mechanics. The local three-dimensional strain tensor ε_{ij} is given by Eq. 1 for isotropic materials, where E is the Young's Modulus, ν is the Poisson's ratio, α is the linear thermal expansion coefficient, σ_{ij} is the local stress tensor, σ_{kk} is the sum of the three normal stresses ($\sigma_{kk} = \sigma_{11} + \sigma_{22} + \sigma_{33}$), the term $(T - T_0)$ defines the temperature rise above a reference temperature T_0, and δ_{ij} is the Kronecker delta [12]. In quasi-steady-state behavior, the actuator establishes a thermal equilibrium with its environment, which develops a constant temperature profile throughout the actuator. The corresponding thermal strain distribution in the

actuator drives motion to a mechanical equilibrium.

$$\varepsilon_{ij} = \frac{1+v}{E}\sigma_{ij} - \frac{v}{E}\sigma_{kk}\delta_{ij} + \alpha(T - T_0)\delta_{ij} \quad (1)$$

Joule Heating and Power Dissipation

The flow of electricity through an electrically resistive material dissipates power according to Ohm's law. Microscopically, the local density of power dissipation $\dot{q}$ is given by the local resistivity ρ, current density $\vec{J}$, and electric field $\vec{E}$ according to Eq. 2.

$$\dot{q} = \vec{J} \cdot \vec{E} = \frac{1}{\rho}\left|\vec{E}\right|^2 = \rho\left|\vec{J}\right|^2 \quad (2)$$

Equation 2 is valid for DC currents and the instantaneous power dissipation from time-varying currents and electric fields. For average power dissipation from time-varying fields, the instantaneous power dissipation is averaged in time t', according to Eq. 3a, where t_0' may, for instance, be defined as the length of time for one period of oscillation. In practice, the result is Eq. 3b for harmonic, time-dependent electric fields and currents [13]. Note that although most thermal actuators rely on heating due to controlled electrical currents, other heating mechanisms exist such as absorbance of electromagnetic waves which may create similar thermal responses.

$$\dot{q}_{\text{ave}} = \frac{1}{t_0'}\int_0^{t_0'} \dot{q}dt' = \frac{1}{t_0'}\int_0^{t_0'} \frac{1}{\rho}\left|\vec{E}\right|^2 dt'$$

$$= \frac{1}{t_0'}\int_0^{t_0'} \rho\left|\vec{J}\right|^2 dt' \quad (3a)$$

$$\dot{q}_\omega = \frac{1}{2\rho}\left|\vec{E}\right|^2 = \frac{1}{2}\rho\left|\vec{J}\right|^2 \quad (3b)$$

Integrating the local power density $\dot{q}$ through the volume of the actuator gives the lumped form of Ohm's law, Eq. 4, where total power dissipation P is readily calculated from measurement of the current flow I, voltage drop V, and total electrical resistance R in the actuator.

$$P = IV = \frac{V^2}{R} = I^2R \quad (4)$$

Frequently the thermal actuator is constructed from materials whose resistivity changes with temperature and strain (i.e., due to piezoresistive effects), such as silicon. In this case, the local resistivity ρ cannot be assumed to be constant for all output displacements and levels of mechanical loading, nor can the total device resistance R. For this reason, power dissipation in thermal actuators should be derived from measurements of current and voltage without assuming a constant resistivity or resistance. Control based on current or voltage alone rather than total power dissipation should be validated experimentally before reliance on these simpler mechanisms to control the thermal actuator mechanical output.

Heat Transfer: Fundamental Concepts

The temperature rise in the actuator is determined by the heat generation and heat transfer throughout the thermal actuator. This behavior is governed by Eq. 5, the heat equation for stationary materials, and Eq. 6, the Fourier heat law [14]. The heat equation is properly written with the full time derivative, $\frac{DT}{Dt'} = \frac{\partial T}{\partial t'} + \vec{v} \cdot \nabla T$, where $\vec{v}$ is the local velocity and t' is time. From a macroscopic view there is no convective mass transport within the solid structures, therefore the velocity components $\vec{v}$ in the full derivative are reduced to zero, and the full derivative reduces to the partial time derivative.

Understanding of the temperature profile of the thermal actuator is developed by solving Eqs. 5 and 6 for the boundary conditions appropriate to specific thermal actuator designs. The local heat generation $\dot{q}$ was defined in Eq. 2 for Joule heating. The average temperature rise ($\Delta T = T - T_a$) in a beam element can be found using Eq. 7.

$$\eta c\frac{\partial T}{\partial t'} = k_\theta \nabla^2 T + \dot{q} \quad (5)$$

$$\vec{q} = -k_\theta \nabla T \quad (6)$$

T

$$\Delta T = \frac{1}{L_i}\int_0^{L_i} T dx' - T_a \tag{7}$$

T Temperature (K)
T_a Initial temperature (K)
ΔT Average temperature change (K)

Heat Transfer: Environment Effects on Actuation

By modifying the boundary conditions for heat transfer from the thermal actuator, the ambient environment surrounding a thermal actuator affects its output motion. Heat transfer mechanisms modify the temperature profile and corresponding thermal strain of the thermal actuator. In vacuum, heat transfer from the thermal actuator, for MEMS dimensions, occurs primarily through conduction through the actuator clamps. Radiative heat transfer is a secondary mechanism for heat loss from the thermal actuator, with energy transferred from the actuator to its substrate and surrounding environment. For initial design considerations, analysis of conductive heat transfer in the solid actuator material in vacuum allows estimation of the order of magnitude of actuator power requirements and temperatures, and is one step to understanding of the thermal behavior of the actuator.

In nonvacuum environments, heat transfer to a surrounding fluid can significantly alter the temperature profile of the thermal actuator. Because of the small dimensions of most thermal actuators, conduction usually dominates over convection in air, and published models generally only account for conduction through air [15–17]. Operation of thermal actuators in environments such as air may require significantly more power than used in a vacuum environment in order to obtain the same output displacement [15]. As an example, 1.4 mA applied to one design in vacuum may lead to the same temperature rise as 5.0 mA applied to the same device in air [15]. This result implies that more than 12 times the power consumption may be needed in air as in vacuum in order to achieve similar output from some thermal actuator designs.

A lower bound on the time constant for response of the thermal actuating system in vacuum can be found by considering a lumped model of the heat capacity and the thermal resistance. Equation 8 demonstrates applications of such a lumped model to a suspended beam with heat flow out the ends of the beam. The time constant τ_θ is calculated from the lumped heat capacity C and thermal resistance R_θ of the actuator beam that experiences the maximum current density. From this time constant calculation it may be expected that the thermal actuator will not move faster than a frequency of f_θ.

$$R_\theta = \frac{L_i}{k_\theta A_i} \tag{8a}$$

$$C = c\eta L_i A_i \tag{8b}$$

$$\tau_\theta = R_\theta C \tag{8c}$$

$$f_\theta = \frac{1}{2\pi\tau_\theta} = \frac{1}{2\pi R_\theta C} \tag{8d}$$

A_i Beam cross-section area (m^2)
f_θ Thermal bandwidth maximum frequency (Hz)
τ_θ Thermal time constant (s)
C Lumped heat capacity (J/K)
R_θ Lumped thermal resistance of a beam (K/W)

Statically Indeterminate Structures

The output motion of thermal actuators derives from statically indeterminate structures, typically beams, subjected to mechanical constraints. Design of these constraints can determine whether motion will occur in-plane or out-of-plane. A number of texts are available that further discuss the concepts of indeterminate structures [18]. Several detailed models have been developed for the output motion of constrained beams within thermal actuators [4, 19]. Some

of these analyses will be examined in the examples below.

Displacement Output and Force Output

Experimental measurement of an output displacement curve recorded versus input power, voltage, or current can provide a fit curve that allows prediction of the freely moving thermal actuator displacement d_0 without requiring detailed analysis of the thermomechanical system. When the thermal actuator is used to provide an output force, this force may be estimated using the spring constant k calculated for the beams of the thermal actuator. The output force F provides a perturbation δd to the free-moving displacement curve, giving actual displacement d. Force is estimated Eq. 9 according to Hooke's law applied to this perturbation from the free-moving displacement d_0 [5]. Simulations indicate that for some device mechanisms the output force may differ significantly from these predicted values in cases when displacement is constrained to nearly zero [20]. Experimental measurement of this effect and calibration of the output forces of thermal actuators remains an ongoing active area of research.

$$F = k\delta d = k\,(d_0 - d) \tag{9}$$

The spring constant k_i of many individual thermal actuator beams can be estimated Eq. 10 according to the solid mechanics of a beam with one end clamped and one end "guided" (prevented from rotation but allowed to displace in one direction), where L_i is the beam length and I_z is its moment of inertia. For beams with width w and thickness t, I_z is given by Eq. 11, and k_i is estimated with Eq. 12. The total spring constant is found Eq. 13 by multiplying the number of beams N by the spring constant k_i for each beam.

$$k_i = \frac{12EI_z}{L_i^3} \tag{10}$$

$$I_z = \frac{tw^3}{12} \tag{11}$$

$$k_i = \frac{Etw^3}{L_i^3} \tag{12}$$

$$k = Nk_i \tag{13}$$

Using k and the mass m calculated based on the density η and volume of the whole actuator assembly (e.g., $m = N\eta L_i wt$), a lower bound to the natural frequency f_0 can be found Eq. 14.

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \tag{14}$$

For operation in laboratory environments, it is important that the natural frequency not be too low, otherwise the actuator may be significantly perturbed by environmentally induced vibrations. A good rule of thumb is $f_0 > 20$ kHz, which implies attenuation of most sounds and other laboratory disturbances.

Applications

Thermal actuators are one of the key mechanisms for effecting motion in microscale and nanoscale solid structures. Other common microelectromechanical system (MEMS) mechanisms typically use electrostatic forces, hydrostatic forces, magnetic forces, or piezoactuation [16]. The advantages of thermal actuators over these other mechanisms lie in low operating voltage, high output force, and compact footprint. Disadvantages include comparatively high power consumption, comparatively slow response time, and dependence of actuation output on ambient environment.

Because thermal actuators dissipate heat, thermal management of the environment surrounding the actuator may be an important design consideration. The substrate supporting a thermal actuator can experience temperature changes due to heating from the actuator. In vacuum the substrate to which the actuator is anchored becomes the primary mechanism for dissipation of heat from the actuator. Material selection for the substrate should allow for temperature changes due to

heating and adequate thermal engineering to prevent overheating. Furthermore, placement of temperature-sensitive materials near the actuator should be carefully planned.

Thermal actuators also face high temperature and low temperature limits to operation. At high temperatures, material creep and failure may occur. At low temperatures such as cryogenic environments, heating of the environment due to the actuator may disrupt the environment. Furthermore, some materials such as semiconductors may be insufficiently conductive to allow much current flow. Other materials such as many metals may develop superconductivity at cryogenic temperatures, which leads to insufficient power dissipation to create significant temperature changes for thermal expansion and actuation.

In the examples discussed below, the V-type actuator design has an advantage over the hot-arm, U-type design in that all beams contribute to actuation motion in the V-type design. In the U-type design, motion is generated by the hot arms but resisted by the cold arms. As a result, a V-type design requires a smaller footprint to achieve the same output as a given U-type design. Furthermore, the inherently linear motion output of the V-type designs makes them easier to incorporate in device designs.

History

The hot-arm, U-type actuators were originally demonstrated in the early 1990s and quickly became a staple for generation of mechanical motion in solid MEMS structures. In the late 1990s, V-type actuators were initially demonstrated, and this design has been subject to much further development in the subsequent years. In particular, V-type actuators have been explored for driving compliant mechanisms, microgripper devices, and micropositioning devices. Bimorph thermal actuators (Example 3 below) have been in use for submillimeter-scale applications since the late 1980s. Extensive review of the history of microfabricated thermal actuators may be found in Ref. [16].

By the early 2000s, the fundamental approaches to thermal actuators, discussed below as examples, had become well-established actuation mechanisms. Designs have advanced at a fundamental level in approaches to thermal management and the application of computational tools in optimization of designs [7, 8, 21].

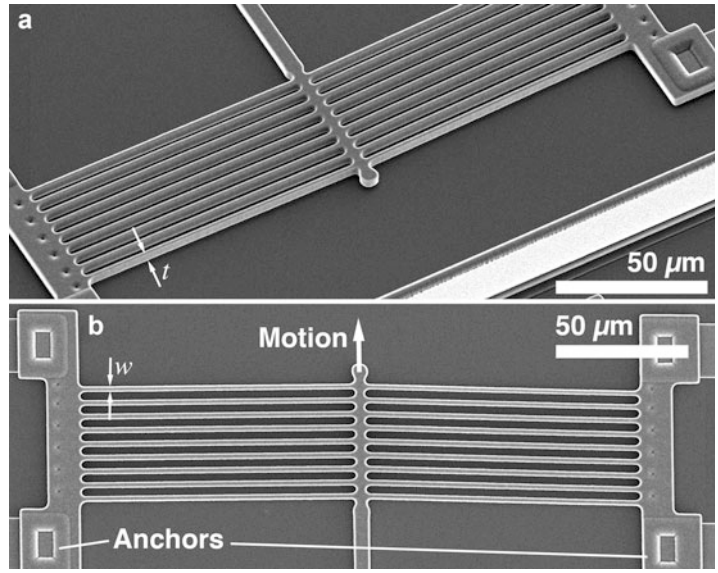
Applications for thermal actuators have been demonstrated in many areas. These include microscale and nanoscale tensile testing; microhandling, nanopositioning, and nanomanipulation; optical and electrical switching, and micromirror positioning; microrobot locomotion; and additional compliant designs [4, 5, 9–11, 16, 20, 22–28]. Thermal actuators were seen in many reports as the drivers of mechanical motion in many geared and pivoting MEMS systems, particularly in the time period of 1994–2002. Such systems are fundamentally limited by frictional wear, and consequently they have not been the subject of much development in more recent years. Newer applications focus more on structures for manipulating and interacting with objects at the microscale and nanoscale.

In the 2010s, the implementation of new materials in microfabrication processing resulted in a diversification of thermal actuators into many material systems. These include the following: conducting polymers and polymer composites; graphene, carbon nanotubes, and other fullerenes; nanocrystalline diamond; Al-W bimetallic systems; and Ni metal [29–33]. Furthermore, the availability of an expanded range of materials in fabrication has enabled both the computational optimization of thermal actuators based on composite materials and a new approach to thermal actuation [34–36]. In this new approach, material membranes are subjected to constraints on biaxial strain and therefore move in an out-of-plane direction as the constituent materials expand upon heating. One demonstration used conducting membranes that heated themselves [35]. A second demonstration used high thermal expansion polymers supported on microfabricated heaters [36].

Examples

In application, three main mechanisms have been implemented as the most common thermal actuators: V-type, hot arm/U-type, and bimorph thermal

Thermal Actuators, Table 1 Some material properties of PolyMUMPS polycrystalline silicon, approximated as an isotropic material [4, 5, 15, 38]



Property	Symbol	Value	Units

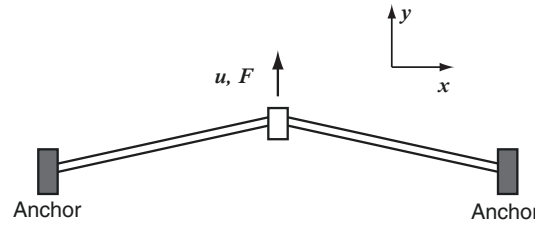
Constant value (at 293 K)	α	2.7×10^{-6}	K^{-1}
Temperature dependent	$\alpha = \left[3.725\left(1 - e^{-5.88\times10^{-3}(T-125)}\right) + 5.548 \times 10^{-4}T\right] \times 10^{-6}$		K^{-1}

actuators. Calculations are provided with these examples in order to walk through the basic design of common thermal actuators. These calculations are intended to help the designer to understand the range of actuator performance and the effect of device geometry on the output behavior. Final design should use multiphysics simulations and experimental characterization of fabricated devices in order to understand the real performance of any particular design.

In order to facilitate design calculations, Table 1 provides some published values on the properties of polycrystalline silicon (or "polysilicon"), a common material for thermal actuators. Because it is a semiconductor, polycrystalline silicon has electrical resistivity that varies with dopant concentration, temperature, and applied strain. The values reported in this table for resistivity and other properties reflect the range of values that have been used in research literature as inputs to simulations of polysilicon layers generated by the PolyMUMPS foundry service (MEMSCAP Inc., NC, USA). In general, many of the properties of polycrystalline silicon are process dependent and can vary widely [37]. Therefore, designs should ultimately be based upon measurements of the properties of material created according to a specific, defined process, and validation of device models against measured experimental output.

Example 1: V-Type Actuators

The first common thermal actuator mechanism has been called, variously, V-type, chevron, bent-beam, or symmetric thermal actuators. In this mechanism (Fig. 1), suspended, opposing beams are connected to a suspended shuttle structure. The ends of the actuator beams are anchored to a substrate that provides electrical current through the beams. Power dissipation leads to expansion of the beams, which experience a buckling motion. When the beams are placed symmetrically, linear motion is achieved in the shuttle. Engineering of the beams guides the buckling motion that they experience. The aspect ratio of the beam is defined asymmetrically in order to confine beam bending motion to one plane, typically chosen as motion in the plane of fabrication. If the beam has a cross section with thickness t, defined by the thickness of the film used for



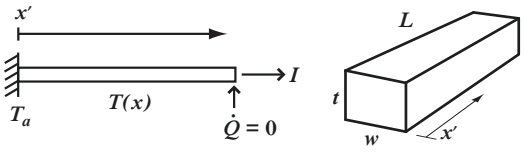
Thermal Actuators, Fig. 1 Examples of V-type "chevron" thermal actuators. (**a**) Tilted, oblique view in scanning electron microscope (*SEM*) image. (**b**) SEM image of the top view of a fabricated V-type thermal actuator. Beams are angled 1° off of perpendicular to the direction of motion of the central shuttle (Image credit: J.J. Brown and V.M. Bright)

fabrication of the beam, and a width w, defined by patterning perpendicular to the film, in-plane motion is achieved when $t > w$. In this case, the beam has a moment of inertia that is smaller for in-plane motion than for out-of-plane motion, so in-plane motion is more probable as buckling is induced. Another technique used to guide the buckling is to angle the beams at their attachment point to the shuttle. Typically the beams are angled a few degrees off of perpendicular to the shuttle, and the device is built with mirror symmetry across the shuttle in order to cancel bending moments that would cause deviations from uniaxial motion. With elongation of the actuator beams, buckling and shuttle motion is achieved in a predictable direction. The choice of angle is made dependent on whether displacement or output force is more important. Smaller angles from perpendicular provide more output displacement for a given actuator power; larger angles provide more output force.

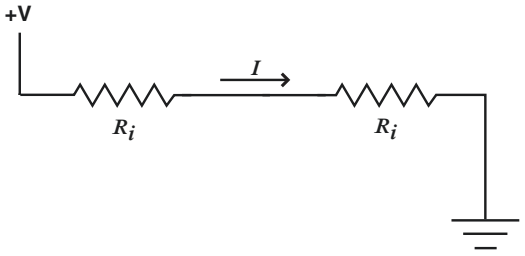
Electrical Calculation

The goals of electrical calculations associated with thermal actuator design are the following:

1. Find the total resistance R of the actuator system in order to allow design of an appropriate power supply.



Thermal Actuators, Fig. 2 Fundamental unit of the V-type actuator, a pair of angled beams. Motion u and output force F occur in direction y. A loading force F may oppose motion in the y direction

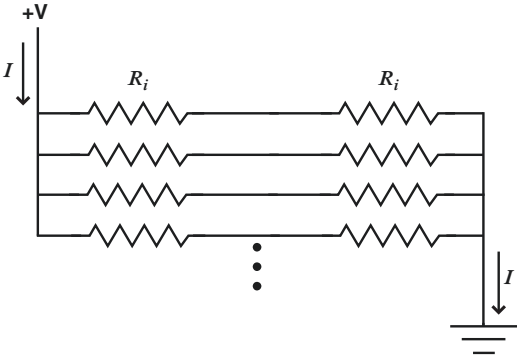


2. Understand how R relates to the actuator geometry.
3. Allow the use of I^2R to determine the total power generation and by extension the thermal power that must be managed by the anchors and other structures supporting the thermal actuator.

Regarding the third goal, the packaging environment surrounding the actuator must be able to remove the steady-state power generated by the actuator in order to establish stable operation.

The fundamental unit of a V-type thermal actuator is a symmetric beam pair as seen in Fig. 2. For simplicity of this example calculation, power consumption in the central shuttle will be omitted from the calculations. Because the actuator is

Thermal Actuators, Fig. 3 Basic geometry of one of the V-type actuator beams, for electrical and thermal calculations. The distance coordinate along the length of the angled beam is defined by x'



Thermal Actuators, Fig. 4 Electrical circuit for the pair of beams in the thermal actuator. Resistance in the central shuttle is omitted for simplicity

formed from symmetric beams, the calculation only necessitates examination of the power consumption in one beam. The geometry of the beam is defined as in Fig. 3. The beam has an electrical resistivity ρ, which is a temperature-dependent property. For the purposes of this initial calculation, ρ will be held constant, and the material of the beam will be defined as polycrystalline silicon, using the property values defined in Table 1. The beam resistance is calculated according to Eq. 15, using example dimensions for one beam: $L_i = 100\ \mu m$, $t_i = 3.5\ \mu m$, $w_i = 2\ \mu m$, $A_i = w_i t_i = 7\ \mu m^2$.

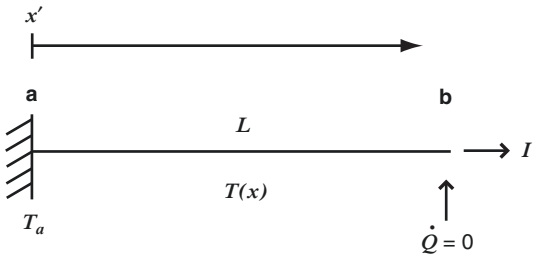
$$R_i = \frac{\rho L_i}{A_i} \tag{15a}$$

$$R_i = \frac{\left(34 \times 10^{-6}\ \Omega m\right)(100\ \mu m)}{(7\ \mu m^2)} = 490\ \Omega \tag{15b}$$

In Fig. 4, the electrical model of the pair of beams in the actuator indicates connection in series, so the resistance of the pair $R_p = 2R_i$. For an actuator built from N_p beam pairs, the beam pair resistance

Thermal Actuators, Fig. 5 Electrical circuit diagram for an assembly of beam pairs such as that seen in Fig. 1. The resistances of each beam pair add in parallel. The central shuttle makes electrical connections in the center of this diagram, but it is omitted from the diagram because there is assumed to be an identical voltage drop in each beam. Therefore, there should be no current flow from one beam pair to another through the central shuttle

adds in parallel, and the total resistance R of the actuator may be found according to Eq. 16. For $N_p = 10$ and the result from Eq. 15b, $R = 98\ \Omega$ (Fig. 5).



$$R = \frac{R_p}{N_p} = \frac{2R_i}{N_p} \tag{16}$$

Thermal Calculation

The goals of thermal calculations for the V-type actuator are the following:

1. Find an average temperature rise ΔT at a given input current in order to estimate the thermal strain in subsequent mechanical calculations.
2. Find maximum temperature as a function of input current, in order to understand the performance limits to the actuator.
3. Find boundaries on the thermal time constant in order to understand the limit to the actuator response time.

The calculation of the temperature profile in the thermal actuator can focus on the profile within a single beam, similar to the electrical calculation. As discussed earlier, for initial design purposes, it is necessary only to examine thermal conduction. Other heat transfer effects should be

Thermal Actuators, Fig. 6 One-dimensional model of the symmetric thermal system for the V-type actuator

considered for a complete understanding of the actuator thermal behavior. Simulations based on the coupled, temperature-dependent electrical, thermal, and mechanical behavior show that V-type thermal actuators may develop nonlinear output force behavior when subjected to displacement constraints [20]. However, for basic understanding, conductive heat transfer generally suffices. As with the electrical calculation, thermal conductivity k_θ and specific heat capacity c are temperature dependent, but for initial design they are considered to be constant.

The calculation can approximate the beam as a one-dimensional element with a temperature varying along position x. The boundary conditions are defined in two locations: the anchored end maintains a constant temperature due to significant heat transfer from the anchor to the supporting substrate. The suspended end of the beam has no heat flow, due to the symmetry of the suspended structure. Consider the diagram in Fig. 3, where T_a is the temperature at point **a**, the beam has a temperature profile that varies along the beam with position x', heat leaves the beam only through point **a**, and a total current I flows through the beam. This diagram can be simplified into a one-dimensional model (Fig. 6) with the following boundary conditions, where $\dot{Q}$ is one-dimensional heat flow with units of watts (W):

$$T(0) = T_a \, \dot{Q}(L_i) = 0$$

In this case, all variables in the thermal model are considered constant across the beam cross section at any given x' position. Using Eq. 17 to set up the one-dimensional model and assuming steady-state operation, the heat equation Eq. 5 can be rewritten as Eqs. 18a and 18b, given for cases without and with air conduction, respectively. In Eq. 18a, constant thermal conductivity is also assumed. For the model with conduction through air to a nearby substrate, S is a shape factor, z_g is the distance between the suspended device and the substrate, $k_{\theta,\text{air}}$ is the thermal conductivity of air, and Z is a thermal insulation term defined by the layers through which heat flows (with thickness z_i, thermal conductivity $k_{\theta,I}$, and total number p) from the suspended beam to a substrate held at a constant temperature [15–17, 38].

$$k_\theta A_i \frac{\partial T}{\partial x'} = -\dot{Q} \tag{17a}$$

$$\frac{\partial \dot{Q}}{\partial x'} = \dot{q} A_i \tag{17b}$$

$$\dot{q} = \rho \left| \vec{J} \right|^2 = \rho \frac{I^2}{A_i^2} \tag{17c}$$

$$S = \frac{t}{w}\left(\frac{2z_g}{t} + 1\right) + 1 \tag{17d}$$

$$Z = \sum_{j=1}^{p} \frac{z_i}{k_{\theta,\,i}} = \frac{z_g}{k_{\theta,\,\text{air}}} \tag{17e}$$

$$0 = k_\theta A_i \frac{\partial^2 T}{\partial x'^2} + \dot{q} A_i = k_\theta A_i \frac{\partial^2 T}{\partial x'^2} + \rho \frac{I^2}{A_i} \tag{18a}$$

$$0 = \frac{\partial}{\partial x'}\left(k_\theta \frac{\partial T}{\partial x'}\right) + \rho \frac{I^2}{A_i^2} - \frac{S(T - T_a)}{tZ} \tag{18b}$$

The temperature profile in the beam in vacuum, Eq. 19, is found by integrating Eq. 18a twice and applying the boundary conditions to determine the constants of integration. A more precise analytical solution to Eq. 18a may be found when k_θ and ρ are allowed to vary with temperature. Reference [17] provides a solution for Eq. 18b for constant k_θ and temperature-dependent ρ. Elimination of air conduction terms in that solution provides a solution for Eq. 18a with temperature-dependent ρ.

The maximum temperature T_{max} is found at the location where the first derivative of temperature is zero, which is where heat flow $\dot{Q}$ is zero. In this case, heat flow is zero at $x' = L_i$, and T_{max} is given by Eq. 20. The average temperature rise in the beam can be calculated by the application of Eq. 19 to Eq. 7, yielding Eq. 21.

$$T = T_a + \rho \frac{I^2}{A_i^2 k_\theta} \left(L_i x' - \frac{x'^2}{2} \right) \tag{19}$$

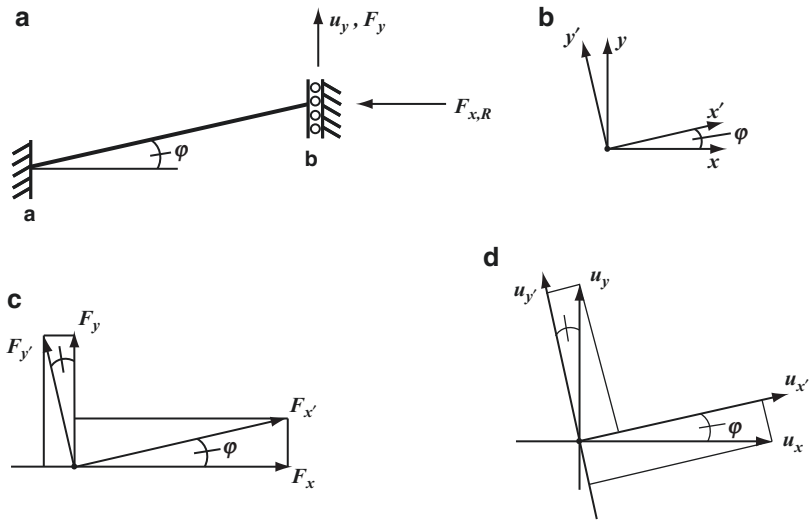
$$T_{max} = T_a + \rho \frac{I^2 L_i^2}{2A_i^2 k_\theta} \tag{20}$$

$$\Delta T = \frac{\rho I^2 L_i^2}{3A_i^2 k_\theta} \tag{21}$$

For an upper bound on the thermal time constant, the lumped thermal resistance R_θ can be calculated using the beam length L_i and assuming that the substrate is an infinitely large thermal reservoir that can adequately remove the generated thermal power P from the actuator without undergoing significant changes in temperature, thereby maintaining T_a at the beam anchor point. Equations 22a and 22b show the resulting time constant and the minimum bandwidth for operation in vacuum, derived from Eq. 8, polysilicon properties from Table 1, and example dimensions for one beam: $L_i = 100$ μm, $t_i = 3.5$ μm, $w_i = 2$ μm, $A_i = w_i t_i = 7$ μm^2. In air, the overall thermal resistance is reduced, thereby decreasing τ_θ and increasing the bandwidth.

$$\begin{aligned} \tau_\theta = R_\theta C &= \left(\frac{L_i}{k_\theta A_i} \right) (c\eta L_i A_i) = \frac{c\eta L_i^2}{k_\theta} \\ &= \frac{(705)(2330)\left(10^{-4}\right)^2}{30} \\ &= 5.5 \times 10^{-4} \text{s} \end{aligned} \tag{22a}$$

$$f_\theta = \frac{1}{2\pi\tau_\theta} = 290 \text{ Hz} \tag{22b}$$



Analysis of Mechanical Behavior

For basic design of a thermal actuator, modeling of the mechanical behavior can help the designer to understand the maximum force and range of displacements that are available from a given actuator design. Mechanical analysis can be performed with the following goals:

1. Find an expression for the maximum force output available from the actuator
2. Find an expression for the maximum displacement from the actuator
3. Develop an understanding of how device geometry impacts the force and displacement

Several contrasting mechanical analyses of V-type actuators have been published [3, 4, 6, 19]. The analysis presented here follows that of Ref. [4]. As with the electrical and thermal analyses, the symmetric device geometry allows simplification of the mechanical analysis to an examination of only one beam. Begin by simplifying the actuator design in Fig. 2 to the free body diagram seen in Fig. 7a, and consider the coordinate system presented in Fig. 7b. At point **a**, the beam is anchored and restricted from displacement or rotation. At point **b**, the end of the beam is restricted from rotation or motion in the x direction, but it can move in the y direction. A reaction force $F_{x,R}$ opposes motion in the x direction. Figure 7b depicts two Cartesian coordinate systems. The xy system rests in the frame of the substrate and actuator support. The actuator output motion u_y is defined in the y direction of the xy coordinate system. The rotated $x'y'$ coordinate system is a local system oriented to the reference frame of the angled actuator beam. Consequentially, the $x'y'$ system is rotated an angle φ from the xy system.

An external force F_i may be applied to point **b** in the y direction, affecting the u_y displacement. In the reference frame of the beam, motion at point **b** can be decomposed to motion $u_{x'}$ in the x' direction and motion $u_{y'}$ in the y' direction (Fig. 7d). Motion in the x' direction is pure elongation, described by Eq. 23a to include thermal strain. Motion in the y' direction is pure bending, described by Eq. 23b for the case where rotation at the beam ends is not allowed.

Thermal Actuators, Fig. 7 Diagrams for mechanical analysis of V-type actuators. (**a**) Free body diagram. (**b**) Coordinate systems for output motion in *xy* and motion in the reference frame of the beam $x'y'$. (**c**) Bending and extensional forces in the beam can be projected into forces in the *xy* coordinate system. (**d**) Motion in the *xy* coordinates is projected into motion in the $x'y'$ coordinates

$$F_{x'} = EA\left(\frac{u_{x'}}{L} - \alpha\Delta T\right) = \frac{EA}{L}u_{x'} - \alpha\Delta TEA \tag{23a}$$

$$F_{y'} = \frac{12EI_z}{L^3}u_{y'} \tag{23b}$$

The forces $F_{x'}$ and $F_{y'}$ can be projected (Fig. 7c) to forces in x and y according to Eq. 24 for elongation and Eq. 25 for bending.

$$F_{x,e} = F_{x'}\cos\varphi \tag{24a}$$

$$F_{y,e} = F_{x'}\sin\varphi \tag{24b}$$

$$F_{x,b} = -F_{y'}\sin\varphi \tag{25a}$$

$$F_{y,b} = F_{y'}\cos\varphi \tag{25b}$$

Summing the F_x forces and F_y forces yields Eq. 26.

$$-F_{x,R} + F_{x,b} + F_{x,e} = -F_{x,R} - F_{y'}\sin\varphi + F_{x'}\cos\varphi = 0 \tag{26a}$$

$$-F_{x,R} - \sin\varphi\frac{12EI_z}{L^3}u_{y'} + \left(\frac{EA}{L}u_{x'} - \alpha\Delta TEA\right)\cos\varphi = 0 \tag{26b}$$

$$F_i + F_{y,b} + F_{y,e} = F_i + F_{y'}\cos\varphi + F_{x'}\sin\varphi = 0 \tag{26c}$$

$$F_i + \cos\varphi\frac{12EI_z}{L^3}u_{y'} + \left(\frac{EA}{L}u_{x'} - \alpha\Delta TEA\right)\sin\varphi = 0 \tag{26d}$$

The displacements $u_{x'}$ and $u_{y'}$ can be written in terms of u_x and u_y by projecting u_x and u_y onto the rotated coordinate system (Fig. 7d).

$$u_{x'} = u_y\sin\varphi - u_x\cos\varphi \tag{27a}$$

$$u_{y'} = u_y\cos\varphi - u_x\sin\varphi \tag{27b}$$

However, $u_x = 0$ at point **b**, so Eq. 27 simplifies to Eq. 28.

$$u_{x'} = u_y\sin\varphi \tag{28a}$$

$$u_{y'} = u_y\cos\varphi \tag{28b}$$

With substitution of Eq. 28 into Eq. 26d and some algebraic manipulation, a very useful final expression Eq. 29 can be derived that relates the average actuator temperature rise ΔT, the actuator output displacement u_y, and the force F_i that may be produced by the actuator and which may constrain the displacement. Substitution of Eq. 28 into

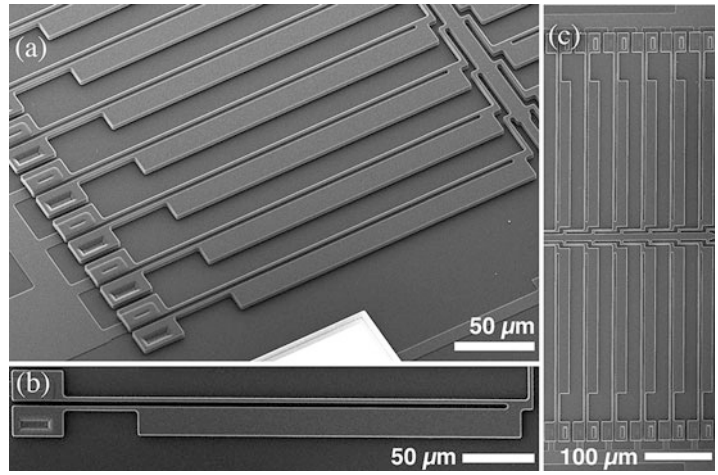
Eq. 26b would yield an expression for the x direction reaction force, if desired. Reference [4] appeared to show reasonable agreement between this model and measured unconstrained experimental displacement output. However, an exploration of force and displacement behavior performed in Ref. [20] demonstrated that V-type actuators undergo asymmetric buckling which complicates the relationship between force and displacement at different power or temperature levels. Therefore, Eq. 29 may be useful for basic design, but it underrepresents the interaction between F_i and u_y when u_y is constrained near zero or when large force is applied.

$$u_y = \frac{\alpha \Delta T E A \sin\varphi}{\left(\frac{EA}{L}\sin^2\varphi + \frac{12EI_z}{L^3}\cos^2\varphi\right)} + \frac{-F_i}{\left(\frac{EA}{L}\sin^2\varphi + \frac{12EI_z}{L^3}\cos^2\varphi\right)} \tag{29}$$

If the force constraint F_i is left at zero, Eq. 29 reduces to an expression for the free-moving actuator displacement. If instead the displacement u_y is constrained to zero, the magnitude of the maximum force generated by the beam Eq. 30 is seen to be the result of plane strain in the beams. A detailed thermomechanical derivation of stresses due to plane strain and thermal expansion applied to Eq. 1 may be found in Ref. [12]. The result is that, under the normal strain condition $\varepsilon_{33} = 0$ and no external traction or internal body forces, no stresses are present except for the compressive normal stress $\sigma_{33} = -\alpha E \Delta T$.

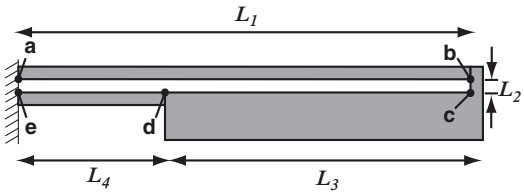
$$F_{i,max} = \alpha \Delta T E A \sin\varphi \tag{30}$$

If the thermal strain $\alpha\Delta T$ is held to zero, then a spring constant k_i for the beam Eq. 31 can be determined using Hooke's Law. This spring constant reduces to Eq. 10 in the small-angle approximation where $\varphi \to 0$. For actuators that contain N angled beams, the total spring constant k can be found according to Eq. 13 by multiplying k_i by N, and the maximum output force from the actuator would be found by multiplying Eq. 30 by N.



$$k_i = \frac{-F_i}{u_y} = \frac{EA}{L}\sin^2\varphi + \frac{12EI_z}{L^3}\cos^2\varphi \tag{31}$$

A final comment about the mechanical analysis of V-type actuators is that it may sometimes be necessary to include a temperature-dependent coefficient of thermal expansion in the average thermal strain calculated as an input to Eq. 29. Because the mechanical analysis presented here only concerns motion at the end of the actuator beam, the thermal strain can be determined as an average over the length of the beam using a modified version of Eq. 7, as shown here in Eq. 32.



$$\overline{\alpha \Delta T} = \frac{1}{L}\int_0^L \alpha(T - T_a)dx' \tag{32}$$

Example 2: Hot-Arm Actuators

The second common thermal actuation mechanism may be referred to by any of the following names: pseudobimorph, U-type, asymmetric, hot-arm, or flexure electrothermal actuators. In these structures (Fig. 8), two parallel beams are provided. These beams are fixed to a substrate at one end and linked to each other at the opposite end. The beams are designed to experience differential thermal expansion such that one beam expands further than the other beam. These actuators can be designed for motion out of a plane of manufacture, but they are more commonly seen for motion within planes. For in-plane motion with one common design, a "hot arm" and a "cold arm" are defined. The cold arm typically consists of a narrow flexure near the attachment point of the arm, and a wider distal portion. The hot arm is a narrow beam of uniform cross section. Electric current flows through this structure. In the wide portion of the cold arm, the current density and thermal resistance are lower than in the other portions of this actuator due to a larger cross-section area. This region is thus subject to less temperature change and less thermal expansion than the other regions. With the flow of electric current, the cold arm elongates less than the hot arm. Because the two arms are constrained to move together, the two arms sweep an arc of motion due to the difference in thermal expansion

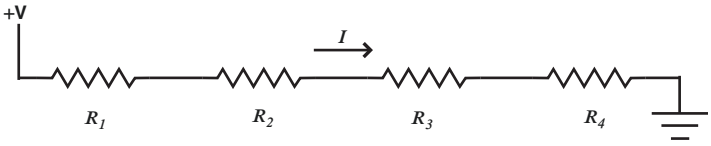
Thermal Actuators, Fig. 8 SEM images of U-type "hot arm" thermal actuators. (**a**) Tilted, oblique view of an actuator array. (**b**) Magnified view of one of the actuators in this array. The actuator is anchored at *left,* and greatest motion occurs in the parts at *right*. (**c**) *Top* view of an array of fabricated U-type thermal actuators (Image credit: J.J. Brown and V.M. Bright)

Thermal Actuators, Fig. 9 Schematic of one hot-arm actuator

between them. By symmetrically placing these U-type actuators around a central shuttle or yoke, and linking them to the shuttle with compliant structures, linear motion can be generated.

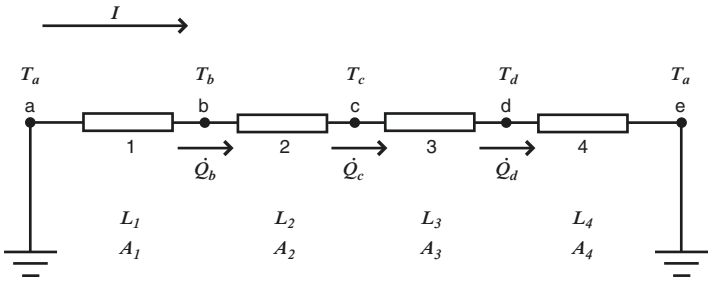
Electrical Analysis

Electrical and thermal analysis of these actuators can be performed by dividing the actuator into four segments, as seen in Fig. 9. Ignoring small discrepancies at the boundaries to the segments, the actuator can be converted into a one-dimensional model similar to that of Example 1 but constructed from a series connection of the four distinct segments, as seen in the electrical circuit diagram, Fig. 10.



The total electrical resistance can be calculated, Eq. 33, by summing in series the electrical resistance for each segment and assuming constant resistivity. The resistance for each segment can be found according to Eq. 15a. In most cases, the thickness will be identical for all segments due to fabrication from a surface-micromachined material layer, so the thickness term can be moved outside of the summation along with the resistivity. For a polycrystalline silicon device with typical dimensions of $L_1 = 100$ μm, $L_2 = 5$ μm, $L_3 = 80$ μm, $L_4 = 20$ μm, $w_1 = w_4 = 2$ μm, $w_2 = 5$ μm, $w_3 = 20$ μm, and $t = 3.5$ μm, and with $\rho = 34 \times 10^{-6}$ Ωm, the total resistance R is 632 Ω.

$$R = \sum_{i=1}^{n} R_i = \sum_{i=1}^{n} \frac{\rho L_i}{A_i} = \rho \sum_{i=1}^{n} \frac{L_i}{w_i t_i} \tag{33}$$



Thermal Analysis

The thermal analysis of the hot-arm actuator can proceed similarly to the electrical analysis, dividing the actuator into four segments according to the schematic in Fig. 11. The four segments are coupled together with temperature T_i and heat flow $\dot{Q}_i$ in each segment i, and with temperature and heat flow boundary conditions described in Table 2. The mechanical anchor points are maintained at constant temperature T_a. Uniform current flow I and constant electrical resistivity are assumed through the actuator.

Solution of Eq. 18a following a similar approach as in Example 1 leads to equations for temperature and heat flow in each segment, given by Eq. 34, with constants C_{1i} and C_{2i} determined for each ith segment by algebraic manipulation of the boundary conditions. The constants are

Thermal Actuators, Fig. 10 Simplified electrical schematic for a hot-arm actuator

Thermal Actuators, Table 2 Boundary conditions for the hot-arm actuator thermal model

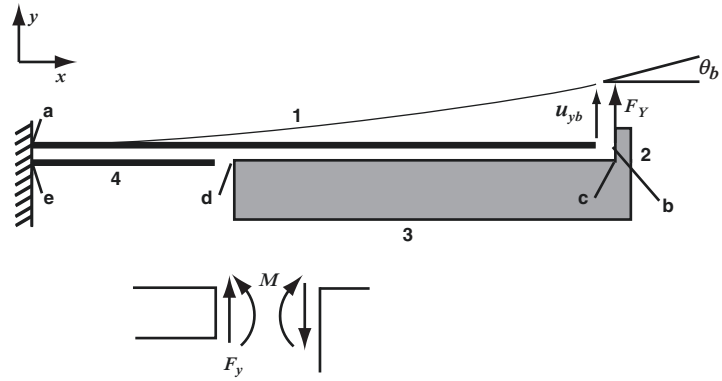
Temperature boundary conditions	Heat flow boundary conditions
$T_1(0) = T_a$ $T_1(L_1) = T_b = T_2(0)$ $T_2(L_2) = T_c = T_3(0)$ $T_3(L_3) = T_d = T_4(0)$ $T_4(0) = T_a$	$\dot{Q}_1(L_1) = \dot{Q}_2(0)$ $\dot{Q}_2(L_2) = \dot{Q}_3(0)$ $\dot{Q}_3(L_3) = \dot{Q}_4(0)$

reported in Table 3. This analysis is similar to the approach of Ref. [17], with the difference that Ref. [16] also examines heat transfer to air in solving the heat equation for the hot-arm actuator.

$$T_i = -\frac{\rho I^2}{A_i^2 k_\theta}\frac{x_i^2}{2} + C_{1i}x_i + C_{2i} \tag{34a}$$

$$\dot{Q}_i = -k_\theta A_i \frac{\partial T}{\partial x_i} = -k_\theta A_i C_{1i} + \frac{\rho I^2}{A_i} x_i \tag{34b}$$

The maximum temperature $T_{\max}$ and its location $x_{\max}$ in the hot arm segment 1 can be found by setting the first derivative of temperature equal to zero. The first derivative of the temperature is proportional to the heat flow, given in Eq. 34b using C_{11}. The resulting temperature and position are given in Eqs. 35 and 36, respectively.



$$T_{\max} = T_1(x_{\max}) = T_a + \frac{I^2\rho}{2k_\theta}\frac{x_{\max}^2}{A_1^2} = T_a + \frac{I^2\rho}{2k_\theta}\left(\frac{1}{4}\right)\left(\frac{L_1}{A_1} + \frac{L_2}{A_2} + \frac{L_3}{A_3} + \frac{L_4}{A_4}\right)^2 \tag{35}$$

$$x_{\max} = \frac{A_1}{2}\left(\frac{L_1}{A_1} + \frac{L_2}{A_2} + \frac{L_3}{A_3} + \frac{L_4}{A_4}\right) \tag{36}$$

The average temperature rise ΔT and the thermal time constant can be calculated as described earlier, subject to the discretion of the designer in choosing the complexity of the system to be represented. One option is to focus solely on the hot arm because this is the segment that experiences the highest temperatures and the most significant thermal strain. In the hot arm the thermal behavior is most important for the actuator operation. In this case, the thermal capacitance C is calculated using the volume of the hot arm $V_m = L_1A_1$. The thermal resistance can be calculated using the location $x_{\max}$ of maximum temperature or the total length L_1 of the hot arm and the hot arm cross-section area A_1. For the average temperature rise ΔT, the average is taken over the length L_1 of the hot arm only, giving Eq. 37.

Thermal Actuators, Table 3 Algebraic constants for Eq. 34 in each segment of the hot-arm actuator

C_{1i}	C_{2i}
$C_{11} = \frac{I^2\rho}{2k_\theta A_1}\left(\frac{L_1}{A_1}+\frac{L_2}{A_2}+\frac{L_3}{A_3}+\frac{L_4}{A_4}\right)$	$C_{21} = T_a$
$C_{12} = \frac{I^2\rho}{2k_\theta A_2}\left(-\frac{L_1}{A_1}+\frac{L_2}{A_2}+\frac{L_3}{A_3}+\frac{L_4}{A_4}\right)$	$C_{22} = T_a + \frac{I^2\rho}{2k_\theta}\left(\frac{L_1}{A_1}\right)\left(\frac{L_2}{A_2}+\frac{L_3}{A_3}+\frac{L_4}{A_4}\right)$
$C_{13} = \frac{I^2\rho}{2k_\theta A_3}\left(-\frac{L_1}{A_1}-\frac{L_2}{A_2}+\frac{L_3}{A_3}+\frac{L_4}{A_4}\right)$	$C_{22} = T_a + \frac{I^2\rho}{2k_\theta}\left(\frac{L_1}{A_1}+\frac{L_2}{A_2}\right)\left(\frac{L_3}{A_3}+\frac{L_4}{A_4}\right)$
$C_{14} = \frac{I^2\rho}{2k_\theta A_4}\left(-\frac{L_1}{A_1}-\frac{L_2}{A_2}-\frac{L_3}{A_3}+\frac{L_4}{A_4}\right)$	$C_{24} = T_a + \frac{I^2\rho}{2k_\theta}\left(\frac{L_1}{A_1}+\frac{L_2}{A_2}+\frac{L_3}{A_3}\right)\left(\frac{L_4}{A_4}\right)$

Thermal Actuators, Fig. 12 Diagram for mechanical analysis of the hot-arm actuator. The lower part of this diagram illustrates the matching of moments and forces at points *b* and *d* where the rigid frame is cut from the two cantilevers

$$\Delta T = \frac{1}{L_1}\int_0^{L_1} T_1 dx - T_a = \frac{I^2\rho}{4k_\theta}\left(\frac{L_1}{A_1}\right)\left(\frac{L_1}{3A_1}+\frac{L_2}{A_2}+\frac{L_3}{A_3}+\frac{L_4}{A_4}\right) \quad (37)$$

Analysis of Mechanical Behavior

Few mechanical analyses of hot-arm actuators have been published. The results of analyses based on energy methods may be found in Refs. [17, 19]. The analysis presented here uses a more straightforward technique based on superposition. Begin by dividing the device depicted in Fig. 9 into three sections: two cantilevers and one rigid frame. As seen in Fig. 12, section 1 becomes a cantilever with clamped attachment at left and applied force F_{1y} and moment M_1 at right. Similarly, section 4 becomes a cantilever with shorter length and with clamped attachment at left and applied force F_{4y} and moment M_4 at right. Sections 2 and 3 become an L-shaped rigid frame that links the two cantilevers together with moment and force reactions at the joining surfaces. Additionally, an external force F_Y is applied at point **b** of this L-frame, and the frame also experiences a bending moment M due to thermal stresses in the cantilevers. In order to maintain simplicity in calculating the coupled bending behavior of the cantilevers for this example, this thermal bending moment is calculated separately rather than combining the axial deformation behavior of the cantilevers with the rotation of the rigid frame and the bending of the cantilevers.

To calculate M from the thermal strain in cantilever 1, use the sum of forces in the x direction, the sum of moments at point **c**, and Hooke's law applied to elongation of the two cantilevers in order to generate Eq. 38. For simplicity, thermal strain is assumed only to be present in cantilever 1. Algebraic manipulation leads to an expression for the displacement of the rigid frame, Eq. 39a, and an expression, Eq. 39b, for the thermal bending moment that drives operation of the hot-arm actuator.

$$F_{xb} + F_{xd} = 0 \quad (38a)$$

$$M - F_{xb}L_2 = 0 \quad (38b)$$

$$F_{xb} = k_1 e_1 = \frac{A_1 E}{L_1}(u_x - \alpha \Delta T L_1) \tag{38c}$$

$$F_{xd} = k_4 e_4 = \frac{A_4 E u_x}{L_4} \tag{38d}$$

$$u_x = \frac{\alpha \Delta T A_1}{\left(\frac{A_1}{L_1} + \frac{A_4}{L_4}\right)} \tag{39a}$$

$$M = \frac{-\alpha \Delta T A_1 L_2 E}{\left(1 + \frac{A_1 L_4}{A_4 L_1}\right)} \tag{39b}$$

In order to calculate the actuator motion, begin by examining the rigid frame and recording a set of force and moment equilibrium equations and compatibility equations that describe the relationship between the rotation and displacements of the cantilever ends Eq. 40. Note that the small-angle approximation is used to simplify Eq. 40d to the relation in Eq. 40e.

$$F_Y - F_{1y} - F_{4y} = 0 \tag{40a}$$

$$-M_4 - M_1 + M + L_3(F_Y - F_1) = 0 \tag{40b}$$

$$\theta_b = \theta_d = \theta \tag{40c}$$

$$u_{yd} + L_3 \sin\theta = u_{yb} \tag{40d}$$

$$u_{yd} = u_{yb} - L_3 \theta \tag{40e}$$

The bending of cantilevers is a well-characterized problem, and nodal equations may be written that relate the force and moment applied to the free end of the cantilever to the displacement and rotation that are present at that end [18]. For the cantilevers of sections 1 and 4 of the hot-arm actuator, these nodal equations are provided in Eq. 41.

$$F_{1y} = \frac{EI_1}{L_1^3}\left(12u_{yb} - 6L_1\theta\right) \tag{41a}$$

$$M_1 = \frac{EI_1}{L_1^3}\left(-6L_1 u_{yb} + 4L_1^2\theta\right) \tag{41b}$$

$$F_{4y} = \frac{EI_4}{L_4^3}\left(12u_{yd} - 6L_4\theta\right) \tag{41c}$$

$$M_4 = \frac{EI_4}{L_4^3}\left(-6L_4 u_{yd} + 4L_4^2\theta\right) \tag{41d}$$

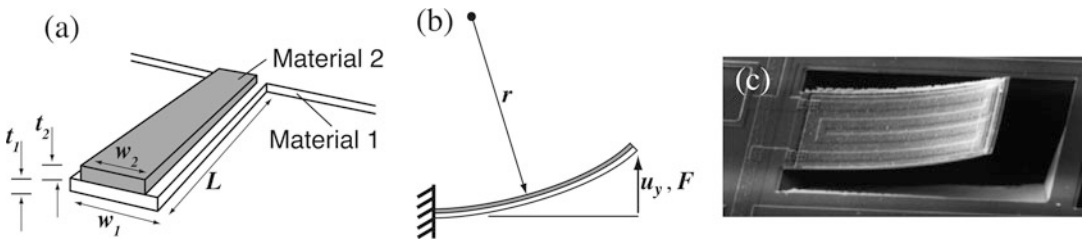
By combining Eqs. 40 and 41, expressions may be derived that relate the force and moment applied in the rigid frame to the displacement and rotation experienced by the end of the actuator. These relations, Eq. 42, may be further manipulated to provide an expression for the actuator displacement as a function of applied force and applied moment, Eq. 43. Using the equation for M found in Eq. 39b, the expression in Eq. 43 relates input temperature and output force and displacement for the hot-arm actuator. Similar to Eq. 29 in Example 1, Eq. 43 may be further manipulated to find a spring constant for the actuator and a maximum output force.

$$\frac{F_Y}{E} = 12u_{yb}\left(\frac{I_1}{L_1^3} + \frac{I_4}{L_4^3}\right) - 6\theta\left(\frac{I_1}{L_1^2} + \frac{2L_3 I_4}{L_4^3} + \frac{I_4}{L_4^2}\right) \tag{42a}$$

$$\frac{M}{E} = -6u_{yb}\left(\frac{I_1}{L_1^2} + \frac{2L_3 I_4}{L_4^3} + \frac{I_4}{L_4^2}\right) + 2\theta\left[2\left(\frac{I_1}{L_1} + \frac{I_4}{L_4}\right) + 6I_4\left(\frac{L_3}{L_4^2} + \frac{L_3^2}{L_4^3}\right)\right] \tag{42b}$$

$$u_{yb} = \frac{\frac{M}{2E}\left(\frac{I_1}{L_1^2} + \frac{I_4}{L_4^2} + \frac{2L_3 I_4}{L_4^3}\right) + \frac{F_Y}{6E}\left[2\left(\frac{I_1}{L_1} + \frac{I_4}{L_4}\right) + 6I_4\left(\frac{L_3}{L_4^2} + \frac{L_3^2}{L_4^3}\right)\right]}{\left(\frac{I_1}{L_1^2} + \frac{I_4}{L_4^2}\right)^2 + \frac{4I_1 I_4}{L_1 L_4}\left(\frac{1}{L_1} - \frac{1}{L_4}\right)^2 + \frac{12L_3 I_1 I_4}{L_1^2 L_4^2}\left(\frac{1}{L_1} - \frac{1}{L_4} + \frac{L_3}{L_1 L_4}\right)} \tag{43}$$

Experimental verification of this or related hot-arm actuator models has not been clearly performed, as most hot-arm actuator experiments have recorded data in air environments, which require different thermal analysis from that performed in this example. In Ref. [17], experimental displacement measurements appear to correspond fairly well with a curve predicted from input current but with ΔT calculated to include the effects of heat loss to air. A final point about this mechanical analysis of hot- and cold-arm actuators is that variations of these actuators exist, but similar analytic approaches can apply to these variations. For instance, if L_3 is set equal to zero, then Eq. 43 describes the motion of a two-arm actuator that has no wide region but does have different length cantilevers and different temperature profiles in each cantilever due to the length difference [39]. The out-of-plane pseudobimorph actuator could be analyzed similarly [16].



Example 3: Thermal Bimorph Actuators

The bimorph thermal actuator predates the designs explored in the previous two examples. The principle of operation of this device is the generation of bending due to a differential in thermal expansion between two materials stacked together to form the actuator. The bimorph actuator is typically constructed as shown in Fig. 13, as a cantilevered beam composed of two (bimorph) or more (multimorph) dissimilar materials and with a resistive heater patterned on top of the beam or formed from one of the beam materials. Advantages of bimorph structures are high force, simple design, and low operating voltage. The major disadvantages of these structures are relatively high electrical power consumption, curling motion, low operating frequency, and laminated construction. Many examples of implementation of bimorph thermal actuators including more discussion of simulation and analytical models may be found in Ref. [16].

Power consumption and average temperature rise can be calculated by applying concepts from Example 1. Others have extensively described the mechanical behavior of bimorph thermal actuators [16, 19, 40]. This example will review the relevant mechanical concepts and results. According to Fig. 13, assume the lengths of the two layers in the actuator are identical to length L. Using the small-angle approximation, deflection due to uniform curvature in the cantilever is given by Eq. 44, where r is a radius of curvature in the cantilever that is generated due to the thermal expansion mismatch of the two materials. Superimposed on this displacement is the deflection due to force applied at the end of a cantilever, Eq. 45, where $\overline{EI}_i$ is the average flexural rigidity of the composite cantilever. Together, these give a total displacement described by Eq. 46, analogous to Eqs. 29 and 43 presented earlier.

$$u_{y1} = \frac{L^2}{2r} \tag{44}$$

$$u_{y2} = \frac{FL^3}{3\overline{EI}_i} \tag{45}$$

Thermal Actuators, Fig. 13 Illustration of bimorph thermal actuators. (**a**) Bimorph cantilever consisting of two materials with identical length but different thicknesses, widths, and composition. (**b**) Diagram of radius of curvature r and cantilever tip displacement u_y used in analysis of the output motion of the bimorph actuator. (**c**) SEM image of a bimorph actuator ~300 μm length, with a heater trace patterned on its *top* surface (Image credit: B. Read and V.M. Bright, Air Force Institute of Technology, 1994)

$$u_y = \frac{L^2}{2r} + \frac{FL^3}{3\overline{EI_i}} \tag{46}$$

The radius of curvature r is determined Eq. 47 using force and moment equilibrium in the composite beam and strain compatibility at the bonded surface between the two materials [19, 40]. The combined flexural rigidity $\overline{EI_i}$ is found for the nonhomogeneous beam according to Eq. 48 after the moments I_1 and I_2 are first calculated for the different layers in relation to the neutral surface of the beam [18, 19]. The result is Eq. 49. In Ref. [40], Eqs. 47 and 44 are derived and shown to lead to agreement with previously reported experimental data. Equations 45, 46, and 49 are derived through continuum solid mechanics analysis [18].

$$r = \frac{\left(E_1 w_1 t_1^2\right)^2 + \left(E_2 w_2 t_2^2\right)^2 + 2E_1 w_1 t_1 E_2 w_2 t_2 \left(2t_1^2 + 3t_1 t_2 + 2t_2^2\right)}{6E_1 w_1 t_1 E_2 w_2 t_2 (\alpha_1 - \alpha_2)\Delta T} \tag{47}$$

$$\overline{EI_i} = E_1 I_1 + E_2 I_2 \tag{48}$$

$$\overline{EI_i} = \frac{\left(E_1 w_1 t_1^2\right)^2 + \left(E_2 w_2 t_2^2\right)^2 + 2E_1 w_1 t_1 E_2 w_2 t_2 \left(2t_1^2 + 3t_1 t_2 + 2t_2^2\right)}{12(E_1 w_1 t_1 + E_2 w_2 t_2)} \tag{49}$$

Future Directions

Materials Development, Optimization, and Miniaturization

Recent years have seen large advancement in materials technologies and computational tools, and it is likely that these advances will continue to impact thermal actuator systems for a significant amount of time. The principles described above are valid for any mechanical system with materials that experience thermal expansion; therefore, thermal actuators provide a pathway to immediate device fabrication using newly demonstrated materials. Furthermore, the phenomena of electrical power dissipation, heat flow, and thermal expansion are valid concepts at submicron size scales. Continued miniaturization may require consideration of additional phenomena such as the effects of dimensional constraints on the motion of phonons and electrons, increased importance of surface forces with smaller sizes, and the Thomson effect in systems where electrical current is flowing [41]. It may be expected that thermal actuator designs will be demonstrated in submicron sizes as fabrication technology improves. Ultimately, thermal actuator designs formed from engineered macromolecular structures may be possible. As molecular-scale thermal actuators are developed, such devices may not be subject to the same friction conditions as current microscale technology, and thus pinned connections and sliding surfaces may be within the range of designs allowed at the nanoscale.

Environmental Robustness

As discussed earlier, the temperature profile of the thermal actuator, and the corresponding output displacement or force, can vary due to the environment in which the actuator is operated. In vacuum environments at ambient temperature, this may be a small effect, but operation in ambient air and gaseous environments can require significant modification to the actuator power. For reliable and predictable operation across a range of environments, improved control systems for thermal actuators are needed. Additionally, many possible studies of environment effects comparing experiment with simulations and analytical models remain to be explored for thermal actuators. These may, for instance, include effects of

vacuum, liquid, high temperature, high radiative heat transfer, low temperature, packaging design, and environmental transients.

Device Control and Sensor Integration

One approach to improved displacement control and robustness would be implementation of closed-loop control systems that rely on data from a displacement sensor integrated to the actuator. In practice, integration of accurate in-plane displacement sensors for actuator control presents a significant design and fabrication challenge. Capacitive sensors have been integrated to thermal actuators, but these sensors typically require a large footprint to achieve useful sensitivity at small displacements [4]. Operation of capacitive sensors must be driven by sophisticated electronics placed physically close to the sensor in order to avoid signal losses due to parasitic capacitance. Piezoresistive sensors require smaller device footprints than capacitive sensors but may be subject to distorted readings due to temperature variation resulting from heat dissipation from the thermal actuator. Furthermore, readings from piezoresistive sensors can be distorted by the electrical operation of the thermal actuator if the sensor is monolithically linked and thus electrically connected to the thermal actuator. Strategies for electrical isolation of piezoresistive sensors are needed. Optical sensors provide the most accurate options for displacement measurement, but they are not yet easily integrated with other chip scale devices for in-plane displacement measurements.

Application Development

As one of the key mechanisms for generating motion in microscale and nanoscale electromechanical systems (MEMS and NEMS), it may be expected that a major thrust of thermal actuator development will track the overall development and use of MEMS and NEMS. Thermal actuators are an important part of the toolkit available to microsystem designers. As new designs proliferate, it may be expected that a certain portion of these designs incorporate thermal actuators. As discussed earlier, current usages include optical and electrical switches, microgrippers, nanomanipulation structures, and tensile test devices. As these tools move into broader use, thermal actuators are likely to remain key components of these devices. Other key opportunities for new application development using thermal actuators include control of optical gratings, lock and security systems, and controlled motion in microscale positioning stages. Many MEMS and NEMS applications may yet be conceived requiring low actuation voltage, compact footprint, and high force output, and thermal actuators provide a useful design option for all such applications.

Force Output Measurement and Calibration

The use of thermal actuators in applications where force is applied to microscale and nanoscale objects raises the question "Exactly how much force is applied?" Answering this question requires calibration and measurement of the force applied with the actuator. No standardized, traceable approaches exist for microscale force calibration, and current best practices rely on measurement of the displacement of a well-characterized spring. Such an approach relies on the characterization of the spring, which itself is not a traceable, standardized practice for microscale and nanoscale devices. Furthermore, many analytical and finite element mechanical models have been presented in literature, but more experimental verification of these models is needed, as the observations of Ref. [20] show. As thermal actuators and other actuators are employed for generation of motion in microscale and nanoscale devices, further strategies are needed for understanding the magnitude of forces within these devices.

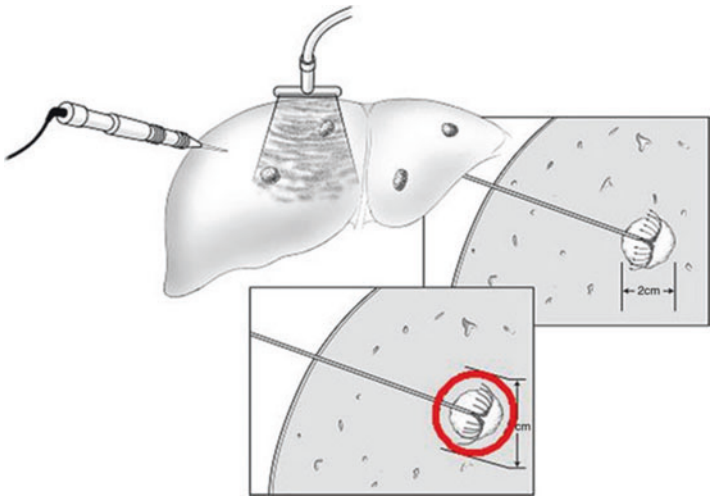
Heat; Magnetic electromagnetic radiation; Near infrared; Radiofrequency

Definition

Nanoparticle-sized materials have interesting physical, chemical, and electronic properties. Among these is the release of heat upon exposure to various types of electromagnetic radiation. For example, iron and other magnetic nanoparticles can be injected directly into malignant tumors and then release heat in response to frictional heating in an alternating magnetic field. The intrinsic plasmon resonance of gold has been utilized to produce near-infrared laser-induced thermal activation of gold nanoparticles to treat malignant lesions on the skin or mucosal surfaces. Finally, several types of conducting and semiconducting nanoparticles have been conjugated successfully to antibodies or peptides to target the nanoparticles to malignant tumor cells or to the tumor neovasculature. The malignant cells are then exposed to a noninvasive shortwave radiofrequency field which results in intracellular heating and thermal cytotoxicity to the malignant cells. Cancer cells generally are more sensitive to thermal injury compared to normal cells; thus, nanoparticle-based thermal tumor ablation has the potential to be an important and hopefully less toxic addition to current anticancer treatments.

Overview

Hyperthermic cancer therapy was first described in Egyptian papyri over 4000 years ago by applying hot oil or cautery to tumors. Modern hyperthermic treatments are now applied to both premalignant and malignant tumors in various locations such as the peritoneal cavity, liver, kidneys, lungs, and prostate. Hyperthermia also potentiates the effects of cytotoxic chemotherapeutic agents and improves the response of tumors to ionizing radiation. Thus, regional or systemic hyperthermia has been induced as part of a treatment regimen in patients with certain types of malignancies. Hyperthermic isolated limb perfusion with melphalan with or without dactinomycin is performed to treat in-transit melanoma metastases and is being investigated as a treatment for advanced extremity soft tissue sarcoma [1]. In the last several years,



there have been a growing number of reports on hyperthermic intraperitoneal chemotherapy combined with cytoreductive surgery for patients with diffuse peritoneal spread of colorectal cancer, gastric cancer, mesothelioma, or pseudomyxoma peritoneii [2].

Although effective at treating several cancer types, recent studies have shown that some mammalian cancer cells are sensitive, whereas others are significantly more resistant to hyperthermia compared to healthy cells [3]. The reasons for the variable sensitivity to hyperthermia in cancer are multifactorial, but are primarily due to the role of heat shock proteins (HSPs) in cancer's resistance to the physical stress of increasing temperature [3]. Mammalian cancer cells that are heat sensitive frequently have mutated or underexpressed HSPs, whereas deregulation in some malignant cells leads to increased expression of HSPs which confers increased thermal protection and reduces apoptosis following thermal stress.

Many hyperthermic devices have been designed to produce low-level total-body hyperthermia (42–46 °C) and have been used to treat a wide variety of advanced malignancies combined with systemic cytotoxic agents. Both regional and systemic hyperthermic treatment systems elevate tissue temperatures from 3 °C to 7 °C above normal over a 1–12-h period. Some populations of malignant cells are sensitive to relatively long durations of exposures to low-level hyperthermia, but results to date suggest that these regional and systemic hyperthermic treatments have produced little benefit in overall patient outcomes at the expense of major regional and systemic toxicities and side effects. Interestingly, exposure of mammalian cells to temperatures of 55–60 °C for periods of a few seconds to less than a minute has been shown to produce apoptosis and necrosis, so a treatment system that can achieve such brief periods of heating in cancer cells would be highly desirable.

Invasive Thermal Ablation Therapies

Thermal tumor ablation is routinely practiced, particularly for malignant liver tumors, through direct intratumoral insertion of radiofrequency (RF) needle electrodes, microwave-emitting probes, or end- and side-firing laser fibers [4]. RF ablation therapy is an invasive treatment that is implemented by inserting needle electrodes directly into the tumor(s) to be treated and applying RF current through the wire into the tumor, resulting in local tumor and adjacent tissue necrosis (Fig. 1). The basis for the observed heating phenomena is understood by the rotational response of the charged ions and proteins in the tissue under the RF field. This rapid molecular rotation results in local frictional heating of the aqueous environment of the tumor and death of

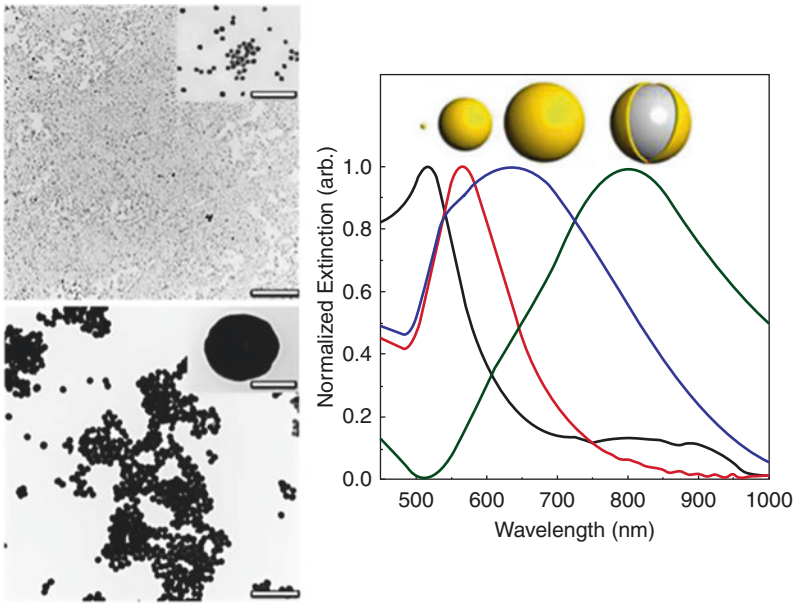
Thermal Cancer Ablation Therapies Using Nanoparticles, Fig. 1 Schematic illustration demonstrating invasive radiofrequency ablation of malignant liver tumors. A multiple array needle electrode is inserted directly into the tumor to be treated using ultrasound guidance to assure proper placement of the needle. An alternating current is then passed across the array resulting in frictional ionic heating in the tumor and tissue surrounding the array

tumor cells through protein denaturation, melting of lipid bilayers, and destruction of nuclear DNA.

Although invasive RFA has demonstrated efficacy in cancer therapy, there are several limitations to this approach. First, clinical studies have shown incomplete tumor destruction in 5–40 % of the treated lesions, allowing significant probability of local cancer recurrence and metastasis. Another limitation of RFA is that the treatment is not targeted (i.e., nonspecific). Placement and insertion of the needle electrode is usually guided by an imaging system with poor spatial resolution (e.g., ultrasonography ~ mm), and therefore, this method is dependent on the experience of the physician that implements RFA. Furthermore, RFA treatments result in significant complications in approximately 10 % of patients due to thermally induced necrosis of healthy noncancerous tissues. The final and the most problematic limiting factor with respect to wire-based RFA is that it is a clinical treatment that is indicated for just a few select organ sites and specific tumor types (e.g., liver, kidney, breast, lung). On the other hand, tissue penetration by noninvasive RF energy fields is known to be excellent. Theoretically, noninvasive RF treatment of malignant tumors at any site in the body should be possible if agents that preferentially respond to RF energy with intracellular release of heat can be delivered to the malignant cells.

Roles for Nanotechnology in Cancer Diagnosis and Therapy

Nanotechnology is a term used to describe the engineering of materials that utilize the unique physical properties of nanometer scale matter. Nanomaterials have been used across all the major scientific disciplines including chemistry, physics, and medicine. It is in the medical realm that nanotechnology is widely heralded as one of the most promising and important approaches to diagnose and treat cancer [5]. Some nanoscale materials are already FDA approved and are used clinically. For example, iron oxide nanoparticles (Feridex™) have been shown to enhance the diagnostic capability of magnetic resonance imaging (MRI) to detect cancer [6]. Conjugating iron nanoparticles to antibodies that target proteins expressed on the surface of human cancer cells may further enhance the accuracy of MRI to diagnose early stage cancer [6].



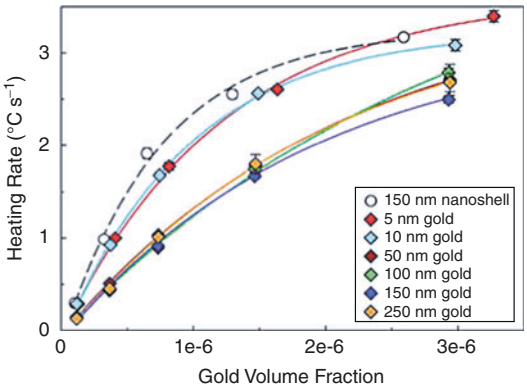
Other nanoparticles such as carbon or polymeric nanoparticles labeled with fluorine-18 deoxyglucose have been studied in preclinical models to enhance tumor diagnosis and detection rates using positron emission tomography. Surface modification of quantum dots, which are semiconducting nanocrystals that fluoresce upon absorption of visible light, is being investigated to improve detection of lymph nodes and other sites of metastases during surgical procedures [7]. Additionally, conjugation of quantum dots with tumor-specific peptides or antibodies may improve targeting of cancer cells and thus improve the diagnostic accuracy of this technique. Optimal imaging techniques using fluorescent nanoparticles targeted to a variety of types of human cancer with immunoconjugation to antibodies are being studied to permit in vivo localization of malignant cells. It is hoped that such imaging techniques will improve the diagnostic accuracy in numerous types of imaging modalities used to detect and follow patients with cancer. It is possible that these techniques may also allow earlier detection of cancer in high-risk populations and guide the duration and type of therapy in patients with more advanced stages of malignant disease. Finally, immunocomplexes consisting of gold nanoparticles and labeled antibodies have been demonstrated to improve the detection of several known serum tumor markers, including carcinoembryonic antigen, carcinoma antigen 125, and carbohydrate antigen 19–9, in a more rapid and accurate fashion than currently available techniques.

Nanoparticles are being used as intravascular carriers to enhance delivery of anticancer agents to malignant cells. Given that most anticancer drugs have a narrow therapeutic index with significant acute and cumulative toxicities in normal tissues, a variety of types of nanoparticles are being studied in preclinical and in vitro experiments to increase the delivery of cytotoxic chemotherapy drugs to cancer cells while reducing

toxicity by limiting exposure of the drug to normal tissues. For example, nanoparticles loaded with hydroxycamptothecin, 5-fluorouracil, docetaxel, and gemcitabine have been used in preclinical studies to improve chemotherapy-induced cytotoxicity in lung, colon, squamous, and pancreas cancers. Colloidal gold nanoparticles bearing tumor necrosis factor-α (TNF-α) molecules are being used in early phase human clinical trials to treat several types of cancer. Preclinical studies demonstrated that delivery of TNF-α to malignant tumors was enhanced using the nanoparticle delivery system, while avoiding the systemic toxicities that usually limit the clinical utility of this biologic agent. Nanoparticles conjugated with targeting agents are also being investigated to deliver gene therapy payloads to malignant cells. Carbon nanotubes have been used to deliver genes or proteins through nonspecific endocytosis in cancer cells. Similar to some cytotoxic chemotherapy drugs, gold or other metal nanoparticles have been shown to improve the therapeutic efficacy of external beam ionizing radiation in preclinical models. In addition to being used to deliver pharmaceutical agents, nanoparticles may be used as intrinsic chemotherapeutic agents. Gold nanoparticles 5–10 nm in diameter have been shown to have antiangiogenic properties in solid tumors and appear to induce apoptosis in chronic lymphocytic B cell leukemias through mechanisms not elucidated entirely.

Nanoparticle-Based Thermal Tumor Ablation Strategies

Recent studies have shown that nanoscale materials are capable of enhancing thermal deposition in cancer cells by absorbing optical energy. Gold-silica nanoshells 150 nm in diameter have a particular plasmon resonance in near-infrared (NIR) wavelengths (650–950 nm) of light and release significant heat when exposed to NIR laser sources (Fig. 2) [8]. In a murine colon carcinoma

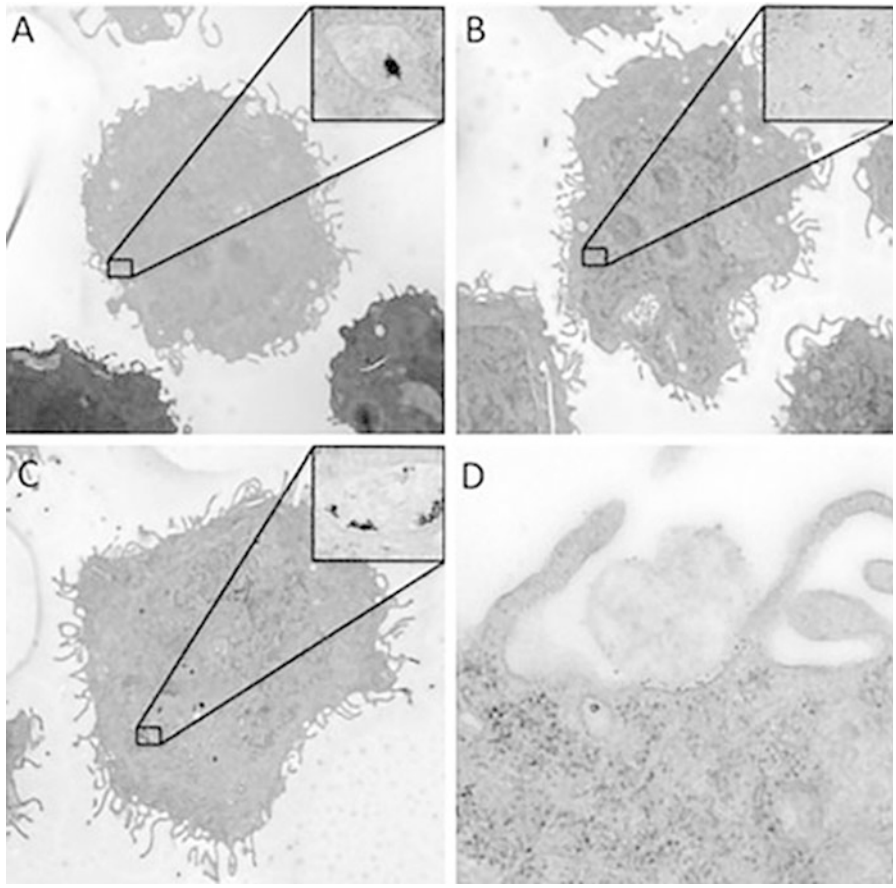


Thermal Cancer Ablation Therapies Using Nanoparticles, Fig. 2 *Left column* – Transmission electron micrographs of 10-nm diameter solid gold nanoparticles (*top*) and 150-nm diameter gold nanoshells (*bottom*). TEM images are ×20,000 magnification and ×500,000 (*inset*) magnification, and scale bars = 1000 nm (main) and 100 nm (*inset*). *Right column* – Diameter-dependent visible spectra of solid gold nanoparticles (*black* = 10 nm, *red* = 100 nm, *blue* = 150 nm) and the red-shifted gold nanoshell spectrum (*green* = 150 nm). Nanoparticle illustrations above each corresponding spectra are drawn to scale. Note, spectra have been normalized, and background subtracted to ease viewing of relative peak positions

subcutaneous tumor model, it was demonstrated that intravenous injection of polyethylene glycol-coded gold-silica nanoshells followed 6 h later by illumination of the tumor with a diode laser (8.0 nm, 4 W/cm^2, 3 min) led to complete destruction of the malignant tumors. Animals treated with laser treatment alone without prior intravenous injection of the nanoshells continued to grow at a rate similar to control animals who received neither nanoshell injection or laser treatment. The authors point out that this is a nontargeted delivery of the gold-silica nanoshells to tumors, and the size of the nanoparticles (130–150 nm) corresponds to the size of the enlarged pores and fenestrations in the neovasculature of tumors. The gold-silica nanoshells circulate and a significant number arrest in these pores, thus allowing thermal destruction of the vasculature of the tumor under laser irradiation. A subsequent study of prostate cancer cells using 110-nm gold nanoshells injected intravenously demonstrated that there was a nanoshell dose-related response. The tumors were again treated with a near-infrared laser at 4 W/cm^2 for 3 min. Tumors treated with laser therapy alone continued to grow at a rate similar to untreated control tumors, while tumors treated at the highest dose of gold nanoshells were over 93 % necrotic following a single laser treatment. A clinical trial using gold-silica nanoshell hyperthermia following NIR light exposure has been initiated for patients with oropharyngeal malignancies. Thermal therapy with NIR energy is limited to the treatment of superficial tumors (less than 1–2-cm deep) due to the significant attenuation of NIR light by biologic tissues.

Iron oxide nanoparticles are also being evaluated to produce alternating current magnetic field-based hyperthermia in tumors, but the limited thermal enhancement of these nanoparticles in a magnetic field requires extremely high concentrations of iron oxide [9]. Human breast carcinomas implanted into mice underwent intratumoral injection of colloidal suspensions of iron oxide particles 10–200 nm in diameter. Twenty minutes after the injection, the animals were exposed to an alternating current magnetic field (6.5kA/m; frequency, 400 kHz) for 4 min. Real-time temperature monitoring revealed that temperatures increased from 12 °C to 73 °C at various areas in the tumor. Subsequent analysis of the tumor showed some areas of coagulative necrosis, but other areas of viable tumor remained. Subsequent studies have attempted to address the issue of variable distribution of the superparamagnetic iron oxide nanoparticles through different regions of the tumor. Tumor cells near blood vessels are more difficult to treat with the magnetic nanoparticles because of the heat-sink phenomena of heat being carried away by blood flow in adjacent vessels coupled with the diffusion of nanoparticles in the tumor microenvironment into the blood vessels. One of the principle issues and limitations is that the iron oxide particles must be injected directly into the tumor. While this allows high concentrations of the magnetic nanoparticles for subsequent magnetic field thermal treatment, it is an invasive technique and allows for only treatment of tumors that can be identified through imaging techniques or during an operation. The magnetic particles can be used as imaging vehicles for tumors, but there are problems with diffusion of the nanoparticles out of the tumor and into the surrounding normal tissues. These high concentrations and the difficulty targeting the iron oxide nanoparticles to only cancer cells lead to destruction of normal (nonmalignant) cells surrounding the tumor, and diffusion of nanoparticles out of some areas of the tumor may cause insufficient heating to produce thermal cytotoxicity.

It was recently demonstrated that gold or carbon nanoparticles and a confined, noninvasive shortwave RF field produces significant local heat release that can be used to produce thermal cytotoxicity in cancer cells in vitro and in vivo with RF field treatments of 2 min or less [10, 11]. The heat release from gold nanoparticles exposed to shortwave RF fields is particularly impressive and is dependent on both the concentration and diameter of gold nanoparticles (Fig. 3). Solid gold nanoparticles smaller in diameter (5–10 nm) heated at a more rapid rate than gold nanoparticles 50–250 nm in diameter.



In addition, this method does not suffer the limitations of other nanoparticle-based

Thermal Cancer Ablation Therapies Using Nanoparticles, Fig. 3 At gold nanoparticle concentrations less than 10 ppm, the heating rate of deionized water in a 13.56 MHz RF field was almost 3 °C/s. This remarkable heating rate at very low concentrations of gold nanoparticles represents a heating efficiency of > 30,000 W/g of nanoparticles and indicates the generation of elevation temperatures in the nanoscale environment surrounding the gold nanoparticles sufficient to denature proteins, melt lipid bilayers, and produce irreparable damage to intracellular structures and organelles

hyperthermia systems given that shortwave radiofrequency (RF) energy has excellent deep tissue penetration, low tissue specific absorption rates (SAR), and documented safety for brief exposures of humans to this form of electromagnetic radiation [12]. Concerns have been expressed about possible mutagenic alterations in cells exposed to nonionizing electromagnetic radiation in the GHz range. However, studies of shortwave RF from 10 to 100 MHz has not been associated with any cytogenetic or cytotoxic damage [13]. Exposure of volunteer test subjects to prolonged periods of shortwave RF irradiation can produce minimal thermoregulatory effects (vasodilation, sweating) but has not been found to cause any acute or long-term damage to normal cells and tissues. Thus, the finding that charged gold nanoparticles release heat in response to shortwave RF exposure for durations of seconds to a few minutes has important implications. The physical mechanism of this phenomenon is being investigated, and data suggests that conductive polarizations of metal nanoparticles may explain the high thermal efficiency and tremendous heat release at low concentrations of nanoparticles exposed to the RF field. Importantly, since tissue penetration by shortwave RF fields is excellent with low attenuation of the signal, it should be possible to treat tumors at almost any site in the body. The crucial component of this treatment will be successful delivery of adequate numbers of gold nanoparticles to cancer cells to produce intracellular temperatures of at least 55 °C following an RF field exposure of no more than a few minutes duration, while ideally limiting uptake of the nanoparticles by normal cells.

It has shown that by directly conjugating 5-nm gold nanoparticles to cetuximab to target epidermal growth factor receptors (EGFRs) expressed on cancer cells, there is enhanced uptake of the gold nanoparticles (Fig. 4). In contrast, cells expressing little or no EGFR should have no enhanced uptake of cetuximab-conjugated gold nanoparticles and, thus, should not be significantly affected by treatment in the RF field. Targeting gold nanoparticles approximately 5–10 nm in diameter to cancer cells to create RF-induced hyperthermic cytotoxicity has several advantages: gold nanoparticles are simple and inexpensive to synthesize; they are easily characterized due to the presence of a characteristic surface plasmon resonance band; their surface chemistry permits manipulation of charge and shape relatively easily; attaching cancer cell targeting molecules, including antibodies, peptides, or pharmacologic agents, is easily achieved; and they are biocompatible and not associated with any acute or chronic toxicities in preclinical studies [14]. In addition to producing significant heat upon exposure to shortwave RF fields, 5–10-nm gold charged nanoparticles easily penetrate through pores and fenestrations in the neovasculature of solid tumors. This method may be promising for focused local or regional application of a noninvasive RF field to treat primary or established metastatic malignant tumors overexpressing EGFR, but would be problematic for whole-body RF therapy to treat diffuse micrometastatic disease. Constitutive expression of EGFR at normal levels occurs throughout many tissues in the body, and the results in SN12PM6 renal cancer cells (low-level expression of EGFR) show that even with low levels of EGFR

Thermal Cancer Ablation Therapies Using Nanoparticles, Fig. 4 (**a**) Transmission electron microscope (*TEM*) image of Panc-1 human pancreatic adenocarcinoma cells (×7500 magnification) that were incubated for 30 min with unconjugated, nontargeted 5-nm gold nanoparticles (control group). Almost no gold nanoparticles are seen within the cytoplasm of the cell, and it is only at a magnification of ×100,000 (*inset upper right*) that an intracytoplasmic vesicle containing a small number of gold nanoparticles is seen. Incubation of Panc-1 cells for 60 or 120 min with the unconjugated gold nanoparticles also produced only a few scattered vesicles in the cytoplasm containing gold nanoparticles. (**b**) TEM image of Panc-1 cells incubated for 30 min with nonspecific IgG-conjugated gold nanoparticles (control group). Similar to the unconjugated gold nanoparticles, the nonspecific IgG-conjugated gold nanoparticles were not readily taken into the Panc-1 cells. The larger image (×7500 magnification) demonstrates few or no obvious intracytoplasmic vesicles containing gold nanoparticles. At higher magnification (×100,000, *inset upper right*), an occasional intracytoplasmic vesicle with a few gold nanoparticles is evident. (**c**) TEM image of Panc-1 pancreatic adenocarcinoma cells incubated for 30 min with C225-conjugated 5-nm gold nanoparticles. At 30 min, a number of intracytoplasmic vesicles (dense *black* vesicles) containing gold nanoparticles are evident in the larger image (×7500 magnification). At a higher magnification (×100,000), numerous vesicles containing dense collections of gold nanoparticles are found throughout the cytoplasm. At 60 and 120 min of incubation with the C225-targeted gold nanoparticles, the number of intracytoplasmic vesicles containing gold nanoparticles was seen to increase. (**d**) A higher magnification TEM image (×100,000) showing details of the cell surface of Panc-1 cells incubated for 30 min with C225-conjugated gold nanoparticles. Numerous gold nanoparticles are seen at the surface of the cell consistent with binding of the C225 to epidermal growth factor receptor (*EGFR*). Pretreatment of the cells with C225 alone completely blocked any binding of targeted gold nanoparticles to the cell surface and led to no gold nanoparticles appearing in intracytoplasmic vesicles 30, 60, or 120 min after incubation

expression, there is enough uptake of cetuximab-targeted gold nanoparticles to produce low levels of thermal apoptosis following exposure to the RF field. It may be possible to modulate or minimize effects on normal tissues expressing a target molecule like EGFR by use of brief duration pulsed RF therapy or repeated short duration exposures, but these effects must be studied in greater detail to confirm this theoretical consideration. Nonetheless, these results indicate that it is possible to use overexpression of a specific cell surface moiety, e.g., EGFR, to enhance delivery and uptake of gold nanoparticles to produce thermal cytotoxicity in the malignant cells following brief exposure to a noninvasive RF field.

There are numerous other possibilities for targeted delivery of nanoparticles into malignant cells. Radiolabeled carbon nanotubes have been conjugated with rituximab and lintuzumab to diagnose and potentially treat lymphoma cells [15]. Recently, aptamers, nucleic acid ligands much smaller than monoclonal antibodies, have been shown to target specific molecules in the neovasculature of tumors or on the surface of different types of cancer cells [16]. These aptamers have been conjugated to gold nanoparticles initially for use as an improved diagnostic technique. However, co-conjugation of cytotoxic agents, or use of our noninvasive RF field treatment technique, could be used as an actual anticancer therapy using this targeting technique. So-called cell-penetrating peptides, generally less than 100 amino acids in length, also have been shown to target certain types of cancer cells. The 86-amino acid HIV-1 Tat protein has been conjugated to gold nanoparticles, with subsequent rapid intracellular uptake of the nanoparticles and localization to the nucleus [17, 18]. The monoclonal antibody-conjugated gold nanoparticles used by our group are found in the cytoplasm of cells within 30 min of adding these nanoparticle conjugates to cancer cells in culture. Localization of the nanoparticles to the nucleus with thermal destruction of DNA following RF field exposure must be investigated as a technique to enhance cancer cell destruction. Chlorotoxin is another small peptide (36 amino acids) cancer cell agent that can be easily conjugated with gold nanoparticles and is currently being investigated as a cancer cell targeting agent in several human malignant cell lines [19]. Identification of cancer-specific ligands not expressed on normal cells will permit targeting of gold nanoparticles to only malignant cells for treatment in our noninvasive RF field generator and should allow treatment of measurable tumors and micrometastatic disease with minimal therapy-related toxicities. Targeting ligands, like EGFR, that are overexpressed but not unique to cancer cells are feasible but will require careful evaluation to determine acute and long-term thermal effects in normal cells and organs following RF field therapy.

Nanoscale thermal therapy of targeted cancer cells is a promising new weapon in the battle against cancer. By combining nonionizing radiation and targeted metallic nanoparticles, noninvasive targeted thermal therapy has the promise of benefiting cancer patients that need a nontoxic alternative to the debilitating effects of conventional chemotherapeutics. Using noninvasive RF fields, magnetic fields, or laser irradiation to heat nanoscale materials that are internalized into cancer cells or the tumor microvasculature has the promise of reducing toxicity and maximizing therapeutic benefit for cancer patients.

Definition

Thermal conductivity (symbols: κ or Λ) is an empirical material property that relates local heat flux (J) across a real or imaginary surface to the temperature gradient ($\partial T/\partial x$) at the same point in direction x normal to the surface. Normally, the concept of thermal conductivity is used for heat conduction not mediated by massive advection of atoms and molecules, or propagation of electromagnetic waves; such heat transport is traditionally referred to as convective and radiative heat transfer, respectively.

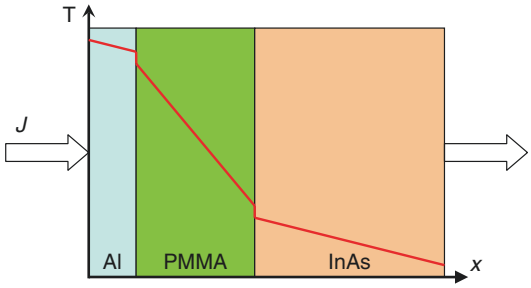
Thermal conductivity is defined according to the Fourier's law of heat conduction given below,

$$J = -\kappa \frac{\partial T}{\partial x}$$

The negative sign indicates that heat flow against temperature gradient, i.e., from the hot side to the cold side. The units commonly used for thermal conductivity include watts per meter-Kelvin (W m^{-1} K^{-1}) and watts per centimeter-Kelvin (W cm^{-1} K^{-1}). The reciprocal of thermal conductivity is called the thermal resistivity.

Overview

As summarized by the second law of thermodynamics, Nature seeks to approach equilibrium in an isolated system, be it a mechanical, chemical, or thermal system. In the context of heat transfer, heat flows from the hot side to the cold side whenever the system is not in thermal equilibrium (i.e., temperature is not uniform), until all temperature difference is ultimately eliminated. Although the second law of thermodynamics is very general and applies to any thermal system, it does not however stipulate how equilibrium is reached. In other words, although heat transfer occurs whenever temperature difference exists according to the second law of thermodynamics, the rate of heat transfer differs from systems to systems depending on the properties of materials or mediums in the thermal system.



Historically, heat transfer is classified as conduction, convection, and radiation, depending on the mediums involved and the mechanisms in which heat is transported across the mediums. Conduction usually refers to heat transfer in solids, in which atoms and molecules are practically immobile and diffusion of atoms and molecules is relatively slow (as long as the solids are not at highly elevated temperatures). In such cases, heat is predominantly carried by vibration of atoms, or other quasiparticles in the crystals such as electrons and holes (see more discussions on quasiparticles below). Also, in still fluids, heat transfer is due to vibration and collisions of atoms and molecules, and thus is also categorized as conduction. On the other hand, the term convection is mainly used for heat transfer from a solid surface to fluids, mediated by diffusion or advection (macroscopic motion) of molecules and atoms. In convection, fluids are driven either by external means such as pumps (forced convection) or by buoyancy forces (natural convection). Lastly, when heat is carried by electromagnetic waves, the heat transfer is called radiation. Unlike conduction and convection, no mediums are required for radiation, since electromagnetic waves can travel through vacuum. For example, heat is transported from the Sun to the Earth by visible or infrared light through radiation. Of course, radiation could also occur through transparent mediums (e.g., glass, air etc.).

For heat conduction, the rate of thermal energy transfer per unit time and unit area is proportional to temperature gradient in the respective direction. This empirical relationship is known as the Fourier's law of heat conduction. Mathematically,

$$J = -\kappa \frac{\partial T}{\partial x}$$

where J is the heat flux across a real or imaginary interface (SI unit: W m^{-2}) and $\partial T/\partial x$ is the local temperature gradient (SI unit: K m^{-1}). Thermal conductivity (κ) is defined as the proportional constant in the Fourier's law of heat conduction and has the SI unit of W m^{-1} K^{-1}. Thermal conductivity for fully condensed solids spans for more than five orders of magnitude, from $\kappa > 1{,}000$ W m^{-1} K^{-1} for carbon allotropes [1, 2], to $\kappa < 0.01$ W m^{-1} K^{-1} for disordered crystals [3]. Theoretically, thermal conductivity is an intrinsic material property and thus should not depend on the geometry and size of the materials. This theoretical definition of thermal conductivity is somewhat relaxed recently for the thermal conductivity of nanostructures. Thermal conductivity of nanostructures depends on the characteristic lengths of the nanostructures, see the discussions below.

The effect of thermal conductivity on heat conduction in solids is illustrated in Fig. 1. For a

Thermal Conductivity and Phonon Transport, Fig. 1 Schematics of a hypothetical multilayered solid of aluminum (Al) with $\kappa > 200$ W m^{-1} K^{-1}, amorphous polymer PMMA with $\kappa \approx 0.2$ W m^{-1} K^{-1}, and semiconductor indium arsenide (InAs) with $\kappa \approx 27$ W m^{-1} K^{-1}, being heated uniformly with a constant heat flux of J. The red solid line is the temperature profile in the hypothetical solid. Different slopes of the temperature profile are due to different thermal conductivity of each layer. Temperature drops at the interfaces are due to finite Kapitza thermal conductance of the interfaces

constant heat flux applied on a hypothetical multilayered solid as in Fig. 1, temperature drop across each layer is inversely proportional to the thermal conductivity of the layer. For a high thermal conductivity material (e.g., aluminum), the temperature drop is minimal since heat could be easily transported across the material. In other words, thermal energy could easily spread across high thermal conductivity materials, resulting in a near-uniform temperature distribution. On the other hand, low thermal conductivity impedes heat transport, and thus higher temperature difference could be maintained in the materials. This simple understanding of thermal conductivity is crucial for many modern applications (such as thermal barrier coatings and thermoelectrics), in which high temperature differences enhance the performance of the devices. Researchers in these fields seek to modify the existing materials, often through nanostructuring, to reduce the thermal conductivity so that a higher temperature difference could be maintained in the devices.

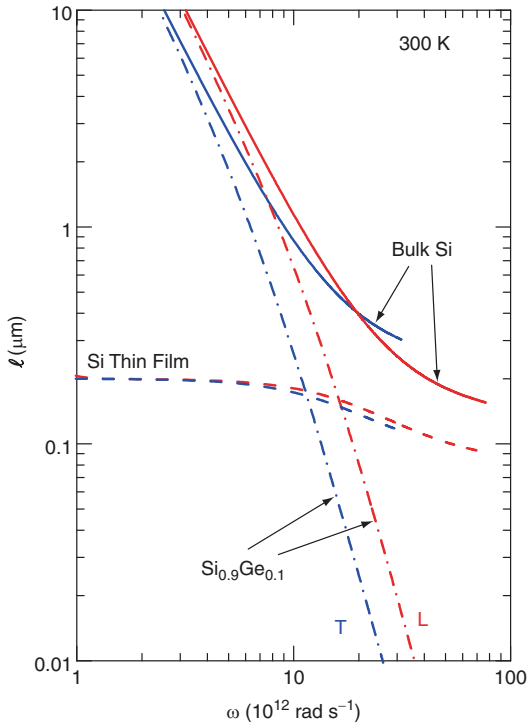
While the thermal conductivity is a bulk property, interfacial or Kapitza thermal conductance [4] (symbol: G) is a property of interfaces. As heat flows across an interface, a finite temperature drop is observed at the interface, as illustrated in Fig. 1, due to resistance of the interface to thermal transport. Kapitza thermal conductance (G) relates this temperature drop (ΔT) to heat flux across the interface; $J = -G\,\Delta T$. Typically, thermal conductance ranges from $G > 1$ GW m^{-2} K^{-1} for metal/metal interfaces [5] to $G \approx 10$ MW m^{-2} K^{-1} for interfaces with highly dissimilar materials [6]. It is important to realize that the Kapitza thermal conductance is not solely due to imperfections of interfaces (e.g., imperfect contact as a result of surface roughness, diffuse interfaces due to intermixing, etc.). Even for atomically perfect interfaces, heat flow is still impeded by finite thermal conductance because differences in the properties (e.g., density of phonon states) of two mediums reduce the probability for heat carriers to transmit across the interfaces. In other words, since interfaces break the reflection and translational symmetry, even perfect interfaces are imperfections by definition. Thus, heat transport is retarded at interfaces due to this break of symmetry engendered by the interfacial imperfections.

Heat Transport by Phonons in Nonmetallic Solids

In a microscopic view, heat conduction in solids is due to quasiparticles that carry heat across the solids. In simple words, quasiparticles (especially those important for heat conduction in solids) are quantized excitation modes resulting from quantum-mechanical interaction of atoms and electrons in the periodic lattices. Strictly speaking, some of these quasiparticles are only theoretically defined for perfect crystals, but this restriction is usually relaxed for imperfect crystals. Quasiparticles behave like real particles with properties and behavior modified from their real particle counterparts.

Common quasiparticles that are important for heat conduction in solids include phonons, electron quasiparticles and holes. Phonons are quantized lattice vibration modes due to interaction of sound waves in solids and are responsible for heat conduction in most nonmetallic solids (dielectrics and semiconductors). Electron quasiparticles are quantized excitation modes due to interaction between electrons and periodic electrical potential

in the lattices. Electron quasiparticles are the main carriers for both heat and charges in metals, and as a result of electron quasiparticles being the common carriers, the thermal conductivity and electrical conductivity of metals are related by a fundamental relationship called the Wiedemann–Franz law. Electron quasiparticles also contribute significantly to heat conduction in highly *n*-doped semiconductors and semimetals. Holes, on the other hand, are empty states available in the crystals that are not filled by electrons. Holes behave similar to electron quasiparticles, except that they carry positive charges and have different effective masses. Holes can contribute significantly to heat conduction in highly *p*-doped semiconductors and semimetals. Note that electron quasiparticles have different behavior (e.g., different effective masses) from stand-alone electrons, even though both carry negative charges and both are fermions. Consistent with the literature and for simplicity, electron quasiparticles are thereafter referred to as "electrons" throughout the text.



To understand heat conduction by phonons in crystalline dielectrics and semiconductors, it is important to realize that phonons do not carry same amounts of heat due to different polarizations (longitudinal or transverse) and a broad distribution of frequencies (ω) and lifetimes (τ) of phonons. Heat conduction by phonons depends on three properties of phonons:

1. The volumetric heat capacity (C) of phonon modes, which affects the amount of heat carried by phonons. The volumetric heat capacity is a function of phonon frequency, polarization, and temperature. At high temperatures, the heat capacity of each phonon mode approaches a classical value of k_B, where $k_B = 1.38 \times 10^{-23}$ J K^{-1} is the Boltzmann constant.
2. The group velocity (υ) of phonons, which determines how fast phonons propagate in the materials and is defined as

$$\upsilon = \frac{\partial \omega}{\partial k}$$

where k is the wavenumber of phonons. The group velocity depends on the slope of phonon dispersion and thus is a function of phonon frequency (ω) and polarization. At low frequencies, the group velocity of acoustic phonons approach the speed of sounds of the materials, while at high frequencies, the group velocity of acoustic phonons approach zero due to interference of reflected waves near the Brillouin zone boundaries.
3. The mean-free-path (ℓ) of phonons, which is the average distance phonons propagate without being scattered. In crystals, phonons are scattered by imperfections including impurities, anharmonicity, and grain boundaries. This scattering of phonons is the source of retardation for heat conduction in crystals, since perfect crystals have infinitely high thermal conductivity. Normally, the scattering process is quantified by the relaxation time (τ) or the mean-free-path (ℓ) of phonons; the relaxation time and mean-free-path are related by $\ell = \upsilon\tau$, where υ is the group velocity of phonons. Both the relaxation time and the mean-free-path strongly depend on the frequency of phonon modes.

At high temperatures, most phonon modes are excited, but heat is carried mainly by a small fraction of these excited modes (long-wavelength acoustic phonons). Acoustic phonons near the edge and the center of the Brillouin zone, and optical phonons are inefficient in carrying heat due to their low group velocity or heat capacity. The mean-free-paths of these heat-carrying acoustic phonons, however, are not constant but span more than an order of magnitude in most crystals depending on phonon frequency. For example, calculations [7] show that ≈ 90 % of heat could be carried by phonons with $0.1 \leq \ell(\omega) \leq 1$ μm in Si. The mean-free-paths of phonons are also sensitive to the purity and harmonicity of materials, since imperfections, such as impurities, point defects and anharmonicity, scatter phonons. In fact, the disparity in the thermal conductivity of different materials is mainly due to differences in the mean-free-paths (instead of the heat capacity or the group velocity) of phonons in these

Thermal Conductivity and Phonon Transport, Fig. 2 Mean-free-path (ℓ) of longitudinal (*red*) and transverse (*blue*) acoustic phonons in bulk Si (*solid lines*), a 200 nm Si thin film (*dashed lines*) and bulk $Si_{0.9}Ge_{0.1}$ alloy (*dash-dotted lines*) calculated from a Callaway-type model [8]. ω is the frequency of phonons. The dominant scattering mechanisms in bulk Si, the SiGe alloy, and the Si thin film are three-phonon process (anharmonicity), Rayleigh scattering, and boundary scattering, respectively

materials, since the heat capacity and phonon velocity of different materials do not vary by more than an order of magnitude.

Despite the importance, understanding of the mean-free-paths of phonons is still incomplete, mainly due to lack of a direct method to measure the mean-free-paths of phonons [8]. The mean-free-paths of phonons are usually inferred from systematic measurements of the thermal conductivity by comparing the experimental results to theoretical calculations. Figure 2 shows an example of calculations of the mean-free-paths of acoustic phonons in bulk silicon, a 200 nm silicon thin film and bulk $Si_{0.1}Ge_{0.9}$ alloy, as a function of phonon frequency. Note that different imperfections are efficient in scattering phonons of different frequency. At room temperature, phonons in bulk Si are predominantly scattered by anharmonicity, which is effective to scatter high-frequency phonons but not low-frequency phonons, see Fig. 2. Similarly, Rayleigh scattering, which is the dominant scattering mechanism for phonons in alloys, is more effective to scatter high-frequency phonons than low-frequency phonons. On the other hand, boundary scattering is effective to scatter low- and medium-frequency phonons. Over the past decade, nanostructures, such as thin films, superlattices, and nanowires, have been widely used to scatter the low-energy phonons to further reduce the thermal conductivity. It is stressed that the scattering rate and mean-free-paths of phonons in most materials are *not* known – calculations as in Fig. 2 are at best just an approximation. In fact, polarization of the dominant heat carriers in silicon was determined as recent as a decade ago [9].

Thermal Conductivity Reduction in Nanostructures

Over the past decade, researchers advanced the understanding of heat conduction in nanostructures through systematic measurements of the thermal conductivity of nanostructures. This understanding on nanoscale heat transport facilitates the design of more efficient thermoelectric materials with reduced thermal conductivity. In this section, prior experimental studies on heat conduction by phonons in different nanostructures, including crystalline thin films, superlattices, nanowires, and semiconductor embedded with nanoscale precipitates, are briefly and selectively review.

Goodson and coworkers [9, 10] reported the in-plane thermal conductivity of Si thin films over a wide film thickness (74–1.6 μm) and temperature (20–320 K) range. The in-plane thermal conductivity was measured by the 3ω method [11], which is discussed below. Heat was previously perceived to be carried by transverse acoustic phonons in Si, but Ju and Goodson [9] find from the in-plane thermal conductivity measurements of Si thin films that longitudinal acoustic phonons

with mean-free-path $\ell \approx 300$ nm are the dominant carriers in Si at 300 K.

Yao [12] first reported the cross-plane thermal conductivity of AlAs/GaAs superlattices, measured using an ac calorimetric method. He finds that the thermal conductivity of a $(AlAs)_{5\ nm}(GaAs)_{5\ nm}$ superlattice approaches the thermal conductivity of AlGaAs alloys at room temperature. The observation that the thermal conductivity of superlattices approaches the thermal conductivity of the alloys is not universal. For example, Lee and coworkers [13] reported the thermal conductivity of fully strained Si/Ge superlattices, measured by the 3ω method. They find that for period <6 nm, the thermal conductivity decreases with decreasing period and is governed by the thermal conductance of interfaces. For longer period of >10 nm, however, the defect density is so high that the thermal conductivity approaches the amorphous limit. Further measurements [14, 15] on other Si/Ge nanostructures are consistent with measurements by Lee et al.

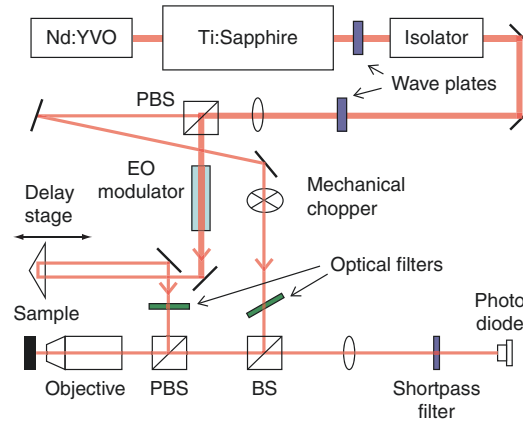
Venkatasubramanian [16] reported the thermal conductivity of Bi_2Te_3/Sb_2Te_3 superlattices as a function of superlattice period and find that the thermal conductivity of short-period superlattice is minimum when the period is ≈ 4 nm. Subsequent measurements on similar samples by Touzelbaev and coworkers [17], however, do not present similar minimum thermal conductivity. The minimum thermal conductivity is also not observed on AlN/GaN superlattices [18], in which the AlN/GaN interfaces are atomically sharp and chemically abrupt.

Li and coworkers [19] first measured the thermal conductivity of Si nanowires using a microfabricated device. Li et al. find that the thermal conductivity of nanowires is reduced by more than an order of magnitude when the diameter of the nanowire is 22 nm. The approach has subsequently been applied to study the thermal conductivity of other nanostructures, including rough Si nanowires [20]. The reduction of thermal conductivity, in most cases, is due to enhanced boundary scattering.

Harman and coworkers [21] estimated the thermal conductivity of PbTe/PbSe nanodot superlattices from their thermoelectric devices. They found that the thermal conductivity is 0.33 W m^{-1} K^{-1}, a factor of 3 lower than the thermal conductivity of the corresponding alloys. More complete and systematic measurements [22] on similar materials, however, indicate that the thermal conductivity of PbTe/PbSe nanodot superlattices is on the order of 1 W m^{-1} K^{-1}, comparable with the thermal conductivity of PbTeSe alloys.

