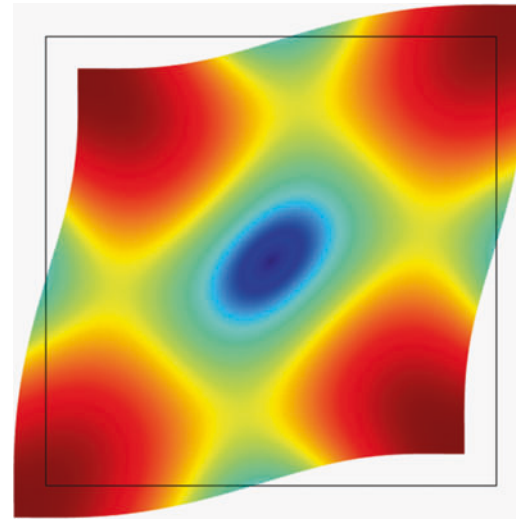
At room temperature, anchor loss does not appear to be the limiting factor on Q. The Lamé mode has five nodes in total: four nodes from each of the corners of the square plate and the last node at the center of the square plate. As such, the square plate can be conveniently clamped at the corners with little interference to the Lamé mode. Various studies have been carried out to assess the effect of the tether design on Q. The most common tether designs include beam tethers and T-shaped tethers as illustrated in Fig. 5. Keeping the size of the square plate the same but supporting the resonator by a T-shaped tether or beam tether, experimental results have suggested that no significant difference in Q between the two tether designs can be observed [13]. The results imply that the shape of the tether has no effect on Q. In a more recent study which focused on variations made to the T-shaped tether, it was found that changing the geometry of the T-shaped tether had no impact on Q either [14]. Taken together, the experimental results suggest that anchor loss does not play a dominant role in determining Q at room temperature.

With respect to TED, it can be shown that the condition for TED is absent in the Lamé mode. This can be seen by considering the volumetric changes caused by the strain field related to the Lamé mode. The fractional change in volume at a given location on the square plate can be found by summing the strains in all three directions. Assuming thin plate theory, the strain along the thickness of the plate can be neglected, leaving only the lateral strains. As seen from Eq. 2a, the lateral strain components are equal and opposite everywhere in the square plate for the Lamé mode. The result is zero volumetric change everywhere in the square plate. As such, the thermal gradients that give rise to TED are absent in the Lamé mode. This isochoric characteristic of the Lamé mode leads to no TED in theory [15]. However, as we will see in the following section, introducing holes into the square-plate annuls this isochoric property of the Lamé mode and consequently introduces TED.



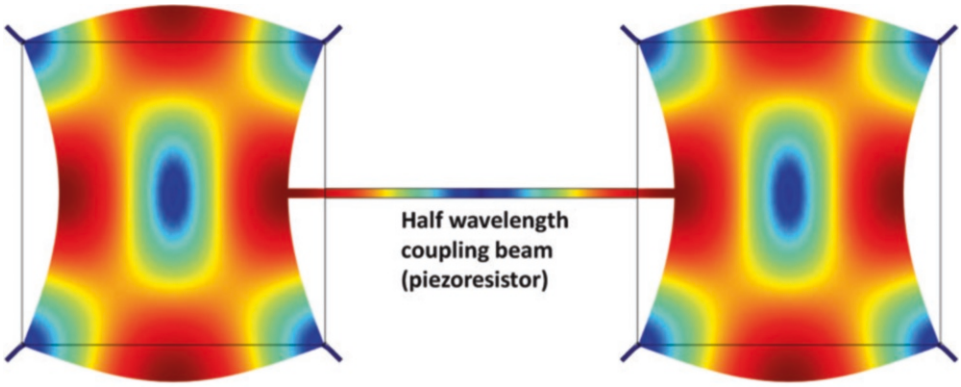
Effect of Etch Holes on *Q*

In the fabrication process of bulk mode resonators in SOl technology, etch holes are often employed. The etch holes are introduced to facilitate the timed HF etch of the buried oxide (BOX) layer underneath the bonded silicon device layer that

defines the resonator structure. Undercutting the structure by etching the BOX releases the resonator from the handling substrate. It has been found that adding etch holes to an otherwise plain square-plate resonator can massively reduce Q by over 95 % [16]. Through the use of finite element (FE) simulations, it has been found that the cause of this drop is TED. The Lamé mode shape is uniquely isochoric, which means that the fractional change in volume is zero at every point of the square plate. This can be shown from Eqs. 2a and 2b, whereby adding up the strain in the x-direction and y-direction at any given point on the square plate yields zero as the answer. Hence in theory, there is no TED in the Lamé mode. By FE analysis, it can be shown that adding holes all over the square plate results in a nonzero sum of x-strain and y-strain manifested as adjacent variations of expansion and contraction. By solving coupled thermoelastic equations using FE analysis, Q_{TED} can be computed for various hole patterns and compared against the measured values of Q reported by Shao [17]. Interestingly, the deviation between the measured Q and FE computed Q was found to be larger where the holes were concentrated in parts of square plate as compared to all over the square plate, suggesting that TED is accompanied by other sources of dissipation.

Effects of Crystal Orientation

Single-crystal silicon is anisotropic with respect to its mechanical properties. On an n-type (100) wafer, a square plate is aligned to the <110> axis when the sides of the plate are parallel to the primary flat. Rotating the same square plate 45° relative to the primary flat aligns the resonator to the <100> axis. Changing the orientation changes the resonant frequency of the Lamé mode MEMS resonator due to the change in the associated shear modulus. With reference to the stiffness matrix for single-crystal silicon, the shear modulus for a square plate aligned to the <110> axis is defined by C_{44}. In the <100> axis, the shear modulus is defined by $(C_{11}–C_{12})/2$ [18]. Apart from differences in resonant



Lamé Mode MEMS Resonators, Fig. 6 Illustration of the face shear mode shape

frequency, the choice of alignment for a silicon Lamé mode resonator to the <110> or <100> axis makes a difference to both its power handling limit and the nature of nonlinear behavior. The effect of orientation has been observed in lateral shear modes, namely, the Lamé mode and the face shear (FS) mode (illustrated in Fig. 6). Both rely on the shear modulus to determine the spring constant of the resonant mode, but their relation to the crystal orientation properties is exactly opposite. As such the nature of the observed nonlinear behaviors in relation to crystal orientation has been found to be opposite. This is summarized in Table 1 based on the measurement results of 800 μm wide square plates driven sufficient hard to observe hysteresis in their electric frequency response.

The observed opposite nature of nonlinearity in relation to crystal orientation is best explained by the intrinsic nonlinear moduli of silicon itself. Geometric nonlinearities alone are unable to explain the difference if the material properties were assumed to be unaffected by crystal orientation because then the resulting nonlinear behavior would be of the same nature (either hardening or softening in both cases). If the nonlinearities were attributed to the capacitive gap transducer, then it

Lamé Mode MEMS Resonators, Table 1 Summary of nonlinear behavior of lateral shear modes in relation to crystal orientation

	Lamé		Face shear (FS)	
Orientation of edge alignment	Shear modulus	Nonlinearity	Shear modulus	Nonlinearity
<110>	C_{44}	Spring softening	$(C_{11}–C_{12})/2$	Spring hardening
<100>	$(C_{11}–C_{12})/2$	Spring hardening	C_{44}	Spring softening

Lamé Mode MEMS Resonators, Fig. 7 Mode shape of a pair of coupled Lamé mode resonators where the coupling beam in the middle acts as piezoresistor through which a bias current flows through. The Lamé mode is detected through measuring changes in the resistivity seen as a modulated current

should be noted that capacitive gap transducers only produce spring softening effects [19].

Mechanically Coupled Lamé Mode MEMS Resonators

Despite very high *Q*s even in the millions possible in Lamé mode MEMS resonators, unless nanoscale gaps can be reliably fabricated, the poor electromechanical transduction based on capacitive drive and sense leads to high motional resistance. As an alternative readout method, the piezoresistive property found in single-crystal silicon can be used as means to convert the lateral deformations into an output motional current via strain fields. On this note, piezoresistive sensing as a readout method has been shown to be highly effective for boosting the transduction of silicon resonators relative to capacitive sensing. However, piezoresistive sensing is not an immediately favorable option for the Lamé mode when one considers its associated stain field. The Lamé vibration mode shape comprises regions of tension and compression, thus greatly reducing the net change in stress required for piezoresistive sensing to be effective. One way of exploiting piezoresistivity in the case of the Lamé mode is to couple a pair of identical Lamé mode resonators mechanically and use the coupling spring as the piezoresistive strain gauge [20] as depicted in Fig. 7. The coupling spring is a longitudinal free-free beam with a length that is half the acoustic wavelength of the Lamé mode resonators. This mechanical coupling design, together with a biasing configuration used to apply a desired combination of electrostatic forces, helps synchronize the coupled pair of square-plate resonators to resonate in phase as illustrated in Fig. 7 at the same frequency.

The plates are excited to vibrate in the Lamé mode just like in a single square plate through capacitive gap electrodes. As the pair of square-plate resonators resonates in phase, the

mechanical coupling beam compresses or elongates accordingly like a longitudinal free-free beam resonator. This has been confirmed by FE simulations, which shows that the deformation profile follows a sine function that corresponds to half of the acoustic wavelength. It has been shown that transmission peak magnitude increases linearly with the bias current level, in agreement with theory. The Q of the coupled resonator pair was a million, which is 20 % lower than the measured Q for a single Lamé mode resonator. But in terms of transduction, compared to a single Lamé mode resonator, the piezoresistive coupled resonator pair produced a peak resonance that was 28 dB higher with 14 mA bias current despite the slight drop in Q [20]. It has also been confirmed experimentally that the increase in transduction is due to the piezoresistive effect through the coupling beam and not the square plates [21]. This device concept also presents an interesting frequency scaling characteristic in that the electromechanical coupling efficiency is independent of the size of the square plates.

Definition

Laser beam machining (LBM) is a nonconventional machining process, which broadly refers to the process of material removal, accomplished through the interactions between the laser and target materials. The processes can include laser drilling, cutting, grooving, writing, scribing, ablation, welding, cladding, milling, and so on. LBM is a thermal process, and unlike conventional mechanical processes, LBM removes material without mechanical engagement. In general, the workpiece is heated to melting or boiling point and removed by melt ejection, vaporization, or ablation [1]. The high degree of monochromaticity enables the laser beam to be focused to very precise locations and makes it extremely useful for machining with high precision. Depending upon the feature size of the laser tool, laser machining can be categorized into micromachining and macromachining. Typically, the laser systems used for micromachining are normally pulsed beams with an average power lower than 1 kW, whereas the ones for macromachining are continuous wave laser beams ranging up to several kW [2]. The applications of laser beam machining include manufacturing processes such as laser cutting, drilling, welding, ablation, and surface texturing. Since laser machining processes are generally thermal in nature, varied laser durations result in different thermal effects; for instance, shorter laser pulses in the order to femtoseconds help in minimizing thermal effects such as melting and burr formation and therefore minimizing the after-process measures [2]. For polymers, however, laser machining processes are more light driven than heat driven, and therefore, the process is more polymerization based. Polymers are of wide interest in the microfabrication and biomedical industries and contribute a large portion in the relatively new but very popular laser micromachining technique called *direct laser writing* also known as *two-photon lithography* or *multiphoton lithography*. The latter is a maskless technique and employs solid-state lasers in conjunction with galvanostatic scanners and focusing optics in order to minimize the beam diameter and

directly use the laser beam to "write" the pattern onto the material. Direct laser writing is based on nonlinear absorption of light direct toward a tight volume of photosensitive materials; the absorption of light leads to local photopolymerization. The beam can be moved in order to generate the desired pattern. The redundancy of the use of photomasks and complex optical systems makes direct laser writing very popular for microfabrication.

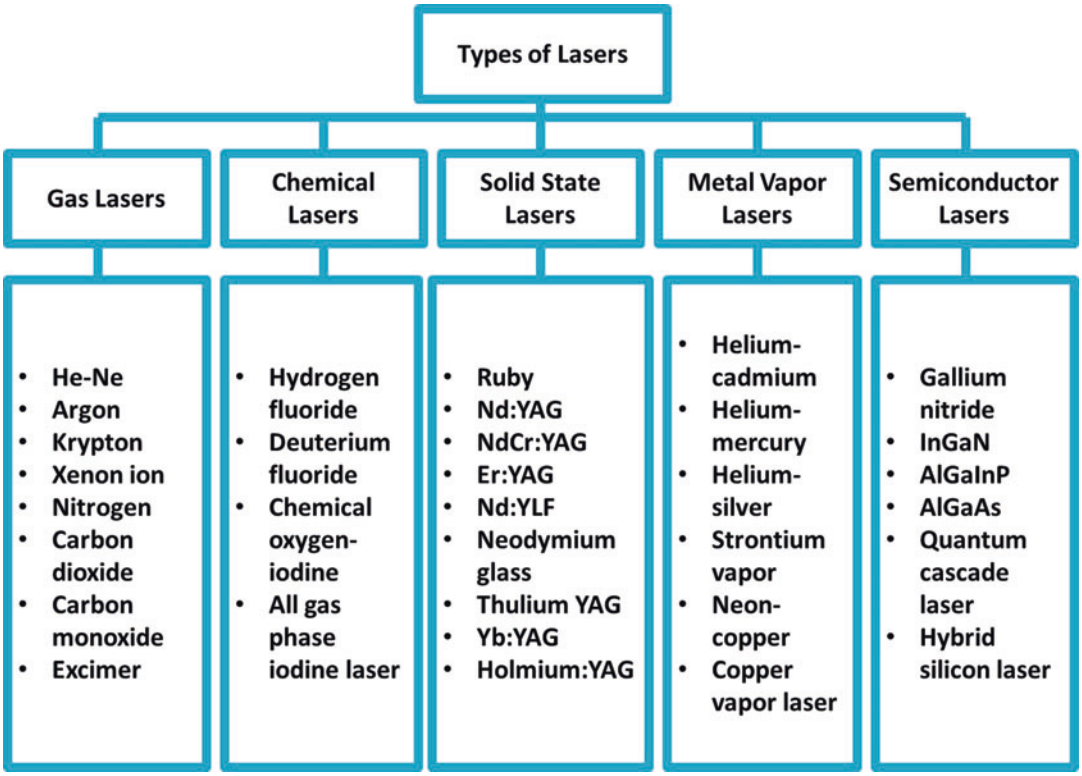
Laser Beam Machining Fundamentals

Introduction to Lasers

The history of lasers dates back to early twentieth century, when Planck propounded the "quantum theory of light." The theoretical foundation of laser was led by Einstein in 1917, using Planck's laws of radiation and probability coefficients for absorption and spontaneous and stimulated emission of electromagnetic radiation. In 1953, Charles Town along with graduate students produced what was known as the "maser (microwave amplification by stimulated emission of radiation)," which was essentially a microwave amplifier and similar to laser but used microwaves instead of visible or infrared light. The first practical laser was demonstrated by Theodore Maiman in 1960. Maiman's laser was based on optical pumping of a synthetic ruby crystal and generated a pulsed red radiation at 694 nm [3]. Later in 1960, Javan, Bennett, and Heriott developed the first gas laser that used a mixture of helium and neon. The first diode laser was developed by Robert Hill; the laser was made of gallium arsenide and emitted a near-IR radiation of 850 nm. Much advancement has been made in laser technology since then.

Features of a laser beam: A laser beam unlike conventional light is *monochromatic*, *directional*, *coherent*, and *bright*. The features of a laser beam are briefly described below:

Monochromaticity – The term monochromatic refers to a "single color" and for light refers to a single wavelength or frequency. In practice, however, no light is ideally monochromatic including a laser beam; nonetheless, a laser is considered to be monochromatic because the laser consists of very close, discrete, and narrow spectral lines [1].



Directionality – The laser beam has a very small divergence angle, which enables the beam to be focused to a very small spot over a long distance. Owing to the striking directionality of laser beams, the output of a laser beam is almost parallel and can therefore be used to transmit data for diagnostic and communication purposes.

Coherence – The laser beam is coherent because there exists a fixed phase relationship between electric fields at different locations across the beam profile (spatial coherence) and between electric fields at one location at different times (temporal coherence).

Brightness – Brightness measures the ability of a laser oscillator to emit high optical power per unit area per unit solid angle [1]. Since the brightness of the laser beam is inversely proportional to the angle, the smaller the divergence angle, the brighter the laser beam.

Types of lasers used for laser beam machining: Gas lasers such as CO_2 and excimer lasers, along with solid-state lasers such as Nd:YAG and YAG lasers and femtosecond lasers, are some of the most popular lasers. The active media of *solid-state lasers* is obtained by embedding transition metals (Ti, Nd, Yb, Er, etc.) into insulating host lattices. The energy levels of the active ions are responsible for lasing actions, while the thermal and physical properties of the host material are crucial for determining the efficiency of the laser operation [3]. In Nd:YAG (neodymium-doped yttrium aluminum garnet) lasers, Nd^{3+} replaces a tiny fraction of yttrium ions in the host crystal of YAG.

Gas lasers are divided into three main categories: atomic (He:Ne), ionic (Ar ion gas laser), and molecular (CO_2 gas laser, nitrogen gas lasers, excimer lasers), depending upon the nature of active medium. These lasers are pumped by *electrical discharge*. After the passage of discharge current, the electrons are accelerated between the electrodes and thereafter collide with the entities

Laser Beam Machining, Fig. 1 Different types of widely used lasers

(atoms, ions, molecules) in the active medium; this causes the transitioning of electrons to higher-energy levels in order to achieve population inversion and stimulated emission [3]. The first gas laser was the He:Ne (helium-neon) gas laser invented by Ali Javan and William R Bennett in 1960.

– The *carbon dioxide laser* is one of the most widely used gas lasers that operates at the infrared wavelength (9.4–10.6 μm) and can provide power in the order of hundreds of kW. It is typically used in the continuous wave mode and is mostly used in industrial applications such as cutting, welding, drilling, engraving, etc.
– *Excimer lasers* – Excimer lasers utilize excimer molecules such as ArF, KrF, XeCl, etc.; essentially an excimer is a combination of rare excimer lasers that operate in the ultraviolet region by a fast electrical discharge in a high-pressure mixture of a rare gas and a halogen gas. The combination of the two determines the final wavelength of the laser. The typical pulse energies for excimer lasers range from a few hundred millijoules to 1 J. The average power ranges from 10 W to 1 kW. Applications of excimer lasers include lithography, ablation, and microfabrication.

Femtosecond lasers – A femtosecond laser is an ultrafast laser emitting optical pulses with a duration well below one picosecond (with 1 ps $= 10^{-12}$s), i.e., in the domain of femtoseconds (with 1 fs $= 10^{-15}$s). The generation of such short pulses is achieved with the technique of mode locking. Methods for producing mode locking in a laser may be classified as either an active method using an external signal to induce optical modulation or a passive method using self-modulation of the light via saturable absorbers. Femtosecond lasers are widely used in direct laser writing.

Figure 1 categorizes different types of widely used lasers. Other types of lasers include X-ray

lasers, dye lasers, nuclear pumped lasers, electron lasers, etc.

Modes of laser operation: Depending upon the desired application, lasers can be operated in different modes. Typically for laser macromachining, *continuous* high-power laser sources are required, while for micromachining, *shorter pulses* are required, and therefore broadly laser modes can be classified into (i) continuous and (ii) pulse generation modes. *Continuous wave* mode operation of laser essentially means that the laser is being pumped continuously and therefore emits light continuously. Laser pulses can on the other hand be generated by using gain switched, Q-switched, and mode-locked modes; *gain switching* is regarded as the most direct method to generate laser pulses. Upon the initiation of pumping, the population inversion builds up, and the laser starts to oscillate once critical inversion is reached. The process continues until pumping is switched off. Pulse durations typically vary from 10 to 10 ms [4]. *Q-switching*, on the other hand also known as giant pulse formation, is used to produce a pulsed output beam usually with extremely high peak power (of the order of gigawatts). This technique provides a single strong and a short pulse of laser radiation [3]. *Mode locking* is used to generate ultrashort laser pulses in the picosecond (10^{-12} s) to femtosecond (10^{-15} s) range. This technique relies on production of a fixed phase relationship between the longitudinal modes of the laser resonator. Mode locking of lasers can be achieved by active (uses an optical modulator) and passive (uses an absorber) mode-locking techniques.

Types of Laser Beam Machining Processes

Laser Welding

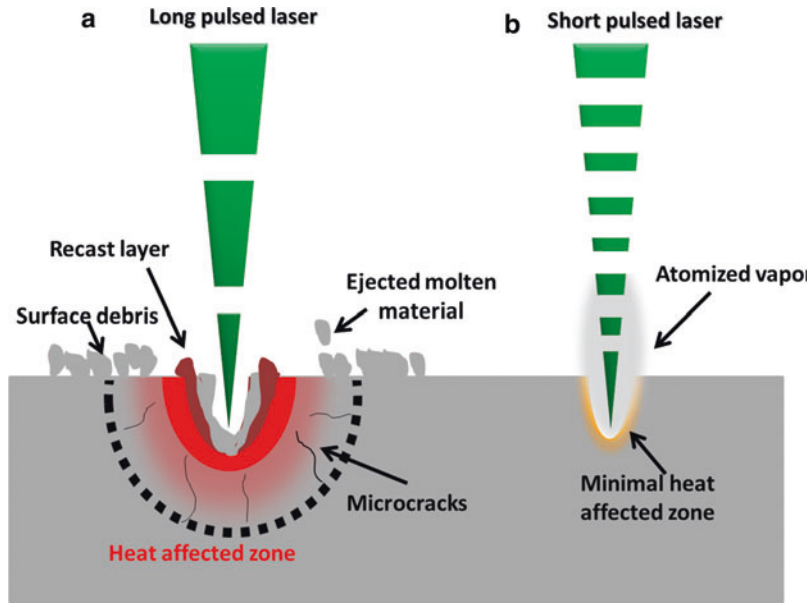
Welding processes that utilize lasers as heat sources are known as *laser welding*. Essentially welding process is a "joining" or "fusion" process of similar or dissimilar materials. Laser beam welding is a versatile technique that finds applications in a host of industries including the aerospace, automotive, biomedical, and electronics. In the welding process, the laser beam is directed toward the work material, whereupon the laser energy is converted into heat energy and surface melting occurs and therefore laser welding is a "pyrolytic" process, where the light energy from the laser beam is converted into thermal energy as a result of photon-electron interactions upon the incidence of the laser on the workpiece. Depending upon the temperature of the surface and the thermal characteristics of the workpiece material, (i) thermal stresses in the heat-affected zone (HAZ) can be generated, (ii) the surface of the material can melt, or (iii) the surface of the workpiece can vaporize. Laser welding is categorized into (i) *keyhole* and (ii) *conduction welding*. In keyhole welding, the laser is focused to achieve very high-power densities at the workpiece. The metal vaporizes at the center where the intensity of the laser is the highest, leaving behind a pit or a "keyhole" in the molten metal pool. Also, the metal vapors transfer the laser energy into the sides of the pit, resulting in a deep aspect ratio structure. Conduction welding on the other hand are shallower; in conduction weld processes, most of the laser energy is absorbed by the surface of the material, while the heat transfer occurs in the rest of the material by heat conduction and hence the name "conduction welding." The HAZ is typically larger for conduction welds as compared to the keyhole welds.

Depending upon the type of application, laser beam welding can be carried out in both continuous and pulsed modes. Solid-state lasers (Nd:YAG) and gas lasers such as CO_2 lasers are widely popular as laser sources for welding processes. Despite their longer IR wavelength, which is typically not absorbable by metals, CO_2 lasers are widely used in laser welding given their ability to generate directional beams with very high powers. The high-intensity beams with smaller spot size particularly are suited for keyhole welding. CO_2 lasers find application in industrial welding of glass, aluminum alloys, and also welding of disparate materials. Pulsed Nd:YAG lasers, on the other hand, produce energy in the order of a few millijoules per pulse and are popular for welding of metals including stainless steel and aluminum alloys and also for spot welding applications. Laser welding is also popular in the microdomain. Laser microwelding offers a

number of advantages over conventional joining methods: (i) the outstanding control of laser allows for the weld energy to be delivered only where it is required; (ii) laser provides stronger welds with smaller number of welds; (iii) the welds are aesthetically pleasing; and (iv) lasers provide better hermetic welds which are desired for microapplications [5]. In addition to Nd:YAG lasers, fiber lasers are also highly popular for microwelding purposes.

Laser Ablation

Laser ablation, in the broadest sense, refers to a process of removal of the material with the aid of a laser beam as the energy source; the material is removed by vaporization or sublimation upon the incidence of the laser beam. Ablation mechanisms are distinguished into *photolytic* and *pyrolytic* processes. In *photolytic processes* the chemical bonding energy is overcome by the use of light energy. Photolytic ablation is observed in the case of polymers where the large polymeric molecules are broken into smaller monomers. When all the laser energy is used to overcome the binding energy, the ideal case is known as *cold ablation*. However, in the case of metals, the laser energy is first absorbed by the metal electrons and transferred into thermal energy which can thereafter induce thermal stresses, melt the surface, or evaporate the surface depending upon the surface temperature and material properties.



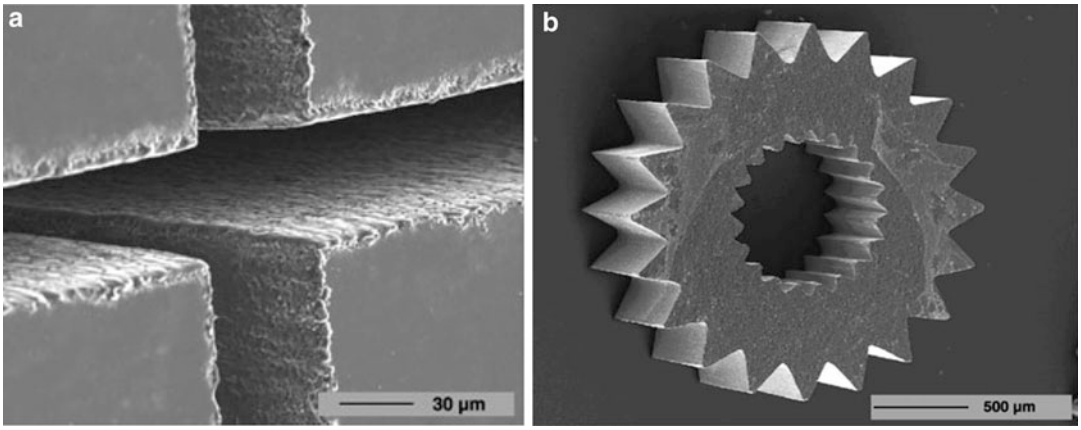
Ablation of organic polymers: As mentioned earlier, ablation of organic polymers is a photolytic process, which means that the energy from the light is enough to overcome the energy "gluing" the atoms together. The relationship between energy and frequency (Planck-Einstein's relation) is given as $\boldsymbol{E = h\nu = hc/\lambda}$, where E is the energy, h is the Planck's constant, v is the frequency, c is the velocity of light, and λ is the wavelength. For organic polymers, the bond strengths of O–H, C–H, and C–C are 4.7 eV, 4.25 eV, and 3.7 eV, respectively. These bond energies can easily be overcome by excimer lasers such as KrCl (225 nm ~ 5.5 eV) and ArF (193 nm ~ 6.42 eV). The removal of these materials is a three-step process: (i) the laser photons are absorbed at a characteristic depth of ~0.2 μm [4]; (ii) longer chains of polymers are broken into shorter chains; and (iii) the material is removed in the form of vapors or small particles. In addition fluency of the laser beam must be controlled in order to obtain finer ablation features.

Ablation of metals: Laser ablation of metals is a pyrolytic or a photothermal process. Given the high thermal conductivities and low melting temperatures of metals, microstructuring of metals is rather challenging with conventional laser pulses longer than *1 ns*, metal ablation is accompanied with large heat-affected zones (HAZ) and molten throw-outs, and therefore machining metals with long pulsed lasers becomes a hassle as the achievable quality and precision is quite inferior. Figure 2 shows a qualitative difference between using long laser pulses and short laser pulses for machining purposes. A significant improvement in metal ablation can be realized by using ultrashort laser pulses. Ti/sapphire femtosecond lasers are quite popular for metal ablation [6].

Ablation of diamond: Diamond is a hard to process material, given its transparency in a wide range of wavelengths. However at high-power densities, diamond transitions into graphite, which absorbs the laser power and is thereafter subsequently removed by ablation. Diamond machining is achieved by using microsecond Nd:YAG lasers and nanosecond excimer lasers. The layers of graphite or amorphous carbon that are found on the diamond surface post machining can be removed via polishing [4].

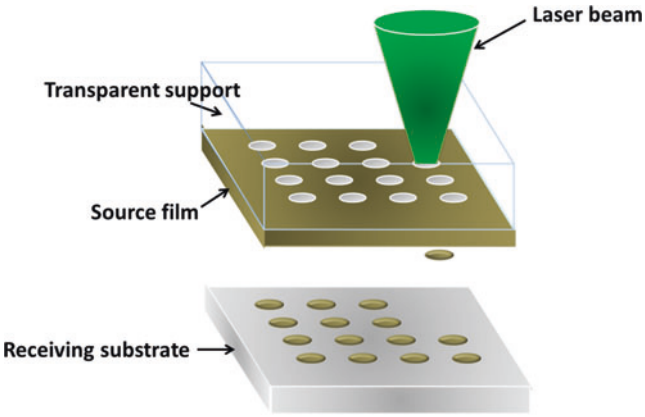
Laser Cutting

As suggested by the name, laser cutting is a technology that employs a laser as the cutting tool. The process involves a high-power laser to cut materials based on a computer-based design. Upon the incidence of the laser, the material is removed by burning, vaporizing, or melting. The advantages of laser cutting over conventional mechanical cutting include the noninvolvement of a mechanical saw to cut the material, which significantly reduces contamination. Moreover since the laser beam does not wear, laser cutting gives high precision. Depending upon the application, CO_2 lasers



Laser Beam Machining, Fig. 2 An illustration of heat-affected zones (*HAZ*) created by using (**a**) a long pulsed laser and (**b**) a short pulsed laser. Notice that the HAZ is much more pronounced for the longer pulse since the relatively longer period of laser irradiation allows for the conduction of heat resulting in large thermal stresses eventually leading into cracking, generation of surface debris from the solidification of the melt ejection, and also voids. The short pulsed laser, on the other hand, has a much smaller HAZ because the laser pulse time is short for thermal transport, leaving behind a much precise and aesthetic structure

and Nd:YAG lasers are very popular for cutting purposes. Nd:YAG lasers are more popular when higher power is required.

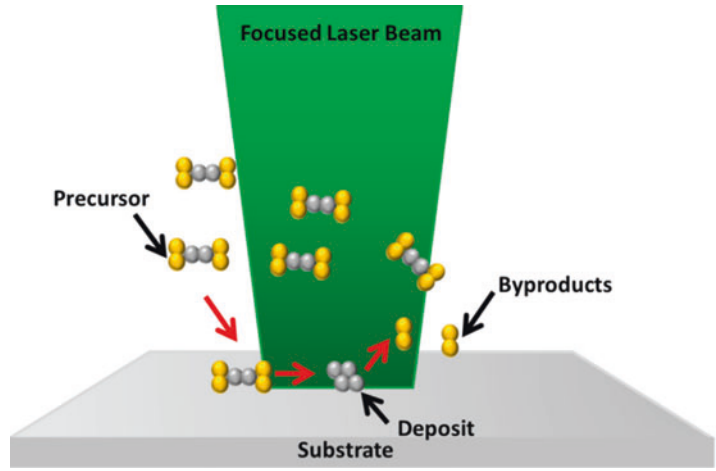


Laser cutting of silicon: Silicon micromachining is extremely popular owing to the dominance of silicon-based devices in microelectronics and medical industries. Silicon in the form monocrystalline wafers dominates the microelectronics and semiconductor industries. Both mono- and polycrystalline silicon along with amorphous silicon are used in high-performance solar cells. High-precision structuring of silicon can be achieved by the use of diode pumped Q-switched Nd:YAG lasers. The short pulses and high-energy short wavelengths allow for alleviated thermal effects including molten material deposition and HAZ at the edges [2]. Shorter laser pulses ensure reduced heat-affected depth and melting and also prevent prolonged and intense plasma heating. The high-energetic short wavelengths Nd:YAG lasers allow for precision and quality structuring of silicon. The accuracy of structuring depends on wavelength, pulse duration, intensity of beam spot, and beam guiding technique. Nd:YAG lasers have been used for cutting silicon in various geometries and cuts. As noted by Klotzbach et al. [2], using a combination of appropriate solid-state laser along with a flexible and well-controllable scanner, suitable structures for micromechanics and microfluidics can also be obtained. Figure 3 shows some of the silicon structures created with UV laser (355 nm); the clean edges in Fig. 3b were obtained with hydrofluoric acid treatment [2].

Laser-Induced Forward Writing

Laser-induced forward writing abbreviated as LIFT uses a laser beam and employs an optically transparent support in order to transfer a thin film to a substrate placed 25–100 μm below the film. Figure 4 demonstrates a schematic of the LIFT technique. The technology of LIFT was introduced by Bohandy et al. [7] in 1986 to deposit copper and silver over silicon and fused silica [8]. The use of the laser pulse leads to vaporization of the material that recondenses on the

Laser Beam Machining, Fig. 3 (**a**) Cross cuts in 550 µm silicon wafer (**b**) toothed gear created with a UV laser [2]



Laser Beam Machining, Fig. 4 Schematic of laser-induced forward transfer (*LIFT*) process. The image on the right shows the final pattern

substrates. The technique of LIFT is popular owing to the simplicity and versatility which enables processing of a wide variety of materials and also allows for patterning of structures with a wide range of geometries.

One of the applications of LIFT is the transfer of transparent materials. Majority of materials are transparent in the visible-IR range, which makes their laser machining difficult; however, the transfer of transparent materials becomes feasible using high-intensity femtosecond lasers which takes place as the two-photon absorption phenomenon. LIFT has shown to be appropriate for patterning a variety of materials including metals such as gold, aluminum, and titanium, oxides such as alumina and ZnO, and high-temperature superconductors [9].

Typically conventional LIFT technique makes use of high-intensity ultrashort laser pulses which may not be appropriate for biological applications as the high-intensity lasers can be harmful for cells, proteins, or other biomolecules. This shortcoming is overcome by pre-coating of the donor substrate with a layer, which is known as the dynamic release layer (DRL), also known as the sacrificial layer. Metals such as titanium, gold, platinum, or chromium are mostly used as DRLs. UV-sensitive photopolymers such as triazene polymers (TP) have also been studied as sacrificial layers [8]. Therefore, the application of LIFT is highly suitable in biomedical fields; the applications include printing of soft materials for biosensors and sensors. Other applications include transfer and printing of liposomes, DNA, etc.

Laser Beam Machining, Fig. 5 Schematic representation of laser chemical vapor deposition (*LCVD*) process

Matrix-assisted pulsed laser evaporation direct write: Matrix-assisted pulsed laser evaporation direct write (MAPLE DW) utilizes laser ablation in order to transfer material from one substrate to another. MAPLE DW is widely used to fabricate electronic devices which utilize matrices containing metals and dielectric or resistive components and also to pattern 3D structures such as chemical-sensitive materials, proteins, antibodies, cells, etc. The MAPLE DW is widely used to fabricate electronic devices which utilize matrices containing metals and dielectric or resistive components and also to pattern 3D structures such as chemical-sensitive materials, proteins, antibodies, cells, etc. MAPLE DW was originally developed by the US Naval Research Laboratory for fabricating electronic devices and later was extended to biological applications [10]. For biological applications, MAPLE DW has been used to transfer hamster ovaries, human osteoblast cells, etc. Patz et al. [11] used MAPLE DW to pattern B35 neuroblast-like cells onto and within polymerized extracellular matrix substrates.

Laser Chemical Vapor Deposition

Laser chemical vapor deposition abbreviated as LCVD is a popular laser direct writing process. Essentially in an LCVD process, a laser beam is used to heat the substrate locally and induce chemical vapor deposition reaction. Chemical vapor deposition (CVD) is a technique that is used to deposit coatings or for growing layers on a substrate and is widely used in the semiconductors, optics, and refractory materials [12]. In the conventional CVD process, gaseous substances are passed over a heated substrate where the reactants either decompose or combine with other constituents to form a layer of the substrate [12]. The advantages of using a laser source are manifold. For instance, the use of laser offers high spatial control and also the availability of non-equilibrium heating and cooling rates. LCVD processes have been used since early 1980s.

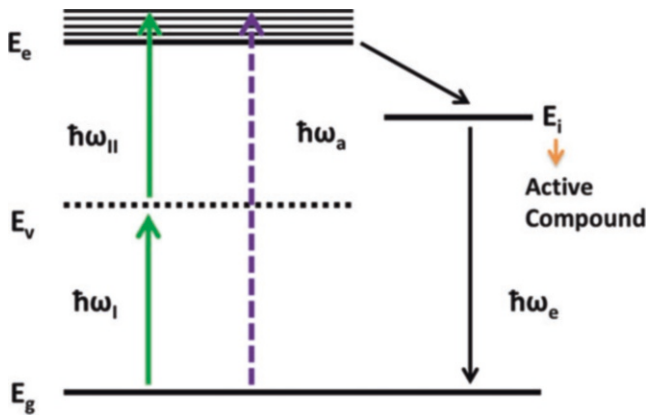
LCVD processes are used for fabrication for both two- and three-dimensional structures. The applications of LCVD includes mask and circuit repair, fabrication interconnects, construction of ohmic contacts, localized coating, and also corrosion-resistant coatings [12]. Figure 5 shows the schematic of LCVD process. The directed laser beam locally increases the temperature of the substrate placed in a chamber that is filled with precursor gas. The precursor gas thereafter is adsorbed on the heated substrate and decomposes into the deposit and by-products.

The deposition rate of LCVD depends on factors such as gas pressure (linearly), power density of the laser (linearly), and the scanning speeds (inversely). For a Gaussian beam profile, the thickness of the laser deposited film is given as [8]

$$h(v_s, t) = \frac{\sqrt{\pi} R_0 r t}{\sqrt{\pi r} + 2(v_s, t)} \qquad (1)$$

where h(v_s,t) is the thickness of the deposited film, R_0 is the diffusion-limited growth rate, r is the radius of the laser beam, t is the time, and vs is the scan speed.

Direct Laser Writing



Multiphoton lithography, also known as direct laser writing, is a powerful three-dimensional printing technology with its ability to realize resolution sub 100 nm. The words multiphoton lithography and direct laser writing are used interchangeably in this chapter. The history of direct laser writing dates back to the early 1980s with its first use in Lawrence Livermore National Laboratory and AT&T Bell Laboratories to create 1-2D features on microelectronic circuits. Later, further advancements were made in direct laser writing technique with the creation of 3D features for microapplications at Max Planck Institute and US Naval Research Laboratory [8]. Since then, much advancement has been made in direct laser writing. The process relies on nonlinear two- or multiphoton absorption; upon the incidence of ultrafast lasers, the photoactive material absorbs the photons in a nonlinear fashion. The absorption of light can initiate photochemical processes in the material including photopolymerization and photoactivation.

Two-Photon Absorption Figure 6 shows one- and two-photon absorption. Two-photon absorption was first predicted by Maria Goppert-Mayer in 1931 and was later verified with the detection of two-photon excited fluorescence that was observed in a europium-doped crystal. The two-photon absorption process can be extrapolated to three or more photons. E_g represents the ground state, and E_e represents the excited energy level. In order to reach a higher-energy level, the molecule can absorb one photon with energy $\hbar\omega_a$. According to the Frank-Cordon principle, the transition in the electronic states is faster relative to the correlated change in nuclear motion [13]. Therefore, the molecule undergoes internal conversion and reaches an intermediate energy level E_i, whereupon the molecule finally relaxes to the ground state releasing energy measuring $\hbar\omega_e$. The emitted energy $\hbar\omega_e$ is lower than the absorbed energy, and therefore the radiation emitted by the molecule upon relaxation is longer than the absorbed wavelength (red shift). Two-photon absorption on the other hand is the excitation of the molecule by absorption of two photons, and therefore in the two-photon absorption process, the energy difference between the ground state and excited state is given as

$$E_e - E_g = \Delta E = \hbar\omega_I + \hbar\omega_{II} \tag{2}$$

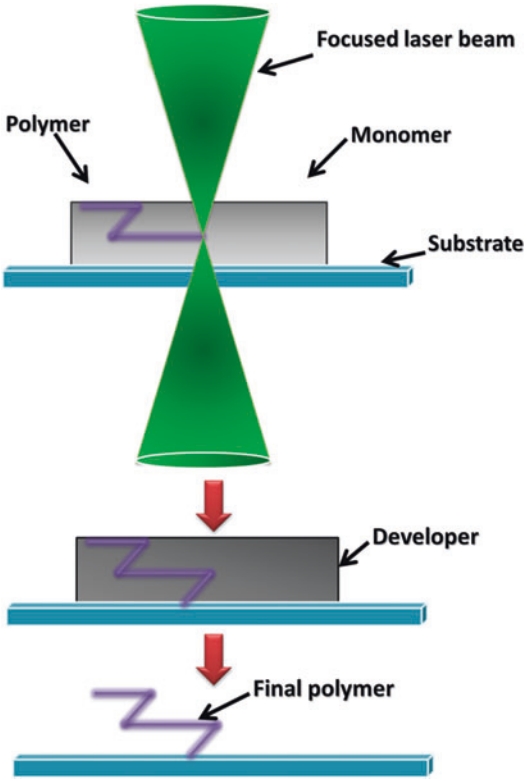
In the two-photon absorption process, a photon with energy $\hbar\omega I < \Delta E$ interacts with the molecule in the ground state and excites it two a virtual level with energy E_v. While the molecule is the in E_v state, a second photon with energy $\hbar\omega II$ is absorbed, and the molecule is transitioned into the final excited level E_e:

$$\hbar\omega_a = \hbar\omega_I + \hbar\omega_{II} \tag{3}$$

Laser Beam Machining, Fig. 6 Energy level diagram for single- and two-photon absorption processes. The dotted violet line shows molecule excitation by one photon, while the two green lines ($\hbar\omega_I$ and $\hbar\omega_{II}$) show two-photon absorption

The degenerate case, where $\hbar\omega_I = \hbar\omega_{II} = \frac{1}{2}\hbar\omega_a$, i.e., the two photons have similar energy, is of practical significance. In terms of technical application, this means only one laser source can initiate two-photon absorption.

Photopolymerization Polymerization processes refer to conversion of small monomers into large polymers through a series of chain reactions, and "photopolymerization," as the name suggests, is light-aided polymerization. The curing source is not limited to lasers operating in the visible, UV, or near-IR radiation range but can extend to x-rays, microwaves, and γ-rays. The starting materials are the monomers or oligomers in the liquid state. Upon light incidence, the monomers or oligomers can be solidified by either polymerization or cross-linking. The polymerization process occurs through a series of chain reactions, while in cross-linking, cross-links are formed with chemical bonds [14]. The distinction between the two processes is the quantum yield, which is defined as:



$$\text{Quantum Yield} = \frac{\text{Number of polymerized units}}{\text{Number of photons utilized}} \tag{4}$$

For cross-linking, the quantum yield is less than 1, since the addition of each monomer unit requires one photon, while in the polymerization process, the quantum yield can range in thousands since the mechanism relies on chain reactions [14]. Typically in order to increase the efficacy of initiation and enhance the quantum yield of photopolymerization, additives such as photoinitiators and photosensitizers are used.

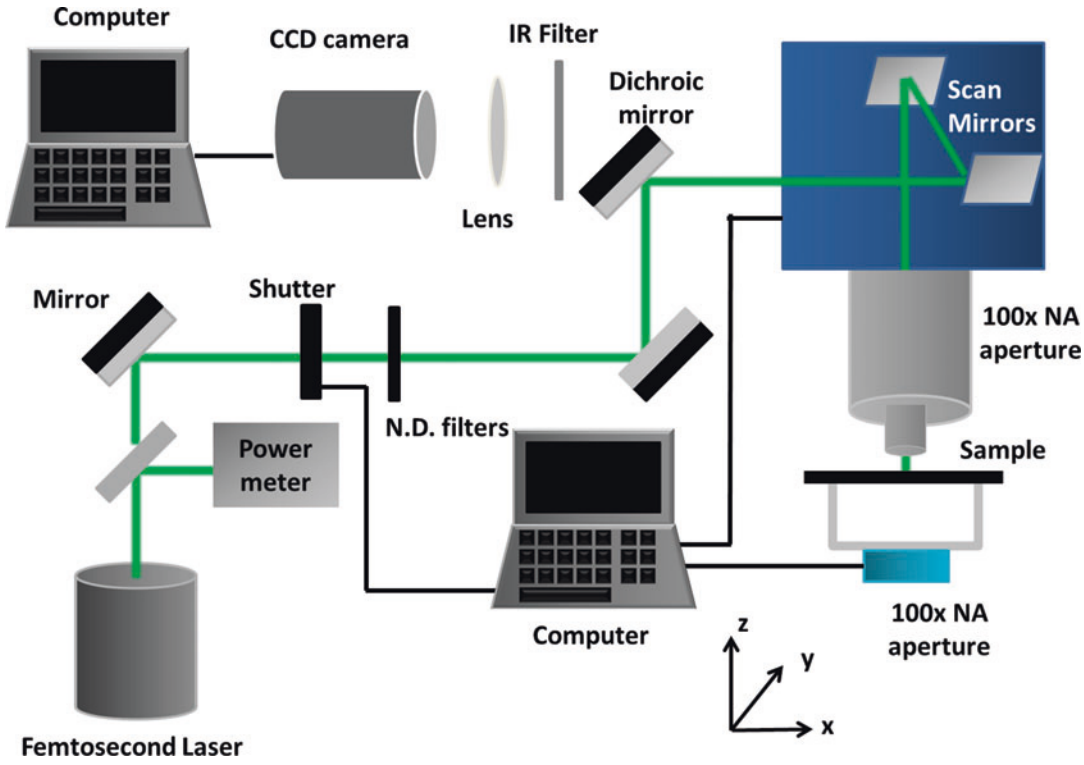
A photoinitiator is a molecule that absorbs a photon and the forms initiating species. A photosensitizer on the other hand is a molecule that absorbs the photon energy and then transfers the energy to a photoinitiator. Depending upon the type of photoinitiator used, photoinitiation processes can be divided into radical initiated and cation initiated. The polymerization process involves various steps that include (i) photoinitiation, (ii) chain propagation, and (iii) termination. Majority of the photopolymerization processes utilize radical photoinitiators. An example of radical type polymerization process will be the double-bond addition of acrylates; ring opening of epoxides on the other hand will be an example of cationic-type polymerization [14].

Quite akin to the conventional photopolymerization processes, two-photon polymerization utilizes photoinitiator molecule excitations to induce chemical reactions between the photoinitiator molecules and the monomeric units [14]. The difference between the two processes is that the two-photon polymerization utilizes the two-photon absorption for the molecule excitation. As explained earlier, two photons are absorbed almost concurrently with the creation of a virtual second for several femtoseconds. Two-photon absorption is a nonlinear optical process meaning that the transition rate is a nonlinear function of the light intensity. Figure 7 shows two-photon laser polymerization process. Two-photon polymerization offers several advantages over conventional polymerization processes for microscale device fabrication. For instance, most materials are transparent to near-IR radiation which is desirable for two-photon polymerization processes. The fact that near-IR radiation is quite low in energy and does not harm biological cells when applied at low intensities makes two-photon polymerization particularly suitable to life sciences and biological applications. Other benefits include the ability of two-photon polymerization processes being able to set up in regular environment and not requiring cleanroom facilities and also their ability to produce feature structures similar to those fabricated using conventional photolithography, deep-reactive etching which require devoted cleanroom work. Moreover, two-photon polymerization does not require masks or molds; it has the ability to directly pattern computer-generated designs, unlike conventional lithography that is a mask projected technique.

Experimental Setup Figure 8 shows a typical experimental setup for direct laser writing. The basic components are (i) an ultrafast laser, (ii) beam motion system, (iii) beam focusing optics, (iv) beam intensity control, and control software [15].

Laser Beam Machining, Fig. 7 Schematic illustration of two-photon polymerization process – first the liquid starting material is patterned using the laser tip as a pen. After the material has been patterned, the unsolidified material is developed, and the remnant photoresist is cleaned leaving behind the desired polymeric pattern

High photon densities are required to initiate nonlinear optical effects, and therefore ultrashort pulsed lasers typically femtosecond lasers in the visible or near-IR radiation are used. A femtosecond laser is an ultrafast laser emitting optical pulse duration in the domain of femtoseconds. Such short pulses are generated by using the lasers in mode-locked mode. The benefits of ultrashort lasers are multifold: (i) the extremely short laser pulses allow for an unprecedented degree of sculpting control of the desired structures, and (ii) the thermal transport and electron-phonon interactions which typically take about nanoseconds to picoseconds to occur are almost impossible to occur given the extremely short-time frame of the pulses and therefore the absence of thermal processes minimizes the surrounding damages. A common laser used for DLW is the Ti/Sapphire laser which operates at around 780 nm. Other examples include YAG lasers operating at green wavelength. The pulse length for the latter is sub-picosecond, and the laser repetition is in the kHz range [15].



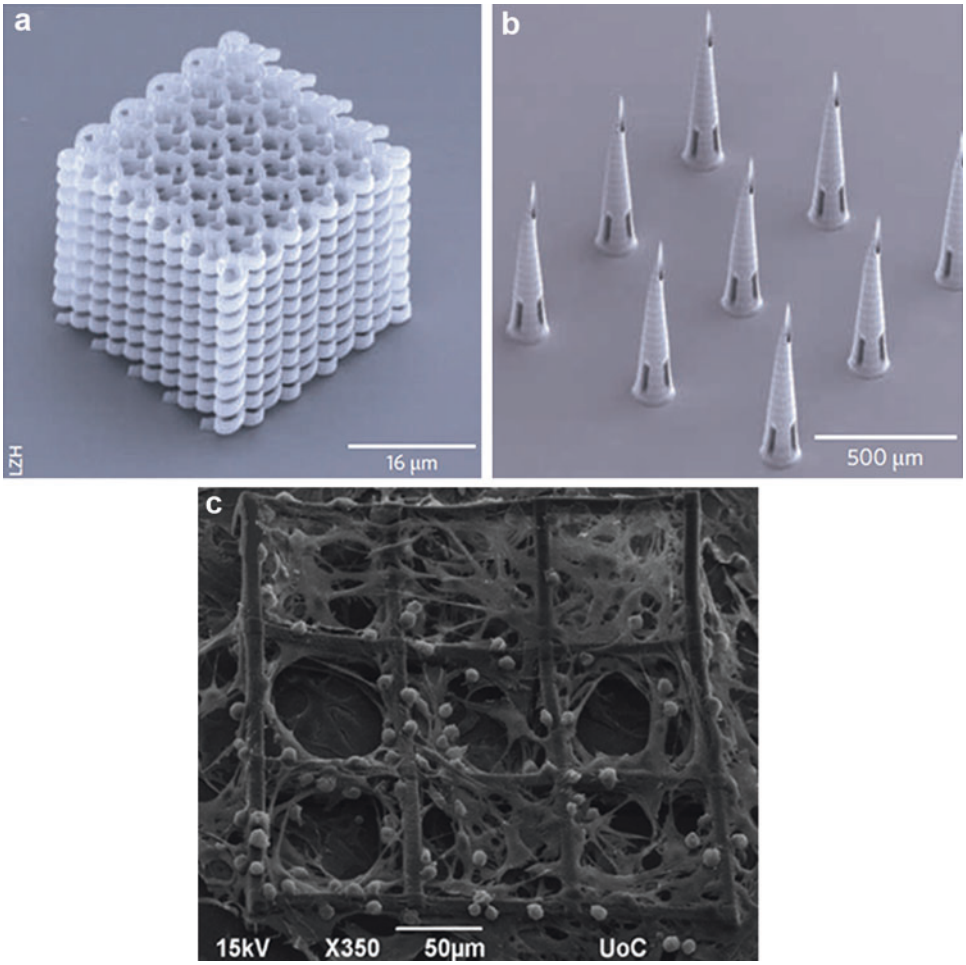
To fabricate the desired pattern, either the beam focus or the sample should be moved. The beam focus motion is achieved by using galvanometric stages, while the sample motion is controlled by using XYZ stages. Most experimental setups are equipped with both systems; this gives the flexibility to move either or both for precise patterning.

The energy distribution is controlled by the focusing optics. The size of the "voxel" is determined by the energy distribution [13–15]. A voxel in general can be understood as a pixel in a three-dimensional space. Pertaining to laser machining, a voxel refers to the volume of the material that is influenced by the laser irradiation. In terms of photopolymerization, a voxel refers to the insoluble volume that is created by the incidence of the laser source at a single spot for a certain amount of irradiation time [13].

The beam intensity is controlled by using neutral density filters, attenuators, waveplates, and polarizers. Control software, on the other hand, essentially controls the components in the experimental setup; these can include 3DPoli or laser scanning software such as Scanning Applications Modules-light (SAM-light) [15].

Applications Laser writing is a maskless fabrication technique and is therefore a one-step process. The ease of direct laser writing makes it very popular in the fields of microelectronics industry; photonics; engineering disciplines including mechanical, biomedical, and microengineering; and life sciences.

Microelectronics: Direct laser writing finds major applications in the *microelectronics industry* which includes fabrication of devices such as capacitors, transistors, resistors, batteries, and integrated chips and also interconnects between the circuit board and microbatteries [4, 8]. Additionally, direct laser writing is used to fabricate microscale inductors, which can be further applied to filters, transformers, and oscillator



Laser Beam Machining, Fig. 8 Typical experimental setup of direct laser writing

circuits. They can be used for generating magnetic fields for mechanical actuation and sensing [16].

Biomedical and life sciences: Direct laser writing is widely used in *biomedical and life sciences*. With direct laser writing, it is possible to create chemically and physically defined cell environments. Direct laser writing provides the possibility to fabricate synthetic structures that mimic the complex human tissue structures, which in turn can be transplanted in case of trauma or injury. Laser-guided writing has made it possible to trap and deliver cells within microscale resolution onto arbitrary surfaces such as human umbilical vein cells which have been deposited in two and three dimensions using laser writing [8]. Ossicular replacement prostheses have also been fabricated using laser-guided writing utilizing two-photon polymerization. Direct laser writing is used to make 3D scaffolds for biomedical applications which can be further modified with desired cell type for the desired application. Yet another application of direct laser writing in biomedical field is the construction of microneedles, which can be used for drug delivery purposes.

Photonics: Photonics is another field, where multiphoton lithography is very popular. Direct laser writing is ideal for creating both planar and nonplanar components of waveguide structures, fiber optics, and synthesis of photonic crystals [16]. Photonic crystals are microstructures with periodical distribution of refractive indices, which are optical analogues of semiconductors with a photonic bandgap. For photonic-crystal application, the period should match that of the wavelength of interest; for instance, for visible and near-IR radiation, the lattice constant should be several hundreds of nanometers [14]. Two-photon polymerization offers great promise to process 3D structures including photonic-crystal optoelectronic devices. SU-8, one of the most popular negative tone photoresists, was used by Deubel et al. [17] to fabricate photonic crystals at telecomm wavelengths. Multiphoton fabrication has been used to fabricate crystals with complex geometries

Laser Beam Machining, Fig. 9 (**a**) A spiral photonic-crystal fabricated using Zr/Si hybrid sol-gel SZ2080 [18], (**b**) test micro-needle array for transdermal drug delivery [18], (**c**) a mineralized scaffold with pre-osteoblastic cells [19]

like diamond unit cell structures, slanted pore structures, etc. Figure 9 shows some of the structures created through direct laser writing.

Summary and Outlook

This entry explained different types of lasers used for laser beam machining processes and different types of laser beam machining processes including laser welding, ablation, cutting, laser chemical vapor deposition, laser-induced forward transfer, MAPLE direct writing, as well as multiphoton lithography. It was seen that laser machining offers several advantages such as (i) the structures obtained by ultrashort laser pulses are highly precise and aesthetic with very little damage by thermal transport; (ii) structuring with lasers does not involve mechanical engagement of lasers, and the final pattern has lower contamination levels if the same processes were carried out with a mechanical tool; (iii) with the right source of laser, it is possible to machine almost any kind of material including metals, ceramics, and polymers; (iv) given the high efficiency of laser, mass production becomes highly feasible with identical replicas; (v) typically laser cutting processes consume less energy as compared to plasma cutting technology; (vi) lasers are extremely popular in biomedical and life sciences applications, given the high precision and nanoscale

resolution of the scaffolds and devices created by laser technology that allows for better control and selectivity of delivery of biomolecules such as proteins and cells; (vii) laser writing equipment for two-photon polymerization does not require devoted cleanroom setup and can be installed in regular environments; and (viii) the advantage of direct laser writing being a maskless technique saves extra time and manual efforts as opposed to traditional mask projection-based photolithographic procedure. However, despite the plethora of advantages of laser beam machining, there are some disadvantages associated with laser beam machining. For instance, power consumption is quite high for laser machining processes and the processes should be extremely timely, otherwise the high intensity lasers may lead to extreme thermal effects and damage to the material; also there exist problems such as handling of samples with arbitrary shapes, maintenance of proper imaging and focusing on the sample surface and proper programming of the system to ensure high degree of accuracy.

Future developments for laser beam machining include more cost-effective laser manufacturing. The use of shorter wavelength lasers in addition to ultrashort pulses to machine a large range of materials with very high precision is also a part of future works. Of high interest is the application of nanostructured materials in the biological sciences and microelectronics, and therefore one of the highly desired prospects for laser micromachining is achieving smaller resolution and feature sizes in the near future.

Aperture trap

Definition

The technique uses nanoapertures in metal films for optical trapping and manipulation of Rayleigh particles, that is, particles that are significantly smaller than the wavelength of light, typically in the 1–100 nm range. The nanoaperture trap works on the principle of self-induced back action, where the presence of the particle in the trap significantly alters the electromagnetic environment (i.e., light transmission) to favor trapping.

Conventional Laser Tweezers

The laser tweezer is an optical tool to immobilize and manipulate small objects using light. Single-beam laser tweezers employ a highly focused laser beam to trap and manipulate micron-sized particle in three dimensions. The diffraction-limited spot produces optical forces around tens of piconewtons, which enables it to hold and manipulate even biological objects like cells, bacteria, and viruses without damage. This was first shown by Ashkin where he used a single-beam laser tweezer to trap dielectric particles down to ~100 nm [1]. Modified beam profiles, such as Bessel beams or vortex beams, have been used for further manipulation of micrometer-sized particles. Nonsymmetric beams are capable of transferring angular momentum from light to particles for their rotation. The laser tweezers have applications in the field of nanoscience, materials, and nanotechnology. For a more detailed insight into

the principle of general laser tweezer, the reader can refer to the section on ▶ **Optical Tweezers**.

Stable Trapping of Rayleigh Particles

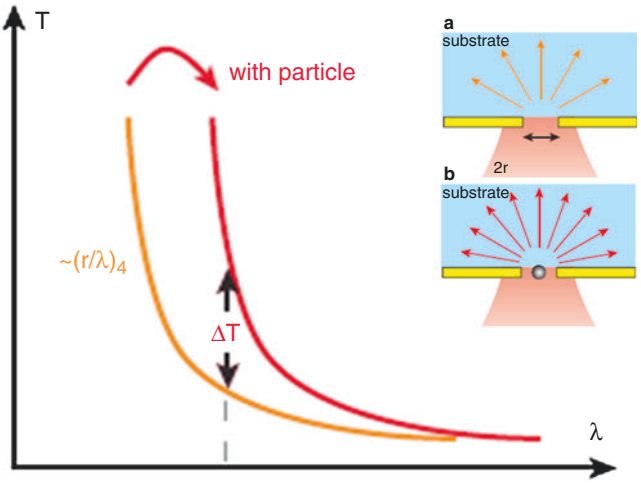
The high-intensity laser spot in an optical tweezer creates a potential well to trap the particles. The stable trapping of Rayleigh particles in an optical trap requires the potential depth of the trap to be sufficiently large to overcome the fluctuating energy of the particles due to Brownian thermal motion [2]. In this case, the particle is unlikely to escape due to Brownian motion if

$$U \gg k_B T$$

where k_B is the Boltzmann constant, T is the temperature, and U is the potential depth of the trap.

The trap potential can be formulated based on the perturbative approximation, where the particle does not significantly change the surrounding electromagnetic field and can be treated as a point dipole. The electromagnetic field constituting the laser beam induces a dielectric polarization (p) in the trapped particle, which depends on the field and the permittivity of the medium. This dipole moment p induced at the sphere by a uniform electric field E is given analytically as [3]

$$p = 4\pi {n_m}^2 \varepsilon_o r^3 \left(\frac{m^2-1}{m^2+2}\right) E$$



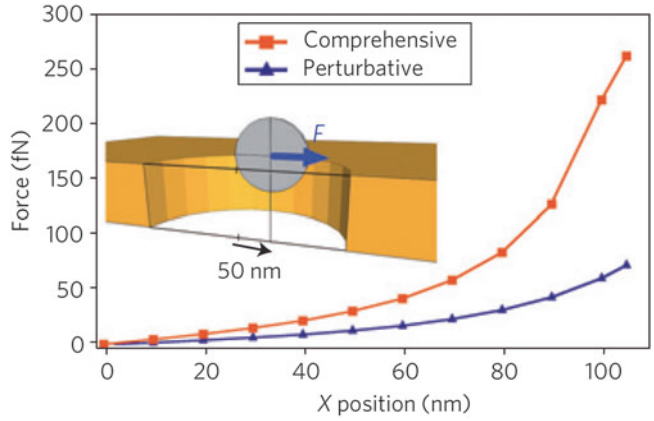
where n_m is the refractive index of the surrounding medium, m is the relative refractive index of the particle, with $m = \frac{n_p}{n_m}$, n_p is the refractive index of the particle, and r is the radius of the sphere. The overall trapping potential can be written as [2]

$$U = -p.E = -\frac{2\pi n_m r^3}{c}\left(\frac{m^2-1}{m^2+2}\right) I$$

The trapping potential is proportional to the third power of the radius of the particle (r^3) and the intensity $I = \frac{1}{2}\varepsilon_0 c|E|^2$ at the trapping point. Hence, the laser tweezer suffers from an inherent limitation when trapping particles in the Rayleigh regime of sizes less than 100 nm. Also, the Stokes drag force in a homogeneous liquid environment scales linearly with particle diameter, giving an additional dependence on the size. (This does not change the trapping potential, but does rescale the time unit, so stable trapping is achieved for less time.) Therefore, stable trapping of particles for this range of sizes using the conventional approach requires higher power, which can have damaging effects on the particle. This is a major issue especially when dealing with biological specimens. Tethering of these small particles to larger micron-sized beads is used as an alternative, which is not always favorable as it sometimes restricts the free motion of the particle while adding complexity to the process [4]. For trapping small dielectric particles, one has to look beyond the perturbative regime and look for a situation where even a small particle can induce a significant change to the electromagnetic field and play a positive role in the trapping process. This can be achieved by nanoapertures in metal films which can overcome these challenges for tweezing particles in the low Rayleigh domain. The presence of the particle in the aperture increases the local electromagnetic field intensity which increases the potential well depth required for stable trapping, without the need of increased laser power.

Bethe Theory

Nanoaperture refers to an aperture in a metal film of size much smaller than the wavelength of light. The small dimension of the aperture compared to the wavelength of light cuts off the propagation of light. This is due to the inability of the propagating wave to satisfy the boundary conditions. Thus, the light is diffracted at the edges of the subwavelength aperture. Hans Bethe first studied the transmission of light through a subwavelength hole in a metal screen, where the light transmitted through the circular aperture is approximated by the emission of magnetic dipole [5]. The transmission through such an aperture is approximated as



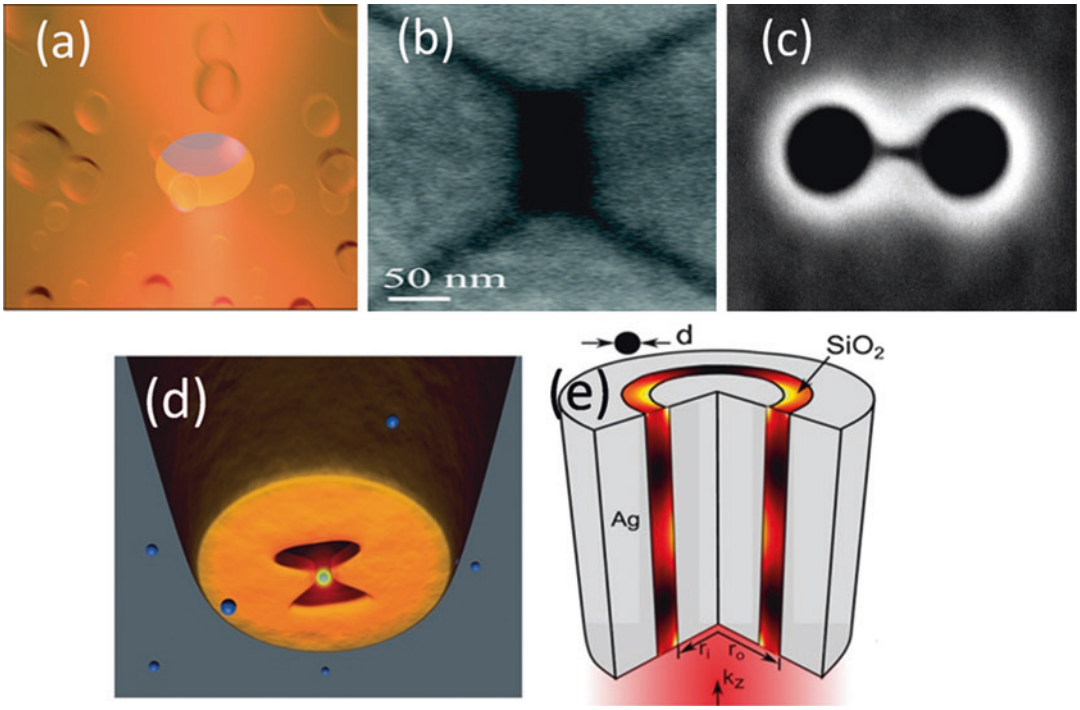
Laser Tweezers Using Nanoapertures in Metal Films, Fig. 1 Optical transmission through a single subwavelength hole: (**a**) without particle and (**b**) transmission enhanced with a dielectric particle in the hole (dielectric loading). The presence of the dielectric particle makes the hole optically larger through dielectric loading, redshifting the transmission curve, and giving the change ΔT in transmission

$$T = \frac{128\pi^3 z_0 H_0^2 r^6}{27{\lambda_o}^4}$$

where Z_o is the free-space impedance, λ_o is the wavelength in free space, r is the hole radius, and H_o is the magnetic field of the incident wave. Normalizing with respect to the area of the circular aperture, according to Bethe's theory the transmission through a subwavelength circular aperture is inversely proportional to the fourth power of the wavelength $T \propto \frac{r^4}{\lambda^4}$ as shown in Fig. 1a. If the aperture is surrounded by a dielectric medium with a refractive index n, the wavelength in the medium is scaled as $\lambda = \frac{\lambda_o}{n}$. Therefore, a larger optical transmission is expected for the same aperture size as shown in Fig. 1b. Since the optical transmission through a subwavelength aperture is very sensitive to the aperture size (scales with the fourth power of the size), any change, including a dielectric loading by a particle, effectively makes the hole "appear" larger to light (the wavelength of light shrinks in inversely with an increase in the refractive index) inside the aperture. This gives a significant change to the optical transmission. Thus, the nanoaperture shows the characteristics of working beyond the perturbative regime by having a strong scaling with the local dielectric environment and therefore is used as a tweezer for small particles in the range of few nanometers.

Nanoaperture Tweezer: Principle, Force Calculation, and Detection

Nanostructures concentrate light into highly localized and intense fields known as hot spots. This is due to the coupling of the propagating field to the evanescent field which unlike the propagating field can be concentrated well below the diffraction limit. This results in strong gradient force which is a necessary but not sufficient condition for stable trapping of the particle. For particles sizes of less than 100 nm, the nanostructures fail to fulfill the potential energy requirement to compensate for high energy events and result in unstable trapping. Since the potential energy is a function of the electric field intensity at the trapping point, it can only be increased by increasing the incident laser power. Nanoapertures not only provide the strong gradient force necessary for optical trapping but also provide a solution to work beyond the perturbative regime where the particle itself plays a major role in trapping. The trapped particle provides a dynamic feedback by increasing the magnitude of the trapping potential in order to compensate the high energy events associated with the trapped particle, which results in stable trapping. This phenomenon is termed as self-induced back action (SIBA) [6]. It is based on the high sensitivity of the nanoaperture to the local environment as shown by Bethe's aperture theory



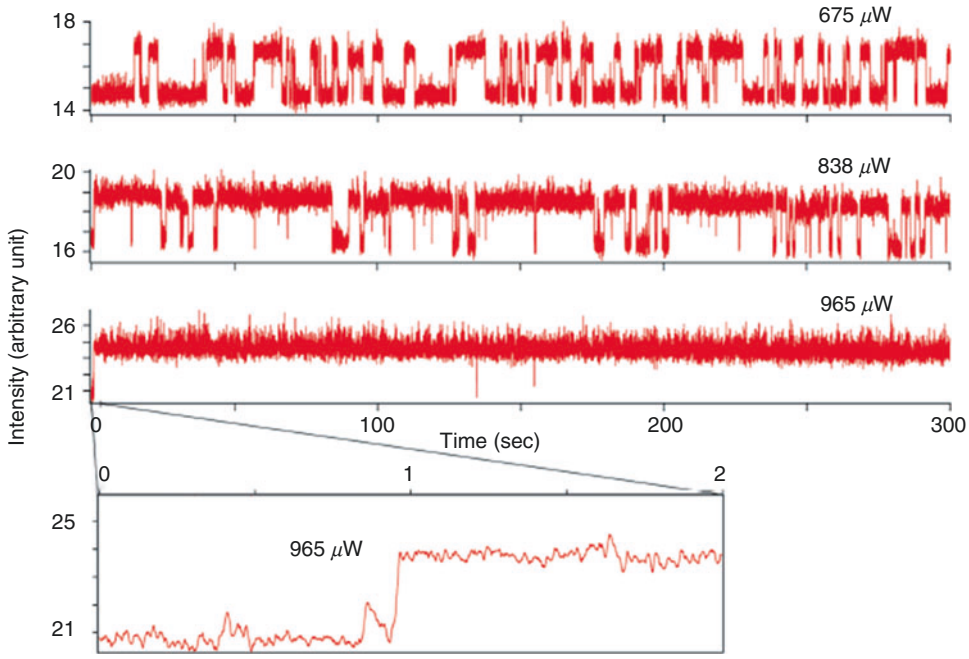
Laser Tweezers Using Nanoapertures in Metal Films, Fig. 2 The numerically computed optical force in the nanohole trap based on finite-difference time-domain (FDTD) simulations in trapping 100 nm polystyrene spheres. Two physical formulations are compared: the comprehensive MST analysis and the perturbative gradient force approximation. It is found that the perturbative gradient force approximation is no longer a good approximation in the nanohole optical trap, and the MST analysis predicts a much larger optical force than the gradient approximation does [6]

above. The presence of a small particle in the aperture significantly increases the electric field intensity which gives a decreased potential energy (increased magnitude) and thus provides a deeper potential well. The deep potential results in strong and efficient trapping of the nanoparticle using much less optical power. Thus, the nanoaperture tweezer provides an inherent feedback mechanism with simple geometry without requiring any outside feedback mechanism [6]. An early work noted increased optical forces inside an aperture in a metal film, but it was limited to particles much greater than 100 nm [7]. The SIBA is based on a more general phenomenon and has been applied with different nanoaperture designs [6, 8–11] and photonic crystals [12]. These geometries have made it possible to trap objects in the range of few nanometers using very small laser powers.

The force calculation for nanoaperture traps using perturbative optical force formulation does not provide a good approximation. This is because the dielectric particle produces a strong change to the ambient field. The rigorous Maxwell stress tensor (MST) analysis is used in this case. This has been done for a subwavelength circular aperture which shows much larger optical forces than calculated using the perturbative approach as shown in Fig. 2 [6].

Several nanoaperture designs have been used with the idea of trapping smaller and smaller particles. Some of the geometries such as circular aperture [6], bowtie aperture [11], rectangular aperture [10], coaxial aperture [9], and double nanohole aperture [8] are shown in Fig. 3. These nanoapertures have been able to show trapping of very small particles down to the size of 1 nm including the trapping of single proteins, DNA strands of a few base pairs (bp), quantum dots, and so on. Also, the planar and small size of nanoaperture make them suitable candidate for dense optical integration and use in a planar microfluidic environment. It also makes it possible to integrate it with other optical techniques like fluorescence microscopy and Raman spectroscopy.

The detection of the trapped particle in the nanoaperture tweezers is usually based on the change in the optical transmission signal through the nanoaperture. The normal optical transmission through a nanoaperture is mainly through diffraction and low, but when a particle of size smaller than the aperture and larger refractive index than the surrounding medium is trapped, the aperture becomes optically larger than the physical size due to dielectric loading. This leads to an increase in transmission indicative of the particle being trapped in the nanoaperture. An example of the



Laser Tweezers Using Nanoapertures in Metal Films, Fig. 3 Nanoaperture designs. (**a**) Circular aperture, (**b**) rectangular plasmonic nanocavity, (**c**) double nanohole aperture, (**d**) bowtie nanoaperture at the fiber tip, (**e**) coaxial nanoaperture [6, 8–11]

trapping based on the detection of change in transmission through a circular aperture is shown in Fig. 4. It is clearly shown that a 100 nm particle can be trapped stably using less than a milliwatt of laser power.

Advantages of Nanoaperture Tweezers

The nanoaperture tweezers provide some additional features compared to the regular laser tweezers, which makes it an important tool for detection, sensing, and studying of very small nanoparticles and biological molecules. The nanoaperture tweezers are able to efficiently trap very small nanoparticles and biological molecules without using tethers as compared to regular tweezer which mostly require tethers to trap and study small biological molecules. This allows the particle to have uninhibited natural motion in a given biological environment, that is, in free solution. The nanoaperture tweezer provides a high signal-to-noise ratio due to the background-free operation from the aperture, as well as a trivial detection approach. Also, the high sensitivity of the transmission signal to the physical attributes and motion of the trapped specimen makes it effective to detect trapping and interaction dynamics, without the need of fluorescent labeling. Thus, nanoaperture tweezers provide a label-free study of the dynamics of the trapped particle. It can be easily integrated into existing laser tweezer microscopy systems. The nanoaperture in metal film efficiently removes heat as the metal film acts as a heat sink which is crucial to prevent damage of biological particles due to heat. This has been shown by experiments which show very small rise in temperature for an aperture, several orders of magnitude smaller than metal nanoparticles [13]. Thus, nanoaperture tweezers provide a real-time, single-molecule, label-free, and free-solution application platform. In addition, it is simple, scalable, and low cost.

The sudden jumps in the signal indicate individual trapping events

Nanoaperture Performance Quantification

The performance of an optical tweezer is evaluated by its trap stiffness. The trap stiffness is a measure of the strength of the trap and shows the efficiency of the tweezer in trapping specific nanoparticles. Techniques like the power spectrum method, the equipartition method, optical potential analysis, the drag force method, and direct measurement of the optical force are used to determine the stiffness of the optical trap. These techniques require precise measurement of the position fluctuations of the particle in the optical trap for calculation of trap stiffness. Nanoaperture trap stiffness can be calculated experimentally using basically two approaches: autocorrelation of Brownian-induced intensity fluctuations and trapping transient analysis [14]. These techniques are analogous to the power spectrum method and the step response method, respectively, used for calculating the stiffness of a conventional laser tweezer. The major difference is that the nanoaperture traps measure directly the intensity fluctuations using a photodiode as compared to conventional tweezer, which measures the position of the particle in the trap using a quadrant photodiode (QPD) or a video microscope. The latter approach is not suitable for nanoapertures as it is challenging to determine the precise position of very small particles (1–100 nm) in the nanoaperture using the QPD or video microscope.

Autocorrelation of Brownian-Induced Intensity Fluctuation and Trapping Transient Analysis

The transmission through the nanoaperture is sensitive to the position of the particle in the aperture, and so Brownian motion-induced fluctuations of the transmission signal can be used to calculate the trap stiffness. Direct observation of the intensity fluctuations reveals little information, as changes at the millisecond time scale are buried in noise. The autocorrelation of the trapped

Laser Tweezers Using Nanoapertures in Metal Films, Fig. 5 Illustration of the trapping transient and the autocorrelation of Brownian-induced intensity fluctuations (*inset*) obtained from a typical trapping event of 20 nm polystyrene nanosphere using double nanohole nanoaperture tweezer (*blue*, untrapped state; *red*, trapped state). *Insets* show expanded region of trapping transient with an exponential fit to calculate the time constant ($\boldsymbol{\tau_t}$) and autocorrelation of the trapped and untrapped transmission signal [14]

transmission signal can be used to measure characteristic time constant (τ_a) which is directly related to trapping stiffness (κ).

Trapping transient technique is analogous to the step response method related to the drag force of the fluid as compared to the autocorrelation analysis based on thermal vibrations. The step response method measures the time constant of the particle to return to the trap center due to trapping forces as opposed to the viscous drag, while the present technique calculates the time constant (τ_t) of the transition from the untrapped to trapped state for calculation of stiffness.