The thermal conductivity of InGaAs with ErAs nanoparticles randomly distributed in the InGaAs matrix was first reported by Kim and coworkers [23]. The thermal conductivity of the nanostructured materials is found to be reduced from the thermal conductivity of the alloys by up to a factor of 2, even when the concentration of the ErAs nanoparticles is relatively small (0.3 %). This reduction of thermal conductivity is explained by enhanced Rayleigh scattering when the size of the nanoparticles better match the wavelength of phonons. Subsequent measurements [24] on InGaAs with higher concentration of ErAs nanoparticles indicate that the thermal conductivity could be further reduced with higher concentration of ErAs nanoparticles.

Modern Techniques for Measurements of the Thermal Conductivity of Nanostructures



For measurements of heat conduction on submicron or nanometer length scales, temperature profile has to be monitored within the similar characteristic length scales (~1 μm) or equivalently the temperature decay profile in nanosecond time scales. Conventional approaches to measure the thermal conductivity are incapable to reach these small length and time scales, and thus are not suitable for measurements of the thermal conductivity of nanostructures. In this section, two important techniques that are capable of characterizing the thermal properties of nanostructures, namely, the 3ω method and the time-domain thermoreflectance (TDTR), are introduced.

The 3ω method [11] is widely used to measure the thermal conductivity of bulk solids and thin

films. In 3ω measurements, a narrow metal line (often Au or Pt with Cr or Ti as the adhesion layer) of ~400 nm thickness and ~30 μm width is patterned on a sample. Electrical current $\boldsymbol{i}$ of frequency ω is applied to the metal line with electrical resistance $\boldsymbol{r}$, generating joule heating of $\boldsymbol{i}^2\boldsymbol{r}$ within the metal line with a frequency component at 2ω. As a result of this oscillating heat source, a temperature oscillation and a corresponding resistance oscillation at frequency 2ω are induced in the metal line. Hence, a component of the voltage oscillation ($\boldsymbol{v} = \boldsymbol{ir}$) across the metal line contains a third harmonic, 3ω. The thermal conductivity of the sample can be deduced from this 3ω voltage oscillation.

The cross-plane thermal conductivity of thin films can be measured by the differential 3ω method [16]. A reference sample without the thin film of interest is prepared simultaneously with the sample containing the film of interest such that the metal line patterned on both samples has the same thickness and width. Both the thin film sample and the reference are measured using similar heating power and the same range of heater frequencies. The temperature drop across the thin film ΔT_f can then be derived from the difference in the amplitude of the temperature oscillation of the sample and the reference. Assuming one-dimensional (1D) heat conduction, the cross-plane thermal conductivity of the thin film is derived from ΔT_f. If the thin film is semiconducting, a thin dielectrics layer is required to electrically insulate the metal lines from the thin films. For semiconducting crystalline thin films, the differential 3ω method is usually only suitable to measure the thermal conductivity of the films if the films are >1 μm thick [24].

Another important technique for measurements of heat conduction on nanometer length scale is the time-domain thermoreflectance (TDTR) [25]. Figure 3 shows a schematic diagram [26] of the TDTR setup. Before TDTR measurements, the samples are usually coated with a thin layer (~80 nm) of metal with high thermoreflectance (e.g., Al) by magnetron sputtering or thermal evaporation. The metal film serves as a transducer to absorb the heating pump beam and to convert the temperature excursions at the surface into changes in the intensity of the reflected probe beam. Usually, Al is used as the metal transducer due to the high thermoreflectance. However, for high temperature measurements, Al is not suitable due to its low melting point; Pt, Ta, or AuPd could be used for high temperature measurements, see [27] for further discussion. The thickness of the metal transducer layer is normally simultaneously determined during TDTR measurements by picosecond acoustics.

Thermal Conductivity and Phonon Transport, Fig. 3 A schematic [26] of the TDTR setup. The optical filters and the shortpass filter are optional and can eliminate the artifacts due to diffusely scattered pump beam leaked into the Si photodiode during TDTR measurements of rough samples (Reprinted with permission from Ref. [26]. Copyright 2008, American Institute of Physics)

In TDTR measurements, the output of a mode-locked Ti:sapphire laser oscillator is split into a pump beam and a probe beam, with the relative delay time between the pump and probe pulses being adjusted via a mechanical stage. Samples are heated by the pump beam, which is modulated by an electro-optic modulator at frequency f, $0.1 < f < 10$ MHz. Cooling of the surface after being heated by pump pulses is then monitored through changes in the intensity of the reflected probe beam using a Si photodiode and a radio-frequency (rf) lock-in amplifier. If the samples are rough, TDTR measurements should be performed using a two-tint configuration [26], see Fig. 3. Normally, heat waves only penetrate <1 μm in TDTR measurements, while the $1/e^2$ radius of the

laser beam is usually >5 μm. Hence, heat flow in TDTR is predominantly one dimensional.

Data analysis in TDTR is considerably complicated. The changes in reflected intensity at frequency f have both an in-phase V_{in} and out-of-phase V_{out} components. Normally, the ratio V_{in}/V_{out} is used for the analysis (instead of just the *Vin* component) to make use of the additional information in the out-of-phase signal and eliminate artifacts created by unintended variations in the diameter or position of the pump beam created by the optical delay line. Measurements of the ratios V_{in}/V_{out} as a function of delay time are compared to numerical solutions of the diffusion equation in cylindrical coordinates using a thermal model [28]. The thermal model normally has two free parameters: the thermal conductance of the Al/sample interface and Λ of the sample. For most cases, these two parameters can be separated from the fitting of the model calculations to the measurements [29].

Future Directions for Research

Detailed understanding of heat transport in crystalline solids, especially on how phonons are scattered in nanostructures, is crucial for the design of new thermoelectric materials and thermal management of electronic devices. In this regard, future research will focus on experimental and theoretically studies on the details of how phonons carry heat across different kinds of nanostructures. One example is recent efforts by researchers in the field to investigate how heat is transported along [1, 2] and across [30] monolayer and few-layer graphenes. By carefully comparing the experimental results to theoretical calculations, these studies advance our knowledge on how phonons are scattered by impurities and nanostructures and thus facilitate future design of more efficient devices.

Definition

Thermally actuated electromechanical resonators are micro- to nanoscale structures whose specific mechanical resonant modes can be actuated by periodic thermal expansion forces resulting from joule heating in parts of their structure.

Introduction

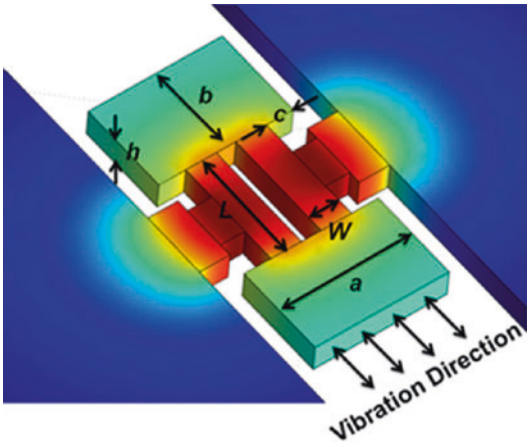
Thermal actuation based on joule heating-induced thermal expansion of solids is a well-known mechanism that can be conveniently implemented at micro- and nanoscale. An electrothermal actuator simply consists of a conductive element that heats up as a result of electrical current flowing through it and therefore can be implemented without any fabrication challenges or the need for material integration. Electrothermal actuators also have great properties such as large actuation force, low operating voltage, and simplicity of design and integration. On the downside, their considerable power consumption makes them an undesirable choice for many applications. Furthermore, thermal actuators are generally considered slow actuators only suitable for DC or very-low-frequency applications. This is mainly based on the general perception emanating from the more familiar macro-world where thermal phenomena have relatively large time constants in the few seconds or even minutes and hours range. However, as will be shown in this section, thermal actuation along with piezoresistive sensing provides an interesting option for transduction of high-frequency resonant modes of micro- and nanostructures.

Micro- and nanoscale electromechanical resonant devices have received a lot of attention over the past decade as a potential emerging technology for next-generation integrated frequency references, electronic filters, and resonant sensors. As a result, a wide variety of high-frequency microelectromechanical resonator technologies have been developed over the past few years, most of which use piezoelectric [1, 2] or electrostatic (capacitive) [3–5] transduction. Despite significant improvements in both piezoelectric and capacitive microresonator technologies, each approach still has certain challenges to overcome. Piezoelectric microresonators require integration of piezoelectric and metallic thin films generally resulting in lower quality factors and frequency and quality control issues. In the case of air-gap capacitive resonators, the weak electromechanical coupling necessitates deep submicron transduction gaps leading to fabrication and reliability challenges, power handling limitations, and excessive squeezed film damping when operating in air. Solid dielectric resonators [5] use electrostatic forces in dielectric thin films (preferably a high-K dielectric) to take advantage of the larger dielectric coefficients and improve the electromechanical coupling strength. The fully solid structure of such device relaxes several problems associated with aggressive reduction of the air gaps such as stiction and pull-in issues and allows reduction of the dielectric gap sizes to a few nanometers. However, similar to the piezoelectric resonators, such devices require integration and physical contact of dielectric thin films and conductive electrodes with the resonant structures which defeats some of the main purposes of moving away from piezoelectric devices. Moreover, large dielectric constants of the very thin dielectric films result in large parasitic capacitors to be associated with such devices.

Frequency tuning and compensation of the temperature-induced frequency drift are among other formidable challenges for both piezoelectric and capacitive resonators. Finally, in order to achieve a strong enough electromechanical transduction and consequently a large signal to noise ratio, both capacitive and piezoelectric resonators require relatively large electrode areas (thousands of μm^2) consuming costly real estate on the chip and limiting the maximum number of devices that can be integrated on a single chip.

Electrothermal actuation presents a third option for actuation of resonant modes of micro- and nanoscale structures that has been neglected to some extent so far, especially for high-frequency applications. Different versions of lower frequency thermally actuated micromechanical resonant devices have been utilized as mass sensors for chemical [6] or

particulate [7] sensing. Utilization of thermal actuation for high-frequency resonant modes has been gaining more attention lately. A 10-MHz MEMS oscillator was demonstrated in [8] via electrothermal actuation of resonant modes in a suspended polysilicon membrane. In [9], thermal actuation and piezoresistive detection of flexural resonant modes of a silicon-carbide nanobeam with frequencies up to 1.1 GHz has been demonstrated. Recent studies and experiments have shown promising results and plenty of unexplored potentials for thermally actuated high-frequency resonators especially as the structural dimensions are scaled down into the nanoscale [10]. Both modeling and experimental measurements suggest that as opposed to the general presumption, thermal actuation becomes a more efficient actuation approach for higher-frequency resonant modes provided that higher frequency is achieved by shrinking the structural dimensions down. Unlike electrostatic and piezoelectric resonators, thermal-piezoresistive resonators perform better as their size is shrunk down and therefore could be a much stronger candidate for realization of highly integrated nanomechanical arrays of resonant signal processors. Self-sustained oscillation capability [11, 12] and robustness and design flexibility for sensory applications [7] are among other unique properties that thermal-piezoresistive transduction offers.



High-Frequency Thermal-Piezoresistive Resonators: Principles of Operation and Modeling

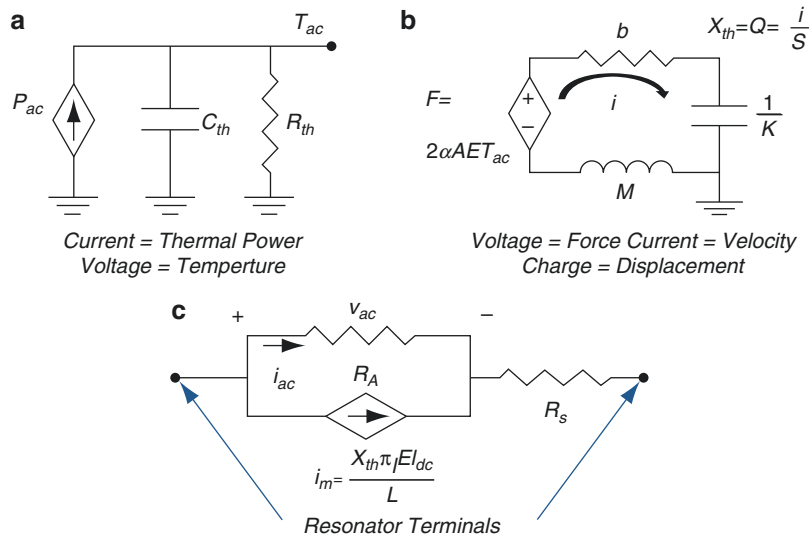
High-Frequency Thermal Actuation: As mentioned earlier, based on the perception from the macro-world, it is hard to imagine a thermal system with small enough thermal time constants to respond to high-frequency excitations. Similar to electrical RC circuits, thermal time constant of a thermal actuator, for example, a suspended conducting beam, is the product of its thermal capacitance and thermal resistance: $\tau_{th} = R_{th} C_{th}$. Thermal resistance can be calculated using a very similar equation to electrical resistance, that is, $R_{th} = \sigma_{th}^{-1} L/A$, where σ_{th} is the thermal conductivity of the structural material and L and A are the length and cross-sectional area of the element. Similar to electrical resistance, thermal resistance increases proportionally as all the dimensions of the element are scaled down. This implies that if a thermal actuator is scaled by a factor of S, its thermal resistance changes by a factor of S^{-1}. On the other hand, thermal capacitance is proportional to the mass and consequently the volume of the element and scales by a factor of S^3. Hence, overall, the thermal time constant of the element scales by a factor of S^2.

On the other hand, if a mechanical structure is scaled by a factor S, its mechanical resonant frequency (ω_m) changes by a factor of S^{-1}, that is, its mechanical time constant changes by a factor of S. The overall conclusion is that if the dimensions of a thermally actuated resonant structure are scaled down, its thermal time constant shrinks faster than its mechanical time constant. To be more specific, both thermal and mechanical responses of the system become faster upon scaling the dimensions down; however, the increase in the speed of the thermal response is sharper (proportional to S^{-2}) than the increase in the mechanical resonant frequency (proportional to S^{-1}). Therefore, as the structural dimensions are scaled down, the performance of thermally actuated mechanical resonators is expected to improve (more actuation force for the same actuation power) as the thermal response of the system can catch up with the mechanical vibrations more effectively.

Thermal-Piezoresistive Transduction: Piezoresistive sensing is the most convenient sensing mechanism to be integrated and utilized along with thermal actuation. Similar to thermal actuation, piezoresistive sensing requires only a conductive element preferably with a high piezoresistive coefficient. To add to the simplicity, the same elements can be used for both thermal actuation and piezoresistive sensing simultaneously.

Thermal-piezoresistive resonators can come in different shapes and sizes. Figure 1 shows the 3D schematic view of a resonant structure, known as I-shaped bulk acoustic wave resonator or IBAR (also known as dog-bone resonator), which is very suitable for thermal-piezoresistive transduction

Thermally Actuated Silicon Resonators, Fig. 1 3D schematic view of a thermally actuated IBAR (dog-bone resonator) showing the qualitative distribution of temperature fluctuation amplitude when subject to a fluctuating current flow (*red* shows the maximum and *blue* shows the minimum)



while being capable of providing relatively high resonance frequencies. In the in-plane extensional resonance mode, the two blocks hanging on the two sides of the structure move back and forth in opposite directions subjecting the two beams connecting them together to periodic tensile and compressive stress. Such resonance mode can simply be actuated by applying the actuation voltage (or current) between the two support pads on the two sides of the structure. The ohmic loss caused by the current flow is maximized in the narrower parts of its path, that is, the extensional pillars in the middle of the structure (the two beams connecting the two blocks to each other). Upon application of a fluctuating actuation voltage, the fluctuating ohmic power generation results in a fluctuating temperature gradient and therefore periodic thermal expansion of the extensional actuator beams. The alternating extensional force resulting from the fluctuating temperature in the beams can actuate the resonator in its in-plane extensional resonance mode. If the ohmic power and consequently the resulting temperature fluctuations have the same frequency as the mechanical resonance frequency of the structure, the mechanical vibration amplitude is amplified by the mechanical quality factor (Q) of the resonator. The amplified alternating stress in the pillars leads to considerable fluctuations in their electrical resistance due to the piezoresistive effect. When biased with a DC voltage, such resistance fluctuations modulate the current passing through the structure resulting in an AC component known as the motional current.

Thermo-electromechanical Modeling: Operation of a thermal-piezoresistive resonator involves phenomena in three different domains of thermal, mechanical, and electrical nature. Ohmic loss turns the electrical input voltage into a temperature, thermal expansion turns the temperature into a mechanical force that causes a mechanical displacement, and finally the piezoresistive effect turns the mechanical displacement back into an electrical signal (motional current).

Figure 2 shows the equivalent electrical circuit models for the three domains. In the thermal domain, the actuator beams act like a low-pass RC combination. The equivalent circuit consists of a current source representing the alternating heating power along with a capacitance (C_{th}) and a resistance (R_{th}) representing the effective thermal capacitance and thermal resistance of the thermal actuators, respectively (Fig. 2a). The resulting voltage across the parallel RC combination (T_{ac}) represents the temperature fluctuation amplitude.

Typically, the fluctuating actuation voltage is provided by a combination of a DC and an AC voltage component. Due to the square relationship between ohmic power generation and electrical voltage (or current), application of only an AC actuation voltage with frequency of f_a results in an ohmic power component with frequency of $2f_a$. In order to have the same frequency as the input AC actuation voltage for the thermal actuation force, a combination of AC and DC voltages (V_{dc} and v_{ac}) needs to be applied between the two terminals of the resonators. The resulting power loss component at the same frequency as v_{ac} in this case will be $P_{ac} = \frac{2V_{dc}v_{ac}}{R_A}$, where R_A is the electrical resistance of the actuator elements (extensional beams in IBARs) and V_{dc} and v_{ac} are the applied DC and AC actuation voltages, respectively.

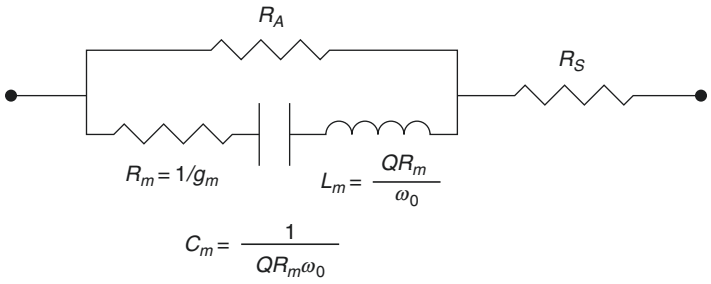
The RLC combination of Fig. 2b represents the mechanical resonance behavior of the structure.

Thermally Actuated Silicon Resonators, Fig. 2 Equivalent electrical circuit for a thermal-piezoresistive resonator: (**a**) the thermal domain; (**b**) the mechanical domain; (**c**) the electrical domain

The voltage source represents the thermally generated mechanical force which is the product of thermal expansion coefficient (α) of the structural material, thermal actuator cross-sectional area (A), and Young's modulus (E) of the thermal actuator along its length. The coefficient "2" has been added since there are two actuator beams in each resonator contributing to the actuation force. The inductor, capacitor, and resistor represent the effective mechanical mass (M), stiffness (K), and damping (b) of the resonator, respectively. Consequently, current represents velocity, and electrical charge ($Q = \int i.dt$) represents displacement (X_{th}), which is the elongation of the thermal actuators (resonator vibration amplitude). The vibration amplitude, which is the output of the mechanical subsystem, acts as an input to the electrical subsystem (Fig. 2c) causing a change in the resistance of the thermal actuators due to the piezoresistive effect. This change in resistance modulates the current flow through the resonator which is shown as a current source in the equivalent circuit. R_s in Fig. 2c represents the parasitic electrical resistances in series with the actuator resistance which mainly includes resistance of resonator support beams.

The overall transfer function that relates the AC motional current (output current) to the AC input voltage is the product of the three transfer functions from the thermal, mechanical, and electrical domains. The simplified transfer function at resonance frequency is

$$H_T|s = j\omega_0 \quad = g_m = 4\alpha E^2 \pi_l Q \frac{AI_{dc}^2}{KLC_{th}\omega_0} \qquad (1)$$



where π_l is the longitudinal piezoresistive coefficient of the structural material, L is the thermal actuator length, and Q and ω_0 are the quality factor and angular resonant frequency of the resonator.

For IBAR structures, knowing that $K = 2EA/L$, Eq. 1 can be further simplified to

$$g_m = 2\alpha E \pi_l Q \frac{I_{dc}^2}{C_{th}\omega_0}. \qquad (2)$$

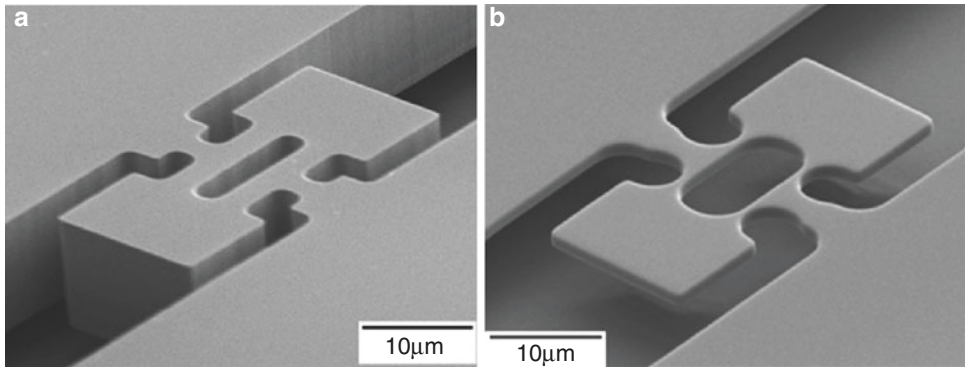
A more detailed version of the modeling and derivations above is available in [10]. The transfer function in Eqs. 1 and 2 can be referred to as small signal voltage to current gain, or motional conductance (g_m) of the resonator at its resonance frequency, which is one of the most important parameters of a thermal-piezoresistive resonator when utilized as an electronic circuit component.

Resonator Equivalent Electrical Circuit: For the resonators discussed here, where the extensional beams acting as thermal actuators are also utilized for piezoresistive readout, the physical resistance of the resonator connects the input and

Thermally Actuated Silicon Resonators, Fig. 3 Compact overall equivalent electrical circuit for one-port thermally actuated resonators with piezoresistive readout

output of the devices. The equivalent electrical circuit in this case includes a resistance $R_A + R_s$ connected between the two terminals of the resonator, which is the overall resistance in the current path between the two pads of the resonator. In parallel to the static resistance of the actuators, there is a series RLC combination that represents the mechanical resonant behavior of the structure. The value of R_m in the RLC has to be set so that at resonance, a motional current of $i_m = g_m \cdot v_{ac} = v_{ac}/R_m$ is added to the feedthrough current passing through R_A. Therefore, $R_m = {g_m}^{-1}$ and L_m and C_m values can be calculated based on the value of R_m as shown in Fig. 3 according to the resonance frequency and quality factor of the resonator.

To calculate the motional conductance (g_m) of a thermal-piezoresistive IBAR, which is the most important parameter to be extracted from the model using Eq. 2, all the parameters except the effective thermal capacitance of the actuators (C_{th}) are known for every set of resonator dimensions and structural material. Due to the distributed nature of the thermal parameters including thermal generator (electrical resistance of the structure), thermal capacitance, and thermal conductance, analytical derivations or finite element analysis should be used to find an accurate value for C_{th}. In [10, 13], finite element analysis has been used to simulate the transient thermal response of the actuators and calculate the fluctuating temperature amplitude (T_{ac}) at different points along the length of the actuator beams. The mean value of the small signal temperature amplitudes at different points along the actuators is the effective temperature fluctuation amplitude for the actuator from which the effective thermal capacitance value can be extracted. As shown in [13], the effective thermal capacitance for a thermal actuator beam is equal to 0.92 of the static lumped element thermal capacitance of the beam with a good approximation.



Resonator Scaling Behavior and Optimization

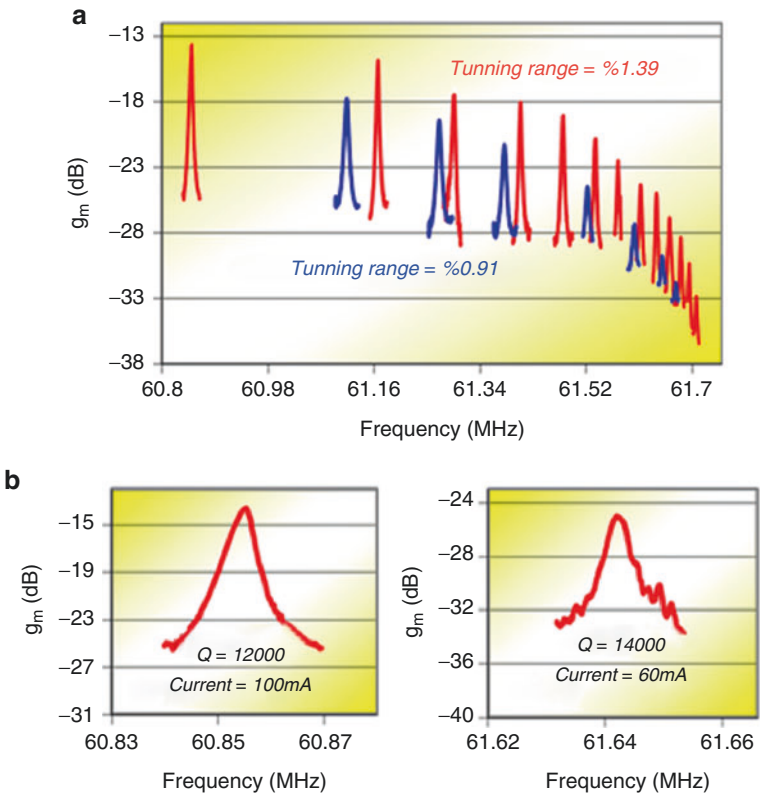
As an electronic component, it is desirable to maximize the resonator motional conductance (g_m) (for improved signal to noise ratio) while minimizing power consumption. Therefore, a figure of merit for the resonators can be defined as the ratio of the resonator g_m to the overall DC power consumption:

$$F.M. = \frac{g_m}{P_{DC}} = \frac{2\alpha E \pi_l Q}{C_{th}\omega_0(R_A + R_s)} \qquad (3)$$

where $P_{DC} = {I_{DC}}^2 \cdot (R_A + R_S)$ is the static power consumption of the resonator. Different parameters that can be used to maximize *F.M.* are as follows:

Actuator Beam Dimensions: Generally, smaller actuator dimensions lead to smaller C_{th} improving resonator figure of merit. However, the effect of actuator dimensions on its electrical resistance (R_A) should also be taken into account. Since the extensional stiffness of the actuator beams defines the resonance frequency of the IBAR, in order to maintain the same resonance frequency for an IBAR while reducing its actuator thermal capacitance, both length and width of the actuator should be scaled down simultaneously. Such scaling does not affect the actuator electrical resistance (R_A). Therefore, scaling down both the length and width

Thermally Actuated Silicon Resonators, Fig. 4 SEM view of single crystalline silicon thermal-piezoresistive IBARs (**a**) a 61-MHz 15-μm-thick IBAR fabricated on a low-resistivity p-type SOI substrate; (**b**) a 41-MHz 3-μm-thick IBAR fabricated on a low-resistivity n-type SOI substrate followed by thermal oxidation to thin down its thermal actuator beams



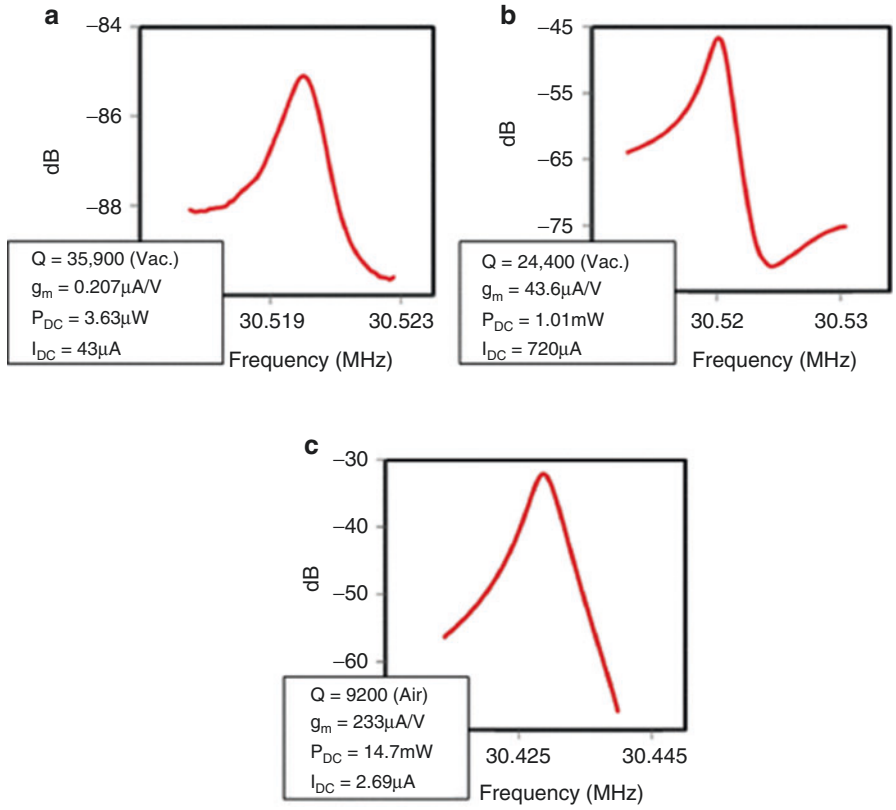
of the actuator beams by a scale S_a results in an improvement in the resonator *F.M.* by a factor of S_a^2 while maintaining an almost constant resonance frequency for the device.

Resonance Frequency and Resonator Scaling: At a first glance at Eq. 3, higher resonant frequencies seem to have a deteriorating effect on resonator figure of merit. However, if higher resonant frequencies are achieved by shrinking the resonator size, at the same time, C_{th} will be shrinking sharply. If all resonator dimensions are scaled down proportionally by a factor S, $C_{th} \propto S^{-3}$, $\omega_0 \propto S$, and $(R_A + R_S) \propto S$. Therefore, *F.M.* $\propto S$, that is, *F.M.* increases proportionally if the resonator dimensions are scaled down, while its resonance frequency increases at the same time. This confirms the validity of the explanation provided previously claiming suitability of thermal actuation for high-frequency applications. It can be concluded from the last two discussions that the capability to fabricate resonator actuator beams with very small (nanoscale) dimensions is the key to achieving very high performance levels for thermal-piezoresistive resonators, both at low and high frequencies.

Electrical Resistivity and Other Material Properties: One of the most important parameters that can also be controlled for some of the most popular resonator structural materials (e.g., Si or SiC) is the electrical resistivity of the structural material. Lower electrical resistivity of the structural material improves the transduction figure of merit by lowering $R_A + R_s$. This can be explained by the fact that, with lower electrical resistivity, the same amount of DC bias current and therefore the same motional conductance can be maintained while burning less ohmic power in the structure.

A number of other structural material properties also affect the figure of merit for thermal-piezoresistive resonators. Higher thermal expansion coefficient and lower specific heat capacity improve the thermal actuation resulting in proportionally higher *F.M.* Higher piezoresistive coefficient improves the piezoresistive readout having the same effect on *F.M.* One interesting and promising fact is the giant piezoresistive effect found in single crystalline silicon nanowires that has been observed and reported by different researchers [14]. Therefore, as the resonators are scaled down to reach higher resonant frequencies in the hundreds of MHz and GHz range, it is expected that the actuator beams with deep submicron width exhibit such strong piezoresistivity significantly improving resonator performances. Finally, using structural materials with higher Young's modulus (E) can also improve the resonator figure of merit while increasing its resonant frequency.

Figure 4 shows the scanning electron micrograph (SEM) of two different microscale single crystalline silicon IBAR structures. Figure 5 shows the motional conductance frequency plots



Thermally Actuated Silicon Resonators, Fig. 5 Measured frequency response of the thermally actuated 61-MHz resonator of Fig. 4a with different bias currents. The vertical axis in the frequency response plots shows the motional conductance of the resonators (g_m) in dB with respect to 50-Ω network analyzer terminations. *Red* and *blue* plots refer to vacuum and air testing conditions, respectively. Current range is 45–100 mA in vacuum and 55–100 mA in air

extracted from the measured frequency response of the 61-MHz resonator in Fig. 4a. The resonator quality factor ranges from 12,000 to 14,000 under vacuum and drops to 6,000–8,000 under atmospheric pressure. A large-frequency tuning range is demonstrated for this resonator by changing its DC bias current. This is mainly due to the raising temperature of the resonating body, especially its extensional beams that provide most of the structural stiffness in the in-plane extensional mode. As expected, as the DC bias current and consequently resonator motional conductance at resonance (g_m) increase, due to higher static temperature and softening of the structural material, the resonance frequency decreases. Despite having high-quality factors and relatively large motional conductance, the large current requirement and power consumption for the resonator in Fig. 5 could be a major drawback against using such electronic components.

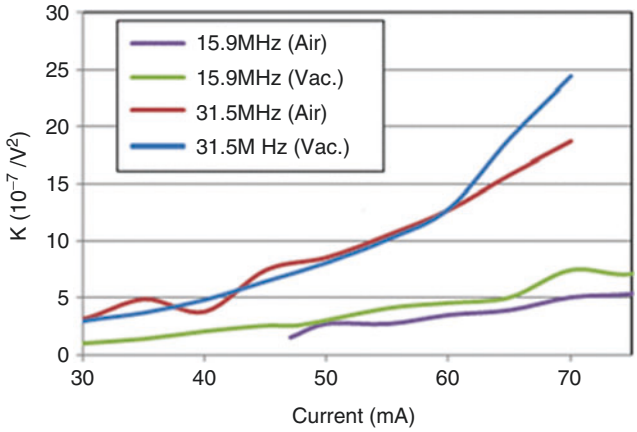


Figure 6 shows a few frequency response plots measured for a 30.5-MHz resonator with narrowed down actuator beams (~750 nm wide) similar to the structure in Fig. 4b. Submicron actuator beams can be achieved by controlled oxidation of the silicon structures followed by oxide removal leaving behind a narrower beam. Because of its much thinner actuators, a resonance peak can be detected for this resonator with currents as low as 43 μA translating into DC power consumptions as low as a 3.6 μW. At the DC bias current of 720 μA (DC power of 1 mW), motional conductance of 44 μA/V was measured for this resonator (Fig. 6b). Maximum currents tolerable for such narrow actuator beams are in the few mA range leading to motional conductances as high as 0.23 mA/V in air with Q of 9,200 (Fig. 6c). According to the derived model, much higher motional conductances can be achieved by consuming the same amount of power using lower-resistivity structural material allowing higher bias currents.

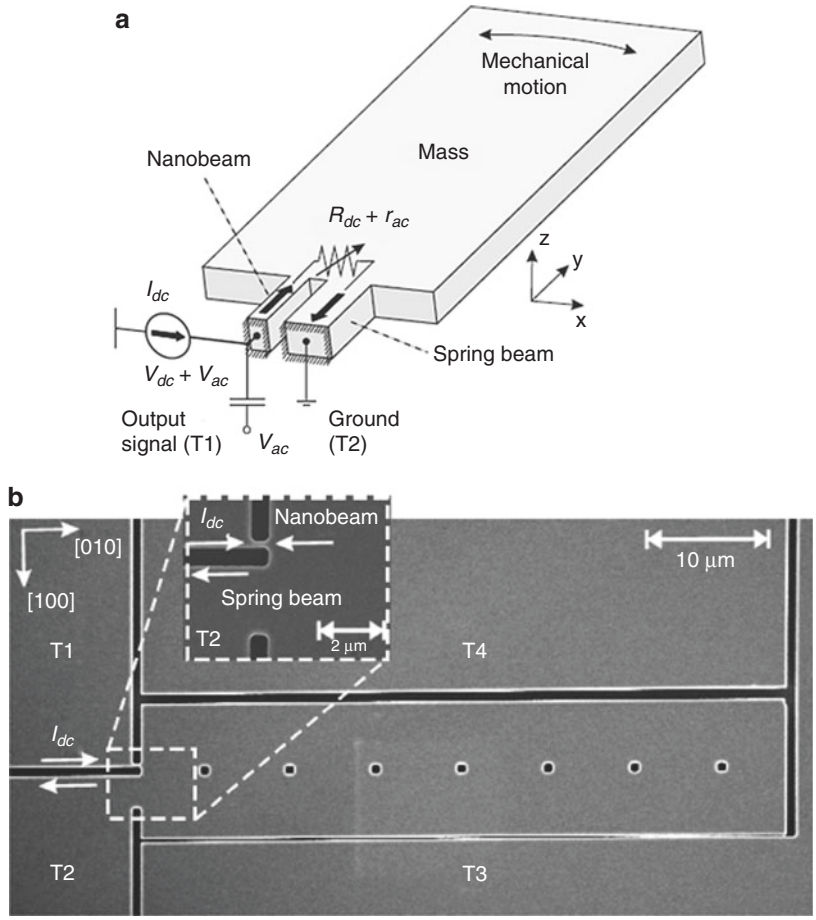
To verify better suitability of thermal actuation for higher-frequency resonators with smaller

Thermally Actuated Silicon Resonators, Fig. 6 Measured motional conductance frequency plots for a 3-μm-thick 30.5-MHz IBAR. The vertical axis in the plots shows the motional conductance of the resonators (g_m) in dB with respect to 50-Ω network analyzer terminations. Due to its very narrow (750 nm wide) actuator beams, clear resonance peaks with motional conductance in the tens of μA/V have been measured for this resonator with sub-mA DC bias currents (sub-mW power consumption)

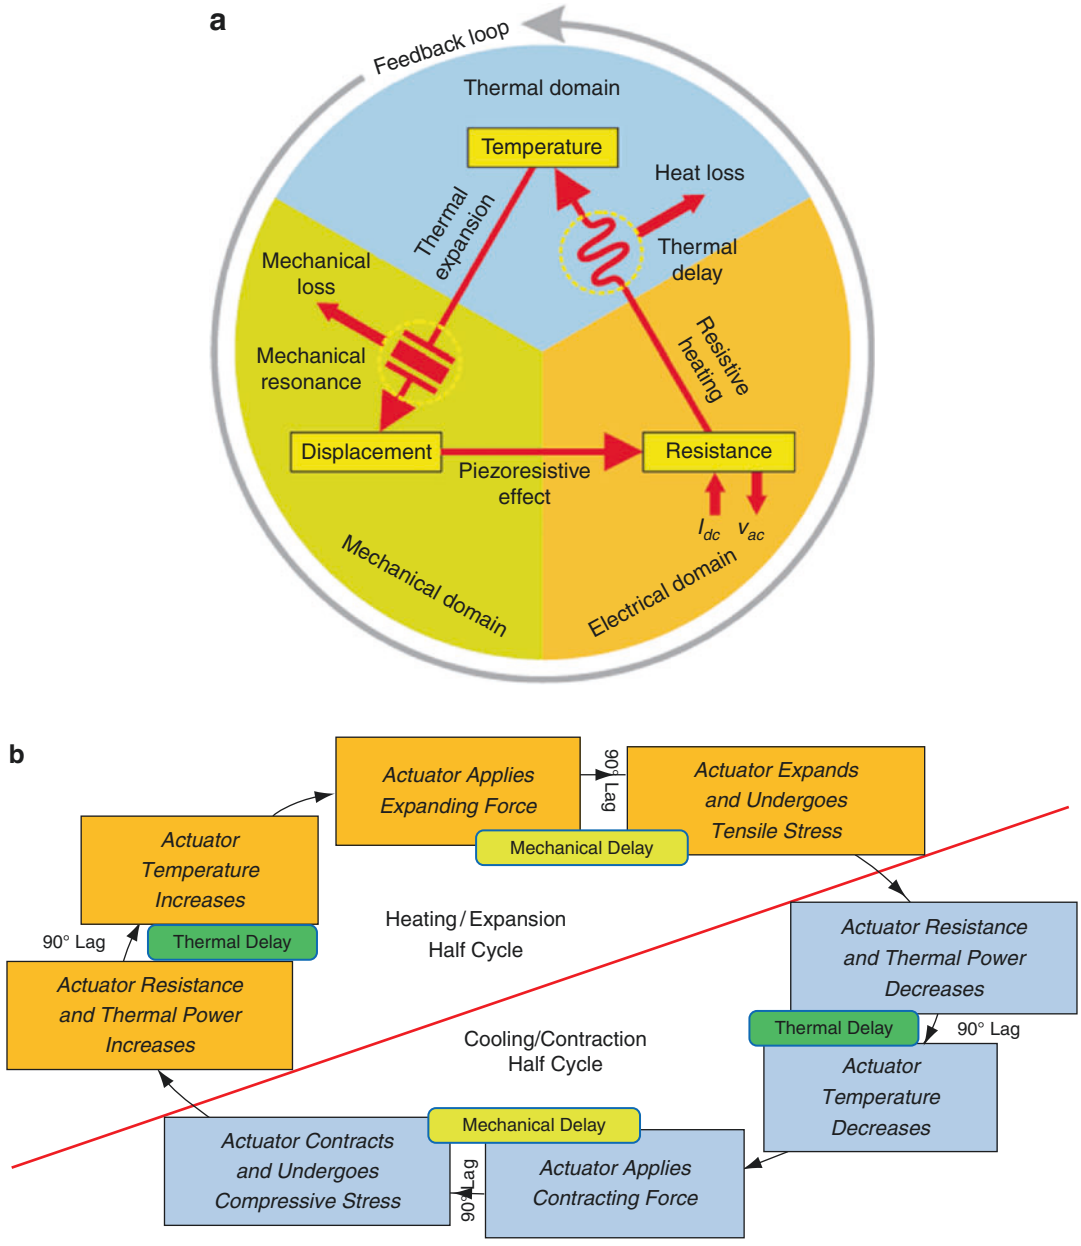
dimensions, Fig. 7 shows the measured transduction figure of merit for two thermal-piezoresistive resonators with the effect of quality factor taken out $\left(K = \frac{F.M.}{Q}\right)$ under different bias currents. The two resonators are fabricated on the same substrate and have similar horizontal dimension aspect ratios with the 32-MHz resonator being a 2X-scaled-down version of the 16-MHz resonator. As expected based on the previously discussed scaling trend and the derived model, the higher-frequency resonator has a higher transduction figure of merit. This further confirms that thermal actuation is not only a potentially suitable actuation mechanism for high-frequency applications, but also it can provide higher performances at higher rather than lower frequencies. Therefore, much higher transduction efficiencies are expected to be achievable for higher-frequency versions of such devices with resonant frequencies in the hundreds of megahertz and even GHz range, provided that the dimensions can be scaled down proportionally into the nanoscale. The derived resonator model backed up by measurement results shows that with sub-100-nm actuator width and submicron actuator length, g_m as high as 1 mA/V can be achieved for thermal-piezoresistive silicon IBARs with resonant frequencies in the gigahertz range with power consumptions as low as a few microwatts [10]. This is not including the giant piezoresistive effect in crystalline silicon that could further improve this by over an order of magnitude [14].



Thermally Actuated Silicon Resonators, Fig. 7 Extracted transduction figure of merit (K) for two IBARs versus resonator bias current. The higher-frequency (31.5 MHz) resonator, which is a 2X-scaled-down version of the 15.9-MHz resonator, has a higher transduction strength. The increase in the transduction figure of merit with bias current, which is not directly predicted by the derivations, is expected to be a result of the effect of increased static temperature at higher currents on different material properties, for example, increased thermal expansion coefficient at higher temperatures

Self-Sustained Thermal-Piezoresistive Oscillators

Generally, in order to implement an electronic oscillator with a mechanical resonator as its frequency reference, the resonator needs to be engaged in a positive feedback loop consisting of amplifying circuitry with appropriate phase shift. One of the interesting aspects of the thermal-piezoresistive mechanical resonators that use the same elements as both thermal actuators and piezoresistive sensors is the internal feedback mechanism formed between thermal actuation force and piezoresistivity. This feedback results from the fact that the piezoresistive motional current of the structure that passes through the thermal actuators also acts as an excitation for the resonator by affecting the ohmic loss in the actuator beams. Depending on the sign of the structural material piezoresistive coefficient, electrical terminations of the resonator, and the phase shift resulting from thermal delays, this could act as a positive feedback stimulating mechanical vibrations or a negative feedback limiting vibration amplitude of the structure or reducing Brownian motion of the structure at that specific frequency (refrigeration [11]). For example, ohmic power generation in a thermal actuator biased with a constant current (terminated with a large electrical resistance) decreases if the actuator is subjected to tensile stress, due to the decreased electrical resistance. As part of a resonant structure, when such actuator is fully stretched and is about to start to compress, its decreased ohmic power and resulting cooling assist the actuator going into compression. In the same manner, after compression of the actuator, increased ohmic power generation helps its expansion via raising its temperature. Mechanical and thermal time delays play a key role here in determining whether the feedback has an amplifying or attenuating effect.



It was demonstrated by researchers at NXP Semiconductors [11] that such positive feedback can be strong enough to initiate and maintain mechanical oscillations upon providing a DC electrical power source to the structure without the need for any external AC stimulation. Figure 8 shows the scanning electron micrograph of the suspended N-type single crystalline silicon structure for which such effect was demonstrated for the first time [11]. The structure is made of N-type silicon because N-type silicon has a negative longitudinal piezoresistive coefficient, which is required for such oscillation under constant current conditions.

Thermally Actuated Silicon Resonators, Fig. 8 Schematic view and SEM top view of a fully micromechanical crystalline silicon oscillator. To operate the oscillator, a DC is applied between the terminals of the device, and the output AC voltage resulting from the resonator's spontaneous mechanical vibrations is measured. The inset shows a zoomed-in view of the nanobeam actuator and the wide beam providing the flexural stiffness of the structure. Output electrical signal amplitude of 27 mV with frequency of 1.26 MHz was measured for this resonator when biased with a current of 1.2 mA (1.2-mW power consumption) under vacuum

Figure 9 schematically shows the feedback loop and the transduction mechanisms connecting the three physical parameters: displacement (x), temperature (T_{ac}), and voltage (v_{ac}) leading to self-sustained oscillation [11]. As shown in Fig. 9b, physically, this can be explained as follows: upon application of a DC bias, the thermal actuator heats up and expands, pushing the mass to the right side. Due to the mass (inertia) of the plate, the nanobeam actuator experiences an overexpansion after pushing the mass and undergoes tensile stress. The negative piezoresistive coefficient turns the tensile stress into reduced electrical resistance for the nanobeam. When biased with a constant DC bias current, this means reduced ohmic power in the actuator forcing it to contract. After structural overcontraction (due to the mass of the plate), the actuator will be under compressive stress and will have increased electrical resistance. This translates into a higher thermal power forcing the structure to expand again. If the resulting driving force (due to heating and cooling) in each cycle is large enough to compensate for mechanical losses of the structure, the same sequence is repeated over and over in a self-sustained manner, and the vibration amplitude keeps increasing until it is limited by nonlinearities. The 90° phase lags (Fig. 9b) resulting from the mechanical and thermal response delays lead to a perfect timing for the abovementioned sequence of physical phenomena to continue.

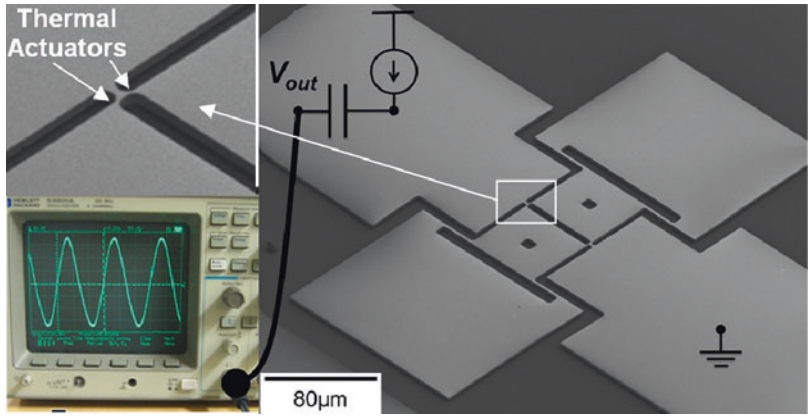


Figure 10 shows the SEM view and time response of an extensional mode 6.7-MHz self-sustained thermal-piezoresistive oscillator operating based on the same principle. Such structure is

Thermally Actuated Silicon Resonators, Fig. 9 (**a**) Schematic demonstration of the feedback loop and the transduction mechanisms linking the thermal, mechanical, and electrical parameters to each other. Thermal delay and mechanical resonance provide the required phase shift for self-sustained oscillation. (**b**) Sequence of phenomena causing an internal positive feedback loop in thermal-piezoresistive resonators biased with a constant current that lead to self-sustained oscillation

a derivative of the IBAR structures discussed in the previous sections with relatively larger plates. It operates in an in-plane resonant mode with its two plates moving back and forth in opposite directions and the extensional actuator beams being stretched and compressed periodically. Extensional resonant modes can provide higher frequencies as well as higher-quality factors both

T

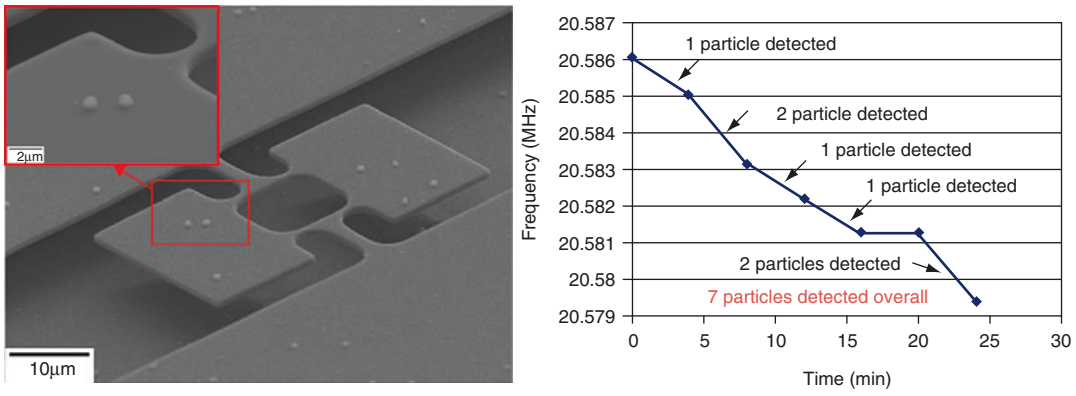
Thermally Actuated Silicon Resonators, Fig. 10 SEM view and output signal of a 6.6-MHz single crystalline silicon thermal-piezoresistive dual-plate resonator capable of self-sustained oscillation. Only a DC bias current of 3.0 mA is being applied to the resonator, and the resonator is operating in air. The power consumption of the oscillator is about 20 mW, and its output voltage amplitude is 70 mV

under vacuum and in air. Dual plate oscillators with frequencies in the few megahertz range, power consumption of a few to tens of milliwatts, and operating under both vacuum and atmospheric pressure have been demonstrated [12]. The output voltage amplitudes range from tens to hundreds of millivolts.

It can be shown that the requirement for self-sustained oscillation in such devices is that the absolute value of the motional conductance of the resonator becomes larger than the physical static conductance of its actuators. The minimum DC power required to achieve this condition is

$$P_{dc_{\mathrm{Min}}} = \frac{KLC_{th}\omega_m}{4\alpha E^2|\pi_l|QA}. \tag{4}$$

Again, the key to having low power consumption is scaling down the resonator dimensions that reduce the power requirement with a square relationship leading to significantly lower power consumption for scaled-down versions of such devices while having higher oscillation frequencies.



Another area where such devices need significant improvement is the output voltage amplitude, which is a small fraction of the DC voltage across the resonator (typically 0.01–0.1). What limits the oscillation amplitude of the resonators is nonlinearities (most likely mechanical nonlinearities) limiting the feedback loop gain to unity after reaching a certain amplitude. Therefore, a thorough study on minimization of the mechanical nonlinearities can possibly lead to fully micromechanical oscillators with higher output amplitudes. Piezoresistive coefficient of the structural material is another parameter that has a direct effect on the output voltage amplitude of such oscillators. With the same mechanical vibration amplitude and bias current, higher piezoresistive coefficient leads to proportionally higher output voltage amplitude. This further shows the significance of fabricating such devices with sub-100-nm actuator width taking advantage of the huge piezoresistivity observed in silicon nanowires [14] to increase the output amplitude.

Elimination of the sustaining amplifier by the self-sustained fully micromechanical oscillators described here might not be a significant improvement as electronics can be cheap and small and readily necessary to support other functions within the systems employing the electromechanical oscillators. However, for applications where large oscillator arrays are required, for example, sensors arrays, elimination of the amplifiers and the associated interconnections could be highly beneficial.

Thermal-Piezoresistive Resonant Mass Sensors

Electromechanical resonators have great potential as highly sensitive mass sensors for gas, biomolecular, or particulate sensing applications. For such sensory applications where the resonator has to be in contact with the surrounding environment, resonator robustness becomes a critical factor. This makes thermal-piezoresistive resonators made of a single monolithic structural material a great candidate for mass sensing applications. Especially for particulate sensing for air quality monitoring or environmental research, thermal-piezoresistive resonators seem to be the most suitable choice [7, 15]. Air-gap capacitive resonators are extremely vulnerable to contaminants or particulates entering and getting stuck in their nanogaps making it practically impossible to use them as particulate sensors. For piezoelectric resonators, it is very hard (if not impossible) to have a uniform mass sensitivity all over the resonator sensing surface or at least a large portion of it. This is due to the fact that such devices generally operate in their bulk resonance modes resulting in different vibration amplitudes and therefore different effective resonator mass at different locations on the surface. Uniform mass sensitivity is a necessity when targeting mass measurement and counting of individual particles. Furthermore, metallic and piezoelectric thin films in a piezoelectric resonant structure are typically less robust than a monolithic crystalline structure, especially when subjected to impact by high-speed airborne particles.

Thermal-piezoresistive resonators can continue to work flawlessly with tens to thousands of particles deposited on them [7]. For the IBAR and dual-plate structures, the vibrating counter masses (plates) act as rigid bodies having almost the same vibration amplitude on their whole surface. This allows measuring the mass of individual deposited particles as they arrive providing the overall count and mass distribution of particles present in air samples. There is still the possibility of particles landing on the actuator beams and experiencing different mass sensitivities. However, the surface area of the actuator beams is typically much smaller than that of the plates making that probability small enough for the resulting error to be within the acceptable range for most applications. Furthermore, the miniaturization capability of thermal-piezoresistive resonators into the nanoscale allows much higher mass sensitivities to be achievable enabling detection and mass measurement of individual nanoparticles not feasible using the larger capacitive or piezoelectric resonant devices. Figure 11 shows the SEM view of an IBAR exposed to a flow of artificially generated airborne particles

Thermally Actuated Silicon Resonators, Fig. 11 SEM view of a 20.5-MHz IBAR with seven artificially generated 1-μm diameter airborne particles deposited on it. The changes in the measured resonance frequency versus time confirm the arrival of seven particles. There are five frequency reduction steps, of which two have a slope twice that of the rest which show that two particles have been deposited on the device during those periods

with the same size and composition along with its measured resonance frequency during the deposition [15]. The effect of arrival of each particle on the resonance frequency is clearly detectable and the same for all the particles. This confirms uniform mass sensitivity on the resonator sensing plates.

Definition

A micromanipulation system is a robotic device which is used to physically interact with a sample under a microscope, where a level of precision of movement is necessary that cannot be achieved by the unaided human hand.

It is well known that pick-and-place is very important for 3-D microstructure fabrication since it is an indispensable step in the bottom-up building process. The main difficulty in sufficiently completing such pick-and-place manipulation at this scale lies in fabricating a very sharp end-effector that is capable of smoothly releasing microobjects deposited on the substrate. Moreover, this end-effector has to provide enough grasping force to overcome strong adhesion forces [1–3] from the substrate as well as being capable of sensing and controlling interactions with the microobjects. Furthermore, compared with the manipulation of larger microobjects under an optical microscope, visual feedback at several microns more suffers from the shorter depth of focus and the narrower field of view of lenses with high magnifications, although different schemes or algorithms have been introduced on techniques of autofocusing [4, 5] and extending focus depth [7]. Compared with vision-based automated 2-D micromanipulation, automated 3-D micromanipulation at the scale of several microns to submicron scale is more challenging because of optical microscope's resolution limit (typically 200 nm). Moreover, additional manipulation feedback is needed that is beyond the capability of optical vision, such as in the cases of vertical contact detection along the optical axis or manipulation obstructed by opaque components. Therefore, multi-feedback is of vital importance to achieve such accurate and stable 3-D micromanipulation at the scale of several microns to submicron scale.

Pick-and-place nanomanipulation is also a promising technique in 3D nanostructure fabrication since it is an indispensable step in the bottom-up building process. It can overcome limitations of bottom-up and top-down methods of nanomanufacturing and further combine advantages of these two methods to build complex 3D

3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 1 (**a**) A photo of the AFM-FRS on the configuration for nanoscale pick-and-place manipulation. (**b**) A SEM image of the cantilever fabricated with a protruding tip

nanostructures. In literature, nanostructures have been manipulated, assembled, and characterized by integrating nanomanipulators or nanogrippers into scanning electron microscopes (SEM) and transmission electron microscopes (TEM) [12–16]. Both the SEM and the TEM provide a vacuum environment where the van der Waals force is the main force to be overcome during the manipulation. 3D nanomanipulation could be also achieved with optical tweezers in liquid, where the adhesion forces are greatly reduced [17–19]. However, the pick-and-place nanomanipulation in air is still a great challenge due to the presence of strong adhesion forces, including van der Waals, electrostatic and capillary forces [20]. In this case, the main difficulties in achieving the 3D nanomanipulation are fabricating sharp end-effectors with enough grasping force, as well as capabilities of force sensing while controlling interactions between the nanoobject and the tool or the substrate.

In this entry, a concept is presented to make a prototype of an AFM-based flexible robotic system (FRS) which is equipped with two collaborative cantilevers. By reconfiguring the modular hardware and software of the AFM-FRS, different configurations can be obtained. With different manipulation strategies and protocols, two of the configurations can be respectively used to complete pick-and-place manipulations from the microscale of several microns to the nanoscale that are still challenges.

This entry is organized as follows. Section I introduces the prototype and experimental setup of the AFM-FRS. In subsection II and III, pick-and-place manipulation of microspheres and nanowires for building 3-D micro/nano structures are performed using the AFM-FRS.

AFM-Based Flexible Robotic System

AFM-FRS Setup

Figure 1a shows the AFM-FRS system setup, which is in the configuration for nanoscale pick-and-place. The system is equipped with an optical microscope and two sets of modules commonly used in a conventional AFM, mainly including two AFM cantilevers (namely, tip I and tip II, ATEC-FM Nanosensors, see Fig. 1b), two sets of nanopositioning devices and optical levers. The motion modules include an open-loop *X-Y-Z* piezoscanner (PI P-153.10H), an *X-Y-Z* closed-loop nanostage (MCL Nano-Bio2M on the *X*- and 7-axis, PI P-732. ZC on the Z-axis), an *X-Y-Z* motorized stage, and an *X-Y-Z* manual stage. Detailed specifications of the motion modules are summarized in Table 1. Figure 1c shows an optical microscope image of the collaborating tips in microsphere grasping mode.

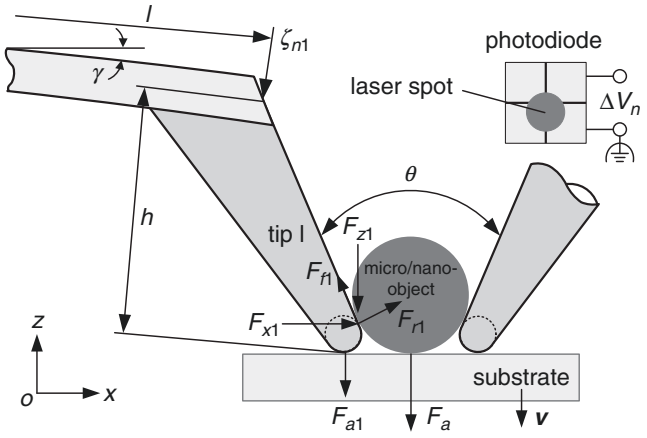
A data acquisition (NI 6289) card is used for high-speed (500 ~ 800 Hz of sampling frequency for force and 600 kHz for amplitude) capture of the photodiode voltage output to estimate deflections on both tips induced by force loading or resonant oscillation. A multi-thread planning and control system based on the C^{++} is developed for AFM image scan and two-tip coordination control during manipulation. This control system enables programming of complex tasks on the highly distributed reconfigurable system.

Force Sensing During Pick-and-Place

Figure 2 shows a schematic diagram of the nanotip gripper for the micro/nanoscale pick-and-place operation that has a clamping angle $\theta \approx 44^\circ$ micro/nanoscale pickup manipulation, for instance, interactive forces applied on tip I include repulsive forces F_{r1}, friction forces F_{f1}, and adhesive forces F_{a1}.

The forces applied on tip I can be resolved into two components on the *X*-axis and the *Z*-axis in the defined frame, namely, F_{x1} and F_{z1}, respectively. F_{x1} is the clamping force that holds the micro/nanoobject. F_{z1} is the pickup force that balances adhesion forces from the substrate. To sense the pickup force, it is necessary to know the normal deflection on both cantilevers. The normal deflection ζ_{n1} associated with the normal voltage output of the optical lever on tip I is given by:

$$\zeta_{n1} = \frac{F_{z1}\cos\gamma + F_{x1}\sin\gamma}{k_n} + \frac{F_{z1}\sin\gamma + F_{x1}\cos\gamma}{k_{xz}} \quad (1)$$



where γ is the mounting angle of the cantilever, $kxz = 2lk_n/3\ h$ is the bending stiffness due to the moment applied on the tip end, where h is the tip height. Assuming the magnitude of F_{z1} and F_{x1} are of the same order, contributions from the Fx_1 to the normal deflection of tip I are relatively very small since $k_{xz} \gg k_n$ and $\gamma = 5^\circ$. Therefore, the normal deflection induced from F_{z1} is only considered in the following calculations of the adhesion force F_a applied on the micro/nanoobject. Thus, F_{z1} can be simplified by estimating the normal voltage output ΔV_{n1} from the tip I:

$$F_{z1} = \beta_1 \times \Delta V_{nl} \quad (2)$$

where β_1 is the normal force sensitivity of the optical lever. A similar pickup force F_{z2} can be also obtained on Tip II. Before the gripper pulls

3D Micro-/Nanomanipulation with Force Spectroscopy, Table 1 Specifications of each motion module

Actuator	Travel range	Resolution
X-Y-Z piezoscanner	10 × 10 × 10(μm)	Sub-nm
X-Y-Z nanostage	50 × 50 × 10(μm)	0.1 nm
X-Y-Z motorized stage	25 × 25 × 25(mm)	50 nm
X-Y-Z manual stage	5 × 5 × 5(mm)	0.5 μm

3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 2 Schematic diagram of the nanotip gripper and force simulation during the pickup manipulation

T

off the substrate, the adhesion force F_a can be estimated as:

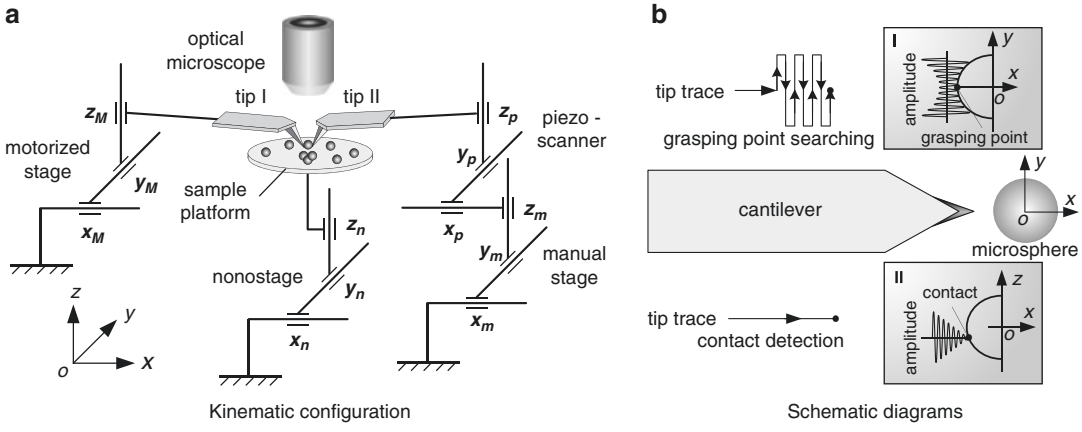
$$F_a = F_{z1} + F_{z2} = \beta_1 \Delta V_{n1} + \beta_2 \Delta V_{n2} - (F_{a1} + F_{a2}) \quad (3)$$

where β_2, ΔV_{n2}, and F_{a2} are respectively the normal force sensitivity, normal voltage output, and adhesive force on tip II. Once the gripper pulls off the substrate, e.g., in the case of nanowire/tube pick-and-place, the adhesion force F_a is estimated as:

$$F_a = F_{z1} + F_{z2} = \beta_1 \Delta V_{n1} + \beta_2 \Delta V_{n2}. \quad (4)$$

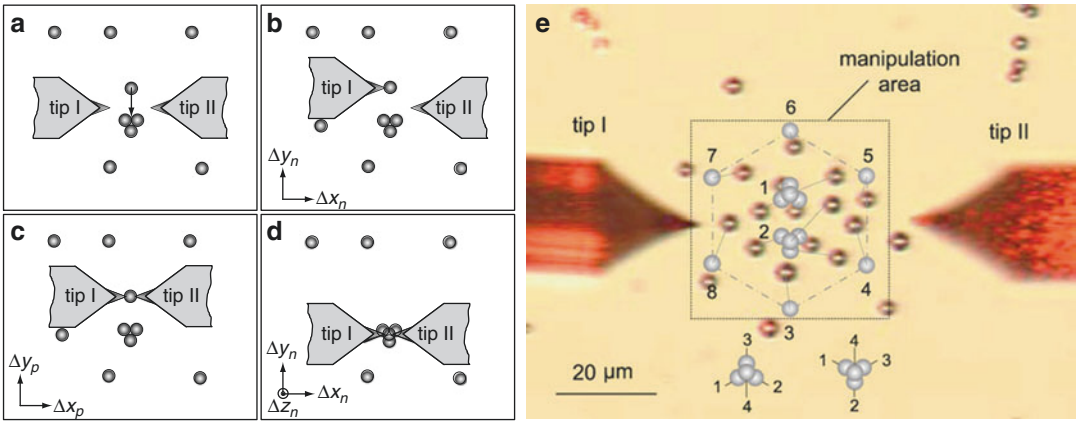
Experimental Results

3-D Micromanipulation Robotic System



System Configuration for 3-D Micromanipulation

As the size of microobjects is reduced to several microns or submicrons, problems will arise with these conventional grippers: (1) Sticking phenomena becomes more severe due to the relatively larger contact area between the gripper and the microobject. (2) The tip diameters of the microfabricated clamping jaws are comparable in size to the microobjects to be grasped. Conventional grippers are not geometrically sharp enough to pick up microobjects of several micrometers deposited on the substrate. Fortunately, the AFM tip has a very tiny apex (typically ~10 nm in radius) with respect to the size of the microobject to be manipulated. Thus, the nanotip gripper can be used to achieve pick-and-place at the scale of several microns since the contact area of the gripper-microobject is much smaller than the microobject-substrate contact. Moreover, real-time force sensing makes the manipulation more controllable.



As shown in Fig. 3, the system configuration for 3-D micromanipulation is reconfigured as follows:

1. For a large manipulation travel range, the nanostage here is used to support the sample platform and transport the microobject during the manipulation.
2. Tip I, immovable during the pick-and-place micromanipulation, is fixed on the motorized stage for coarse positioning.
3. Tip II is actuated by the piezoscanner for gripper opening and closing operations. The piezoscanner is supported by the manual stage for coarse positioning.

Benefiting from AFM-based accurate and stable amplitude feedback of a dithering cantilever, the grasping state can be successfully achieved by the amplitude feedback, with very weak

3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 3 A kinematic configuration and schematic diagrams for 3-D micromanipulation at a scale of several micrometers or grasping point searching (*inset* I) and contact detection (*inset* II) with amplitude feedback of the dithering cantilever

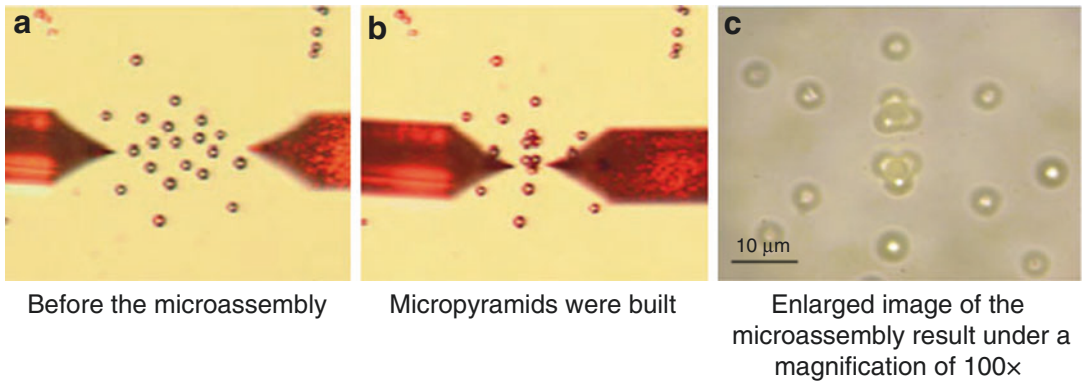
interaction at the nano-Newton scale, protecting the fragile tips and the microobjects from damage during manipulation. As shown in inset I of Fig. 3, the dithering cantilever with its first resonant mode is used to locate grasping points and detect contact. When approaching the microsphere with a separation between the tip and the substrate (typically 500 nm), the tip laterally sweeps the microsphere over the lower part of the microsphere. By this means, the grasping point can be accurately found by locating the minimum amplitude response of each single scan.

From the scheme depicted in inset II of Fig. 3, the amplitude feedback is also used for contact detection. Tip-microsphere contact is detected as the amplitude reduces to a steady value close to zero. As shown in Fig. 4, a protocol for pick-and-place microspheres mainly consists of four steps:

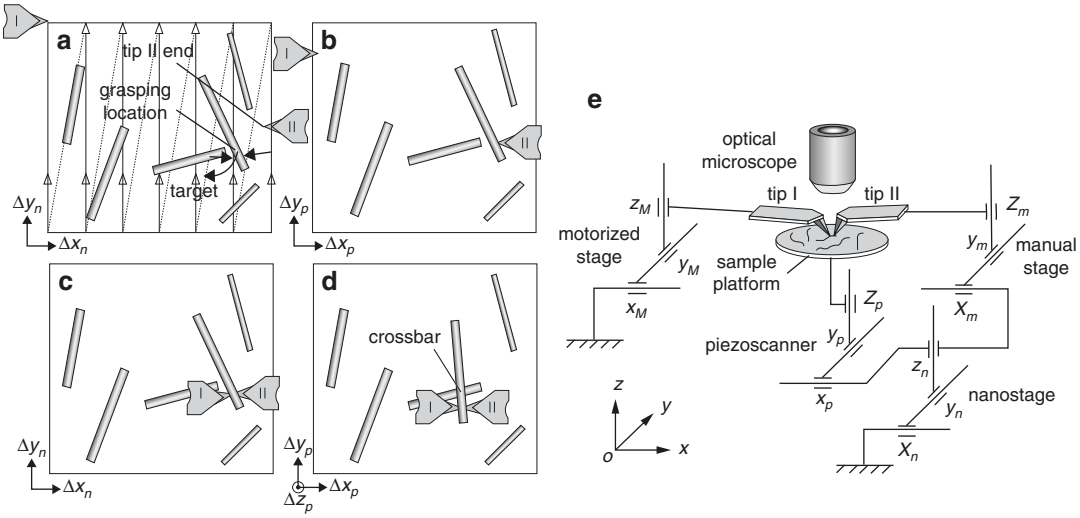


- System initialization and task planning: Each axis of the nanostage and the piezoscanner are set in a proper position, supplying the manipulation with enough travel range on each axis. Then the task is planned in Fig. 4a with a global view of the manipulation area that provides coarse positions of the microspheres and tips.
- Making tip I-microsphere in contact: In Fig. 4b, tip I has started to approach the microsphere by moving the nanostage with amplitude feedback to search for the grasping point and detect contact.
- Forming the gripper: Similarly, tip II approaches the microsphere by moving the piezoscanner. Once tip II and the microsphere are in contact, a nanotip gripper is configured in Fig. 4c for a manipulation.
- Pick-and-place micromanipulation: In Fig. 4d, the microsphere is picked up, transported, and released by moving the nanostage with a proper displacement on each axis that depends on the diameter of the microsphere and its destination. The whole process of 3-D micromanipulation is monitored by real-time force sensing.

3-D Microsphere Assembly

Nylon microspheres with diameter of about 3 ~ 4 μm were manipulated to build 3-D microstructures in experiments. The microspheres were deposited on a freshly cleaned glass slide and then an area of interest was selected under the optical microscope. Figure 4 shows a plan view of the selected area, in which 14 microspheres separated in a 50 μm square frame are going to be manipulated to build two 3-D micropyramids and a regular 2-D hexagon labeled by assembly sequences from 1 to 8. Each pyramid is constructed from four microspheres with two layers and the

3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 5 Experimental results



3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 6 A microassembly result

assembly sequences are shown in the bottom insets for two different arrangements of the pyramids.

Figure 5 shows a result of grasping point searching, in which the dithering tip II laterally sweeps the microsphere within a range of 1.75 μm on the *y*-axis and with a free oscillating amplitude of about 285 nm. Ten different distances to the microsphere were tested from 100 to 10 nm with an interval of 10 nm and, consequently, the grasping point is well located with an accuracy of ±10 nm. Figure 5 shows a full force spectroscopy curve during the pick-and-place of a microsphere deposited on a glass slide with an ambient temperature of 20 °C and relative humidity of 40 %. In this curve, point A represents the start of the pick-and-place, point B the pull-off location of the microsphere-substrate contact, point C nonlinear force restitution due to the tip-microsphere frictions, and point D the snap-in point between the microsphere and the substrate. The force spectroscopy curve is synthesized from force responses on tip I and tip II.

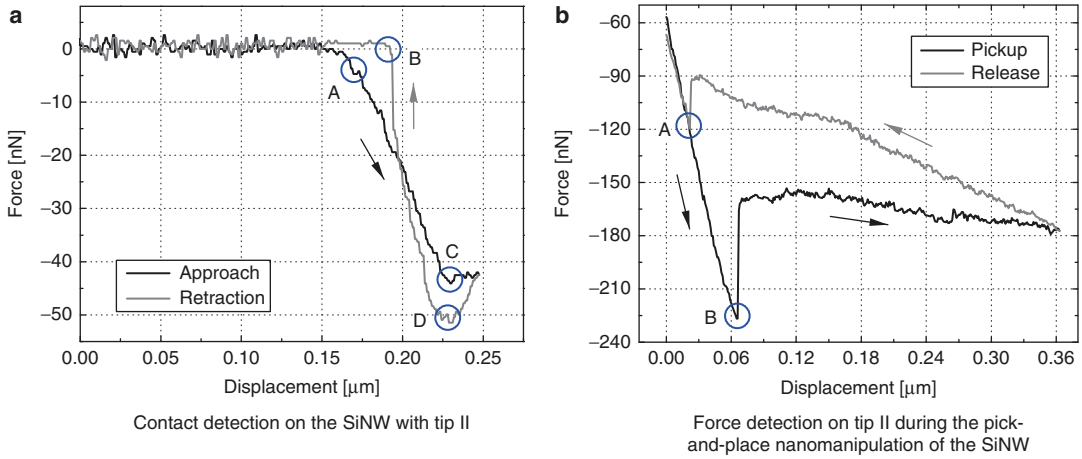
Figure 6 shows an automated microassembly result consisting of two 3-D micropyramids and a 2-D pattern of a regular hexagon. The whole

(**c**) Tip I is in contact with the nanowire, forming a nanotip gripper. (**d**) Pick up and release a nanowire to its target position (**e**) A kinematic configuration of the AFM-RFS for nanoscale pick-and-place

manipulation process was completed in 11 min, so the average manipulation time for each microsphere is about 47 s, which mainly breaks down into about 20 s for microsphere grasping including the grasping point search and contact detection processes using amplitude feedback, 10 ~ 35 s for microsphere release and, the remaining time for transport.

Assembly of the fourth is the key to success in building a micropyramid. During pick-and-place of the fourth microsphere, microscopic vision was firstly used for coarse positioning it target, then the normal force feedback of the gripper was used to detect the vertical contact between the fourth microsphere and other three microspheres on the base. When the contact is established, a small vertical force was applied on the fourth microsphere by moving the nanostage upward and it will adjust to contact with all the base microspheres.

3-D Nanomanipulation Robotic System



System Configuration for 3-D Nanomanipulation

Compared with the 3-D micromanipulation, tip alignment precision is the key factor in succeeding the nanoscale pick-and-place. Therefore, the closed-loop nanostage is considered in this configuration for accurate tip alignment. As shown in Fig. 7, the system configuration for 3-D nanomanipulation is reconfigured as follows:

1. The nanostage is used for image scan with tip I.
2. Nanoobjects are supported and transported by the piezoscanner.
3. Tip I, fixed on the motorized stage for coarse positioning, is immovable during the pick-and-place micromanipulation. Before manipulation, cantilever I acts as an image sensor for nanoobject positioning.
4. For accurate gripper alignment between Tip I and Tip II, Tip II is fixed on the nanostage rather than the piezoscanner. Tip II is supported by the manual stage for coarse positioning.

Nanowires and nanotubes are being intensively investigated. Thus, a protocol is developed here for nanowire or nanotube pick-and-place. However, applications can easily be extended to, for example, pick-and-place of nano-rods or nanoparticles dispersed on a substrate.

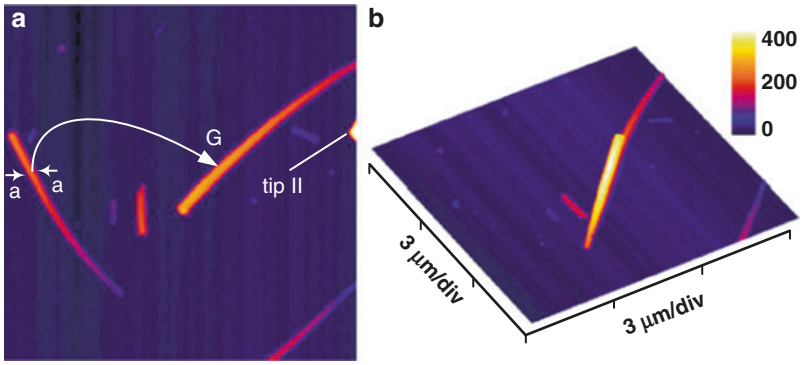
Once the manipulation area is selected under the optical microscope, both the tips are aligned as

3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 8 Contact and force detection

a quasi-gripper above the center of the manipulation area. Each axis of the nanostage and the piezoscanner is initialized at an appropriate position to allow for enough manipulation motion travel.

In this step, tip I is used to fully scan the relevant area obtaining a topographic image that contains nanoobjects to be manipulated and the end of tip II. Figure 7a shows a simulated image that contains the topography of two nanowires and the end of tip II. The image provides the following pick-and-place with relative positions between tip I, tip II and the nanoobjects to be manipulated. However, after a long period image scan, relocating tip II is recommenced to eliminate system's thermal drift.

As shown in Fig. 7b, tip II approaches the nanowire to make contact by moving the *X*-axis of the piezoscanner. A gap (typically ~20 nm above the snap-in boundary) between Tip II and the substrate should be maintained during the approach to enable a negative deflection response in the form of a tiny force applied on tip II, and hence, sensitive detection of the tip-nanowire contact.



Similarly, in Fig. 7c, once tip I is in contact with the nanowire, a nanotip gripper is configured for pick-and-place manipulation of the nanowire.

The nanotip gripper in this step is used to pick up, transport, and release the nanowire to its target position by moving the piezoscanner on the *X*, *Y*, or *Z*-axis. The displacement on each axis depends on the dimensions of the nanowire and the location of the destination. Figure 7d shows a simulated post-manipulation image, in which a nanowire crossbar is built. The complete pick-and-place procedure is monitored by force sensing.

Pick-and-Place Nanomanipulation

In experiments, silicon nanowires (SiNWs) were deposited on a freshly cleaned silicon wafer coated with 300 nm silicon dioxide. AFM images show that the SiNWs have a taper shape and have diameters of 25 nm (top), ~200 nm (root), and lengths of about 4 ~ 7 μm.

Figure 8 shows an example of the contact detection with tip II: Point A and point C are where the tip contacts with the SiNW and the Si substrate, respectively; Point B and point D are where the tip breaks the contact with the Si substrate and the SiNW, respectively. Figure 8 shows a curve of the peeling force spectroscopy on tip II for the pick-and-place manipulation of the SiNW: point A and point B are where the tip snaps in and pulls off the Si substrate, respectively. The shape of curve of the force responses on tip I are similar except for the force magnitude due to different force sensitivities on each tip and uneven grasping due to asymmetric alignment of the SiNW relative to the grasping direction. This force spectroscopy during the pickup operation shows stable grasping for further SiNW transport.

3D Micro-/Nanomanipulation with Force Spectroscopy, Fig. 9 Pick-and-place results of the SiNWs. (**a**) A pre-scanned image. In which a–a and G are the grasping location and the target position, respectively. (**b**) A post-manipulation image verifies that the manipulated SiNW is piled upon another nanowire deposited on the Si substrate

Figure 9 shows an experimental result of 3-D SiNW manipulation. A prescanned image (9 × 9 µm) is shown in Fig. 9a, which includes the topographic image of SiNWs and the local image of tip II. A grasping location of the nanowire to be manipulated is marked with a–a, where the SiNW has a height of 160 nm. Figure 9b is a post-manipulation image. It can be seen that the SiNW has been successfully transported and piled onto another SiNW. The manipulation procedure is described as follows. Once the SiNW was reliably grasped, the piezoscanner moved down 560 nm at a velocity of 80 nm/s. In this step, the SiNW was transported a distance of 4.4 µm along the *X*-axis at a velocity of 120 nm/s and 0.12 µm along the *Y*-axis at a lower velocity of 3.3 nm/s. In the releasing step, the piezoscanner moved up at a velocity of 100 nm/s. As tip II was slightly bent upward leading to a positive response of 0.015 V, tip I and tip II were separated by moving both the nanostage and the piezoscanner on the *X*-axis to release the SiNW from the nanotip gripper.

Conclusion and Future Directions

A flexible robotic system developed for multi-scale manipulation and assembly from nanoscale to microscale is presented. This system is based on the principle of atomic force microscopy and comprises two individually functionalized cantilevers. After reconfiguration, the robotic system could be used for pick-and-place manipulation from nanoscale to the scale of several micrometers. Flexibilities and manipulation capabilities of the developed system are validated by pick-and-place manipulation of microspheres and silicon nanowires to build three-dimensional micro/nanostructures in ambient conditions. Complicated micro/nano manipulation and assembly can be reliably and efficiently performed using the proposed flexible robotic system. 3-D nanomanipulation methods are indispensible for heterogeneous integration of complex nanodevices. Serial nanomanipulation systems could only enable low-volume prototyping applications. However, high-volume and high-speed nanomanipulation systems are indispensable for future nanotechnology products. Therefore, autonomous and massively parallel AFM systems are required.

Definition

The tight-binding (TB) method [1] refers to both a theoretical formalism and a practical procedure for the calculation of the single-particle electronic structure of solid-state systems. The essence of the method is the representation of the energy eigenvalue problem in a basis of atomic-like states. Although it can be formulated as an exact method, its most extended use is the so-called semiempirical version. This version is based on (a) several plausible and well-controlled approximations, (b) the judicious simplification of the problem taking into account the symmetry of the system, and (c) finally, the consideration of the remaining Hamiltonian matrix elements as parameters to be fitted against reliable experimental or theoretical data. Although designed originally for bulk systems, it can be easily adapted to the calculation of the electronic structure of nanostructures. The TB calculations permit to investigate phenomena at an atomic scale hardly accessible by other techniques, thus emerging as a fundamental tool for addressing open issues regarding nanostructured systems. Among them, the class of systems called nanowires (NWs) [2] is particularly interesting. For the purposes of this essay, nanowires must be understood as one-dimensional (1D) free-standing single-crystal structures formed by bottom-up synthesis, with diameters of a few to tens of nanometers and lengths of tens of nanometers to tens of microns. They have received much attention since, by virtue of its large surface-to-volume ratio, they exhibit properties that are interesting for the applications in fields such as electronics, photonics, sensors, and the life sciences.

Foundations of the Tight-Binding Method

The tight-binding (TB) methodology provides a systematic approach to the calculation of the electronic structure of multiatom systems, from molecules to macroscopic bulk solids, passing by intermediate systems, such as atomic or molecular wires, nanostructures, and in particular nanowires. In general terms, the goal is to solve for the single-particle energy spectrum determined by the mean-field potential $V(\boldsymbol{r})$ associated to a system of atoms located at positions $\boldsymbol{R}_I$. In order to do so, one must solve the Schrödinger equation:

$$H\,\Psi(\boldsymbol{r}) \;=\; [\,T \;+V(\boldsymbol{r})\,]\,\Psi(\boldsymbol{r}) = \;E\,\Psi(\boldsymbol{r}). \quad (1)$$

The driving concept behind the TB method, introduced by Felix Bloch already in 1928 [3], is the attempt at solving the eigenvalue problem (1) by expanding $\Psi(\boldsymbol{r})$ as a linear combination in terms of a complete basis of orbitals $\psi_{\boldsymbol{R}_I,a}(\boldsymbol{r})$ localized around the atomic sites $\boldsymbol{R}_I$. These orbitals can correspond to some reference atomic problem or simply have been chosen by its convenient mathematical form. In the following, we call them atomic-like orbitals irrespective if they carry or not any physical meaning. The label a contains the necessary information to fully specify the orbital, and in particular, it specifies its symmetry properties.

The potential V in Eq. 1 contains the interaction of the electron with the system of nuclei and the best possible mean-field account of the electron-electron interaction effects. One reasonable starting point would be the so-called ab initio GW approximation. In practice, this complicated unknown potential is further approximated at various levels, leading, e.g., to Kohn–Sham, Hartree–Fock, and Hartree potentials. In principle, these potentials and the corresponding eigenfunctions must be solved self-consistently.

Rigorously speaking, one should take a complete infinite set of orbitals on every atomic site starting from the lowest one. However, the single-particle states relevant for most physical and chemical properties are those with energies in the neighborhood of the Fermi energy or around the fundamental bandgap. Therefore, many approaches to the electronic structure introduce the so-called frozen-core approximation, in which the core (nucleus together with inner closed electronic shells) is represented by a pseudopotential. In the context of the TB method, this allows to select a truncated minimal set of orbitals on each atomic site, which is expected to be sufficient for an

accurate description of the highest occupied and lowest unoccupied states of the system. In virtually all implementations of the TB method, one works within the frozen-core approximation with a finite basis of atomic-like orbitals.

Since most of the applications of the TB method to nanostructures are based on their bulk counterpart, it is convenient to first review the TB method for infinite crystalline systems. In this case, the method proceeds in a special way to take advantage of the Bloch theorem [3, 4]. First, in a crystal, the atomic sites must be relabeled as $\boldsymbol{R}_l \rightarrow \boldsymbol{R}_n + \boldsymbol{d}_\alpha$, where $\boldsymbol{R}_n$ points to the lattice site labeled by integer numbers abbreviated as n and $\boldsymbol{d}_\alpha$ is the position of atom of type α within the primitive unit cell. Next, it is convenient to construct, for each orbital a associated to atom α, the following function, called Bloch sum:

$$\chi_{\alpha,a}^{(\boldsymbol{k})}(\boldsymbol{r}) = \sqrt{\frac{\Omega_c}{(2\pi)^3}} \sum_{\boldsymbol{R}_n} e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_n + \boldsymbol{d}_\alpha)}\, \psi_{\boldsymbol{R}_n,\alpha,a}(\boldsymbol{r}), \tag{2}$$

where the wavevector $\boldsymbol{k}$ runs over the Brillouin zone and Ω_c is the volume of the unit cell. The Bloch sums satisfy the Bloch theorem and therefore are best suited for an expansion of the crystal states. It is convenient to first introduce the composite label $j = (\alpha, a)$ and then write the energy eigenfunction $\Psi_{\boldsymbol{k}}(\boldsymbol{r})$ as a linear combination of all the Bloch sums (2), with coefficients $C_j^{(\boldsymbol{k})}$ to be determined:

$$\Psi_{\boldsymbol{k}}(\boldsymbol{r}) = \sum_j C_j^{(\boldsymbol{k})}\, \chi_j^{(\boldsymbol{k})}(\boldsymbol{r}). \tag{3}$$

The insertion of ansatz (3) into the original eigenvalue problem (1) leads to the generalized matrix eigenvalue problem:

$$\sum_{j'} \left[H_{jj'}^{(\boldsymbol{k})} - E(\boldsymbol{k}) S_{jj'}^{(\boldsymbol{k})} \right] C_{j'}^{(\boldsymbol{k})} = 0, \tag{4}$$

where the Hamiltonian matrix elements are given by

$$H_{jj'}^{(\boldsymbol{k})} = \sum_{\boldsymbol{R}_{n'}} e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_{n'} + \boldsymbol{d}_{\alpha'} - \boldsymbol{d}_\alpha)}\, H_{0,j;\boldsymbol{R}_{n'},j'}, \tag{5a}$$

$$H_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'} = \int \psi_{\boldsymbol{R}_n,j}^*(\boldsymbol{r})\, H\, \psi_{\boldsymbol{R}_{n'},j'}(\boldsymbol{r})\, d^3\boldsymbol{r}, \tag{5b}$$

and the overlap matrix elements are given by

$$S_{jj'}^{(\boldsymbol{k})} = \sum_{\boldsymbol{R}_{n'}} e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_{n'} + \boldsymbol{d}_{\alpha'} - \boldsymbol{d}_\alpha)}\, S_{0,j;\boldsymbol{R}_{n'},j'}, \tag{6a}$$

$$S_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'} = \int \psi_{\boldsymbol{R}_n,j}^*(\boldsymbol{r})\, \psi_{\boldsymbol{R}_{n'},j'}(\boldsymbol{r})\, d^3\boldsymbol{r}. \tag{6b}$$

In some cases, it is necessary to include into the Hamiltonian H the effects of the spin–orbit interaction. This is almost always done by (i) changing to a basis of spin-orbitals $\psi_{\boldsymbol{R}_n,j} X_\sigma$, where X_σ $(\sigma = \uparrow, \downarrow)$ are the spin up and down spinors, and (ii) adding an atomic spin–orbit interaction energy term $H^{(\mathrm{SO})}$ so that the Hamiltonian matrix elements become [5]

$$H_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'} \rightarrow \delta_{\sigma\sigma'} H_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'} + \left(1 - \delta_{\sigma\sigma'}\right) \delta_{\boldsymbol{R}_n\boldsymbol{R}_{n'}} \delta_{\alpha\alpha'} H_{a,\sigma;a',\sigma'}^{(\mathrm{SO})}.$$

The necessary input to solve Eq. 4 are the matrix elements $H_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'}$ and $S_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'}$ between the atomic-like orbitals. The orbitals associated to a given atomic site are easily forced to be orthonormal, but in general there will be nonzero overlaps $S_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'}$ between orbitals taken on different sites, therefore leading to a generalized eigenvalue problem. This is amenable to numerical solution, but the computational burden is heavier than for standard diagonalization problems. Fortunately, there exist formal procedures that allow, starting from the nonorthogonal orbitals on a given crystalline structure, $\psi_{\boldsymbol{R}_n,j}$, to obtain a set of orthonormal orbitals $\varphi_{\boldsymbol{R}_n,j}$ (Löwdin orbitals) with the same site symmetry as the original ones [6, 7]. The Löwdin orbitals are still localized in the vicinity of the atomic sites, but they happen to have a larger spatial extent than the original ones. When the TB method is

formulated in terms of the Löwdin orthonormal basis, then $S_{\boldsymbol{R}_n,j;\boldsymbol{R}_{n'},j'} \rightarrow \delta_{\boldsymbol{R}_n,\boldsymbol{R}_{n'}}\delta_{j,j'}$ and Eq. 4 reduces to a more manageable standard eigenvalue problem.

The procedure explained contains the core of the TB methodology as applied to bulk systems. In principle, one can obtain at this point, for each $\boldsymbol{k}$, the energies $E(\boldsymbol{k})$ and eigenfunctions $\Psi_{\boldsymbol{k}}(\boldsymbol{r})$ by solving the matrix eigenvalue problem (4). However, this requires the prior knowledge of all the Hamiltonian (and overlap) matrix elements in the basis of atomic-like orbitals, which is still a formidable problem. Therefore, before attempting the solution of Eq. 4, the calculation must be made affordable by incorporating several considerations and approximations that we summarize below [4]:

1) The summations in Eqs. 5a and 6a can be organized as an expansion in neighbor shells of increasing distance. Since it is reasonable to expect that the integrals in Eqs. 5b and 6b will decrease as the interatomic distance increases, a first natural simplification is to truncate that expansion after a certain number of shells. One can then use only nearest neighbors or only nearest and second nearest, etc.
2) Since the system potential V can always be decomposed as a sum involving contributions $V_\alpha(\boldsymbol{r} - \boldsymbol{d}_\alpha)$ centered on the atomic sites, then the Hamiltonian matrix elements are formally classified into one-center, two-center, and also three-center integrals. The three-center integrals are certainly smaller than the two-center integrals, but they are more numerous. Thus, its importance is not clear a priori. Notwithstanding, a popular choice at this point is the so-called two-center approximation, in which all three-center integrals are neglected.
3) In general terms, many of the matrix elements Eq. 5b and Eq. 6b are related through demands of crystal symmetry. These relations can be elucidated with the help of group theory and lead to a reduction of the number of independent matrix elements to consider. This simplification procedure is particularly transparent and effective when the atomic-site potentials are approximated as spherically symmetric, i.e., $V_\alpha(|\boldsymbol{r} - \boldsymbol{d}_\alpha|)$, and the orbitals are chosen to have definite angular momentum. Then the treatment of the multicenter integrals becomes equivalent to the one developed for molecular structure calculations. Slater and Koster [4] showed how to reduce all the two-center integrals, under the above assumptions, to a minimum set of independent matrix elements, which depend solely on the interatomic distance. This represents the maximum possible simplification of the problem.

At this point, one has to decide how to deal with the resulting matrix elements. Their explicit calculation requires the knowledge of the exact potential of the system. As said before, this can be obtained, in a self-consistent manner, from ab initio calculations. This way of proceeding leads to the so-called ab initio tight-binding approach [8, 9]. Alternatively, Slater and Koster proposed in his pioneering work [4] to use the rigorous TB formalism rather as a simple interpolation method. This means that neither the system potential nor the atomic-like orbitals are explicitly calculated, but the few independent matrix elements are instead considered as disposable parameters which are fitted to appropriate targets (experimental data or reliable ab initio calculations). This is the essence of the so-called Slater–Koster semiempirical (or empirical) TB method. It represents a great simplification that leads to an extremely useful approach to understanding electrons in materials. It has been said that "Of all the methods for treating electrons, the Slater-Koster approach provides the simplest, most illuminating picture of electronic states" [1]. The semiempirical TB method has become very popular, and many variants have been devised for the analysis of various properties in many crystals. However, one should remember that, being of semiempirical nature, studies aimed at different aspects of the electronic structure may require different parametrizations even for the same material. One important figure in any implementation of the TB method is the order of the Hamiltonian matrix, $N_H = N_S \times N_{\text{atom}} \times N_{\text{orbital}}$, where N_{atom} is the number of atoms per unit cell, N_{orbital} is the number of

T

orbitals per atom, and N_S is 2 or 1, depending whether spin-orbit is taken into account or not. The TB problem then reduces, for each $\boldsymbol{k}$, to the solution of a matrix eigenvalue problem of order N_H.

A great variety of specific implementations of the TB method are available in the literature. One important feature distinguishing them is the choice of the basis of atomic-like orbitals. Here is a short summary of the most common models found in the literature:

- sp^3 model ($N_{orbital} = 4$): In this model one considers a small basis containing one s orbital and three p orbitals (p_x, p_y, p_z) located on each atom. This is appropriate for a fair description of the upper valence bands and the bandgap energy of direct gap semiconductors. However, they fail to reproduce the conduction band minima of indirect gap semiconductors.
- sp^3s^* model ($N_{orbital} = 5$): It has been found that an effective solution to cure the above deficiencies is to enlarge the sp^3 model by the addition of an auxiliary s^* orbital. The model is now flexible enough to accommodate the possibility of an indirect bandgap but does not reproduce other important features of the conduction band.
- $sp^3d^5s^*$ model ($N_{orbital} = 10$): The inclusion of the full shell of empty d state allows at last a nearly perfect modeling of the relevant part of the band structure, including the lowest conduction bands.

As a summary, a given TB model can thus be characterized by the choice of the basis set of atomic-like orbitals, by its orthogonality or not, by the range of the considered matrix elements (i.e., whether they are kept up to first- , second- , or third-nearest neighbors) and by the enforcement or not of the two-center approximation.

Specifics of Nanowires

The TB method lies at the center of the catalogue of nanostructure simulation methods in both computational cost and reliability. Its main advantages are its atomistic and full Brillouin zone representations. The application of the TB method to nanostructures and in particular to one-dimensional (1D) ones, like nanowires, is relatively straightforward. We concentrate here on free-standing NWs surrounded by vacuum. The procedure to adapt the bulk TB methodology introduced above for the modeling of nanostructures requires first to build the nanostructure geometry. Although there are some treatments of genuine three-dimensional elongated structures, one usually focuses on the study of idealized infinitely long nanowires. The NW axis is conventionally taken as the Z axis. Then one only needs to define the minimal supercell that contains the relevant cross section of the system, since the infinite NW is generated by translating the supercell along the Z axis by the axial lattice vectors $\boldsymbol{Z}_n = n a_z \hat{\mathbf{z}}$, where n is an integer and a_z is the axial lattice parameter. The atoms in the supercell are denoted by μ and located at positions $\boldsymbol{D}_\mu$. A set of atomic-like orbitals $\psi_{\boldsymbol{Z}_n,\mu,a}(\boldsymbol{r})$ is taken on each of these atoms.

On account of the 1D lattice periodicity, the procedure runs parallel to the one presented for bulk systems. First, one has to construct the NW Bloch functions:

$$\chi^{(k_z)}_{\mu,a}(\boldsymbol{r}) = \sqrt{\frac{a_z}{(2\pi)}} \sum_{\boldsymbol{Z}_n} e^{i\,k_z\cdot(\boldsymbol{Z}_n+\boldsymbol{D}_\mu)}\,\psi_{\boldsymbol{Z}_n,\mu,a}(\boldsymbol{r}),$$

where the wavevector $\boldsymbol{k}_z = k_z\hat{\mathbf{z}}$ runs over the one-dimensional Brillouin zone, i.e., $k_z \in \left]-\frac{\pi}{a_z}, +\frac{\pi}{a_z}\right]$. It is convenient to first introduce here the composite label $l = (\mu, a)$ and then write the energy eigenfunction $\Psi_{k_z}(\boldsymbol{r})$ as a linear combination of Bloch sums, with coefficients $c_l^{(k_z)}$ to be determined:

$$\Psi_{k_z}(\boldsymbol{r}) = \sum_l c_l^{(k_z)}\,\chi_l^{(k_z)}(\boldsymbol{r}). \tag{7}$$

When Eq. 7 is inserted into the original eigenvalue problem (1), the following generalized matrix eigenvalue problem results:

$$\sum_{l'}\left[\, h_{ll'}^{(\boldsymbol{k}_z)} \;-\; \epsilon(\boldsymbol{k}_z)\, s_{ll'}^{(\boldsymbol{k}_z)}\right] c_{l'}^{(\boldsymbol{k}_z)} = 0, \qquad (8)$$

where it is seen that the electron energy spectrum is organized into subbands as a function of the wave vector $\boldsymbol{k}_z$. The matrix elements are now given by:

$$h_{ll'}^{(\boldsymbol{k}_z)} = \sum_{\boldsymbol{Z}_{n'}} e^{i\boldsymbol{k}_z\cdot\left(\boldsymbol{Z}_{n'}+\boldsymbol{D}_{\mu'}-\boldsymbol{D}_{\mu}\right)} h_{0,l;\boldsymbol{Z}_{n'},l'}, \qquad (9a)$$

$$h_{\boldsymbol{Z}_n,l;\boldsymbol{Z}_{n'},l'} = \int \psi^*_{\boldsymbol{Z}_n,l}(\boldsymbol{r})\, H\, \psi_{\boldsymbol{Z}_{n'},l'}(\boldsymbol{r})\, d^3\boldsymbol{r}. \qquad (9b)$$

$$s_{ll'}^{(\boldsymbol{k}_z)} = \sum_{\boldsymbol{Z}_{n'}} e^{i\boldsymbol{k}_z\cdot\left(\boldsymbol{Z}_{n'}+\boldsymbol{D}_{\mu'}-\boldsymbol{D}_{\mu}\right)} s_{0,l;\boldsymbol{Z}_{n'},l'}, \qquad (10a)$$

$$s_{\boldsymbol{Z}_n,l;\boldsymbol{Z}_{n'},l'} = \int \psi^*_{\boldsymbol{Z}_n,l}(\boldsymbol{r})\, \psi_{\boldsymbol{Z}_{n'},l'}(\boldsymbol{r})\, d^3\boldsymbol{r}. \qquad (10b)$$

If the interatomic topology and the crystalline structure are retained in the NW structure, the positions of the atoms in the supercell can still be labeled with reference to the underlying bulk lattice. In other words, one can write $\boldsymbol{D}_\mu \rightarrow \boldsymbol{\rho}_m + \boldsymbol{d}_\alpha$, where $\boldsymbol{\rho}_m$ is an in-plane lattice vector pointing to the unit cells in the cross section and m is an integer index, and α indicates the type of the atoms in the unit cell.

The label l can then be rewritten as $l = (\mu, a) = (\boldsymbol{\rho}_m, \alpha, a) \equiv (\boldsymbol{\rho}_m, j)$, and the atomic-like functions and matrix elements become:

$$\psi_{\boldsymbol{Z}_n,l}(\boldsymbol{r}) \rightarrow \psi_{\boldsymbol{Z}_n,\boldsymbol{\rho}_m,j}(\boldsymbol{r}) = \psi_{\boldsymbol{Z}_n+\boldsymbol{\rho}_m,j}(\boldsymbol{r}), \qquad (11)$$

$$h_{\boldsymbol{Z}_n,l;\boldsymbol{Z}_{n'},l'} = \int \psi^*_{\boldsymbol{Z}_n+\boldsymbol{\rho}_m,j}(\boldsymbol{r})\, H\, \psi_{\boldsymbol{Z}_{n'}+\boldsymbol{\rho}_{m'},j'}(\boldsymbol{r})\, d^3\boldsymbol{r}, \qquad (12a)$$

$$s_{\boldsymbol{Z}_n,l;\boldsymbol{Z}_{n'},l'} = \int \psi^*_{\boldsymbol{Z}_n+\boldsymbol{\rho}_m,j}(\boldsymbol{r})\, \psi_{\boldsymbol{Z}_{n'}+\boldsymbol{\rho}_{m'},j'}(\boldsymbol{r})\, d^3\boldsymbol{r}, \qquad (12b)$$

which turn out to be formally similar to the bulk matrix elements, since $\boldsymbol{Z}_n + \boldsymbol{\rho}_m$ is nothing but a three-dimensional lattice vector. However, H corresponds here to the nanowire potential, which is different from the bulk potential, due to the termination of the system at the surface and the possible atomic rearrangements induced by it. A rigorous account of that difference can only be made with ab initio calculations. Although there are a few ab initio tight-binding treatments of small nanowires [10], the application of the TB method to nanowires is still dominated by the semiempirical approach. The use of this approach implies therefore the neglect of the difference between the nanowire and bulk and the assumption that the implicit basis set is the same used in bulk calculations. Under this assumptions, the matrix elements (12) coincide with those in Eq. 5b and Eq. 6b, and the same parametrization of the constituent bulk materials can be used in the modeling of NWs.

Nevertheless, the presence of free surfaces implies the existence of dangling bonds for the surface atoms. The most common procedure to deal with this problem is to passivate the dangling bonds at the surface by adding pseudo-hydrogen atoms [11]. The passivating pseudo-hydrogen atoms are supposed to interact only through their s orbital with the NW atoms. This is somewhat equivalent to the hard-wall boundary condition imposed in the models based on the effective mass approximation. This approach, though crudely representing realistic surface effects, has already proved to be highly successful in describing intrinsic quantum confinement.

If the crystalline structure of the NW is distorted by a moderate change of the bond lengths and angles, as happens, for example, under mechanical loading or when one takes into account the rearrangement of the atoms due to the surface reconstruction or during TBMD simulation (see below), the TB method can still be used, but the TB matrix elements must be recalculated for the new configuration with the help of some scaling law that gives their variation with the interatomic distance.

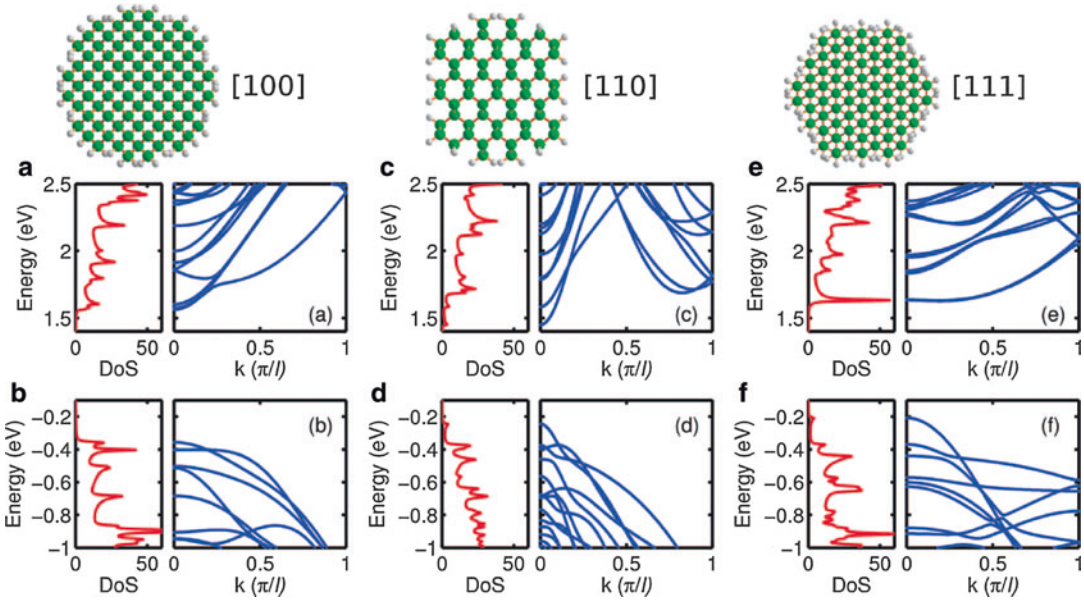
Finally, once the bulk TB model (with associated order N_H has been chosen, the NW TB problem reduces to the numerical solution, for each k_z, of a matrix eigenvalue problem of order $N_{wire} = N_{xy} \times N_H + N_{surface}$, where N_{xy} is the

number of unit cells in the supercell cross section and $N_{surface}$ is the number of orbitals on the surface passivating pseudo-hydrogen atoms. Due to the local interactions of the model, the resulting matrices are sparse. The standard techniques that have been applied are the Lanczos and iterative Jacobi–Davidson algorithms. In this way, it is possible to compute a finite number of conduction and valence subbands around the NW bandgap.

Applications of the TB Method to Nanowire Modeling

The TB methodology has been applied in a range of studies on NW systems, touching upon all the properties that ultimately depend on the electronic structure. These studies embrace all types (semiconducting, metallic, oxide, and other) of nanowires and nanotubes. Among semiconductor NWs, the whole range of materials, with diamond, zincblende, wurtzite, and other crystalline structures, have been investigated. Most of the studies deal with the calculation of the subband electronic structure of technological semiconductors and its dependence on geometry, composition, orientation, etc. This is so because this information translates immediately into the associated optical and transport properties. Some examples of this kind of calculations are reviewed in the following, and later on other less explored topics will be mentioned.

Subband Electronic Structure of Semiconductor Nanowires

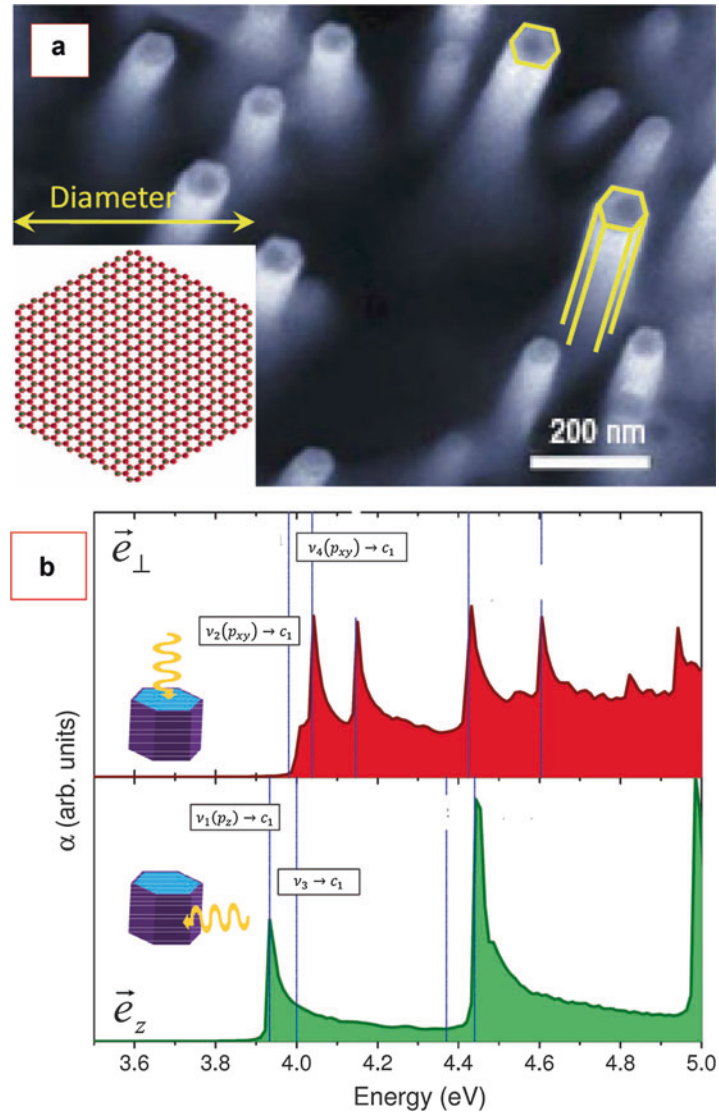


If the nanowire cross section has a size comparable to the de Broglie wavelength, there appear significant quantization effects in the electronic structure that are strongly dependent on the material composition and wire geometry, and this influence needs to be well understood in order to design new devices. At the lowest end of this nanometer scale, the application of the effective mass approximation for the calculation of the electronic structure is highly questionable. The TB methodology stands here as an optimum choice.