Figure 5 shows an example of a trapping event of 20 nm polystyrene bead using nanoaperture. The insets show the trapping transient and autocorrelation of Brownian-induced intensity fluctuations used to find the respective time constant for calculation of trap stiffness.

Trap Stiffness Calculation

The time constant obtained from the trapping transient and the autocorrelation analysis, $\boldsymbol{\tau_t}$ & $\boldsymbol{\tau_a}$, are used to evaluate the stiffness of the nanoaperture trap. The motion of a particle in an optical trap under the influence of thermal fluctuation and drag force can be modeled by an overdamped Langevin equation as

$$\frac{dx(t)}{dt} = \frac{\kappa}{\gamma}x(t) + \left(\frac{2k_BT}{\gamma}\right)^{\frac{1}{2}}\zeta(t)$$

where $x(t)$ is the particle displacement from the equilibrium position, κ is the stiffness of the optical trap, γ is the Stokes drag coefficient, and $\zeta(t)$ is the white noise. Using this equation, τ_a and τ_t are related to the trap stiffness, as [15]

$$\tau_a = \tau_t = \frac{\gamma}{\kappa}$$

For the particles trapped at the nanoaperture site, additional drag force can arise due to the wall effects from the wall of the aperture. The boundary effect is included in the calculation by using a modified Stokes drag coefficient, estimated using Faxén's law as

$$\gamma = \frac{6\pi\eta r}{1 - \frac{9}{16}\left(\frac{r}{h}\right) + \frac{1}{8}\left(\frac{r}{h}\right)^2 + \frac{45}{256}\left(\frac{r}{h}\right)^4 + \frac{1}{16}\left(\frac{r}{h}\right)^5}$$

where η is the viscosity of the medium and h is the distance from the center of the nanosphere to the wall.

It should be noted that for an accurate measurement (10 % precision) of the time constant from autocorrelation, the measurement time should be more than $\sim$1000 τ. This is important for precise

calculation of the stiffness value obtained from autocorrelation due to Brownian fluctuations. Table 1 shows a comparison of the trap stiffness of different laser tweezers. The values have been scaled for 10 nm polystyrene particles. It is clear from this table that nanoapertures are 3–4 orders of magnitude more efficient than conventional tweezers. There are also other non-aperture-type nanostructures for enhanced trapping; however, those require high local field intensities.

Applications of Nanoaperture Tweezers

Nanoparticle Sensor

One of the proposed applications of nanoaperture tweezers is the sensing of nanoparticle size, concentration, and refractive index. The idea is derived from simple diffusion theory based on simple microfluidic conditions. The diffusion time (τ) of the nanoparticle in the trapping solution inside a microfluidic chip is directly proportional to the time to trap (τ_{trap}). Time to trap is the time taken by the nanoaperture tweezer to trap the nanoparticle after the laser beam is turned on, and a statistical analysis of time to trap can be used to quantify the concentration and size of the nanoparticles in the solution [16]. Furthermore, it is possible to determine the refractive index of the particle by examining the percentage change in the transmission intensity at the trapping instant which scales with the Clausius–Mossotti factor.

The diffusion coefficient D is defined as

$$D = \frac{l^2}{\tau}$$

where l is a characteristic diffusion length and τ is a characteristic diffusion time. Considering the simple case of spherical particles, the diffusion constant can also be expressed using the Stokes–Einstein equation as

$$D = \frac{k_B T}{6\pi\eta r}$$

Since the time to trap scales linearly with the diffusion time (i.e., faster diffusion makes trapping occur faster since the nanoparticle visits the trapping region more quickly), this gives

$$\tau_{trap} \propto r$$

Therefore, there is a linear dependence of time to trap with size of the nanoparticles. The above assumption is made for spherical nanoparticles, but the idea can be extended for particles of other defined shapes by making necessary change in the diffusion constant term in the above expressions wherever necessary.

The average diffusion length to the trap is related to the concentration, c, as

$$l \propto c^{\frac{-1}{3}}$$

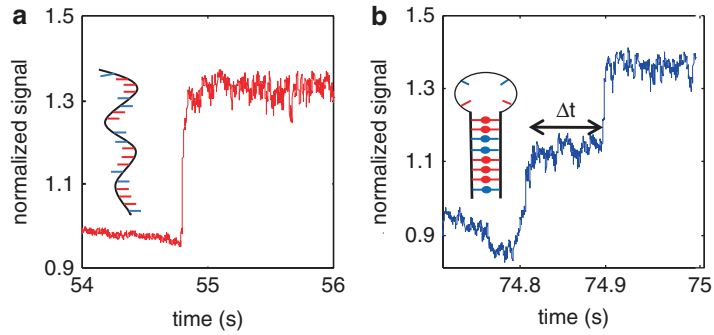
Using the definition of diffusion constant from above, we get

$$\tau_{trap} \propto c^{\frac{-2}{3}}$$

Thus, the time to trap of a particle in a nanoaperture tweezer under simple microfluidic consideration would show a -0.67 power-law dependence with the concentration of the nanoparticles.

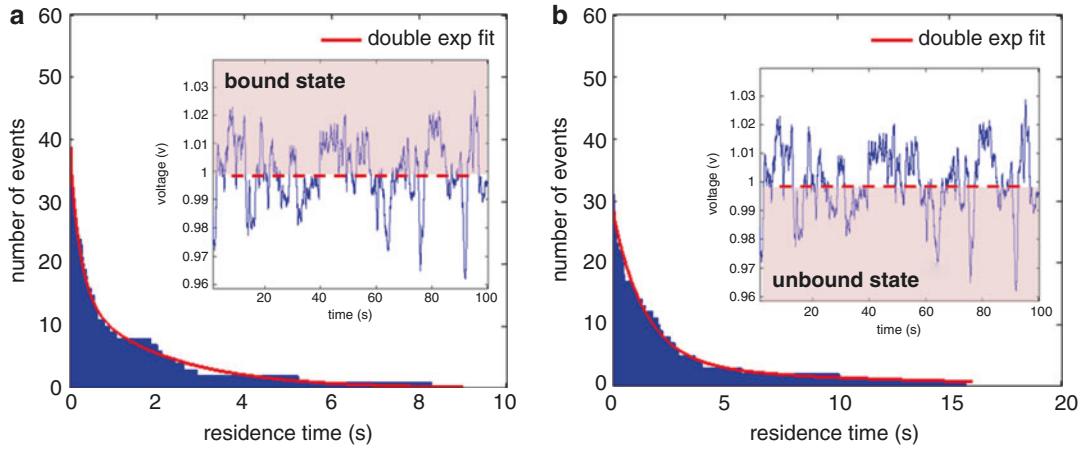
The refractive index of the particle trapped using nanoaperture tweezer can be determined by observing the percentage change in the transmission signal when the particle is trapped. One of the factors which determine the amount of change in transmission level as the particle goes from the untrapped to trap state is the refractive index contrast of the particle $(n_p - n_m)$. This is attributed to trapping efficiency for particles which is expected to scale, at least to first order, as the Clausius–-Mossotti factor K given by

$$K = \frac{\varepsilon_p - \varepsilon_m}{\varepsilon_p + 2\varepsilon_m}$$



where ε_p is the dielectric permittivity of the particle and ε_m is the dielectric permittivity of the surrounding medium.

Based on these results, with suitable calibrations it is possible to determine the refractive index of the particle by observing the percentage change in the transmission signal at the onset of trapping to a previously known sample. It is important to make sure that both the particles are of similar shape and size, and the trapping is done on the same nanoaperture for accurate measurements. This is done to minimize the possible errors in measurements, as these parameters also affect the change in transmission signal at the instant of trapping.



The nanoaperture tweezers as sensor are mainly limited by the acquisition time. This is because it requires a large sample space of the trapping events to accurately predict the time to trap value with maximum precision. This has been a major challenge for low-concentration sensors in general. This limitation can be overcome by imaging multiple traps in a narrower channel, thereby parallelizing the process. Some deviation from simple microfluidic theory may arise at higher concentrations or due to hydrodynamic effects. The potential applications are in size selectivity in heterogeneous samples and isolation/analysis (e.g., spectroscopy) of particles once trapped. This could be useful in the study of virus populations in biological samples, where the population levels vary over many orders of magnitude and there is great heterogeneity in the population.

Biomolecular Dynamics and Interactions

The nanoaperture tweezer is used as a label-free and free-solution single-molecule probe for biomolecular studies. The conventional optical tweezers mostly use tethering and fluorescent labeling of the biomolecules for their studies. Tethering is used to hold the biological specimen in the trap without using damaging laser powers. Fluorescent labels are used to monitor dynamic processes, such as protein binding and unzipping. These techniques suffer from some inherent limitations, such as modification of the natural state of protein–DNA, restriction of free motion, heating of the molecule, photobleaching, poor signal-to-noise ratio, large particles (e.g., DNA strands), as well as adding cost and complexity. The nanoaperture tweezer can trap very small biological particles like proteins, small DNA strands of few base pair or other ligands, without needing tethers and while using small power levels (in the mW range). Valuable information regarding the dynamics and interaction of the biological molecules can be extracted from the transmission signal obtained during the trapping of the given biological specimen. This is because of a high sensitivity of the detected signal to the change in size, shape, conformational structure, and motion of the particle in the trap. The parameters of interest are the changes in the magnitude and time scales of transmission intensity due to the molecular dynamics. A statistical analysis of these parameters provides information that is useful in understanding the dynamics at single-molecule

The *inset* shows the interaction of HSA with tolbutamide during trapping in the double nanohole aperture [20]

level and in real time. In this respect, the nanoaperture tweezers have shown the unfolding of proteins such as bovine serum albumin (BSA) and also unzipping of hairpin DNA [17, 18]. Figure 6 shows the unzipping of the hairpin DNA using a double nanohole aperture tweezer. There are two-step changes in the transmission signal, where the first step corresponds to the trapping and the second to the increase in the polarizability of the molecule due to elongation of DNA.

Another approach of simply comparing the time constants of the autocorrelation functions of the transmission signal can be used to distinguish between the bounded and unbound form of proteins [19]. Small-molecule binding to a protein alters its molecular dynamics. Aperture trap can study the real-time binding kinetics of protein – small molecule interactions and determine the disassociation constant. This can be done by using a statistical approach of measuring the resident time in the bound and unbound states as shown in Fig. 7 [20]. The nanoaperture tweezer system can detect the bound and unbound forms from the transmission signal as the protein in the bound state has a higher polarizability and hence higher transmission through the aperture, compared to the protein in the unbound state.

This makes the nanoaperture tweezer an exciting tool for studying dynamics of biomolecules in a label-free way and also shows interactions among them like protein–DNA interactions and protein–small molecule interactions.

(**a**) Schematic of experimental configuration with the laser directly coupled into the fiber. (**b**) Experimental time trace of the reflected signal showing trapping of a single 50 nm polystyrene sphere. [11]

The information obtained from these studies could aid researchers in the study of diseases and drug discovery applications.

Three-Dimensional Manipulation

The nanoaperture trap can be fabricated at the end of a scanning near-field optical microscopy (SNOM) tip or an optical fiber to trap and manipulate nanoparticles. For this, a metallic film is deposited at one end of the fiber, and the nanoaperture is fabricated on the film to form the optical trap. The trap laser is transmitted through the other end of the fiber, and the assembly is used to trap the particle of interest. Due to the unique configuration of the setup, the particle can be moved in three dimensions by moving the fiber with the aperture, after the particle is trapped. This is because the alignment of the laser is not disturbed during the movement of the fiber, which prevents the release of the particle from the trap. A bowtie aperture at the end of a tapered fiber has been used to trap and translate polystyrene spheres of size 50 nm in three dimensions as shown in Fig. 8. The ability to manipulate nanoparticles with high precision will open applications in the field of nanoscience, noninvasive manipulation of biological molecules, and material technology [11].

Key Research Findings

Nanoaperture tweezer can trap and manipulate Rayleigh particles of sizes 1–100 nm. The SIBA mechanism results in efficient trapping of the nanoparticles with small incident laser powers in the mW range. The detected trapping signal due to Brownian fluctuation of the particle in the trap and during the transition from untrapped to trapped state are used to quantify the efficiency of the aperture tweezers. The aperture traps provide high signal-to-noise ratio (SNR), greater sensitivity of the detected signal to trapped particle characteristics as compared to conventional tweezers, high temporal resolution, and natural heat sink, which make it suitable for different biological applications. Nanoaperture trap are used for sensing and studying molecular dynamics of proteins, DNA, and protein–small molecule interactions. The integration of nanoaperture tweezer with the existing fiber technologies, microfluidics, and other optical techniques can make nanoaperture tweezers a nano-optical tool for multiple applications in a single platform.

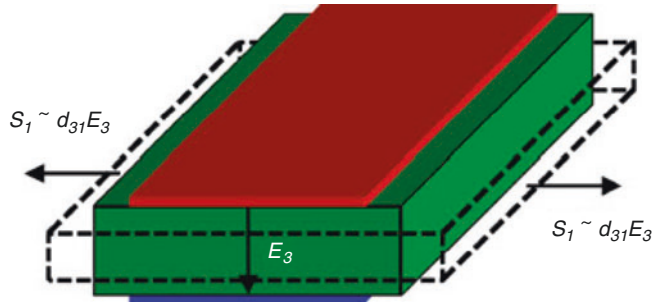
Definition



A laterally vibrating piezoelectric resonator is a particular class of microelectromechanical (MEM) devices, whose resonant motion is transduced via thin-film piezoelectrics and occurs primarily in the in-plane lateral directions of the structure (e.g., width extensional or length extensional motion). The resonant frequency is therefore set by the lateral dimensions of the device, which can operate in the few MHz to several GHz range on the same chip and is generally employed for the making of filters and oscillators.

Principle of Operation

Laterally vibrating piezoelectric resonators are formed either entirely by a thin-film piezoelectric film sandwiched between metallic electrodes [1] or by a composite constituted by the same piezoelectric film stacked on top of another structural layer such as a semiconducting or insulating material (Fig. 1). As shown in Fig. 2, the application of a potential across the piezoelectric film induces a lateral strain in the plane of the device. When the frequency of the excitation signal coincides with the mechanical resonance of the piezoelectric/

Laterally Vibrating Piezoelectric Resonators, Fig. 1 Mock-up view of laterally vibrating piezoelectric resonators formed either by (**a**, **b**) pure piezoelectrics ((**a**) representing a single finger and (**b**) the so-called multi-finger embodiment) or (**c**, **d**) composite stack ((**c**) representing a single finger and (**d**) the so-called multi-finger embodiment) of a piezoelectric and semiconducting or insulating material (structural layer)

Laterally Vibrating Piezoelectric Resonators, Fig. 2 Principle of transduction of a laterally vibrating piezoelectric resonator. The application of an electric field, E_3, across the film thickness induces lateral expansion and contraction of the piezoelectric layer. The induced strain (s_1) is approximately proportional to the electric field via an equivalent piezoelectric coefficient (d_{31})

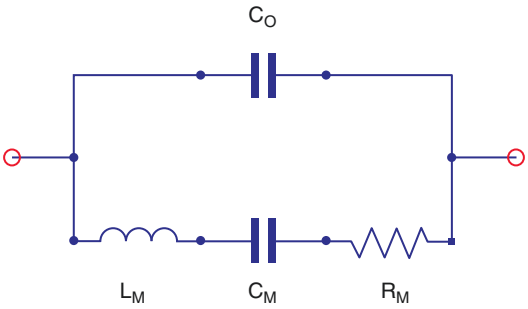
composite body, the device exhibits enhanced amplitude of vibration, which is translated to an electrical signal by the direct piezoelectric effect and generates a charge proportional to the amplitude of the displacement.

The main geometry of the laterally vibrating structure is designed such that one of the in-plane lateral dimensions, W, is used to set the resonant frequency of the structure:

$$f_o = v_{ac}/2W \tag{1}$$

where v_{ac} is the acoustic velocity of the piezoelectric/composite that forms the resonator, and depends on the square root of the ratio of the Young's modulus and mass density of the material. This is the main important feature of laterally vibrating resonators. In fact, the ability to set frequency via the in-plane lateral geometrical variables of the structure makes it possible to lithographically define multiple frequency devices on the same substrate and effectively produce components that are capable of operating over a broad spectrum and dynamically reconfigure radio receivers. Furthermore, as with transistors, lithography scaling is accompanied by an increase in the frequency of operation of the resonator.

The second in-plane lateral dimension, L, and the piezoelectric film thickness, T_p, are used to properly define the capacitance, C_o, of the piezoelectric transducer and therefore its electrical impedance.



$$C_o = \varepsilon \frac{WL}{T} \tag{2}$$

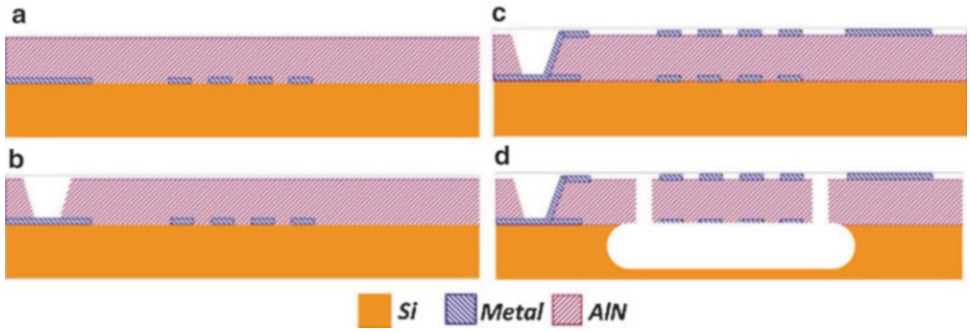
In the case of a composite structure, an additional design parameter is set by the thickness of the main structural layer, T_s. This layer has generally been introduced to enhance the quality factor, Q, (an inverse measurement of the mechanical damping in a resonator) of the pure piezoelectric device. In various demonstrations, materials with intrinsically high Q have been used, such as silicon [2–6], diamond [7], and silicon carbide [8]. Although beneficial, its insertion introduces a trade-off between Q and the electromechanical coupling coefficient, k_t^2, a parameter that describes how effectively the input electrical energy in the resonator is converted into mechanical (i.e., motion). In the case of pure piezoelectrics, the k_t^2 is set exclusively by the mode of vibration and the material properties. In the case of a composite, the intrinsic electromechanical coupling is approximately scaled by the ratio of the thickness of the piezoelectric layer to the total thickness of the composite ($T_s + T_p$). Therefore, the selection of the thickness of the main structural layer, T_s depends on the resonator application and should be tailored to either enhance the device Q or maintain a certain k_t^2. The most important figure of merit (FOM) of an electromechanical resonator is in fact defined as the product of k_t^2 and Q (FOM $= k_t^2 Q$). The FOM is the main factor in determining the performance of the system

in which it will be used, and affects parameters such as insertion loss and bandwidth in a filter, and power consumption and phase noise in an oscillator. Different from the pure piezoelectric device, the composite structure permits, within fabrication limits, the tuning of k_t^2 values and Q by varying the thickness of T_s.

Various thin-film piezoelectrics have been used for making these resonators, with zinc oxide (ZnO), lead zirconate titanate (PZT), and aluminum nitride (AlN), being the most commonly available. The selection of one over the others is dictated by material properties, process compatibility, reproducibility, and specific application of interest. For example, PZT offers a very large k_t^2, but exhibits very low Q and therefore is exclusively used in a composite configuration with other materials such as silicon. AlN is easily sputter-deposited and has very reproducible properties with high Q and intermediate values of k_t^2, therefore often making it a preferred material for the fabrication of laterally vibrating resonators formed by pure piezoelectrics.

The piezoelectric layer thickness can range between 100 and 3 μm. The structural layer forming the composite can be as thick as 50 μm for low frequency (10–200 MHz) devices made out of silicon, but it is generally thinner for higher frequency (0.5–3 GHz) devices and in the few μm range if made out of materials such as SiC or diamond. The in-plane dimensions of the device are generally in the 50–200 μm range for each side if arranged in a rectangular geometry. This area is kept rather constant for devices operating at different frequencies so that the device capacitance does not change significantly. At higher frequency (>200 MHz), this is attained by effectively arraying many of the basic aforementioned elements (which are called fingers in this configuration) and exciting adjacent elements 180° out of phase with respect to each other so as to induce an overtone vibration in the overall plate. In this case, the standing wave generated into the body of the resonator closely resembles a symmetric Lamb wave. From a practical standpoint, this is achieved by simply patterning small feature electrodes on top of the piezoelectric plate and applying opposite polarity voltage to the adjacent fingers (Fig. 1b or d).

Laterally Vibrating Piezoelectric Resonators, Fig. 3 Equivalent electrical circuit for an electromechanical resonator

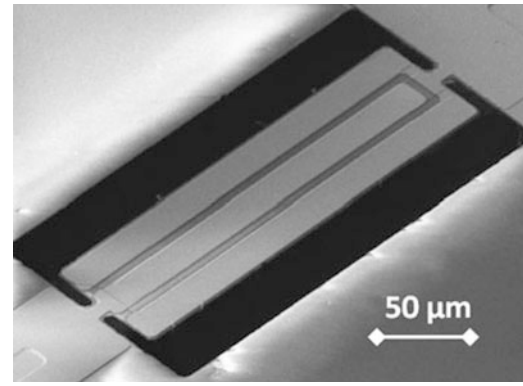


The previous sections intuitively describe the principle of operation of these resonators. More rigorously, an equivalent electrical model can be used to describe the device operation as a passive electronic component. The simplest equivalent circuit (Fig. 3) is formed by a capacitor representing the physical transducer in parallel with a series LCR, which models the mechanical portion of the resonator.

The circuit components are completely defined by the geometry of the resonator and its electromechanical coupling and are given by the following expressions:

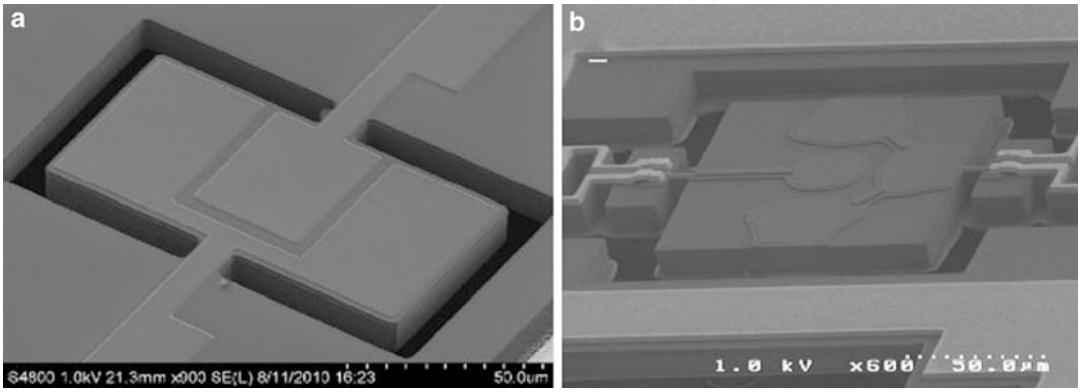
$$R_M = \frac{1}{\omega_o C_o \frac{\pi^2}{8} k_t^2 Q} \quad C_M = \frac{8}{\pi^2} k_t^2 C_o \quad L_M = \frac{1}{\omega_o^2 C_M} \tag{3}$$

Methods of Fabrication



Laterally vibrating piezoelectric resonators are generally fabricated by micromachining techniques. Although each process has its own specific implementation, there are common steps. In particular, standard integrated circuit (IC) processes are used for the deposition and patterning of the metals that sandwich the piezoelectric film. The deposition of the piezoelectric film is one of the most challenging steps and requires the most attention since the most characteristics of the

Laterally Vibrating Piezoelectric Resonators, Fig. 4 Schematic representation of the fabrication process used for the making of pure AlN resonators. (**a**) Bottom electrode is deposited and patterned; AlN is sputter-deposited and (**b**) access to the bottom electrode is defined; (**c**) top electrode is deposited and patterned; (**d**) the main resonator body is defined by a dry etching step and the structure is released from the substrate



resonators are affected by the property of this film. ZnO and AlN are preferentially sputter-deposited, whereas a sol–gel technique is used for the deposition of PZT films. The as-deposited film quality is generally assessed by monitoring its orientation via x-ray diffraction measurements (note that these films are poly-crystalline). A rocking curve measurement is generally performed with the same equipment to quantitatively assess the degree of orientation. A film is considered to be of good quality when the full width half maximum (FWHM) of the rocking curve measurement is less than 2°. Although higher values of the FWHM will likely not affect the piezoelectric properties of the film, they will further increase the Q of the device (intrinsic material damping).

Specialized recipes have been developed for the etching of the piezoelectric layers, but ultimately use gases and equipment that are readily available in any IC fabrication facility. It is worth noting that compatibility with standard IC processes is of paramount importance for enabling large-scale manufacturing of these devices, which will be produced in the billions if commercialized for filtering or frequency setting applications. In addition, a longer term vision is to integrate these mechanical devices with electronics (mainly complementary metal oxide semiconductors [CMOS]) so that they are readily available to circuit designers and can be broadly employed for design of low-loss components. In this case, AlN emerges as the most suitable candidate since it is very stable and is not considered to be a contaminant; it is already employed in some CMOS facilities. A simple schematic of the fabrication process for an AlN laterally vibrating resonator is shown in Fig. 4. Figure 5 is a scanning electron micrograph of the same type of AlN devices. This is an individual resonator formed by an AlN films sandwiched by three patterned metal electrodes, so as to excite an acoustic wave in the plane of the film and operate at a frequency around 200 MHz. In this case, the device release is straightforward and is generally performed by a dry fluorine etch chemistry that removes the underlying silicon.

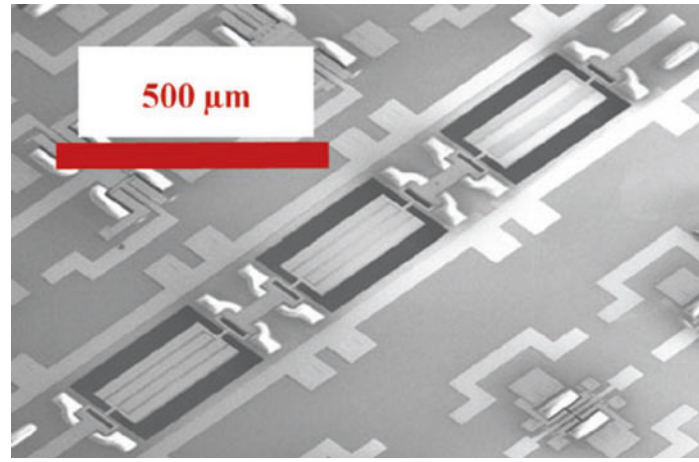
Bosch-type process, which etches through the entire substrate, has generally been used when Si is present. Examples of microfabricated structures are shown in Fig. 6. SiC and diamond are generally thinner and standard reactive ion etching has been employed for their patterning. In the case of a composite structure incorporating silicon, generally a silicon dioxide sacrificial layer is employed and a wet etch step is used to remove it to accomplish device release.

Main Research Accomplishment



The main accomplishments in terms of device performances such as k_t^2, Q and frequency of operation are reported herein for the pure piezoelectrics and the composite laterally vibrating resonators.

In terms of pure piezoelectrics, the reproducibility of AlN deposition and its compatibility with CMOS fabrication make it the piezoelectric of choice for laterally vibrating resonators. These devices have exhibited k_t^2 around 2 % and quality factors as high as 4,000 in ambient conditions [1, 9]. These k_t^2 and Q values are sufficient to satisfy stringent power and phase noise requirements for oscillators and have proven adequate to meet the specifications for narrowband filtering. More recently the frequency of operation of these resonators has been extended around 10 GHz [10, 11] and there is no fundamental limit to operating them at higher frequencies. This implies that this technology is effectively broadband and could be employed to synthesize filters and oscillators for a wide range of communication systems that operate over different frequency bands.

In terms of composite resonators, some of the best results have been attained by the integration of AlN on Si[2]. These devices exhibit k_t^2 that are generally <1 % and have attained Qs in excess of 15,000 at low frequency (<200 MHz) and above 5,000 at about 1 GHz. It is clear that a trade-off between k_t^2 and Q is intrinsic to the composite structure over the pure piezoelectric solution and its choice depends on the particular application.

Examples of Application

The main advantage of laterally vibrating resonators over other type of resonant devices consists in the ability to define multiple frequencies on the same substrate (for a fixed film thickness) and therefore address some of the emerging needs of reconfigurable and multi-band radio solutions, which need to operate efficiently over a broad range of the electromagnetic spectrum. Currently available solutions are either too bulky or lossy to meet the needs of a broadband and widely reconfigurable radio and will ultimately be replaced by small footprint and low power devices

Laterally Vibrating Piezoelectric Resonators, Fig. 7 Scanning electron microscope image of a filter formed by electrical coupling of AlN laterally vibrating resonators

such as the laterally vibrating MEMS resonators described here.

Resonators are primarily employed as individual components that form the frequency reference in electronic oscillators or arrayed and coupled for filtering applications.

To this extent, reconfigurable and multi-frequency oscillators based on AlN laterally vibrating resonators have been demonstrated [12–14], experimentally proving that these device have high performance and could effectively enable new applications. Currently, no such solution exists commercially because the large size of the available resonators and the use of exotic substrates that are non-integrable with electronics would render them prohibitively bulky.

Simultaneously, similar pure AlN resonators have been electrically coupled [15] (Fig. 7) to form low-loss band pass filters. These devices are very good candidates to replace surface acoustic wave (SAW) filters given their smaller size and integrability with CMOS. These micromachined filters occupy 20–30 X times smaller area and offer a reduction in insertion of losses of about 2–3 dB with respect to SAW devices.

Definition

Lattice Boltzmann method (LBM) applications – with emphasis on hydrodynamics at the small scales (nanofluidics) – are discussed.

Introduction

The quantitative study of the flowing state of matter relies upon two major levels of description: continuum and atomistic. In the continuum picture fluids are described in terms of fields, such as density, velocity, pressure, which vary smoothly in space and time. Such a description is fairly adequate for most applications, to the point that the physics of fluids is often implicitly identified with continuum fluid mechanics. Nevertheless, for over a century, it is known that fluids (gas and liquids) are ultimately composed by a collection of individual entities, atoms and molecules, whose discrete nature becomes apparent at scales around the nanometer and below. Much less known, at least to the general public, is the existence of a third, intermediate level of description, in which fluids are represented in terms of the probability density to find a molecule with a given velocity field as a function of space and time. Lattice Boltzmann methods (LBMs) are a minimal form of Boltzmann kinetic equation which is meant to simulate the dynamic behavior of fluid flows without directly solving the equations of continuum fluid mechanics. Instead, macroscopic fluid dynamics emerges from the underlying dynamics of a fictitious ensemble of particles, whose motion and interactions are confined to a regular spacetime lattice [1–3]. Historically, the main successful applications in the context of computational fluid dynamics pertain to the weakly compressible Navier–Stokes equations [1, 2]. The LBM does not solve directly the hydrodynamic conservation equations but rather models the streaming and collision (i.e., relaxation toward local equilibria) of particles, thus offering a series of advantages [1–3], among them the capability of handling boundary conditions associated with highly irregular geometries, its nearly ideal amenability to parallel computing, and the possibility to describe nonideal fluids with phase transitions/phase separation [3, 4]. This contribution is meant to be a short summary of LBM applications with emphasis on those issues which are relevant for the modeling of the hydrodynamics at the small scales, which includes a

huge variety of applications in micro- and nanofluidics. In such situations, complexity derives from complex fluid properties (e.g., nonideal fluids, thermal fluctuations) and boundary conditions (e.g., confinement, slip).

LBM Model

The goal of LBM is to have a kinetic approach to reproduce the continuity and the Navier–Stokes equations for both density and momentum transport (repeated indexes are meant summed upon) [5]

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial r_\beta}\left(\rho u_\beta\right) = 0 \tag{1}$$

$$\rho\left[\frac{\partial u_\alpha}{\partial t} + u_\beta \frac{\partial u_\alpha}{\partial r_\beta}\right] = -\frac{\partial p}{\partial r_\alpha} + \frac{\partial \sigma_{\alpha\beta}}{\partial r_\beta} + g_\alpha. \tag{2}$$

In the above equations, ρ is the fluid density and $p = c_s^2\rho$ the internal pressure of the fluid, while $c_s = \sqrt{K_B T/m}$ is the isothermal speed of sound (a constant in the model), with m and T being the mass and temperature respectively. The α-th component of the velocity $\boldsymbol{u}$ is denoted with u_α. The term g_α refers to the α-th component of the internal and external forces with density $\boldsymbol{g}$. The viscous stress tensor $\boldsymbol{\sigma}$ in Eqs. 1 and 2 is given by

$$\sigma_{\alpha\beta} = \eta_s\left(\frac{\partial u_\beta}{\partial r_\alpha} + \frac{\partial u_\alpha}{\partial r_\beta} - \frac{2}{3}\frac{\partial u_\gamma}{\partial r_\gamma}\delta_{\alpha\beta}\right) + \eta_b \frac{\partial u_\gamma}{\partial r_\gamma}\delta_{\alpha\beta}. \tag{3}$$

The continuum hydrodynamical equations emerge after a suitable multiscale Chapman-Enskog expansion of the Boltzmann kinetic equations is made [2]. The memory of the kinetic description remains in the definition of the transport coefficients η_s and η_b in terms of the relaxation to local equilibrium of the kinetic evolution (see below). The LBM equation evolves in time the discretized probability density function $f_i(\boldsymbol{r}, t)$ to find at position $\boldsymbol{r}$ and time t a fluid particle with velocity $\boldsymbol{c}_i$ according to the LBM updating scheme

$$f_i(\boldsymbol{r} + \boldsymbol{c}_i, t+1) = f_i(\boldsymbol{r}, t) + \Delta_i + \Delta_i^g \tag{4}$$

with the time step set to a unitary value. The collision operator Δ_i expresses the relaxation of the probability distribution function toward the local equilibrium $f_i^{(eq)}$

$$\Delta_i = \sum_j \mathcal{L}_{ij}\left(f_j - f_j^{(eq)}\right) \tag{5}$$

where the equilibrium distribution is a result of the projection of a local Maxwellian onto the lower-order (second) Hermite polynomials [6, 7]

$$f_i^{(eq)} = w_i \rho\left[1 + \frac{u_\alpha c_{i\alpha}}{c_s^2} + \frac{u_\alpha u_\beta\left(c_{i\alpha}c_{i\beta} - \delta_{\alpha\beta}\right)}{2c_s^4}\right] \tag{6}$$

and the weights w_i are a priori known through the choice of a suitable quadrature [8]. Moreover, in Eq. 14 the term Δ_i^g stems from the discretization of the external forcing contributions. Practical applications based on the LBM are largely dominated by the single-time relaxation (BGK form, for Bhatnagar-Gross-Krook [9]) identifying the collisional operator with a diagonal operator. This is mostly a matter of simplicity, for it is known that BGK suffers some obvious physical limitations (with just a single relaxation parameter, the transport of mass, momentum, and energy is forced to proceed at the same pace). To cope with these problems, a number of authors (see [6, 7] and references therein) have developed optimized versions of the original collision matrix in scattering form [10], now known as MRT (multiple relaxation time). The operator $\mathcal{L}_{ij}$ in Eq. 5 is constructed in such a way as to be diagonal in the so-called mode space: the basis vectors $\boldsymbol{e}_k$ of mode space are constructed by orthogonalizing polynomials of the dimensionless velocity vectors [6, 7]. The basis vectors are used to calculate a complete set of moments, the so-called modes $m_k = \sum_i e_{ki} f_i$. The lowest-order modes are associated with the hydrodynamic variables. In particular, the zeroth order momentum gives the density

$$\rho = m_0 = \sum_i f_i. \tag{7}$$

The next three momenta $\tilde{\boldsymbol{m}} = (m_1, m_2, m_3)$ are related to the velocity of the fluid

$$\boldsymbol{u} \equiv \frac{1}{\rho}\tilde{\boldsymbol{m}} + \frac{1}{2\rho}\boldsymbol{g} = \frac{1}{\rho}\sum_i f_i \boldsymbol{c}_i + \frac{1}{2\rho}\boldsymbol{g}. \quad (8)$$

The other modes are the bulk and the shear modes (associated with the viscous stress tensor) and groups of kinetic modes which do not emerge at the hydrodynamical level [6]. Since the operator $\mathcal{L}_{ij}$ is diagonal in mode space, the collisional term describes a linear relaxation of the nonequilibrium modes:

$$m_k \to (1 + \lambda_k) m_k + m_k^g \quad (9)$$

where the relaxation frequencies $-\lambda_k$ (i.e., the eigenvalues of $-\mathcal{L}_{ij}$) are related to the transport coefficients of the modes. After the Chapman-Enskog expansion [2], one gets the following expression for the hydrodynamical transport coefficients entering in the Navier–Stokes equations:

$$\eta_s = -\rho c_s^2 \left(\frac{1}{\lambda_s} + \frac{1}{2}\right) \quad \eta_b = -\frac{2}{3}\rho c_s^2 \left(\frac{1}{\lambda_b} + \frac{1}{2}\right). \quad (10)$$

The term m_k^g is related to the k-th moment of the forcing source Δ_i^g associated with the forcing term with density $\boldsymbol{g}$. While the forces have no effect on the mass density, they transfer an amount $\boldsymbol{g}$ of total momentum to the fluid in one time step. The forcing term is determined in such a way that the hydrodynamical Eqs. 1 and 2 are recovered and can be written as [11]

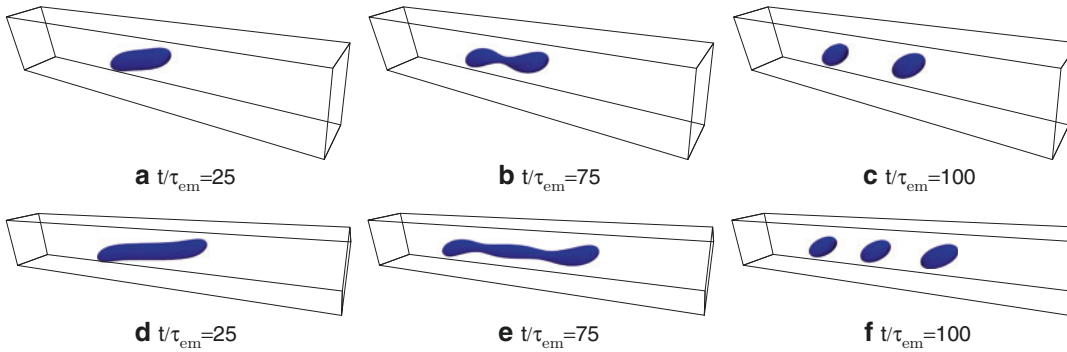
$$\Delta_i^g = \frac{w_i}{c_s^2}\left(\frac{2 + \lambda_M}{2}\right) g_\alpha c_{i\alpha} + \frac{w_i}{c_s^2}\left[\frac{1}{2c_s^2} G_{\alpha\beta}\left(c_{i\alpha}c_{i\beta} - c_s^2 \delta_{\alpha\beta}\right)\right], \quad (11)$$

where the components of the tensor $\boldsymbol{G}$ are defined as

$$G_{\alpha\beta} = \frac{2 + \lambda_s}{2}\left(u_\alpha g_\beta + g_\alpha u_\beta - \frac{2}{3} u_\gamma g_\gamma \delta_{\alpha\beta}\right) + \frac{2 + \lambda_b}{3} u_\gamma g_\gamma \delta_{\alpha\beta}. \quad (12)$$

Summarizing, the basic LBM is based on a very transparent stream-collide microscopic mechanism, from which the familiar advection–diffusion structure of hydrodynamic equations spontaneously emerges in the limit of small Knudsen number [2], i.e., the ratio of the molecular mean free path to the typical macroscopic length. The stream-collide paradigm offers several advantages over the advection–diffusion representation, primarily the fact that information always travels along straight constant lines, rather than spacetime varying material lines, regardless of the spacetime complexity of the fluid configuration. This is key to mathematical transparency of LBM and their ensuing computational efficiency, especially on parallel computers.

Nonideal LBM Models



Multiphase fluids, such as droplets and bubbles, are commonly found in recent microfluidic applications, such as biotech lab-on-a-chips. One of the most brilliant outgrowths of the basic LBM theory is the extension to the case of interacting (nonideal) fluids. Recent work is also hinting at the possibility that multiphase LBM may provide a methodological framework for the description of nonideal fluid-fluid and fluid–solid interactions, which play a crucial role for microfluidic and nanofluidic applications [12]. For example, the possibility to model slip boundary conditions and wetting properties [13, 14] has been recently achieved within the framework of the LBM. More detailed comparisons between the mesoscopic technique and atomistic molecular dynamics simulations [15, 16] have pointed out that lattice Boltzmann may become a method of choice for physical problems where supramolecular details play a major role. By supramolecular, we refer to situations which escape a purely continuum treatment and yet still exhibit sufficient universality to do away with a fully atomistic description. Arguably, a wide range of multiphase flows out of equilibrium falls within this class. LBM turned out to be a very effective method to describe mesoscopic physical interactions and nonideal interfaces coupled to hydrodynamics.

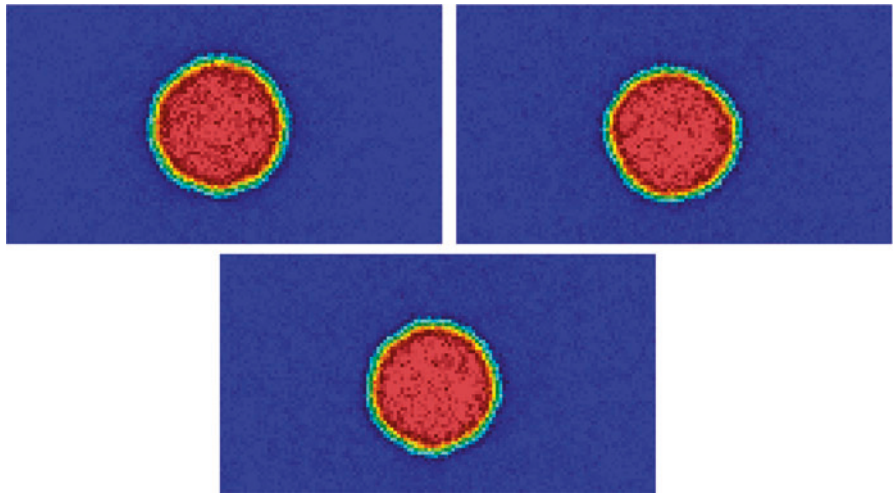
Many multiphase and multicomponent LB models have been developed, on the basis of different points of view, including the Gunstensen model [17], the free-energy model [18], and the "Shan-Chen" (SC) model [4], the latter being widely used thanks to its simplicity and efficiency in representing interactions between different species and different phases [19–22]. Here we shall give a few details of the latter method which relies on the modeling of nonideal interactions directly on the lattice. The SC approach augments the LBM equation with the following force term:

$$\boldsymbol{g} - \mathcal{G}\psi(\boldsymbol{x}) \sum_{i \in NS} w_i \psi(\boldsymbol{x} + \boldsymbol{c}_i)\boldsymbol{c}_i \qquad (13)$$

where $\mathcal{G}$ is a constant of proportionality dictating the overall strength of these nonideal interactions and ψ is a density-dependent pseudopotential, incorporating the effects of potential energy interactions through a simple nearest-shell (NS) coupling. One important feature of the multiphase LBM is that phase separation is achieved automatically from the interactions, if only the interaction strength $\mathcal{G}$ exceeds a critical value. This identifies the strength $\mathcal{G}$ as an inverse temperature or more precisely as the ratio between potential and thermal energy, $k_B T$.

An interesting application to micro- and nanofluidics is the study of droplet deformation and breakup [23, 24]. These problems are relevant in the characterization of emulsions, which play an important role in a huge variety of applications, including foods, cosmetics, chemicals, and material processing [25]. Deformation, breakup, and coalescence of droplets occur during flow, and the control over these processes is imperative to synthesize the desired macroscopic behavior of the emulsion. The problem is challenging also from the theoretical point of view: it is intrinsically multiscale, as it bridges between the "microscopic" dynamics of single constituents (i.e., droplets) and the macroscopic behavior of the emulsion. Most times, the synthesis of the emulsion takes place under confinement: this is the case of microfluidic technologies, which are gaining increasing importance as a promising technological route for the emulsion fabrication [12]. The "single" droplet problem has been considered to be the simplest model: in the case of dilute emulsions with negligible droplet-droplet interactions, the dynamics of a single droplet provides indeed complete information about the emulsion behavior. An example of droplet deformation in a confined microfluidics environment is provided in Fig. 1. Other applications of LBM in the context of multiphase fluids in

Lattice Boltzmann Methods for Nanofluidics, Fig. 1 Droplet deformation in a confined microfluidic channel obtained with the LBM. The droplet is placed in a confined microfluidic environment and is sheared by the application of opposite velocities at the confining walls. Breakup takes place after the startup of the shear flow. We report the time history of droplet deformation and breakup including three representative time frames: initial deformation (*left column*); deformation prior to breakup (*middle column*); post breakup frame (*right column*). The simulation time is made dimensionless with respect to the droplet emulsion time τ_{em}, representing the characteristic time for viscosity to damp the capillary waves at the interface. The *top panel* reports an unbounded case, where the droplet breaks into two equally sized daughter droplets. The effect of confinement is visible in a different breakup mechanism (*bottom panel*), leading to a triple breakup



microfluidics pertain to the modeling of droplets in more complex geometries (T-shaped channels, flow-focusing devices) [26] and fluids with complex rheological properties [19].

Thermal Fluctuations

Thermal fluctuations are crucial for a proper mesoscale description of a broad variety of flows in soft matter and biological physics [27]. Theoretically, thermally fluctuating mesoscopic flows are most conveniently dealt within the framework of fluctuating hydrodynamics [28]. This approach, pioneered by Landau and Lifshitz for simple fluids, promotes the nonequilibrium fluxes to stochastic variables, thereby enabling their statistical mechanical description. The idea of including noise in LBM is also an active research field, as witnessed by the various publications of the recent years [6, 29–31]. The basic idea has been pioneered by Ladd [30], who suggested the introduction of noise on the nonconserved hydrodynamic modes, thus reproducing fluctuating viscous stresses in the corresponding hydrodynamic limit (small wavevectors). However, besides the hydrodynamic modes, there exist also higher-order degrees of freedom, the so-called ghosts [31]. The ghost sector, which is coupled to the transport sector at small length scales, acts as a sink for the thermal stress fluctuations and thereby compromises the balance between fluctuation and dissipation. Consequently, the thermalization of the fluid remains incomplete. Adhikari et al. [31] were the first to recognize the necessity to include noise on all the nonphysical ghost modes, and Dünweg et al. [6] reformulated this approach to follow a detailed-balance condition. All these implementations, however, consider ideal-gas descriptions. Only recently there was significant progress in extending fluctuating LBM to nonideal equations of state for single component fluids [29]. In the works by Gross et al. [29], a theoretical framework for the fluctuating LBM is provided based on the theory of linear regression of fluctuations due to Onsager and Machlup [32]. The fluctuating LBM augments the LBM equation with a stochastic term

$$f_i(\boldsymbol{r}+\boldsymbol{c},t+1)=f_i(\boldsymbol{r},t)+\Delta_i+\Delta_i^g+\hat{\Delta}_i. \quad (14)$$

The fluctuating terms $\hat{\Delta}_i$ are assumed to be zero-mean Gaussian random variables, uncorrelated in time and with constant variances (which may however be space dependent). The derivation of the precise expression of the noise covariance has been a central aspect of many recent works [6, 29]. In Fig. 2 we report results of fluctuating LBM simulations for a droplet in a nanofluidic channel moving under the effect of thermal fluctuations only. Thermal fluctuations in LBM represent an open research topic, with many important applications in confined microfluidic and nanofluidic channels, where the usual continuum description of hydrodynamics is coupled with small-scale noise mimicking molecular agitation. Many open ends still remain as to the implementation of fluctuating LBM, especially in the regime of strong fluctuations, where LBM could serve as an effective time-averaged molecular dynamics, with no coarse-graining in space. Such an extension is fascinating and highly nontrivial, as it involves a tangle of fundamental nanoscale physics, in fact the thermodynamics of small systems, and highly technical implementation details. Among the fundamental issues, an outstanding one is whether the fluctuation-dissipation theorem (FDT) still holds under strong confinement and, if not, how should the fluctuating LBM be modified in order to accomodate departures from FDT. Another important issue regards the extension of LBM to the regime of strong thermal fluctuations, $\theta \equiv k_B T/mc_s^2 = O(1)$. Current fluctuating LBM operate around $\theta \sim 10^{-4}$, which leaves outside many emergent nanoscale applications (Casimir effects). On a similar vein, it is still unclear how far one can take LBM down the spatial ladder before touching the barrier of molecular individualism. Such question is paramount to extend LBM to applications where subnanometric resolution is a must, such as the study of hydrogen-bond networking in water-like fluids [33]. These are only some of the basic questions that must be faced in order to further LBM research into the fascinating territory of nanoscale fluid dynamics.

Lattice Boltzmann Methods for Nanofluidics, Fig. 2 Droplet migration due to thermal fluctuations in a confined nanofluidic channel. The results are obtained with the fluctuating LBM proposed by Gross et al., which augments the traditional LBM description with stochastic terms mimicking molecular agitation [29]

Conclusions

The LBM was born as a computational alternative to the discretization of the partial differential equations of continuum mechanics (Navier–Stokes equations), hence in connection with the numerical simulation of macroscopic fluids. In the recent years, however, LBM has made proof of a remarkable versatility in describing a wide host of micro- and nanofluidic situations for which the continuum picture may become inaccurate or even physically untenable and yet sufficiently universal to dispense with atomistic details. The LBM portfolio of applications keeps expanding across scales of motion, particularly toward micro- and nanofluidics [3, 5, 19] with active thermal fluctuations [6, 29]. Realizing the full potential of the method in the latter case, however, still raises many challenges ahead.

Definition

The nanoshuttle is a relatively novel nanosystem formed by the self-assembly of colloidal gold nanoparticles with M13 bacteriophage, which occurs due to electrostatic interactions. The nanoshuttle is a fractal network of phage and gold nanoparticles that maintains the phage's ability to selectively target cells and become internalized via specific cellular receptors. The nanoshuttle also has the unique ability to efficiently incorporate other molecules and nanoparticles of interest and "shuttle" them to a specific tissue in a ligand-directed manner, which has diverse applications for both medical diagnostics and therapeutic strategies.

Procedures

Nanoparticle Synthesis via Citrate Reduction

The standard nanoshuttle is created by mixing phage and gold nanoparticles and allowing time for the assembly to take place. Colloidal gold nanoparticles are synthesized via a citrate reduction method [1]. First, 1 % (w/v) solutions of auric chloride ($Au(III)Cl_3$) and sodium citrate in ultrapure deionized water are prepared. The solutions are then sterile filtered and stored at 4 °C. Clean glassware is filled with ultrapure deionized water, and a magnetic stir bar is added. Typical starting volumes of water are 100–500 mL. Preferably, the citrate reduction takes place while boiling under reflux, but alternatively, the flask can be capped with aluminum foil to reduce evaporative losses. Once the water is brought to a boil under a fume hood while stirring, the aluminum foil is carefully peeled back and 1 % of the water volume of the 1 % $Au(III)Cl_3$ solution is added and stirred for 10 s before quickly adding 0.8 % of the water volume of the 1 % sodium citrate solution. For example, if making a batch of gold nanoparticles with a starting volume of 100 mL of water, 1 mL of the 1 % $Au(III)Cl_3$ solution and 800 μL of the 1 % sodium citrate solution would be added. The aluminum cap is then placed back on the flask, and nanoparticle formation can be observed. Within 2 min, the solution changes from clear to cloudy, to dark gray, to black/dark purple and finally settles at red. The solution is allowed to boil for an additional 3 min after the color has settled before the aluminum foil cap is removed, and the solution is allowed to boil off approximately 80 % of its volume in order to concentrate the gold nanoparticle solution. Alternatively, the gold nanoparticle solution can be concentrated via centrifugation (7000 rcf for 10 min); however, this process is more time, work, and materially intensive, especially for larger batches.

The gold nanoparticle solution can then be evaluated by measuring the visible and ultraviolet

(UV–vis) absorbance spectrum from 350 to 900 nm. Two dilutions of the nanoparticle solution, 1:5 and 1:10, are tested. A narrow absorbance peak centered at 530 nm, which corresponds to a nanoparticle size of 44 ± 8 nm, should be observed. If the peak absorbance is not at 530 nm, the size of the nanoparticles can be determined following [2]. To resynthesize nanoparticles using the same materials, the size of the resulting nanoparticles can be adjusted by using different ratios of the 1 % $Au(III)Cl_3$ and the sodium citrate solutions to obtain the desired size. A solution with a lower ratio of $Au(III)Cl_3$ to sodium citrate will yield smaller nanoparticles whereas a higher ratio will yield larger nanoparticles. The optical density of the 530-nm peak for the undiluted nanoparticle solution should be between 4 and 5. The nanoparticle solution can then be sterile filtered, wrapped in aluminum foil, and stored at 4 °C for later use.

Phage Production and Quantification

Bacteriophage particles are produced and quantified following protocols described in [3].

Bottom-Up Assembly of Nanoshuttles

Once the gold nanoparticles have been prepared, the baseline nanoshuttles are synthesized by selectively adding phage, gold nanoparticles (AuNP), and either an imidazole hydrochloride solution or deionized water. There are two currently used formulations of the nanoshuttle: AuNP/phage and AuNP/phage/imidazole. The difference between the two is the presence of imidazole, a metal chelating agent that induces gold nanoparticle clustering. To produce nanoshuttles that incorporate imidazole, 100 μL of a 1 M solution of imidazole hydrochloride is added to rows B through H and 180 μL are added to row A of a standard 96-well plate. Twenty microliters of phage with a titer of approximately 1010 TU/μL is then added to each well in row A. Using a pipette, 100 μL of the phage-imidazole solution in row A is added to row B and pipetted up and down to ensure the solution is well mixed, and then 100 μL of the phage-imidazole solution from row B is added to row C. This 2× dilution process is repeated until row G. Every well in rows A–G should now have 100 μL of a phage-imidazole solution, and each row should correspond to a 2× dilution compared to its preceding row. Row H serves as a control and should contain 100 μL of 1 M imidazole only. To synthesize nanoshuttles without the presence of imidazole, deionized water is substituted for the 1 M imidazole solution. Lastly, a volume of 100 μL of gold nanoparticles is added to every well. The plate is then covered, and nanoshuttles are allowed to form overnight at room temperature. Visible nanoshuttle formation should occur within minutes of adding the gold nanoparticles. A color change from red to purple is observed in all columns after two dilutions (row C). The next day, the UV–vis absorbance spectrum of each well containing AuNP/phage is measured from 350 to 900 nm. The final nanoshuttle solution is made by mixing the rows where nanoshuttle formation has taken place. When there is an insufficient concentration of phage to keep the clustered gold nanoparticles in solution, the gold will precipitate and coat the bottom of the well. This can be observed by eye as well as on the UV–vis spectrum by comparing the near-infrared (NIR) spectrum of the control imidazole-gold row (H) to the phage-gold-imidazole rows (A–G). The gold-imidazole spectrum will have a linearly increasing absorbance throughout the NIR region whereas the phage-gold-imidazole will not. The NIR absorbance of the nanoshuttles will increase as the relative gold-imidazole to phage ratio increases. If necessary, one can determine whether the phage-gold-imidazole solution has precipitated manually by pipetting up the solution to see if it aspirates easily. If it does not, then the gold-imidazole has likely fallen out of solution. Following this procedure, rows A–F are typically combined in sterile glassware or polypropylene FACS tubes to form the nanoshuttle solution. The resulting nanoshuttle solution is then concentrated via centrifugation at 44 rcf for 2 min. The supernatant is then pipetted out and can be saved for further analysis such as phage or gold concentration, or discarded. The final solution of phage-gold-imidazole is the nanoshuttle.

Incorporation of Additional Materials into the Nanoshuttle

The baseline nanoshuttle serves as a scaffold or backbone enabling the incorporation of other materials, such as diagnostic or therapeutic compounds. So far, silicon and various magnetite nanoparticles have been successfully incorporated into the scaffold [4, 5]. To incorporate other components into the nanoshuttle, the synthesis protocol is slightly changed. The compound that needs to be incorporated is first mixed in with the gold nanoparticle solution before adding it to the phage-imidazole solutions.

Results

Biological Characterization of the Nanoshuttle

The initial characterization studies of the nanoshuttle focused on determining its physical and chemical properties. The base nanoshuttle was first synthesized by determining the phage input concentration needed to transform colloidal gold solutions into hydrogels. Filamentous phage were chosen as the backbone of the nanoshuttle because of their many unique and desirable properties including the ease of production in host bacteria compared to the complex chemistry and by-products involved in polymer synthesis. Other advantages of the phage backbone include the fact that the phage pIII minor capsid protein can be engineered to display targeting peptides, as well as the phage's innate resilience to severe conditions such as high salinity, acidic pH, high temperatures, chaotropes, and prolonged storage [1]. Altering the content of the phage-gold nanoparticle solution by adjusting the phage or gold concentration or by adding imidazole allows for precise tuning of the system for different purposes. Once the prototype nanoshuttle was formed, it was found that the phage backbone of the system still maintained its ability to infect bacteria and target mammalian cells. The nanoshuttle was first tested for biocompatibility and cytotoxicity in C17.2 murine neural stem cells. It was found that the cells incorporated into the nanoshuttle solution and continued to proliferate, indicating that the system was suitable for further biomedical study [1]. Since the initial studies, the nanoshuttle has been tested on multiple cell lines with the same biocompatibility and lack of cytotoxicity previously observed. The nanoshuttle has also been used in murine models of cancer with comprehensive toxicity studies under way.

Fractal Analysis of the Nanoshuttle

The nanoshuttle system was physically characterized using fractal dimension analysis because many self-assembly processes contain fractal geometry. Images of the nanoshuttle were acquired using transmission electron microscopy (TEM) [1]. Using the TEM images, a two-dimensional fractal analysis showed that the nanoshuttle with imidazole had a higher fractal dimension than without imidazole: 1.78 ± 0.14 versus 1.32 ± 0.12 [1, 6]. This observation corresponded to an increase in the density of gold nanoparticle packing by imidazole-induced aggregation. These results were consistent with measurements made using angle-dependent elastic light-scattering fractal dimension analysis of the nanoshuttle in solution. The nanoshuttle's fractal geometry likely improves its binding ability by making the phage pIII minor capsid protein more available to cellular receptors due to the high surface area of fractals.

Mechanism of Assembly

The binding mechanism between the phage and the gold nanoparticles was also investigated. It was hypothesized that the phage pVIII major capsid coat proteins served as the binding site for the gold nanoparticles. Given the fact that there are no typical metal-binding amino acids such as histidine on the pVIII major capsid, it was suggested that the binding must be the result of electrostatic interactions between the two components [1]. It is well known that varying the ionic conditions of the nanoparticle solution can induce gold nanoparticle aggregation. Using a competitive binding assay between an ionic solution and phage, it was found that the presence of phage reduced the amount of gold nanoparticle aggregation as the phage's input titer was increased [1]. This result implied that phage and gold nanoparticle binding

was similar to gold nanoparticle and gold nanoparticle binding. Testing the formation of the nanoshuttle in solutions of varying pH further validated this hypothesis. When the pH of the solution was greater than 7, nanoshuttle formation did not occur indicating that the mechanism for nanoshuttle formation is the electrostatic interaction between the gold nanoparticle and phage. Nanoshuttle assembly with a mutant phage was tested to further validate an electrostatic mechanism of assembly. This phage had its pVIII major capsid mutated to contain more cationic amino acid residues compared to the wild-type phage. By altering the pH of the nanoshuttle assembly solution, it was found to still be possible to induce the mutant phage to form nanoshuttles under conditions where the wild-type phage could not [7]. These results illustrate the fine control that one has over nanoshuttle formation, even with variations in its base components.

Optical Characterization of the Nanoshuttle

The optical properties of the nanoshuttle were studied by looking at the UV–vis absorbance spectrum of the system. It had been noted that the assembled nanoshuttle network contained a shift in the surface plasmon absorbance to the near-infrared (NIR) regime, indicating that the average distance between the nanoparticles is less than their diameter [8]. As expected, the more densely packed imidazole-containing nanoshuttles exhibited a larger red shift in their absorbance spectrum than the nanoshuttles without imidazole. To ensure that the NIR photons were actually being absorbed and not just scattered, heating measurements were made on the nanoshuttle solutions under NIR laser illumination. The temperature of the nanoshuttle solution dramatically increased, indicating that the NIR photons are indeed being locally absorbed via the surface plasmon absorption shift into the NIR [1]. It had previously been reported that imidazole-gold chelates have up to a 10^8 increase in NIR surface-enhanced Raman scattering (SERS) signal than imidazole alone [8]. NIR-SERS spectrum measurements of the nanoshuttle were taken to determine whether the gold-imidazole clusters still maintained this reporter property, as well as to characterize the relationship between the phage, imidazole, and gold nanoparticles. By comparing the spectra of the nanoshuttle's constituent components alone to the fully assembled nanoshuttle, it was possible to identify specific NIR-SERS bands intrinsic to the nanoshuttle.

Applications

The list of potential applications of the nanoshuttle continually grows, and the focus has become directed to possible uses within the biomedical sciences. The initial characterization studies found that the nanoshuttle can be used to enhance fluorescence and dark-field microscopy, serve as a NIR-SERS reporter, and convert near-infrared laser light into heat. The gold in the nanoshuttle increases light scattering due to its large elastic scattering cross section, leading to its use as a dark-field microscopy image contrast agent. Treating cells with the targeted nanoshuttle greatly increases dark-field image signal intensity compared with nontargeted nanoshuttle or plain nanoparticles. The discovery that the nanoshuttle had a unique NIR-SERS signal as well as heating properties led to research on noninvasively detecting and ablating tissue, using NIR-SERS and NIR laser light, respectively. These studies are ongoing.

After the initial characterization studies, several new lines of research began simultaneously, and many are still under active investigation. It was found that the gold nanoshuttles could be utilized as a scaffold for three-dimensional tissue culture [5]. Three-dimensional tissue culture better re-creates in vivo conditions in vitro than traditional two-dimensional tissue culture leading to an improved model with a higher degree of translational viability. Three-dimensional tissue culture was achieved by incorporating magnetic iron oxide (MIO) nanoparticles into the nanoshuttle and plating it on top of human glioblastoma cells. After plating, it was possible to levitate the cells using a variety of different magnets and grow them three-dimensionally. The human glioblastoma cells grown using this

method showed higher morphological and molecular similarities to orthotopic human tumor xenografts than did the cells cultured using the traditional two-dimensional method. By varying the geometry of the magnetic field, the shape of the cellular mass could be controlled and was successfully manipulated into two geometries: a traditional spheroid and a torus. Using the nanoshuttle-enabled three-dimensional tissue culture approach also enabled different types of cells to be cocultured in order to simulate the heterogeneity of in vivo tumor masses. These findings led to the start-up company, n3d Biosciences, Inc., which sells this system, known as the Bio-Assembler™, for commercial and academic use.

Future Directions for Research

The nanoshuttle is still a subject of ongoing research on both its basic properties and its applications. Current research into the nanoshuttle's basic properties involves characterizing its loading capabilities of gold and other metallic nanoparticles as well as other nanosystems. The nanoshuttle's in vivo binding properties such as specificity, toxicity, and biodistribution are also under active investigation. Research into the applications of the nanoshuttle is focused on utilizing the system as a multimodal theranostic device for the diagnosis, imaging, and treatment of a wide array of cancers. Depending on the composition of the nanoshuttle, it can act as a contrast agent for various imaging modalities such as NIR-SERS, computed tomography, and magnetic resonance imaging. Loading the nanoshuttle with different substances can also enable it to act as a therapeutic agent for cancer treatments such as targeted chemotherapy, laser ablation, and radiation therapy. Determining how the nanoshuttle can aid or enhance these imaging and treatment modalities is still under investigation. Another line of research currently being pursued is using the nanoshuttle to target other nanomedicine modalities to specific sites in the body. For example, coating other therapeutic agents such as porous silicon nanoparticles with the nanoshuttle provides a vascular targeting capacity, thereby increasing their specificity [4]. Despite the fact that the nanoshuttle is a relatively young nanosystem in the growing field of nanotechnology, it has already proven that it has many significant translational applications warranting further active research.

Light Emitting Diodes

Talal Al Tahtamouni
Department of Physics, Yarmouk University, Irbid, Jordan

Light-Emitting Diode (LED)

LED is an optoelectronic device; it consists mainly of a p-n junction. LEDs are particularly designed so that the radiative recombination dominates to produce a photon. This radiative

recombination process of electrically injected electrons and holes from n-type and p-type regions occurs efficiently in the active region of LEDs. The wavelength of the emitted photon depends on the bandgap energy of the semiconductor material in the active region.

The Working Principle of LED

The typical structure of LED is a p-n junction diode, mainly consisting of one layer uniformly p-doped in one side and one n-doped on the other side. Once the p-n junction has been created, a space charge layer and a built-in voltage (energy barrier) will automatically be formed due to the carrier balance process. By applying an external forward voltage to the diode, the electrons and holes in the conduction band and valance band respectively see a lower energy barrier and start the minority injection process. The electrons will be injected to the n-type layer and the holes to the p-type layer. When they reach the active region, the electrons in the conduction band recombine with holes from the valence band creating a photon. The wavelength of the emitted photons is associated to the bandgap energy of the active region.

Active Region

The active region is the core of the LED structure, and this region in the LED determines the way that the photons created by electron–hole radiative recombination are emitted. Quantum well structure is typically employed as active region in LED structure.

Quantum Well

A quantum well (QW) is a thin layer sandwiched between two larger–energy gap materials. The width of the QW corresponds to the thickness of the sandwiched layer, so the well width is controlled by changing the thickness of this layer. The QW structures are used as active regions in the LED structure because they have a small volume, therefore when carriers are injected into a QW structure, the free carrier concentration in QW is high so nonradiative recombination probability is less. QW structures give a freedom to design the transition energies through changing the well width.

Recombination

There are two fundamental recombination mechanisms in LED, radiative recombination and nonradiative recombination. During a radiative recombination, electrons and holes recombine followed by the emission of photons, whereas in a nonradiative recombination process, the energy is converted to phonons, generating extra heat to the material.

Turn-On Voltage

The LED turn-on voltage is the voltage at which the LED first emits light or at which the diffusion current starts to dominate. This turn-on voltage depends on the bandgap of the active region.

LED Efficiencies

- **Injection efficiency**
  Injection efficiency of LED is the fraction of injected current that can be captured in the active region for the recombination process.
- **Recombination efficiency**
  Recombination efficiency is the fraction of injected carriers in the active region that recombine radiatively generating photons.
- **The internal quantum efficiency**
  The internal quantum efficiency of LED is the ratio of photons generated inside the active region to the total number of electrons injected into the active region (the efficiency of converting carrier current to photons).
- **The optical extraction efficiency (light extraction efficiency)**
  The optical extraction efficiency of LED is the ratio of photons able to escape from the LED

into free space to photons generated in the active region.

- **Power efficiency (wall-plug efficiency)**
  The power efficiency of LED is the ratio of the light output power to the electrical input power.
- **The total (external) quantum efficiency**
  The external quantum efficiency of LED is the ratio of the extracted photons emitted into free space to the injected electron–hole pairs.

Light Localization for Nano-optical Devices

Dmitri K. Gramotnev
Nanophotonics Pty Ltd, Brisbane, QLD, Australia

Synonyms

Metallic waveguides; Nanofocusing of light; Near-field optics; Plasmonic waveguides; Sub-wavelength waveguiding

Definition

Conventional dielectric structures like dielectric waveguides, fibers, lenses, etc., do not allow localization of electromagnetic waves within the regions that are significantly smaller than the wavelength of light in the medium. For example, if a dielectric lens is used to focus a laser beam, then the minimal beam waist at the focal point will be $\sim\lambda_{vac}/(2n)$, where λ_{vac} is the wavelength in vacuum and n is the refractive index of the medium where the laser beam is propagating (and is being focused by the lens). This is the so-called diffraction limit of light. Sub-wavelength localization of light is the focusing or concentration of light energy, or guiding of a light signal within spatial regions that are much smaller than the wavelength and could be as small as a few nanometers in size [1, 2].

Major Physical Principles

The current way of achieving sub-wavelength localization of light and light signals is associated with using material with negative dielectric permittivities. Such materials involve

- Metals below plasma frequency ωp [3]
- Ionic crystals in the infrared range of spectrum between the frequencies of transverse and longitudinal optical phonons [3]
- Any other material near sufficiently sharp line of resonant absorption

However, metals below plasma frequency ωp are the most readily available and commonly used materials with negative dielectric permittivity.

Metals support a special type of electromagnetic waves that are coupled to collective oscillations of the electron plasma in the metal. These waves are called plasmons. A very important and useful physical effect is that metallic surfaces can guide a special type of plasmons that are called surface plasmons. Surface plasmons are somewhat similar to waves on a surface of water, but they occur on a surface of electron plasma – the surface that coincides with the metal interface. The field of surface plasmons exponentially decays into the metal and into the adjacent dielectric medium (i.e., vacuum). Their dispersion on a flat metal surface is given by a simple equation [4]:

$$q = \frac{\omega}{c}\sqrt{\frac{\varepsilon_d \varepsilon_m}{\varepsilon_d + \varepsilon_m}}, \quad (1)$$

where q is the wave number of the surface plasmon, ε_m and ε_d are the dielectric permittivities of the metal and the adjacent dielectric medium, respectively, ω is the plasmon frequency, and c is the speed of light in vacuum. Equation 1 shows that if ε_m is real, i.e., dissipation in the metal is neglected, the surface plasmon exists only if

$$\varepsilon_m < 0 \quad (2)$$

and

$$|\varepsilon_m| > \varepsilon_d. \quad (3)$$

Indeed, if condition (Eq. 2) is not satisfied, i.e., ε_m is positive (which occurs in metals at frequencies $\omega > \omega_p$ [2]), then $q < k_d \equiv \omega\sqrt{\varepsilon_d} = c$, where k_d is the wave number of the bulk wave in the adjacent dielectric medium. This means that the surface plasmon must leak into the bulk wave in the dielectric medium at an angle given by the ratio: $\cos(\theta) = q/k_d$. This angle is determined by the Snell's law that represents the momentum conservation in electrodynamics [5]. In this case, the plasmon is not a surface wave localized near the metal surface and guided by this surface, but is rather a leaky wave that propagates, rather than exponentially decays, in the adjacent dielectric medium. If condition (Eq. 3) is not satisfied but $\varepsilon_m < 0$, then q is imaginary (see Eq. 1) and the surface plasmon does not exist either.

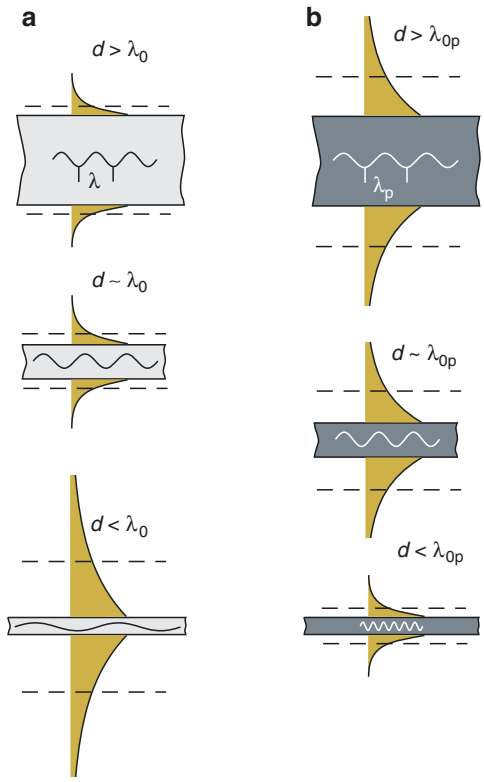
Because the wave number q for a surface plasmon is larger than the wave number k_d for the bulk wave in the adjacent dielectric (see Eq. 1), the tangential component of the wave vector of the bulk wave $(\mathbf{k}_d)t$ can never be equal to the wave vector $\mathbf{q}$ of the surface plasmon. Therefore, the Snell's law (that requires the equality of the tangential components of the wave vectors of the waves involved [5]) and the momentum conservation can never be satisfied by a bulk wave and a surface plasmon (having the same frequencies) on a flat smooth metal surface. Therefore, surface plasmons on a smooth flat surface are not coupled to bulk radiation. However, surface plasmons can be generated by bulk radiation on surface nonuniformities (such as, for example, an edge of the surface – end-fire excitation of surface plasmons [1]), or in periodic gratings, or in the presence of a prism coupler in the Otto or Kretschmann geometries [4].

The recent years have seen an explosion of theoretical and experimental research in the area of surface plasmons and their applications for integrated nano-optics: development of a new generation of nano-optical sensors, near-field imaging techniques with the spatial resolution as good as a few nanometers, manipulation and trapping of small nanoparticles and separate molecules, detection and imaging of separate molecules, design of nanomechanical systems, etc.

These areas of application and research involving surface plasmons have started to rapidly expand when it was realized that metallic nanosructures could guide and concentrate plasmon energy far beyond the diffraction limit of light and within nanoscale regions as small as a few nanometers. The first demonstrations of such unique capabilities were the original papers on sub-wavelength guiding using plasmons in metal nanorods and metallic nanoholes [6], and plasmon nanofocusing in gradually tapered metal structures [7]. In fact, the smallest dimensions of a localization region for surface plasmons are limited only by the atomic structure of matter, dissipation in the metal, and spatial dispersion, i.e., nonlocal dielectric response of materials [5, 8].

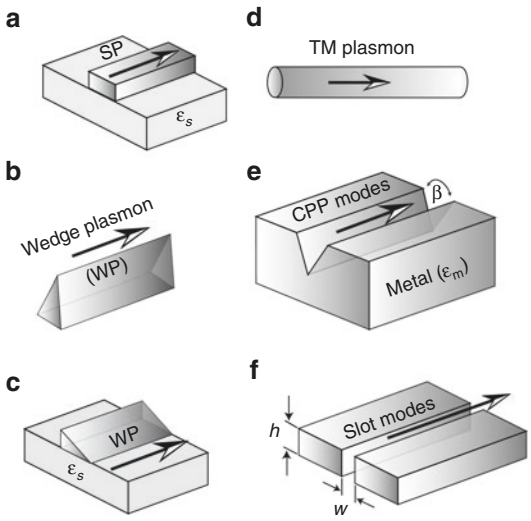
Key Research Findings

Sub-wavelength Waveguiding



Modern electronic is fast approaching its fundamental speed and bandwidth limits. Therefore, further increase of efficiency and speed of information-processing systems relies upon the development of new approaches and physical principles. One of the most feasible current options is based on using light signals and optical circuits instead of their less efficient electronic counterparts. However, one the major current problems of integrated optics is the insufficient

level of miniaturization of optical components and interconnects, which is not even close to that typically achieved in electronics. Therefore, design of efficient sub-wavelength waveguides, interconnects, and optical devices with the localization of light signals within spatial regions with dimensions much smaller than the wavelength is the major goal of the modern integrated nanophotonics.



As indicated above, unfortunately, dielectric waveguides do not normally allow such localization. For example, though an optical fiber can be made arbitrarily thin, this does not lead to sub-wavelength localization of the fundamental mode guided by this fiber. As the diameter of the fiber is reduced to zero, the field of the guided mode extends further into the surrounding medium (Fig. 1a), and the size of the guided mode tends to infinity. No two such fibers can be placed close to each other, as the overlapping guided modes in these fibers will produce a significant crosstalk and signal interference.

A completely different situation occurs in sub-wavelength plasmonic waveguides, such as, for example, cylindrical metal nanowires (Fig. 1b). Decreasing diameter of a metal nanowire results in a monotonic decrease of the wavelength of the fundamental guided plasmon mode having the TM polarization. This leads to a monotonic increase of the mode localization or, equivalently, to a monotonic decrease of the dimensions of the localization region for the fundamental mode (these regions are shown by the *dashed lines* in Fig. 1).