Figure 1 displays a comparative study of the subband structures and densities of states (DoS) of a Si NW with radius R = 1 nm for three different orientations, namely, along the [100], [110], and [111] crystal directions [12]. An orthogonal second-nearest neighbor three-center sp^3 TB model, without including the spin–orbit coupling, has been used. The Van Hove singularities typical of 1D subbands are clearly visible in the DoS. It is apparent that the electronic structure obtained is very sensitive to the wire orientation. The position and curvature of the conduction band (CB) minimum is particularly sensitive, exhibiting a different character of direct, quasi-indirect, and indirect gap as the orientation is changed. The general trends can be qualitatively understood in terms of the zone folding of the bulk band structure. While the valence band (VB) maximum always lies at $k_z = 0$, there is significant mixing and splitting of the various valence subbands. In [110]- and [111]-oriented Si NWs, the highest valence subband is rather dispersive and well separated from the other bands. In [100]-oriented Si NWs, the upper valence subbands are closer to each other and much flatter. From these results, one can anticipate that the [110] direction will be the best orientation for electron transport, while the [110] and [111] directions will be the best orientations for hole transport.

The TB methodology has also been applied to NW heterostructures made of different materials, such as core-shell NWs and quantum disks and tunnel barriers embedded in NWs, where strain and piezoelectric fields may be important. Other problems that have been treated are the effects on the electronic structure due to the presence of impurities, alloy disorder, interface roughness, and surface treatment and the importance of the screening induced by the dielectric mismatch between the NW and the surrounding environment.

Anisotropic Optical Absorption of Semiconductor Nanowires



The detailed knowledge of the electronic structure provided by the TB calculations, as illustrated above, gives access to other related properties.

Tight-Binding Simulations of Nanowires, Fig. 1 *Top panel*: Cross sections of [100]- , [110]- , and [111]-oriented Si nanowires with radius $R = 1$ nm. *Middle* and *bottom panels*: Associated conduction and valence subband structures and density of states (DoS) (after [12], with permission)

The most immediate ones are the optical properties that are fully determined by the single-particle states. The easiest to compute is the spectrum of the optical absorption coefficient, α(E).

An example of such calculations is reviewed here. The anisotropic optical absorption of wurtzite GaN NWs is calculated with an orthogonal nearest neighbor two-center sp^3 TB model, including the spin–orbit interaction [11]. A sketch of the NW under study is shown in Fig. 2a. The NWs are oriented along the wurtzite c-axis. For the purposes of modeling, the NW is considered to be infinite and to have a hexagonal cross section. The electronic structure for a nanowire with diameter 3.1 nm (not shown here) exhibits a set of conduction and valence subbands whose edges are denoted as c_1, c_2 and v_1, v_2. The fundamental NW bandgap $E_{c_1} - E_{v_1}$ is located at 3.92 eV. The TB method allows a detailed analysis of the symmetry of the corresponding wavefunctions, which can thus be characterized by the dominant contribution of the atomic-like orbitals (either s or $p_{xy} = (p_x, p_y)$ or p_z) and by the overall symmetry of the envelope function. The states c_i have dominant s character. On the other hand, due to the interplay of confinements and the anisotropy of the band structure of wurtzite GaN, the state v_1 has dominant p_z character, whereas in state v_2, the content of p_{xy} dominates. Moreover, c_1 and v_1 have the same envelope symmetry, which is different from that of v_2. Therefore, it is necessary to distinguish the absorption spectra for light polarized along the c-axis ($\boldsymbol{e}_z$) or polarized in-plane ($\boldsymbol{e}_\perp$). Figure 2 presents the absorption spectrum for both polarizations, corresponding to different possible experimental geometries as indicated in the inset. The characteristic 1D density of states is visible in the whole energy range for both polarizations. The lowest transitions are also indicated. The edge of the $\boldsymbol{e}_\perp$ spectrum is blue shifted with respect to the NW bandgap, since it is due to the excited transitions v_3, $v_4 \rightarrow c_1$ at ∼4.05 eV. The optical transition $v_1 \rightarrow c_1$ is optically inactive due to the dominant p_z character of the state v_1, whereas $v_2 \rightarrow c_1$ is inactive due to the difference in the symmetry of the corresponding envelope functions. On the other hand, the absorption edge of the $\boldsymbol{e}_z$ spectrum coincides with the NW bandgap, since the transition $v_1 \rightarrow c_1$ is now optically active.

Atomistic Simulations of Nanowire Transistors

The constant request for performance improvement of electronic devices is mainly satisfied by reducing the size of their active components, the transistors. Thirty years of aggressive scaling have pushed the dimensions of the modern devices to the nm range, thus opening the new research field called nanoelectronics. Semiconductor NWs may play an important role in the future of this field, since they can act both as wire connectors and active devices. One typical case is the NW field-effect transistors (FET) that use NWs as active channel. Modeling the current flow in these devices requires to include quantum-mechanical phenomena and atomic granularity. The TB method is well suited to study these problems, and quantitative estimates of the elastic mean free paths, charge mobilities, and localization lengths in semiconductor NWs are routinely calculated [13].

In recent years, there have been reports of state-of-the-art full-band transport simulation tools based on the TB methodology that allow to simulate the operation of realistic devices. As an example, illustrative results obtained with a 3D quantum transport simulator based on the

Tight-Binding Simulations of Nanowires, Fig. 3 Schematic view of a triple-gate nanowire transistor, composed of a square 2.1 nm × 2.1 nm Si NW channel, laterally coated by an oxide layer of thickness 1 nm and electrically coupled to source and drain contacts and to a surrounding gate. The device is deposited on a buried oxide. The source, the drain, and the gate measure $L_s = 9.7$ nm, $L_d = 9.7$ nm, and $L_g = 13$ nm. The oxide layers do not participate to the transport calculation, but they are included to obtain the 3D electrostatic potential (after [14], with permission)

Tight-Binding Simulations of Nanowires, Fig. 4 Full-band transfer characteristics of triple-gate nanowire transistors with a gate length of $L_g = 13$ nm. The *left part* of the plot compares the I_d (V_{gs}) characteristic (with $V_{ds} = -0.4$ V) of *p*-FETs with transport directions along [100], [110], [111], and [112]. In the *right part* of the figure, the I_d (V_{gs}) (with $V_{ds} = +0.4$ V) of *n*-FETs with the same channel orientations are compared (after [14], with permission)

orthogonal nearest neighbor two-center $sp^3d^5s^*$ TB model, neglecting the spin–orbit coupling, will be reviewed here [14]. The simulation code implements open boundary conditions to simulate the action of the gates and is self-consistently coupled to the three-dimensional computation of the electrostatic potential in the device. This simulator allows the analysis of the performance of Si NW FETs with different channel orientations, gate lengths, etc. Figure 3 shows a sketch of the simulated NW FET.

The transfer characteristics of the Si NW FET sketched in Fig. 3 are simulated in the subthreshold regime by applying a variable potential V_{gs} to the gate, with $V_s = 0$ V on the source and $V_{ds} = \pm 0.4$ V on the drain. Figure 4 shows

T

the I_d (V_{gs}) characteristic of *n*-FETs (right) and *p*-FETs (left) with channel orientation along the [100], [110], [111], and [112] crystal axes. The channel orientation [110] offers the highest ON-current in the case of *n*-FETs. For *p*-FETs, the trends are qualitatively the same. The prominence of the [110] channel for both *n*-FETs and *p*-FETs is a consequence of the good compromise between the electron velocity (proportional to the inverse of the effective mass) and the number of available states (proportional to the effective mass) that is reached by the lowest subbands of the [110] wire. The lowest [111] conduction subbands, for example, have too heavy electrons that cannot flow efficiently from source to drain.

Although the above simulations correspond to the ballistic transport regime, it is also possible to incorporate the effects of elastic scattering (due to interface disorder and alloy disorder) as well the inelastic scattering due to the electron–phonon interaction [15], which may play a considerable role in the performance of NW transistors.

Other Applications

The applications of the TB method can be extended to other less studied properties of NWs that also depend directly of the electronic structure. Here are two further representative examples:

1. Thermoelectric properties: By using the electronic structure obtained from an atomistic $sp^3d^5s^*$ TB model with spin–orbit coupling and the associated scattering rates due to surface roughness, impurity, and electron–phonon scattering mechanisms, as input to the linearized Boltzmann equation, it has been possible to calculate the electrical conductivity, the Seebeck coefficient, and the thermoelectric power factor of narrow Si NWs with diameters from 12 nm down to 3 nm [16]. The results reflect an enhancement of the *ZT* figure of merit and may provide guidance in the design of efficient thermoelectric nanodevices.
2. Magnetic properties: The TB method is also a useful method to study the interplay of nanostructure and magnetic properties as manifested, e.g., in ultrathin metallic nanowires. Thus, the electronic and magnetic properties of the rhodium nanowires have been calculated using a spin-polarized *spd* TB Hamiltonian in the unrestricted Hartree–Fock approximation [17]. It has been found that, even though bulk rhodium is a nonmagnetic solid, all the NWs studied are ferromagnetic. The magnetic properties of rhodium nanowires are related not only to their size but also to their atomic structure, with the small diameter center-atom core wires (i.e., the centered pentagonal and hexagonal wires) being more favorable to a larger magnetization.

Since the TB is an electronic structure method, it does not give directly information on lattice-related properties, such as mechanical, thermal, or vibrational properties. These properties are usually accessed from simulations based on molecular dynamics (MD), either expensive ab initio MD or oversimplified empirical classical MD. However, in the past two decades, an intermediate scheme called tight-binding molecular dynamics (TBMD) has been developed. In the TBMD, the ground state total energy is approximated as a sum of two terms, $E_{GS} = U_{REP} + E_{BS}$ [8]. U_{REP} is an ion-ion repulsive potential energy, which in most cases is modeled simply as a sum of short-ranged two-body repulsive interatomic potentials. E_{BS} is the band structure energy, determined by the sum of the energies of the set of occupied single-particle states of the system. The essence of the TBMD method consists in taking advantage of the TB method for the calculation of E_{BS} as a function of the instantaneous configuration of the system. The interatomic forces are finally evaluated in a straightforward way based on the Hellmann–Feynman theorem, and the rest of the procedure is almost identical to the standard MD simulation, but now the quantum-mechanical many-body nature of the interatomic forces is taken into account naturally by calculating the quantum state of the electrons at each MD time step. Since the TBMD scheme uses a minimal basis set for the electronic structure calculations and the Hamiltonian matrix elements are parametrized or tabulated, it allows to study the lattice-related properties of much larger systems than the

ab initio method while maintaining better accuracy than empirical MD. The scheme has been demonstrated to be a powerful method for studying various structural, dynamical, and electronic properties of covalent as well as metallic nanostructures. In the field of NWs, it has been successfully used, e.g., for the calculation of the mechanical properties of wurtzite ZnO unsaturated NWs [18] and the study of the vibrational spectrum of Si NWs [19].

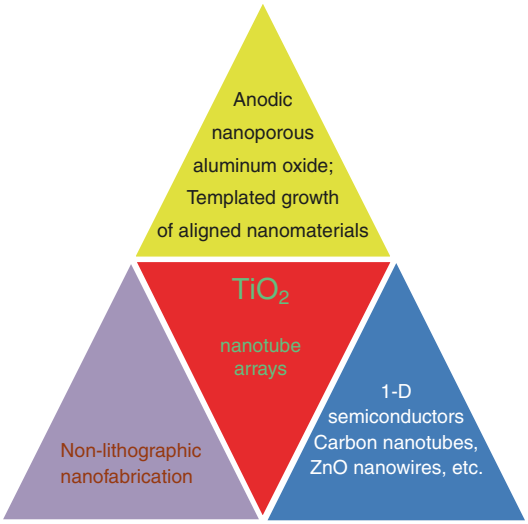
TiO_2 Nanotube Arrays: Growth and Application

Karthik Shankar
Department of Electrical and Computer Engineering, W2-083 ECERF, University of Alberta, Edmonton, AB, Canada

Definition

TiO_2 nanotube arrays (TNAs) denote self-organized tubular nanostructures of titanium dioxide grown by the process of electrochemical anodization. When it is titanium metal which is

subjected to electrochemical anodization, the TNAs grow directly in a single step without the assistance of a template. When it is aluminum metal which is subjected to anodization, the formation of TNAs is said to be templated and requires multiple steps including (1) the formation of the nanoporous alumina template, (2) a process to coat the walls of the template with TiO_2 or infiltrate a TiO_2 precursor into the template followed by heating, etc. (3) release of the alumina template by selective chemical etching to form TNAs. TNAs produced by the one-step process shall henceforth be referred to as anodic TiO_2 nanotube arrays and TNAs produced by the multistep process as templated TiO_2 nanotube arrays. In either process, the titanium dioxide nanotubes grow in arrays with their long axis aligned orthogonal to the substrate, due to which they are commonly referred to as vertically oriented TiO_2 nanotube arrays.



Introduction

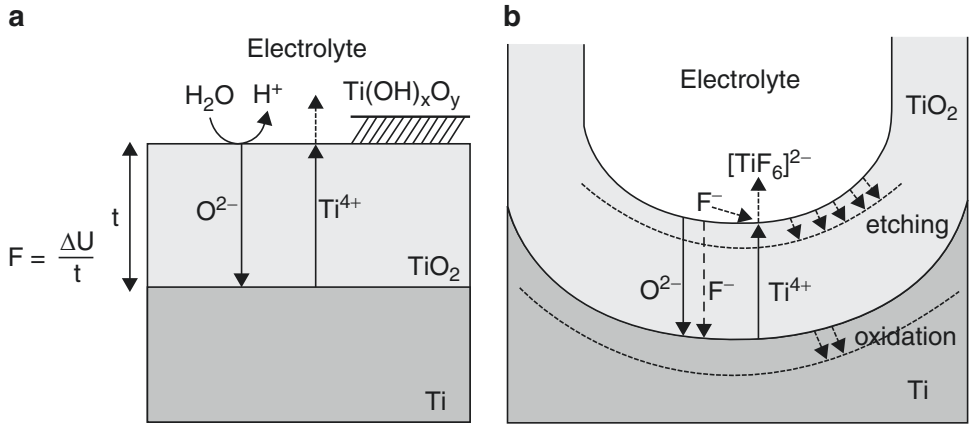
The formation of anodic porous titania by using fluoride-based electrochemistry was first reported by Zwilling in 1999 [1]. However, it was Gong et al. [2] in 2001 that first formed nanoporous TiO_2 with a clearly identifiable nanotubular structure. Pioneering contributions to the field of TNAs were made by the research groups of Craig Grimes [3] at Penn State University and Patrik Schmuki [4] at the University of Erlangen. Initially, anodic TiO_2 nanotube arrays could only be grown on titanium foil substrates. In 2005, Mor et al. reported the successful formation of anodic TNAs on Ti-coated glass substrates. Since then, anodic TNAs have been formed on silicon wafers and on transparent conducting oxide (TCO) coated glass substrates. Correspondingly, the first report on templated TNAs emerged in 1996 [5], but more detailed studies commenced in late 2001 [6].

TiO_2 is a highly versatile compound with applications as a pigment for paints, nontoxic biocompatible material for orthopedic implants, gas sensor, germicide, photocatalyst, n-type semiconductor scaffold for sensitized solar cells, optical coating, structural ceramic, electrical circuit varistor, spacer material for magnetic spin-valve systems, and more. TiO_2 is also relatively inexpensive owing to its stability and the plentiful abundance of Ti and O in the earth's crust. TiO_2 occurs in three allotropes: anatase, rutile, and the much less common brookite. The metastable anatase phase has superior electronic properties. The key motivation behind the development of TNAs is to enhance and exploit the versatility inherent in TiO_2 using the specific nanostructured morphology of TNAs. The oriented and aligned one-dimensional TNA architecture offers access to the anatase phase, a high surface area and directed electron percolation pathways for electronic and optoelectronic applications. For other applications of TNAs such as their use in stem-cell differentiators, antibiotic elution and energy transfer-based light harvesting, the specific properties of TiO_2 are less important; these applications derive instead from size selectivity, confinement in nanochannels, and other geometrical attributes of the nanoscale TNA architecture.

The research area of TNAs has witnessed an explosion of interest in the last decade with more than 1,000 research papers on this topic. Apart from the versatility of TiO_2 referenced above, another reason for the intense interest is the location of self-organized vertically oriented TiO_2 nanotube arrays at the intersection of three major trends in nanotechnology research over the last decade as shown in the schematic of Fig. 1. One such trend has been the drive to form one-dimensional structures such as nanorods and nanotubes in semiconductors, inspired by the unique properties of carbon nanotubes. Another trend, which is also one of the driving motivations underlying nanotechnology, is the exploitation of self-assembly and self-organization to form complex structures from the "bottom-up" as an alternative to patterning and fabricating structures from the "top down." The third trend has been the use of ordered anodic nanoporous alumina as a template to form a variety of oriented and aligned nanomaterials.

The use of electrochemical anodization to form nanoporous alumina has been known since the 1950s. However nanoporous alumina is an

TiO_2 Nanotube Arrays: Growth and Application, Fig. 1 TNAs sit at the intersection of three major nanotechnology trends



insulator which limits its device applications. Anodic aluminum oxide (AAO) is widely used as a template to form functional nanomaterials. Since crystalline TiO_2 is a semiconductor, anodically formed TiO_2 nanotube arrays can be directly used as a functional material after the induction of crystallinity. A major difference between AAO and TNAs is that a wider range of morphologies are achievable in TNAs. Ordered AAO has been formed in a close-packed hexagonal pore architecture and in square and triangular lattices. In TNAs, the anodization electrolyte has a decisive role in determining the morphology of the resulting structure. By anodization in ethylene glycol-based electrolytes, TNAs may be formed in a close-packed hexagonal architecture similar to AAO. At the same time, nanotube arrays with a distinctive cylindrical cross section may be achieved in other electrolytes. The wall thickness can be varied to change the porosity of the architecture. In comparison with nanochannels in AAO or in track-etched polycarbonate membranes, the nanotubular structure has a significantly higher surface area due to the availability of both the inner and outer surfaces of the nanotube walls.

In the course of the last 10 years 2001–2010, a high degree of control has been achieved over the geometrical dimensions of the anodic TNA architecture by optimizing the anodization process. Potentiostatic anodization is most commonly used either by direct application of a constant anodization voltage or though a linear sweep of the potential to a final constant value. The key parameters involved in the fabrication process are the composition of the anodization electrolyte, the anodization voltage applied, the temperature of the anodization bath, and the anodization duration. For applications involving increased pattern order of the TNAs and for TNA growth on nonnative substrates such as glass, Si, etc., the nature of the Ti film or Ti foil specifically its density, roughness, grain size, and crystallographic texture (if any) are also critical. By tuning the various anodization parameters listed above, control over the geometrical dimensions of TNAs has been demonstrated over remarkably broad length scales [4, 7–9]; the diameter of nanotubes has been varied from 16 to 900 nm, the tube length from 250 to 1 mm, the wall thickness from 5 to 45 nm and the inter-tube spacing from 0 (close packed nanotubes) to several micrometers (widely separated nanotubes). Of these geometrical features, only the diameter and the tube length are independently controllable to date. The wall thickness and inter-tube spacing depend on the diameter and the tube length.

Growth of Anodic TiO_2 Nanotube Arrays

When a Ti foil or a Ti film coated electrode is subjected to anodization in highly conductive electrolytes, the anodization current experiences a steep drop in the first several seconds of the process. The drop in current occurs due to the rapid formation of a passivating oxide layer (called the barrier layer) through which electronic conduction can only occur through tunneling. In the simplest case, the anodization current density J for Fowler-Nordheim tunneling through the oxide barrier layer (BL) may be expressed as:

$$J = C\left(\frac{\Delta U}{t}\right)^2 e^{-\frac{\beta_{FN} t}{\Delta U}} \quad (1)$$

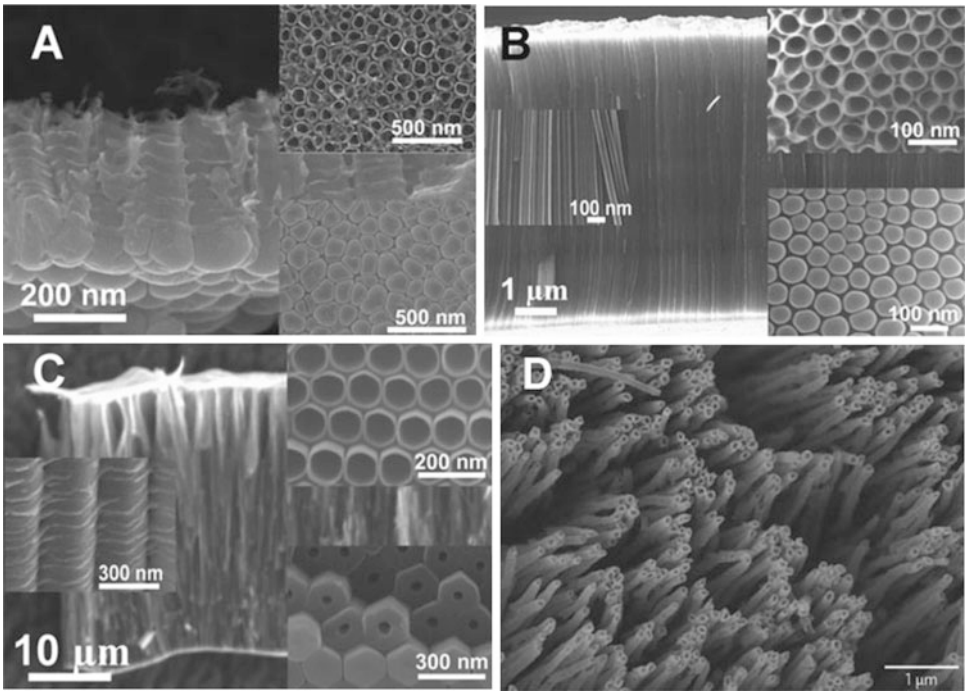
TiO_2 Nanotube Arrays: Growth and Application, Fig. 2 Schematic representation of the Ti anodization (**a**) in absence of fluorides (results in flat layers), and (**b**) in presence of fluorides (results in the tube growth) [4] (Reprinted with permission from Elsevier)

where ΔU is the portion of the anodization voltage which drops across the barrier layer, t is the oxide thickness and C, β_{FN} are constants. Equation 1 shows that the tunneling current reduces exponentially with increasing BL thickness. As the passivating layer increases in thickness, tunneling weakens and the formation of nascent gases at the anode due to electron transfer reactions is suppressed. Visually, this is indicated by the cessation of bubbling activity at the anode. At this point, current flowing through the oxide consists almost entirely of ions. The solid state migration of ions through the oxide is described by the high-field transport model in which the anodization current density J is given by:

$$J = A_e^{\frac{\beta_{HF}\Delta U}{t}} \tag{2}$$

where A and β_{HF} are constants.

Later in the anodization process, the growth process is under mass-transport control as the anodization current is controlled by diffusion of fluoride ions through the tubes to the pore bottoms and results in an inverse dependence of the anodization current on the tube length [4]. The current density is given as:



$$J = -pD\frac{\partial c}{\partial x}(0 \le x \le L) \tag{3}$$

where D, c, x, and L are the diffusion coefficient and concentration of the ionic species, thickness of the diffusion layer, and length of the nanotubes, respectively, and p is the ratio of the weight of dissolved oxide to the weight of produced oxide.

The anodic formation of TNAs is a highly nonequilibrium process which occurs at high overpotentials as a result of the interplay between three competing and essential processes (see Fig. 2): Field-assisted oxide dissolution and cation migration, field-assisted oxidation of Ti and chemical etching. It is chemical etching which is responsible for the development of nanotubes as opposed to mere nanopores. In contrast, the formation of nanoporous alumina is controlled mainly by the field-assisted processes. The field-assisted reactions occur on either side of the barrier layer at the bottom of the nanotubes and are responsible for driving the Ti/TiO_2 interface deeper into the Ti foil or Ti film, a process which increases the length of the nanotubes. Chemical etching shortens the length of the nanotubes. The reactions involved in the form ation of TNAs are:
Field assisted migration:

$$Ti + 2H_2O \rightarrow TiO_2 + 4H^+ + 4e^- \tag{4}$$

Field assisted migration:

$$TiO_2 + 6F^- + 4H^+ \rightarrow [TiF_6]^{2-} + 2H_2O \quad (6)$$

Chemical dissolution:

$$TiO_2 + 6HF \rightarrow [TiF_6]^{2-} + 2H_2O + 2H^+ \quad (7)$$

The as-anodized nanotube arrays are amorphous and non-insulating. Manifestation of the semiconductor properties of TiO_2 requires induction of crystallinity, which is typically accomplished by annealing the nanotube arrays in air or in an oxygen-rih ambient at elevated temperatures of 350–580 °C. For annealing temperatures of up to 500 °C, the nanotubes are transformed into polycrystalline anatase alone; at higher temperature, increasing amounts of rutile are present as well. Annealing at temperatures higher than 580 °C results in the destruction of the nanotubular architecture.

The evolution of different fabrication recipes for anodic TNAs has occurred in four generations to date [3, 7, 8]. The first three generations were defined by the maximum length of nanotubes that was achieved and they all used fluoride ions to effect the necessary chemical etching. The fourth generation was defined by its nonuse of fluoride ions. First-generation nanotubes were up to 500 nm long and were grown by anodization in strongly acidic aqueous electrolytes containing 0.1–0.5 wt% HF (pH $\leq$1). Other additives such as acetic acid were sometimes added to improve the mechanical strength and quality of the nanotubes. The tube length in first-generation TNAs was limited by the strong chemical etching by HF. Typical morphology obtained in first-generation nanotubes is shown in Fig. 3a. The steady-state TNA film thickness (corresponding

to the tube length) occurred when the rate of movement of the Ti/TiO_2 interface deeper into the metal was exactly balanced by the chemical etching at the mouths of the nanotubes. In the second generation, fluoride ion-bearing aqueous electrolytes were still used but the rate of chemical etching was tightly controlled by adjusting the pH by adding buffers to the anodization electrolyte. Typically, trisodium citrate and sodium dihydrogen sulfate were used as buffering agents in the electrolyte and salts such as ammonium fluoride, sodium fluoride, and potassium fluoride were used as sources for fluoride ions. As the pH was varied from 1 upward toward 5, the nanotubes grew correspondingly longer due to the reduction in chemical etching. The maximum nanotube length in aqueous electrolytes of 6.6 μm was achieved at a pH of 5. The maximum growth rate was ~0.25 μm/h. When the pH was increased beyond 5, nanotube formation did not occur. Nanotube formation in both the first and second generations occurred in aqueous electrolytes in a narrow window of anodization voltages ranging from 10 to 27 V, which restricted the inner diameters of the nanotubes to the range 22–100 nm. In the third generation (Fig. 3b–d), fluoride-bearing organic electrolytes were used to vastly expand the morphological parameter space achievable. Nanotubes as long as 1 mm were grown by complete conversion of the underling Ti foil to TNAs. Thus, the nanotube growth is limited in length only by the thickness of the underlying substrate and in principle can be extended even longer by choosing thicker substrates. The inner diameter of the nanotubes could be varied from 17 to 900 nm. When chemical etching is minimized, the slow solid state ionic transport of reactants through the barrier layer is the rate-limiting step preventing further increase in tube length. From Eq. 7, it is clear that the high-field ionic current is increased by a thinner barrier layer. This key insight motivated the use of organic electrolytes in the third generation which provided more reducing conditions than aqueous electrolytes and ensured the formation of a thinner barrier layer. The thinner barrier layer allows growth rates as high as 15 μm/h to be achieved. Third generation electrolytes consist of a fluoride-ion bearing salt dissolved in an amphiprotic organic solvent of moderate to high viscosity such as formamide, *N*-methyl formamide, ethylene glycol, glycerol, etc. About 1–5 % of water is typically added to form organic electrolytes in order to provide oxygen-bearing hydroxyl ions during anodization for oxide formation. Nanotubes do not grow well when low-viscosity protic solvents such as methanol or ethanol are used as the base solvent to form the organic electrolyte (although mixtures with water and HF have been found to result in anodic TNAs). The same is true of aprotic solvents such as propylene carbonate and acetonitrile. An exception is dimethylsulfoxide, an aprotic solvent which has been used to form high-quality TNAs. By detaching the nanotube arrays from the foil substrate, TNA membranes similar to nanoporous alumina membranes may be produced. The nanotube arrays need to be at least 10 μm long for the detached film to be mechanically robust enough to a form free-standing membrane. Some of the methods used to detach the TNAs from the native Ti foil substrate include the use of natural stresses in the thick TNA films through ultrasonication, selective etching of the Ti substrate by immersion in a solution of CH_3OH/Br_2, and the use of induced stresses by double-step anodization. The membranes have a strong tendency to curl up due to capillary forces. The membranes can be kept planar by processing with low surface tension solvents or by supercritical CO_2 drying. Fourth-generation nanotubes were formed in fluoride-free electrolytes (Table 1).

Growth of Templated TiO_2 Nanotube Arrays

Both hard templates such as anodic nanoporous aluminum oxide (AAO) and soft templates such as polycarbonate membrane filters have been used to form TNAs. Soft templates have two major disadvantages: (1) an elevated temperature (~450–500 °C) thermal annealing step is frequently to induce or improve the crystallinity of the templated TNAs. However, most polymers are not able to withstand temperatures above 200 °C.

TiO_2 Nanotube Arrays: Growth and Application, Table 1 Common recipes for TNAs and the resulting morphological parameters

Electrolyte	Anodic potential (V)	Inner diameter (nm)	Length (μm)
Aqueous 0.5 % HF	10	22	0.2
Aqueous 0.5 % HF	10–23 (nanocones)		0.4
Aqueous buffered 0.1 M KF (pH ~ 5)	25	110	6.6
0.1 M NH_4F in 1:1 DMF:H_2O	15 porous		
0.15 M NH_4F + 5 % H_2O in formamide	10	12	3.6

Consequently, the polymer template pyrolyzes before the phase transition in TiO_2 thus eliminating the mechanical support provided by the template and/or result in the undesirable incorporation of carbonaceous materials in the TNAs; (2) the pore densities are smaller and the nanochannels in polymeric membrane filters are frequently tilted from the surface normal and sometimes intersect within the membrane [10]. Therefore, discussion shall be restricted to AAO-templated TNAs.

AAO templates are formed by electrochemical anodization of aluminum metal in three common electrolytes based on sulfuric acid, oxalic acid, and phosphoric acid. The choice of electrolyte is determined by the desired pore size. The Al metal maybe a native substrate such as aluminum foil or could be a film deposited by vacuum evaporation or sputtering on nonnative substrates such as glass and silicon. High-ordered templates approaching ideal hexagonal, square, or triangular lattices may be prepared by techniques such as two-step anodization and various imprinting methods to guide pore formation [11].

Methods to synthesize TNAs in AAO templates can be classified into liquid phase and gas-phase methods. Sol-gel hydrolysis, electrochemical hydrolysis and electrophoretic deposition of nanoparticles are examples of liquid phase methods. Atomic layer deposition (ALD) and chemical vapor deposition (CVD) are gas-phase methods. The growth of nanotubes as opposed to nanorods in nanoporous alumina requires preferential formation of TiO_2 on the walls of the template. This is accomplished by preferential wetting of the template walls by TiO_2 precursors in sol-gel methods, by preferential reduction or oxidation at the walls in electrochemical methods, by preferential concentration of the electric field lines at the pore walls in electrophoretic deposition, and by the non-line-of-sight conformal deposition on the walls in gas-phase methods. ALD is a self-limiting film growth process in which alternate saturative surface reactions are made to occur by pulsing the vapors of two or more precursors in the reaction chamber alternately [12]. ALD is capable of producing highly conformal coatings even on substrates with complex features and offers exceptional control in tuning the wall thickness of the nanotubes. Consequently, ALD is the most widely used method to form the templated growth of TNAs. Typically, a flow reactor configuration is employed and the precursors used to grow TiO_2 films are a titanium alkoxide, whose generic formula is $Ti(OR)_4$ and water (H_2O). The deposition temperatures used in ALD of TiO_2 films for templated TNA growth vary widely, from 100 °C to 325 °C. The exposure times of the template to each precursor pulse are typically

limited to a few seconds and the chamber is evacuated prior to the introduction of the next pulse. In addition, in some recipes, an inert gas is used to purge the chamber before the next pulse. The main disadvantages of ALD are the high cost and complexity of ALD equipment and the extremely slow film growth rate. A brief overview of other processes used to form templated TNAs is now provided. The operating principle of the sol-gel method is the use of capillary forces to drive a TiO_2 sol into the nanochannels of the template which transforms into TNAs upon thermal annealing. A sol-gel process based on TiF_4 hydrolysis with hydroxypropylcellulose added as a gelling agent, has been used to form 200 nm diameter TNAs in an AAO template. However, the process was highly nonuniform over large areas with irregular deposition of the TiO_2 and poor penetration of the sol particles into the template nanochannels. Much better results were obtained using the pressure-assisted infiltration of liquid titanium isopropoxide (TiO_2 precursor) into the AAO nanochannels followed by thermal decomposition method of the precursor at 500 °C in an oxygen stream to yield TiO_2 nanotube arrays [6]. In the electrophoretic sol-gel method, an electric field is used to provide significantly larger forces than mere capillary action to drive the charged particles created by sol-gel processing into the nanochannels [13]. A triple step templating process has been used to form TiO_2 by the anodic oxidative hydrolysis of $TiCl_3$ [5]. In this process, the AAO template morphology was transferred to a polymer mold which contained a negative replica of the template pattern. Gold nanorods were formed by electroless deposition on to the polymer mold. Then the gold nanorods served as a conducting template to form TNAs (Fig. 4).

Biological Applications of TiO_2 Nanotube Arrays

Biosensing Applications

Biosensors are devices that combine a biological component (a recognition layer) and a physicochemical detector component (a transducer). The majority of biosensors are targeted to proteins but biosensors for cells and for metabolically important small molecules are also being investigated. Molecular labels have enabled the construction of biosensors of high sensitivity and specificity. However, labels often disrupt the accurate measurement of kinetic constants, particularly binding equilibria, and problems, such as antibody cross reaction or impure solutions, can occur. Due to these drawbacks, label-free biosensors are highly desired for a variety of biotechnology applications such as disease diagnostics, drug discovery, environmental monitoring, and food safety. For label-free optical biosensors, the transduction methods can be divided into two categories: optical interferometric and surface plasmon methods [14]. In interferometric sensors, sensing is achieved by extracting the refractive index of the porous matrix from the Fabry-Perot interference fringes in the reflectance spectrum. Some of the prerequisites for an effective optical interferometric sensing material are a large internal surface area, ease of fabrication, and a chemically modifiable surface. TiO_2 nanotube arrays satisfy the above requirements but in addition possess a high refractive index ($n = 2.5$ for TNAs) and superior chemical stability over a wide pH range in comparison with other candidate materials such as porous

TiO_2 Nanotube Arrays: Growth and Application, Fig. 5 TNA-based interferometric biosensors: (**a**) representative reflectivity spectrum of anodic TNAs showing the characteristic interference fringes and (**b**) time-dependent optical thickness measurements showing sequential binding of Protein A and rabbit IgG within TiO_2 nanotubes (Reprinted with permission from [14])

silicon and nanoporous alumina. The larger index contrast between the porous host and the aqueous matrix in which the biomolecular binding measurement is carried out is expected to provide greater contrast in the interferometric spectrum, leading to lower noise and higher sensitivity [14]. Mun et al. [14] demonstrated the highly specific label-free interferometric sensing of rabbit immunoglobulin G (IgG) using protein A (derived from *Staphylococcus aureus* bacteria) immobilized on the walls on the nanotubes as the capture probe (Fig. 5).

Orthopedic Implant Applications

Because of their mechanical strength, chemical inertness, and biocompatibility, TiO_2 and its alloys (particularly Ti-6Al-4 V) have been used extensively in orthopedic and dental implants since 1970 [15]. Osteogenesis is the process of formation of new bone tissue by cells called osteoblasts. Ideal implants are those whose surfaces will promote in vitro and in vivo osteogenesis. However, the influence of surface micro- and nanotopography on osteogenesis is still not well understood. High surface area porous materials are used in implants to mimic bone, which is a naturally occurring porous ceramic material composed of nano-sized organic and mineral phases that form a large macrostructure. Proteins in extracellular bone matrix and calcium phosphate, important constituents of the bone matrix, are nanostructured but the porosities in human bone are predominantly in the range 1–100 μm [15]. Spark anodization is a process which leads to the formation of a disordered oxide structure with porosities in the same regime as bone and is therefore commonly used to increase the biocompatibility of titanium and its alloys. However, recent studies using nanoporous alumina and nanotubular titania have revealed that their much smaller pores (20–200 nm) allow bone ingrowth. TNAs, in particular, have been demonstrated to be favorable templates for bone cell growth and differentiation, and also shown to significantly enhance osteoblast activity [8, 15]. The nanoporous architecture of TNAs provides a framework in which osteoblasts produce new bone. The anatase phase of TiO_2 is much more efficient for nucleation and growth of bone than rutile. Another advantage of TNAs is their strong adherence to the underlying Ti substrate. In cell culture experiments, increased adhesion to TNAs of cells which produce and maintain cartilage (chondrocytes) was observed and in animal trials, chronic inflammation was found to be absent in TNAs implanted below the skin in rats. Furthermore, the calcium and phosphorous concentrations were 50 % higher on these surfaces, suggesting that deposition of the bone matrix was accelerated on TNAs [8, 15]. SEM images have been used to show that the microspike extensions (filopodia) of migrating osteoblast cells go into the nanotube pores and in general progagate much faster on TNA surfaces. It has been speculated that the nanotube pore and the gap between the nanotubes serve as a useful pathway for continuous supply of ions, nutrients, and proteins, which is likely to positively contribute to the health of the growing cells [8].

Drug Eluting Coatings for Medical Implants

Bacterial infection and acute inflammation at the site of the implant are the most common postsurgical complications of bone implants, dental implants, and vascular stents. To reduce the chance of complications and to prevent early stage implant failure, antibiotic therapy is indicated 6–8 weeks after surgery [15]. Systemic administration of drugs such as antibiotics to avoid or treat the infection is often ineffective at reaching infected tissues near the implant and in addition, can cause toxicity and other adverse side effects. On the other hand, localized drug delivery from the site of an implant has more efficient therapeutic effects and fewer side effects. In general, an ideal drug eluting coating must have the ability to incorporate a drug, preserve it, and deliver it gradually over the time to a specific target site [16]. TiO_2 nanotube arrays are being actively researched for localized drug delivery for implants because they combine the appropriate biointegration and biocompatibility with the ability to controllably release drugs (a process known as elution) confined in their channels to their surroundings. Drug loading is performed through capillary action by either immersing the templates in the concentrated drug solution or dropping the solution slowly on the template surfaces. In addition, simulated body fluid (SBF)-assisted physical adsorption of antibiotics and anti-inflammatory agents was found to be a superior method of drug loading which also resulted in improved prolonged release of both types of drugs [16]. The elution of gentamicin (a powerful aminoglycoside antibiotic used against gram-negative bacteria) from titania nanotubes has been studied [8]. In TNAs of 80 nm pore diameter

and 400 nm length loaded with gentamicin (70–85 % loading efficiency), drug release kinetics were found to be dependent on initial loading; and there was a sustained release, for 45, 90, and 150 min for loadings of 200, 400, and 600 μg, respectively. In addition, it was found that bacterial adhesion on the surface of gentamicin-loaded titania nanotubes was reduced significantly (in comparison with titanium surface and unloaded nanotubes), whereas normal osteoblast adhesion and proliferation is retained [8, 15]. It has also been shown that TiO_2 nanotubes can control small molecule delivery in the order of weeks, and larger molecules in the order of months. The total drug loading as well as elution was mostly affected by nanotube length, and maximum small molecule elution was reached at ~2 weeks. TNA-based drug eluting coatings are superior to the conventional strategy of drug elution through a drug-loaded polymer coating, because even though the polymer coating is effective in delivering a drug for long periods, it has been known to induce an inflammatory response due to eventual degradation of the polymer. Such inflammation is implicated in late-stage implant failure.

TiO_2 Nanotube Arrays for Stem-Cell Differentiation

Recent studies on cell interactions with TNAs have demonstrated that stem cell fate is dictated by the diameter of the nanotubes. Using amorphous (unannealed) TNAs, Schmuki et al. found the adhesion, proliferation, migration, and differentiation of rat bone marrow mesenchymal stem cells to be highest on nanotubes 15 nm in diameter and dramatically decreased on 70- and 100-nm nanotubes. In contrast, Jin et al. found using crystalline (annealed) TNAs and human mesenchymal stem cells that the optimum length scale for cell vitality and differentiation was 100 nm. More recent studies seem to indicate that nanotube size plays a more important role than crystallinity and nanotube chemical composition although more research is necessary to clarify the nature of topographical cues for cell behavior in this emerging field.

Applications of TiO_2 Nanotube Arrays in Light Harvesting Devices

One of the factors limiting maximum achievable efficiencies in conventional light harvesting devices including photovoltaic cells, photoelectrochemical cells, and photocatalytic films is the ever-present trade-off between light absorption and charge generation on the one hand, and charge separation and carrier collection on the other. This trade-off is best illustrated by considering the case of a planar p-n junction solar cell where only electron-hole pairs generated close to the depletion region are swept apart by the inbuilt electric field and efficiently collected. On the one hand, the light absorbing semiconductor layer needs to be thick enough to absorb a majority of the incident photons and on the other hand, the large thickness means that a portion of the minority charge carriers generated away from the junction are lost to recombination as they diffuse toward the junction. The vertically oriented TiO_2 nanotube array architecture overcomes this trade-off by orthogonalizing the processes of light absorption/charge generation and charge separation/carrier collection so that the trade-off is no longer as severe. The process of charge separation now occurs in the radial direction while light absorption occurs in the longitudinal direction along the axis of the nanotubes. To facilitate charge separation, the diameter of the nanotubes can be made smaller or the nanotube walls may be made thinner while simultaneously making the nanotubes longer to maximize light absorption. The porosity of the ordered structure allows the incident photons to be more effectively absorbed, due to scattering effects, than on a flat electrode. For these reasons, the vertically oriented nanotube array architecture has been posited as nearly ideal for light harvesting applications.

TNAs for the Photocatalytic Reduction of CO_2 to Methane

The free energy for overall methane formation through the chemical reaction is about 801 kJ/mol, a process requiring eight photons:

$$CO_2 + 2H_2O(g) \rightarrow CH_4 + 2O_2 \quad (8)$$

Hydrogen formation from water involves a free energy change (ΔG^0) of 237 kJ/mol and an enthalpy change (ΔH^0) of 285 kJ/mol; the corresponding values for CO formation from CO_2 are 257 and 283 kJ/mol at 25 °C (1 atm.). Hence, the minimum energy required for water and CO_2 splitting processes are, respectively, 1.229 and 1.33 eV (per photon). In theory, the bandgap of a photocatalyst used for co-splitting of CO_2 and water should be at least 1.33 eV, which corresponds to absorption of solar photons of wavelengths below about 930 nm. Considering the energy loss associated with entropy change (about 87 J/mol · K) and other losses involved in the CO_2 splitting process (forming CO and O_2), a bandgap between 2 and 2.4 eV is optimal [17]. Using nitrogen-doped TiO_2 nanotube arrays, with a wall thickness low enough to facilitate effective carrier transfer to the adsorbing species, surface-loaded with nano-sized islands of platinum and copper cocatalysts, efficient sunlight-driven conversion of CO_2 into CH_4 and other hydrocarbons was achieved, with hydrocarbon production rates as high as 160 μL/(g h).

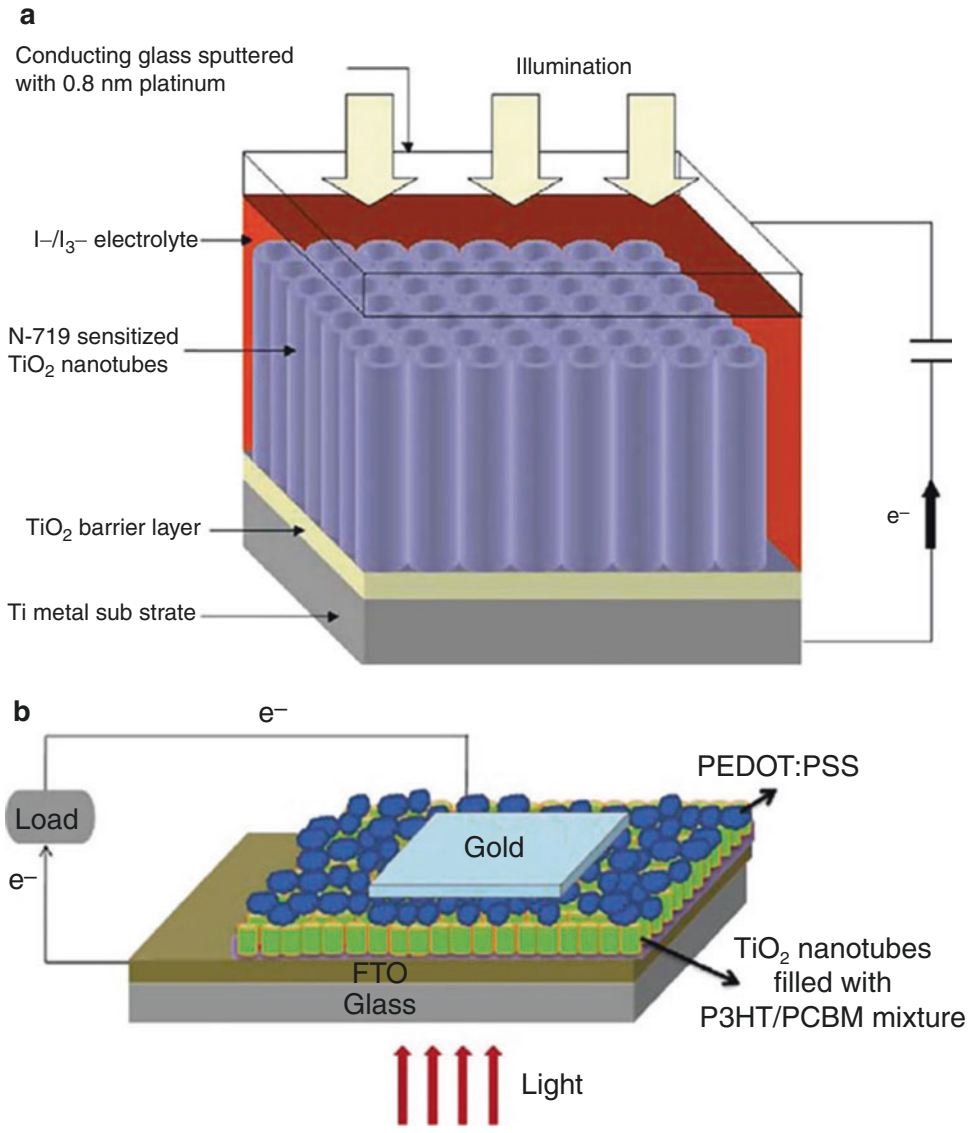
The outstanding nature of TNAs as a platform to perform the photocatalytic reduction of CO_2 is shown by the fact that the above rate of CO_2 to hydrocarbon production obtained under outdoor sunlight is at least 20 times higher than previous published reports [8, 17].

TNAs for Oxidative Photochemistry

Due to the large oxidizing power of photogenerated valence band holes in titania, TiO_2 nanotube arrays are excellent catalysts for oxidative photochemistry. OH radicals and superoxide (O_{2-}) anions produced by photogenerated charge carriers in TiO_2 can oxidize essentially all organic molecules present in the solution into carbon dioxide and water [4]. It has been shown that crystalline TiO_2 nanotubes show considerably higher efficiency for the decomposition of organic small molecules than a compacted Degussa P25 layer (20–30 nm diameter nanopowder composed of anatase and rutile) under comparable conditions [4]. The TNA architecture is also exceptionally stable with no degradation observed in the samples with exposure to UV/visible light over a course of a several months. For sunlight-driven water photolysis, the titania nanotube array architecture results in a large effective surface area in close proximity with the electrolyte thus enabling diffusive transport of photogenerated holes to oxidizable species in the electrolyte. In the TNA architecture, most minority carriers generated within a "retrieval" length from the material surface, i.e., a distance from the surface equal to the sum of the depletion layer width and the diffusion length, and such carriers escape recombination and reach the electrolyte redox species. Consequently, bulk recombination is greatly reduced and the quantum yield (incident photon-to-electron current efficiency) is close to unity. Under visible light illumination, the efficiency of TNAs is limited by the large bandgap of TiO_2 (3.0–3.2 eV), which renders the TNAs sensitive only to ultraviolet photons. A photoconversion efficiency for photoelectrolysis of 12.25 % was obtained under UV (320–400 nm) illumination using second-generation nanotubes 6 μm long annealed at 580 °C. High quantum yields >80 % were obtained indicating that the incident UV photons were effectively utilized by the nanotube arrays for charge carrier generation. The corresponding hydrogen evolution rate was 76 mL/h W. The water-splitting reaction was confirmed by the 2:1 ratio of evolved hydrogen to oxygen. Using third-generation nanotubes ~200 nm in diameter and 30 μm long formed by anodization at 35 V in a formamide-based electrolyte, the water-splitting efficiency improved to 16.25 % [7].

TiO_2 Nanotube Arrays as Scaffolds in Excitonic Solar Cells

In excitonic solar cells, photons of energy larger than the absorption threshold of the excitonic absorber do not create free electron-hole pairs as in a conventional inorganic semiconductor. Instead excitons (electron-hole pairs bound by Coulombic attraction) are generated. Unless these excitons are dissociated at a suitable interface, they are lost to recombination. Therefore, the trade-off in excitonic solar cells is between light



absorption and exciton diffusion. As alluded to before, vertically oriented TNAs orthogonalize the processes of exciton generation and exciton diffusion overcoming the trade-off. Also, TNAs provide electron percolation pathways for the directed (nonrandom) movement of electrons in the structure. TNAs provide flexibility in device design since the excitonic absorbers may be coated on the nanotube walls thus exploiting the large internal surface area of the TNA architecture or the absorbers may be volumetrically filled inside the hollow cylindrical spaces of the nanotubes. Due to these reasons, TNAs are very attractive materials for use as n-type semiconducting scaffolds for excitonic solar cells. TNAs are used in two different kinds of excitonic photovoltaic devices: dye sensitized solar cells, where the absorber is a broadly absorbing dye molecule anchored to the surface of the TNAs and ordered bulk heterojunction solar cells, where the absorber is filled inside the nanotubes. Templated TNAs formed by a sol-gel method were found to have very large roughness factors which enabled them to adsorb >500 nmol cm^{-2} of N-719. Using 17.6 μm long transparent anodic TNAs grown on conductive glass substrates, Varghese et al. obtained N-719 sensitized solar cells with an efficiency of 6.9 % under AM 1.5 1 sun illumination and quantum yields higher than 65 % in the spectral range 400–670 nm [9]. Using a free-standing membrane consisting of 63 μm long TNAs transferred to a FTO:glass substrate, dye-sensitized solar cells subjected to 1 sun AM.15 illumination demonstrated an open circuit photovoltage of 0.77 V, a short-circuit photocurrent of 18.5 mA cm^{-2} and a fill factor of 0.64, resulting in an overall efficiency of 9.1 % [18]. There is also increasing research interest in sensitized solar cells where the sensitizers are quantum dots of CdS or CdSe or CdTe instead of molecular dyes. Quantum yields as high as 55 % have been demonstrated in quantum dot-sensitized TNA solar cells [19]. An ordered double heterojunction solar cell was constructed by infiltrating a blend of regioregular poly (3-hexylthiophene) (RR-P3HT) and a methanofullerene (PCBM) into transparent anodic TNAs on FTO coated glass. The configuration used is termed a double heterojunction because of the availability of two interfaces for charge separation, namely, the TiO_2/P3HT and PCBM/P3HT interfaces. The resulting solar cell had an overall conversion efficiency under 1 sun AM 1.5 illumination of 4.1 % [8] (Fig. 6).

Chemical Sensing Applications of TiO_2 Nanotube Arrays

Chemical sensors often suffer from unwanted contamination, or poisoning which limits the sensor's operational lifetime. Volatile organic compounds are a frequent source of sensor contamination. In this respect, an important advantage of TNA-based chemical sensors is their self-cleaning ability in the presence of ultraviolet radiation [8]. The strong oxidizing power of photogenerated holes in crystalline TiO_2 oxidizes organic contaminants and results in self-cleaning.

TNA-Based Ultrasensitive H_2 Gas Sensors

One of the first applications of TNAs was in hydrogen gas sensing by measuring a change in the electrical resistance of the nanotubes upon exposure to hydrogen. A metal-semiconductor-metal (MSM) structure was employed for resistive H_2 gas sensing wherein Ti metal underlying the nanotube arrays was used as the ohmic contact and a high work function metal (mainly platinum) was used as the Schottky contact. Initial work used first-generation nanotubes at high operating temperatures (e.g., 290 °C) to obtain a three-order change in resistivity when exposed to a few ppm of hydrogen. By sputtering a thin overlayer of Pd on the nanotubes to enable facile dissociation of molecular hydrogen into atomic form, the operating temperature of the resistive gas sensors were brought down to room temperature. By using second-generation nanotubes anodized in aqueous electrolytes at pH 4.5 in combination with Pd sputtering, an unprecedented high sensitivity of 8.7 orders of magnitude was achieved. Room temperature operation coupled with the high sensitivities ushered in applications such as transcutaneous hydrogen sensors. The quantification of

TiO_2 Nanotube Arrays: Growth and Application, Fig. 6 Schematics of TNA-based solar cells (**a**) Liquid junction dye-sensitized solar cells and (**b**) ordered bulk heterojunction solar cells (Reprinted with permission from [8])

ppm-ppb hydrogen gas concentrations escaping from blood through the skin has medical relevance as an indicator of lactose intolerance, fructose malabsorption, microbial activity, bacterial growth, fibromyalgia, diabetic gastroparesis, and neonatal necrotizing enterocolitis. The prevailing explanation for the remarkable change in resistivity is that chemisorption of hydrogen atoms on the nanotube surface results in partial charge transfer to the TiO_2 resulting in an electron accumulation layer on the nanotube surface which drastically improves the electrical conductance of the MSM structure. In addition, hydrogen adsorption reduces the work functions of Pd and Pt. Consequently, the height of the potential barriers at the TiO_2/Pt and TiO_2/Pd interfaces are lowered, thus again increasing the conductance of the MSM structure.

TNA-Based H_2O_2 Sensors

TNAs on which horseradish peroxidise (HRP) and thionine were co-immobilized have been used as electrochemical sensors to detect and quantify hydrogen peroxide [8]. Due to the high electrocatalytic activity of the immobilized HRP for thionine oxidation in the presence of H_2O_2, a large increase of reduction current occurs for the Th/HRP/TiO_2 electrode due to peroxide. The detection limit for H_2O_2 was estimated to be as low as 1.2 μM.

TNA-Based Amine Sensors

Amines are one of several chemical pollutants released in oil and gas spills which contaminate fresh and seawater. In the light of the fact that many amines are proven or suspected to be carcinogenic and have been implicated in inducing bladder cancer, environmental monitoring of amine levels assumes significance. In this regard, TNAs coated with an electrostatically adsorbed layer of ruthenium tris(bipyridinium) ions [$Ru(bpy)_3^{2+}$] have been used in an electrochemiluminescence sensor to detect and quantify the tripropylamine concentrations in water as low as 1 nM [20].

Toward bioreplicated texturing of solar-cell anodes

Definition

Biological species have developed myriad photonic structures to efficiently interact with light. The results of these interactions include large angular fields of view, reduced surface reflection, Bragg diffraction, and multiple scattering. Bioreplicated texturing of solar cell surfaces and photoanodes takes advantage of these excellent optical properties in biology. The aim is to convert biological structures into exact replicas made out of semiconductors, metals, and polymers and incorporate these replicas into solar cells to enhance light harvesting and light–matter interactions.

Introduction

The development of efficient, inexpensive, and environmentally benign energy sources is one of the biggest technological challenges of the twenty-first century. Even the most conservative predictions suggest worldwide demand for energy will triple within the next 40 years [1]. This rapidly growing energy demand, coupled with economic and ecologic impacts of fossil fuel–based

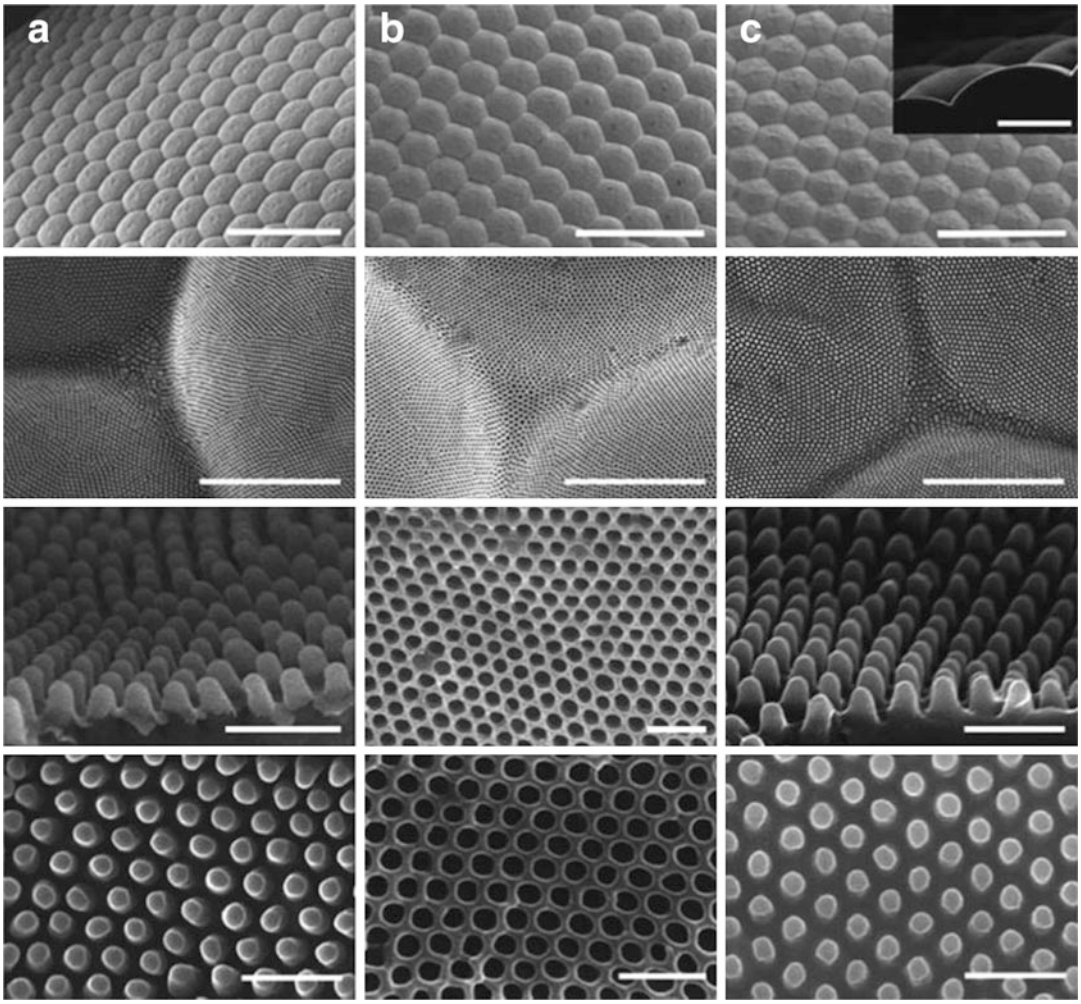
energy sources, has sparked research into low-cost and environment-friendly alternatives. Given the immense amount of energy the sun delivers to earth daily, solar power constitutes by far the most promising and attractive alternative to fossil fuels. However, to become the primary energy source for future consumption, highly efficient yet inexpensive strategies for direct conversion of solar power into thermal energy, electricity and chemical fuels are needed. A central challenge in solar energy conversion and photocatalysis is to optimize "light management" at the nanometer scale – from capture of sunlight to transfer and conversion of solar light into energy, fuels, or drivers of chemical reactions.

A prime example of highly evolved light management is photosynthesis – one of the most fundamental processes in biology. Calculations show photosynthesis produces approximately 90 TW of energy annually, approximately six times the current worldwide total energy consumption per year [1]. In addition, the light-independent phase of photosynthesis fixes carbon dioxide from the atmosphere, providing a potential mechanism for carbon dioxide sequestration. Photosynthetic organisms capture sunlight and channel solar energy from light-harvesting outer units to a reaction center by transferring energy along multiple functional units and converting it to fuel. It is this elaborate, integrated energy conversion system consisting of controlled and cooperative interaction between functional nanoscale components that results in efficient capture, transfer and use of solar energy. In contrast, artificial solar conversion units are still far from achieving the sophistication of their counterparts in nature. The goal is thus to examine simple models of biological systems, to learn from nature's complex energy conversion systems and to unlock and mimic its mechanisms [2–4].

For example, in biological materials, such as the wings of a butterfly or the exoskeleton of an insect, chitin and air are organized in ordered structures to produce optical interference leading to structural colors, camouflage and the control of solar radiative heat intake for thermal regulation. An early study calculated the effects of total solar radiation absorption and emissivity in the forms of beam radiation, which travels directly from the sun to a surface; diffuse radiation, which is a uniform distribution of light on a surface from all possible angles; and reflected radiation, which is light reflected from the ground on an insect thin film [5]. The outcome of this study suggests minute changes in the thickness of these biological thin films, typically 100 nm thick, strongly influence intake of energy from solar radiation. For example, changes in butterfly wing scale film thickness could significantly shift absorption levels (by up to 25 %) over a span of 80 nm, while diffuse solar absorption and emissivity remain relatively constant. Furthermore, iridescence has been found to be strongly correlated with higher absorption of the solar radiation [6].

In this entry, several novel concepts inspired by biological systems are introduced to enhance the first steps in solar energy conversion: the capture of sunlight through bioreplicated surfaces and light–matter interactions driving the conversion process. In the first section, strategies to increase the light-harvesting capability of conventional solar cells are discussed. These strategies are based on the excellent optical properties of insect eyes. In these structures, called compound eyes, intricate microscale and nanoscale features result in significantly enhanced angular fields of view, while minimizing surface reflectivity. Since these parameters are of utmost importance for optimizing light harvesting in conventional solid-state junction solar cells, researchers have recently started to develop methods for mass-replicating these biological structures as polymer films for deposition onto the surface of solar cells [7, 8]. In the second section, focus will be directed on methods to increase light–matter interactions in a new type of solar cell, the Grätzel-type electrochemical cell [9]. The heart of this low-cost alternative to solid-state junction devices is a nanocrystalline titania photoanode sensitized with visible-light absorbing dyes. Interestingly, coupling this photoanode to photonic crystal structures can increase its optical path, and therefore results in higher solar conversion efficiency [10, 11]. Since some of the most effective photonic crystal structures are found in biological systems, such as colored beetles and butterflies

[12], researchers are devising ways to replicate these remarkable architectures into nanocrystalline titania [13]. These efforts are reviewed and several examples of attempts to generate bioreplicated photoanodes are given.



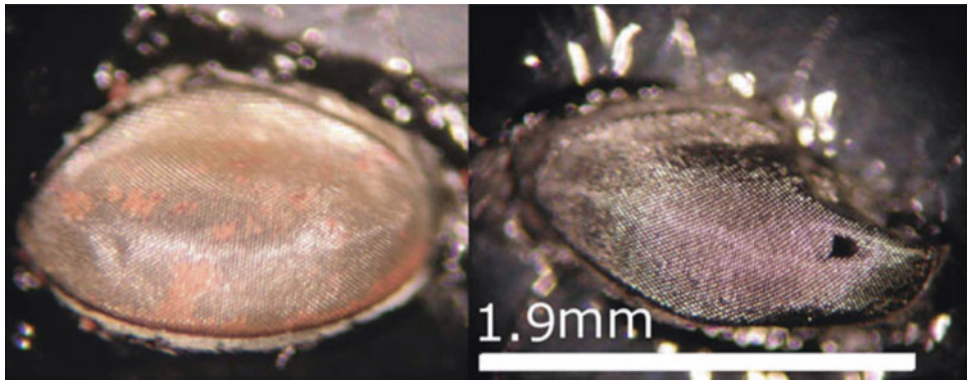
Surface Structuring of Solar Cells

A dominant factor in the performance of any solar conversion device is the amount of incident sunlight coupled into the active module of a given solar cell. The key considerations for efficient coupling of light into solar cells are to maximize the angular field of view of the solar absorption module and to minimize the overall reflection of light at the cell's surface. Increasing the angular field of view aims to harvest as much light as possible, in terms of direct illumination from the sun, as well as diffuse light. Harvesting the direct illumination of sunlight is highest when it hits the solar cell surface at a 90° angle. While, in principle, this can be achieved simply by installing a mechanical device that rotates the solar cell surface in response to the sun's position, such motion devices increase the cost of solar cells, require maintenance and use up part of the cell's energy. In addition, these motion devices would only minimally increase harvesting of diffuse light – scattered and reflected light that hits the solar cell from any possible angle.

During the course of millennia, biological structures have evolved to capture light from a wide range of directions. Indeed, houseflies have optimized their angular field of view through eye placement and underlying structure such that these insects can see 270° around them from a horizontal plane [2]. This remarkable ability stems from a compound eye structure, consisting of an array of microscale cylindrical lenses arranged on a curved surface. These tiny lenses not only capture light along the axis of the cylinder, but also can absorb light propagating in other directions through the cylinder's sidewalls. In addition, compound eyes can have nanometer-scale surface structures, which serve both as an antireflective [7] and a superhydrophobic surface [14]. These properties are the result of a gradual change in refractive index between the air and the eye. While superhydrophobicity keeps the eye clean, reduced reflection from insect eyes protects them from being visible to predators, and it also significantly enhances their photosensitivity in dim environments. As a result, these surfaces are an important enhancement strategy that could be used to boost efficiency in a solar cell.

Although these biological structures have complex nano-to-microscale features, recent advances in engineered biomimicry now allow scientists to replicate these structures using materials optimal for harvesting light for solar cells. Both physical and chemical nanofabrication techniques such as atomic layer deposition, conformal-evaporated-film-by-rotation technique, chemical vapor deposition, soft lithography and nanocasting are now employed by researchers to generate replicas of various biological structures in technologically relevant materials. For example, a research group developed a soft lithographic patterning technique to replicate a nanometer-scale antireflective coating found on the lens of a moth's compound eye [7]. A three-dimensional mold of this coating was designed with perfluoropolyether, an elastomeric polymer material capable of capturing nanometer-scale surface features. This mold was then used to create polyurethane replicas with antireflective behavior. As shown in Fig. 1, this approach results in high-fidelity replicas preserving topographical features as small as 100 nm. In addition, the group successfully used this technique to emboss antireflective nanoscale patterns in a widely used polymer blend for the photoactive region of an organic photovoltaic cell.

In an attempt to scale up compound eye bioreplication methods to mass-produce antireflective/large-field-of-view solar cell components, researchers developed a method to create reusable master negatives [8]. Specifically, corneas of the common blowfly were used as templates and replicated into metallic nickel. To achieve both a high-fidelity imprint of the hierarchically organized cornea surface and a stable and reusable master negative, the replication process was conducted in two steps. First, a modified version of the conformal-evaporated-film-by-rotation method was used to deposit a thin layer



Toward Bioreplicated Texturing of Solar-Cell Surfaces, Fig. 1 Scanning electron micrographs of (**a**) the *Attacus atlas* moth eye structure, (**b**) the negative polymer replica, (**c**) the positive replica made by polymerization in the negative mold. *Inset* of (**c**) shows curved surface of the replica. Scale bars are 100 μm for the top images (*inset*: 20 μm), 5 μm for the second row images, and 500 nm for the third and fourth row images (Reproduced from Ref. [7] with permission of The Royal Society of Chemistry. doi:10.1039/C1SM05302G)

of nickel onto the surface relief of the cornea sample. In a second step, additional nickel was deposited by electroforming to strengthen the initial thin film replica. Finally, after removal of the biotemplate, a free-standing negative copy of the original cornea was obtained (Fig. 2). This group also showed this negative master could be successfully used (and reused) to create polymer replicas by a casting technique to faithfully reproduce micrometer-sized surface features. In addition, it was suggested by using stamping instead of casting, nanometer-sized features could be transferred into mass-produced polymer replicas.

Biotemplating of Photoanodes

Along with light-harvesting techniques, engineered biomimicry is a promising approach to enhance light–matter interactions in solar conversion systems. This is a particularly important area of research in next-generation, low-cost

devices based on nanostructured semiconductors, conducting polymers and various hybrid device architectures. For example, theoretical studies recently showed coupling the photoanode of a Grätzel-type solar cell to a photonic crystal could significantly enhance its efficiency [10, 11]. Photonic crystals are periodically ordered structures with lattice parameters comparable to the optical wavelength of interest [15]. Due to this periodic variation in the refractive index, light within a photonic crystal experiences a combination of Bragg diffraction and multiple scattering events. As a consequence, light of certain frequencies undergoes multiple reflections as it slowly percolates through this structure. This results in a greatly increased nominal optical path length, an increase in light–photoanode interactions and significantly enhances the probability of light-to-charge conversion.

Interestingly, millions of years before we "discovered" photonic crystals, biological systems created such structures to produce vibrant colors, control solar absorption and enhance bio-fluorescence for a variety of reasons, ranging from camouflaging to frightening predators and attracting mates [12, 13]. Biological photonic structures thus were optimized to produce a wide range of optical effects and function under various illumination conditions. Not surprisingly, the range of photonic structures found in biological species is virtually limitless, ranging from simple one-dimensional multilayers, to two-dimensional lattices found in skeletons and hairs of sea animals and bird feathers and to various three-dimensional architectures within colored cuticle scales of many species of beetles and butterflies. For example, scientists discovered certain beetles obtain their color from diamond-based photonic crystals – one of the most effective lattice structures [16]. What's more, such photonic structures (as an example, Fig. 3 shows the green Brazilian beetle *Lamprocyphus augustus*) are still beyond our engineering capabilities. Similarly, photonic structures found in many butterfly wing scales have an astonishing hierarchy, consisting of ridges, lamellae and ribs, as well as highly periodic honeycomb and gyroid structures [12]. These elaborate hierarchical-scale structures act as optical components interacting with sunlight, such as multilayer reflectors, diffraction gratings and photonic crystals.

Only recently have scientists begun to use this invaluable portfolio of biological photonic crystal lattices for engineered biomimicry approaches. The method of choice is bioreplication: here, a biological photonic structure is used as a template to create positive or negative copies out of photocatalytically active compounds. An example of this approach is shown in Fig. 4 for conversion of the diamond-based photonic structure of the beetle *L. augustus*. Replication is achieved by a sol–gel double-imprint method using a sacrificial

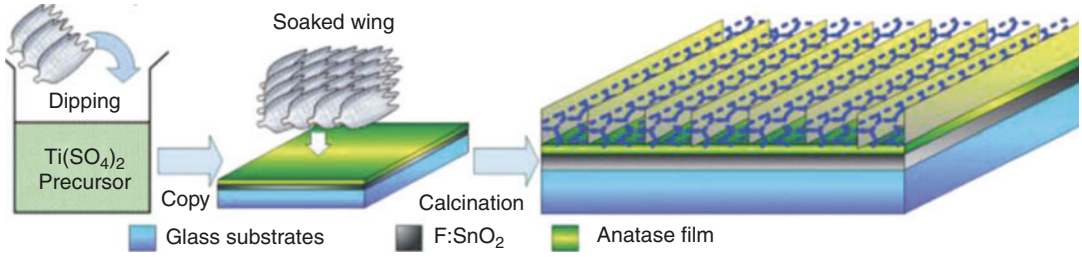
silica glass intermediary [17]. Sol–gel templating is quite attractive due to its simplicity and low cost. The original biological templates were backfilled with liquid precursors of the desired inorganic compound (e.g., silica, titania, alumina). After solidification of the inorganic compound, the original template was selectively removed by etching or heat treatment. This approach enabled a positive copy ("inverse-of-the-inverse") of the original structure composed of photocatalytically active nanocrystalline titania.

Along with sol–gel chemistry, other physical and chemical deposition methods can be used for replication of biological structures – as long as they operate under mild deposition conditions and temperatures. Successful methods include atomic layer deposition [18] and conformal-evaporated-film-by-rotation techniques [19]. In general, these techniques can be applied under noncorrosive reaction environments, mild pH conditions, and relatively low deposition temperatures (below 100–200 °C). Since these replicas are formed by deposition from a gas phase, these methods are highly efficient in infiltrating even complex three-dimensional frameworks as long as the internal structure is fully accessible. Furthermore, the deposition parameters can readily be controlled, enabling the amount of deposited material to be carefully controlled. As shown in Fig. 5, control of atomic layer deposition can be used to create shell-like replicas of the original biological structures with finely tuned replica shell thickness and, as a result, well-controlled optical properties.

Recently, a group of scientists took such bioreplication approaches one step closer to solar conversion applications by devising strategies to construct a Grätzel-type titania photoanode



Toward Bioreplicated Texturing of Solar-Cell Surfaces, Fig. 4 Sol–gel bioreplication route of photonic weevil scales into titania replicas (*top left*). coupled to arrays of replicated butterfly scales [20]. In this approach, 1 × 1 cm^2 samples of butterfly wings were soaked in a titania sol–gel precursor and arranged on top of a Grätzel-type photoanode (Fig. 6). This composite structure was then heat-treated to allow the top butterfly-wing replica layer to bond to the bottom titania layer. This heat treatment (500 °C in air) also induced

Toward Bioreplicated Texturing of Solar-Cell Surfaces, Fig. 6 Schematic illustration of creating bioreplicated titania photoelectrodes. titania crystallization into polycrystalline anatase and removed the biopolymeric template. Despite structural shrinkage during the heat-based framework densification-crystallization treatment, these replicated materials displayed improved light absorption behavior as compared to anodes without the replicated butterfly wings. While this outcome is an important step toward bioreplicated solar cells, these researchers also note major challenges remaining in generating such biotemplated anodes, optimizing their electrical conductivity and integrating these structures into functional solar conversion devices.

Concluding Remarks

Engineered biomimicry has arrived as a serious contender in materials research and engineering. While a few years ago the concepts of supervision from bug eyes, ultrastrong fabrics from spiders, vertically climbing gecko-like robots, or optical devices from beetles was more the stuff of Hollywood science fiction, these ideas have found their way into research laboratories and inspire the development of new devices in electronics, optics and mechanics. Indeed, although the pure beauty of natural iridescence in the form of opal gem stones, jewel beetles and feather ornaments has fascinated and inspired mankind for thousands of years, today, these materials and optical concepts offer revolutionary new ways to manipulate light. In addition, these materials hold great potential for more efficient solar cells and photocatalysts, new optical reflectors and sensors and ultrafast switches.

An exciting area in engineered biomimicry is bioreplication, in which complex biological structures are converted into replicas made of semiconductors, metals or polymers. In this entry, a few examples of solar-related bioreplication strategies to increase light-harvesting ability and light–matter interaction efficiency in various types of solar cells were discussed. While many of these approaches are promising and first successful steps have been achieved, it should be emphasized there are also several limitations and challenges in bioreplication. For example, biological samples have an inherent size limit given by the dimensions of the eyes, scales, or feathers used as templates. Direct use and integration of biological samples, therefore, have limited applications, suggesting more efficient mass-duplication routes have to be developed. In addition, most natural structures have a much higher defect density than what is tolerated by current engineering standards, and no two natural structures are exactly the same. For example, the structural parameters of colored scales taken from different parts of a beetle, or even within a single scale, can vary by as much as 20 %.

Consequently, bioreplication must be viewed in its correct and just perspective: Although materials prepared by bioreplication will perhaps never achieve the precision, uniformity and reproducibility of their counterparts engineered by micro- or nano-fabrication methods, bioreplication opens the door to the full portfolio of highly complex

hierarchical structures found in nature – structures still far from our engineering capabilities. It will therefore be of vital importance to devise strategies to use and integrate materials created by engineered biomimicry with micro- or nanofabrication methods and combine the appealing aspects of two worlds – biology and materials science – in a concerted approach. Engineered biomimicry has found its way from science fiction into the laboratories; whether it makes the next step from fundamental research to wide-scale applications will depend on scientific creativity and imagination.

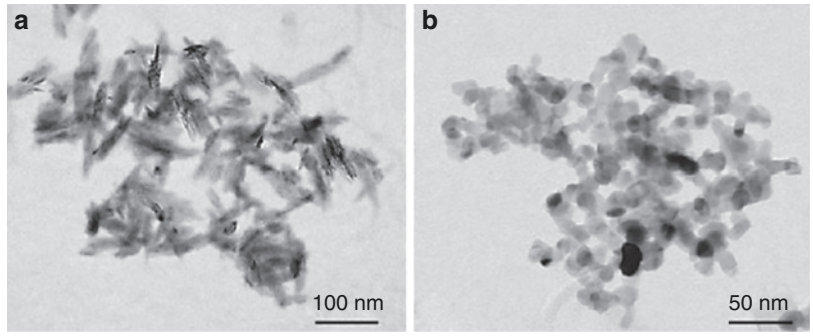
Definition

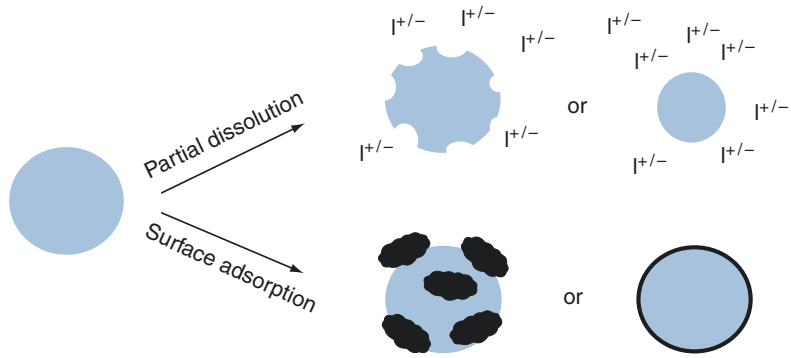
Impact of engineered nanoparticles (ENP) on plant growth, development, physiology, and morphology.

Key Research Findings



Three research areas are currently being investigated to define engineered nanoparticle (ENP) impacts on plant development (seed germination, root and shoot elongation, etc.), on plant physiology, and ENP uptake and translocation through plants.

Impact on Plant Development



In this research area, regulatory tests are used, such as the ones described in EPA guidelines [1]. These guidelines have been developed for toxicity testing of chemical pollutants, and their relevance for toxicity testing of ENPs is under debate, with several groups working on their implementation to render them accurate. Among these tests, seed germination, root and shoots elongation assays have been intensively used to assess ENP impact on plant development, and the obtained results are either positive, or negative, or inconsequential. For instance multi-walled carbon nanotubes (CNT) have been shown to cause plant biomass decrease, particularly on *Cucurbita pepo* [2], while they showed no impact on rye grass, lettuce, rape, radish, corn, and cucumber [3]. The same is true for TiO_2 nanoparticles, which were shown in some studies to alter leaf growth and transpiration on maize [4], while they did not cause any alteration in the growth of willow tree plantlets [5].

Described results are difficult to compare, since model plant species are often different, and the considered nanoparticles are often different as well: Multi-walled CNTs may differ in their production process, post-synthesis surface treatment, and in the preparation of dispersed suspensions. TiO_2 nanoparticles may differ in their primary diameter, specific surface area, shape (round, elongated, see Fig. 1), crystalline structure, etc. These conflicting effects are easily explained by the broad panel of tested ENPs, and their very different physicochemical properties.

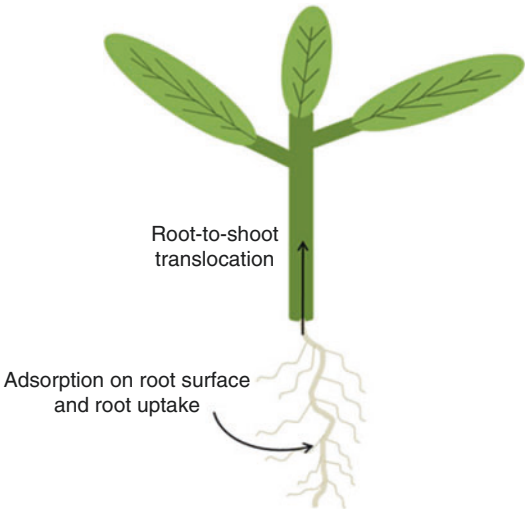
Moreover indirect effects such as ENP dissolution or impact of the solvent (or other environmental pollutants) which may be adsorbed on ENP surface have to be considered (Fig. 2).

Toxicology: Plants and Nanoparticles, Fig. 1 Titanium dioxide nanoparticles, rutile and elongated-shaped (**a**) or anatase and round-shaped (**b**)

Toxicology: Plants and Nanoparticles, Fig. 2 Schematic representation of potential ENP evolution in the environment: ENPs may partially dissolve, releasing free ions ($I^{+/-}$). They may also adsorb environmental pollutants or solvent on their surface

The best examples of the impact of ENP dissolution on plant development was demonstrated with Cu and ZnO nanoparticles. Even if the impact of dissolved ions did not explain all the toxic effects observed in the following studies, they greatly contributed to them. Indeed, Cu NPs have been demonstrated to cause inhibition of plant growth and to accumulate in mung beans and wheat [6], but also have some influence on the germination of lettuce [7]. Among all the ENPs tested for their impact on rye grass, lettuce, rape, radish, corn, and cucumber, only Zn and ZnO NPs reduced germination of ryegrass and corn, respectively. These two ENPs also reduced root elongation [3]. ZnO-NP dissolution was then considered by the same team the year after [8].

Uptake and Translocation



Despite the relative impermeability of plant roots to particulate matter, due to their small size, ENPs have been demonstrated to penetrate plant root wall, even if most of the ENPs remain adsorbed on root surface. It has for instance been demonstrated for Fe_3O_4 NPs on pumpkins [9], for TiO_2-alizarin red nanoconjugates on *Arabidopsis thaliana* [10], and CeO_2 nanoparticles on alfalfa, cucumber, corn, and tomato [11]. The consequence of such result is that ENPs may then be transferred to the food chain. Note that the ENP content in these plants is very low: ENP uptake is not an efficient process; consequently the amount of ENPs reaching the food chain would also be low.

Several techniques are available to demonstrate ENP uptake by plants. First, electron microscopy, due to its very high spatial resolution (typically 1 nm or below), is the method of choice to identify the presence of ENPs in biological samples, and particularly in plants. Scanning electron microscopy (SEM) permits to observe ENPs on the surface of plant tissues (roots or leaves), but does not give access to the internalized ENPs. Conversely transmission electron microscopy (TEM), achieved on dehydrated plant samples included in a resin and cut in ultrathin sections, permits the detection of nanosized materials in

plant cells or extracellular compartments. TEM has been successfully used to prove that carbon-based ENPs were accumulated in rice plantlets [12]. Coupling these two techniques with energy-dispersive spectroscopy (EDS) allows a local chemical identification of the electron-dense spots observed by TEM or SEM in plant samples, proving that they contain the chemical element constituting the ENP (when EDS analysis is performed, then spatial resolution ranges from 30 to 50 nm).

Another valuable technique is micro-X-ray-fluorescence (μ-XRF), achieved either on a laboratory source or using synchrotron radiation. This technique allows local identification of chemical composition, and basically the identification of hot spots of one particular element constituting the ENP. With this technique, spatial resolution can be as high as 100 nm on some synchrotron beam lines such as ID22 (ESRF, Grenoble, France). On some synchrotron beam lines, this technique is coupled to X-ray absorption spectroscopy (XAS), which allows describing the local environment of the analyzed element, giving the absolute proof that the element is in the nanoparticulate form, and not present as dissolved ions. Moreover it informs on ENP crystal structure, and sometimes on their size (it is the case for TiO_2-NPs). For instance this technique has been used to evidence that alfalfa, cucumber, corn, and tomato plants accumulated CeO_2-NPs in their roots [11].

Regarding the detection of CNTs, TEM enables the observation of single or clusters of NTCs. However, images obtained by TEM can be misinterpreted, since the shape of CNT is close to the structure of natural vegetal compounds. In order to avoid any misinterpretation, very specific techniques such as photothermal and photoacoustic detection have been developed and used for the identification of their accumulation and translocation in tomato plantlets [13]. These techniques are highly sensitive and specific, allowing detecting single MWCNT in plant tissues. Raman spectroscopy is also a very specific technique, which has been used to identify the presence of CNTs inside plant seeds thanks to their G band (1568 cm^{-1}) [14].

Toxicology: Plants and Nanoparticles, Fig. 3 Schematic representation of ENP adsorption on root surface, root uptake, and transfer to the shoot

Another point is that, when taken up in plant roots, ENPs are in some cases transferred from the roots to the shoots (Fig. 3). This phenomenon, also called translocation, was demonstrated for instance with Au-NPs in tobacco [15] and Fe_3O_4 NPs on pumpkins [9]. Carbon-based NPs have also been demonstrated to translocate from the roots to the shoots and from the shoots to the seeds. The newly developed plantlets, resulting from the germination of these contaminated seeds, also contained carbon-based NPs, meaning that ENPs were transmitted to the next generation [12].

Very recently, thanks to these techniques, gold NPs were shown to be transferred to higher trophic levels: hornworms fed with Au-NP-exposed tobacco were shown to be contaminated with Au-NPs [15]. In this particular case, gold maximal concentration in tobacco reached less than 100 mg Au kg^{-1} dry tobacco.

Impact on Plant Physiology

The impact of ENP exposure on plant physiology and metabolism is poorly described, underlining that the area of research of ENP phytotoxicity is at its infancy. A very recent study describes the impact of NTC on plant gene expression [13]. Many stress-related genes are activated

upon exposure to NTC, and among them the gene encoding the protein constituting water channels (aquaporins) [13]. This channel regulates water permeability, and therefore is significantly implicated in seed germination and plant growth. In one study TiO_2-NPs have also been demonstrated to inhibit root growth and transpiration by interference with water transport [4]. Actually, ENPs blocked apoplastic water flow in plant roots (within a plant, the apoplast is the free diffusional space outside the plasma membrane), certainly by obstructing nanosized cell wall pores, but also by reducing the exclusion diameter of these pores. However TiO_2-NPs are likely to agglomerate when dispersed in a saline, neutral aqueous solution. Therefore, exposing plant roots to TiO_2-NPs dispersed in a $CaCl_2$ solution at near-neutral pH, even if it is more physiologically relevant, means that plants were exposed to highly agglomerated ENPs. It is thus not surprising that water flow through the plant was blocked, and it rather derives from root exposure to a high concentration (0.3 or 1 gl^{-1}) of agglomerated material, than by a specific effect of ENPs.

Several studies reported that ENPs impacted plant photosynthetic activity. In a series of articles, TiO_2-NPs were shown to induce an increase in spinach germination, growth, nitrogen metabolism, and photosynthesis, and protected plants from oxidative damage induced by UV radiation [16]. Indeed TiO_2-NPs promote energy transfer from chlorophyll b and carotenoids to chlorophyll a, but also to the P680 chlorophyll a of D1/D2/Cyt 559 complex, in vitro. The authors conclude that nanosized TiO_2 would enter spinach cells and chloroplasts more easily due to their small size, then bind to the D1/D2/Cyt 559 complex and improve absorption, transfer, and conversion of light energy in chloroplasts [16].

Lastly, genotoxic effects of ENPs are currently investigated on several plant species. Root exposure to Ag-NPs reduce the mitotic index of exposed cells in *Allium cepa*, and more generally impair the cell division process, resulting in chromatin bridges, stickiness, disturbed metaphase, chromosomal breaks, and cell disintegration [17]. In the same test (*A. cepa* test is a standardized assay) TiO_2-NPs show no genotoxic impact, neither chromosomal aberration nor micronuclei [18]. Conversely DNA damage is detected in *A. cepa* and *Nicotiana tabaccum* exposed to TiO_2-NPs, by using comet assay and DNA laddering experiment. This genotoxic effect is correlated with the induction of malondialdehyde production, which is a marker of lipid peroxidation, as a result of oxidative stress [19].

Concluding Remarks

As a conclusion, the impact of ENPs on plants is still poorly documented; however some effects have been reported. Some ENPs, particularly those which partly dissolve, impact plant developments, i.e., seed germination, root and shoot elongation, and plant biomass. Some ENPs are taken up by plant roots, sometimes translocated to the shoots, and even transmitted to the next generation via their transfer to seeds. When accumulated in plant leaves, some ENPs can be transferred to primary consumer, for instance hornworms, meaning that they reach the food chain. The genotoxic potential of some ENPs has been demonstrated, although other articles relate opposite results. Some ENPs would modulate photosynthesis by impacting photosystem activity. Note that only some ENPs have these properties and exert these effects, the results described herein definitely cannot be generalized to all ENPs. Note also that almost all the results were obtained on plants exposed to ENPs in vitro, but only one publication describes the impact of ENPs-amended soil on plant development. Data thus need to be collected on environmentally relevant systems, i.e., plants cultivated on natural soils and contaminated with low doses of ENPs since massive contamination of the environment with ENPs would improbably occur.

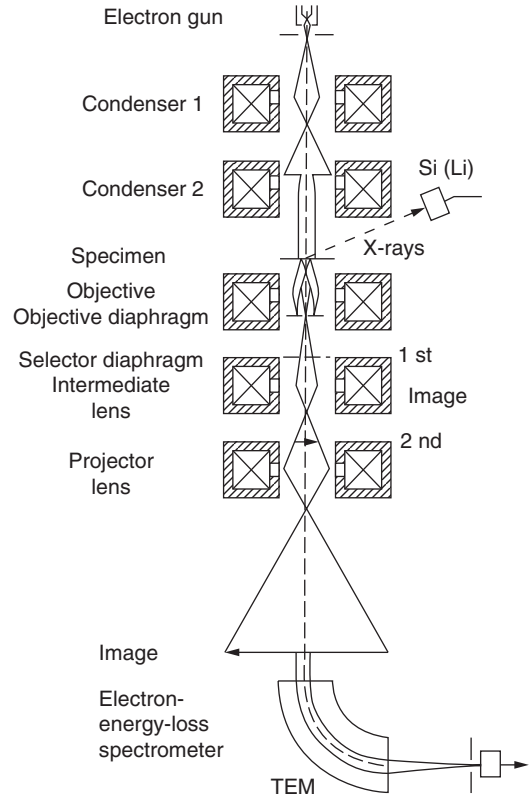
Transmission Electron Microscopy

Helmut Kohl
Physikalisches Institut, Westfälische Wilhelms-Universität Münster, Münster, Germany

Definition

Transmission electron microscopy is a method to image small thin objects by the use of the transmitted electrons.



The Transmission Electron Microscope (TEM)

Similar to the general scheme of a light microscope, a transmission electron microscope [1, 2] consists of an electron source, a condenser system, an objective lens, and a projector system as shown in Fig. 1. Many transmission electron microscopes have additional instruments attached to it, such as an X-ray detector and/or an energy loss spectrometer in order to be able to perform elemental analyses. These techniques will be explained later on.

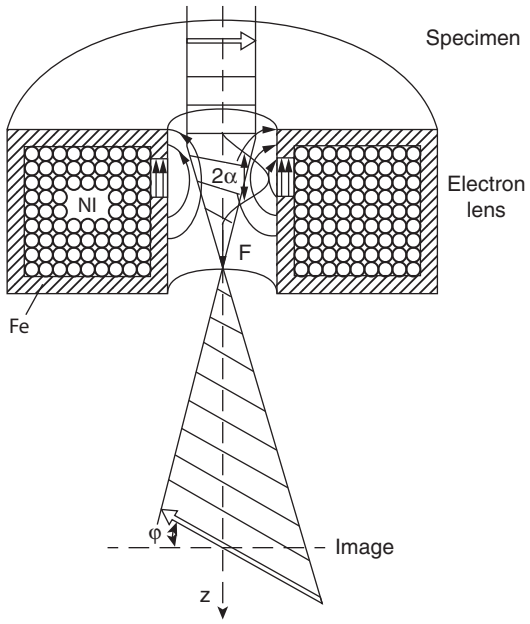
The electron source, commonly called "gun," is composed of a cathode and an accelerating system. There are different types of cathodes being used:

- Thermal cathodes
- Schottky emitters, often misleadingly called (hot) field emission cathodes
- (Cold) field emission cathodes

Thermal cathodes make use of thermal emission of electrons at high temperatures. Most often they use tungsten or LaB_6 as emitting material. The emission barrier can be lowered by applying a strong electrostatic field to a tip (Schottky effect). This is the basic principle of a Schottky emitter. Using an even stronger electrostatic field at a sharp tip, one can extract electrons by means of the quantum mechanical tunnel effect. The resulting field emission cathodes require ultrahigh vacuum to operate, because otherwise positively charged ions will be accelerated toward the tip eventually leading to its destruction. All of these cathodes are followed by an accelerating system ending with the anode. Most transmission electron microscopes usually operate at voltages of 100–300 kV, even though there are special low-voltage TEMs operating at voltages from 20 kV upward and high-voltage TEMs operating at voltages up to 1.2 MeV.

Transmission Electron Microscopy, Fig. 1 Schematic ray paths for a transmission electron microscope (*TEM*) equipped with an additional X-ray spectrometer and an energy loss spectrometer [1]

The role of the condenser system is to transfer the electrons from the gun onto the specimen. It is composed of two to five electron lenses to allow to independently vary the illumination angle and the size of the illuminated area. The transmitted electrons are then focused to a magnified intermediate image which in turn is magnified and transferred into the final image plane.



Magnetic Electron Lenses

To focus an electron beam, we need lenses operating similar to glass lenses in light optics. These can be constructed by coils encapsulated by a ferromagnetic material as shown in Fig. 2. To understand their working principle, let us consider the movement of an electron in the homogeneous magnetic field of a long coil. The Lorentz force on the electron is given by

$$\boldsymbol{F} = -e\boldsymbol{v} \times \boldsymbol{B} \tag{1}$$

The velocity $\boldsymbol{v}$ can be separated into a component parallel v_{II} to the magnetic induction $\boldsymbol{B}$ and one perpendicular component $v_{\perp}$. As there is no force operating on the parallel component, v_{II} remains constant. Perpendicular to the magnetic induction $\boldsymbol{B}$, the electron performs a circular motion with a radius r that is determined by the equivalence of the Lorentz force to the centrifugal force:

$$\frac{mv_{\perp}^2}{r} = ev_{\perp}B \tag{2}$$

Transmission Electron Microscopy, Fig. 2 Schematic diagram of an electromagnetic lens [1]

or

$$r = \frac{mv_{\perp}}{eB} \tag{3}$$

An electron starting from the optic axis will cross it again after it has completed one circle – in other words, the electrons starting from the initial plane are all imaged in the latter plane. For a homogeneous magnetic field, it can be shown that the focal length f is determined by

$$\frac{1}{f} = \frac{e}{8m\phi^*}B^2L \tag{4}$$

where $\phi^* = \varphi(1 + e\varphi/(2E_0))$ is the (relativistically corrected) potential, φ the electrostatic potential, $E_0 = 511$ keV the rest energy of the electron, and L the length of the coil. As can be seen from Eq. 4, the focal length depends strongly on the magnetic induction $\boldsymbol{B}$. This general fact is also true for the commonly used "short magnetic lenses" that use an inhomogeneous magnetic field. The focal length of a magnetic electron lens in an electron microscope can therefore be easily modified by adjusting the current through the coil, thus changing the magnetic field.

Unfortunately, electron lenses suffer from strong spherical and chromatic aberrations [3, 4] that limit the spatial resolution limit for conventional electron microscopes to about 0.15 nm. Just in the very last years, it has become possible to correct for aberrations so that with the most advanced instruments one can achieve a resolution limit of about 0.05 nm.

As the focal length of every lens can be easily varied by changing the lens current, the ray paths in a transmission electron microscope can be chosen within a wide range. In particular, it is easily possible to change the illumination from a large area to a small spot mode. Whereas the illumination of a large area is used for conventional imaging, the small spot mode allows the investigation of small areas whose size may well approach the 0.1 nm level. By changing the excitations of the projector lenses, it is easily possible to vary the magnification over a large range.

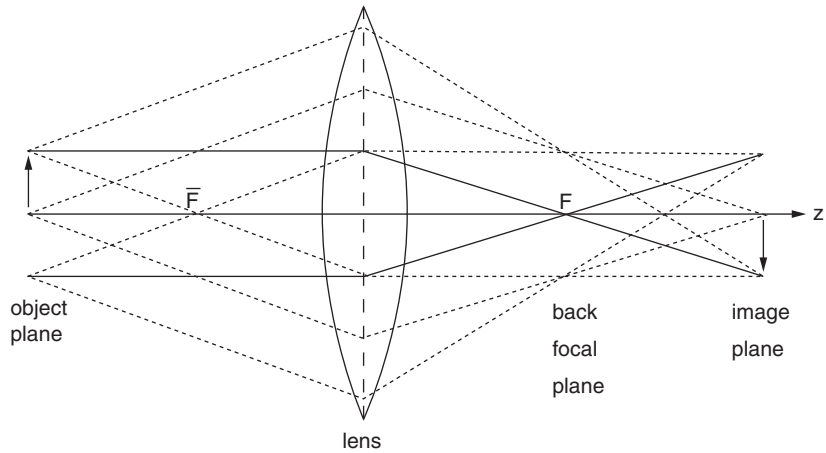
Image Formation in the Transmission Electron Microscope

Figure 3 shows schematically the image formation process for a periodic specimen. The incident electron beam has to be treated quantum mechanically as a wave that is diffracted by the periodic object. Constructing the ray paths in the usual way, one finds that all the rays diffracted in a particular direction are recombined in one point in the back focal plane of the objective lens. Rays emitted parallel to the optic axis are focused in the focal point. In other words, in the back focal plane, the electrons are selected according to the scattering angles or, to put it differently again, one obtains a diffraction pattern in the back focal plane. Therefore, the back focal plane is often called the diffraction plane.

For a general, nonperiodic specimen, the diffraction pattern consists of a continuous distribution rather than of individual spikes. Its intensity distribution is proportional to the squared modulus of the Fourier transform of the electron wave just below the specimen.

In the case of ideal imaging, all rays originating in one point of the specimen will be refocused into one point in the image plane. As in light optics, the image formation in an electron microscope can be viewed as a sequence of two Fourier transforms – the first one between the specimen and the back focal plane and the second one between the back focal and the image plane. Consequently, any manipulation in the back focal plane will influence the final image.

One example is the insertion of a circular aperture which prevents electrons scattered by an angle larger than α_0 from entering into the image. If the first diffraction angle of a periodic specimen is larger than α_0, only the undiffracted beam will enter into the image. In that case, the diffraction amplitude beyond the aperture is identical to the amplitude without any specimen, and thus one obtains an image without any structure. This example demonstrates that the resolution is then limited by the maximum angle passing through the objective aperture. Using Bragg's law



$$2a \sin\theta = n\lambda \tag{5}$$

where a is the lattice spacing and θ the scattering angle for nth order diffraction, one obtains for the lattice resolution limit d

$$d \approx \frac{\lambda}{2 \sin\alpha_0} \tag{6}$$

Contrast Mechanisms in Transmission Electron Microscopy

As the fast incident electrons pass through the thin specimens used for transmission electron microscopy, there is practically no absorption. Therefore, an "ideal" image (without any aperture or any other optical element in the back focal plane)

Transmission Electron Microscopy, Fig. 3 Ray paths showing the imaging by a lens. All rays emitted by the specimen in a given direction are focused to an off-axis point in the back focal plane

does not exhibit any contrast. In order to see anything in the image, the electron wave in the back focal plane has to be influenced in order to discern the structure of the specimen. This can be done in several ways leading to different types of contrast.

Scattering Absorption Contrast

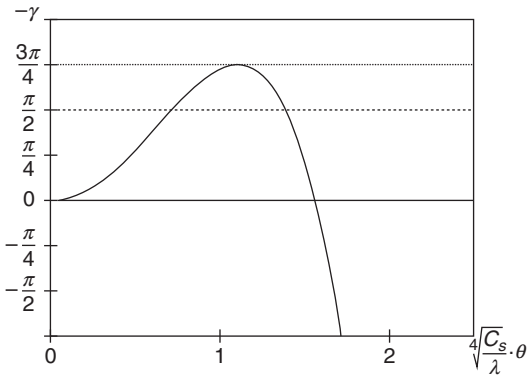
A circular diaphragm, inserted into the back focal plane, intercepts all the electrons scattered at angles larger than $\alpha_0 = r/f$, where r is the radius of the hole in the diaphragm and f the focal length of the objective lens. Strong scatterers, who scatter a substantial fraction of the incident electrons into angles larger than α_0, appear darker in an otherwise bright image. It has to be stressed that no electrons are absorbed in the specimen. The scattering takes place in the specimen, the absorption in the diaphragm in the back focal plane. The contrast is strongest for small aperture angles, because then a large fraction of the scattered electrons will be removed from the beam. Equation 6 shows that for small scattering angles, the resolution deteriorates. Even though this method is very simple, it can only be used for low- and medium-resolution images (coarse structures). For practical applications, a suitable compromise has to be found between contrast and resolution.

Dark-Field Imaging

To avoid the conflict between resolution and contrast, one can use a completely different way to obtain contrast. One major problem of scattering absorption contrast is the fact that in the image one sees only a minor decrease of intensity, which is hard to discern, in an otherwise bright image. Therefore, it is of great interest to visualize strong scatterers as bright spots. To form such an image, the unscattered electrons have to be removed so that only the scattered electrons remain in the image. This can be done by the use of a beam stop in the back focal plane intercepting all unscattered electrons that have left the specimen in a direction parallel to the optic axis. One way of doing this is to mount the beam stop on a thin wire and place it in the diaphragm in the back focal plane. It is difficult, however, to properly adjust the beam stop.

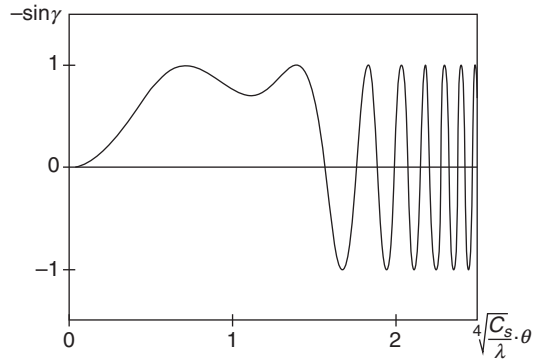
The essential requirement for the dark-field imaging mode is that the unscattered electrons are removed in the back focal plane. As in light microscopy, this can also be achieved by inserting a circular diaphragm in the back focal plane and using a hollow-cone illumination whose angle is larger than the objective aperture angle α_0. In electron microscopy, such an illumination can be most easily obtained by using deflection coils in the condenser system to tilt the incident beam and rotate the direction of incidence by properly addressing the deflection coils.

A dark-field image exhibits bright spots at the positions where scattering is strong on an otherwise dark background. The resolution is determined by the aperture angle α_0. Usually, only a small fraction of the incident electrons is scattered. Therefore, the intensity in dark-field images is rather low.



Phase Contrast Imaging

In quantum mechanics, the influence of a thin specimen on the incident electron wave can be described by a spatially varying phase shift ϕ, which is proportional to the projected potential $V(\boldsymbol{\rho}, z)$



$$\varphi(\boldsymbol{\rho}) = -\frac{i}{\hbar v}\int_{-\infty}^{\infty} V(\boldsymbol{\rho}, z)\, dz$$

where $\boldsymbol{\rho}$ is a two-dimensional vector describing the lateral position in the object plane, v is the speed of the electron, z is the direction of incidence, and $\hbar$ is Planck's constant.

Is it possible to obtain an image whose intensity is proportional to the phase shift? In light optics this can be achieved using Zernike's phase contrast method using a phase plate in the back focal plane to introduce a phase shift of $\pi/2$ between the unscattered and the scattered beam. To achieve this, one has to fabricate a glass plate

Transmission Electron Microscopy, Fig. 4 Phase shift γ introduced by the spherical aberration of the objective lens

Transmission Electron Microscopy, Fig. 5 Transfer function $L(\theta) = -\sin\gamma(\theta)$ for phase contrast imaging

of the proper thickness. How can this effect be utilized in electron microscopy?

As mentioned earlier, electron lenses suffer from severe spherical aberrations that correspond to a phase shift increasing with scattering angle. Including the effect of a small defocus Δf, this phase shift γ is given by

$$\gamma(\theta) = k\left\{\frac{C_s}{4}\theta^4 - \Delta f\frac{\theta^2}{2}\right\}$$

where C_S is the spherical aberration constant, $k = 2\pi/\lambda$ the wave number of the electrons, and θ the scattering angle. By a proper choice of the defocus, one can obtain a phase shift of approximately $\pi/2$ over a large range of scattering angles. This is shown in Fig. 4. To optimize phase contrast, the defocus is chosen so that γ stays close to $\pi/2$ for a large range of scattering angles.

The performance of this method can best be described by the use of a transfer function. Such transfer functions are well known in electronics, where they determine to what extent an electric signal of a given frequency f is transmitted through a circuit. To describe the transmission of a general electric signal, the latter is decomposed into its frequencies – in other words, it is Fourier transformed. The concept of a transfer function can readily be generalized to two-dimensional spatial signals. Due to the circular symmetry of an aligned microscope, the transfer function depends only on the modulus of the spatial frequency θ/λ. For phase contrast imaging, the "phase contrast transfer function" is given by the sine of γ:

$$L(\theta) = -\sin\gamma(\theta)$$

Figure 5 shows its behavior for the optimum defocus, the so-called Scherzer focus:

$$\Delta f \approx 1.2\sqrt{C_s\lambda}$$

The first zero of the phase contrast transfer function determines the resolution limit d, which is given by $d = 0.67\sqrt[4]{C_s\lambda^3}$. It can be shown that spherical aberration is unavoidable for electric–magnetic round lenses, provided they are time independent and that there is no electrostatic charge within the lens. Typical values of the spherical aberration constant C_S are about 1 mm. Inserting $C_S = 1$ mm and assuming an accelerating voltage of 300 kV, corresponding to a wave length $\lambda = 2$ pm, one obtains a resolution limit of $d = 0.2$ nm. One can thus obtain high-resolution images with good contrast.

High-Resolution Electron Microscopy

So far the discussion has been confined to thin objects, where multiple scattering can be neglected. Frequently, high-resolution electron

microscopy is applied to crystals oriented so that the incident electron beam is parallel to a low index axis [5]. Often the resolution is then sufficient to discern atomic columns. In such crystals, however, multiple elastic scattering plays an important role. These processes strongly influence the intensity distribution in the image. It is therefore no longer possible to interpret high-resolution images of crystals directly. Instead, one has to simulate an image of a model crystal, compare the result with the experimental data, modify the model, recalculate, compare, etc., until a good match between the simulated and the experimental image has been achieved.

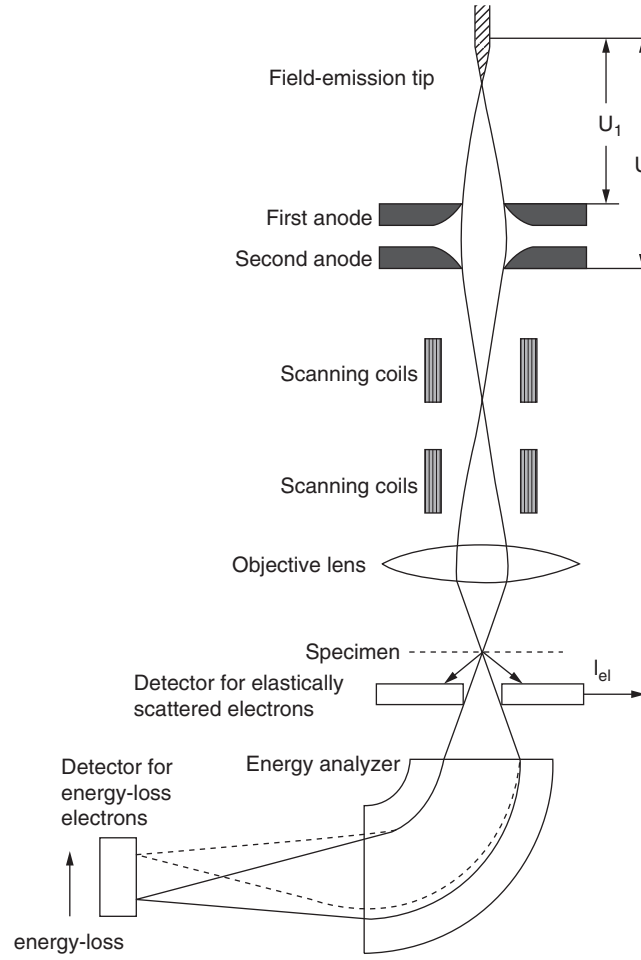
In recent years it has become possible to determine the amplitude as well as the phase of the electron wave function at the exit surface of the specimen either by a focal-series reconstruction or by electron holography. A comparison of the exit wave function with a corresponding simulation provides an even more rigorous test for the model structure.

Correctors

Due to the spherical aberration of the objective lenses, the resolution limit of electron microscopes has stayed at values well above 0.1 nm for decades. The correction for this aberration has been a challenging task, which has been achieved only very recently by using lenses without rotational symmetry [4]. Nowadays, several correctors using sextupole or quadrupole and octupole lenses are commercially available, some of which do not only correct for the spherical aberration but also for chromatic aberration. In this way, a resolution limit of 0.05 nm can be achieved.

Scanning Transmission Electron Microscopy

It is also possible to obtain images by focusing the beam to a small spot that is scanned in a raster-like manner over the specimen. The number of counts, e.g., of the scattered electrons, is then stored as intensity value for that pixel. The setup of a scanning transmission electron microscope (STEM) is schematically shown in Fig. 6. To obtain an image in a STEM, one commonly uses an annular detector subtending angles outside the cone of the incident rays. This produces a dark-field image; hence, the detector is called an annular dark field (ADF) or, for a large inner angle, a high-angle ADF (HAADF) detector. A major advantage of scanning transmission electron microscopy is the possibility to use other secondary signals to determine the intensity in the corresponding pixel of the image. In particular, the use of an element-specific signal (e.g., X-rays of a particular transition) permits to acquire images showing the distribution of that element within the specimen. Whereas dedicated STEMs are not very widely spread, many modern TEMs have a scanning attachment permitting to perform scanning transmission electron microscopy in addition to the conventional operating modes.