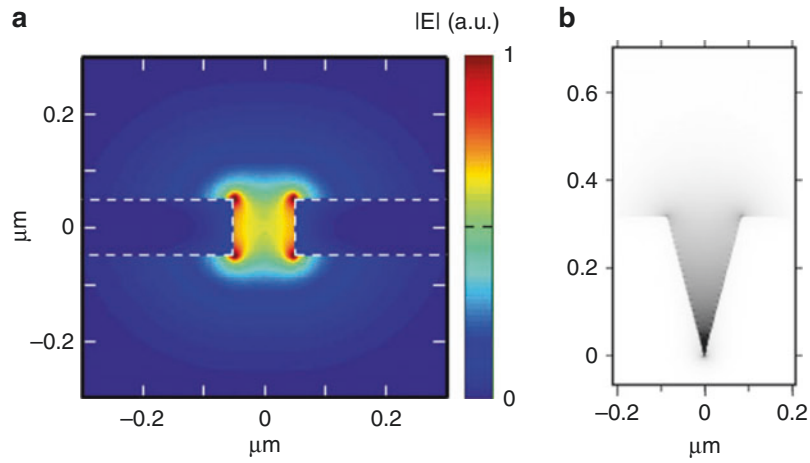
Several different guiding plasmonic structures have been proposed and analyzed in detail. These included metal nanorods (cylindrical nanowires), nanostrips on a dielectric substrate, sharp metal wedges guiding wedge plasmons, metallic grooves guiding a special type of strongly localized plasmons called channel plasmon-polaritons (CPP modes), or nanoslots in a thin metal membrane or film [1] – see Fig. 2a–f. It is important to note that not all plasmonic modes guided by different types of metallic guiding nanostructures can experience strong sub-wavelength localization. For example, a thin metal film surrounded by a uniform dielectric can guide two different types of plasmonic modes – with symmetric and antisymmetric charge distribution across the film. If the thickness of the film is reduced to zero, it is only the plasmon with the symmetric charge distribution that experiences increased confinement to the metal film (i.e., increased localization). The other mode with the antisymmetric charge

Light Localization for Nano-optical Devices, Fig. 1 The differences between the dielectric fibers and metallic nanowires in achieving sub-wavelength waveguiding. (**a**) As the fiber diameter d decreases from infinity to zero, the wavelength of the guided fundamental mode λ monotonically increases from the wavelength in the material of the fiber λ_0 to the wavelength in the dielectric medium surrounding the fiber. Simultaneously, the typical mode size reduces as the fiber diameter is reduced to about λ_0 and then starts to increase to infinity (as the fiber diameter tends to zero) – no sub-wavelength localization. (**b**) As the diameter of a cylindrical metal nanowire d decreases from infinity to zero, the wavelength of the guided fundamental TM plasmonic mode λp monotonically decreases from the plasmon wavelength on the flat metal surface $\lambda_0 p$ to zero. Simultanously, the typical mode size also monotonically decreases to zero, leading to sub-wavelength waveguiding

Light Localization for Nano-optical Devices, Fig. 2 Major examples of different types of plasmonic sub-wavelength waveguides: (**a**) metal nanostrip on a dielectric substrate; (**b**) free-standing sharp metal wedge surrounded by a uniform dielectric, guiding strongly localized wedge plasmons; (**c**) tapered section of a metal film in the shape of a metal wedge on a dielectric substrate with the permittivities of the substrate and cladding being εs and εc, respectively; (**d**) cylindrical nanorod or cylindrical nanowire guiding strongly localized TM plasmons; (**e**) V-groove of a metal surface, guiding strongly localized channel plasmon-polaritons (CPP modes); and (**f**) slot plasmonic waveguide in a metal membrane of thin film guiding strongly localized slot modes

distribution across the film – the so-called long-range surface plasmon – becomes less localized and in the limiting case of zero thickness of the metal film transforms into a bulk wave propagating in the surrounding dielectric.

These are the only strongly localized ("short-range") plasmonic modes that present a significant interest for the design of sub-wavelength waveguides, interconnects, and nano-optical devices. The indicated plasmonic structures including metal strips, nanorods, metal grooves, wedges, and nanoslots are all capable of guiding strongly localized plasmonic modes. The localization of the guided "short-range" plasmons increases with decreasing geometrical dimensions of the guiding structure, such as slot width and film thickness for a nanoslot waveguide, taper angle for a V-shaped metallic groove or a metal wedge, diameter of a nanorod, and width and thickness of a metal strip.



For example, in the approximation of continuous electrodynamics, the dimensions of the guiding region for a strongly localized plasmon mode near the tip of a V-shaped metal groove or metal wedge tend to zero with decreasing taper angle. In fact, there is a critical value of the taper angle $\beta = \beta c$:

$$\beta_c \approx \begin{cases} -2\varepsilon_d = \mathrm{Re}(\varepsilon_m), & \text{for V} - \text{grooces} : \\ -(\varepsilon_s + \varepsilon_c) = \mathrm{Re}(\varepsilon_m) & \text{for wedges,} \end{cases} \tag{4}$$

below which the guided mode does not exist because of its infinite localization near the infinitely sharp tip. Here, ε_d is the permittivity of the dielectric medium in the metal groove (Fig. 2e), and ε_s and ε_c are the permittivities of the dielectric substrate and cladding for a tapered section of a metal film in the form of a metal wedge (Fig. 2c).

The typical distribution of the magnitude of the electric field in the fundamental plasmonic mode of a nanoslot of 100 nm width in a silver membrane of thickness 100 nm suspended in vacuum is shown in Fig. 3a for the vacuum wavelength $\lambda_{vac} = 632.8$ nm (He-Ne laser) and metal permittivity $\varepsilon m = -16.2 + 0.5i$. The localization of the field in this case is ~150 nm, which is significantly smaller than the vacuum wavelength. Reducing the gap width and film thickness to 25 nm results in a significant reduction in the typical dimensions of the field localization region below ~50 nm. The typical field distribution in the fundamental CPP mode in a V-groove waveguide of finite depth is shown in Fig. 3b, also illustrating guiding with sub-wavelength localization.

Increasing localization of a guided plasmonic mode comes at a price of increased dissipative losses and thus decreased propagation distance. For example, for the 100 × 100 nm slot the propagation distance of the fundamental mode (Fig. 3a) appears to be ~15 μm, whereas for the 25 × 25 nm slot it is ~2.3 μm. Similar situation occurs for the other types of the plasmonic waveguides, such as V-groove and wedge waveguides [1].

Light Localization for Nano-optical Devices, Fig. 3 Typical distributions of the magnitude of the electric field in sub-wavelength plasmonic waveguides: (**a**) fundamental mode in a 100 × 100 nm slot waveguide in a silver membrane in vacuum at $\lambda_{vac} = 632.8$ nm (He-Ne laser); (**b**) fundamental mode in a 30° V-shaped 314 nm deep groove filled with vacuum on a silver surface at $\lambda_{vac} = 632.8$ nm

Significant dissipation of the propagating signals in plasmonic sub-wavelength waveguides is a major problem of integrated plasmonics. On the other hand, the typically achievable propagation distances of around at least a few microns are sufficient for the design of interconnects between highly integrated nano-optical devices, or interconnects between the existing optical telecommunication systems and nano-electronic devices and components. However, the development of all-optical information-processing integrated circuits with high level of integration will require a resolution of the dissipation problem.

One of the current approaches to the dissipation problem is to use materials with gain to compensate for the dissipation. However, the high level of dissipation of strongly localized plasmons $\sim$1,000 cm^{-1} and higher is above what could be expected to be compensated by most gain media. Therefore, dissipation compensation or partial dissipation compensation was claimed for rather weakly localized plasmonic modes [1, 9] that cannot normally be used to design nano-optical devices and interconnects. Therefore, strong dissipation of localized plasmonic modes in sub-wavelength waveguides is a standing problem that currently imposes limitations upon the design of highly integrated nanophotonic circuits for efficient all-optical signal processing.

Strong dissipation of plasmonic modes in metallic nanostructures is also an obstacle for the development of nanoscale optical sources. An efficient nanoscale optical source that would result in stimulated and coherent emission of surface plasmons would be a major technological step in nanophotonics. Such a source of surface plasmons is called "spaser" using the analogy with a "laser" as a light source based on stimulated emission of photons. A significant recent advancement in this direction was the first experimental observation of stimulated plasmon emission in gold nanoparticles covered in high-brightness luminescent dye doped silica shells [10]. Each of such gold-silica particles worked as a spaser nanocavity with the dimensions of $\sim$44 nm. Using the optical pumping, plasmon oscillations are stimulated in each of the gold-silica nanoparticles, and outcoupling of these oscillations into radiative photonic modes constituted a nanolaser operating in the visible range and having the cavity dimensions of $\sim$44 nm [10]. Coupling such a spaser cavity to a sub-wavelength plasmonic waveguide could lead to a plasmon source in a plasmonic information-processing circuit.

Plasmon Nanofocusing

A special area of interest and significant applications of strongly localized plasmons lies with plasmon nanofocusing. Nanofocusing is the process of concentration and localization of electromagnetic waves by means of tapered metallic nanostructures into regions as small as a few nanometers, i.e., far beyond the diffraction limit

of light [1, 2]. Plasmon nanofocusing occurs when a strongly localized plasmonic mode propagates along a gradual taper of a plasmonic guiding structure. For example, if a plasmon with TM polarization propagates along a tapered conical rod, it experiences a gradual increase in its localization combined with a significant local field enhancement, despite the dissipative losses in the metal [1, 2]. Disregarding the atomic structure of matter and spatial dispersion, the local field enhancement tends to infinity, and the localization region tends to zero as the infinitely sharp tip of the conical rod is approached. Realistically, the field localization region and local field enhancement are limited by the smallest practically achievable radius of the tip of the metal cone, which is typically limited by a few nanometers.

Similar nanofocusing effects can be achieved in other tapered metal structures including tapered metal gaps, metal wedges, tapered metal strips on a dielectric substrate with gradually reducing width and/or thickness of the strip, etc. All of these structures are typically characterized by a significant increase of plasmon localization and enhancement of its local field near the tip of the taper. An interesting case of nanofocusing of channel plasmon-polariton modes was considered and observed experimentally in V-shaped metal grooves with gradually reducing taper angle and depth. In this case, the channel plasmon-polariton mode guided by the groove experienced gradual increase in its localization, combined with the local field enhancement, caused by the gradually changing groove parameters [1].

Nanofocusing is typically efficient if the taper angle of the metal structure is sufficiently small, such that:

$$\left|\frac{\partial Q_1^{-1}}{\partial z}\right| << 1, \tag{5a}$$

where Q_1 is the real part of the plasmon wave number in the structure, and the z-axis is parallel to the direction of the taper. If this condition is satisfied, the variations of the plasmon wave number within one plasmon wavelength are negligible, the plasmon does not "feel" the taper, and thus does not experience noticeable reflections from the taper. This is the so-called geometrical optics approximation or, equivalently, adiabatic regime of nanofocusing. Usually, the applicability condition (Eq. 5a) for the adiabatic approximation can be replaced by a significantly less restrictive inequality

$$\left|\frac{\partial Q_1^{-1}}{\partial z}\right| < 0.8, \tag{5b}$$

which was obtained from the comparison of the rigorous numerical results with the outcomes based on the adiabatic approximation.

Condition (Eq. 5b) determines a critical taper angle for the structure βc above which the adiabatic approximation cannot be used for the analysis of plasmon nanofocusing. For a tapered nanogap in a metal medium, or a metal wedge, the values of the critical taper angle are given by Eq. 4. This highlights an interesting physical aspect that adiabatic nanofocusing in V-grooves and wedges is antagonistic to the existence of the strongly localized guided modes in these structures. This is because, in the approximation of continuous electrodynamics, the conditions for adiabatic nanofocusing ($\beta < \beta c$) and for existence of localized modes ($\beta > \beta c$) in infinitely sharp metal V-grooves and wedges are exactly opposite.

Optimal parameters for different nanofocusing structures were determined from the adiabatic approximation and rigorous numerical analysis. For example, if the taper angle is much smaller than βc, then adiabatic condition (Eq. 5a) is satisfied, but the plasmon must propagate large distances along the taper until it reaches the tip. This means that it will experience large dissipative losses, and the local field enhancement at the tip will not be the strongest. On the other hand, if the taper angle is large, so that condition (Eq. 5b) is not satisfied, then the plasmon will experience significant reflections from the taper, and only part of its energy will be able to reach the tip. This will also lead to a reduction of the achievable local field enhancement at the tip. Therefore, there is an optimal taper angle $\beta = \beta_{opt}$ at which the local field enhancement at the tip is the strongest. For example, for a gold cone in vacuum at $\lambda_{vac} = 632.8$ nm (He-Ne laser) and $\beta_{opt} \approx 35°$

[1]. Optimal taper angles for gaps (~20°) tend to be smaller than for cones, but larger than for wedges (~7°). The optimal taper angle for a tapered gap or a metal wedge is close to the critical taper angle below which adiabatic nanofocusing takes place, i.e., $\beta_{opt} \approx \beta c$. This is expected, as both the angles are physically related to the same phenomenon – the appearance of significant reflections of the plasmon from the taper.

Another important parameter is the optimal length of the taper L_{opt}. If the plasmon is generated too far from the tip, it has to propagate a large distance until it reaches the tip and starts experiencing significant focusing effects. This leads to excessive dissipative losses. If the plasmon is generated too close to the tip, it does not have "an opportunity" to take all the advantage of the nanofocusing effect to enhance its field. Therefore, there is an optimal distance from the tip of a nanofocusing structure (or the optimal length of the nanofocusing structure L_{opt}), at which a localized plasmon mode should be generated to ensure the maximal possible local field enhancement at the tip. For example, the optimal length of a nanofocusing conical metal rod can be determined by a simple equation [11]:

$$L_{opt} = \frac{e_1(\varepsilon_d + e_1)}{e_2 \varepsilon_d Q_0} \cos(\beta = 2), \qquad (6)$$

where e_1 and e_2 are the real and imaginary parts of the metal permittivity $\varepsilon_m = e_1 + ie_2$, ε_d is the permittivity of the dielectric medium surrounding the metal cone, and Q_0 is the real part of the plasmon wave number on a flat and smooth interface between the considered metal and dielectric medium. Equation 6 is applicable if the taper angle β is not too small:

$$\mathrm{Sin}\ (\beta = 2)\ >> \frac{e_2 \varepsilon_d}{e_1(\varepsilon_d + e_1)}. \qquad (7)$$

For example, Eq. 6 gives $L_{opt} \approx 10$ μm for a gold cone in vacuum at $\lambda_{vac} = 632.8$ nm, and this estimate is correct within a broad range of taper angles $20° < \beta < 160°$.

Typical achievable local field enhancements at the tip may vary for different nanofocusing structures. For example, conical rods represent one of the best options for plasmon nanofocusing, resulting in the largest local field enhancements up to ~1,600 times for a gold rod in vacuum [1] with the localization of the enhanced field within a region of ~5 nm. Tapered gaps are less efficient from this point of view and typically yield the local field enhancements of ~50 to 100 times. Metal wedges are the least efficient nanofocusing structures compared to the gaps and conical rods with the typical enhancement factors of ~10. Further enhancement of the local field at the tip can be achieved through optimizing the shape of a nanofocusing rod. For example, it has been demonstrated that if an annually converging plasmon is initially generated on a flat surface and then coupled into a conical rod (made in the form of a wizard hat), the local field enhancement at the tip could be as strong as ~10,000 [12].

Importantly, such local field enhancements should lead to a Raman signal enhancements from Raman-active molecules near the tip of the structure up to $\sim 10^{16}$, which is two orders of magnitude larger than what is required for the single molecule detection. Therefore, the analyzed nanofocusing structures may present a unique opportunity for the development of reliable structures for sensing, detection, and imaging of single molecules and traces of substances in the environment surrounding the nanofocusing structure [12].

Strong concentration of the local field near the tip of a nanofocusing structure provides not only the substantial field enhancements, but also enormous field gradients within the distances of about a few nanometers around the tip. This opens a unique opportunity for near-field trapping and manipulation of small nanoparticles and separate molecules with the efficiency up to ~4 orders of magnitude higher than those achievable by other means [12].

Examples of Application

This naturally leads to the discussion of numerous and important applications of plasmon nanfocusing. As indicated above, one of the

major areas of these applications is the development of a new generation of nano-optical sensors and near-field optical imaging techniques with the spatial resolution as good as a few nanometers – far beyond the diffraction limit of light. These will likely to include a new generation of nano-optical sensors for the detection and identification of traces of explosives, drugs, and chemicals in the environment for security and environmental monitoring. Another major area of future applications of nanofocusing will involve cellular and intercellular manipulations, imaging and testing in nanobiophotonics and medicine. These might include new techniques for DNA manipulations and diagnostics, mapping of the local refractive index in a living cell, testing of macromolecules, intercellular fluids and membranes, highly targeted delivery of electromagnetic energy to nanoscale regions of a living cell with equally localized and controlled heat discharge, etc.

A new generation of nonlinear devices is expected to emerge from plasmon nanofocusing structures, such as nonlinear all-optical switches, nanoscale bolometers, active and passive optical devices, new techniques for the investigation of the local material response to highly localized heat discharge on the femtosecond scale, etc. Another important practical application of nanofocusing structures will be related to their natural capability of efficiently coupling relatively large-scale light signals from the conventional optical communication systems to nanoscale electronic chips for further information processing. This means overcoming the major problem with the efficient delivery of light energy in the visible and infrared ranges to nanoscale devices, structures, and separate molecules. A separate area of applications and further research is related to the analysis of single plasmon propagation and focusing, quantum and nanomechanical systems.

A range of other nano-optical devices and techniques based on strongly localized plasmonic modes in metallic nanostructures has been considered and analyzed, including nanoscale plasmonic resonators, filters, couplers, optical adaptors, elements for integrated optical circuitry, nanoantennas, nanolasers, photodetectors and photovoltaic devices, heat-assisted magnetic recording, etc. [1, 2].

Synonyms

Boron- and/or nitrogen-doped carbon nanotubes

Definition

Light-element nanotubes, as specifically defined here, refer to boron (B) and/or nitrogen (N) substitutionally doped carbon (C) nanotubes (C-NTs), including both the selectively doped CB_x and CN_x nanotubes and the co-doped ternary system $B_xC_yN_z$ nanotubes. For either the CB_x or CN_x nanotubes, it is expected that high dopant concentrations will lead to new phases with well-defined stoichiometry; the two most eminent examples are BC_3 and C_3N_4 nanotubes. These stoichiometric nanotubes cannot be simply treated as highly B- or N-doped carbon nanotubes as their structures and electronic properties are inherently different than the pristine C-NTs.

Introduction

The discovery of carbon nanotubes (C-NTs) in the early 1990s has evoked much interest in nanotubular materials as an important frontier area of research that is still flourishing [1–4]. Shortly after the discovery of C-NTs, it was experimentally confirmed that substitutional doping of C-NTs with B and/or N heteroatoms was feasible [5, 6]. As the nearest neighbors of C in the Periodic Table and given their size proximity to C, B, and N, probably the only elements that can be substitutionally doped in a hexagonal C network without severely distorting the lattice. Furthermore, considering the isoelectronic and isostructural relationship between a B–N pair and a C–C pair, it is expected that the simultaneous B and N doping (i.e., co-doping) of C-NTs through partially substituting for C–C units in the tube-shell lattice will lead to the formation of ternary system $B_xC_yN_z$ nanotubes. To some extent, the $B_xC_yN_z$ nanotubes can be treated as random or ordered hybrids or solid solutions of C-NTs and boron nitride (BN) nanotubes [1–11]. On the other hand, selective doping of C-NTs with B or N alone will give rise to binary CB_x and CN_x nanotubes, respectively [12–15]. $B_xC_yN_z$, CB_x, CN_x nanotubes, along with pristine C and BN nanotubes, constitute the family of light-element nanotube materials.

As there have been many reviews available for C and BN nanotubes, the focus of this entry will be constrained to the doped system $B_xC_yN_z$, CB_x, and CN_x nanotubes. Theoretical and experimental aspects concerning their crystal structures, electronic structures, electrical transport properties, state-of-the-art synthesis, characterization of bonding environments, and the atomic distribution of dopants will be surveyed.

Structure and Electronic Structure

The Ternary System $B_xC_yN_z$ Nanotubes

The existence of stable layered bulk structures is usually suggestive of the existence of corresponding stable nanotubular structures. Topologically, a single-walled carbon nanotube (C-SWNT) can be constructed by rolling a single layer of graphite (i.e., graphene) into a seamless tube. Likewise, one can view a BN-SWNT as a rolled up sheet of sp^2-bonded boron nitride (h-BN). Known as the III–VI homology of C nanotubes, BN nanotubes are structurally identical to their C counterparts except that the C atoms are fully substituted by alternating B and N atoms [1, 3]. However, despite the structural similarity between C and BN nanotubes, their electronic band structures are vastly

different. It is well-known that pristine C-NTs can be either semiconducting or metallic, with electronic band structures being sensitively determined by specific tube geometries, that is, diameters and chirality, whose control remains a formidable (if not impossible) challenge for all known synthetic methodologies. By contrast, as a consequence of the ionic character of B–N bond, BN nanotubes are electrical insulators with a large electronic band gap of around 5.5 eV that is almost independent of the diameter and the chirality of the BN tube [1, 3]. It is therefore inferred that the intermediate ternary system $B_xC_yN_z$ nanotubes will exhibit tunable semiconducting properties in between metallic or small band gap C-NTs and insulating BN-NTs [7–11]. Importantly, the electronic band structures of $B_xC_yN_z$ nanotubes are governed largely by the B/C/N chemical stoichiometry rather than by the specific geometry [7–11].

As the most prominent example of $B_xC_yN_z$, BC_2N nanotubes have been theoretically studied by Miyamoto et al. through first principles and tight-binding (TB) band structure calculations [7, 8]. They showed that BC_2N nanotubes would be semiconductors and could be either p- or n-doped depending on the detailed B and N concentrations [8]. In a later study, the evolution of electronic band structures of $B_xC_yN_z$ nanotubes as a function of the B and N concentrations were systematically evaluated within a TB framework by Yoshioka et al. [9]. This relatively simple model gave essential qualitative features of the electronic structures of $B_xC_yN_z$ nanotubes with varied stoichiometry. The calculated results clearly showed the opening of a band gap for metallic (9, 0) nanotubes and the band gap increasing for a semiconducting (10, 0) nanotubes with increasing (x + y) concentration [9].

In a recent study by the present authors, Xu et al. have performed a series of ab initio band structure calculations of $B_xC_yN_z$ nanotubes in a framework of generalized gradient approximation (GGA) [11]. As a first step, various co-doped structures were searched, and as expected, it was found that B and N atoms have a strong preference to neighbor each other and form B–N pairs. The total energy of a unit cell containing an adjacent B–N pair is about 2.0–2.6 eV lower than those with separately doped B and N atoms at isolated sites. By starting from a (5,5) metallic C-SWNT, the incorporation of one B–N pair in a unit cell (with B or N component ratio of 5 %) resulted in the opening of a small band gap of about 0.1 eV at the Fermi level. With further incorporation of one more B–N pair to the unit cell (the two adjacent B–N pairs are separated by six carbon atoms), the energy gap is widened to about 0.5 eV. These results clearly revealed a transition of electronic structure of the (5, 5) nanotube from metallic to semiconducting after B–N co-doping. Other metallic SWNTs at different B–N co-doping concentrations were also calculated, and the results showed a similar band structure crossover from metallic to semiconducting, independent of the chirality of the nanotubes despite the different gap values. The gap opening is found to be fairly sensitive to B/N components and widens monotonically with increasing B/N co-doping concentration. The detailed geometry of the B/N atomic pairs may change the width of the gap slightly, but the overall trend remains the same [11].

Selectively Doped CB_x and CN_x Nanotubes

When considering selective doping of C-NTs solely with electron-deficient B or electron-rich N, one is reminded of the substitutional doping of Silicon (Si) upon which microelectronics relies. The selective doping of Si with substitutional acceptor or donor type atoms results in a sensitive shift of the Fermi level, a concept known as the rigid-band model (i.e., shifting the Fermi level without altering the band structure). However, it is important to note that the doping levels in conventional Si technology are very low, typically on the order of parts per million (ppm). For B- or N-doped nanotubes, the rigid-band model is valid only for a very low dopant concentration [12–15]. In general, as the typical dopant concentrations are on the order of a percent and tenths of a percent, the substitutional B or N doping of nanotubes cannot be solely explained in the framework of a rigid-band model, and the modifications of band structures and density of states (DOEs) must be taken into account [12–15].

Structurally, the B dopant is expected to be incorporated into the honeycomb tube-shell lattice

primarily by direct substitution of C atoms with a triple-coordinated bond [12, 13]. In the case of low B concentration, the formation of an acceptor state in the band gap just above the valence edge is expected. For instance, an early theoretical work by Yi and Bernholc in 1993 has revealed an acceptor state located at 0.16 eV above the Fermi energy for a (10, 0) nanotube with 1.25 wt% B concentration [12]. In a more recent study by Wirtz and Rubio, the authors theoretically studied the evolution of an acceptor-like level that is caused by a periodic distribution of the B dopant as a function of the B-doping ratio. They found that doping profoundly affected the physical properties [13]. Specifically, for pristine C-SWNTs, the DOS is symmetric around the band gap for the first and second van Hove Singularities (vHSs), whereas the incorporation of more B dopants led to an increasing asymmetry near the band gap due to the mixing of the *p* and *s* orbitals [13].

As far as N-doped CN_x nanotubes are concerned, the situation is a little more complicated than an intuitive expectation that the incorporation of N heteroatoms will lead to n-type doping of nanotubes with localized states above the Fermi level [6]. This is the case only if a foreign N atom directly substitutes for a C atom on the honeycomb tube-shell lattice, in a bonding environment just like that of the aforementioned B dopants [6, 14, 15]. For example, a substitutional N dopant may also generate structural defects in the tube-shell lattice and lead to a rearrangement of the neighboring C atoms. In this case, it is not immediately obvious that n-type behavior will result, because the electrical behavior depends on the details of the new geometry. As a result, the as-formed new tube-shell structure can be p type [6, 14, 15].

For either B- or N-doped nanotubes, it is expected that higher dopant concentrations may lead to new phases with defined stoichiometry, for example, BC_3 and C_3N_4 [16–18]. Just like graphene sheets, the stability of the planar structures of these stoichiometric compounds could make it possible for nanotubes with the same stoichiometry to exist. Band structure calculations have revealed that individual BC_3 nanotubes will act as semiconductors. Bundles of tubes are expected to exhibit metallic behavior due to inter-tube cohesive interactions [16]. As far as both crystallographic and electronic structures are concerned, the stoichiometric BC_3 compound nanotubes cannot simply be regarded as highly B-doped nanotubes. Similarly C_3N_4 nanotubes, which are also theoretically predicted to be well-defined semiconductors, are inherently different from substitutionally doped CN_x nanotubes [17]. To date, studies on BC_3 and C_3N_4 nanotubes are limited to theoretical modeling. The experimental synthesis of these stoichiometric compound nanotubes is still elusive.

Synthesis of $B_xC_yN_z$, BC_x, and CN_x Nanotubes

Generally speaking, there are two different strategies for the production of B- and/or N-doped nanotubes, namely, direct synthesis and post-synthetic nanotube-substitution reactions. The direct synthesis methods were in fact inherited from those that have been well established for pure C-NTs synthesis, mainly including arc-discharge, laser-ablation, and chemical vapor deposition (CVD) [19–33]. The post-synthetic nanotube-substitution reaction approach, on the other hand, refers to the use of pristine C-NTs as starting precursors that undergo carbothermal reactions with B_2O_3 vapor at elevated temperature (1,200–1,700 °C) in N_2 or NH_3 atmosphere; this reaction process will induce partial substitution of the carbon lattice by foreign B and/or N atoms, thereby resulting in the formation of doped nanotubes [34].

Synthesis of B- and N-doped C-NTs in the form of multi-walled nanotubes (MWNTs) was reported by Stéphan et al. early in 1994 using the arc-discharge method [5]. Since then, a great deal of research has been directed toward B- and/or N-doped nanotubes. However, despite the considerable progress in synthesis of doped MWNTs [1–4], substitutional doping of SWNTs turn out to be much more difficult, and it was not until very recently that reports of successful synthesis of high-quality B- and/or N-doped

SWNTs have emerged [4, 10, 11, 19–33]. Typically, B- and/N-doped MWNTs suffer from large percentages of severe topological modifications and therefore usually exhibit highly defective, bamboo-like structural features. Doped SWNTs, however, normally exhibit straight, non-buckled tubular structures, close to pristine C-SWNTs [4, 10, 11, 19–33]. For SWNTs, it is likely that the B- and/or N doping introduces topological defects in the tube-shell, but not necessarily defective, bamboo-like structures.

Direct Synthesis: Chemical Vapor Deposition

Over the past decade, catalytic decomposition of carbon-containing precursor gases over transition metal catalyst nanoparticles in a CVD growth has proved to be an elegant strategy for the controlled synthesis of MWNTs and SWNTs. In comparison with the physical evaporation approaches such as arc-discharge and laser-ablation, CVD growth holds advantages in terms of experimental facility, potential for large-scale production at low cost, and control over tube location and orientation. CVD synthesis of B- and/or N-doped nanotubes has also been extensively exploited, but the majority of reported studies have been limited to doped MWNTs. In 2006, a breakthrough in CVD growth of ternary $B_xC_yN_z$-SWNTs was made by the present authors through a bias-assisted hot filament CVD (HFCVD) growth process [10]. $B_xC_yN_z$-SWNTs growth by HFCVD was achieved over a high-activity powdery-type catalyst, namely, porous MgO supported Fe–Mo (denoted as Fe–Mo/MgO) with CH_4, B_2H_6, and ethylenediamine vapor as the reactant gases and inert He as the diluting gas. Transmission electron microscopy (TEM) imaging showed that the as-grown SWNTs had a clean and smooth morphology with diameters in the range of 0.8–2.5 nm. In some cases, double-walled nanotubes (DWNTs) with slightly larger diameter coexisted with the SWNTs, but the amount was not significant. The electron energy loss spectroscopy (EELS) spectra taken from the SWNT bundles showed the core-loss K-edges of B, C, and N located at 188, 284, and 401 eV, respectively. The sharply defined 1 s $\rightarrow \pi^*$ and 1 s $\rightarrow \sigma^*$ transition features of the C–K edge is characteristic of well-graphitized sp^2-bonding carbon networks. The B and N K-edges, though being much weaker, also showed discernible π^* peak as well as σ^* band, indicating that the B and N atoms were in the same sp^2-hybridized state as their C counterparts. Importantly, all as-grown $B_xC_yN_z$-SWNTs had straight cylindrical tube walls, a morphological feature similar to that of pristine C-SWNTs. This is in sharp contrast to the previously reported defective, "bamboo-like" tube structures of doped MWNTs. Other than SWNTs and DWNTs, the HFCVD growth also produced a small amount of carbon onions and "bamboo-like" MWNTs. These by-products were hard to remove completely but their amount could be effectively reduced by optimizing the growth parameters and the use of the Fe–Mo/MgO catalyst [10].

In recent years, there have also been a few studies concerning the synthesis of N-doped SWNTs by conventional thermal CVD. Keskar et al. reported on the growth of isolated CN_x-SWNTs on quartz and SiO_2/Si substrates via a liquid injection CVD process by using the mixture of xylene and acetonitrile (CH_3CN, N precursor) as the feeding source [19]. The catalysts they used were nanoparticles deposited onto the SiO_2/Si substrates prior to the growth. The resulting surface-grown SWNTs were characterized by resonant Raman spectroscopy. It was found that the intensity of the radial breathing mode (RBM) of the as-grown nanotubes decreased with increasing N precursor concentration in the feeding source, while the relative intensity of D/G-band increased with the appearance of the D′-band. The authors attributed these observations to the N doping in SWNTs [19]. In another CVD experiment, Villalpando-Paez et al. synthesized long strands of N-doped SWNTs through an aerosol-assisted CVD process using a mixture of ferrocene/ethanol/benzylamine, with benzylamine ($C_6H_5CH_2NH_2$) acting as the N precursor and ferrocene as the Fe catalyst precursor [20]. As the relative ratio of benzylamine to ethanol increased, the SWNT yield decreased gradually with the bundled SWNT strands getting shorter and thinner. At higher benzylamine concentrations, SWNT growth was completely inhibited. Neither EELS nor Energy

Dispersive X-ray (EDX) spectra detected the presence of N in the as-grown SWNTs,, indicating that the N-doping ratio, if any, was rather low and likely below the detection limit of these instruments (e.g., <1 wt%) [20]. In the following study, the same CN_x-SWNT samples were reexamined and the N-dopant concentration was determined to be about 0.3 at.% [21].

As for the CVD growth of B-doped SWNTs, to date there is only one reported by Ayala et al. [22]. The authors utilized triisopropyl borate as precursor and Fe-based supported catalyst in a CVD system working under controlled high-vacuum conditions. It was found that although high-quality C-SWNTs could be formed in a wide temperature range, B doping was not always successful, with less than 1 at.% B concentration confirmed [22].

Direct Synthesis: Arc-Discharge and Laser-Ablation

The carbon arc-discharge method, initially used for producing C_{60} fullerenes, led to the experimental discovery of C-NTs by Iijima in 1991 [23], and later the first synthesis of C-SWNTs [24, 25]. In 1994, Stéphan et al. initiated the direct synthesis of B- and N-doped MWNTs by means of arc-discharge [5]. One-year later, the arc-discharge synthesis of MWNTs with nominal stoichiometry of BC_2N and BC_3 was reported by the Zettl group [6]. Nevertheless, the direct synthesis of doped SWNTs in an arc-discharge experiment is not easily achieved. A study in 2002 by Droppa et al. first examined the possibility of doping SWNTs with N by the arc-discharge evaporation of graphite in a He–N_2 atmosphere in the presence of Fe–Co–Ni catalysts [26]. It was found that a pure He atmosphere could produce pure C-SWNTs bundles whereas a mixed He–N_2 atmosphere instead gave rise to nested nanofibers rather than SWNTs. As such, their attempt to produce doped SWNTs was unsuccessful [26]. The successful arc-discharge synthesis N-doped SWNTs was achieved later on by Glerup et al. [27, 28]. What is unique about their synthesis was the use of N-rich precursors (melamine, $C_3N_3H_6$) as additives in the anode rod rather than relying on a nitrogen gas-containing atmosphere [27]. With an appropriate amount of melamine, the doped SWNTs with a N content around 1 at.% could be successfully produced. The as-grown N-doped SWNTs were well graphitized and exhibited straight non-buckled nanotube walls, similar to pristine C-SWNTs. When BN powder was used as precursor, the incorporation of $\sim$ 1 at.% N into the SWNTs was also achieved but no B doping was detected by EELS. The authors concluded that B doping is more difficult than N doping in SWNTs [27].

Both arc-discharge and laser-ablation belong to the high temperature vaporization methods that have demonstrated remarkable success in the synthesis of standard C-SWNTs. The use of the laser-ablation technique for B-doped SWNT synthesis was first reported by McGuire et al. [29, 30]. In their growth experiments, ablation targets were prepared by mixing different amounts of elemental B with C paste and a Co–Ni catalyst. It was found that the amount of B in the target strongly affected the final products of laser-ablation growth. SWNT bundles could be observed in the final products only when there was no more than 3 at.% B in the target, whereas the presence of excess B precursor would severely inhibit the SWNT growth. The authors examined the as-grown SWNT bundles by EELS, but no B was detected. Nonetheless, some indirect evidence for B doping came instead from Raman spectra, which showed appreciable changes in the intensity and/or the position of the D-band, G'-Band, and RBM [29, 30]. Later on, a breakthrough in the synthesis of B-doped SWNTs was achieved by Blackburn and coworkers using the laser-ablation method [31]. In their work, a high-yield of doped SWNTs with B contents up to 1.8 at.%, as determined by EELS measurements, was successfully produced. The unique feature of their synthesis was the use of nickel boride (NiB) alloy as both the B precursor and the catalyst. NiB was loaded in the graphite targets with appropriate ratios, and laser vaporization of the composite target in a N_2 atmosphere produced B-doped SWNTs bundles that were comparable in quality to the pure C-SWNTs from traditional laser ablations synthesis. Although the B-doped SWNTs were produced in a N_2 atmosphere, EELS as

well as [34] C-NMR measurements excluded the possibility of B and N co-doping and thus the formation of ternary $B_xC_yN_z$-SWNTs [31]. Besides NiB, the authors also tested the use of elemental B as a precursor for B doping, but laser vaporization of the targets produced only low-yield SWNTs which showed little B incorporation. This comparison further confirmed the unique role of NiB alloy in high-yield laser-ablation synthesis of B-doped SWNTs [31].

More recently, Lin et al. reported the successful synthesis of N-doped SWNTs by laser vaporization [32, 33]. The N-doping concentration was determined by means of EELS in a TEM. They also performed the first combined STS-TEM study of N-doped SWNTs; however, identifying the N bonding environment was difficult from a spectral deconvolution of the N core level edge [32, 33].

In another study, the phase-separated ternary $B_xC_yN_z$-SWNTs, that is, SWNTs made of BN nanodomains in a tube-shell hexagon lattice, were synthesized by laser-ablation using a target consisting of carbon and boron mixed with a Co/Ni catalyst under N_2 atmosphere [34]. HRTEM and nanoelectron EELS (nano-EELS) provided direct evidence that B and N co-segregated with respect to C and formed nanodomains within the hexagonal lattice of the graphene layer in a sequential manner [34].

Post-synthetic Nanotube-Substitution Reaction Route

The post-synthetic nanotube-substitution reaction approach was initially reported by Han et al. and latterly by Golberg et al. [35–37] using multi-walled C-NTs as a precursor for substitution. They demonstrated successful synthesis of the multi-walled BN-NTs and $B_xC_yN_z$-NTs in bulk quantities. Unfortunately, this approach was found to be far less effective when applied to the B/N co-doping of SWNTs. The use of a substitution reaction approach for SWNTs was first reported by Golberg et al. in 1999 [38, 39]. In the synthesis, laser-ablation produced C-SWNTs bundles were employed as the starting materials, which were heated together with B_2O_3 in a flowing N_2 atmosphere. By examining the as-treated SWNTs with HRTEM and EELS, the authors investigated the effects of synthesis temperature and reaction time on the B- and N-doping levels. The maximum yield of doped SWNTs was obtained at 1,553 K for 30 min, with an accumulating B-dopant concentration up to ~ 10 at.% and N concentration up to ~ 2 at.%: effective B/N co-doping was thus achieved [38, 39]. It was also found that the corrosive B_2O_3 vapor at such high temperature severely deteriorates the tubular morphology of SWNTs, while the problem is alleviated at lower temperatures. In a later study, Borowiak-Palen et al. revisited the same B/N substitution reaction process for SWNTs. But they were able to produce only binary B doped CB_x-SWNTs, rather than the ternary B/N co-doped $B_xC_yN_z$-SWNTs. More corrosive ammonia (NH_3) was used as the N source in place of N_2 in their study. A maximum B-doping ratio up to ~ 15 at.% could be reached in the as-generated CB_x-SWNTs [40].

The main stumbling point for effective B/N co-doping of SWNTs via a post-synthetic reaction process lies in the bundling phenomena of the C-SWNTs. As a result of the extraordinary cohesive interactions between adjacent nanotubes, SWNTs have a strong tendency to spontaneously form densely bundled ropes in their native state. When such bundled C-SWNTs are subjected to the carbothermal substitution reaction process, only a small fraction of SWNTs localized at the outermost fragments of bundles will be chemically accessible to the gaseous B and N reactants, whereas the inner of SWNTs are largely intact [38–40]. Aiming at solving this problem, the present authors have recently developed an innovative wet-chemistry approach for high-yield synthesis of the ternary $B_xC_yN_z$-SWNTs in bulk quantities [41]. An initial and key step of this approach involved the unbundling and dispersion of the starting C-SWNTs (HiPCO, super-purified) in an ionic liquid (IL) at room temperature, followed by the wrapping of the unbundled SWNTs with boric acid and then carbothermal substitution reaction at an optimized temperature of 1,000 °C with a NH_3 gas flow. The as-synthesized $B_xC_yN_z$-SWNTs are of high purity and quality rivaling that of the super-purified

HiPCO C-SWNTs. TEM and EELS investigations revealed that the ternary $B_xC_yN_z$-SWNTs typically have straight and smooth tube-shell structures, and a fairly homogenous B and N concentration. As a result of B/N co-doping, the thin film electrical devices built from $B_xC_yN_z$-SWNTs exhibit good electrical performance characterized by semiconducting behaviors [41].

Depth of Characterizations: Bonding Environments and Dopant Distribution

sp^2 bonding plays a fundamental role in all light-element nanotubes made of B, C, and N. Besides the information on chemical compositions and doping concentrations, a clear understanding of the bonding configuration and atomic distribution of B and/or N dopants is an important issue. Studies in this regard have been most advanced in the N-doped C-NTs [1, 4, 14, 15]. There have been a number of theoretical works modeling the bonding configuration of N within the CN_x nanotubes. Three main structural models have been proposed: pyridine-like, pyrrole-like, and substitutional (also named as "graphitic"), among which the pyridinic and substitutional N are both sp^2 coordinated whereas the pyrrolic N is sp^3 coordinated [1, 4, 14, 15]. Experimentally, the evidence of pyridinic and substitutional N is often from the results of XPS and/or EELS measurement on CN_x-MWNTs. In a recent study on the N-doped SWNTs, Glerup et al. observed in the EELS spectra that the N K-edge splits into two weak π^* peaks located at 398.6 and 402 eV, which could be attributed to π^* states associated with the pyridinic and substitutional N, respectively [27]. It is interesting to notice that CN_x-MWNTs often exhibit "bamboo-like" morphology rather than the regular tubular morphology, suggesting the N dopants may induce local structural distortion and a high concentration of pyridinic N will lead to the formation of the compartmentalized bamboo-like structure [1, 4, 14, 15]. On the other hand, the doped SWNTs normally exhibit a non-buckled straight tubular morphology. In this vein, the N-doped SWNTs provide us with a model system to study and establish the correlation between the bond configuration of dopants and their atomic distribution. Unfortunately, relevant studies are still lacking up to date. Nevertheless, it is plausible to argue that the doped SWNTs should contain more substitutional N atoms than pyridinic N atoms, and the overall N distribution should be more homogenous in doped SWNTs than in the bamboo-like MWNTs.

As for the B-doped C-NTs, there are very limited studies available concerning the bond configuration and the atomic distribution of B dopants. In an early study, Carroll et al. proposed the presence of BC_3 island nanodomains within the B-doped MWNTs, which could explain their experimental observation of the metallic behavior of the doped nanotubes with B concentration in the range of 1–5 at.% [42]. Recently, in the B-doped SWNTs produced from substitution reaction, Fuentes et al. have also assumed the formation of BC_3 nanodomains instead of a homogeneous random B substituted C-NT [43].

In the case of the ternary $B_xC_yN_z$ nanotubes, the situation is more complicated when considering the B/N co-doping in the nanotube lattice. Two types of atomic distributions have been theoretically predicted: one proposes that the B, C, and N species are randomly and homogeneously distributed in the tube lattice with a ternary B–C–N bonding nature, whereas the other one proposes a phase separation of the C-rich and BN-rich domains [3, 4, 7–11, 34, 44–47]. In the latter case, the C/BN phase separation would result in the formation of heterojunctions, superlattices, or quantum dots, or even the formation of the "sandwich-like" structures consisting of the separated pure C and BN shells [44–47]. Given the relatively higher stability of C–C and B–N bonds over that of C–B and C–N bonds, thermodynamically there should be a tendency for such a phase separation [44–47]. However, one must note that kinetics rather than thermodynamics can govern the configuration of nanotubes, so the formation of homogenous ternary $B_xC_yN_z$ nanotubes is also possible. In earlier studies via the post-synthetic substitution route, Golberg and Terrones et al. have successfully

obtained homogeneous $B_xC_yN_z$-MWNTs [37]. In the $B_xC_yN_z$-SWNTs grown by HFCVD method, the present authors studied the atomic distribution of B, C, and N in the nanotubes by means of spatially resolved EELS and energy-filtered electron microscopy [10]. It turned out that the constituting B, C, and N elements were homogenously distributed in the SWNTs, without appreciable phase separation. In other words, the HFCVD grown $B_xC_yN_z$-SWNTs are homogenously structured with a ternary-bonding nature. As we know, the bias-assisted HFCVD growth process occurs in a highly non-equilibrium condition, as such, a kinetic-controlled nanotube growth mechanism may come into play, which leads to the formation of homogenous ternary B–C–N tube shells rather than segregated C and BN domains. Complementary evidence for the ternary-bonding nature of $B_xC_yN_z$-SWNTs also comes from the XPS characterization. In the XPS spectra of B 1 s and N 1 s core level electrons, the existence of a significant amount of B–C and C–N bonds that are prevailing over the B–N bonds are confirmed [10]. It is worth mentioning that the spatial resolution of the energy-filtered electron microscope images (by Omega filter TEM instrument) was estimated to be ~ 0.5 nm, and detecting sub-nm domains is beyond the capabilities of most state-of-the-art instruments, hence the existence of sub-nanometer fragments made of pure BN and pure C phases could not be completely ruled out.

Electrical Transport Properties

Investigating doping effects on the electrical transport properties of doped C-NTs is of fundamental importance to the use of nanotubes in electronic devices. To date, most studies in this area are theoretical, as experimental design and transport measurements are restricted by the lack of high-quality doped nanotube samples, especially SWNT samples. In a recent study, electrical transport measurements on individual CN_x-SWNTs exhibited *n*-type conduction when there was a high concentration of graphite-like nitrogen bonding [28]. On the other hand, reports on the electrical transport properties of individual CB_x-SWNTs are scarce. We note that thermopower measurements on the CB_x-SWNTs bundle exhibited sustained *p*-type characteristics [29]. Also worth mentioning is that more recently, superconductivity was observed in CB_x-SWNTs thin films [48].

As for ternary $B_xC_yN_z$ nanotubes, theoretical studies predicted that that they may display semiconducting behavior intermediated between C-NTs and dielectric BN nanotubes [7–11]. Owing to the advances in synthesizing high-quality $B_xC_yN_z$-SWNTs by HFCVD, the present authors for the first time fabricated field effect transistor (FET) devices made of $B_xC_yN_z$-SWNTs [11]. Gate-dependent transport measurements revealed that the $B_xC_yN_z$-SWNTs were *p*-type semiconductors, and importantly, by surveying a large number of devices, the abundance of semiconducting nanotubes was estimated to be more than 97 %, in contrast to the nearly two thirds abundance of semiconducting nanotubes in pristine C-SWNTs.

The influence of substitutional B and/or N dopants on the electrical transport properties of nanotubes, the localized transport phenomena, and the problem of resonant scattering are general concerns [49–51]. For isolated substitutional B or N dopants, it is commonly accepted that they will not only transfer holes or electrons to the graphitic C lattice but also give rise to quasibound impurity states [49–51]. In this vein, the electronic quantum conductance will be reduced and strong localization may set in: the mean-free path of electrons would be drastically damped around the corresponding quasibound state energies whereas pristine nanotubes display ballistic behavior [49–51]. However, in the B–N pairs co-doping tubes, Khalfoun et al. recently reported an interesting finding that that a pair of adjacent B and N atoms was practically transparent for conducting electrons close to the Femi level [52]. In other words, the substitution of a B–N pair in the C lattice does not significantly modify the quantum transport of the nanotubes at low gate voltage [52].

Concluding Remarks

Light-element nantoubes and related structures constitute a fertile research area that awaits further experimental and theoretical efforts. From a fundamental viewpoint, doped nanotubes provide model systems for understanding dopant-induced perturbations on the physical properties of one-dimensional electron systems. Meanwhile, doping C nanotubes with B and N can lead to electronic properties that are more dependent on chemistry than the specific geometry of tubes. Keeping in mind the possibility of creating an entire range of ternary nanotubes intermediated between C and BN underlies a fascinating prospect for systematical band gap engineering in the ternary $B_xC_yN_z$ nanotube systems. In particular, the semiconducting $B_xC_yN_z$-SWNTs are promising candidates for envisioned applications in nanotube-based electronics and optoelectronics, sensors, and other systems. On the other hand, there is still a long way to go toward this fascinating goal due to the challenges in producing ternary SWNTs with controlled and variable B–C–N stoichiometry.

Lipid Vesicles

► Liposomes

Liposomes

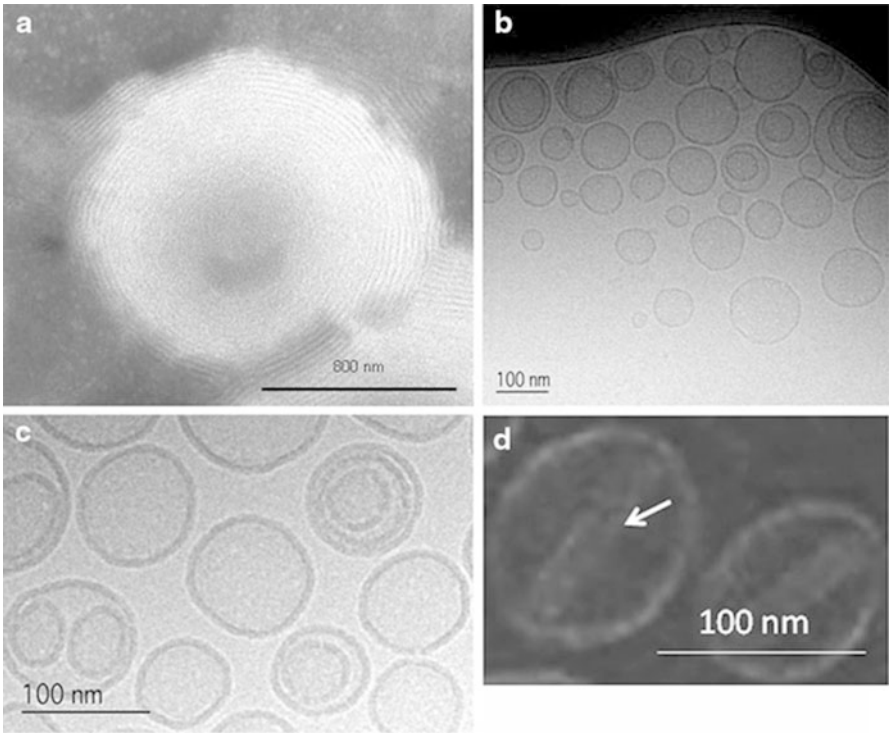
Seyed Moein Moghimi
Department of Pharmaceutics and Analytical Chemistry, Centre for Pharmaceutical Nanotechnology and Nanotoxicology, University of Copenhagen, Copenhagen, Denmark

Synonyms

Large unilamellar vesicle (LUV); Lipid vesicles; Multilamellar vesicle (MLV); Small unilamellar vesicle (SUV)

Definition

Liposomes are vesicular structures of colloidal dimension, consisting of amphiphilic lipid forming bilayers enclosing part of the aqueous phase in which they are dispersed. The lipids used are predominantly glycerophospholipids and/or sphingophospholipids; liposomes therefore exhibit many of the properties of natural membrane-bounded structures. Liposomes are characterized by their membrane composition, morphology, and particle size distribution. Liposomes have diverse applications in science, engineering, and medicine.



Morphology

Morphologically, one may distinguish between small (S), large (L), giant (G), unilamellar (U), oligolamellar (O), and multilamellar (ML) vesicles (V) [1, 2]. Small unilamellar vesicles (SUVs) are composed of a single lipid bilayer and are typically below 100 nm in size, whereas large and giant terminology are indicative of liposomes larger than 100 nm (but below 1 μm), and 1 μm or larger, respectively. Oligolamellar morphology refers to vesicles composed of between two and five concentric lamellae, whereas liposomes containing more than five lamellae are typically called multilamellar vesicles (MLVs). There are other combinations such as multivesicular liposomes in which smaller liposomes are entrapped in larger vesicles. Figure 1 represents different liposomal morphologies.

Many physicochemical characteristics of liposomes are controlled by their morphology and size [1, 3, 4]. These include encapsulated volume, thermotropic behavior, leakage, aggregation, deformability, and stability. For example, the fraction of encapsulated volume in LUVs is much higher than in SUVs at the same lipid concentration; the entrapped volume increases with $(r-\delta)^3$ where r is the vesicular radius and δ is the thickness of the membrane. SUVs are also less stable due to stored tension compared with LUVs. The membrane of SUVs can freeze only partially where regions of unfrozen lipids at the edges make vesicles more deformable and unstable; at high temperature phase SUVs are rigid spheres. Both LUVs and GUVs, however, become deformable in the liquid crystalline phase.

Historical Background

Liposomes were first observed by Alec Bangham and colleagues in the early 1960s [5] as lipid

Liposomes, Fig. 1 Micrographs representing different liposomal morphologies. A transmission electron micrograph (*TEM*) of MLV preparation (**a**), cryo-TEM images showing a plethora of different morphologies (SUVs, LUVs, OVs, and multivesicular liposomes) (**b** and **c**) (Courtesy of Dr. Thomas L. Andresen, Technical University of Denmark), and a cryo-TEM image of regulatory approved Doxil® (**d**) showing stacks of precipitated doxorubicin in the centre of oval-shaped vesicles (*arrow*)

spherules (the form when viewed by negative staining technique in the electron microscope) capable of trapping whatever ionic species that was dissolved in the aqueous phase at the time of their formation. They further realized that these structures were osmotically active and could exhibit different permeability properties to different molecules and ions. The term "liposome" was first used in 1967.

Historically, however, Virchow in 1854 under polarizing microscope recorded the formation of normal and helical myelin figures following swelling of dry lipids. Lehmann, at the turn of the twentieth century produced a micrograph, which today is referred to as MLVs. In 1934, a British patent also described drug depots composed of lecithin, cholesterol, and water.

Geometrical Packing of Amphiphiles

A useful parameter (but with limitations) in predicting the aggregate shape of amphiphilic molecules is a packing parameter P (2), defined as:

$$P = v/a_l$$

where v is the volume of the molecule, a is the area occupied by the polar head group, and l the length of the hydrocarbon chain(s). For single-chain amphiphiles (e.g., soaps, lysophospholipids) the polar head is relatively large with respect to the nonpolar segment and pack either into spherical $\left(P < \frac{1}{3}\right)$ or rod-like $\left(\frac{1}{3} < P < \frac{1}{2}\right)$ micelles (aggregates of colloidal dimension that exists in equilibrium with the molecules that they are formed). With double-chained lipids

(phosphatidylcholine, phosphatidylserine, dicetylphosphate, sphingomyelin) $P \sim 1$ (cylindrical shape) and pack into lamellar structures such as liposomes. Lipids with relatively small polar heads ($P > 1$, cone shaped) tend to pack into inverse structures; examples include phosphatidylethanolamine, phosphatidic acid, cardiolipin, and cholesterol. The packing model is often useful in cases of different lipid mixtures where an average P can be defined as:

$$P = \sum\nolimits_i n_i P_i$$

where *ni* are mol fractions. For instance equimolar mixtures of phosphatidylethanolamine with cholesterol or lyso lipids can form liposomes.

Methods of Liposome Preparation

There are numerous methods for liposome preparation and these have been reviewed extensively [2, 3]. The method of choice usually depends on the lipid composition, the desired morphology or the sensitivity of the material to be encapsulated. Also, the same type of liposomes prepared by different methodologies may exhibit different properties to include encapsulation efficacy, bilayer permeability, and vesicular stability in vitro and in vivo.

The most common applied method for the laboratory-scale liposome preparation is the thin-film hydration, which yields predominantly very heterogeneous populations of MLVs and some SUVs, GUVs, and GOVs. The procedure begins by dissolving lipids in an organic solvent usually chloroform (chloroform normally contains 1 % ethanol; however, the use of pure chloroform should be avoided as this may cause lipid peroxidation). If charged lipids are present, addition of methanol (20–30 vol%) aids solubilization and most lipid mixtures are soluble in this solvent combination. Methanol, however, forms hydrogen bonds with the phospholipid polar heads and is difficult to remove. Therefore, inclusion of methanol is only recommended if absolutely necessary. For instance, for preparation of giant liposomes, it is necessary that solvent evaporates slowly resulting in the formation of a very smooth lipid film; for such cases larger amounts of methanol are used. Once the lipids are thoroughly mixed in the organic solvent, the solvent is removed by rotary evaporation yielding a thin lipid film on the sides of a round bottom flask. After removal of residual solvent, by placing the flask on a vacuum pump overnight, the film is hydrated by addition of an appropriate volume of an aqueous medium (that may contain a water-soluble drug for encapsulation) and agitation from a few minutes to several hours. The temperature of the aqueous phase should be above the gel-liquid crystal transition temperature (Tc) of the lipid with the highest Tc. Lipid composition, the type of aqueous media, and energy and power of agitation all influence vesicular morphology and size distribution. For instance, charged bilayers yield smaller and less lamellar liposomes.

A relatively homogeneous population of liposomes composed of a single bilayer can be produced by extruding the MLV preparation through a filter with well-defined pore sizes under high pressure (up to 100 atm) in a high-pressure cell or alternatively by sonication (e.g., probe sonication). Repeated extrusions tend to decrease the number of lamellae. In the case of not fully hydrated liposomes large myelin figures of greater than 10 μm may grow from the cylindrical worm-like structures into solution. The nonencapsulated aqueous cargo can then be removed by dialysis or gel-permeation chromatography. Hydrophobic and amphiphilic molecules or drugs can be associated with the bilayer during any of these steps.

Other methodologies for liposome preparation include detergent depletion techniques, solvent (ethanol, ether) injection, and demulsification (reverse-phase evaporation, double emulsions) [2, 3]. In addition to these, there are methods that use already preformed vesicles to prepare vesicles with higher encapsulation efficiencies of water-soluble molecules [2, 3]. These methods are based on freeze-thawing or dehydration-rehydration of SUVs or on fusion of SUVs induced by fusogenic agents. For instance SUVs made from phosphatidylserine (PS) fuse into cylindrical rolls in the presence of Ca^{2+} at

concentrations slightly above the half of PS concentration. Such entities are referred to as cochleate cylinders; chelation of calcium by EDTA or its removal by ion exchange results in the formation of LUVs.

Some advanced nanotech-based methodologies for liposome preparation includes inkjet printing and controlled microfluidic mixing and nanoparticle determination (COMMAND) [6, 7]. The latter utilizes microfluidic hydrodynamic focusing to precisely control the convective-diffusive mixing of miscible liquids under laminar flow, which provides a method for both on-chip liposome preparation and the controlled experimental investigation of self-assembly process of lipid molecules into vesicles. A key advantage of COMMAND use is the elimination of size homogenization post-processing procedures. COMMAND allows controlled formation of vesicles in the size range of 50–150 nm with relative standard deviations ranging from <10 % for smaller vesicle distributions to <20 % for larger vesicle distributions.

A Proposed Mechanism for MLV Formation

In contact with water, the outer monolayer of dry phospholipid film hydrates more rapidly than the inner layers resulting in the formation of convex contusions, since the surface area of polar heads increases with the increasing hydration. Due to water penetration bilayers grow from contusions into tubular fibrils thus exposing polar heads to water maximally. Fibrils may further grow into helices if there are packing defects at one side of the primary contusion as this induces torque. The bilayers are subsequently stabilized into their equilibrium distance. Following agitation, tubular fibrils detach and immediately seal off their exposed edges to form MLVs.

Related Structures

Two commonly related structures to liposomes are niosomes and polymersomes. Niosomes (also known as nonionic liposomes) are composed from diacyl or monoacyl polyglycerol or polyoxyethylene-based amphiphiles in mixtures with cholesterol and prepared by similar methods to liposomes. Polymersomes are self-assembled polymer shells that are composed of block copolymer amphiphiles. By tailoring the block lengths and chemistry, the physicochemical characteristics of polymersomes such as permeability, contents release rates, and stability can be manipulated.

Biological and Medical Applications of Liposomes

Due to their versatile nature, physicochemical properties and morphological characteristics liposomes have long been served as useful model systems in many fundamental biochemistry, biophysics, cell biology, and immunological studies [2]. These include biochemical investigations of conformational and function of membrane proteins (e.g., ion pumps like ATPases), membrane fusion processes and biological recognition events, vesicular budding and pinching-off mechanisms that operate in Golgi apparatus, exocytosis and formation of synaptic vesicles, and artificial photosynthetic models.

The benefits and applications of liposomes in medicine are numerous [8–11]. The use of liposomes as drug delivery systems substantially influences pharmacokinetics and biodistribution of the drug. In several cases this can be used to improve the therapeutic efficacy and minimize drug-related adverse effects. For such applications, liposomes can be formulated as suspension, lyphophilized powder for reconstitution, aerosol, cream or lotion, and therefore practically amenable for all routes of administration into the body. However, the vast majority of liposomal medical applications uses parenteral injection [8, 10, 11], where the main applications include:

1. Improved solubility of lipophilic and amphiphilic drugs (or even emulsions).
2. Encapsulation of certain hydrophilic drugs at concentrations several fold above their

aqueous solubility as a result of drug precipitation or gel formation inside the liposome with appropriate substances encapsulated (Fig. 1d).

3. Passive targeting to macrophages in contact with the blood, notably the Kupffer cells (also known as hepatic sinusoidal macrophages) and macrophages located at the marginal zone and the red-pulp regions of the spleen [10]. This offers an unprecedented approach for precision targeting, delivery and release of metabolic enzymes, antimicrobials, toxins, immunomodulators, and immunosuppressive agents for treatment and disorders of the macrophage system as well as for modulating their accessory functions (e.g., tumoricidal function). Indeed, the idea and the application of liposomes for enzyme replacement therapy was put forward and tested soon after their discovery [12, 13]. First patients injected with liposomes in 1974.
4. Passive accumulation at pathological sites where the integrity of endothelial barrier is perturbed by inflammatory process (e.g., infection, infarction) or by tumor growth. For such applications, the surface of liposomes are often engineered with hydrophilic polymers such as poly(ethylene glycol) as this will dramatically reduce macrophage interception, which results in prolonged liposomal circulation times within the vasculature and better opportunities for liposome extravasation from the blood into pathological regions [10, 11].
5. Site-specific targeting to accessible cells and structures within the vasculature (or beyond) following grafting of biological recognition molecules such as monoclonal antibodies, saccharides, peptides, etc., to specialized lipids incorporated into the liposomal bilayer [10, 11, 14]. Here, target sites have included vascular endothelial cells, blood cells such as erythrocytes, lymphocytes, and platelets, as well as circulating tumor cells.
6. Controlled intracellular release of therapeutic agents such as nucleic acids as well as antigens with triggered-release vesicles (e.g., pH-sensitive, fusogenic liposomes, light-sensitive liposomes). For example, pH-sensitive liposome maintains stable structure at neutral pH but destabilizes at low endosomal (intracellular vesicles formed from the cell membrane, which are involved in intracellular transport) pH. This subsequently disrupts endosomal integrity causing cargo release into cytoplasm [15]. Indeed, antigen delivery to the cytosol of dendritic cells, and hence channeling into the major histocompatibility complex class I route is dramatically enhanced by triggered release in late endosomes with the aid of pH-sensitive and fusogenic liposomes.
7. Controlled extracellular drug release at pathological sites such as infections and solid tumors with specialized formulations (temperature-sensitive liposomes, phospholipase A2-sensitive liposomes).
8. Slow-release system within the blood (intravenous administration) or at selected sites following local administration.
9. As adjuvant (an immune potentiator that triggers early immune responses that subsequently assist the generation of potent and persistent adaptive immune responses) for vaccines following intramuscular and subcutaneous routes of administration. Liposomes further offer antigen protection from degradation and elimination following local injection [8].
10. Site-avoidance systems where drug encapsulation offers protection to the drug vulnerable sites (e.g., doxorubicin-mediated cardiotoxicity, amphotericin B-mediated nephrotoxicity); following intravenous injection liposomes do not accumulate appreciably in the heart, kidneys, and the brain [8].
11. Medical imaging and diagnostics following encapsulation of grafting of contrast agents (as in magnetic resonance imaging).
12. Lubrication systems for joints.
13. Artificial oxygen delivery systems.

Table 1 lists some examples of regulatory approved liposomal formulations for infusion into human subjects for treatment of selected cancers and infections. In addition to the above-

Liposomes, Table 1 Examples of regulatory approved (Food and Drug Administration, USA) liposomal products in the market

Product	Liposome type	Lipids[a]	Active ingredient	Indication(s)
Doxil® (approved 1995)	Stealth SUV	mPEG-DSPE, HSPC, cholesterol	Doxorubicin hydrochloride	Treatment of patients with ovarian cancer whose disease has progressed or recurred after platinum-based chemotherapy
				AIDS-related Kaposi's sarcoma after failure of prior systemic chemotherapy or intolerance to such therapy
				Multiple myeloma in combination with bortezomib in patients who have not previously received bortezomib and have received at least one prior therapy
DaunoXome® (approved 1996)	SUV	DSPC and cholesterol	Daunorubicin citrate	Advanced AIDS-related Kaposi's sarcoma
Ambisome® (approved 1997)	SUV	HSPC, cholesterol, DSPG, α-tocopherol	Amphotericin B	Empirical therapy for presumed fungal infection in febrile, neutropenic patients
				Treatment of *Cryptococcal* Meningitis in HIV-infected patients
				Treatment of patients with *Aspergillus* species, *Candida* species and/or *Cryptococcal* species refractory to amphotericin B deoxycholate, or in patients where renal impairment or unacceptable toxicity precludes the use of amphotericin B deoxycholate
				Treatment of visceral leishmaniasis
Depocyte® (approved 1999)	Multivesicular	Cholesterol, triolein, DOPC, DPPG	Cytarabine	Intrathecal treatment of lymphomatous meningitis

[a]*mPEG-DSPE N*-(carbonyl-methoxypolyethylene glycol 2000)-1,2-distearoyl-*sn*-glycero3-phosphatidylethanolamine sodium salt, *HSPC* hydrogenated soy phosphatidylcholine, *DSPC* distearoylphosphatidylcholine, *DSPG* distearoylphosphatidylglycerol, *DOPC* dioleoylphosphatidylcholine, *DPPG* dipalmitpoylphosphatidylglycerol

mentioned applications, liposomes are also used as in vitro diagnostics (e.g., rapid screening test for coagulation system with liposomes containing recombinant human tissue factor).

Other Applications

Liposomes have received considerable attention in cosmetics (for skin moisturizing and delivery of humectants, nutrients, enzymes, etc., in to the skin) as well as in agro-food industry (e.g., as sustained release systems for enzymes in various fermentation processes and in the preservation of cheeses, sustained release systems for biocides), environmental cleaning and protection (e.g., delivery of agents to oil spills to speed up the degradation), and paint industry.

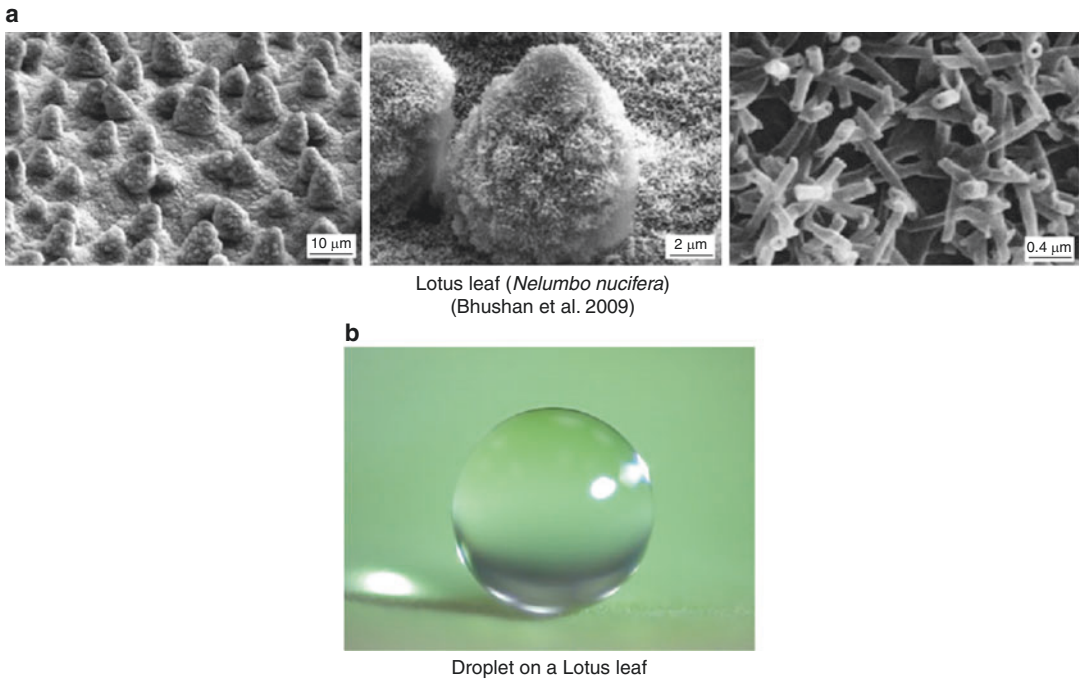
[2]Department of Mechanical Engineering, University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Synonyms

Self-cleaning; Superhydrophobicity



Definition

Lotus effect is surface roughness–induced superhydrophobicity and self-cleaning. These surfaces have a water contact angle (CA) larger than 150° and a low (usually <5°) contact angle hysteresis. These surfaces also exhibit low drag during fluid flow.

Introduction

Superhydrophobic surfaces with a high static contact angle above 150° and contact angle hysteresis of less than 10° exhibit extreme water repellence and self-cleaning properties [1–4]. At a low value of contact angle hysteresis, the droplets may roll in addition to slide which facilitates removal of contaminant particles. Surfaces with low contact angle hysteresis have a low water roll-off (tilt) angle, which denotes the angle to which a surface must be tilted for roll off of water drops. These surfaces exhibit low drag during fluid flow. Superhydrophobic and self-cleaning surfaces are of interest for various applications including self-cleaning windows, windshields, exterior paints for buildings and navigation of ships, utensils, roof tiles, textiles, solar panels, and applications requiring antifouling and a reduction of drag in fluid flow, e.g., in micro/nanochannels. These surfaces can also be used for energy conversion and energy conservation [1]. Condensation of water vapor from the environment and/or process liquid film can form menisci, leading to high adhesion in devices requiring relative motion. Superhydrophobic surfaces are needed to minimize adhesion between a surface and liquid.

A model surface for superhydrophobicity and self-cleaning is provided by the leaves of the Lotus plant (*Nelumbo nucifera*) (Fig. 1a) [3]. The leaf surface is very rough due to so-called papillose epidermal cells, which form asperities or papillae. In addition to the microscale roughness the surface of the papillae is also rough with submicron sized asperities composed of 3-D epicuticular waxes. The waxes of Lotus are tubules, but on other leaves waxes exist also in the form of platelets or other morphologies. Lotus leaves have hierarchical structures. The water droplets on these surfaces readily sit on the apex of nanostructures because air bubbles fill in the valleys of the structure under the droplet. Therefore, these leaves exhibit considerable superhydrophobicity (Fig. 1b). The water droplets on the leaves remove any contaminant particles from their surfaces when they roll off, leading to self-cleaning. It has been reported that nearly all superhydrophobic and self-cleaning leaves

Lotus Effect, Fig. 1 (**a**) SEM micrographs (shown at three magnifications) of Lotus (*Nelumbo nucifera*) leaf surface which consists of microstructure formed by papillose epidermal cells covered with 3-D epicuticular wax tubules on surface, which create nanostructure, and (**b**) image of water droplet sitting on the Lotus leaf [3]

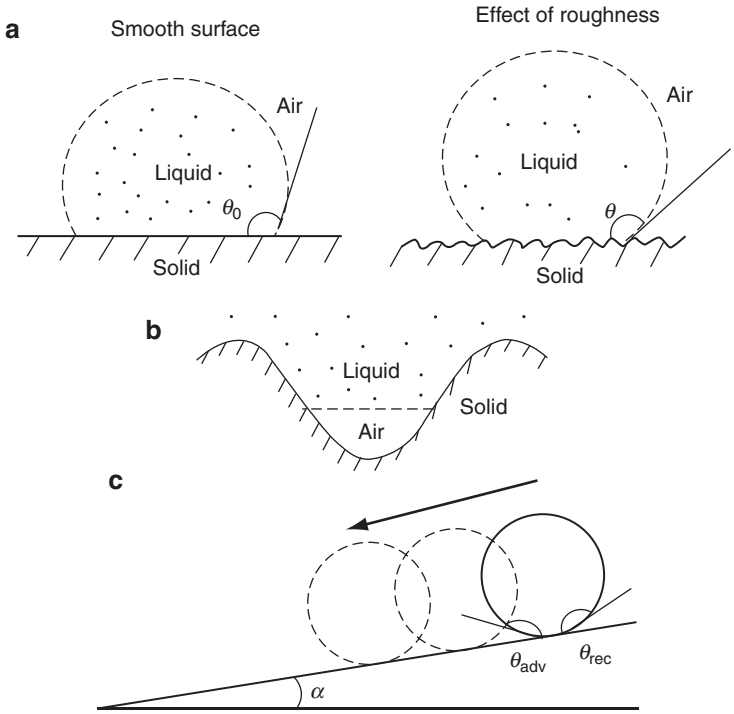
consist of an intrinsic hierarchical structure. Water on such a surface forms a spherical droplet, and both the contact area and the adhesion to the surface are dramatically reduced.

Based on the Lotus effect, one of the ways to increase the hydrophobic property of the surface is to increase surface roughness, so roughness-induced hydrophobicity has become a subject of extensive investigations.

Modeling of Contact Angle for a Liquid in Contact with a Rough Surface

As stated earlier, superhydrophobic and self-cleaning surfaces should have both high contact angle and low contact angle hysteresis. Liquid may form either a homogeneous interface with a solid, or a composite interface with air pockets trapped between the solid and liquid. In this section, mathematical models which provide relationships between roughness and contact angle are discussed.

Homogeneous (Wenzel) Interface



Consider a rough solid surface with a typical size of roughness details smaller than the size of the droplet as shown in Fig. 2a. For a droplet in contact with a rough surface without air pockets, referred to as a homogeneous interface, the contact angle is given as [5]

$$\cos\theta = R_f \cos\theta_0 \tag{1}$$

where θ is the contact angle for a rough surface, θ_0 is the contact angle for a smooth surface (Fig. 2a), and R_f is a roughness factor defined as the ratio of the solid–liquid area A_{SL} to its projection on a flat plane, A_F. The model predicts that a hydrophobic surface ($\theta_0 > 90°$) becomes more hydrophobic with an increase in R_f, and a hydrophilic surface ($\theta_0 < 90°$) becomes more hydrophilic with an increase in R_f.

Composite (Cassie-Baxter) Interface

For a rough surface, a wetting liquid will be completely absorbed by the rough surface cavities

Lotus Effect, Fig. 2 (**a**) Schematic of a liquid droplet in contact with (*top left*) a smooth solid surface (contact angle, θ_0) and (*top right*) a rough solid surface (contact angle, θ), (**b**) schematic of formation of a composite solid–liquid-air interface for a rough surface, and (**c**) tilted surface profile (tilt angle, α) with a liquid droplet; advancing and receding contact angles are θ_{adv} and θ_{rec}, respectively

while a non-wetting liquid may not penetrate into surface cavities, resulting in the formation of air pockets, leading to a composite solid–liquid-air interface as shown in Fig. 2b. Cassie and Baxter [6] extended the Wenzel equation for the composite interface, which was originally developed for the homogeneous solid–liquid interface. For this case, there are two sets of interfaces: a solid–liquid interface with the ambient environment surrounding the droplet and a composite interface involving liquid-air and solid-air interfaces. In order to calculate the contact angle for the composite interface, Wenzel's equation can be modified by combining the contribution of the fractional area of wet surfaces and the fractional area with air pockets ($\theta = 180^\circ$)

$$\cos\theta = R_f \cos\theta_0 - f_{LA}\left(R_f \cos\theta_0 + 1\right) \qquad (2)$$

where f_{LA} is fractional flat geometrical areas of the liquid-air interfaces under the droplet. According to Eq. 2, even for a hydrophilic surface, the contact angle increases with an increase of f_{LA}. At a high value of f_{LA}, a surface can become hydrophobic; however, the value required may be unachievable or formation of air pockets may become unstable. Using the Cassie-Baxter equation, the value of f_{LA} at which a hydrophilic surface could turn into a hydrophobic one is given as [1, 2]

$$f_{LA} \geq \frac{R_f \cos\theta_0}{R_f \cos\theta_0 + 1} \quad \text{for } \theta_0 < 90^\circ \qquad (3)$$

Contact Angle Hysteresis

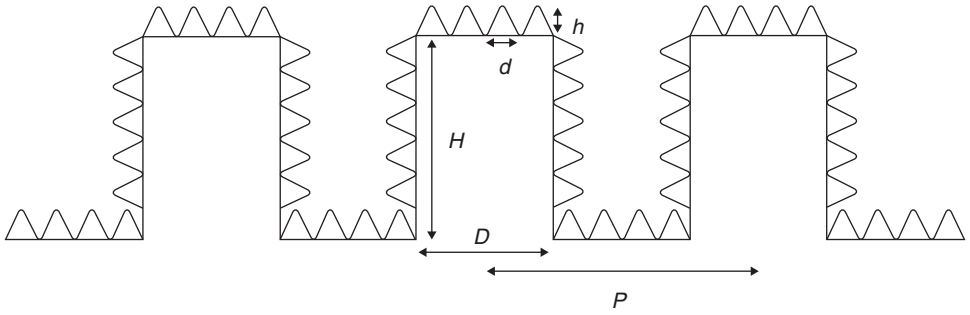
The contact angle hysteresis is another important characteristic of a solid–liquid interface. If a drop sits over a tilted surface (Fig. 2c), the contact angle at the front and back of the droplet corresponds to advancing contact angle and receding contact angle, respectively. The advancing angle is greater than the receding angle, which results in contact angle hysteresis. The contact angle hysteresis occurs due to surface roughness and heterogeneity. Although for surfaces with the roughness carefully controlled on the molecular scale it is possible to achieve a contact angle hysteresis as low as $<1^\circ$, hysteresis cannot be eliminated completely, since even atomically smooth surfaces have a certain roughness and

heterogeneity. The contact angle hysteresis is a measure of energy dissipation during the flow of a droplet along a solid surface. Surfaces with low contact angle hysteresis have a very low water roll-off angle, which denotes the angle to which a surface must be tilted for roll off of water drops. Low water roll-off angle is important in liquid flow applications such as in micro/nanochannels and surfaces with self-cleaning ability.