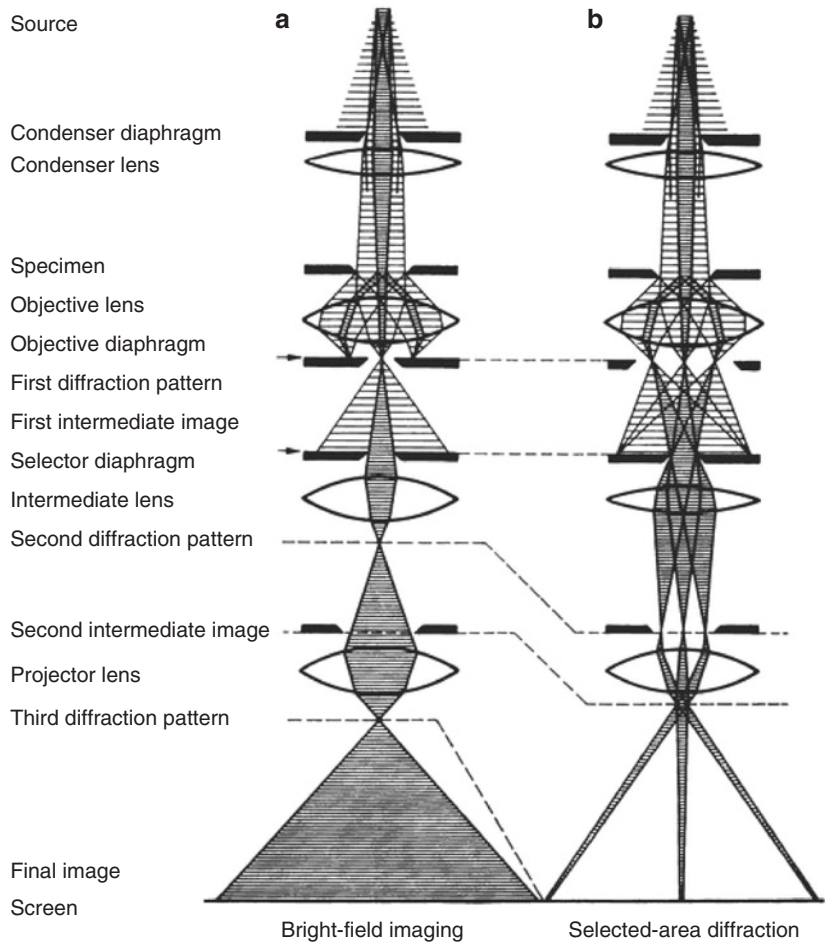
Electron Diffraction

In the previous entries, the various possibilities to obtain an image in an electron microscope have been discussed. By adjusting the intermediate lens, which is the first lens in the projector system, it is easily possible to switch to the diffraction mode, where the back focal plane, i.e., the diffraction pattern, is imaged on the final screen [6, 7]. Essentially in this mode the second and further intermediate image planes and diffraction planes are interchanged as can be seen from Fig. 7.

Using diffraction mode, one can obtain a wealth of information on the structure of a crystallite with any standard TEM. To obtain the position of the diffraction spots, one can use Laue's equation which states that the difference between the wave vector $\mathbf{k}_0$ of the incident and $\mathbf{k}_f$ of the diffracted beam must be equal to a reciprocal lattice vector $\mathbf{g}$:

$$\mathbf{k}_f - \mathbf{k}_0 = \mathbf{g}$$

Every spot in a diffraction pattern corresponds to a reciprocal lattice vector. Electron diffraction thus permits to measure the reciprocal lattice, which in

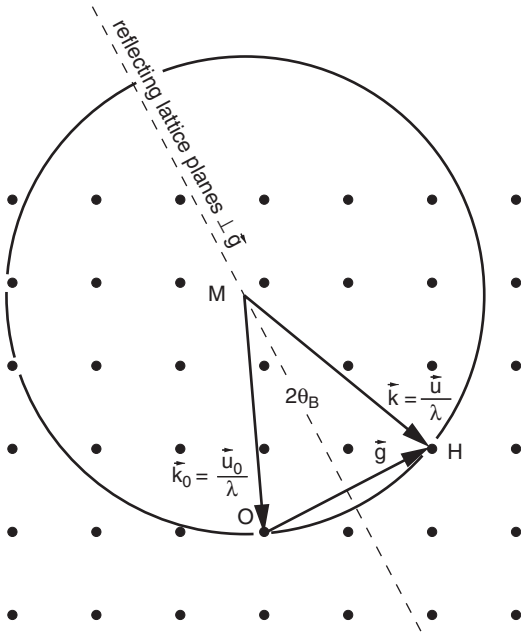


Transmission Electron Microscopy, Fig. 6 Field emission scanning transmission electron microscope equipped with an energy loss spectrometer [1]

turn allows determining the Bravais lattice of the illuminated crystallite. The position of the spots can most easily be visualized using Ewald's construction (Fig. 8). There are two conditions for the appearance of a diffraction spot:

1. The energy of the electrons, and therefore the magnitude of their wave vector, remains unchanged during the scattering process (elastic scattering). This can be visualized by drawing a sphere around the origin of the wave vector of the incident electron with a radius corresponding to its length. The wave vectors of both the incident and the scattered electron must end on the surface of this so-called Ewald sphere.
2. Drawing the wave vector of the incident electron as to end in the origin of the reciprocal lattice, the wave vector of the scattered electron has to end in another reciprocal lattice point.

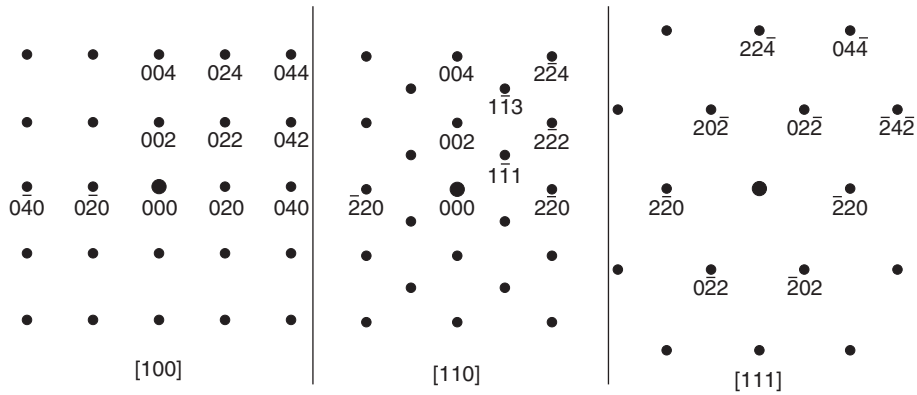
Putting these two conditions together, one finds that electrons can only be diffracted if the Ewald sphere crosses a reciprocal lattice point. This condition is equally valid for the diffraction of X-rays, neutrons, and electrons. Fast electrons with energies of the order of 100 keV or more have wavelengths of a few pm – much smaller than the lattice constant of a crystal (about 1 nm). Consequently, the length of the wave vector of the electron beam is two or three orders of magnitudes larger than the length of a reciprocal lattice vector.



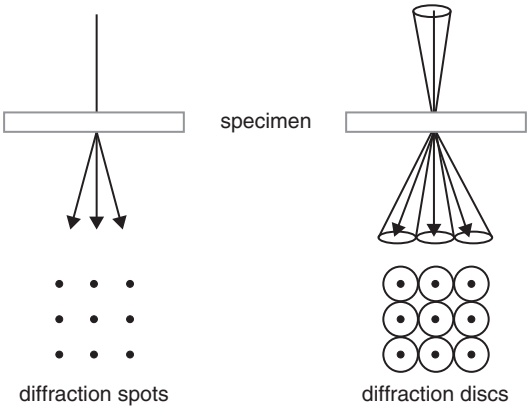
Transmission Electron Microscopy, Fig. 7 Ray diagram for a TEM for (**a**) bright-field imaging and (**b**) diffraction [1]

In the area near the origin of the reciprocal lattice, the Ewald sphere can then be approximated by its tangential plane. Thus, Ewald's construction states that in electron diffraction near the central spot, one observes a planar cut through the reciprocal lattice. The plane through the origin is called the zero-order Laue zone. As an example, Fig. 9 shows the arrangements of spots for a face-centered cubic lattice illuminated along different zone axes. For larger scattering angles, this planar approximation is no longer valid, and the Ewald sphere cuts through reciprocal lattice vectors of planes parallel to the zero order Laue zone, which are denoted as first-order, second-order, etc., Laue zones.

So far electron diffraction has been discussed for using a parallel beam for illumination. This method results in a spot pattern giving information of the illuminated crystallite. If there are many randomly oriented crystallites in the illuminated area, one obtains Debye–Scherrer rings just like in powder diffraction patterns. The determination of the crystal potential, however, is more complicated due to the fact that in electron diffraction, multiple scattering effects cannot be neglected. These depend strongly on the thickness of the crystal and on the exact direction of the incident beam. Instead of varying the incident beam direction with time, one can illuminate the crystal with a range of incident beam directions all at once. This technique is called convergent beam electron diffraction (CBED) (Fig. 10). Instead of the diffraction spots for parallel illumination, one then observes circles that exhibit an internal



structure. Comparing the intensity distribution within these circles with the results of simulations, one can determine the crystal potential with high accuracy. As long as the illumination angle is smaller than the Bragg angle, the circles do not overlap and each one corresponds to a specific reciprocal lattice vector.

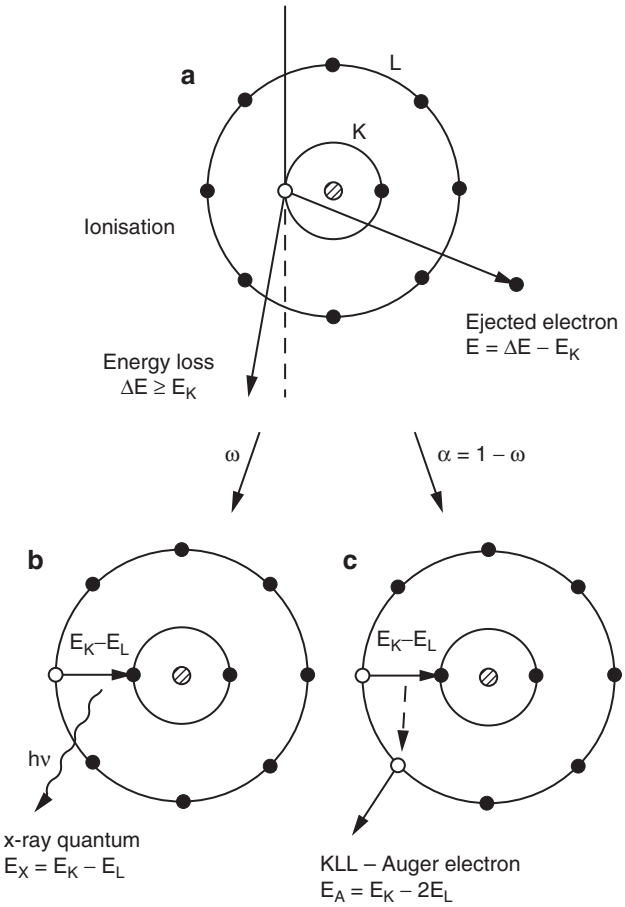


Transmission Electron Microscopy, Fig. 8 Ewald sphere construction to determine the directions of diffracted radiation [1]

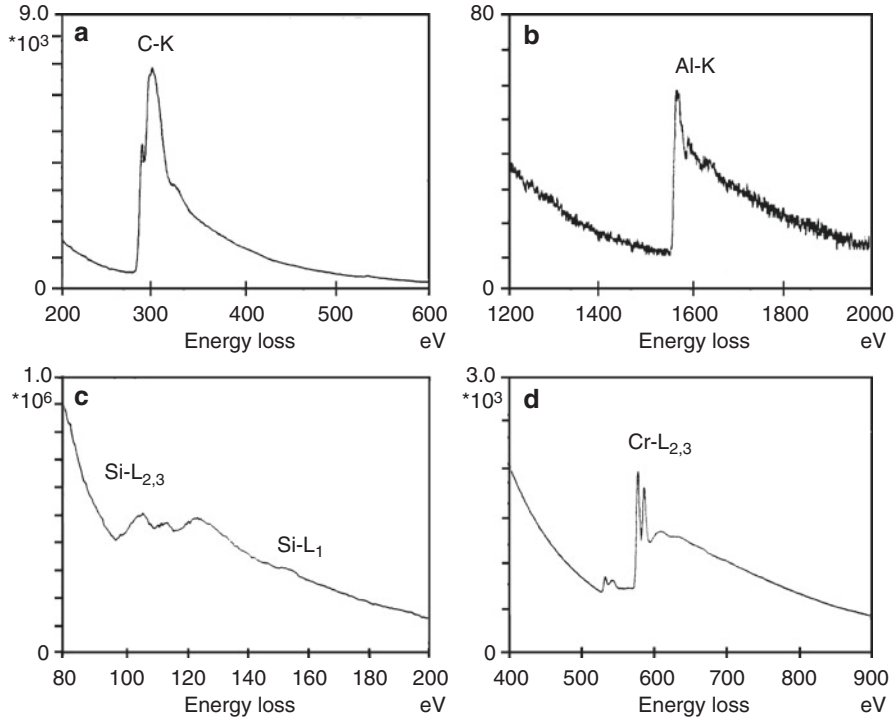
Analytical Electron Microscopy

Taking a broader view of the scattering of electrons in a thin specimen, one can see that in addition to the elastic scattering processes discussed up to now, many electrons experience inelastic scattering [1, 2, 6]. In doing so, they lose part of their energy. The various processes are shown schematically in Fig. 11. In order to excite an inner-shell electron into an unoccupied state, the incident electron has to transfer an energy corresponding to at least the binding energy of the original inner-shell electron (Fig. 11a). As these binding energies are characteristic for the element, they can be used as a signature of that particular element. Measuring the energy loss of the scattered electrons thus permits to determine the chemical composition of the illuminated area of the specimen. This is the basis of a technique called EELS for electron energy loss spectroscopy. Shortly after its excitation, the atomic electron decays into its ground state releasing the energy via an X-ray photon (Fig. 11b) or an Auger electron (Fig. 11c). Both of these secondary processes can in principle be used to determine the chemical composition of the specimen. Due to the small mean free path length, the emission of Auger electrons is very surface sensitive. As their detection requires an UHV environment, they are frequently used in surface science, but not in transmission electron microscopy. X-ray

Transmission Electron Microscopy, Fig. 9 Diffraction pattern of a face-centered cubic crystal illuminated along the [100], [110], and [111] zone axes near the central spot [1]



Transmission Electron Microscopy, Fig. 10 Schematic diagram demonstrating the effect of a converging beam on the diffraction pattern (CBED)



spectroscopy, however, is a very common technique in electron microscopy.

Electron Energy Loss Spectroscopy

Using a monoenergetic incident beam and measuring its energy distribution after it has passed through a thin specimen, one obtains an energy loss spectrum [8]. A few examples are shown in Fig. 12. At characteristic energies, corresponding to the binding energy of an inner shell, the signal shows a marked increase followed by a slow decay. The latter is due to the fact that it is also possible to excite an electron into any state above the Fermi level. The excitation probability, however, decreases for final states with relatively large

Transmission Electron Microscopy, Fig. 11 Schematic representation of (**a**) the ionization process, (**b**) the X-ray emission, and (**c**) the Auger emission [1]

Transmission Electron Microscopy, Fig. 12 Examples of energy loss spectra for the K-edges of (**a**) carbon and (**b**) aluminum and the L23-edges of (**c**) silicon and (**d**) chromium [1]

energies. In order to obtain a quantitative measure of the concentration of an element in the specimen, the background stemming from the tails of edges with lower energies has to be extrapolated. This is most often done by using a power law model for the background intensity I_b as a function of the energy loss E:

$$I_b = AE^{-r} \tag{12}$$

where A and r are free parameters that need to be fitted to experimental data. The signal intensity remaining after background subtraction is proportional to the area density of the element N_A, the intensity of the incident beam I_0, and the excitation cross section σ_A (α_0, ΔE), which depends on the acceptance angle α_0 and the energy loss window ΔE. For two elements A and B, one obtains the two equations:

$$I_A = N_A I_0 \sigma_A(\alpha_0, \Delta E) \tag{13}$$

and

$$I_B = N_B I_0 \sigma_B(\alpha_0, \Delta E) \tag{14}$$

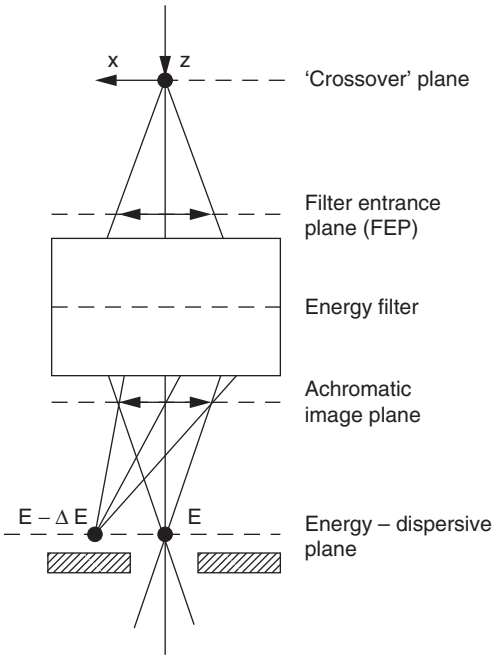
Dividing Eq. 13 by Eq. 14, one obtains

$$\frac{I_A}{I_B} = \frac{N_A \sigma_A(\alpha_0, \Delta E)}{N_B \sigma_B(\alpha_0, \Delta E)} \tag{15}$$

and for the concentration ratio

$$\frac{N_A}{N_B} = \frac{I_A \sigma_B(\alpha_0, \Delta E)}{I_B \sigma_A(\alpha_0, \Delta E)} \tag{16}$$

The concentration can thus easily be determined from the background-corrected intensities above the energy loss edges multiplied by the inverse of the ratio of the cross sections. To measure an energy loss spectrum, it is most convenient to attach a magnetic sector field spectrometer underneath the image plane of a transmission electron microscope. Modern commercial instruments



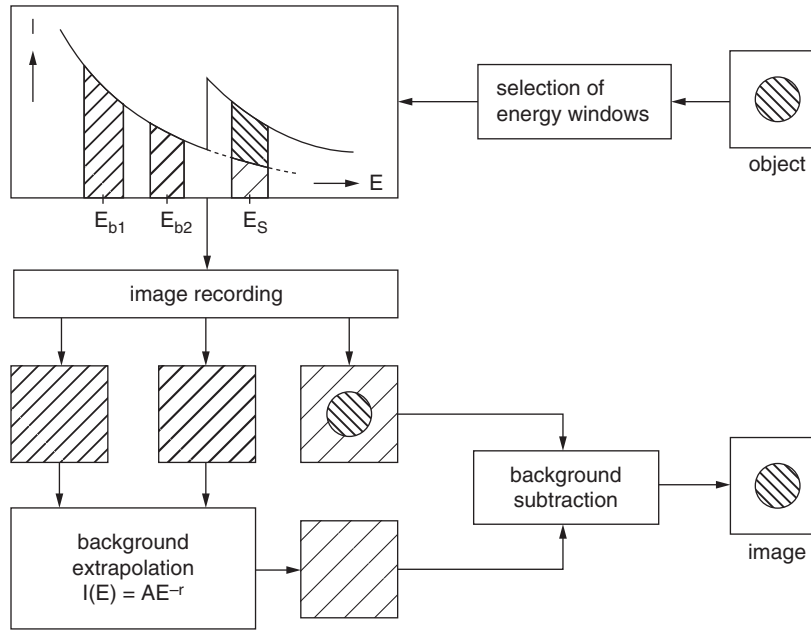
allow measuring a large part of the spectrum in parallel with a diode array.

Using such a spectrometer in a scanning transmission electron microscope, it is possible to obtain the spatial distribution of the elements in the specimen for each pixel. This technique results in images called elemental maps with a resolution at the atomic level in favorable cases.

Alternatively, one can obtain elemental maps by using an imaging energy filter, which turns the TEM into an energy-filtered transmission electron microscope (EFTEM). Such a filter is inserted in the ray path after the first part of the projective system and intercepts all electrons except for those lying within a well-defined energy window. Ideally, such an energy filter should provide an image without any chromatic aberration, but at the same time, it needs an energy dispersion to be able to select the desired energy range. These two conditions are met by a setup which images an intermediate image plane – the filter entrance plane – into an achromatic image plane and images the corresponding diffraction plane – the crossover plane – into the energy-dispersive plane (Fig. 13). In the achromatic image plane, the energy loss is "coded" by a tilt proportional to the energy loss resulting in a spatial displacement in the corresponding diffraction plane. The energy selection takes place in this energy-dispersive plane.

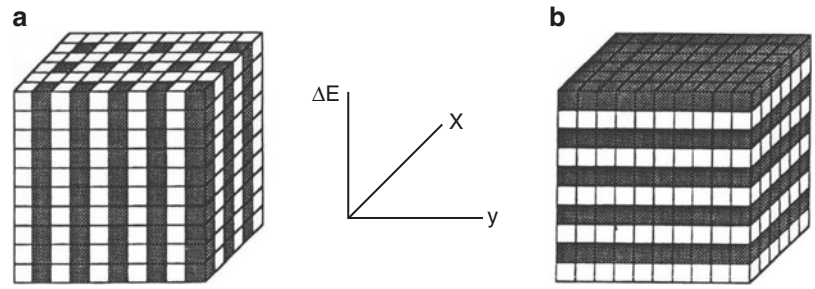
To obtain an elemental map in an EFTEM, one takes a series of at least three images at different energy losses – two below and one above the edge. With the images below the edge, one determines the parameters A and r on a pixel-by-pixel basis; from these, the background intensity is computed and subtracted from the image above the edge (Fig. 14).

The total information that can be obtained via EELS in a STEM or in an EFTEM is conveniently visualized as a data cube with two spatial coordinates and one energy loss coordinate (Fig. 15). In a STEM many energy channels corresponding to one pixel are measured at the same time (Fig. 15a), whereas in an EFTEM one measures the entire picture for one energy channel (Fig. 15b). The efficiency of both methods depends on the number of pixels and energy channels to be acquired.



Transmission Electron Microscopy, Fig. 13 Schematic diagram showing the ray paths and the relevant planes in an imaging energy filter [1]

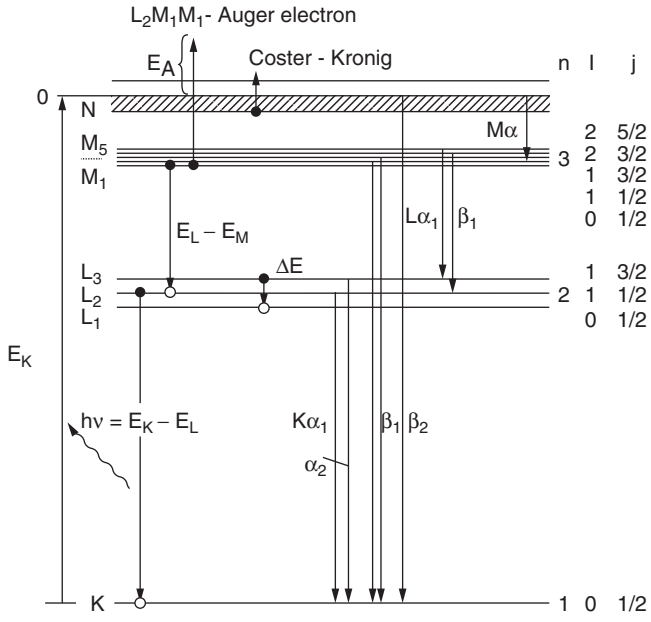
Taking a closer look at a spectrum just above an edge, one finds fine details in the structure that depend on the chemical environment. These details can be used to determine the bonding of the element. The energy loss near-edge structure (ELNES) is similar to the X-ray absorption near-edge structure (XANES).



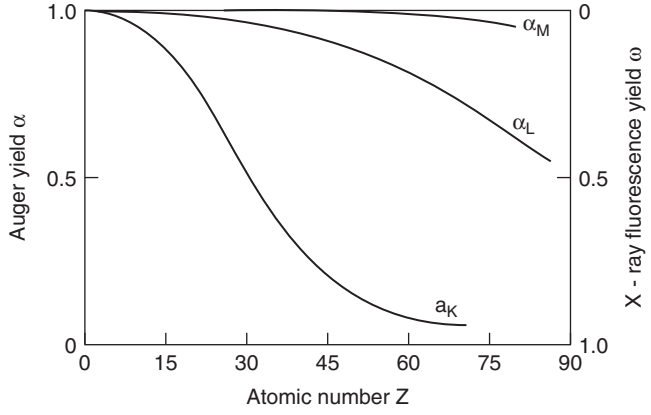
At lower energy losses (<50 eV), EELS can be used to determine the dielectric function of a specimen [8]. Recently, it has been demonstrated that lattice vibrations in the meV regime can be detected by using a spectrometer with an extremely high energy resolution.

Energy-Dispersive X-Ray Spectroscopy

Rather than detecting the inelastically scattered electrons, it is also possible to use secondary processes for the determination of the elemental distribution [6]. This is the basis of X-ray



Transmission Electron Microscopy, Fig. 14 The steps necessary to acquire an elemental map



Transmission Electron Microscopy, Fig. 15 The data cube depicting the complete information that can be explored in different ways. (**a**) A STEM acquires spectra point by point. (**b**) In EFTEM, the information is obtained energy slice by energy slice

spectroscopy for elemental analysis. The inner-shell levels of an atom and the corresponding transitions are shown schematically in Fig. 16. The energy difference between the excited and the ground state can be released either by emission of an X-ray or an Auger electron. The probability for the emission of an Auger electron, called Auger yield, and the corresponding fluorescence yield are shown in Fig. 17 for K-, L-, and M-shell transitions. From these graphs one can clearly see that for large atomic numbers the fluorescence yield dominates.

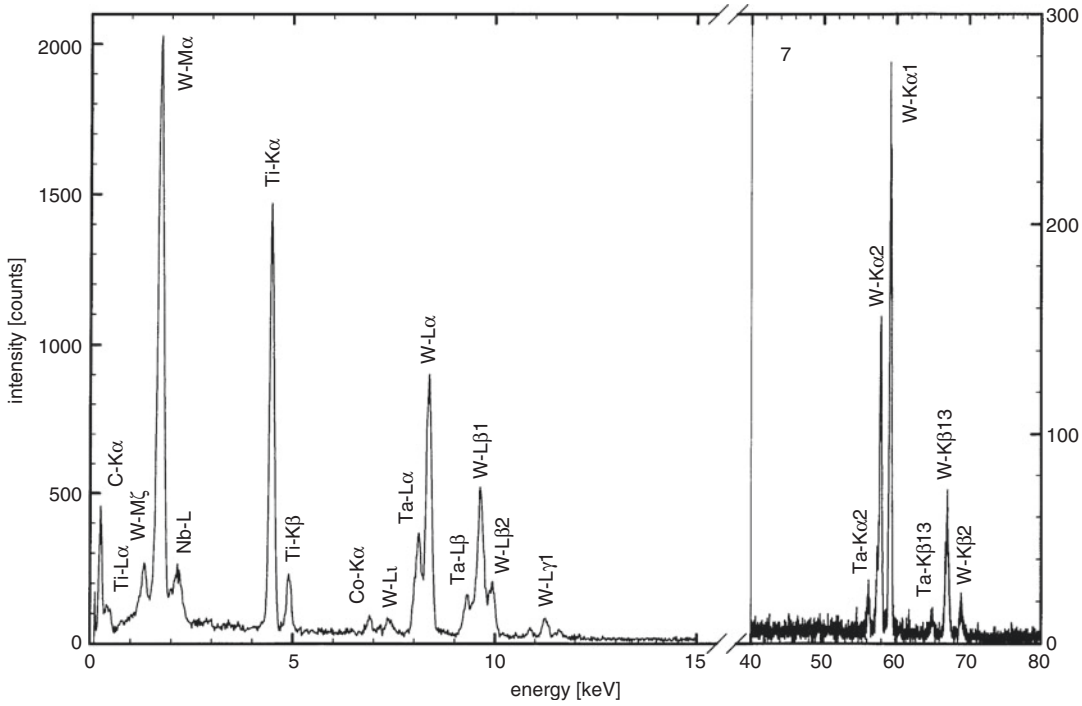
To determine the chemical composition of the specimen, one needs to measure the energy spectrum of the emitted X-rays. This can be done either by using Bragg reflection from a crystal spectrometer to obtain the wavelength or by measuring the number of electron–hole pairs created after absorption of the X-ray photon in a semiconductor detector. Whereas the use of the first method called wavelength-dispersive X-ray spectroscopy (WDX or WDS) is confined to electron microprobes and scanning electron microscopes, the latter method named energy-dispersive X-ray spectroscopy (EDX or EDS) is used in transmission electron microscopes as well as in scanning electron microscopes. An example of an EDX spectrum, taken with a high-purity germanium detector, is shown in Fig. 18. The position of the lines reveals the elements present in the illuminated area of the specimen. To determine the chemical composition, one has to establish a

Transmission Electron Microscopy, Fig. 16 Energy levels of the atomic subshells with their quantum numbers n, l, j and possible transitions to fill a hole in the K-shell including the nomenclature of the emitted X-ray lines [1]

Transmission Electron Microscopy, Fig. 17 Auger electron yield a and fluorescence yield $\omega = 1 - a$ as a function of atomic number [1]

relation between the intensity of the X-ray line and the number of corresponding atoms. Even though there are many factors entering into this relation (angular range subtended by the detector, fluorescence yield, detection efficiency, etc.), it is obvious that the number of counts is proportional to the concentration of the element. For two elements A and B, one can lump all these unknown factors into the two parameters k_A and k_B, thus obtaining for the counts I_A and I_B:

$$I_A = k_A c_A \quad \text{and} \tag{17}$$



$$I_B = k_B c_B. \tag{18}$$

Dividing Eq. 17 by Eq. 18, one obtains

$$\frac{C_A}{C_B} = k_{AB} \frac{I_A}{I_B} \tag{19}$$

where the "k-factor" $k_{AB} = k_B/k_A$ is a parameter that needs to be determined. This can be done experimentally by the use of well-defined standard specimens. In practice, one can measure the

T

Transmission Electron Microscopy, Fig. 18 Energy-dispersive X-ray spectrum of a hard metal (WC-TaC-TiC-Co) recorded with a high-purity germanium detector [1]

k-factors with respect to one element, e.g., Fe or Si, and use the relation

$$k_{AB} = k_{AC}/k_{BC}.$$

This should be done once for every instrument and can then be used as long as the conditions remain the same.

Comparing the limits of EELS and EDX for the detection of an element, one finds that the dependence of the fluorescence yield on the atomic number favors EELS for light elements. The relatively large background in EELS measurements as compared to an X-ray line indicates that the detection of low concentrations is easier with EDX than with EELS. On the other hand, the fine structure in an EELS spectrum yields additional information about the chemical bonding not accessible in an EDX spectrum. Thus, both methods have their merits and their drawbacks; and the choice strongly depends on the specimen and the information to be gained from it. In favorable cases both methods allow the acquisition of atomically resolved elemental maps.

Definition

Tunable RF MEMS filters are defined as microelectromechanical filters for radio frequency (RF) applications that (a) are capable of tuning or reconfiguring and (b) may use microelectromechanical systems (MEMS) switches or capacitors for realizing the tuning, e.g., the frequency or bandwidth.

Introduction

The need for tunable or reconfigurable filters is becoming more apparent as the radio technologies advance and the radio spectrum becomes more crowded. Bandpass filters, specifically, can improve the radio performance by improving the signal to noise ratio, avoiding any saturation due to out-of-band noise contributions [1]. Low-loss tunable filters can replace several surface acoustic wave (SAW) filters currently used in the radios operating in the ultra high frequency (UHF) band, defined as frequencies between 300 MHz and 3 GHz by the International Telecommunication Union (ITU). The UHF band is also extensively used for satellite communication and broadcasting, in paging systems, and by fourth-generation (4G) wireless and long-term evolution (LTE) services. To support all these applications, advances in radio technologies demand reconfigurable RF front-end filters that can support different frequencies and communication standards [2]. Systems employing tunable filters can offer smaller size at a lower cost compared to conventional radios employing multiple single-frequency filters. Some of the important performance specifications of tunable filters are insertion loss, tuning range, tuning speed, power consumption, size, power handling limit, linearity, and cost. Designing a tunable filter that meets the application specified criteria in all these aspects is very challenging, leading to extensive research that has been carried out for years on developing tunable bandpass filters.

Based on their resonator type, tunable filters can be classified as cavity, planar transmission line, or lumped *LC* filters (see Fig. 1). Among them, cavity filters can offer the highest unloaded quality factor (Q_u) resulting in low insertion loss, especially for narrow-band application. But they suffer from large volume, complicated fabrication, and difficulty of integration with other system components. The planar transmission line (microstrip, coplanar waveguide or coplanar

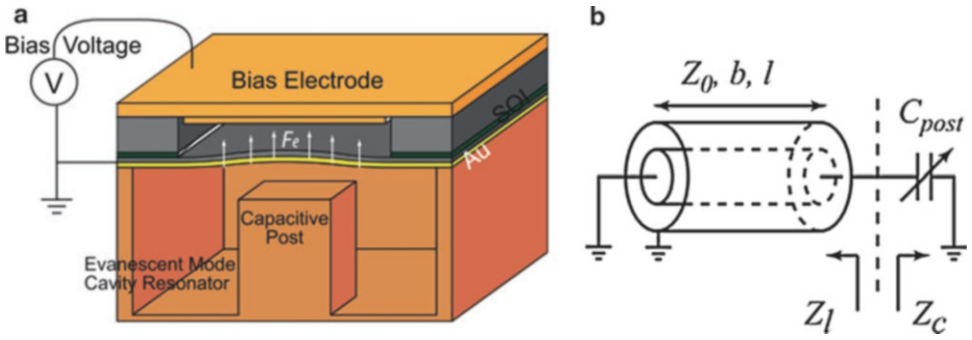
Tunable RF MEMS Filters: A Review, Fig. 1 Tunable filter architectures at different frequency ranges of operation. Common among these schemes is the MEMS technology used as the tuning mechanisms. Figures are reprinted from [3–8]

stripline) filters have moderate Q_u and can be readily integrated with other components and circuits. In the sub-gigahertz frequency regime of UHF band, lumped *LC* filters offer the smallest size compared to the two aforementioned alternative implementations. However, the realization of integrated *LC* tunable filters remains a great challenge at low UHF frequencies, as in this range, the ohmic loss is dominant and the quality factor (Q) of the integrated passives is very low (e.g. inductor Q is less than 30). The key challenge in designing lumped *LC* filters is to implement high-Q inductors and capacitors.

The tuning elements in all types of filters can be implemented electronically – by semiconductor varactors or switches, RF microelectromechanical systems (MEMS) switches/varactors, variable dielectric capacitors, magnetically – using yttrium-iron-garnet (YIG), or thermally – using the more recently developed phase change RF switches [9]. In either case, the most common type of tuning element is to employ either switches or variable capacitors [1]. The semiconductor varactors (PIN diodes or gallium arsenide (GaAs) Schottky diodes), which feature low price, low tuning voltage, and high tuning range, have been demonstrated in many tunable planar filters [10–12]. However, the major drawbacks of semiconductor varactors are their low Q of less than 150 and non-linear performance at high RF power levels. Ferroelectrics with voltage tunable permittivity can also be used to implement variable capacitors. The advantage of this technique is the low voltage requirement to achieve significant capacitive tuning [13]. The main challenge, on the other hand, lies in the deposition process. Most ferroelectrics, such as barium strontium titanate (BST), are sputter deposited on small two inch wafers. The uniformity and quality of the deposited film suffer significantly by going to larger size wafers. Also, these films can only be sputtered in high quality on specific metals and substrates, such as platinum on sapphire [14]. RF MEMS technology is a promising candidate for providing tuning elements. Because of their high Qs, RF MEMS varactors and switched capacitors have been utilized to design tunable filters with excellent tuning performances. In addition, RF MEMS technology can be used to implement monolithically integrated high-Q capacitors and inductors, meeting most – if not all – the requirements of wireless systems. There exist several implementations of tunable filters based on MEMS tuning elements (Fig. 1). In this paper, we present a brief review of classical tunable filters designed in the UHF or higher frequency C band (4–8 GHz) or X band (7–11.2 GHz) with emphasis on the UHF filters. In providing the review, we also compare the advantages and challenges of each technology.

Tunable Filter Technologies

Tunable Filters Using Cavity Resonator

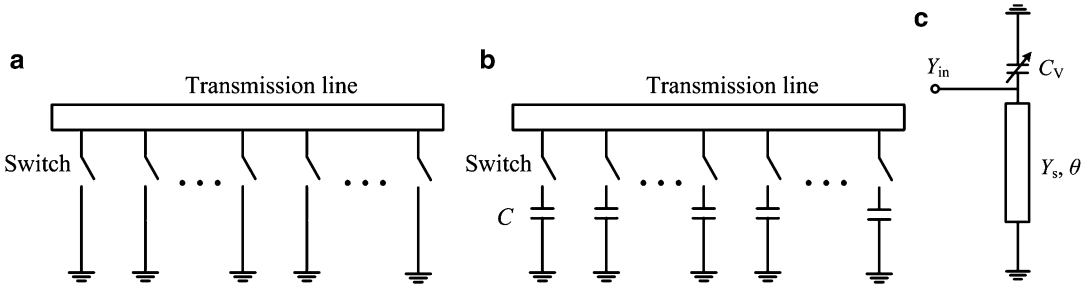


Three dimensional (3D) cavity resonators, including evanescent-mode (EVA) resonators, dielectric resonators (DR), and substrate integrated waveguide (SIW) resonators, are mostly used to design narrow-band tunable filter. The cavity resonators exhibit high Q_u of more than 1000; however, to be tunable, they require complicated assembly of a tuning element (e.g. a semiconductor or MEMS varactor) inside the cavity, which results in significant degradation of their Q_u.

The EVA resonator is composed of a rectangular or circular cavity with an electrically shorted center post. Fig. 2a, b show a schematic of an evanescent-mode cavity resonator and its equivalent circuit [15]. The gap between the post and waveguide wall represents a shunt capacitance, C_{post}. Due to this loaded capacitor, the size of the EVA resonator can be largely reduced (at the cost of lower Q). The resonant frequency can be tuned by changing the value of C_{post}. The most common tuning method is to tune the gap between the metal post and the cavity ceiling (or cap). A cavity filter can be implemented by coupling two or more cavity resonators. For example, in [15], a second-order filter was designed by coupling two cavity resonators. First, the low-pass Butterworth prototype was designed with elements g_i, i = 0, 1, 2, 3. Given the specifications including the frequency tuning range and the 3-dB fractional bandwidths (BW_{3dB} or Δ), the desired values of external quality factors Q_{ext} and the coupling coefficients k_{12} of the cavity resonators were obtained using Equation (1). The required coupling coefficient k_{12} was obtained by changing the distance between the two capacitive posts and the opening width of the coupling iris. The required Q_{ext} was realized by changing the length of the shorted CPW feed lines in the input and output feed structure.

$$Q_{ext} = \frac{g_1 g_2}{\Delta}, \quad K_{12} = \frac{\Delta}{\sqrt{g_1 g_2}} \tag{1}$$

Using a similar principle, two EVA resonators based filters with MEMS tuners, electrostatic diaphragm actuator and piezoelectric disk actuator, achieved Q_u of 300–650 at 5.0–1.9 GHz [15] and Q_u of 310–225 at 0.8–1.43 GHz [16], respectively.



The same tuning technology was also extended to realize tunable helical filters [17], which showed a Q_u of 100–542 at 257–365 MHz. In addition, by inserting the RF MEMS switching network inside the EVA, a tunable filter operating from 4.07 to 5.58 GHz with Q_u of 300–500 was demonstrated in [18]. However, these technologies attain high Q_u at the cost of a complex fabrication process needed for precise assembly of the tuners, and large volume needed to store the EM energy. Also they require high actuation voltages (>100 V) as small gaps (in the order of few micrometer) cannot be easily and precisely defined between the capacitance tuner and the post using current technologies.

To achieve a high Q_u using a simple process, 3D cavities integrated with commercially available surface mount tuning components are alternative solutions. In [19], the center metal post in the EVA resonator is extended to be on the same plane as the ceiling/cap, where solid-state varactors are placed across the gap between the post and the cap. This tunable resonator has a 0.5–1.1 GHz tuning range with Q_u of 90–214. In [20], packaged RF MEMS switches mounted on a SIW are used to achieve Q_u of 132–93 at 1.6–1.2 GHz. RF MEMS capacitor banks mounted on a combline cavity resonator resulted in Q_u of 1,300–374 at 2.50–2.39 GHz [21]. Table 1 summarizes the performance of RF tunable cavity filters, with different tuning technologies.

Tunable Filters Using Transmission Line Resonators

Planar transmission line resonators, such as microstrip, stripline, and coplanar waveguide (CPW) resonators based RF/Microwave filters, are widely used in wireless communication systems due to their compact size (at super high frequencies (SHF)) and low manufacturing cost. The tuning arrangement is mainly implemented by loading the planar resonators with tuning elements (switches or capacitors) to change their effective electrical length. Figure 3 shows the three main tuning methods. The first method is to change the physical length of the resonator by using switches. Switching different loading capacitors can also realize the frequency tuning as done in the second method. However, these two methods suffer from limited number of tuning states. The third approach is to tune the capacitance value in a varactor-loaded resonator. This approach is mostly used in the design of wide-range continuously or digitally tunable filters. The challenging aspect in the design process of such resonators is implementing a wide tuning range varactor. Reducing the length of transmission line can extend the frequency tuning range to some extent, but it also reduces the Q_u of the resonator. Thus, a simple and effective design method for wide tuning planar resonator is an ongoing challenge.

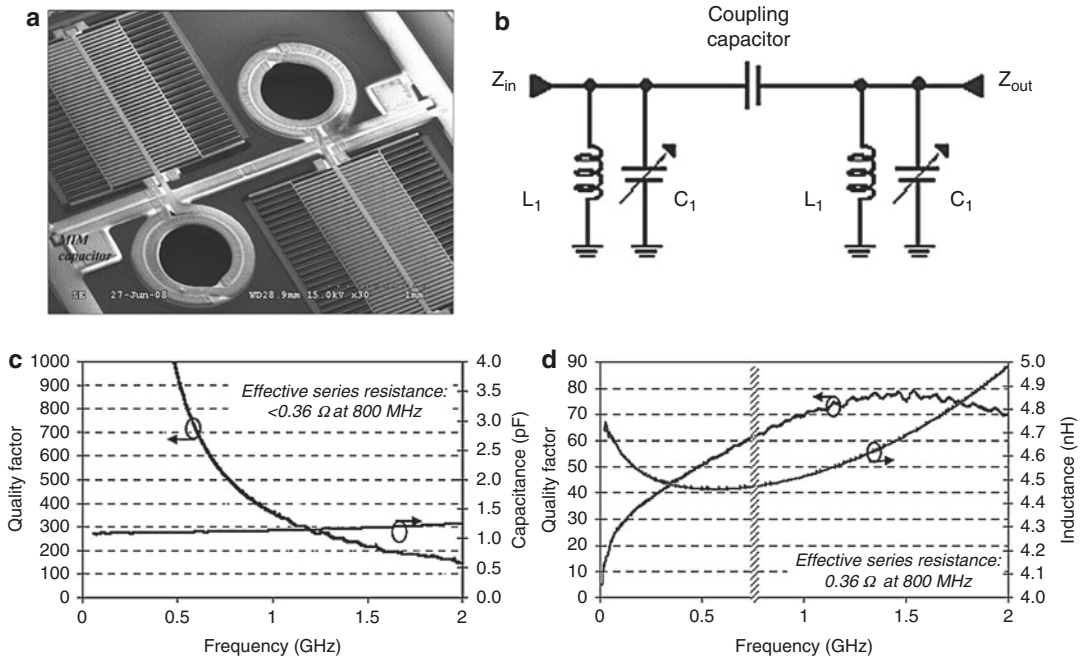
The design procedure for planar filter is similar to the one described earlier for cavity filters. For example in [22], first, the second-order low-pass is design in 0.01-dB Chebyshev prototype

configuration. Given the specifications including the tuning frequency range and the BW_{3dB}, the desired values of Q_{ext} and the coupling coefficients k_{12} of the combline resonators were obtained using Eq. 1. Next, the dimensions of transmission line resonators were determined, according to the required frequency tuning range and the capacitance ratio of the varactors. Finally, the space between the resonators was fine tuned to achieve the needed coupling coefficient k_{12} that satisfied the bandwidth requirement. The shorted coupling line structure was adopted to satisfy the requirement of Q_{ext} over the tuning range.

The tuning elements in planar resonators have been implemented by semiconductor varactors, or RF MEMS switches/varactors [10, 11, 22]. The major drawbacks of designs with semiconductor varactors are their low Q_u (<150) and poor linearity. Thus, they are limited to applications such as radar communication systems. On the other hand, high-Q and low-loss RF MEMS varactors and switches have been utilized to design tunable filters with excellent tuning performances, with low loss and high linearity [23, 24]. The major disadvantage of MEMS tunable planar filters is their limited tuning speed.

Tunable Filters Using Lumped LC Resonators

At the lower UHF band (<1 GHz), tunable passive filters have been implemented mostly using lumped LC elements as the wavelength becomes substantially large in this range of frequency. The size of LC filter is more compact, allowing their low-cost and on-chip integration with silicon circuitry. The Q of a lumped LC resonator or a so-called LC tank is directly related to the Q of the lumped components by $1/Q = 1/Q_{ind} + 1/Q_{cap}$. The Q of the integrated passives is mainly limited by the ohmic loss and is in the range of 50–100 [25]. For wide-band filters, high-Q inductors can be soldered to the filter chip and still a reasonable insertion loss can be obtained [26]. However, size reduction will become an issue when using off-chip elements. To achieve both size reduction and high performance, monolithic integration of LC components using MEMS technology on a single substrate is the most promising approach.



A second-order fully integrated tunable lumped filter on silicon using a low-temperature silver micromachining process is shown in [3] (Fig. 4a, b). The thick silver micromachining technique results in significant reduction of metal loss, which ensures high-Q inductors and tunable capacitors. To achieve frequency tuning, a MEMS varactor was employed in each tank. The two LC tank circuits were coupled using a fixed coupling capacitor, resulting in bandwidth variation as the filter center frequency was tuned.

The measured characteristics of the tunable capacitor and on-chip inductors are shown in Fig. 4c, d. The measured filter has an insertion loss of 4–6 dB with a BW_{3dB} of 5–6 % over the 786–836 MHz tuning range. Using the same technique, an insertion loss of better than 3 dB has been achieved [27] for a second-order filters across 220–640 MHz with unloaded Q as high as 50. The wide tuning range was realized by forming a three-way filter array fully integrated on silicon.

Y. Shim et al. at the University of Michigan developed a continuously tunable three-pole filter on a glass substrate using on-chip inductors and MEMS varactors (Capacitance ratio $C_r = 5.91{:}1$, $C = 220$ fF-1.3 pF) [28]. The filter design procedure was as following: First, the lowpass prototype in Chebychev configuration was designed. The lowpass filter was then converted to a coupled resonator bandpass filter configuration using admittance inverters. With this configuration, values of the lumped components are easily realizable using MEMS surface micromachining technologies. The inductive networks were converted into mutually coupled inductors (Fig. 5a). To achieve frequency tuning, a tunable capacitor bank was employed in each resonator section, which consisted of one fixed capacitor (MIM capacitor), one continuously-tunable capacitor, and three capacitive switches. The miniature filter showed a tuning range of 602–1011 MHz with a fractional bandwidth of 13–14 % and an insertion loss of 3.0–3.6 dB. The measured IIP_3 is greater than 20 dBm. The temperature stability of the center frequency from −50 ° C to 50 ° C is better than 2 %. The measured tuning speed of the filter is better than 80 μs.

A similar filter was packaged using a low-temperature packaging process first described in [29]. The packaged filter showed

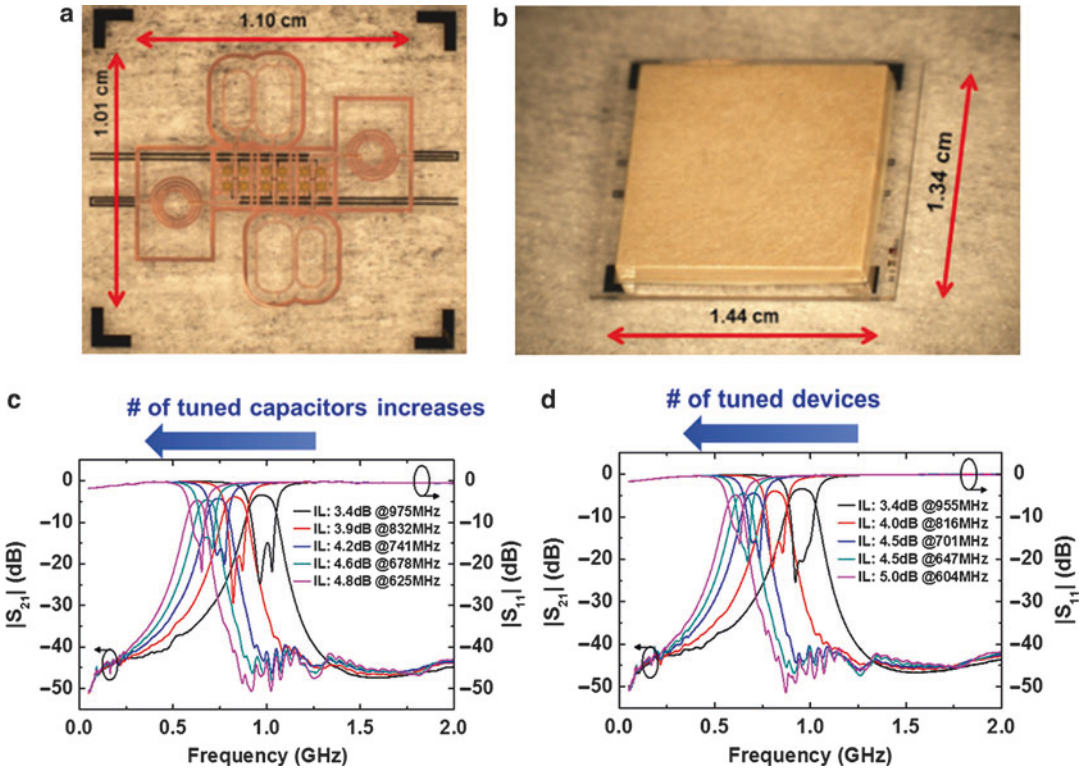
negligible degradation in performance compared to the unpackaged filter (Fig. 5).

Tunable Filters Based on The Frequency Range



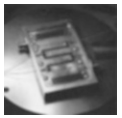
Another way to classify tunable filters is by the frequency range of operation. Most tunable filters are implemented at frequencies above 200 MHz. There have been many reports on MEMS reconfigurable filters centered at 12 GHz and above. Such filters are mostly implemented using distributed filter architectures (Fig. 1) and are not the focus of this paper. In the two subsections below, state of the art tunable filters in UHF and SHF bands are compared.

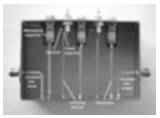
UHF Filters

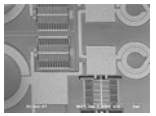
Since most cellular communication bands fall in the UHF range, there is a great demand for reconfigurable UHF filters. Table 2 summarizes the performance of reported MEMS tunable filters in the UHF range, built with different technologies. The first two works [4, 30] describe integrated MEMS tunable capacitors on a PCB. Due to the large size of RF circuits on PCB, this type of integration has larger size than complete integration of MEMS technology [18]. The customized multilayer PCB technology [32] can provide much smaller size than other technologies, but the filter implemented using this technique does not show a proper response across the entire tuned spectrum mainly due to the low Q of passive components embedded in the lower PCB layers. The listed filters can be also classified into two categories based on their fractional bandwidths: wideband filters with more than 10 % of BW_{3dB} and narrow-band filters with ~5 % of BW_{3dB}. Monolithic integration of RF components using micromachining technologies is clearly more beneficial for the narrow-band filter implementations, which require passive components with high Q values.

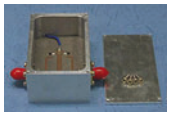
SHF Filters in C and X Bands

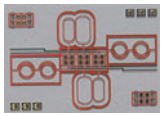
Table 3 summarizes the performance of RF tunable filters centered in the C-band and X-band

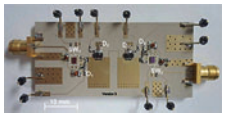






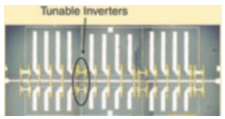


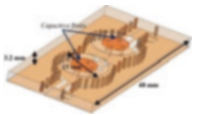


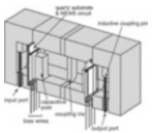


Tunable RF MEMS Filters: A Review, Fig. 5 (**a**) Micrograph of a fully integrated *LC* tunable filter before (**a**) and after (**b**) packaging. Measured S_{21} of the filter at different tuned state (**c**) before and (**d**) after packaging [2]

ranges. References [35–38] describe planar transmission line filters whereas references [16, 18], and [39] implemented tunable cavity filters. Among them, cavity filters offer the lowest insertion loss, especially for narrow-band ($BW_{3dB} < 1$ %) applications, owning to their high Q_u. However, as mentioned earlier, cavity type filters suffer from large volume and complicated fabrication processes. The frequency tuning in these designs are realized using ferroelectric (BST) capacitor [36], magnetic material (YIG) [37], varactor diodes [16], and MEMS varactor [18, 35, 38, 39]. Among them, the MEMS varactors can provide the lowest loss. By inserting the RF MEMS switching network inside the dielectric resonator, a tunable filter tuning from 5.20 to 5.02 GHz with Q_u from 800 to 550 is demonstrated in [39], showing one of the highest unloaded *Q*s for tunable resonators in the SHF range.







Discussion

Despite advances in microfabrication technologies, design and implementation of high-*Q* reconfigurable filters with fast tuning speed is an ongoing challenge. MEMS components have slower tuning speed compared to other switch technologies, limiting the application of MEMS tunable filters. The main advantage of MEMS filters, besides the small size, that has been the biggest push behind their use is that MEMS filters are very linear. The reliability and packaging of MEMS needs further improvement. MEMS switches with remarkable reliability has been in production for years but a more complex and complete system product using such components does not currently exist and highly needed. New technologies, such as GaN on silicon RF switches [40] and fast switches using phase change materials [41, 42], are now being developed and it is

envisioned that they will be soon integrated with other components to implement tunable RF modules, such as filters. From the cost perspective, implementation of MEMS filters mentioned above requires only a small number of photolithography masks, much smaller than those needed in a standard semiconductor fabrication process. Therefore, improved reliability and yield of MEMS processes should result in reduced cost for tunable RF modules and would make them more attractive [9].

Conclusion

The design challenges for developing tunable MEMS bandpass filters were discussed. For applications in which the size is not the major concern but low insertion losses and narrowband are needed, cavity resonators can be employed. While the transmission line resonators can be employed for applications requiring easy fabrication and convenient integration with other planar components and circuits. For low UHF band applications, lumped *LC* filters offer the smallest size compared to cavity and transmission line resonator implementations.

Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering

Keqin Yang, Dale Hitchcock, Jian He and Apparao M. Rao
Department of Physics and Astronomy, Clemson University, Clemson, SC, USA

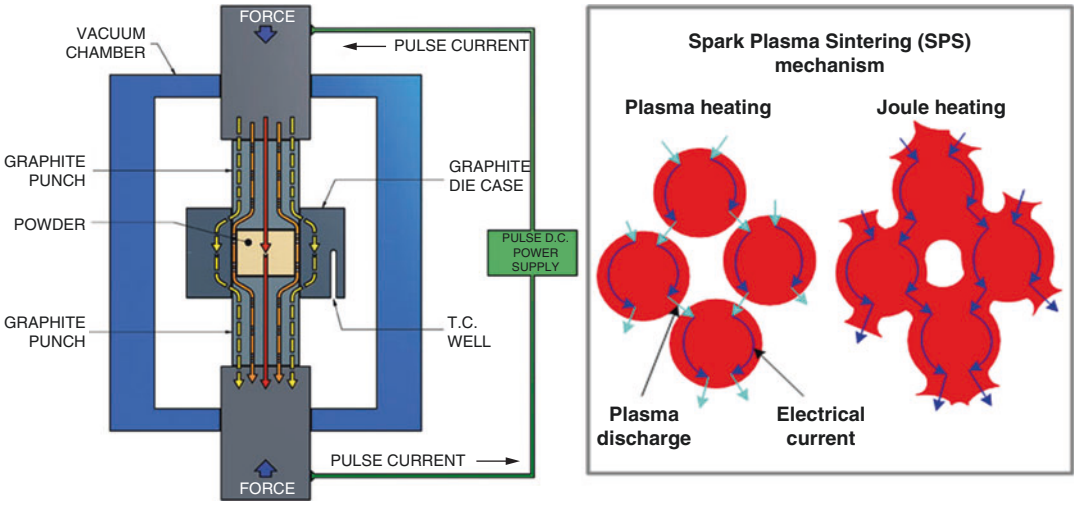
Definition

The spark plasma sintering technique utilizes highly localized intensive Joule heating and

discharging generated by a self-adjusted high-density current flow to alter the micromorphology of carbon nanotubes.

Introduction

Carbon comes in many forms, ranging from *sp*-bonded metastable carbene chains, sp^2-bonded graphite, graphene, single-wall and multiwall nanotubes, fullerenes, and amorphous soot to sp^3-bonded diamond. In particular, carbon nanotubes (CNTs) exhibit unique electrical, magnetic, thermal, chemical, mechanical, and optical properties that stem from their tubular topology and reduced dimensionality. Topologically, a single-wall nanotube (SWNT) can be viewed as one sp^2-bonded graphene sheet rolled into a seamless tube. A sibling of the SWNT is the multiwalled nanotube (MWNT), made of a few to tens of concentric shells with random chiral registries, spaced by $\sim$ 0.34 nm, and coupled through van der Waals interactions as in graphite. In the past few decades, CNTs have been extensively studied from fundamental research and technological points of view. With a nm scale diameter and a large aspect ratio, CNTs are one of the closest material realizations of a 1-D system, offering unprecedented opportunities to study 1-D physics. Furthermore, CNTs are prime candidates for molecular electronics, one of the most promising directions of nanotechnology.



The electrical properties of CNTs are sensitive not only to intrinsic parameters such as the number of shells, tube diameter, and chirality but also to extrinsic parameters such as defects, dopants, and the environment in which they reside [1]. For example, devices based on macroscopic forms of CNTs such as arrays, yarns, and films are gaining intensive interest. In these devices, the primary factor governing the macroscopic electrical transport is the micromorphology, comprised of three basic aspects: (1) the crystal chemistry of an individual CNT such as chirality, defects, and dopants, (2) the topology of the interconnected CNTs, and (3) the density and nature of inter-tube junctions. It is often the case that aspects (2) and (3) matter more than (1) in determining the electrical properties of a macroscopic CNT network. The control of these intrinsic and extrinsic parameters remains challenging and relies on techniques capable of tailoring CNT structures on the atomic, nm, and μm scales.

Tailoring CNT Morphology to Realize New Functions

Many methods have been used to alter the structure of CNTs, from simply hot pressing to more advanced techniques such as electron or ion irradiation, which gives rise to a seemingly endless number of new phenomena and potential functions. In an early attempt to densify CNTs, Ma et al. employed hot pressing at 2,000 °C and 25 MPa in an argon atmosphere to form a "soft sintered" CNT network without altering the tubular morphology of CNTs [2]. In addition, Rubio et al. showed that it is possible to cut and introduce defects into CNTs with very high precision using an STM tip, which has the salient advantage of real-time monitoring of the change of structure [3].

Using Irradiation to Tailor CNT Morphology

More recent research has focused on altering the structure of CNTs using electron or ion irradiation. How would CNTs respond if atoms were removed from the hexagonal lattice continuously [4]? At first glance, irradiating CNTs should lead to a detrimental effect on their crystal structure and thereby properties; however, it has been demonstrated that proper irradiation conditions can have beneficial effects on the properties of CNTs. This is due mainly to the CNT's innate ability to self-heal. The lattice of CNTs can be rapidly rearranged to accommodate the formation of defects and restore a new local coherent structure from a state that is driven far away from equilibrium during the irradiation process. For example, vacancies in SWNTs lead to the formation of pentagons and heptagons, while in MWNTs, they result in inter-shell bonds. This extraordinary innate ability renders a way to tailor the nanostructure of CNTs and facilitates a

Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering, Fig. 1 (*Left*) The schematic of a SPS system and (*right*) two major heating mechanisms in the SPS process

controlled method of self-assembly [5]. The main advantage of using irradiation is to tailor the CNT structure on a nm scale, while the focused electron beam of an aberration-corrected scanning transmission electron microscope can even reach Å scale resolution. The major drawback of this approach is the low throughput of beam-modified CNTs. Lastly, it should be mentioned that when dangling bonds are formed in adjacent tubes, it is often energetically favorable to form a junction between the tubes rather than the reconstruction of individual tubes. The goal of this chapter is to introduce the spark plasma sintering (SPS) process as an alternate approach for controlling inter- and intratubular bonding in CNT networks, at nm and μm scale lengths. In electron beam irradiation, it is known that only a small portion of the impinging electron energy can be transferred to and displace nuclei due to conservation of momentum. As such, a very high electron energy (on the order of 10–100 keV) is needed to alter the structure of CNTs. The SPS process utilizes a low-voltage high-density current and the accompanied localized intensive joule heating or discharging to modify CNTs. The SPS process can control the structure of CNTs in much the same way as irradiation but using macroscopic control rather than the microscopic control of irradiation.

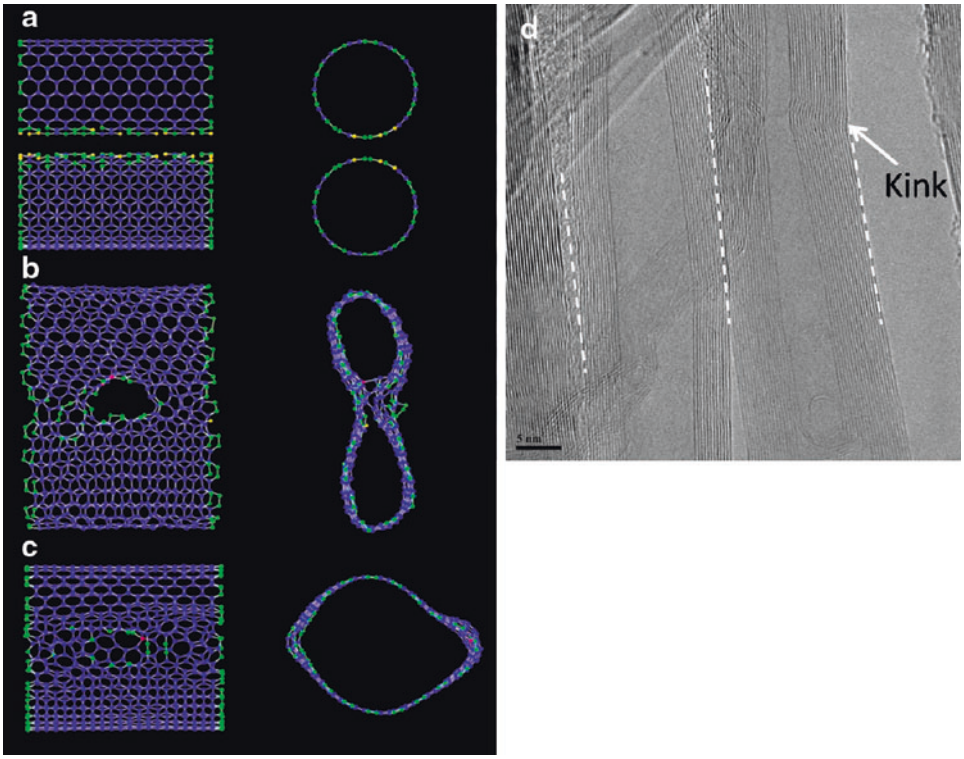
Mechanisms of Spark Plasma Sintering

The SPS technique has been used widely in powder metallurgy, and densification of nanomaterials and nanocomposites [6]. The basic idea dates back to 1930s but was not put into wide use until recently, primarily due to the lack of applications and the high cost of equipment. SPS is a pulsed plasma discharge process that can generate intensive heating (up to 2,000 °C and above) in a short time (few minutes). The voltage is merely on the order of 1–10 V, while the current density is typically on the order 10^2-10^3 A/cm^2 and is highly concentrated at the intergranular contact or interfacial boundaries. The SPS process features a high thermal efficiency because of the direct heating of the sintering mold and sintered materials, and it results in a homogeneously sintered and densified sample because of the "self-adjusting" uniform heating mechanism [7], surface decontamination, and surface activation. The densification mechanism is related to plastic deformation and grain rotation coalescence and sliding, aided by the premelting of grain boundaries. A schematic diagram of the SPS system and the primary heating mechanisms are shown in Fig. 1.

The control parameters of SPS process are macroscopic: they are the sintering pressure, current density, ON/OFF ratio, and sintering time.

It should be noted that heating and current flow are interdependent but are regarded as separate mechanisms in the SPS process. The sintered materials are under a combination of one or more of the following effects [6]: spark plasma, spark impact pressure, Joule heating, and electric field-induced diffusion. In particular, the surface of sintered materials is more easily degassed and chemically activated, promoting strong mass transport at atomic, nano-, and macroscopic levels at a relatively lower temperature and in a shorter time than conventional processes such as hot pressing. Mass transport in SPS is commonly believed to be driven by electric field diffusion. In view of the self-healing ability of CNTs, the current density in the SPS process can be varied to control the deviation from equilibrium, yielding a controllable number of permanent defects. At present, a comprehensive detailed model of the impact of SPS process on CNTs is lacking so that most ongoing work is experimental and exploratory in nature.

Using SPS to Tailor CNT Morphology



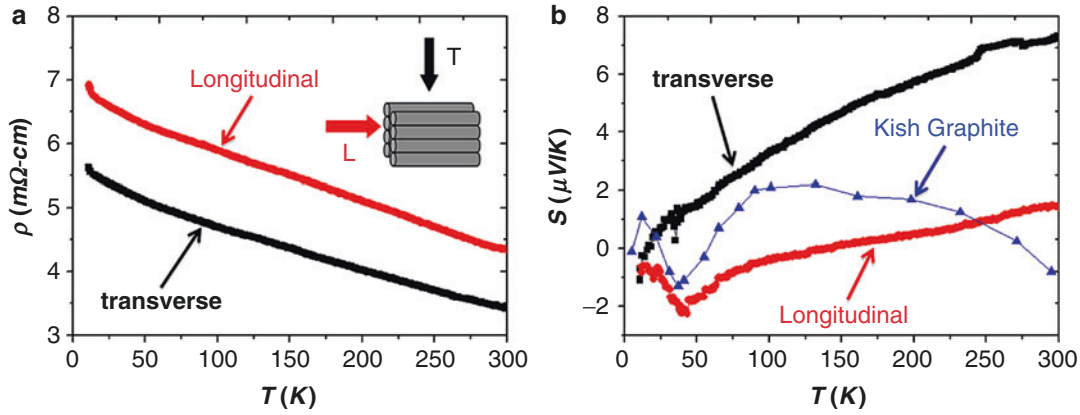
It has been shown that the SPS process may cause the bonding in CNTs to transform from van der Waals in a rope or yarn, to robust sp^2, and then to sp^3 in micro-diamonds [8] or lead to graphitization and crystalline–amorphous heterojunctions in amorphous carbon fibers [9]. Depending on whether CNTs survive the SPS process, the SPS process can be *loosely* categorized into two regimes. The first regime is the mid-power range, where most research is done. In this regime, the tubular morphology is preserved, and there is enough energy to introduce intratubular restructuring (including defects and doping) and create coherent intertubular bonding (i.e., junctions). At present, all experimental evidence suggests that the intra-tube restructuring and inter-tube bonding occur simultaneously during the SPS process. The process of densification also occurs in the mid-power regime. Despite the complexity of inter-tube interactions, the inter-tube spacing and relative orientation of CNTs are the two most important factors which determine the nature of the resulting inter-tube junctions and the packing density. Densification of CNTs is of practical importance in a number of applications such as the electrodes for supercapacitors, biosensors, and artificial bone scaffolds in which one takes advantage of the high surface-to-volume ratio and the outstanding mechanical and electronic properties of CNTs.

The other regime is the high-power regime where the temperature and current density are high enough to destroy tubes, forming other carbon allotropes. The boundary between the mid-power range and high-power range is not clear-cut. Preliminary studies suggest a boundary temperature of 1,000–1,200 °C for MWNTs, while the boundary temperature is lower for SWNTs and depends more on the perfectness of CNT structure and environment.

This section mainly addresses the effects of SPS in the mid-power range, focusing on the SPS-mediated (1) intra-tube restructuring (defects and doping) and (2) formation of inter-tube and inter-shell junctions. These modifications are crucial for controlling the electrical and thermal properties of CNT networks. When a high-density current is pulsed though a CNT assembly, the contact resistance between tubes is much higher than the intrinsic resistance of the tubes, which leads to a highly localized intensive Joule heating or discharging, and the temperature can be sufficiently high to cause rearrangement of atoms/bonds.

Inter-tube and Inter-shell Junctions

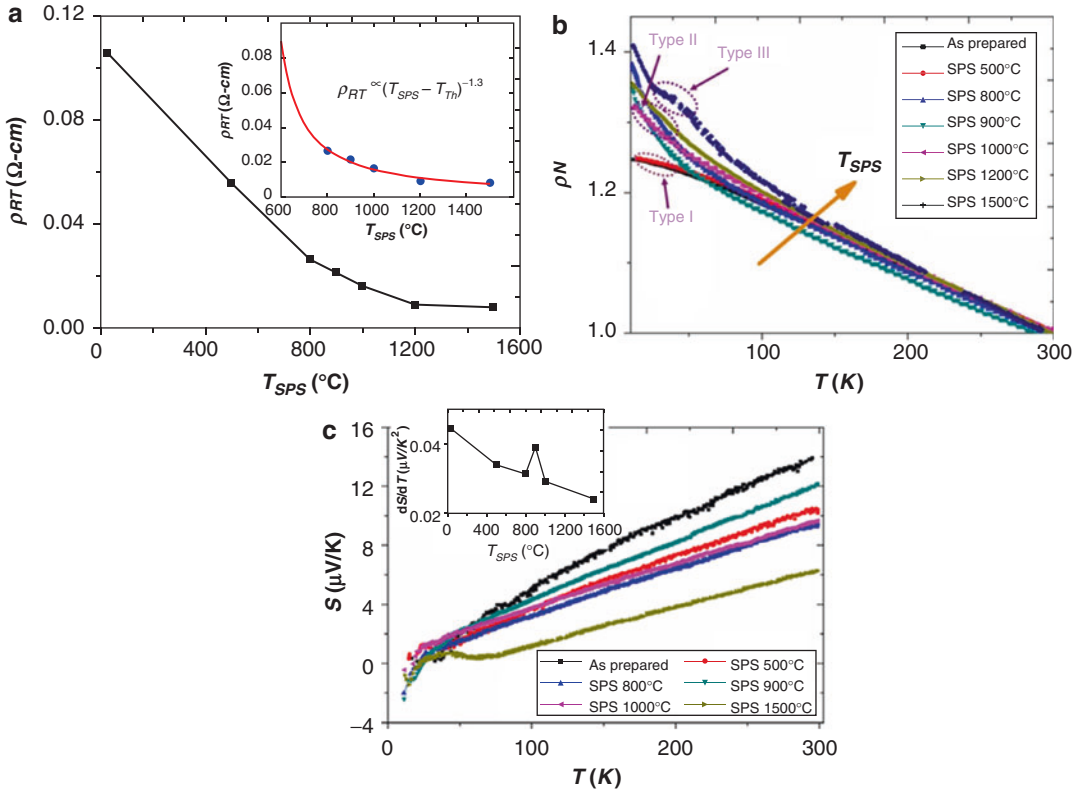
It is known that inter-tube junctions dominate the electrical properties of a CNT network. An important objective of ongoing research is to study to what extent and in what aspects the transport properties of a SPSed network are inherited from individual CNTs. Therefore, the manipulation and formation of inter-tube junctions, especially coherent bonding, is of utmost importance in nanoelectronics (molecular electronics) and transparent conductors [10]. A direct impact of the formation of coherent inter-tube bonding is the change of the effective dimensionality of a CNT assembly. In particular, phonons and electrons may have different effective dimensionality in a SPSed CNT network. With coherent inter-tube



Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering, Fig. 2 (**a**–**c**) Three stages from a theoretical model of the coalescence of two SWNTs. (**d**) Shows that several MWNTs are welded with some degree of corrugations in the sidewalls

junctions, the CNT assembly offers a flexible network architecture, opening up opportunities for several applications.

The modification of inter-tube bonding from van der Waals type to robust sp^2 inter-tube bonding is a nontrivial task, since the topologically complicated arrangement of sp^2 bonds in the inter-tube bonding is not energetically favored. For this reason, high-energy nonequilibrium processes are needed. One example of inter-tube junctions is the coalescence of single- or double-wall CNTs to form a single SWNT of larger diameter [4]. Charlier et al. have proposed a mechanism for the coalescence of tubes using molecular dynamics simulations. The model begins with unzipping of a nanotube to form a carbene chain, and if the metastable carbene chain comes in contact with a neighboring nanotube, it will initiate a reaction to minimize its energy and form a coalesced nanotube. Three steps in Charlier's model are shown in Fig. 2a–c. In spark-plasma-sintered aligned MWNTs, Yang et al. have observed that coherent inter-tube bonding can be formed at a sintering temperature of 1,500 °C for 7 min under 7 MPa axial pressure. The current is applied in the direction perpendicular to the tube direction. As shown in Fig. 2d, the SPS process welds part of two parallel MWNTs together [11].

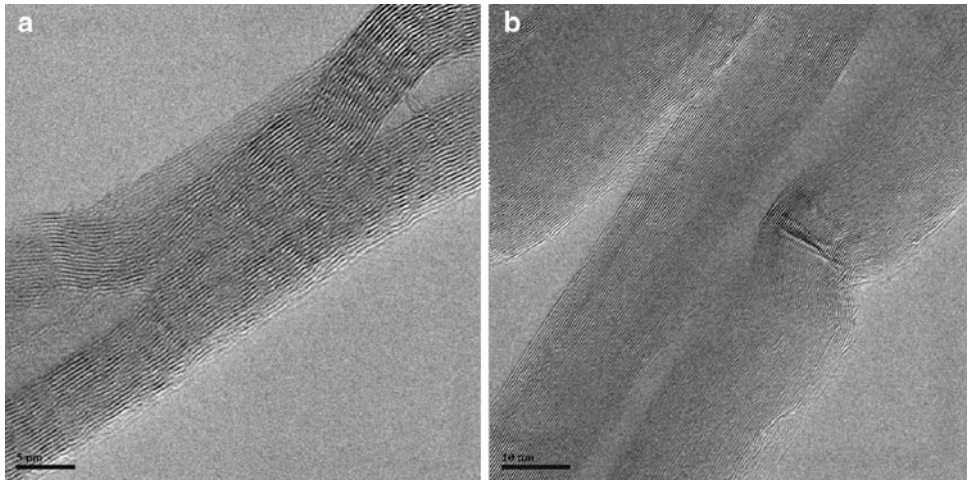


Several interesting properties of SPSed MWNTs have been uncovered through electrical and thermal transport measurements [11]. First, the transverse resistivity (ρ_T) of a low-dimensional electron system such as CNTs is expected to be much higher than the longitudinal resistivity (ρ_L), as is the case in thin films made of aligned CNTs [12]. The MWNTs SPSed at 1,500 °C, however, showed lower resistivity in the transverse direction than the longitudinal direction (Fig. 3a). This surprising observation

Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering, Fig. 3 MWNTs SPSed at 1,500 °C. (**a**) The resistivity is lower in the transverse direction than the longitudinal direction. (**b**) Thermopower in the longitudinal direction shows a strong phonon drag peak below 50 K, which is similar to Kish graphite

may be due to the following reasons: the SPS process creates coherent inter-tube bonds that account for the lower ρ_T, the SPS-induced defects within the tubes may lower ρ_L, and finally lower ρ_T may be due to the larger cross section of the conduction surface in the transverse direction than in the longitudinal direction due to the hollow core and inter-tube spacing of CNTs. Second, although MWNTs are typically metallic, the resistivity in both directions shows nonmetallic behavior ($d\rho/dT < 0$) as in aligned CNT think films, suggesting that inter-tube junctions dominate the overall electrical conductivity of the CNT network. The temperature dependence of the resistivity is also unusual and cannot be satisfactorily interpreted in the frameworks of the Luttinger liquid model, variable-range hopping, or weak localization theory. Nonetheless, the temperature dependence of resistivity is reminiscent of the results of individual highly disordered MWNTs in which the $T^{1/2}$ dependence has been attributed to electron–electron scattering in the presence of random impurities [11]. Third, the thermopower is not only of different magnitudes in the transverse and longitudinal directions but also shows different temperature dependences, with the longitudinal thermopower showing a pronounced phonon drag peak below 50 K very similar to that of Kish graphite (Fig. 3b). In view of electron–phonon coupling, the phonon drag features in the thermopower are due to carriers being preferentially scattered by the phonons in the direction of heat flow, when the mean free paths of both electrons and phonons are long enough. For individual CNTs, the quantized electronic band structure and phonon dispersion relations lead to a reduced phase space for electron–phonon coupling. Hence, the observed phonon drag feature supports the argument that the SPS process leads to an increased effective dimensionality of the CNT assembly.

Subsequently, Yang et al. [13] showed that the electrical connectivity of a network made of randomly oriented MWNTs can be effectively tuned by varying the SPS temperature. An increase in the SPS temperature from 500 °C to 1,600 °C leads to an increase in the packing density from ~ 0.6 to ~ 1.25 g/cm^3, reflecting a change in the inter-tube spacing. The concomitant changes in the magnitude (Fig. 4a) and temperature dependence (Fig. 4b) of resistivity strongly suggest a change in the nature of the inter-tube junctions and thereby the electrical connectivity of the network. As shown in Fig. 4a, the room temperature resistivity as a function of SPS temperature follows a power-law T-dependence, suggesting a percolation behavior. Percolation phenomena are important for the operation of electronic devices based on CNT conducting networks. In Fig. 4b, it is noted that the normalized resistivity $\rho_N(T)$ below 100 K can



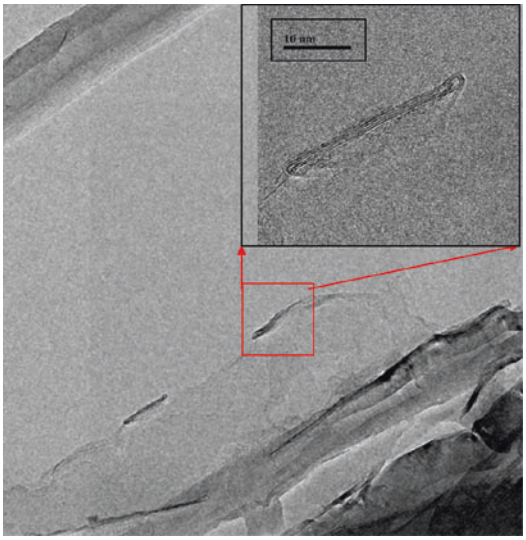
Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering, Fig. 4 (**a**) Room temperature resistivity value as a function of SPS temperature, the inset shows the power-law fitting to a percolative model. (**b**) The crossover in the temperature dependence of normalized resistivity, types I, II, and III, reflects the change of the nature of inter-tube junctions, and the normalization is performed by dividing the $\rho(T)$ by its corresponding room temperature ρ_{RT}. (**c**) The temperature dependence of thermopower of the sample SPSed at 1,500 °C shows a strong phonon drag peak below 50 K [13]

be categorized into three characteristic *T*-dependencies. The as-prepared (AP) sample and the sample SPSed at 500 °C (S500) exhibit a sublinear *T*-dependence, which is labeled as type I. In traces grouped into type II (S800, S1000, and S1200) and type III (S1500) dependencies, there is an upturn below 60 K. This upturn may be associated with the formation of coherent inter-tube junctions. In addition, a plateau is evident below 50 K in sample S1500. The "S" shape anomaly in the thermopower for the S1500 sample (Fig. 4c) resembles the thermopower behavior of Kish graphite (Fig. 3b), as noted above. It is interesting to note that this feature in the thermopower data occurs at the same temperature as a plateau in the resistivity data for the SPS1500 sample, which suggests that there is a single unified mechanism governing both phenomena. The possibility of a Kondo effect has been ruled out [13].

SPS can also induce coherent bonding between CNTs and neighboring graphitic particles. In a CNT bundle where graphitic particles are not bonded to CNTs, Zhang et al. have shown that though the graphitic particles have lower intrinsic resistivity than CNTs, their contribution to the overall conduction will be small [14]. Without bonding to CNTs, the conduction of graphitic particles is restricted to variable-range hopping (VRH) conduction, which will be very small as long as the concentration of graphitic particles is small.

Intra-tube Restructuring

It is also possible to introduce intra-tube defects by the SPS process, including creation of vacancies,



Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering, Fig. 5 The SPS-induced defects in MWNTs (**a**) the collapse of a MWNT (**b**) the kink formed on the wall of a MWNT [11]

collapsing/zipping tubes (Fig. 5a), and kinks on the tube wall (Fig. 5b) [11]. The local curvature change of CNTs often indicates the removal of carbon atoms from the lattice and the subsequent reconstruction of a new coherent structure containing non-hexagonal rings and other types of defects. Defects may profoundly affect the electronic properties of CNTs by creating new localized states near the Fermi level. Electrical transport is also affected in view of the quasi-1-D molecular nature of CNTs. Finally, these SPS-induced crystal lattice imperfections, especially vacancies, serve as a good platform for doping CNTs since the dopant atoms tend to lodge themselves at these energetically favorable positions.

Doping CNTs

Doping is a powerful tool for controlling the electrical properties of CNT networks because it offers a way to vary the carrier concentration and thereby tune the electron–electron and electron–phonon coupling that basically govern the electrical properties of CNTs. It has been shown that through doping the majority carrier conduction in a CNT network can be varied from p-type to n-type in a controllable way [15]. However, doping CNTs is technically challenging for several reasons. First, it is difficult to attain a uniform doping level, due to the finite length effect, the subtle differences in capping topology, the amount and distribution of defects, and the proximity environment. This situation is worsened by the low solubility limit of dopants in carbon allotropes (e.g., the solubility of B in graphite is limited to $\sim$ 4 at.% at 1,200 °C). Second, in small-diameter CNTs, substitutional doping inevitably compromises the integrity of the hexagonal lattice. Third, electric field doping does not work well in MWNTs and thick films. Apparently, controlling crystal chemistry in the synthesis stage is *not* adequate for controlling the doping of CNTs, some post-synthesis treatment is needed. Ion implantation or low-energy ion bombardment has been often used to dope carbon nanostructures [5, 16], but the application is limited by expensive equipment. It is also possible that by varying the doping conditions, the nature of the doping could be varied from low-energy endohedral (filling) or exohedral (intercalation) doping to higher energy substitutional doping. The SPS process is a promising candidate for post-growth doping of CNTs.

Recently, Hitchcock et al. have shown that a post-growth treatment of SWNT bundles with boric acid solution followed by SPS process is a viable method for doping CNTs and controlling their carrier concentration. Using boric acid concentration as the control parameter, they were able

Tuning Electrical Properties of Carbon Nanotubes via Spark Plasma Sintering, Fig. 6 Graphitic nanostructures formed in SPS by unzipping MWNTs [11]

to alter the carrier concentration of the SPSed CNT networks. As a result, the resistivity, thermopower, and Hall coefficient measurements show a doping-induced shift of the Fermi level and the accompanied changes in electron–phonon coupling [17].

Altering the Morphology of Tubes (Beyond the Soft Sintering)

At high SPS temperatures (>1,500 °C), it is possible to alter the morphology of CNTs. In an extreme case, it is possible to "unzip" CNTs to form graphitic nanostructures (Fig. 6) [18, 19]. This has been proposed as a novel method for generating large amounts of graphene in a short amount of time. Under the proper conditions, SPS can also change the sp^2 bonds of CNTs to sp^3 bonds, forming diamond [8]. Shen et al. [20] have shown that using the SPS, it is possible to grow diamond particles up to 100 μm in diameter at very low pressure (80 MPa). It is noteworthy that SPS under a moderate pressure of 10–100 MPa leads to the conversion of CNTs to diamonds, whereas a relatively higher pressure in the GPa range is usually required for diamond formation by other methods. It is proposed that the nucleation of diamond is from the core of carbon nano-onions, which is an intermediate product from the breakage of carbon–carbon bonds and unzipping CNTs [8]. The nano-onions behave as compression cells ("self-compression") to help nucleate and grow diamonds. Hence, the SPS process provides for a new path for diamond synthesis, which could offer many applications in industry due to the exceptional hardness and thermal conductivity of diamond.

Conclusion

Since their discovery, carbon nanotubes have been a topic of much research due to their amazing physical properties. However, in order to take CNTs from the lab to applications, scalable techniques must be developed to tune their properties. While it is possible to alter the structure and morphology of CNTs with very high precision using an irradiation technique, this method involves microscopic control parameters and the throughput is very low. In this regard, the SPS technique utilizes high-density current without the need to focus or align the electron beam, the control parameters of SPS are macroscopic, and the throughput is very high. One can envisage a combination of these two techniques to give some control of the structure and properties of CNTs at multiple length scales, which is a very promising approach to move CNTs from materials used solely in research to viable materials with real-world applications.

Nanomachining; Nano-mechanical machining

Definition

Ultraprecision machining refers to the ultimate ability of a manufacturing process wherein processing of a material at its lowest scale that is, at the atomic scale, is achieved. It is known that the lattice distances between two atoms are of the order of 0.2–0.4 nm; therefore, the ultraprecision machining refers to processing or removal actions of a manufacturing process in the vicinity of 1 nm. The process is also referred as "atomic bit" processing. To remove or process atomic bits, extremely large energy density is required, which is equivalent to the atomic bonding energy. The conventional cutting tools neither have high strength to sustain high specific cutting energy nor have hardness to sustain the tool wear. Therefore, ultraprecision machining refers to use of single crystal diamond (SCD) tools for ultrafine cutting

or very fine abrasives for lapping or polishing. It may also refer to use of high-energy elementary particles like photons, electrons, ions, and reactive atoms to undertake removal [1].

Historical Perspective

In early 1970s, Japanese researcher N. Taniguchi illustrated historical evolution of precision in manufacturing through "Taniguchi curves" [1]. It was realized that it takes about 20 years to improve precision by one decimal point; see Table 1 depicting the progression of precision.

He extrapolated the curves further to postulate that the resolution of machining processes would reach to 1 nm in the year 2000 [1]. True to the expectations, today, a number of ultraprecision machining processes are available.

Applications

Ultraprecision processing is required in the manufacture of high-precision block gages, diamond indenters and tools, 3D metallic mirrors, etc., in the mechanical domain; Si wafers, ICs memory, thin film, ULSI devices in electronics field; and optical flats, diffraction gratings, mirrors, and aspherical lenses in the optical field.

Types of UPM Processes

The ultraprecision machining processes can be broadly classified into three categories [1]:

1. Nanomechanical processing: These processes use either SCD tools to perform diamond turning or very fine abrasives in the bonded or loose form to perform nanogrinding, nanolapping, or nanopolishing. The other processes in this category include progressive mechanochemical polishing for Si wafers, pitch polishing for aspherical lenses.
2. Nanophysical processing: It involves use of high-energy elementary particles like photons, electrons, ions, and reactive atoms to perform direct ablation of substrate or carry out lithography.
3. Nanochemical or electrochemical processing: These processes involve use of chemical or electrochemical principles to effect material removal. They are chemical milling, photochemical machining, and other processes.

In the following sections, principles of nanometric removal in ultraprecision machining processes are elucidated along with their applications.

Nanomechanical Processing

In these processes, the processing unit, defined as the size of chip generated in a single stroke of tool, should be of the order of single or subatomic magnitude.

Principle of Ultraprecision Removal

The removal of atomic bits in nanomechanical processes requires specific cutting energy of varying degree as the scale of the process decreases and cutting tools with certain sharpness and hardness as discussed below:

Size-Effect Implications

As the processing scale reduces from simple tension testing to grinding, where submicrometric chips are generated, the specific shear or breaking energy becomes extremely large. This effect is called as *size effect*. See Table 2 showing processing scales and shear energies [2].

Extending this trend further, when the machining scale reaches an atomic-bit, the specific

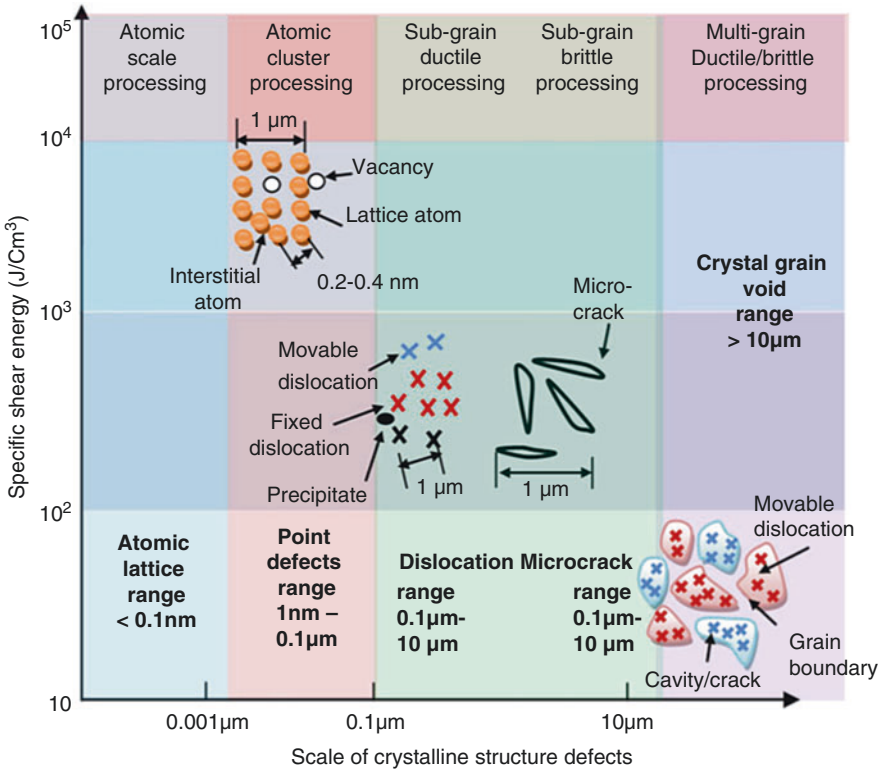
Ultraprecision Machining (UPM), Table 1 Evolution of ultraprecision

Year	1900	1920	1940	1960	1980	2000
Resolution (μm)	>10	5	0.5	0.05	0.005	0.001

shear energy reaches atomic bonding energy [1] or the theoretical shear strength of a defect-free material given by

$$\tau_{th} = \frac{G}{2\pi} \quad (1)$$

For carbon steel with the modulus of rigidity, G = 82 GPa, the theoretical shear strength is given by



$$\pi_{thCarbonSteel} = 13GPa \quad (2)$$

Ultraprecision Machining (UPM), Table 2 Size-effect in processes as a function of chip thickness

Process	Process scale	Chip thickness (μm)	Resisting shear stress (N/mm^2)
Tension test	Multicrystal grain	300–500	300
Turning	Subcrystal grain	40–50	500
Precision milling	Subcrystal grain	5–10	1,000
Grinding	Atomic cluster region	0.5–1	10,000

The reason for increasing the specific shear energy is attributed to the kind of defects available in the crystalline structure at that processing scale. At the atomic bit scale (0.001 μm), the energy required is comparable to the theoretical shear strength (10^5 J/cm^3) [1] (Fig. 1). At the atomic cluster scale, deformation of a material can take place only with the help of point defects (Fig. 1) and requires energy of the order of 10^3–10^4 J/cm^3 [1].

Nevertheless, at some higher scale (0.1–10 μm), called as subcrystal grain size, 2D or 3D defects in the crystalline structure cause a significant reduction in the specific shear energy to 10^2–10^3 J/cm^3

Ultraprecision Machining (UPM), Fig. 1 Defect distribution and scale of specific shear energy required

(Fig. 1) [1]. In the crystal grain size range, (>10 μm), all kinds of dislocations and defects at grain boundaries lower the processing energy further to 10^1–10^2 J/cm^3 [1]. Unlike the case of the ductile (metallic) materials discussed above, the brittle materials have a network of microcracks in place of the network of dislocations (Fig. 1). In the ductile materials, below the point defect scale (1 nm to 0.1 μm) (Fig. 1), and in the brittle materials below the microcracks scale (0.1–10 μm) (Fig. 1), the specific shearing energy is equal to the theoretical shear strength of the work material.

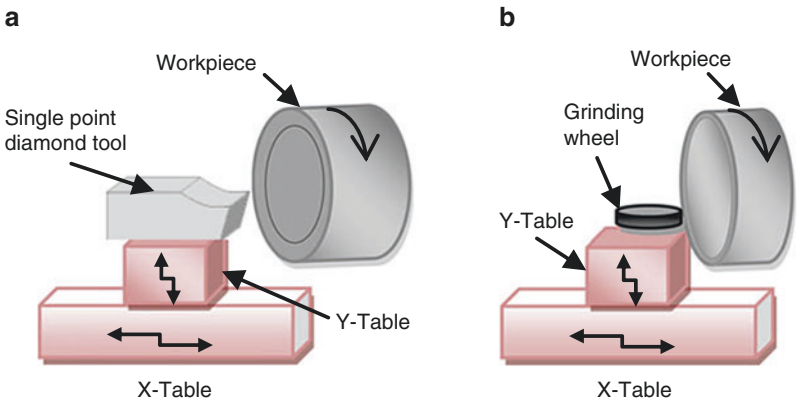
Cutting Tool Material and Geometry Implications

The cutting tool edge in ultraprecision machining being subjected to extremely high cutting pressure should withstand not only the pressure but also the wear. In addition, the edge should have high degree of sharpness to perform atomic bit removal. The SCD tools, possessing the desired properties, are the most suitable tool materials for ultraprecision machining. However, their limitation stems from the achievable cutting edge sharpness, which normally is limited to hundreds of nanometers. Therefore, in UPM, several atomic layers or atomic clusters are processed than atomic bits, primarily on softer metallic materials like Al and Cu. On the other hand, on hardened steels, and other brittle materials, SCD tools undergo rapid wear, thereby necessitating the use of diamond abrasive process like nanogrinding.

Ultraprecision Machining Systems

It uses time-tested principles of precision engineering along with (1) the recent advancements in the control, feedback, and drive systems, (2) CAD/FEM for designing, followed by (3) fine-tuned assembly as well as system integration. This combination results in a machine that is thermally stable, highly reliable, and flexible and at the same time faster in response [3]. Several features of an ultraprecision machine are summarized in Table 3.

Ultraprecision Machines and Processes



A number of ultraprecision machines and processes have evolved using nanomechanical removal principles. They are discussed below.

Single Point Diamond Turning

It is a nanomechanical processing machine that was developed primarily for 3D shaping and surface finishing of soft metals such as copper and aluminum and polymers. The machine with the features listed in Table 3 uses very sharp SCD tools to perform ultraprecision cutting. The chips formed during the process are extremely thin,

Ultraprecision Machining (UPM), Table 3 Salient features of an ultraprecision machining system

Machine elements/ purpose/types	Main features
Machine base	
• Provides thermal and mechanical stability, damping characteristics	• Made of cast iron, natural or epoxy granite, polymer concrete
Work spindle	
• Spindle motion errors significantly affect surface quality and accuracy of machined features • Use aerostatic or hydrostatic, recent grooved air bearings	• Both the spindle types have high rotational accuracy and rotational speeds • Aerostatic spindles are for low/medium loads, hydrostatic bearings take heavy loads
Drives	
• Slide drives provide stiffness, acceleration, speed, smoothness of motion, accuracy, and repeatability • Spindle drives are usually AC/DC motors • Slides are usually provided with linear motor or friction drives	• Servo drives are used in contouring operations • Small and precise motions of tools for tool positioning and fine motion are achieved by piezoelectric actuators
Controls	
• Controls are required for linear and rotary drives, limiting, position, and time switches, sensors • They also control thermal, geometrical, and tool setting errors	• A multiaxes CNC controllers are used • PC-based controls are used more recently • Feedback controls have a resolution of nm or sub-nm
Measurement and inspection systems	
• Provides rapid and accurate positioning of cutting tool towards work surface • It also monitors the tool wear condition	• Online measurement and error compensation • Laser interferometer for tool position control

Ultraprecision Machining (UPM), Fig. 2 Typical schematics of (**a**) Single-point diamond turning (**b**) Diamond grinding machine

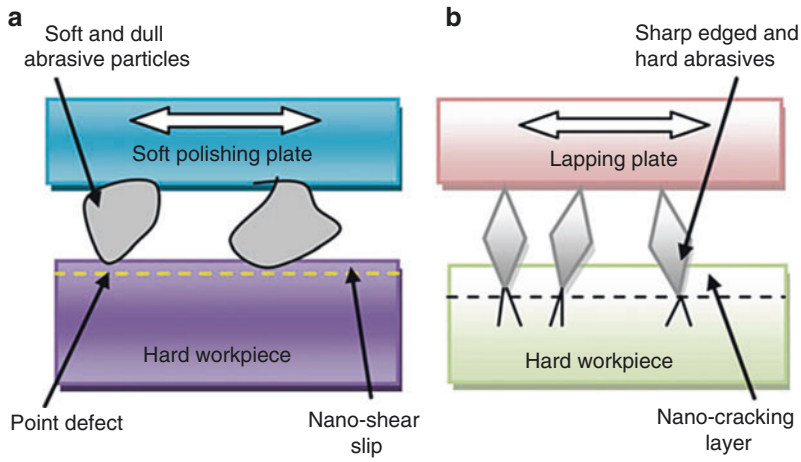
which indicates ductile deformation of the material during machining. At the same time, the process leaves extremely thin degenerated layer of the work surface as the process initiates shear slip using dislocations (Fig. 1).

Applications of the process include fabrication of metallic mirrors, precision component fabrication in laser, and space and optics fields. A typical diamond turning lathe has T-axis configuration (Fig. 2a). The main machine slide moves along x-axis, and the cutting tool is moves along Z-direction.

Nanogrinding

Single-point diamond turning machine is usually provided with add-on grinding attachment (Fig. 2b) for nanogrinding. This way, harder work materials can also be processed on the machine using the grinding attachment. However, it increases the stiffness requirement of the machine. In nanogrinding process, shear slip is generated due to very low (tens of nm) depth of cut (Fig. 1). This causes crackless ductile failure of hard/brittle materials under the abrasive grains in the diamond grinding wheels. Since the working stress on the abrasives is extremely high, only fine-grained diamond abrasives can be used for this process. The process can achieve mirror like finish on hard and brittle materials like glasses and ceramics. Its other applications involve grinding of mould inserts, glass lenses, and aspherical lenses.

Electrolytic In-process Dressing (ELID) Grinding



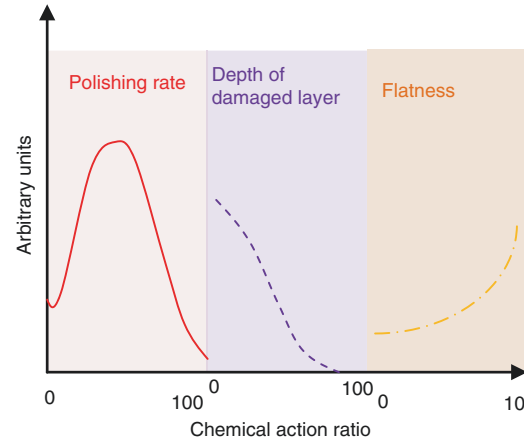
It is a type of nanogrinding process in which metal-bonded diamond grinding wheels are used. The process uses an electrolytic solution as a grinding liquid. Upon application of voltage, anodic dissolution of bonding metal from the grinding wheel occurs. This ensures that worn abrasive particles on the grinding wheel are removed quickly (a wheel dressing action), thereby ensuring continuous availability of sharp particles for the grinding process. The sharp particles initiate shear slip at low depth of cut (Fig. 3) causing crackless material removal. The process therefore is capable of achieving mirror like surface finish on glasses and ceramics.

Nanolapping and Nanopolishing

Unlike nanogrinding, which uses fixed abrasives, these processes use free abrasives to achieve mirror-like finish. The processes involve atomic cluster processing.

Nanopolishing involves sliding of soft abrasives between a soft polishing pad and work surface (Fig. 3a). The abrasives are usually soft and dull; they include Fe_2O_3, Cr_2O_3, CeO_2, or MgO [1]. The abrasives get embedded in the soft pad and originate shear slip at the point defects to effect removal [1] (Fig. 3a). This ensures smooth polishing of hard metallic surfaces.

The nanolapping on the other hand uses a medium to hard pad besides extremely sharp and hard abrasives such as diamond, CBN, SiC, SiO_2, or B_4C [1]. The fine and hard abrasives initiate cracking at the point defects to effect removal [1] (Fig. 3b). This helps generate mirror-like finishing on hard and brittle materials.



Ultraprecision Machining (UPM), Fig. 3 (**a**, **b**) Nanopolishing and nanolapping

P-MAC

The progressive mechanical–chemical (P-MAC) polishing is a hybrid nanopolishing process that uses mechanical as well as chemical action to effect removal to achieve mirror-like finish and damage-free polishing of Si wafers. The process uses ultrafine SiO_2 abrasives (size ~10 nm) suspended in an alkaline (pH ~10) solution along with an artificial leather foam to perform polishing in four stages. The abrasive particle size and the polishing pressure and the stock removal are gradually reduced after each stage [1].

In P-MAC, the greater the chemical action, the higher is the polishing efficiency and the lower is the damaged layer [1] (Fig. 4). However, the increased chemical action reduces control over accuracy (flatness), Fig. 4 [1].

Ultraprecision Machining (UPM), Fig. 4 General processing characteristics of P-MAC

Aspherical Lens Polishing

Aspherical profiles are required at the edges of the lenses to ensure that light beams from the lens edges converge at the focal point. Therefore, the aspherical lens polishing involves polishing over free-form surfaces. The process is often required for polishing of highly accurate X-ray optics and lenses in commercial cameras.

It involves gradual removal using a pitch polishing tool that has very small contact area as compared to the dimensions of the workpiece. The polishing rate is governed by Preston's rule of thumb [1].

$$h = \alpha \cdot v \cdot \Delta t \qquad (3)$$

The pitch polishing tool acts as a pad and supports the abrasives. It remains solid at room temperature but flows with time when heated or under pressure. The composition of the pitch material is usually proprietary of various manufacturers but contains materials like tar, oil, wood, paraffin wax, shellac, and so on. The properties of pitch material include [1] viscosity in the range of 10^7–10^9 Pa · s), softening point, (55–7 °C), penetration hardness (60–80 by Shore D). In this process, the surface roughness tends to improve as the penetration number of the pitch increases, i.e., as the pitch becomes softer. It is seen that CeO_2 and ZrO_2 give better surface finish than super hard diamond abrasives.

Nanophysical Processes

The principle of removal in these processes involves photothermal or photochemical interactions with the work surface. The photothermal interaction causes melting and vaporization of work material due to energy of photon or laser beams. On the other hand, the photochemical interaction involves use of photon energy to break bond between work elements [1]. It is understood that usually laser beams with metallic materials perform removal action by the photothermal principle. However, when the polymeric materials interact with laser beams, photochemical reaction takes place. With the ceramics, the interaction is partly by the photothermal and partly by photochemical reactions.

The photon beams owing to their wavelength of the order of 10–0.1 μm and the photon energy of the order of 0.1–10 eV cause thermal energy transfer that is smaller than the atomic bonding energy of materials. Hence, the photon beams are not suitable for nanometric material removal. Similarly, an electron beam due to small size (2.8×10^{-6} nm), mass (9×10^{-31} kg), and low energy of several hundred kilovolts penetrate deep (several micrometers) into the work surface. Therefore, the electron beams are also not suitable for nanometric material removal.

Unlike the electrons, most of the ions interfere with the surface atoms of a workpiece because their mean diameter is ~0.1 nm and the mean atomic distance is ~0.3 nm. Consequently, the projected energized ions frequently collide with the nuclei of atoms of the workpiece and knock out or sputter the surface atoms. Hence, ion beams are most suitable for atomic bit removal. The process is also called as ion sputter machining. In the process, the electrically accelerated inert-gas ions such as Ar ions with average energy of 10 keV (which corresponds to a speed of ~200 km/s) are unidirectionally oriented and projected on to the workpiece surface in a high vacuum (1.3×10^{-4} Pa) [1]. Hence, they adhere firmly on the target surface. A beam of focused ions can also be used for cutting of extremely hard materials like diamond or sharpening of SCD tools.

Nanochemical or Electrochemical Processing

The chemical reactions inherently involve atomic bit processing. A chemical reaction is a change in the atomic combination of reacting molecules, in which the atomic bonding of a reacting molecule is broken and a new molecule is generated.

In the process, a chemically reactive gas or liquid is applied to a specified position on the solid surface of the workpiece. The reacted molecules are removed or diffused into the surrounding reacting gas or liquid. If the reacted molecules are insoluble or not in vapor form, chemically reactive deposition occurs on the workpiece surface. But if the reacted or reagent molecules diffuse into the surface layers of the workpiece and react with the atoms or molecules there, they perform a chemically reactive surface treatment [1]. The dimensional accuracy obtainable in chemical reactions is in the nanometer range when the processing conditions are stable. In addition, the following aspects are necessary for nanometric processing [1]:

1. In-process measurement and feedback control of position of the processing point and control of the processed volume (area) are necessary. However, it is difficult to realize these in practice. In the photoresist method, control of the processing point position or area is achieved by the patterned mask.
2. The control of the processing volume or depth can be done only by adjusting the processing time and flow rate of etchants.

In the electrochemical process, the basic reaction is the same, but activation energy for the reaction is given by electric field potential and differs from the ordinary activation energy of the chemical reactions based on the thermal potential energy.

Summary

Ultraprecision machining uses mechanical, physical, chemical, or electrochemical sources of energy for effecting material removal to the nanometric scale. Grain size, load applied on the grains, and

the type of work material govern removal in nanomechanical processes. Size of the energy beam particle governs the processing resolution in nanophysical processes. In-process measurement and feedback control are essential for the nanochemical or electrochemical processes.

Definition

Ultra-precision surfaces and structures with nanometer accuracy comprise surface shapes and/or surface structures with the highest achievable processing accuracy of nanometer or even picometer rms range. Root mean square (rms) is a value calculated from differences of the surface measuring data and the desired (designed) surface shape data. Its value is a measure of how far on average the error is from zero. The ultimate accuracy of surface shapes and structures is a prerequisite for their physical functioning in many of today's fields of science, technology, and products like electronics, microsystems, and mainly in advanced optics. Examples range from small millimeter size microscope lenses for deep ultraviolet (DUV) light to large telescope mirrors of up to meters in size. In high-performance optics, the extremely low rms values have to be realized for part or the complete surface spatial wavelength spectrum from the full aperture down to the micrometer. In special cases, the processing accuracy must be within few atomic layers for spatial wavelength up to some micrometers. In general, ultra-precision surface machining requires and is done in repeated loops in turns with adequate surface measurements. Advanced measuring equipment of different kinds for the coverage of more than eight orders of magnitude of spatial wavelength is necessary for it.

Ultra-precision surfaces are fabricated by multistep processing chains starting from coarse shaping like grinding up to final fine shaping like polishing. Ion beam and plasma jet techniques besides others, such as magnetorheological finishing (MRF), chemical vapor machining (CVM), and elastic emission machining (EEM), are highly deterministic. They belong to the class of finishing tools that are favorable to achieve the ultimate accuracy.

Ion beams and plasma jets or plasma-assisted techniques, respectively, base upon physical

and/or chemical interaction on atomic level between atomic particles out of the ion and plasma tool, respectively, with surfaces. Generally, such processes are adaptable for different machining in wide application ranges. The capability to set appropriate parameters together with their tight controllability adequate to the required processing condition qualify them as key tools to achieve the desired ultra-precision of surfaces and structures.

High-vacuum ion beam processing uses accelerated mostly inert ions of some hundred eV to about 2 keV (i) to remove atoms from a surface by atomic impact – the so-called ion or atom sputtering; (ii) to deposit films by secondary ion beam sputter deposition or to assist film deposition; (iii) to create nanostructures by complex ion-induced self-assembling effects; or (iv) to smooth surfaces. Combined with additional chemical active species by adding respective gases to the ion source, chemical reaction with surface atoms is exploited to enhance removal rates and/or etching selectivity between two materials like an adhesive mask and the underlying glass substrate. This is called reactive ion beam etching (RIBE). A second version is chemical-assisted ion beam etching (CAIBE). In this case the source is operated by an inert gas and the reactive gas is directed to the surface processed.

Plasma jets or torches are free-burning electrically excited gas discharges under atmospheric or rough vacuum conditions using mostly inert gases like argon. By admixture of adequate gases as precursor, chemical reactive atomic particles like radicals are produced in the plasma. Depending on the application, different gas types are used. They can (i) chemically react with surface atoms to form volatile compounds, thus removing material by dry etching, or (ii) dissociate to deposit thin films. Just the transfers of energy out of the plasma to the surface can (iii) smooth rough surfaces.

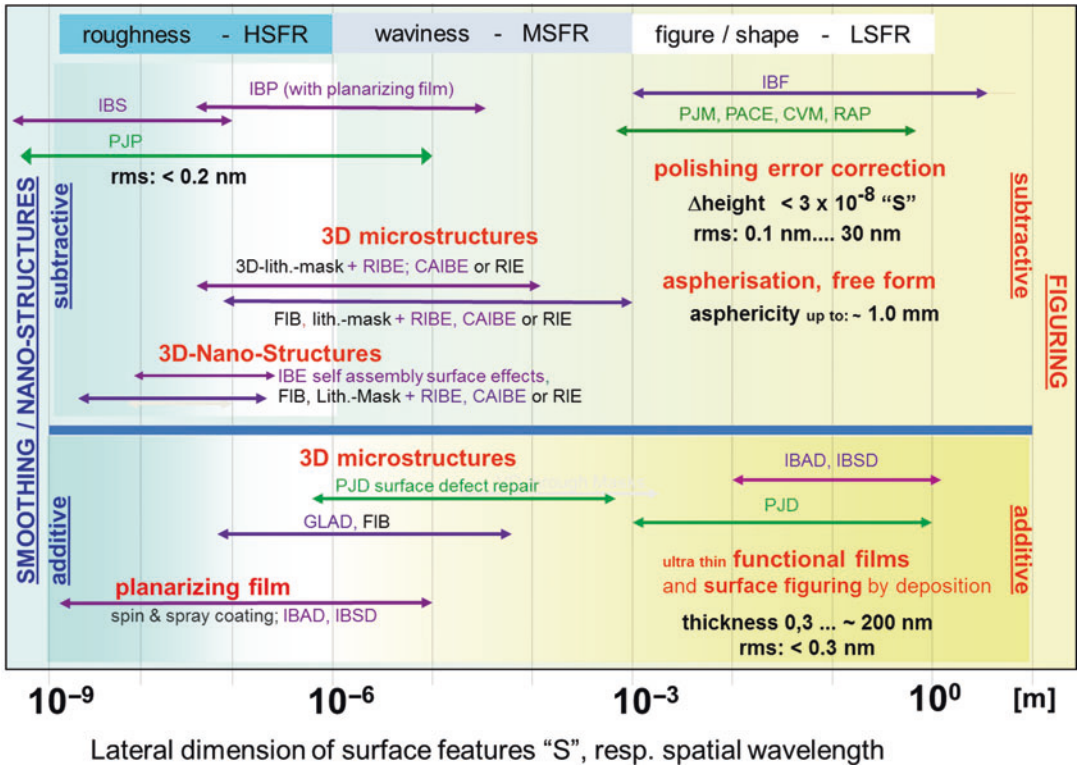
Ion beam techniques especially ion beam figuring (IBF) is well established in optics production today, whereas plasma jet techniques like plasma jet machining (PJM), plasma-assisted chemical etching (PACE), and rapid atomic processing (RAP) are at the doorstep to enter in production. Nevertheless, presently both principles are improved further by intense research and development for higher performance, productivity, and new applications.