Bhushan et al. [2] derived a relationship for contact angle hysteresis as a function of roughness, given as

$$\theta_{\text{adv}} - \theta_{\text{rec}} = (1 - f_{LA}) R_f \frac{\cos\theta_{a0} - \cos\theta_{r0}}{-\sin\theta} = (\sqrt{1 - f_{LA}}) R_f \frac{\cos\theta_{r0} - \cos\theta_{a0}}{\sqrt{2(R_f \cos\theta_0 + 1}} \quad (4)$$

For the homogeneous interface, $f_{LA} = 0$, whereas for the composite interface f_{LA} is a nonzero number. It is observed from Eq. 4 that for a homogeneous interface, increasing roughness (high R_f) leads to increasing (high values of $\theta_{\text{adv}} - \theta_{\text{rec}}$), while for a composite interface, an approach to unity of f_{LA} provides both high a contact angle and a small contact angle hysteresis. Therefore, the composite interface is desirable for superhydrophobicity and self-cleaning.



Stability of a Composite Interface and Role of Hierarchical Structure

Formation of a composite interface is a multiscale phenomenon which depends upon the relative sizes of the liquid droplet and roughness details. The composite interface is metastable, and its stability is an important issue. Even though it may be geometrically possible for the system to become composite, it may be energetically profitable for the liquid to penetrate into the valleys between asperities and form the homogeneous interface. The composite interface is fragile and can be irreversibly transformed into the homogeneous interface, thus damaging superhydrophobicity. In order to form a stable composite interface with air pockets between solid and liquid, the destabilizing factors such as capillary waves, nanodroplet condensation, surface inhomogeneity, and liquid pressure should be avoided. For high f_{LA}, a nanopattern is desirable because whether the liquid–air interface is generated depends upon the ratio of distance between two adjacent asperities and droplet radius. Furthermore, nanoscale asperities can pin liquid droplets and thus prevent liquid from filling the valleys between asperities. High R_f can be achieved by both micropatterns and nanopatterns.

Nosonovsky and Bhushan [1] have studied destabilizing factors for the composite interface and found that a convex surface leads to a stable interface and high contact angle. Also, they have suggested the effects of a droplet's weight and curvature among the factors which affect the transition. They have demonstrated that a combination of microroughness and nanoroughness (multiscale roughness) with convex surfaces can help to resist destabilization by pinning the interface. It also helps in preventing the gaps between the asperities from filling with liquid, even in the case of a hydrophilic material. The effect of roughness on wetting is scale dependent, and mechanisms that lead to destabilization of a composite interface are also scale dependent. To effectively resist these scale-dependent mechanisms, it is expected that a multiscale roughness is optimum for superhydrophobicity.

Ideal Surfaces with Hierarchical Structure

For stability of a composite interface, Bhushan et al. [2] suggested the structure of an ideal hierarchical surface as shown in Fig. 3. The asperities should be high enough that the droplet does not touch the valleys. As an example, for a structure with circular pillars, the following relationship should hold for a composite interface. For a droplet with a radius on the order of 1 mm or larger, a value of H on the order of 30 μm, and D on the order of 15 μm, a P on the order of 130 μm is optimum. Nanoasperities can pin the liquid–air interface and thus prevent liquid from filling the valleys between asperities. They are also required to support nanodroplets, which may condense in the valleys between large asperities. Therefore, nanoasperities should have a small pitch to handle nanodroplets, less than 1 mm down to few nm radius. Values of h on the order of 10 nm and d on the order of 100 nm can be easily fabricated.

Lotus Effect, Fig. 3 Schematic of structure of an ideal hierarchical surface. Microasperities consist of circular pillars with diameter *D*, height *H* and pitch *P*. Nanoasperities consist of pyramidal nanoasperities of height *h* and diameter *d* with rounded tops [3]

Artificial Lotus-Effect Surfaces

Two main requirements for a superhydrophobic surface are that the surface should be rough and that it should have a hydrophobic (low surface energy) coating. These two requirements lead to two methods of producing a superhydrophobic surface: first, it is possible to make a rough surface from an initially hydrophobic material and, second, to modify a rough hydrophilic surface by modifying surface chemistry or applying a hydrophobic material upon it. Note that roughness is usually a more important property than a low surface energy, since both moderately hydrophobic and very hydrophobic materials can exhibit similar wetting behavior when roughened [1].

In general, the same techniques that are used for micro- and nanostructure fabrication, such as lithography, etching, and deposition, have been utilized for producing superhydrophobic surfaces (Table 1). Pros and cons of these techniques are summarized in Table 2. An especially interesting development is the creation of switchable surfaces that can be turned from hydrophobic to hydrophilic by applying electric potential, heat, or ultraviolet (UV) irradiation. Another important requirement for potential applications to optics and self-cleaning glasses is the creation of transparent superhydrophobic surfaces. In order for the surface to be transparent, roughness details should be smaller than the wavelength of visible light (about 400–700 nm) [1–3].

Fabrication using Nature's Route – To verify the understanding of the mechanism responsible for the Lotus effect, first structures using nature's routes were fabricated to verify that contact angle data of the fabricated structures were comparable to that of the Lotus leaves found in nature. Bhushan et al. [3] fabricated surfaces with a hierarchical structure with micropatterned epoxy replicas, and Lotus leaf microstructure, and created a second level of structuring with wax platelets and wax tubules. Platelets and tubules are the most common wax morphologies found in plant surfaces, and exist on superhydrophobic leaves, such as Lotus and *Colocasia esculenta* leaves. The structures developed mimic the hierarchical structures of superhydrophobic leaves.

A two-step molding process was used to fabricate several structurally identical copies of the micropatterned Si surface and Lotus leaves. The technique used is a fast, precise, and low-cost molding process for biological and artificial surfaces. Nanostructure was created by self-assembly of synthetic and plant waxes deposited by thermal evaporation. Hierarchical structures fabricated with microstructured Lotus leaf replicas and micropatterned Si replicas covered with a nanostructure of Lotus wax tubules are shown as Fig. 4. The grown tubules provide the desired nanostructure on microstructured surfaces. The recrystallized Lotus wax shows tubular hollow structures, with random orientation on the surfaces. Their shapes and sizes show only a few variations. The tubular diameter varied between 100 and 150 nm, and their length varied between 1,500 and 2,000 nm.

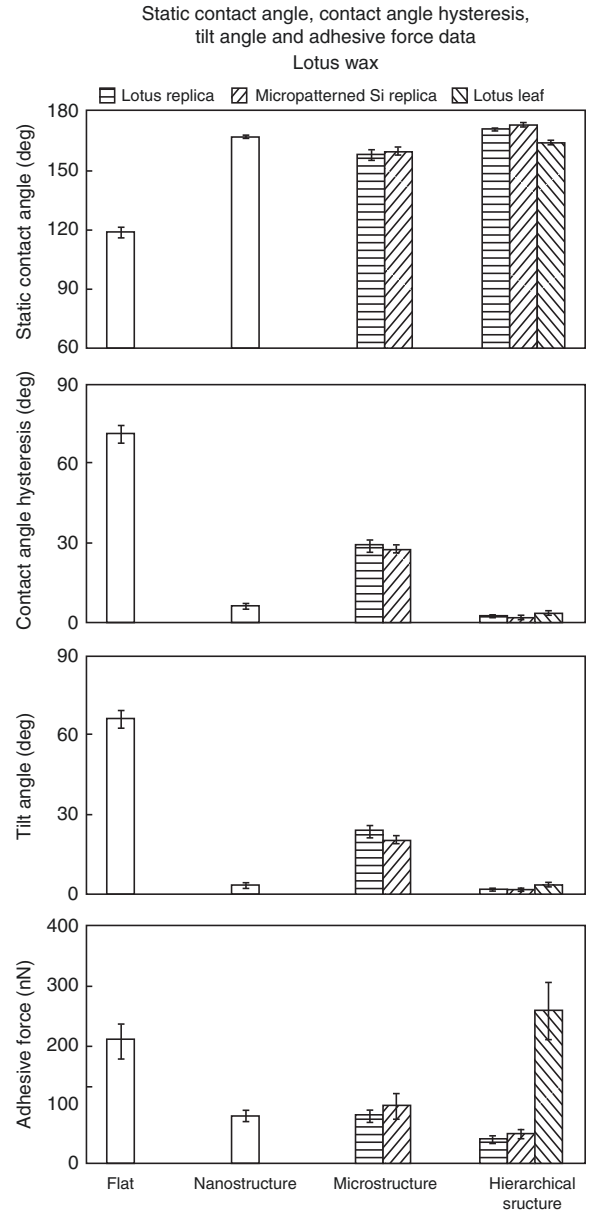
Lotus Effect, Table 2 Pros and cons of various fabrication techniques [2]

Techniques	Pros	Cons
Lithography	Accuracy, large area	Slow process, high cost
Etching	Fast	Chemical contamination, less control
Deposition	Flexibility, cheap	Can be high temperature, less control

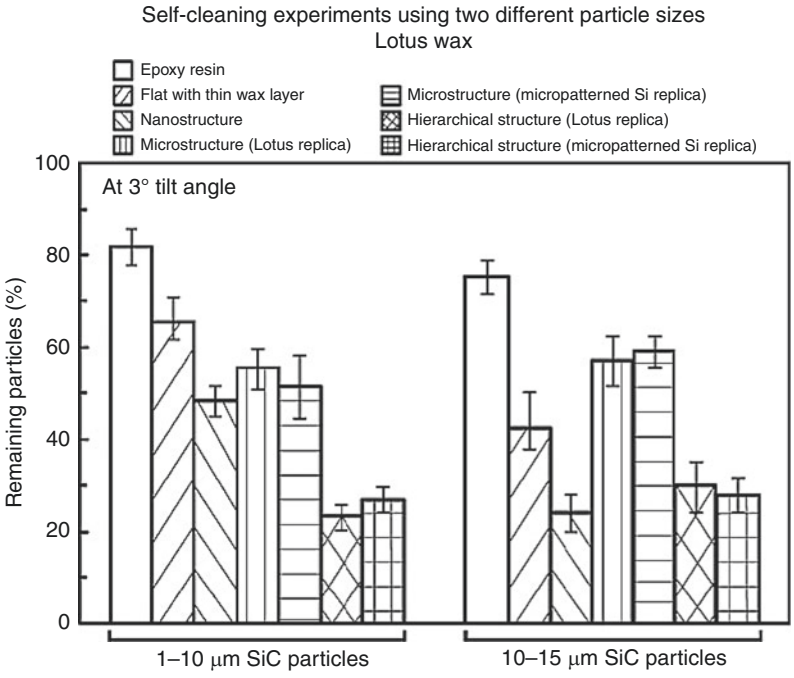
To study the effect of Lotus wax tubule nanostructures on superhydrophobicity, static contact angle, contact angle hysteresis, and tilt angle were measured on flat, microstructured Lotus replica; micropatterned Si replica; and hierarchical surfaces. Hierarchical surfaces were made of the Lotus leaf replica and micropatterned Si replica with a nanostructure of wax tubules on top. Additionally, fresh Lotus leaves were investigated to compare the properties of the fabricated structures with the original biological model. Figure 5 shows that the highest static contact angles of 173°, the lowest contact angle hysteresis of 1°, and tilt angle varying between 1 and 2° were found for the hierarchical structured Si replica. The hierarchical structured Lotus leaf replica showed a static contact angle of 171°, and the same contact angle hysteresis (2°) and tilt angles (1–2°) as the hierarchical Si replica. Both artificial



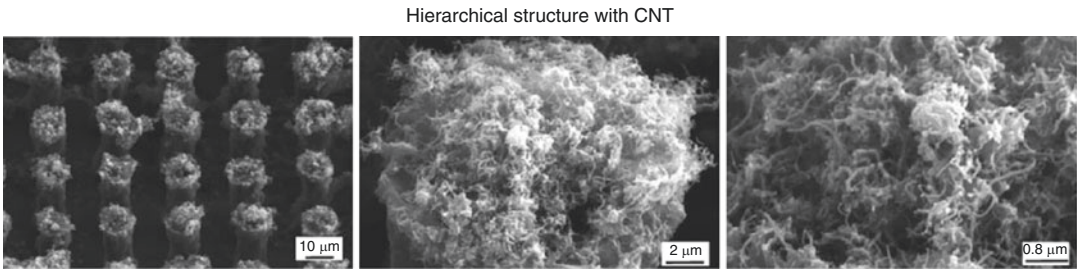
Lotus Effect, Fig. 4 SEM micrographs taken at 45° tilt angle (shown using three magnifications) of hierarchical structure using Lotus and micropatterned Si replicas. Nano- and hierarchical structures were fabricated with mass 0.8 μg mm^{-2} of Lotus wax after storage for 7 days at 50 °C with ethanol vapor [3]

hierarchical structured surfaces show similar values as the fresh Lotus leaf surface investigated here, with static contact angle of 164°, contact angle hysteresis of 3°, and a tilt angle of 3°. However, the artificial hierarchical surfaces showed higher static contact angle and lower contact angle hysteresis. Structural differences between the original Lotus leaf and the artificial Lotus leaf produced here are limited to a difference in length of wax tubules, which are 0.5–1 μm longer in the artificial Lotus leaf.

Adhesive force measured using a 15 mm radius borosilicate tip in an AFM also shows a similar trend as the wetting properties for the artificial surfaces. The adhesion force of the hierarchical surface structure was lower than that of the micro-, nanostructured, and flat surfaces because the contact between the tip and the surface was lower as a result of the contact area being reduced. However, for the fresh Lotus leaf, there is moisture within the plant material that causes softening of the leaf, and so when the tip comes into contact with the leaf sample, the sample deforms, and a larger area of contact between the tip and the sample causes an increase in the adhesive force.



To test self-cleaning efficiency of hierarchical structured surfaces, silicon carbide particles in two different size ranges of 1–10 and 10–15 μm used as the contaminant were deposited. SiC particles were chosen because of their similarity in shape, size, and hydrophilicity to natural dirt contaminations. For the cleaning test, specimens with the contaminants were subjected to water droplets of approximately 2 mm diameter, using two microsyringes. Figure 6 shows that none of the investigated surfaces was fully cleaned by water rinsing. The data represent the average of five different investigated areas for each experiment. Most particles (70–80 %) remained on smooth surfaces, and 50–70 % of particles were found on microstructured surfaces. Most particles were removed from the hierarchical structured surfaces, but approximately 30 % of particles remained. A clear difference in particle removal, independent of particle sizes, was only found in flat and nanostructured surfaces, where larger particles were removed with higher efficiency. Observations of droplet behavior during movement on the surfaces showed that droplets rolled only on the hierarchical structured surfaces. On flat, micro-, and nanostructured surfaces, the droplets first applied did not move, but the continuous application of water droplets increased the droplet volumes and led to sliding of these large droplets.

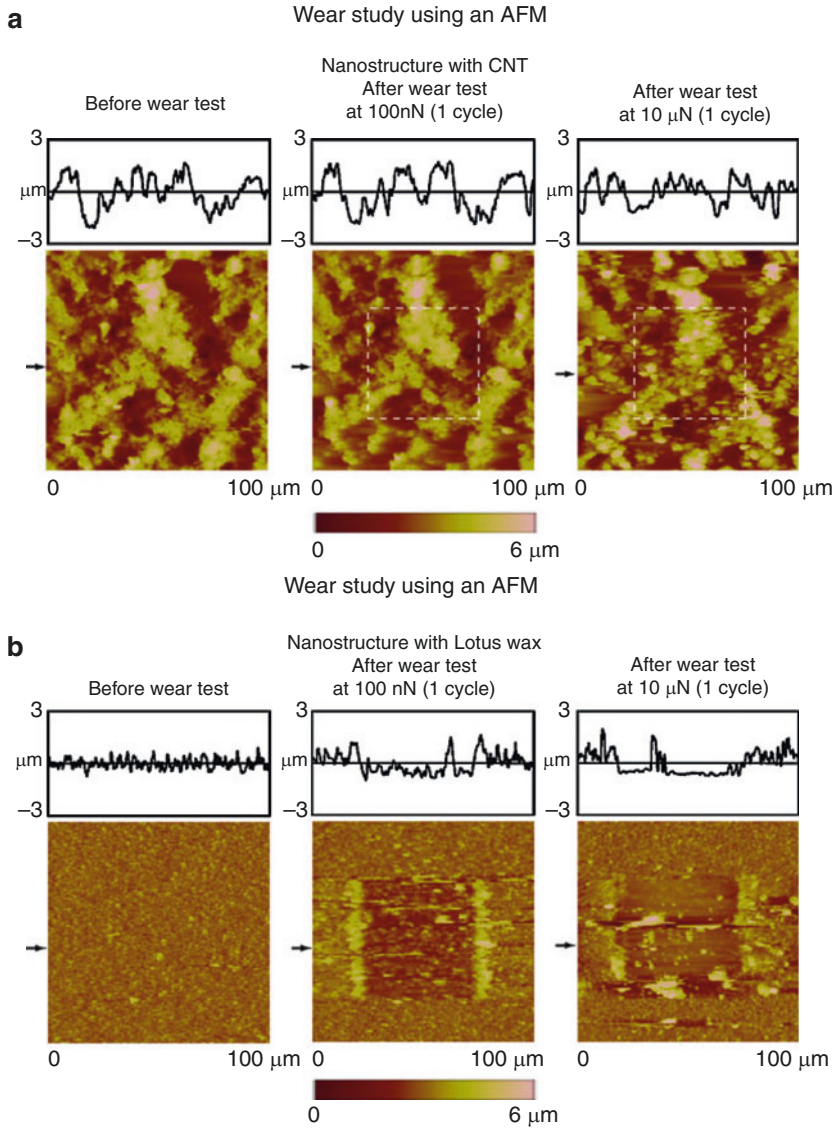


Lotus Effect, Fig. 5 (**a**–**c**) Bar charts showing the measured static contact angle, contact angle hysteresis and tilt angle on various structures fabricated with 0.8 μg mm^{-2} mass of Lotus wax after storage at 50 °C for 7 days with ethanol vapor. (**d**) Bar chart showing the adhesive forces for various structures, measured using a 15 μm radius borosilicate tip. Hierarchical structures were fabricated using Lotus and micropatterned Si replicas superimposed with nanostructures of Lotus wax tubules. The error bar represents ±1 standard deviation [3]

During this, some of the particles were removed from the surfaces. However, rolling droplets on hierarchical structures did not collect the dirt particles trapped in the cavities of the microstructures. The data clearly show that hierarchical structures have superior cleaning efficiency.

Fabrication of Durable Surfaces – For many commercial applications, the surfaces should have mechanical strength and chemical stability. Jung and Bhushan [7] prepared hierarchical superhydrophobic structures using carbon nanotube (CNT) – epoxy composite applied by spray method. Figure 7 shows SEM micrographs taken of the CNT-epoxy composite at three magnifications. The surface shows a homogeneous distribution of CNTs. As a benchmark, structured surfaces

The experiments on the surfaces with Lotus wax were carried out on stages tilted at 3°. The error bars represent ±1 standard deviation [3]



Lotus Effect, Fig. 7 SEM micrographs taken at 45° tilt angle showing three magnifications of hierarchical structures fabrication with CNT-epoxy composite [7]

with Lotus wax were also prepared to compare with the durability of CNT composite structures. To investigate the durability, wear tests were conducted by using an atomic force microscopy over 50 × 50 μm^2 area at two nominal loads of 100 nN and 10 μN. Figure 8 shows surface height maps before and after wear tests. These superhydrophobic CNT composite structures showed good mechanical durability, superior to the structured surfaces with Lotus wax. These structures may be suitable for real-world applications.

Closure

The Lotus effect provides one of the most successful examples of biomimetic surface effects. While theoretical foundations of wetting of rough surfaces have been developed decades ago, emerging applications and the need to design non-sticky surfaces has led to the intensive modeling and experimental research in the area. These findings provide new insights on the fundamental mechanisms of wetting and can lead to creation of successful nonadhesive surfaces.

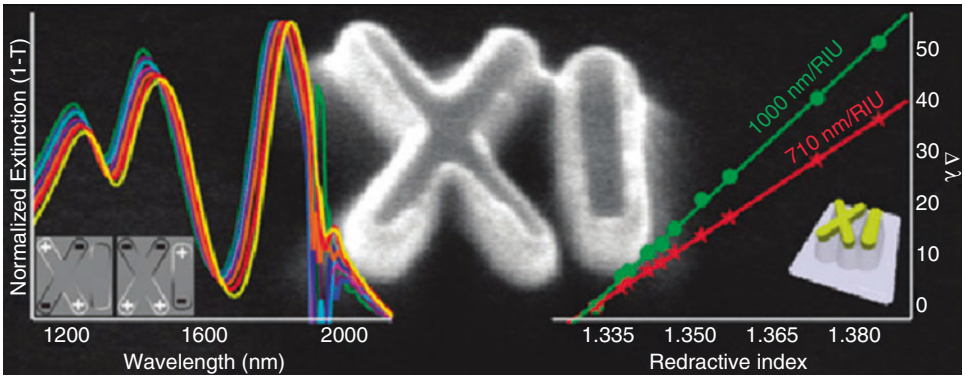
Definition

A localized surface plasmon resonance sensing device allows probing a modification in the properties of a surface plasmon mode supported by a metal nanoparticle, in order to extract information on its local environment. For example, metal nanoparticles functionalized with a specific receptor will present a shift of their plasmon wavelength when the target molecule attaches to the metal interface.

Context

Plasmonics emerged mostly in the 1990s as an extremely rich new domain in optics, exploiting the particular optical modes supported by metal nanoparticles. When such a system is excited by an external light source, a resonant coupling between the surface charge of the metal-free electrons and the electromagnetic field scattered by the particle takes place at a specific wavelength, resulting in the excitation of a so-called localized surface plasmon (LSP) [1]. These modes are characterized by the squeezing of the optical field in very small volumes with typical dimension well below the light wavelength, where the intensity of light is enhanced. Such "hotspots" are usually localized at sharp tips of metal particles [2] and inside gaps of a particle dimer [3] or confined in between a particle and a metal film [4]. Its field of

LSPR in Plasmonic Nanostructures: Theoretical Study with Application to Sensor Design, Fig. 1 Principle of a LSPR-based biosensor. An interface is decorated with metal nanoparticles, themselves functionalized with a receptor specifically associated to a target molecule. In a reference situation where all receptors are free, the plasmon wavelength is λ_{LSP}, but it shifts by $\Delta\lambda_{LSP}$ in the presence of the target molecule which will change the environment of the nanoparticle (and its refractive index) when attached to the receptor



applications is very wide, ranging from simply downscaling the conduction of light on subwavelength scale [5], improving Raman spectroscopy for single molecule detection [6], increasing the efficiency of solar cells [7], creating new treatment in medicine using thermal properties of metal nanoparticles [8], or designing an entirely new type of metamaterials with optical properties not found in nature. Moreover, surface plasmon modes are very sensitive to small variations of their local environment, which make them suitable candidates for biosensing devices with very small detection volume [9–11].

The first plasmon-based sensing devices have early been proposed by Nylander et al. [12, 13] on the principle of *propagative* surface plasmon (PSP) modes, which are surface waves traveling along the extended interface between a metal and a dielectric. PSP-based biosensing devices have already been commercialized for more than 20 years now [14] and are widely used in medicine, biology, or food safety. However, they suffer from several limitations, mostly due to their cost and difficulty of use, as this technique is mostly accessible to specialists in surface chemistry and are not easily portable, which prevent them from being more widely used as in certain immunoassays which could be routinely performed and accessible to everyone. LSPs offer a parallel route to cheaper and more flexible sensing devices, as they have large enhancement of the electric field intensity near the particle, the penetration depth of light is one order of magnitude shorter than for the PSP, and the resonance wavelength can be tuned in the visible range by modifying the shape of noble metal nanoparticles. For instance, small spherical gold spheres in water support LSPs around 520 nm with electromagnetic fields localized within a few 10 nm from their surface. That wavelength will slightly shift with as a small modification of the refractive index around the particle [15], induced, for example, by adsorption of a target molecule on its surface, as pictured in Fig. 1.

The performances of sensors based on surface plasmons are usually quantified with the refractive-index sensitivity S and the figure of merit (FoM):

$$S = \frac{\Delta\lambda_{LSP}}{\Delta n}, \quad FoM = \frac{S}{\Delta\lambda}$$

The refractive-index sensitivity is equal to the shift of the excitation wavelength per refractive

LSPR in Plasmonic Nanostructures: Theoretical Study with Application to Sensor Design, Fig. 2 Nanocross/nanobar plasmonic system and their sensitivity properties, from Verellen et al. [22]

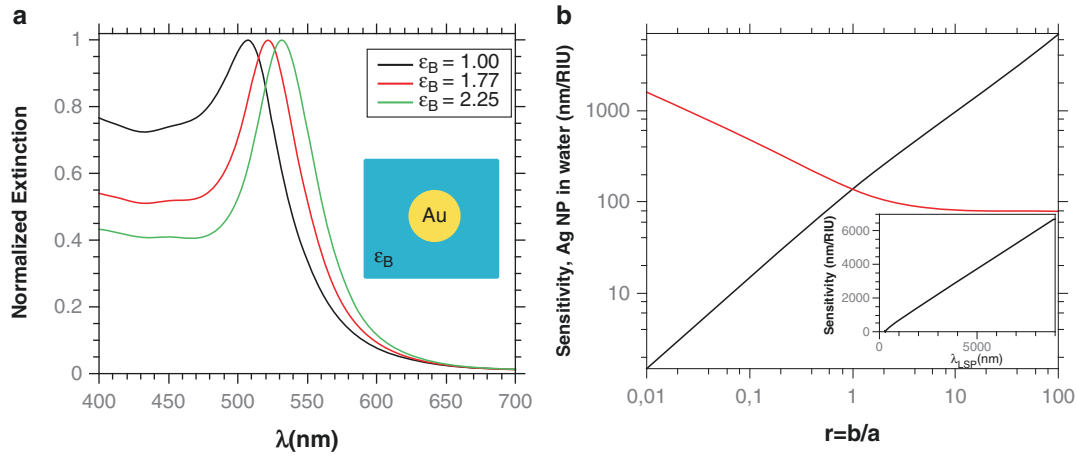
index units (RIU), whereas the figure of merit is equal to the ratio of the refractive-index sensitivity to the resonance full half width maximum (FWHM), $\Delta\lambda$. Finally, the resolution characterizes the minimum measurable variation of refractive index, in RIU.

Currently, the largest optical sensitivities are obtained with PSP-based sensors [16]. The typical device is based on the standard prism Kretschmann configuration and allows typical resolution of about $10^{-7} - 10^{-8}$ RIU, with refractive-index sensitivities of about $10^4 - 10^5$ nm/RIU. In the first place, LSP modes seem less interesting as their bulk sensitivity is much lower than for PSP modes: typically, a gold nanosphere of 50 nm in diameter exhibits an optical sensitivity of about 60 nm/RIU. However, as the detection volume is much smaller, few molecules adsorbed on the particle lead to a large wavelength shift: finally, interfacial sensitivities are much larger. A great deal of work has been done in trying to improve the sensitivity and decrease the FWHM of the plasmon resonances. The first method is to replace gold with silver, as this metal has much lower losses in the visible. This is not easy in practical because silver is easily oxidized in wet environment. In 2001, Malinsky et al. [17] demonstrated an optical sensitivity of about 150 nm/RIU for a grating of silver nanoparticles fabricated by nanosphere lithography, when particles are functionalized with self-assembled monolayers. By playing with more complex shapes, bulk refractive-index sensitivities above 800 nm/RIU were obtained in gold nanorice, nanorings, and nanocrescents [18–20]. Gold nanorice and nanocrescents showed in addition plasmonic modes located in the near-infrared region. A lot of new approaches have also been proposed more recently and demonstrated to improve the sensing performance by shifting the plasmon excitation into the near infrared. They often rely on designing complex particles supporting subradiant plasmon modes with asymmetric profiles. For example, a double split nanoring cavity designed to suppress radiative damping showed bulk sensitivities of 1200 nm/RIU [21], whereas Verellen et al. demonstrated the coherent coupling of bright and dark plasmon modes in a gold nanocross and nanobar, with bulk RI sensitivities exceeding 1,000 nm/RIU and near-infrared plasmons [22]. With a completely different approach, Lodewijks et al. [23] have recently shown that the FoM of a LSP-based sensing device could be largely increased using phase measurement. With an average refractive-index sensitivity of about 200–300 nm/RIU, they claimed linewidths one order of magnitude smaller and a FoM four to six times larger than intensity-based measurements using random ensemble of gold disks and rings (Fig. 2).

For sake of simplicity, this entry is only based on the first approaches, based on the wavelength shift of the LSP resonance.

LSPR in the Electrostatic Approximation

The basic principles of localized surface plasmon resonances and its application to sensing can be easily captured when the particle is much smaller than the wavelength of the incident light (quasistatic approximation). In that limit, a metal spherical particle of volume V with complex dielectric constant $\epsilon(\lambda)$ at wavelength λ, placed in a homogeneous transparent substrate of dielectric constant ϵ_B, is fully characterized by its polarizability $\alpha(\lambda)$:



$$\alpha(\lambda) = 3V\epsilon_B \frac{\epsilon(\lambda) - \epsilon_B}{2\epsilon_B + \epsilon(\lambda)}$$

As in the visible range of wavelengths the dielectric constant of a noble metal particle is negative, the modulus of the polarizability can reach very large values when $\Re\{\epsilon(\lambda)\} \approx -2\epsilon_B$ (in case of negligible losses), where $\Re$ is the real part. The wavelength for which the polarizability modulus is maximum corresponds to the excitation wavelength of the localized surface plasmon mode, which, in this quasistatic limit, is a dipole parallel to the direction of the incident electric field.

As an illustration, Fig. 3a shows the normalized extinction spectra, proportional to the imaginary part of $\alpha(\lambda)$, for a spherical gold nanoparticle in the quasistatic approximation in air ($\epsilon_B = 1.00$), water ($\epsilon_B = 1.77$), and silica ($\epsilon_B = 2.25$). The dielectric constant for gold was taken from [24]. Hence, the LSPR is sensitive to a change in the refractive index of the environment. The refractive-index sensitivity can be estimated to about $S = 45$ nm/RIU in that situation, which gives a FoM $= 0.75$ RIU^{-1}, quite low compared to what can be achieved with more complex designs.

The refractive-index sensitivity can be improved by working with elongated nanoparticles like spheroids or nanorods. For these geometries, the electrical field is more enhanced at the tips of the particle and an increase in the particle aspect ratio results in an increase in S. For a spheroidal particle in the quasistatic approximation, the electric field created inside the particle is generally not parallel to the induced dipole. In each i direction of the three particle main axes, the particle responds to the excitation with a polarizability equal to

$$\alpha_i = V\epsilon_B \frac{\epsilon - \epsilon_B}{\epsilon_B + L_i(\epsilon - \epsilon_B)} \quad i = 1, 2, 3$$

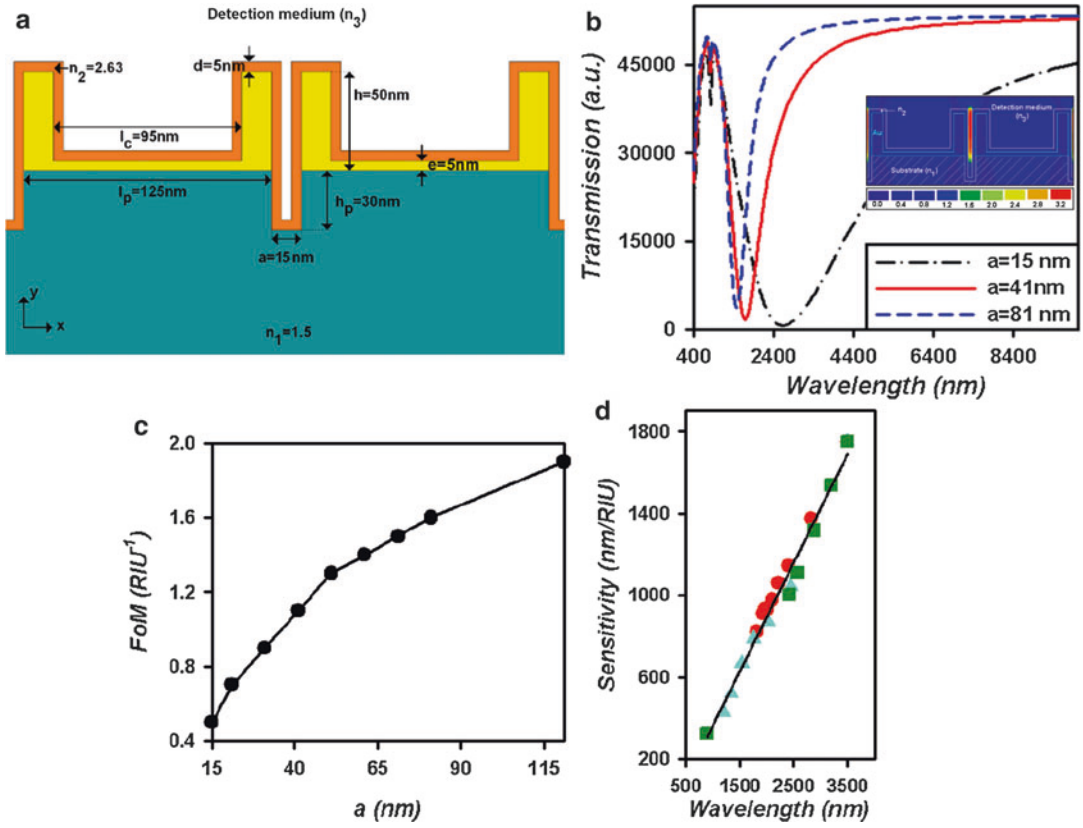
LSPR in Plasmonic Nanostructures: Theoretical Study with Application to Sensor Design, Fig. 3 **(a)** Normalized extinction spectra of a spherical gold nanoparticle inside substrates of different dielectric constant; **(b)** Evolution of the refractive-index sensitivities of a spheroidal silver nanoparticle for the transverse (*red*) and longitudinal (*black*) LSP modes as a function of the aspect ratio r of the ellipsoid; *inset*: refractive-index sensitivity as a function of the resonance wavelength

where the coefficient L_i is a geometrical factor describing the shape of the spheroid (for a spherical particle, $L_i = 1/3$). The expressions of the depolarization factors can be found in [25]. Then, to each i direction corresponds one specific localized plasmon mode excited at one specific wavelength. Taking a Drude model for the metal, it is easy to evaluate the resonance wavelength and the refractive-index sensitivity of each plasmon mode:

$$\epsilon(\lambda) = \epsilon_\infty\left(1 - \lambda^2/\lambda_p^2\right)$$

$$\rightarrow \frac{\lambda_{LSP}^i}{\lambda_p} = \sqrt{1 + \frac{\epsilon_B}{\epsilon_\infty}\left(\frac{1}{L_i} - 1\right)}$$

$$S_i = \frac{d\lambda_{LSP}^i}{dn} = \frac{n\lambda_p\left(\frac{1}{L_i} - 1\right)}{\epsilon_\infty\sqrt{1 + \frac{\epsilon_B}{\epsilon_\infty}\left(\frac{1}{L_i} - 1\right)}}$$



$$= \frac{1}{n}\left(\lambda_{LSP}^i - \frac{\lambda_p^2}{\lambda_{LSP}^i}\right)$$

This equation shows that, in the quasistatic approximation, the refractive-index sensitivity of the metal nanoparticle is only a function of the plasmon resonance wavelength. The dependency on the shape, included here in the coefficients L_i, occurs only through the position of the plasmon wavelength [26]. Figure 3b shows the evolution of the refractive-index sensitivity of the spheroid in water as a function of the aspect ratio $r = b/a$, b being the long axis and a the two equal short axes of the ellipsoid. The particle is supposed to be made of silver, described by the Drude model with $\epsilon_\infty = 4.0$ and $\lambda_p = 284.0$ nm. It has two degenerated dipolar plasmon modes along the section of the spheroid (transverse mode) and one along its symmetry axis (longitudinal mode). The inset shows the mode-independent evolution of the sensitivity S as a function of the particle surface plasmon wavelength, where it appears that it can reach very high values, either for very elongated or very flat particles, but at the expense of a large redshift of the surface plasmon resonance wavelength. This fact has to be taken into account in biosensor design, as they must work at a wavelength lower than 1900 nm in order to avoid absorption of water.

A More Advanced Example

As an illustration of sensor design beyond the electrostatic approximation, Fig. 4 shows the optical properties of a periodic arrangement of more complex plasmonic particles [26]. The structure consists in a planar interface superposed with an array of dielectric pillars supporting a U-shaped gold nanostructure. The whole system is eventually covered with a thin dielectric layer (Fig. 4a). The pillars decrease the spatial overlap between the substrate and the plasmon field generated at the resonance, resulting in higher refractive-index sensitivities. Typical transmission spectra obtained by finite difference time domain (FDTD) simulations are shown in Fig. 4b, for several interparticle spacing a, the detection medium being air. Such a structure shows a transmission spectrum dominated by one peak in the infrared domain, at $\lambda = 2621$ nm for $a = 15$ nm. The position of that peak is very sensitive to every parameter of the structure, in particular the spacing a, as the shift is about 1,000 nm when the interparticle distance varies from 15 to 81 nm. The origin of the large dependency of the infrared plasmon band is due to the high electrical field confinement in the U-shaped gold nanostructures. The inset of Fig. 4b shows that maximum field enhancement is observed in between the two arms of two consecutive U-shaped gold nanostructures, with a very low but not zero electrical field within the U cavity.

For the shortest interparticle spacing, the wavelength shift obtained by increasing the refractive index of the detection medium from 1.00 to 1.50 is equal to 875 nm, which corresponds to a sensitivity of $S = 1{,}750$ nm/RIU, much larger than the sensitivities reported by Verellen et al. and Liu et al. using nanocross/nanobar structures [22] or double split nanoring cavities [21]. However, the rather broad plasmon band in the near-infrared spectral region results in low FoM, as the

LSPR in Plasmonic Nanostructures: Theoretical Study with Application to Sensor Design, Fig. 4 **(a)** U-shaped plasmonic structure investigated in [26] and its geometrical parameters. In the calculations, the nanostructure is illuminated by a p-polarized plane wave from below, the transmission is computed above the structure.; **(b)** Transmission spectra computed for several values of the interparticle distance a; **(c)** Evolution of the figure of merit with a.; **(d)** Sensitivity as a function of the resonance wavelength, varying a (*red circles*), e (*blue triangles*), and l_c (*green squares*)

FWHM $\Delta\lambda \approx 3{,}400$ nm gives a figure of merit of about $FoM = 0.5$ RIU^{-1}. It compares to that obtained by Chen et al. on ensembles of gold spheres ($FoM = 0.6$) [27] but is much lower than for gold nanocrescents ($FoM = 2.4$ RIU^{-1}) [20], gold stars ($FoM = 5.4$ RIU^{-1}) [28], nanocross/nanobar structures ($FoM = 12.5$ RIU^{-1}) [22], or double split nanoring cavities by Liu et al. ($FoM = 8.5$ RIU^{-1}) [21].

The influence of all the morphological dimensions (a, e, l_c) on the interface plasmonic response is summarized in the following table. It appears that whatever the parameter is changed, the sensitivity seems to increase linearly with the resonance wavelength, following the properties of spheroidal particles in the electrostatic approximation (Fig. 4d).

a	e	l_c	λ	S	FoM
nm	nm	nm	nm	nm/RIU	1/RIU
15	5	95	2621	1750	0.5
51	5	95	1608	980	1.3
121	5	95	1409	823	1.9
15	15	95	1599	868	0.5
15	25	95	109	667	0.7
15	5	75	2427	1540	0.5
15	5	55	2221	1318	0.4

For clinical applications it will be relevant to work with plasmonic interfaces with resonance wavelength just below the water absorption band

at 1900 nm. The best compromise between sensitivity and resonance wavelength has been found for the following parameters:

- U-shaped gold nanostructure: $l = 120$ nm, $h = 50$ nm, $a = 45$ nm, $e = 10$ nm, $l_c = 90$ nm
- Dielectric pillar $l_p = 120$ nm, $h_p = 30$ nm
- Substrate and dielectric overlayer: $n_1 = 1.45$, $n_2 = 2.63$, $d = 5$ nm

The resonance wavelength is then 1,200 nm for $n_3 = 1.00$, and the corresponding refractive-index sensitivity and FoM are respectively $S = 783$ nm/RIU and $FoM = 1.4$ RIU^{-1}.

Definitions

Biological macromolecules are large molecules or biopolymers which are made of smaller organic components that are linked together; they usually include proteins, nucleic acids, carbohydrates, and lipids.

Crystal comes from the Greek word "krustallos" meaning "clear ice." Crystals are geometrical solids with regular faces and with well-defined edges. They are formed by atoms, molecules, ions, or molecular assemblies that are arranged in an ordered and repeating pattern which extends over all three spatial dimensions. Crystals formed from biological macromolecules such as proteins are smaller than their inorganic and small molecule counterparts. Bio-macromolecular crystals are also very fragile as they may have between 20 % and 80 % solvent content; hence they are prone to dehydration which leads to cracking and destruction of the crystal. For this reason, bio-macromolecular crystals need to be kept in a constant solvent saturated environment [1].

Crystallization refers to the process of forming or creating crystals, this process can be naturally or artificially induced. The term "protein crystallization" is often used instead of bio-macromolecular crystallization, and although strictly speaking it should only apply when referring to proteins. However, the crystallization techniques and methods are the same. There are many ways to crystallize a compound and the crystallization processes depend on the molecule or substrate to be crystallized. However, all crystallization process have two things in common: Firstly, all types of crystallizations are multiparametric processes, which means that a variety of factors such as temperature, pH, purity, time, and pressure, among others, can affect the outcome of the process; secondly, they all involve three steps: nucleation, growth, and cessation of growth. These steps will be reviewed later in the chapter.

Structural Biology refers to the study of tridimensional structures of biological macromolecules in order to better understand their function and interactions with other molecules at a molecular level.

Introduction

To understand the importance of using nano-volumes to improve the crystallization of biological macromolecules, it is necessary to look at the historical motivation behind it. More than a century ago, scientists were fascinated with the creation of crystals of biological nature. In 1840, Hünefeld observed hemoglobin crystals in samples of almost dry blood. In 1851, Funke described a method to crystallize pure hemoglobin [2]. This was followed by the crystallization of urease by Sumner and pepsin by Northrop. They showed that urease and pepsin were pure proteins but also that they had an enzymatic activity. This was an important discovery, as at the time it was believed that proteins were incapable of catalyzing biological reactions, with proteins regarded as just carriers for the true catalytic molecules, enzymes. In 1946, the Nobel Prize in Chemistry was awarded to Sumner for the discovery that enzymes can be crystallized and to Stanley and Northrop for their preparation of enzymes and viruses in pure form [1].

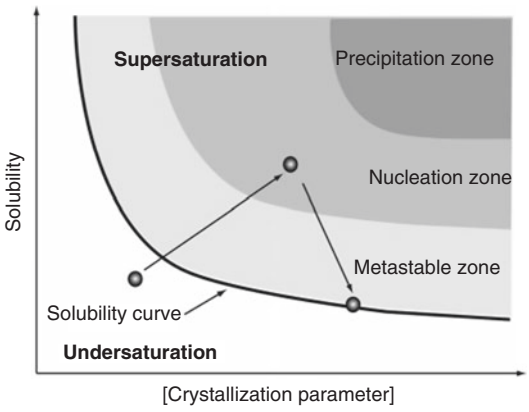
It was not until 1934 that Bernal and Hodgkin produced the first X-ray diffraction pattern of a protein, pepsin. They showed that in order to obtain a good diffraction pattern, protein crystals should not be kept dry but studied surrounded by the liquid solution where they were grown from. This prompted the interest of many scientists and soon after the tridimensional structure of several proteins were reported including myoglobin by Kendrew et al.; hemoglobin by Perutz and Kendrew; and penicillin, vitamin B12, and insulin by Hodgkin [3].

The latest big push in protein crystallization came as a result of the various Genome projects carried out in the 1990s, when a large number of genes from different organisms were sequenced. Many of these genes coded for proteins of unknown function; consequently in the late 1900s and early 2000, a number of initiatives known as Structural Genomics Projects were set up across the world to determine in a high-throughput format the tridimensional structure of those proteins. The results of these projects have applications in many fields such as medicine, pharmacology, veterinary, and agriculture.

Determining the tridimensional structure of unknown proteins allows scientist to better understand their function and interactions with other biological molecules at a molecular level. This is done by comparing different parts of the tridimensional structure of an unknown protein to a structural database of proteins of known function, revealing similarities from which biochemical and biological function may be deduced.

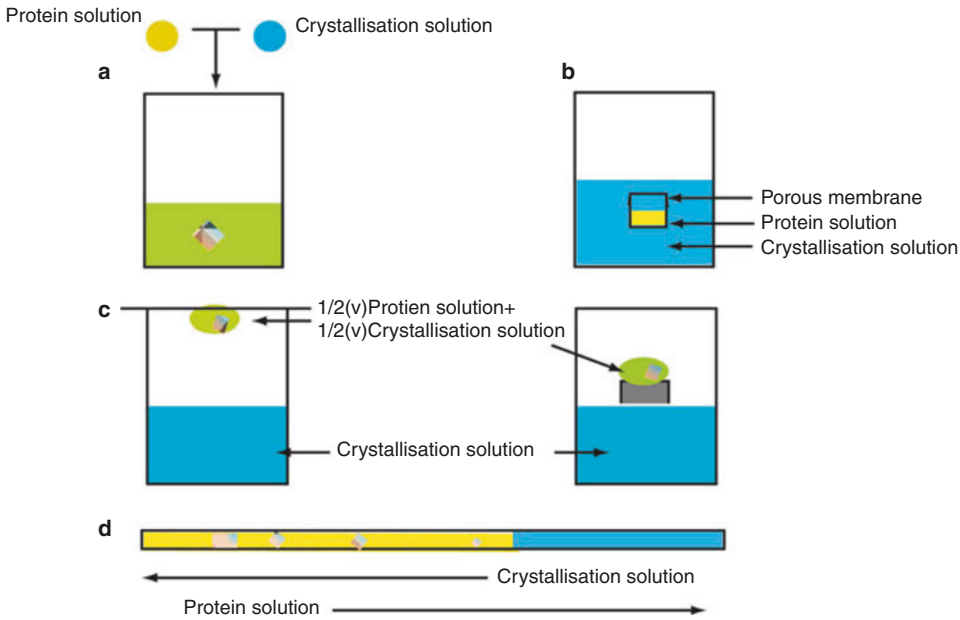
Knowing the tridimensional structure of proteins of known function is also important for rational drug design, where the protein is usually involved in a disease process and can be used as a target where drug candidates can bind to inhibit, block, or modify its function. In rational drug design, scientists analyze the tridimensional structure of the target (usually a protein) and computer-generate a number of drug candidates (or fragments that can later be joined to form a drug candidate) that can bind to the target with high affinity. These drug candidates are then produced in the lab and tested against the target. The goal is to generate drugs that have higher affinity and selectivity for the target, therefore reducing the number of side effects [4, 5].

There are two main techniques for determining the tridimensional structure of a protein; these are nuclear magnetic resonance (NMR) and X-ray diffraction. The use of NMR is currently limited by the size of the macromolecule, (currently around 35 kDa) although advances in procedures may increase this limit. X-ray diffraction is the most common technique but requires the generation of biological crystals that are capable of diffracting at high resolution. Unfortunately, there is no way to know a priori if a biological molecule will crystallize or under what conditions. Hence, the common practice is to screen the target molecule against a large number of crystallization parameters including, but not limited to: pH, ionic strength, temperature, and chemical additives. Consequently, the crystallization of biological macromolecules has remained as the bottleneck of structural genomics.



Protein Crystallization Theory

In order to create a protein crystal, it is necessary to have a highly pure and stable protein in solution and then force the protein molecules to aggregate in an ordered manner by modifying one or more of the crystallization parameters highlighted above. The formation of a protein crystal can be divided in three stages: *nucleation*, *growth*, and *cessation of growth*:



- *Nucleation*: This is the stage where small aggregates of protein are formed. If the aggregates have an internal order they will yield a macroscopic crystal, if not, an amorphous precipitate will be formed. The nucleation can be subclassified into a number of processes, namely:
  - *Primary nucleation*: It is defined as the initial aggregation of the same type of molecules as a consequence of a crystallization process at a high degree of supersaturation. Furthermore, primary nucleation can be divided into a homogeneous or heterogeneous process. The former is produced when only the target macromolecules form a crystal in the bulk solution. The latter is when other molecules or the walls of the crystallization chamber act as a nucleation center.
  - *Secondary nucleation*: It occurs after primary nucleation in the presence of the already formed crystals. It can be divided into attrition and catalytic mechanisms. In the former, the waves of diffusion or convection that transport the molecules in solution to the surfaces of the crystal collide directly with the crystal and can detach part of it. Thus, a new stable crystal nucleus is formed and can grow in this zone. The second type of secondary nucleation occurs when a defect on the surface of the crystal appears due to the addition of a new molecule in a disorientated way or due to the addition of an impurity. This creates a new nucleus, which may form a twin crystal [6].
- *Growth*: Once a stable nucleus is formed, its growth is thermodynamically favored. Molecules of smaller size than the stable nucleus are transported to the surface of the stable nucleus to crystallize [6].
- *Cessation of growth*: A crystal stops growing when the concentration of the macromolecules in solution decreases to the solubility level or when the surface of the crystal changes. These changes can be due to the addition of impurities that "poison" the surface of the crystal, such that the addition of new molecules becomes unfavorable [6].

Importance of Solubility in Protein Crystallization

In order to control the crystallization of proteins, it is important to understand phase diagrams, which describe the solubility of proteins (Fig. 1). Initially the protein is in a concentrated, stable but soluble state of maximum solubility (undersaturation zone). By altering one or more crystallization parameters, it is possible to make the system shift out of equilibrium toward the supersaturation zone. Once the system arrives at a critical point in the supersaturation where it can overcome the free activation barrier, a spontaneous nucleus will form (nucleation zone). In this zone, the solid

Macromolecular Crystallization Using Nano-volumes, Fig. 1 Schematic description of a phase diagram for the crystallization of Bio-macromolecules

Macromolecular Crystallization Using Nano-volumes, Fig. 2 Shows a schematic representation of the most common protein crystallization methods: (**a**) batch; (**b**) dialysis; (**c**) vapor diffusion and (**d**) liquid diffusion crystallization methods. The schematic does not describe the dimensions of the containers as it is intended only to describe the process; however, any of these methods can be implemented in macro- or microscale

phase cannot accumulate and the system slowly returns to equilibrium, on its way it crosses a metastable zone where no more spontaneous nucleation will occur but it allows the already formed nucleus to grow. Once the system returns to equilibrium by reaching the solubility curve, the crystal will not grow any further nor will it dissolve as the solid phase is in equilibrium with the saturated protein in solution [7].

Protein Crystallization Methods

There are four basic methods to crystallize a protein: *batch*, *dialysis*, *vapor diffusion*, and liquid *diffusion* crystallization methods. It is important to mention that no method is considered superior to any other. The choice depends on the protein involved, its quality, and the preference of the researcher [8].

Batch crystallization method (Fig. 2a): This is the simplest and oldest method. Here the solution containing the protein of interest is mixed with the crystallizing solution that is at a concentration designed to reach the supersaturation zone instantaneously, forming a number of nuclei that can grow by returning to the metastable zone [8, 9].

Dialysis crystallization method (Fig. 2b): The solution that contains the protein is separated from the crystallizing solution by a semipermeable membrane of a specific pore size, which is smaller than the size of the protein and only allows small molecules (ions, additives) into and out of the protein compartment. This exchange of molecules allows the system to reach supersaturation and then equilibrium [8, 9]. Dialysis is a method that is suitable for independently optimizing the nucleation phase from the growth phase, as the nucleation phase requires a higher concentration of protein while the growth phase requires lower protein concentration.

Vapor diffusion crystallization method (Fig. 2c): This technique involves having a drop containing the protein and the crystallizing agents in a concentration lower than that required for the formation of a crystal. Then the drop is equilibrated against a reservoir containing the crystallizing agent at a higher concentration. Equilibrium

is achieved by diffusion of the volatile species (water or organic solvents) out of the protein drop toward the more concentrated crystallizing agent reservoir. Consequently, the protein drop becomes more concentrated forcing the system into the supersaturation zone. Vapor diffusion can be achieved by hanging the protein drop from a sealing structure or by placing the drop on a plastic bridge [8].

Liquid diffusion crystallization method (Fig. 2d): This technique exploits the use of restricted geometries such as thin glass capillaries and microfluidic channels to force the protein solution and the crystallizing solution to mix only by diffusion. In this method, the protein solution and the crystallizing solution are placed next to each other in direct contact or separated by a physical buffer such as a permeable membrane, a gel, or by a physical barrier such as a valve. The two solutions mix into each other when the physical barrier is removed or by diffusing through the physical buffer. The liquid diffusion method has been implemented in two ways namely: *free interface diffusion* (*also known as liquid-liquid diffusion*) *and counterdiffusion*.

Counterdiffusion (Fig. 2d): In this method, the experiment starts at high values of supersaturation. Then when the protein solution and the crystallizing solution diffuse into each other, amorphous precipitate or microcrystals will form at the interphase. Immediately after, the concentration of protein in the vicinity of the precipitate decreases, but the molecules of the crystallizing agent will continue diffusing further into the protein solution. As the process continues, simultaneous events of diffusion and crystallization are created. As a consequence, a supersaturation gradient will be formed along the length of the glass capillary or microchannel. Typical concentration values for the protein solution vary between 4 and 20 mg mL^{-1}, the concentration for the crystallizing agent solution can be close to saturation. The length of the channel or capillary should be sufficiently long to allow a supersaturation gradient to be formed [10].

Free interface diffusion (Fig. 2d): The aim of this method is to achieve critical supersaturation for nucleation at a very slow rate in order to obtain a single nucleation event. Consequently, the concentrations of protein and crystallizing agent are lower than in the counterdiffusion method. The length of the capillaries of channels used in this method is usually shorter compared to the previous method. The free interface diffusion method can be viewed as a batch method conducted at very slow rate of mixing. This characteristic compared to the traditional batch method offers the advantage of a wider screening of crystallization conditions [10].

Unfortunately, protein crystallization is not a straightforward process, requiring the setting of several experiments to find clues on where the nucleation zone may lay. This is known as the screening process and consumes considerable amounts of protein. This is often problematic as many of the most interesting proteins are only available in limited quantities. Therefore, there is a demand for techniques that can obtain as much information on the crystallization conditions while consuming minimal amounts of protein. Once the nucleation zone is found, it is possible to move to the optimization process. Here the crystallization conditions found during the screening process (which do not necessarily result in a good quality crystal) are modified to obtain a large single crystal that can diffract at high resolution.

In practice, the most common way of searching for adequate crystallization conditions is by mixing the protein solution with already prepared commercial crystallization kits. Crystallization kits consist of a set of solutions which screen different crystallization parameters. Crystallization assays are usually performed in commercial plastic plates known as microplates. These plastic plates come in different formats, e.g., 24, 48, 96, 384, and 1,526 well plates. The first two formats are suitable for setting crystallization conditions manually while the later ones are used for automated liquid dispensing systems. Protein solution volumes used in each experiment can vary from nanoliters to a few microliters, depending on the protein and the purpose of the experiment, e.g., screening vs. optimization.

Nano-crystallization

In the 1990s, the development of automated liquid handling technology made it possible to dispense nanoliter volumes. This had a significant impact in a number of life science applications as it allowed multiple experiments to be performed in parallel while using reduced amounts of sample, which in many cases is expensive and difficult to produce or available in limited quantities. Protein crystallization samples presented an additional challenge to the automated liquid handling manufacturers as the solutions used vary greatly in terms of viscosity, vapor pressure, and surface tension. In addition, the solutions usually contain high concentrations of salts that can block the dispensing tips [11]. Despite these complications, some liquid handling robots can dispense sample volumes as small as 25 nL, although currently the majority of the systems dispense minimum volumes of 50 nL.

The use of automated liquid dispensing systems delivering nanoliter volumes in protein crystallization allowed screening of a vast number of crystallization conditions in a fast and reliable manner. Now in a matter of minutes, hundreds of experiments could be set up in a reproducible format [11]. Also nano-crystallization may produce better ordered crystals since convection is significantly reduced. Some authors argue that this may also result in new crystal forms that are not produced in larger volumes [12]. An additional advantage is that nanoliter drops are easier to inspect using automated visualization systems as they have less depth to focus on compared to microliter drops [11]. The implementation of nano-crystallization methods has taken two different avenues namely: microarrays and microfluidic devices.

The Use of Microarrays for Nano-crystallization

The easiest way to work with nano-volumes in protein crystallization is by using an automated liquid dispensing system to set up crystallization trials in standard 96 well crystallization plates. However, evaporation of the sample while the system was setting up the experiment became an issue. The traditional method of sealing a crystallization experiment involved sealing the complete top of the crystallization plate with an optical clear sealing tape after the robot had finished setting up the experiment. This problem could worsen if the sealing tape was not applied correctly leaving air gaps between the microplate contents and the environment. To help solve this problem in 1992 Chayen et al. described a method now known as "batch crystallization under oil" where the mix of protein and crystallizing agent solution is dispensed inside a few microliters of inert oil to prevent evaporation [13]. In 1996 D'Arcy et al. proposed the use of mixtures of different oils to allow controlled evaporation, thus effectively implementing a vapor diffusion crystallization method under oil [14].

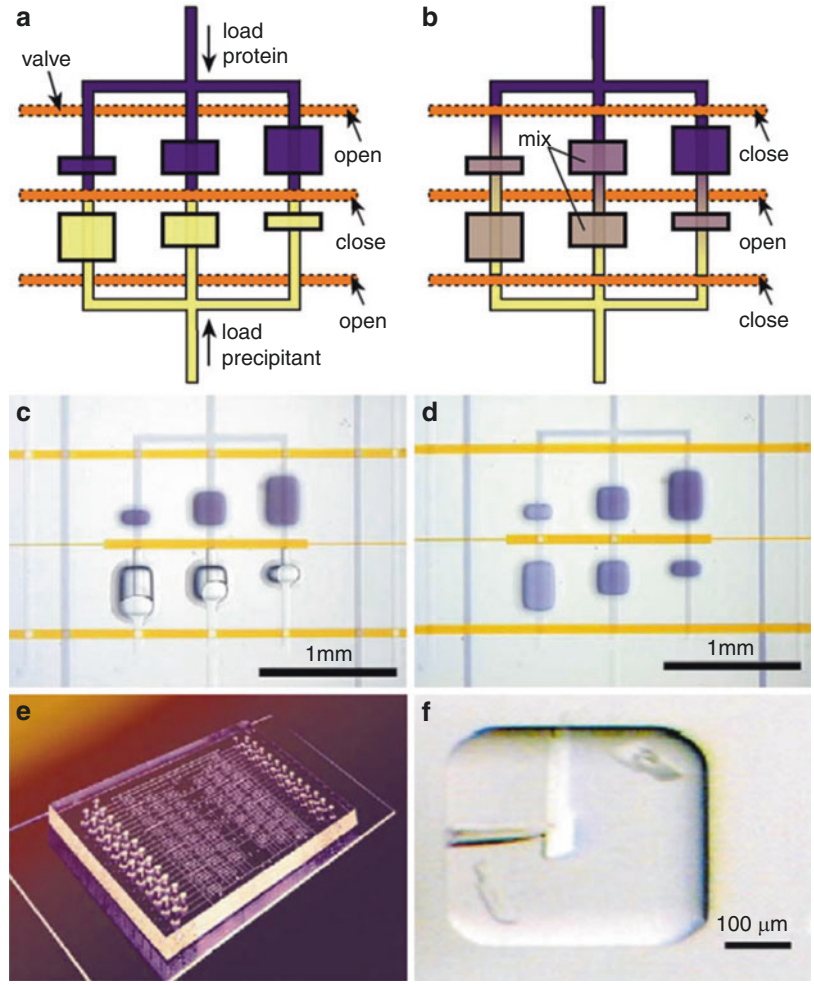
Another way of implementing nano-crystallization using a microarray format was reported by Bodenstaff et al. in 2002 [15]. They described the fabrication of a microarray with 70 wells made of an epoxy resin; each well had a maximum volume of 250 nL. Inside these wells Bodenstaff et al. set up batch crystallization experiments using sample volumes from 1 nL to 250 nL. The dispensing of the sample was done by adapting a piezoelectric dispensing system and sealing was achieved by dispensing a layer of oil as reported previously by Chayen [13]. Bodenstaff showed that in practice, it was possible to crystallize in nanoliter volumes; however, setting up experiments in microsized arrays required a level of finesse, in practice, it is easier to set up nano-crystallization experiments in standard microplates.

The Use of Microfluidic Devices for Nano-crystallization

Microfluidic devices are ideal for screening a given protein against a vast number of crystallization conditions. These devices offer an additional advantage, that the mixing of the crystallization solution and the protein solution takes place by diffusion rather than convection,

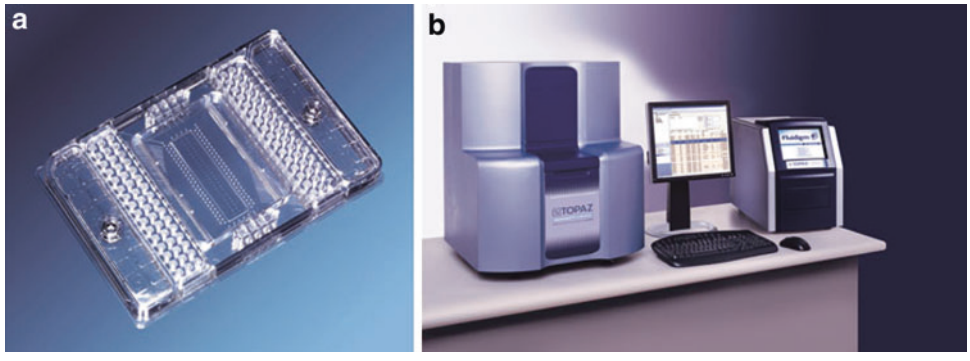
resulting in higher quality crystals. In one way or another, all four basic crystallization methods have be implemented in a microfluidic format.

The list of reported microfluidic crystallization chips is large, as a number of the academic groups working in protein crystallization are now collaborating with groups involved in microfabrication technologies to come up with new microfluidic devices that better suit their research needs. The following is a brief review of current microfluidic devices used for protein crystallization, which is based on the crystallization method that they implement (batch, vapor diffusion, dialysis, and liquid diffusion). In some cases, a single device can be used to implement more than one crystallization method. The commercial microfluidic crystallization devices currently available to scientists are also presented.



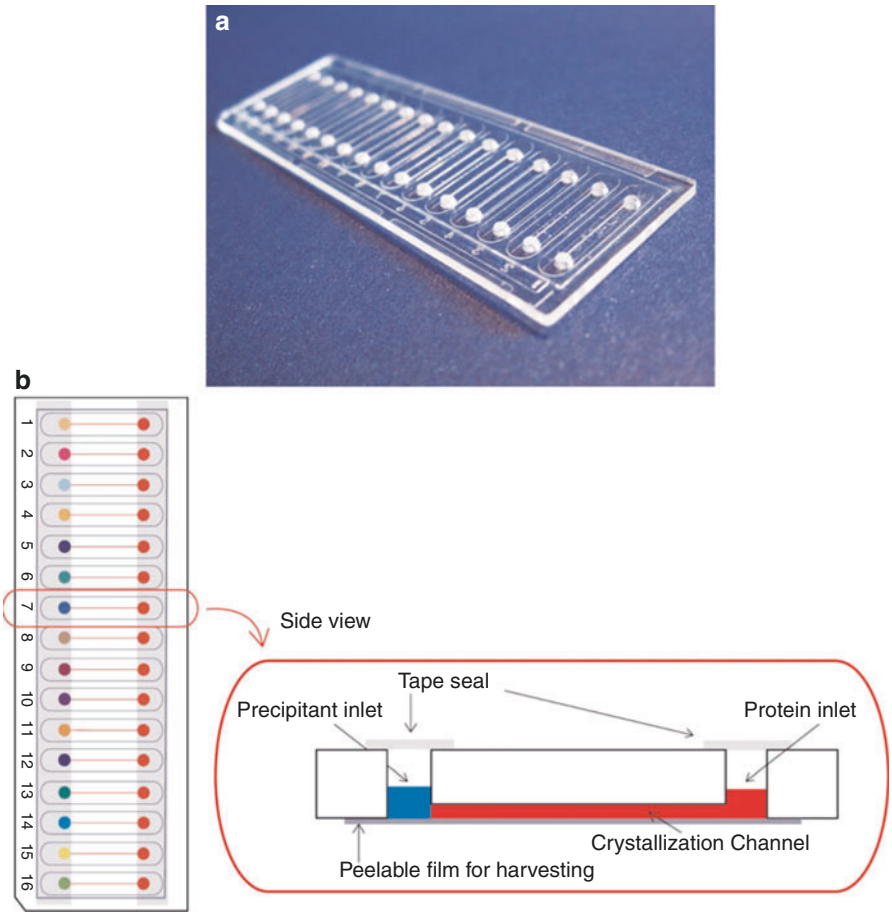
Implementation of the Liquid Diffusion Crystallization Method Using Microfluidics

The first crystallization method to be implemented in a microfluidic format was the liquid diffusion method, specifically the free interface diffusion method [16]. It could be said that the traditional counterdiffusion method in glass capillaries [10] was the beginning of crystallizing using microfluidics, since the narrow capillaries offered a reduced or free convection environment depending on the diameter used. Setting up traditional liquid diffusion experiments in glass capillaries required a reasonable level of expertise and this method was not suitable for employing automated systems in the way batch and vapor diffusion methods are. The intrinsic characteristics of the liquid diffusion methods allowed a wider screening of crystallization conditions in a single experiment. These methods were logically much more suitable for implementing in microfluidic format, which offered a good alternative to the glass capillaries [17]. Commercial versions also allowed nonexperts to set up hundreds of experiment in a fast and easy manner.



The implementation of the free interface diffusion method was presented by Hansen and Quake in 2003 [16]. Their device consisted of a glass substrate where microfluidic channels and microchambers were etched and multilayers of silicon elastomer provided flexible valves that opened and closed to allow the protein and crystallization solutions to mix at the required point. This device allowed the screening of 48 different crystallization solutions at 4 different concentrations (Fig. 3). In 2003 Fluidigm Inc., a company founded by Stephen Quake and Gajus Worthington, launched a commercial version of this device known as the TOPAZ chip (Fig. 4). Later an advanced version of this system was launched; here the glass substrate was replaced by a polymer. It combined free interface diffusion with controlled vapor diffusion, which was possible due to the gas-permeable material used in the construction of the TOPAZ chip. Fluidigm Inc., also developed software and peripheral instrumentation to facilitate liquid handling inside the TOPAZ chip as well as the inspection and analysis of the crystallization results.

Another commercial implementation of the free interface diffusion method was introduced by Microlytic Inc., where their crystallization chip, known as the Crystal Former (Fig. 5), consists of 16 channels, each 10-mm long, allowing a volume of 150 nL per channel. Each channel has two inlets at opposite ends to allow the protein solution and the crystallization solution to be loaded. The channels are covered by a thin removable foil which acts as a seal and allows extraction of the crystals that have formed.



Initially commercial microfluidic chips for protein crystallization were expensive ($600 per chip); making them only affordable to large academic institutions and pharmaceutical companies. Current prices are more accessible ($50 USD per chip) to smaller laboratories. However, price and the need for microfluidic devices that fit a specific research need prompted many academic groups to develop their own chips. A recent example of this is from Dhouib and coworkers who in 2008 [18] reported the design of a microfluidic chip named the CD chip to implement the counter-diffusion crystallization method. The CD chip was later enhanced in 2009 [19]. The CD chip consists of eight microchannels with a total volume of 169 nL

Macromolecular Crystallization Using Nano-volumes, Fig. 3 Shows the free Interface diffusion (*FID*) microfluidic device designed by Hansen et al. in 2003. per channel. All eight channels converge at the protein solution inlet. On the opposite end of each channel another inlet is created to allow the loading of the crystallization agent. Each channel is 4.5-cm long which represented an advantage over other chips with shorter channels as the longer the channel, the larger the gradient of crystallization conditions that can be formed, hence increasing the chances of obtaining a better quality crystal. Additionally this chip was designed to be suitable for in situ X-ray diffraction analysis without the need to remove the crystals from the chip, avoiding potential physical damage. The other advantage is that a number of labels were placed along the length of the channel to facilitate locating the exact position of a given crystal when the sample is placed in the X-ray diffractometer. This device is made of cyclo-olefin copolymer (COC) which also provides good optical clarity and X-ray compatibility (Fig. 6) [19].

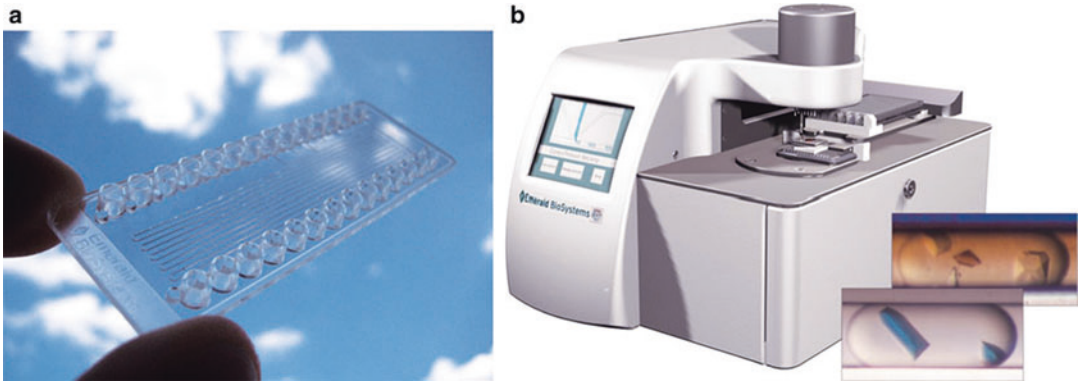
Implementation of Batch Crystallization Method Using Microfluidics

In 2004, Zheng et al. [20] reported a microfluidic platform for screening hundreds of crystallization conditions using less than 4 nL of protein solution and a total sample volume of 7.5 nL per crystallization experiment (Fig. 7). This device consisted of a PDMS block from which inlets and interconnecting microchannels were fabricated.



Macromolecular Crystallization Using Nano-volumes, Fig. 6 Shows (**a**) the CD chip designed by Dhouib and coworkers; (**b**) the Crystal Former chip from Microlytic Inc; (**c**) a microfluidic chip from Greiner Bio One GmbH, and (**d**) a micrograph of a thaumatin crystal grown inside one of the channels of the CD chip. (**b**) A micrograph showing the droplet formation. (**c**) A photograph of the composite device. All inlets and channels were filled with $[Fe9SCN)x]^{(3-x)+}$ solution for clarity. (**d**) A micrograph of thaumatin crystals grown inside droplets in a capillary (Figure and caption reprinted from Ref. [20] Copyright © 2004 with permission from Wiley-VCH Verlag GmbH & Co)

These channels converged to a single point where a thin glass capillary was inserted. The protein solution, buffer solution, and crystallization solutions were briefly allowed to flow through the channels into a stream of fluorinated oil (the carrier), thus creating a small drop containing a mixture of the aqueous solutions. The composition of the drops was changed by varying the flow rates of each of the aqueous streams. The flow was stopped once the glass capillary was full. The capillary was then disconnected from the PDMS block and the extremes sealed with wax. The crystals formed inside the droplets and no evaporation of the sample was observed even after 6 months of incubation without any humidity control. An advantage of this microfluidic chip

was that if a good crystal was formed inside the glass capillary, the capillary could be mounted directly on the goniometer head of an X-ray diffractometer and a diffraction pattern of the protein crystal could be obtained.

In 2008, the Accelerated Technologies Center for Gene to 3D Structures created the Microcapillary Protein Crystallization System (MPCS). This is an instrument capable of generating hundreds of crystallization drops in a microfluidic format in a fast and convenient way (Fig. 8). Each crystallization drop is separated from the other by a volume or plug of oil. The main advantage of this system is its precise and finely controlled concentration gradients that can be performed over a series of drops, thus effectively creating a concentration screening for optimizing protein crystals [21].

The MPCS uses microfluidic chips known as Crystal Cards made of COC and containing two separated microfluidic channels, each channel with approximately 10 μL of useful volume; an independent crystallization experiment can be performed in each channel. The Crystal Cards together with the MPCS represented the commercial implementation of the method proposed by Zheng et al. in 2004. This also simplified the experimental process, as it was no longer required to disconnect the capillary for incubation and X-ray analysis. The Crystal Cards allow growing crystals inside the chip cards and are compatible with in situ X-ray diffraction analysis [21].

Implementation of the Vapor Diffusion Crystallization Method Using Microfluidics

The microfluidic system proposed by Zheng et al. in 2004 (Fig. 7) also allowed the implementation of the vapor diffusion method where the goal is to change the concentration of the droplet containing the protein solution by extracting water molecules from it. Zheng et al. achieved this by injecting droplets containing the mixture of the protein, buffer, and crystallization solution in a stream of water permeable oil into the glass capillary. These drops were alternated with drops containing a high concentration of salt. This procedure enabled water from the protein drop to diffuse through the water permeable oil to the drop containing a high concentration of salt until the system reached osmotic equilibrium. The ability to concentrate the protein drops allowed the crystallization process to proceed and also allowed crystals to form where the original protein and crystallization agent concentrations were too low to allow the formation of crystal nuclei.

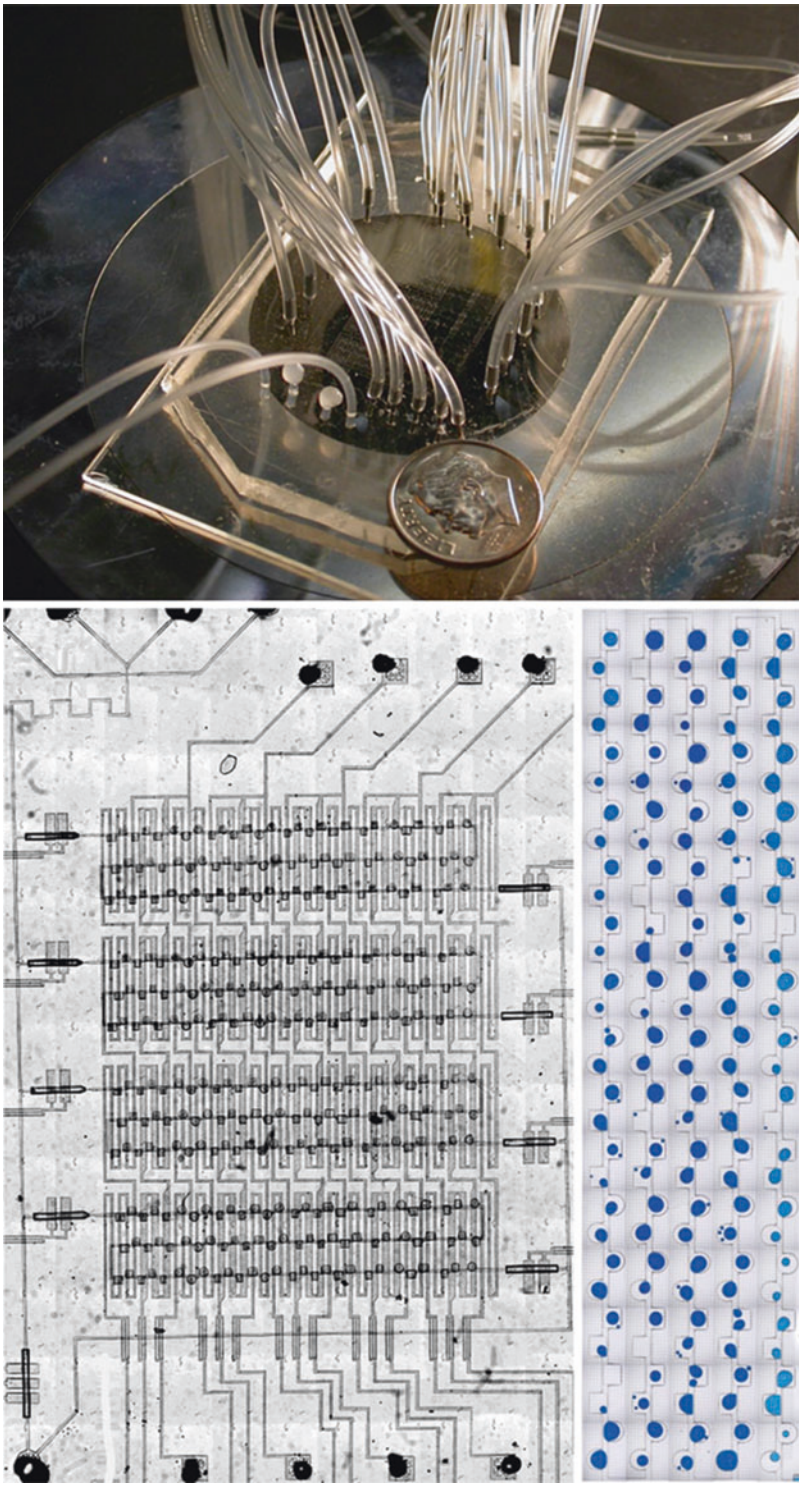
Implementation of the Dialysis Crystallization Method Using Microfluidics

Dialysis is probably the most difficult method to implement in a microfluidic format as it requires

the careful manipulation of the liquids inside the microfluidic chip. In dialysis, the protein solution can be concentrated or diluted by allowing aqueous solution containing higher or lower concentrations of salt to be in contact with the protein solution through a water-permeable membrane. This membrane allows the passage of water molecules but not protein molecules. In 2007, Shim et al. designed a microfluidic chip known as the Phase Chip (Fig. 9) [22], which used an advanced crystal optimization method called "seeding" combined with the dialysis method.