Overview

N. Taniguchi introduced the term "nanotechnology" in a keynote paper of the International Conference on Production Engineering (ICPE) in Tokyo in 1974. This time nanotechnology was initially proposed to provide precise target accuracy for fabrication processes that involve ultra-precision surface finishing [1, 2]. In the frame of developments of high technologies like semiconductor, laser, x-ray, synchrotron radiation, space telescopes, and advanced military technologies beginning about 1980 worldwide, big efforts had been started for the development of deterministic machining technologies to meet the steadily growing demands of extreme high-quality surfaces mainly for optics. In high-performance optics, the extremely low rms values have to be realized for the complete surface spatial wavelength spectrum from the full aperture down to micrometer or for parts of it. Only these extreme accuracies near the physical limits for processing of (i) macroscopic surface shapes like lenses for electronic circuit lithography or meter-sized giant space telescope mirrors and of (ii) sub-nanometer uniformity of thin film thickness, for example, of mass storage hard disks, enable the functionality of those components in modern equipment and products. The same applies for dimensional control of micro- or nanostructures on wafer surfaces for electronics or micromechanics and micro-optics as used, for example, in miniaturized camera systems for smartphones.

For ultra-precision surfaces, there is a wide variety of shapes from flat to spherical and aspherical or recently even so-called free forms on a similarly wide diversity of work sizes. Materials range from monocrystalline silicon over many types of glass or metal up to very hard and brittle ceramics. Binary and 3D micro- and nanostructures on flat and more and more on curved surfaces are needed, for example, for diffractive lenses or antireflection enhancement.

Different surface shaping and finishing technologies targeting ultra-precision quality have been developed. Besides ion beam and plasma jet techniques described here, there are SPDT (single-point diamond turning), CCP (computer-controlled polishing), chemical mechanical polishing (CMP), MRF, RAP, CVM, EEM, and some others. Summarizing overviews on advanced deterministic surface machining and finishing technologies have been published very early at the beginning of the ongoing development and recently [3–7].

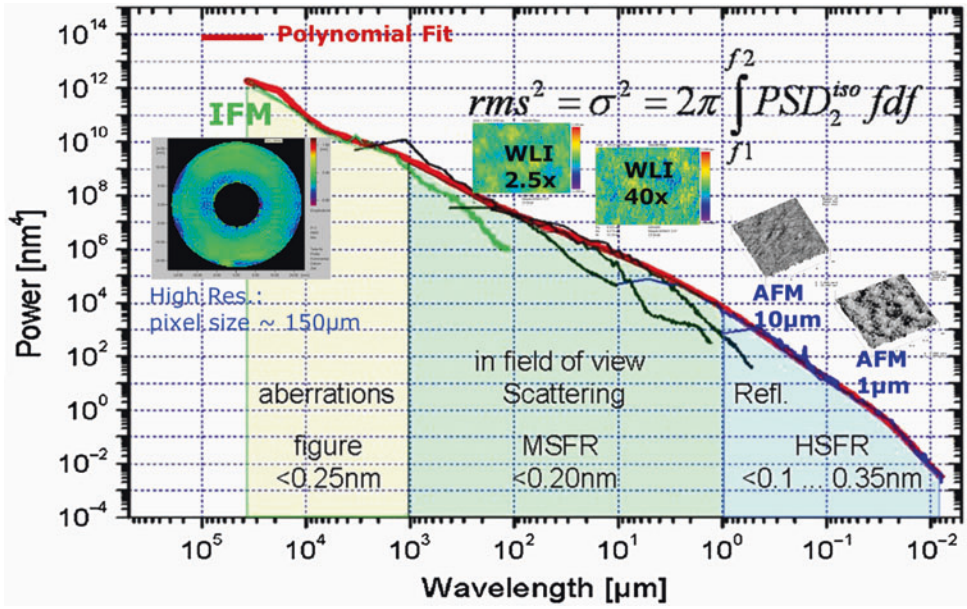


Ion beams and plasmas including recently developed atmospheric plasma jets with their different but well-defined physical and/or chemical characteristics for their interaction with material surfaces are the main tools to achieve ultra-precision accuracies. The heavy atomic particles involved in these technologies are ions, atoms, molecules, and radicals. The capability to tightly control their parameters like mass, kinetic energy, excitation, density, charge state, incidence angle to the surface, chemical reactivity, and others in wide ranges allows tailoring of respective particle tools for the individual processing of surfaces to achieve the demanding surface quality. Automation, long-term stability, and flexibility of ion beam and plasma jet sources combined with advanced surface processing algorithms and reliable machinery including computer control make these technologies efficient for production up to high volumes. Further, in high-end optics fabrication ion beam figuring (IBF) and ion beam smoothing (IBS) are able to overcome physical constraints of the conventional full lap and small tool abrasive polishing processes. For ultra-precision ion beam and plasma jet processing, there are two basic principles: (i) material removal as sputtering and/or dry etching and (ii) material deposition.

Surface patterning includes techniques for preparing, patterning, and structuring surfaces, from the arrangement of single molecules to the macroscale, for example, through etching, electrochemical patterning, and film deposition. Patterning and structuring in most cases are a combination of a mask, binary, or 3D that is defining the pattern and one or more subsequent etching steps to transfer the pattern onto the substrate or a film. Mask structuring is performed by lithography. Photolithography, e-beam lithography, laser writing, laser holographic interference lithography, and ion beam lithography are used. Main etching techniques are the ion-based ones, RIE (reactive ion etching) or RIBE/CAIBE, due to their most important characteristic of being anisotropic (no mask under-etching) and highly selective for different materials (e.g., mask and substrate). Both techniques comprise physical sputtering and chemical reaction between reactive species and surface atoms to remove material.

Not included in this survey of ultra-precision surface processing of ion beams and plasma jets is the special field of focused ion beam techniques. The physical and or chemical ion-induced processes are more or less the same, but the technique similar to electron beam microscopy is very different. Applications are in the field of fabricating prototype nano- and microstructures and mainly on mask repair, basic research, and sample preparation for surface and structure analytics and depth profiling as well. Recently reviews have been published [8–10].

Figure 1 shows schematically the usage of different ion beam and plasma jet techniques with respect to the spatial wavelength over more than eight orders of magnitude.



The main technology driver in this field was and is still lithography for semiconductor technology. Advanced deep and extreme UV lithography (DUVL and EUVL) use 193 nm light wavelength and EUV soft x-rays of 13.4 nm, respectively [11]. Advanced high end aspheric lenses and mirrors riqire demanding surface precision in the sub-nanometer range of rms surface shape errors across the entire spatial wavelength range with respect to the mathematical design. This has to be realized from the full aperture range down to micrometer spatial roughness in series production on all surfaces of projection optics for lithography for instance. Figure 2 shows measured power spectral density (PSD) curves of an EUV mirror substrate surface. PSD function represents the surface error amplitude distribution over the spatial wavelength. The measurements were performed over the entire spatial wavelength

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 1 Scheme of summarizing of ultraprecision ion beam and plasma jet methods for large surface processing represented with respect to the spatial wavelength. Some typical target parameters are given (*black*). using different equipment according to their appropriate spatial resolutions. From nanometer to micrometer spatial range, atomic force microscopy (AFM, blue curves) from micrometer to millimeter white light interference microscopy (WLI, black curves) and from millimeter to full aperture (green curve) high-resolution interferometry (IFM) was used. The red curve is a polynomial fit comprising the individual PSDs. The three colored areas represent the impact of the different spatial wavelength surface error ranges on the optical performance of the imaging EUV optic for the 13.4 nm light wavelength. The figures are the rms value specs for EUV optics. Shape errors from full aperture up to 1 mm wavelength (LSFR) cause image aberrations. MSFR from 1 mm to 1 μm leads to field of view light scattering resulting in flare or blurring of the image, and HSFR (<1 μm spatial wavelength) causes wide-angle light scatter lowering the image contrast. The overall rms value of the surface σ is related to the integral of the PSD over a considered part or the entire spectral wavelength (formula insert).

As Fig. 2 exemplarily shows, surface topology measurement is the crucial point for final ultraprecision accuracy. This is necessary not only for the final steps but for all phases of the processing chain. Because generally surfaces

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 2 Power spectral density functions (*PSD*) of a well-finished EUV optic surface calculated from individual 3D surface topology measurements [12]. For HSFR, AFM measurements (*blue curves*) with two scan areas, for MSFR white light interference microscopy (*black curves*) with two magnifications and for figure large area interferometry (*green curve*) have been used. The *red curve* is the polynomial fit of all measured data. The three colored areas "figure," "MSFR," and "HSFR" represent the different impact of surface errors of the spatial wavelength ranges on the optical performance of the surface. The indicated figures are the error specs for EUVL optics (Courtesy of U. Dinger, Carl Zeiss SMT GmbH, Oberkochen, Germany)

must be measured for all parts of the spatial wavelength spectrum, different measuring equipment is necessary since each measuring principle is bandwidth limited with respect to the spatial wavelength spectrum as shown in Fig. 2. Therefore, the development of ultra-precision surface processing is characterized by alternating stimulation between measurement development and technology performance, which is still going on [13, 14]. In Table 1 major requirements for surface shape and profile measurements together with some status quo figures for advanced optics are given.

Ion Beam Technologies

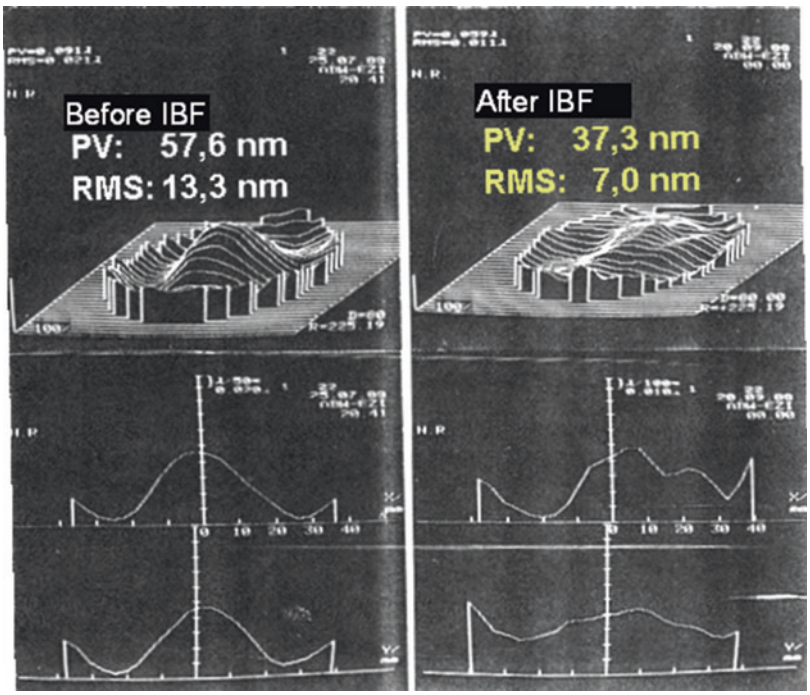
Ion Beam Figuring

At the beginning of the 1980s, worldwide efforts had been started for the development of deterministic ultra-precision machining technologies to meet the steadily growing demands of extreme high-quality optics surfaces. This time digital interferometry was in an early stage of its development with very limited performance especially concerning its spatial resolution because CCD cameras had pixel figures of only 32 × 32. Nevertheless, ion beam figuring for polishing error correction of lenses could be demonstrated. Besides scientists from Arizona State University, USA, German researchers in Leipzig in cooperation with Carl Zeiss from Jena obtained early IBF result in 1989 as shown in Fig. 3.

In the middle of the 1990s, IBF brought the breakthrough for efficient volume production in DUV lithography optics due to its high processing determinism connected with the capability to overcome physical constraints of the conventional full lap and small tool abrasive polishing processes as it is their unstable tool behavior at the edges of the optic.

Using multistep scanning schemes combined with dwell time algorithms, processing by

sub-aperture ion beams of different sizes results in an efficient correction of low and part of mid-spatial frequency surface errors down to the sub-nanometer amplitude level with almost no or minimum surface or subsurface damage, respectively, due to the gentle beam surface interaction. Figuring involves specified scanning paths, like meander, spiral, and cycloid, with a variation of the scan speed according to the calculated dwell times. In a standard procedure the pathway of the ion beam spot on the surfaces follows a spherical bowed meander along the lines of latitude. The path velocity of the beam spot on the work surface results from a dwell time distribution proportional to the desired material removal depth distribution. Typically IBF processing software involve the calculation of the dwell times (deconvolution between the error 3D topology to be removed and the 3D removal function of the ion beam tool) for a given topology to be removed and the simulation of the removal process (convolution). Main standard procedures for both are fast Fourier methods. At given local speeds, dwell times t, and the material removal function r, the dwell time procedure can be expressed as follows:



$$h = t * r + \varepsilon \tag{1}$$

where h stands for the heights of the removed material and the symbol * denotes the convolution operator. Matrix notation yields

$$h_{ij} = \sum_k \sum_l t_{i-k,j-l} r_{kl} + \varepsilon_{ij}, \tag{2}$$

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Table 1 Surface shape and profile measurement requirements for ultra-precision surface processing mainly for optics

Requirement	Influenced by	Current specification rms [nm]

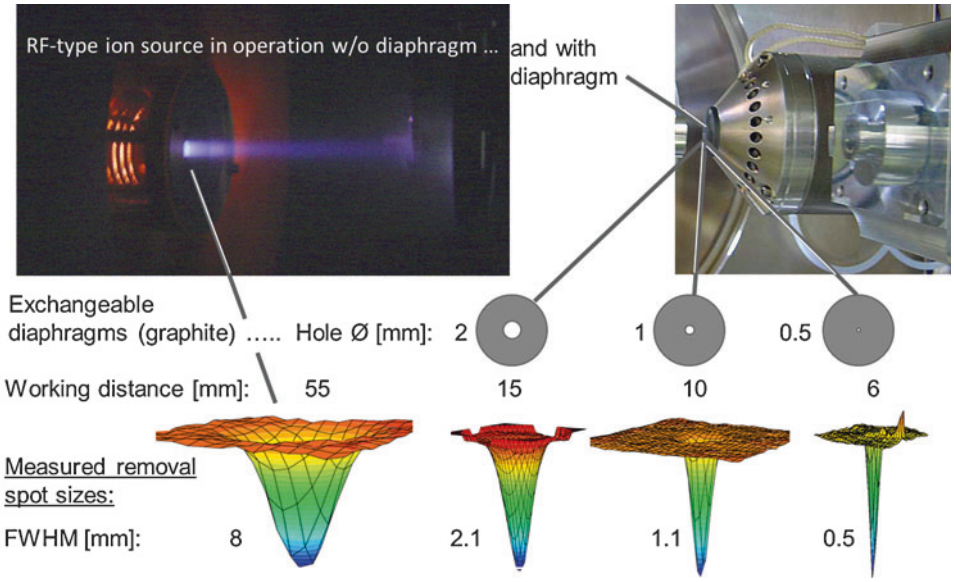
Reproducibility	Handling	0.5 . . . 1.0
Accuracy	Calibration	0.7 . . . 1.5
Precision	Deviation from: (i) an ideal surface or (ii) a given reference	

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 3 Historical early result on IBF: Interferograms (taken with a 32 × 32 pixel CCD camera) of an 80 mm diameter convex lens before and after IBF obtained by researchers in Leipzig, Germany 1989



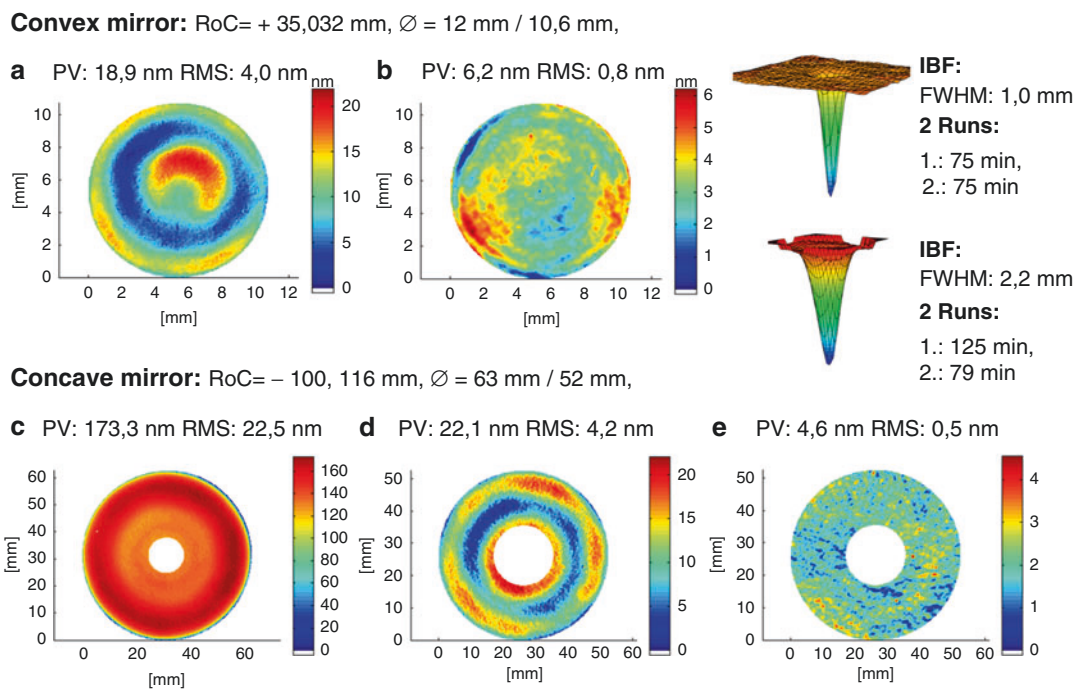
where ε_{ij} denotes a certain amount of error. The summation extends over all values of the material removal function r_{kl}, which are assumed to be nonzero. The amount ε_{ij} is composed of errors resulting from height measurements of the topology, fluctuations in the removal function, and errors coming from speed and location of the motion system. The calculation of the dwell times and the arising final topology are based for planar and spherical surfaces on modified iteration methods selectable according to Van Cittert, Lucy-Richardson, Wiener, and regularized filter [15] and for aspherical surfaces or local dependency removal function on enhanced Gold's method [15]. The relevance of the dwell times with respect to acceleration and speed limits of the motion system is examined, and if necessary, it is immediately corrected by additional smoothing procedure calculations in order to get a final topology with highest quality at a minimum in etching time. The iteration is stopped if (i) the rms value falls below the targeting data of the residual error topology, (ii) the maximum acceleration of the motion system is exceeded despite the abovementioned numerical smoothing procedure, and (iii) the maximum number of iterations is achieved or no better dwell times leading to smaller rms values are calculable. The material removal function of the ion beam can either be generated as a data file of the etching rate matrix or by parameters of superimposed two-dimensional Gaussians. The parameters of the material removal function are externally foreseeable by a corresponding nonlinear parameter fit of the superimposed function to the measured values of a footprint, grove, or meander etching.

The assumption of modeling the removal process by using an isotropic removal function and etching proportional to the dwell times enables the application independent of the physical removal process. The removal function of the ion beam is estimated experimentally by etching the same material as for the figuring and measuring the etched topology by interferometry together with the etching time. Ion beam figuring methods have been reviewed recently [16]. Recently IBF technology development is aimed to extend surface correction of millimeter spatial size range down to below nanometer dimension in height to meet the demanding requirements of the MSFR especially for aspheres or free forms for lithography DUV, EUV, and synchrotron optics. High spatial resolution in deterministic figuring of such tiny surface error features tight technical specs reqirements have to be fulfilled: (i) for the ion beam tool with beam size, stability, and linear etching behavior with time, (ii) for the surface figure measuring with the sufficient spatial resolution, (iii) for the adjustment of the beam tool with respect to the work, and (iv) for the adjustment of the measured data matrix to the physical work surface. Improvements of all these items have been realized already and are still under development to make them mature for production.

For the correction of smaller spatial error features, for instance, an 8 mm FWHM high-current-density beam of a compact 13.56 MHz RF source is reduced by diaphragms of different sizes to 2 mm, 1 mm, and 0.5 mm FWHM (Fig. 4). Figure 5 shows exemplarily the polishing error correction of small spherical optics down to rms <1 nm.

Ion Beam Figuring Plant

IBF high-vacuum plants for workpiece sizes from millimeter up to 2–3 m in diameter are today available on the market. The main components of the systems are (i) a stainless steel processing chamber with a base vacuum of 10^{-4} Pa, (ii) a computer-controlled precision 5-axis (x, y, z + orthogonal rotational axes A and B) or 3-axis (x, y z) system for the scanning path movement of the ion source, (iii) an RF-ion source with an automated Faraday cup system for measuring beam profile and beam position, (iv) a workpiece handling system, (v) a vacuum load-lock chamber for small- and medium-sized optics up to about 70 cm in diameter enabling uninterrupted operation of the high-vacuum and fast workpiece change, (vi) power supply, and (vii) a process gas handling system. The machines are computer controlled and operate fully automatic including workpiece data handling and process modeling. 3-axis systems are preferred as they are more stable in their dynamic behavior compared to the 5-axis systems. In contrast motion to 5-axis in the case of



Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 4 RF-type ion source (13.56 MHz) for IBF; *left upper corner*: ion source in operation with an Ar ion beam; *right upper corner*: same ion source equipped with a frame for beam shaping diaphragms made from graphite and hosting inside a hot filament electron emitting neutralizer for avoiding charging up insulating workpieces by the positively charged ions. In the *middle* row, three diaphragms with different hole diameters are shown and below interferometrically measured removal spot sizes (footprints) of the beam without and with the beam shaping apertures, respectively. Also given are the respective work distance between diaphragm front side and workpiece surface and the beam sizes at full width at half maximum (*FWHM*)

3-axis motion system, the ion beam centerline cannot be directed perpendicular to each point of the curved workpiece surface; instead, the beam direction is parallel to the z-axis and the source in this case is maintained in a constant distance to all surface points. Thus, the removal spot size on the one hand and the atomic sputter yield on the other change depending on the curvature of the surface causing variation of the incidence angle of the ion beam. This behavior is now fully included in the IBF processing software for calculating the dwell time matrix to control the ion beam scan path motion. Figure 6 shows state-of-the-art IBF plants for high-end optics production.

The IBF processing simulation module on the base of the measured ion beam removal function and the measured initial surface figure date calculates a dwell time of the ion gun for each point of the surface to get the desired final surface figure. After the checking of the simulation results by the operator, they are fully automatically converted into motion data for the multi-axis system and the ion gun, respectively.

Ion Beam Sources

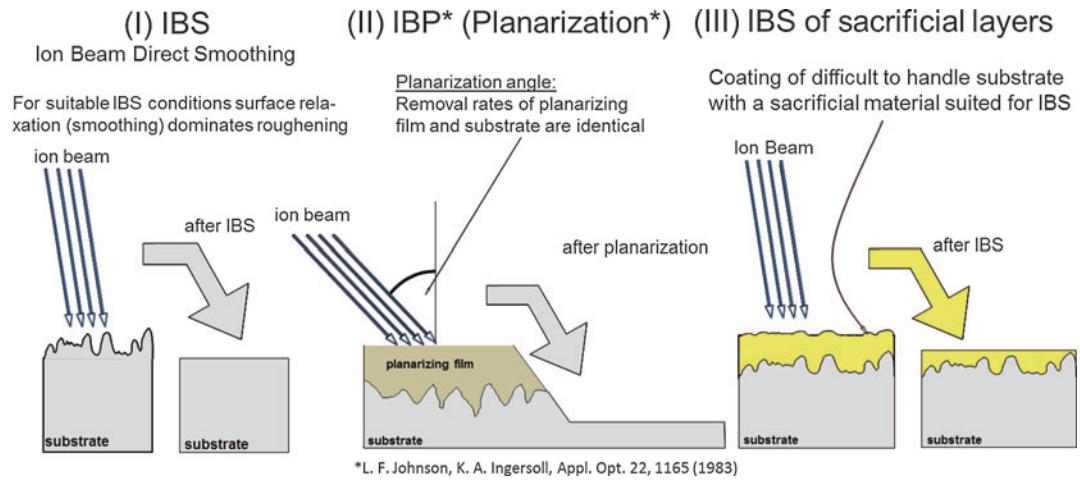
Ion energies for ion beam etching and figuring are in the range of about 400 eV up to 2 keV. Different types of ion sources hot filament (Kaufman type), RF type (inductively coupled 13.56 MHz), and ECR type (ECR: electron cyclotron resonance) energized by 2.45 GHz microwave are in use. The ion beam is extracted by a high-voltage-powered multigrid ion extraction system forming a compact ion beam out of the individual beamlets from the grid holes. Different grid designs allow variable beam shapes, divergent, parallel, and convergent. With the help of the grid voltages, the beam shape can be adjusted within some limits. For IBF technology mainly Kaufman-type and RF-type sources are used. The RF-type ion source (Fig. 4) is preferred for IBF production purposes due to lower machine downtime by

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 5 Interferograms of IBF with small spot ion beam for ULE® mirror substrates of a Schwarzschild optic for EUV application; (**a**) convex mirror initial surface, (**b**) result after 2 IBF runs using a 1.0 mm FWHM beam size, (**c**) concave mirror, initial surface, (**d**) after 1st run and (**e**) final result after 2nd run. For the concave mirror, a 2.2 mm FWHM beam size was used. The IBF machining times are given together with the interferometrically measured shape of both beam sizes. *RoC* radius of curvature, the second diameter value is the optically active area

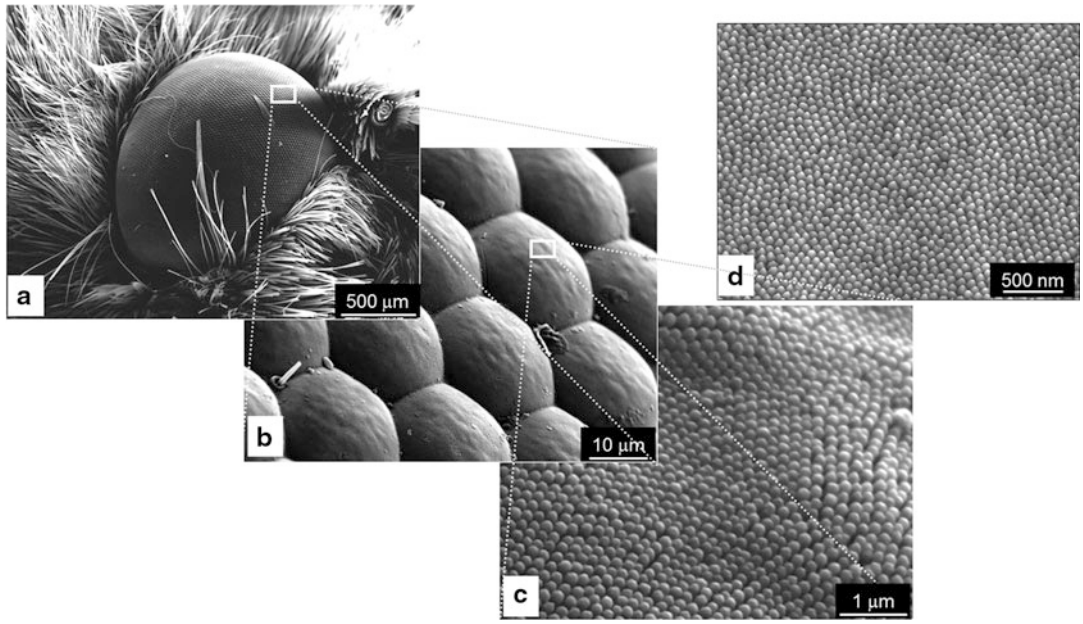
maintenance (no hot filaments exchange after their breaking). Sources are available for different beam sizes in the range of about 5 mm to 200 mm FWHM of the near-Gaussian beam shape with reasonable working distances by means of different extraction grid designs. Additional diaphragms mounted in front of the source are used to reduce beam sizes down to ~0.5 mm FWHM. Hot filament or so-called plasma bridge neutralizer mounted outside of the beam area ejects electrons and compensates the positive charge of the ion beam. This is necessary for a stable processing of insulating materials.

Ion Beam Erosion Self-Assembled Nanostructures and Smoothing

Stringently deterministic IBF finishing technologies with macroscopic beam tool sizes as described above are now well established in production for shape correction and figuring of high-performance optics. In contrast, ion beam-induced smoothing of spatially micrometer and nanometer features is strongly coupled to atomistic processes that are characteristic for the much smaller spatial length scales and are less deterministic. Low-energy ion beam techniques (ion energy <2 keV) have been developed to improve the microscopic surface roughness of solid surfaces on a nanometer to some ten micrometer spatial scale to achieve ultrasmooth surfaces with rms roughness values <0.2 nm. Two processing schemes *ion beam direct smoothing* and *smoothing with planarization or sacrificial layers* are demonstrated [17]. In ion beam direct smoothing (IBS), favorable relaxation mechanisms in the development of surface topography during the ion beam erosion are exploited. For the second method, the smoothing effect results from



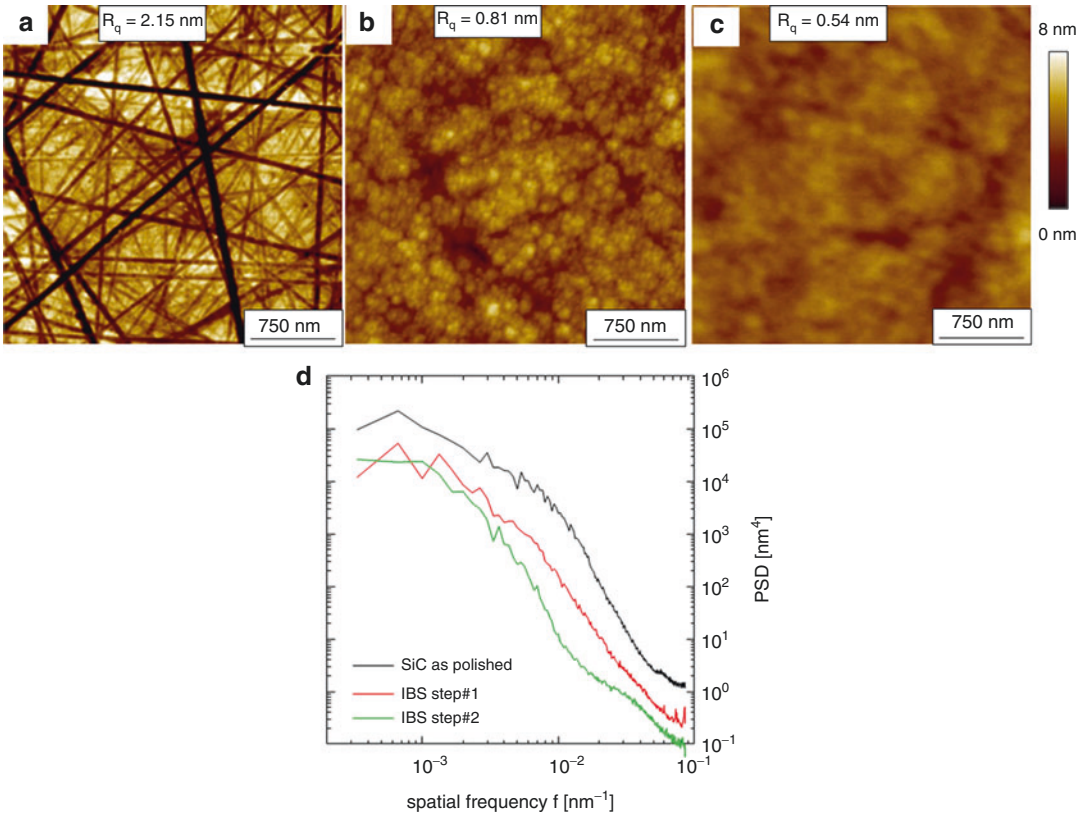
Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 6 State-of-the-art ion beam plants for IBF and partly for IBS (5-axis motion system necessary, as in plant (**a**)); (**a**) plant is for high-throughput production of workpieces up to 100 mm in diameter and (**b**) IBF plant for large mirrors up to 1.5 m in diameter, up to 520 mm thickness including mechanical frame of the assembly of large mirrors, and up to 1000 kg weight. On the *left* of the photograph, the mechanical interface including slide system for mounting the mirrors is shown (Courtesy NTG GmbH, Gelnhausen, Germany; www.ntg.de)



the removal of a planarizing layer deposited on the substrate (IBP – ion beam planarization). Both smoothing techniques were investigated for a wide range of various materials. In Fig. 7 ion beam smoothing working principles are shown schematically.

Generally, the surface topography evolution on the nanometer and micrometer spatial scale during low-energy ion beam sputtering is rather complex. A multitude of topographies can result from the surface erosion due to different roughening and smoothing mechanisms. Besides the actual removal of material, the surface erosion process often gives rise to a pronounced topography evolution, generally accomplished by a kinetic roughening of the surface and the generation of so-called self-assembling nanostructures [17]. Figure 8 shows 3D structures in the range of 100 nm spatial dimensions: a moth eye as a result of the evolution of life (Fig. 8a–c) and fabricated by self-assembling effects by Ar ion beam erosion of an InP semiconductor wafer surface (Fig. 8d) [19].

One goal of ongoing intensive research and development is to get insight in the physics of the surface atomic processes responsible for such structures. The second one follows the vision to exploit the ion-induced self-assembling surface effects to develop techniques to generate nanostructured surfaces efficiently without costly mask techniques. Theoretical and experimental research during the last several years brought much progress for the understanding of the ion-induced nanoscale surface topography evolution by self-assembling effects. Several atomic-level effects have been identified. They are all connected with stimulated motion of surface atoms along the surface. Surfaces can be smoothed via thermally driven surface diffusion at sufficient temperatures under ion bombardment-related defect production. Ion-induced directed or random fluxes of recoil atoms moving parallel to the surface are able to compensate the curvature-dependent sputtering or can contribute to ballistic surface diffusion process. For amorphous materials or ion beam amorphized surface regions, defect-mediated ion-enhanced viscous flow may also occur. The individual conditions of material, ion species, energy, angle of incidence, and surface temperature or the participation of third-party



Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 7 Ion beam-assisted methods for surface smoothing. The planarization technique was described first by L. F. Johnson and K. A. Ingersoll [18]

particles (intentionally or unintentionally added to the ion beam processing), to mention the most important ones, determines the resulting surface structure.

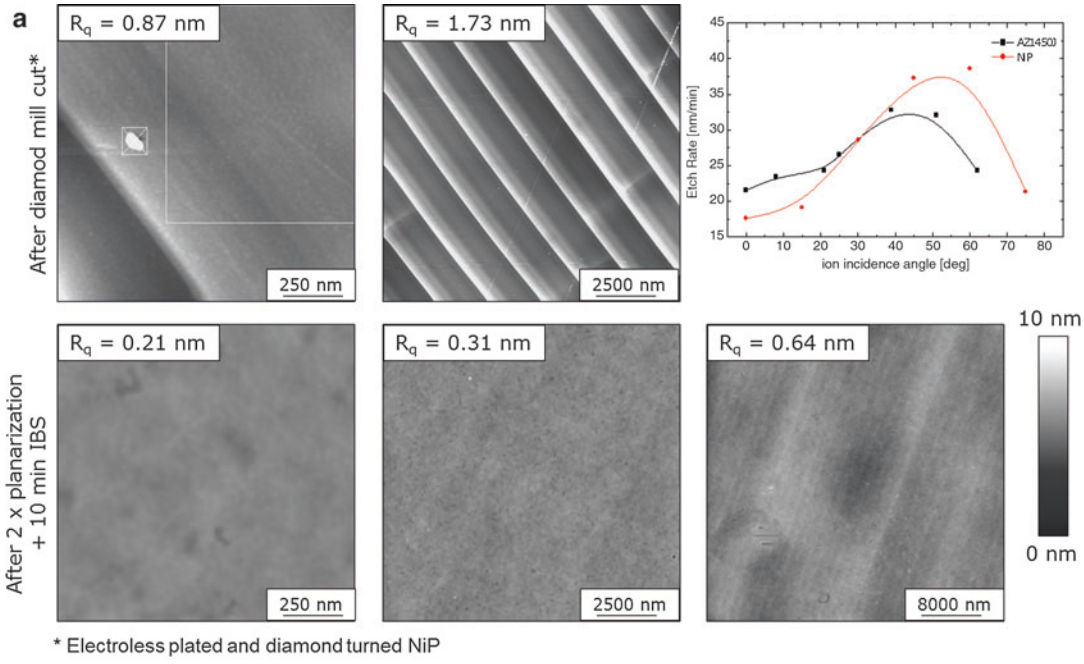
However, dependent on the same physical effects, also favorable ion beam erosion conditions can be realized where surface smoothing dominates the topography evolution on the

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 9 Example for ion beam direct smoothing of a polished SiC surface (Ar^+, E_{ion} = 800 eV, j_{ion} = 250 μAcm^{-2}, simultaneous sample rotation). AFM images show (**a**) the initial as polished surface, (**b**) after IBS step1 (ion incidence angle 70°) and (**c**) after IBS step2 (ion incidence angle 0°). The rms roughness was reduced from R_q = 2.15 nm to R_q = 0.54 nm. (**d**) shows the calculated power spectral density curves from the three AFM data [20]

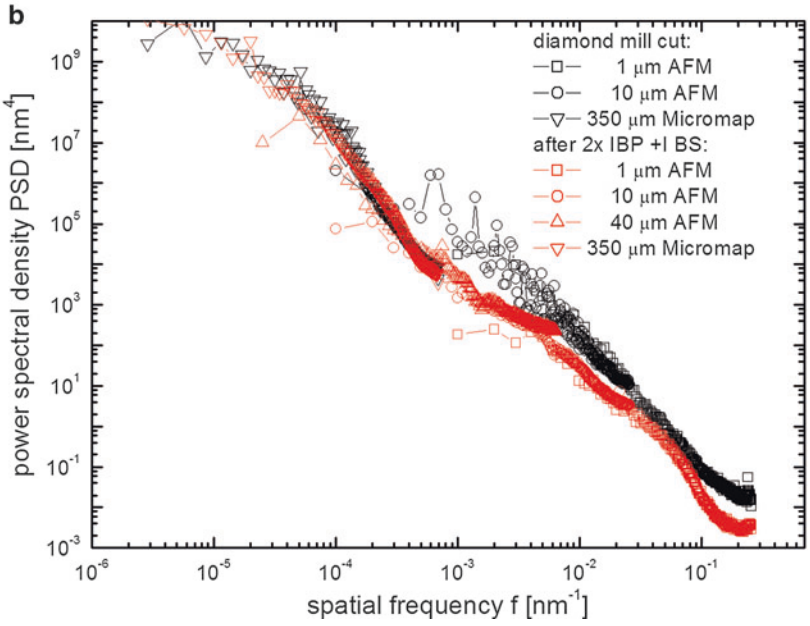
microscopic spatial scale. This is illustrated in Fig. 9 for ion beam direct smoothing of hard-to-polish polycrystalline SiC. Starting with a mechanically polished surface (Rq = 2.15 nm, Fig. 9a) after Ar^+ IBS (E_{ion} = 800 eV, j_{ion} = 250 μA cm^{-2}) at 70° incidence under simultaneous sample rotation (Fig. 9b), 0.7 nm rms was achieved, and after a second IBS step at 0°, 0.54 nm rms (Fig. 9c). The PSD functions in Fig. 9d show for the first IBS step a uniform reduction of the roughness over the whole spatial frequency spectrum, whereas for spatial frequencies <0.002 nm^{-1}, the smoothing drops down. This indicates a long spatial wavelength limit for efficient ion beam direct smoothing owing to the limited spatial range of the related atomic surface transport processes mentioned above, which are responsible also for this kind of smoothing.

Therefore, ion beam direct smoothing is less efficient for spatially larger roughness features. Alternatively, a modified planarization technique can be used for the reduction of surface roughness at lower spatial frequencies. In ion beam planarization (IBP), the rough surface is spin or spray coated by a suited sacrificial layer with a low viscosity (e.g., photoresist) to level out the surface roughness. Subsequently the sacrificial layer is removed by ion beam etching at the planarization angle. This angle is defined as the local ion beam incidence angle where the removal rates (sputter yields) of the sacrificial layer and the underlying substrate are nearly identical.

Thus, the smooth surface of the sacrificial layer is transferred into the substrate. Using this technique, roughness components with spatial wavelength up to some tens of microns can be reduced. In Fig. 10 NiP surface smoothing by IBP combined with IBS steps after single-point diamond turning is shown. The efficient removal of the diamond tool marks is evident from the AFM pictures in Fig. 10a for different resolutions. Also shown in the right upper corner are the etch rates dependent on the ion incidence angle for NiP and resist type AZ1450J used for the planarizing film, indicating ~30° as the planarization angle in this case. The resist was spray coated with a thickness of ~80 nm. The PSD in Fig. 10b comprises measurements by AFM and optical profilometry and clarifies the range of spatial wavelength where smoothing operates is up to some 10 μm.

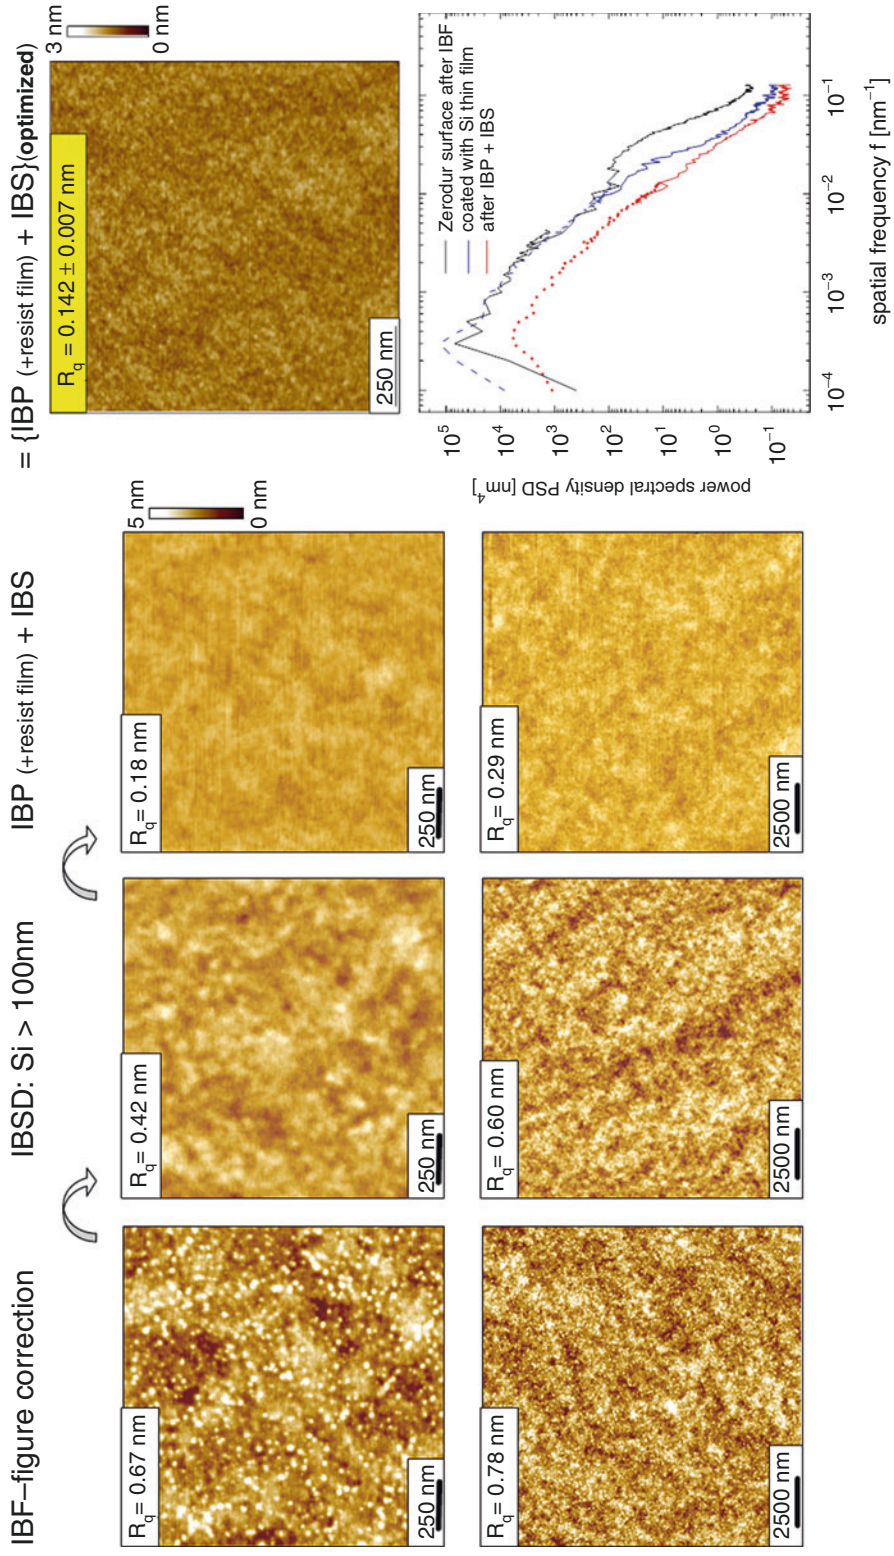


In Fig. 11 a sequence of ion beam smoothing steps and thin film Si deposition to reduce the ion beam etched-related roughness enhancement resulting from IBF for polishing error correction of Zerodur® is shown. First, an IBF shape correction was performed. Zerodur® as a glassy ceramics in contrast to glass, fused silica, or Si has a nonuniform chemical and structural composition leading to different ion sputter removal of the material constituents. Therefore, during lBF surface roughness is enhanced above the EUVL spec of the HSFR (<0.15 nm rms) (left in Fig. 11). In a second step, the substrate is coated with a thin a-Si layer by IBSD. The surface roughness of the Si film surface is reduced (middle in Fig. 11). Next an IBP step and finally an IBS step were applied (right in Fig. 11). After optimization loops were performed, an HSFR of <0.15 nm rms could be achieved. One has to exercise care in doing such technical trick not to remove the Si layer completely at any point. This would cause again roughness enhancement on Zerodur. The procedure all at all does not destroy the initially achieved shape accuracy by IBF due to the minimum film thicknesses applied and hence the minimum and deterministic material removal for the smoothing. The error values given correspond to the standard deviations obtained from at least ten measurements on a two-inch substrate. The PSD graph shows the effective surface smoothing for spatial frequencies that are $>f = 1 \times 10^{-4}\,nm^{-1}$ corresponding to a long wavelength limit in the range of some 10 μm.



Three examples of ion beam-related surface smoothing of very different materials und surface conditions shown here demonstrate conclusively the high application potential for fabrication of ultrasmooth surfaces. Meanwhile, the effects were demonstrated for a wide variety of materials and different applications. At present developments are going on to qualify ion beam equipment and processing schemes for making ion beam smoothing ready for an efficient production technology. It will definitely supplement existing technologies for such cases where they come to technical or performance limits.

Finally, a further machining method with high smoothing potential, the gas cluster ion beam technique [22], exists. Here clusters of up to some 1000 atoms are formed when high-pressure gas flows through a tight nozzle. Then they are ionized and accelerated up to some 10 keV. The gas cluster ions break when they hit a surface, and every individual atom gets only a small part of the kinetic energy in the range of some 10 eV. Their preferred motion is parallel to the surface; thus, they transfer momentum to top most surface atoms and smooth, and additionally they generate only minimum or no subsurface damage.



RIBE Pattern Transfer

In modern microsystems and micro-optics technologies, there is a growing need of micro- and nano-patterned surfaces. Besides binary structures, 3D-shaped complex patterns for a variety of materials are required, e.g., refractive micro lens arrays or diffractive blazed Fresnel lenses. Advanced 3D mask techniques like dose dependent e-beam lithography, laser direct writing lithography, grey tone mask, and holographic interference lithography have been developed. The majority of substrates are plane wafers but also thick curved quartz glass substrates, for example, for molds to fabricate polymer imaging blazed diffraction gratings by embossing must be processed. The standard procedure for micro- and

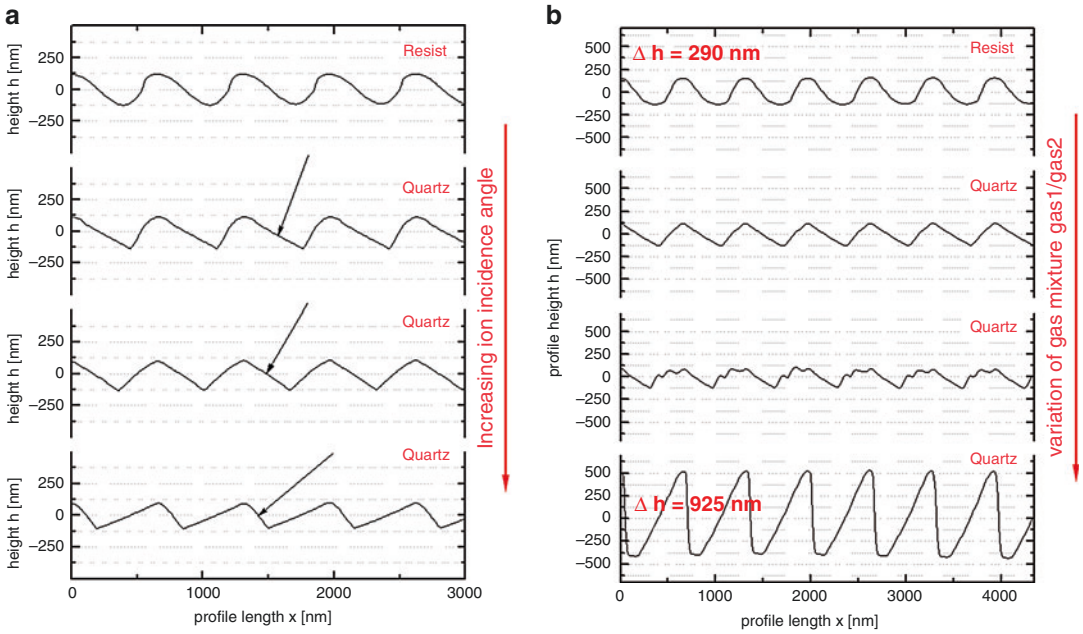
nano-patterning is the transfer of masks by reactive plasma or ion-based etching. In 3D case the mask is sacrificial and the transfer can be either proportional or altering the shape. Reactive ion etching (RIE) as inductively coupled plasma etching (ICPE) or capacitively coupled plasma (CCP) is the mainly used process due to its high performance for etch rates and material selectivities [23, 24]. Ion beam techniques IBE, RIBE, and CAIBE offer the advantage of separating the workpiece from the plasma. This allows additional parameters with respect to RIE. Thus, the transfer etching behavior can be adjusted beneficially: angle of particle incidence, independent control of process parameters, sample manipulation during processing (rotation), and co-deposition of other materials featuring, e.g., to etch profiles of predetermined sidewall angles. Figure 12a shows the schemes for IBE, RIBE, and CAIBE, Fig. 12b shows a RIBE-etched blazed grating on a thick quartz substrate, and Fig. 12c shows AFM measurements of profiles of the resist mask and the blazed grating RIBE transferred into fused silica. Figure 13 shows examples of tailoring of profile structure during RIBE by variation of ion beam incidence angle and process gas mixture.

Plasma Jet Technologies

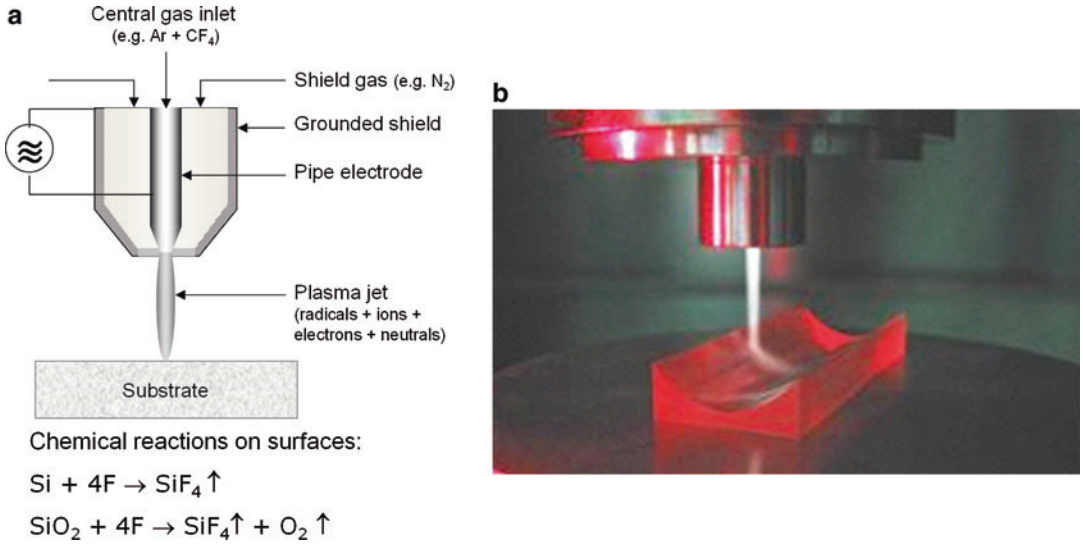
PJM: Deep Aspherization and Polishing Error Correction

Early developments of plasma-assisted chemical etching (PACE) originate from Bollinger and Zarowin [25]. A variety of atmospheric plasma jet (APJ) tools with different removal rates and tool sizes have been developed covering different applications by material removal but also including thin film deposition. In advanced high-tech optics, there is a growing demand for precision aspherical and free-form optical elements with large deformations from standard flat, cylindrical, or spherical shapes. Plasma Jet machining (PJM) is a noncontact, locally dry-etching method that can be beneficially used in the fabrication of such elements. The working principle is pure chemical reaction between reactive species originated within the plasma and the surface atoms. In the case of silicon or silicon compounds, fluorine radicals or atoms are used to build together with Si atoms the volatile molecule SiF_4. This escapes and the etching proceeds. Figure 14 shows the plasma jet source operating scheme and the simplified chemical surface reaction of F with Si and fused silica together with an atmospheric plasma jet source in operation machining a concave fused silica cylinder lens.

Preferred precursors admixed to the plasma inert source feed gas (e.g., He or Ar) are the standard process gases usually used in silicon wafer technology like CF_4, SF_6, and the like. For fused silica and ULE®, material removal rates of up to 50 mm^3/min are easily achieved. Besides such high-rate PJM with removal rate performances comparable to grinding, very low removal rates can be achieved as in the case of IBF by reducing RF power, reactive gas concentration, or gas flow. Also wide changes in the size of the removal function are possible by changing the diameter of the nozzle of the plasma jet source. Thus, large parts can be as efficiently processed to achieve deep aspheres as the correction of spatial millimeter size error features with nanometer deviation can be performed on up to large surfaces. The processing algorithm is mostly the same dwell time principle as described above for IBF. Primary advantages of the plasma-assisted chemical methods are the following: (i) there are nearly no limitations arising from local curvatures of the parts to be machined, and most importantly (ii) no subsurface damages of the material are generated during the pure chemical machining process. Therefore, plasma-assisted chemical etching leads to machined surfaces with unchanged material characteristics equal to the volume. This is in beneficial contrast to the subsurface damaged layers originating from mechanical or chemomechanical machining (e.g., grinding, lapping, polishing, and others) where the processing modifies up to some 10 μm thick surface layers by mechanical forces and/or the incorporation of contaminants from polishing slurry. Even the bombardment of low-energy heavy ions during IBF leads to comparable low material modification within some 10 nm from the surface. PJM can also completely remove all such



Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 12 Schemes of IBE, RIBE, and CAIBE with variation of ion beam incidence angle and workpiece rotation (**a**), RIBE-etched blazed grating on a thick quartz substrate (**b**), and measured profiles of the resist mask and the blazed grating RIBE transferred into fused silica (**c**), (Fig. 12b) (Courtesy Carl Zeiss Jena GmbH)



damage layers. This reduces the polishing effort afterwards largely. Shape conserving post polishing after PJM is usually necessary for ultra-precision surfaces in cases with several micrometer plasma jet removals because the spontaneous chemical etching, which starts preferred at the statistical distributed microscopic surface defects with their weakened atomic binding forces, results in a slight roughness enhancement.

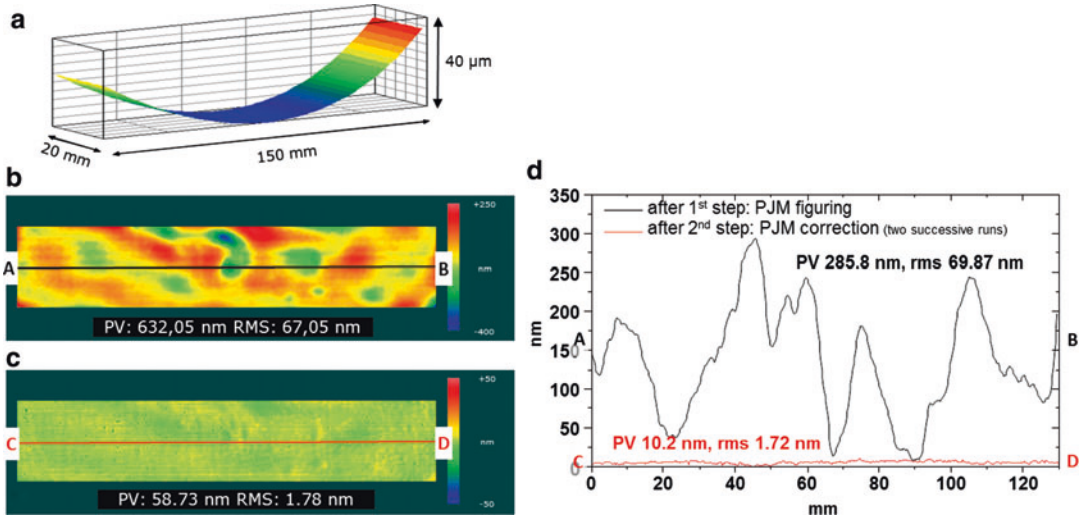
Mid-spatial surface error features are typical for modern CNC coarse machining (grinding and lapping), and if existing on a surface, they are hard to remove. They originate mainly from unavoidable residual noise or vibrations from the machine mechanics transferred to the tool that is in more or less hard contact with the workpiece surface. Plasma-assisted high-rate removal technology is contactless as is ion beam, and therefore, it can a priori avoid or at least minimize such hard to remove features.

On the other hand, there are some critical points for at least high-rate plasma jet machining that

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 13 Resist grating pattern transfer into quartz by CHF_3/O_2/Ar-RIBE: tunable blaze, anti-blaze angle, and length ratio of a sawtooth structure by variation of the ion beam incidence angle but with constant profile depth; (**a**) only Ar-IBE (selectivity quartz/resist ~1) and (**b**) CHF_3/O_2-RIBE with variation of the flow rate ratio of process gases CHF_3/O_2 which allows to alter the profile depth in situ (selectivity ~3)

Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 14 (**a**) Scheme of an atmospheric plasma jet source with a coaxial electrode configuration typical for the use of 2.45 GHz microwave or standard RF frequencies plasma excitation, indicated are simplified chemical reactions for Si and SiO_2 etching by plasma generated F radicals with surface atoms; (**b**) plasma jet source machining of a fused silica concave cylinder lens, in this case an additional shielding aperture in front of the plasma source prevents the contact of the microwave excited primary plasma with the surface in favor of a radical beam [26]

should be considered and that indeed slows down the progress to implement PJM into production: (i) the etching process is very sensitive to surface structural defects and contaminant chemical impurities, which means that perfect cleaning of surfaces to remove any traces of grease or other contaminating materials that will inhibit chemical reaction by the plasma-generated reactive species is crucial for plasma-assisted chemical etching; (ii) in contrast to semiconductor industry, hazardous chemicals like F radicals that are produced in the plasma jet are not common in standard optics fabrication; and (iii) plasma etching rate is proportional to two independent parameters: (a) linear to the flow density of the reactive species on the surface and (b) exponential to the surface temperature in the reaction zone, which causes principally a nonlinear etching rate. The chemical reaction is characterized by an activation energy that causes an exponential Arrhenius behavior of the etching rate on temperature. The plasma jet delivers both the flow of radicals and the thermal energy for the reaction. Therefore, in the usual case of dwell time controlled figuring, the removal is nonlinear with respect to the dwell time in contrast to IBF. Especially for materials with rather low thermal conductivity as fused silica (quartz glass), the local surface temperature in the contact point of the jet and the extension of the reaction zone around this point are strongly dependent on the scan velocity of the jet. Additionally, superimposed to this is the heating up of the whole workpiece with proceeding machining time. For a reliable technology, measures must be taken to linearize the removal rate with dwell time. Recently a first attempt was made to compensate for the nonlinearity of the fast local heating effects from the dwell time variation and of the slowly changing temperature distribution within the whole workpiece. The procedure calculates the dynamical heat flow from the jet throughout the workpiece including the geometrical and thermal data of the sample and the relevant data from the jet and its dwell time-related motion across the surface in a FEM model [27]. In the simple case of a flat quartz cylinder workpiece used to demonstrate the feasibility of the procedure and to check it experimentally, an accuracy improvement from 10 % residual error from the design shape without nonlinearity compensation to 1 % with the compensation was achieved.



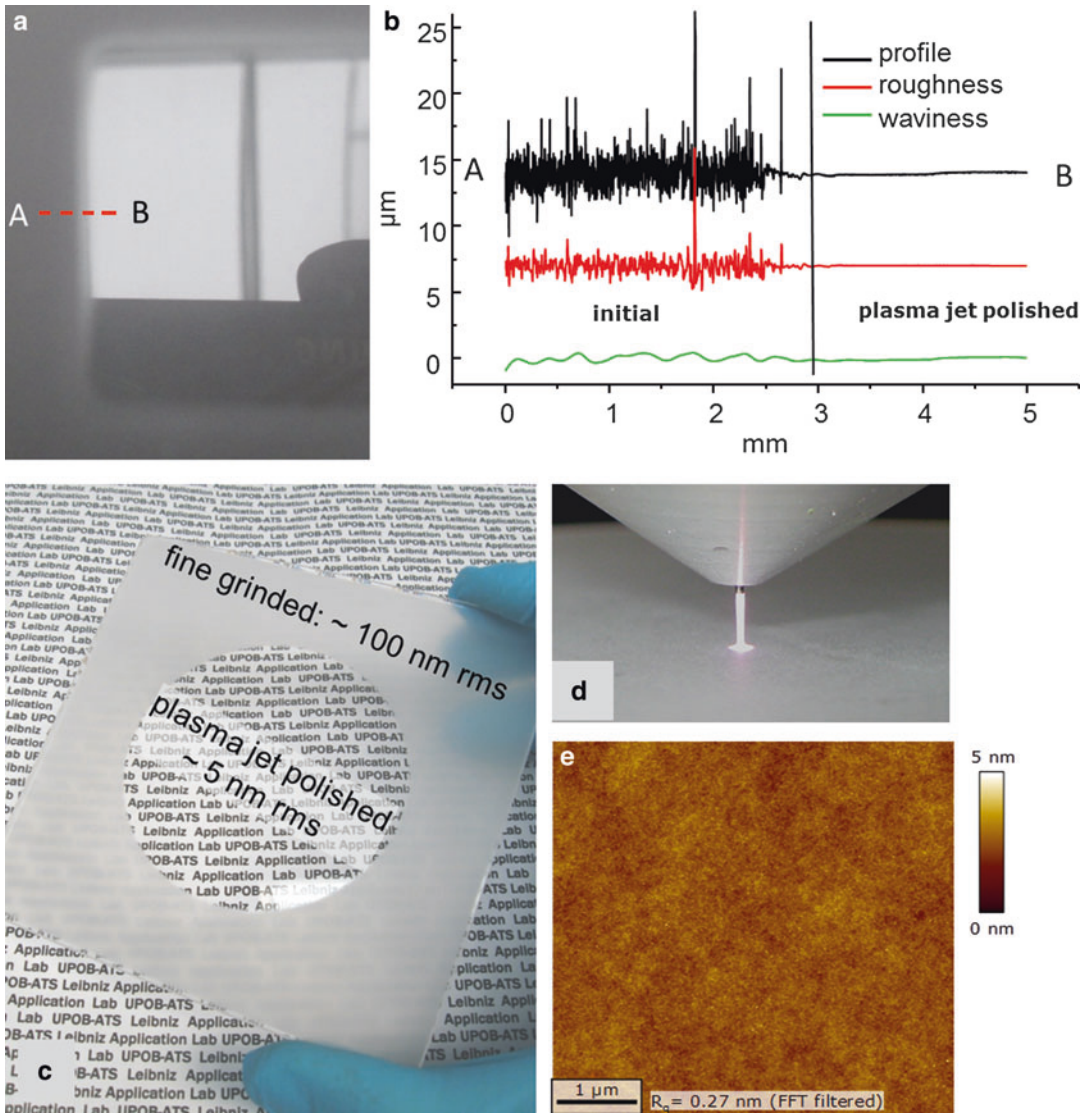
In addition to deep aspherization, also deterministic surface machining up to sub-mm spatial wavelength range with nanometer depth accuracy can be performed by PJM [25]. In such cases main PJM source processing parameters, namely, electrical power and reactive precursor gas flow, will be downsized to reduce the etching rate by several orders of magnitude. The size of the removal function can be reduced up to about 0.5 mm FWHM by using appropriate diameter pipe electrodes. Figure 15 shows results of the manufacturing of a fused silica cylindrical off-axis asphere using a two-step PJM, (i) a high-rate PJM for aspherization and (ii) a low-rate high spatial resolution figure error correction. For the low etching rate regime of PJM, nonlinear effects as described do not occur.

PJP: Plasma Jet Polishing Demonstration

A third atmospheric plasma jet (APJ) processing technique in optical surface fabrication is smoothing of, e.g., ground surfaces with nearly no material removal and hence with minimum changing of the surface figure. Furthermore, due to the possible small size of the plasma jet tool, all APJ techniques can be performed very locally. This gives the opportunity either to polish small subareas or small-sized and strongly curved parts. Now, the idea for the future is to establish a cost-efficient two-step process chain consisting of precision grinding and plasma jet polishing for the manufacturing of aspheres and free forms. If higher shape accuracy is necessary, the plasma jet-based surface error correction should be included just by switching the plasma jet process from smoothing to etching. Figure 16 shows examples of plasma jet polishing of fine grounded fused silica surfaces [28].

Outlook

Ion beam etching-based surface finishing is a versatile technology with a high degree of



Ultraprecision Surfaces and Structures with Nanometer Accuracy by Ion Beam and Plasma Jet Technologies, Fig. 15 PJM – nanometer figure error correction of a fused silica plano-elliptical mirror blank for synchrotron radiation optics, (**a**) 2D surface design profile of the optic, (**b**) and (**c**) stitching interferometer topology measurements, (**b**) initial surface after high-rate PJM figuring and post polishing of clear aperture of 130 × 25 mm^2, (**b**) after two plasma jet correction cycles with a 1 mm FWHM PJ-tool, (**d**) center profile lines of the measurement of (**b**) and (**c**) [26]

predictability due to the high stability of state-of-the-art ion sources and the acquired knowledge of the physics of beam surface interaction. The independent control of the ion energy and the ion current density over wide ranges and the possible additional use of chemical reactive species in combination with physical sputter removal allow solving tasks in a wide variety of applications of ultra-precision surface figure and patterns.

The developed techniques, the productive machines, and the finishing results show that ion beam etching technologies are advanced and powerful tools for present and future surface processing and finishing in ultra-precision technology. Ongoing developments on ion beam finishing technology will concentrate on further improvement of accuracy, reliability, new applications, and materials. Presently higher spatial resolution figuring is a challenging target just as the introduction of the ion beam smoothing techniques in production chains. New supplementary approaches will possibly further improve the performance of the technologies. One example is pulse width modulation ion sources combined with standard continuous beam to extend the dynamic range of the dwell times by a controlled reduction of the average ion beam power. Thus, two orders of magnitude and more dwell time reduction should be possible with an apparent benefit for the removal of very small amounts of material as in cases of small beam sizes. Further, locally controlled beam switching on and off in situ during dwell time processing allows figuring of separate areas of a surface, leaving other parts unaffected. This allows to generate different shapes on one surface, enabling multifunctional ultra-precision surfaces. Another new approach is ion beam figuring by dwell time-controlled deposition of materials using ion beam sputter deposition [29] instead of removal. Targets of ongoing development of pattern transfer are experimental data-backed process modeling for future adaptive RIBE processing to enhance versatility and reliability on the one hand and sub-aperture RIBE by scanning large surfaces like IBF technique on the other.

During the last years new research fields with high technological potential for precision surface processing emerged in ion beam and in plasma jet techniques. Related keywords are ion

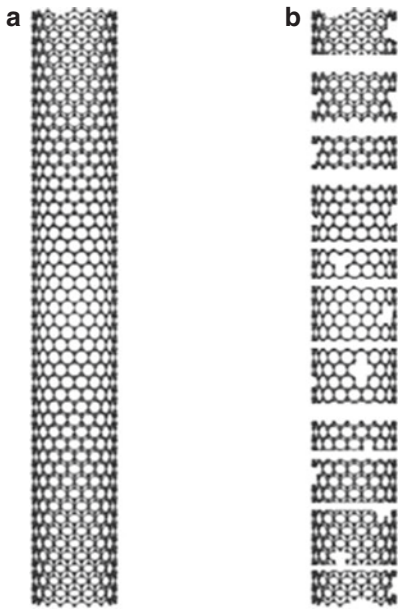
US-tubes

Definition

Ultrashort carbon nanotubes (US-tubes) are 20–100 nm segments of single-walled carbon nanotubes (SWNTs).

Overview



In recent years, single-walled carbon nanotubes (SWNTs) have been extensively studied for their use in biomedical applications. Owing to their peculiar physical and chemical properties, SWNTs have become a widely used platform for the design of medical therapeutic and diagnostic agents [1, 2]. Nevertheless, the biocompatibility and biodistribution of SWNTs still remain uncertain and are under current investigation. The ideal length of SWNTs for biomedical applications has yet to be determined, but it has been suggested that discrete, individualized SWNTs of shorter (<300 nm) lengths are more ideal for in vivo use [3]. Therefore, ultrashort carbon nanotubes (US-tubes), which are 20–100 nm segments of SWNTs, may be best suited for biomedical applications (Fig. 1).

Methodology

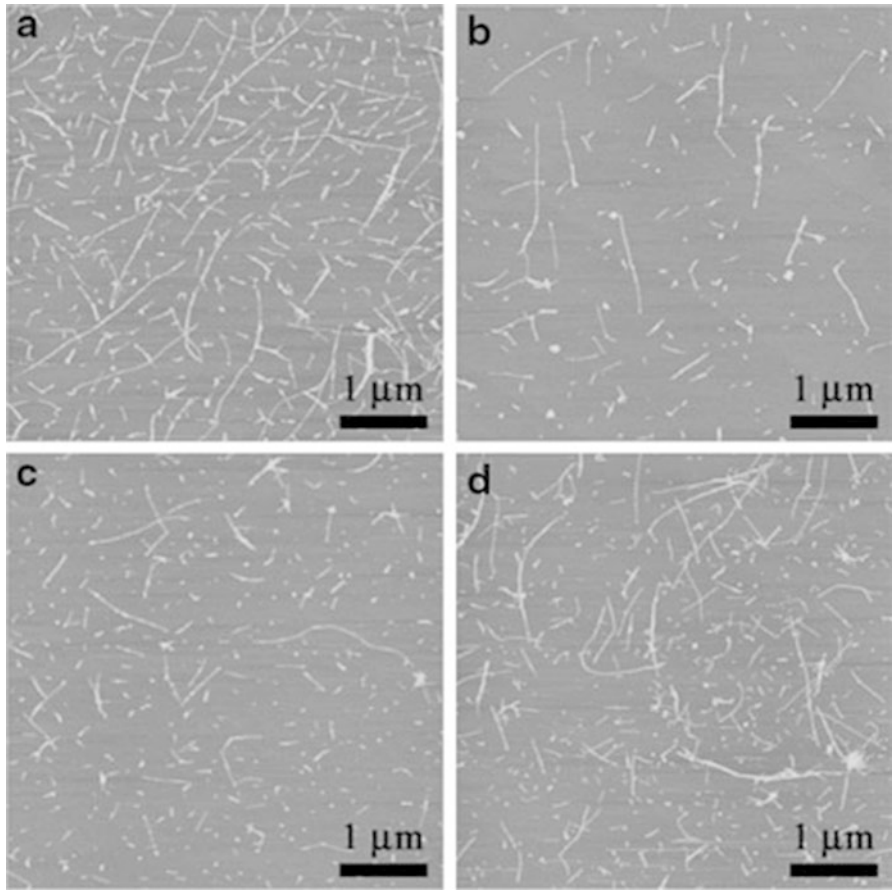
Synthesis

Chemical Cutting

Generally, the chemical cutting process of SWNTs into US-tubes can be viewed as a two-step procedure: (1) the modification of the SWNT sidewalls with functional groups or defect sites, and (2) the removal of or the cutting at these sidewall modifications. While the predominant mechanism of chemical SWNT cutting is debatable, there are two proposed methods under consideration: (1) the "fuse burning" mechanism, with carbon etching occurring at the bond-strained tube ends, and (2) defect site propagation, with cutting occurring at the random defect sites on the SWNT walls. Both oxidizing and nonoxidizing methods to chemically cut SWNTs have been explored.

Ultrashort Carbon Nanotubes, Fig. 1 Illustration of (**a**) a single-walled carbon nanotube and (**b**) a collection of ultrashort carbon nanotubes (with sidewall defects) derived from a single-walled carbon nanotube

Various oxidative processes using different strong oxidizing agents (HNO_3, H_2SO_4, and H_2O_2) have been proposed for the cutting of SWNTs. However, the efficiency and length distributions of these synthetic methods vary with the type and concentration of the oxidizing agents used, the reaction temperature and time, the method of dispersion during the reaction (refluxing or sonication), and the length and diameter of the SWNTs being cut. Although more severe reaction conditions result in more reaction exposure of SWNTs and, thus, shorter lengths of resulting US-tubes, less severe reaction conditions are preferred in order to minimize amorphous carbon production.



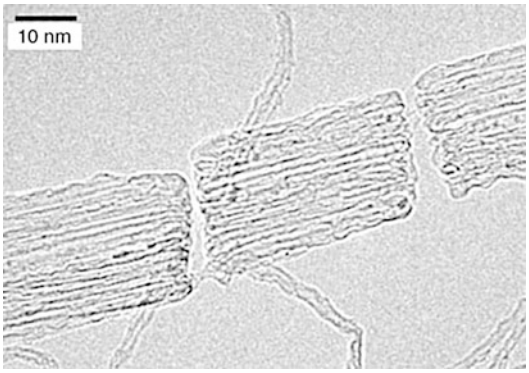
For instance, it has been shown that 4:1 (vol/vol 96 % H_2SO_4/30 % H_2O_2) piranha solutions are able to attack existing damage sites on the nanotube sidewalls to chemically shorten SWNTs [4]. While hot (70 °C) piranha solutions can induce more damage sites, room-temperature (22 °C) solutions can react with existing sidewall defects but are incapable of initiating further damage sites, resulting in minimal carbon loss and slow etch rates (Fig. 2). On the other hand, high-temperature conditions produce increasingly shorter US-tubes with increasing reaction time, with approximately half of the starting material destroyed due to chemical etching. Therefore, room-temperature piranha solutions offer the ability to exploit active damage sites in the sidewalls of the nanotube in a controlled manner without the counterproductive destruction of the nanotubes.

The aggressive oxidation of SWNTs with oleum (100 % H_2SO_4 with 20 % SO_3) and nitric acid can simultaneously shorten and carboxylate the SWNTs, rendering water-soluble US-tubes less than 60 nm in length [5]. Purified SWNTs are first dispersed in oleum to disentangle individual SWNTs from their rope-like bundles. Next, the SWNT-oleum dispersion is extensively oxidized with strong HNO_3 at elevated temperatures to cut the SWNTs into US-tubes. The oxidation of the SWNTs also forms carboxylic acid groups at the sidewall defects of the SWNTs, making US-tubes that are up to 2 wt% soluble in polar organic solvents, acids, and water.

One nonoxidative process to synthesize US-tubes involves the chemical shortening of SWNTs to lengths of less than 50 nm by a fluorination/pyrolysis treatment [6]. Briefly, purified SWNTs are exposed to fluorine gas, during which fluorine atoms tend to arrange around the circumference of the nanotube to form band-like regions along the nanotube sidewalls. Upon pyrolysis of the fluorinated SWNTs at 1000 °C in an inert atmosphere, the chemically bound fluorine atoms are driven off in the form of CF_4 and COF_2. This leaves behind chemically cut US-tubes with partial sidewall defects along the nanotube axis.

Mechanical Cutting

There have been various documented methods to mechanically cut SWNTs into shorter segments, including ultrasonication, grinding, and ball milling. However, these techniques lack length control; such mechanical methods create extensive sidewall



Ultrashort Carbon Nanotubes, Fig. 2 Atomic force microscopy (AFM) images of (**a**) purified SWNTs and SWNTs after piranha treatment at 22 °C for (**b**) 1 h, (**c**) 3 h, and (**d**) 9 h (Reproduced with permission from Ref. [4])

damage and are not able to achieve sub-100 nm lengths. Therefore, more precise mechanical cutting techniques have been developed.

Microlithography can be used to cut SWNTs into US-tubes [7]. This technique involves a protective photoresist polymer layered on top of a SWNT-covered solid substrate in a patterned manner to protect portions of nanotubes from lithographic damage and modification. Reactive ion etching using an oxygen plasma is then used to remove the unprotected sections of the SWNTs. After etching, the newly formed nanotube ends remain, with dangling carboxylic acid and ether groups. The photoresist polymer can then be removed, leaving cut segments of SWNTs. Regardless of whether the SWNTs are previously aligned or properly dispersed prior to cutting, microlithography offers a straightforward method to shorten SWNTs with a narrow and selective length distribution.

Electron beam etching has also been used to cut SWNTs with nanometer precision [8]. Using electron energy beams exceeding 100 keV, which is made possible by currently available electron microscopes, partial and complete cuts into SWNTs can be made with great control without the need of covering portions of SWNTs with a protective layer. Similar methods have been developed using high voltage-bearing scanning tunneling microscope (STM) tips. Interestingly, upon cutting into a SWNT bundle, the newly formed tube ends immediately form hemispherical

Ultrashort Carbon Nanotubes, Fig. 3 Transmission electron microscopy (TEM) image of the complete cutting of a SWNT bundle into US-tubes using electron beam etching (Reproduced with permission from Ref. [8])

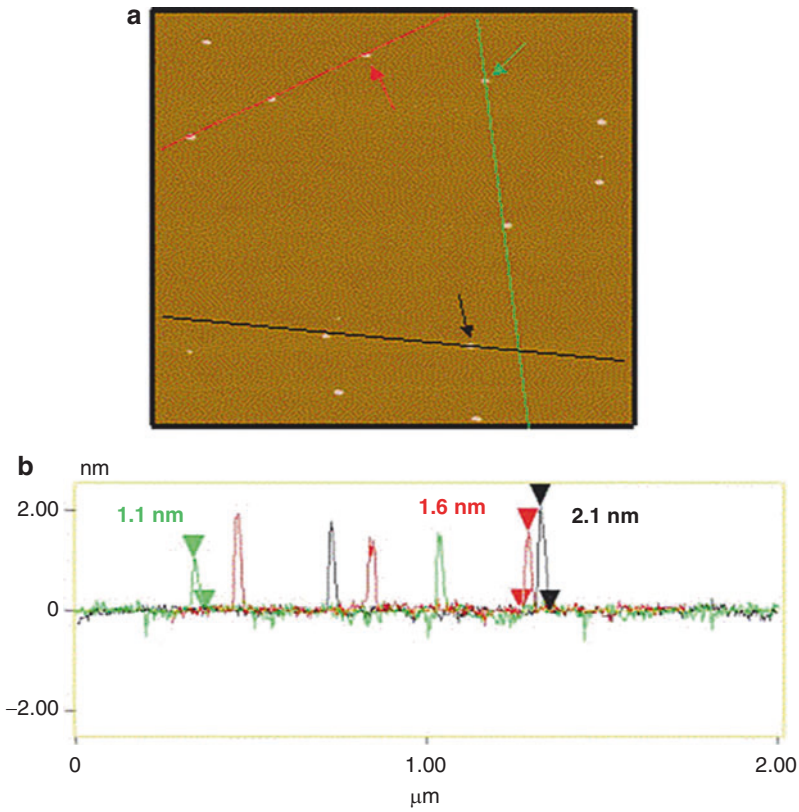
caps, enhancing the stability of the cut US-tubes (Fig. 3). Another peculiar observation is that forming a second cut within 10–50 nm from a preexisting cut proves more difficult to perform. This increase in stability is thought to be a result of the generation and annealing of vacancy-interstitial atom pairs.

More recently, an ultramicrotome has been used to cut frozen layers of magnetically aligned SWNT membranes, or Buckypapers [9]. Enough mechanical control was obtained to create open-ended US-tubes with minimal sidewall damage, typically seen after chemical oxidative methods. When the Buckypaper was cut into 50 nm segments, the mean length was about 87 nm, with about 60 % of the tubes ranging from 50 to 150 nm. However, the large pressure exerted by the diamond knife tip in its proximity can cause deformation and cracking of the nanotubes.

Individualization of US-tubes

Like their SWNT precursors, US-tubes have a large tendency to bundle together, which renders it difficult to form single-tube suspensions. Although it is possible for full-length SWNTs to disperse in solution with the aid of polymers and surfactants, US-tubes cannot disperse as readily in these same conditions [10]. Because of their high aspect ratios, SWNTs are relatively flexible and can "peel" more readily from each other upon introduction to surfactant wrapping. On the other hand, US-tubes have a much lower aspect ratio, therefore making them more rigid and more difficult for surfactant molecules to insert between individual US-tubes. Therefore, chemical means to debundle and individualize US-tubes have been explored to better disperse US-tubes.

Reduction of US-tubes



Chemical reduction can be used to individualize, or debundle, US-tubes [10]. Upon sonication with K° metal in THF, the negative charge imparted on the US-tubes electrostatically overcomes the bundling forces to yield individualized US-tubes (Fig. 4). It is thought that the individualization of US-tubes via chemical reduction increases US-tube dispersion in solution, thus allowing for more even chemical functionalization.

Functionalization of US-tubes

The chemical functionalization of US-tubes is thought to occur at carboxylic acid end groups of the sidewall defects. This allows for the attachment of various chemical groups that would render the US-tubes more soluble in different solvent systems. One functionalization method utilizes an in situ Bingel-Hirsch (CBr_4/DBU) cyclopropanation to functionalize US-tubes with the water-soluble malonic acid bis-(3-tert-butoxycarbonylaminopropyl)ester to yield four to five adducts per nm [10]. Another documented functionalization method involves cyclopropanation using diazoacetic ester in the presence of $Rh_6(CO)_{16}$ [11]. This allows for the US-tube to be readily reactive with primary amines, thus making possible the functionalization of US-tubes with a number of amino acid derivatives, such as water-soluble serine, with 3–19 groups per nm. Other biologically relevant moieties, such as antioxidants [12] and oligonucleotides [13], have been successfully attached onto US-tubes and are described below. Alkylation-based reduction can also be performed on US-tubes to improve nanotube dispersion in nonpolar environments [14].

Loading of US-Tubes

In addition to being able to chemically functionalize the sidewalls of US-tubes, the

Ultrashort Carbon Nanotubes, Fig. 4 AFM image of individualized US-tubes after chemical reduction (Reproduced with permission from Ref. [10])

hollow interior of the US-tubes can be loaded or filled with various ions and small molecules, such as Gd^{3+} ions [15], molecular I_2 [16], and ^{211}AtCl radionuclides [17]. This property is especially relevant for drug design, as the carbon structure of the US-tube serves as an encapsulating sheath to protect potentially toxic moieties from their surrounding environment. Although the loading mechanism is not completely clear, it is likely that ions and small molecules load into the US-tubes through the sidewall defects.

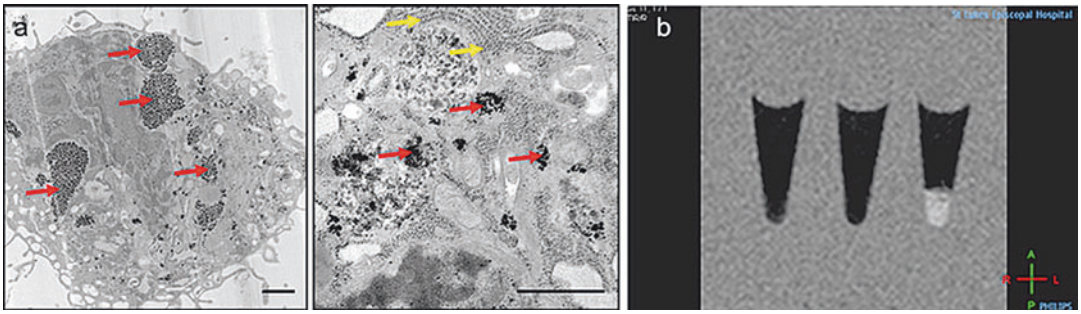
Phenomena

Toxicology

Before US-tubes are considered for biomedical applications, their toxicological profiles must be known. A recent study documented the toxicology as well as the acute and subchronic effects of high doses (50–1000 g/kg bodyweight) of Tween-suspended US-tubes in Swiss mice [3]. Oral administration of US-tubes did not result in death or any behavioral abnormalities for up to 14 days. Intraperitoneal administration allowed for the US-tubes to reach systemic circulation and various tissues through the lymphatic system. As opposed to unfunctionalized SWNTs, well-individualized US-tubes had the ability to pass through the reticuloendothelial system, excreting via the kidneys and bile ducts. High doses of US-tubes can induce strongly adherent granuloma formation on and inside organs due to large (>10 μm) nanotube aggregation into fiber-like structures. However, small (<2 μm) aggregates of US-tubes can readily enter various cell types without granuloma formation or any sign of toxicity. Neither death nor growth or behavioral abnormalities were observed for the animals used in the experiment.

Applications

Diagnostic Agent Design



Magnetic Resonance Imaging (MRI) Contrast Agents

Gadonanotubes, or US-tubes loaded with Gd^{3+} ions, have been shown to outperform currently used clinical T_1-weighted MRI contrast agents by approximately 40-fold [15]. Although the exact loading mechanism is unclear, it is likely that the Gd^{3+} ions enter the US-tubes through the sidewall defect sites, where they form nanoscale clusters. Because of the lipophilicity of the carbon sidewalls and their short lengths, Gadonanotubes can also readily translocate across cell membrane, allowing for Gadonanotubes to become an effective T_1-weighted cellular MRI contrast agent. It has already been shown that Gadonanotubes can be readily internalized and imaged inside a variety of cells, including mesenchymal stem cells (Fig. 5) [18].

In the absence of Gd^{3+} ions, the US-tubes alone can perform as a T_2-weighted MRI contrast agent [19]. The US-tubes are approximately three times more efficacious than Ferumoxtran®, a clinically used Fe_3O_4-based contrast agent. Although the US-tubes contain much less (<1 %) iron catalyst than unpurified SWNTs, the US-tubes exhibit a much higher *r2* performance, suggesting that the carbon nanotube material itself is contributing to the superparamagnetic nature and that the iron particles are not the only contributing factor to the superparamagnetic signature of the US-tubes. The shorter lengths and the sidewall defects of the Gadonanotubes may also contribute to the high performance. This also implies that Gadonanotubes can concurrently perform as both a T_1- and T_2-weighted MRI contrast agents. Gadonanotubes have previously been used as a T_2-weighted contrast agent in vivo, with r_2 relaxivities as high as 578 mM^{-1} s^{-1} at 7 T [20]. This suggests that the Gadonanotubes are useful T_1 positive agents at lower magnetic fields and T_2 negative agents at higher fields.

Computed Tomography (CT) Agents

Molecular I_2 has also been loaded into US-tubes for CT X-ray imaging contrast agent design [16]. After being functionalized with serinol amide groups via the Bingel-Hirsch reaction, the US-tubes were filled with gaseous I_2 at 100 °C, then washed with ethanol and reduced with NaH to remove excess I_2 from the nanotube exterior. A 10 wt% loading of I_2 was observed for the US-tubes. Using XPS and X-ray-induced Auger emission spectroscopy, it was confirmed that the molecular I_2 was sequestered within the US-tubes. Micro-CT images were obtained to show that the iodine-loaded US-tubes were more X-ray opaque. These serinol amide-functionalized, I_2-loaded US-tubes are the first water-soluble CT contrast agent derived from SWNT materials.

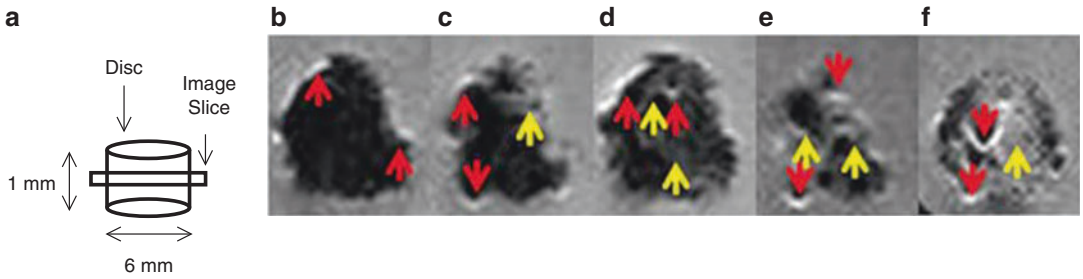
Therapeutic Agent Design

Radionuclide Containment and Delivery

Similar to the loading of Gd^{3+} ions and I_2 molecules into US-tubes, $^{211}At^-$ ions can be loaded and oxidized into $^{211}AtCl$ within US-tubes to contain and deliver the alpha-emitting radionuclides in the nanotube capsule [17]. Upon oxidizing the $^{211}At^-$ ions with chloramine-T or *N*-chlorosuccinimide, the AtCl molecules labeled the US-tubes to a great extent, with 91.3 % by aqueous loading. Subsequent PBS washing and serum exposure removed excess AtCl residing on the exterior or at the sidewall defects of the nanotubes, but the US-tubes exhibit reasonable stability toward physiological challenge.

Bone Tissue Scaffold Composites

US-tubes have also been used to dope the highly porous (poly(propylene fumarate)) polymer for bone tissue scaffold engineering [14]. These composites are injectable, thermally cross-linkable, and cytocompatible, making them ideal for trabecular bone tissue scaffolding biomaterials. While high (75–90 vol.%) porosity is preferred to allow for cell adhesion, proliferation, and vascularized tissue ingrowth, the mechanical properties of highly porous polymer scaffolds become compromised. Therefore, US-tubes have been added to PPF polymer scaffolds to improve the mechanical properties. It was found that dodecylated US-tubes functionalized with dodecyl groups better dispersed into PPF, improving their reinforcing effects. While there was no significant difference in porosity, pore size, and pore interconnectivity among US-tube-doped PPF and PPF alone, the compressive modulus, offset yield strength, and compressive strength of the dodecylated US-tube nanocomposites were higher than or similar to that of PPF alone. The US-tube/PPF nanocomposite has also been shown to be osteoconductive, allowing marrow stromal cells to attach and proliferate readily on the scaffold.



Gadonanotubes have also been incorporated into poly(lactic-co-glycolic acid) (PLGA) polymer scaffolds in order to explore the degradation process of the scaffold and the biodistribution of the Gadonanotubes upon their release from the polymer matrix in vivo [20]. T_2-weighted MR imaging of the Gadonanotube-PLGA nanocomposites and their degradation process were obtained in vitro, showing the strong influence of the Gadonanotubes on surrounding water proton relaxation (Fig. 6). In addition to providing mechanical reinforcement from the US-tube structure, the Gadonanotube-reinforced PLGA scaffolds may elucidate the mechanism of the biodegradation of the polymer and the release and biodistribution of the Gadonanotubes in vivo.

Free Radical Scavengers

US-tubes have also been functionalized as a scaffold for the phenolic antioxidant, butylated hydroxytoluene (BHT) using DCC/DMAP coupling [12]. As expected, the higher amount of BHT functionalization (either via covalent or noncovalent interactions) to the carboxylic acid groups on the oxidized US-tubes corresponded to higher overall antioxidant activity, with performances more than 200 times better than that of the radioprotective dendritic fullerene, DF-1. Strikingly, PEGylated US-tubes alone without any BHT functional groups are extremely effective antioxidants, performing nearly 40 times greater than DF-1 in oxygen scavenging ability. Even though the US-tubes have heavily compromised sidewalls from the oxidative cutting process, US-tubes are still able to sequester oxygen radicals due to the sp^2-hybridized carbon nanotube framework.

Oligonucleotide Delivery

US-tubes have also served as delivery vehicles for oligonucleotide (ODN) decoys, which are synthetic ODNs containing the DNA-binding sequence of a transcription factor [13]. Because US-tubes can inherently translocate into cells, US-tubes can efficiently facilitate the intracellular delivery of ODN decoys into target cells so that ODN decoys can better target transcription factors of interest for gene therapy. Specifically, US-tubes have successfully delivered a decoy ODN against nuclear factor-κB (NF-κB), which is a transcription factor that regulates genes important in immune and inflammatory responses. Using carbodiimide chemistry, the amino groups at the

5′ end of the double-stranded ODN was covalently coupled to the carboxylic acid groups of the oxidized US-tubes. To test the performance of the US-tubes as a delivery vehicle, NF-κB-dependent gene expression was significantly downregulated in monocyte-derived human macrophages incubated with ODN-functionalized US-tubes, as compared to macrophages incubated with US-tubes functionalized with nonspecific ODN decoys.

Future Directions

While there have been significant strides made in the development and application of US-tubes, many challenges still must be addressed. In order to produce more uniform US-tubes from SWNTs, better size control during the cutting procedure and size sorting after synthesis must be achieved. Additionally, improving the solubility and dispersion of US-tubes in biological media must be achieved to fully realize their potential in biomedical applications.

Taking advantage of the exterior functionalization and the interior loading capabilities of US-tubes, a nearly limitless number of possibilities abound for advanced US-tube-based therapeutic and diagnostic agent design. US-tubes can either be used as a nanocapsule, sequestering biologically relevant ions or molecules that may be inherently toxic if not sequestered, or as a nanovector, delivering various drug payloads or peptide sequences to target cells. Nevertheless, much work still needs to be completed to better characterize the acute effects, long-term toxicity, and biodistribution of US-tubes, as well as other types of carbon nanostructures, in living systems.

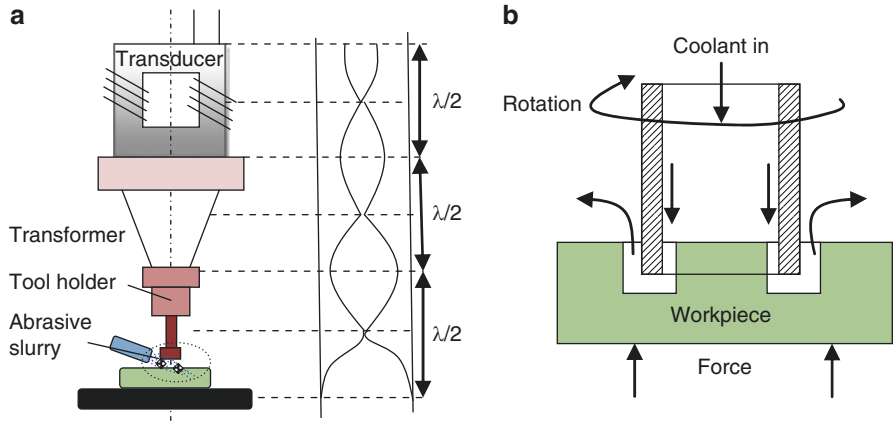
Non-conventional machining; USM; Vibration assisted machining

Definition

Ultrasonic machining involves imparting ultrasonic vibrations (of frequency ~20 kHz) to a tool to effect material removal. The process is more effective on materials that have hardness more than RC 40, but it is used on almost all including metallic and nonmetallic materials such as glasses, ceramics, and composites.

Process Variants



The process is configured into two main types (Fig. 1a–b) depending upon how the force is transferred from the vibrating tool to the work surface. If the transfer of vibration energy is achieved by introducing a liquid containing abrasive grits in the gap between the tool and work surface, the process is called "ultrasonic impact grinding" or simply "ultrasonic machining." On the other hand, if the abrasive grits are not present in the carrier liquid, then the tool is rotated besides being vibrated, and the process is called as "rotary ultrasonic machining" [1, 2].

Basic differences in these two processes are illustrated in Table 1.

Basic Equipment

Equipment for ultrasonic machining is available in various forms, like dedicated machines or as an attachment to other machines as well as table-top machines. Typical machine elements for performing both the ultrasonic machining (USM) and rotary ultrasonic machining (RUM) are identical. They include [1, 2]:

1. *Power Supply*: a power supply that provides electrical output at ultrasonic frequency
2. *Transducer*: a transducer that converts high-frequency electrical supply to tool displacement at ultrasonic frequency. The transducers work on magnetostrictive or piezoelectric principles. The magnetostrictive effect involves application of alternating current to a ferromagnetic coil, which induces vibrations at the applied frequency in the coil. The phenomenon allows transfer of vibrations over wider frequency band of (17–23 kHz). However, it also causes high electrical losses (e.g., eddy current loss) and has low energy conversion efficiency (~50 %). Most of the energy losses appear as heat; hence, these transducers require air or water cooling. Consequently, such systems are bulky. On the other hand, the piezoelectric transducers comprise of a stack of ceramic discs placed between a high-density material base and low-density material radiating face. The energy conversion efficiency can be in the range of (~90–96 %). Therefore, they do not require cooling.
3. *Horn*: the horn is referred with various names such as tool holder, sonotrode, stub, concentrator, or acoustic coupler. With appropriate design of horn, the vibration amplitude can be amplified by as high as 600 % over its initial value at the transducer surface of ~0.001–0.1 μm. The increase in the vibration amplitude is inversely proportional to the reduction in the area ratio between top and bottom faces of the horn. Usually, the horn is made from Monel, titanium 6–4, stainless steel, aluminum, or aluminum bronze.
4. *Tool*: the tool is shaped such that it is the inverse of the cavity to be made. The tool is attached to the horn either by brazing or soldering. This helps avoid possible fatigue failure or self-loosening of the threaded fasteners. The tool is designed such that the amplitude of vibrations is maximum at its free end. Mass and length of the tool are also important. While the bulky tools absorb ultrasonic vibrations, very long tools will flutter during the process. Therefore, tools with slenderness ratio of less than 20:1 are recommended. Often when the tools are of large cross-sectional area, the tool center faces slurry starvation. Therefore, the tools with larger perimeter for same cross-sectional area are preferred. The tools should be designed to have flutes to aid slurry flow away from the cut. Sometimes the tools are relieved

Ultrasonic Machining, Table 1 Comparison between the two variants of USM

Parameters	USM	RUM
Tool motions	Reciprocation	Reciprocation and rotation
Tool-work interaction	No contact	Contact
Tool materials	Tough and ductile metals, mild steel, stainless steel	Diamond tools
Tool shape	Mirror image of the desired cavity	Core drill type tool
Abrasives	Diamond, CBN, boron carbide, silicon carbide, aluminum oxide	Diamond particles impregnated in the tool
Carrier liquid functions	Carrying abrasive grits and cooling	No abrasive grits hence only cooling
Force transfer	Tool vibrations force abrasive grits to impinge on work surface	Vibrating diamond tool contacts work surface to cause removal
Removal mechanism	Indentation and chipping	Indentation and abrasion
Shapes generated	Mirrors tool shape	Holes and other axisymmetric shapes
Size of features generated	About 90 mm diameter and 64 mm deep	Maximum diameter 38–50 mm

behind the face. In the case of longer tools, availability of center holes for feeding abrasive slurry is of great advantage as it avoids sidewall friction. The tool materials should be tough and ductile and should have high wear and fatigue resistance. The tool materials usually include mild steel, stainless steel, brass, Monel, bearing steel, and molybdenum. Softer materials like aluminum or brass may face significant tool wear.

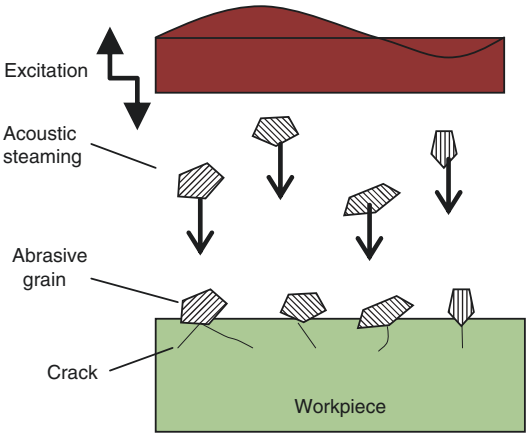
5. *Abrasives*: the abrasives transfer the force of vibrations to the work surface and impinge on the surface to perform removal operation. The abrasives material should be harder than the work material, and the size of the abrasive grits should be the same as that of the amplitude of vibrations being used. Abrasives are normally carried by slurry containing 50 % volume of abrasives and 50 % volume of water. The rate of penetration of tool in the work surface increases with increasing abrasive concentration but reaches a maximum, beyond which the jamming of the abrasives takes place, thereby the tool penetration reduces. The abrasives used for the USM process include diamond, cubic boron nitride, boron carbide, silicon carbide, and aluminum oxide. Boron carbide is the most widely used abrasive material. It is often used in the processing of tungsten carbide, ceramics, minerals, metals, and precious and semiprecious stones. Silicon carbide is used for low-density ceramics, glasses, Si, Ge, and mineral stones. Aluminum oxide is used for machining of glasses and sintered or hard powder components.

Mechanism of Removal

Typical sequence of events that occurs in ultrasonic machining includes (Fig. 2) [3]:

1. Indentation by abrasive particles leading to generation of an inelastic deformation zone around the particle.
2. At some threshold, deformation induced flow develops into a microcrack, termed as a "median" or "lateral" crack.
3. An increase in load further causes steady growth of the median crack.
4. During unloading action, the median crack begins to close inducing formation of lateral vents.
5. Upon complete unloading, the lateral vents continue their extension towards specimen surface and lead to chipping or forming a fragmented section on the work surface.

The critical load for the initiation of the median crack is given by [4]



$$P_c = \alpha \frac{K_{IC}^4}{H_v^4} \tag{1}$$

where, α is a dimensionless factor. The size of the mean crack (C_s) is given by [5]

$$(C_s)^m = K \cdot P \tag{2}$$

where $m = 1$–1.5 and k is a coefficient. This indicates that the size of the median crack grows with an increase in the load and a decrease in the fracture toughness of the work material.

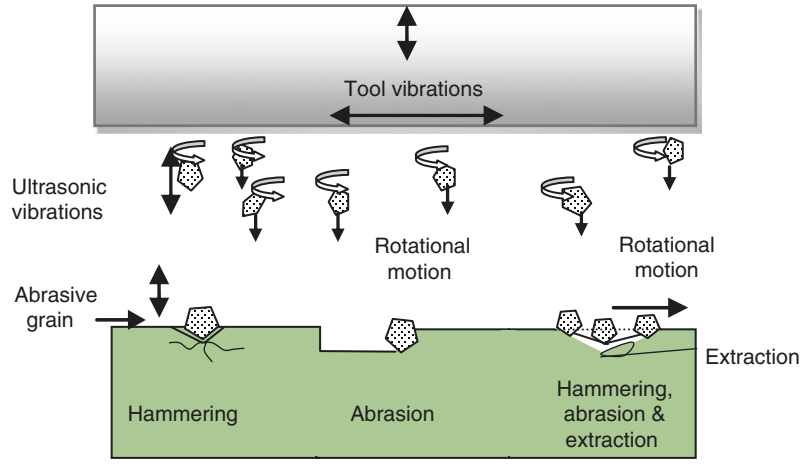
A simple model to evaluate material removal rate (MRR) in ultrasonic machining, which gives contribution of direct impact of the abrasive particles on the work surface in total MRR, was developed by Shaw [6]. The model is primarily based on the assumption that the work volume removed is proportional to the number of particles making impact per cycle and the volume of work material removed per particle impact. The abrasive grains are assumed to be identical and spherical in shape. The MRR therefore is given by [6]

Ultrasonic Machining, Fig. 2 Schematic of crack formation due to impact in USM

$$Z_w = k \cdot n \cdot f \left(d_g \cdot \delta\right)^{\frac{3}{2}} \tag{3}$$

where δ is the depth of indentation, n is the number of impacting particles per cycle, f frequency of ultrasonic vibrations, and k coefficient.

In the above equation, the depth of indentation is given by



$$\delta = \left[\frac{8F_s A d_g}{\pi k_1 H_v C(1+q)}\right]^{\frac{1}{2}} \tag{4}$$

where F_s is static force, A is amplitude of ultrasonic vibration, k_1 is the constant of proportionality, H_v is the hardness of workpiece, C concentration of slurry, and q ratio of the hardness of the workpiece to that of the tool.

Therefore, substituting Eq. 3 in Eq. 4, we get, MRR for ultrasonic machining as

$$Z_w = k\,nf\left(d_g\right)^{\frac{3}{2}} \left(\frac{8F_s A d_g}{\pi k_1 H_v C(1+q)}\right)^{\frac{3}{4}} \tag{5}$$

The Shaw's model is the most widely used because of its simplicity, despite its limitations. It predicts monotonous increase in the MRR with an increase in static force, F_s. However, in practice, this is not so. After a certain increase in the static force, the abrasive particles tend to crack, thereby reducing the MRR.

Ultrasonic Machining, Fig. 3 Removal mechanism in RUM

The above mechanism prevails mainly during machining of brittle work materials that are more susceptible to fracture. However, when the work materials are ductile, such as metals, the abrasives have tendency to get embed in the surface. The embedded particles work harden the surface, and upon successive impacts, chipping removal from the work surface occurs.

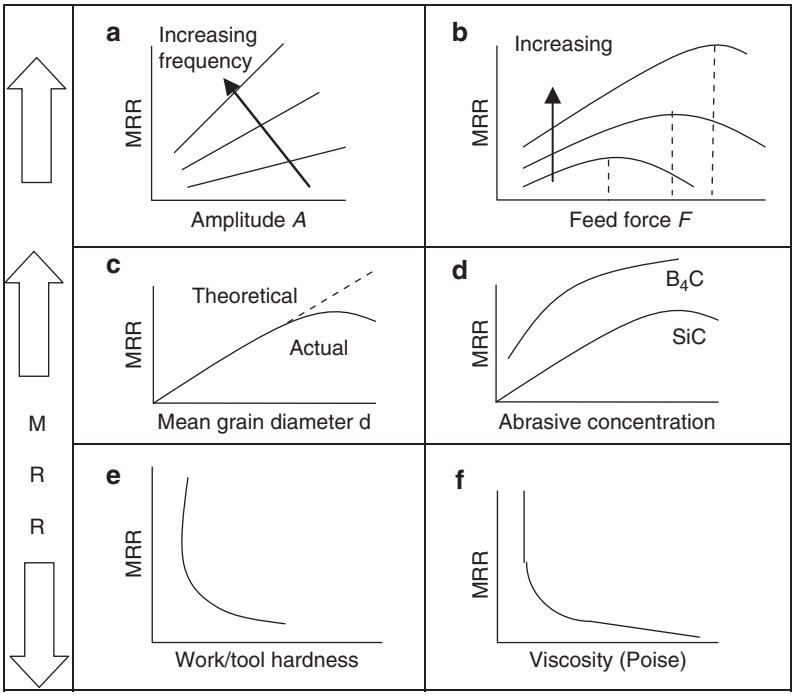
Thus, though USM can be used on both brittle and ductile work materials, it is more effective in the case of former than the latter.

In the RUM, the removal mechanism involves linear as well as rotational motion to the abrasives that are bonded to the tools, (Fig. 3). Therefore, the actions involved include hammering followed by abrasion and extraction [7].

Extensive work on the mechanism of removal shows that besides indentation, multiple mechanisms operate in USM process; these include [8]:

1. Mechanical abrasion by hammering of abrasive particles
2. Microchipping by impact of free abrasives
3. Cavitation effects from abrasive slurries
4. Chemical action associated with the fluid employed

Process Parameters



The theoretical as well as experimental investigations on the process have shown that the MRR in the ultrasonic machining is a function of a large number of parameters such as [9] (1) frequency, (2) amplitude, (3) static force, (4) hardness ratio (q) of the work to tool, (5) grain size, and (6) concentration of abrasive slurry. A pictorial summary of these effects is presented in Fig. 4a–f.

It is understood that the MRR increases with an increase in the frequency and the amplitude of ultrasonic vibrations (Fig. 4a). The MRR increases with an increase in the static force, but after a certain increase in the static force (Fig. 4b), the abrasive particles tend to break thereby reducing the MRR. A decrease in the hardness of workpiece in the ratio (q) causes a rapid reduction in MRR (Fig. 4e). This indicates that the brittle work materials are machined rapidly by USM. A table showing relative removal rate of USM in machining of glass by considering it as 100 is presented in Table 2.

The MRR increases in proportion to the increase in the grain size (Fig. 4c) until the grain size becomes more than the amplitude of vibrations, that is, where the particles tend to fracture.

The MRR increases proportional to the one-fourth power of slurry concentration, i.e., $C^{1/4}$ (Fig. 4d). However, the increasing trend continues till concentration reaches 30 %, beyond which an increase in the concentration does not help. The MRR decreases significantly with a decrease in the viscosity of the carrier liquid (Fig. 4f).

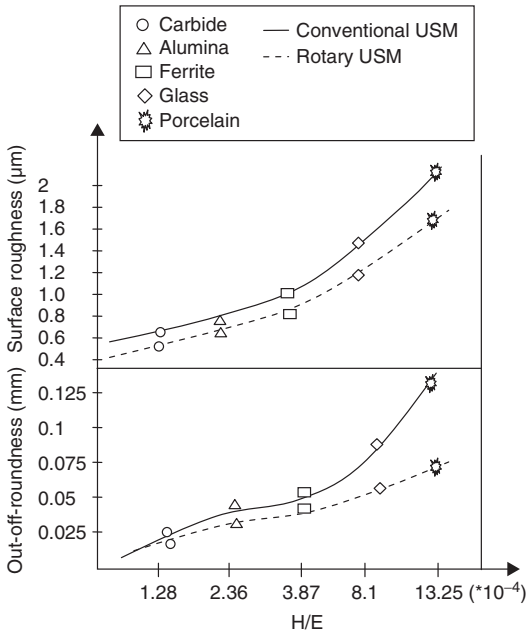
The machined surface roughness using USM depends upon grain size of abrasives [8]. The smaller the grain size, lower the roughness.