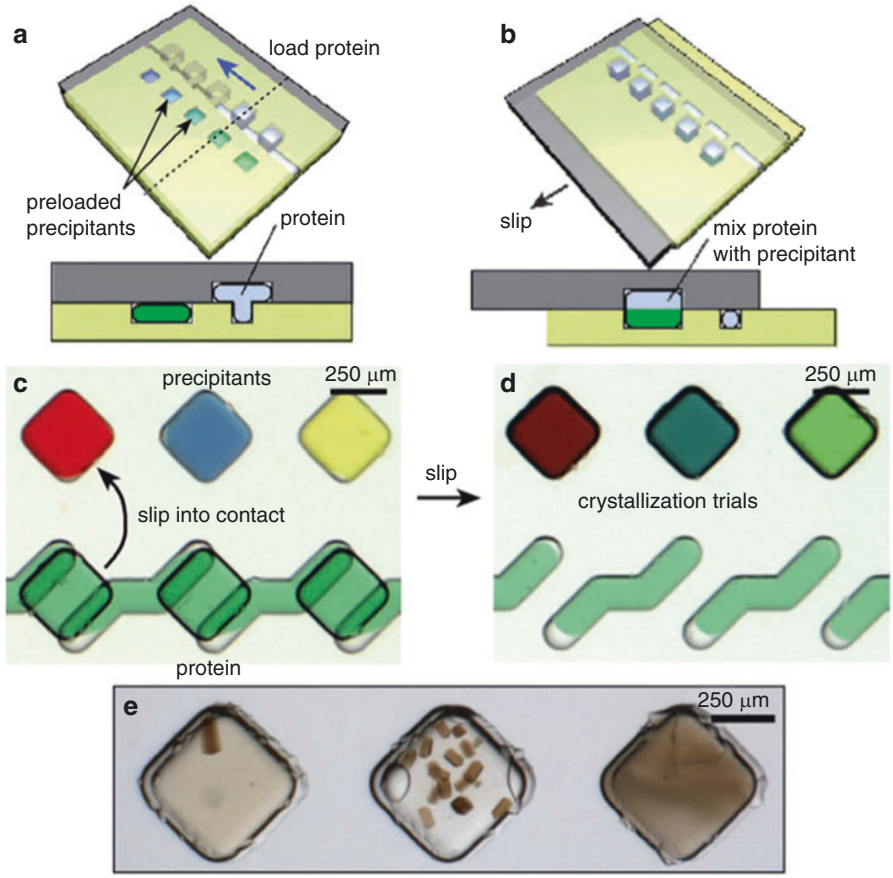
Seeding is a crystal optimization technique that involves crushing a larger protein crystal in order to produce many microcrystals that are then used as seeds that are added to new supersaturated crystallization solutions. These seeds act as stable nucleation sites which protein molecules can use to form larger crystals under less supersaturated conditions [23].

The Phase Chip is made of PDMS and uses the method described previously by Zheng et al. to create drops of protein inside a continuous stream of oil. The Phase Chip exploits surface tension forces to guide each protein drop into wells that are located at the side of the channel, spaced 500 μm away from each other. The wells are also deeper than the flow channel. To implement the dialysis method, the bottom of each well is made of a thin layer of PDMS (15-μm thick) which allows water molecules to pass but not protein molecules. On the other side of the membrane, there is a 100-nL reservoir which can be filled with dry air, a solution with a high concentration of salt or with water. If the reservoir is filled with either dry air or salt solution, the protein solution will shrink, thus concentrating the solution, as water molecules will flow into the reservoir. Alternatively, if the reservoir is filled with pure water, the protein solution will become diluted as water molecules will now flow in the other direction.



The initial goal was to fill each well with protein solution drops at different concentrations. This was achieved by changing the flow rate of the different solutions injected in the chip. Then all protein drops were concentrated by introducing dry air into the reservoir that in many cases lead to the formation of many microcrystals inside the wells. These microcrystals were considered seeds that were later transformed into large crystals by introducing pure water into the reservoir. The water molecules diffused from the reservoir to the protein well and diluted the protein solution, by doing this the smallest and least stable nuclei dissolved and only the larger microcrystals grew into even larger and higher quality crystals.

Another way to classify microfluidic devices for protein crystallization is by the type of mechanism used to create and mix the final crystallization solution. This classification was proposed by Liang and Ismagilov in 2010 [24] and classifies the devices as: *valve-based systems*, *droplet-based systems*, and *Slip Chip systems* (any combination of the above is called *hybrid systems*).



In *valve-based systems*, the protein solution and the crystallization solution are placed in different chambers within the microfluidic chip and the mixing takes place by opening a valve that connects the two chambers [24]. A good example of this is the device described by Hansen [16] and commercialized by Fluidigm Inc. as shown in Fig. 4.

In *droplet-based systems*, drops containing the protein and the crystallization agents are created by injecting these solutions into a flow of oil or other immiscible carrier fluid. Systems using this method are shown in Figs. 7 and 9. Droplet-based microfluidic systems have been useful to crystallize membrane proteins, which are traditionally difficult to work with as they are highly hydrophobic [24]. Crystallizing a membrane protein usually involves reconstituting it inside a lipidic mesophase, which is highly viscous and then incubating it against a set crystallizing solutions hoping to induce nucleation and crystal growth.

The *slip chip systems* [24, 25] consist of two different plates, each containing a number of wells. One plate is loaded with various crystallizing solutions and the other is loaded with

Macromolecular Crystallization Using Nano-volumes, Fig. 9 Shows a composed image of the Phase Chip. The *top* image shows the complete phase chip showing the inlet connections, the *bottom left* figure shows a schematic of the microfluidic circuit with the channels arranged in an "s" shape and the protein microwells arranged on the side of the channels. [25] Copyright © 2009 with permission of the Royal Society of Chemistry)

protein solutions. Then the plates slide on each other bringing both solutions into contact to form individual crystallization assays, as shown in Fig. 10. The Slip Chip represents another way of implementing the batch crystallization method and could be considered a hybrid between microarrays and microfluidic devices. The volumes of the protein solution and crystallizing solution are defined by the volumes of the corresponding wells. The wells are filled by a series of microchannels and microwells and storage under paraffin oil to prevent evaporation.

Future Trends

The crystallization process has been one of the main bottlenecks in structural biology. Now with the use of methods and technologies coming from biology, physics, biochemistry, and engineering, the screening part of the process has been improved and hundreds of crystallization conditions can be screened with small amounts of sample. This will allow us to increase our chances of finding the right crystallization conditions for a given protein or at least to find initial clues on where to start the optimization phase.

The challenge now is to focus on understanding the effect of alternative crystallization parameters that have not been sufficiently mastered and which may allow to control the crystallization process with more precision. These may include temperature, pressure, and electric and magnetic fields. Although a few academic groups have designed and built their own instrumentation to use these parameters to improve the quality of protein crystals, these instruments have not been available to the wider scientific community, with the exception of the TG40 System from Centeo Biosciences Ltd, which allows users to use temperature as an additional optimization parameter. The use of these parameters may also be useful for the crystallization of novel proteins coming from organisms that live in extreme environments such as deep-sea creatures.

Also with the incorporation of peripheral instrumentation it may be possible to analyze pre-crystallization conditions via dynamic light scattering or fluorescence techniques, allowing to know in advance if a given protein will crystallize under a given condition.

Acknowledgments The author would like to thank Phillip Dobson and Philipp Steinmann for reviewing this manuscript, to Abel Moreno, Claude Sauter, and Jose Antonio Gavira for their useful discussions and comments, and to the academic groups and companies that provided many of the images for this entry.

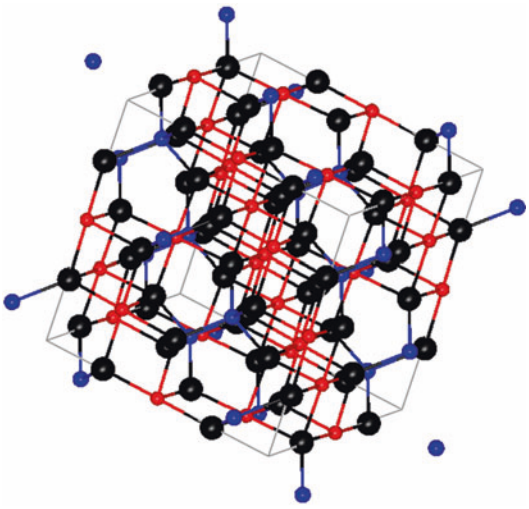
Definition

The physical and also chemical properties of ferri- or ferromagnetic particles in the size regime of 10–1000 nm [1] vary drastically from typical bulk materials which makes them interesting for biomedical applications. In the following, a basic overview of main synthesis routes, physical properties, as well as main uses and applications in biomedicine of magnetic nanoparticles is given.

Introduction

Magnetic nanoparticles offer attractive possibilities for application in biomedicine. Living cells are in a size regime of 10 μm. Magnetic nanoparticles are smaller by three orders of magnitude, and their size is comparable to the size of

viruses, proteins, or genes, which means that they are "close to" the entity of interest [1]. When the particles are covered with specific biomolecules, they can be directed or linked to special areas in a body or in a cell. Additionally, such nanoparticles can be manipulated by an external magnetic field, which opens the possibility to direct the particles to particular regions of interest in a body. Furthermore, magnetic nanoparticles can resonantly respond to an alternating external magnetic field. This creates the possibility to transfer energy from the field to the nanoparticles.



Therefore, in the recent years a lot of efforts have been done in the development of magnetic nanoparticles and the understanding of their behavior due to their unique response to an external magnetic field. Magnetic nanoparticles normally consist of a magnetic core and a shell which stabilizes the particle. The magnetic core can be arranged in two ways: as an accumulation of ferromagnetic crystallites in a nanoparticle or as randomly dispersed crystallites in a matrix shell. The shell sometimes with an additional surface coating is used in order to ensure tolerance and biocompatibility [2].

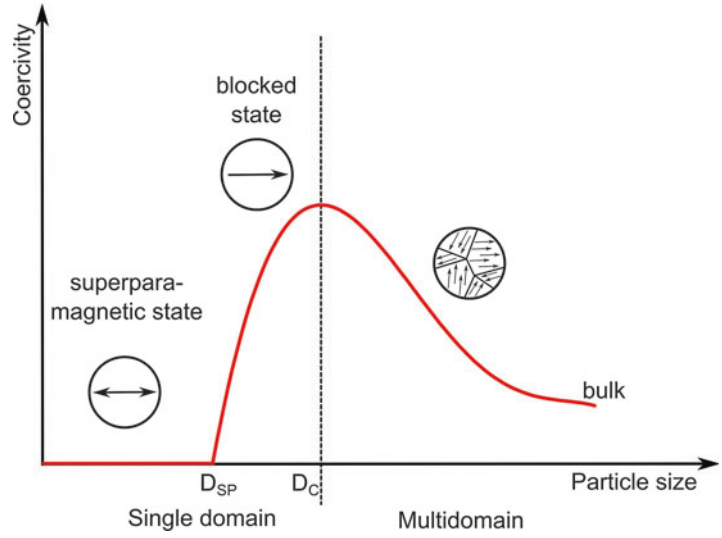
Synthesis and Stabilization

For magnetic nanoparticles, the precise control over their synthesis conditions as well as the surface functionalization is crucial, because it influences their physical and physicochemical properties and their stability and biological behavior, i.e., pharmacokinetics, toxicity, and biodistribution, drastically.

The main representatives of magnetic nanoparticles are the iron oxides, namely, magnetite (Fe_3O_4) and maghemite ($\gamma - Fe_2O_3$), due to the fact that they are biocompatible and biodegradable [3]. In magnetite, the oxygen atoms form a face-centered cubic structure. Between the oxygen atoms there are two different types of interstitial positions, tetrahedral and octahedral positions, which are occupied by iron atoms, as presented in Fig. 1.

The iron atoms on both different positions have opposite orientation of the spin. Since there are twice more iron atoms in the octahedral positions than in the tetrahedral positions, a resulting net magnetic moment is observed, leading to the ferrimagnetic behavior of this iron oxide [4]. When magnetite completely oxidizes, it is known as maghemite.

Magnetic Nanoparticles for Biomedical Applications, Fig. 1 Crystal structure of magnetite (*black*: oxygen atoms, *blue*: tetrahedral positions of iron, *red*: octahedral positions of iron)



There are many routes of the synthesis of iron oxide-based magnetic nanoparticles. In general they can be classified in three groups [2]:

1. Physical methods like gas phase deposition and electron beam lithography
2. Wet chemical methods like sol-gel synthesis, oxidation methods, chemical coprecipitation, or sonochemical decomposition
3. Microbial methods

The simplest and most efficient way to obtain magnetic nanoparticles is the coprecipitation method. To fabricate magnetic iron oxide nanoparticles, a stoichiometric solution of ferrous and ferric salts is mixed in an aqueous alkaline medium [5]:

$$Fe^{2+} + 2Fe^{3+} + 8OH^- \rightarrow Fe_3O_4 + 4H_2O.$$

Magnetite tends to oxidize and an additional phase of maghemite can be formed [5]. This method

Magnetic Nanoparticles for Biomedical Applications, Fig. 2 Dependence of the coercivity on the size of a magnetic nanoparticle

generates nanoparticles with a broad particle size distribution. Synthesis of iron oxides with more uniform dimensions can be also performed in synthetic and biological nanoreactors [3].

The obtained iron oxide crystallites are extremely reactive toward water, air, as well as the living organism. This is related to the fact that they have huge specific surface which enhances their reactivity and additionally stimulates the tendency of the nanoparticles to agglomerate. To ensure a biocompatible colloid, it is usually necessary to stabilize the prepared nanoparticles by appropriate modification of their surface or by incorporation into an appropriate biocompatible matrix [5]. Several compounds with carboxylic, phosphate, and sulfate functional groups are known to bind to the surface of magnetic nanoparticles and stabilize them. Furthermore, if magnetic nanoparticles were synthesized in the presence of a stabilizing agent such as dextran, further functionalization of the surface can be necessary in order to increase the stability and to target the surface [6]. There are several coating strategies which depend on the chemical state of initial particle surface as well as the final application of the magnetic nanoparticles. In general, all strategies should have in common the achievement of hydrophilic nanoparticles, which are stable in a broad pH range and have a high ionic strength [6].

Characteristics of Magnetic Nanoparticles

The behavior of ferromagnetic material strongly depends on the domain structure of this material. Normally a ferromagnet consists of several domains separated by domain walls. When the particle size is reduced, these domains start to rearrange. A well-known example for influence of the domain structure on the macroscopic properties is the behavior of the coercivity in dependence of the particle size, as presented in Fig. 2. With the decrease of the particle size, the coercivity increases and reaches a maximum for the multidomain – single domain – transition. Below this critical size the creation of two separate domains is energetically unfavorable. With a further decrease of the particle size, the coercivity decreases drastically and reaches zero in the superparamagnetic state of the nanoparticle. Caused by thermal effects, the transition to the superparamagnetic state is not a direct phase transition.

Nanoparticles in a single domain state can be described by assuming that they exhibit an effectively uniaxial anisotropy with only one anisotropy constant, since the particles are so small, that all spins are aligned parallel [7]. The anisotropy energy can be described by

$$E = K_1 V \sin^2\theta,$$

where K_1 is the first anisotropy constant, V the particle volume, and θ the angle between the easy axis of magnetization and the magnetization vector. The anisotropy of a nanoparticle depends on several features, not only size but also shape and defects. The anisotropy energy directly depends on the volume of the particle. When the particle size decreases, the anisotropy energy can reach the same order of magnitude as the thermal energy k_BT. Due to this fact jumps between the two energetic minima are possible and the nanoparticle behaves like a paramagnetic material. The time scale of such jump can be described by the Neel relaxation time, which is an exponential function

$$\tau_N = \tau_0 \exp\left(\frac{K_1 V}{k_B T}\right),$$

where τ_0 is the Neel relaxation constant in the order of 10^{-9} s. It describes the time constant necessary for a particle to relax into an energetic minimum after a perturbation. When the Neel relaxation time of a nanoparticle is in the same order of magnitude as the measurement time, the superparamagnetic state is observed. This measurement time can be different for different measurement methods, and therefore also the transition to the superparamagnetic state can be observed for different particle sizes. When nanoparticles have the anisotropy energy significantly bigger than the thermal energy, a stable ferromagnetic state can be observed in a measurement. This state is referred to as the blocked state.

When the nanoparticles are suspended in a liquid, they are free to move and can perform physical rotations of the whole particle, which is characterized by the Brownian relaxation time [8]

$$\tau_B = \frac{3\eta V'}{k_B T},$$

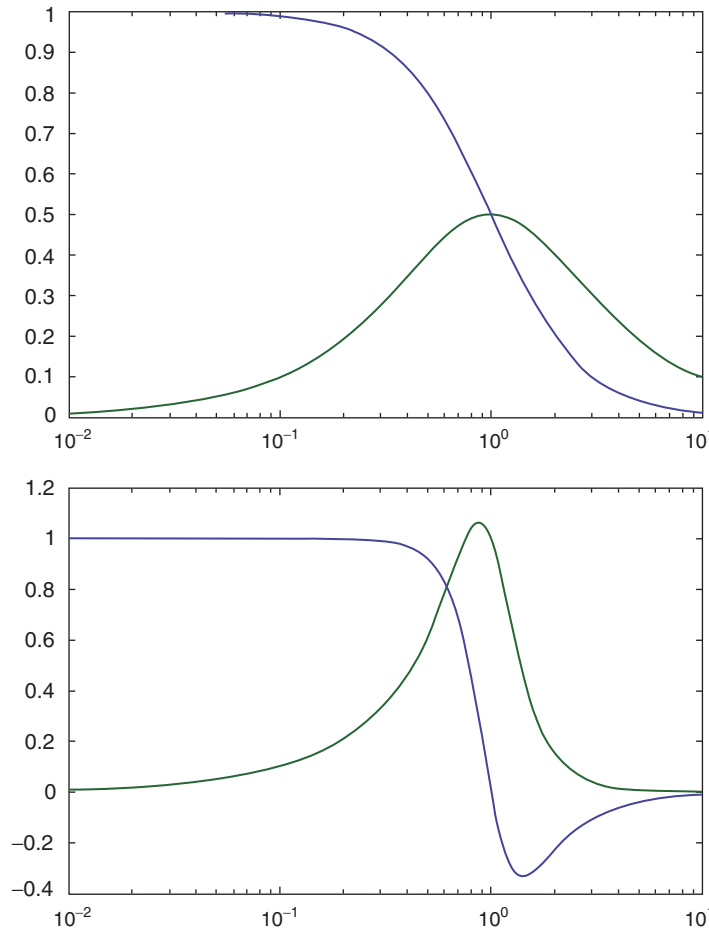
where η is the viscosity of the fluid and V' the hydrodynamic volume of the particles. Since both relaxation mechanisms are possible in a solution, an effective relaxation time τ_{eff} as a linear combination of both relaxation processes can be observed [8]

$$\tau_{\text{eff}} = \frac{\tau_N \tau_B}{\tau_N + \tau_B}.$$

The relaxation behavior of nanoparticles with different diameters is dominated by different relaxation mechanisms. This is due to the fact that the nanoparticle tries to reach the equilibrium state in the shortest possible time. For small particle sizes the Neel relaxation mechanism is dominant, while for larger particle sizes the Brownian rotation mechanism is more pronounced.

There are two ways to illustrate the relaxation mechanisms – description in the time domain and in the frequency domain. Using the dynamic magnetic susceptibility, Neel and Brownian relaxation mechanisms can be identified. In an alternating magnetic field the magnetic susceptibility can be described by

$$M = \chi H = (\chi' - i\chi'')H,$$



where χ' is the real and χ'' the imaginary part of the susceptibility. The behavior of the susceptibility for the Brownian relaxation and the Neel relaxation is slightly different in dependence of the frequency, as presented in Fig. 3. In both cases the resonance can be observed. In the case of Brownian motion, the resonance can be described by Debye distribution, while in the case of Neel relaxation, it can be described by Lorentz distribution.

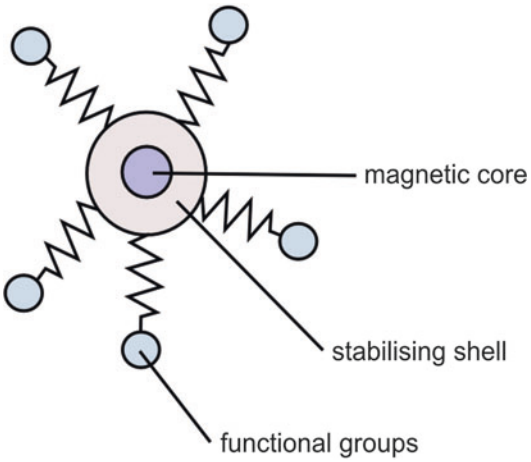
Biomedical Applications

The unique response of magnetic nanoparticles led to the development of various applications in areas of bioscience, biotechnology, as well as environmental technology. The applications in biomedicine are mainly divided into in vitro and in vivo applications. The in vitro applications are mainly characteristic of magnetic separation procedures, while the in vivo applications are drug targeting, magnetic resonance contrast enhancement, magnetic particle imaging, and hyperthermia treatment of cancer cells.

Magnetic Separation

Magnetic separation is in biomedicine probably the most used application of magnetic

Magnetic Nanoparticles for Biomedical Applications, Fig. 3 Real part (*blue*) and imaginary part (*green*) of the susceptibility in dependence of the normalized frequency. *top* – resonance behavior in the Brownian relaxation, *bottom* – resonance behavior in Neel relaxation



nanoparticles, since it is a simple and efficient tool for the fast isolation of target molecules, cell organelles, cells from complex biological tissues, as well as samples like blood, bone marrow, and other biological materials. The big advantage of using magnetic nanoparticles compared to other separation methods is that the biological tissue is usually pure and unaltered.

In biomedicine it is often of advantage to separate a special biological target structure from its native environment in order to achieve a concentrated sample. The magnetic nanoparticles are used as a carrier. Particles are covered with molecules which have an affinity to structure which is supposed to be isolated, as shown schematically in Fig. 4. In the incubation period the target structure is supposed to bind with the nanoparticle. Afterwards, an external magnetic field gradient is applied with an appropriate magnetic separator, and the whole magnetic complex can be rapidly isolated. After washing out the contaminants, the target structure is finally isolated [1].

Nowadays various equipment utilizing magnetic nanoparticles for the purification of DNA and RNA is commercially available. Furthermore, magnetic nanoparticles can be used in immunoassay, for example, for the detection of viruses or the assay of hormones. The use of magnetic nanoparticles for separation can reduce the duration of adsorption as well as separation steps [1, 9].

Drug Targeting

A major disadvantage of conventional chemotherapy is that it is nonspecific. Therapeutic drugs are injected intravenously, leading to a general distribution of the drug into the whole system. This also

Magnetic Nanoparticles for Biomedical Applications, Fig. 4 Schematics of a functionalized magnetic nanoparticle

affects healthy cells and tissue and not only the actual targeted tumor. The idea of using magnetic nanoparticles was developed in the 1970s and is twofold. First the systemic distribution of the drug should be reduced and with this side effects as well. Second also the required dosage should be reduced since the target is localized [10].

The physical principles of magnetic drug targeting are comparable to those of magnetic separation and are based on the magnetic force applied onto the magnetic nanoparticles via an external magnetic field. In this kind of therapy, a cytotoxic drug is attached to a magnetic nanoparticle carrier in a stable ferrofluid. When the ferrofluid is injected into the patient, the magnetic particles can be directed into the region of interest with the help of an external magnetic field gradient. Due to this fact, the drugs attached to the magnetic carrier can be concentrated at the site of the target tissue. Different ways of releasing the drug in the tumor from the carrier are possible, e.g., enzymatic activation or changes in the physiological conditions as pH value, osmolality, or temperature.

How effective such a therapy can be depends on several parameters such as the field strength, the applied gradient, or the volumetric as well as the magnetic properties of the magnetic nanoparticles used. Also parameters as the blood flow rate, the concentration of the ferrofluid, the circulation time of the nanoparticles in the blood, the position of the tumor, and the binding strength of the drug to the tumor will influence the effectiveness of such a therapy [1, 10].

Magnetic Resonance Contrast Enhancement

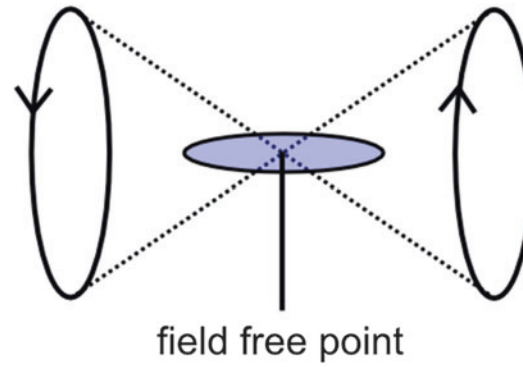
The magnetic resonance imaging is based on the principle of nuclear magnetic resonance of hydrogen nuclei. The target is placed in a strong homogeneous static magnetic field. Due to the magnetic field, a Zeeman splitting of the nuclear magnetic moment appears. The energy difference between the energy levels is characterized by the Larmor frequency. A transition between these two states can be achieved by applying an orthogonal high-frequency pulse with the Larmor frequency leading to a torque of the system. The precession of the magnetic moment can be described by Bloch equations, introducing two relaxation times, T_1 and T_2. The relaxation time T_1 describes the direct relaxation of the whole magnetization parallel to the external magnetic field into the energetic minimum, while the relaxation time T_2 describes the characteristic decay time of the magnetization induced in the plane orthogonal to the external magnetic field.

The images are generated by spatially encoding a nuclear magnetic resonance signal from nuclei present in an object, applying a time-varying linear magnetic field gradient. A high resolution and the ability to distinguish soft tissues are the main advantages of the magnetic resonance imaging. In some cases the contrast between different tissues is not sufficient, and additional contrast agents are required to achieve sufficient contrast in the magnetic resonance image. Compared to conventional contrast agents, nanoparticle-based contrast agents offer enhanced cellular internalization and slower clearance from tumors [11]. Furthermore conventional contrast agent can lead to severe adverse effects [6].

The function of the magnetic nanoparticles as agents for contrast enhancement can be explained considering the relaxation mechanism in hydrogen nuclei in the presence of the magnetic nanoparticles. The magnetic nanoparticles show a strong T_1 relaxation. They also introduce strong

inhomogeneities in the local magnetic field due to their high susceptibility, which also reduces the relaxation time T_2. Depending on the size of the nanoparticles, a strong influence of the T_1 or T_2 relaxation time can be observed. Smaller magnetic nanoparticles rather tend to shorten the relaxation time T_1, while bigger ones shorten relaxation time T_2, which results in dark areas in magnetic resonance images [12]. Therefore, the nanoparticles used for contrast enhancement are divided into two groups: superparamagnetic iron oxides (SPIOs) with diameters greater than 50 nm and ultrasmall SPIOs (USPIOs) with diameters smaller than 50 nm. It is worth to mention that several clinical applications in imaging of bowel, liver, or spleen have been already presented [11].

Magnetic Particle Imaging



Magnetic particle imaging is a novel imaging technique first reported in 2005 [13]. This technique takes advantage of the nonlinear magnetization curves which generate harmonic response to a time-varying field. This can be detected using lock-in methods with a high degree of precision and a high signal to noise ratio [14].

The target is placed in a constant magnetic field, in which the magnetization of the magnetic nanoparticles is mainly saturated. Due to this fact there is no harmonic signal from these particles. Only a small area is kept field free, and a harmonic signal from this specific area can be detected [15]. The field free point can be generated by a Maxwell coil pair which consists of two opposing coils driven by current flowing in opposite directions, as illustrated in Fig. 5. To image a volume, the field free point has to be moved over the tested volume.

The magnetic particle imaging has a great potential for medical applications such as vascular or small intestine imaging where fast dynamic information is required and the targets are located relatively deep below the skin. This is related to the fact that the signal from magnetic particles is unaffected by intervening tissue.

Hyperthermia Treatment

Hyperthermia is based on the idea that malignant cells are more sensitive to heat than healthy tissues. Therefore an artificially induced local hyperthermia could be used to treat cancer [16].

Magnetic Nanoparticles for Biomedical Applications, Fig. 5 Schematic of the principle of magnetic particle imaging

During hyperthermia treatment magnetic nanoparticles are dispersed into the target tissue, and an external alternating magnetic field with a certain field strength and frequency is applied. This leads to a heating of the particles via Neel loss, Brown loss, or hysteresis loss [6]. Additionally, a dissipation of the heat to the surrounding tissue itself takes place. When the temperature is kept above a therapeutic threshold of 42 °C for 30 min or more, cancer tissues can be destroyed. The big advantage of using magnetic nanoparticles for such an application is that only the targeted tissue is heated while the other part of the body stays unaffected [10]. Furthermore, the particles can be functionalized by coupling to antibodies in order to enhance the uptake [17].

The main parameter determining the heating of the tissue is the specific absorption rate (SAR). It is defined as the rate at which electromagnetic energy is absorbed by a unit mass of a biological material and is proportional to the temperature increase [17]

$$\mathrm{SAR} = C_e \frac{dT}{dt},$$

where C_e is the specific heat capacity of the sample, T the temperature, and t the time. The deposition of heat into the particles by an external field is proportional to the SAR and can be described

by the frequency f, the imaginary part of the susceptibility of the magnetic nanoparticles χ'', and the square of the magnetic field strength H^2

$$P = \mu_0 \pi f \chi'' H^2.$$

This means that basically the deposition of heat into the target should be resonant for a certain magnetic field strength, and it strongly depends on both relaxation times of the nanoparticles. Still the product of frequency and applied field strength is limited for a certain coil diameter. This limitation shall ensure that a person can withstand a treatment for more than 1 h without major discomfort [17]. Due to this fact and that the resonance frequency of magnetic nanoparticles strongly depends on their size, shape, and morphology, the resonant excitation of the nanoparticles is a challenging task.

Summary and Future Prospects

The vast majority of magnetic nanoparticles used in biomedicine consists of magnetite and/or maghemite crystallites covered with a matrix shell which stabilizes them. The nanoparticles can be produced via several routes and can be additionally functionalized by adding functional groups to the surface of the matrix shell. The properties of the nanoparticles strongly depend on their morphology, size, and shape. Especially, the magnetic anisotropy of the nanoparticles is affected to a great extent by the particle size. Two kinds of relaxation phenomena can be observed for the magnetic nanoparticles, namely, the Brownian and the Neel relaxation. In an alternating external magnetic field, the relaxation of the particles can be induced, and the particles can be excited resonantly at the resonance frequencies which depend on their relaxation time.

The unique properties of magnetic nanoparticles make them an ideal tool in biomedicine. The nanoparticles functionalized with different biomolecules can be used for magnetic separation of proteins, DNA/RNA, or cells as well as for drug targeting in chemotherapies applying magnetic field gradients to localize the magnetic nanoparticles.

The particles can be used as well as the contrast enhancement medium in magnetic resonance imaging where the particles are mainly used as negative contrast agents. A novel imaging technique is the magnetic particle imaging. In comparison to the magnetic resonance imaging, the particles do not lead to a negative contrast, but to a positive contrast, where the measured signal is unaffected by intervening tissue. Furthermore, due to an alternating magnetic field, relaxation processes are induced in the nanoparticles, which leads to a heating of the particles placed inside a body. This way a hyperthermia treatment of localized cancer cells can be performed.

Presented here are the main applications of magnetic nanoparticles in biomedicine. Many different applications of magnetic nanoparticles in tissue engineering or biosensing are developing [10].

Beside the magnetic separation and the magnetic resonance contrast enhancement, the application of magnetic nanoparticles in biomedicine is not market-based yet. Drug delivery already undergoes human trials, while the hyperthermia treatment of cancer was already shown to be effective in tests on animals. Since the application of the nanoparticles is affected by numerous factors, the transfer of the hypothetical process from laboratory conditions to an actual process performed in real conditions is still a challenging task.

Definition

Nanostructures featuring magnetic properties and devices for the elaboration and/or storage of information based on electron spin transport.

The need of storing and elaborating binary information permeates everyday life. Today's computers are mainly charge-transfer devices; this means that inside a processing unit the information chain corresponds to a physical electron (hole) drift current, characterized by diffusion lengths and flow times that strongly limit the evolution toward faster computations and smaller sizes. Codifying binary information into a spin-polarized current could allow much faster logic operations, due to the possibility of reversing spins without stopping the carrier flow. The main difficulty of implementing spin-electronic ("spintronic") devices is that typical spin diffusion lengths are well below the hundredth of nanometer for diamagnetic metals and between some tenths of nm and some nms for ferromagnetic metals and alloys, meaning that the typical device must be nanostructured. Furthermore, since spin-flip scattering must be prevented to process

uncorrupted data, both interface quality and material purity must be extremely controlled. High and ultra-high vacuum deposition equipments are needed, and perfect control of geometries down to the nm scale requires extremely sophisticated lithographic steps. Such technological issues have slowed down the challenge of bringing spintronic devices into the core of our logic devices. On the contrary, commercial data storage still relies almost entirely on magnetic nanostructures: both granular media for hard disk drives and tunneling magnetic junction-based read/write heads are worldwide diffused.

Due to their technological relevance, the most important effects on which commercial spintronic devices are based will be considered: Giant Magnetoresistance, Tunneling Magnetoresistance and Spin Torque. Two more subsections are addressed to particularly hot topics: Semiconductor Spintronics and Data Storage. In all these cases, physical systems and/or devices are authentic nanostructures, that is, artificial, nanosized structures characterized by carefully controlled geometries in spite of their reduced dimensions. On the other hand, magnetic nanoparticles, although increasingly gaining attention because of their potential applications in different fields (ranging from ICTs to biomedicine) are excluded from this entry because the synthesis processes, even when characterized by extremely narrow size distributions, do not allow complete control on the assembly geometries, not (yet) resulting in the fabrication of bonafide ordered nanostructures. A subsection related to magnetic anisotropies at the nanoscale represents an essential premise to the rest of the work.

Magnetic Anisotropies at the Nanoscale

The magnetic properties of various classes of nanomaterials and nanostructures are strongly influenced by many types of magnetic anisotropy which determine their behavior. As a general rule, it can safely be stated that all anisotropies existing in bulk, macroscopic material play a role at the nanoscale [1]; in addition, novel types of anisotropy, typical of nanostructured materials, appear. A brief overview of the different magnetic anisotropies and their effects follows.

Shape Anisotropy

Shape anisotropy, emerging from the requirement that the magnetostatic energy of the magnetic system must be a minimum, effectively dictates the direction of the local magnetization vector in ultrathin films of a ferromagnetic material and in non-spherical magnetic nanoparticles. In thin films of a ferromagnetic material the direction of the magnetization vector is preferentially forced to stay parallel to the film plane by shape anisotropy. This property is widely exploited in spintronic devices. For similar reasons, in elongated (either ellipsoidic or acicular) nanoparticles, the zero-field magnetization stays aligned to the major axis. This anisotropy determines the coercivity of an assembly of randomly oriented magnetic nanoparticles, and plays, therefore, a central role in the magnetic response of particulate media for high-density magnetic recording and hybrid materials containing nanoparticles embedded in a diamagnetic, organic matrix such as a polymer. Finally, shape anisotropy is fundamental for patterned media also determining the local direction of magnetization and the magnetic domain structure within a magnetic nanodot or nanopillar, consequently influencing the magnetization reversal mechanism and its duration.

Magnetocrystalline Anisotropy

Magnetocrystalline anisotropy may concur in determining the local magnetization direction of magnetic nanoparticles; however, its effects often emerge only when the shape anisotropy is negligible, that is, for almost perfectly circular/spherical nanoparticles. One of the most important examples of the role played by magnetocrystalline anisotropy is provided by FePt thin films, which have been largely investigated owing to their potential as novel media for high-density perpendicular magnetic recording. In these films, shape anisotropy which would impose a parallel-to-the plane magnetization state is largely overcome by a very strong magnetocrystalline anisotropy term, such that the easy axis is pointing perpendicular to the plane. This term results from the development

of a tetragonal distorted phase (L_{10}) which is obtained by submitting cubic FePt to controlled heating.

Stress (Magnetoelastic) Anisotropy

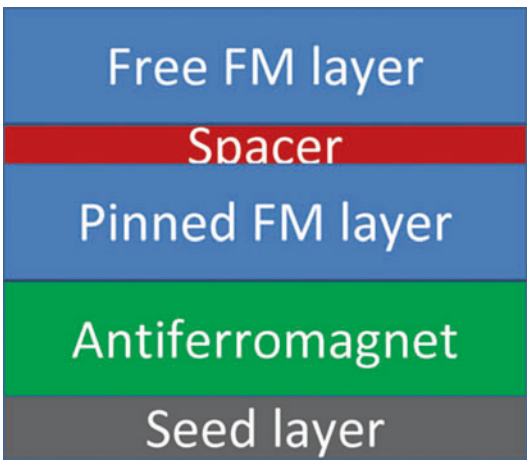
In nanostructured materials obtained by means of deposition or growth techniques followed by lithographic process, the concentration of local stress fields can reach high levels. The magnetization direction of a thin ferromagnetic film or patterned medium can be affected by stress through magnetoelastic (magnetostrictive) coupling. The resulting stress anisotropy often plays a detrimental role on the magnetic response of a thin ferromagnetic film, because it acts to break the symmetry of the system, generating local disturbances in the magnetization pattern of the material and acting to reduce its performance.

Surface/Interface Anisotropy

In thin ferromagnetic films, specific additional forms of magnetic anisotropy exist [1]. Surface anisotropy may play a relevant role because it can be one order of magnitude larger than typical bulk anisotropy values. Surface anisotropy of transition-metal elements or alloys can be understood in terms of the different band filling of 3D states for magnetic atoms at a surface/interface, and can be either perpendicular or parallel to the film plane in dependence of the band filling level, that is, in dependence of the transition metal considered. For symmetry breaking reasons, some of the five 3D states of transition-metal atoms at a surface/interface (i.e., those whose wavefunctions extend in a direction perpendicular to the surface plane) take quite different energies with respect to bulk atoms, while other 3D states (those mainly extending along the surface plane) have almost identical energies in the bulk and at the surface. Interface anisotropy is important in magnetic multilayers also, because of the hybridization of electron states of the adjacent metals (one typically being Fe, Co, Ni; the other one being either a noble metal or an early (or late) transition element). A variety of effects emerges as a consequence of such hybridization, including strong perpendicular anisotropy.

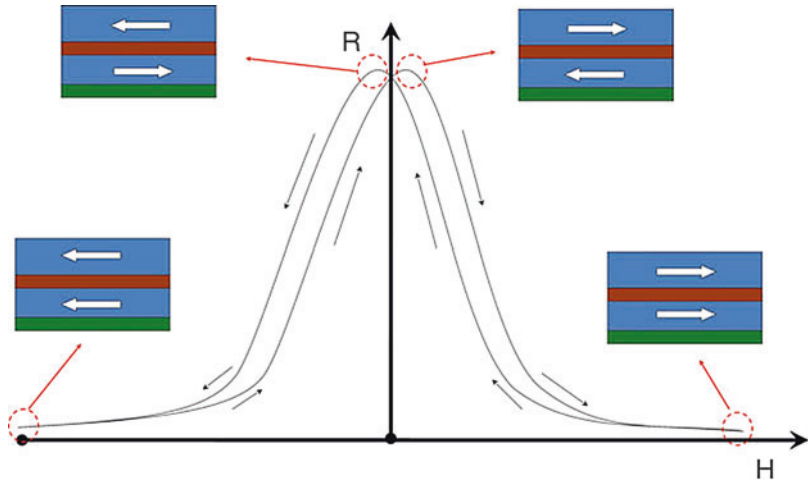
Interlayer Exchange Anisotropy

The transmission of a magnetic anisotropy through an interface between two magnetic materials – that is, the occurrence of a common axis of easy magnetization shared by the two materials across the interface – is a peculiar effect of layered magnetic films and plays a central role in the optimization of the properties of a number of spintronic devices, including the spin valve [2]. As known from the physics of bulk magnetic systems, long range order (ferromagnetic, antiferromagnetic, ferrimagnetic) is assured by the exchange interaction between pairs of adjacent spins. Exchange interaction, a purely quantum effect, is particularly strong between spins belonging to the nearest neighbor atoms, and goes rapidly to zero with increasing inter-spin distance. When the interface between two different magnetically ordered metals is sharp, spin information can be transmitted from one material to the other and vice versa. In particular, if one material is strongly anisotropic, it can influence the anisotropy of the adjacent layer through exchange coupling. The most interesting case from the application side arises by placing together a ferromagnet and an antiferromagnet. In this case, the antiferromagnetic layer (it can be a transition metal oxide of a transition metal, such as NiO or CoO), although acting as a definite source of magnetic anisotropy for the ferromagnetic layer, is magnetically "dead," that is, not contributing at all to the magnetic response of the device in the range of magnetic fields of interest. Such a feature is exploited, for example, in spin valves, where the magnetization of one of the two ferromagnetic layers must remain fixed in space ("pinned") while that of the other layer is free to reverse under the action of the same weak magnetic field. The pinning force is typically provided by the exchange anisotropy between an antiferromagnetic layer in close contact with the pinned ferromagnetic layer [3].



Exchange Bias

Exchange bias [4] is strictly related to exchange anisotropy, even though resulting in a different variety of applications. The effect, discovered in 1956 – that is, well before the rise of interest



toward nanomagnetism and spintronics – is again associated to the exchange anisotropy between an antiferromagnetic and a ferromagnetic layer. After proper thermal pretreatment (e.g., field cooling through the ordering [Néel] temperature of the antiferromagnet), the hysteresis loop of the FM material is permanently shifted along the field axis. This brings about a different absolute value of the material's coercivity under decreasing and increasing fields. The mean coercivity can also increase. Possible applications of novel exchange-biased bi- or multilayers are permanent magnets and magnetic recording media. Moreover, the loop shift induced by exchange bias can act to reduce the field needed to observe giant magnetoresistance effects in spin valves or magnetic multilayers with respect to the field needed in unbiased systems.

Giant Magnetoresistance

In 1975, experiments on a Fe/GeO/Co junction led to the discovery of tunneling magnetoresistance (TMR) by M. Jullière, which was again verified in 1995 by T. Miyazaki, N. Tezuka, and J. S. Moodera. This great delay was caused by the fact that the experiment was done at cryogenic temperatures; the interest on the phenomenon was mainly academic because commercial electronics was and is still now unable to operate at such low temperatures, where the carriers in a semiconductor are typically freezed. So in 1988, experiments on layered thin films of ferromagnets alternated to a nonmagnetic metal led to the simultaneous and independent discovery of the giant magnetoresistance (GMR) by A. Fert and P. A. Grünberg, who were awarded for this discovery with the Nobel prize in 2007. They found that submitting those layered structures to a current perpendicular to the interfaces, the conduction electrons were submitted to a spin-dependent scattering whose probability depends on the relative alignment between the macroscopic magnetization of the two ferromagnetic thin films. In case they are parallel the scattering probability is low, hence the electrical resistance is low too. Typical materials used to realize a GMR stack are thin films of Co/Cu, Fe/Cr, Co/Ag, Co/Ru, $Co_{90}Fe_{10}$/Cu; a typical structure is shown in Fig. 1. When applying an external magnetic field, if the two ferromagnetic films feature different coercivities, it is possible to act on the orientation of the magnetically softer one and produce a high resistance state. Different coercivities are obtained either realizing films of different thicknesses or coupling one of them, the so-called pinned layer, to an antiferromagnet by exchange bias. Between the materials used to implement exchange bias, selected ones are NiO, FeMn, Fe_2O_3, $Mn_{76}Ir_{24}$, and MnPt. Generally the highest values of GMR, defined as total resistance variation normalized by the resistance in case of parallel alignment times 100, are obtained for epitaxial thin films working at cryogenic temperatures: GMR between 100 % and 200 % were measured at temperatures lower than 5 K, while at room temperature typical values approach 50 % at maximum. GMR systems are commercially used as magnetic field sensors, isolators and hard-disk read heads [5]. The typical electrical response is presented in Fig. 2.

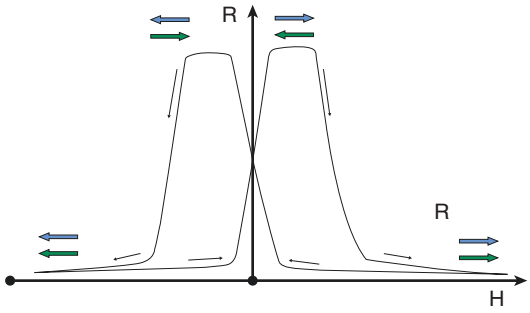
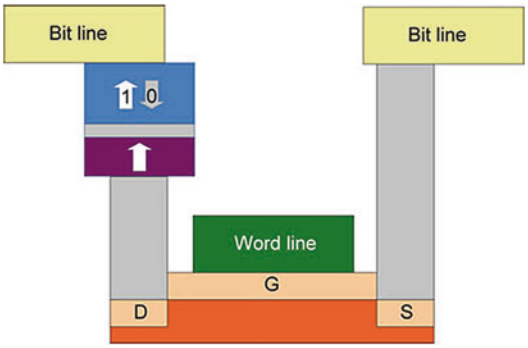
Tunneling Magnetoresistance

As already stated, TMR was observed before GMR and is still under intensive study, due to extreme industrial interests; devices showing TMR are called magnetic tunneling junctions (MTJs) and, if compared to more classical all-metal devices (such as GMR), are characterized by a high impedance, representing the optimal choice for electronic drivers operating at rather high frequencies. This is of particular interest for at least two applications: the elements of digital nonvolatile memories and the stray field sensors used in TMR read heads for high-density storage media. A TMR device is composed by a stack of two ferromagnets, one soft and one hard (see Fig. 3) separated by an insulator; in analogy to spin-valves they have a hysteretic three-state electrical response and could act as magnetically operated switches. Generally the materials used for soft electrodes are FeNi, CoFeB, or a thick layer of Co, Fe, or Ni; for the hard electrodes CoFe, CoCr, or an extremely thin layer of Co, Fe, or Ni are used; the tunnel barrier may be realized in Al_2O_3, MgO (best performances), and many other hybrid materials such as Ta_2O_5, $SrTiO_3$, and NiO [6]. Since the best electrical response is given by a single domain structure (Fig. 4), each MTJ should be nanostructured, for example, as a nanopillar with top and bottom contacts. Furthermore monocrystalline epitaxial materials, although displaying many technological problems, provide the best performances giving TMR values as high as



Magnetic Nanostructures and Spintronics, Fig. 3 Structure of a nanoengineered stack of a magnetic tunneling junction, comprehensive of a synthetic ferromagnetic pinned layer and a cap layer to prevent oxidation



15,000 %, versus typical TMR of sputtered devices below 1,000 %. Since monocrystalline materials require extremely expensive equipments such as molecular beam epitaxy, engineers found that also sputtered materials could guarantee reasonable performances when *texturized*, that is, thermally treated in order to undergo solid state epitaxy, consisting in a pseudo-conformal growth at the interfaces between insulating barrier and ferromagnetic electrodes.

Spin-Torque Effects and Devices

Most spintronic effects have their own opposites; this circumstance engenders a variety of novel

Magnetic Nanostructures and Spintronics, Fig. 4 Typical tunneling magnetoresistance curve with a representation of the magnetization configuration in the free layer (*blue arrow*) and in the pinned one (*green arrow*)

Magnetic Nanostructures and Spintronics, Fig. 5 Structure of a spin transfer magnetic RAM, seen in section. The bit and word line connections address a single memory cell, directly switching on or off the control transistor; when it is switched on, the current emitted by the drain (*D*) transfers the perpendicular magnetization of the hard layer (*purple*) to the free one (*blue*), writing data. Reading is done by lowering the voltage on the gate (*G*) and measuring the resistance across the two bit lines, which depends on the parallel/antiparallel configuration of the MTJ electrodes

potential applications. As known, the giant magnetoresistance effect is the result of a modulation of a spin-polarized current by spin-dependent scattering. In a spin valve, the direction taken by the magnetization vector in one ferromagnetic layer can modulate the current across the device, depending on the direction taken by the magnetization of other ferromagnetic layer, that is, the magnetization affects the current.

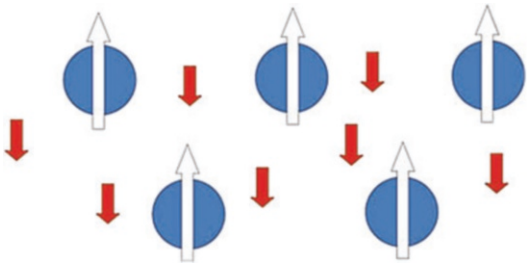
In magnetic nanostructures, the opposite effect is observed: a strongly spin-polarized electrical current applies a torque on the magnetic moment of a ferromagnetic layer initially pointing in a different direction [7, 8]. This effect is called "spin torque" or spin-transfer switching and is exploited in various nanodevices. A typical structure resembles the spin valve: two thin magnetic layers (pinned and free) are separated by a diamagnetic spacer. When an electrical current passes through the first layer, the spin of the electrons becomes oriented in the direction of that layer. This polarized current then passes through the second layer and again the electron spins align to the direction of the magnetic moment. However, because angular momentum is conserved, the difference in the orientation of the electrons caused by the magnetic layers is seen as a torque. On the contrary, if the current is first passed through the free layer, the fixed layer works as a filter, allowing only the component of parallel magnetic moments carried by the current, and reflecting back toward the free layer the reminder; therefore, a torque again acts on the free layer. It can be easily shown that a torque can be applied to the free layer in different directions. Therefore, the torque can either force the magnetization of the free layer toward or away from the direction of the fixed layer magnetization. If the torque is large enough, it can lead to switching of the magnetic moment of the free layer. Magnetization dynamics is described by the Landau–Lifshitz–Gilbert equation, whose terms represent spin precession, magnetization damping, and spin transfer torque [9]. Depending on the direction and strength of the polarized current, the magnetization of the free layer will end either parallel to the applied field, or antiparallel to the magnetization of the fixed layer, or even will indefinitely precess around the applied field direction in steady state.

Spin torque effects are being investigated in view of their potential applications as alternative methods to efficiently write data in nonvolatile MRAMs exploiting smaller currents with respect to standard writing techniques involving transient magnetic fields [10]. ST-MRAMs are characterized by notable write endurance, good compatibility with standard CMOS processing and fast operation (Fig. 5). In fact, spin-transfer-driven switching of magnetization can take 1 ns or less.

The same effect can also be exploited in the design of fast electronic devices such as microwave (RF) oscillators microwave oscillators, converters, microwave sources and antennas. These devices are interesting because of their small size, low power consumption and good response to frequency modulation and phase locking.

However, the current density needed to achieve fast magnetization reversal is often too high to ensure a reasonable lifetime of a spin-torque device (of the order of one decade for a MRAM's operation time). Another major issue is the control over all parameters entering the Landau–Lifshitz–Gilbert equation in order to optimize the efficiency of the device.

Recently, spin torque effects and related magnetization switching have attracted much attention in connection with the development of spintronic memristors at the nanoscale. In memristors, the resistance is a function of the history of the current through and voltage across the device. Spintronic sensing elements based upon spin torque effects can be designed to explore and memorize continuously varying current and voltage applied to the device [11].



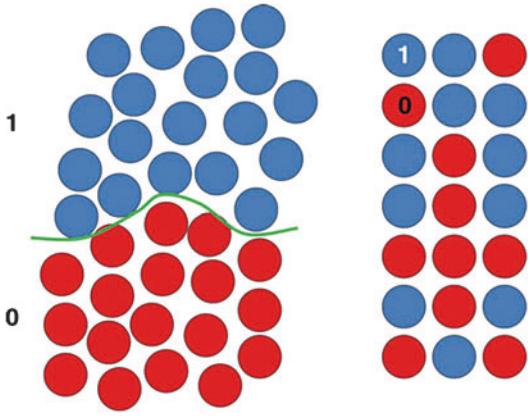
Semiconductor Spintronics

Spintronics in semiconductors – as opposed to or complementary to spintronics in metals – has been thoroughly investigated since the very beginning of research on spin-polarized currents. Semiconductor materials provide a variety of quantum effects which make them the ultimate choice for applications to micro- and nanoelectronics. Semiconductor-based solid state physics can be easily applied to nanostructures which in turn provide appropriate quantum confinement effects for carriers. Moreover the fabrication technology, based on reliable, accessible techniques of materials growth and process, has reached full maturity in the past decades.

From this viewpoint, applying spintronics concepts to semiconductor materials was a straightforward step; however, research in the field has faced various difficulties and drawbacks which have so far prevented widespread applications. The main reason being that standard semiconductors are diamagnetic materials without a self-sustained degree of spin polarization of the carriers, contrary to the case of ferromagnetic metals.

Two main strategies have been developed in order to cope with this shortcoming. The first one is based on injection of a spin-polarized current from a ferromagnetic metal such as Fe or Co into a semiconductor [12]. Of course both materials must be in the form of thin films in (more or less) close contact. In this way, a polarized current naturally produced in the ferromagnet can be injected in the semiconductor and propagate within it, although gradually losing the polarization degree. However, it can be shown that the time needed by the spin-polarized current to fully de-polarize through spin relaxation processes, although intrinsically short (being of the order of 100 ns in GaAs and up to 100 μs in GaAs quantum dots) would be enough for electrons to travel across the semiconductor over mesoscopic distances without losing spin coherence (tens to hundreds of μm), therefore allowing one to design new devices. The residual polarization degree can be experimentally checked by analyzing the light emitted in the recombination process of polarized electrons with unpolarized holes in the quantum well of a layered heterostructure (this is called the "spin-LED"). The emerging electromagnetic radiation appears to be circularly polarized. A measurement of the polarization of emitted light is therefore a measure of polarization degree of electron spins. The drawback of this approach is represented by its low efficiency, in turn determined not only by the rate of loss of spin memory within the semiconductor, but mostly by the loss of spin polarization during the injection process from the ferromagnetic metal. In fact, the Schottky barrier existing at the metal–semiconductor interface hinders the injection and reduces the efficient injection of a spin-polarized current. This difficulty can be partially – although not entirely – circumvented by adopting solutions which include, for instance, the presence of a tunnel barrier contact between the metal and the semiconductor.

The second strategy consists in building novel semiconductor materials which display



Magnetic Nanostructures and Spintronics, Fig. 6 Sketch of a dilute magnetic semiconductor spin configuration: the blue dots represent localized moments (Mn ions), while the *red arrows* represent itinerant spins (holes)

ferromagnetic properties while keeping their semiconducting features [13]. Adding moderate concentrations of specific dopants carrying a magnetic moment may result in obtaining the so-called dilute ferromagnetic semiconductors. Magnetic dopants exist; trivalent Mn atoms act as acceptors in GaAs-like semiconductors (i.e., those belonging to the (III,TM)V series, TM being a metal provided with intrinsic magnetic moment) and have a high permanent magnetic moment (entirely related to the spin quantum number $S = 5/2$). The key concept is that when magnetic Mn atoms occupy substitutional sites in the GaAs structure, they induce a polarization of the free carriers of the GaAs host. These are holes, rather than electrons, owing to the acceptor nature of dopants. Therefore, a magnetization of the itinerant carriers is sustained by the magnetization of localized moments on Mn ions; the latter is in turn sustained by that of itinerant carriers, in a sort of mutually sustained exchange effect (Fig. 6). It has been shown that, as a result, the spins of both Mn ions and mobile holes display a ferromagnetic ordering below the ordering temperature, although their magnetizations are opposite (strictly speaking, the semiconductor is therefore a ferrimagnetic rather than ferromagnetic material). However, spin-polarized, mobile holes can be transferred over long distances across the semiconductor always keeping their spin memory. A strict condition for the success of this strategy is to completely avoid clustering or agglomeration of magnetic dopants: their atoms must be evenly distributed in space. As a consequence, an upper dopant concentration limit (around 5 %) exists. Unfortunately, the Curie temperatures of these ferromagnetic semiconductors are still quite low (100 K). This has prevented widespread diffusion of dilute magnetic semiconductor materials so far.

Finally, it should be noted that many different spintronic devices based on semiconductors have been designed and/or achieved as demonstrators. Many borrow their working principles from classical optics of polarized, coherent light, exploiting the analogies existing between coherent optics and quantum coherence of ballistic electrons moving in one-dimensional semiconductor "channels" and between classical polarization of light and spin polarization. A popular spintronic device has been, for example, the spin-FET proposed by Datta and Das as early as 1990, which keeps the overall geometry and general working principle of a conventional FET, while exploiting ferromagnetic source and drain electrodes to produce a spin-polarized electron flow in the channel. The transmittance of the device is modulated by the gate voltage which may, or may not, induce a flip of the electron spin during the ballistic motion in the channel, therefore modifying the current intensity by quantum interference effects. In this interesting device, the spin flip is induced by an electrical rather than a magnetic field by thoroughly exploiting the spin–orbit interaction of ballistic electrons in the one-dimensional nanoconduit.

Data Storage and Patterned Media

Hard disk drives (HDDs) represent one of the most diffused systems for data storage, featuring extremely low costs per bit and reasonable data transfer rates. Nanostructured magnetic materials are present both in the read head and in the disc surface. The development of magnetic field sensors from magnetoresistive systems, to devices earlier based on GMR and nowadays based on TMR allowed the continuous increment in data areal density. On the other hand, recording materials, starting from structures magnetized in the disc plane, evolved to earlier structures with perpendicular magnetization, up to today's antiferromagnetically coupled layers that increase data

Magnetic Nanostructures and Spintronics, Fig. 7 Hard disk media magnetic domain structure. On the *left* conventional media for perpendicular recording, with randomly distributed magnetic domains and irregular bit contour. On the *right* patterned media, where each nanostructured element may carry one single bit of information

stability thanks to interlayer exchange coupling [14]. For what concerns recording media (Fig. 7), generally based on sputtered CoPtCrB alloys, the main problem is data retention rate: the smaller the size of a magnetic domain, the higher the effects of the demagnetizing field, the higher the switching probability. Reducing the magnetic domain size below the superparamagnetic limit would result in a useless media containing randomly distributed information. Nowadays the commercial data density is approaching an areal density of 100 Gbit/inch^2, while laboratory demonstrators are available approaching 1 Tbit/inch^2, based either on patterned media (PM) or thermally assisted magnetic recording. In particular, PM provides the key to break the superparamagnetic limit, because each nanometric magnetic domain corresponds to a confined physical grain that can be kept far from others avoiding self-demagnetization. The challenge of patterning a wide surface (some square inches) with homogeneously distributed 25-nm-big elements has been accomplished by means of *density multiplication*, a particular process where only a small fraction of the elements is patterned thanks to an electron beam system and the full feature density is achieved thanks to a block copolymer assembly guided by the underlying chemically modified former pattern [15]. Large area–patterned nanostructures are studied also for their interesting collective behavior [16], resulting in peculiar electrical properties [17] and potentially suitable to implement full magnetic logics, particularly promising for their low electrical consumption [18].

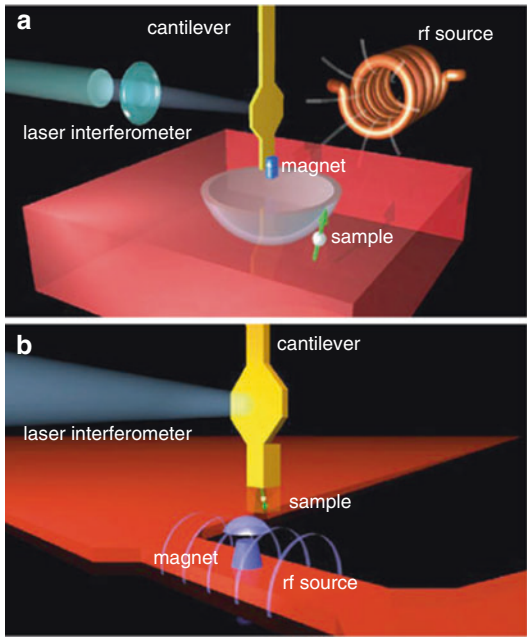
Force-detected magnetic resonance

Definition

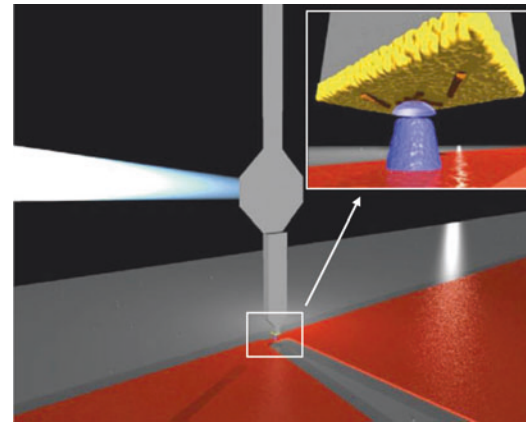
Magnetic resonance force microscopy (MRFM) is a type of magnetic resonance imaging (MRI) now capable of acquiring three-dimensional (3D) images of tiny samples with a spatial resolution better than 10 nm. By applying the techniques of scanning probe microscopy (SPM), MRFM surpasses the sensitivity of conventional, inductive MRI by eight orders of magnitude. MRFM images the interior of nanoscale objects noninvasively and with intrinsic chemical selectivity and, in 2009, it was used to capture 3D images of individual virus particles.

Overview



MRFM relies on the mechanical measurement of the weak magnetic force between a microscopic magnet and the magnetic moments in a sample. These moments are due to either the atomic nuclei with nonzero nuclear spin or electron spins present in a sample. For a single magnetic moment $\boldsymbol{\mu}$ in a magnetic field $\boldsymbol{B}$, this force can be expressed as:

$$\mathbf{F} = \nabla(\boldsymbol{\mu} \cdot \boldsymbol{B}) \tag{1}$$



Using a compliant cantilever, one can measure the component of $\mathbf{F}$ along the cantilever's deflection direction $\hat{x}$:

$$F_x = \frac{\partial}{\partial x}(\boldsymbol{\mu} \cdot \boldsymbol{B}) = \mu \frac{\partial B_z}{\partial x} = \mu G, \tag{2}$$

where $\boldsymbol{\mu}$ points along $\hat{z}$ and $G \frac{\partial B_z}{\partial x}$ is a magnetic field gradient. First, either the sample containing nuclear or electronic moments or the nano-magnet must be fixed to the cantilever. The sample and magnet must be in close proximity, sometimes up to a few tens of nanometers from each other. A nearby radiofrequency (rf) source produces magnetic field pulses similar to those used in conventional MRI, causing the moments to periodically flip. This periodic inversion generates an oscillating magnetic force acting on the cantilever. In order to resonantly excite the cantilever, the magnetic moments can be inverted at the cantilever's mechanical resonance frequency. The cantilever's mechanical oscillations are then measured by an optical interferometer or beam deflection

Magnetic Resonance Force Microscopy, Fig. 1 Schematics of an MRFM apparatus. (**a**) Corresponds to the "tip-on-cantilever" arrangement, such as used in the single-electron MRFM experiment of 2004 [1]. (**b**) Corresponds to the "sample-on-cantilever" arrangement, like the one used for the nanoscale virus imaging experiment in 2008 [2]

Pictured is the cantilever, the laser beam used for position sensing, and the Cu microwire rf source. The *inset* shows a close-up representation of the gold-coated end of the cantilever with attached virus particles. On *top* of the microwire, is the magnetic FeCo tip with the "mushroom"-shaped resonant slice hovering *above*

detector. The electronic signal produced by the optical detector is proportional to the cantilever oscillation amplitude, which depends on the number of moments in the imaging volume. Spatial resolution results from the fact that the nano-magnet produces a magnetic field which is a strong function of position. The magnetic resonance condition and therefore the region in which the spins periodically flip is confined to a thin, approximately hemispherical "resonant slice" that extends outward from the nano-magnet (see Figs. 1 and 2). By scanning the sample in 3D through this resonant region, a spatial map of the magnetic moment density can be made. Different types of magnetic moments (e.g., ^{1}H,^{13}C, ^{19}F, or even electrons) can be distinguished due to their different magnetic resonance frequencies, giving an additional chemical contrast.

In conventional nuclear magnetic resonance detection, the sample is placed in a strong static magnetic field in order to produce a Zeeman splitting between spin states. The sample is then exposed to an rf magnetic field of a precisely defined frequency. If this frequency matches the Zeeman splitting, then the system absorbs energy from the rf radiation resulting in transitions between the spin states. The resulting oscillations of this ensemble of magnetic moments produce a time-varying magnetic signal that can be detected with a pickup coil. The electric current induced in the coil is then amplified and converted into a signal that is proportional to the number of moments (or spins) in the sample. In MRI this signal can be reconstructed into a 3D image of the sample using spatially varying magnetic fields and Fourier transform techniques. The magnetic fields produced by nuclear moments are, however, extremely small: more than one trillion (10^{12}) nuclear spins are typically needed to generate a detectable signal.

The advantage of force-detected over inductive techniques is that much smaller samples can be measured. In the latter case, the measurement can only be sensitive if the spins significantly alter the magnetic field within the pickup coil, i.e., if the spins fill a significant fraction of the coil volume.

For spin ensembles with volumes significantly smaller than $(1\ \mu m)^3$, it is extremely challenging to realize pickup coils small enough to ensure an adequate filling factor. As a result, even the best resolutions achieved by inductively detected MRI require sample volumes of at least $(3\ \mu m)^3$ [3]. Mechanical resonators, in contrast, can now be fabricated with dimensions far below a micron, such that the sample's mass (which is the equivalent to the filling volume in a pickup coil) is always significant compared to the bare resonator mass. In addition, mechanical devices usually show resonant quality factors that surpass those of inductive circuits by orders of magnitude, resulting in a much lower baseline noise. For example, state-of-the art cantilever force transducers achieve quality factors between 10^4 and 10^7, enabling the detection of forces of $aN/Hz^{1/2}$ – less than a billionth of the force needed to break a single chemical bond. In addition, scanning probe microscopy offers the stability to position and image samples with nanometer precision. The combination of these features allows mechanically detected MRI to image at resolutions that are far below 1 μm and – in principle – to aspire to atomic resolution.

Basic Methodology

Despite the large magnetic field gradients produced by specially made magnetic tips, the forces produced by small number of magnetic moments remain astoundingly small: in an achievable gradient of 10^6 T/m, a single ^1H moment, for example, produces a force of about 10^{-20} N. In order to detect forces due to small ensembles of moments, the most sensitive MRFM takes advantage of the thermally limited force resolution of specially made nanomechanical cantilevers. In addition, it utilizes the fact that the force of interest can be made to occur in a narrow bandwidth around the cantilever's mechanical resonance.

The sensitivity and resolution of MRFM hinge on a simple signal-to-noise ratio, which is given by the ratio of the magnetic force power exerted on the cantilever over the force noise power of the cantilever device. For small enough volumes of spins, one must measure statistical spin polarizations; therefore one is interested in force powers (or variances) rather than force amplitudes:

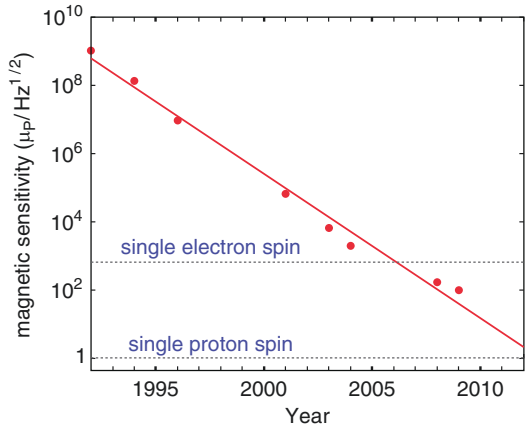
$$\mathrm{SNR} = N\frac{(\mu G)^2}{S_F \Delta f}. \tag{3}$$

Here, N is the number of spins in the detection volume, μ is the magnetic moment of the relevant spin, G is the relevant magnetic field gradient at the position of the sample, SF is the force noise spectral density set by the fluctuations of the cantilever sensor, and Δf is the bandwidth of the measurement, determined by the spin relaxation rate. This expression gives the single-shot signal-to-noise ratio of a thermally limited MRFM apparatus. The larger this signal-to-noise ratio is, the better the spin sensitivity will be.

From the four parameters appearing in Eq. 3, only two can be controlled and possibly improved. On the one hand, the magnetic field gradient G can be enhanced by using higher quality magnetic tips and by bringing the sample closer to these tips. On the other hand, the force noise spectral density SF can be reduced by going to lower temperatures and by making intrinsically more sensitive mechanical transducers.

Key Findings

The use of force-detection techniques in nuclear magnetic resonance (NMR) experiments dates back to Evans in 1955 [4], and was also used in torque magnetometry measurements by Alzetta and coworkers in the 1960s [5]. In 1991, Sidles, independent of this very early work, realized that highly sensitive magnetic resonance detection could be achieved using microfabricated cantilevers and nanoscale ferromagnets. In these early days of scanning probe miscroscopy, he proposed the MRFM technique as a method to improve the resolution of MRI to molecular length scales [6, 7]. Subsequently, the first micrometer-scale experimental demonstration using cantilevers was realized by Rugar [8], demonstrating mechanically detected electron spin resonance in

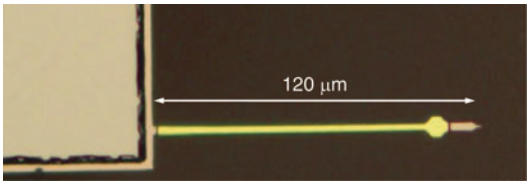


a 30-ng sample of diphenylpicrylhydrazyl (DPPH).

The visionary goal of the MRFM proposal was to eventually image molecules atom by atom, so as to directly map the 3D atomic structure of macromolecules [9]. Such a "molecular structure microscope" would have a dramatic impact on modern structural biology, and would be an important tool for many future nanoscale technologies. While this ultimate goal has not been achieved to date, the technique has undergone a remarkable development into one of the most sensitive spin detection methods available to researchers today. Among the important experimental achievements are the detection of a single electronic spin [1] and the extension of the spatial resolution of MRI from several micrometers to below 10 nm [2].

First Demonstration

The first MRFM apparatus operated in vacuum and at room temperature with the DPPH sample attached to the cantilever. A millimeter-sized coil produced an rf magnetic field tuned to the electron spin resonance of the DPPH (220 MHz) with a magnitude of 1 mT. By changing the strength of a polarizing magnetic field (8 mT) in time, the electron spin magnetization in the DPPH was modulated. In a magnetic field gradient of 60 T/m, produced by a nearby NdFeB permanent magnet, the sample's oscillating magnetization resulted in a time-varying force between the sample and the magnet. This force modulation was converted into mechanical vibration by the compliant cantilever. Displacement oscillations were detected by a fiber-optic interferometer achieving a thermally limited force sensitivity of 3 fN/$\sqrt{\text{Hz}}$.



During the years following this initial demonstration of cantilever-based magnetic resonance detection, the technique has undergone a series of developments toward higher sensitivities that, as of today, is about 10^7 times that of the 1992 experiment (see Fig. 3). The following touches on two important demonstrations during this development. Several review articles and book chapters have appeared in the literature that discuss the historical progress of the technique more broadly and in richer detail [15–22].

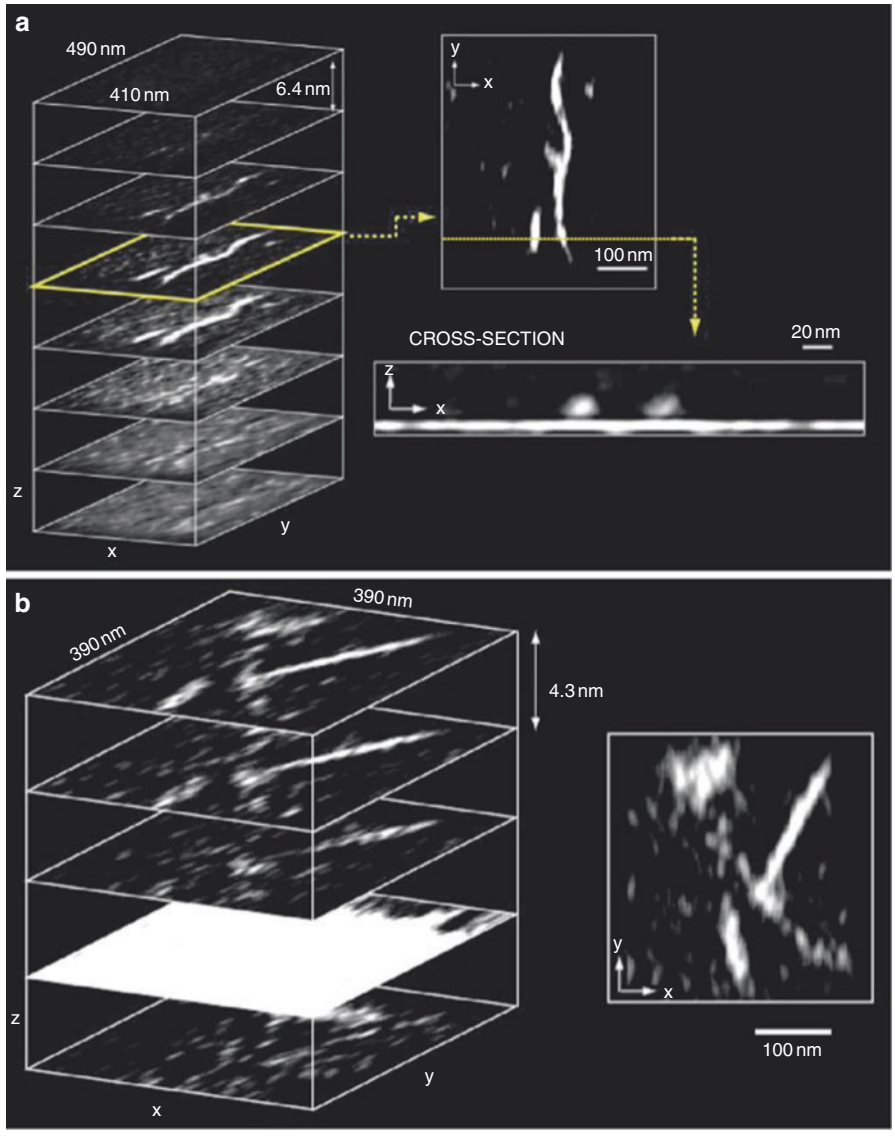
Magnetic Resonance Force Microscopy, Fig. 3 Advances to the sensitivity in force-detected magnetic resonance over time. Remarkably, improvements have closely followed a "Moore's law" for over a decade, with the magnetic moment sensitivity doubling roughly every 8 months. *Dots* are experimental values [1, 2, 8, 10–14], and *dashed lines* indicate sensitivities of one electron and one proton magnetic moment (μ_P), respectively

Single-Electron MRFM

The measurement of a single electron spin by Rugar et al. in 2004 concluded a decade of development on the MRFM technique and stands out as one of the first single-spin measurements in solid-state physics. A variety of developments led to the exceptional measurement sensitivity required for single-spin detection. These include the operation of the apparatus at cryogenic temperatures and high vacuum, the ion-beam milling of magnetic tips in order to produce large gradients, and the fabrication of mass-loaded attonewton-sensitive cantilevers [23] (shown in Fig. 4). The thermal noise in higher order vibrational modes of mass-loaded cantilevers is suppressed compared with the noise in the higher order modes of conventional, "flat" cantilevers. Since high-frequency vibrational noise in combination with a magnetic field gradient can disturb the electron spin, the mass-loaded levers proved to be a crucial advance for single-electron MRFM. In addition, Rugar et al. developed a sensitive interferometer employing only a few nanowatts of optical power for the detection of cantilever displacement [24]. This low incident laser power is crucial for achieving low cantilever temperatures and thus

Magnetic Resonance Force Microscopy, Fig. 4 Image of an ultrasensitive mass-loaded Si cantilever taken from an optical microscope. This type of cantilever, which has a spring constant under 100 μN/m, has been used as a force transducer in the many of the latest MRFM experiments [23]

minimizing the effects of thermal force noise. A low-background measurement protocol called OSCAR based on the NMR technique of adiabatic rapid passage was also employed [10]. Finally, the experiment required the construction of an extremely stable measurement system capable of continuously measuring for several days in an experiment whose single-shot signal-to-noise ratio was just 0.06 [1].



Nano-MRI

The detection of a single nuclear spin is far more challenging than that of single electron spin. The intrinsic magnetic moment of a nucleus is much smaller than that of an electron; as a result the force produced by a nuclear moment in Eq. 2 is proportionally smaller. A ^{1}H nucleus (proton), for example, possess a magnetic moment that is only $\sim 1/650$ of an electron spin moment. Other important nuclei, like ^{13}C or a variety of isotopes present in semiconductors, have even weaker magnetic moments. In order to observe single nuclear spins, it is necessary to improve the state-of-the-art sensitivity by another two to three orders of magnitude. While not out of the question, this is a daunting task that requires significant advances to all aspects of the MRFM technique. Despite these challenges, significant progress has been made. In particular, one experiment that used single tobacco mosaic virus (TMV) particles as the sample shows both the feasibility of MRI imaging with nanometer resolution and the applicability of MRFM to biologically relevant samples.