Ultrasonic Machining, Fig. 4 (**a**–**f**) Variation of MRR with process parameters in USM

In addition, surface roughness is proportional to {hardness (H)/elastic modulus (E)}^{n} as depicted in Fig. 5a. The work materials that have low H/E ratio are found to give lower surface roughness.

Again, in most of the cases, the RUM process is found to give better surface finish than the USM (Fig. 5a). Nevertheless, the values as low as 0.4 μmRa for surface roughness are obtainable by using the process.

The holes made by USM are oversized and have form errors [8]. The oversize is maximum at the entry the of hole, and it increases as the length of the hole increases. Usually, the upper limit on the oversize is equal to the maximum size of the abrasives used. The oversize and out of roundness are found to reduce with increasing the static load, as it suppresses the lateral vibrations of the tool. Again, the work materials with lower H/E ratio again show lower out of roundness (Fig. 5b).



Tool Wear

Tool wear is an important variable in USM that affects both MRR and hole accuracy [8].

Ultrasonic Machining, Table 2 Relative removal rates in USM (For $f = 16.3$ kHz, $A = 12.3$ μm, mesh size of abrasives = 100) [9]

Work material	Relative removal rate
Glass	100.0
Brass	6.6
Tungsten	4.8
Titanium	4.0
Steel	3.9
Chrome steel	1.4

In general, the tool wear occurs along the length (W_L) as well as along the diameter (W_D) of the tool. It is understood that the tool wear is maximum when the static load is maximum. Also, at the maximum static load, the MRR is also maximum. Therefore, the maximum static load may be considered as the optimum point for the tool wear. The tool wear tends to increase with an increase in the hardness and size of the abrasives. W_L is more influenced by the product of hardness (H) and impact strength (K_i) of the tool material. On the other hand, the W_D is more influenced by the hardness (H) of the tool materials. Therefore, Nimonic 80A, thoriated tungsten, or silver steel

Ultrasonic Machining, Fig. 5 Effect of *H*/*E* on (**a**) surface roughness for various materials under USM and RUM (**b**) out of roundness [8]

is highly recommended as tool materials. The tool wear also increases with an increase in the depth of hole drilled and machining time.

A number of times, fatigue failure of the tools is observed in the USM process. Therefore, the tool materials should have high fatigue strength too.

Recent Trends

The recent developments in ultrasonic machining include use of various tools and techniques to improve performance of the USM process and the application of ultrasonic vibrations in various other manufacturing processes to improve their productivity.

These developments include (a) use of automatic and intelligent machining control systems, (b) use of elliptical vibrations during ultrasonic machining to improve MRR, (c) use of numerical tools to design the horn for efficient conversion of longitudinal vibrations to mixed lateral and longitudinal vibrations thereby maximizing the MRR, and (d) combining the ultrasonic vibrations with other machining processes, for example, in electric discharge machining, where the vibrations help better debris disposal.

Summary

- USM is a nonthermal process and is the most preferred method for machining of hard and brittle materials with hardness above 40 HRC.
- Of the two process variants, USM and RUM, the RUM gives better machining performance than USM; however, the process application is limited to axisymmetric shapes.
- The removal mechanism in the process involves mainly indentation, impact, and chipping leading to generation of lateral crack and followed by the materials removal on brittle work surfaces.
- On the other hand, on ductile work surfaces, removal involves impact induced work hardening followed by chipping.
- In USM, the MRR increases mainly with an increase in the amplitude, frequency, and the static force.

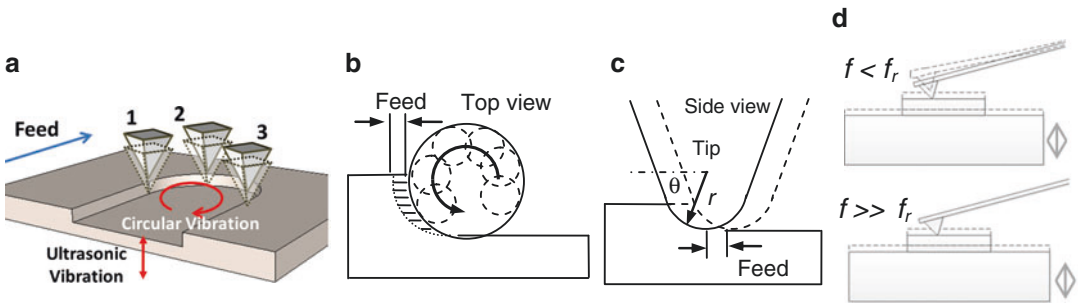
Ultrasonic force-assisted nanomachining; Ultrasonic force-regulated nanomachining

Definition

Ultrasonic vibration-assisted nanomachining is a mechanical machining-based nanofabrication approach using sharp cantilever tips, in which controlled ultrasonic vibration between the tip and the sample is utilized to regulate the dimension of the fabricated features and to improve the performance and speed of nanolithography.

Introduction

Ultrasonic vibration-assisted nanomachining is one of the tip-based nanolithography techniques that enable high-rate tunable nanofabrication on polymeric and metallic substrates. The sharp tip of the microcantilever provides capabilities for low-cost fabrication of polymeric or metallic nanostructures in the sub-50 nm regime and has potentials for fabricating 3D nanostructures. As a mechanical modification approach with an atomic force microscopy (AFM) tip, the ultrasonic vibration-assisted nanomachining overcomes many limitations from traditional nanomachining approaches (e.g., nano-scratching and dynamic plowing lithography). One major disadvantage of traditional mechanical nanomachining is their low efficiency, since the fabricated feature width is mainly determined by the AFM tip size. Multi-scratching steps have to be taken to fabricate a large feature. Moreover, poor process controllability is the other disadvantage of the traditional nanomachining. In nano-scratching, the sharp tip modifies the sample surface by plastic deformation and has been successfully used to produce sub-50 nm features on many samples (e.g., polymers, silicon, aluminum, etc.) [1–8]. A large normal force is generally required to push the tip into the sample for mechanical modification. This normal force depends heavily on properties of the sample materials and the cantilever used. Control of feature dimension in fabrication for different samples and features is very difficult. In dynamic plowing lithography [9, 10], the cantilever tip operating at the tapping mode is used in fabrication. The capability to regulate the machining behavior is limited by the large tip-sample interaction at the resonant frequency of the cantilever, since the cantilever oscillation is very sensitive to the tip-sample gap and set-point force.



Ultrasonic vibration-assisted nanomachining provides high-rate tunable fabrication for polymeric or metallic nano-features. The ultrasonic tip-sample z-vibration can reliably regulate the fabrication depth. A high-frequency in-plane circular tip-sample vibration controls the width of the fabricated features in one scan and significantly improves the speed of the nanolithography. The ultrasonic tip-sample vibration also reduces the normal force and friction during nanomachining and improves the issue of tip wear in traditional tip-based nanomachining.

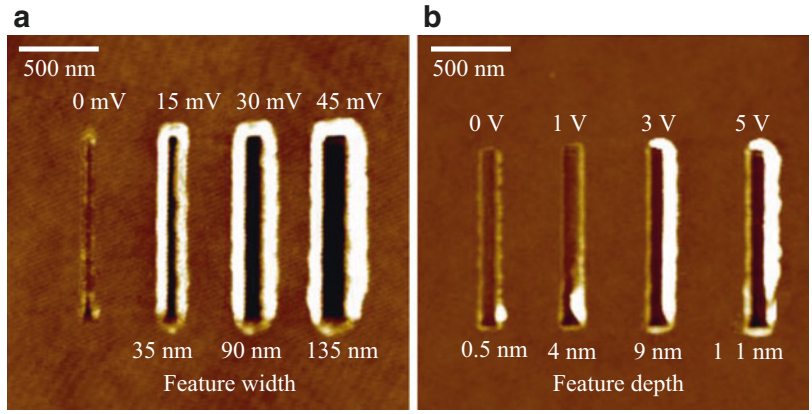
Schematic of Ultrasonic Vibration-Assisted Nanomachining

In ultrasonic vibration-assisted nanomachining, controlled high-frequency vibration between the cantilever tip and the sample is generated to increase the speed and controllability of the nanomachining process. The tip-sample vibration includes an ultrasonic z-vibration and in-plane circular vibration. The ultrasonic z-vibration is utilized to regulate fabrication depth and reduce friction in nanomachining. The high-frequency in-plane circular vibration is used to control the width of the fabricated features and to improve the speed of nanolithography. The schematic illustration of ultrasonic vibration-assisted nanomachining is shown in Fig. 1.

Ultrasonic tip-sample vibration in z-direction effectively increases the dynamic stiffness of the cantilever and improves the machining performance. Here the ultrasonic vibration frequency needs to be much larger than the resonant frequency of the cantilever. When the sample is brought into contact with the cantilever and vibrated with a frequency f that is below the resonant frequency f_r of the cantilever ($f < f_r$), the cantilever follows the sample vibration. When the ultrasonic vibration is applied with its frequency much higher than the resonant frequency of the cantilever, the cantilever cannot follow the sample vibration due to its inertia, which makes the tip immerse into the sample surface on average. With the vibration amplitude larger than the initial deflection of the cantilever, in one vibration circle, the tip experiences a contact phase and a detach phase. During contact, the sharp tip is indented into the sample since the cantilever is dynamically frozen at ultrasonic frequency. The ultrasonic force, as an additional force from the tip-sample interaction under static condition, has been estimated in ultrasonic force microscopy (UFM) [11–14], which is the average of the repulsive force that depends on the surface elasticity and vibration amplitude, and is insensitive to the oscillation frequency and set-point force. Such ultrasound excitation has been used in Ultrasonic Force Microscopy (UFM) as an imaging technique to obtain elastic or subsurface images of the sample. In ultrasonic vibration-assisted nanomachining, the ultrasonic tip-sample z-vibration is used to control the machining depth. For a chosen sample material, the depth of indentation mostly depends on the vibration amplitude and is insensitive to the oscillation frequency, which provides a reliable method to control the machining depth.

In ultrasonic vibration-assisted nanomachining, besides the ultrasonic z-vibration, a high-frequency circular tip-sample motion in the xy-plane is utilized to achieve better control of the fabrication process and to overcome many limitations from direct mechanical scratching, such as large tip-sample interaction and slow machining speed. The feature dimension, such as line width, can be regulated by changing the amplitude of the circular vibration/motion. As shown in Fig. 1b, the outer edge of the circular path can be viewed as the edge

Ultrasonic Vibration-Assisted Nanomachining, Fig. 1 (**a**) Schematic illustration of vibration-assisted nanomachining. (**b**, **c**) The top view and side view show the tip-sample engagement of the virtual tool (when the tip is vibrated with an in-plane circular path) with the sample during one rotation cycle. (**d**) At low frequency, cantilever follows the sample vibration. At high frequency ($f>>f_r$), cantilever begins to indent into the sample



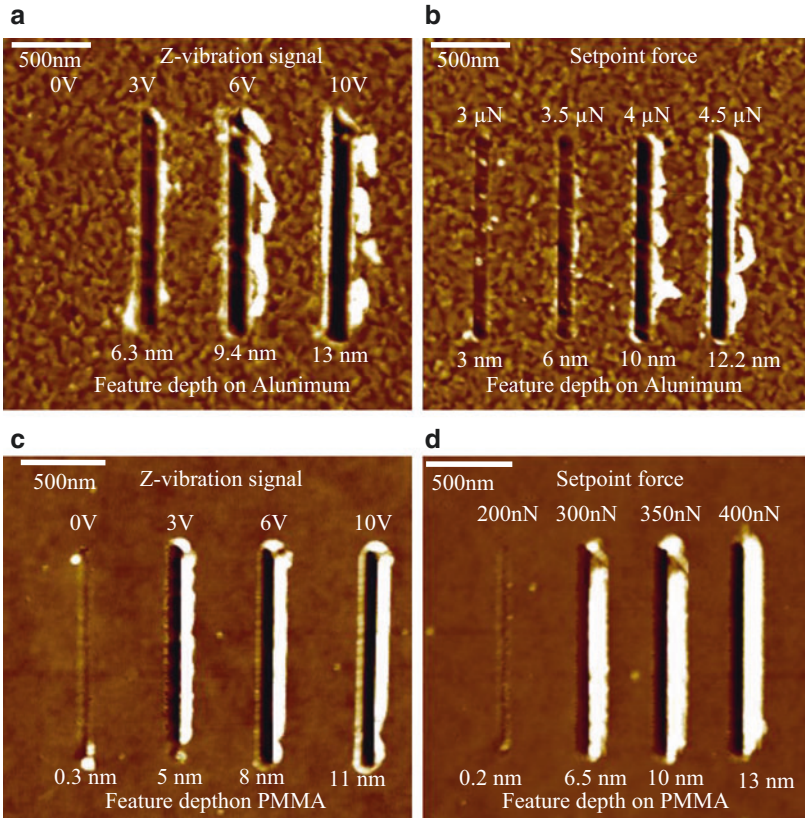
of a virtual tool with a single cutting tooth, and the effective cutting edge is the edge of the tip that is tangent to the virtual tool at that moment. The diameter of the virtual tool is controlled by the amplitude of vibration. This machining scheme is similar to the conventional-scale single-tooth fly-cutting, in which the rotation of the virtual tool is obtained by the circular motion of the tip.

By rotating the tip in *xy*-plane with high frequency, the tip-sample interaction can be distributed to each rotation cycle. During each cycle, only a thin slice of material defined by feed per rotation is removed. Thus, tip-sample interaction force can be significantly reduced and the machining speed can be significantly increased. Given the feed per rotation f and the rotary speed of the tool N, the machining speed can be expressed as $V = fN$. Even with a small feed per rotation to reduce the tip-sample interaction in each cycle, if a high rotary speed is used, a large machining speed can still be achieved. For example, assuming f is 10 nm and N is 10 kHz, the lithography speed can be as large as 100 μm/s, which is very difficult to be obtained by other mechanical modification approaches with an AFM. Moreover, by choosing different feed per rotation, the machining force during each rotational cycle can be controlled. The process has better controllability to improve the overall performance (e.g., better finish/topography uniformity) and to achieve more efficient material removal.

The ultrasonic *z*-vibration and in-plane rotation for ultrasonic vibration-assisted nanomachining is produced by a high-speed *xyz* nanopositioner as a nano-vibrator [15, 16], which is mounted onto the AFM scanner to provide the high-frequency-controlled vibration in *xyz* directions. The vibration amplitude of the nano-vibrator in *xy* directions ranges from sub-nm to a few microns depending on the command voltage to the piezo actuator, which provides good tunability for the nanomachining process.

The experiments of the ultrasonic vibration-assisted nanomachining were performed on a 200 nm thick PMMA film, which is spin-coated on a cleaned silicon substrate. A tapping mode cantilever was used in the nanomachining experiment. Compared with direct scratching and dynamic plowing, the ultrasonic vibration-assisted nanomachining process provides a faster machining speed and greater material removal rate. In Zhang and Dong [15], straight line patterns are machined on the PMMA film under different vibrational conditions to characterize the capability of ultrasonic vibration in regulating both machining depths. After an *xy*-circular vibration is excited with a frequency of 10 kHz and machining speed of 20 μm/s, even with a small set-point force of 100 nN, a noticeable cutting depth about 1 nm can be achieved, compared with direct scratching. With circular xy-vibration, tunable line width can be achieved in one machining path by just changing the *xy*-vibration amplitude, which is controlled by the command voltages given to the *xy*-piezo actuators, as shown in Fig. 2. From the fabrication results in Fig. 2a, clearly a large vibrational command produces a wider trench feature, and a small vibration signal corresponds to a narrow trench. The line width ranges from 35 to 135 nm, as the vibrational commands increase from 15 to 45 mV. Since the cutting load is distributed to each small cutting cycles, good surface finish is obtained; surface roughness in the trench along the machining direction is less than 1 nm. The machined trench width follows a nearly linear relationship with the *xy*-piezo driving signal amplitude.

Set-point z-force has been widely used to control the cutting depth in tip-based nanomachining. However, large z-force can bring large friction and reduce tip life. It was found that ultrasonic z-vibration is able to control the fabrication depth and, at the same time, to reduce friction [15, 16]. The effect of ultrasonic z-vibration is shown in Fig. 2b. The machining speed in the tests is set to be 20 μm/s. Without ultrasonic z-vibration, using a small set-point force of 100 nN, the cantilever can barely make any modification on the sample. After the sample is vibrated at ultrasonic frequency (2 MHz), noticeable trenches were fabricated on the sample surface. The depth of the trench depends on the vibration amplitude in z-direction. The trench depth is directly controllable by the vibration amplitude in the z-direction, as shown in Fig. 2b. With a larger command to z-piezo, a large trench depth is obtained. With or



Ultrasonic Vibration-Assisted Nanomachining, Fig. 2 (**a**) Effect of *xy*-circular vibration on nanomachining. Larger *xy*-vibration amplitude results in large trench width with a nearly linear relationship. (**b**) Effect of ultrasonic z-vibration on nanomachining. Z-vibration amplitude and trench depth follow a nearly linear relationship

without *xy*-circular vibration, the trench depth follows an approximately linear relationship with the z-vibration amplitude, which provides a reliable method to regulate the cutting depth. By using larger z-vibration amplitude, thicker slice of materials (as thick as 80 nm) can be machined in one scan with the same machining speed.

Robust Material-Insensitive Feature Depth Regulation by Ultrasonic Vibration

It was demonstrated by the nanomachining experiments on aluminum and PMMA in Zhang et al. [16] that when the set-point force is used to control fabrication depth (i.e., without ultrasonic z-vibration), a much larger normal set-point force is required to fabricate features with similar depth on aluminum, compared with the required set-point force for PMMA (a few micro-Newtons for aluminum vs. a few hundred nN for PMMA). These results are very easy to understand, since aluminum is a much stiffer material than PMMA. However, when using ultrasonic z-vibration, with the same small set-point force (200 nN in Fig. 3) and the same vibration amplitude, the ultrasonic vibration-assisted nanomachining produces similar feature depth on both PMMA and aluminum, even though these two materials have very different mechanical properties. The fabrication depth is predominantly controlled by the amplitude of the ultrasonic z-vibration and is insensitive to substrate materials and other process conditions, which indicate the great potential of using ultrasonic z-vibration in regulating the feature depth.

The depth regulation by ultrasonic vibration can be explained by the increased dynamic stiffness of the vibrating cantilever at the ultrasonic frequencies. When the sample vibration frequency is much higher than the resonant frequency of the cantilever, the cantilever cannot follow the sample vibration due to its inertia. In other words, the cantilever is dynamically frozen at the ultrasonic frequency, due to its extremely large dynamic stiffness. For a rectangular beam cantilever, its static stiffness can be expressed by $K_s = 3EI/L^3$, where E is Young's modulus, I is the moment of inertia, and L is the cantilever length. At an ultrasonic frequency, the effective dynamic stiffness of a cantilever can be expressed by $K_d = 3EI/b^3\lambda^3$, where λ is the wavelength of ultrasonic flexural wave and b is the constant of order unity. By making $K_s = K_d$ at the resonant frequency of the cantilever, the constant b can be derived, and the dynamic stiffness can be expressed as $K_d = K_s\,(L/0.298\,\lambda)^3 = K_s\,(\omega/\omega_0)^{3/2}$, where ω_0 is the angular resonant frequency of the cantilever. As an example, for a tapping mode cantilever with a static stiffness of 48 N/m and resonant frequency of 190 kHz, when it is excited at the ultrasonic frequency of 3 MHz, the effective dynamic stiffness of 1,350 N/m can be obtained. Compared with the extremely large dynamic stiffness of the cantilever, the sample stiffness is

Ultrasonic Vibration-Assisted Nanomachining, Fig. 3 Comparison of nanomachining with and without z-vibration on aluminum (**a**, **b**) and PMMA (**c**, **d**). (**a**, **c**) Feature depth controlled by ultrasonic z-vibration with a small set-point force of 200nN. (**b**, **d**) Feature depth controlled directly by set-point force

relatively much smaller for many materials, including aluminum and PMMA. Using Hertzian approximation, the sample stiffness can be estimated as $k_s = (6RE^{*2}F)^{1/3}$, where F is the tip-sample contact force, E^* is the effective elasticity which can be expressed as

$$\frac{1}{E^*} = \frac{1-v_t^2}{E_t} + \frac{1-v_s^2}{E_s},$$

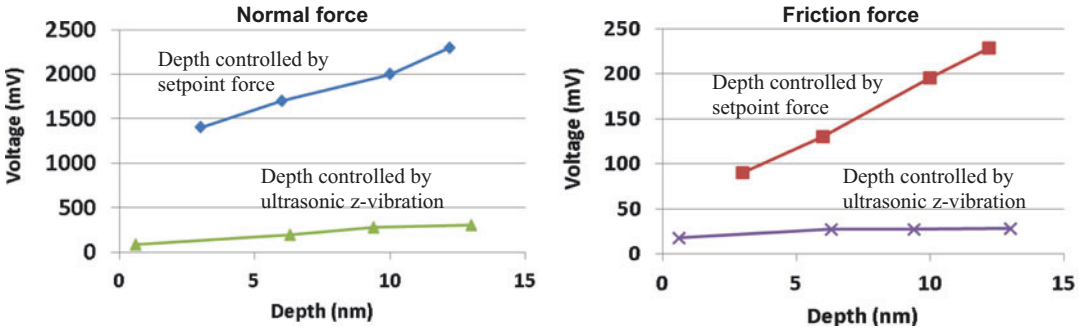
and E_t, v_t and E_s, v_s are Young's modulus and Poisson's ratio of the tip and sample, respectively. If we assume an elastic contact between the tip and sample surface and a 10 nN contact force, the effective sample stiffness of PMMA and aluminum is 24.5 and 153 N/m, respectively. The dynamic stiffness of the cantilever at ultrasonic frequency is 10 times larger than the sample stiffness of aluminum and more than 50 times larger than PMMA. Moreover, the above sample stiffness is based on the full contact between the cantilever and the tip. In ultrasonic vibration-assisted nanomachining scheme, since the vibration in the z-direction (MHz) is much faster than in the xy-plane (~10 KHz), the tip-sample contact in each z-vibration cycle is far less than the full sphere-plane contact, which will further decrease the effective sample stiffness.

Simply speaking, at ultrasonic frequency, the cantilever is much stiffer than the sample. The ultrasonic vibration, especially its vibration amplitude, is not affected by the tip-sample interaction. During vibration, the tip can easily indent into relatively soft samples for mechanical modification without much resistance. The tip-sample engagement or cutting depth is mainly controlled by the vibration amplitude. Therefore, even at a small set-point normal force, using the same vibration amplitude, ultrasonic vibration-assisted nanomachining produces similar feature depth on PMMA and aluminum samples. The fabrication depth is predominantly controlled by the

amplitude of tip-sample ultrasonic z-vibration and is insensitive to substrate materials.

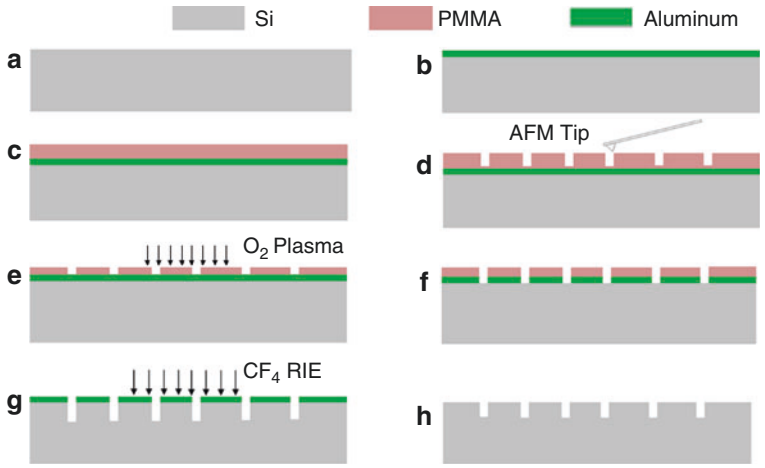
Reduction of Friction and Machining Force by Ultrasonic Vibration

After applying ultrasonic tip-sample vibration in the z-direction, a significant reduction of the normal force and lateral force (friction) was observed during nanomachining [16]. To compare the effect of ultrasonic z-vibration on machining forces, a set of linear patterns were fabricated with depth controlled by the amplitude of the ultrasonic z-vibration and by the set-point z-force without vibration. Force data is compared for features with similar depth and width. The normal force and friction were acquired by measuring the cantilever normal deflection (A–B from the photodiode detector) and torsion deflection (C–D from the photodiode detector).



For the linear trench features machined on aluminum with depth controlled by ultrasonic z-vibration and by set-point z-force, the acquired normal and lateral force signals were plotted in Fig. 4. When the feature depth is controlled by the set-point force (no ultrasonic z-vibration), large normal forces have to be applied to fabricate features with the same depth. Ultrasonic tip-sample vibration in vertical direction significantly reduces the normal and lateral force in nanomachining, and the machining force only has a weak dependence on the fabricated feature depth. For ultrasonic vibration-assisted nanomachining, for feature depth up to about 12 nm, normal force and lateral force are kept at a very small value with normal force less than 400 mV (compared with 1,400 to 2,300 mV without vibration) and lateral friction force less than 30 mV (compared with 90 to 228 mV without vibration). For example, to fabricate a trench with a depth of 12 nm, 10 V z-vibration is required for ultrasonic vibration-assisted nanomachining, or a set-point force of 4,500 nN has to be used for nanomachining without z-vibration. When using the ultrasonic z-vibration, the normal force is 400 mV, about 1/6 of 2,300 mV for nanomachining without ultrasonic z-vibration, and the lateral force is 28 mV, only 1/8 of 230 mV for nanomachining without ultrasonic z-vibration.

The decrease in machining forces by ultrasonic z-vibration can be attributed to the small normal force required in nanomachining and intermittent tip-sample contact from ultrasonic z-vibration. The reduced normal force improves the applicability of ultrasonic vibration-assisted nanomachining to a broad set of materials, especially for hard materials. For traditional nanomachining of hard materials, custom-designed cantilevers with extremely large stiffness have to be used to provide the required huge normal force. Furthermore, the reduced machining force by ultrasonic vibration can potentially reduce tip wear and elongate tip life for the nanomachining process.



Ultrasonic Vibration-Assisted Nanomachining for Nanolithography

Besides fabricating patterns directly on many substrates, ultrasonic vibration-assisted nanomachining can be used as a nanolithography process to fabricating features on polymer films and then transfer to other functional substrates. A typical nanomachining-based nanolithography process [15] is illustrated in Fig. 5. A silicon substrate is evaporated with a thin aluminum layer and then spin-coated with PMMA film. Then, nanomachining is applied to make features on the PMMA film. To protect the cantilever tip from severe wearing and to elongate its lifetime, the machining depth is set to slightly less than the PMMA thickness to prevent the tip from direct contact with the aluminum layer. The residue PMMA can be removed by oxygen plasma asher to expose the underneath aluminum layer. After wet aluminum etching, the pattern is transferred from the PMMA to the aluminum layer. The RIE process can be further used to transfer the pattern from the aluminum mask to silicon.

Using nanomachining-based nanolithography process, features with width of 120 nm are machined on a 35 nm thick PMMA, as shown in Fig. 6. The depth of feature on the PMMA film is about 25 nm. The roughness at the bottom of the

slots is ∼1 nm. The remaining PMMA in the features after nanomachining is removed in oxygen asher. After that, the sample is placed in aluminum etchant to transfer the slot patterns from the PMMA to the aluminum layer. After aluminum etching, the roughness at the bottom of slots is about 0.7 nm, indicating the exposed silicon surface. After RIE etching and aluminum mask striping, the AFM image shows a cut depth of ∼30 nm in silicon substrate as shown in Fig. 6f and h. The SEM image of the fabricated line patterns is shown in Fig. 6h. The patterns can be reliably transferred from features that are machining on PMMA film to silicon substrate.

Future Directions

The ultrasonic vibration-assisted nanomachining has demonstrated promising potentials for improving the speed and material removal rate of nanomachining, reducing the machining force and tip wear, and increasing the controllability of the nanomachining processes. Future work aimed at modeling the nanomachining process to predict the feature produced and machining force at different process parameters will be important to make ultrasonic vibration-assisted nanomachining a viable and reliable process for nanofabrication. vibration-assisted nanomachining in the fabrication of 3D nanostructures can also be expected, which is actually a unique capability of mechanical machining-based nanofabrication processes.

Definition

Upconversion is a process in which the sequential absorption of two (or more) low-energy photons leads to the emission of one photon with higher energy. The upconversion process can occur in materials such as lanthanide-doped nanoparticles and can be enhanced by the strong local electric field found in the proximity of metallic (plasmonic) nanostructures.

Overview

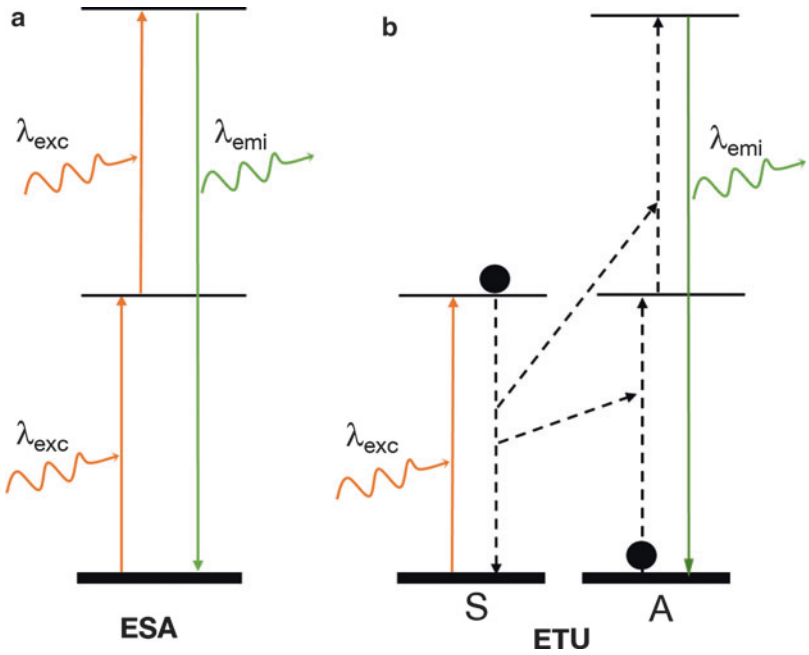
Nanomaterials have attracted considerable attention due to their size-dependent properties, allowing many interesting and sometimes novel features to be observed [1]. Of particular interest are luminescent nanoparticles as they have been touted to find widespread integration in applications ranging from the realization of display devices to bioimaging [2]. One particular class of luminescent nanomaterials that has garnered considerable interest is the lanthanide (Ln^{3+})-doped upconverting nanoparticles (UCNPs). These UCNPs are particularly attractive as they possess the capability of converting low-energy (long λ) light such as near infrared (NIR) into high-energy (short λ) emission spanning the UV, visible, and even the NIR, in a process known as upconversion [3]. The ability to generate light covering the UV-NIR regions of the spectrum via NIR excitation implies that this material can be useful in optical applications such as the realization of lighting materials, anti-counterfeiting measures, displays, and imaging to name a few [4]. However, since upconversion is a multiphoton process, it suffers from low efficiency (or low quantum yield which is defined as the ratio between emitted photons and absorbed photons) [5] in comparison to other direct excitation approaches (i.e., standard fluorescence). Additionally, alternative depopulation routes of the excited states of the lanthanides result in loss of energy that otherwise could be used to promote upconversion emission. Consequently, scientists have looked at ways to enhance the upconversion emission via several routes including the

development of novel low-energy phonon hosts, higher crystallinity materials, the preparation of core/shell architectures, where a shell passivates the luminescent core, and, finally, the exploitation of the synergistic effects that arise due to the combination of plasmonic nanomaterials with UCNPs. The latter is the subject of this work and is discussed in detail below.

Upconverting Nanoparticles

Prior to discussing the synergy between UCNPs and nanoplasmonic materials, we define upconversion in greater detail. Upconversion is a physical process that involves the conversion of lower-energy photons into higher-energy photons using the real (intermediate) states of an atom. This phenomenon has been observed in transition metals and actinides, but mainly in the lanthanide elements. In their trivalent state, Ln^{3+} ions have valence electrons in an inner shell with the $4f^n$ electron configuration that is protected from the environment by outer energy levels (shells). The abundant and unique energy level structures remain, thus, largely unmodified by a change of environment, and for this reason, they are widely used as dopants in transparent materials to add narrow and well-defined emission and absorption bands in the UV, visible, and NIR ranges [6]. When the lanthanide ions are exposed to a light source with photons of energy equal to the energy distance between two levels, i.e., the ground and an excited state of the ion, the electrons can be promoted from the lower to this higher-energy state. Absorption of another photon from the excitation light, and/or energy from electrons in neighbor ions, can result in the excitation to higher-energy levels. If the excited electrons then release their energy and return to the ground state, the result is the emission of photons featured by shorter wavelengths (such as UV or visible).

Processes that also account for NIR to visible light transformation, such as two-photon absorption, can be observed in other materials. However, it is noteworthy to mention that the excitation of Ln^{3+}-doped UCNPs occurs via real electronic states featured by defined (relatively long) lifetimes, in contrast to the case of two-photon absorption. As a consequence, high-power, ultrafast, expensive laser setups are not required for the efficient excitation of Ln^{3+}-doped UCNPs, which can be achieved by using low-power, readily available solid-state laser diodes.



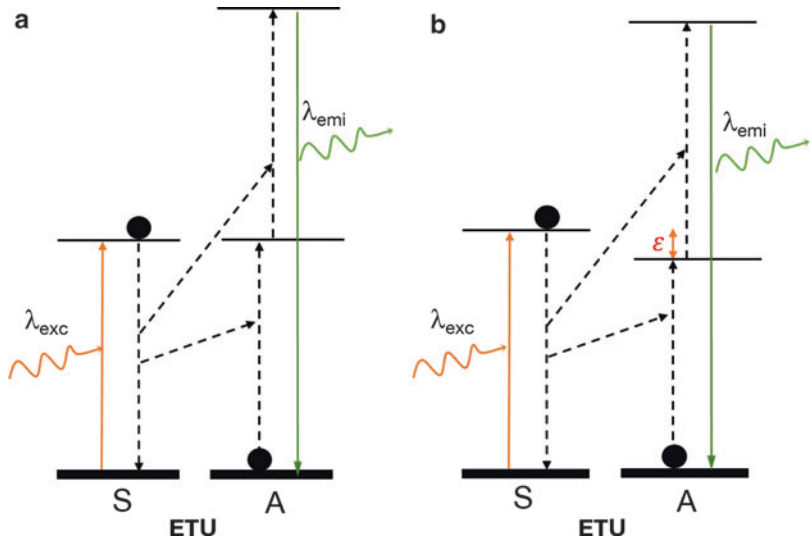
Upconversion is known to occur via three distinct mechanisms, namely, excited state absorption (ESA), energy transfer upconversion (ETU), and photon avalanche (PA). The latter is not commonly observed in the cases covered by this text and will not be discussed below.

Excited State Absorption

In an ESA mechanism, electrons of the ground state absorb one or more photons, sequentially, from the excitation source. When one electron in the ground state absorbs one photon, it is excited into an intermediate state. Then, after sequentially absorbing a second photon, it can be promoted to a higher excited state, and, upon returning to the ground state, it can emit higher-energy photons (Fig. 1a). Although in the simplest case, the energy levels are equidistant; ESA may be observed in systems with non-equal energy levels through phonon-mediated processes. Moreover, since this is a single ion process, it is generally observed in materials with low Ln^{3+} dopant concentrations where the Ln^{3+}-Ln^{3+} distances are too far for any interactions between ions to occur.

Energy Transfer Upconversion

Energy transfer upconversion is known to be the most efficient upconversion process in Ln^{3+}-doped nanomaterials [6]. It occurs between two different ions with nearly equally spaced energy levels, with another requirement being the nearby localizations of the ions involved in the process (distance typically of the order of one nanometer) so that the transfer of energy can easily occur from one ion to its neighbor. These two ions are normally called the sensitizer (S) (or donor) and the activator (A) (or acceptor). The sensitizer is an ion with a high-absorption cross section and that can absorb the photons from the excitation source efficiently, so electrons are promoted from their ground to an excited state. Subsequently, the sensitizer transfers this absorbed energy to the



Upconversion Enhancement in Lanthanide-Doped Nanoparticles Using Nanoplasmonics, Fig. 1 Schematic diagram of two common upconversion mechanisms: (**a**) excited state absorption and (**b**) energy transfer upconversion

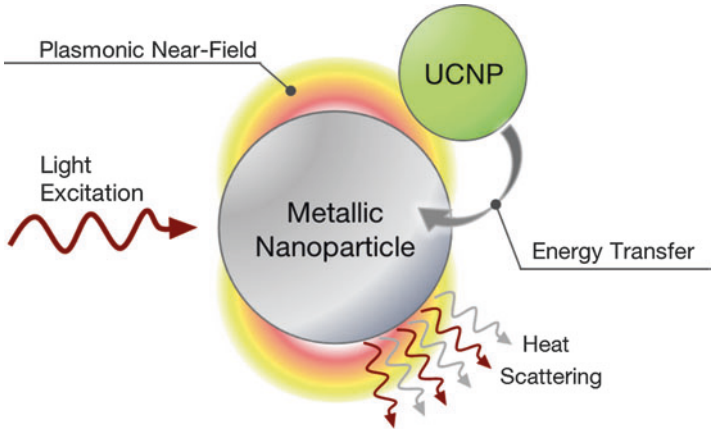
electrons of the activator, allowing them (after several steps) to reach higher-energy states, from which the electrons will decay by emitting the upconverted luminescence (Fig. 1b).

In the energy transfer process between sensitizer and acceptor ions, two situations, namely, resonant non-radiative transfer and phonon-assisted non-radiative transfer, can occur. In resonant non-radiative transfer, the energy levels of both S and A are equally spaced, while, in the phonon-assisted non-radiative transfer, an energy mismatch exists between the energy levels of the sensitizer and acceptor ions, so energy from the lattice (quantized in the form of phonons) is necessary to fulfill energy conservancy constrains. Figure 2 shows schematic diagrams of the ETU processes between two ions. In these images, we observe resonant non-radiative transfer (Fig. 2a) and phonon-assisted non-radiative transfer (Fig. 2b). Theoretically, most lanthanide ions can undergo the NIR to visible upconversion process; however, relatively efficient upconversion is only possible with a few trivalent lanthanide ions (e.g., Er^{3+} and Tm^{3+}) under low pump densities. To date, the Yb^{3+}/Er^{3+} or Yb^{3+}/Tm^{3+} dopant ion combinations have been greatly employed in co-doped nanomaterials. This is due to the fact that their energy levels are reasonably matched allowing for efficient energy transfer following NIR excitation.

Interactions Between Metallic Nanostructures and Upconverting Nanoparticles

As it was mentioned in the introduction, upconversion processes are intrinsically limited in terms of quantum yield due to their nonlinear nature. As such, in a two-step process in which two NIR photons are absorbed to emit one green photon, as it happens in the very common upconversion of co-doped Er^{3+}/Yb^{3+} ions, the quantum yield cannot be higher than 50 %. In the same way, blue emission through the upconversion of Tm^{3+}/Yb^{3+}, a three-step process, reduces the theoretical maximum quantum yield to 33 %. Moreover, as there are additional depopulation routes besides upconversion that can affect every energy state involved in the process, the

Upconversion Enhancement in Lanthanide-Doped Nanoparticles Using Nanoplasmonics, Fig. 2 Schematic diagram of a resonant (**a**) and a phonon-assisted (**b**) upconversion process



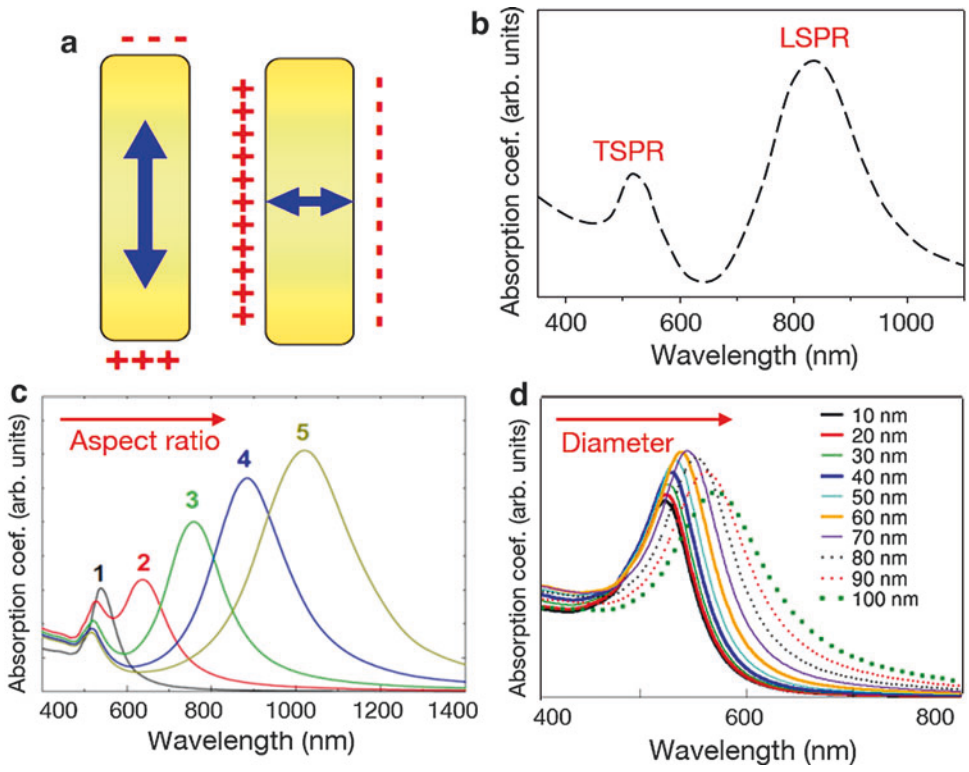
quantum yield is typically significantly lower than the predicted maximum. The list of alternative depopulation processes includes radiative and non-radiative transitions to lower-energy states, as well as additional energy transfer mechanisms, including the quenching triggered by molecules adsorbed on the surface of nanoparticles, defects, etc. Altogether, the upconversion quantum yield is normally below 10 % and in nanoparticles often below 1 % (depending on the concentrations of the sensitizer and the activator, their nature, the host material, the size of the nanoparticles, the excitation power density, etc.) [5].

It has been demonstrated that the plasmonic properties of metallic nanostructures can be applied to enhance the emission probabilities of emitters (atoms, molecules, or quantum dots) in their close proximity [7]. With regard to upconversion, the fact that the resultant emissions are due to multistep processes amplifies the possibility for enhancement upon coupling to suitable plasmonic nanostructures. To fully describe the interaction between metallic nanostructures and UCNPs, two different physical phenomena must be considered (Fig. 3). One is the influence of the plasmonic near-field, and the second is the non-radiative energy transfer between the UCNP and the metallic nanostructures [8, 9]. Prior to delving into the precise nature of the interactions of luminescent and plasmonic nanostructures, we introduce the relevant concept of surface plasmon resonance.

Plasmonic Nanomaterials and Surface Plasmon Resonance

It has been long known that the properties of materials change once they enter nanoscopic dimensions (in the 1–100 nm range). This can be as a result of confinement (such as limitations imposed on the movement of electrons), or alternatively of an increased surface-to-volume ratio. In fact, optical and magnetic properties are dependent on the electron motion characteristics of a system, while, surface properties can gain importance compared to volume properties in a nanoscale scenario [10]. In the case of metallic nanostructures, one of the best examples is related to the excitation of localized surface plasmons, resulting from the interaction between the free electrons of the metal and the optical electromagnetic field.

A metallic nanoparticle, for example, can be described as a lattice of ionic cores with conduction electrons moving almost freely inside the nanoparticle (the Fermi sea). When it is illuminated by a light source, the corresponding electromagnetic field applies a force on the conduction electrons at the nanoparticle surface. This results



Upconversion Enhancement in Lanthanide-Doped Nanoparticles Using Nanoplasmonics, Fig. 3 The interaction between metallic nanostructures (a nanoparticle in this case) and upconverting nanoparticles (*UCNPs*) is mainly driven by the plasmonic near-field generated by the metallic particle and by nonresonant energy transfer between both. Additionally, the metallic nanostructure can scatter light or release heat

in a negative charge accumulated on one side of the nanoparticle, leaving the other side positively charged, thus creating an electric dipole. This dipole gives rise to an electric field with opposite direction to that of the illuminating light and, thus, drives the electrons into returning to the equilibrium position. The displaced electrons will naturally tend to oscillate with a certain frequency that is known as surface plasmon frequency. If the frequency of the excitation light matches the frequency of the nanoparticle surface plasmon, a resonant effect occurs (called localized surface plasmon resonance – localized SPR), which involves the collective oscillations of the electrons in the nanoparticles. This in turn causes an increase in the kinetic and electrostatic energies associated with the electric fields of the dipole which is supplemented by the exciting radiation [10]. As a result, the incident light is partially extinguished when exciting SPRs.

Noble metal nanostructures have the ability to confine the radiation well beyond the diffraction limit. This phenomenon happens when the incident light is at the SPR of the nanostructures. The SPR is strongly affected by the particle shape and size. This is clearly exemplified by gold nanorods (GNRs). In this case, since rods are geometrically anisotropic, the electron oscillation can occur differently along the rod's two main axes, depending on the polarization of the incident light. The charge accumulations will be different for the electrons oscillating along the rod long axis (longitudinal plasmons) and those moving along the perpendicular direction (transversal plasmons) (Fig. 4a). Accordingly, GNRs show two surface plasmon resonances, one strong longitudinal SPR (called LSPR) which is usually located in the NIR region and one transverse surface plasmon resonance (TSPR), which lies in the visible range (Fig. 4b). The LSPR of GNRs strongly depends on the aspect ratio (length/width) of the GNRs, that is, the higher the aspect ratio of the rods, the greater is the red shift associated to the LSPR, and vice versa (Fig. 4c). The strong LSPR of GNRs in the NIR region offers the possibility to use excitation light of larger wavelength, which is preferable for biological applications as these wavelengths are less harmful to the biological tissues. This contrasts to other geometries such as nanospheres where only one SPR is observed and its location can vary depending on the particle radius (Fig. 4d).

Effect of the Plasmonic Near-Field on Upconversion

The relaxation rate of each excited state of a lanthanide ion, incorporated as a dopant in a

Upconversion Enhancement in Lanthanide-Doped Nanoparticles Using Nanoplasmonics, Fig. 4 (**a**) Schematic of electron accumulation on the surface of a GNR (reproduced with permission from [10]), (**b**) the absorption spectra for GNRs showing the TSPR and LSPR, (**c**) the absorption spectra for GNRs with different aspect ratios from 1 to 5 (reproduced with permission from [10]), and (**d**) the absorption spectra for spherical nanoparticles with different diameters from 10 to 100 nm (reproduced from [11])

certain host, is characterized by a radiative emission probability (when energy is released in the form of light, i.e., photons), W_{rad}, and a non-radiative emission probability (when energy is released in the form of heat, i.e., phonons), W_{nr}. Typically, their sum is inversely related to the experimental lifetime of the excited state, τ_{exp}. However, we note that a third term can be added when energy transfer is possible from this state. In this case, τ_{exp} can be defined as:

$$\frac{1}{\tau_{exp}} = W_{rad} + W_{nr} + W_{ET} \qquad (1)$$

where W_{ET} is the probability of energy transfer. In general, upconversion processes benefit from long lifetimes in the intermediate states and large radiative emission probabilities in the final emitting state. Accordingly, these are the parameters to consider in order to improve the upconversion efficiency. Normally, these values depend on both the lanthanide and the host (via the crystal field, the phononic modes, and the presence of other lanthanides). Thus, in order to modify these parameters, a change of the host structure is often necessary. The so-called Purcell's effect states that the radiative properties of an emitter are dependent on its environment and, therefore, offers an alternative to optimize the upconversion. In the presence of a metallic nanostructure, the plasmonic interaction induces an increase in the density of states which, according to Fermi's golden rule, will consequently increase the radiative transition rate of the ions [7].

Equation 1 considers the different depopulation routes of an energy state. Naturally, absorption must take place prior to depopulation. Therefore, its control constitutes an additional option for improving the quantum yield, as the plasmonic electromagnetic field (which is connected with an inhomogeneous redistribution of the photon energy density in the nanostructure surroundings) clearly affects this important parameter.

In order to promote absorption enhancement, the plasmon must be resonant with one (or more) among the absorption lines of the lanthanides, which can then absorb its energy. In upconversion processes, the emission intensity, I, is strongly dependent on the excitation power density, P, due to the nonlinearity of this excitation scheme. This dependence follows a power function, $I \propto P^n$, where n is a positive value related to the number of excitation photons needed to complete the upconversion process, i.e., the number of upconversion steps [12]. Thus, it is clear that the high-photon energy densities achieved in the plasmonic field can strongly affect the intensity emitted by the UCNPs, through the enhancement of the absorption process. In this case, both the absorption processes originating from an excited state (e.g., ESA), as well as stimulated-type emissions, should be considered toward an optimized process and this in addition to the standard absorption from the ground state [7, 8].

The different ways in which the plasmonic field can affect all the steps in an upconversion process make the final enhancement larger than in a standard fluorescent particle [13]. In that regard, one further difference between upconversion and standard fluorescence is that, in upconversion, absorption and emission wavelengths are well separated, while this is not normally the case in standard fluorescence. This offers an additional route to engineer the upconversion emission, since the anisotropy of certain metallic nanostructures, allowing for more than one SPR, can be used to have enhancement both at the excitation and at the emission wavelength of the UCNPs [14]. The overall enhancement is not described by a general rule, as it depends on each particular upconversion process through parameters such as donor-acceptor distances, nature of the process (ETU vs ESA), and the number of upconversion steps.

The Non-Radiative Energy Transfer

When an excited UCNP is in the close environment of a metallic nanostructure, there is a certain probability of having a non-radiative energy transfer from the UCNP to the metallic counterpart, resulting in some energy loss and, as a consequence, quenching of the emission. In such cases, the distance between the emitter or sensitizer (the UCNP, S) and the acceptor (the metallic nanostructure, A), R_{SA}, is a critical parameter in defining the process probability. Note that UCNPs are by definition nanoparticles of transparent crystals with lanthanides distributed as dopants in the lattice. Consequently, the characteristics of the particle play a role in determining R_{SA}, which is thus not described by a single value, but rather by a probability distribution that should consider the dimensions, morphology and dopants concentration of the nanoparticle.

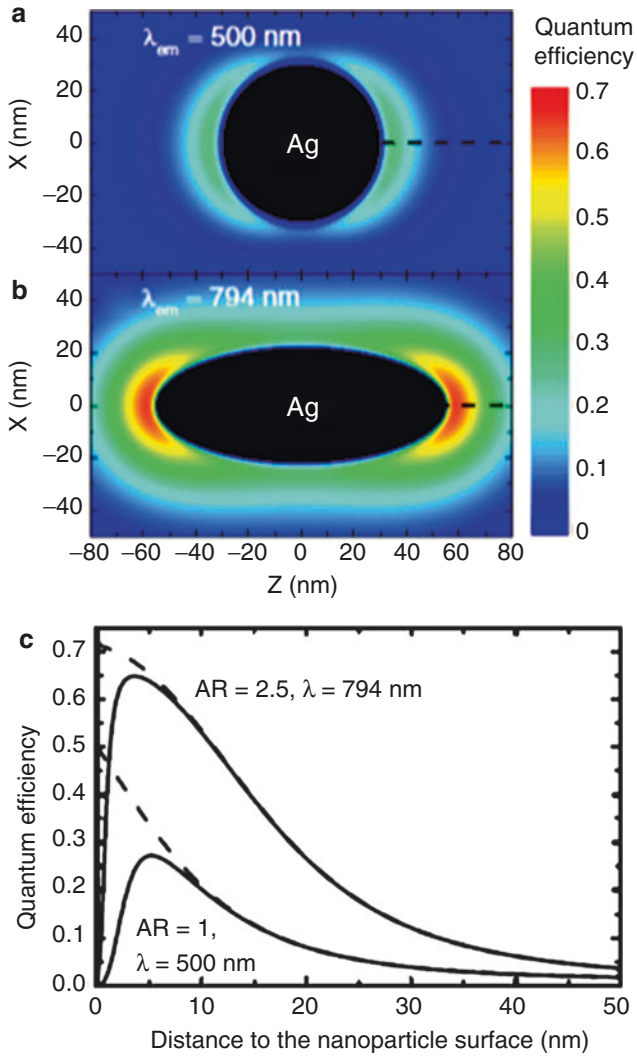
The non-radiative energy transfer can happen through three different processes: exchange (overlap of the electronic wave functions), multipolar electric, and multipolar magnetic interactions. Due to the nature of the first process, Ln^{3+} ions must be very close to the metallic nanostructure (few Å) for it to happen, and thus, (although it can be indeed important at short distances) it is often negligible in real experimental settings. Magnetic interaction is also relevant at very short distances, but only when exchange and electric interaction are otherwise forbidden by the relevant selection rules. Consequently, it is the multipolar electric interaction, defined by the Coulomb law, which more often accounts for energy transfer [15].

In many cases, the electric interaction can be described via a dipole-dipole approximation where the Förster formalism can be applied [16]. When this approximation is valid, the probability of the non-radiative energy transfer is related to R_{SA} through the relation $W_{ET} = C_{SA}/R_{SA}^6$, where C_{SA} is known as the energy transfer microparameter. This relationship clearly shows the strength of the dependence of the degree of quenching

on the interparticle distance, so that the process has a particular relevance when the surface of the UCNP is in contact with the metallic nanostructures (in which case, additional interactions and multipolar electric terms might be relevant).

However, R_{SA} is not the only quantity that affects the probability of the process, since the microparameter C_{SA} contains a dependency on the refractive index of the environment as well as on the emission and absorption energies of sensitizer and activator. Following Förster's model, C_{SA} can be defined as

$$C_{SA} = \frac{3\hbar^4 c^4}{4\pi n^4} \frac{Q_A}{\tau_0} \int \frac{L_S(E) \cdot L_A(E)}{E^4} dE \qquad (2)$$



where the subindex S refers again to the sensitizer, i.e., the ion in the UCNP that provides energy in the transfer process and A refers to the activator, i.e., the receptor of the energy, which in the present case is the metallic nanostructure. Accordingly, L_S and L_A are the normalized line shapes of the sensitizer's emission and the activator's absorption, respectively, so the integral represents the overlap between both transitions. Q_A is the integrated absorption cross section of the activator, ħ is the Planck constant, c is the speed of light in vacuum, n is the refractive index of the medium, and, finally, τ_0 is the radiative lifetime of the sensitizer in the absence of the activator. Looking at this definition, it becomes clear that for a metallic nanostructure with a high-absorption cross section and in resonance with at least one emission line of the lanthanides, the quenching related to the energy transfer can become very relevant.

Controlling Enhancement in a Real System: The Key Parameters

The physical phenomena explained thus far are the main reasons that account for the modification of the upconversion intensity. Although the emission enhancement of the UCNPs in close proximity to the plasmonic nanostructures is now well established, studies on this matter have reported a wide range of enhancement factors or even quenching in some cases. A comparison between different approaches and efforts generated to date shows that upconversion emission enhancement can be strongly dependent several features that can affect any of the two main physical phenomena, plasmon mediated enhancement and energy transfer, behind the metallic nanostructure-UCNP interaction. Here, we describe a few of these features to illustrate which parameters are more relevant.

Impact of the Nanostructure Architecture

Plasmon-induced electromagnetic fields are strongly dependent on the shape, size, and composition of the metallic nanostructure. Thus, wide ranges of luminescence enhancement factors were found in previous works due to the interplay of UCNPs and metallic nanostructures in different configurations. For example, regarding the choice of material, it has been shown that silver nanoparticles induce a higher emission enhancement in comparison to gold nanoparticles with the same size, since the former possesses stronger plasmonic resonances [17]. On the other hand, for the same composition but different morphology, recent theoretical studies show that prolate-shaped metallic nanoparticles can lead to much higher enhancements than the corresponding spherical nanoparticles (Fig. 5). It was demonstrated by the work of Mertens and Polman that the emission enhancement in the proximity of a prolate geometry can be up to two times higher in comparison to the case in which the nanoparticle is a sphere with the same volume [18]. This significant improvement is due to two effects. Firstly, the coupling between the UCNP emitter and the plasmon mode is more effective in the prolate geometry due to the higher shape-induced field enhancement near the sharp tips [18]. Secondly, the drop in quantum efficiency close to the prolate-shaped nanoparticle surface sets in at smaller separations. For example, the distance to the metal surface at which the quantum efficiency reaches half the maximum value is 2.2 nm for a spherical nanoparticle and only 0.8 nm for its prolate-shaped counterpart. Quenching due to coupling with higher-order plasmon modes is thus less effective for prolate-shaped nanoparticles [18]. In a different work by Mertens et al. [19],

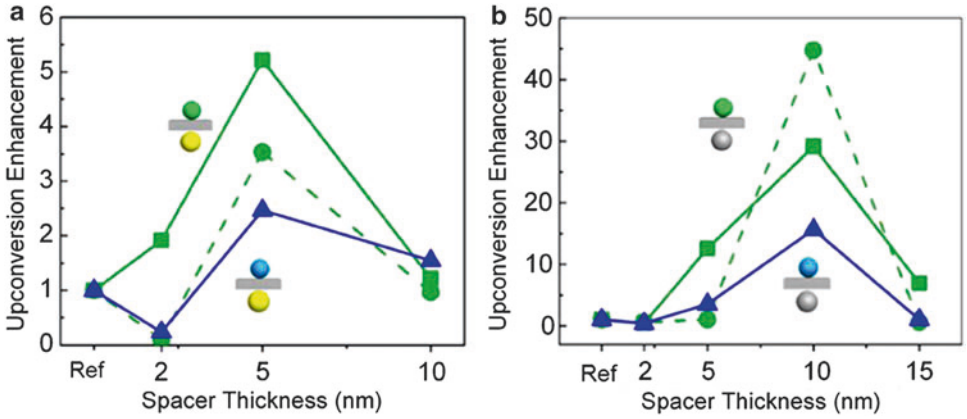
Upconversion Enhancement in Lanthanide-Doped Nanoparticles Using Nanoplasmonics, Fig. 5 Luminescence quantum efficiency of a dipole emitter as a function of its position in a plane through the nanoparticle's major axis for (**a**) a 60-nm-diameter Ag sphere and (**b**) an Ag prolate spheroid-shaped nanoparticle with an aspect ratio of 2.5 and a volume that is equal to the volume of the sphere. The orientation of the source dipole is set as parallel to the *z*-axis, and the refractive index of the embedding medium is 1.5. The emission wavelengths thus correspond to the maximum radiative decay rate enhancement: 500 nm for the sphere and 794 nm for the prolate-shaped nanoparticle. (**c**) Line traces of the luminescence quantum efficiency along the *dashed lines* indicated in (**a**) and (**b**), taking into account coupling to either all multipole modes up to $l = 100$ (*solid lines*) or to the dipole mode only (*dashed lines*) (Reproduced with permission from Mertens et al. [18]. DOI 10.1063/1.3078108. Copyright [2009], AIP publishing LLC)

the composition and shape of the metal nanoparticle are kept constant to address another possible contribution: the effect of the size of spherical plasmonic nanoparticles. It was proven that there is an optimal diameter in the range of 30–110 nm (depending on the material properties) for which maximum enhancement takes place, defined by the competition between two different mechanisms: emitter-plasmon coupling, which is more effective for small spheres, and coupling of

plasmons into radiation, which is more efficient for large spheres [19].

Emission/Absorption Enhancement in Upconversion

As described earlier, at wavelengths resonant with the metallic nanostructure plasmon frequency, the interaction between the incident light and the metal nanostructure results in local electric field strengths that are much higher than the incident electric field. This field enhancement is the main reason for the luminescence enhancement in UCNPs. However, it should be noted that the plasmon resonance of the metallic nanostructure could be designed to overlap with either the absorption wavelength of the UCNPs (in the NIR region), with the emission wavelength of the UCNPs (visible region), or both. To date, most works have focused on the resonant emission enhancement. For example, in the work by Saboktakin et al. [17], metal nanoparticles of gold or silver were fabricated to match the plasmon resonance with the emission wavelength of the UCNPs (the SPR of gold nanospheres was at 534 nm, which is in resonance with the green emission of Er^{3+} ions centered at 545 nm), and the enhancement was found to be 5.2-fold in proximity of Au nanospheres. However, the use of nanostructures such as GNRs that can possess two surface plasmons resonant with both the absorption and emission wavelength is expected to give rise to even higher enhancement values. GNRs can be tailored to have their longitudinal SPR overlapping with the excitation wavelength of the UCNPs and their transverse SPR overlapping with the upconversion emission of UCNPs. In such structures, the overall enhancement mechanism can be a combination of resonant enhancement in both absorption and emission, which can lead to an overall increase of the total enhancement.



Effect of the Excitation Pump Power

As previously discussed, upconversion efficiency itself is a function of the excitation power density, $I \propto P^n$, and, thus, the enhancement factors from the same sample could vary widely depending on the excitation power. In this equation, n is presumed as the number of photons needed to excite the emitting state, also known as the order of the upconversion process. For example, for a two-photon upconversion process, the value of n should be close or equal to 2. However, it is theoretically proven that this relation strictly refers to the case of small upconversion rates at low excitation powers, and an efficient upconversion system will exhibit an intensity-versus-power dependence with lower n [12].

Due to the characteristics of the upconversion emission, a dependence of the plasmonic enhancement on the excitation power becomes intuitive. Its effect on the different contributions to upconversion enhancement (absorption, emission, and Förster energy transfer between Ln^{3+} ions) has been studied in the experimental work by Lu et al. [20]. In this work, a silver nanograting coated with a spacer of Si_3N_4 and featured by a plasmon resonance at the excitation wavelength of the UCNPs was probed at power densities between 1 and 100 kW/cm^2. It was found that the described general behavior of the upconverted luminescence was preserved in the presence of the surface plasmon, meaning that the upconverted luminescence intensity depends quadratically on the excitation power for a weak excitation, and linearly in the strong excitation limit. Yet, the intensity-versus-power dependency curves were shifted to lower-power densities, revealing an enhanced local electromagnetic energy density due to the surface plasmons. Additionally, through a numerical analysis based on rate equations, it was concluded that the enhancement of the upconversion luminescence results from an increase in absorption and energy transfer rates. The absorption enhancement was found to play a dominant role at high-power densities, while both absorption and energy transfer enhancement contributed in the weak excitation regime (here, the absorption enhancement was described by Maxwell's equations and energy transfer by Förster's theory) [20].

Impact of the UCNP-Metallic Nanostructure Interparticle Distance

As described earlier, the local field enhancement can lead to an increased upconversion emission,

Upconversion Enhancement in Lanthanide-Doped Nanoparticles Using Nanoplasmonics, Fig. 6 Upconversion luminescence enhancement of two types of UCNPs ($NaYF_4$:Yb^{3+}, Er^{3+} and $NaYF_4$:Yb^{3+}, Tm^{3+}) in close proximity of Au (**a**) and Ag (**b**) spherical nanoparticles with a diameter of 5 nm as a function of the spacer thickness between the two nanostructures. The *green solid lines* correspond to the 540 nm emission band of $NaYF_4$:Yb^{3+}, Er^{3+}. The *green dashed lines* correspond to the 650 nm emission band of $NaYF_4$:Yb^{3+}, Er^{3+}. The *blue solid lines* correspond to the 475 nm emission band of $NaYF_4$:Yb^{3+}, Tm^{3+} (Reproduced with permission from Saboktakin et al. [17])

which may impose the idea that the closer the UCNPs are to the plasmonic nanostructures, the better is the enhancement. However, the non-radiative energy transfer from the UCNPs to the plasmonic nanostructures can happen in very close proximity, leading to a decrease of the luminescence quantum yield (quenching). The combination of the plasmonic field enhancement of the upconversion intensity and the non-radiative energy transfer from UCNPs to plasmonic nanostructures is such that the luminescence intensity can be either enhanced or quenched depending on their relative distance [14]. Consequently, this results in the existence of an optimal distance (d_{opt}) for luminescence enhancement. Anger et al. investigated, both theoretically and experimentally, the effect of a gold nanoparticle on a fluorescent molecule [9]. They illustrated that a simple change in the relative distance can lead to a luminescence emission widely ranging from enhancement to quenching, thus proving the existence of a well-defined d_{opt}. In addition, they showed that d_{opt} depends on the size of the plasmonic nanoparticle, where, for larger nanospheres, d_{opt} was found to be smaller. However, there are reports of either fluorescence enhancement or fluorescence quenching of the upconversion in the presence of metallic structures. While this can appear somehow confusing, it can be readily explained by the lack of control over the interparticle distance in the experimental design. In recent years, the study of the effect of interparticle distance on the luminescence enhancement has been extended to upconversion. For instance, in an experimental work by Saboktakin et al., the effect of the distance between UCNPs and two different types of metallic nanospheres (gold and silver) with 5 nm diameters was studied. Preliminary series of control experiments in this work showed that, in a random configuration (without a spacer between the two types of materials), the luminescence intensity was greatly reduced. However, by using a nanometer-scale oxide layer as the spacer between the nanostructures, the existence of an optimum distance was revealed and found to be dependent on the metallic nanosphere composition. For gold nanospheres, d_{opt} was equal to 5 nm, while, for silver nanospheres with the same diameter, d_{opt} was 10 nm (Fig. 6). This could be explained as the result of a higher per volume extinction cross section of silver in comparison to gold.

Note that the extinction coefficient in metallic nanostructures arises both from absorption and scattering processes; although following Mie's theory, it is dominated by absorption for small diameter nanoparticles (5 nm in this case) [17]. Therefore, the higher absorption cross section of Ag nanoparticles generates a stronger non-radiative energy transfer (Eq. 2) followed by a stronger quenching effect. Accordingly, a larger optimal distance for emission enhancement is observed in this case.

Definition

This entry examines the applications of nanotechnology during pregnancy (current, research, and potential applications), the unique pregnancy-related characteristics that relate in the application of nanoscale materials, and the concerns on maternal/fetal well-being.

Overview

Nanotechnology is being progressively researched, and nanoscale products are manufactured for various engineering devices, consumer products, diagnostic, and therapeutic applications to be utilized during different human life stages including pregnancy. Pregnancy is a life stage combined with the unique physiological changes and characteristic remodeling of maternal tissues supporting the growth and development of the fetus(es). As a result of these adaptive mechanisms to support fetal growth, the drug metabolism, particle distribution, and elimination kinetics during pregnancy are significantly different from both males and nonpregnant females. The gestational transformations are primarily dependent on hormonal changes and are initiated in the preimplantation stage, progressing to its maximum in the third trimester. These physiological changes evolve into the lactation phase and are partially reversed postpartum. Such alterations, when occurring at the molecular level in conjunction with the changes in tissue permeability, become significant particularly when designing, developing, and applying nanoscale technologies during pregnancy. Three main entities, the mother, the fetus, and the placenta along with their physical/functional connections and interdependency, are the key considerations for nanotechnology use during pregnancy.

The development and application of nanotechnology becomes crucial during the pregnancy conditions along two different aspects. The positive aspect is that the products incorporating nanoscale technologies can be used from a biomedical perspective and also in consumer nano-products during all stages of pregnancy. The negative aspect and implications are the reported and postulated detrimental effects of nanoparticle exposure during this vulnerable, transforming life stage.

Constructive Applications of Nanotechnology in Pregnancy

The properties of nanoparticles make them resemble biological molecules and are modifiable, making nanotechnology utilizable during the very early stages of pregnancy. Commercially available home pregnancy test is one example where nanoparticles are currently in use to confirm gestation during early pregnancy. These diagnostic concepts can be further extended to nanoelectromechanical systems (lab-on-a-chip devices) for detailed diagnostics during the different stages of pregnancy in both the mother and fetus. These include early detection of fetal congenital abnormalities by analyzing maternal serum, amniotic fluid, and cord blood. The relatively higher sensitivity of the nanoscale analyzing techniques can be very useful in early pregnancy where minute volumes (nano- to microscale) of biological materials and tissues are involved. Nanoscale technologies are considered for utilizing in contraception

by incorporating various binding, transporting, release, and strength-related properties. Research is currently ongoing for designing intrauterine contraceptive devices (IUCD) containing nanoparticles to replace the conventional copper IUCD [1]. The applicability of nanotechnology for further strengthening the barrier contraceptive devices is also currently under investigation.

The ability to functionalize nanoparticles and tailor them to support individual tissue-specific needs makes it a very versatile technology especially in the mid- and later gestational stages. In circumstances such as in severe preeclampsia and cancer treatment, the benefits of maternal drug/nanoparticle administration outweigh the risks of minute fetal exposure to nanomaterials [2]. These nanoparticulate drug delivery systems offer a potential avenue to deliver diagnostic, therapeutic, or theranostic agents to tissues that are not directly in contact with the fetus and can be separated by the placental barrier properties. One example that is currently under investigation is the treatment of ectopic placental tissue or placental tumors by targeted nanoparticle delivery of chemotherapeutic agents such as doxorubicin. In these studies, EnGeneIC Delivery Vehicles (EDVs) which are nanocells that can promote tissue-specific delivery of drugs were loaded with the chemotherapeutic doxorubicin. These nanocells were targeted to the epidermal growth factor receptor (EGFR) that is very highly expressed on the placental surface and was reported to be able to regress placental cells *in vitro*, *ex vivo*, and *in vivo* [3].

Potential Negative Consequences of Using Nanotechnology in Pregnancy

The occupational, therapeutic, and general environmental exposure to nanoparticles during the preconceptional, gestational, and lactation periods may impose unknown risks affecting the healthy progression and outcome of pregnancies. Considering the currently available distribution profiles of different nanoparticles, these adverse effects can be manifested as alterations in pulmonary, cardiovascular, hepatic, renal, and immunological functions of the maternal side. The emerging evidence on selective placental transfer of nanoparticles raises concerns on their utility in obstetrics and on the possible harmful effects to fetal development. Similarly, detrimental effects of nanoparticle exposure as postulated with animal studies can influence conception, implantation, placentation, embryogenesis, organogenesis, growth, and development in human pregnancies. These toxicity concerns and their poorly understood mechanisms are controversial and may at times contribute to decelerate the application of nanotechnology during reproductive life stages.

Key Research Findings

Relatively less number of studies is reported in literature on the application of nanoparticles, nanoparticle distribution, and toxicity during pregnancy; hence, literature reviews on nanotechnology and nanotoxicity relevant to gestational stages are scarce. Almost all the *in vivo* studies are carried out in animal models including zebra fish, mice, and rats.

Distribution of Nanoparticles During Pregnancy and Placental Transfer

Research and the in-depth understanding of the distribution kinetics of nanoparticles are critical as such knowledge is essential in both therapeutics and toxico-pharmacology. Several studies have focused on the distribution of different types of nanoparticles during pregnancy. The studies on intravenously administered nonfunctionalized radiolabeled C_{60} fullerenes formulated in polyvinylpyrrolidone (PVP) have reported distribution (24 and 48 h post-administration) in both maternal and fetal tissues in pregnant rats when administered on the fifteenth day of gestation. Radioactivity (~6 %) was also distributed to the reproductive tract, placenta, and fetuses of the pregnant rats. The relative tissue distribution patterns varied between the pregnant and lactating female rats that may be dependent on the physiological changes related to gestation, permeability differences, and structural properties of various maternal tissues. While the majority of the C_{60} were

distributed to the maternal liver, there was a limited distribution to the maternal lungs during pregnancy. In contrast, this study reported a higher distribution in the lungs in the lactating stage [4].

Relatively larger and longer carbon-based nanoparticles such as multiwalled carbon nanotubes (MWCNT) also cross the placental barrier as revealed by a study using isotopic tracers in mice. Oxidized MWCNT had crossed the placental barrier and were detectable in the fetal tissues [5]. Similarly, in a study where rats were periconceptionally exposed with gavages of zinc oxide nanoparticles, the distribution of zinc to mammary tissue in the pregnant rats and the liver and kidney of the pups was reported [6]. Metallic silver nanoparticles, when gavaged to pregnant and lactating rats, were also detected in the fetal tissues and breast milk [7].

Placenta is the key organ undergoing remodeling throughout the pregnancy, contributing to the systemic changes in pregnancy while facilitating nutrient, antibody, and other material particle transfers between maternal and fetal tissues. It also performs an important barrier function protecting the fetus from the maternal insults. The nanoparticle transfer across the placenta and the permeability characteristics are emerging as research foci in the field of reproductive nanomedicine and nanotoxicology [8]. Studies in pregnant mice exposed to different functionalized gold nanoparticles have reported placental and fetal accumulation of maternally administered nanomaterials suggesting the placental transfer of these materials. This particle transfer across the placenta is influenced by both stage of embryonic or placental maturation and nanoparticle surface composition [9]. The initial *in vivo* and *ex vivo* studies demonstrate that the ability of the nanoparticles to cross the placental barrier and passage to the fetus is dependent on the size and the surface coating of nanoparticles as well as on the experimental model [10].

The abovementioned studies were done in animal models, and the basic structural differences and deviations from the human placental function have to be considered in interpreting these findings as relevant to human exposures. Placenta is a species-specific organ, and the speculation of these findings particularly in relation to particles with less than 100 nm size range needs to be done with caution as the differences at cellular/molecular level may have a significant influence on these inferences. Studying the distribution of nanoparticles in the human placenta is an ethical challenge, and the only available research tools are the *ex vivo* perfusion of the expelled placenta and *in vitro* assessments of placental cells [8]. Previously reported studies in the human placenta have not observed any transfer of gold nanoparticles to the fetal side of the placental circulation [11]. Another study which used the *ex vivo* human placental perfusion model to investigate whether nanoparticles can cross the placental barrier has demonstrated that fluorescently labeled polystyrene beads with diameters up 240 nm were taken up by the placenta and were able to cross the placental barrier without affecting the viability of the placental explants [12].

Nanotoxicological Studies During Pregnancy

Most of the researches on pregnancy and nanotechnology have focused on the adverse effects of occupational, environmental, and medical-related nanoparticle exposure during pregnancy. The available literature on toxicological studies on pregnancy have focused primarily on pulmonary, intravenous, and oral exposure to different nanomaterials including silver, gold, silica, iron, cobalt, titanium, cerium oxide, carbon-based nanoparticles, and quantum dots. These studies have been done in different animal models in varying doses (usually higher doses), sizes, and formulations of nanoparticles. These *in vivo* exposures in mice have resulted in adverse effects in both fetal and maternal components. Increased acute cellular inflammation, inhibition of maternal weight gain, and changes in pregnancy hormones were reported in pregnant dams [5, 11]. The fetal outcomes include reduced body weights of pups, changes in gene expression related to development or function of central nervous system in male pups, increased susceptibility to allergy in pups, reduced number of Sertoli cells, and alterations in epididymal sperm motility in pups.

C_{60}, quantum dots, silica, and titanium nanoparticles are reported to be associated with embryological abnormalities, placental abnormalities, and early pregnancy loss [11, 13].

The changes observed in these studies in the fetal weight and the placental structure were dependent on the type, size, and surface chemistry on the nanoparticles [13]. The oxidized MWCNT which cross the placenta induced gestational age and parity-dependent abortion rates and also resulted in narrowed blood vessels and decreased the number of blood vessels in the placenta as assessed by histology [5]. Quantum dots are potential nanoparticles for imaging which can be used in pregnancy-related diagnostic, imaging, and monitoring progression of diseases/treatments. Studies in rats exposed with CdSe/ZnS or CdTe quantum dots on the 6th, 13th, and 18th days of embryogenesis did not report any direct embryotoxic or teratogenic effects. However, they reported adverse effects on the maternal organism as they induced necrosis in the tissues of the peritoneal cavity. In the same study, spectroscopic and microscopic tissue examination revealed the accumulation of quantum dots in the placenta in the absence of penetration to the embryonic tissues [14].

Gold nanoparticles are potential drug carriers that can be coated or formulated differently to make them biocompatible. In a study with intravenously administered gold nanoparticles with different surface modifications (ferritin, PEG, and citrate) at 5.5–15.5 days of gestation in mice, it was demonstrated that prior to gestation day 11.5, all tested nanoparticles could be visualized and detected in fetal tissues in significant amounts. Subsequently, fetal gold levels declined dramatically after gestation day 11.5. In contrast, gold nanoparticle accumulation in the extra embryonic tissues increased 6–15-fold with gestational age. Fetal and extra embryonic accumulation of ferritin- and PEG-modified gold nanoparticles was considerably greater than citrate-capped nanoparticles [9]. These and other studies on placental and fetal transfer of nanoparticles suggest that fetal exposure to nanoparticles and their toxicity in pregnancy is influenced by both stage of embryonic/placental maturation (gestational stage) and physicochemical properties of nanoparticle.

The changes in the fetal growth and abnormities induced by nanoparticle exposure are speculated to be due to several mechanisms. The first mechanism is explained by the placental transfer of specific nanomaterials and their directed effects on the fetal tissues. The interruptions of the placental and uterine blood supply and the contribution of the maternal cardiovascular system during pregnancy in mediating the effects of nanoparticles are combined as the second mechanism and are emerging as a significant area in research. The changes in maternal and fetal microvascular function and the contribution of these have been studied with exposure to titanium nanoparticles [15]. In addition, studies using C_{60} and multiwalled carbon nanotubes have reported vascular bed, suspension medium, and route of exposure-dependent changes in the vascular tissue responses and fetal growth during pregnancy [16, 17]. The inflammatory responses in the maternal side (generally following a pulmonary exposure) are another mechanism that can contribute to both maternal and fetal responses following gestational exposure.

Future Directions for Research

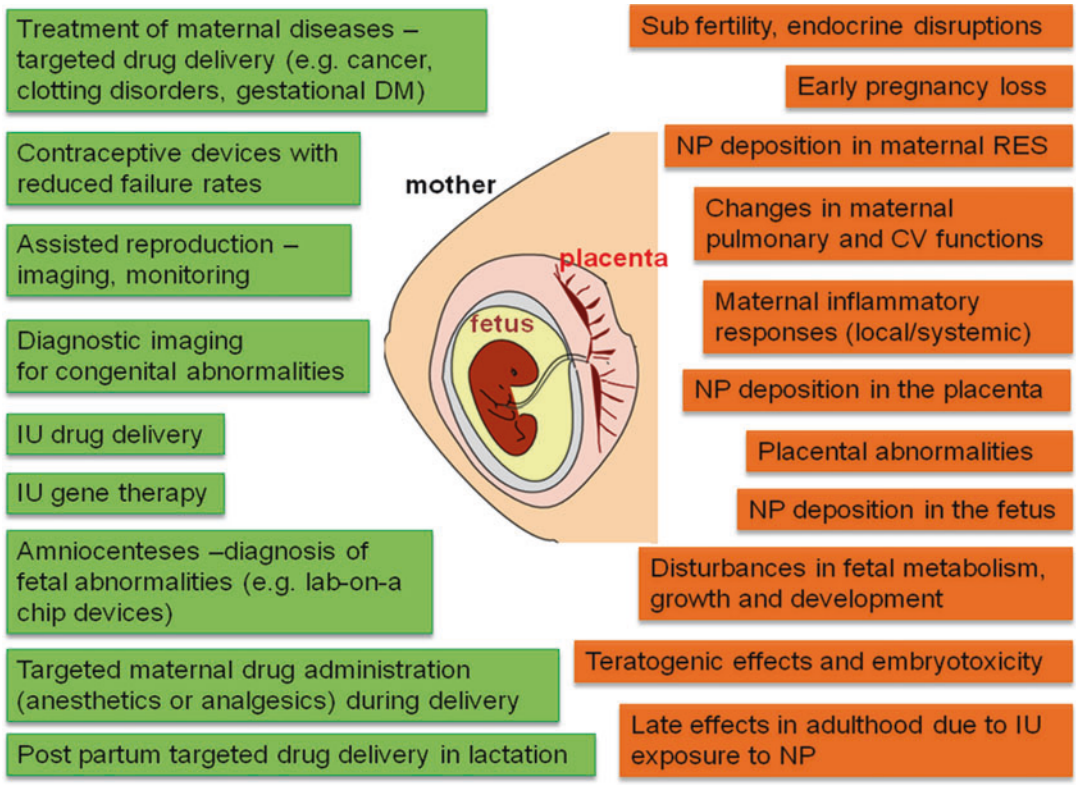
Pregnancy and nanotechnology in combination initiate a wide spectrum of research with infinite possibilities of applications that can be studied. These range from nano-engineering, basic molecular mechanisms, preclinical studies in animal models or *in vitro* systems, clinical trials, and toxicological (teratogenic and embryotoxic) assessments.

Interactions of the Nanoparticles with the Placenta

The main obstacle in applying nanotechnology during pregnancy is the lack of proper understanding on the precise nanoparticle interactions with the placenta. Limited studies focusing on this topic suggest a considerable uncertainty and

ambiguity regarding the transplacental deposition and passage of nanoparticles [2]. Our understanding on the criteria that determine placental transferability of nanoparticles is inadequate. Designing different nanoscale particles and manipulating their functional properties can potentially control the placental function as a barrier, filter, or a target to nanoparticles, provided the properties of placenta that contribute to these functions are properly understood. These are the first-line focus areas for future research in this field. In order to adequately understand nanomaterial-biokinetics and placental toxicity in early gestation (particularly the first trimester where teratogenic effects are critical), the special architecture of the placenta, the hypoxic condition, the bilayer of villous trophoblast, the plugging of spiral arteries, the contribution of intrauterine glands to nutrition, and the delicate immunologic situation at the implantation site need to be considered [18]. The physicochemical properties, functionalizing potential, targeting mechanisms, and radiolabeling ability of nanoparticles can be used as a research tool to study placental transport mechanism in further studies.

Almost all the current reported studies on nanotechnology in pregnancy are in animal models, and the speculations of these results to human populations are limited by the species-dependent differences in the placental structure, gestational periods, litter size, and particle distribution. Descriptive, retrospective studies on exposed human populations and further *ex vivo* placental perfusion studies on expelled human placentae can be utilized to fill this knowledge gap. The emerging knowledge and applications of nanoscale biophotonics expand the possibilities of applying these fine imaging techniques to study the human placental molecular mechanisms that govern the placental functions including their derangements in conditions such as preeclampsia.



Utilizing Nanotechnology During Pregnancy

One of the significant and ambitious research questions is whether these nanoparticles can be used as modes of drug delivery during pregnancy. This can be in the form of targeted drug delivery to specific maternal tissues while minimizing the fetal adverse effects during pregnancy. The existing knowledge on targeted drug delivery for cancer treatment can be extended and applied to the pregnant state to selectively deliver drugs to the placenta and the fetus. These technologies can be then utilized to diagnose and treat congenital conditions during the intrauterine life. Intrauterine gene therapy and immunomodulation are few examples of the potential applications that could be used during pregnancy. Alternatively, these applications can be studied and applied in treating maternal disease conditions such as progressive cancers, diabetes mellitus, coagulopathies, transplant rejection, preeclampsia, and immunological disorders (e.g., asthma, rheumatoid arthritis, systemic lupus erythematosus) during pregnancy. These applications include imaging, diagnostics, monitoring, and theranostics for maternal disease treatments without affecting the fetal growth [8]. Minimizing fetal side effects using the permeability and transfer properties of the placenta and engineering the nanoparticles to suit these barrier mechanisms will lay the foundations for such applications.

Further areas of research for pregnancy-related nanotechnology include the management of subfertility and diagnosis of preeclampsia using serum or placental markers. Novel fine nanoscale sensing mechanisms such as nanoscale biophotonics can be developed for procedures and functions that need nanoscale sensitivity. These include sensors that can be applied in subfertility and in planned pregnancies. Assisted reproductive procedures such as artificial insemination, *in vitro* fertilization, and implantation would benefit from such devices.

Refined Nanotoxicological Studies

The current nanotoxicological studies are limited largely to nonfunctionalized, higher doses of nanoparticles and are aimed at more mechanistic approaches. The actual formulations of nanoparticles that can be utilized in nanomedicine are different and involve tissue-specific

Use of Nanotechnology in Pregnancy, Fig. 1 The future of nanotechnology use during pregnancy. Pregnancy consists of three critical entities (the mother, fetus, and placenta) and is a unique stage where nanotechnology can be used for various applications. The fine balance between these constructive applications (in *green boxes*) and potential maternal or fetal adverse effects (in *orange boxes*) needs to be considered with caution before incorporating nanotechnology in pregnancy (*CV* cardiovascular, *DM* diabetes mellitus, *IU* intrauterine, *NP* nanoparticles, *RES* reticuloendothelial system)

functionalization in realistic doses and formulations. In addition, the adverse effects of nanoparticles during the first trimester are relatively understudied, but critical [18] and should be a main research focus in the future. This also includes the prepregnancy ovum production (starting as early as the intrauterine stage of the female), puberty, fertilization, and implantation stages when the molecular mechanisms can be disrupted or manipulated by using nanotechnology. The contribution of nanoparticles on miscarriages, intrauterine growth restriction, preterm deliveries, and preeclampsia also need to be further studied. These conditions are reported with other toxins and inflammatory conditions. Such adverse consequences need to be excluded before nanotechnology can be applied to the pregnant status. Limited/narrow-scale research and anecdotal evidence on pregnancy-related complications are reported in pregnant mothers working in nanoparticle production facilities. These need to be further confirmed with extensive research on exposed populations.

The unique properties of nanoparticles that are technically constructive such as high surface-to-volume ratio, protein corona, and its evolution within the biological systems also increase their potential for toxicity. These properties make it difficult to assess the risk of nanomedical or nanotechnological products using the current risk

assessment methods particularly during pregnancy in which the maternal, fetal, and placental components are functioning in a complex environment. Pregnancy may be one scenario where the nanotechnology itself can be applied to assess the toxicity of different nanomaterials and other drugs.

Nanoscale technologies are very versatile with many advantageous applications during pregnancy if used with caution. The fine balance between the type, dose, frequency, formulation of nanoparticles, and stage of gestation with the relevant physiological changes will guide to the effective use of nanotechnology in pregnancy (Fig. 1). The effect of nanoparticle exposure on pregnancy stages need to be addressed before releasing any nano-combined diagnostic, therapeutic, or theranostic applications. As with any other cosmetic, consumer, or pharmacological product, teratologic risk assessment is essential with nanomedical applications. These include engineering, mechanistic, preclinical, clinical, and post-marketing monitoring strategies that need to be meticulously carried out prior to applying nanotechnology during pregnancy.

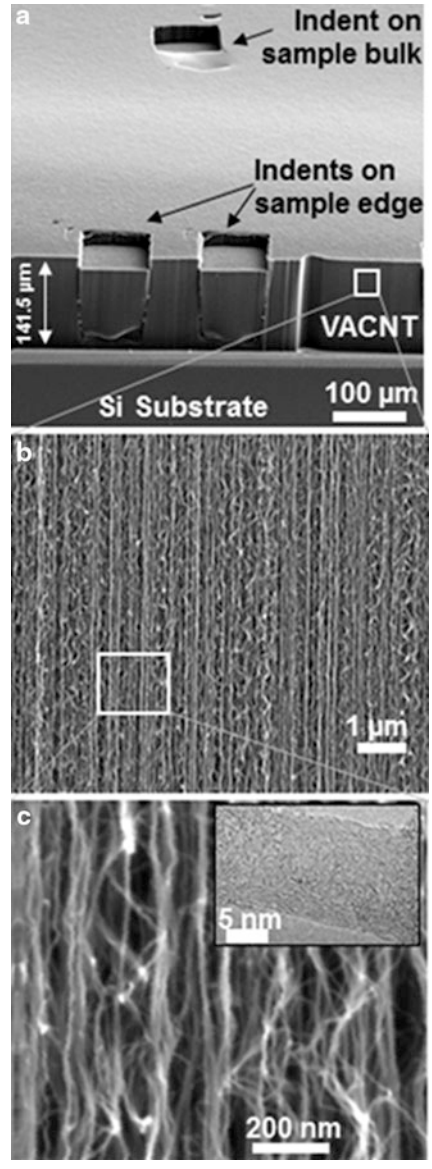
Definition

Vertically aligned carbon nanotubes are complex, hierarchical structures of intertwined tubes arrayed in a nominally vertical alignment due to their perpendicular growth from a stiff substrate. They are a unique class of materials having many of the desirable thermal, electrical, and mechanical properties of individual carbon nanotubes, while exhibiting these properties through the collective interaction of thousands of tubes on a macroscopic scale.

Introduction



While individual CNTs have been announced as the strongest material known and have shown extremely high strength and Young's modulus in tensile tests on individual tubes (see ▶ Carbon Nanotubes), VACNTs are more likely to find use in applications requiring large compliance and deformability. Examples of these include microelectromechanical systems (MEMS) and impact mitigation/energy absorption, where they are promising candidates for their multifunctional nature, wide-ranging thermal stability, well-defined large surface area, and relative ease of manufacture. A proper understanding of the collective mechanical behavior of these structures, especially instabilities leading to buckling and inhomogeneities which weaken mechanical performance, is thus of great importance for their design and success in these and other future applications.

VACNTs are distinct from other CNT structures (see ▶ Nanomaterials) in that the tubes that make up the material grow perpendicularly to the support substrate, making them *nominally*

vertically aligned. An important characteristic all VACNTs share is that the tubes themselves are long enough to become intertwined with each other during the growth process, leading to a highly complex and hierarchical microstructure with distinct organizational details at different magnification levels. This is in contrast to arrays of vertically aligned CNTs that are short and/or sparse enough that each CNT stands alone [1, 2]. Figure 1 shows the complex hierarchical nature of the VACNT microstructure with their distinct organizational details across multiple length scales. Thus, while the VACNT appears as a continuous film at lower magnifications of 260× (Fig. 1a), the nominally vertical alignment of CNTs growing perpendicularly to the support substrate in the VACNT bundle becomes visible at a higher magnification of 30,000× (Fig. 1b). Increased magnification of 240,000× reveals significant intertwining in the long, curved lengths of individual CNTs, revealing the isotropic CNT network [3]. As a result, in their as-grown states, certain segments of the CNT forest appear to be pre-buckled/pre-bent, and the favorable contact energy between the tubes (van der Waals) is thought to balance the bending strain energy of their arrangement, resulting in a stable low-energy configuration. At still higher magnifications (nanometer length scales; see TEM image in Fig. 1c inset), individual, discrete CNTs dominate the mechanical performance with details like CNT diameter, number of walls, etc., governing their deformation. Such hierarchy in the VACNT microstructure governs its overall mechanical behavior, which is a result of not only the properties of individual CNTs but also of their complex mutual interactions and distribution throughout the array.

The method by which these structures are synthesized is the primary factor affecting their complex, hierarchical morphology. This microstructure, in turn, affects their mechanical behavior, in particular the modulus, buckling strength, and recoverability. Synthesis techniques for VACNTs can be divided into two main categories:

Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 1 SEM images reveal the hierarchical morphology of the (**a**) 141.5 μm-thick VACNT films (magnification 260×), which consist of (**b**) nominally vertical aligned CNTs visible at a lower magnification of 30k× and (**c**) a complex intertwined network seen at higher magnifications of 240k×. SEM pictures are taken at a 60 tilt angle. (**c**, *Inset*) Individual-multiwalled CNTs of outer diameter 8.8 ± 2.1 nm (average ± standard deviation) are visible in the TEM image ([4] reproduced with permission)

the chemical vapor deposition (CVD) synthesis method and the carbide-derived carbon (CDC) synthesis method – which relate to the top-down versus bottom-up growth processes, respectively. In the CVD process, the VACNT film is coated onto an existing substrate. This is accomplished by depositing a thin layer of catalyst (e.g., Fe) on the substrate (typically Si or Quartz) and flowing a carbon source (e.g., ethylene) over the substrate at atmospheric pressure and temperatures typically around 750 °C. In the CDC method [5], on the other hand, carbon is formed by selective extraction of the metal or metalloid atoms in the carbide (e.g., silicon carbide) at high temperatures (>1,600 °C), transforming the carbide structure into pure carbon. Since the CNT layer is formed by inward growth, this usually retains the original shape and volume of the precursor.

VACNTs grown by these different techniques demonstrate very different structure and mechanical properties. Even within materials grown via CVD, control of the growth conditions, such as the atmosphere, catalyst activity, and pressure, is known to significantly affect the repeatability of the VACNT's morphology and hence the consistency of mechanical properties [6]. For example, using "floating" versus "fixed" catalysts [7] in the CVD syntheses has been shown to result in vastly different VACNT morphologies. Differences in the growth processes used are revealed in the widely varying VACNT information reported in literature, as seen in the large range in properties in Table 1. This is not to mention variations in tube diameter (from 2–3 nm [8] to 20–50 nm [3] to greater than 100 nm [9]), number of walls in the CNT structure, and degree of tube alignment, properties which are sometimes neither measured nor reported. Further, the different stages of the CNT growth process can result in a height-dependent inhomogeneity [10]. This manifests as a gradient in both the density and the alignment of the tubes within the same VACNT structure. As discussed later in this entry, such a structure gradient may lead to a corresponding strength and stiffness gradient along the VACNT height. As an extreme example of the microstructure-property relationship, CDC-VACNTs are known to have a considerably higher average density (roughly ten times higher than typical VACNTs), due to the conformal transformation of the carbide into carbon. This in turn leads to significantly larger values for the elastic modulus and yield stress in CDC-VACNTs [8] (see Table 1). These promising characteristics, however, are unavailable for applications requiring macroscopic films as currently only VACNTs grown via CVD can reach macroscopic heights (~mm). Growth of CDC-VACNTs remains limited to only a few micrometers in height. Only CVD-VACNTs when used in combination with conformal coating methods, where the CNTs are coated with nanoscale coatings of ceramics like Al_2O_3 [11], amorphous SiC [12], etc. (Table 1), are able to reach a similar level of mechanical performances as compared to the CDC-VACNTs.

Figure 2 highlights four literature examples of the differences in the mechanical response of various CVD-VACNT micro-pillars subjected to compression. Note in particular the higher stiffness and strength of the VACNTs grown using the floating catalyst technique in Fig. 2a [13], as compared to the ones grown using the fixed catalyst method (Figs. 2b [7], 2c [17], and 2d [3]). Other differences between these nominally identical VACNT samples are the ability of some of them to recover almost completely after large compressions (Fig. 2a, c), [13, 17] while others deform permanently even at modest strains (Fig. 2b, d), [3, 21–31].

Figure 2 also demonstrates the similarities in the deformation characteristics of the various VACNT systems. All of the four VACNT systems show three distinct regimes in their stress-strain response – elastic, plateau, and densification – similar to open-cell foams. Unlike foams, however, the plateau region in the VACNTs generally has a positive slope, which can vary significantly between VACNT samples. The slopes of the plateau region were calculated to be 11, 5, and 0.6 MPa for Figs. 2a, c, d, respectively. Note also that all VACNT systems shown in Fig. 2 exhibit a bottom-to-top sequence of buckling.

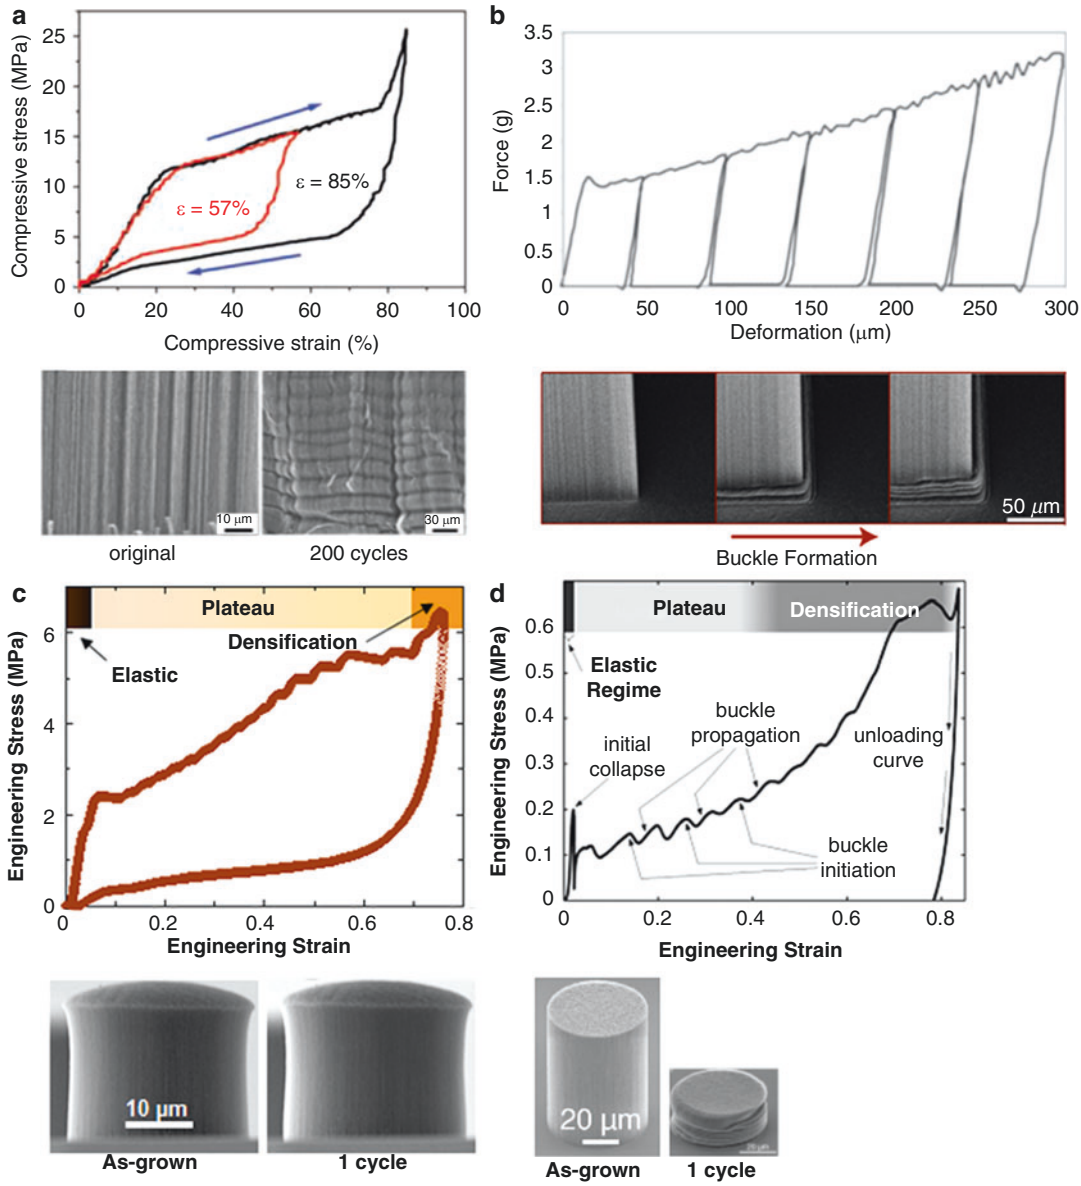
Here the first buckle generally nucleates close to the substrate, and each subsequent lateral collapse event initiates only after the preceding one was completed, thus sequentially collapsing the entire structure [3, 7, 13, 17]. A recent report by [18] has suggested that such sequential bottom-to-top buckling and hardening in stress-strain response are observed in samples with smaller relative density at the bottom. When the density gradient was insubstantial or reversed, a different buckling sequence was observed where the bottom regions were always found to buckle last and a flat stress plateau was obtained.

Experimental Techniques for Studying VACNT Mechanics

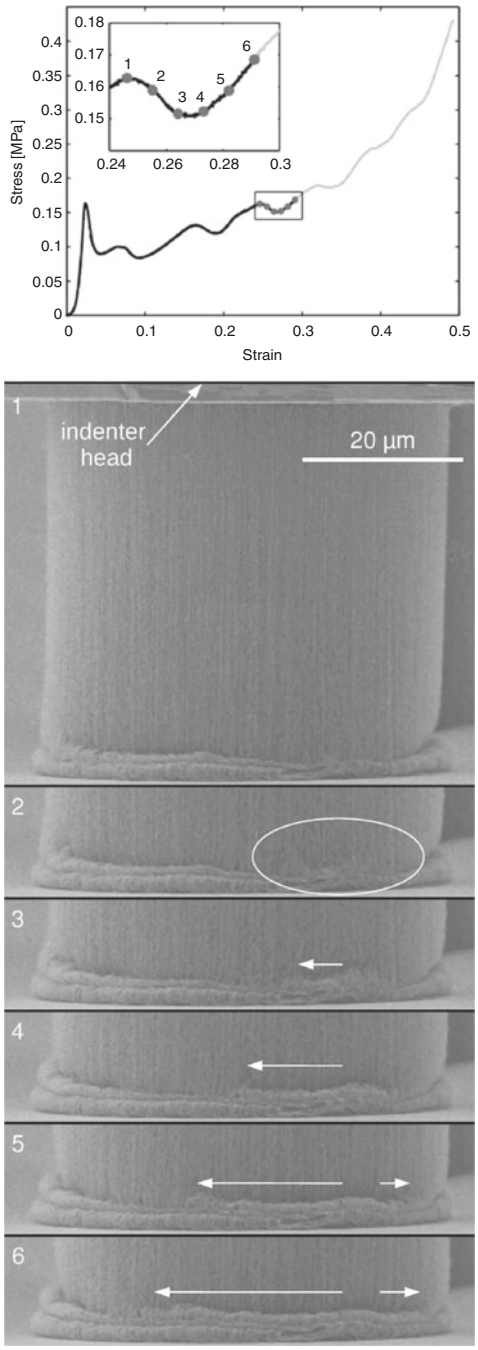
Instrumented indentation, using a variety of tip geometries such as flat punch, spherical, Berkovich, and cube corner, has been the most common method for studying mechanical properties of VACNTs [9]. Each geometry has its own strengths and weaknesses. While maintaining parallel contact between the indenter and the sample is a major concern for flat punch indentation, it does allow for more uniaxial-like, compressive loading. The sharper Berkovich or cube corner geometries can cause the CNTs to bend away from the indenter, testing a slightly different mode of behavior [1, 2, 9]. In both cases, modulus and hardness are measured from the unloading portion of the test. On the other hand, spherical indentation is advantageous in that it allows indentation stress-strain curves to be extracted from the raw load-displacement data, which enables resolution of the evolution of the mechanical response in the VACNT array: from initial elasticity to the initiation of buckling to post-buckling behavior at finite strains [8]. Though indentation is a relatively simple test to perform, analyses of the results, especially nonlinear elastic behavior, are difficult due to their highly localized stress fields. It is also limited in total strain.

Another testing geometry, that of uniaxial compression, eliminates these localized, applied stress fields and helps reveal the existence of a localized deformation mechanism in VACNTs. In these tests, the samples are either large (~1 mm tall) bulk films and compressed between two platens [13] or microscale (up to tens of microns in height) cylinders and compressed using a flat punch indenter [3, 7].



Both indentation and compression tests can be performed in situ, where the load-displacement data is gathered simultaneously with micrographs in an optical or scanning electron microscope (SEM). These tests can offer valuable insights on

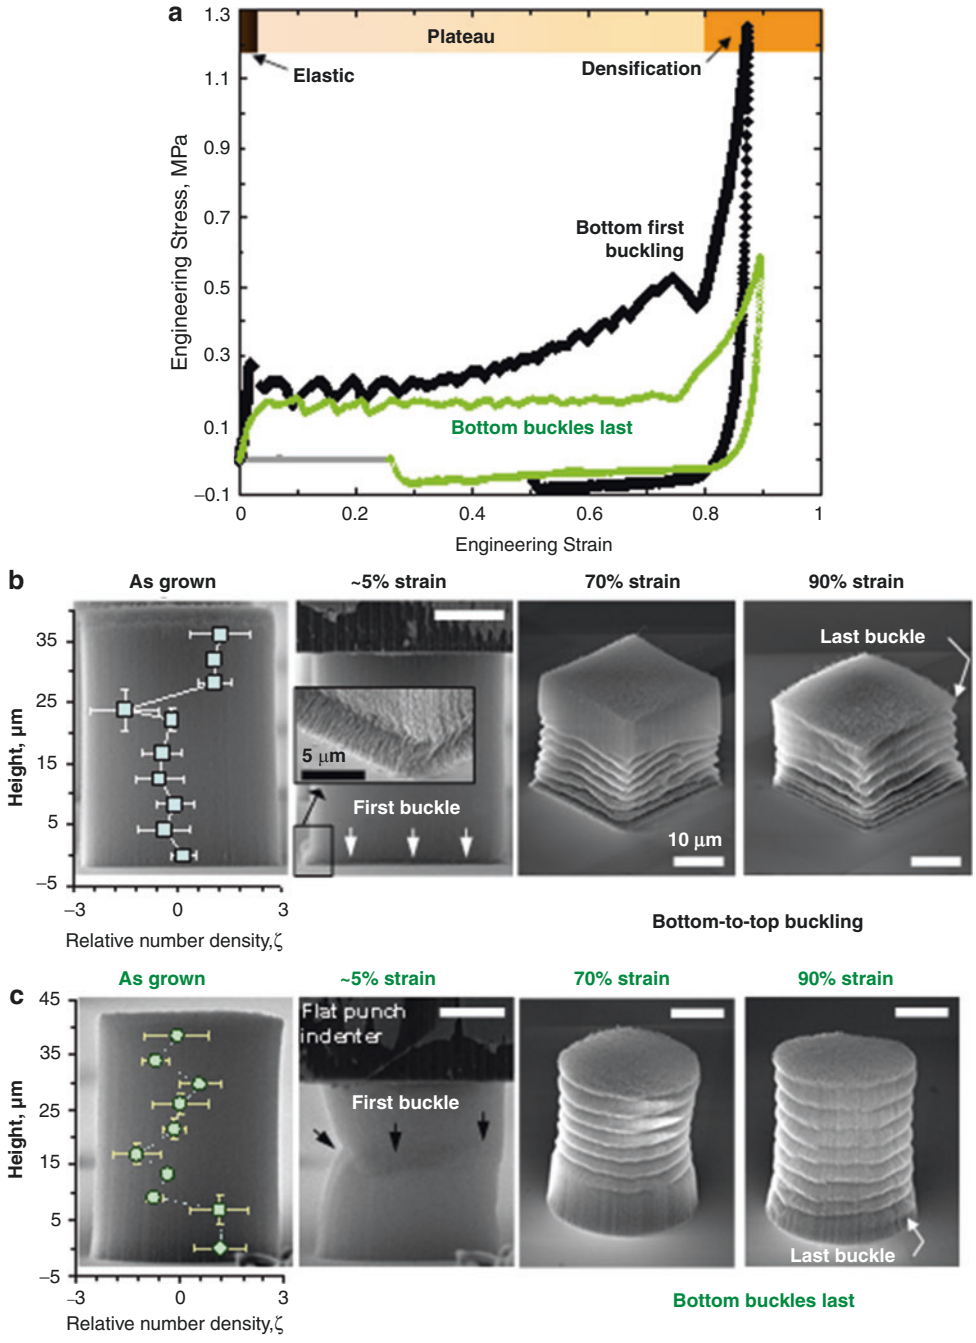
the morphological evolution in the VACNTs during deformation and are discussed in detail in the next sections.



Compression Response Under Large Strain

The deformation of VACNTs is governed by their hierarchical microstructure, collective intertube interactions, and inherent property gradient. Taken as a whole, their highly porous nature gives them an overall foamlike response. The idealized stress-strain response of traditional foams under compression is characterized by three distinct loading regimes: an initial elastic loading at low strain, followed by a plateau in the stress during which the struts bend and buckle, and finally a densification regime in which the space between struts has been nearly eliminated and the material begins to approach behavior intrinsic to the struts themselves. For such a response, it is the intermediate plateau regime that is responsible for the bulk of energy absorption in the material, since the area under this region of the stress-strain curve, corresponding to the work done on the material, is the largest. This foamlike response of a bulk VACNT film is apparent in the three distinctly differently sloped regions of the stress-strain responses shown in Fig. 2. Locally, however, the response of VACNTs is quite unlike that of traditional foams. In VACNTs, the accommodation of strain during uniaxial compression is accomplished entirely through the formation of folds or buckles of small regions of the structure, while the remaining portion remains nearly undeformed. This is in contrast to traditional foams, where cell-edge bending and cell collapse are primarily responsible for the elastic-plastic foam response [32, 33]. The superposition of an overall foamlike response with localized strain accommodation is the key characteristic of VACNT deformation.

Experimental characterization of this buckle formation yields several interesting qualitative results. In their early study, [13] compressed relatively large structures (area, 0.5–2 cm^2; height, 860 μm–1.2 mm) and observed that the buckles formed near the bottom of the structure (the end from which the CNTs grow perpendicularly to the substrate) are more deformed than those that formed near the top (Fig. 2a). Motivated by this observation, they hypothesized that the bottom buckles form first. A reversal of the loading direction, by flipping the sample upside down, resulted in the same deformed morphology, with the tightest buckles forming at what was the end of the sample attached to the growth substrate. These observations point to the idea of an inherent, axial property gradient being responsible for the sequential nature of the buckling. Note that each individual buckle is on the order of 12–25 μm in size (depending on sample height) so that several tens of buckles form during deformation. The sequential, localized buckling phenomenon was later observed in much smaller samples by other researchers (Fig. 2b–d) illustrating the universality of this response in VACNTs. Buckles in these microscopic studies were 12 μm [28] and 7 μm [3] in wavelength (measured from the unbuckled conformation) for cylindrical samples with diameters of 30–300 μm [28] and 50 μm [3], respectively. The bottom-first buckling mechanism was visually verified by [3] through in situ experiments that further revealed the mechanism by which a single, localized buckle evolves. As shown in their study, each individual buckle does not form all at once, but rather nucleates at one point and then propagates laterally across the cylindrical sample until completion [3]. In addition, each subsequent buckle begins only after the previous buckle has completely formed, i.e., the crease had spread across the entire cylinder [3, 7, 13, 17]. Figure 3 illustrates the evolution and localization of deformation for a uniaxially loaded VACNT cylinder. Cross-correlation of the in situ images with the accompanying stress-strain data reveals that the localized buckle formation and propagation correspond to undulations in the nominal stress-strain curve. Specifically, softening corresponds to the first appearance of the buckle and the subsequent hardening coincides with the lateral propagation of the buckle. This localized response overlays the aforementioned overall foamlike behavior seen in these materials.



Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 2 VACNT behavior under compression for (**a**) 860 μm-thick VACNT array (Reprinted from [13] with permission from AAAS), (**b**) 400 μm-diameter CNT column [7] (Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission), (**c**) 30 × 30 μm (diameter × height) VACNT micro-pillar (Adapted with permission from [17] Copyright 2012 American Chemical Society), and (**d**) 50 × 60 μm (diameter × height) VACNT micro-pillar [3] (Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission). All of these VACNT systems show three distinct regimes in their stress-strain response – elastic, plateau, and densification – similar to open-cell foams. Unlike foams, the plateau region in the VACNTs generally has a strong positive slope. All VACNT systems shown here also exhibit a bottom-first sequence of buckling. These VACNT systems differ widely in their ability to recover from large deformations. Thus while both VACNT systems in (**a**) and (**c**) show an almost complete recovery, even after multiple cycles, the VACNT systems in (**b**) and (**d**) do not exhibit any appreciable recovery

Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 3 In situ video micrographs and accompanying nominal stress-strain data illustrating bottom-first buckling and buckle initiation and propagation events [3] (Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission)

Notable differences between the classic foamlike stress-strain behavior and the overall response of VACNTs in uniaxial compression studies of VACNT structures have also been observed in both macroscopic [13–15] and microscopic [3, 21] samples. First, the plateau regime is highly sloped. In typical foams, a sloped plateau indicates some homogeneous variation in strut buckling stress due either to random strut alignment, a distribution of strut sizes (aspect ratio, diameter, etc.), or both. While both kinds of inhomogeneities exist in VACNTs, the plateau regime is too highly sloped to be explained by these small fluctuations. Moreover, the nonlocal nature of the buckling points to an alternate cause. In fact, the sloped plateau regime is suggestive of the presence of an axial property gradient in VACNTs. As discussed previously, a gradient in tube density arises in VACNTs as a result of the CVD growth process. This gradient can be such that there is a lower tube density at the bottom of the structure (i.e., the point at which the substrate attaches) than the top. It follows that such a tube density gradient would result in a corresponding strength and stiffness gradient. This property gradient is evident in the stress-strain responses seen in Figs. 2 and 3 in the progressive increase in peak stress values for undulations in the plateau region. Throughout this plateau, buckles are known to form sequentially, bottom to top, and therefore each subsequent buckle forms at a higher (and more dense) location within the cylinder than the previous buckle, requiring a larger stress in order to form a new fold.

A recent study by [18] has reported a different buckling sequence in VACNTs. In addition to the commonly reported bottom-to-top buckling pattern (where the bottom buckle forms first), these authors also observed VACNT samples where the bottom buckle was instead the *last* buckle to form (Fig. 4c). These experiments were performed on two sets of VACNT micro-pillars, both grown by the same chemical vapor deposition (CVD) synthesis on the same Si substrate but located on different regions of the substrate. In situ uniaxial compression experiments conveyed that the

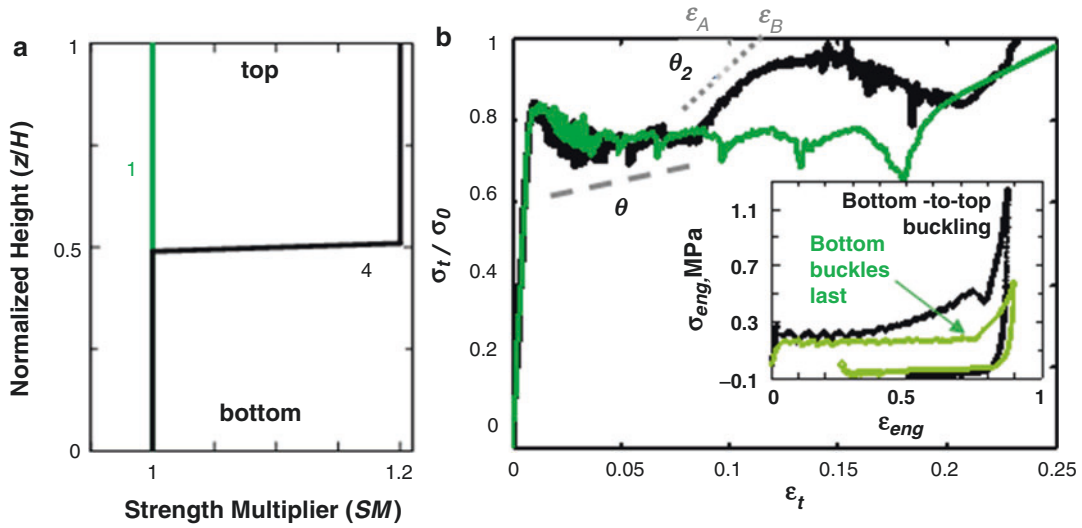
Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 4 (**a**) Comparison of the stress-strain responses of two VACNT pillar systems grown on the same substrate: one showing the commonly reported bottom-to-top buckling sequence where the bottom buckle is the first one to form (**b**) versus the ones where the bottom buckle is the last buckle to form (**c**). (**b**) and (**c**) also show the relationship between the relative tube number density ζ and the sequence of buckle formation in these pillars (Adapted with permission from [18] Copyright 2013 American Chemical Society)

sequence in the localized fold formation was unique for each sample type (Fig. 4b, c). In the first set (Fig. 4b), the first buckling-like instability, which corresponded to the transition from elastic loading to plateau in the stress-strain data, always formed at the bottom of the sample. After initiation, the fold propagated laterally until it fully spanned the pillar width. Bottom-to-top buckling occurred in succession, with each subsequent buckle initiating only after the previous one, located below it, had completed, similar to the observations in [3, 13]. Unloading from maximum compression of ~70 % strain left the top third of the pillar relatively undeformed (Fig. 4b, third panel from left), and the buckle closest to the top always formed last (Fig. 4b, rightmost panel). In contrast, post-compression SEM images of the second set of VACNT pillars, unloaded from the same maximum strain of 70 %, showed that it was the *bottom* third of the pillar that remained relatively undeformed (Fig. 4c, third panel from left). The first instability in these pillars always formed somewhere at their mid-height (Fig. 4c, second panel from left), and the buckle closest to the substrate always formed last (Fig. 4c rightmost panel).

The authors in [18] have suggested that the substantial differences in the deformation responses between the two pillar types shown in Fig. 4 were likely caused by their differing microstructural features and density gradients (the shapes of VACNT pillar cross sections – square versus circular – did not appear to influence their deformation characteristics). In order to capture the density gradients in these two pillar types, the authors used edge detection analysis of systematically obtained SEM images to calculate the average relative number density, ζ, of tubes in each SEM image. Image analysis revealed that the two types of pillars exhibited opposite trends in relative density, which can be used to predict the location of initial buckling instability in a VACNT matrix (Fig. 4b, c). For example, it is reasonable to expect the first folding/buckling event during compressions of VACNTs to originate close to the substrate because of its rigid constraint [21]. Pillars showing a bottom-to-top buckling sequence corroborated this notion (Fig. 4b). These VACNT pillars had highest ζ in the top 10 μm, and their density profiles resembled a step function, where $\zeta \approx 1$ for all locations above the height of ~23 μm and $\zeta \leq 0$ at all locales below. In contrast, the incipient instability in pillars where the bottom buckles formed last occurred somewhere in the middle of pillar height, at the locales with the lowest relative CNT density (Fig. 4c). Maximum ζ in these pillars was located in the bottom ~10 μm, close to the substrate, while the minimum ζ was in the midsection of the pillars. It appears that the lower relative density trumps the constraining effects of the substrate in driving the location of the buckling instability in these pillars. The last buckles in both sets of pillars occurred in the regions with the highest relative CNT densities: near the top in the samples showing bottom-to-top buckling sequence and at the base in the ones where the bottom buckles formed last.

In addition, these two pillar types also show some key differences in their stress-strain response (Fig. 4a). The stress plateau in the pillars showing bottom-to-top buckling had two separate slopes: a relatively flat section up to 30 % strain and a steeper region, with the slope of 0.65 MPa up to unloading at 75 % strain. In contrast the pillar set where the bottom buckles formed last had a nearly flat plateau (slope ~ 0.02 MPa) up to a strain of 75 %. There was also a noticeable difference in the amount of recovery between the two sample types when unloaded from post-densification regime: pillars showing bottom-to-top buckling ($R \approx 57.9 \pm 0.9$ %) showed an almost 45 % higher recovery than those where the bottom buckles formed last ($R \approx 39.8 \pm 3.9$ %).

It has been suggested that such differences in the compressive responses of VACNTs can be predicted based on their local variations in density along the VACNT sample heights. Such property dependence was initially modeled by [3] in a viscoplastic finite element framework which showed a direct correspondence between the presence and extent of an applied property gradient and the amount of hardening within the plateau.



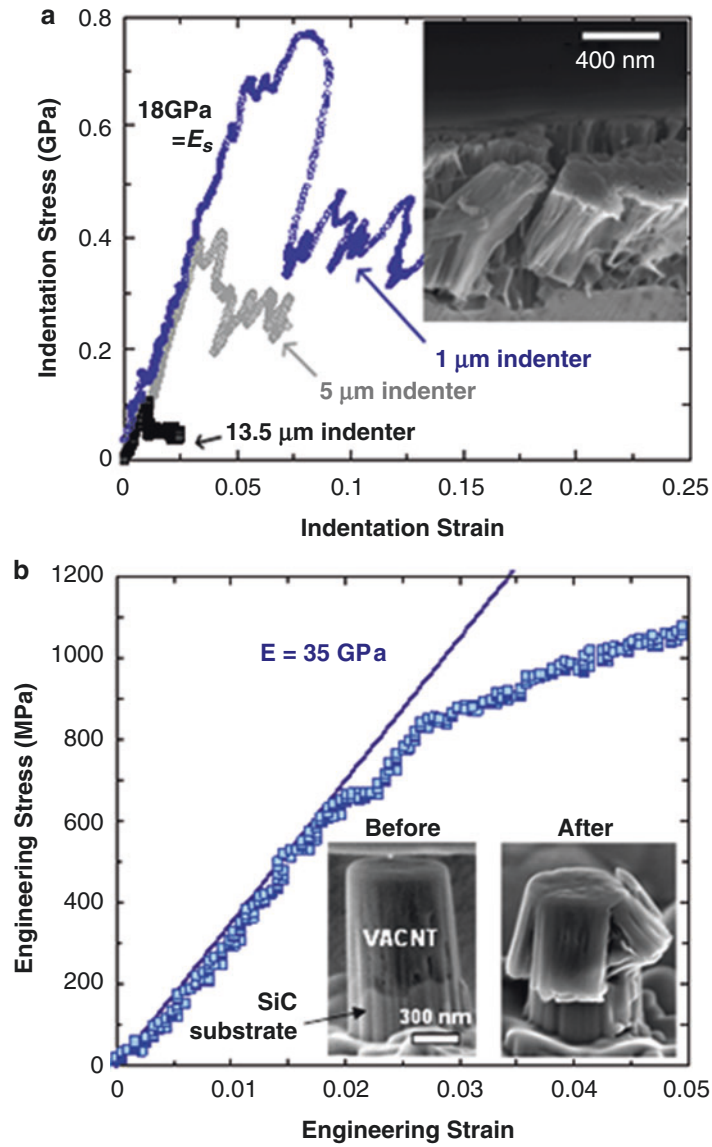
Details of this and other efforts to capture VACNT deformation mechanisms through modeling are summarized in the next section.

Modeling of VACNT Deformation

Only a few preliminary models exist to describe the mechanical deformation of VACNTs. Motivated by both the morphology of the VACNTs (a series of nominally vertical struts) and the observed buckling behavior, many researchers utilize an Euler buckling framework to mechanistically describe their findings. In Euler buckling, an ideal column (perfectly straight, homogeneous, and free from initial stress) is determined to buckle when the applied load reaches some critical value that causes the column to be in a state of unstable equilibrium. Up to the point of buckling, the column is assumed to be perfectly elastic. Scaling calculations by [13] utilize this critical stress to estimate the transition stress value for departure from linear elastic behavior, i.e., the buckling stress, given a reasonable estimate of the tube number density. Similarly, [25] included an additional intertube contact energy to account for favorable van der Waals interactions between tubes in their energetic treatment of VACNTs. Another Euler-based model by [21], motivated by the formation of buckles they observed, proposes piecewise buckling that assumes the top of the pillar deforms via simple shear while the bottom undergoes collapse. Using this framework, they predict that the buckling stress increases asymptotically with decreasing pillar height (for similar aspect ratio pillars). Notably, however, none of these models make predictions concerning the length scale of the buckles formed or their dependence on material parameters such as density, stiffness, tube alignment, or size as the parameter space is difficult to grow in these materials.

Another subset of mechanical analyses utilizes an alternating hardening-softening-hardening local constitutive relation and is the only theories that attempt to capture material response beyond the initial buckling event. The first, a hierarchical bistable spring model, captures the *quantitative* stress-strain response of VACNTs in compression [33]. A subsequent finite element viscoplastic solid with a positive-negative-positive sloped flow strength captures the *qualitative* sequential periodic buckle morphology. The bistable spring model consists of mesoscale elements characterized by elastic-plateau-densification and, most importantly, hysteresis in the unloading curve. These mesoscale elements were shown to be the limiting case of infinitely many bistable spring elements in series. Briefly, a bistable spring consists of two thermodynamically stable elastic loading sections separated by an unstable, negative stiffness region of the stress-strain curve across which the material snaps, similarly to a phase transition. When placed in series, these mesoscale elements capture the hysteretic unloading response seen by [13] very closely. Thus, this model can be utilized to characterize the energy dissipation in VACNTs. In a similar vein, [34] postulate a positive-negative-positive stress-strain relation reminiscent of a bistable spring, but rather than being elastic, it is used as a plastic flow strength function governing the local deformation of an element post-elastic loading. The latter analyses find that this constitutive relation is capable of producing sequential, periodic buckles in an axisymmetric, circular cylindrical mesh with fixed boundary conditions at the base, identical to those in VACNTs. In addition, an axial gradient in the strength is not necessary to initiate bottom-first buckling, as seen in experiments; rather, the fixed boundary conditions are sufficient. However, a reversal of buckle initiation, top to bottom, can be achieved for a sufficient inverse axial gradient (having lower strength at the top of the pillar than the bottom). Both of these analyses capture essential elements of VACNT deformation, but do so for two very different sets of experimental observations: recoverable deformation and plastic deformation.

An example of the approach proposed by [34] is shown in Fig. 5. Here the same model was utilized to predict the stress and strain responses of the two VACNT pillar types shown earlier in Fig. 4, assuming the stiffness of VACNTs to be linearly related to its density, $E \sim \zeta$.



Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 5 (**a**) Two variations of the *SM* (strength multiplier) function used for simulations: Case 1 (constant *SM* function, *green curve*) versus Case 4 (step variation of the *SM* function over the pillar height, *black curve*). (**b**) Corresponding normalized stress-strain curves for these two cases. Note that the plateau region in Case 4 can be further subdivided by two distinct slopes, θ_1 and θ_2. (**b**, *Inset*) Experimental uniaxial stress-strain responses of the two VACNT pillars shown earlier in Fig. 4 showing the similarity in their responses as compared to the two simulation cases in (**a**) (Adapted with permission from [18] Copyright 2013 American Chemical Society)

The mechanical property gradient was represented by a strength multiplier, *SM*, which is a multiplier giving the spatial variations of E (Young's modulus) and σ_0 where $SM = E/E_{\text{bottom}}$ and similarly for σ_0. Two particular cases are of interest (which matches the experiments most closely): Case 1, *SM* is constant throughout the pillar height, and Case 4, *SM* has a step increase at the midpoint of the pillar height, i.e., at $z/H = 0.5$, where z is the coordinate along the pillar height. Strength gradients over the height in terms of *SM* for the two cases considered are shown in Fig. 5a, and normalized stress-strain data are shown in Fig. 5b. Of special note is the similarity between the experimental and simulated stress versus strain relationships (Fig. 5b inset) in these two cases – such as the flat plateau region for a constant *SM* function (Case 1), similar to the experimental case where the bottom buckles form last, as compared to the two different hardening slopes observed for the step function in *SM* (Case 4), similar to the experimental case of bottom-to-top buckling.

Carbide-Derived Carbons (CDC) VACNTs

While most of the previous sections in this chapter have focused on CVD-VACNTs, VACNTs prepared by the carbide-derived carbon (CDC) synthesis method also deserve special mention. As discussed earlier, CDC-VACNTs refer to a bottom-up growth process, where carbon is formed by selective extraction of the metal or metalloid atoms in the carbide (e.g., silicon carbide) at high temperatures (>1,600 °C), transforming the carbide structure into pure carbon. It has been shown [35] that high-temperature decomposition of SiC by the reactions SiC → Si (g) + C, SiC + 1/2O_2 (g) → SiO (g) + C, leads to the formation of CNTs growing normal to the carbon-terminated $(000\bar{1})$ C-face of hexagonal SiC with primarily zigzag chirality [36] and graphite growth on the Si-terminated (0001) Si-face. These carbide-derived carbon (CDC) nanotube brushes have been shown to have a density close to 0.95 g/cm^3 [37], which is significantly (ten times or more) higher than in catalytic

Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 6 (**a**) Indentation stress-strain response on 1.3 μm-thick CDC-VACNT brush as a function of indenter size (radius) showing an initial elastic behavior followed by the buckling instability (Reproduced from [8] with permission from Elsevier). (**b**) Uniaxial compression of a CDC-VACNT micro-pillar of diameter ~600 nm. The *inset* images show the VACNT micro-pillar before and after compression (Reproduced from [27] with permission from Elsevier)

CVD growth of any kind of nanotubes. This higher density is generally thought to be due to a conformal transformation of SiC into carbon. These dense CDC CNT brushes consist of small-diameter (1–3 nm outer diameter, one to four walled) non-catalytic CNTs with double-walled CNTs being the most common, as determined from transmission electron microscopy (TEM) and a strong RBM mode in Raman spectra [37]. Assuming an average outer diameter of 3 nm and 0.35 nm as the intertube distance, this would correspond to an aerial density of ~100,000 tubes per μm^{-2} for a hexagonal arrangement of CNTs and ~89,000 tubes per μm^{-2} for a square arrangement. The actual aerial density of the CNTs packed randomly in a dense brush is likely to be somewhere in between.

The higher density of these CDC-VACNT brushes is evident in the SEM image in Fig. 6a inset of the CNT brush grown at 1,700 °C, where no apparent porosity is visible. Such dense VACNTs are ideal for indentation testing using

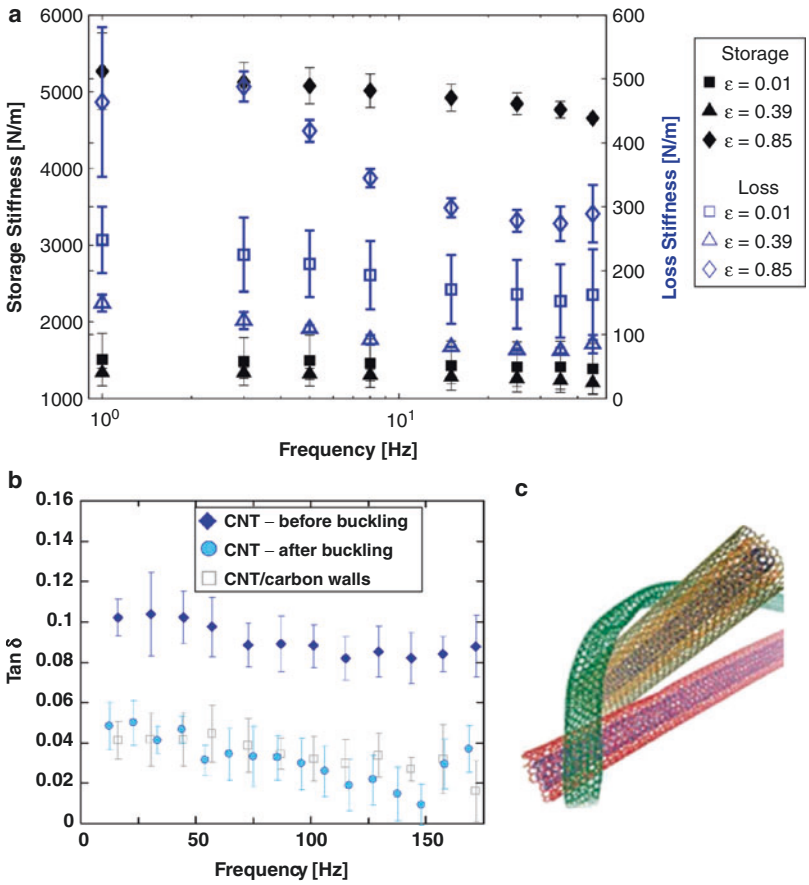
smaller spherical indenters, something that is not possible for the wider spaced CVD-VACNTs (where the CNTs tend to simply bend away from the indenter). The use of spherical indenters is also advantageous in that, by using appropriate data analysis protocols [27, 38], the extracted load-displacement data from these tests can be transformed into meaningful indentation stress-strain curves. The indentation stress-strain curves in turn enable one to follow the entire evolution of the mechanical response in the VACNT array, from initial elasticity to the initiation of buckling to post-buckling behavior at finite plastic strains. In addition, the indentation stress-strain curves also allow one to estimate the Young's modulus and the stress at buckling in the indentation experiment. For example, using a 1 μm spherical indenter, the Young's modulus of 200 nm-thick CDC-VACNT brushes was estimated to be ~17 GPa, and the critical buckling stress was estimated as ~0.3 GPa at a load of 0.02 mN [8].

The authors in [8] also used indentation stress-strain curves from different indenter radii to explore the effects of indentation zone sizes and the material defect density on the VACNT buckling stress. This is shown in Fig. 6a where the indentation response on a thicker VACNT brush (thickness 1.2–1.4 μm; see Fig. 6a inset) is shown as a function of three different indenter radii. In general, all three indenter sizes show a similar trend in the VACNT response: an initial elastic behavior (Young's modulus ~18 GPa), followed by a sharp drop at a critical stress corresponding to CNT buckling. Note however that the values of buckling stresses vary significantly between the three different indenters, where indentation with the smaller 1 μm indenter shows the highest buckling stress, followed by the 5 μm indenter, while buckling with the largest 13.5 μm indenter occurs at a significantly lower indentation stress.

Such differences in buckling stresses can be understood by a closer analysis of the indentation zone sizes between the three indenter radii used. The indentation zone sizes at buckling for the larger 13.5 μm indenter (~3.58 μm) extend well beyond the VACNT brush thickness (1.2–1.4 μm), while only a limited thickness of the VACNT brush (~0.39 μm) is exposed to indentation stress for the smaller 1 μm indenter. The corresponding differences in buckling stress are thus largely a consequence of the effective buckling length available in each case; with smaller indenters, there is only a smaller buckling length and the material is able to withstand higher buckling stresses. Interestingly the authors in [8] also report a larger variation in the values of the buckling stress for the small 1 μm radii indenter as compared to the larger indenters. These values seem to indicate that defect density varies from one location to another in one VACNT brush. Thus the smaller volume sampled by the 1 μm indenter is more sensitive to the variation in defect density when different regions of the sample are probed and causes a larger spread of the buckling stress values when using this indenter. The larger indenters, on the other hand, encounter a bigger volume, and hence they mostly register a combined VACNT-defect response leading to a lower buckling stress and a smaller spread in the buckling stress.

The above results have been validated by conducting compression tests on VACNT micro-pillars machined using a focused ion beam (FIB) on the same sample. This is shown in Fig. 6b which shows the uniaxial compression data for a ~600 nm-diameter VACNT pillar. As seen from this figure, the values measured from indentation and compression tests are complementary to one another. The increase in the Young's modulus values in the micro-pillar compression tests (~30 GPa as compared to ~17–18 GPa in indentation) is due to ion beam irradiation during the micromachining process using FIB. This modifies the structure of the outer rim of CNTs in the VACNT pillar, which potentially results in intertube bridging between the densely packed CNTs and hence an increase in their Young's modulus [39].

These numbers suggest that these CDC-VACNT brushes perform significantly better and exhibit considerably higher mechanical properties compared to CVD-VACNT turfs; CDC-VACNTs have values of Young's modulus one to two orders of magnitude higher [25] and buckling strengths several orders of magnitude higher [1, 2] compared to a CVD-VACNT turf – a difference which is explained by the much higher density of the



tubes per unit area in the CDC-VACNT resulting in considerably higher mechanical properties. These higher properties are of extreme importance for making selective CNT membranes for gas or liquid filtration/separation or CNT coatings for tribological applications.

Viscoelasticity

In addition to their distinctive buckling behavior and their ability to recover from large deformations, VACNTs have also been reported to demonstrate another case of extreme mechanical performance – a unique viscoelastic response that spans a truly wide temperature range from −196 to 1,000 °C – something no other material has shown so far. Viscoelastic materials exhibit both viscous and elastic characteristics when subjected to load. Thus, a viscoelastic material is able to both dissipate energy through viscous behavior (as in honey), while storing energy through elasticity (as in rubber band). The stress-strain response of viscoelastic materials is typified by hysteresis in the loading-unloading cycle.

Viscoelastic behavior in a material is generally characterized in terms of its loss (E'') or storage modulus (E') (or by the ratio, known as $\tan\delta = E''/E'$, of these two moduli). E'' relates to the amount of energy dissipated, while E' represents the stored energy in the material. The angle δ is the phase lag between the oscillatory load and displacement responses under a sine wave load. In a typical experiment, the material is loaded to a predetermined strain and the mechanical probe is oscillated across a range of frequencies. By measuring the resultant load amplitude, displacement amplitude, and the phase lag during the test, the values of loss modulus, storage modulus, and tan δ are determined. Similarly, viscoelasticity can also be quantified by the memory or hysteresis effects during load-unload cycles under deformation, where the energy dissipated is given by the area of the hysteresis loop. These viscoelastic effects have recently been documented in the highly intertwined random networks of VACNTs. Viscoelasticity in CVD-VACNTs has been demonstrated by [3], where both storage and loss stiffness were studied in a frequency range from 1 to 45 Hz at different strain levels (Fig. 7a). Note that these stiffness values are proportional to moduli given a known Poisson's ratio which is lacking for VACNTs. The elastic response is clearly frequency independent, indicating that the VACNT's elastic deformation is likely due to the same mechanism (likely tube bending) over the range of timescales tested. As shown in Fig. 7a, more energy is dissipated (higher values of loss stiffness) at larger strain levels when a higher fraction of the VACNT pillar has buckled. Interestingly, for the more dense CDC-VACNTs, the opposite seems to be true (Fig. 7b). For the highly dense CDC-VACNTs, [8] have shown a significant drop in the tan δ values of the CNTs after buckling, i.e., when the material was highly compacted. These observations indicate that while an increase in density can significantly increase the viscoelastic behavior of CNTs, there appears to be a cutoff beyond which the contacting CNTs became increasingly bundled resulting in a decrease in their ability to dissipate energy.

A recent report by [26] also suggests a rubber-like viscoelastic behavior in a random network of long, interconnected, and tangled CNTs, similar in many ways to VACNTs but significantly less aligned, over a very wide temperature range – from −196 to 1,000 °C – with a possibility of extending this behavior beyond 1,500 °C. While the oxidizing nature of carbon may limit the application of these materials to only vacuum or protective (reducing) environments, CNTs are nevertheless the only known solids to demonstrate such behavior at extremely low or very high temperatures. The authors attribute the reversible dissipation of energy in CNTs over this remarkable range to the zipping and unzipping of the CNTs upon contact (see Fig. 7c) caused by the van der Waals interactions. In this instance, "reversible" means that beyond a critical strain, the zipping/unzipping process was no longer possible everywhere as more and more tubes become permanently entangled at higher strain. This would lead to a loss in their viscoelasticity, similar to the observations in the highly dense CDC-VACNTs (Fig. 7b).

(**c**) Atomistic modeling image of a possible entangled arrangement of single-, double-, and triple-walled CNTs leading to their rubberlike viscoelastic behavior (Reprinted from [41] with permission from AAAS)

The unique combination of superior mechanical properties and the ability to dissipate energy during deformation are expected to have significant implications in damping applications utilizing VACNTs. These, combined with the wide temperature range of its viscoelastic behavior, make VACNT-based materials a promising choice for use in mechanical applications under extreme temperatures or temperature gradients. Possible environments range from the cold of interstellar space to down-to-earth viscoelastic applications, such as MEMS devices to high-temperature vacuum furnaces.

Applications

Multiwall carbon nanotubes are well known for a variety of exceptional properties. These include a high tensile modulus, on the order of 1 TPa; high strength, on the order of tens of GPa; high thermal conductivity; recoverability after large bending angle deformation; and a range of electrical properties depending on the chirality of the graphene walls. For these reasons, they are currently the subject of a wide range of research. In the form of VACNTs, these individual tube properties may be significantly altered by the collective interaction of thousands of tubes. Several applications of VACNT structures currently under study rely on the mechanical behavior described earlier in this chapter. A remarkable but incomplete list includes components of highly compliant thermal contacts for microelectromechanical systems (MEMS) and microelectronics [6, 21], dry adhesives, thermally robust energy-dissipating rubber [26, 40], and energy absorption or impact mitigation [41]. Other applications, such as optical coatings and cold cathode arrays, may rely less on the

Vertically Aligned Carbon Nanotubes, Collective Mechanical Behavior, Fig. 8 Ashby plot of loss coefficient versus modulus showing the performance of VACNTs

mechanical properties for optimization and design, but understanding is still necessary for evaluation of robustness and in-use lifetime analysis.

We go through each application briefly to highlight the VACNT-specific mechanical behavior of interest. First, thermal contacts for delicate electronic devices have two requirements. They must be highly thermally conductive and make conformal contact (to increase heat transfer) while avoiding damage to the components they are transferring heat to and from. CNT foams are ideal for this application due to the high compliance that comes from the reduced load capacity of the CNT struts as they buckle. Dry adhesive applications of VACNTs take advantage of the hierarchical structure which can, as desired in MEMS switches, make conformal contact to surfaces at a variety of roughness length scales, thereby increasing the attractive interactions between the tubes and the surface. Third, energy-dissipating and energy-absorbing applications require more in-depth knowledge of the deformation mechanism. As mentioned in the previous section, energy dissipation is currently thought to be due to tube zipping/unzipping or tube-to-tube sliding and rearrangement [8, 14, 25, 26, 40], while energy absorption is certainly maximized during buckle formation. Future applications may be able to take advantage of yet undiscovered traits of the incompletely characterized VACNTs.

Summary and Outlook

Although the mechanisms governing VACNTs collective mechanical behavior are still largely uncharacterized, the special properties of multiwall carbon nanotubes combined with the complex interactions that arise between them in the hierarchical VACNT microstructure have generated significant research interest. Their wide range of properties, mechanical, electrical, and thermal, make them ideal candidates as multifunctional materials, particularly for applications in which soft materials (such as polymers) have traditionally dominated. Notably, VACNTs occupy a unique niche among engineering materials as shown in the Ashby property chart in Fig. 8 with the ability to span a wide range of properties given a tunable microstructure. There remain two major hurdles to rationally designing VACNTs for any application: control of the CNT growth process and understanding of the relationship between the microstructure and mechanical response. These hurdles are interrelated through the fact that the design space cannot be systematically probed until the microstructure can be systematically controlled. Mastery of these unknowns will not only further VACNT's place as novel materials in the current applications under study, but may reveal previously undiscovered behaviors in microstructures yet to be created or characterized.

Synonyms

Landmark detection; Key point detection

Definition

Animals are frequently required to navigate accurately from one location to another. The means an animal uses to perform a navigational task depends on the available environmental cues, their specific sensory systems, and particularly whether they are in a familiar or unfamiliar area. A *familiar area* can be defined as one of which the animal has extensive experience, leading to detailed knowledge of the environment and available navigational cues.

Waypoints are geostationary locations used by an animal to navigate in a familiar area. Specifically they are small-scale regions of space that the animal returns to as part of the navigational task. A waypoint may be associated with a memorized *landmark* which allows the animal to identify the waypoint from a distance and direct itself toward it. Navigation toward an eventual goal may involve visiting an ordered succession of waypoints finishing at the final location – this mechanism is generally referred to as *pilotage*. Alternatively waypoints may be a by-product of navigational constraints imposed by the environment; if, for example, the goal can be reached only by passing through a narrow passage, that passage will act as a waypoint.

While waypoints may be associated with landmarks – recognizable sensory features such as prominent visual cues or memorable odors – the task of waypoint detection is not in general synonymous with landmark detection. Landmarks may be identified and used by the animal at a distance, without necessarily visiting the landmark's true location. Conversely, as noted above, a waypoint may exist independently of any memorable feature. Instead, waypoints are more accurately defined as importance regions of space and segments of movement paths, whose salience may be the result of a variety of cues and constraints, which cause discernable effects upon the animal's movement.

Waypoint detection is the task of identifying waypoints from observations of the animal's movements. Since the definition of a waypoint requires the animal to return to the specific area,

DOI 10.1007/978-94-017-9780-1

this therefore constitutes a classification task, identifying the segments of the animal's movement trajectory, or *path*, that correspond to waypoint locations. This entry gives an overview introduction to the purpose and methods of waypoint detection, examining three methods for isolating particularly salient elements of movement paths.

Purpose

The principle purpose of detecting waypoints is to understand what drives and facilitates navigation. It is a way of identifying important areas which may contain salient information the animal uses to recall a memorized path or important resources the animal must utilize. Examples of this might include visually striking features, high food concentrations, or unseen constraints on the animal's movement (strong wind patterns acting on flying creatures, for instance). Waypoint detection can be useful for biomimicry, allowing both an understanding of how animals use key features to navigate and replication of this process in artificial navigating agents such as robots.

In the literature, waypoint detection has been used as the basis for understanding which features animals attend to in the landscape [6, 7, 10], determining the extent of an animal's knowledge of the area [5] and determining where animals forage [1, 4]. The technique of isolating important regions of the path for further analysis is a basis for linking animal movement behaviors and the surrounding environment, such as the landscape, sensory cues, and other animals, by determining what the environmental conditions are in the spatial and temporal vicinity of the detected waypoints.

Three Methods for Detecting Waypoints

Specific identification of waypoints from recorded animal movements is a novel task, and there are consequently few formalized examples in the scientific literature that deal explicitly with this problem. However, the likely existence of waypoints in specified regions of space is implicit in several analyses of movement paths. The three principle methods for identifying these spatial regions can be broadly classified as:

- Localized variability *between* multiple movement paths – *Path similarity*
- Changes in speed and direction *within* a single path – *Path complexity*
- Information content of a path segment – *Path predictability*

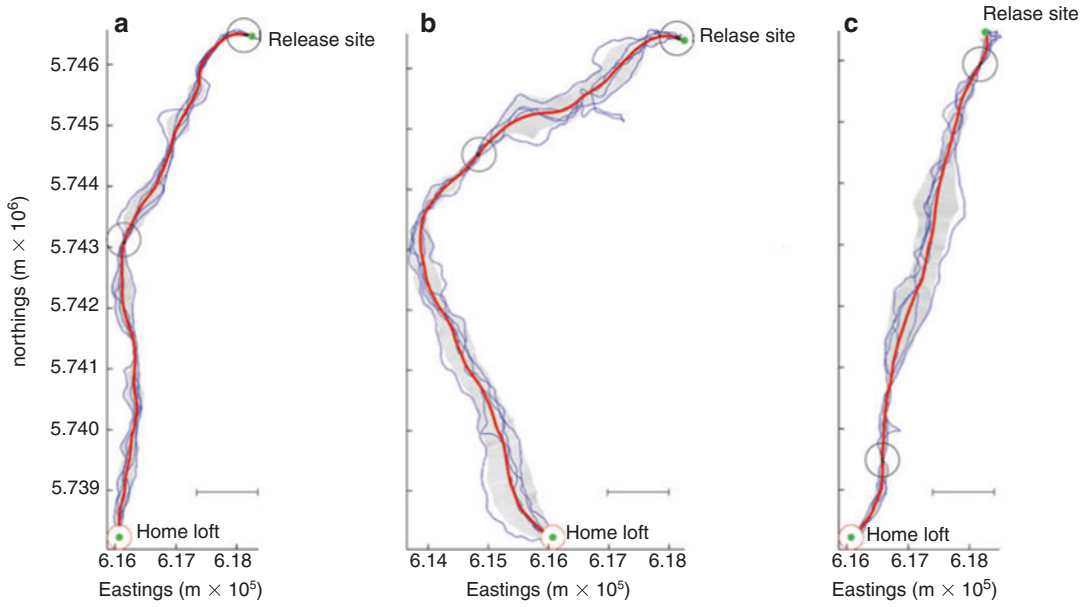
This entry describes these methods largely in the context of experiments on homing pigeons, where the use of global positioning satellite (GPS) devices has created a huge amount of data calling for novel analysis. This has led to the development of methods for path analysis, which are generalizable and applicable to movement paths from other species.

Path Similarity

Path similarity presents an intuitive method for waypoint detection. The principle property of a waypoint is that it is a *restricted* region of space which the animal will pass through on its way to the objective. A waypoint therefore is likely to present itself as a relatively small region of space to which the animal repeatedly returns. In this case it is likely, though not guaranteed, that the movement paths of the animal will be significantly more similar in the vicinity of the waypoint, since their freedom to vary is constrained, than outside these regions where the animal's movements may vary more widely. Increasing path similarity over time has been linked to the emergence of detailed visual memories of the landscape and the use of pilotage as a navigational strategy [2, 3, 12].

To use path similarity objectively requires an algorithmic measure of the variability between different paths. To identify specific regions of space demands a *localized* measure – one that varies through space – rather than a *global* measure which relates the overall similarity of the paths. Here several options present themselves. None can be considered the sole correct way to

measure variability, nor are these options exhaustive. Different measures of variability are necessarily highly correlated but the specific choice depends on the exact nature of the analysis. The basic principle is to measure the spatial separation between paths within some localized region. For this purpose it is helpful to define the concept of the *nearest-neighbor distance* (NND). This is the distance from a point on one path to the closest point on another. Using this distance allows the path separation to be determined in a purely spatial manner. The alternative approach of measuring the distance between paths *at the same point in time* measures a spatiotemporal separation. Ordinarily it is purely spatial separation that best describes the expected effect of waypoints.



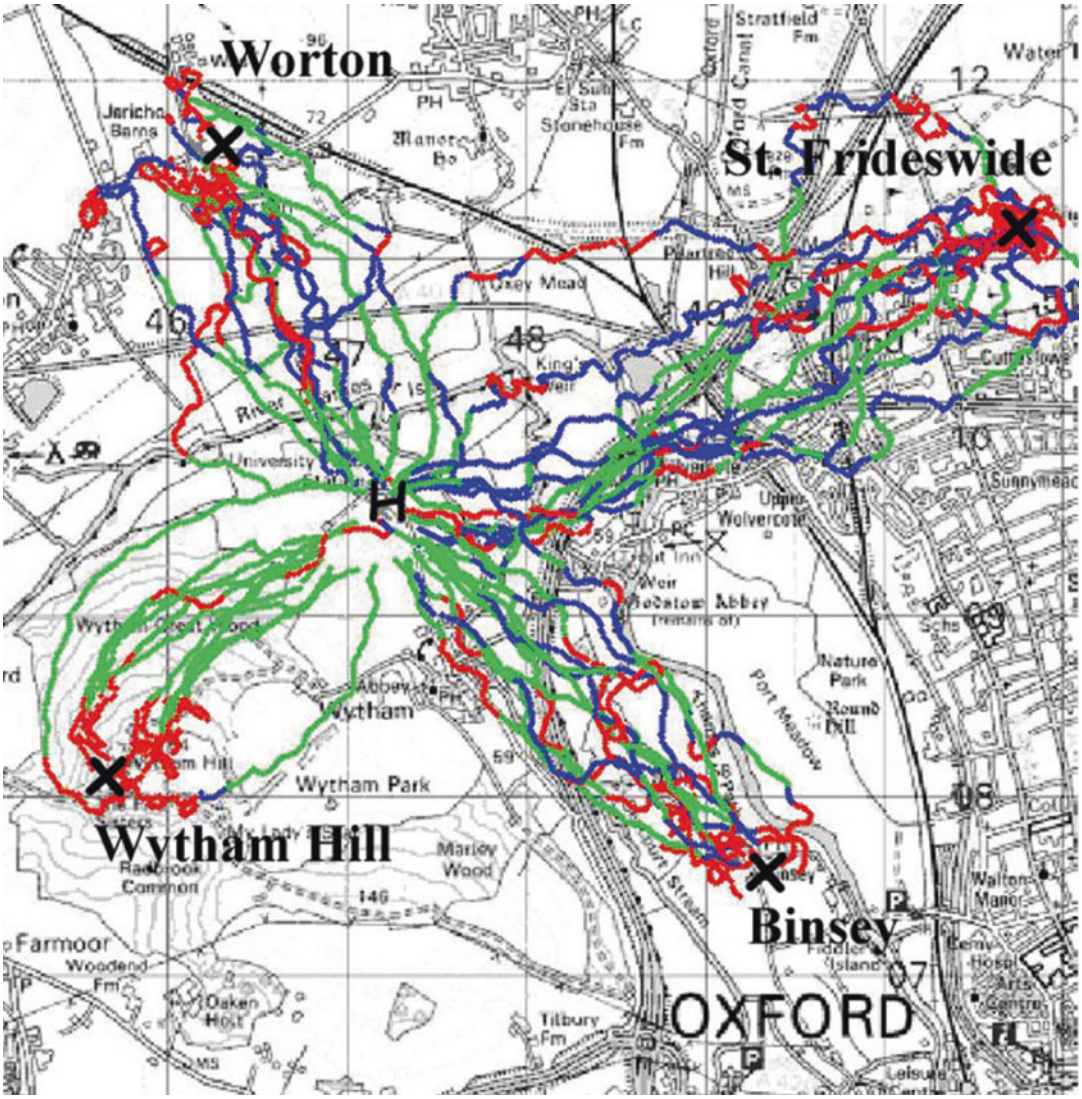
A simple means of calculating path separation is to measure the NND from every point on a path to every other path. The value of the separation can then be taken as the mean, median, minimum or maximum of these values as desired, giving a value for separation at every position along the path. This provides a measure of separation along each path, but not a single description of the overall separation of all the paths as a single variable, which may make it difficult to identify single points where variation is low. This may be ameliorated by the fact that areas where the separation is low will also be areas where the paths are very close, so regions of low variability will be spatially restricted.

It is also possible to measure a single value of separation, using variation around a constructed *mean path*. A mean path is a single path that is representative of the full set of paths. As with path separation there is no absolute way to construct such a path. In analogy with the mean of a set of scalar variables, a mean path can be constructed to minimize a particular measure of separation relative to the original paths, much as the scalar mean minimizes the square distance between itself and the original variables. This approach is used, for example, by Freeman et al. [5], where a mean path is generated which minimizes the total nearest-neighbor separation from itself to the true paths. Constructing such a path may require an iterated approximation method rather than a direct calculation. See Fig. 1 for examples of constructed mean paths and mean path similarity in relation to the original paths. Similarly to the case where path similarity is calculated along each route, the mean path will be most representative of the true paths in regions of peak similarity, which correspond to waypoint locations. Therefore, having calculated similarity along the mean path, one can be sure that the waypoints identified from this similarity will be in approximately the correct spatial location.

A related approach is that used by Lipp et al. [8], for investigating the propensity of pigeons to follow roads and other linear features. Here the spatial area containing the paths is segmented into a two-dimensional grid. The number of paths passing through each grid element is recorded and compared with a null hypothesis for the distribution of paths (see [8] for an example of generating an appropriate null hypothesis). In the original paper, the analysis demonstrates that grid elements containing roads also contain significantly more paths than expected. The converse argument can also be applied – grid elements containing more paths than expected (judged by some significance test) are likely to contain waypoints. The disadvantage of this method is the difficulty in striking a balance between the size of the grid and the density of paths. If the grid elements are too small there will be few paths in any single element and it will be impossible to distinguish from the null hypothesis. If the grid elements are too large, the resolution will be limited to the size of the element, making it difficult to pinpoint the location of the waypoint accurately.

Path Complexity

Less intuitive than path variability, but applicable even when only a single path is observed, path complexity segments the movement path into regions of high and low localized complexity. Increased complexity can be an indicator of waypoint location since waypoints may be associated with decision points, where the animal must first adjust its heading to reach the waypoint and subsequently readjust again to direct itself toward the



Waypoint Detection, Fig. 1 Five flights each from three pigeons (*light blue*) showing the calculated mean path (*bold red*), variance around the mean path (*grey band*), and location of areas of peak route similarity (*black circles*). The peak similarity regions correspond to variance below a threshold value. Each peak similarity region can contain multiple successive points, but for clarity only one circle is shown per region (Reprinted from Ref. [5], Copyright [2010], Creative Commons open access license)

next objective. Conversely when the animal is far from any known locations, it would be expected to follow a smooth path since there is no external cue available to correct the heading and any other variation would lead to unnecessary energy loss.

The complexity of a path segment can be viewed as a measure of how much information is required to describe it. A straight line or a very smooth curve can be described simply by stating the end points and the degree of curvature. A segment whose curvature is constantly changing, which may change direction discontinuously or which returns back to a previously covered point (looping) will require far more information to adequately describe. To understand the relationship between complexity and information, imagine having to describe a path segment to someone who is unable to see it, well enough that they could draw it themselves. The more details that are required to convey that path segment, the more complex it is.

As with path similarity, path complexity can be measured in a variety of ways, which are similarly highly correlated with each other. These range in abstractness from *tortuosity*, the local degree of inefficiency in the path, to the highly abstract concept of spatiotemporal positional entropy introduced by Roberts et al. [13]. Figure 2 shows a plot of a number of recorded movement paths, color-coded by the local degree of complexity, to demonstrate how high complexity and low complexity path segments present themselves visually. Each path is segmented into low-, medium-, and high-complexity regions, using positional entropy as a measure of complexity. In the figure, it can be clearly seen that low complexity (green) regions are smooth, with low curvature and few if any sharp changes of direction. High-complexity (red) regions often include loops, sharp turns, and many changes of direction. The medium-complexity (blue) regions lie between these extremes. The figure also shows that high-complexity regions are often short, indicating

Waypoint Detection, Fig. 2 Identified regions of low (*green*), medium (*blue*), and high (*red*) complexity in a variety of homing pigeon flight paths, as determined by positional entropy (Reprinted from Ref. [6], Copyright [2004], with permission from Elsevier)

some local effect on the path, and occur particularly around the release point, when the pigeons are deciding on a heading to take.

Another similar measure that has been used to detect foraging within movement paths is *passage time*. This is amount of time taken by an animal from the moment when it enters a (typically circular) region of space to the moment when it leaves. This can be measured as the first passage time [4, 11] – the time from first entering to first leaving the region or total passage time [1] – the time from first entering to the final time leaving. This is strongly related to path complexity, since highly complex, inefficient path segments with lots of changes of direction will have high passage times. The use of passage time to detect foraging within directed movement is broadly analogous to waypoint detection, since foraging stops within a directed path will form waypoints by virtue of the concentration of the food source.

Complexity measures have associated spatio-temporal scales which must be appropriate for the detection task. Tortuosity is measured as the inefficiency of a path segment, the length must be selected. Likewise positional entropy measures the complexity of a moving segment of the path. Passage time is measured with respect to a spatial region whose size must be chosen. These scales must bear in mind the classic trade-off between resolution and signal-to-noise ratio; the smaller the scale, the more fine structure will be detected and the more tightly determined will be the position of identified waypoints. Longer scales improve the signal-to-noise ratio by filtering out high-frequency noise from the behavior but also reduce the resolution of the measurement.

Variation in complexity measures has been suggested to correlate with changes in the animal's behavioral state [1, 2, 4, 6, 11] and to segment the path into distinct behavioral phases [1, 6, 13] supporting the use of complexity to identify key path segments that may correspond to waypoint locations. Path complexity has also been linked to the surrounding visual environment [7], indicating that the waypoints identified may correspond to visual landmarks, as expected under the pilotage hypothesis.

Path Predictability

Path predictability differs distinctly from the previous two approaches since it uses complete movement paths in a global analysis, rather than examining only localized properties of the paths. Waypoints are selected as those segments of the path that can be used to provide the best prediction of the complete path and other paths (where these exist). The logic of this approach depends on the hypothesis of navigation by *pilotage*. This hypothesis claims that the animal makes it way from its original position to its final objective by successively visiting an ordered sequence of fixed waypoints, as per the definition above. The path predictability method argues that if this hypothesis is accurate, the path(s) of the animal must be defined by the locations of those waypoints, the segments between waypoints being subject to constraints such as energy minimization and random variation from environmental and internal factors. These waypoints are thus analogous to the fixed positions in a curve-fitting exercise, with the constraints given above acting similarly to the constraint of curvature minimization in spline fitting. The upshot of this is that those segments of the path(s) close to the waypoints should provide the maximum amount of information about the rest of path(s).

Similarly to path complexity, path predictability is intimately linked to information. Consider trying to convey to someone not just a path segment but instead a set of complete paths. Now imagine that the only information you are allowed to send is the position of the paths at a small set of times. If your friend subsequently "joins the dots" to link these points, how well will they approximate the true paths? The most informative, or predictive, locations are those that allow the best estimate of the real paths using this technique.

Technically, the information contained in a path can be defined how it affects the probability of another path. If path B is informative about path A then the probability of path A will increase as a result of knowing path B. Mathematically, the information contained in path B about path A is related to the ratio of probability of path A, conditional on knowing path B through some model M, compared to the probability of path A when B is unknown. Information is defined as the log of this probability ratio:

$$\mathrm{Information(A|B)/bits} = \log_2 \mathrm{p(path\,A \mid path\,B, M)} - \log_2 \mathrm{p(path\,A \mid M)} \quad (1)$$

The probability P(path A | path B, M) depends on the choice of model. A simple model might be that each point on path A should be the same as on path B at the equivalent point in time, give or take some amount of Gaussian noise to account for natural variation. More realistic models should take account of the correlations over time that lead to the spatial structure of the path. Mann et al. [10]

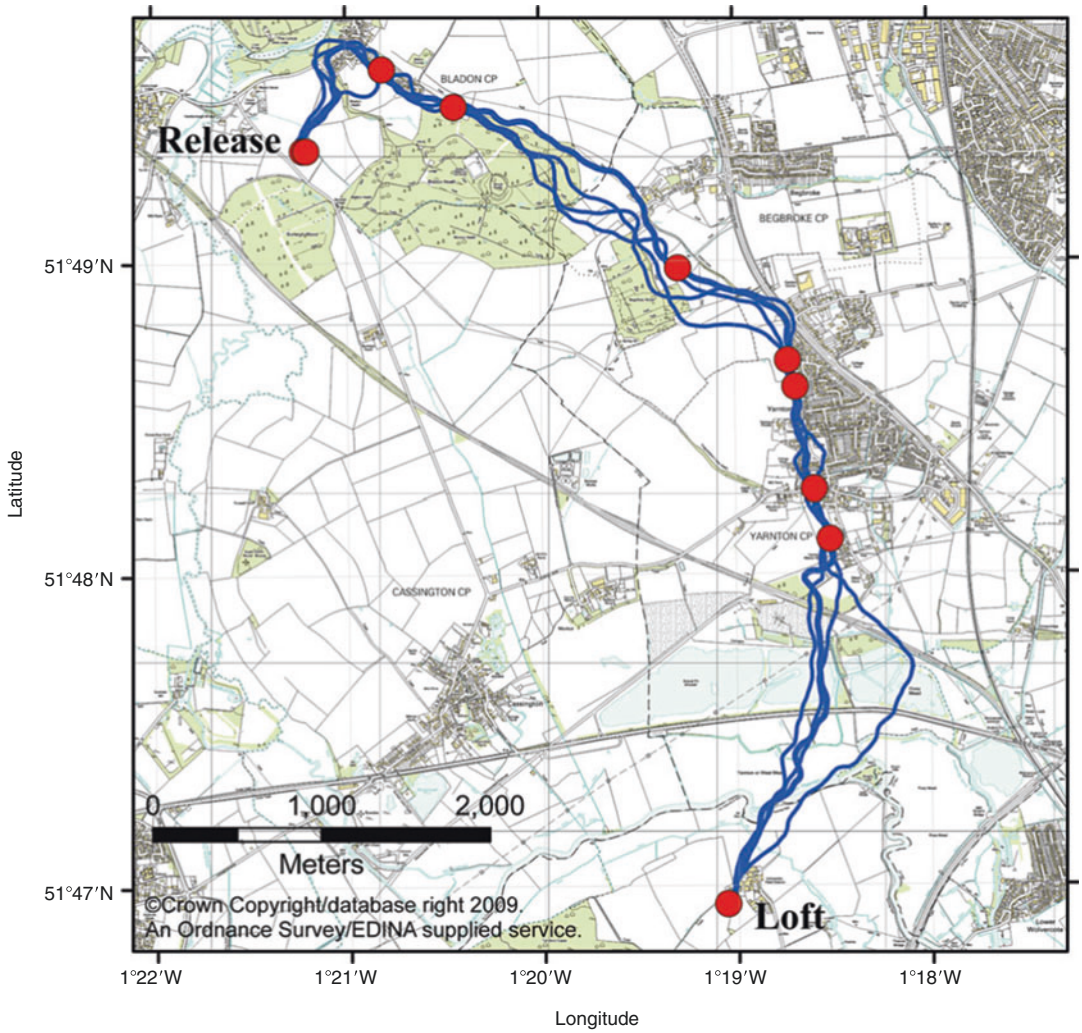
provide a more sophisticated model choice implemented via the use of Gaussian processes, allowing for autocorrelation within the path over time as well as the correlations between paths. In this implementation, all paths are assumed to be samples from a distribution centered on a mean path – similar to the mean path defined as part of the path similarity measure. Constructing a model to describe the probability distribution of movement paths is a complicated task which is not readily reducible to a simpler scheme. This task is necessary, however, to specify the mutual information contained between paths and between elements of the same path and thus to be able to use path predictability as a measure. See Mann et al. [10] for guidance on model construction.

Having defined a model and therefore a probability distribution from one path to another, the task of identifying the waypoints can be clarified as follows. Path B will be a recorded path, with positions recorded at a set of time points, t. Let t' be a subset of those timesteps such that path B' is the recorded positions at times t'. The information in those positions is calculated as

$$\begin{aligned} \mathrm{Information}(t') &= \mathrm{Information}(A \mid B') \\ &= \log_2 p(\mathrm{path}\, A \mid \mathrm{path}\, B', M) \end{aligned} \tag{2}$$

Having hypothesized that waypoints correspond to the most informative segments of the path, the task is now rephrased as finding the subset of t, t*, that maximizes Eq. 2,

$$t^* = \mathrm{argmax_}t' \mathrm{Information}(t') \tag{3}$$



Finding a limited number, m, of waypoints can be accomplished simply by searching for the t* restricted to subsets of size m. Optimization of Eq. 2 can be accomplished by "greedy" forward selection, gradient ascent, Monte Carlo sampling, or other established optimization techniques. Standard texts on learning algorithms, for example, [9], can provide comprehensive details of optimization algorithms.

Predictability between different paths tends to be maximal under two circumstances. The first is in regions where the two paths are very similar. Here knowing one path gives good information about the likely location of the other. This then is similar to the path similarity criterion. The other case is where the location of the path is highly unpredictable either a priori, or conditional on the other chosen waypoints. Locally this bears a resemblance to the path complexity measure, but also takes account of the global unpredictability – for example finding path segments that are locally smooth but globally far from the straight-line path between start and finish. This corresponds to an intuitive analysis of the path. If the bird consistently flies to a location far from the most efficient route this is unlikely to be due to chance; there must be a waypoint at this location.

Figure 3 shows an example of waypoints selected by maximizing the path predictability, taken from Mann et al. [10]. In this demonstration, the number of selected waypoints is ten and the information in Eq. 2 is maximized by forward selection. It can be seen from this example that the selected waypoints each exhibit at least one of the three properties that maximize information content. Many of the waypoints are located where the paths coalesce into narrow corridors, exhibiting high path similarity. Others are located where the paths turn sharply, which correspond to high path complexity. Finally there are waypoints located in the regions furthest from the most efficient beeline path, at the apex of the curve, which is the most unlikely area for the pigeons to visit a priori.

Summary

Detection of waypoints in recorded movement paths is a novel problem that has potential future applicability in studies of animal movement and biomimicry. The methods described in this entry constitute a basis for identifying important regions of the movement path based on hypotheses about the likely effects of waypoints upon the animal's movement. These methods span a range of mathematical complexity and intuitive applicability. More recent developments such as the path

Waypoint Detection, Fig. 3 Ten waypoints identified from five flight paths from a single homing pigeon, using path predictability as a criterion. The waypoints are identified preferentially in flight segments that a similar between paths, where the path exhibits high complexity and where the path is far from the most efficient straight "beeline" between start and finish (Reprinted from Ref. [10], Copyright [2010], Creative Commons open access license)

predictability tend toward higher levels of abstraction. The methods explored in this entry are not mutually exclusive and combinations should be explored to achieve the best detection results. With animal movement tracking still developing as an experimental field, methods for the analysis of recorded data are being created in parallel and the development of further methods for identifying salient regions from movement paths can be expected in the near future.

Wet Adhesion in Tree and Torrent Frogs

Thomas Endlein and W. Jon. P. Barnes
University of Glasgow, Institute of Molecular Cell and Systems Biology, Centre for Cell Engineering, Joseph Black Building, University Avenue, Glasgow, Scotland, UK

Overview

Biomimetics of Animal Adhesion

Our understanding of the adhesive mechanisms of climbing animals has increased rapidly in recent years, in no small way due to advances in materials science providing both the tools and the theoretical background. This research has shown that, as a result of millions of years of evolution, the adhesive mechanisms of climbing animals are highly dynamic, showing many features that are the envy of materials scientists. Unlike most man-made adhesives, they (i) cope well with rough and anti-adhesive substrates, (ii) have self-cleaning mechanisms and so recover quickly following contamination, (iii) can control attachment so that it only occurs when required, and (iv) possess mechanisms for effortless detachment. Finally (v), since animals attach and detach their adhesive pads every time they take a step, sticking ability is not lost with repeated application, this being mainly due to their resistance to wear and contamination. To date, most research effort has been directed at investigating the adhesive mechanisms of geckos (gecko adhesion) and insects (adhesion in insects), but tree and torrent frogs, adapted to living in habitats with a high rainfall, offer solutions to different problems, namely, adhesion under wet conditions.

Climbing and Adhesion

It goes without saying that climbing animals, in addition to adaptations for climbing, need mechanisms for maintaining a grip and thus avoiding falling. Taking, for example, an animal on an

inclined tree trunk, the force of gravity will cause this animal to fall unless it can generate a reaction force between itself and the trunk that is equal and opposite to the force generated by the gravitational pull. Such forces can be generated in a number of ways, namely, mechanical interlocking, friction, and bonding. *Interlocking* involves interlocking the surface of the animal with that of the support. This is how claws, present in many climbing animals (e.g., squirrels and members of the cat family), work. Claws may either catch on preexisting surface irregularities or be pushed into the surface if it is soft enough. Many animals without claws (e.g., monkeys and humans) utilize a simple *friction* grip. It only works, however, when hands or feet can span almost the entire branch diameter – i.e., a vertical wall cannot be climbed by friction alone. Many specialist climbers, however, possess specialized adhesive pads on their feet and adhere by *bonding* (bioadhesion). Such bonds need to be reversible; otherwise, they would only be good for permanent attachment. The main mechanisms of bonding are dry and wet adhesion. In *dry adhesion*, the adhesive pads are able to get so close to the substrate that adhesion is primarily by van der Waals forces. Such forces can hold molecules together in liquids and solids and only operate at distances of a few nanometers. In *wet adhesion*, on the other hand, there is a fluid joint, secreted liquid between the pad and substrate, and adhesion is thought to be mainly by capillarity. It is generally accepted that dry adhesion is found in lizards such as geckos [1], while wet adhesion is found in insects [2], in amphibians [3] and, among mammals, in arboreal possums [4] and at least one bat species [5].

Two rather different types of adhesive pads – smooth and hairy – have evolved that allow animals to climb and adhere to vertical and overhanging surfaces. Hairy adhesive pads are found in many insects, spiders, and lizards. In geckos, they consist of millions of tiny branching hairs (setae), each branch ending in a flattened spatula no more than 200 nm across. This allows the tips of the hairs to form extremely close contact to rough surfaces, enabling intermolecular van der Waals forces (as described above) to provide strong adhesion [1]. In contrast, the smooth adhesive pads of tree frogs, arboreal salamanders, and insects such as ants secrete a fluid so that contact is maintained by wet adhesion [6]. Interestingly, the hairy pads of insects also secrete tiny amounts of fluid, so that, in contrast to geckos, adhesion is also likely to be by wet adhesion. Until recently, spiders were thought to use dry adhesion, but there is new evidence of a fluid secretion from the adhesive setae [7], so it is possible that they, like insects, use wet adhesion.

Adhesion in Tree and Torrent/Stream Frogs

Among the Amphibia, adaptations for climbing are found in neotropical salamanders of the genus *Bolitoglossa* and at least ten families of frogs. Where the habitat is vegetation (herbs, shrubs, trees), the frogs are known as tree frogs, while those found clambering on wet rock in the vicinity of streams and waterfalls are known as rock and torrent frogs, respectively. All are characterized by the presence of adhesive pads on their digits. In spite of the fact that these pads have evolved independently in different families, their structures are very similar, consisting of polygonal (mostly hexagonal) flat-topped cells separated by narrow channels. Interestingly, similar structures are also found on the smooth adhesive pads of some insects (e.g., grasshoppers) [8]. The development of adhesive pads is thus an excellent example of convergent evolution. This points toward a favorable design (in frogs at least), and this is important for biomimetics. Most frog adhesion research has been carried out on tree frogs of the families Hylidae and Rhacophoridae, while work on torrent frogs of the family Ranidae is still at an early stage.

Physical Principles

Although the dominant force in tree frog adhesion is believed to be capillarity, hydrodynamic forces based on viscosity are also considered to play a role. Additionally, since the thickness of the fluid layer was measured to be less than 35 nm in some areas of the contact zone, it is probable that there is direct contact between nanostructural features of the pad surface and the substrate [9]. Thus,

van der Waals forces may also be involved, but to what extent is unknown. The physical principles underlying capillarity and viscous forces are outlined below.

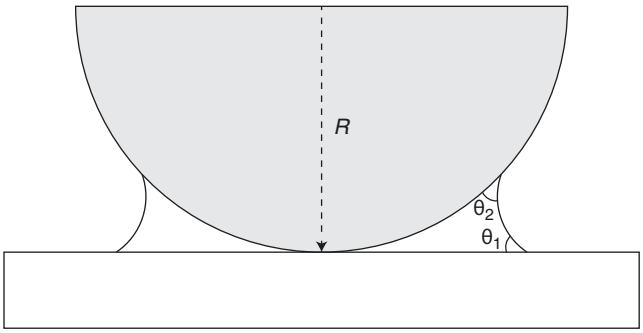
Wet Adhesion: Capillary Forces

A common model that has been used for quantifying capillary forces consists of a sphere on a plane surface, connected by a drop of liquid (Fig. 1). In this model, the surface tension of the meniscus results in a pressure difference, where the pressure inside the liquid is lower than it is outside, as long as the meniscus is concave. This pressure difference, the Laplace pressure, will resist the separation of the two surfaces. The attractive Laplace force (F_L) for a macroscopic, perfectly smooth, and homogeneous sphere in contact with a plane is given by

$$F_L = -2\pi R\gamma(\cos\theta_1 + \cos\theta_2) \quad (1)$$

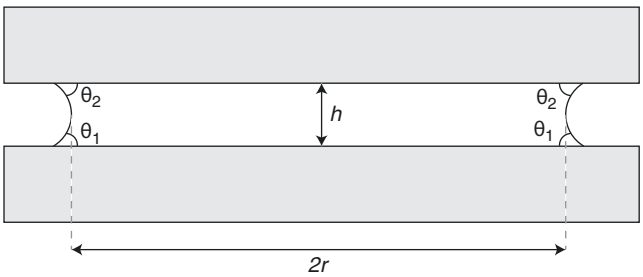
where R is the radius of the sphere, γ is the surface tension of the liquid, and θ_1 and θ_2 are the contact angles of the liquid with the plane surface and sphere, respectively. If the liquid completely wets both surfaces (i.e., $\theta_1 = \theta_2 = 0$), Eq. 1 simplifies to

$$F_L = -4\pi R\gamma \quad (2)$$



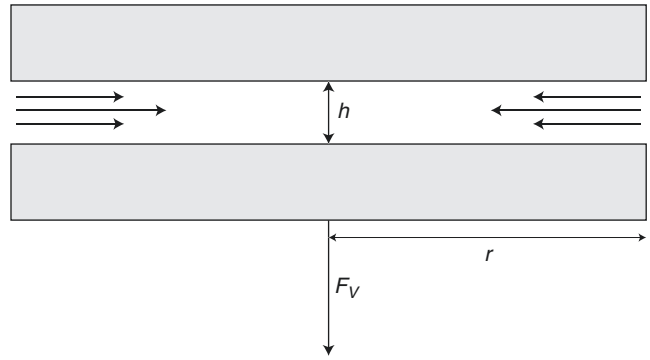
An alternative model examines capillary forces between two rigid plates, separated by a thin layer of fluid (Fig. 2). This model produces substantial forces if the radius (r) of the area of contact is large and the separation distance of the plates (h) is small, according to the equation:

$$F_L = \pi r^2\gamma\left[r^{-1} - (\cos\theta_1 + \cos\theta_2)h^{-1}\right] \quad (3)$$



In a large flat meniscus where $r \gg h$ and $\theta_1 = \theta_2 = 0$, Eq. 3 approximates to Eq. 4, namely,

$$F_L \approx -2\pi r^2\gamma/h \quad (4)$$



A second component of the adhesive force is the tensile force (F_T) of the meniscus. In the rigid plate model, this surface tension force is

Wet Adhesion in Tree and Torrent Frogs, Fig. 1 Capillarity model of a sphere on a plane surface connected by a drop of fluid

Wet Adhesion in Tree and Torrent Frogs, Fig. 2 Capillarity model of two flat, rigid surfaces separated by a small volume of fluid

Wet Adhesion in Tree and Torrent Frogs, Fig. 3 Stefan adhesion model of two flat rigid plates, fully immersed in a fluid, subject to an external force

$$F_T = -2\pi r\gamma \sin\theta \tag{5}$$

The total meniscal force (F_M) is the sum of F_L and F_T:

$$F_M = F_L + F_T \tag{6}$$

F_T is negligible in any single large meniscus (e.g., ones with a radius of 0.5–3 mm as occur in tree frog toe pads), but would contribute to a larger extent to the adhesive forces in a fly's adhesive pad where you have large numbers of microscopic menisci (radii of ca. 1 μm).

In a recent study, Eq. 2 has been extended from hard, undeformable surfaces and spheres to soft, elastic materials, such as the toe pad of a tree frog. The mathematical equations relate the capillary attraction between the bodies to their elastic repulsion. Although they do not lend themselves to any easy calculation of the adhesive force, they are of interest as they predict that F_M scaling will gradually change from length scaling to area scaling with increasing R, this change occurring more rapidly for materials with a lower effective elastic modulus (E_{eff}). For instance, in Eq. 7 which deals with the Laplace pressure component of adhesion, the first term is proportional to R and is identical to the force with a hard sphere (Eq. 2), while the second term is proportional to R^2. It is negligible for high Young's moduli, but becomes significant for soft materials.

$$F_L = -4\pi R\gamma - \left(\frac{\pi\gamma}{2r'}\right)^3 \cdot \frac{2R^2}{3\left(E_{eff}^2\right)} \tag{7}$$

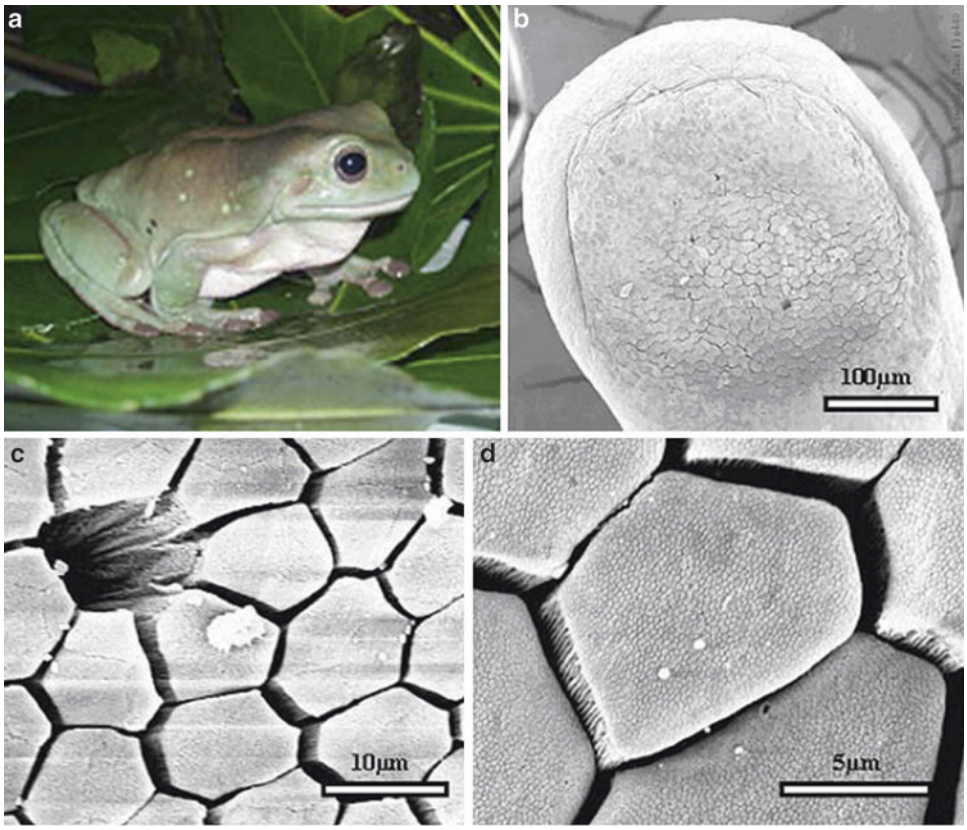
where r' is the radius of curvature of the meniscus.

Wet Adhesion: Viscous Forces

The second component of wet adhesion is provided by time-dependent viscous forces (such as Stefan adhesion). Consider two rigid plates fully submersed in a fluid (Fig. 3). Separating the plates involves fluid flowing into the gap between them, so that separation is resisted by a viscous force until the fluid movements are complete. This force (F_V) will be greater for more viscous fluids and for smaller values of h. As Eq. 8 indicates, F_V scales with area squared.

$$F_V = -\frac{dh}{dt} \cdot \frac{3\pi\eta r^4}{2h^3} \tag{8}$$

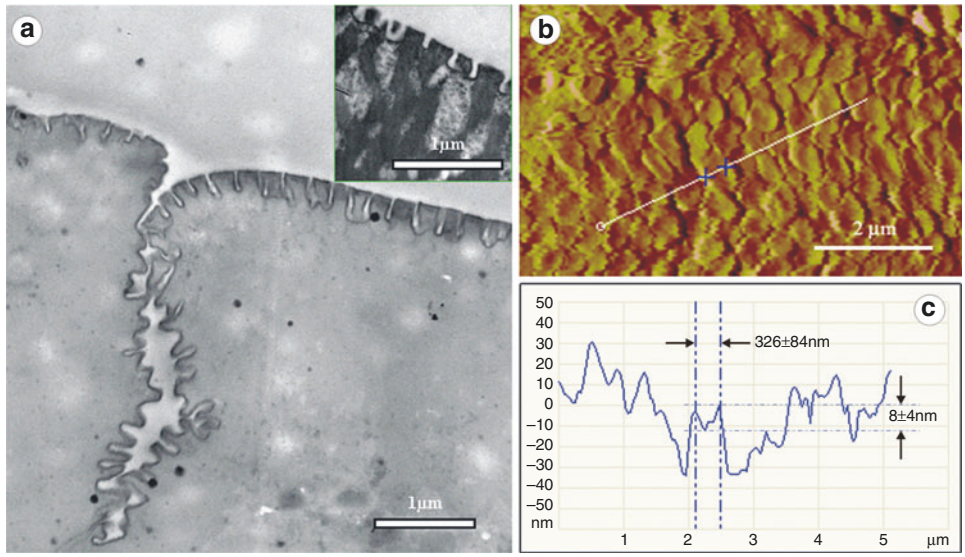
where η is the viscosity of the liquid and t is the time needed to separate the two plates. For completeness, the equation for the hydrodynamic force between a sphere and a plate (Eq. 9) is also included.



$$F_V = -6\pi\eta r \frac{dh}{dt}\left(1 + \frac{r}{h}\right) \tag{9}$$

When the sphere touches the plate, as in Fig. 1, $h = 0$. There is a need to extend such studies to soft, deformable materials.

Key Research Findings



Toe Pad Micro- and Nanostructure

In both tree and torrent frogs, soft domed pads occur on the ventral surface of the tip of each digit, the specialized pad epithelium being delineated from normal skin by distinct grooves (Fig. 4).

Wet Adhesion in Tree and Torrent Frogs, Fig. 4 (**a**) White's tree frog, *Litoria caerulea*. (**b**–**d**) Scanning electron microscopy of toe pad epithelium. (**b**) Low-power micrograph of whole pad. (**c**) Micrograph showing a mucus pore and (largely) hexagonal epithelial cells separated from each other at their distal ends by channels. (**d**) Higher-power micrograph indicating the presence of nanostructuring on the "flat" surface of the epithelial cells (From Scholz et al. [15])

There are also much smaller adhesive areas located elsewhere on the ventral surface of the feet, in particular the subarticular tubercles located more proximally on the digits. Tree frog adhesive pads have a stratified columnar epithelium, the cells being separated from each other at their apices. Scanning electron microscopic studies (scanning electron microscopy) show that most of these cells are hexagonal, but, as Fig. 4 shows, some are pentagonal and a few heptagonal. Pores of mucous glands open into the channels between the cells. The toe pad epithelium thus consists of an array of flat-topped cells (approx. 10–15 µm in diameter each) separated by mucous-filled grooves (approx. 1 µm wide) [3, 10–12]. In functional terms, having the cells separated at their tips enables the pads to conform to the shape of surface irregularities to which the frog is adhering. The mucous glands are necessary to produce the watery secretion that forms an essential part of the adhesive mechanism of the pad. The hexagonal array of channels that surround each epithelial cell presumably functions to spread mucus evenly over the pad surface and, under wet conditions (most tree frog species live in rainforests), remove surplus water. Finally, the presence of grooves could aid adhesion by reduction of crack propagation (peeling) [13]. Pull-off stress is spread between a larger number of hexagons rather than being concentrated at the edge of the contact zone. Such features have been incorporated into bioinspired artificial patterned surfaces to increase their adhesion [14]. In torrent frogs, the epithelial cells have

Wet Adhesion in Tree and Torrent Frogs, Fig. 5 White's tree frog, *Litoria caerulea*, (**a**) Transmission electron micrograph of a toe pad showing a section of one of the channels that separate adjacent epithelial cells and the surface nanostructures, which are themselves separated from each other by narrow channels. The *inset* shows similar nanostructures on a toe pad of the hylid tree frog, *Scinax ruber*. Here the nanostructures are associated with filaments running at right angles to the cell surface. (**b**) Atomic force microscope deflection image showing the shape of the dense array of peg-like nanopillars that constitute the adhesive surface of the pad. (**c**) Height profile of line in **b**. The two crosses delineate a columnar nanopillar that lay precisely on the profile line, showing that these peg-like structures have a small dimple at their center. The figures are means ± standard deviations of nanopillar width and dimple depth. (NB The height of the nanopillars cannot be measured by the atomic force microscope as the cantilever cannot reach the base of the channels between them) (Redrawn from Scholz et al. [15])

become elongated along the pad's proximal-distal axis, which results in the channels between them being straighter and shorter in this direction, presumably an adaptation for efficient drainage of excess water.

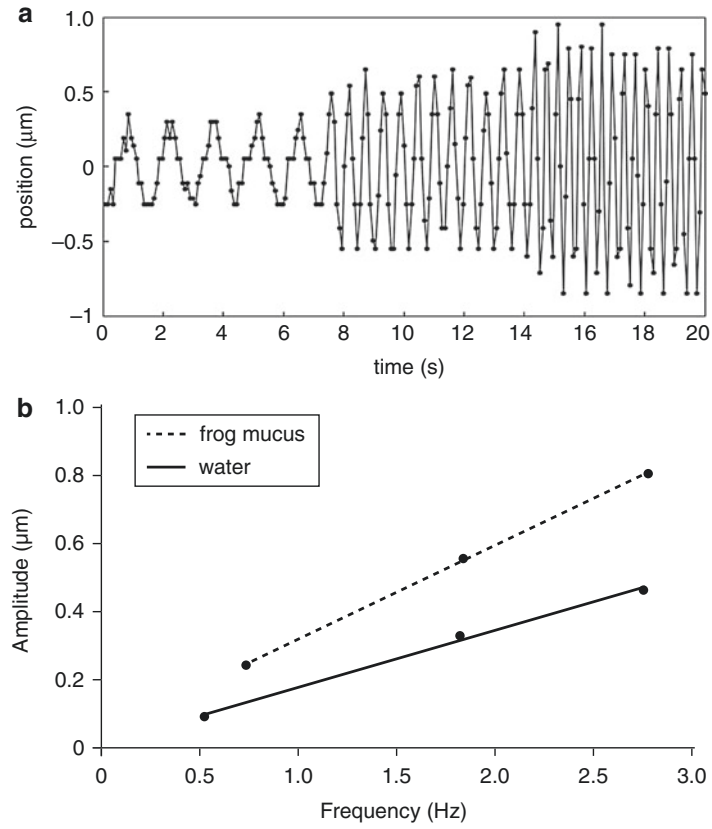
At the nanometer scale, the pad surface is not smooth but is covered by a dense array of nanopillars, 300–500 nm in diameter and 200–300 nm in height. Under the atomic force microscope, they can be clearly seen to have small dimples at their tips (Fig. 5). In many species, these nanostructures are the ends of fiber bundles lying within the cytoplasm of the epithelial cells that run at right angles to their external surface. Similarly, oriented fibers are found in the smooth adhesive pads of insects. As in tree frogs, they form the cytoskeleton of the pads. The functions of the nanopillars that constitute the so-called "flat" surface of these cells remain a matter for speculation. The following is a list of obvious possibilities, none of which are mutually exclusive. (1) Like the epithelial cells and the channels that surround them, the nanopillar array may allow close conformation to surface irregularities, but on a much smaller length scale (nanometers rather than micrometers) than applies to whole epithelial cells. (2) The narrow channels between them could serve to absorb excess water (like a sponge), much as sipes (fine-scale grooves) do on a wet weather car tire [13]. This would allow rapid optimization of the thickness of the intervening fluid layer (as thin as possible, but without any air pockets). (3) The nanopillars could be very important in the generation of friction forces, in that their tips will be in actual contact with the surface (see later). (4) It cannot be excluded that the dimples give rise to a suction effect.

Neotropical salamanders of the genus *Bolitoglossa* are also arboreal. Some species have toe pads, whereas in others, digits are much reduced, and there is extensive digital webbing

[16]. In these cases, the whole foot appears to function as a single smooth pad. In smaller species, adhesion is thought to be by wet adhesion, but in some larger species, there is circumstantial evidence that suction may play a role [16]. In most species, the surfaces of the cells are smooth, although in *Bolitoglossa odonelli*, the surface is covered by nanopillars that appear very similar to those found in tree frogs. Many newts can also climb smooth vertical surfaces but do not show the complexity of structures found on (tree and torrent) frog pads.

Physical Properties of Toe Pads

The elastic modulus (or in this case the effective elastic modulus, as Poisson's ratio for toe pads is not known) provides a quantitative measure of material stiffness, an important parameter for adhesion. Stiffness is estimated from force-distance curves, resulting from indentation of the toe pads, using equations based on, for instance, the Johnson-Kendall-Roberts (JKR) theory. Such equations will also allow calculation of the work of adhesion and the pull-off force. Micro-indentation usually involves specialized microtribometers, while, at the nano-level, either a nanoindenter or an atomic force microscope can be used.



Use of atomic force microscope in nanoindenter mode indicates that the outer keratinized layer of tree frog toe pads, which is about 15 μm thick, has an effective elastic modulus (E_{eff}) of 5–15 MPa, equivalent to that of silicone rubber [15]. However, it gives no information on the physical properties of deeper structures. To measure the stiffness and elasticity of the pad as a whole, micro-indentation is used. It demonstrates that tree frog toe pads are among the softest of biological tissues and that they show a gradient of stiffness, being stiffest on the outside due to increasing keratinization of the outer cell layers. Estimates of E_{eff} lie in the range 4–25 kPa [17]. Although not as soft as adipose tissue ($E_{\text{eff}} \approx 3$ kPa), values are much lower than for aorta ($E_{\text{eff}} \approx 500$ kPa), cartilage ($E_{\text{eff}} \approx 20$ MPa), or the adhesive pads of locusts ($E_{\text{eff}} = 250$–750 kPa). At the opposite extreme, tooth enamel has an E_{eff} value of 60,000 MPa. Functionally, the stiffer outer surface provides a degree of resistance against wear, while the softer interior provides an increased ability to form intimate contact with various surface profiles. Since the epithelium as a whole is a living, growing tissue, the long-term solution to the wear problem is a simple one; the outer cell layer is shed at intervals, presumably after the cell layer below it has become keratinized.

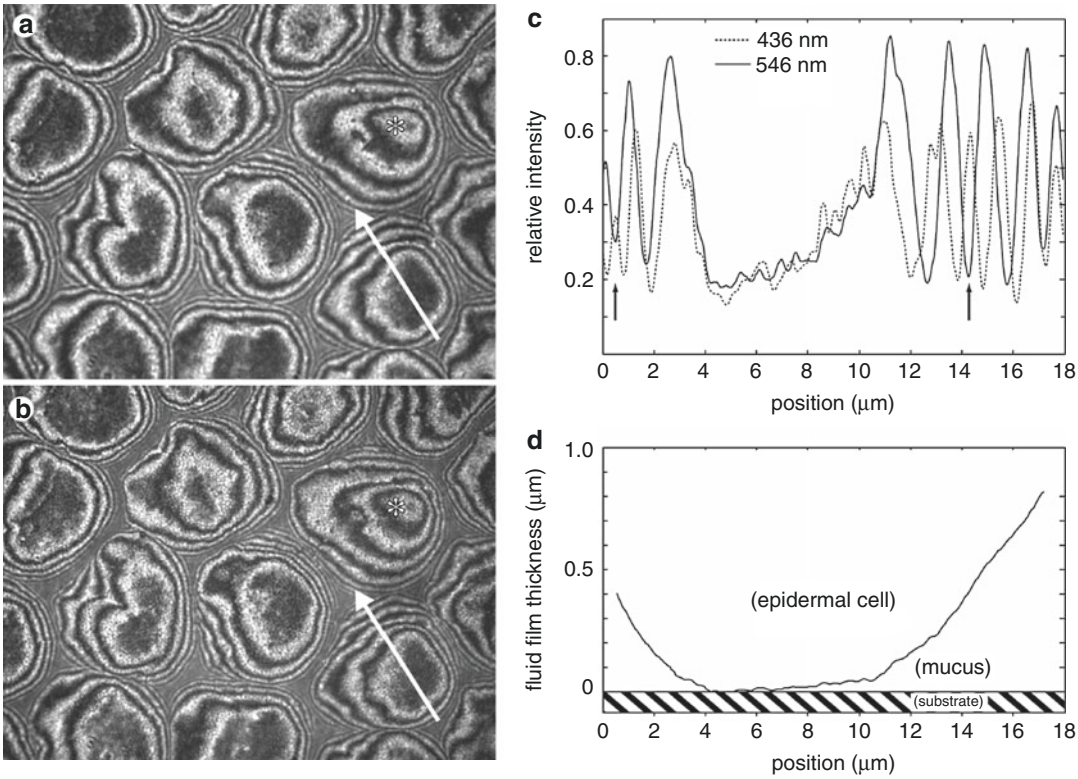
A dense network of blood capillaries lies below the pad epithelium. This may well have a mechanical function, acting as a shock absorber. This could be particularly important when a tree frog lands on a vertical surface after a jump. Having soft inelastic material beneath the pad allows the pad to mold to the surface the frog has landed on without any tendency for elastic recoil.

Viscosity and Thickness of Fluid Layer

Microrheometry of toe pad mucus has been undertaken using a laser tweezer technique (optical tweezers) [18]. Latex beads (2.8 μm in diameter) were mixed with droplets of toe pad mucus (ca. 5 μL in volume) on a coverslip on a motorized stage of a microscope equipped with a laser tweezer. The laser tweezer traps individual beads in its focus. The stage was then oscillated sinusoidally at a number of different frequencies. The fluid movement exerts a drag on the beads, which is dependent on the velocity and also on the viscosity of the fluid. Graphs are plotted of the amplitude of the bead's lateral displacement against oscillation frequency. The viscosity of the mucus was calculated by comparing the slopes of the regression lines obtained for frog mucus and for pure water. Such measurements (Fig. 6) show that the viscosity of toe pad mucus is approximately 1.43 mPa · s (i.e., approx. 1.4 × the viscosity of water). No evidence for non-Newtonian properties was found, but it is possible that the situation changes for more concentrated mucus.

The thickness of the mucus layer beneath the frog's toe pad has been investigated by a technique called interference reflection microscopy. This enables the calculation of the fluid layer thickness from an optical interference pattern of reflected wave fronts [18]. Monochromatic light was reflected both from the surface of the pad and

Wet Adhesion in Tree and Torrent Frogs, Fig. 6 Microrheology of mucus from White's tree frog, *Litoria caerulea*, using a laser tweezer technique. (**a**) Amplitude of bead displacement elicited by sinusoidal movement of the microscope stage (stimulus amplitude ≈ 10 µm) at three different frequencies. (**b**) Relationship of bead displacement amplitude to the stimulus frequency, measured for both toe pad mucus and pure water. The difference between the slopes of the two lines indicates that this sample of toe pad mucus was 1.65 times more viscous than water (Redrawn from Federle [18])

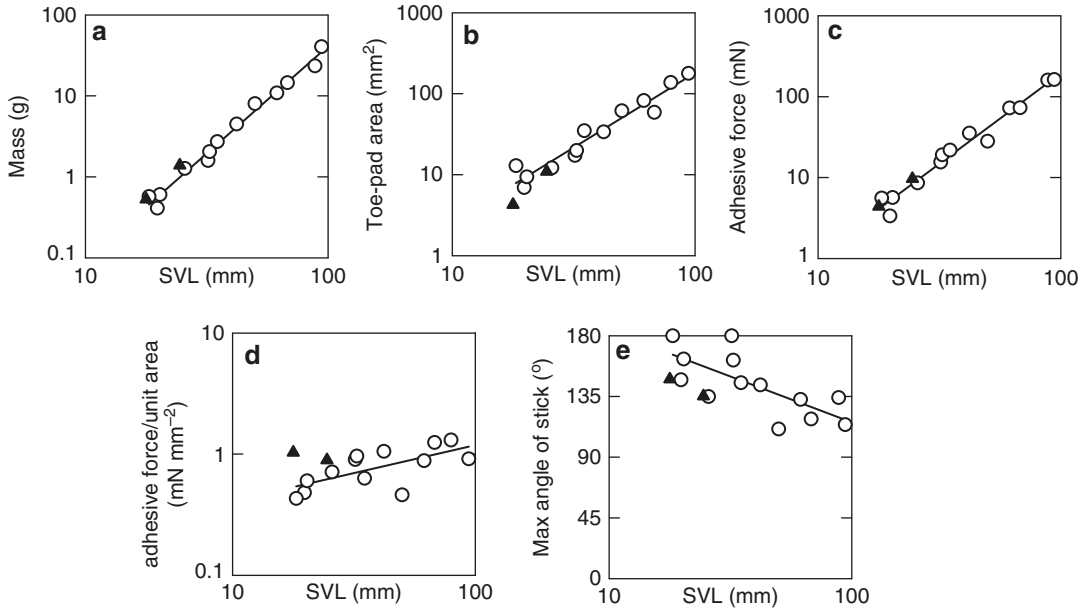


from the top surface of the glass plate on which the frog was sitting (a large coverslip). This leads to interference effects, and the intensity of the reflection allows estimation of the thickness of the fluid layer. Different interference fringes are distinguished by comparing image pairs obtained by light of different wavelengths (Fig. 7).

Examination of images shows that most of the toe pad epithelial cells had dark zones in the center, which correspond to zero-order interference minima (i.e., to a mucus film thickness of less than 100 nm). Further analysis of the intensity of these central areas in relation to interference maxima and minima leads to the conclusion that the film thickness ranges from 0 to 35 nm and is indistinguishable from zero in many epithelial cells (median 6.0 nm). Given that there will be fluid in the narrow channels between the nanopillars, it cannot be excluded that the tops of many nanopillars will be in actual contact with the substrate in an attached toe pad. Additionally, in some species, an increase in the area of closest contact is observed as frogs are tilted from the horizontal toward the vertical.

Adhesion and Friction Forces

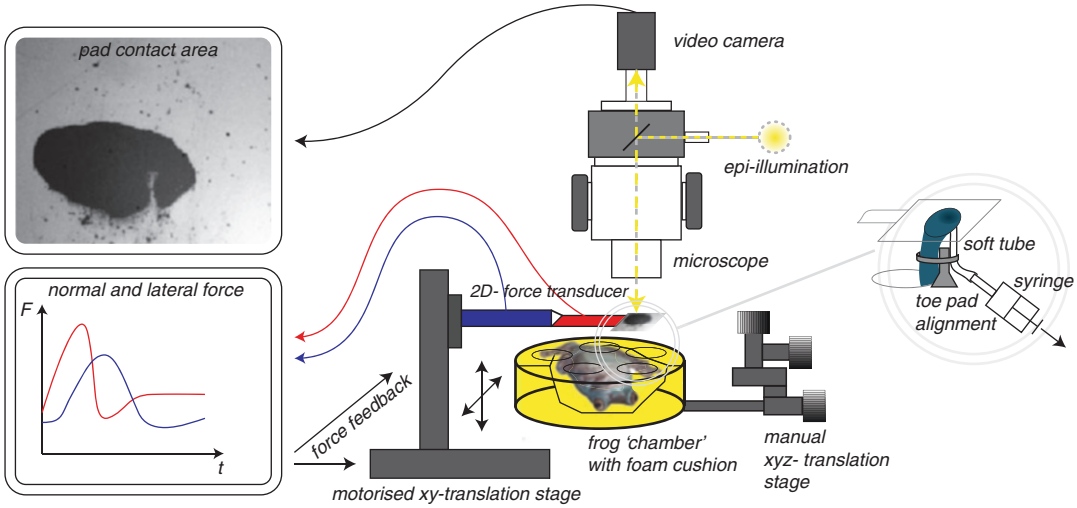
Tree frogs are good climbers, many tropical species being found high in the canopy of rain forests. When supports such as twigs are available, they are grasped, and frogs climb by extending limbs and pulling like human climbers. Toe pads come into their own on smooth substrates such as leaves. Unlike geckos, tree frogs cannot run across a ceiling, but they can climb vertical and overhanging surfaces, and a small tree frog can hang on to an inverted glass plate using just its toe pads. At rest, thigh and belly skin aid adhesion.



Quantitative measurements of the adhesive (normal) and friction (parallel) forces that can be generated by tree frogs have been made by a simple procedure first developed by Emerson and Diehl [11]. Immediately after being weighed,

Wet Adhesion in Tree and Torrent Frogs, Fig. 7 In vivo analysis of White's tree frog, *Litoria caerulea*, toe pad contact with glass using interference reflection microscopy. (**a**, **b**) Images of the same area of the contact zone using different wavelengths (**a**, 436 nm; **b**, 546 nm) using an illuminating numerical aperture of 0.27. *Asterisks* indicate an epithelial cell that is not in close contact (fluid film thickness > 40 nm). (**c**) Intensity profile along the *arrow* shown in **a** and **b**. *Arrows* indicate that the position of the second-order "green" minimum coincides with the second-order "blue" maximum. From this, it can be deduced that the central dark areas of most epithelial cells are zero-order minima. (**d**) Reconstruction of the fluid film thickness along the *arrow* shown in **a** and **b** (Redrawn from Federle [18])

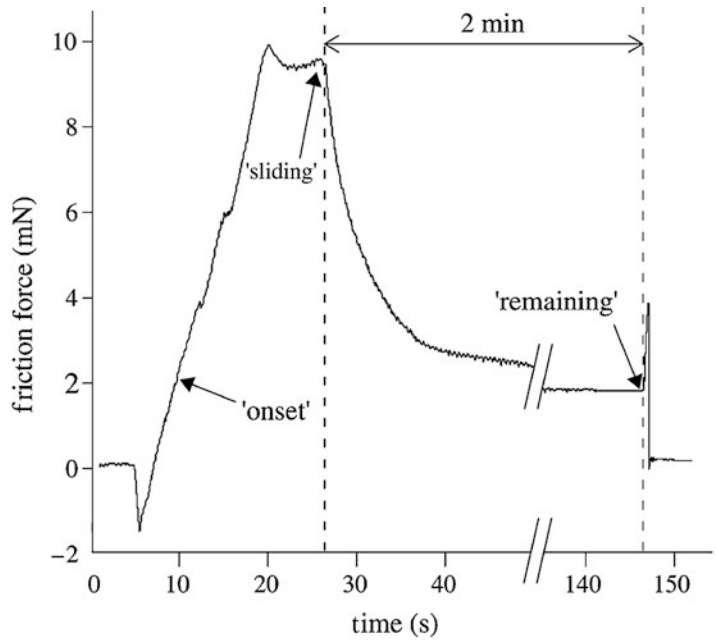
each frog was placed "head up" on a smooth surface on a rotation platform that is rotated slowly from 0° (horizontal) through 90° (vertical) to 180° (upside down). The angles at which the frog first slips on the surface (slip angle) and falls from the surface (fall angle) were recorded. These slip and fall angles are used to calculate maximum shear and adhesive forces, respectively, by simple trigonometry. If the total toe pad area is also measured, these values can be converted to the force per unit area that toe pads can generate. In all species studied, toe pad adhesive force per unit area lies in the range 0.7–2.0mNmm^{-2} (0.7–2.0 kPa) [19].



Frogs are good models for allometric studies, as general body shape is maintained from metamorphosis to full adult size, i.e., frogs grow approximately isometrically. By plotting mass, toe pad area, and adhesive force against frog length on log-log coordinates, both between and within species, it can be seen that adhesive force (F_A) scales approximately with toe pad area or length squared ($F_A \propto a$ or $F_A \propto l^2$) (Fig. 8; [11, 12, 20]. This presents a problem for larger frogs, since mass is proportional to the cube of linear dimensions, while adhesive force, depending upon area, would only be proportional to the square of the linear dimension. A within-species study of hylid tree frogs in Trinidad [12] shows that toe pad area increases as length squared, consistent with area dependence, but mass increases by a factor rather less than the expected

Wet Adhesion in Tree and Torrent Frogs, Fig. 8 Allometric relationships of 13 hylid species (*open circles*) and two nonhylids (*filled triangles*) plotted against snout-vent length (SVL). (**a**, **b**) Morphometric relationships between frog mass, toe pad area, and length (log-log plots); mass $\propto$ SVL$^{2.65}$, significantly different from expected value of 3.0 ($p < 0.01$), and area $\propto$ SVL$^{1.85}$, not significantly different from expected value of 2.0. (**c**, **d**) Adhesive force and force per unit area plotted against length (log-log plots); force $\propto$ SVL$^{2.24}$, not significantly different from 2.0, the value expected from area scaling, and unit force $\propto$ SVL$^{0.46}$, a significant positive relationship ($p < 0.05$); (**e**) fall angle against length (log-linear plot). The regression line shows a significant negative relationship ($p < 0.01$) (Redrawn from Barnes et al. [22])

length cubed. Also, toe pad efficiency (force per unit area) increases with age, perhaps associated with the increased structural complexity of adult toe pads. However, in the majority of the species studied, adult frogs did not completely overcome the allometry problem, for they fell from the rotation platform at smaller angles than younger frogs. In ecological terms, this disadvantage is less than one might expect, in that frogs can use their digits to grasp objects such as twigs, as described above. There is even a positive correlation between adult size and degree of arboreality, in that the largest species are often found high in the canopy, while smaller species are most commonly found in shrubs no more than a meter or so above the ground. Finally, the way in which forces scale with size can provide insights into the underlying mechanisms of adhesion. Classic formulae for wet adhesion, based on flat metal disks (e.g., Eq. 4), show capillarity forces scaling with toe pad area and have therefore been used as evidence for the importance of capillarity in tree frog adhesion. However, at the small values of h measured by interference reflection microscopy, they predict adhesive forces several orders of magnitude greater than toe pads produce. Indeed, the softness of the pad material makes this model clearly inapplicable to tree frogs. Equation 2 predicts forces in the right range, but scaling with length and not area. Peeling models, applicable to the forces that prevent peeling in adhesive tape, are also worthy of consideration because of the way in which toe pads detach (see below). However, they also have force scaling with length, the forces being concentrated in a very narrow zone along the peeling line and thus dependent on the width of the tape. Probably, the solution lies in the recent analysis of Butt et al. [21] for adhesion using the model illustrated in Fig. 1. This analysis predicts a change from length to area scaling with increasing r and decreasing E_{eff}.

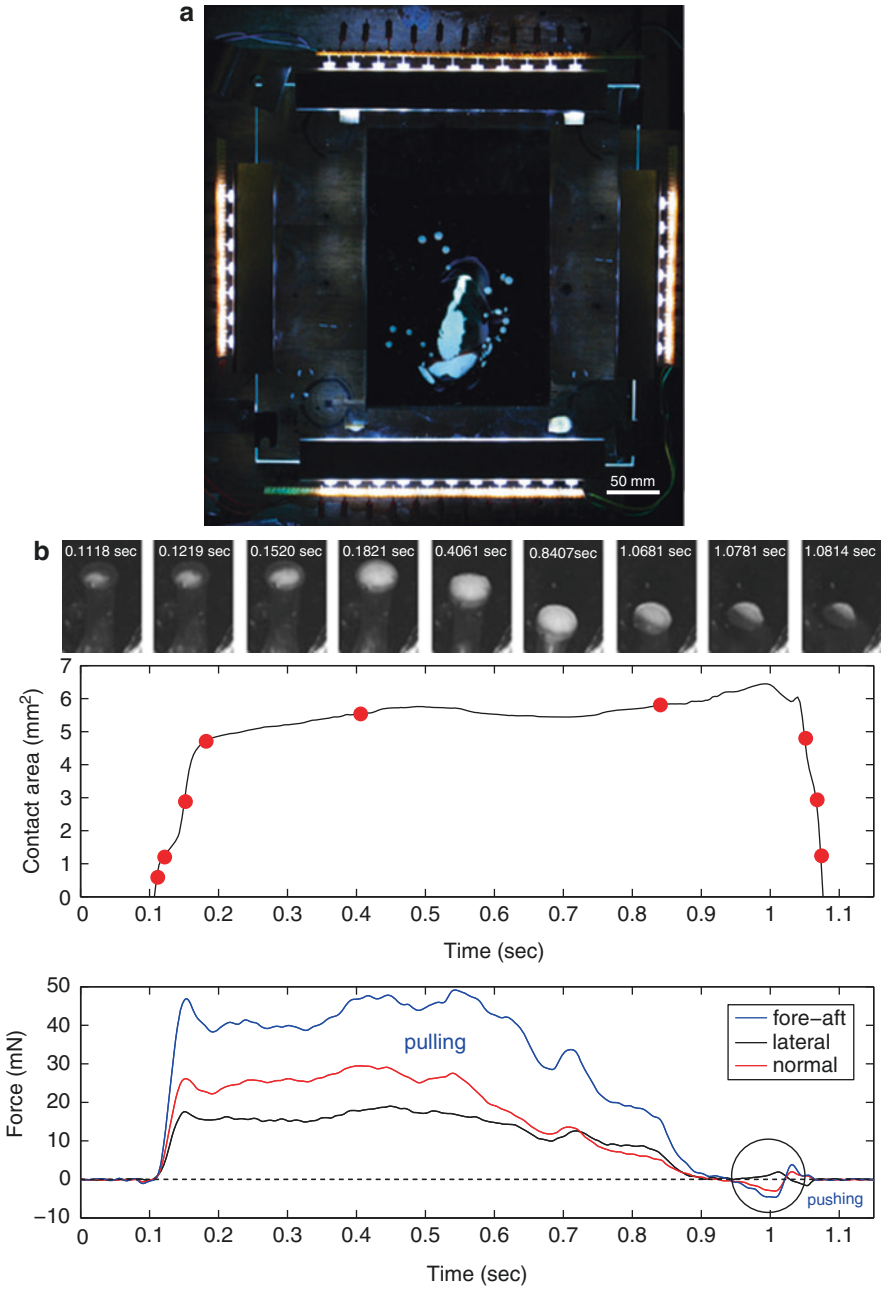


A common misconception is that the subdivision of the surface by the channels between the

Wet Adhesion in Tree and Torrent Frogs, Fig. 9 Experimental setup for measuring adhesion and friction forces from single toe pads of tree frogs. Frogs are held stationary in a small chamber (foam padding not shown), with a toe pad protruding through a hole in its base. Using a micromanipulator, a toe pad is brought into contact with a glass force plate attached to a 2D bending beam force transducer for measuring friction (shear) and adhesion (normal) forces. A computer-controlled XZ translational stage moves the frog in relation to the bending beam. Normal forces can be controlled by a feedback mechanism when required. Contact area is imaged from below using reflected light. Toe pad alignment is achieved by holding the backside of the toe by gentle suction coming from a soft rubber tubing attached to a syringe (From Crawford et al. [24])

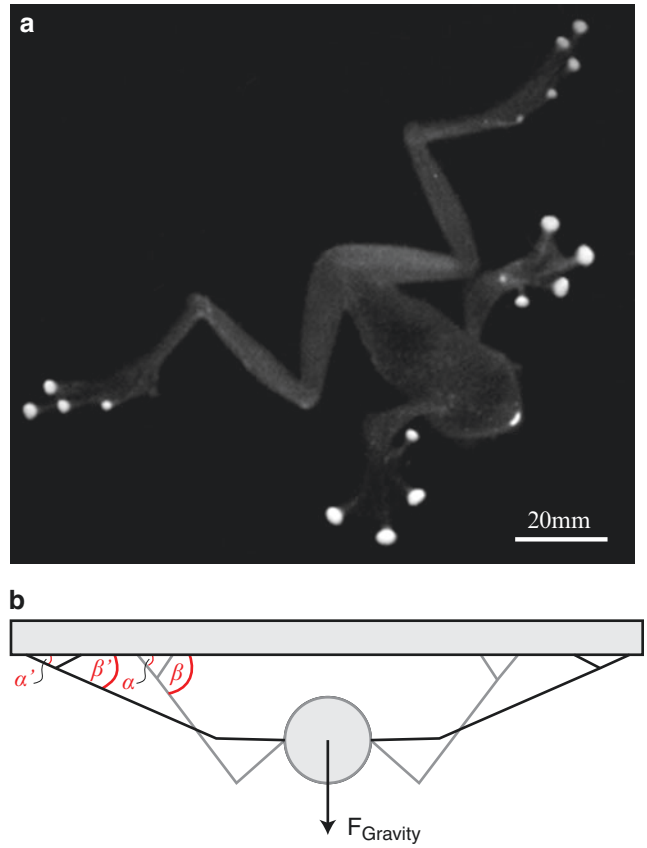
cells increases adhesion according to the principle of contact splitting. This theory states that adhesive force is proportional to the length of the contact; therefore, by splitting up the contact zone into many small areas of contact, the total adhesive force can be increased by the square root of the density of these small areas [23]. This principle clearly applies to wet adhesion. However, as the major force component of wet adhesion is capillarity, it is necessary that an air-water interface (meniscus) should surround each small area of contact. This is true of the hairy pads of insects, but is not applicable to tree frogs, where the meniscus surrounds the whole toe pad, not the individual epithelial cells.

In recent years, the development of a technique to measure adhesion and friction forces from single toe pads (Fig. 9) has resulted in a number of interesting findings. The frog is held in a container with holes in its base through which individual digits can protrude. Toe pad forces are measured by a two-axis force plate, manipulated so that it makes contact with the protruding toe. As well as recording forces, the plate has a feedback facility so that, for instance, load can be kept constant while recording friction forces. This technique has provided good evidence for the presence of static friction in tree frog toe pads [18]. This is demonstrated both by the buildup of friction force at the onset of sliding and also from the presence of a remaining shear force 2 min after the sliding motion had stopped (Fig. 10). This is strongly indicative of actual contact of the nanopillars with the substrate, in accord with the findings of interference reflection microscopy (see above). By making measurements from pads of different sizes, one can also do scaling experiments with single pads. Such experiments demonstrate that friction forces are independent of load but correlate well with the area of contact. This is contrary to what one would expect of classic (Coulomb) friction, but in line with rubber friction. This conclusion fits well with the results of indentation experiments (see above), since the low elastic modulus of tree frog toe pads allows close contact between pad and substrate. Adhesion forces of single pads scale with pad area when pads are pulled off the force plate at a low angle



Wet Adhesion in Tree and Torrent Frogs, Fig. 10 Shear force measurement in single toe pads of White's tree frog *Litoria caerulea*. The recording shows the result of a 20 s sliding movement toward the body (500 μms^{-1}), followed by a 2 min period when no movement occurred. The *arrows* indicate the force when the pad began to slide ("onset"), the force when sliding ended ("sliding"), and the force when the experiment was terminated after the 2 min rest ("remaining") (Redrawn from Federle [18])

(20–50°), in line with whole animal measurements. However, they scale with length when the pull-off is at right angles to the surface. This has significance for toe pad detachment mechanisms (see below).



Finally, such single pad experiments provide evidence for the dominant role of capillarity in tree frog adhesion, since toe pad adhesive forces fall to low levels when the meniscus surrounding the pad is removed by submerging the whole pad in a drop of water. However, recent results from studies on rock frogs of the genus *Staurois* demonstrate that they are exceptionally good (in comparison to similarly sized tree frogs) at adhering to rough surfaces when they are completely flooded with water [25]. This is made possible by the frogs using large areas of their ventral surface (especially belly and thighs) in addition to their toe pads. This experiment clearly demonstrates a role for hydrodynamic forces (or possibly van der Waals forces resulting from direct contact), as the depth of the water will have abolished most of the air-water interfaces needed for capillarity.

Toe Pad Detachment

During locomotion, toe pads are detached by peeling, a mechanism that obviates the need for the frogs to pull their feet from the substrate every time they wish to jump or take a step [3]. During forward walking, climbing, or jumping, toe pads are peeled from the rear forwards, i.e., in a proximal to distal direction. Indeed, use of a force platform to measure directly the forces generated by the feet during locomotion shows that, during forward locomotion, this peeling is not accompanied by any significant detachment forces. It appears to occur as a natural consequence of the way in which toes are lifted off surfaces from the rear forwards during forward locomotion. This is supported both by observations of peeling in single toe pads of anesthetized frogs and by the inability of frogs to adhere to vertical surfaces in a head-down orientation. Indeed, frogs on a rotating vertical surface have been observed to adjust their orientations back toward a "head-up" orientation whenever their deviation from this orientation reached $85 \pm 21°$. The peeling process is seen most clearly when the pad is viewed from the ventral side using high-speed video imaging (Fig. 11b), recording both toe pad contact area and ground reaction forces. For instance, recordings during climbing on a vertical surface show that fore-aft forces (along the longitudinal snout-to-vent axis of the frog) drop to zero during the

Wet Adhesion in Tree and Torrent Frogs, Fig. 11 Toe pad dynamics of the tree frog *Litoria caerulea* climbing a vertical surface. (**a**) A glass plate is illuminated from the side by arrays of light-emitting diodes that direct the light within the thickness of the plate, the light only escaping (and therefore visible to the camera) when an object, here the frog, contacts the glass. (**b**) Change of a (*right*) forelimb pad contact area during a complete step (data acquisition rate 1,613 Hz, video rate 300 Hz) showing the attachment and detachment process by peeling (*red dots* correspond to the time stamps of the image sequence). Ground reaction forces (corrected for the alignment of the toe to the sensor) show a sign change at the beginning of the detachment process (encircled area). Unpublished data kindly provided by Diana Samuel, University of Glasgow

Wet Adhesion in Tree and Torrent Frogs, Fig. 12 (**a**) Video image of a ventral view of the tree frog (*Rhacophorus pardalis*) clinging to an inverted translucent surface, illuminated with internally reflected light (see Fig. 11a). Note how both fore- and hind limbs stretched out sideways. *Bright spots* are areas in contact with the surface. (**b**) Two-legged explanatory model. Both toes and legs are extended (from *gray* to *black* figure) to reduce the angles α (toe/substrate angle) and β (leg/substrate angle) to α' and β' and thus reduce the chances of peeling

detachment process and may even change in sign, indicating that the frog actively pushes outward to release any shear strain on the pads and thus facilitates peeling.

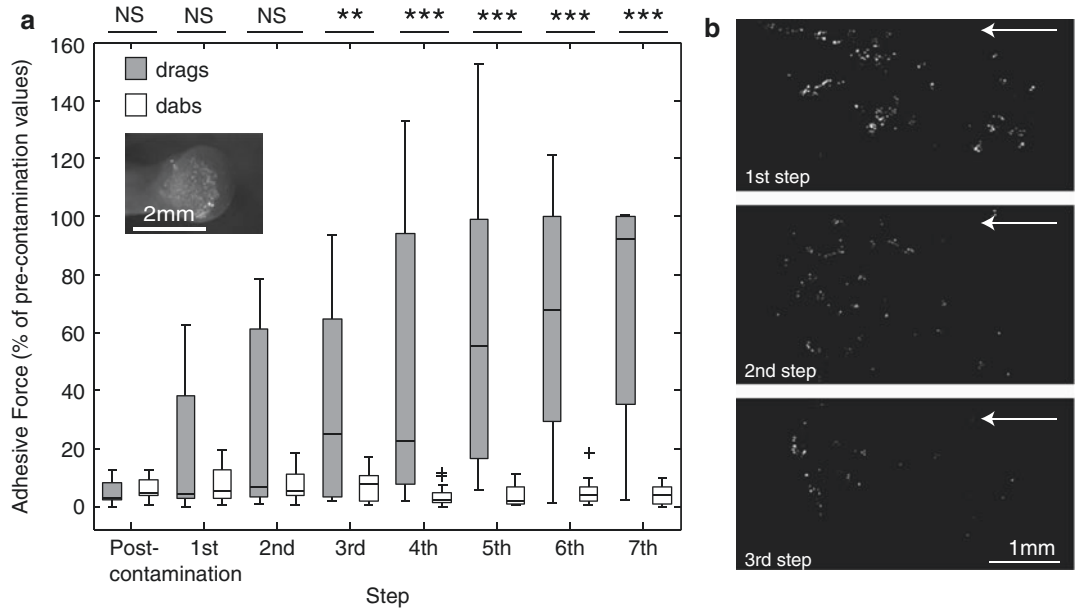
When frogs are induced to walk backward, peeling occurs in the opposite direction, from the front of the pad rearward in a distal to proximal direction. In this situation, peeling is an active process involving the distal tendons of the toes. Clear detachment forces can be recorded, as also occur when belly skin inadvertently comes into contact with the force platform.