Figure 2 is a representation of the MRFM apparatus used in the experiment. The virus particles were transferred to the cantilever end by dipping the tip of the cantilever into a droplet of aqueous solution containing suspended TMV. As a result, some TMVs were attached to the gold layer previously deposited on the cantilever end. The density of TMV on the gold layer was low enough that individual particles could be isolated. Then the cantilever was mounted into the low-temperature, ultra-high-vacuum measurement system and aligned over a magnetic tip and rf field source.

After applying a static magnetic field of about 3 T, resonant rf pulses were applied to the rf source in order to flip the ^{1}H nuclear spins at the cantilever's mechanical resonance. Finally, the end of the cantilever was mechanically scanned in 3D over the magnetic tip. Given the extended geometry of the region in which the resonant condition is met, i.e., the "resonant slice," a spatial scan does not directly produce a map of the ^{1}H distribution in the sample. Instead, each data point in the scan contains force signal from ^{1}H spins at a variety of different positions. In order to reconstruct the 3D spin density (the MRI image), the force map must be deconvolved by the point spread function defined by the resonant slice. Fortunately, this point spread function can be accurately determined using a magnetostatic model based on the physical geometry of the magnetic tip and the tip magnetization. Deconvolution of the force map into the three-dimensional ^{1}H spin density can be done in several different ways; for the results presented in [2] the authors applied the iterative Landweber deconvolution procedure suggested in an earlier MRFM experiment [25, 26]. This iterative algorithm starts with an initial estimate for the spin density of the object and then improves the estimate successively by minimizing the difference between the measured and predicted spin signal maps. The iterations proceed until the residual error becomes comparable with the measurement noise.

The result of a representative experiment is shown in Fig. 5. Here, clear features of individual TMV particles, which are cylindrical, roughly 300-nm-long and 18 nm in diameter, are visible and can be confirmed against a scanning electron micrograph (SEM) of the same region. Both whole virus particles and particle fragments are

Magnetic Resonance Force Microscopy, Fig. 5 Nanoscale MRI images of tobacco mosaic virus (*TMV*) particles acquired by MRFM [2]. (**a**) The series of images *to the left* depicts the 3D ^{1}H spin density of virus particles deposited on the end of the cantilever. *Black* represents very low or zero density of hydrogen, while *white* is high hydrogen density. The *right side* shows a representative xy-plane, with several viral fragments visible, and a cross section (xz-plane) of two virus particles that reveals an underlying molecular layer of hydrocarbons covering the cantilever surface. (**b**) 3D ^{1}H spin density recorded on a different region of the same cantilever as in (**a**), showing an intact and several fragmented virus particles. The *right side* shows a representative xy-plane

observed. The imaging resolution, while not fine enough to discern any internal structure of the virus particles, constitutes a 1,000-fold improvement over conventional MRI and a corresponding improvement of volume sensitivity by about 100 million.

Comparison to Other Techniques

The unique position of MRFM among high-resolution microscopies becomes apparent when comparing it to other, more established nanoscale imaging techniques. As a genuine scanning probe

method, MRFM has the potential to image matter at atomic resolution. While atomic-scale imaging is routinely achieved in scanning tunneling microscopy and atomic force microscopy, these techniques are confined to the top layer of atoms and cannot penetrate below surfaces [27, 28]. Moreover, in standard scanning probe microscopy (SPM), it is difficult and in many situations impossible to identify the chemical species being imaged. Since MRFM combines SPM and MRI, these restrictions are lifted. The 3D nature of MRI permits acquisition of subsurface images with high spatial resolution even if the probe is relatively far away. As with other magnetic resonance techniques, MRFM comes with intrinsic elemental contrast and can draw from established NMR spectroscopy procedures to perform detailed chemical analysis. In addition, MRI does not cause any radiation damage to samples, as do electron and X-ray microscopies.

MRFM also distinguishes itself from super-resolution optical microscopies that rely on fluorescence imaging [29]. On the one side, optical methods have the advantage of working in vivo and they have the ability to selectively target the desired parts of a cell. Fluorescent labeling is now a mature technique which is routinely used for cellular imaging. On the other side, pushing the resolution into the nanometer range is hampered by fundamental limitations, in particular, the high optical powers required and the stability of the fluorophores. Moreover, fluorescent labeling is inextricably linked with a modification of the target biomolecules, which alters the biofunctionality and limits imaging resolution to the physical size of the fluorophores.

MRFM occupies a unique position among other nanoscale spin detection approaches. While single electron spin detection in solids has been shown using several techniques, these mostly rely on the indirect readout via electronic charge [30, 31] or optical transitions [32, 33]. In another approach, the magnetic orientation of single atoms has been measured via the spin-polarized current of a magnetic STM tip or using magnetic exchange force microscopy [34–36]. These tools are very valuable to study single surface atoms; however, they are ill-suited to map out subsurface spins such as paramagnetic defects. In contrast, MRFM *directly* measures the magnetic moment of a spin, without resorting to other degrees of freedom, making it a very general method. This direct measurement of magnetic moment (or magnetic stray field) could also be envisioned using other techniques, namely, SQuID microscopy [37], Hall microscopy [38], or recently introduced diamond magnetometry based on single nitrogen-vacancy centers [39–41]. So far, however, none of these methods have reached the level of sensitivity needed to detect single electron spins, or volumes of nuclear spins much less than 1 μm [42, 43]. It is certainly possible that future improvements to these methods – especially to diamond magnetometry – may result in alternative techniques for nanoscale MRI that surpass the capabilities of MRFM.

Outlook

Despite the tremendous improvements made to MRFM over the last decade, several important obstacles must be overcome in order to turn the technique into a useful tool for biologists and materials scientists. Most existing MRFM instruments are technically involved prototypes; major hardware simplifications will be required for routine screening of nanoscale samples. Suitable specimen preparation methods must be developed that are compatible with the low-temperature, high-vacuum environment required for the microscope to operate at its highest sensitivity and resolution. While this is particularly challenging for biological samples, protocols exist which could be adapted to MRFM. In cryo-electron microscopy, for example, dispersed samples are vitrified to preserve their native structure by plunge-freezing in liquid nitrogen [44]. As objects become smaller, isolation of samples and suppression of unwanted background signals from surrounding material will become increasingly important.

The conditions under which the latest MRFM imaging experiments were carried out are remarkably similar to those prevailing in cryo-electron

microscopy, the highest resolution 3D imaging technique commonly used by structural biologists today. Cryo-electron microscopy, like MRFM, operates at low temperatures and in high vacuum, requires long averaging times (on the order of days) to achieve sufficient contrast, and routinely achieves resolutions of a few nanometers [45, 46]. Unlike MRFM, however, electron microscopy suffers from fundamental limitations that severely restrict its applicability. Specimen damage by the high-energy electron radiation limits resolution to 5–10 nm if only a single copy of an object is available. Averaging over hundreds to thousands of copies is needed to achieve resolutions approaching 10 Å [47]. In addition, unstained images have intrinsically low contrast, whereas staining comes at the expense of modifying the native structure.

MRFM has the unique capability to image nanoscale objects in a noninvasive manner and to do so with intrinsic chemical selectivity. For this reason the technique has the potential to extend microscopy to the large class of structures that show disorder and therefore cannot be averaged over many copies. These structures include such prominent examples as HIV, influenza virus, and amyloid fibrils. Virtually all of these complexes are associated with important biological functions ranging from a variety of diseases to the most basic tasks within the cellular machinery. For such complexes, MRFM has the potential not only to image the 3D macromolecular arrangement, but also to selectively image specific domains in the interior through isotopic labeling.

While the most exciting prospect for MRFM remains in its application to structural imaging in molecular biology, its applications are not limited to biological matter. For example, most semiconductors contain nonzero nuclear magnetic moments. Therefore, MRFM may prove useful for subsurface imaging of nanoscale electronic devices. MRFM also appears to be the only technique capable of directly measuring the dynamics of the small ensembles of nuclear spin that limit electron spin coherence in single semiconductor quantum dots. Polymer films and self-assembled monolayers – important for future molecular electronics – are another exciting target for MRFM and its capability to image chemical composition on the nanoscale. Finally, isotopically engineered materials are becoming increasingly important for tuning a variety of physical properties such as transport and spin. Researchers currently lack a general method for noninvasively imaging the isotopic composition of these materials [48–50]; MRFM techniques could fill this void.

Magnetic assembly; Magnetic self-assembly

Definition

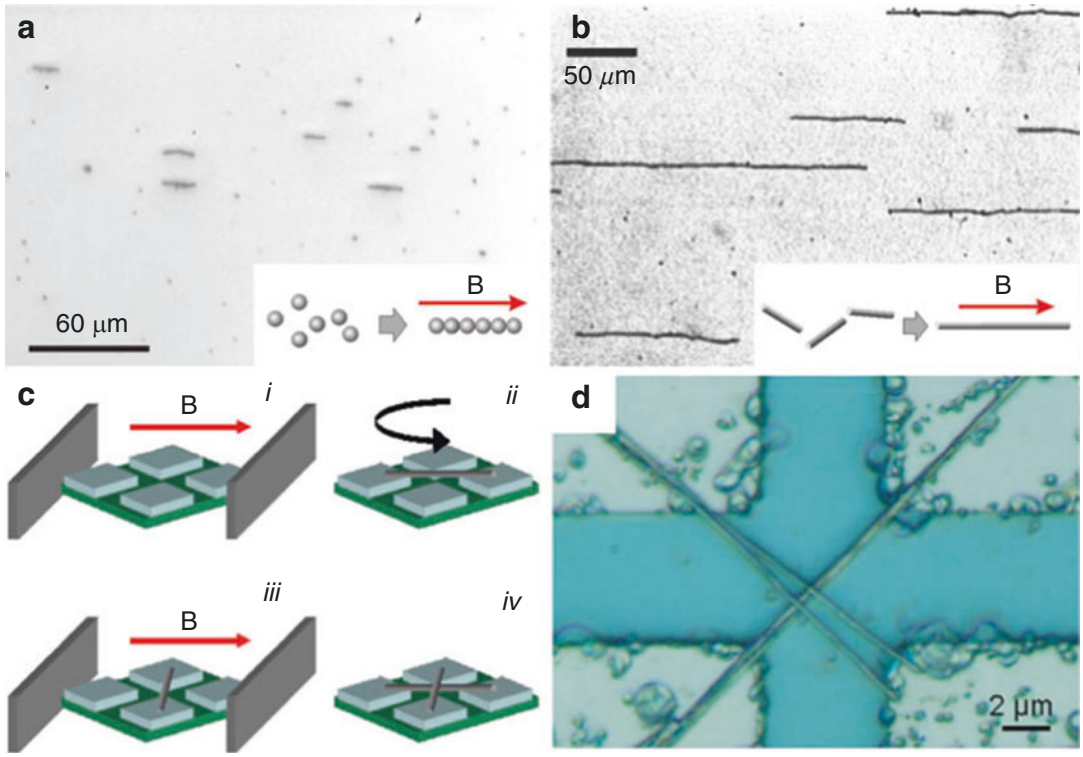
Magnetic-field-based self-assembly refers to the autonomous organization of discrete components to form ordered patterns, structures, devices, and systems driven by an external magnetic field or by magnetic fields from permanent dipoles incorporated into parts. The magnetic-field-based self-assembly approach can be applied for the assembly of individual magnetic components such as magnetic nanoparticles and nanowires. It can also be applied for the self-assembly of multiple components, such as components with complementary micromagnet arrays or a mixture of magnetic and nonmagnetic components.

Overview and Concepts

For magnetic self-assembly, a magnetic interaction between magnetic components is required [1]. The strength of the magnetic interaction force is dependent on the distance and orientation between the magnetic components, the magnetization of the materials, and the dimensions and shapes of the magnetic components. Most research studies have used either ferromagnetic materials or superparamagnetic particles as magnetic components for magnetic assembly. Generally, ferromagnetic materials are classified as either hard magnetic or soft magnetic depending on their coercivity [2]. For hard magnetic materials that are permanently magnetized, an external magnetic field may not be required for self-assembly. The magnetization of soft-magnetic materials is highly dependent on the external magnetic field, and they tend to return to their nonmagnetized state as the field is removed because of their low remanence magnetization. When the dimensions of ferromagnetic material are reduced to a single magnetic domain, superparamagnetism occurs in which the saturation magnetization can be as high as that in a ferromagnetic state but its remanence magnetization decreases to zero. Therefore, an external field is required for the magnetic self-assembly of soft magnetic or superparamagnetic components. Furthermore, shape effect, i.e., the geometrically

Magnetic-Field-Based Self-Assembly, Fig. 1 Overview of magnetic self-assembly: concept and applications

induced directional dependency of the magnetic properties within the magnetic component [2], significantly influences how the components magnetize and, hence, how soft-magnetic or superparamagnetic components assemble. In addition, the environment for self-assembly is crucial, since the components move with respect to one another [1]. One issue that can occur for micro-/nanoscale components is that van der Waals interactions and other surface forces dominate gravitational forces and other volume forces at this scale. One way to reduce these interactions is to perform self-assembly in liquid or at a liquid-air interface.



Magnetic-field-based self-assembly has many advantages [3], for instance, it is compatible for both wet and dry environments; it does not require physical contact for assembly; it is scalable in a large range, i.e., from nano-/meso- to macroscale; it has robust control of angular and lateral alignment; and, in addition, a weak-strength magnetic field is considered safe for in vivo applications.

Magnetic assembly has potential applications in different fields, such as microfluidics and lab on a chip [4–7], wireless biosensing [8], biomedical engineering [9], microelectronics [10–12], and microrobotics [13–15]. An overview of magnetic self-assembly including concepts and applications is shown in Fig. 1.

Key Research Findings

Static Self-Assembly of Single Magnetic Components

Magnetic particles and nanowires are two fundamental components for magnetic self-assembly of one-dimensional (1-D) structures. Figure 2a shows a suspension of superparamagnetic beads, after a uniform magnetic field has been applied. The beads are driven to form chains and align with the external field. Self-assembly is caused by the induced magnetic moments in the beads, and the magnetic alignment of the chain resembles an elongated

Magnetic-Field-Based Self-Assembly, Fig. 2 Magnetic self-assembly of superparamagnetic beads and Ni nanowires. (**a**) Self-assembly of 1 μm diameter superparamagnetic microbeads suspension to form straight chains. The applied field strength (*B*) is 2.5 mT. (**b**) Ni nanowire chains are formed when a low strength magnetic field is applied. The applied field strength (*B*) is 0.8 mT. The individual nanowires have a diameter of 350 nm and a length of 12 μm (Reprinted with permission from Ref. [16]. magnetic body aligned with the applied field [6]. In comparison to individual magnetic beads, which have no magnetic shape anisotropy, a magnetic nanowire has an "easy" magnetized axis along its long axis. When a magnetic field is applied to nanowire suspensions, they are driven to form chains and self-align their easy axis along the magnetic field, (see Fig. 2b) [16]. The results also indicate that to self-assemble magnetic micro-/nanoparticles and nanowires in fluid, a weak-strength magnetic field, i.e., in a range of milli-Tesla (mT), is sufficient, which is approximately three orders of magnitude lower than most clinical magnetic resonance imaging (MRI) systems. Therefore, the magnetic self-assembly approach is considered noninvasive for biomedical applications such as cell manipulation and biosensing.

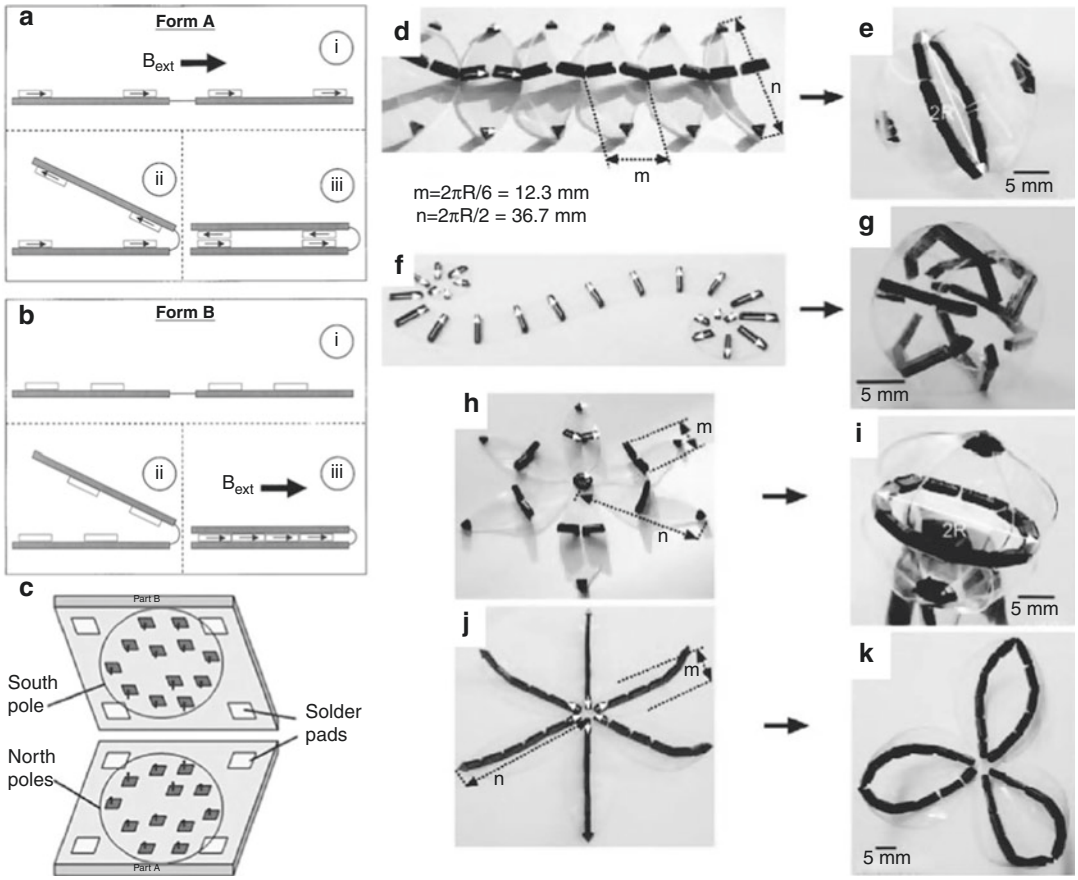
The construction of 2-D or 3-D patterns using single magnetic components is not straightforward. One method to overcome this issue is to perform the assembly in steps. Magnetic assembly of ferromagnetic nanowires to create networks comprised of cross-shaped and T-shaped junctions was shown by Hangarter et al. [17]. The hierarchical 2-D patterns were obtained using two steps of magnetic alignment in which



crossing angles from 30° to 90° were obtained. The magnetic self-assembly and alignment process were conducted by placing two permanent magnets around the substrate covered with droplets of the nanowire suspensions. The pattern configuration was controlled by changing the direction and the strength of the applied field in two steps. Magnetic field strengths of 28, 76, and 124 mT were applied in the experiments by adjusting the distance between the two permanent magnets [17]. It was also demonstrated that on a patterned substrate with ferromagnetic electrodes, the electrodes act as micromagnet arrays which can be interconnected by magnetic nanowires due to the dipole interaction. Magnetic nanowire cross junctions were realized by a two-step alignment as shown in Fig. 2c–d.

Static Self-Assembly of Multiple Components

For self-assembly of more complex structures than simple periodic structures or crystals, multiple components in a mixture must come together in an organized way [1]. Unlike the magnetic self-assembly, using single components such as beads and nanowires, Yellen and coworkers reported that 3-D flower-like colloidal structures with a rotational symmetry are formed using multiple components, i.e., nonmagnetic and paramagnetic colloids mixed in a ferrofluid consisting of magnetite nanoparticles suspended in water, when a static and uniform magnetic field is applied [18]. The results showed that the paramagnetic and nonmagnetic colloids interact anti-ferromagnetically in the multiple-component suspensions, leading to the formation of ring structures as shown in Fig. 3 [18]. This is because the colloids less magnetizable than the ferrofluid exhibit diamagnetic property, which implies that the particle moments prefer to align antiparallel with respect to the direction of the applied uniform field. Figure 3a, b show schematics of magnetic self-assembly from two and three colloidal components, respectively, which were mixed into ferrofluid. Figure 3c shows the experimental results of the fluorescence-labeled colloids, corresponding to the schematic in Fig. 3b, hierarchically self-assembling to ring-like structures with multipole symmetry configurations. Additionally,

Magnetic-Field-Based Self-Assembly, Fig. 3 (**a**) Illustration of magnetic assembly of two-component colloidal particle (*red* and *gray spheres*) mixed with ferrofluid (*brown dots*). No structures form without an external magnetic field. When a field is applied (*black arrows*), equatorial and polar arrangements form when the particle magnetizations, respectively, have the opposite and the same sense. Particle dipole moments are indicated by the *yellow arrows*. (**b**) Self-assembly in three-component suspensions is illustrated. "Two-tone" structures consist of simultaneous polar and equatorial arrangements assembling on a single core particle, whereas "flower" structures are formed by the fractal assembly of multiple equatorial arrangements. the concentration of the magnetic nanoparticles and the strength of the external magnetic field are two crucial factors for such a self-assembly process. In those tests, the applied uniform magnetic field was not higher than 100 Oe (in free air 100 Oe is equal to 10 mT).

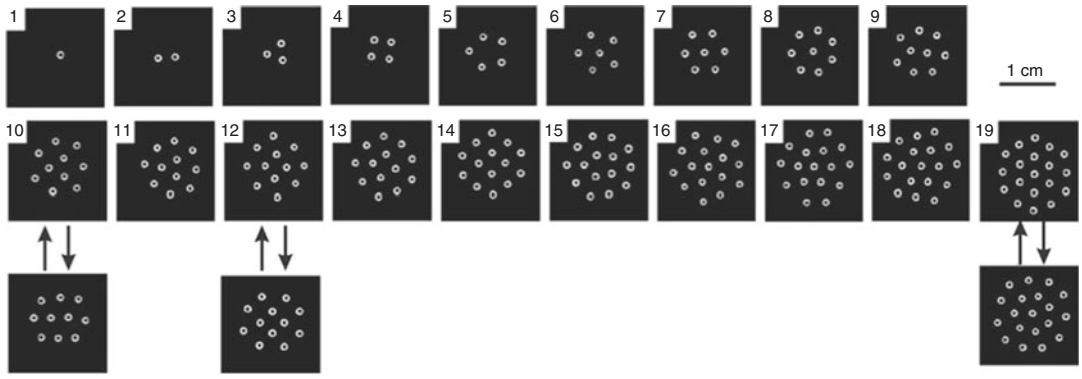
An alternative approach to construct 3-D patterns is using the origami technique to fold planar components. The magnetic assembly approach is used for the alignment of the components with a high positioning precision and efficiency. Barbasathis et al. showed the self-alignment of thin films with nanomagnets on the surfaces [10]. The film are folded into 3-D configurations using a magnetic field. The nanomagnet arrays were prepared by lithographic patterning technique. Two types of alignment methods (form A and B) were investigated as presented in Fig. 4a, b, in which the magnets are magnetized before and after folding, respectively. There are two main advantages to perform the alignment after the folding process (i.e., form B): (1) the magnetic interaction forces are enhanced by one order of magnitude due to the applied field;

(2) since an external field is "ON" during the assembly process, it can be applied for a broader range of ferromagnetic materials and the shapes of the nanomagnets. Magnetic alignment tests of folding a freestanding Si_3N_4 membrane on its own substrate, both are patterned with 75 nm thick cobalt nanomagnets, are conducted, and the layer-to-layer alignment accuracy of approximately 250 nm was achieved [10]. The applied field strengths were in the range of several hundred milli-Teslas. The layer-to-layer magnetic self-assembly using permanent magnet arrays was reported by Arnold et al. to assemble different microscale components (see Fig. 4c), in which solder pads were designed for permanent bonding of the assembled parts [11]. Moreover, the results indicate that the magnetic bonding force is enhanced by using an array of micromagnets compared to a single piece of magnet with the same volume.

Spontaneous folding of flexible 2-D components to form freestanding hollow 3-D objects using magnetic self-assembly was demonstrated by Whitesides' group. To construct a spherical shell, they investigated elastomeric sheets with three different 2-D shape designs [19]: an equatorial cut (see Fig. 4d), an orange-peel cut (see Fig. 4f), and a flower-petal cut (see Fig. 4h, j). To self-fold the sheets, different patterns of magnetic dipoles generated by permanent magnets were examined. The self-assembly processes were performed in water or at the air-water interface with some minutes of agitation. The magnetic and mechanical interactions influence the self-assembly significantly [19].

Dynamic Self-Assembly at a Liquid-Air Interface



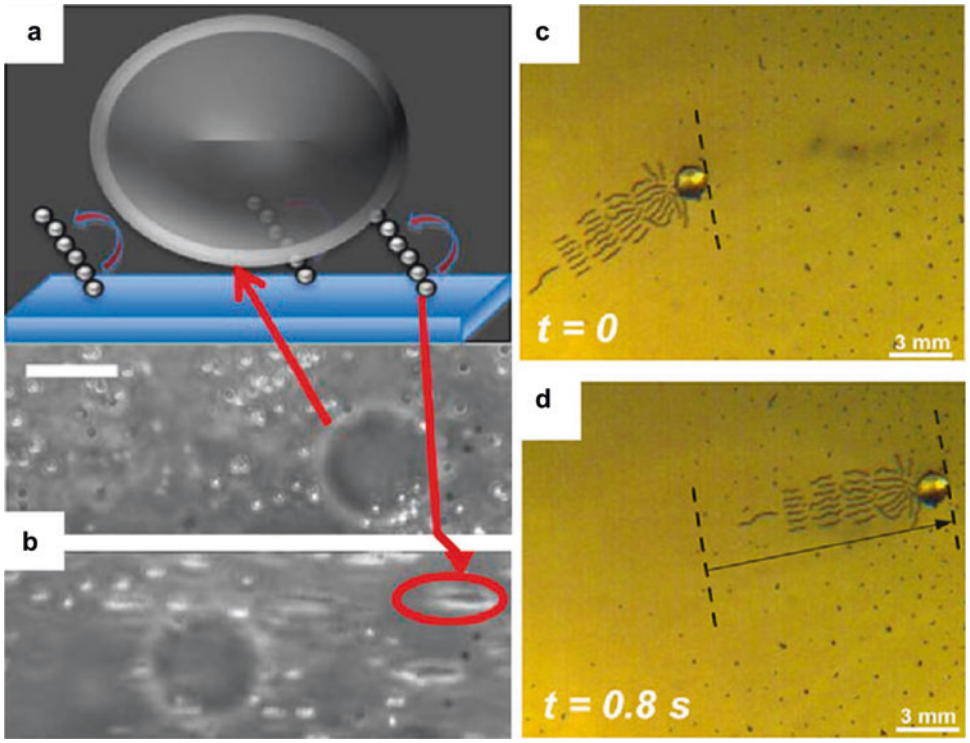
Self-assembly processes can be classified into two categories: static self-assembly and dynamic self-assembly [1]. The self-assembly approaches presented in the previous section all belong to the static self-assembly category. An assembly is defined as static when the ordered structure is in a stable equilibrium not dissipating energy [20]. Unlike the static self-assembly, in a dynamic self-assembly process, an ordered pattern/structure only occurs when it is dissipating energy [1]. Recently, dynamic self-assemblies were demonstrated using millimeter-size magnetic disks at a liquid-air interface. When a rotating magnetic field was applied by placing a rotating bar magnet underneath the container, the magnetic disks spun around their axis and created different dynamic patterns depending on the number of the disks. The dynamic self-assembly patterns are induced by the interplay between the attractive forces (magnetic interactions) and the repulsive forces (hydrodynamic interactions) [20]. In the case of a single magnetic disk, it stays at a stable position with its center coinciding with the rotational axis of the bar magnet, when the number of magnetic disks is varied from 2 to 19, various patterns are formed in a dynamic mode rotating at the liquid-air interface as shown in Fig. 5 [20]. More recently, Kwok et al. showed that, using a vertical (perpendicular to the liquid-air interface) alternating magnetic field, nickel microbeads with a diameter of 80–100 μm suspended at the liquid-air interface form complex 2-D patterns resulting from dynamic self-assembly [5]. The formation of the snake-like pattern is driven by the coupling of the hydrodynamic and magnetic interactions at the liquid-air interface. More detailed explanation of this dynamic assembly is shown in Ref. [5].

Examples of Application

Self-assembly is expected to be applied for crystallization at all scales, and in the fields of robotics and manufacturing, nanoscience and technology, microelectronics, and netted systems [1]. Numerous groups explored the applications using magnetic self-assembly, and some examples are given in the following section.

Artificial Microswimmers for Cargo Transport

Self-assembled magnetic micro-/nanobeads and nanowires have been investigated extensively for various applications. One example is the actuation of 1-D magnetic chains for individual cargo transport and manipulation of microfluid. Figure 2a shows that when a uniform magnetic field is applied, magnetic bead suspensions form 1-D

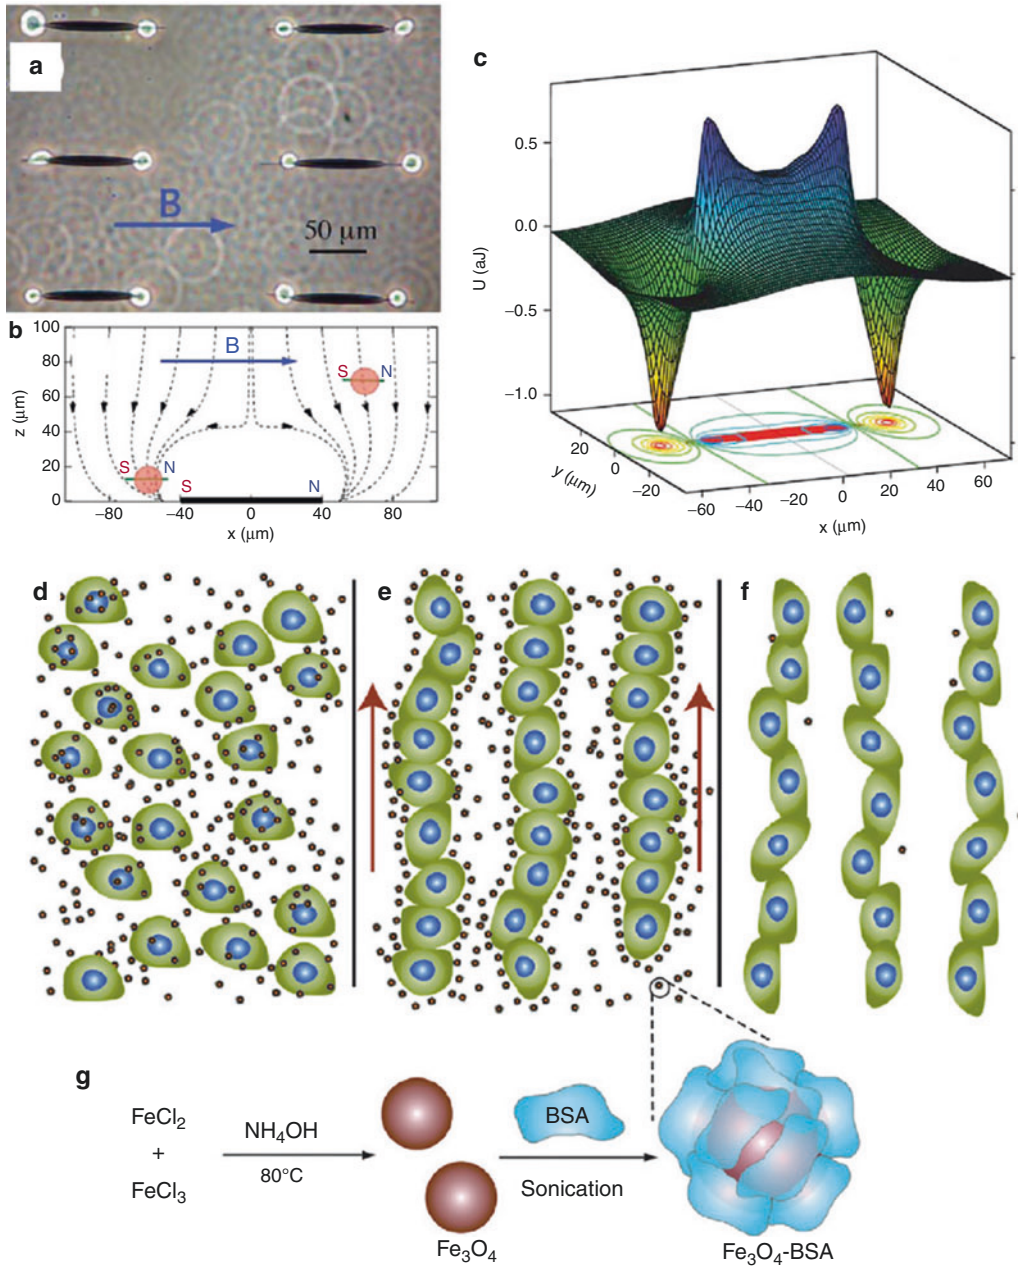


Magnetic-Field-Based Self-Assembly, Fig. 5 Dynamic patterns formed by various numbers (n) of magnetic disks rotating at the ethylene glycol/water-air interface. This interface is 27 mm above the plane of the external magnet. The disks are composed of a section of polyethylene tube (*white*) of outer diameter 1.27 mm, filled with poly (dimethylsiloxane), PDMS, doped with 25 wt% of magnetite (*black center*). All disks spin around their centers at $\omega = 700$ rpm, and the entire aggregate slowly ($\Omega < 2$ rpm) precesses around its center. For $n < 5$, the aggregates do not have a "nucleus" – all disks are precessing on the rim of a circle. For $n > 5$, nucleated structures appear. For $n = 10$ and $n = 12$, the patterns are bistable in the sense that the two observed patterns interconvert irregularly with time. For $n = 19$, the hexagonal pattern (*upper*) appears only above $\omega \approx 800$ rpm, but can be "annealed" down to 700 rpm by slowly decreasing the spinning rate. Without annealing, a less symmetric pattern exists at $\omega = 700$ rpm (Adapted with permission from Macmillan Publishers Ltd.: Ref. [20]. Copyright 2000)

chains. Upon rotation of the uniform field, the self-assembled chains rotate, resembling a microscale rotor, due to the induced magnetic torque [6]. Moreover, the rotating chains are capable of propulsion as they are near a solid surface. The change of motion from simple rotation to rotation plus translation results from wall effects. The drag on an object increases when it is closer to a solid boundary. This induces a drag force imbalance on the object resulting in propulsion along the surface in the direction of the rotating field. This type of motion is commonly referred to as tumbling motion. Rotating devices, such as self-assembled magnetic-bead-chains and magnetic nanowires, generates a localized flow around them, which implies that they can act as tools for microfluid and microobject manipulation [6, 7]. Controlled transport of dispersed microobjects such as vesicles near a solid boundary by self-assembled tumbling chains is shown in Fig. 6a, b [6]. Self-assembled magnetic structure can also perform micromanipulation at a liquid-air interface. In the previous section, it was shown that snake-like pattern can be created at the liquid-air interface by dynamic self-assembly approach. Kwok et al. reported the transport of individual 1–2 mm diameter glass or polystyrene beads using such a snake-like swimmer as shown in Fig. 6c, d. The self-propulsion of the surface microswimmer with the cargo is attributed to the breaking of symmetry of the surface vortex flow when a bead is placed near one end of the swimmer [5].

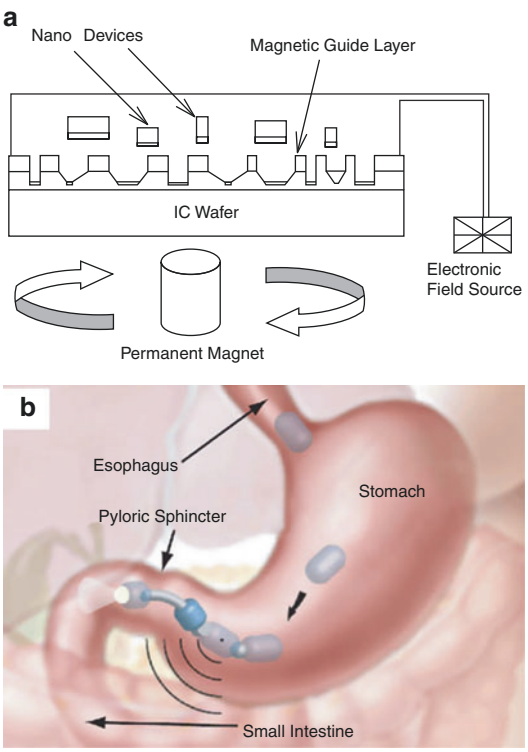
One advantage of utilizing self-assembled microswimmers for microfluid and microobject manipulation is that no complex microfabrication techniques are required, and moreover, the self-assembly and disassembly processes are reversible and controlled on demand [6].

Magnetophoretic Cell Manipulation



Low-strength magnetic fields have a minimal impact on living cells and biological tissues; therefore, they are promising for biomedical applications [15]. Among the different magnetic materials, magnetic nanoparticles and nanowires are interesting components for cell manipulation. In principle, two methods can be applied for magnetophoretic cell manipulations, i.e., positive and negative magnetophoresis. Positive magnetophoresis means that magnetic

Magnetic-Field-Based Self-Assembly, Fig. 6 (**a**–**b**) The presence of a flow field created by using the rotors enables the transport of large, dispersed objects like the vesicles (*large dark circle*). The flow is generated by using a carpet of surface walkers randomly positioned (*bright*, *short*, *chain-like regions* in **b**) actuated at 32 Hz. The snapshots in (**b**) are *top* view. (**c**–**d**) Magnetic surface swimmer is composed of self-assembled 90 μm diameter Ni microbeads. The swimmer is capable of cargo transport, such as glass bead with a diameter of 1.5 mm, at a liquid-air interface using an alternating magnetic field. The input frequency is 80 Hz and the field strength is 10 mT (**c**–**d** Reprinted with permission from Snezhko, A., Belkin, M., Aranson, I. S., Kwok, W. K.: Phys. Rev. Lett., 102, 118103 (2009) (Ref. [5]). Copyright 2009 by the American Physical Society)



components are attracted toward the area with highest magnetic field intensity and are repelled from the area with lowest magnetic field intensity. For cell manipulation, the cells are tagged with magnetic components directly, resulting in higher permeability than the fluidic environment. The alternative approach for cell manipulation is to employ negative magnetophoresis, in which fluid, e.g., ferrofluid, with a high permeability is employed to manipulate cells. One example of 3-D colloidal structure assembly using negative magnetophoresis was shown in the last section (see Fig. 3). For cell manipulation, one advantage of the negative magnetophoresis is that it is capable of performing cell manipulation without binding the cell or uptake of the magnetic components by the cells [9]. The magnetophoretic manipulation can be achieved if the magnetic potential energy is significantly larger than the thermal fluctuation energy [9].

Figure 7a–c shows targeted patterning of 3 T3 mouse fibroblasts cells on a substrate using positive magnetophoresis. In the experiments, the cells were attached to ferromagnetic nanowires, and then self-assembled on the substrate pre-patterned with ellipsoidal permalloy micromagnet arrays. The results show that the cells are trapped separately at the two ends of the micromagnets forming an ordered 2-D pattern (see Fig. 7a). The schematics in Fig. 7b, c indicate

that the two ends and the center of the micromagnet are the magnetic field intensity maxima and minima, respectively, therefore all cells are trapped at the two ends but never land at the center [4]. Three different species of cells, 3 T3, HeLa, and MCF10A breast cells, were employed in the cell manipulation tests. One example of cell manipulation using negative magnetophoresis is illustrated in Fig. 7d–f, in which the cells are self-assembled to form linear structures using ferrofluid. Krebs et al. demonstrated that using bovine serum albumin (BSA) functionalized magnetic nanoparticles in ferrofluid (see Fig. 7g) can efficiently avoid the potential cytotoxicity due to the attachment of particles onto the cells or the cellular uptake of the nanoparticles during the manipulation [9]. HUVECs (human umbilical vein endothelial cells) were employed in the tests, and it was reported that the assembled cellular chains are intact and stable after the removal of external magnetic field and ferrofluid. Organized cell structures can be utilized in tissue engineering research [9].

Magnetic Assembly for Microelectronics and Microrobotics

Another promising application using self-assembly is to integrate various functional components for microelectronics. To date, robotic assembly, e.g., performing pick-and-place and alignment tasks using robotic arms, is still the main approach in industry for integration of microelectronic devices and systems. However, because the dimensions of individual components for an integrated circuit (IC) are miniaturized to a micrometer or even smaller scale, the throughput of robotic assembly is reduced significantly due to the high precision requirement in the assembly process. Moreover, van der Waals forces and other surface interactions can lead to a severe releasing problem in robotic assembly as the size of the component is reduced to a micro-/nanoscale. Therefore, magnetic self-assembly processes were explored to improve the throughput and accuracy of the assembly process for electronic devices.

One straightforward method is to pre-pattern the device surface with micromagnet arrays for the self-assembly and then interconnect the components permanently by fusing the solder pads as shown in Fig. 4c. A 3-D electrical circuit was constructed from planar components consisting of micromagnets, solder pads, copper wires, and six LEDs (light-emitting diodes), and the results show that all LEDs illuminate when a battery is connected [19]. It is notable that the reliability of the magnetic assembly can be enhanced by combination of other self-assembly method. For example, multiple-magnetic-components assembly on an IC wafer is shown schematically in Fig. 8a. The components have unique shapes that fit into the patterned surface. During the process, all components fall on the surface due to

gravity and with the help of a permanent magnet under the IC wafer, they are assembled and retained [12].

In the field of microrobotics, magnetic self-assembly is a promising approach to build modular robotic systems, which is particularly interesting for robotic endoluminal surgery [13, 14]. For minimal invasive medical diagnosis and treatment, swallowable capsule endoscopes were developed; however, the size and the functionality of the capsule are the two main challenges. One idea to overcome these issues is to swallow the individual modules one at a time and final assembly is performed inside gastrointestinal tract. This allows the size and the complexity of the final robot to be significantly greater than that of its individual modules [13]. If the modules are designed to be heterogeneous, each having a specific dedicated function, the difficulty in fabrication and packaging will be reduced, and relatively large devices could be included in the robotic system. As an example, Fig. 8b shows a snake-type robot with heterogeneous modules that assembles in the stomach and then moves through the intestine [13]. Magnetic alignment and assembly of such kind of robotic modules with permanent magnets have been investigated, and though the research is still in an infant stage, the recent development shows that the self-assembled modular capsules are a promising approach for the development of next-generation microsurgical devices [13, 14].

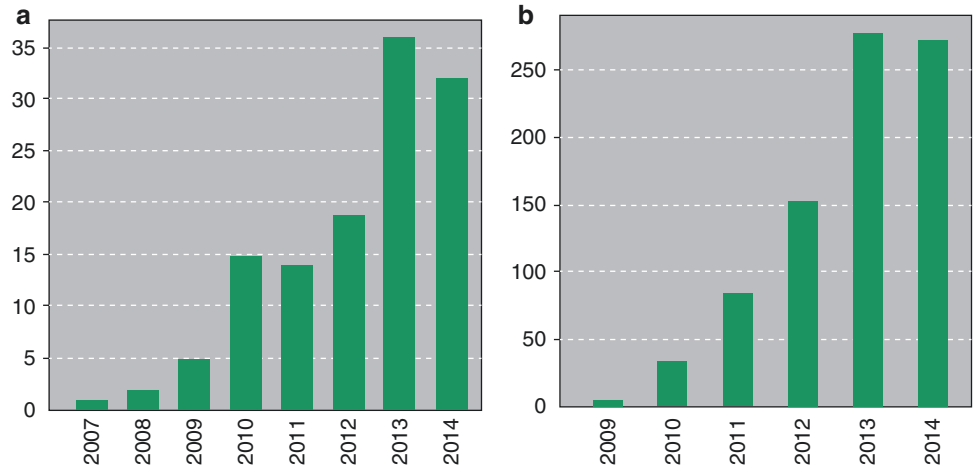
Definition

Magnetoplasmonics (MP) studies the effects arising from the interplay between plasmonic and magneto-optical (MO) phenomena typically occurring in metallic nanostructures. Plasmonic field enhancement allows for large MO activity while magnetic functionalities give access to independent control of plasmonic properties by tailoring intensity and direction of an external magnetic field.



Introduction

Overview

Metallic nanostructures supporting Surface Plasmon Polaritons (SPP) and Localized Surface Plasmons (LSP) are characterized by their unique ability to control and manipulate light at the nanoscale [1]. Yet the necessity to realize nanometric integrated photonic components, such as switches or modulators, requires finding a way to control the optical properties of a nanostructure by means of an external factor. If high switching and modulation speeds are required, control mechanisms resting on temperature and voltage change must be discarded, and the all-optical option remains the main viable solution. Nevertheless, a compelling alternative to pure photonic control for active nanophotonics and plasmonics may be found in the adoption of a magnetic field modulation, which allows tailoring of optical properties as a function of the magnetic field intensity and direction. Performances comparable to all-optical configurations are expected, since magnetism can be inherently considered an ultrafast property [2, 3].

In the following we point our attention, both from the theoretical and experimental viewpoints, to magnetoplasmonics, i.e., to the entwined effects emerging from the mutual interaction of plasmonic and MO phenomena. This is a very fascinating and fast-growing research field as indicated by the bibliometric figures related to the word "magnetoplasmonics" reported in Fig. 1.

The present section is dedicated to a brief introduction to plasmonics, magneto-optics (Kerr and Faraday effects, in particular) and optimized

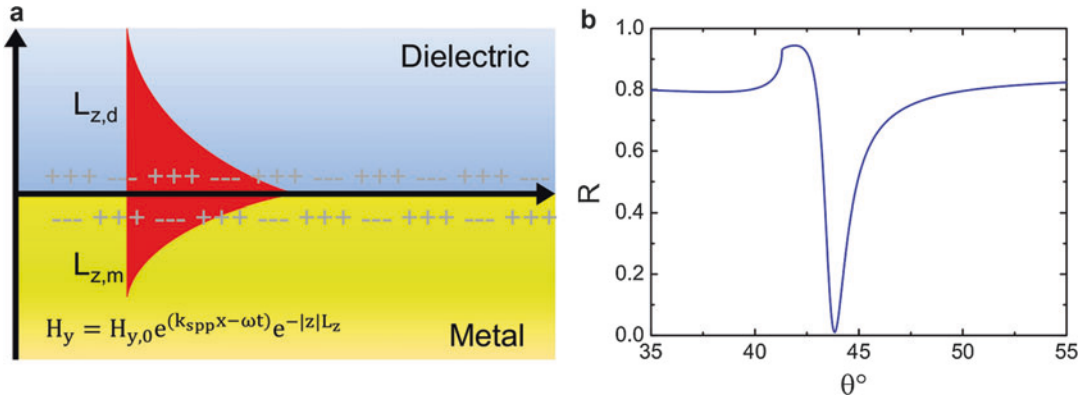
solutions for MP materials. The following two sections will be devoted to the description and understanding of MP phenomena emerging in extended (SPP) and localized (LSP) structures. Finally, the last part of this contribution will focus on actual and potential applications, with special consideration to biosensing and theranostics (i.e., the combination of therapeutic plus diagnostic nanomedicine).



Surface Plasmon Polaritons and Localized Surface Plasmons

Surface Plasmons (SPs) are defined as surface bound electromagnetic waves coupled to collective oscillations of free charges (typically free electrons in metals). They are supported at the interface between different media, with the mandatory condition that the involved media must exhibit dielectric constants with real parts of opposite sign (e.g., a metal and a dielectric). Paramount characteristic of SPs is their strong dimensional localization at the interface; this is in practice observed for a large variety of metallic (especially noble metals) structures, since metals are often characterized by optical constants with a strongly negative real part at optical frequencies. Surface plasmons are best classified in two main categories, depending on the dimensionality of the supporting structure: LSPs are plasmon oscillations typically supported by 0-dimensional (0D) or 1-dimensional (1D) structures, i.e., by structures confined to a sub-wavelength scale in two or three spatial dimensions, such as noble metal nanoparticles and nanowires (Fig. 2a). On the other hand, SPPs are supported at planar or nanostructured interfaces such as thin films or gratings (Fig. 3a). Regardless of the structure dimensionality, the charge oscillations typical of SPs are able to focus large electromagnetic fields within nanoscale volumes well beyond the diffraction limit. Direct consequence of the field localization and enhancement is a strongly increased light-matter interaction which reveals itself in a twofold way: on one hand, large field localization allows strong interactions with molecules, light emitters and analytes placed in the field hot-spots, while conversely small perturbations of the local refractive index manifest as a sizable modification of the far-field optical properties, making nanostructures supporting SPs an ideal platform for the development of sensing applications.

The optical fingerprint of a SPP is, for instance, a sharp dip in the reflection spectrum, corresponding to a condition where energy and momentum matching between incident radiation and the SPP wave are simultaneously satisfied, as displayed in Fig. 3b. The extra momentum needed for the photon-SPP coupling is obtained in attenuated total reflection (ATR) configuration, where

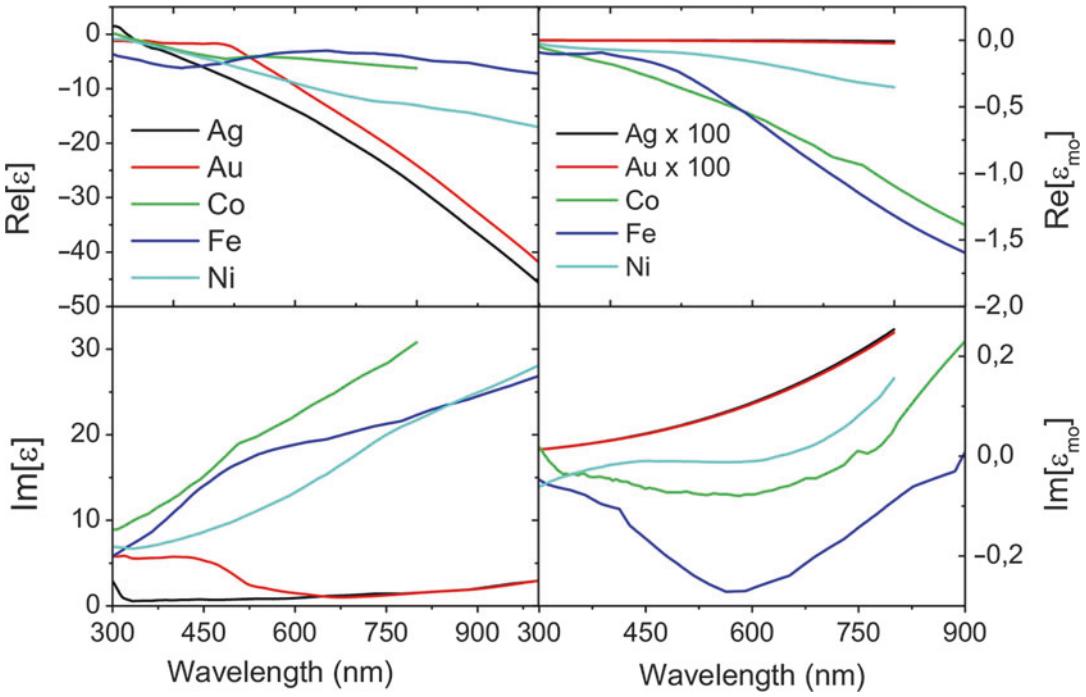
the momentum matching is provided by a glass prism (e.g., Kretschmann coupling), or with a grating coupler, where the phase matching is assisted by the periodic structure. Given the strong SPP wavevector dependence on the surrounding dielectric medium, small changes of the local environment cause large momentum changes that are visible as resonance shifts in the reflection spectrum. In this context a resonance redshift corresponds to an increase of the surrounding refractive index, whereas the opposite is true in the case of a blue shift.

The far field optical response of LSPs is associated with an intense and narrow absorption and/or scattering of the light (Fig. 2b): indeed, noble metals nanoparticles, like Au and Ag, embedded in a solution or in a glass exhibit very bright colors. Historical examples can be found in ancient glass or artifacts, where the light produces different colors depending on the direction of the observer. Moreover, induced LSP resonances (LSPRs) give rise to strong amplification and confinement of the electric field at subwavelength distances from the plasmonic surface. These properties thus make LSP based devices very promising for advanced technological applications, such as the realization of sensors and nanoantennas. The LSP features are affected by several parameters such as material, size, morphology, coating, and environment. Indeed, the interaction between

light and nanoparticles involves both absorption and scattering mechanisms, and the ratio between them depends critically on the size of the nanostructures (e.g., larger sizes produce larger scattering). Moreover, a change of the refractive index of the surrounding medium has a relevant effect in shifting the energy of the LSP resonance: normally, increasing the environment refractive index produces a redshift of the LSP wavelength. Nevertheless, the direction of this shift can be influenced by the chemical environment of the particle surface and both blue- and red-shifts have been experimentally observed. In addition, the amplitude and the width of LSP resonances are strictly related to the electronic damping described by the imaginary part of the dielectric function. All these effects provide different degrees of freedom for the design of custom LSP plasmonic materials.

The LSP phenomenon is not limited to spherical nanoparticles: it can be observed also in other confined geometries, such as ellipsoids, spheroids, disks, rods, wires, where, due to the lower symmetry, different spectrally separated plasmon resonances can be excited, corresponding to oscillations of its conduction electrons along different axes of the system.

Magneto-Optical Effects



A magnetic field can modify the optical properties of materials. The modification of the light–matter interaction is detected as a variation of the polarization state or of the intensity in the transmitted (Faraday effect) or reflected (Kerr effect) light. The optical response of the medium to the external excitation of the incident light can be described by the dielectric tensor or permittivity, whose general form in a magnetic medium is [3]:

$$\boldsymbol{\varepsilon} = \begin{pmatrix} \varepsilon & \varepsilon_{xy} & \varepsilon_{xz} \\ -\varepsilon_{xy} & \varepsilon & -\varepsilon_{yz} \\ -\varepsilon_{xz} & \varepsilon_{yz} & \varepsilon \end{pmatrix} = \begin{pmatrix} \varepsilon & iQ_z & iQ_y \\ -iQ_z & \varepsilon & -iQ_x \\ -iQ_y & iQ_x & \varepsilon \end{pmatrix}. \quad (1)$$

The diagonal terms correspond to the (complex) isotropic dielectric function of the material in absence of an external magnetic field, while the off-diagonal terms are expressed as $\varepsilon_{mo} = iQ_j$, with Q_j the magneto-optical constants of the material. If dealing with paramagnetic (at room temperature) and diamagnetic materials (for which a linear relationship $\boldsymbol{M} = \chi_m \boldsymbol{H}$ exists, where χ_m is the magnetic susceptibility) the Q_j term is proportional to the j-component of the applied magnetic field, $\boldsymbol{H}$, while in the case of ferromagnets (or ferri- or antiferro magnets), for which the relationship between $\boldsymbol{M}$ and $\boldsymbol{H}$ is nonlinear and saturable, the spin–orbit coupling makes Q_j proportional to the j-component of the magnetization, $\boldsymbol{M}$.

If we first focus on the magnitude of the off-diagonal terms, which as stated above depends both on the external magnetic field and the intrinsic material properties, the importance of finding and exploiting materials with optimal MO properties in order to obtain sizable MO effects is immediately clear. In most cases, spin–orbit coupling is the mechanism responsible of the MO properties of a material: as a rule, the stronger the spin–orbit interaction the larger is the MO activity. In practice, under the effect of an external incident electromagnetic field, the spin–orbit interaction couples the spin of the electron to its motion, i.e., to its linear momentum. Furthermore, the spin also interacts with the internal magnetic field of the material thus producing a correlation between magnetic and optical properties of a magnetic material.

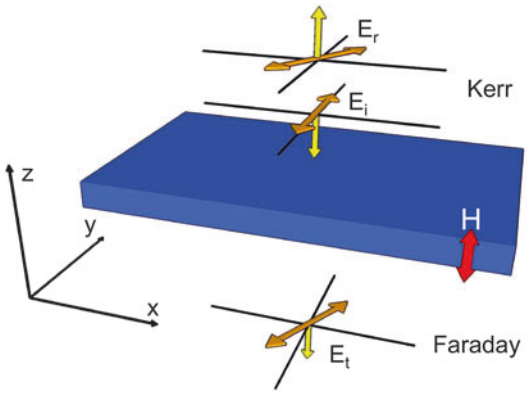
Quantum mechanics describes more precisely the MO effects in terms of transition probability induced by the external electromagnetic field between two states, as described by the Fermi Golden rule [3] and controlled by the dipolar selection rules for the optical transitions ($\Delta l = \pm 1$). Most magnetic metals, characterized by a large spin–orbit coupling, display very complex and rich MO spectra as different interband and intraband transitions are allowed in the Vis-NIR range. However, metals strongly absorb light in this range and the effective MO effect is limited to some tens of nanometers of light penetration from the surface. On the other hand, for magnetic oxides the MO transitions occur mainly between localized

Magnetoplasmonics, Fig. 4 Real and imaginary part of optical and MO constants for ferromagnetic and noble metal materials (All the optical constants are plotted from experimental data [2] and refs. therein), with the exception of Au and Ag MO constants (computed at 1T external magnetic field)

bands (nearby the Fermi level) and weak MO effects are generally observed, mainly triggered by crystal field or charge transfer interactions in which selection rules are partially broken.

The MO properties of noble metals are promptly described in the classical framework of the Drude model, since their physical origin rests mostly on the properties of the conduction band electrons. Noble metals MO optical constant may indeed be formulated as [2]:

$$\varepsilon_{mo} = i\frac{\omega_c(\omega_p\tau)^2}{\omega\left[(1-i\omega\tau)^2+(\omega_c\tau)^2\right]}, \qquad (2)$$



with $\omega_c = eH/m^*$ being the cyclotron frequency, $\omega_p = \sqrt{Ne^2/\varepsilon_0 m^*}$ the plasma frequency, N the electronic density, m^* the effective electron mass, e the electron charge, ε_0 the vacuum permittivity, H the external magnetic field and τ the electron relaxation time. Plugging into Eq. 2 realistic values for all the physical parameters in the case of Au and Ag, one might see that the obtained MO constants are roughly three orders of magnitude smaller than those of ferromagnetic materials such as Co, Ni, and Fe (Fig. 4 and Table 1).

If we now consider the tensorial nature of the MO dielectric constant, it is clear that not only the intensity, but also the direction of the applied magnetic field plays a fundamental role in the system optical response. In this context, MO effects are better understood if schematized as in Fig. 5. The material surface (xy plane) is illuminated by an electromagnetic radiation (linearly or circularly polarized) and the MO effects can be observed either in transmitted or reflected light. The mutual orientation among the plane of incidence (xz), the light polarization and the magnetic field directions is the distinguishing feature to classify the MO effects.

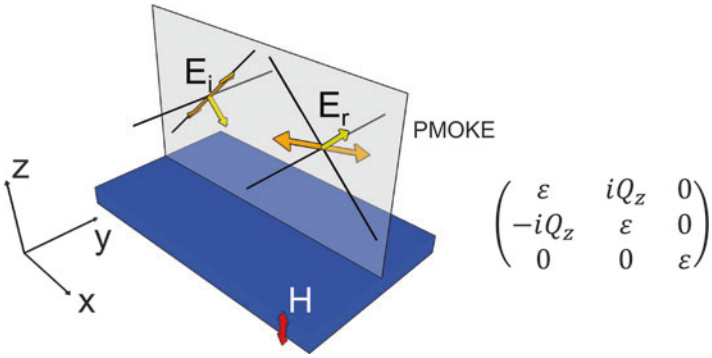
The first considered configuration, represented in Fig. 6, is characterized by z-oriented (normal to the xy plane) magnetic field. In this case the field is

Magnetoplasmonics, Table 1 Optical constants at 633 nm for typical plasmonic and magnetic metals. Both diagonal (dielectric) and off-diagonal (magneto-optic) components are reported. MO values are calculated at 1T of external field (Au, Ag) or measured at saturation (Ni, Fe, Co)

Element	$Re(\boldsymbol{\varepsilon})$	$Im(\boldsymbol{\varepsilon})$	$Re(\boldsymbol{\varepsilon}_{mo})$	$Im(\boldsymbol{\varepsilon}_{mo})$
Au	−11.74	1.26	-8.68×10^{-5}	1.23×10^{-3}
Ag	−18.28	0.48	-2.74×10^{-5}	1.26×10^{-3}
Ni	−12.93	16.36	−0.19	-1.26×10^{-3}
Fe	−1.03	17.74	−0.71	−0.24
Co	−12.49	18.45	−0.64	−0.067

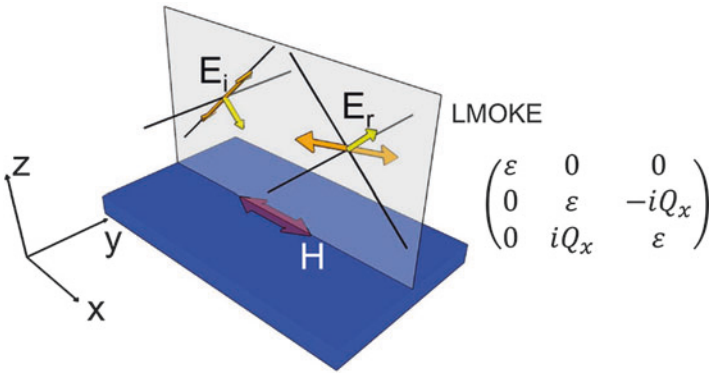
Magnetoplasmonics, Fig. 5 Sketch of a Kerr and Faraday MO effects in case of a linearly polarized plane wave illuminating a MO active slab

also normal to the sample surface and thus this configuration corresponds, in reflection, to the so called Polar Kerr configuration (PMOKE). In this setup all the off-diagonal components of the dielectric tensor vanish, with the exception of the ε_{xy} and ε_{yx} terms which in this case provide cross-coupling between s ($\boldsymbol{E}$ field perpendicular to xz plane) and p ($\boldsymbol{H}$ field perpendicular to xz plane) polarization states. The direct consequence is that a linearly polarized incident plane wave is reflected or transmitted as an elliptically polarized beam, and therefore the measurable quantities are the beam rotation (ϑ) and ellipticity (ϵ), represented as the complex Kerr rotation $\Phi = \vartheta + i\epsilon = r_{ps}/r_{pp}$, where $r_{ps}(Q)$ and r_{pp} are the Fresnel reflectivity coefficients.



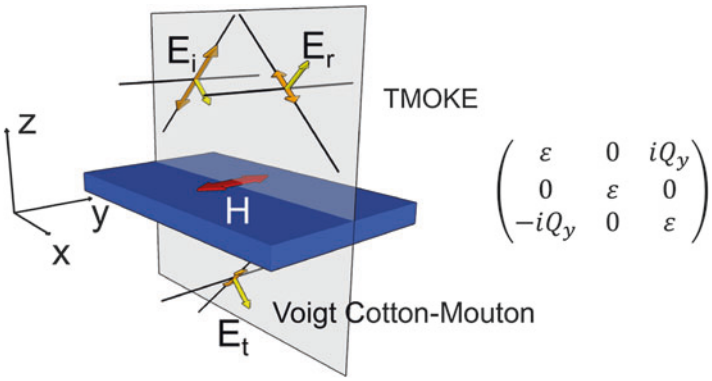
An analogous effect is seen for an x-oriented (normal to the yz plane) external magnetic field (Fig. 7), where a reflection configuration of the present arrangement is known as a Longitudinal Kerr setup (LMOKE). The coupling between s and p polarization states, provided in this case by the only nonvanishing off-diagonal coefficients ε_{yz} and ε_{zy}, finally leads to MO effects similar to what observed in the PMOKE case, where the complex Kerr rotation represents the principal observable.

Slightly different is the case of an y-oriented (normal to the xz plane) external magnetic field, also known as transverse Kerr configuration in a reflection setup (TMOKE) and Voigt or Cotton-Mouton configuration in a transmission one (Fig. 8). In this arrangement no polarization coupling is provided by the nonzero terms ε_{xz} and ε_{zx}, the only visible effect being a variation of the reflectance or transmittance of p-polarized incident light.



A qualitatively different MO phenomenon is finally represented by the Magnetic Circular Dichroism (MCD), which is defined as the difference in absorption (or reflection) between two spectra acquired using light with opposite helicity in the presence of an external magnetic field (usually but not necessarily parallel to the incident light direction, as depicted in Fig. 9).

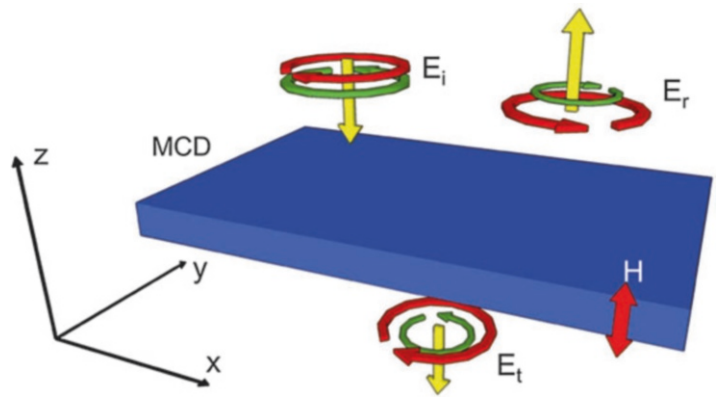
Materials Viewpoint



Actually there are no materials that simultaneously exhibit optimal plasmonics features and important magnetic and magneto-optical properties. If we first consider the magnetic properties of the most common plasmonic materials, Au and Ag, it emerges that they are diamagnetic in nature and thus huge unphysical magnetic fields (in the order of thousands of Teslas) are required to induce magnetizations and magneto-optical effects comparable to those of standard magnetic metals or oxides [12]. If instead we focus on the plasmonic properties of efficient magnetic materials, only the metallic ones exhibit plasmonic resonance in the Vis-NIR range. Nevertheless

Magnetoplasmonics, Fig. 6 Sketch of a typical PMOKE configuration and corresponding dielectric tensor

Magnetoplasmonics, Fig. 7 Sketch of a typical LMOKE configuration and corresponding dielectric tensor



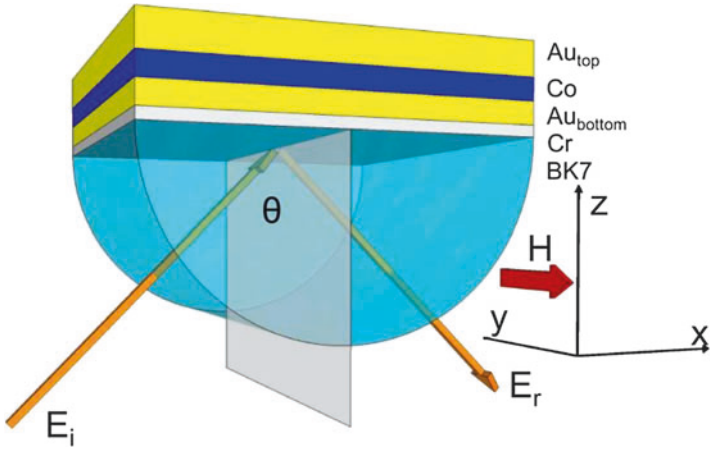
Magnetoplasmonics, Fig. 8 Sketch of typical TMOKE (reflection) and Voigt Cotton-Mouton (transmission) configurations and corresponding dielectric tensor

both interband and intraband transitions are allowed in the same range, opening relaxation channels that damp the plasmon resonance through nonradiative processes, essentially heat.

Table 1 summarizes the optical constants at 633 nm of typical plasmonic (Au, Ag) and magnetic (Fe, Co, Ni) metals [2, 4]. While all metals exhibit $Re(\varepsilon) < 0$ required for plasmonic resonances to occur, the $Im(\varepsilon)$ values are quite large for the magnetic materials, naturally explaining the strong SPR damping.

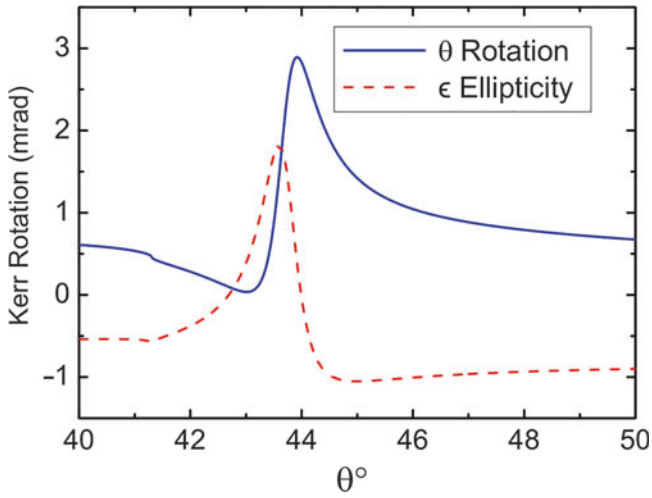
Hybrid nanostructures built upon noble and ferromagnetic metals building blocks represent at the moment the state of the art in terms of magneto-plasmonic structures. Nevertheless, a very promising solution for achieving both plasmonic and magnetic functionalities required by magnetoplasmonics can be the growth of a

Magnetoplasmonics, Fig. 9 Sketch of a typical MCD configuration. *Left* and *right* circular polarizations are transmitted and reflected with different intensity



solid solution between magnetic transition metals and noble metals. However, except for the Ni-Au and Ni-Ag alloys, the two classes of metals are in general immiscible as bulk phases. Metastable solid solutions can be obtained by techniques like ion implantation, sputtering or laser ablation, yet achieving simultaneous plasmonic and MO properties in structures such as Au-Fe nanoparticles still represents a significant challenge: for instance, Au_{60}-Fe_{40} alloy nanoparticles obtained by sequential ion implantation in silica [5] exhibit a quenching of the LSPR (which is regained upon thermally induced segregation between Au and Fe) and a ferromagnetic order at room temperature. The coupling between optical and magnetic properties stems as a strong MCD signal and a photoswitchable magnetization upon irradiation with photons with wavelength of 514 nm (i.e., close to the region of Au SPR). Hence it is clear that, in spite of its importance, the research of single magnetoplasmonic metals remains a mostly unsolved challenge for the future while, as it will be shown, almost all the current studies focus their attention on hybrid nanostructures composed of magnetic and plasmonic moieties.

Magnetoplasmonics in Nanosystems Supporting Surface Plasmon Polariton Resonances



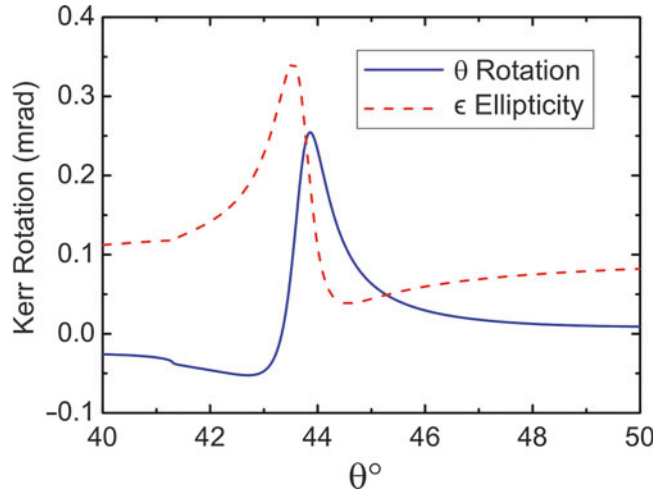
Multilayered Thin Films

In the present section we are going to discuss, from a theoretical viewpoint, the MP properties of structures supporting extended SPPs. Given the vast variety of structures capable of supporting this kind of excitation, we shall focus our attention only on a specific one, namely a noble metal-ferromagnetic multilayer, where a thin layer of Co is sandwiched between two Au layers and illuminated at 633 nm, with p or circularly polarized light, in an ATR geometry (Glass/Au/Co/Au/Air, Fig. 10). Such a structure has the advantage of being simple to analyze and study, and yet presents a richer phenomenology than that of a simple ferromagnetic or noble metal thin film. In this discussion the attention will be focused on the effect of MP phenomena on observable quantities like Kerr rotation and variations in reflectivity in PMOKE, LMOKE, and TMOKE configurations, and finally an MCD setup will be also analyzed. The effect of SPs on the MO properties will be studied first, then the modulation of SPP propagation upon change of the MO properties of the system will be scrutinized.

The PMOKE configuration is an ideal setup to analyze the effect of a SPP on the MO properties of the structure since the preferred observable in this case, the complex Kerr rotation Φ, is expressed as $r_{ps}(Q)/r_{pp}$ where r_{pp} and $r_{ps}(Q)$ are again the first two Fresnel coefficients [3]. From a quick glance to the previous expression it is clear that the excitation of a SPP is able to modulate the magnitude of Φ by strongly modifying the r_{pp} term value. In ideal light-plasmon coupling conditions we indeed have $r_{pp} \to 0$, therefore obtaining a relevant enhancement of Kerr rotation and ellipticity, as it may be seen in Fig. 11.

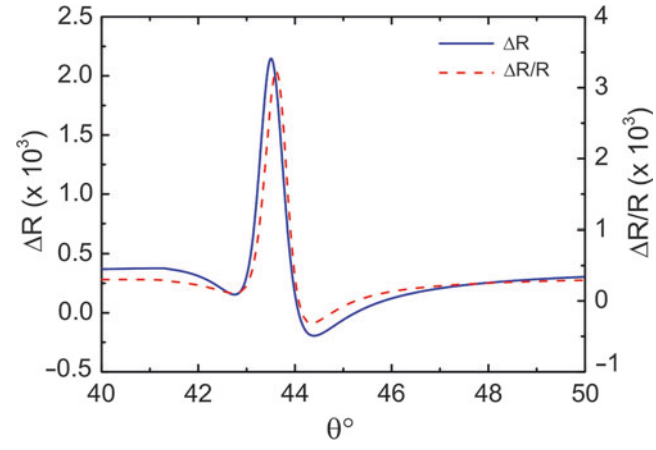
Magnetoplasmonics, Fig. 10 Sketch of a typical Au/Co/Au multilayer on glass substrate (e.g., BK7) in Attenuated Total Reflection Configuration (*ATR*). The Cr layer is an adhesion layer for Au on glass

Magnetoplasmonics, Fig. 11 Kerr rotation (θ) and ellipticity (ϵ) for an Au/Co/Au multilayer illuminated in p polarization at 633 nm in PMOKE configuration



It is appropriate to underline that in this context the SPP contribution to the MO activity is purely optical, meaning that no leverage of the MO properties of the ferromagnetic material is needed to obtain the enhancement. On the other hand, for our multilayer structure the numerator term $r_{ps}(Q)$ may be expressed as [2]:

$$\left|r_{ps}(Q)\right| \propto \langle E_p E_s \rangle d \left|\varepsilon_{mo}(Q)\right| \qquad (3)$$



where $\langle E_p E_s \rangle$ stands for the mean value of the product of both components of the field, d is the Co layer thickness and $|\varepsilon_{mo}(Q)|$ is the MO optical constant of the ferromagnetic material. Thus, in the presence of a SPP the local-field enhancement at the metal-dielectric interface is going to boost the $\langle E_p E_s \rangle$ factor and as a consequence the MO activity and the complex Kerr ellipticity.

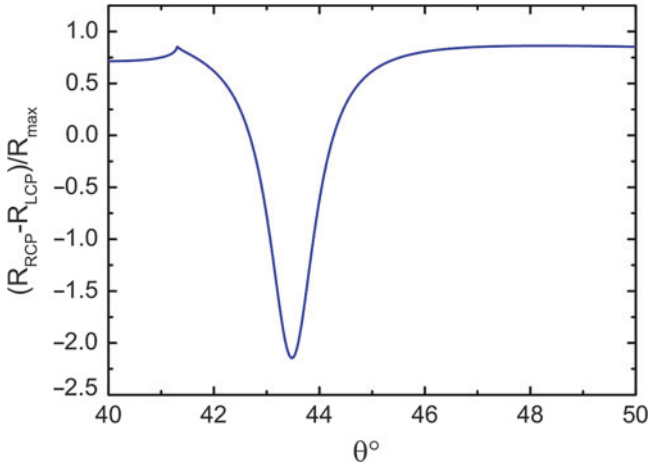
The overall MP performance of the system is finally determined by a delicate balance of the SPP optical r_{pp} and MO r_{ps} contributions, keeping in mind that strong plasmon resonances demand for low optical losses and therefore low Co amounts, for the multilayer considered, while on the contrary large MO contributions require a large Co thickness and field intensity inside the ferromagnetic layers, and thus high optical losses.

In close analogy to what described in the previous MO section, a similar situation is found for magnetoplasmonic LMOKE configurations. The original discussion of the PMOKE arrangement

Magnetoplasmonics, Fig. 12 Kerr rotation (θ) and ellipticity (ϵ) for an Au/Co/Au multilayer illuminated in p polarization at 633 nm in LMOKE configuration

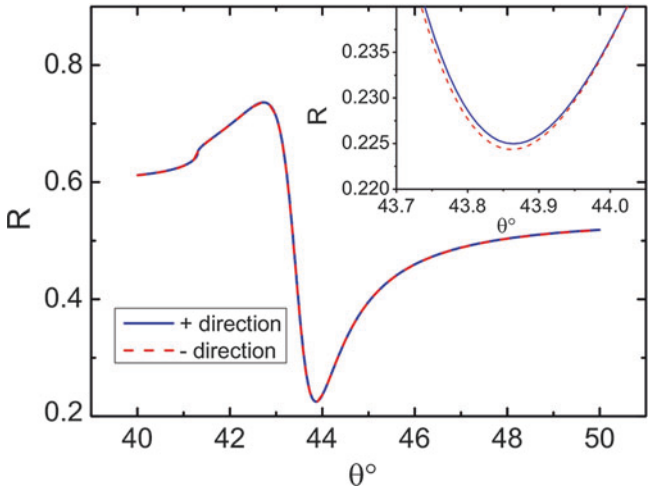
Magnetoplasmonics, Fig. 13 Differential reflectance ΔR and ΔR/R for an Au/Co/Au multilayer illuminated in p polarization at 633 nm in TMOKE configuration

also applies to the present case, where an enhancement of the MO signal is seen in correspondence of the SPP resonance, as displayed in Fig. 12.