Behavioral Strategies of Adhering Frogs

Interestingly, peeling has consequences for frog behavior. This is because pads can produce strong adhesion and friction when the angle of force application is low, but peel easily off the surface when the pull-off angle approaches 90°. On vertical and overhanging surfaces, frogs must therefore adjust their posture so that gravity acts on the pads at angles where they can withstand the force and not fall from the surface. On a rotation platform, the first response to the changing angle occurs at angles between 60° and 100°, heavier frogs tending to respond first. Any frog not already in a head-up position will turn to face head up, so that gravity will not be acting to pull the pads off the surface. At still higher angles, both tree and torrent frogs spread their legs out sideways (Fig. 12). This is an adaptation to prevent peeling, since, as the figure shows, spread out limbs have a much smaller pad-substrate angle than limbs held close to the body. Gravity, of course, will tend to pull the limbs inward, but this is resisted by pad friction forces. In this way, friction and adhesion both play roles in helping frogs to maintain their grip under challenging conditions. The term frictional adhesion has been coined to describe adhesion in geckos. It is unclear whether this term should also be applied to tree frog adhesion, but there is certainly

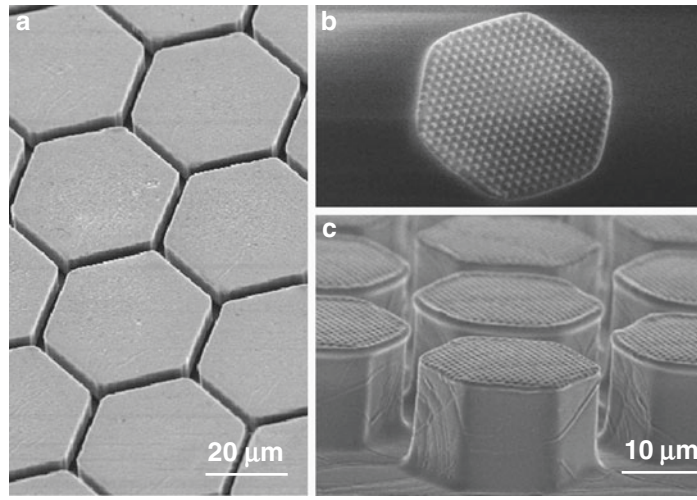
interplay between friction and adhesion forces in frog toe pads too.

A recent study by Endlein et al. [26] has explained the frog's spreading behavior by studying the underlying ground reaction forces during this behavior. By using an array of multiple force transducers embedded in a walkway, the authors were able to record the ground reaction forces of a frog clinging on to the platform at varying slopes. When the incline of the platform reached an overhanging position (at inclines past the vertical), the frogs spread their legs out sideward as described above. By using opposing legs, frogs pulled their legs inward which resulted in a dramatic increase in the lateral forces (forces perpendicular to the animals' longitudinal snout-to-vent axis). These large lateral forces caused the overall resulting force vector (the vectorial sum of all three force components) to adopt a very shallow angle toward the surface. As explained above, this can be compared to the peeling of an adhesive tape where a low angle of peel makes it very difficult to remove the tape from the surface, thus enhancing the adhesive capability of the frog. However, as the lateral forces increased, legs tended to slide slowly inward (toward the body). This in turn increased the risk of peeling (larger peeling angle), and frogs compensated for this by intermittently placing their feet outward again.



Self-Cleaning of Toe Pads

For any organism which uses adhesive pads, keeping them clean and contaminant-free is key for efficient climbing, as the presence of particles on the pad interface can have a detrimental effect on adhesion. However, the natural world is full of loose particles like dust, sand grains, or even plant coatings which have evolved to break off in order to clog up the adhesive pads and thus prevent the attachment of climbing animals. It was shown by Crawford et al. [24] that a self-cleaning mechanism (which works passively as the frog is climbing, rather than requiring grooming) exists in the toe pads of tree frogs which allows pads to become decontaminated quickly and therefore regain adhesive ability. This was studied by firstly challenging the frogs to cling on to increasingly steeper inclines using a tilting platform. After testing the performance of uncontaminated, "clean" toe pads, the pads were artificially contaminated using 50 μm glass beads and tested again for recovery of sticking ability. It was found that frogs which moved and used their pads more while climbing removed more contaminant and therefore recovered their sticking ability quicker. In order to understand the mechanism behind this recovery of adhesion, the authors measured the adhesive forces produced by a single toe pad using a force transducer mounted to a motorized stage. This way, controlled movements of the pads ("simulated steps") could be performed while measuring their adhesion. It was found that the inclusion of a short shear drag of the pad against the surface ("drag" vs. "dab"; Fig. 13a) before detachment drastically improved the detachment of the contaminant particles by rolling off. This was also aided by the adhesive fluid left behind on the surface with each step where contaminants would gather (Fig. 13b). Like geckos and insects, tree frogs' self-cleaning toe pads provide a novel trait of dynamic adhesives in nature which would be highly useful in man-made adhesives.



Biomimetic Advances

As far as tree frog adhesion is concerned, the process of micro- or nanofabrication of toe pad replicas, where the effect of the individual design parameters can be analyzed and quantified precisely, is in its infancy. An early attempt at copying the hexagonal cell structure of tree frog toe pads in polydimethylsiloxane (PDMS) is illustrated in Fig. 14a, whereas a recent mimic of structure of a tree frog's toe pad epithelium that replicates both nano- and microstructures, from del Campo's research group at the Max Planck Institute for Polymer Research in Mainz, Germany, is shown in Fig. 14b, c.

However, the role of surface patterning in increasing adhesion is well established. Adhesive tape detaches by the spreading of cracks along the interface from the point of peeling. When all the energy can be concentrated at a single crack, then peeling occurs readily, but micropatterning can

Wet Adhesion in Tree and Torrent Frogs, Fig. 13 Recovery of adhesive forces after contamination. (**a**) Adhesive force (normal component of pull-off force) as a percentage of the mean pre-contamination values for both the "drag" (*filled boxes*) and "dab" (*open boxes*) forms of the experiment. The *boxes* represent consecutive simulated "steps" taken by the toe pad on the force plate following pad contamination. Statistical tests were performed on each pair, with the results for each shown above the plots; *NS* not significant, *: $p < 0.05$, **: $p < 0.01$, ***: $p < 0.001$. *Inset*: contaminated toe pad. (**b**) Example of deposited beads after three consecutive steps (including a drag movement). Beads are deposited in characteristic "footprints" and frequently toward the end of the "drag" in clusters caused by the mucus. The *arrows* indicate the direction of the drag (Modified from Crawford et al. [24])

The PDMS was made hydrophilic by treatment in a plasma chamber and has an elastic modulus in the range 1–5 MPa (Image: Max Planck Institute for Polymer Research, Mainz (Germany))

increase the force required to produce peeling by up to a factor of three by the principle of contact separation. Cracks form wherever there is a groove in the pattern, so that the energy is spread between many cracks, resulting in an increased force being required to produce separation [14]. Recently, this principle has been taken a step further, and the role of subsurface structures (air- or oil-filled micro-channels) has been investigated. These have crack-arresting properties just like the transverse grooves of a patterned surface, but the effect is much more dramatic, for adhesion can be increased up to 30-fold. The adhesive itself remains elastic, which renders it reusable with no reduction in adhesive efficiency [27].

Turning from patterned dry adhesion to wet adhesion, some of the published work is insect rather than frog inspired. Of particular interest are studies of the frictional properties of a structure like that in Fig. 14a. Although the addition of fluid lowered friction as would be expected, the micropatterned surface was able to generate significantly higher frictional forces during sliding than an otherwise identical smooth one [28, 29], presumably by preventing aquaplaning. It has also been demonstrated that hydrophobic hexagonal patterns can be beneficial for adhesion under wet conditions, depending on the topographic design. For instance, mushroom-shaped pillars can produce a tenfold increase in adhesion underwater against flat controls [28, 30]. Whether this increase is due to a suction effect remains to be confirmed.

The effect of hydrodynamic forces on toe pad-inspired mimics was investigated recently by Shahsavan and Zhao [31] and Gupta and Fréchette [32]. Both studies confirmed a reduction of hydrodynamic force for squeezing out the fluid in the presence of channels, thus facilitating the close contact of a structured toe pad to the substrate.

Examples of Possible Applications

Since adhesive tapes inspired by the dry adhesive mechanisms of gecko toe pad setae are now reaching a stage where commercialization is imminent, it is appropriate to consider whether the rather different wet adhesion mechanism of tree and torrent frogs might also have biomimetic relevance. Improved wet weather tires [13, 33, 34], nonslip footwear, plasters for surgery able to adhere to tissue, and holding devices for neurosurgery or MEMS devices are obvious examples of the many uses to which these toe pad analogues might be applied. However, as biomimetics is as much to do with inspiration as copying, a beetle-inspired device providing reversible adhesion based on capillarity is worthy of mention as it utilizes wet adhesion [35]. It generates an adhesive force through the formation of a large number of liquid bridges between two plates, which can be quickly made or broken by a low-voltage pulse that drives electroosmotic flow. There is good potential for the development of a grab-and-release device that could carry significant loads.

A recent study by Tsipenyuk and Varenberg [36] showed the advantage of using structured surfaces (hexagonal patterns inspired by tree frogs and some insects) for disposable safety razors. In their study, the authors replaced the standard stretching unit of the razors with bioinspired ones and reported significantly enhanced friction forces against human skin. This was due to more effective channeling of the lubricant fluid out of the contact zone.

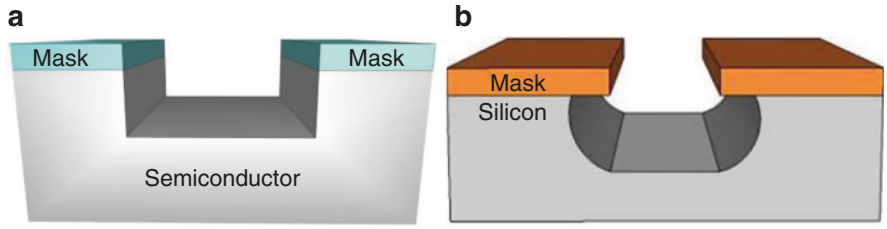
Isotropy and Anisotropy

When a material is attacked by a liquid or vapor etchant, the material will be removed isotropically (uniformly in all directions) or through anisotropic etching (uniformity in vertical direction). The difference between isotropic etching and anisotropic etching is shown in Fig. 1. Material removal rate for wet etching is usually faster than the rates for many dry etching processes and can easily be changed by varying temperature or the concentration of active species.

Wet Etch

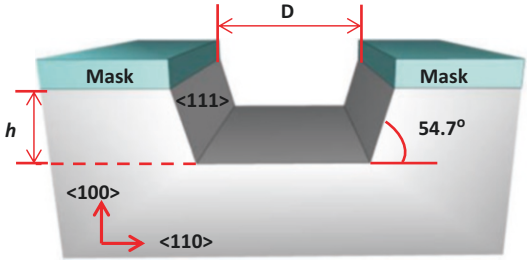
Synonyms

Chemical etching; Liquid etching



Definition

Wet etching is a material removal process that uses liquid chemicals or etchants to remove materials from a wafer. The specific patters are defined by photoresist masks on the wafer. Materials that are not protected by this mask are etched away by liquid chemicals. These masks are deposited on the wafer in an earlier fabrication step called lithography.

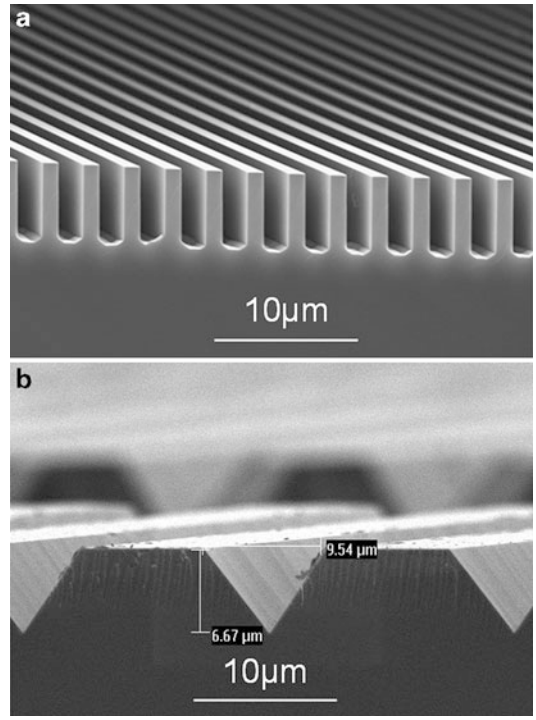


A wet etching process involves multiple chemical reactions that consume the original reactants and produce new reactants. The wet etch process can be described by three basic steps (1) diffusion of the liquid etchant to the structure that is to be removed and (2) the reaction between the liquid etchant and the material being etched away. A reduction-oxidation (redox) reaction usually occurs. This reaction entails the oxidation of the material then dissolving the oxidized material. (3) Diffusion of the byproducts in the reaction from the reacted surface.

Anisotropic Wet Etching

Liquid etchants etch crystalline materials at different rates depending upon which crystal face is exposed to the etchant. There is a large difference in the etch rate depending on the silicon crystalline plane. In materials such as silicon, this effect can allow for very high anisotropy [1]. Some of the anisotropic wet etching agents for silicon are potassium hydroxide (KOH), ethylenediamine pyrocatechol (EDP), or tetramethylammonium hydroxide (TMAH). Etching a (100) silicon wafer would result in a pyramid-shaped etch pit as shown in Fig. 2. The etched wall will be flat and

Wet Chemical and Electrochemical Etching Processes, Fig. 1 (**a**) Completely anisotropic etching of a semiconductor (**b**) Isotropic etching where the semiconductor is etched all around uniformly if not masked

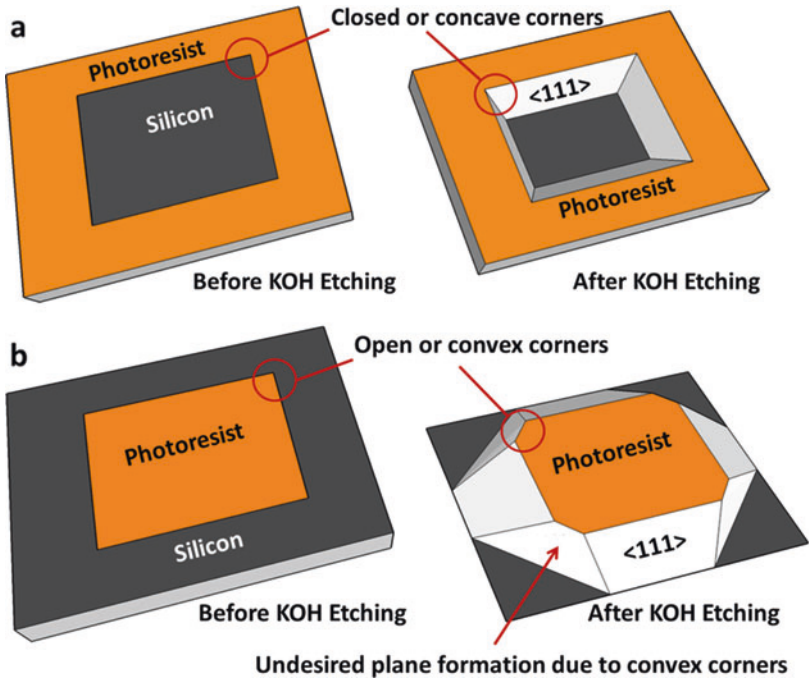


Wet Chemical and Electrochemical Etching Processes, Fig. 2 Example of an etch profile in anisotropic of (100) silicon wafer. The etchant in this case is aqueous KOH that etches the unmasked areas of the silicon wafer till it encounters the <111> plane

angled. The angle to the surface of the wafer is 54.7°.

The relationship between mask dimensions, etch depth and the floor width is given in Eq. 1.

$$d = D - \left(\frac{2h}{\tan(54.7^\circ)}\right) \qquad (1)$$

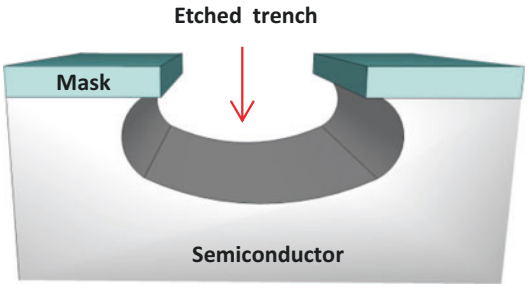


On the other hand, the orientation of the 111 plane on <110> oriented silicon lies horizontally to its surface at exactly 90°. Therefore, KOH etching of the <110> oriented silicon wafer results in perfectly anisotropic trenches as depicted in the scanning electrode microscopy picture in Fig. 3a unlike.

Wet Chemical and Electrochemical Etching Processes, Fig. 3 Anisotropic etching of (**a**) <110> and (**b**) <100> oriented Si in KOH solution

Problems Related to Anisotropic KOH Etching

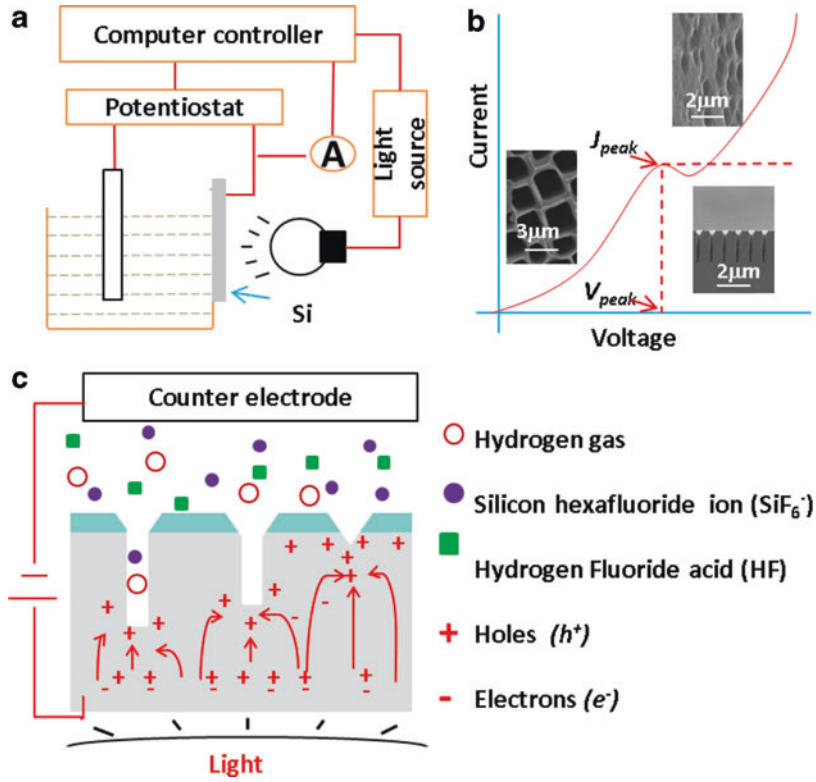
Structures with open corners commonly termed as convex corners loose the integrity of the corners during KOH etching. The widely accepted understanding describes that the higher-order planes confining these corners tend to etch faster resulting in undesirable corner formation [2]. In order to compensate for the corner undercutting for open ends in KOH, compensation structures are added to these open corners. However, the space consumed by the compensation structures is a major impediment toward the use of the corner compensation concept. In extreme cases, compensation structures twice as wide as the etch depth targeted with KOH etching may be required [3]. For through wafer KOH etching, the use of larger



Wet Chemical and Electrochemical Etching Processes, Fig. 4 Convex corner undercutting with KOH etching

and more efficient compensation structures is needed. Design and fabrication of space-efficient compensation structures to provide sharp resultant corners after KOH etching is an actively pursued research topic in the field of silicon processing [4] (Fig. 4).

Isotropic Wet Etching



For isotropic wet etching, a mixture of hydrofluoric acid, nitric acid, and acetic acid (HNA) is the most common etchant solvent for silicon. The concentrations of each etchant determines the etch rate. Silicon dioxide or silicon nitride is usually used as a masking material against HNA. As the reaction takes place, the material is removed laterally at a rate similar to the speed of etching downward. This lateral and downward etching process takes places even with isotropic dry etching which is described in the dry etch section. The isotropic wet etch is shown in Fig. 5. Wet chemical etching is generally isotropic even though a mask is present since the liquid etchant can penetrate underneath the mask. Since directionality is usually important for high-resolution pattern transfer, wet chemical etching is normally not used.

Wet Chemical and Electrochemical Etching Processes, Fig. 5 Isotropic etching of masked semiconductor

Electrochemical Etching Techniques

Apart from chemical approaches, semiconductors and even other materials such as metals can be etched by application of an external electrical current. Here, a potentiostat or galvanostat provides the electrical charge required to perform the etching [5]. It further provides a means of

Wet Chemical and Electrochemical Etching Processes, Fig. 6 (**a**) The setup for photoelectrochemical of *n*-type semiconductors such as silicon. For *p*-type silicon, the light source and lamp is not included. (**b**) The current versus voltage characteristics of a *p*-type and strongly illuminated n-type silicon wafer under anodic biasing. The SEM images show etching characteristics of the semiconductor surface at various potentials. Notice that at voltages above *Vpeak* and current bellow J_{peak}, good control of anisotropic etching can be achieved. (**c**) The etching mechanism of an *n*-type silicon. Holes are generated at the backside of the wafer. Due to the applied potential, an electric field created therein causes the holes to travel to the surface of the wafer which is in contact to the electrolyte where a reaction leads to dissolution of silicon

controlling the etching process and profiles of the features to be etched through increasing or decreasing either the etching current or potential as desired. In a typical setup for such an etching process, a semiconductor to be etched is arraigned in an electrochemical cell with the surface of the semiconductor to be etched exposed to an electrolyte as shown in Fig. 6a. The electrolyte is composed of a liquid and ions that are needed to conduct electrical charge as well as dissolve the semiconductor upon application of the required electrical current. The back of the semiconductor is connected to the anode of the power supply [6]. Successful electrochemical etching is dependent on several factors such as:

(i) Type of semiconductor
(ii) Doping density (resistivity) of the semiconductor
(iii) Type of doping (*n* or *p*) doped

Although theoretically any semiconductor can be anodically dissolved in an acidic electrolyte which contains F^- ions if holes (h^+) are available, this condition is not met for *n*-doped semiconductors since it does not have holes. This can be achieved by illuminating the sample from the back as illustrated in Fig. 6a. So far, most developed recipes have been using silicon wafers whose resistivity lies in the range of 1–30 Ω.cm. The etching mechanism for dissolution of silicon

has been established. In the presence of holes at a surface, hydrofluoric acid dissolves silicon according to the reaction as shown in Eq. 2 below [5].

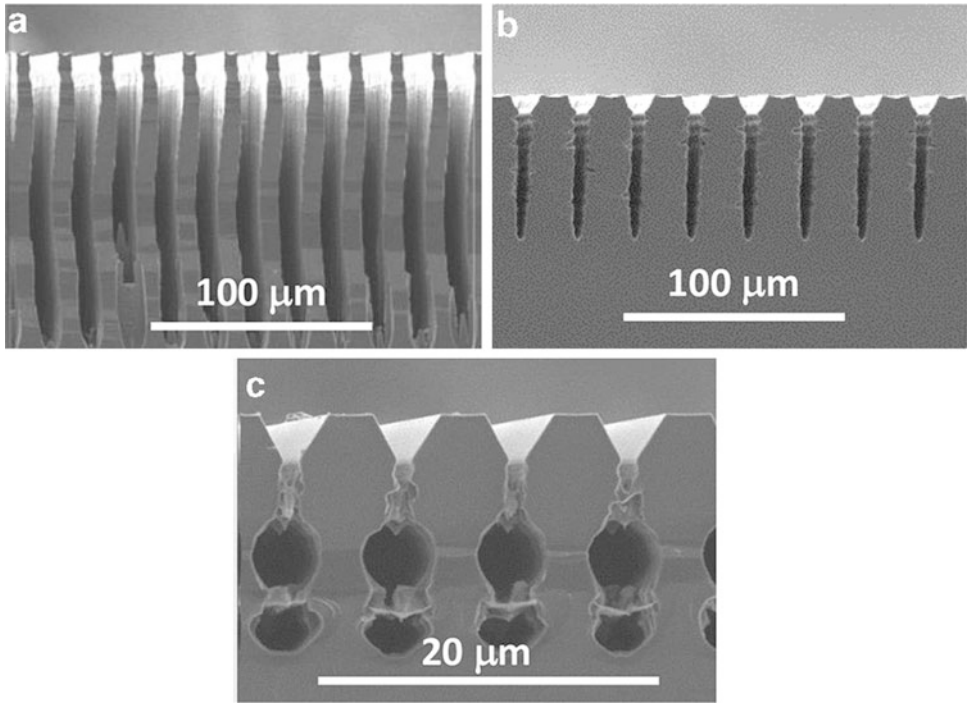
$$Si_{(s)} + 6HF_{(aq)} + 2h^{+} -> SiF_6{}^{2-}{}_{(aq)} + 4H^{+}{}_{(l)} + H_{2\,(g)} \tag{2}$$

where e^{-} and h^{+} denote an electron and hole respectively. The current voltage relations of either *p*-type or illuminated n-type silicon under anodic biasing are shown in Fig. 6b. For current densities above J_{peak}, electropolishing (uniform surface etching) occurs, while below that, the semiconductor surface forms a porous layer. However, at voltages higher than V_{peak} and current density below J_{peak}, successful control of anisotropicity can be achieved [7].

For anisotropic dissolution of *n*-type silicon to form deep trenches or holes, a silicon wafer is first patterned with KOH to form reverse pyramids or "V" grooves on the surface of silicon like those depicted in Fig. 3b. Upon illumination of the wafer from the back while under anodic biasing, generated holes travel to the opposite surface of the wafer. The holes preferentially accumulate at the trench depth due to the electric field generated from the applied potential. Once at the trench depth, the reaction depicted in Eq. 2 occurs. The number of holes generated can be controlled by varying the intensity of the light. This can have an effect of modulating the reaction rate as well as the anisotropicity of the generated holes or trenches. This is depicted in Fig. 6c. The same process can occur in *p*-type wafer since the charge carriers therein are holes [8]. However, light has no effect in that case. Holes with uniform and nonuniform diameters can be easily generated by maintaining the current/voltage ratio over time as shown in Fig. 7a. However, by modulating the applied current over time, trench or hole diameters can be changed as depicted in Fig. 7b, c.

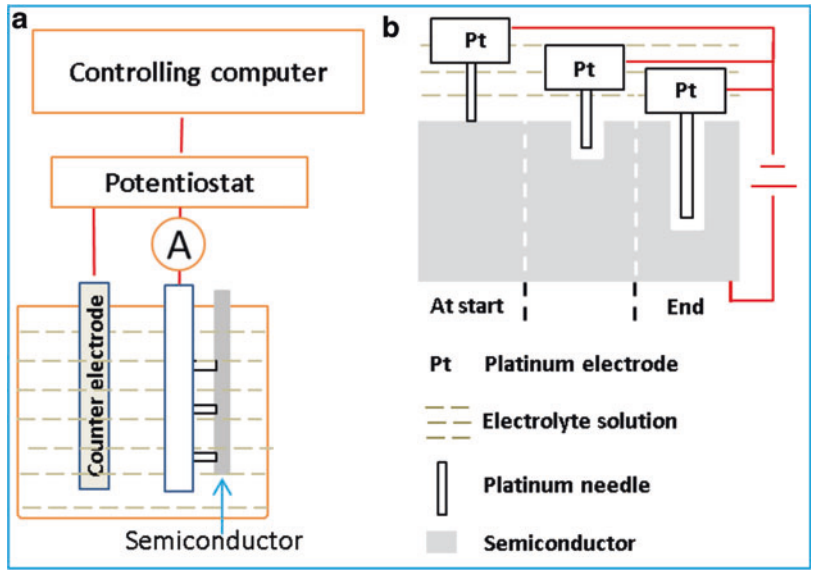
Rather than appling potential anodically on a semiconductor to be etched, holding the anodizing electrode next to the electrode can catalyze the dissolution of the semiconductor just below the electrode [9]. As long as this contact is maintained, etching proceeds. Anisotropy is achievable by applying pressure on the anodizing electrode. The electrolyte to be used is dependent on the semiconductor to be used. For silicon, an aqueous 30 M HF electrolytic solution was used. Anisotropic etching of SiC on the other hand uses sulfuric acid in combination with hydrofluoric acid [10]. Just like the noncontact electrochemical etching, dissolution of Si via contact anodization is achieved using a similar mechanism as the noncontact dissolution. Hence, Eq. 3 is still valid. However, the holes are injected into the semiconductor from the electrode as depicted in Fig. 8.

Metal Assisted Chemical Etching



In this technique, a semiconductor substrate is selectively etched in an aqueous solution of HF with the help of noble metal in the presence of a strong oxidizing agent like peroxide in the normal plane. The reaction mechanism can be summarized in Eqs. 3 and 4. Here, the oxidant (hydrogen peroxide) first oxidizes the metal catalyst (Eq. 3). The oxidized metal then reacts with the semiconductor (silicon) in the presence of the acidic ions to produce soluble silicon hexafluoride ion while the metal is reduced to its metallic state as shown in Eq. 4 [11, 12].

$$H_2O_{2(aq)} + 2H^{+}{}_{(aq)} + Ag_{(s)} <- > 2H_2O_{(l)} + 2Ag^{+}{}_{(Aq)} \tag{3}$$



$$4Ag^{+}{}_{(aq)} + Si + 6F^{-}{}_{(aq)} <- > 4Ag_{(s)} + SiF_6{}^{2}{}_{-(aq)} \tag{4}$$

The first reaction is known to be thermodynamically favorable and stops with the depletion of the peroxide around the metallic surfaces which effectively decreases the etching rate for *n*-type silicon given that Ag^{+} is pertinent in Si etching.

High aspect ratio and uniform trenches and holes with diameters as low as 20 nm can be generated. Etching progresses as long as the catalytic film is in contact with the semiconductor. This is achieved gravitationally. Overly wide catalyst films tend to slow the etching process and sometimes may cause nonuniform features. Some of the large structures obtained via this method in our laboratory are depicted in Fig. 9.

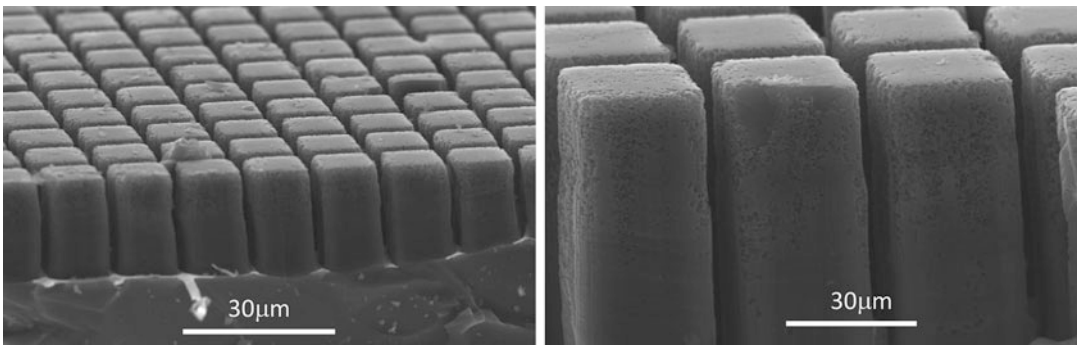
The anodizing potential is applied directly on the surface of the semiconductor directly with an electrode. (**b**) A schematic depicting the progress of the etching process. Over time, the anodizing electrode burrows into the semiconductor

Magnetically Guided Metal Assisted Chemical Etching



Here, an additional magnetic metal is incorporated into the etchant metal film such that it can respond to external magnetic stimuli so as to guide and manipulate the etching process [13]. The etching mechanism as described in Eqs. 3 and 4 is still valid. The additional magnetic field can

Wet Chemical and Electrochemical Etching Processes, Fig. 9 Schematic of metal-assisted chemical etching process. In the magnetically assisted version, a ferrous metal is sandwiched inside the catalytic noble metal film

Wet Chemical and Electrochemical Etching Processes, Table 1 Comparison of semiconductor etching systems other than the traditional CMOS adapted ones

	Method	Advantages
Photoelectrochemical etching of n-type silicon	Strong source of light N-doped silicon (1–30 Ω.com) 2–5 % HF solution Potentiostat Platinum reference and counterelectrode required	High aspect ratio structures achieved Good control of the anisotropic etch Low acidity used High etch rate (up to 10 μm/min) Accommodated wider range of substrate resistivity (1–30 Ω.com)
Electrochemical etching of p-type silicon	Strong source light N-doped silicon (20 Ω.com) 2–5 % HF solution Potentiostat Platinum reference and counterelectrode required	High aspect ratio structures achieve Low acidity used No light requirement High etch rate (up to 10 μm/min)
Contact anodical etching of semiconductor	28 % HF solution Nobel metal to be in contact with substrate	No light requirement Etch rate of up to 3 μm/min Can produce structures at acute angles
Metal-assisted electroless etching	5 M HF, 0.5 M H_2O_2electrolyte required Nobel metal pattering High etch rate	High aspect ratio structure achieve No light requirement Etch rate approaching 2 μm/min
Magnetically controlled metal-assisted electroless etching	5 M HF, 0.5 M HF, H_2O_2electrolye required Nobel metal and ferrous metal sandwich patterning Magnet manipulation require Low etch rate	Infinite possibilities on 3-dimensional etch profiles The etch rate can be modulated by the strength of the magnet Can produce structures at any angle Has no restriction on the crystal orientation of the wafer

Wet Chemical and Electrochemical Etching Processes, Fig. 10 SEM images silicon micropillars prepared by metal-assisted chemical etching

potentially be manipulated in such a way that intricate three-dimensional features that cannot be obtained via any other etching method are realized. A key impediment however lies with the incorporation of the ferrous metal onto the metallic etchant which involved tandem deposition of metallic trilayers in which the latter sandwiches the former for protection from the strong reducing etching solution. Additionally, unlike electrical field which is straight, the shape of the magnetic field often changes with distance hence it is difficult to exclusively manipulate the metallic etching system. The resolution of the resultant three-dimensional features is therefore a little low. Table 1 is a summary of these etching techniques (Fig. 10).

Wetting Transitions

Edward Bormashenko
Laboratory of Polymers, Physics Department, Ariel University, Ariel, Israel

Definition

The wetting transition is an abrupt change, spontaneous or induced by external stimulus, in the wetting properties of a flat or rough solid surface.

Wetting of Rough Surfaces and Wetting States

Wetting is a spreading of liquid on a solid or liquid substrate. It is ubiquitous and of primary importance in chemical, automobile, and food industries and medicine, soil, and climate sciences. Various technological applications call for surfaces with a

controlled wettability, in particular water- and oil-repellent surfaces. Rapid progress of *nanotechnologies* has allowed the fabrication of biomimetic surfaces demonstrating pronounced water repellence (the so-called lotus effect [1]). A variety of natural objects, such as birds' and butterflies' wings and legs of water striders, demonstrate extreme water repellency (superhydrophobicity, which is one of the *surface tension effects of nanostructures*) [2–4]. Various sophisticated experimental techniques, including UV lithography and plasma etching, were successfully applied for manufacturing lotus-like biomimetic surfaces [4, 5]. Superhydrophobic surfaces demonstrate a potential for a variety of green technologies, including energy conversion and conservation, and environment-friendly self-cleaning underwater surfaces [5].

The wetting of flat and rough surfaces is characterized by a contact angle, which is defined as the angle between the tangent to the liquid–fluid interface and the tangent to the solid surface at the contact line between the three phases (solid, liquid, and vapor) [6, 7]. The Young (or equilibrium) contact angle θ is the angle that a liquid makes with an ideal (smooth, rigid, chemically homogenous, insoluble, and nonreactive) surface. The Young angle θ is given by the well-known Young equation:

$$\cos\theta = \frac{\gamma_{SA} - \gamma_{SL}}{\gamma} \tag{1}$$

where γ, γ_{SL}, and γ_{SA} are the surface tensions at the liquid/air (vapor), solid/liquid, and solid/air (vapor) interfaces, respectively. The contact angle of a droplet deposited on a solid depends on external parameters, such as temperature. Change in temperature may stimulate the transition from the partial wetting to the complete wetting of the solid substrate. In this case, one observes a wetting transition (WT) on a smooth solid surface [8].

The Young equation supplies the sole value of a contact angle for a certain combination of solid, liquid, and gaseous phases. However, the experimental situation is much more complicated; even on atomically flat solid surfaces, a diversity of contact angles is observed. This is due to the long-range interaction between molecules forming the triple (three-phase) line of the droplet and molecules forming the solid substrate. The maximal possible contact angle observed on the surface is called the advancing angle θ_{adv}; the minimal one is called the receding angle θ_{rec} [6, 7]. The difference between advancing and receding contact angles $\theta_{\mathrm{adv}} - \theta_{\mathrm{rec}}$ is called the contact angle hysteresis [6, 7]. Experimental establishment of advancing and receding angles is a challenging task, and it should be mentioned that the reported contact angles are sensitive to the experimental technique used for their measurement. Both advancing and receding are equilibrium (though metastable) contact angles [7].

The wetting of rough and chemically heterogeneous surfaces is described by the apparent contact angle θ^* (APCA), which is different from the local contact angle given by Young's relation [6, 7]. The APCA is an equilibrium contact angle measured macroscopically. The detailed topography of a rough surface cannot be viewed with regular optical means; therefore, this contact angle is defined as the angle between the tangent to the liquid–vapor interface and the apparent solid surface, as macroscopically observed [7]. Superhydrophobic surfaces are characterized by high values of APCA (usually $>150^\circ$). However, high APCA does not necessarily guarantee the true superhydrophobicity and self-cleaning properties observed in nature. Moreover, high-stick surfaces demonstrating a high APCA were reported recently. Low contact angle hysteresis resulting in low sliding angles and high stability of "lotus-like" wetting state, as well as high APCA, supply water-repellent and self-cleaning properties to the surface. The design of such surfaces, allowing emerging green applications, remains a challenging scientific and technological task.

Chemical heterogeneities and roughness strengthen the hysteresis of a contact angle. The wetting of flat, chemically heterogeneous surfaces is characterized by the APCA θ^*, predicted by the Cassie–Baxter wetting model [9]. Consider wetting of a composite flat surface comprised of several materials. Each material is characterized by its own surface tension coefficients $\gamma_{i,\,SL}$ and $\gamma_{i,\,SA}$,

and by the fraction f_i in the substrate surface, $f_1 + f_2 + \ldots + f_n = 1$. The APCA in this case is supplied by the Cassie–Baxter equation:

$$\cos\theta^* = \frac{1}{\gamma}\sum_1^n f_i(\gamma_{i,SA} - \gamma_{i,SL}) = \sum_1^n f_i \cos\theta_i \quad (2)$$

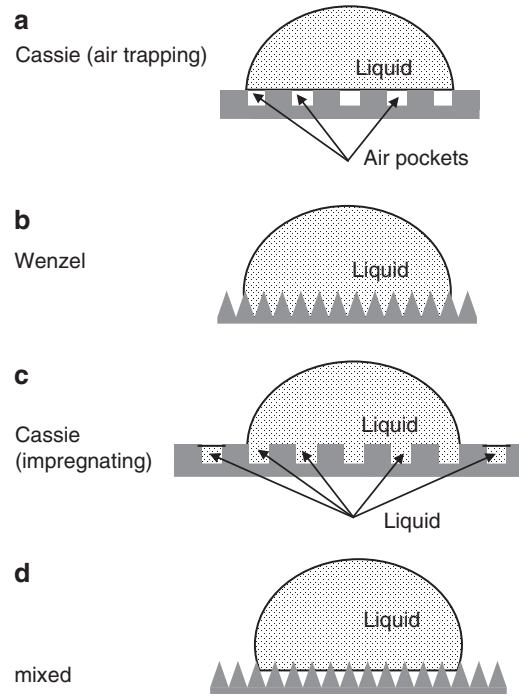
where θ_i are equilibrium contact angles for the i^{th} material. The Cassie–Baxter equation can be applied to the solid surface comprised of pores (the contact angle for pores is π and $\cos\theta = -1$; see Fig. 1a). In this case, the Cassie–Baxter equation yields

$$\cos\theta^* = -1 + f_S(\cos\theta + 1) \quad (3)$$

where f_S and $1-f_S$ are the relative fractions of the solid and air fractions underneath the drop, respectively. The Cassie air-trapping wetting state is also called the "fakir state." The Cassie-like air-trapping wetting provides easy sliding of water droplets. When the relief is hierarchical, the Cassie–Baxter equation obtains more complicated forms, taking into account the interrelation between the scales constituting the topography of the relief.

The wetting of rough, chemically homogenous surfaces is governed by the Wenzel model [10]. According to the Wenzel model, surface roughness r, defined as the ratio of the real surface in contact with liquid to its projection onto the horizontal plane, always magnifies the underlying wetting properties (see Fig. 1b). Both hydrophilic and hydrophobic properties are strengthened by surface textures. The apparent Wenzel contact angle is given by Eq. 4:

$$\cos\theta^* = r\cos\theta \quad (4)$$

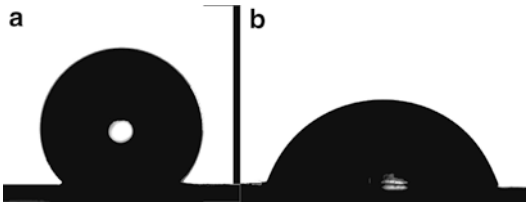


The Cassie wetting is featured by low contact angle hysteresis, whereas Wenzel-wetted surfaces demonstrate high hysteresis of the contact angle. Actually, pure Cassie and Wenzel wetting situations are rare in occurrence, and a mixed wetting state is often observed [11]. In the mixed wetting state, a droplet partially wets the surface and partially sits on air pockets, as described in Fig. 1d. The APCA θ^* is supplied in this case by Eq. 5:

$$\cos\theta^* = r_f f\cos\theta + f - 1 \quad (5)$$

In this equation, f is the fraction of the projected area of the solid surface that is wetted by the liquid, and r_f is the roughness ratio of the wet area. When $f = 1$, $r_f = r$ and Eq. 5 turn into the Wenzel Eq. 4; when $r_f = 1, f = f_S$ and Eq. 5 turn into the Cassie–Baxter Eq. 3.

One more wetting state is possible. This is the Cassie impregnating state, depicted in Fig. 1c. In this case, liquid penetrates into grooves of the solid, and the drop finds itself on a substrate viewed as a patchwork of solid and liquid (solid "islands" ahead of the drop are dry, as shown in Fig. 1c) [6]. The APCA is expressed as



$$\cos\theta^* = 1 - f_S + f_S\cos\theta \quad (6)$$

Wetting Transitions, Fig. 1 Various wetting states occurring on rough surfaces: (**a**) Cassie air-trapping state, (**b**) Wenzel state, (**c**) Cassie impregnating wetting state, and (**d**) mixed wetting state

It should be stressed that Eqs. 3, 4, 5, and 6 could be applied when the radius of the droplet is much larger than the characteristic scale of the surface heterogeneities. The rigorous thermodynamic derivation of Eqs. 3, 4, 5, and 6 may be obtained within the general variational approach [12].

The physical mechanisms of WT on flat and rough surfaces are quite different. WTs on rough surfaces are related to the penetration of liquid into the grooves constituting the relief and result in the change of the APCA (see Fig. 2) [13–20]. Wetting transitions were observed under various experimental techniques utilizing a diversity of factors: gravity, pressure, bouncing and evaporation of droplets, electric field in the electrowetting experiments, and vibration of droplets [13–18]. WT was observed with the use of various experimental techniques, including reflection interference contrast microscopy and environmental scanning electron microscopy [20].

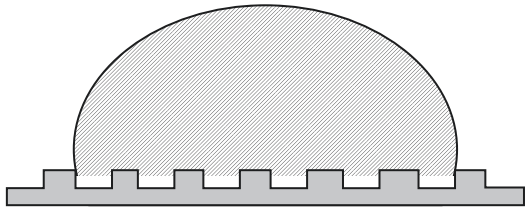
Wetting Transitions, Fig. 2 Wetting transitions observed by vibration of 15 μl waterdrop deposited on the micrometrically rough PDMS surface: (**a**) the initial Cassie state and (**b**) the Cassie impregnating state induced by vibrations

Energetic Approach to Wetting Transitions

Various wetting states featured by very different APCA can coexist on the same heterogeneous surface. The diversity of APCA could be easily understood if one takes into account that the Gibbs energy curve for a droplet on a real surface is characterized by multiple minima points. It could be shown that the Wenzel state (Fig. 1b) is energetically favorable compared to the pure Cassie air-trapping one, shown in Fig. 1a, when the inequality Eq. 7 holds:

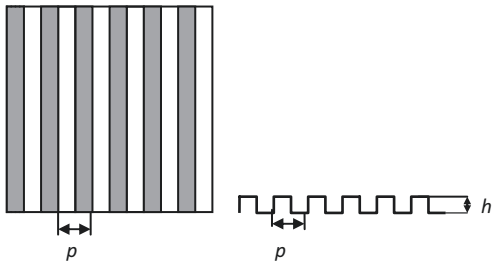
$$\cos\theta > \frac{f_S - 1}{r - f_S} \tag{7}$$

The Wenzel state will be energetically favorable when compared to the mixed trapping state depicted in Fig. 1d, when the inequality Eq. 7a holds:



$$\cos\theta > \frac{f - 1}{r - r_f f} \tag{7a}$$

Obviously for hydrophilic materials, the Wenzel state is always favorable in relation to the Cassie one, whereas for the hydrophobic materials, the situation is more complicated. When the hydrophobic material is very rough ($r >> fs$), the Cassie state will be favorable for any obtuse θ. For single-scale hydrophobic materials, the Cassie air-trapping wetting state usually corresponds to the highest of the multiple minima of the Gibbs energy of the droplet deposited on a rough surface. Thus, for the WT, the energy barrier should be surmounted [18]. It was supposed that this energy barrier is equal to the surface energy variation between the Cassie state and the hypothetical *composite* state, with the almost complete filling of surface asperities by liquid, keeping the liquid–air interface under the droplet and the contact angle constant, as shown in Fig. 3.



Wetting of hydrophobic side surfaces of asperities constituting the relief is energetically unfavorable; this gives rise to the energetic barrier. The collapse of the Cassie state will occur when the liquid filling the grooves will eventually touch the bottoms of the substrate pores, and the liquid–air interface will disappear. Contrasting to the equilibrium mixed wetting state, the composite state is metastable. For the simple topography depicted in Fig. 4, the energy barrier could be calculated as follows:

$$\begin{aligned} E_{\text{trans}} &= 2\pi R^2 h(\gamma_{SL} - \gamma_{SA})/p \\ &= -2\pi R^2 h\gamma\cos\theta/p \end{aligned} \tag{8}$$

where h and p are the geometrical parameters of the relief, shown in Fig. 4, and R is the radius of the contact area. The numerical estimation of the energetic barrier according to the Formula (8) with the parameters $p = h = 20$ μm, $R = 1$ mm, $\theta = 105°$ (corresponding to low-density

Wetting Transitions, Fig. 3 The composite wetting state

Wetting Transitions, Fig. 4 Geometrical parameters of the model relief illustrating the calculation of the Cassie–Wenzel transition energetic barrier

polyethylene (LDPE)), and $\gamma = 72\ \mathrm{mJ{\cdot}m^{-2}}$ gives a value of $E_{\mathrm{trans}} = 120$ nJ. It should be stressed that according to (8), the energy barrier scales as $E_{\mathrm{trans}} \sim R^2$. The validity of this assumption will be discussed below. The energetic barrier is extremely large compared to thermal fluctuations $\frac{E_{\mathrm{trans}}}{kT} \approx \left(\frac{R}{a}\right)^2 >> 1$, where a is an atomic scale. On the other hand, it is much less than the energy of evaporation of the droplet $Q: kT << E_{\mathrm{trans}} << Q$. Actually, this interrelation between characteristic energies makes wetting transitions possible. If it were not the case, a droplet exposed to external stimuli might evaporate before the wetting transition.

The energy barrier height from the side of the metastable (higher energy) wetting state is always much lower than that from the side of the stable one. The mentioned energy dependence is weak for large apparent angles and strong for low ones; this leads to a high asymmetry of the energy barrier, i.e., to a large difference between barrier heights. As a result, wetting transitions on rough surfaces are irreversible for both hydrophobic and hydrophilic materials.

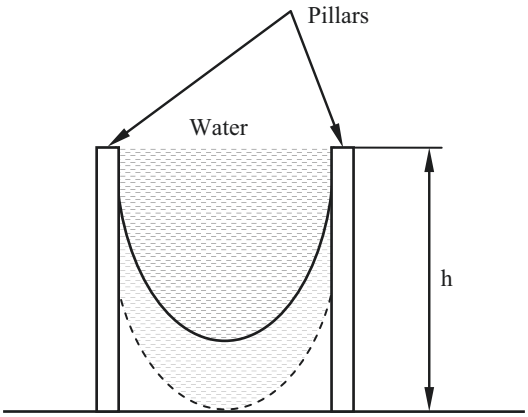
Single- and two-stage pathways of WT were observed, including Cassie (air trapping)–Wenzel–Cassie (impregnating), Wenzel–Cassie (impregnating), and Cassie (air trapping)–Cassie (impregnating) transitions.

The Concept of the Critical Pressure

Various experimental methods used for the study of WT supplied the close values of the pressure necessary for the Cassie–Wenzel transition, which is of the order of magnitude of 100–300 Pa for 10 μl droplets deposited on micrometrically scaled rough surfaces. It is noteworthy that the Cassie air-trapping wetting regime observed on natural objects (birds' wings) is much more stable when compared to that on artificial surfaces.

The important parameter characterizing WT is the critical pressure under which the transition takes place [19]. For a single-scaled pillar-based biomimetic surface, with pillar width a and groove width b, the critical pressure equals

$$p_c = -\frac{\gamma f_s \cos\theta}{(1-f_s)\lambda} \tag{9}$$

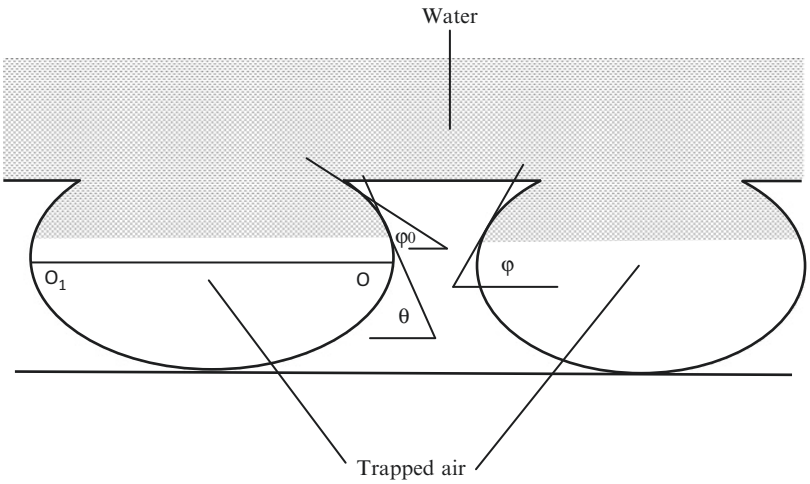


where $\lambda = \frac{A}{L}$, and A and L are the pillar cross-sectional area and perimeter, respectively. For the Teflon surface, $\theta = 114^\circ$, $a = 50$ μm, $b = 100$ μm yield $p_c = 296$ Pa, in agreement with experimental results, reported by various groups [15, 17]. Recalling that the dynamic pressure of rain droplets may be as high as 10^4–10^5 Pa, which is much larger than $p_c \approx 300$ Pa, it could be inferred that creating biomimetic reliefs with very high critical pressure is of practical importance. The concept of critical pressure leads to the conclusion that reducing the microstructural scales (e.g., the pillar diameters and spacing) is the most efficient means to enlarge the critical pressure [19].

The mechanism of WT based on the concept of critical pressure was proposed. It was supposed that as the pressure applied to the droplet increased, the meniscus will move toward the flat substrate, as shown in Fig. 5. The meniscus will eventually touch the substrate; this will cause the collapse of the Cassie wetting and consequently lead to a Cassie–Wenzel transition.

Wetting Transitions on Hydrophilic Surfaces

The Cassie wetting was observed on inherently hydrophilic surfaces. For the hydrophilic materials, the difference $\gamma_{SL} - \gamma_{SA}$ is negative, and liquid penetration into pores might have to proceed spontaneously, without the energy barrier. For the explanation of the roughness-induced superhydrophobicity of inherently hydrophilic materials, it was supposed that air is entrapped by cavities constituting the topography of the surface. The simple mechanism of "geometrical" trapping could be explained as follows: consider a hydrophilic surface ($\theta < 90°$) comprised of pores as depicted in Fig. 6. It is seen that air trapping is possible only if $\theta > \varphi_0$, where φ_0 is the angle between the tangent in the highest point of the pattern and the horizontal symmetry axis O_1O. Indeed, when the liquid level is descending, the angle φ is growing (see Fig. 6), and if the condition $\theta > \varphi_0$ is violated, the equilibrium $\theta = \varphi$ will be impossible.



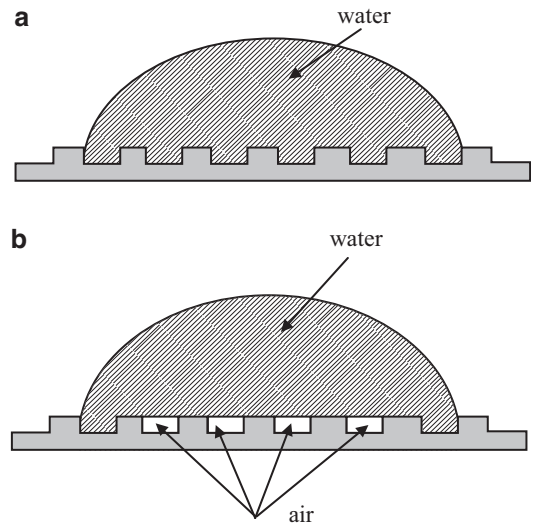
In the equilibrium position, small fluctuations of the contact angle lead to the appearance of curvature on the plane air–water interface that is energetically unfavorable. Below the central plane $O - O_1$ where $\varphi > 90°$, the equilibrium is impossible in the case of $\theta < \frac{\pi}{2}$. For a large pore, small fluctuations of θ can lead to touching the pore bottom near its center by the curved air–liquid interface, followed by filling the pore and the consequent collapse of the Cassie air-trapping wetting regime.

Wetting Transitions, Fig. 5 Pressure-induced displacement of the waterfront, leading to the collapse of the Cassie wetting state

The Dynamics of Wetting Transitions

The dynamics of WT is not clearly understood. The characteristic time of Cassie–Wenzel transition was established with reflection interference contrast microscopy as less than 20 milliseconds [20]. Two regimes of droplet front displacement were observed: zipping and non-zipping. In the zipping regime, the velocity of the front in one direction (to advance to the next row of pillars) is much smaller than the velocity in the other direction (liquid filling up one row of micro-pillars). It was established that the velocity of the wetting front increases with increasing gap size,

Wetting Transitions, Fig. 6 Geometrical air trapping on the hydrophilic reliefs



decreasing pillar height, or decreasing contact angle. A velocity of the wetting front as high as 1.5 m/s was registered.

The "Dimension" of Wetting Transitions

One of the unsolved problems in the field of WT is the problem of the "dimension" of the transitions or, in other words, whether all pores underneath the droplet should be filled by liquid (the "2D scenario") or, perhaps, only the pores adjacent to the three-phase (triple) line are filled under external stimuli such as pressure, vibrations, or impact (the "1D scenario"). Indeed, the APCA is dictated by the area adjacent to the triple line and not by the total area underneath the droplet. 1D and 2D scenarios of WT are illustrated by Fig. 7. The experiments carried out with vibrated drops supported the 1D scenario of wetting transitions. It has been established that the transition occurs when the condition $F_{cr} = \text{const}$ is fulfilled, where F_{cr} is the critical force acting on the unit length of the triple line, and the transition is caused by de-pinning of the triple line [17]. The critical value of the de-pinning force F_{cr} has been established experimentally for various microscopically structured surfaces as $F_{cr} \approx 200 - 350\ \text{mN} \cdot \text{m}^{-1}$ [17]. The energy barrier E_{trans} to be surmounted for the elementary displacement of the triple line δr could be estimated as

$$E_{trans} \approx 2\pi R F_{cr} \delta r, \qquad (10)$$

which scales as R. This scaling law corresponds to results obtained with vibrated drops, but contradicts the scaling law given by expression (8). The electrowetting stimulated WT also supported the 1D mechanism of transitions. De-pinning of the triple line was observed directly with the use of reflection interference contrast microscopy [20]. The potential barrier E_{trans}, according to expression (10) for a drop with a radius of $R \approx 1$ mm deposited on the LDPE relief, presented in Fig. 4 ($F_{cr} \approx 350\ \text{mN} \cdot \text{m}^{-1}$, the elementary displacement $\delta r \approx p/2 \sim 10^{-5}\text{m}$) equals $E_{trans} \approx 20$ nJ, smaller than the value predicted by formula (10), but still much larger than thermal fluctuations.

Wetting Transitions, Fig. 7 (**a**) 2D mechanism of WT (all pores are filled). (**b**) 1D scenario of WT (only pores adjacent to the triple line are filled)

It has been also suggested that the Cassie–Wenzel transition occurs via a nucleation mechanism starting from the drop center. In spite of intensive theoretical and experimental effort expended for the study of wetting transitions, the numerous aspects of these phenomena, including the dynamics of transitions and their "dimension," remain unclear and call for future investigations.

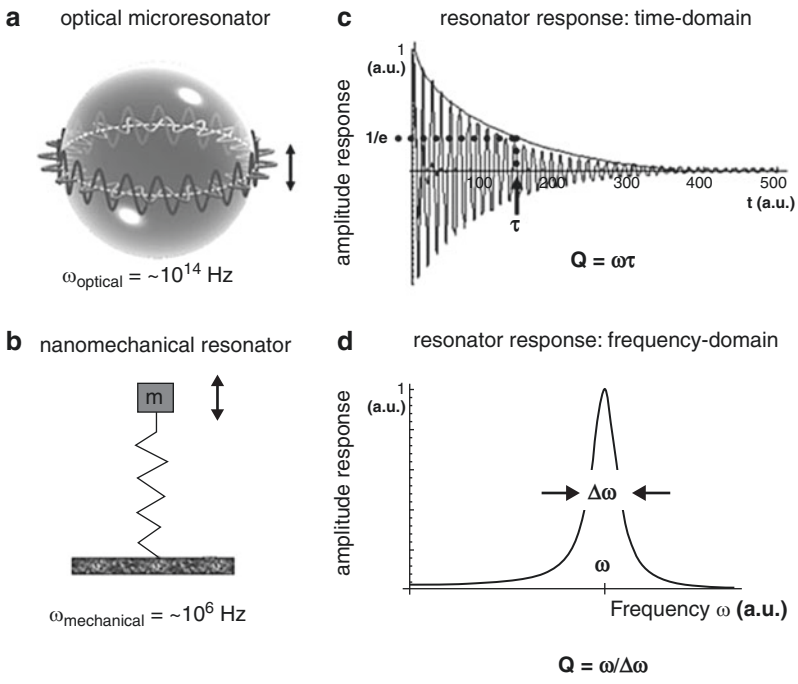
Definition

A whispering gallery mode resonator biosensor monitors optical resonances in microcavities for label-free detection of molecules and their interactions.

Overview

Whispering Gallery mode (WGM) resonators are named for the "whispering gallery" of St. Paul's Cathedral in London where sound waves propagate by reflection around the curved conduit of the gallery such that a word whispered at the front end of the gallery can be easily heard by a listener at the far end of the acoustic gallery. Similarly, optical Whispering gallery modes occur when light waves confined by total internal reflection in a dielectric microstructure are reflected back on



the same optical path where they interfere constructively. Interference generates the optical resonance signal, which occurs whenever exactly an integer number of wavelengths fit on the confined (circular) light path (Fig. 1). Molecules binding to the microresonator and interacting with the evanescent field generated at the sensor surface are detected from a change in optical resonance frequency. The frequency response is rendered specific for molecular binding events by functionalization of the sensor surface with biorecognition elements such as antibodies or oligonucleotides. WGM biosensors achieve single particle, single virus, and potentially single molecule detection capability by monitoring changes in the optical resonance frequencies in microspheres, microrings, microcapillaries, and microtoroids. Glass microspheres and microtoroids are particularly sensitive WGM biosensors because of their high Quality (Q) factor and their small modal volume (V). However, other types of optical resonators (microcavities) of different shapes and made of different materials are similarly suitable for biosensing applications, examples of these are ring resonators (made of silica, silicon, or transparent polymers) and photonic crystals (fabricated in silicon-on-insulator or in silicon-nitrate wafers). WGM biosensors and optical resonator derivatives have emerged as the one of the most sensitive microsystem biodetection technology that does not require chemical amplification or labelling of the analyte.

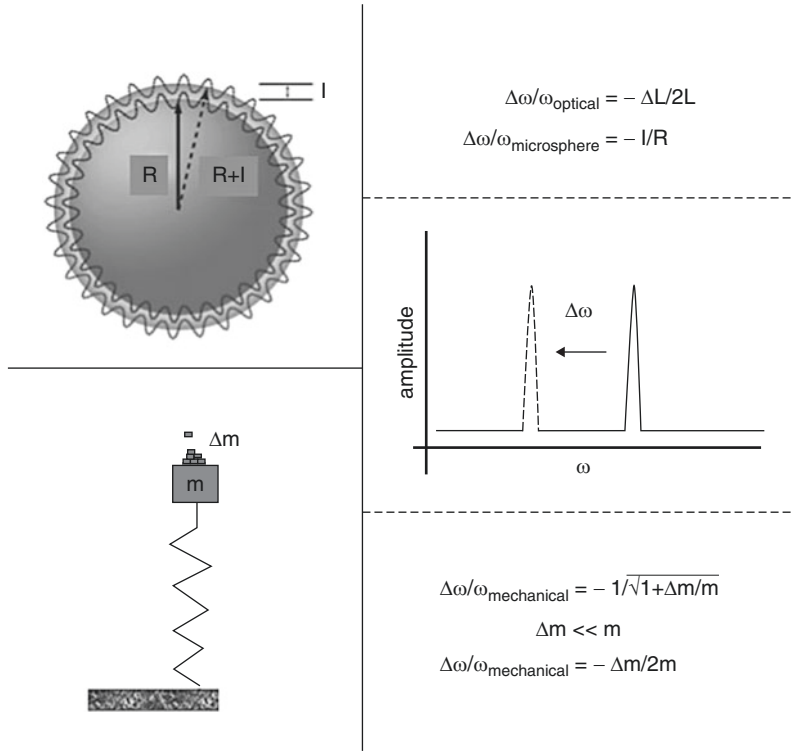
Whispering Gallery Mode Resonator Biosensors, Fig. 1 Schematic representation of light confined inside a resonant microcavity by total internal reflectance

Optical Resonator Physics: Confining Light at High Q-Factor

A high-quality (Q) factor is necessary for achieving sensitive detection using optical resonance in microcavities. Optical resonance is created by confining coherent light inside a miniature dielectric structure such that the returning light wave interferes constructively [1–3]. Figure 1 illustrates the example of an optical resonance confined by total internal reflection in a glass microsphere. Ideally, optical resonators (also referred to as cavities or microcavities) would confine light indefinitely. Real-world divergence from this condition due to damping losses results in a finite resonance lifetime τ. This finite resonance lifetime can be measured, i.e., by charging the microcavity with light, terminating the light source, and then measuring the time it takes for the intensity of the confined light wave to drop to 1/e of its initial value. This exponentially decaying intensity-amplitude of the optical resonator is analogous to the decreasing amplitude of a (nano) mechanical resonator, here illustrated as mass-on-a-spring (Fig. 2b). To compare optical, mechanical, and other resonant systems which can exhibit very different resonance lifetimes, one defines a time-independent and dimensionless figure of merit, the quality (Q)-factor. The Q-factor is proportional to the total number of oscillations stored in the resonator, and this definition is independent from the type of resonator (optical, mechanical, etc.) and the nature of its oscillation. For example, in an optical resonator, the value of the Q-factor is 2π times the number of electromagnetic oscillations before amplitude of the confined light wave drops below 1/e of its initial value. Similarly, the value of the mechanical Q-factor is just 2π times the number of (Pendulum-)swings before that same limit is reached. For any resonant system, the Q-factor is thus defined as $Q = \omega\,\tau$, where τ is the resonator lifetime and where ω is 2π times the resonance frequency (Fig. 2). The resonance frequency for optical microresonators ranges from a few TeraHertz (10^{12} Hz) to one PetaHertz (10^{15} Hz), whereas nanomechanical resonators operate at a few MHz at most. Although resonance lifetimes of very large mechanical resonator

Whispering Gallery Mode Resonator Biosensors, Fig. 2 (**a**) and (**b**) Comparison of optical and nanomechanical resonators. (**c**) Definition of Q-value in the time domain. (**d**) Definition of Q-value in the frequency domain

(i.e., Feaucault Pendulum) exceed those of optical resonators (many hours compared to microseconds), the optical microresonators exhibit much higher Q values as compared to their large mechanical and nanomechanical counterparts: in fact, microcavities exhibit the highest measured Q-factor of almost $\sim 10^{10}$, whereas a good nanomechanical resonator reaches a Q value of a few million at best and a Pendulum operated in vacuum reaches a Q of about 100,000. In fact, the "ultimate" Q-factor has been measured in a microsphere cavity where an optical resonance (a whispering gallery mode, WGM) is efficiently confined by total internal reflection – with only residual damping due to absorption in the glass material.



Apart from the time-domain response, a resonator also has a frequency-domain response (Fig. 2c) and it is important to realize that a large Q-factor is associated with a very narrow spectral linewidth where $\Delta\omega_{\text{line}} = \omega/\text{Q}$ (Fig. 2d). A narrow linewidth allows for precise measurements of resonance frequency and changes thereof, which is of paramount importance for achieving high sensitivity in biosensing applications. Ultimate-Q microsphere resonators are therefore the ideal choice to build a sensitive WGM biosensor [4]. The direct relationship between a high-Q factor and a narrow linewidth can be intuitively understood from the fact that the frequency-domain response of the resonant system (Fig. 2d) is just the Fourier-transform of the time-domain response (Fig. 2c). The Q-factor is not only related to the time-domain and the frequency-domain signal of a resonator, but also to the energy stored in a resonant system. The Q-factor can be calculated from the total energy W_{total} stored in the resonator divided by the energy ΔW lost per oscillation (multiplied by 2 Pi), $\text{Q} = 2\pi\ W_{\text{total}}/\Delta W_{\text{per oscillation}}$. For example, the lifetime and Q-factor of an ultimate WGM microsphere resonator is limited only by residual absorption and calculated as $\text{Q} = 2\pi\ (W_{\text{total}}/\Delta W)_{\text{per oscillation}} = 2\pi\ n/\lambda\alpha$, where α is the extinction coefficient of glass, about 7 dB/km, λ is the wavelength (here 633 nm), and n the refractive index of the glass (here $\sim$1.45). Table 1 gives an overview of Q-factors of resonant optical, electrical, and mechanical systems.

Principles of Resonant WGM Biosensing

An optical resonator transduces the binding of molecules into a resonance frequency shift signal which can be detected with great precision due to the high Q-factor of the optical detection system [5]. Optical resonators have no moving parts and maintain a high Q-factor even in a liquid biosensing environment [4] where any mechanical system would be heavily damped (low Q). The change in resonance frequency of an optical resonator occurs in response to the binding of molecules which increase the round-trip optical path length. This is different from a mechanical resonator where the frequency shift would occur due to mass loading by the added molecules (Fig. 3). Such a frequency shift, i.e., for a nanomechanical resonator can be easily calculated: Additional molecular mass loading, Δm, on a system with a nominal mass, m, will cause a resonance frequency shift of $\Delta\omega_{\text{mechanical}} = -\omega_{\text{mechanical}}\ \Delta m/2m$ (Fig. 3), where only nanomechanical systems are useful for such measurements due to their small mass. For an optical resonator instead, the binding of molecules add additional optical path length ΔL causing the resonance frequency ω_{optical} to shift by $\Delta\omega_{\text{optical}} = -\omega_{\text{optical}}\ \Delta L/2L$, where $2L$ is the round-trip optical path length in the microcavity (Fig. 3). For the special case of a spherical WGM optical resonator where bound molecules form an optically contiguous layer of thickness l (Fig. 3), the resonance frequency shift is calculated as $\Delta\omega_{\text{microsphere}} = -\omega_{\text{microsphere}}\ l/R$, where l is the thickness of the adsorbed molecular layer and R is the radius of the microsphere. This estimate assumes an identical refractive index for

microsphere and adsorbed molecular layer, $n_{glass} = n_{molecules}$, a good approximation for the case of proteins adsorbing to a glass microsphere ($n_{glass} = n_{protein} \sim 1.45$). Further assuming the ability to detect the resonance frequency shift (Fig. 3) with a resolution of S = 1/50 of the linewidth, and assuming a modest Q of 10^7, which can be readily obtained with a 100 100 μm mu;m diameter glass microsphere in a liquid biosensing environment, the smallest detectable thickness l of a molecular layer bound to a WGM microsphere cavity is calculated as l = S/Q * R = (0.02/10^7)* 50 μm = 10^{-7} = 0.1 pm! Biomolecules are several nm in diameter (~3.5 nm for a typical protein such as BSA), so detection of a small fraction of a monolayer coverage is an easy task for a WGM biosensor. Achieving such a feat with a (nano)-mechanical system is impossible due to the heavy damping (low Q) of any mechanical resonator after immersion in a liquid biosensing environment. In contrast, high-Q optical resonators have no moving parts and the Q-factor (and corresponding resonance lifetime) is mainly limited by the absorption of the light in the resonator material and in the surrounding medium (ultimate Q). By choosing a wavelength with minimal absorption losses, and by optimizing the material and size of a microsphere resonator, it has been estimated that unprecedented, label-free single molecule detection capability is achievable [6]. This possibility combined with the great variety of materials and geometries available for the design of high-Q optical systems has spurred the tremendous interest in the development and application of microcavity biosensors.

WGM Biosensing: Reactive Sensing Principle

The frequency shift $\Delta\omega$ of an optical resonance due to binding of any kind of molecule to any kind of resonator can be precisely calculated from first-order perturbation theory. Assuming that bound molecules do not change the light field, then the fractional change in resonance frequency $\Delta\omega/\omega$ (and corresponding fractional wavelength $\Delta\lambda/\lambda$) is calculated [6] by comparing the energy it takes to polarize the molecule bound to the microcavity surface at position $\vec{r}_0$, $\Delta W_{particle} = h\varpi = \frac{1}{2}\alpha \vec{E}\left(\vec{r}_o\right)^2$, to the total electromagnetic energy confined in the microcavity $W_{total} = \int \varepsilon \vec{E}\left(\vec{r}\right)^2 dV$:

$$\frac{\Delta\lambda}{\lambda} = \frac{\Delta W_{particle}}{W_{total}} = \frac{\alpha \vec{E}\left(\vec{r}_0\right)^2}{2\int \varepsilon \vec{E}\left(\vec{r}\right)^2 dV} \quad (1)$$

This so-called reactive sensing principle can be applied to any microcavity structure and to any biomolecule. Furthermore, a large frequency shift and therefore a high sensitivity is obtained for a small denominator in Eq. 1, which is achieved by confining the resonant light field within a small modal volume defined as $V = \int \varepsilon \vec{E}\left(\vec{r}\right)^2 / \vec{E}\left(\vec{r}\right)^2_{max} dV$, where $\vec{E}\left(\vec{r}\right)_{max}$ is the highest field intensity measured in the cavity. For high-sensitivity biosensing applications, it is therefore important not only to operate at a high Q value, enabling precise measurement of resonance frequency, but equally important to use a miniature optical resonator with small modal volume V, producing a large frequency shift signal due to the binding of molecules. Biosensing applications, therefore, require optimizing the Q/V value. WGM microsphere biosensors typically exhibit modal volumes ~500 um^3 at Q ~ 10^7 and therefore achieve Q/V ~ 2 × 10^4 (1/μm^3). Photonic crystal microcavity structures may further boost current Q/V values since these resonators can confine light in record-low modal volumes of V < $(\lambda)^3$/n ~ 0.2 μm^3 (where n is the refractive index of the resonator), a volume which is less than a wavelength cubed! This strong spatial localization of light in a photonic crystal cavity is possible due to multiple Bragg scattering from many lattice elements, different from a WGM resonator where the light field is confined by internal reflection. Although photonic crystals can confine light in record low modal volumes, Q-factors of photonic crystal cavities are typically lower as compared to WGM

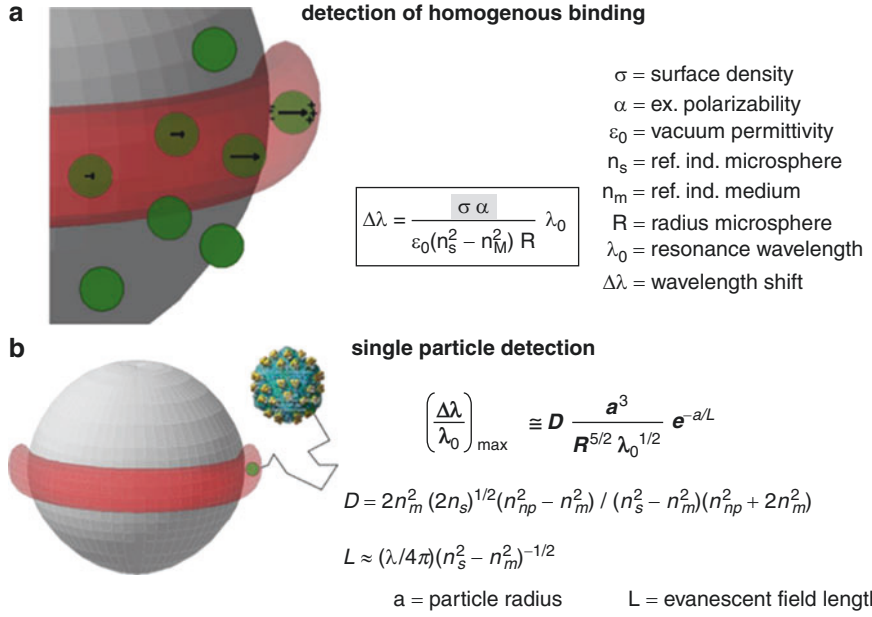
resonators and reach only ~one to a few million. Here, the Q-factor is mainly limited by the finite precision of the nanoscale photonic crystal fabrication process where residual surface roughness causes additional damping of the resonant light field. With further improvements of the nanoscale fabrication processes, however, photonic crystal microcavities may surpass current record Q/V's of WGM biosensors and are therefore an interesting resonator structure that can be potentially mass produced by deep UV lithography.

WGM biosensors to date are more sensitive as compared to any other commercialized label-free biosensor technology such as surface plasmon resonance sensors (SPR) and quartz crystal microbalances (QCM). WGM biosensors routinely achieve sensitivity far below 1 pg/mm^2 molecular mass loading, approaching the specific detection of the binding of molecules from fM (and less) solution concentration levels. Impressively, WGM technology was used to demonstrate the detection of a single Influenza A virus particle from fM solution concentration [7], a noteworthy feat considering that a single Influenza A virus particle measures only ~50 nm in radius and weighs less than ~500 attograms.

WGM Biosensing: Label-free Analysis of Homogenous Molecular Binding Events

For WGM microsphere resonators, Eq. 1 can be used to derive an analytic equation for the observed fractional frequency shift $\Delta\omega/\omega$ due to homogenous binding of nanoscale molecules or particles at random location on the microsphere sensor surface [4, 6]. Then, the frequency shift $\Delta\omega/\omega$ and the corresponding wavelength shift $\Delta\lambda/\lambda$ is calculated from (Fig. 4):

$$\frac{\Delta\lambda}{\lambda} = -\frac{\Delta\omega}{\omega} = \frac{\sigma\alpha}{\varepsilon_0\left(n_s^2 - n_m^2\right)R} \qquad (2)$$



where σ is the surface density of bound molecules, α is their excess polarizability (in excess to the displaced water), ε_0 is the vacuum permittivity, n_s and n_m are the refractive indices of the glass microsphere and the surrounding water, respectively, and R is the radius of the microsphere. The negative sign for $\Delta\omega/\omega$ results from the fact that a shift to a longer resonance wavelength corresponds to a shift to lower resonance frequency. The excess polarizability α can be estimated from tabulated "dn/dc" values for each biomolecule [8] measured in aqueous solution. The refractive index increment "dn/dc" is defined as the increase Δn of the refractive index n measured for the increase Δc of the biomolecule solution concentration c in the limit for c - > 0: $dn/dc = \lim(\Delta n/\Delta c)c_{->0}$. The excess polarizability α is then calculated from dn/dc values according to,

$$\alpha = \varepsilon_0 2n\frac{dn}{dc}m \qquad (3)$$

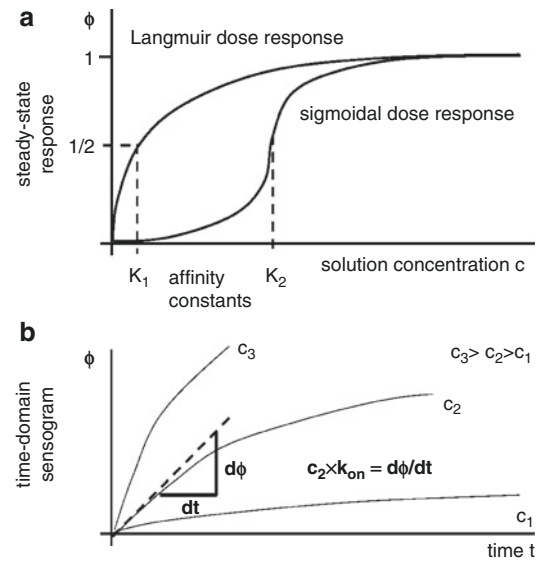
where n is the solvent refractive index (water), and m is the mass of the single biomolecule. Proteins such as bovine serum albumin (BSA) have a typical dn/dc value of about 0.183 cm^3/g. The excess polarizability of BSA is then calculated as $\alpha_{BSA} = 4\ \pi\ \varepsilon_0\ 3.85\ *\ 10^{-21}$ cm^3, where the mass of a single BSA molecule is ~66,432 (g/mol)/6.02 10^{23} (1/mol) = 1.1 10^{-19} g. The excess polarizability α is proportional to the molecular mass, m, of a protein and may vary only slightly between different proteins of similar molecular weight but of different amino acid sequence, such as for BSA and HSA (human serum albumin). Similar arguments can be made for many other biopolymers [8]. Table 2 lists typical dn/dc values of various biopolymers and biomolecules, in different solvent conditions.

Note that dn/dc values depend on many additional parameters such as temperature, solvent, ionic strength, and probing wavelength (Table 2). Interestingly, one can also calculate the wavelength dependence of polarizability values from Kramers-Kronig transformations by integration over the respective absorption spectra [8].

In biosensing experiments, one often measures the resonance wavelength shift $\Delta\lambda$ instead of the frequency shift: $\Delta\lambda = \lambda_{res,\ after} - \lambda_{res,before}$. The wavelength shift $\Delta\lambda$ can be converted in the associated frequency shift Δf by:

Whispering Gallery Mode Resonator Biosensors, Fig. 4 (**a**) Detection of homogenous binding of biomolecules in the evanescent field of a WGM. (**b**) Detection of single particle interacting with WGM

$\Delta f = c_{\text{light}}\,(1/\lambda_{\text{res, after}} - 1/\lambda_{\text{res, before}}) = -\,c_{\text{light}}\,\Delta\lambda/\lambda^2$, where λ is the initial resonance wavelength and c_{light} is the speed of light. In all WGM biosensing experiments, the wavelength shift, $\Delta\lambda$, or frequency shift, Δf, reports on the surface density σ of molecules bound to the microsphere resonator, at a specific time point. Depending on specific cavity material or surface functionalization, the saturation surface density of bound molecules may vary between 0 and $10^{15}/\text{cm}^2$. To achieve a surface coverage of more than $10^{15}/\text{cm}^2$ requires molecules to form multiple layers or to bind within less than a nm distance, certainly a physical limit as the size of an atom is, ~0.1 nm = 1 Å. High-Q microcavities are invaluable tools for studying the binding of molecules to the sensor surface since precise measurements of high-surface densities can reveal interactions between closely spaced molecules, and precise measurements at low surface densities $<10^9/\text{cm}^2$ can reveal intricate mechanisms of adsorption on non-fouling surfaces.



The time scale of resonance wavelength shift depends on the diffusion of molecules and on the time scales associated with their interactions at the

resonator surface. The simplest steady-state kinetic model which can be applied to the binding of molecules to a surface is given by the Langmuir-like model [9] which assumes equilibrium binding between molecules and a fixed number of surface binding sites, further assuming equal affinity and no interaction between the sites. To determine a Langmuir binding isotherm, one first calculates the fractional surface coverage Φ by dividing the equilibrium frequency shift by the shift at saturation (measured at high solution concentration). Then, one plots the measurement of fractional surface coverage Φ versus the different solution concentration levels (Fig. 5a). The rate equation for the Langmuir model is given by $d\Phi/dt = k_{on}*c*(1 - \Phi) - k_{off}*\Phi$, so that in steady state $d\Phi/dt = 0$ and $\Phi/(1 - \Phi) = k_{on}/k_{off}*c$. For half-maximal surface coverage at $\Phi = 1/2$, the solution concentration is just equal to the equilibrium (dissociation) constant $c = K = k_{off}/k_{on}$, which can be conveniently determined from the Langmuir isotherm (Fig. 5a). The affinity (dissociation) constant is, e.g., measured at ~1 nM for BSA proteins binding to an aminosilanized microsphere [4]. For more complex binding and adsorption processes, different kinetic models can be applied such as the random sequential adsorption (RSA) model, which is derived from the Langmuir model by taking into account the additional exclusion volume of bound molecules. Another kinetic model considers conformational changes by modeling bound proteins as discs with radii that may change in a post-binding step. The reader is referred to standard pharmacokinetic textbooks for further analysis of dose–response curves and their importance in analytical and clinical chemistry. Obtaining such dose–response curves is essential for relating the solution concentration of analyte molecules to the measured surface concentrations as measured by the resonator shift signal.

Instead of analyzing molecular recognition and binding in the steady-state regime, the interaction of biomolecules at a resonator surface can also be analyzed in the time domain by plotting the resonance frequency or wavelength shift signal versus time (sensogram, Fig. 5b). The sensogram and its derivative report on the kinetics and the rate of

Whispering Gallery Mode Resonator Biosensors, Fig. 5 (**a**) Steady-state response of WGM biosensor. (**b**) Time-domain response (sensogram) of a WGM biosensor

adsorption or desorption, respectively. It is common to extract the derivative (rate of adsorption or desorption) at the onset of the experiment where $d\Phi/dt = k_{on} * c$ in a binding experiment started at $c > 0$ and $\Phi = 0$, and $d\Phi/dt = k_{off}$ for an unbinding experiment started at $c = 0$ and $\Phi > 1$. Since time scales for binding can be fast, it is often necessary to start the experiment rapidly using microfluidic techniques that allow a rapid change of solution concentration. In principle, optical resonators follow such a fast response without problem since the time resolution of a microcavity is principally limited only by the resonator photon lifetime τ, which is on the order of micro to nanoseconds, and dependent on the Q-value.

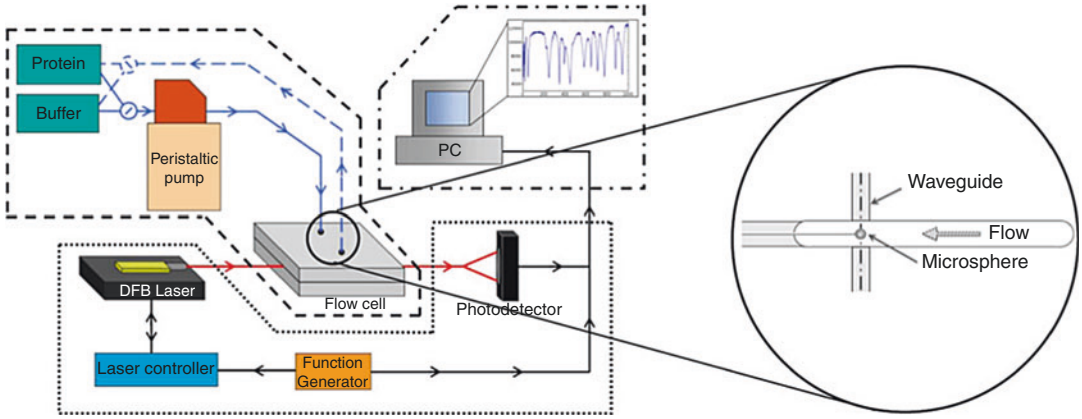
WGM microsphere cavities have a further advantage as compared to SPR and QCM techniques in that they exhibit multiple optical resonances signals, which are useful for detection. In fact, optical resonances appear throughout an optical resonator spectrum since the resonance condition states that a multiple number of resonance wavelengths have to fit the optical path. The precise calculation of the resonances requires Maxwell's equations and has many solutions,

and a more versatile sensor uses more than one resonance shift signal to analyze the binding of molecules to the resonator surface. For example, differently polarized (TE and TM) optical resonances can be used to determine the orientation of molecules at the sensor surface [5]. Each one of the two resonances (TE and TM) probe the surface of the microsphere in a different direction, and the specific arrangement of molecules in a monolayer and changes thereof can be measured by comparing the TE and TM wavelength shifts. Different resonance wavelength shifts have already been used to determine conformational changes in photosensitive bacteriorhodopsin membrane and to measure the orientation of the photochrome retinal within a lipid bilayer [5]. It is also possible to compare the resonance wavelength shifts for resonances excited at different wavelength (e.g., at 763 nm and 1,310 nm) in parallel. Using this approach, it is possible to directly determine the thickness and the permittivity (refractive index) of an adsorbed nanolayer, and changes thereof [10].

$$\frac{\left(\frac{\partial\lambda}{\lambda}\right)_1}{\left(\frac{\partial\lambda}{\lambda}\right)_2} \approx \frac{L_1[1-\exp(-l/L_1)]}{L_2[1-\exp(1-l/L_2)]} \tag{4}$$

Where l is the thickness of the adsorbed layer and L_1 and L_2 are the evanescent field length at probing wavelength λ_1 and λ_2, with $L \approx (\lambda/4\pi)\left(n_s^2 - n_m^2\right)^{-1/2}$.

WGM Biosensing: Label-free Single Particle Analysis



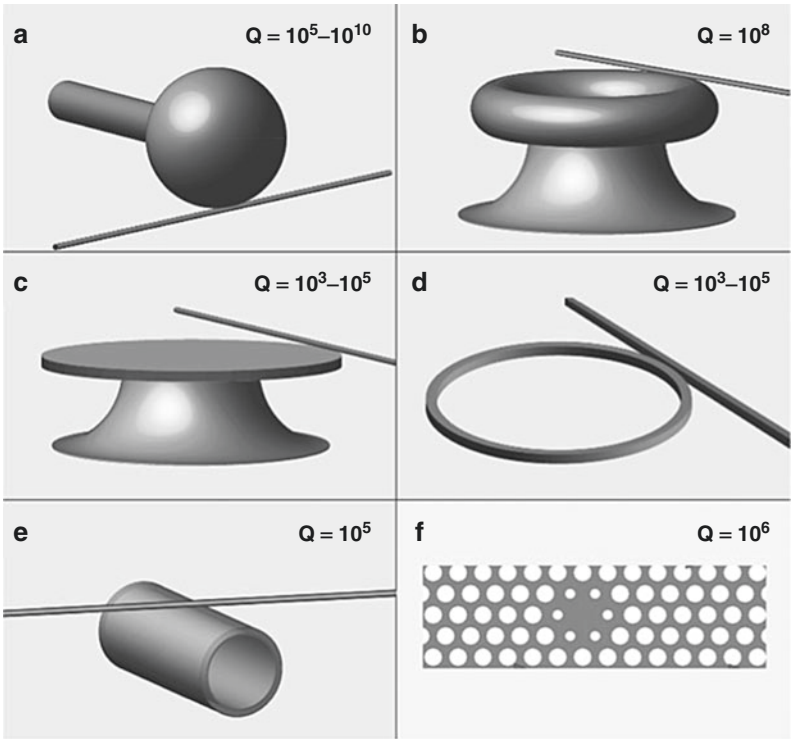
On the single particle level, the frequency shift (or rather "step") associated with a single binding event depends on the location of the particle on the resonator surface. For a microsphere WGM biosensor, the light field is confined along the equator of the sphere (Fig. 4) and the largest frequency shift is recorded for an equatorial binding event. The frequency shift associated with the equatorial binding event can be calculated from the reactive sensing principle [7] Eq. 1, where the fractional wavelength shift now depends on particle size, a, and the evanescent field length, L (Fig. 4b). Single bioparticle detection was demonstrated for a single Influenza A virion, and analysis of the discrete frequency shift signals (Fig. 4b) was used to determine the size of the particle (~50 nm radius) as well as its weight (~500 attograms) [7]. The size of a bound nanoparticle can also be determined independently of binding location by measuring resonance frequency shift as well as changes in Q-factor in parallel [11]. In general, single particle detection opens up the possibility to determine size and shape of nanoparticles by monitoring frequency shifts of different optical resonances (TE, TM, etc.) and associated Q-factors in parallel. Even without binding, but already within the evanescent field, the Brownian motion of a single particle causes resonance wavelength fluctuations [5], a signal that can be used to extract single particle diffusion constants. Furthermore, the frequency shift signal associated with a single particle trapped by the optical field of the resonator can be used to determine a chemical surface potential: If a particle of radius a is trapped in the optical field of the resonator, the resonance wavelength shift reports on the radial position of the particle measured as the distance h from the microsphere surface [12]:

$$\frac{\Delta\lambda_r(h+a)}{\Delta\lambda_r(a)} = \frac{\exp[-(h+a)/L]}{\exp[-a/L]} = \exp[-h/L] \tag{5}$$

From this measurement, a histogram of equilibrium particle positions can be replotted as a Boltzmann-distribution in kT units (k = Boltzmann constant, T = Temperature), revealing the trapping potential consisting of a chemical potential on the resonator surface and the optical potential of the evanescent field.

Implementation and Operation of a WGM Resonator Biosensor

In its simplest implementation (Fig. 6), the WGM biosensor device is build by coupling light from a tapered optical fiber to a microsphere optical



Whispering Gallery Mode Resonator Biosensors, Fig. 6 Schematic representation of WGM biosensor experimental setup comprised of fluidics component (*dashed lines*), excitation source and detector (*dotted line*), and data acquisition software (*dash-dot line*), and sphere-on-stem resonator housed in a flow cell (*inset*)

resonator [4]. The microsphere itself is fabricated from an optical fiber piece where one end is melted in a hot flame, forming a sphere on-a-stem structure. The sphere is then positioned adjacent to the tapered fiber region, where the light can couple from the optical fiber to the resonator. Light from a tunable laser is coupled into one end of the optical fiber from where it is delivered to this tapered coupling region. The output end of the optical fiber is connected to a photodetector, which records the transmitted intensity. As the laser wavelength is tuned to match the resonance wavelength of the microsphere, light starts to couple from the tapered fiber region to the resonator where it remains confined as WGM optical resonance. Due to interference in the coupling region, the light then no longer reaches the photodetector, which now records a minimum in the transmitted intensity. A computer identifies and tracks the minimum in the recorded transmission spectrum and plots the resonance wavelength versus time, at ms to μs time resolution, typically limited by the speed of the acquisition system, as well as by the speed of the laser control system. The sensogram is analyzed either *post hoc* or in real time and contains information on the binding and interaction of molecules at the WGM biosensor surface.

Several other experimental configurations exist for coupling light into WGM biosensors and for detecting resonances. Earlier studies of WGM resonances even employed "free beam" coupling methods in which the incident laser is guided through external optics and focused onto the microcavity to excite the resonance. Only a small fraction of the incident light, however, can couple radiatively to the microcavity. It is also possible to use light sources other than lasers, e.g., light sources with a broader emission spectrum, such as an ASE (amplified spontaneous emission) light source operating in the telecom band. In this case, however, a high-resolution monochrometer is necessary to resolve the narrow linewidth resonances, certainly a limitation when using a high Q cavity. In other implementations, it is possible to use spheres labeled with a fluorophore and resolve resonances in the emission spectrum, which is collected on a bead-by-bead basis. This implementation limits the operation of the biosensor to lower Q factors, but allows the use of freestanding fluorescent spheres, such as 10 um-diameter polystyrene spheres soaked with rhodamine 6G fluorophore [13].

Most common experimental setups utilize tapered fiber optic waveguides or planar waveguides to deliver the light to various resonator geometries such as discs, rings, toroids, or spheres (Fig. 7). Light sources typically consist of a tunable distributed feedback laser (DFB) with 300 kHz linewidth available at various nominal wavelengths (760–1,550 nm) and which can be tuned by a fraction of a nm simply by ramping the

Whispering Gallery Mode Resonator Biosensors, Fig. 7 Schematic illustration of different resonator geometries. (**a**) Sphere, (**b**) Toroid, (**c**) Disk, (**d**) Ring, (**e**) Cylinder, (**f**) Photonic crystal

operating (laser diode) current [4]. A simple (silicon or InGaAs) photodetector is sufficient to detect the intensity, and a standard computer can record the spectrum and locate the resonance wavelength. Biosensing experiments often require the integration of the resonator with a microfluidic flow system. Figure 6 shows the integration of a complete microsphere WGM biosensor with a simple flow cell.

Resonator Geometry

One of the primary benefits of WGM biosensors is the unprecedented sensitivity provided by high Q-factors in optical microcavities. High Q-factors are found for a variety of resonator shapes and fabricated by different procedures (Fig. 7). The decision for particular sensor geometry depends on the required sensitivity, cost, multiplexing capability, and need for integration with microfluidics and other photonic or electronic components. Often, the most important factor remains sensitivity and to date the highest Q-factor was reported for a microsphere resonator at $Q \sim 10^{10}$ which is thus the ideal choice for building highly sensitive WGM biosensors. The ultimate sensitivity obtained in ultrahigh-Q resonators enables sensing of single virus particle and molecules. However, more modest Q factors ($Q = 1 \times 10^4$ to 1×10^7) observed in other resonator geometries and materials (Fig. 7) are sufficient in most biosensing applications and can already achieve detection limits superior to SPR sensors (<1 pg/mm^2). As pointed out in previous sections, reducing the modal volume, V, of the resonator, thus optimizing the Q/V value, further enhances the sensitivity. High Q/V values are observed in photonic crystal cavities, which are an interesting alternative to micospherical and microtoroidal optical resonators (Fig. 7f).

High-Q Resonators

Disk and Ring Resonators

Ring and disk resonators (Fig. 7c, d) are perhaps the most commonly implemented resonator geometry due to their ease of fabrication

[14]. The 2-D and quasi 1-D geometries can be manufactured with photolithographic techniques and in different material systems. For example, rings and disks can be fabricated in SiO_2, Si, nanocrystalline diamond, and organic polymers. Photolithography allows for fabrication of large sensor arrays with multiplexed detection capability [15]. Within such an array, individual sensors are used as internal references to eliminate noise from thermal fluctuations and nonspecific molecular binding. This is a significant advantage over systems utilizing only one resonator and greatly simplifies experimentation and data analysis. Due to their ease of fabrication using standard "CMOS techniques," ring and disk resonators are ideal candidates for integration into standardized platforms compatible with portable electronic devices and commercial bench-top systems. Microfabricated ring/disk resonator arrays are also quite easily incorporated with microfluidics due the planar nature of the substrates on which they are fabricated. This feature of chip-based resonators is critical for achieving sensitivities and signal-to-noise ratios that surpass those of currently available systems, as well as allowing handling of the increasingly small samples found in lab-on-chip applications. Commercial systems based on silicon ring-resonator arrays are currently in development and should be available in the near future.

Ring and disk resonators typically possess a low modal volume, which as discussed previously is key to ensure a large resonant shift for detection of molecules. However, rings and disks tend to exhibit relatively low Q-factors, especially after immersion in water ($Q \approx 10^{3-4}$), which makes determination of resonant frequency less precise and limits the ultimate sensitivity of resonators with these geometries. While such Q-factors are sufficient for many biosensing applications, these geometries may not be suitable for single virus or single molecule detection. For the time being, however, ring and disk resonators provide the most attractive option as sensing elements for commercially available bench-top and portable systems.

Liquid Core Optical Ring Resonators (LCORRs)

A relatively new class of microcavity resonators is the liquid core optical ring resonator (LCORR) [16]. This class of resonator utilizes the cylindrical geometry of microcapillaries to excite WGM resonances about the inner and outer circumference of the thin microcavity wall (Fig. 7e). Microcapillaries are fabricated from quartz or glass preforms by drawing under high heat to a final outer capillary diameter of ~100 μm, and a wall thickness of a few microns. The LCORR can then be mounted on a waveguide or tapered fiber, which is used to couple light to the LCORR and excite the WGM resonances. The microcapillary sensors are sensitive to molecules binding to the inside of the capillary and one of the main advantages of this approach is the ease of fluid handling. In the capillary configuration of WGM biosensors, it is not necessary to create a completely separate flow cell, or mount fluidic channels on top of a wafer that holds the resonator structures. Instead, LCORRs can be arranged in parallel on waveguides to create sensor array already integrated with microfluidics. By employing multiple waveguides along a single capillary, it is possible to interrogate the region about each waveguide as an independent sensor. This linear configuration is well suited to such applications as capillary electrophoresis, where sensing regions at defined intervals can be used to monitor the speed of a profile of analyte passing a region. Additionally, LCORRs support high-Q resonances (~10^5), which provide them with the necessary sensitivity to compete with established biosensing methods such as SPR and QCM. Investigation into applications of LCORRs is on going and remains an intriguing alternative to other geometries.

Ultrahigh-Q Resonators

Toroids

Silica toroidal resonators (Fig. 7b) exhibit the highest Q-values measured in water [17] in excess of $Q = 10^8$. These types of resonators are fabricated from layers of silica (glass) grown on crystalline silicon substrate, etched into discs with hydrofluoric acid, and then undercut with, i.e., xenon difluoride etch to form a free standing silica discs held on a silicon post. Reflow of the silica disk is achieved in a self-terminating process by heating the silica with a CO_2 laser results in a

toroidal (donut) shape. Toroidal resonators exhibit modal volumes lower than those of microspheres of comparable diameter, and exhibit ultrahigh Q-factors due to an atomically smooth surface produced by reflow of glass. Thus, the toroid geometry boasts a high sensitivity and is a good candidate for single molecule detection. To date, only high-Q toroidal resonators made from silica material in the sensing region have been reported, as successful fabrication relies on the reflow of glass under high heat. Therefore, these geometries are difficult to fabricate using higher refractive index materials, such as sapphire, diamond, and alkali halides. Silica-based toroidal resonators are amenable to chemical functionalization by standard silane chemistry as well as other means of covalent and noncovalent modification and are thus useful as ligand-specific biosensors. This resonator geometry can be potentially integrated into on-chip arrays, similarly as described for disks and rings. However, integration with waveguides or optical fiber requires secondary fabrication steps and still remains a challenge. Whether or not practical implementation of microtoroid arrays with integrated waveguides will be achieved still remains a topic of research. As such, they are excellent for bench-top applications that require ultrahigh sensitivity.

Spheres and Spheroids

Next to rings, spherical resonators are perhaps the most common resonator geometry employed. Spherical silica resonators are very easy to fabricate by melting the end of an optical fiber and exhibit ultimate Q-factors of up to 10^{10}. Light can be coupled to a sphere, or sphere-on-stem by tapered fiber, waveguide, prism, or free beam coupling allowing a wide range of possibilities in implementation. Additionally, free standing spheres can be fabricated using a variety of alternative procedures and materials. Silica microspheres are most common, but reports have demonstrated the utility of spheres made from or coated with high refractive index polymers such as polystyrene. Free standing spheres can be used in top-down fabrication schemes that allow a great deal of flexibility in experimental configuration. In addition, the symmetry of a sphere allows for easy analysis and quantification of the WGM resonance signals. The inherent flexibility and simplicity of the spherical geometry makes it perhaps the most promising for future implementations of WGM biosensors. Integration with microfluidics and multiplexing remains challenging, although there are proposals for generating large arrays of microspheres, which can be read out in parallel. Microsphere resonators are currently mainly used in bench-top proof-of-principle experimental applications. However, as the technology develops, the spherical resonator will find applications to commercial instruments as well.

Applications

Protein Detection

Many applications of WGM biosensors are focused on the label-free detection of proteins from solution [18]. In 2002, Vollmer and coworkers [4] demonstrated the quantification of the thickness and surface density of a layer of bovine serum albumin (BSA) adsorbed on a microsphere functionalized with the silane aminopropyltrimethoxysilane (APTES). This result provided the proof-of-principle for using resonance frequency shifts in WGM for real-time biosensing applications. Furthermore, this experiment demonstrated that the glass surface resonators could be functionalized with various recognition elements such as proteins and antibodies, and showed the utility of the reactive sensing principle (Eqs. 1 and 2).

Due to the remarkable sensitivity of WGM biosensors, they hold great promise for the detection of low copy numbers of biomarkers that are indicative of early stage disease. Andrea and coworkers published work demonstrating the detection of molecule binding events for Interleukin-2 (IL-2), a molecule indicative of immune response [17]. This combination of sensitivity and the ability to create highly specific sensor surfaces makes WGM sensors ideal candidates for sensor elements in point of care devices and fieldable instrumentation. A similar approach was also demonstrated by Washburn and coworkers in 2009 who reported the detection of the cancer marker carcinoembryonic

antigen (CEA) from clinical samples containing serum [19]. This was the first demonstration of detection of a disease marker from a complex biological sample by WGM frequency shift.

DNA Detection

In the post-genomic era, the ability to detect and sequence DNA from low copy number is critical for clinically relevant applications. Despite advances in polymerase chain reaction (PCR) methods, it is still desirable to be able to detect and discriminate DNA sequences directly from unlabelled samples. In this respect, WGM biosensors offer the potential to detect down to single-molecule binding events for DNA using resonators functionalized with complementary strands of DNA. Vollmer and coworkers [20] demonstrated the sequence-based discrimination of DNA binding to complementary sequences immobilized on a glass microsphere [20]. In these experiments, two microspheres functionalized with different complementary sequences were coupled to a single waveguide. Solutions with target DNA sequences were added and the response from the microspheres was simultaneously measured. It was shown that a single base-pair mismatch could be discriminated. Thus, WGM is a highly suitable technique for the sequence-based detection and discrimination of DNA molecules.

Virus Particle Detection

In addition to the detection of protein and DNA molecules, it is very desirable to be able to detect single particles such as viruses. As a single virus particle has the potential to infect a cell and replicate itself billions of times in a relatively short period of time, it is obviously worthwhile to have sensors capable of detecting virions on the ultimate single particle level. In 2008, Vollmer and coworkers [7] demonstrated the ability to detect the binding and unbinding of single particle of the Influenza A (InfA) virus to an unmodified microsphere.

Sensor Arrays

Due to the ease of fabrication of these types of sensing elements, it is possible to incorporate resonators of tailored geometries into large arrays that can be individually addressed. This is perhaps one of the most promising aspects of WGM biosensors, in that they not only provide sensitivity and specificity better than currently available optical methods, but can also apply these benefits to potentially massive arrays of sensing elements. Washburn and coworkers have taken a first step in this direction by applying arrays of ring resonators for the detection of CEA from complex biological samples [19]. Here it was shown that an array of 16 individually addressable resonators could be interrogated in real time for the detection of their target antigen. Furthermore, due to the redundancy provided by an array of sensors, it was possible to utilize a subset of the resonators as internal controls for compensating for fluctuations in temperature.

Future Directions

The future is bright for the application of WGM biosensors. With the myriad benefits associated with the method and the proof-of-concept work performed to date, much rests on the ability to control surface functionalization and engineering of the associated sensor components (laser source, detectors, electronics, sample handling, etc.) to miniaturize the systems to a truly portable handheld format. Similar as electronic devices that have become smaller and more portable, it is inevitable that the components of WGM biosensors will one day be packaged in a form small enough for a primary health care giver or technician to use devices of this type on a regular basis at either the bed side of a patient, or in the field testing for biological agents or environmental contaminants. Further refinement of quantification methods and sensor design (geometry, materials, etc.) will provide unmatched sensitivity and accuracy in point-of-care devices.

Nanocrystalline Functional Materials in Bulk Form with Grain Size Below 50 nm
Nanocrystalline Materials
Nanodentistry
Nanodevices
Nano-ecotoxicology
Nano-effects
Nanoelectrodes
Nanoelectromechanical Systems
Nanoelectromechanical Systems (NEMS)
Nanoencapsulation
Nanoengineered Concrete
Nanoengineered Hydrogels for Cell Engineering
Nanofabrication
Nanofatigue Tester
Nano-FET
Nanofibrous Materials and Composites
Nanofluidic Channels
Nanofluidics
Nanofocusing of Light
Nanogap Biosensors
Nanograppers
Nanohardness
Nanohardness Tester
Nanohelix
Nanoimmunology
Nanoimprint Lithography
Nanoimprinting
Nanoindentation
Nanointerconnection
Nanojoining
Nanolayered Coatings
Nanolayers
Nanomachining
Nanomagnetism
Nanomanipulation for Cell Analysis
Nanomanipulation of Biocells
Nanomanufacturing with Magnetically Recorded Nanotemplates and Directed Self-Assembly

Nanomaterials
Nanomaterials and Nanoproducts
Nanomaterials for Electrical Energy Storage Devices
Nanomaterials for Excitonic Solar Cells
Nanomaterials for Sensors
Nanomechanical
Nano-mechanical Machining
Nanomechanical Properties of Nanostructures
Nanomechanical Resonant Sensors and Fluid Interactions
Nanomechanical Resonators Based on III–V Semiconductors
Nanomechanics
Nanomedicine
Nanometric
Nanomotors
Nano-optical Biosensors
Nano-optics Biosensing
Nano-optics, Nanoplasmonics
Nano-optomechanical Systems (NOMS)
Nanoparticle
Nanoparticle Cytotoxicity
Nano-particle Image Velocimetry
Nanoparticle Self-Assembly
Nanoparticle Tracking Analysis
Nanoparticle–Adsorbome
Nanoparticle–Biocorona
Nanoparticle–Biomolecular Corona
Nanoparticle–Protein Corona
Nanoparticles
Nanoparticles Toxicity Examined In Vivo in Animals
Nanoparticulate Materials and Core/Shell Structures Derived from Wet Chemistry Methods
Nanopatterned Substrata
Nanopatterned Surfaces for Exploring and Regulating Cell Behavior
Nano-patterning
Nanophotonic Fabrication
Nanophotonic Structures for Biosensing
Nano-piezoelectricity
Nano-pillars
Nanoplasmonic Enhancement
Nanoplasmonic Sensing
Nanoplasmonics Involved in Localized Photopolymerization
Nanopolaritonics
Nanopores
Nanopowders
Nanoprinting
Nanoribbons
Nanorobotic Assembly
Nanorobotic Manipulation of Biological Cells
Nanorobotic Platforms for Biological Studies
Nanorobotic Spot Welding
Nanorobotics
Nanorobotics for Bioengineering
Nanorobotics for Bioengineering and Medical Interventions
Nanorobotics for MEMS and NEMS
Nanorobotics for NEMS Using Helical Nanostructures
Nanorobotics for Synchrotron Radiation Applications
Nanorods
Nanoscaffold
Nanoscale Drug Vector
Nanoscale Fluid Dynamics
Nanoscale Fluid Mechanics
Nanoscale Heat Transport
Nanoscale Mass Transport
Nanoscale Metal Alloys
Nanoscale Metals
Nanoscale Particle
Nanoscale Printing
Nanoscale Properties of Solid–Liquid Interfaces
Nano-scale Structuring
Nanoscale Technologies
Nanoscale Thermal Analysis

Nanoscratch Tester
Nano-sized
Nanosized Nanocrystalline and Nanotwinned Metals
Nano-sized Particle
Nanoslits
Nanosoldering
Nanospring
Nanostructure
Nanostructure Field Effect Transistor Biosensors
Nanostructured Antireflective Surfaces
Nanostructured Functionalized Surfaces
Nanostructured Hydrogels
Nanostructured Materials
Nanostructured Materials for Sensing

Nanostructured SERS-Active Metal Oxides
Nanostructured Solar Cells
Nanostructured Thermoelectric Materials
Nanostructures
Nanostructures and Characteristics of Carbon Nanofibers
Nanostructures and Characteristics of Graphene and Graphene Oxides
Nanostructures Based on Porous Silicon
Nanostructures by Electrospinning
Nanostructures for Coloration (Organisms Other Than Animals)
Nanostructures for Energy
Nanostructures for Photonics
Nanostructures for Surface Functionalization and Surface Properties
Nanostructures: Nanodevices
Nanotechnology
Nanotechnology Applications in Polymerase Chain Reaction (PCR)
Nanotechnology in Cardiovascular Diseases
Nanotechnology in Dental Medicine
Nanotechnology in Pulmonary Disease
Nanothermodynamics
Nano-TiO_2 Life-Cycle Assessment Perspective
Nanotoxicity
Nanotoxicology
Nanotransfer Printing
Nanotribology
Nanotribology Applications in Microprojector Technology
Nanotube Adsorption Sensor
Nanotube Force Sensor
Nanotube Mass Sensor
Nanotube Resonant Sensor
Nanotube Resonator
Nanotubes
Nanotweezers
Nano-twinned Materials
Nanovaccinology
Nanowire FET Biosensor
Nanowire FET Simulations Based on the Nonequilibrium Green's Function Formalism
Nanowire-Based Field Effect Transistor (NWFET)
Nanowires
Nature Inspired Microneedle
Near Infrared
Near-Field Focusing and Heating
Near-Field Molecular Optics
Near-Field Optics
Near-Field Scanning Optical Microscopy (NSOM)
NEMS
NEMS Gravimetric Chemical Sensors
NEMS Gravimetric Sensors
NEMS Mass Sensors
NEMS Piezoelectric Switches
NEMS Resonant Chemical Sensors
NEMS Resonant Mass Sensors
Neural Activity-Dependent Closed Loop
Neural Interfaces
N-Methyl-2-pyrrolidone (NMP)
Nonadiabatic dynamics
Non-conventional Machining
Nonlinear and Parametric NEMS Resonators
Nonlinear Electrokinetic Transport
Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures
Nonlinear Parametric MEMS
Nonlinearity
NS300
NS500
NTA
Nucleation of Silica Nanowires
Nucleic Acid Amplification

O

Officinal Skink
Oil-Repellency of Fish Scales
Oligonucleotide Amplification
Oligonucleotide Synthesis
OMFR
On-Chip Flow Cytometry
193-nm Lithography
Optical and Electronic Properties
Optical and Mechanical Nanostructured Coatings for Future Large-Scale Manufacturing
Optical Cavity Biosensor
Optical Frequency Magnetic Dipole Transitions
Optical Lithography
Optical Lithography by Liquid Immersion
Optical Properties
Optical Properties of Metal Nanoparticles
Optical Reflectance Spectroscopy of Ancient Paper
Optical Resonance Biosensor

Optical Response of Metal Particles
Optical Ring Resonator Biosensor
Optical Spectroscopy for Ancient Paper Diagnostic