In the case of TMOKE configuration, the observable is defined as:

$$\Delta R = R(+H) - R(-H), \tag{4}$$

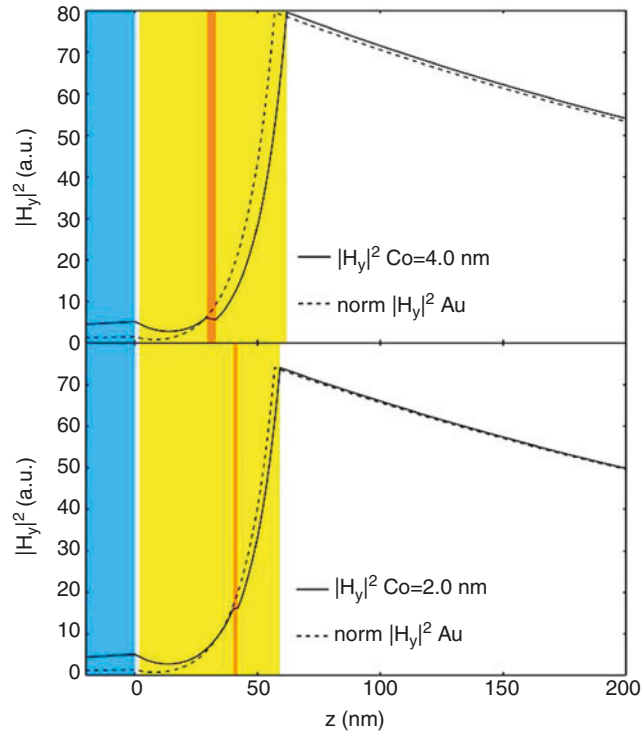


with $\boldsymbol{H}$ the applied magnetic field. In this case ΔR (Fig. 13) corresponds to a purely MO term, i.e., its magnitude is directly proportional to the ferromagnetic layer thickness and the intensity of the local-field inside that layer. An analogy to the previous cases may be recovered by introducing a denominator defined as $R = R(+H) + R(-H)$. Such a normalization factor takes small values in the presence of an optimal light plasmon coupling and therefore boosts the magnitude of the normalized TMOKE signal defined as $\Delta R/R$.

This same Kerr configuration is also suitable for monitoring the presence of plasmon enhanced MCD signals when the Au/Co/Au multilayer is illuminated with circularly polarized light. The MCD signal reported in Fig. 14 indeed shows a MP fingerprint as a spectral dip around 44°, the SPP coupling angle, where the MCD signal reaches its maximum in modulus. It is finally clear from the previous examples how SPP may influence and enhance the MO properties of a system, and how a balance of MO and SPP properties must be achieved in order to maximize the overall MP properties.

The adopted model multilayer structure is also ideal to study the magnetic field effects on SPPs.

Magnetoplasmonics, Fig. 14 MCD signal (defined as the normalized difference of reflectance for *right* and *left* circular polarization) for an Au/Co/Au multilayer illuminated at 633 nm

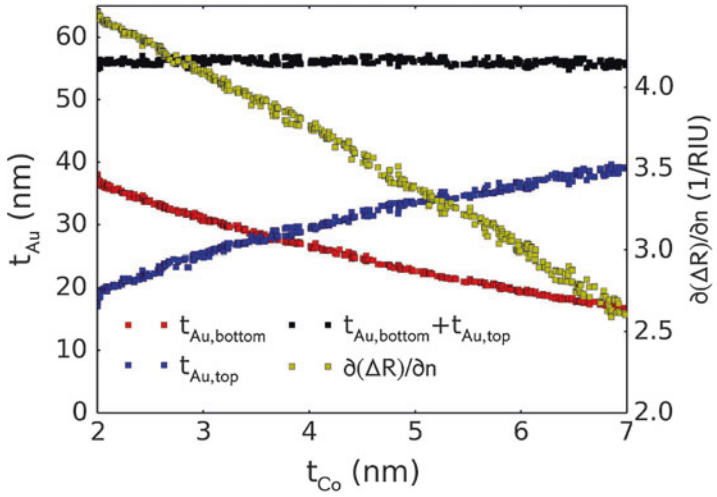


Magnetoplasmonics, Fig. 15 Reflectance spectra for an Au/Co/Au multilayer computed for the same incident angle but opposite incident directions in TMOKE configuration. The MO effects, and the consequent absence of local reciprocity, cause the k_{SPP} wavevector modulation and finally a modification of coupling angles for opposite incident directions, as seen in the inset

This phenomenology is understood by reminding that an external magnetic field modifies the optical constants of a material according to Eq. 1. Thus, in the framework of Maxwell equations, different optical constants imply a modification of the boundary conditions and finally of the electromagnetic field distribution and SPP propagation constant k_{SPP}.

More explicitly, dealing first with the TMOKE configurations for simplicity, these effects produce different SPP coupling conditions, and therefore different coupling angles, in presence of an external magnetic field. Moreover, in the absence of local reciprocity, equal incident angles but opposite incident directions lead to different coupling conditions and thus to slightly different reflectance spectra as seen in Fig. 15. Formally, the modulation of the SPP wave vector may be expressed as $k_{SPP} \sim k_{SPP,0} + \Delta k_{SPP}(Q)$, and the nonreciprocity and consequent different coupling conditions may be written as $k_{SPP,0} + \Delta k_{SPP}(Q) \neq -k_{SPP,0} + \Delta k_{SPP}(Q)$. It is finally interesting to note that for our multilayer structure the wave vector modulation can directly be written as a function of the local magnetic component of the electromagnetic field as [2]:

$$\Delta k_{SPP} \sim \frac{k_0 \varepsilon_d \varepsilon_{Au} \sqrt{-(\varepsilon_d + \varepsilon_{Au})}}{{\varepsilon_d}^2 - {\varepsilon_{Au}}^2} \times \frac{i\, \varepsilon_{mo,Co}}{\varepsilon_{Co}} \left| H_y^{Co} \right|^2, \quad (5)$$



Magnetoplasmonics, Fig. 16 Magnetic field component of the local-field distribution for two different Au/Co/Au multilayers (solid lines) and Au layers (dashed lines) in ATR configuration. The SPP excitation contributes to a strong local-field enhancement in the ferromagnetic layer (From Ref. [9])

where k_0 is the light wavevector in vacuum, ε_d, ε_{Au} and ε_{Co} are the glass, Au and Co optical constants, respectively, $\varepsilon_{mo,Co}$ is the MO optical constant of Co and H_y^{Co} is the magnetic field in the Co layer, which varies strongly depending, among other things, on the Co layer position and thickness (Fig. 16).

Now focusing on PMOKE and LMOKE configurations, the first effect of a magnetic field on the SPP propagation is to introduce a Transverse Electric (TE) component in an otherwise purely Transverse Magnetic (TM) wave, in close analogy with the *s* and *p* polarization coupling outlined in the preceding paragraph. It may also be shown that the SPP wavevector k_{SPP} undergoes a more complex modulation that is quadratic in the term Q and may be finally be expressed as $k_{SPP} \sim k_{SPP,0}, + \beta Q^2$, where β is a proportionality constant and $k_{SPP,0}$ is again the unperturbed wavevector [2].

An elegant demonstration of the modulation of the SPP wavevector by an external applied magnetic field has been performed using a slit-groove plasmonic interferometer [6]: this technique potentially allows nanometre-resolved measurements of the electromagnetic field distribution inside a metal at optical frequencies. Momentum modulation of 2 % can be reached with nonoptimized Au/Co/Au multilayers and a further improvement of interface quality and the use of a high dielectric covering layer [7] increases the modulation up to a value of 12 %, comparable to the 15–20 % ones of other nonmagnetically active plasmonic modulators. Finally, Belotelov et al. [8] successfully demonstrated the magnetic field modulation of reflected light in magnetoplasmonic crystals consisting of an Au grating deposited on a magnetic garnet film. All the abovementioned experiments constitute cornerstone examples of magnetic-field-driven active plasmonics in the high frequency (GHz-THz) regime, as required by telecom applications.

It is finally worth mentioning that, while trial and error design and optimization of such MP structures is possible, the task is certainly cumbersome. In the case of our simple model multilayer structure, for instance, it is necessary to optimize at once all the structural parameters (all the layer

Magnetoplasmonics, Fig. 17 Ideal multilayer Au/Co/Au SPP sensors as a function of the Co layer thickness obtained by genetic algorithm optimization technique. On the x-axis, t_{Co} represent the Au/Co/Au Cobalt thickness. On the y-axis, $t_{Au,bottom}$ and $t_{Au,top}$ represent the Au/Co/Au Gold thickness, thus defining a sensor of sensitivity $\partial(\Delta R)/\partial n$. Thicker Co layers must be positioned farther from the metal dielectric interface in order to minimize the optical losses, while thinner Co layers may be positioned closer to the surface to maximize the MO activity. In order to obtain an ideal sensor, low optical losses take precedence on high MO activity, since thinner Co layers provide final better sensitivities (from [9])

thicknesses, i.e., four parameters) plus the light wavelength and angle of incidence, thus obtaining a six-dimensional parameter space to explore. It is then clear that a different approach is desirable to tackle the design of this kind of structures. Recently, powerful genetic optimization tools have been successfully introduced for the design of such devices [9]. This kind of approach allows an easy exploration of the whole parameter space, and finally the determination of illumination and multilayer structural conditions that are optimal for the task at hand, e.g., the maximization of the MO activity, a minimization of the optical losses, or an ideal balance between SPP and MO features. Figure 17 shows an example of this process for a MO SPP Au/Co/Au multilayer designed to be an intensity interrogated Magneto Optical Surface Plasmon Resonance (MOSPR) sensor. In this case, in order to maximize the sensor sensitivity $\partial(\Delta R)/\partial n$, where n is the monitored refractive index, the genetic algorithm outputs multiple ideal sensors, providing a different tradeoff between the MO activity (thick Co layers) and low optical losses (thin Co layers), burying the ferromagnetic layer at different depths to modulate the balance between the two [9].

As a final remark it is extremely important to underline that in a real life scenario the quality of the adopted materials and the adopted synthesis processes play a major role in the final device MP properties, with epitaxially grown materials providing vastly improved performances if compared with more traditional approaches such as evaporation and sputtering [2].

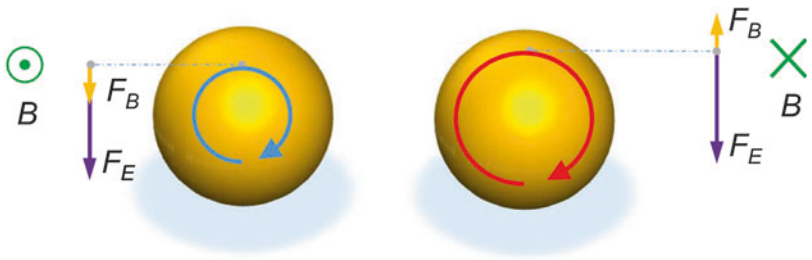
Hybrid Nanohole Arrays

Thin metallic film with 2D ordered arrays of holes with sub-wavelength size (nanohole arrays, NHA) exhibit the so-called extraordinary optical transmission (EOT), whose explanation has been inherently linked to the excitation of SPPs propagating at both interfaces. Since the periodicity of the holes provides the extra momentum needed for direct photon-SPP coupling, NHAs received growing attention also as effective platforms to investigate the coupling between plasmonic and MO effects.

Extraordinary optical transmission and enhanced Faraday rotation have been found by Belotelov et al. [10] in bilayer metal/dielectric heterostructures, where the Au metallic plate

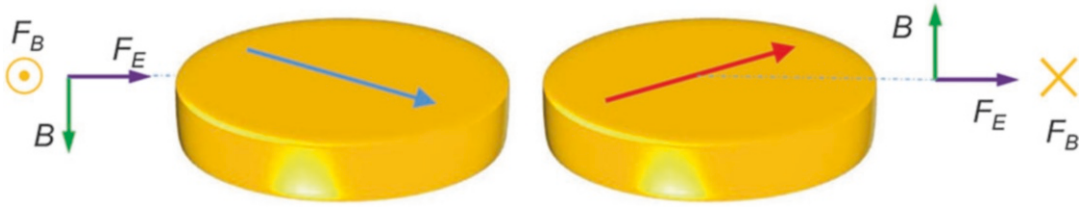
(68 nm thick) was perforated with a periodic hole arrays (pitch $a = 750$ nm, hole size $d = 395$ nm) and the Bi-substituted yttrium, iron garnet magnetic dielectric plate (118 nm thick) was magnetized in polar geometry perpendicularly to its plane. The measured simultaneous enhancement of transmittance and MO Faraday and Kerr effect in the NIR range is a clear demonstration of the SPP-MO interplay: the incident light excites the SPP propagating as a Bloch wave at the upper surface of the metallic film. The SPP tunnels through the NHA film to excite the SPP Bloch wave at the metal/dielectric interface. Finally, the MO activity of the dielectric layer produces two effects: (i) a TM-TE conversion (i.e., a Faraday rotation), whose efficiency depends on the dielectric layer thickness and (ii) a localization of the TE mode as a guided wave into the dielectric layer. The far-field optical signal is generated by photons radiated by the scattering of the SPP at the holes.

Nonreciprocal effects in EOT from NHA embedded in MO-active medium have been theoretically predicted by Khanikaev and coworkers [11]. The nonreciprocity was shown to give rise to one-way EOT, so that the structure behaves as a one-way mirror or an optical isolator. This effect can be explained as a result of the modification of the phase-matching condition for the evanescent coupling between leaky SSP modes existing at the opposite interfaces of the NHA film, which exhibit nonreciprocal dispersion due to the coupling with the MO film.



Magnetoplasmonics in Systems Supporting Localized Plasmon Resonances

Noble Metal Nanostructures

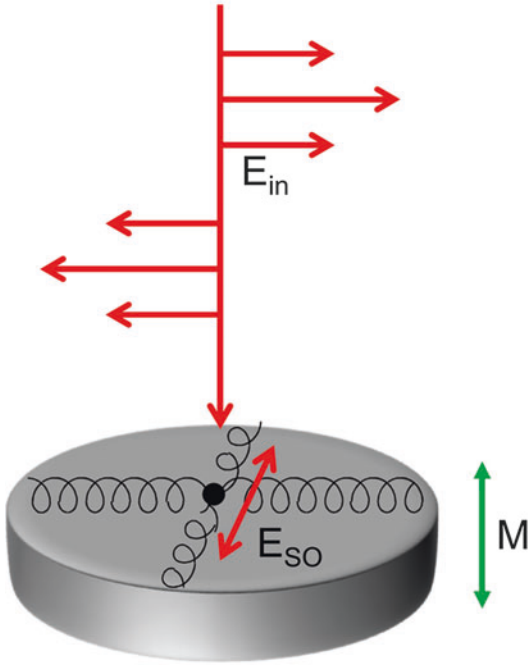


Examples of magnetic field-modulated LSPR have been recently observed and rationalized in the MO response of pure noble metal nanostructures, such as Au nanoparticles and nanodisks. Although metals such as Au, Ag, or Cu are diamagnetic, experimental results clearly showed that their magneto-optical effect is directly correlated with the LSPR excitation. Similar results were also observed in other geometries, e.g., Au dots and rods.

The influence of the magnetic field on the LPSR has been demonstrated by Pineider et al. [12] in colloidal dispersions of Au nanospheres, characterized with MO spectroscopy. The interpretation of their MCD response (i.e., the difference between two absorption spectra acquired using light with opposite helicity in the presence of an external magnetic field parallel to the incident light direction) introduces the essential role of the LSPR: conduction electrons interacting with the electric field of a light wave move as an oscillating dipole so that, if a magnetic field is also present, the oscillating charges undergo an additional Lorentz force. In the case of MCD, circularly polarized light provides to the LSPR electrons a peculiar collective rotating motion, yielding to circular plasmon resonance modes. The left- and right-polarized modes are degenerate in zero applied magnetic field, but the activation of an external magnetic field induces an energy shift, removing the degeneration. Observation of such a small energy shift by direct absorption measurements can be very challenging, whereas MCD spectroscopy easily allows its detection and measurement due to the derivative-like shape of the MCD spectrum crossing zero at the optical resonance (see Fig. 18).

Similar effects have been observed by Sepúlveda et al. [13] in arrays of Au nanodisks deposited on a glass substrate, separated by sub-wavelength distances, fabricated by large scale colloidal lithography. In this case, the system has been studied in reflection geometry by means of polar MOKE spectroscopy. It has been shown that in such structures it is possible to excite a LSPR and a sizeable MO signal related to LSPR excitation has been observed. In this case, the phenomenon has been equivalently described in terms of the linear polarization of incident light. The Lorentz force, generated by the external magnetic field, causes the LSPR direction to shift by a complex angle with respect to the incident light polarization, thus giving rise to MO effects of rotation and ellipticity (see Fig. 19).

Magnetoplasmonics, Fig. 18 Schematic representation of the Lorentz force affecting the *left*- and *right*-circular plasmon resonance in Au nanospheres



Magnetoplasmonics, Fig. 19 Schematic of the effect of the Lorentz force on linear plasmon resonance modes in Au nanodisks

Ferromagnetic Metal Nanostructures

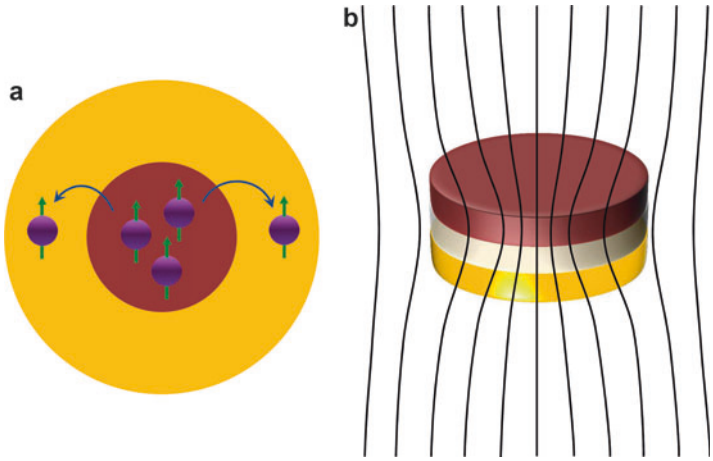
A complementary approach to magneto-plasmonics is represented by the investigation of the phenomenon in pure ferromagnetic nanostructures. Any nearly free-electron metal can support surface plasmon resonances in the optical regime and several experimental and theoretical works have evidenced the modification in the MO response near the surface plasmon frequency. Guided by the common intent of magneto-optics in increasing the interaction between the light and the magnetic medium, also the magnetoplasmonic community focused initially on the enhancement of MO effects.

An example is given by the studies conducted by Gonzalez-Diaz et al. [2] on the MO enhancement in Ni nanowires embedded in a dielectric matrix. The amplitude of the MO signal is known to be basically proportional to the amount of the magnetic material. However, the experimental results of that study show a comparable Kerr rotation in both continuous Ni film and Ni nanowires in correspondence of the spectral region where LSPRs take place. Two important aspects have been introduced and discussed: the necessity of a theoretical MO calculation support, in this case represented by a scattering matrix method adapted to MO, and subsequently, the longstanding question about the role played by the reduction of the purely optical component in the MO enhancement. As already introduced in the SPP section, the MO response is indeed a ratio between the off-diagonal and the diagonal elements of the dielectric tensor of the material and for this reason, any reduction in the pure optical contribution results in an increase of the MO activity.

Apart from the MO enhancement, an interesting and basically new effect arising from the combination of LSPR and MO is represented by the possibility to manipulate the light phase which turns into a modified polarization of the light reflected by the nanostructure. Maccaferri et al. [14] have experimentally finalized such a tuning and have introduced and developed a complete computational model able to reproduce the experimental Kerr rotation and ellipticity of noninteracting magnetic nanostructures deposited on a nonabsorbing substrate. A key point of those studies is represented by the theoretical model employed to describe the coupling between LSPR and MO activity: Contrary to the intuitive argument that a MO enhancement is associated with the LSPR that is directly excited by the electric field of the incident light, only the LSPR excitation transverse to the electric field of the

Magnetoplasmonics, Fig. 20 A schematic of the two orthogonal damped harmonic oscillators coupled by the spin–orbit (SO) interaction in a ferromagnetic disk (Figure based on Ref. [14])

incident light, due to the spin–orbit coupling, determines the MO response observed in the ferromagnetic nanostructures (Fig. 20).



Finally, treating magnetoplasmonics in pure ferromagnetic nanostructures cannot overlook a mention of the effects of the LSPR-enhanced electric field on the nonlinear MO response. A recent example of the interplay between optical and magneto-optical second harmonic generation (MO-SHG) is the work by Valev et al. [15] where the role of LSPR is evidenced in the magnetic response of G-shaped Ni nanostructures. Upon rotating the G-shaped structures, an asymmetric MO-SHG signal is reported inverting the magnetic field direction. More generally, the nonlinear MO effects measured under SHG excitation are orders of magnitude larger than the linear MO effects. This extreme sensitivity of the nonlinear MOKE effect to weak plasmonic modes can actually be the breakthrough for effective applications in MO.

Hybrid Magnetic-plasmonic Nanostructures

Hybrid magnetic-plasmonic systems are subject of intense research due to the fact that they bear a double functionality. This is particularly exciting in view of applications in several fields, such as theranostics or heat-mediated magnetic recording. In a perspective more specific to magnetoplasmonics, they are in principle ideal platforms to observe both the effect of the magnetic component on the field-dependent behavior of LSPR, and the effect of plasmon confinement of the EM field on the MO response of the magnetic material. So far, research on hybrid magnetic-plasmonic nanosystems has been primarily focused on the latter effect, and no unambiguous report has been published to date on the direct effect of the magnetic moiety on the plasmonic one.

LSPR-enhanced MO activity has been reported for a number of systems, prepared both by chemical synthesis and through physical methods. Jain et al. [2] were among the first to describe a MO enhancement in gold@maghemite core-shell colloidal nanoparticles, which resulted in the observation of an electronic transition from maghemite located at the same energy of LSPR, and that is too weak to be observed in plain maghemite. Other similar enhancement effects have been reported for colloidal hybrid magnetic-plasmonic nanoparticles such as Co@Ag core-shells and Ag-$CoFe_3O_4$ heterodimers [2].

The finer control on morphology achievable by physical fabrication methods allows a wider range of geometries for magnetic-plasmonic hybrid systems. In addition, the more regular structures than those prepared by chemical routes are easier to model with analytical or numerical methods. Sizeable effects have been found in Au nanostructures embedded in dielectric garnet magnetic layers by Tomita et al., while Du et al. studied the size and shape effects on the MO enhancement in Au/CoPt/Au nanodisks [2]. The most accurate correlation between theory and experiment is found in the work by Armelles group [2]: by using a trilayer Au/Co/Au nanodisk geometry, they correlated various positions of the Co layer with respect to the top and bottom Au layers to the

Magnetoplasmonics, Fig. 21 (**a**) Sketch of the hybridization (gray region) of the plasmonic (shell) and magnetic (core) moieties. (**b**) Sketch of the effect on local magnetic field arising from the vicinity of a magnetic material (core) to a plasmonic structure (shell)

intensity of the MO signal, and through accurate numerical modeling they found it to be related to the local electromagnetic field intensity concentrated by the Au structures. They also studied the effect of a dielectric (silica) spacer on similar systems and found that the lower optical losses afforded by the spacer further increase the MO enhancement by LSPR.

The vicinity of a magnetic component is expected to influence the MO response of the plasmonic moiety in several ways. Here two of the main effects are considered: (i) electronic hybridization between the two materials, due to which part of the uncoupled spins of the magnetic material are transferred to the plasmonic part (Fig. 21a) and (ii) proximity effects, in which the local static magnetic field is increased with respect to the applied field due to the permeability of the magnetic material (Fig. 21b). The former phenomenon requires at least a partial metallic nature of the magnetic moiety, for electronic delocalization to take place, while the latter can in principle be observed independently of the nature of the magnetic material.

Possibly the only report of a magnetoplasmonic system in which delocalization gives rise to hybrid magnetoplasmonic modes can be found in Armelles group's work on Au/Co/Au disks prepared by colloidal lithography [2], in which a single hybrid plasmonic mode arising from both the Au and Co layers is influenced by the magnetic field, resulting in strong magneto-optical activity at the plasmon resonance peak. The authors however focused more on plasmon-mediated MO-enhancement aspects, so a detailed analysis of the phenomenon is not possible for the time being. In general, the underlying idea to observe magnetic-plasmonic hybridization is to obtain nanostructures in which the magnetic material is a conductor (metallic or semimetallic) and does not completely damp the LSPR of the noble metal structure; promising candidate structures include core-shell and heterodimeric nanoparticles prepared via colloidal chemistry methods [16] or layered magnetic-plasmonic nanodisks prepared by physical fabrication methods [2], in which the plasmonic metal can be either Au or Ag, and the magnetic metal one among the ferromagnetic ones (Fe, Co, Ni). Another possible configuration is the combination of the two materials into alloys, so that the nanostructure and its electronic properties are homogenous.

The enhancement of the effect of a magnetic field on LSPR relies on the fact that a strongly magnetic material will significantly affect the magnetic field distribution in its vicinity: if a noble metal nanostructure is found in the area of field hot-spot, an increased MO response is expected. The only stringent requirement for this phenomenon is that the MO response of the magnetic material does not significantly overlap with LSPR: in such case the magnetoplasmonic response would be drowned by the MO signal of

the magnetic material. Since no direct interaction between the two moieties is required, dielectric spacers, such as silica, can help reducing the damping introduced by strongly absorbing magnetic materials. A wide range of hybrid materials are potentially suitable for the observation of such phenomenon, chiefly gold-silica-iron oxide core-shell systems prepared following colloidal chemistry routes [16] and layered noble metal-silica-magnetic metal nanodisks prepared via physical methods [2]. Again, no direct observation has been reported so far on this effect, mainly due to fact that the opposite type of magnetoplasmonic enhancement has been sought after by the scientific community.

Applications of Magnetoplasmonics

The field of application of magnetoplasmonic devices spans a range similar to that of purely plasmonic nanosystems, aiming at improving the functionalities of traditional optical devices with novel active features triggered by the magnetic field. In particular, among the most relevant and up-to-date applications of magnetoplasmonic devices, we will address theranostics, sensing (mostly of biomolecules) and optical telecommunications.

Plasmonic and magnetic materials show, individually, extremely promising optical properties that are in some cases already exploited in applications such as diagnostics, food quality control, and environmental monitoring. Prompted by the need of further improving the functionalities of these devices, material science researchers are nowadays exploring the feasibility of combining the two classes of materials so as to realize new engineered magnetoplasmonic systems with innovative and intriguing enhanced properties.

On one hand plasmonic nanomaterials such as Au, Ag, and Pt NPs have a widespread range of applications. Gold NPs are often used in scattering-based optical imaging as contrast agents in the visible range. Moreover, as they can be engineered into various shapes such as nanoshells, nanorods, or nanocages, they can exhibit LSPR also in the NIR range. Indeed, the region around 900–1000 nm is particularly favorable for in vivo imaging of biological tissues, since shorter wavelengths (>750 nm) are extinguished by endogenous pigments or b-hemoglobin, and longer wavelengths (<1300 nm) are strongly attenuated by water. The only drawback is that the tissue penetration depth of optical imaging is limited to few millimeters. Moreover, metal NPs, thanks to their strong field localization, can be also employed to produce localized photothermal effects for selective destruction of malignant tissues, the breaking of chemical bonds, or disintegration of carrier matrices, joining optical imaging with potential therapeutic action. This combined approach, which is often called *theranostic*, is probably one of the most fascinating promises offered by nanomedicine. While Ag NPs can be employed as antibacterial agents, Au NPs can be further used for biosensing by monitoring changes of the LSPR frequency, or as proper substrates for surface enhanced Raman spectroscopy (SERS) since SH thiol groups readily bind to Au surfaces, making them a good choice for bioconjugation.

On the other hand magnetic NPs (MNPs) are already clinically employed for improving the contrasting magnetic resonance imaging (MRI), offering high resolution and excellent tissue penetration depth. However, despite the good spatial resolution, MRI is not as sensitive as optical imaging and of difficult adoption for the visualization of microscopic tissue samples. Therefore, it is highly desirable to have novel nanomaterials enabling new imaging modes for enhanced contrast specificity and complementary use. Similarly to plasmonic nanomaterials magnetic NPs may also provide local heat dissipation which can be exploited for the hyperthermic treatment of tumors. Moreover, a magnetic field gradient can be used to externally drive magnetic NPs to target tissue or to enhance uptake by cells. Finally, magnetic NPs also play a key role in many lab-on-chip systems in transport, separation and recognition of biological compounds. In these cases, the indirect recognition of a biological compound often occurs via magnetoresistive sensors.

Multifunctional Magnetoplasmonic Theranostics

By properly combining magnetic and plasmonic materials at the nanoscale, a number of desirable properties, including magnetic attraction, NIR absorption, multimodal imaging, photon scattering and easy biomolecular conjugation through stable thiolate–metal interaction can be achieved (Fig. 22). Moreover, magnetic hyperthermia and photodynamic therapy with plasmon states can be used for cancer treatment (Fig. 23).

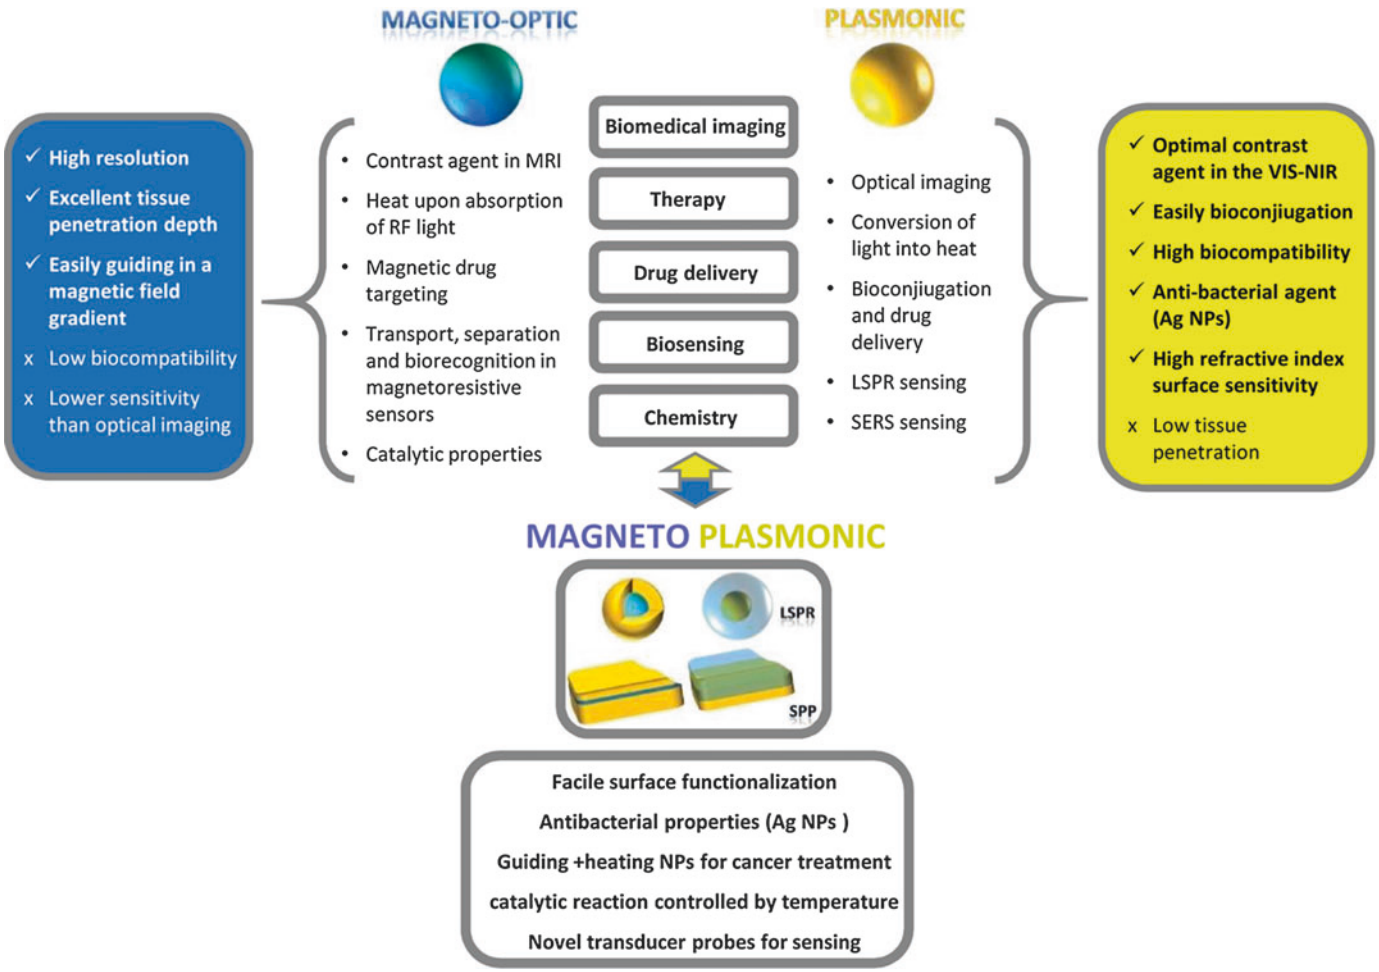
For instance, the use of magnetoplasmonic nanostructures facilitates the simultaneous manipulation and imaging of single NPs, by taking advantage of both optical and magnetic properties. The ability of simultaneously manipulating and imaging single NPs inside living cells demonstrated their potentiality as novel bio-nanoprobes for applications in single molecule measurements, drug delivery, and in vitro or in vivo diagnostics and therapy.

Different combinations of materials at the nanoscale can be found in the literature for a wide range of applications, e.g., therapy of various types of cancer, Alzheimer, virus-induced infections, etc.. . .

Magnetoplasmonic hybrid nanosystems have been used for improving optical imaging in living cells. Zhang et al. proposed a new magnetoplasmonic nanomaterial based on the integration of one dimensional FePt and Au sections [17]. The unique, strongly polarization dependent, and highly anisotropic plasmonic response of these nanomaterials enabled the visualization of their position and orientation down to the individual segments well beyond the diffraction limit, thus demonstrating the possibility to simultaneously manipulate and image single NPs inside live cells.

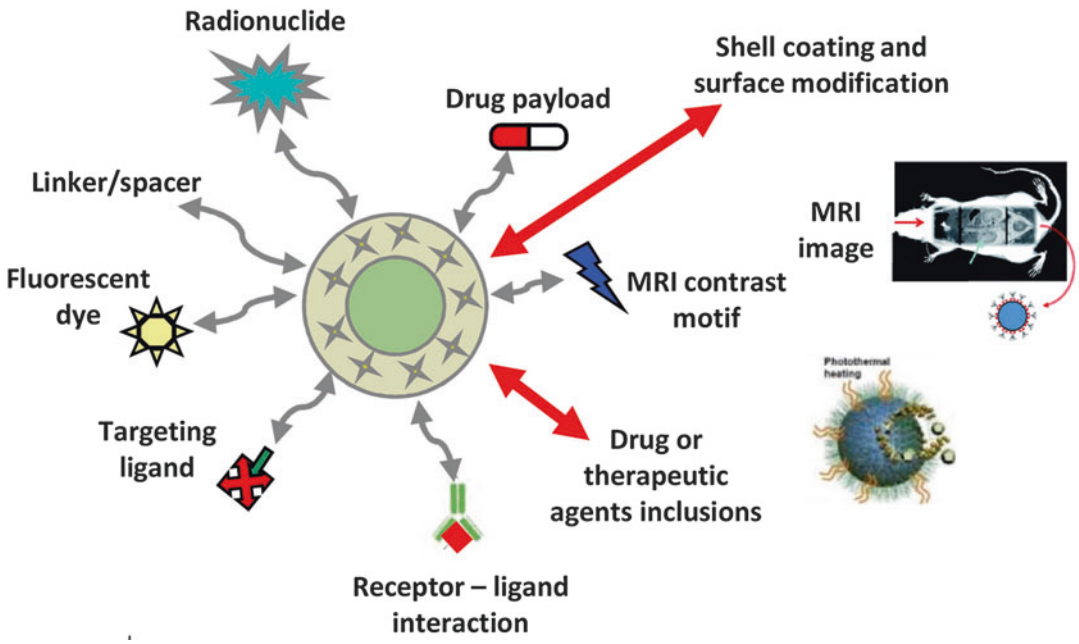
Biophotonic imaging based on a dynamic mode of optical contrast has been discussed also by Wei et al., who used Au nanostars with super paramagnetic cores as novel optical contrast agents [18]. The nanostars exhibit polarization-sensitive NIR scattering and produce a frequency-modulated signal in response to a rotating magnetic field gradient. This periodic modulated signal can be converted into Fourier-domain images with a dramatic reduction in background of the recorded images.

Chen et al. prepared magnetoplasmonic core-shell nanoparticles based on a magnetic Fe_3O_4 core encapsulated in a silica shell, in turn surrounded in a crown-like fashion by Au nanoparticles. The particles are also coated by poly(ethyleneglycol) chains to extend the blood circulation time [19]. The work demonstrated the remarkable imaging and therapeutic capabilities of the NP assemblies against leukemia HL-60 cells.



Finally, a new imaging mode, called magnetomotive photoacoustic imaging, has been proposed by Jin et al. based on iron oxide and gold-coupled core-shell NPs with well-defined structural characteristics and physical properties, simultaneously compact in size and responsive in the NIR spectrum. Beyond conventional NP-based imaging modalities such as TEM, optical imaging, MRI and photo acoustic imaging (PA), coupling of magnetic motion with photothermal conversion enables the new modality with remarkable contrast enhancement compared with conventional PA imaging using conventional NP contrast agents [20].

Magnetoplasmonic Biosensing



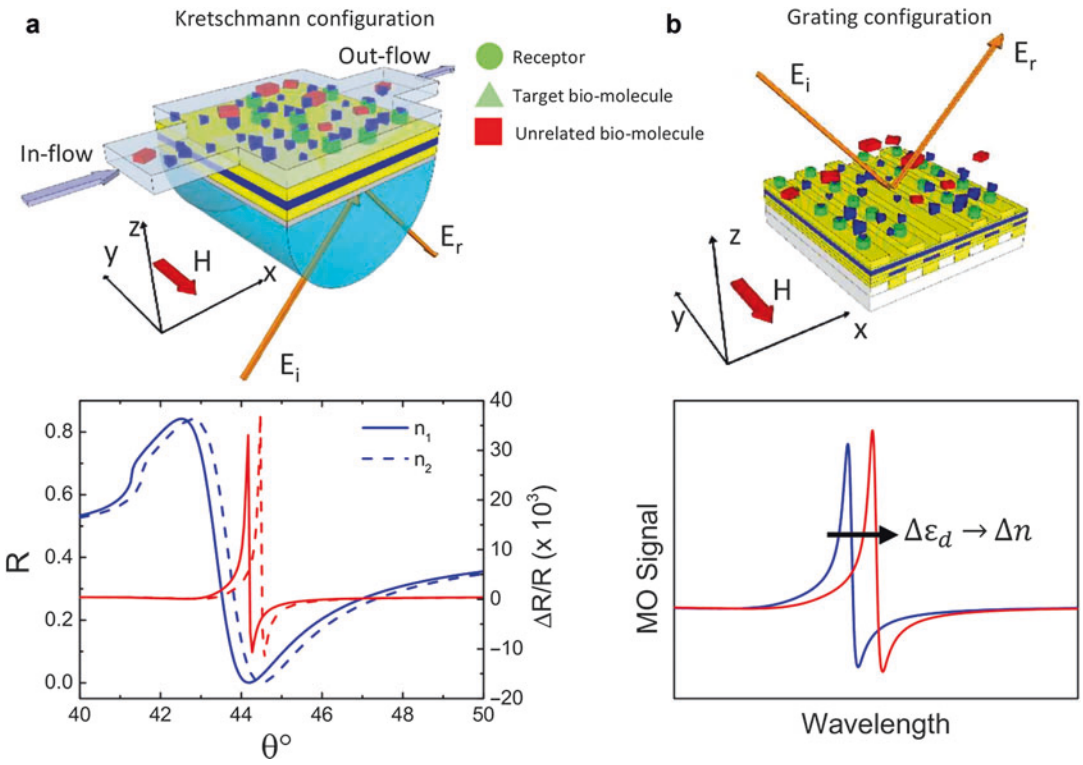
Beyond the use in theranostics, magnetoplasmonic nanomaterials attracted a huge interest as novel transducers in gas or biosensing devices.

Magnetic modulation of plasmonic properties is a novel modulation scheme for SPR–based sensor, alternative to the established mechanical and phase modulations, allowing for a better signal-to-noise ratio and, therefore, an enhanced limit of detection in any kind of sensor. This is an intriguing issue since the detection performance of the current SPR bio-sensors is often insufficient to monitor low concentrations of small biomolecular analytes (e.g., drugs, vitamins or antigens).

Sepúlveda et al. [21] first proposed the use of a proper combination of magnetic materials and plasmonic layers as novel transducers for sensing. Such a combination produced a sharp enhancement of the MO effects strongly dependent on the

Magnetoplasmonics, Fig. 22 Schematic representation of functional properties of magnetic, plasmonic and magnetoplasmonic nanomaterials and relative potential applications in biological analysis and nanomedicine

Magnetoplasmonics, Fig. 23 Scheme of multifunctional magnetoplasmonic nanoparticles for molecular imaging, drug delivery and therapy. Functionalized nanoparticles can be tailored for individualized diagnosis and treatments



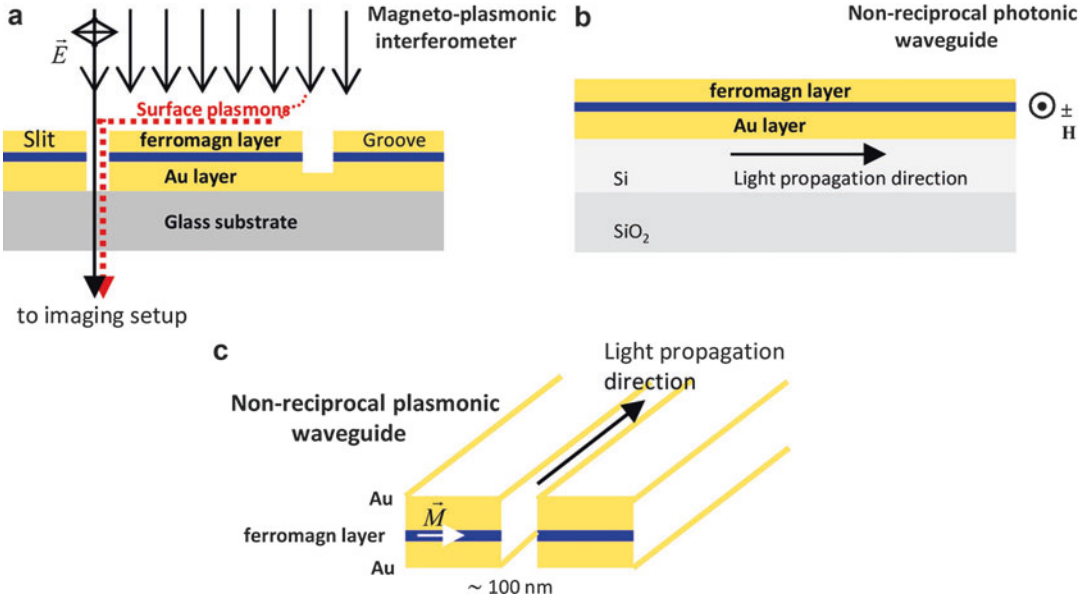
optical properties of the surrounding medium, allowing its use for biosensing applications. They demonstrated the possibility to record the adsorption of biomolecules onto the transducing multilayers structure with an increased limit of detection if compared with standard sensors (Fig. 24a).

Manera et al. [22] demonstrated the possibility to use the enhanced MO signal of metal/ferromagnetic materials trilayers for investigating biomolecular interactions in liquid phase. To this purpose, the transducer surface was functionalized with thiols for chemical anchoring of Bovine Serum Albumin molecules and the binding between immobilized molecules and their complementary target molecules was recorded. Finally higher sensing performance in term of sensitivity and lower limit of detection of the MOSPR biosensor with respect to traditional SPR sensors was demonstrated.

The same research group also demonstrated that a similar approach can be used to improve gas sensing performances of traditional SPR sensors. In this case using a thin nanostructured TiO_2 sensing layer it was shown that the new magnetoplasmonic transductor used in resonance condition had a better sensitivity than a plasmonic transductor used in a classical SPR sensor technique [23].

Martín-Becerra et al. [24] discussed theoretically the possibility to use the planar multilayer configuration as sensing transducer in a magnetically modulated plasmonic interferometer. The modulation of the SPP wavevector induced by an external applied magnetic field in Au/Co/Au trilayers represents a new physical parameter offering a higher sensitivity to refractive index changes.

A different approach was used by Chou et al. [25] to exploit strong transverse MO Kerr effect on a ferromagnetic surface Plasmon grating for developing a highly sensitive sensor. The surface plasmon grating, made of a hybridized Au/Fe/Au layer, exhibits a strongly dispersive Kerr parameter variation near the surface plasmon polariton wavelength via coherent scattering of the SPP on the grating structure. Kerr's parameter monitoring can be used to detect chemical or biological objects in a fluid medium (Fig. 24b).



Magnetoplasmonics, Fig. 24 Examples of magnetoplasmonic nanomaterials for biosensing applications. (**a**) Magneto-optical Surface Plasmon Resonance transduction (*MOSPR*) technique achieved in a Kretschmann ATR configuration. (**b**) Magneto–optic Kerr effect on surface plasmon grating biosensors. In both cases, a proper combination of metallic and magnetic nanomaterials is chosen as transducer platform. Outer metal surface allows for easy functionalization with biorecognition molecules able to detect the presence of target molecules specifically. The detection is recognized as a change in the refractive index at the metal/dielectric interface, which can be revealed sensitively by the magnetoplasmonic signal

Optoelectronics and Telecommunications

Apart from biological and nanomedicine applications, active plasmonic systems have been designed also to control plasmon propagation in on-chip miniaturized all-optical circuits. Modulation of plasmonic properties by an external magnetic field as well as enhanced magneto-optical (MO) Faraday and Kerr effects arising in gyrotropic media attracted much attention due to their possible applications in light control at a submicron scale, in the field of telecommunications, in data storage and lastly in the new field of spinplasmonics (Fig. 25).

To this respect, magnetoplasmonics can be one of the enabling technologies for the development of innovative photonics and telecommunication devices. An excellent example is given by garnets, which are currently being employed into commercial optical insulators for telecommunications. Promising MO improvements, induced by the introduction of SPR components, were indeed observed in hybrid films composed of Au NPs dispersed in garnet films and in Au-Fe oxide hybrid NPs. On the other hand, since the garnets and the Faraday effect technologies cannot be easily integrated into photonic microtechnologies, the nonreciprocity of SPPs offers an interesting way to design alternative integrated optical isolators. Garnet films deposited on Au or Ag films or metallic magnetic films deposited on semiconductors optical waveguides are now being proposed [2], integrated in most of cases into an interferometer in Mach-Zehnder configuration. Similarly, Khurgin et al. considered propagation of a

Magnetoplasmonics, Fig. 25 Examples of application of magnetoplasmonic nanomaterials for optoelectronic devices. (**a**) Working principle of a magnetoplasmonic microinterferometer which can find application in telecommunications Ref. [6]; (**b**) working principle of a nonreciprocal photonic waveguide; (**c**) working principle of a nonreciprocal plasmonic waveguide Ref. [21]

plasmon polariton on the interface between a metal and a MO material, demonstrating that, in the presence of transverse magnetic field, a strong nonreciprocal phase shift occurs [26]. This phenomenon can be used to achieve optical isolation action in short nanoplasmonic guides with low insertion loss.

Chau et al. [27] proposed a novel high-speed MO modulator based on the optical excitation of surface magneto-plasmon waves in bismuth-substituted yttrium iron garnet (Bi-YIG) under an applied magnetic field perpendicular to the plane of incidence. The device was able to provide about 50 % efficiency modulation at GHz speed in the IR range (at 1550 nm), demonstrating a much faster switching ability over other driving agents, such as thermo-optical or electro-optical effects.

An innovative application of magneto-plasmonic materials as compact isolators for circularly polarized waves has been found by Davoyan et al. [28]. They suggested a principle for isolation of circularly polarized waves in magnetically active extreme parameter meta-materials. Using theoretical analysis and numerical simulations, they showed that metamaterials with extreme parameters, such as epsilon-near-zero materials, when merged with MO materials, become transparent for forward circularly polarized waves of a given handedness and opaque for backward propagating waves of the same handedness. The concept may find useful applications also in magnetically controlled light modulation and polarization modulation and nonreciprocal optical antennas.

Conclusions

This entry focused on understanding magnetoplasmonic effects arising from the interaction of plasmonic and MO phenomena typical of metallic and magnetic materials. Theoretical and experimental considerations show that these phenomena are strongly correlated, whereas plasmonic effects are able to enhance MO properties, and likewise magnetic materials are able to modulate plasmonic properties at high frequency. The mutual interaction that leads to

magnetoplasmonic phenomena is observed in a large variety of structures, ranging from extended or nanostructured thin-films to a broad class of nanoparticles characterized by marked structural and compositional differences. The ability to simultaneously exploit enhanced plasmonic and MO properties, and the wide diversity of emerging applications spanning disciplines such as nanomedicine, telecommunications and sensing, illustrate the importance of the fascinating and fast-growing research field of magnetoplasmonics.

Maxwell–Wagner Effect

Mitsumasa Iwamoto
Department of Physical Electronics, Tokyo Institute of Technology, Meguro-ku, Tokyo, Japan

Synonyms

Interfacial charging effect

Definition

The Maxwell–Wagner effect accounts for charge accumulation at the two-material interface on the basis of the difference of charge carrier relaxation times in these two materials. Macroscopically, basic electrical properties of materials are specified using two physical parameters, dielectric constant ϵ and conductivity σ. The ratio of these two parameters, $\tau = \epsilon/\sigma$, gives relaxation time and stands for spreading time of excess free carriers in the materials. Charge accumulation is allowed at the interface between two materials with different relaxation times. When a current flows across the interface, charges are accumulated at the interface. This is nothing but the effect called the Maxwell–Wagner (MW) effect, and this effect appears in all kinds of two-material interface, such as metal–insulator interface, metal–semiconductor interface, insulator–semiconductor interface, and others. The current which flows through materials is given by $\vec{j} = \sigma \vec{E}$, where $\vec{E}$ represents the electric field and σ is conductivity of the materials. In steady state, $\nabla \cdot \vec{j} = 0$ is satisfied. This relation is also satisfied when a steady-state current flows across the two-material interface. As the electric field $\vec{E}$ is given by $\vec{E} = \vec{D}/\epsilon$, using electric flux density $\vec{D}$ and dielectric constant ϵ, the following relation concerning electric flux density $\vec{D}$ at the interface is obtained as [1]

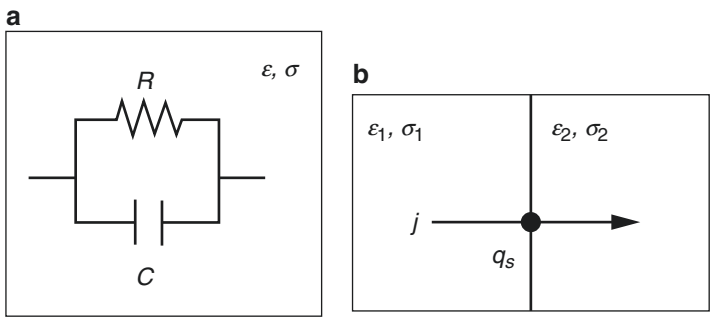
$$\nabla \cdot \vec{D} = \nabla \cdot \epsilon \vec{E} = \nabla \cdot \left(\frac{\epsilon}{\sigma}\right) \vec{j} = \nabla\tau \cdot \vec{j} = q_s(\neq 0)$$

where $q_s(\neq 0)$ is accumulated charge density at the interface. This simple relation shows that charge $q_s(\neq 0)$ is accumulated at the interface between two materials with different relaxation times, i.e., at the meeting point satisfying the relation $\nabla(\epsilon/\sigma) = \nabla\tau \neq 0$. In addition, accumulated charge $q_s(\neq 0)$ is given as the inner product of the spatial gradient of relaxation time $\nabla\tau$ and steady-state current density $\vec{j}$. This is the Maxwell–Wagner effect and accounts for charge accumulation at all kinds of two-material interface.

Introduction

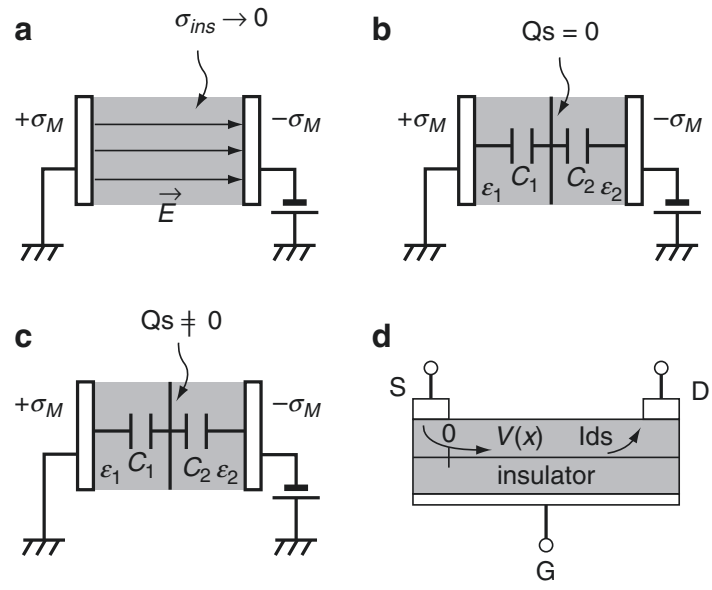
"Interface" plays an important role in electronic devices. For general capacitors with a structure of metal–insulator–metal, the metal–insulator interface is working to prevent charge injection from metals into insulator and accumulates charges on the metals, in proportion to applied voltage. For p–n junctions, the main function of the p–n interface is rectifying carrier transport across the interface and results in the formation of charge distribution that is asymmetric with respect to the interface. For field-effect transistors, mobile charges are accumulated at the gate insulator–semiconductor interface and they are conveyed along the interface. These typical examples show that "interface" is a meeting place of two different materials, where charges are accumulated. Accordingly, much attention should be paid to "interface" in electronic device fabrication. The Maxwell–Wagner (MW) effect accounts for charge accumulation at these two-material interfaces, such as metal–insulator interface, semiconductor–semiconductor interface, and insulator–semiconductor interface. The basic concept of the MW effect lies in the electromagnetic

field theory described by Maxwell's equation. In this entry entitled "Maxwell–Wagner Effect," the Maxwell–Wagner effect is explained, and then some examples of electronic devices are shown, in which the Maxwell–Wagner effect is actively working. In the following, special attention is paid to organic devices, because organic devices, including organic field-effect transistors, organic solar cells and organic electroluminescence (EL) devices, etc., are the most possible candidates of electronic devices in the twenty-first century, and the "interface" plays a dominant role in these device performances.



Maxwell–Wagner Effect

Macroscopic electrical properties of materials are characterized by using two physical parameters. These are dielectric constant ϵ and conductivity σ. The ratio $\tau = \epsilon/\sigma$ gives a relaxation time and stands for spreading time of excess free carriers in the materials. That is, a steady-state charge distribution is established after an elapsed time of around $\tau = \epsilon/\sigma$. In other words, this value $\tau = \epsilon/\sigma$ specifies the electrical properties of materials in terms of carrier transport. Charge accumulation is allowed at the interface between two materials with different relaxation times when a current flows across the interface. This is nothing but the effect called the Maxwell–Wagner (MW) effect, and this effect appears at all kinds of two-material interface, such as metal–insulator interface, metal–semiconductor interface, insulator–semiconductor interface, and others. Further, it is instructive to note that according to Maxwell's electromagnetic theory, a total current flowing across organic materials is the sum of the conduction current and Maxwell's displacement current. In other words, there are two paths for the current flow. This situation is described by using a parallel equivalent circuit model as illustrated in Fig. 1a, where the resistance R represents a path due to conduction current and capacitance C represents a path due to Maxwell's displacement current. R and C are given by $R = l/A\sigma$, $C = \epsilon A/l$, respectively (A: cross section, l: length of path). Consequently, the relaxation time $\tau = \epsilon/\sigma = RC$ represents response time of the equivalent circuit.



For simplicity, let us discuss a case of steady-state current flowing across the interface of the two-material system, as illustrated in Fig. 1b. The two materials are described using a set of two parameters, dielectric constant ϵ and conductivity σ, and constant steady-state current with a current density j is flowing across the interface. The current flow is given by $\vec{j} = \sigma \vec{E}$, where $\vec{E}$ represents the electric field and σ is conductivity of materials. In this situation, $\nabla \cdot \vec{j} = 0$ is satisfied over the entire region of the two-material system. The electric field $\vec{E}$ satisfies the relation $\vec{E} = \vec{D}/\epsilon$, where $\vec{D}$ is electric flux density. Hence the following relation concerning electric flux density $\vec{D}$ at the interface is obtained as [2–4]

$$\nabla \cdot \vec{D} = \nabla \cdot \epsilon \vec{E} = \nabla \cdot (\epsilon/\sigma)\ \vec{j} = \nabla\tau \cdot \vec{j} = q_s (\neq 0). \quad (1)$$

In more detail, from Eq. 1, the following relation is obtained as

Maxwell–Wagner Effect, Fig. 1 (**a**) Equivalent circuit of materials and (**b**) Maxwell–Wagner effect

Maxwell–Wagner Effect, Fig. 2 (**a**) MIM, (**b**) double-layer structure device ($Q_s = 0$), (**c**) double-layer device with Q_s, and (**d**) a three-electrode system

$$(\tau_2 - \tau_1)J = \sigma_s(\neq 0). \tag{2}$$

Here $\tau_1 = \epsilon_1/\sigma_1$ and $\tau_2 = \epsilon_2/\sigma_2$ are relaxation times of materials 1 and 2, respectively. J is steady-state current density per unit area, which flows normal to the interface, and σ_s is charge accumulated at the interface per area. Equations 1 and 2 show that charge is accumulated at the interface between two materials with different relaxation times, i.e., $\tau_1 \neq \tau_2$. In addition, accumulated charge σ_s is given as the product of time difference $\Delta\tau = \tau_2 - \tau_1$ and steady-state current density J. This is the Maxwell–Wagner effect and accounts for charge accumulation phenomena observed in all kinds of two-material interfaces.

Examples of Maxwell–Wagner Effect in Electronic Devices

Metal–Insulator–Metal System

Figure 2a shows a structure of metal–insulator–metal (MIM) device. Typical examples are seen in power cable systems, capacitors, etc., and these are modeled as shown in Fig. 2a. In MIM system, there is a metal–insulator interface. The conductivity of metal, σ_m, is generally very high, and it is infinity in the limit. On the other hand, the conductivity of insulator σ_{ins} is extremely low and it is nearly zero in an ideal case. In that situation, relaxation times of the metal and the insulator are $\tau_m \to 0$ and $\tau_{ins} \to \infty$. As a result, current flowing across the insulator becomes nearly zero in steady state, $J \to 0$, in the presence of external electric field $E = V/L$, where V is applied voltage across the insulator and L is the distance between the two electrodes. Substituting these relations into Eq. 2, the induced charge on metals $\sigma_M(=\sigma_s)$ is derived as

$$\begin{aligned}\sigma_M &= (\tau_{ins} - \tau_m)J \\ &= (\epsilon_{ins}/\sigma_{ins})\sigma_{ins}E_{ins} - (\epsilon_m/\sigma_m)\sigma_m E_m \\ &= \epsilon_{ins}E_{ins} - 0 = +\epsilon_{ins}V/L.\end{aligned} \tag{3}$$

In the derivation of Eq. 3, $E_m = 0$ is assumed with consideration of the fundamental property of metals, i.e., there is no electric field in metals. Equation 3 is the general equation of capacitors that describes induced charge on metals of MIM systems. That is, induced charge on electrodes is proportional to the applied voltage, V.

Metal–Double-Layer–Metal System (Two-Electrode System)

Figure 2b and c shows structures of metal–double-layer–metal device. Typical examples are seen in double-layer dielectric and insulator systems,

double-layer EL devices, double-layer solar cells, etc. In these systems, there is a double-layer interface. As mentioned in section "Maxwell–Wagner Effect," no charge is accumulated at the interface, when the relaxation times of the two materials are the same as $\tau_1 = \tau_2$ (see Fig. 2b), i.e., $q_s = 0$ and $\sigma_s = 0$ (see Eqs. 1 and 2). In that situation, the electric field formed in the two-material system satisfies the following relation:

$$\epsilon_1 E_1 = \epsilon_2 E_2. \tag{4}$$

Equation 4 suggests that the ratio of the electric field formed in the two materials depends on the dielectric constants of the two materials. Obviously for electrical insulation, the conductivity of insulator should be extremely small, but in a case of multilayer insulator system that satisfies the relation $\tau_1 = \tau_2 = \tau_3 \ldots$, charge accumulation at the interface is discarded even when a leakage current flows steadily. Hence the space charge field formation caused by accumulated charge is negligible, and the electric field distribution in the multilayer system is regulated only by the dielectric constants of materials used.

Generally, the electric field distribution in multilayer systems depends on distribution of accumulated charges at the interface, caused by the difference in relaxation times, i.e., $\tau_1 \neq \tau_2 \neq \tau_3 \ldots$. For a double-layer system with different dielectric relaxation times, $\tau_1 \neq \tau_2$, as illustrated in Fig. 2c, the electric field distribution depends on external electric field formed by applied voltage V as well as accumulated charges at the interface. Assuming charge $Q_s = S\sigma_s$ (S: electrode area) is accumulated at the interface, the electric fields in materials 1 and 2 are derived as follows:

$$E_1 L_1 = \frac{\sigma_M L_1}{\epsilon_1} + \frac{Q_s}{(C_1 + C_2)}. \tag{5.1}$$

$$E_2 L_2 = \frac{\sigma_M L_2}{\epsilon_2} + \frac{Q_s}{(C_1 + C_2)}. \tag{5.2}$$

Here $\sigma_M = Q_M/S$ is the charge induced on metal electrodes with $Q_M = C^* V$, where $C^* = C_1 C_2/(C_1 + C_2)$ is a series capacitance of the double-layer system with $C_1 = \epsilon_1 S/L_1$ and $C_2 = \epsilon_2 S/L_2$. Here σ_M is given by Eq. 3 with $L = L_1$, and accumulated charge is given by $Q_s = S\sigma_s$, using relation (2). That is, the electric field formed in the double-layer system changes depending on the accumulated charge at the interface, $Q_s = S\sigma_s$. From a viewpoint of device application in electronics, information on the charge Q_s and the electric field distribution is crucially important. These important information can be obtained by using novel experiments based on electric field-induced optical second-harmonic generation (EFISHG) measurement, charge modulation spectroscopy, and others.

For $\sigma_1 >> \sigma_2$, i.e., in a case of materials 1 and 2 showing conducting and insulating properties, respectively, $E_1 = 0$, $E_2 = V/L$ with $V = Q_s/C_2$ are obtained in steady state. That is, no electric field is formed in conducting material 1 and an electric field is present in material 2.

FET System (Three-Electrode System)

For double-layer devices with a sandwich structure as shown in Fig. 2, the potential along the double-layer interface is constant, while it is not the case when devices with a three-electrode configuration are discussed. As illustrated in Fig. 2d, a typical example is found in field-effect transistors, where the three electrodes are source, drain, and gate electrodes. In this system, the potential varies along the interface, depending on gate-source voltage, V_{gs}, and drain–source voltage, V_{ds}. What kind of potential distribution should be postulated? To answer this question is difficult, but a constant-slope potential distribution along the interface would be the most simple (gradual channel approximation) and most probable one. In other words, the electric field along the interface is constant and given by $-(V_{ds} - V_{gs})/L$. In that situation, the potential at $x = x$ from position of the source electrode edge is described as

$$V(x) = V_{gs} + \frac{x}{L}\left(V_{ds} - V_{gs}\right). \tag{6}$$

As the charge induced on the interface is given by $C_g(V(x) - V_{th})$ ($C_g = \varepsilon_g/d$, gate capacitance per unit area; V_{th}, threshold voltage; ε_g is the dielectric

constant of gate insulator, and d is the thickness of gate insulator), the charge induced at the interface between source and drain electrodes is given by

$$Q_{\text{int}} = C_g\left(V_{\text{gs}} - V_{ds}/2 - V_{\text{th}}\right) \tag{7}$$

per unit area. The accumulated charge given by Eq. 7 is of course the result of the Maxwell–Wagner effect at the gate insulator–active layer interface. In general FETs, the active layer is very conducting in comparison with the gate insulator; the relation $\tau_g >> \tau_{\text{act}}$ thus holds. Here τ_g and τ_{act} are dielectric relaxation times of gate insulator and the active layer. The situation of charge accumulation is very similar to the case expressed by Eq. 3 with $\tau_g = \tau_{\text{ins}}$ and $\tau_{\text{act}} = \tau_m$. In other words, the electric field in gate insulator is much higher than the field in the active layer. The drain–source current I_{ds} is the flow of charge Q_{int} at a constant velocity of $u\left(= \mu\overline{E}_{\text{ds}}\right)$ under the average electric field along the channel between drain and source electrodes, $\overline{E}_{\text{ds}} = V_{\text{ds}}/L$. Consequently, the I_{ds} is written as [2, 3]

$$\begin{aligned} I_{\text{ds}} &= Q_{\text{int}}\frac{hW}{h}\mu\frac{V_{\text{ds}}}{L} \\ &= \mu\frac{W}{L}C_g\left[\left(V_{\text{gs}} - V_{th}\right)V_{\text{ds}} - V_{\text{ds}}^2/2\right]. \end{aligned} \tag{8}$$

Here L/W and h are the channel length/width and thickness of the channel, respectively. Equation 8 is nothing but the equation of drain–source current of field-effect transistors, which is derived under gradual channel approximation on the basis of general semiconductor device physics. Nevertheless, it should be noted that Eq. 8 is derived on the basis of classical electrostatic analysis with consideration of the Maxwell–Wagner effect. In other words, charge accumulation at semiconductor–insulator interface is a result of the Maxwell–Wagner effect.

Note that in the case of constant current flowing across the FET channel, the potential distribution such as [5]

$$V(x) = V_0\sqrt{1 - \frac{x}{L}} + V_{\text{th}} \tag{9}$$

is obtained. Here V_0 is the potential below the source electrode with respect to the gate potential. Hence, the electric field along the channel is no longer constant and dependent on the position as

$$E(x) = \frac{V_0}{2\sqrt{L(L-x)}}. \tag{10}$$

In this case, the drain current is described as

$$I_{\text{ds}} = \mu\frac{W}{L}C_{\text{g}}\left[\left(V_{\text{gs}} - V_{\text{th}}\right)V_{\text{ds}} - \frac{2}{3}V_{\text{ds}}^2\right]. \tag{11}$$

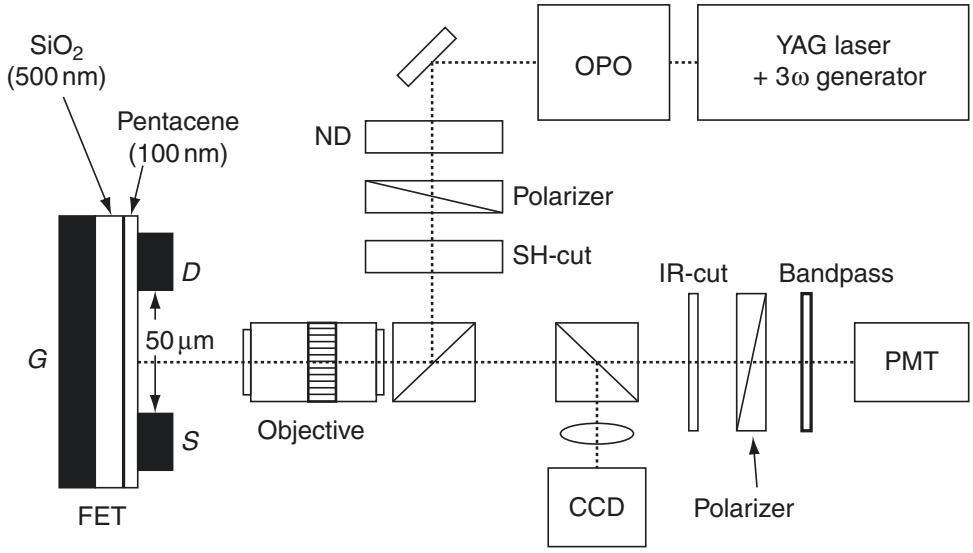
The deviation of the current Eq. 11 from Eq. 8 is small, but the positional dependence of the electric fields is rather different between them. Hence, it is important to measure the electric field distribution along the FET channel.

As has been described above, the Maxwell–Wagner effect is actively working in field-effect transistors.

Maxwell–Wagner Effect as Interfacial Polarization Phenomena

As mentioned in section "Metal–Double-Layer–Metal System (Two-Electrode System)," charge σ_{s} is accumulated at the interface between two materials with different relaxation times, $\tau_1 \neq \tau_2$ (see Eq. 2). The interfacial charge accumulation process is a macroscopic dielectric polarization process, and it is called as interfacial polarization process. This process is a single polarization process, and the charge accumulation at the interface of the double-layer system illustrated in Fig. 2c is written as

$$\begin{aligned} &\sigma_{\text{s}}(t) = \sigma_s(1 - \exp(-t/\tau_{\text{MW}})) \quad \text{with} \\ &\tau_{\text{MW}} = \frac{C_1 + C_2}{G_1 + G_2} \end{aligned} \quad . \tag{12}$$



Here $C_1 = \epsilon_1 S/L_1$, $C_2 = \epsilon_2 S/L_2$, $G_1 = \sigma_1 S/L_1$, and $G_2 = \sigma_2 S/L_2$. τ_{MW} is Maxwell's dielectric relaxation time and it differs from relaxation times of the two materials, τ_1 and τ_2. It depends on not only material properties, dielectric

constant ϵ and conductivity σ, but also on geometrical factors, film thickness L and working area S. This is the characteristic of the interfacial charging caused by the Maxwell–Wagner effect.

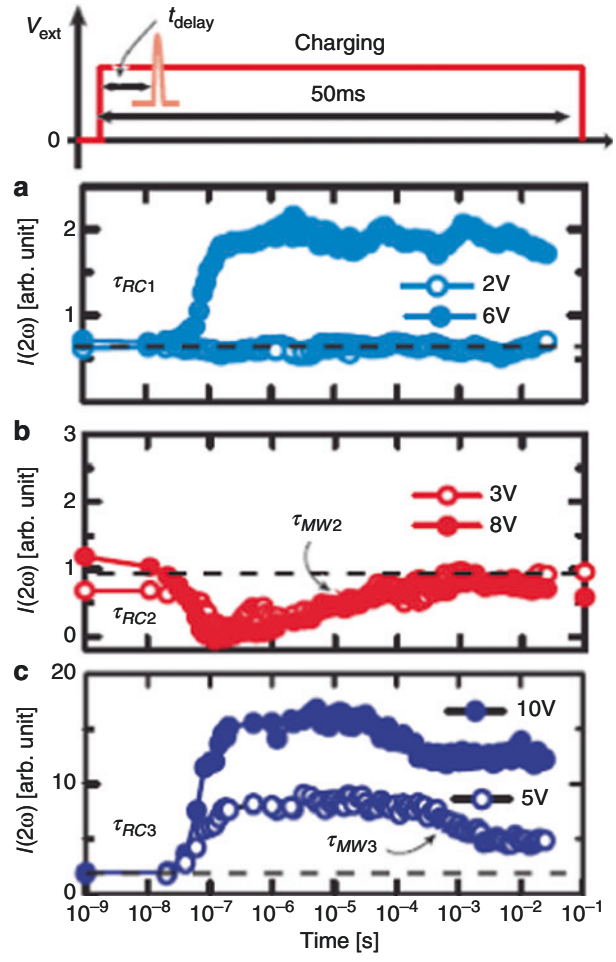
Probing of Interfacial Charge Caused by Maxwell–Wagner Effect

As described in section "Metal–Double-Layer–Metal System (Two-Electrode System)," accumulated charge at the interface is a source of space charge field. This results in the modification of the electric field distribution in a double-layer device in accordance with amount of accumulated charge at the interface (see Eqs. 1 and 2). This scenario is also applicable to the case of any other device systems with material–material interfaces. In that situation, probing the electric field in devices is a very important research subject. Many techniques for probing the electric field distribution have been developed. Among them are electrical measurements, i.e., charge decay method, thermally stimulated current method, and so on. However, these techniques are indirect ones and cannot directly probe carrier process. On the other hand, optical method based on optical second-harmonic generation is available for directly probing carrier process related to the interfacial charging caused by the Maxwell–Wagner effect [5–10]. Figure 3 portrays the experimental setup of the optical second-harmonic generation method using a light source of YAG laser [8, 10]. The attached CCD camera visualizes carrier motion in active layer of the FET device [10], and the PMT probes the intensity of generated SHG signals.

Using this technique, the electric field distributions in electronic devices are obtained, e.g., organic field-effect transistors, electroluminescence devices, solar cells, and others [10, 11]. As charges injected from electrodes are excess charges, they act as a source of electric field. As a result, materials accepting these excess charges would be polarized. In other words, electron clouds of molecules are distorted in the presence of a space charge field arisen from injected carriers. In that situation, by probing this polarization, carrier motion in devices will be probed. The polarization to be probed is second-order nonlinear dielectric polarization that is generated in materials, due to coupling of electron clouds and electromagnetic waves. This is the electric field-induced nonlinear polarization, and this polarization is probed in the electric field-induced

Maxwell–Wagner Effect, Fig. 3 Optical setup for the SHG measurement. The sample has the FET structure

optical second-harmonic generation (EFISHG). In more detail, EFISHG is generated due to the coupling of electrons in molecules and electromagnetic waves $\mathbf{E}(\omega)$ in the presence of electrostatic local electric field $\mathbf{E}(0)$. Hence the EFISHG generation is allowed from even symmetric molecular systems, such as pentacene, tetracene, phthalocyanine, etc.



The EFISHG intensity is given as [10–13]

$$I(2\omega) \propto |\mathbf{P}(2\omega)|^2 = \left|\epsilon_0 \chi^{(3)}(0,\omega,\omega) \vdots \mathbf{E}(0)\mathbf{E}(\omega)\mathbf{E}(\omega)\right|^2, \quad (13)$$

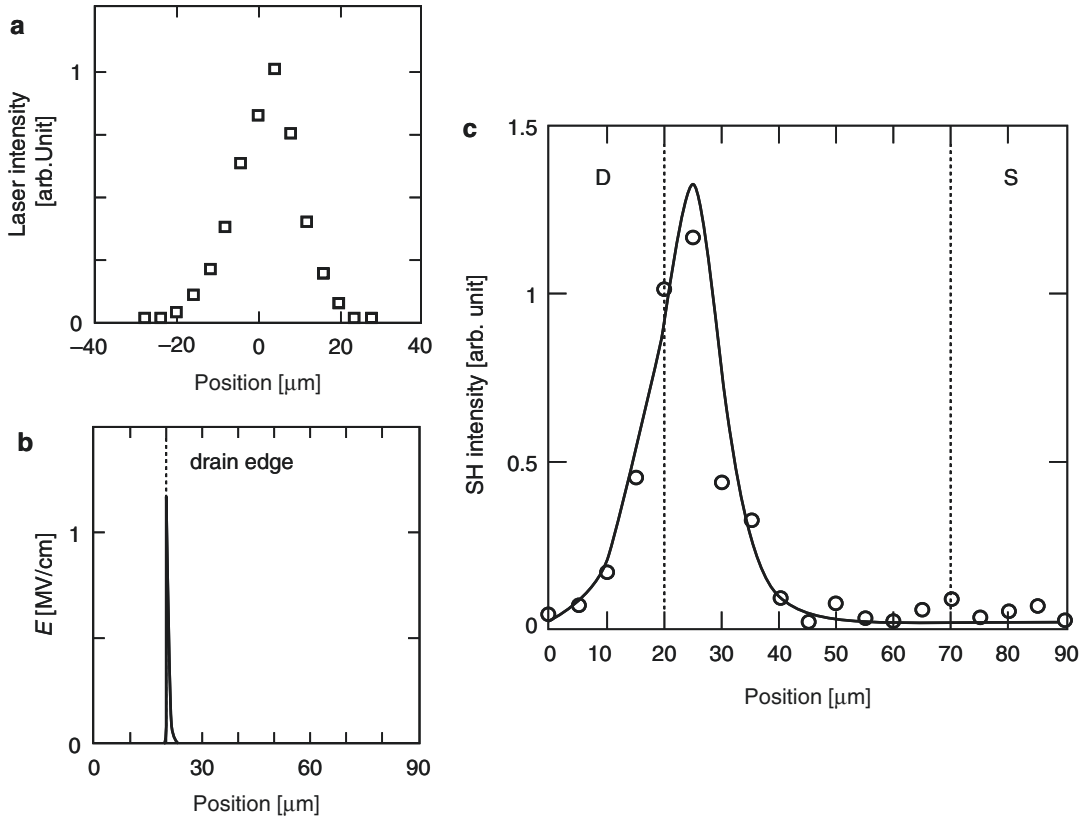
where $\mathbf{P}(2\omega)$ is the nonlinear polarization induced in the materials, ϵ_0 is the dielectric permittivity of vacuum, $\chi^{(3)}$ is the third order nonlinear susceptibility tensor, $\mathbf{E}(0)$ is the electrostatic local field in materials, and $\mathbf{E}(\omega)$ is the electric field of incident electromagnetic wave. Generally, laser beam is used as a source of $\mathbf{E}(\omega)$. The local electric field is sum of the external electric field $\mathbf{E}_0$ and other fields such as space charge field, inner electric field due to workfunction difference of electrodes, and so on. Hence, carrier motion is probed as propagation of nonlinear polarization in the EFISHG measurements. In the following, some examples are shown.

Double-Layer Devices

Figure 4 shows transient EFISHGs generated from double-layer devices by applying a step voltage, i.e., ITO/polyimide/α-NPD/Au (Fig. 4a), ITO/polyimide/pentacene/Au (Fig. 4b),

Maxwell–Wagner Effect, Fig. 4 Transient SHG response from double-layer devices applying a step voltage: (**a**) α-NPD/polyimide device, (**b**) pentacene/polyimide device, and (**c**) α-NPD/Alq3 device

and ITO/α-NPD/Alq3/LiF/Al (Fig. 4c) [14–17]. Here pentacene and α-NPD are hole-transport layers, and Alq3 is an electron-transport layer, and polyimide is a blocking layer. The delay time (t_{delay}) in Fig. 4 represents the time interval between fundamental laser beam used as incident electromagnetic wave $E(\omega)$ and the wave front of the applied square voltage. In the SHG experiments, the SHG wavelength was chosen so that the electric field in α-NPD and pentacene layers was probed [14–17]. The black dash lines represent baselines for each device ("zero level"), with no applied voltage. At the beginning $t < 10^{-7}$ s, the three devices show similar transient characteristics. The SH intensity begins to increase at around $t \sim 10^{-7}$ s and then reaches some saturated value. This response time is independent of applied voltage and reflects charging to the electrodes. This response time of $\tau_{RC} \sim 10^{-7}$ s corresponds well with the response of the device circuit R_s C* (see section "Metal–Double-Layer– Metal System (Two-Electrode System)") for C*).



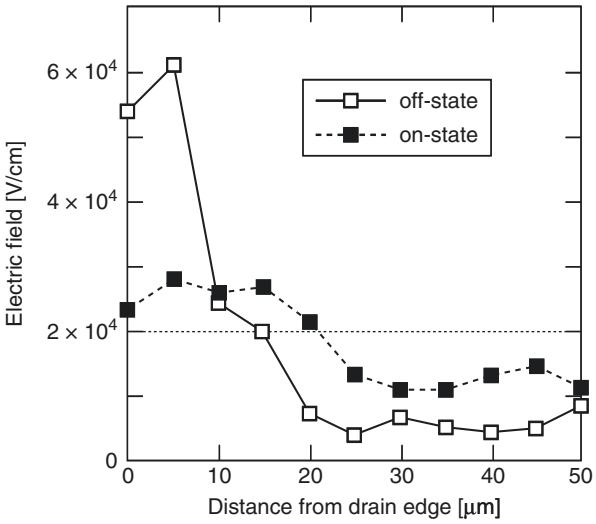
By contrast, the transient SHG in the region $t > 10^{-7}$ s depends on the device and applied voltage. Figure 4a shows the transient SHG of ITO/polyimide/α-NPD/Au. Here polyimide layer is a blocking layer for hole and electron injection, and only hole injection from the Au electrode to the α-NPD layer is allowed. However, in actual experiments, after the charging of the electrodes, the SH intensity saturates and never changes. The results suggest that there is no charge accumulation at the interface, i.e., $Q_s = 0$ (see Eq. 1). In other words, the α-NPD layer works like an insulating blocking layer. Figure 4b shows the transient SHG of ITO/polyimide/pentacene/Au devices. Here polyimide is a blocking layer. In this case, hole injection from the Au electrode is expected. Actually, after charging of the electrodes, rapid relaxation of SH intensity to zero level is significant. The decrease of the SHG intensity indicates charge accumulation at the pentacene/PI interface, i.e., $Q_s \neq 0$, as a result of the MW effect. Moreover, accumulated holes completely compensate the external electric field in the limit $t \to \infty$ (see Eqs. 1 and 2). Note that the relaxation time given by Eq. 12 satisfies the relation $\tau_{MW} \geq \tau_{RC}$ (10^{-7} s) in this experiment. Figure 4c shows the transient SHG of ITO/α-NPD/Alq3/LiF/Al device. This device is a typical two-carrier transportation OLED device with hole and electron injected from opposite electrodes. After the charging of the electrodes, these carriers are conveyed into α-NPD and Alq3 layers from opposite sides and reach at the α-NPD/Alq3 interface, where they recombine for electroluminescence. Nevertheless, from viewpoints of Maxwell–Wagner effect, electric field in this device is modified as excess charges remained at the interface. Observed SHG decaying after its saturation was due to this MW effect. In this case, the experiment shows that the relation $\tau_{MW} >> \tau_{RC}$ is satisfied. Interestingly, the electroluminescence was generated at the very time when the SHG decay was started.

OFET Devices

As described in section "FET System (Three-Electrode System)," charge is accumulated at the interface [18–20]. For double-layer devices illustrated in Fig. 2, it is easy to expect charge is homogeneously distributed at the interface, and as a result, constant potential is built at the interface. On the other hand, at the interface of three-electrode devices such as FET, the distribution is dependent on configuration structure and current flowing through the system, though the Maxwell–Wagner effect suggests that charge must be accumulated at the interface. Hence, it is a fundamental task to determine experimentally charge distribution along the channel. Probing electric field distribution along the channel is of great help and EFISHG measurement is available (see Eq. 13). Interest topics here are the charge distribution in steady state and charge accumulation process along the channel. In the following, these two points are focused.

In Steady State

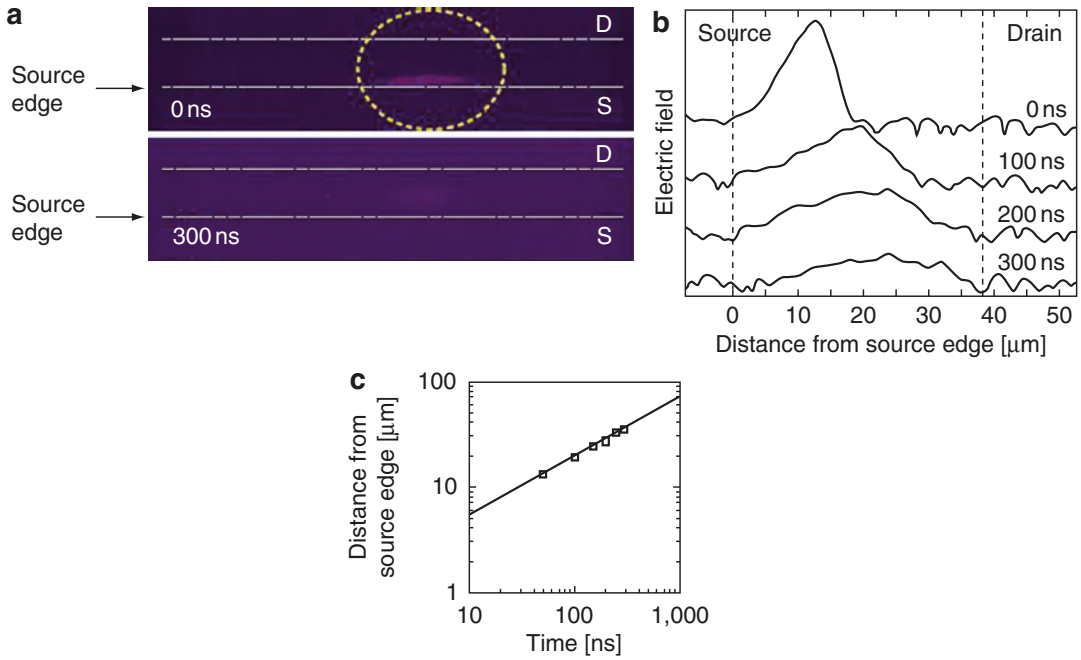
As is well known, Laplace fields are theoretically calculated if the electrode configuration and its potential distributions are known a priori. Figure 5 shows the SHG experiment employed for OFETs to determine the electric field distribution along the channel. Figure 5a and b shows the intensity profile of the fundamental laser at a focal point and the field distribution calculated using the



Maxwell–Wagner Effect, Fig. 5 SHG experiment. (**a**) Intensity profile of the fundamental laser at a focal point, (**b**) theoretical field distribution calculated using the finite element method, and (**c**) SHG profile estimated using (**a**) and (**b**). *Open circles* represent the observed SHG intensity at off-state of OFET device applying $V_{dg} = V_{sg} = -100$ V

finite element method on account of the actual electrode configuration. The separation between source and drain electrodes is $L = 50$ μm. At off-state of the device, i.e., without injected carriers along the channel, the potentials of the source and gate electrodes are the same, whereas potential difference between drain and gate (source) electrodes is -100 V. In this case, a Laplace field is formed in the device system, and the electric field is concentrated at the edge of drain electrodes due to edge effects. Figure 5c shows the SHG profile estimated from the convolution of the Laplace field and the intensity profile of the fundamental laser. Open circles represent the observed SHG intensity at each spot position. The theoretical curve reproduces well the experimental results, indicating actual electric field distribution in FETs is evaluated by carrying the deconvolution of the SHG profile. For simplicity, assuming the laser beam profile as delta function, the electric field distribution is roughly evaluated. Figure 6 shows the evaluated electric field distribution in the pentacene FET channel. At first glance, electric field is concentrated at the drain edge in the off-state (open squares). On the other hand, electric field distribution profile is getting flat in the on-state (filled squares), and it is approaching a constant electric field distribution (Eq. 6, gradual channel approximation).

Transient Charge Accumulation Process



As mentioned in section "Probing of Interfacial Charge Caused by Maxwell–Wagner Effect," using a transient SHG technique can directly probe carrier motion in organic materials by monitoring the propagation of induced polarization

Maxwell–Wagner Effect, Fig. 6 Evaluated electric field distribution in the pentacene FET channel from SHG intensity: *open squares*, off-state; *closed squares*, on-state. *Dotted line* represents the average field calculated as V_{ds}/L, where L is the channel length

along with carrier motion [18–20]. According to the Maxwell–Wagner effect, at the interface between two materials with different relaxation times, the charge Q_s is accumulated. In OFETs, carriers injected from the source electrode are accumulated at the interface between active organic layer and gate insulator, and they are conveyed along the channel. Note that the injected carriers are excess charges and they are acting as a source of space charge field E_s. Hence actual local electric field E is a sum of the external field E_0 and space charge field, i.e., $E = E_0 + E_s$. Obviously, E_0 is the Laplace field and it never changes after applying voltages to the source, drain, and gate electrodes, and it is the same with that at time $t = 0$. On the other hand, E_s is the Poisson field and changing with time in accordance with carrier propagation, i.e., carrier injection, accumulation, and transport. Of course, it stabilizes in the limit $t \to \infty$, i.e., in steady state. Carrier migration along the channel is considered as an interfacial charging process and modeled using a ladder *RC* circuit model.

Visualization of carrier migration is of great help to verify the above carrier migration along the OFET channel. In such situation, transient EFISHG technique is available. Substituting $E = E_0 + E_s$ into $\mathbf{E}(0)$ of Eq. 13, it is found that SH intensity distribution along the channel changes with the distribution of space charge field E_s originating from moving carriers. For the transient SHG measurement, time-resolved microscopic SHG (TRM–SHG) measurement is useful. This approach allows to directly probe carrier motion. Figure 7 shows the TRM–SHG experiments using top-contact pentacene FET with Au source and drain electrodes. The samples were prepared on gate insulator surface with a 500 nm of SiO_2 gate insulator. The thickness of the pentacene layer was 100 nm. Figure 7a shows the TRM–SHG image obtained at various times after a positive voltage pulse of 70 V was applied to the source electrode with the gate and drain electrodes shorted and grounded. At $\tau = 0$ ns, the laser pulse coincided with the rising edge of the voltage pulse, and SHG signals were found near the edge of source electrode, indicating that carrier injection was just started, and the Laplace field E_0 is formed only around source electrode. Interestingly, as is clearly shown in the image, the emission band of the SHG signal gradually moved in the channel from source to drain electrode with time. Motion of the emission band from source electrode, not from drain, is the direct evidence of hole injection from the Au source electrode. That is, pentacene FET shows a p-type behavior. The SHG intensity profile plotted in Fig. 7b clearly shows that holes travel in direction from the Au source electrode to the drain electrode, on satisfying the square root time dependence (see Fig. 7c). Results show that carrier transient is an interface charge propagation process, and the square root time dependence verifies the RC ladder model.

The area of the laser spot is indicated by the *dashed circle*. (**b**) Plots of SHG intensity profile. (**c**) Log–log scaled time evolution of the peak position of the SHG intensity

Future Directions

The Maxwell–Wagner effect is based on the classical electromagnetic theory and accounts for charge accumulation phenomena at the interface between two materials. It can widely apply to all kinds of material interfaces, from macro- to nanomaterials. Also it can apply at molecular level. Many new materials will be coming out, but physics related to charge accumulation is the same.

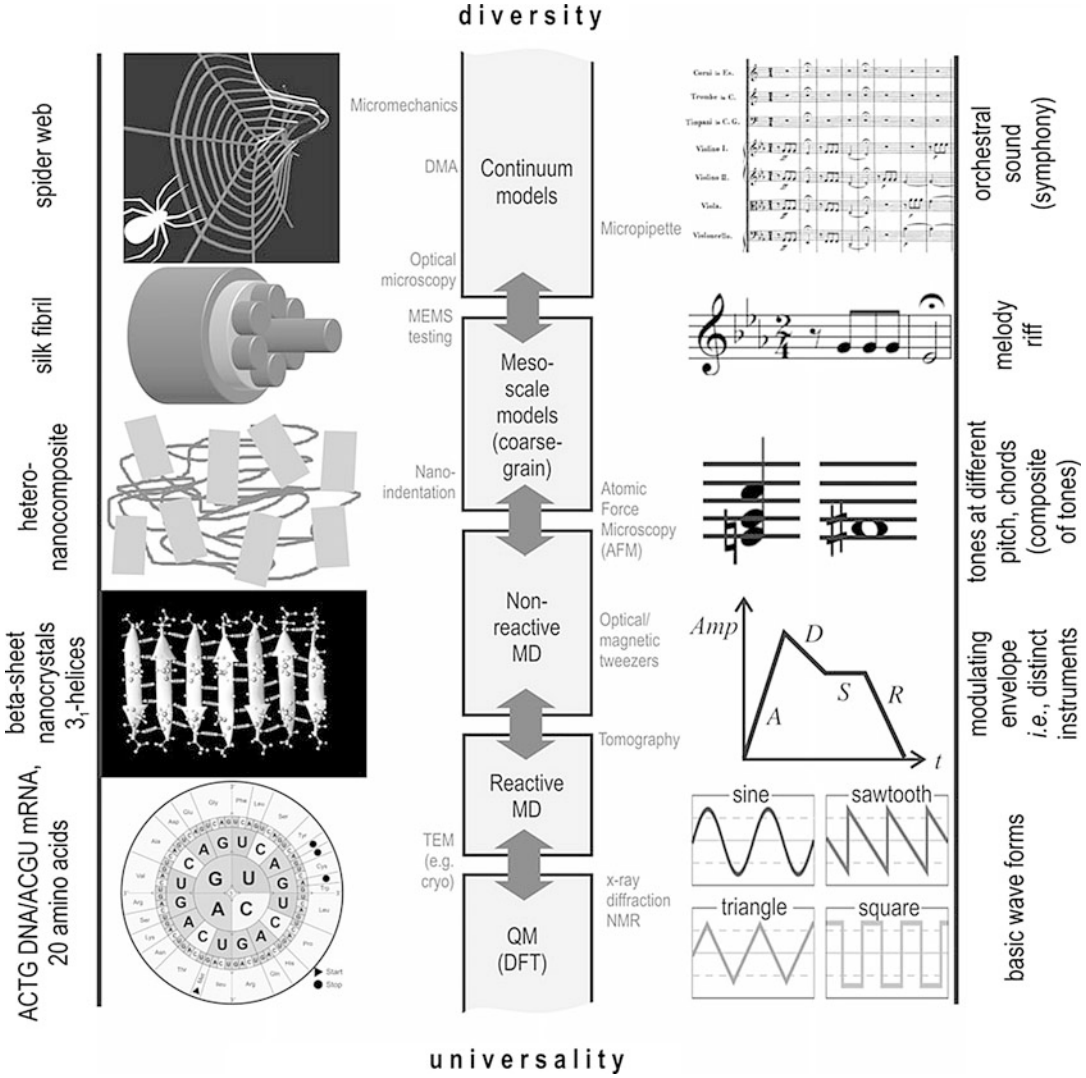
Definition

Mechanical properties of proteins define the behavior of the deformation and failure of proteins and protein-based biological and synthetic materials.

Overview

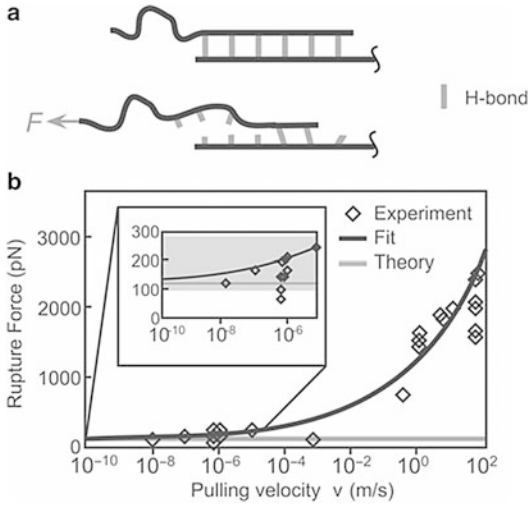


With only 20 standard amino acids as universal building blocks, evolutionary adaptation has resulted in a multitude of polypeptides and protein structures with a wide range of properties and applications [1]. A fundamental application of protein materials is mechanical, providing static and dynamic support and defenses for the organisms they comprise. To achieve specialized mechanical properties, animal tissue shows a wide range of complex, structured composites composed of proteins (e.g., collagen, keratin, chitin) and inorganic minerals (e.g., calcite, hydroxyapatite, and aragonite) [2, 3]. Instead of summarizing primarily single-molecule protein mechanics studies [4–8], the main goal of this entry is to give an introduction to the current knowledge of the nanomechanical properties of important structural protein materials and to explain the generic role of the hierarchical structures that give rise to exceptional mechanical properties that are superior to many synthetic engineering materials. For example, shell, bone, and antler are hierarchically structured composites of collagen and minerals and have toughnesses that are about one order of magnitude greater than engineering ceramics [9]. Natural polymers and polymer composites like collagen, keratin, and silk show elastic moduli and tensile strengths larger than those of engineering polymers made from similar building blocks. For example, silks have elastic moduli between 2 and 20 GPa and strengths in the range from 0.3 to 2 GPa [9]. Of synthetic polymers, only Kevlar has a higher stiffness at 200 GPa and a strength up to 4 GPa, which it achieves through a highly oriented molecular structure which is, in fact, characteristic of biological materials. Natural elastomers, including skin, muscle, cartilage, abductin, resilin, and elastin, exhibit elastic moduli and densities similar to those of engineering elastomers. Muscle is unique in combining a low modulus on the order of an elastomer with a high strength on the order of steel [9]. Natural cellular materials like cancellous bone have low densities because of the high volume fractions of voids they contain [10].

Whether natural composite, polymer, or elastomer, many biological materials achieve their notable mechanical properties through a balance of strong covalent bonds and weaker noncovalent bonds (e.g., hydrogen bonds) in a multilevel hierarchical structure that spans from nanoscopic to macroscopic length scales [11, 12]. Known as the universality-diversity paradigm [13] and summarized in Fig. 1, a limited number of universal protein structures or mineral components can provide a wide diversity of geometrical arrangements within the natural composites that give rise to exceptional bulk mechanical properties as compared to the material properties of the individual constituents. Certain specially constructed geometrical arrangements can enhance bulk properties much more than the rule of mixtures can predict. This puts the concept of geometry, assembly, and, more generally, the architecture of hierarchical structures at the forefront of the science of protein materials.

This entry will first discuss how protein materials are limited by an intrinsic strength limit at the nanoscale that exemplifies the constraints under which many biological systems operate, how these are overcome, and how such materials exemplify a powerful paradigm of how weakness is turned into strength. Next, the multilevel structures of silk, collagen fibers, and bone are presented as specific examples of how specialized geometrical arrangement of respective protein and mineral components into a hierarchical structure can overcome the strength limit at the base level to yield highly functional macroscale materials that rival engineering composite materials.

Hierarchical Structures Overcome Strength Limits

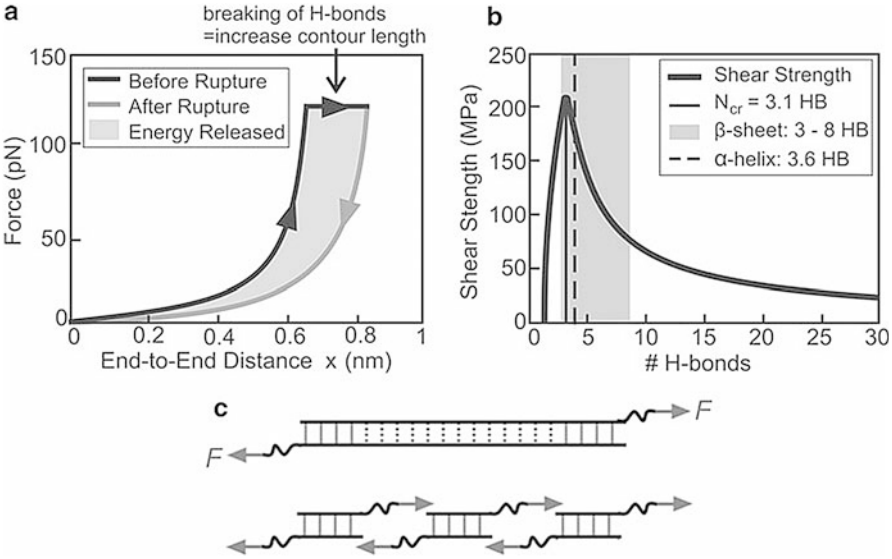


While covalent peptide bonds make up the backbone of a protein, noncovalent bonds, in particular

Mechanical Properties of Hierarchical Protein Materials, Fig. 1 Overview over the universality-diversity paradigm (*UDP*) [11, 13]. The hierarchical structure of protein materials is analogous to the construction of symphonic music. In much the same way that all music is made from a superposition of "simple" sound waves, a limited list of universal building blocks – here, amino acids of proteins – can be combined in various ways at multiple hierarchical levels to yield a diverse groups of protein-based biomaterials. Only a small subset of this diverse group exhibit exceptional mechanical properties, e.g., an orb-weaver spider web or bone, akin to Bach or Mozart

weak bonds such as hydrogen bonds (H-bonds), are indispensable to biological function in defining the native folding and stability of protein structures. The amino acid sequence defines a protein's secondary and higher-level structures via folding, but arrays of parallel adjacent H-bonds govern major universal secondary and tertiary structural motifs, chiefly α-helices and β-sheets, that organize the three-dimensional structure of polypeptides and thus determine their mechanical properties at a fundamental level. For example, the rupture of parallel interstrand H-bonds during β-sheet failure defines the true ultimate strength of such proteins (Fig. 2a for a schematic). Atomistic simulation combined with single-molecule force microscopy studies [7]

M



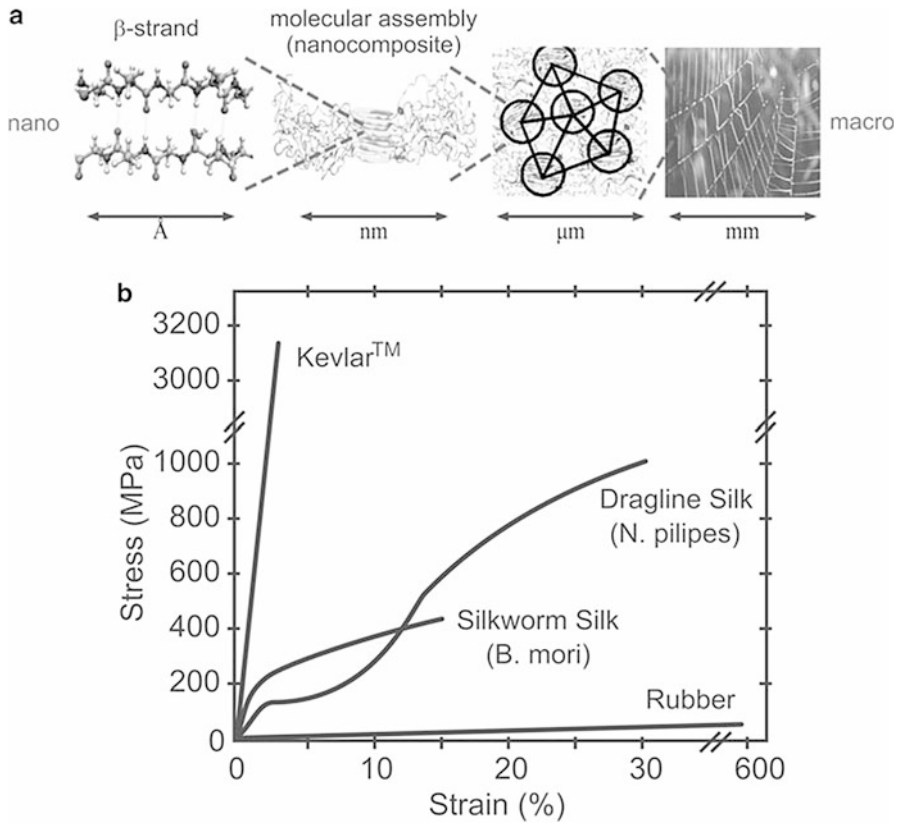
Mechanical Properties of Hierarchical Protein Materials, Fig. 2 Strength limit of H-bond clusters under shear loading (see *panel* (**a**) for schematic of geometry before and after rupture). As shown in *panel* (**b**), at vanishing pulling rates (see *inset* for a detailed view of the data), clusters of H-bonds resist a force limit of 100–300 pN. At high pulling rates, considerably more force is needed to unfold and rupture H-bonds, according to experimental and computational results from fibronectin, immunoglobin, and titin deformation (for references to source data, see Ref. [18]). This data reflects the rate dependence of failure seen in many biomaterials [18]

have shown that proteins rich in β-sheets exhibit higher rupture forces since they employ parallel strands with numerous H-bonds that act as strong mechanical clamps under shear loading. At experimental pulling rates, most mechanical proteins exhibit a rupture force of a few hundred piconewtons (pN) [14], as seen in Fig. 2. An asymptotic limit at very low pulling rates can be inferred from a limit analysis for deformation through equilibrium, which suggests an upper strength limit for the unfolding β-sheet-rich proteins [15–17] (see results in Fig. 2b). Based on this analysis for typical single-molecule length scales at a temperature of 300 K and a vanishing pulling rate, the asymptotic force of rupture is found to be on the order of 100–300 pN [18] (Fig. 2b). This asymptotic force limit depends strongly on the H-bond dissociation energy, which can vary with solvent conditions and which explains the range of strengths obtained.

The asymptotic strength limit for the unfolding β-sheet-rich proteins can be explained based on fracture analysis inspired by Griffith's analysis that was originally applied to solids, and is here used to describe the strength of protein domains [18]. We briefly review the key concepts behind this analysis that is also shown in Fig. 3. At low force levels, the elasticity of the polypeptide chain is primarily due to entropic effects (rather than energetic effects). The Marko-Siggia Worm-like Chain (WLC) model is one of the most widely used expressions to predict the entropic elasticity of the polypeptide backbone. Indeed, comparative studies provide substantial evidence that WLC theory is a good model for the behavior of individual, unconstrained polypeptide chains [19]. In the WLC theory, the force is a function of end-to-end chain length, the persistence length, the contour length, and the temperature. The asymptotic strength limit for the unfolding β-sheet-rich proteins can be obtained by considering the energy dissipation during the process of first stretching of a β-strand protein (described by the WLC theory) followed by subsequent breaking of H-bonds, where the energy released must equal the energy stored in the H-bonds (Fig. 3a); where the energy released is properly normalized to describe how many H-bonds exist per unit contour length of the protein. This analysis is similar to a fracture analysis of solids where the elastic energy stored in the material (here often described using linear elastic continuum theory and not by the WLC theory as in the case of proteins) is being dissipated into the creation of new surfaces.

For a given H-bond dissociation energy the force limit is independent of the number of H-bonds being sheared simultaneously, given that the number of H-bonds in a deformed cluster is *larger* than a critical H-bond cluster size N_{cr}, which can be calculated for each case [18, 20]. This is because it is found that no more than $N_{cr} = 3$–4 H-bonds can rupture concurrently, thus defining a critical H-bond cluster size beyond which the strength can no longer increase and at which scale the asymptotic strength limit is reached.

Therefore, while the shear strength of β-sheets with *less* than $N_{cr} = 3$–4 H-bonds benefits from

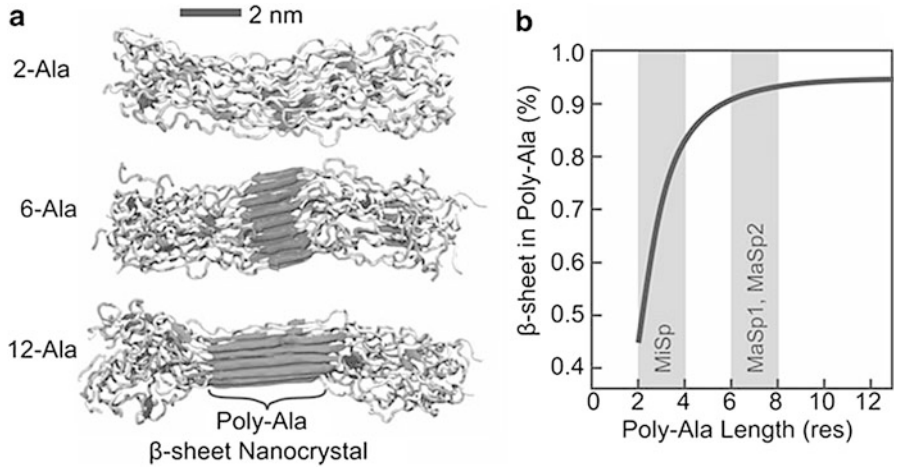


Mechanical Properties of Hierarchical Protein Materials, Fig. 3 Mechanistic view into the H-bond rupture process (**a**), and scaling of shear strength over size of H-bond cluster (**b**). (**a**) The area enclosed between loading and unloading curves is equivalent to the change in free energy, i.e., the adhesion energy per unit length. The increase in contour length is due to fracture, which involves breaking of H-bonds and as a result, the release of previously attached polymer length that now contributes to entropic elasticity. (**b**) A β-sheet of 3–4 residues in length displays the theoretical maximum shear strength, meaning that up to 3–4 H-bonds can rupture simultaneously. The structure of H-bond clusters in α-helices are in this range, with 3.6 residues per turn; and similarly, most β-sheet protein domains feature 3–8 H-bonds in each cluster. (**c**) Illustration of the physical concept behind the scaling law shown in *panel* (**b**), where the breaking of H-bond clusters is confined to a critical cluster size of $N_{cr} = 3–4$ (Figures adapted from Ref. [20])

addition of H-bonds, the shear strength (the maximum force divided by the sheared area) decays for β-sheets of 4 H-bonds or longer, as seen in b, as the H-bonds along the full length of the β-sheets do not rupture concurrently since they can only rupture in groups of $N_{cr} = 3–4$ H-bonds (see Fig. 3c for an illustration of this concept). Notably, following this scaling law, most protein materials are indeed found to intersperse many small β-sheets close in size to N_{cr}, in order to turn the weakness of the building block (H-bond) into strength by using geometry as a paradigm to achieve this goal. For example, β-sheets show a typical H-bond cluster size of 3–8 H-bonds across thousands of proteins in the Protein Data Bank, and α-helices have 3–4 H-bonds per turn [18, 20]. It is interesting to note that the scaling law of the shear strength, increasing for small values of H-bonds to a maximum value followed by a decay represents a biological material analogue of the Hall–Petch relationship known from polycrystalline engineering materials (e.g., metals) [21]. The intrinsic strength limit can only be overcome and scaled up by using structural hierarchies that circumvent β-sheet saturation and other limiting factors at critical length scales. Silk, as will be discussed in the following section, is a prime example of how H-bond cooperativity within β-sheets of controlled lengths and a hierarchical structure of networks and fibrils can overcome molecular strength limits and create unusually strong and tough protein fibers at the macroscale.

Structure and Mechanics of Exemplary Hierarchical Protein Materials

Silk



Silk is a hierarchically structured protein fiber (Fig. 4a) with a high tensile strength and great extensibility, making it one of the toughest and

Mechanical Properties of Hierarchical Protein Materials, Fig. 4 Hierarchical structure of silk from nano to macro (**a**) and a summary of stress–strain plots superior strain-hardening behavior of dragline and silkworm silks (**b**). Rubber is extensible but not strong. Kevlar™ is stiff and strong, but not tough. Silk, especially dragline silk, behave with a combination of strength and toughness not typically found in synthetic materials (Figure adapted from Ref. [31])

most versatile materials known [22–24]. In contrast to synthetic polymers based on petrochemicals, silk is spun into strong and totally recyclable fibers at ambient temperatures, low pressures, and with water as the solvent. However, biomimetic reproductions of silk remain a challenge because of silk's unique microstructural features that can only be achieved by controlled self-assembly of protein oligomers with molecular precision [25, 26]. Unlike silkworms, some spiders can use different glands to create up to seven types of silk, from the strong structural dragline to the viscoeleastic capture silk and tough egg sack casing [23]. Dragline silk, containing a high fraction of densely H-bonded domains, is used to provide the structural frame for the web and has an elastic modulus of around 10 GPa [24]. Capture silk, on the other hand, is a viscid biofilament containing cross-linked polymer networks and has an elastic modulus that is comparable to that of other elastomers [27].

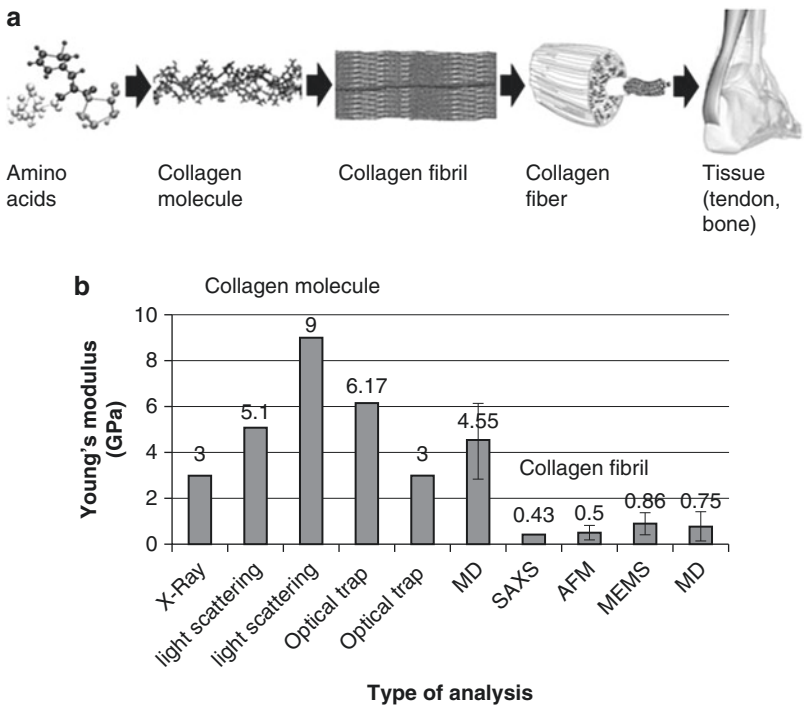
The stress–strain behavior of silks is compared to Kevlar™ and rubber in Fig. 4b. While rubber is extensible, and Kevlar™ is stiff and strong, silks feature a combination of strength and toughness not typically found in synthetic materials. It is known that β-sheet crystals at the nanoscale play a key role in defining the mechanical properties of silk by providing stiff and orderly cross-linking domains embedded in a semi-amorphous matrix that consists predominantly of less orderly structures [28, 29]. These β-sheet nanocrystals, bonded by means of assemblies of H-bonds, have dimensions of a few nanometers and

Mechanical Properties of Hierarchical Protein Materials, Fig. 5 Tuning the structure of spider silk by controlling the genetic makeup of silk proteins, used to define the structure of the material at the nanoscale (obtained using Replica Exchange Molecular Dynamics). (**a**) Computational structure predictions of MaSp1 agglomeration in dragline silk show that the size of the β-sheet nanocrystal may be tuned by changing the poly-alanine length [32]. (**b**) Percentage of β-sheet nanocrystal formation in the poly-alanine region of the silk protein, measuring the success of the genetic signal to achieve the desired structure. The structure prediction indicates a critical poly-alanine length of 3–4 alanine residues for the establishment of a well-defined nanocrystal. The MaSp1 and MaSp2 proteins of dragline silk typically have poly-alanine repeats 6–8 residues in length, while the MiSp protein of capture silk has poly-alanine repeats of only 2–4 residues [33]

constitute roughly 10–15 % of the silk volume. When silk fibers are stretched, the β-sheet nanocrystals reinforce the partially extended and oriented macromolecular chains by forming interlocking regions that transfer the load between chains under lateral loading, similar to their function in other mechanical proteins [30]. The hierarchical network of spider draglines, contrasting synthetic elastomers like rubber, enables quick energy absorption and efficiently suppresses vibration during an impact [31]. Rubbers, composed of random polymer chains, display an elasticity primarily due to the change in conformational entropy of these chains. In contrast, the amorphous chains in silk filaments are extended and held in partial alignment with respect to the fiber axis in its natural state, resulting in remarkably different mechanical behaviors from rubbers [29, 30]. Mesoscale simulations reveal that the characteristic, cross-linking β-sheet nanocrystals govern the coupled effects of silk network realignment and strain-hardening behavior beyond the regime of unfolding amorphous chains [28].

Advances in nanotechnology may allow for an optimization of silk and silk-like synthetic fibers for specific applications by modifying the governing network at critical length scales. At the base of the structural hierarchy, β-sheet nanocrystal size may be tuned though genetic modification and control of the self-assembly process. Computational structure predictions of MaSp1 agglomeration in dragline silk, seen in Fig. 5a, shows that the size of the β-sheet nanocrystal may indeed be tuned by controlling the poly-alanine length [32], which in turn affects the stability and "quality" of the resulting nanostructures. A critical poly-alanine length of 3–4 residues is predicted for the amyloidization of a defined and stable β-sheet nanocrystal. A sampling of amino acid sequences of both orb-weaving and non-araneoid spiders shows that the MaSp1 and MaSp2 proteins of strong and tough dragline silk typically have poly-alanine repeats 6–8 residues in length, while the MiSp protein of elastic capture silk has poly-alanine repeats of only 2–4 residues [33]. Combined with the structure predictions, this shows

that the size of the β-sheet nanocrystals has a fundamental effect on the mechanical properties of the macroscopic silk threads (Fig. 5b). Further computational studies of spider silk proteins reveal that the nanoscale confinement of β-sheet nanocrystals in silks indeed has a fundamental role in achieving great stiffness, resilience, and fracture toughness at the molecular level of the structural hierarchy [28, 34], where H-bond cooperativity depends quite strongly on the size of the crystals and breaks down once β-sheet nanocrystals exceed a critical size. Larger β-sheet nanocrystals are softer and fail catastrophically at much lower forces owing to crack-like flaw formation. This catastrophic breakdown leads to rapid disintegration of silk fibers, whereas reducing the nanocrystal dimensions below 3 nm increases the ultimate strength and the modulus manyfold [34]. Furthermore, noncovalent H-bonds are able to reform during stick–slip deformation, allowing smaller crystals a self-healing ability until complete rupture occurs.



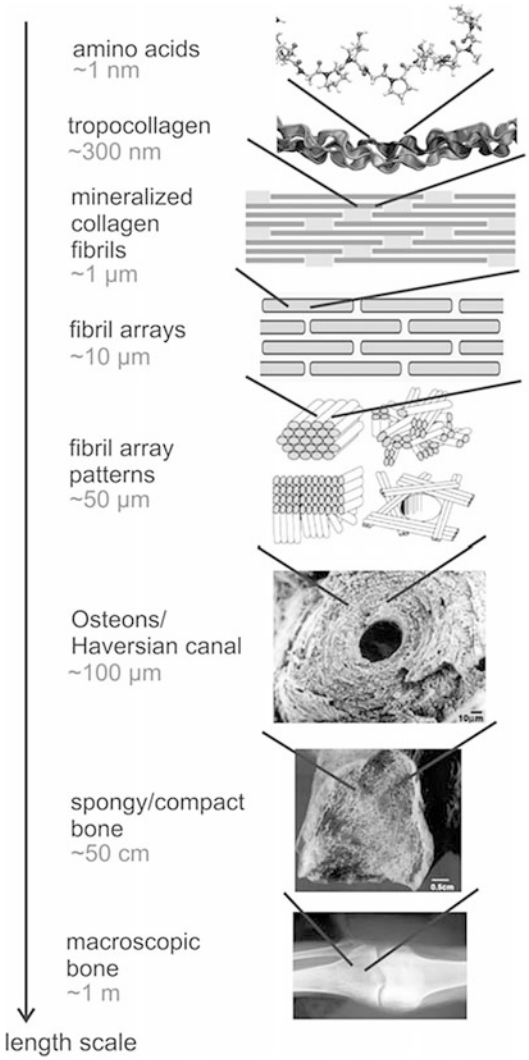
It is also noted that at the macroscale, experiments have demonstrated that when the size of β-sheet nanocrystals is reduced by moderating the reeling speed or by metal infiltration, silk shows enhanced toughness and greater ultimate strength, exceeding that of steel and other engineered materials [30]. By understanding and controlling how H-bonded silk threads can reach great strength and toughness and overcome strength limitations at the molecular scale, the behavior of a broader class of β-sheet-rich protein materials and similar synthetic composite fibers can also be tuned and adapted.

Collagen-Based Protein Materials

The concepts discussed above are important for many other protein materials. Collagen, for example, is present in various forms in almost all structural animal tissue and represents how the limitations of protein subunits can be overcome by the complex way they are assembled (Fig. 6a). Skin, tendon, and cartilage are all largely collagenous composites [2]. In skin, collagen is sandwiched between a basement membrane and an overlying keratinized epidermis. In tendon, collagen fibers form rope-like structures which make up 70–80 % of the volume, with the remainder being a combination of non-collagenous protein, polysaccharides, and inorganic salts. In cartilage, the collagen fibers are in a proteoglycan matrix with a small fraction of elastin fibers. Bone, shell, and antler are composites of calcite, hydroxyapatite, or aragonite platelets dispersed in a helical matrix of collagen. A diverse class of materials result from the universal collagen protein.

Variations in the polypeptide sequence of collagen chains gives rise to different types, termed Type I through Type XIX. Type I and Type III collagen are the most abundant, with Type I in skin and bone and Type III in blood vessel walls [2]. Three collagen chains, each of about 1,000 amino acids, arrange in the basic subunit of functional collagen, a left-handed triple-helix 300 nm long and 1.5 nm in diameter called tropocollagen. Typically, tropocollagen aggregates into a microfibril of five triple helices. About 1,000 microfibrils aggregate laterally and end to end to form a collagen fibril that displays periodic banding every 65 nm. Comparing the Young's moduli of tropocollagen and a collagen fibril, seen in Fig. 6b, shows that the structures at distinct hierarchical levels have very different mechanical properties, where single collagen molecules are much stiffer than collagen fibrils. About 500 fibrils aggregate into a collagen fiber, which then aggregate into fiber bundles. The diameters and specific hierarchical structures of fibrils and fibers vary by function among skin, tendon, and muscle. A bundled-fiber architecture connected by solvent-mediated intermolecular and intramolecular cross-linking of aldehyde groups provides stability, strength, and viscoelasticity [35, 36].

Beyond collagen fibers, a broad range of materials are available with the addition of mineral platelets within collagen. Bone and nacre belong to a family of natural ceramic composites that also includes coral, antler, and dental enamel [37, 38] that are made of mineral particles (e.g., hydroxyapatite, calcite, or aragonite) in a matrix of collagen. Their elastic moduli are lower than those of engineering ceramics, but their tensile strengths are similar, and their toughnesses are greater by a factor of 10 due to an ordered,



Mechanical Properties of Hierarchical Protein Materials, Fig. 6 Structure (**a**) and scale-dependent mechanical properties of collagen at the scale of single molecules and fibrils. (**a**) Hierarchical structure of collagenous tissues. The specific scales highlighted here are the collagen molecule and the collagen fibril. (**b**) A summary of small-strain Young's moduli for a single collagen molecule and a collagen fibril shows that the structure of fibrils sacrifice stiffness for increased extensibility and toughness (Data taken from various experimental and computational sources, for original references please see Refs. [40–44]). The data clearly demonstrates the importance of scale-dependent properties in biological protein materials

M

hierarchical structure [9]. The hierarchical structure of bone is outlined in Fig. 7 as an example. Bone must likewise survive cyclic compressive loading, bending, and impulses for the lifetime of large and active animals. Bone is suitable for a wide range of loading rates: the failure stress of bulk bone increases by as much as 44 % when the stress rate is increased by a factor of 10^3 [2]. In addition, since bone is continuously rebuilt, bones can adapt to creep and changes in local loading after injuries. Large bones like the femur have a structure similar to bamboo: strong and dense cortical bone tissue forms an outer sheath around a porous network of cancellous (i.e., trabecular or spongy) bone tissue with a core of marrow called the medullary cavity, and many reinforcing, longitudinal cortical tubes called osteons. Both cortical and cancellous bone tissue are differently organized structures of the same biomineral composite created by osteoblast cells, which secrete an amorphous protein matrix of predominantly Type I collagen. Over time, mineralization and ion deposition introduce reinforcing globular and plate-like crystals of carbonated hydroxyapatite [2].

There exist two cases of this matrix: woven bone, with a random arrangement of collagen fibers, is formed quickly in fetal bones and after fractures. Over time, woven bone is slowly converted to lamellar bone, made of ordered, concentric, parallel sheets of collagen fibers. Cancellous bone exhibits a wide range of local architecture and density, with volume fractions ranging from 0.05 to 0.6. Several factors affect mechanical property studies of cancellous bone, including donor age, sample hydration, anatomic

Mechanical Properties of Hierarchical Protein Materials, Fig. 7 The many hierarchical levels of bone allow this material to reach high levels of strength, toughness, as well as the ability to self-repair. Bone has at least seven hierarchical levels, each with a structure that contributes toward enhancing the mechanical property advantages available at that length scale [38]

location, and diseases such as osteoporosis, osteoarthritis, bone cancer, and *osteogenesis imperfecta*, but typical elastic moduli of cancellous bone are between 0.01 and 2 GPa and ultimate strengths between 0.1 and 30 MPa [39]. The rods and plates that form the individual trabeculae of cancellous bone have a uniform composition similar to cortical bone, but are slightly less mineralized, allowing plasticity during network deformation. Although the anisotropic mechanical properties of cancellous bone depend on the density of the network, the porous structure allows yielding at 1–2 % strain and can sustain large deformations up to nearly 50 % strain while maintaining its load-carrying capacity [2], allowing considerable impact energy dissipation before fracture.

An analysis of the molecular mechanisms of protein and mineral crystal phases under large deformation of the mineralized collagen fibrils reveal a fibrillar toughening mechanism that leads to a dramatic increase in energy dissipation compared to fibrils without a mineral phase. This fibrillar toughening mechanism increases the resistance to fracture by forming large local yield regions around crack-like defects, a mechanism that protects the integrity of the entire structure by allowing for localized failure that can later be healed. As a consequence, mineralized collagen fibrils are able to tolerate micro-cracks on the order of several hundred micrometers without causing any macroscopic failure of the tissue. At the microscale, mineralized collagen fibrils have a Young's modulus of 6.23 GPa, yield at a tensile strain of 6.7 %, and feature a fracture stress of 0.6 GPa. This shows a dramatic increase over unmineralized collagen fibrils, which only show a Young's modulus of 4.6 GPa and fracture stress of 0.6 GPa. Other deformation and fracture mechanisms exist in bone at larger hierarchical levels, including the breaking of sacrificial bonds between discrete mineralized fibrils, the formation of microcracks ahead of the crack tip, crack bridging by collagen fibrils arranged orthogonal to the crack, and the formation of large plastic zones around crack tips that contribute to an increase in bone's overall toughness [38].

Conclusion

Nature has much to offer for the next generation of both macroscale and nanoscale materials, in particular relating to the linking of vast and seemingly separated scales (from nano to macro). The expansion of the structural design space through

the concept of merging structure and material (Fig. 1) is a powerful concept that enables us to create highly functional materials through the use of relatively simple building block, a mechanism established in the universality-diversity paradigm of materials science [11, 13]. The transfer of concepts derived from biological materials, for example, mimicking of the strain-hardening behavior of spider silk, can give rise to the design of advanced functional materials with exceptional kinetic energy buffering and absorption. Developing ordered nanocomposites that are based on the structures found in bone, antler, or nacre can dramatically increase the toughness of typically brittle structures and may enable us to use abundant materials such as silica in the design of tough, elastic, and strong materials. Even the architecture of collagen's reinforced helices, fibrils, and fibers offer much inspiration in creating advanced tensile struts from seemingly inferior materials. The key issue is to better understand the mechanisms of the origin of the mechanical properties of proteins from the bottom-up, and the identification of systematic approaches to transfer the insight from biology to engineering design through an approach referred to as materiomics [11].

Mechanical behavior of nanostructured metals

Definition

Materials are classified into four groups in terms of the value of grain size: large-grained materials, micrograined materials, ultrafine-grained (UFG) materials, and nanocrystalline (nc) materials. Large-grained materials are characterized by grain sizes larger than 20 μm, micrograined materials by grain sizes in the range 1–10 μm, ultrafine-grained materials by grain sizes in the range 300–900 nm, and nc-materials by grain sizes less than 200 nm. The grain size ranges associated with the above classifications are approximate and are based on consideration of observations reported in literature.

Figure 1 provides a transmission electron microscopy (TEM) micrograph for the grain size in nc-nickel. The grain size ranges from 3 to 60 nm with an average value of about 24 nm.

Because of the small grain sizes characterizing nc-materials, features such as grain boundaries, junction lines, and nodes have significant volume fractions and influence properties far more strongly than in more conventional microstructures [1, 2]. Nc-materials have novel physical, chemical, biological, and mechanical properties that may have important engineering uses. As a consequence, they are attracting wide attention in materials research.

Mechanical Properties of Nanocrystalline Metals, Fig. 1 Bright field transmission electron microscopy micrograph showing the nanograin distribution in nc-nickel. The ring configuration at the *upper right corner* represents the diffraction pattern for the nc-grain structure

While the chemical and electromagnetic properties of nc-materials have received most of the attention, their mechanical properties are also important. It is both necessary and useful that these properties be thoroughly understood. Understanding mechanical properties is necessary since materials in almost all devices experience mechanical loads that must not only be supported but also be predicted to produce reliable designs. If the mechanical properties are unknown, even promising chemical or electromagnetic applications may be very difficult to achieve. Understanding the mechanical properties of nc-materials would be useful because of the following considerations:

- It is possible to make nc-materials with exceptionally high strengths for use as hard coatings or high-strength structural elements.
- The potential of using nanomaterials as machine components; if the nc-materials are used as cutting tools, localized shear should be avoided to increase the tool life.

Over the past two decades, considerable progress has been made in terms of providing a better understanding of mechanical behavior in nc-materials. In particular, considerable progress has been made in areas related to the following four aspects of the mechanical behavior of nc-materials: (a) creep behavior, (b) yielding and hardness, (c) ductility, and (d) superplasticity. Before presenting key research findings in these areas, it is useful to provide information on some of the parameters that are important in terms of characterizing mechanical behavior in materials.

Mechanical Properties Basic Parameters

Activation Volume

The activation volume, v, is the rate of decrease of the activation enthalpy with respect to flow stress at constant temperature. It provides useful insight into the nature of deformation mechanisms because it is characterized by a definite value of stress dependence for each atomistic process. Measurements of the activation volume during

deformation are made by (a) making either a small change in applied stress, and measuring the corresponding strain rate after the change, or a small change in strain rate and measuring the corresponding stress, and (b) applying the following equation:

$$v = kT\frac{\partial \ln \dot{\gamma}}{\partial \tau} \tag{1}$$

where k is Boltzmann's constant and T is the absolute temperature, τ is the shear stress, and $\dot{\gamma}$ is the shear strain rate.

Apparent Activation Energy

When the plastic deformation of a material is controlled by a thermally activated process, the strain rate for the i-the process may be expressed in terms of rate reaction theory as:

$$\dot{\gamma}_i = A_i(\tau, T)e\left[-\frac{\Delta \mathrm{H}_i(\tau, T)}{RT}\right] \tag{2}$$

where A_i is a function of stress, τ, temperature, T, and substructure; R is the gas constant; and $\Delta \mathrm{H}_i$ is the activation enthalpy. $\Delta \mathrm{H}_i$ is an important parameter in the deformation equation, and it must be determined in any attempt to identify the rate-controlling process. According to Eq. 2, $\Delta \mathrm{H}_i$ is uniquely defined by the following expression:

$$\Delta \mathrm{H}_i = R\left[\frac{\partial \ln \gamma i}{\partial\left(\frac{-1}{T}\right)}\right]_{\tau, d} \tag{3}$$

where $\boldsymbol{d}$ is the grain size. Equation 3 suggests a direct method for estimating $\Delta \mathrm{H}_i$. In deformation experiments, $\Delta \mathrm{H}_i$ is approximated by the apparent activation, $\boldsymbol{Q_a}$:

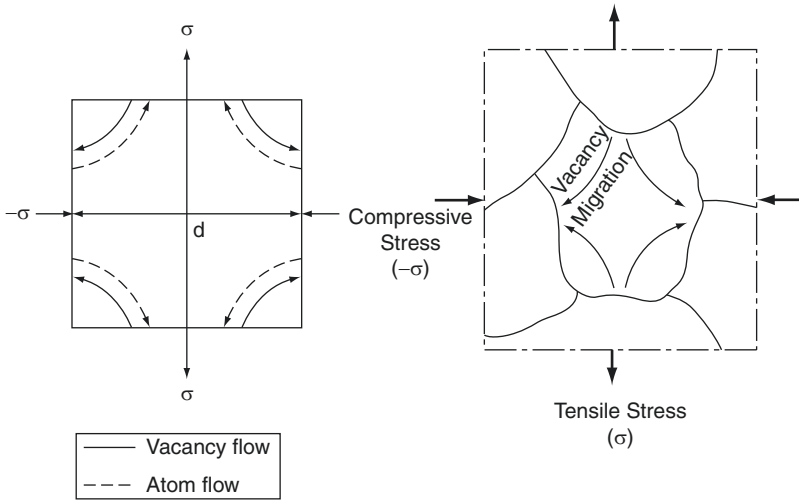
$$Q_a \approx \Delta \mathrm{H}_i = -R\left[\frac{\partial \ln \gamma}{\partial\left(\frac{1}{T}\right)}\right]_{\tau, d} \tag{4}$$

Apparent Dependence of Strain Rate on Applied Stress

The apparent dependence of strain rate on applied stress is an important parameter that receives attention in studies on the mechanical behavior of materials. In investigations focusing on high temperature deformation behavior, such dependence is represented by the stress exponent, n, which is defined as:

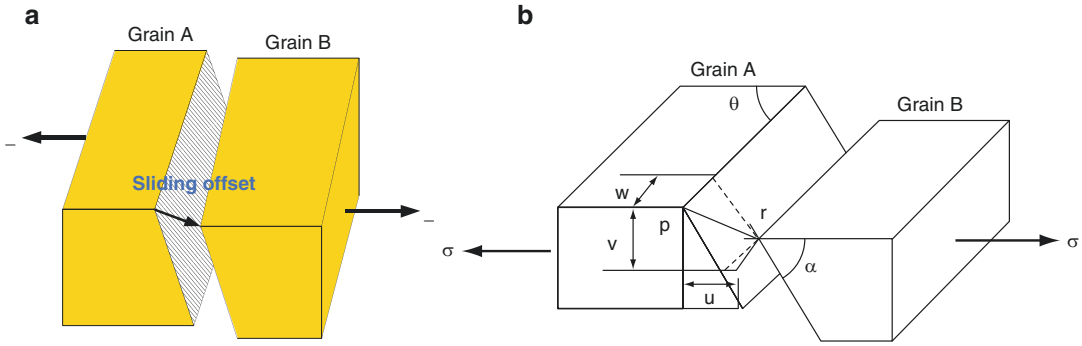
$$\mathrm{n} = \left.\frac{\partial \ln \dot{\gamma}}{\partial \ln \tau}\right| T, d \tag{5}$$

There is also another parameter that has been extensively used to express the relation between strain rate and stress, and is termed strain rate sensitivity, m. This parameter is given by:



$$\mathrm{m} = \left.\frac{\partial \ln \tau}{\partial \ln \dot{\gamma}}\right| T, d \tag{6}$$

Under steady-state high deformation conditions, $n = 1/m$. In addition to mentioning briefly the aforementioned four areas, it is useful to touch upon crystal imperfections that play key roles during plastic deformation.

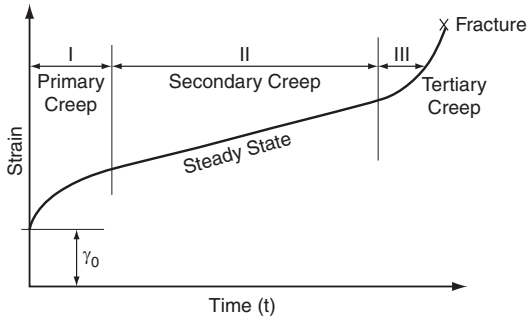


Crystal Imperfections

Metallic or ceramic crystals are not perfect. They contain imperfections [3] that include: point imperfections, line imperfections, and surface imperfections. Point imperfections include vacancies, substitutional atoms (e.g., magnesium in aluminum), and interstitial atoms (e.g., carbon in iron). Line imperfections refer to dislocations. Surface imperfections include grain boundaries.

While substitutional and interstitial atoms are responsible in many ways for strengthening in materials, the creation and diffusion of vacancies provide a mode of deformation at very low stress and small grain sizes [4]. Figure 2 can illustrate this mode of deformation, known as diffusional creep [4]. According to this figure, three steps are associated with diffusional creep: (a) the creation of a vacancy in the grain volume near the grain boundary under tensile stress, (b) the migration of the vacancy to the boundary that is under compressive stress, and (c) the annihilation of the vacancy at that boundary. The flow of vacancies is matched by an equal and opposite flow of atoms resulting in a longitudinal extension and lateral

Mechanical Properties of Nanocrystalline Metals, Fig. 2 Stress-directed diffusion of vacancies in a polycrystalline material



Mechanical Properties of Nanocrystalline Metals, Fig. 3 (**a**) Sliding offset as a result of boundary sliding. (**b**) Sliding displacement associated with boundary sliding

contraction of the grain with time under stress. If the migration of vacancies occurs in the interior of the grain, the deformation process is referred to as Nabarro-Herring creep. If, on the other hand, the migration of vacancies takes place in the grain boundary, the process is known as Coble creep.

Dislocations play a key role in plastic deformation. Their presence and movement in crystals account for the fact that the experimental yield strengths of materials are much lower than their theoretical shear strengths [3]. Their multiplication and interactions produce strain hardening while their annihilation results in crystal recovery. By using the details of dislocation theory, several investigators were able to develop a number of deformation mechanisms that have provided plausible interpretations for mechanical behavior under various conditions.

Grain boundaries are regions of misorientation that separate grains. At low homologous temperatures ($T/T_m < 0.2$), grain boundaries act as a source for strengthening by serving as obstacles to the propagation of deformation from one grain to the next [3]. At high homologous temperatures ($T/T_m > 0.4$), grain boundaries become mobile especially at low stresses, producing strain via grain boundary sliding. Figure 3 illustrates the process of boundary sliding. When enough stress is applied to a polycrystalline material, the grains slide past each other and the metal changes shape or deforms, a phenomenon known as "boundary sliding." As a result of boundary sliding, steps

M

Mechanical Properties of Nanocrystalline Metals, Fig. 4 An example for a normal creep curve

(offsets) are produced on the surface of a flat specimen. Detection of these steps provides evidence for the occurrence of boundary sliding, a process that may lead to the formation of voids and cavities in the material. The formation of voids in turn results in premature failure of the material. However, in micrograined materials, the strain contributed by boundary sliding may become considerable, leading to the occurrence of micrograin superplasticity [5].

Key Research Findings

Creep Behavior

A polycrystalline material subjected to an applied stress or load deforms continuously. This progressive accumulation of strain with time is known as creep [4]. Creep takes place as a result of thermal activation of deformation processes. The curve in Fig. 4 illustrates the idealized shape of a creep curve. The slope of this curve, $d\gamma/dt$, is referred to as the creep rate (or the strain rate). Following an initial rapid elongation of the specimen, the creep rate decreases with time (primary creep, or primary stage), then reaches a steady state (secondary creep, steady-state stage), and finally the creep rate increases with time until fracture occurs (tertiary creep or tertiary stage). Major differences among creep curves of various materials, however, are noted over the primary creep stage.

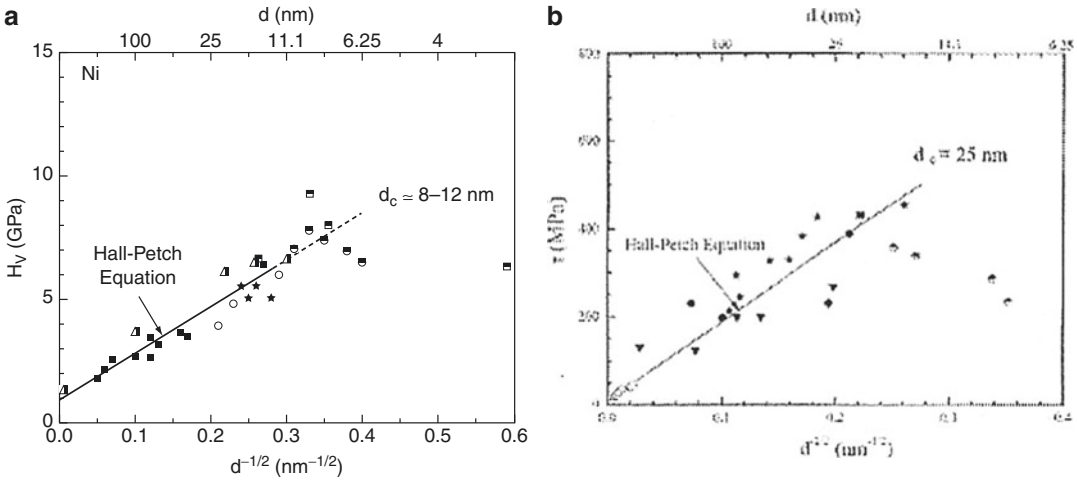
Nc-materials offer interesting possibilities related to many structural applications. In order to explore some of these possibilities, an understanding of the deformation of these materials under creep conditions is essential. In order to develop this understanding, *guiding information* is needed. This guiding information can be obtained from comprehensive experimental creep measurements.

During the period of 1990–2005, experimental measurements dealing with the creep behavior of nc-materials were reported. However, these measurements not only were limited in scope but also were obtained under questionable conditions. For example, the total strain measured in creep experiments conducted on nc-materials in several investigations did not exceed in most cases 0.01. With such small strains, it is difficult to ascertain whether the steady-state creep is reached. The problem of the lack of experimental measurements that would characterize creep and deformation-induced grain size growth in nc-materials was recently addressed in a detailed investigation [6], in which the creep behavior of nc-Ni was studied *for the first time* under the conditions of large strains and constant stresses. In the investigation, creep testing was performed over more than five orders of magnitude of strain rate ($10^{-9}\,s^{-1}$ to $2 \times 10^{-4}\,s^{-1}$) at 393 K (0.23 T_m, where T_m is the melting point). In addition, information regarding the stress and the temperature dependence of strain rate, the activation volume, and deformation-induced grain growth was obtained. The results of the above investigation have shown that the behavior of nc-Ni exhibited a variable stress exponent, an activation energy close to that expected for boundary diffusion, and an activation volume of about 19.5 b^3; and that upon loading nc-Ni specimens at 393 K, there is a grain growth, and this growth is driven by a combination of stress and time. However, once steady-state creep is reached, significant grain growth ceases.

Yield Strength and Hardness

One of the aspects of the mechanical behavior of nc-materials that has been extensively studied is the influence of grain size on flow shear stress, $\tau\ (= \sigma/2)$. In general, as the grain size, d, is refined, the strength increases as $1/\sqrt{d}$ according

to the Hall–Petch relation [3] that can be represented by the following expression:



$$\tau = \tau_0 + c/\sqrt{d} \tag{7}$$

where τ_0 is a friction stress and c is a constant. Equation 7 is also valid when the yield strength is replaced by the hardness, H ($H = 6\,\tau$). The mechanistic source of the Hall–Petch relation is not entirely clear, and more than one mechanism may pertain [3]. The effect of Eq. 7 in the nanoscale regime is, however, striking; if Eq. 7 holds, decreasing d from 20 to 20 nm increases the strength by a factor of 30. In general, Hall–Petch behavior for both hardness and yield strength holds to grain sizes well within the nanoscale range. However, experimental observations have suggested that when the grain size of some nc-materials falls below a critical value in the nanoscale range, the strength may decrease, that is, nanoscale softening (an inverse Hall–Petch behavior) occurs. The observations related to nanoscale softening were initially controversial since some of them could be attributed to the presence of flaws in the material [7]. For example, the loss in strength in the nanoscale range can be the result of pores in the material whose presence leads to a decrease in both the shear stress required for deformation and the shear modulus.

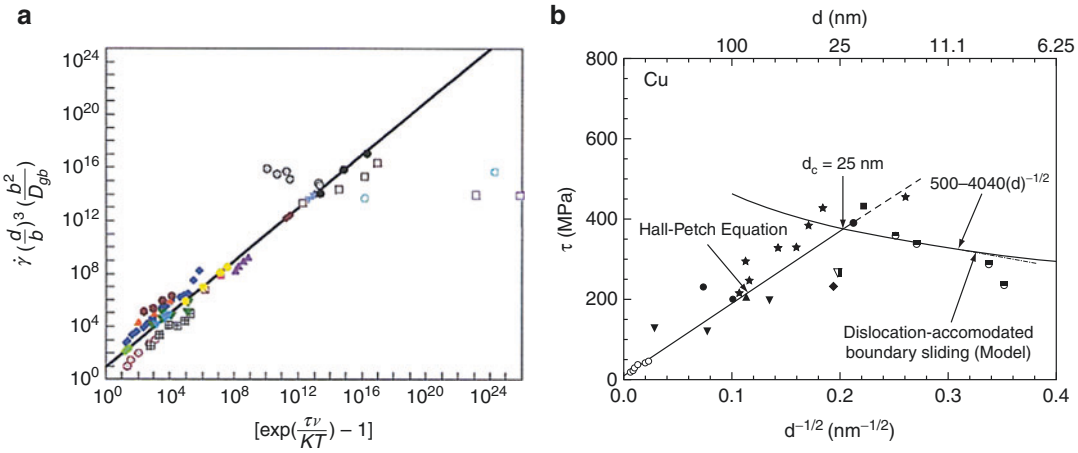
Despite the aforementioned controversy and others related to contaminations and grain size measurements, three pieces of information lend support to the occurrence of softening in the nanoscale range. First, it does seem reasonable that Hall–Petch behavior would be lost at the smallest grain sizes in the nanoscale region partly because it is no longer possible to maintain dislocation structures within grains, and partly because grain boundary activity assumes significance at very small grain sizes. Second, recent experimental results reported for the variation of hardness against grain size in nickel, nickel-tungsten alloys, and copper (see Fig. 5) have provided clear evidence for the occurrence of nanoscale softening [8, 9]. Finally, the results of recent molecular dynamics simulations have shown [10] the presence of a maximum in the flow stress of copper when its grain size becomes smaller than 15 nm.

Deformation Processes

An understanding of the origin and nature of deformation processes in nc-materials is essential.

Mechanical Properties of Nanocrystalline Metals, Fig. 5 (**a**) Plot of hardness versus the inverse square root of grain size for nc-nickel. (**b**) Data on copper plotted as yield strength as a function of the inverse square root of the grain size for Cu

Such understanding is important in two ways. First, when the origin of the deformation process is uncovered in sufficient detail, it should be possible to predict the mechanical behavior under a variety of conditions (stress, temperature, and grain size). Second, when the basic deformation process is known (successfully identified or developed), it is possible to introduce microstructural features that can improve the mechanical behavior of the materials in terms of ductility, toughness, etc.



As a result of recent investigations on nc-materials, several deformation mechanisms have been proposed. These mechanisms are different in terms of concept and details. The proposed mechanisms include: *(a) Coble creep, (b) Triple Junction Model, (c) Atomic Scale Boundary Sliding Model, (d) Modified Coble creep (inclusion of a threshold stress), (e) Grain Boundary Sliding with Back Stress, (f) Boundary Sliding under the Condition of Nonlinear-Viscous Behavior*, (*g*) *Thermally Activated Grain Boundary Shearing Process*, (*h*) *Thermally Activated Grain Boundary Shearing Process*, (*i*) *Composite model involving amorphous boundary layer, (j) Model of strongest size*, *and (k) Dislocation Accommodated Boundary Sliding*. These mechanisms were reviewed in Ref. [11].

As a result of investigations on nc-materials, extensive experimental data on the mechanical behavior of nc-materials such as nc-Ni and nc-Cu have become available [11]. The availability of the experimental data on these two metals provides an opportunity to closely examine the validity of deformation mechanisms that were proposed to account for the characteristics of deformation in nc-materials.

An analysis of the data reported led to the identification of the requirements [10] that a viable deformation mechanism should meet in terms of accounting for the mechanical characteristics, which were revealed by the data. These requirements are: (a) an activation volume whose value is in the range 10–40 b^3, (b) an activation energy that is close to the activation energy for boundary diffusion but that decreases with increasing applied stress, (c) the magnitudes of deformation rates that cover wide ranges of temperatures, stresses, and grain sizes, (d) inverse Hall–Petch behavior (softening), and (e) limited ductility.

The validity of aforementioned deformation mechanisms for nc-materials has been closely examined in the light of these requirements. The results of the examination have led to the following findings [11]:

(a) Coble creep and thermally activated Grain Boundary Shearing process are ruled out as viable mechanisms not only because they predict an activation volume smaller than those experimentally reported but also because they yield unrealistic critical grain sizes for a transition from conventional Hall–Petch behavior (hardening with decreasing grain size) to inverse Hall–Petch behavior (softening with decreasing grain size).
(b) Mechanisms such as modified Coble creep and thermally activated grain boundary shearing process are not applicable since they predict a very small value of the activation volume; they predict an activation energy of *b3* energy compared to experimentally reported values of 20–40 *b3*.
(c) While the composite model involving a grain boundary layer yields critical grain sizes for a transition from conventional Hall–Petch behavior (hardening with decreasing grain size) to inverse Hall–Petch behavior (softening with decreasing grain size) that agree well with those inferred from experimental results, it fails to account for the experimental data for nc-Cu and nc-Ni.
(d) The predictions of the model of dislocation accommodated boundary sliding [11] are consistent with several deformation characteristics reported for nc-materials including the range of the activation volume, (b) the value of activation energy and its dependence on stress, (c) the trends and magnitudes of experimental data on nc-Cu and nc-Ni, and (d) the critical grain sizes for transitions from conventional Hall–Petch behavior to inverse Hall–Petch behavior in nc-Cu and nc-Ni. Figure 6a, b illustrate characteristics (c) and (d), respectively.

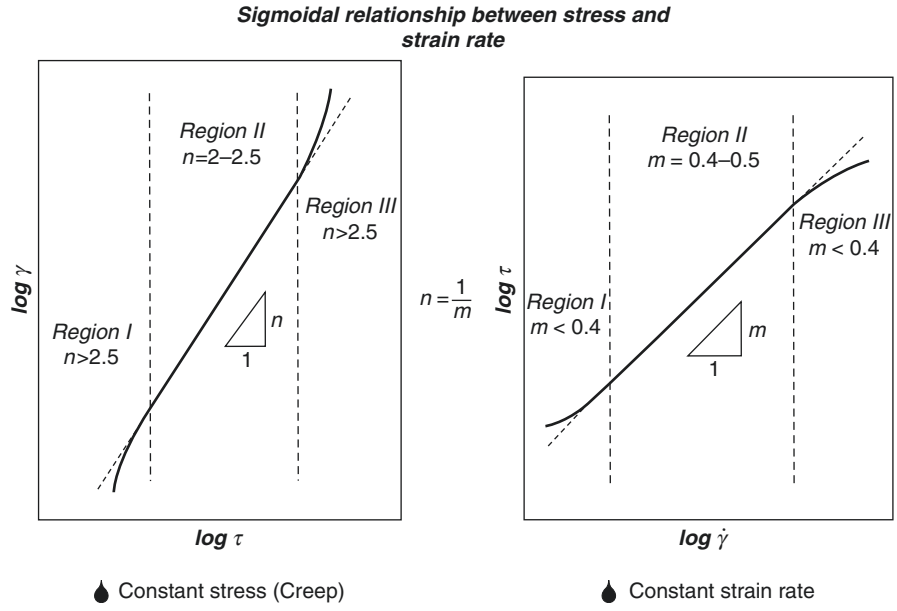
Ductility

Ductility is an important mechanical property that denotes the total elongation experienced by a tensile sample prior to fracture, *ef*. It is defined by the following equation [12]:

$$e_f = L - L_o/L_o \tag{8}$$

where L is the final length and L_o is the initial length.



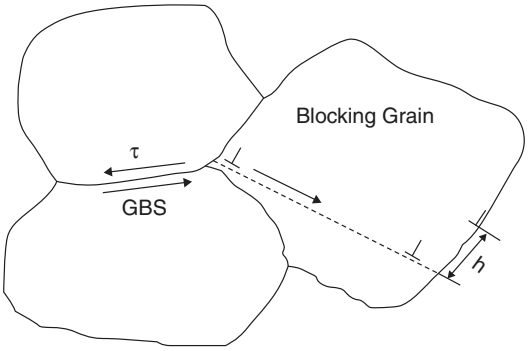
Although nc-materials always possess higher strength than their coarse-grain counterparts, they usually exhibit low ductility. For engineering applications, low ductility is undesirable for two primary reasons. First, low ductility does not permit metalworking processes to effectively produce required configurations. Second, low ductility impairs the material's ability to absorb overload, a condition that reduces the margin of safety in design. The source of low ductility nc-materials is not entirely clear, but it probably arises from either extrinsic flaws such as porosity or loss of work hardening due to the lack of dislocation interactions and accumulations [7].

Recently, the concept of improving ductility via enhancing dislocation interactions and accumulations has received considerable attention. This attention has led to several approaches that include the introduction of a bimodal grain size distribution, deformation twins, or dispersion of nanoparticles.

The role of both bimodal grain distribution and twins in achieving high ductility can be attributed to two primary factors. First, the presence of large grains enhances strain hardening, which prevents excessively large local strains (plastic deformation becomes localized), and suppresses the propagation of cracks nucleated in the surrounding regions of the very small grains. Second, twins in the interiors of the large grains in the bimodal grain distribution can block moving dislocations, a process that results in dislocation interaction and accumulation. Dislocation interactions and accumulation in turn promote strain hardening.

Superplasticity

Before discussing superplasticity in nc-materials, it is appropriate to provide a brief review for superplastic behavior in micrograin materials. Superplasticity refers to the ability of micrograined materials ($d < 10$ μm, where d is the grain size) particular materials to exhibit extensive neck-free elongations (>300 %) during deformation at elevated temperatures ($T > 0.5\ T_m$, where T_m is the melting point).



Mechanical Properties of Nanocrystalline Metals, Fig. 7 Relationship between shear stress and shear train rate for superplastic materials

The behavior of micrograin superplastic alloys has been extensively studied. As a result of these investigations, three findings are well documented [5]. First, micrograin superplasticity is a diffusion-controlled process. Second, the relationship between stress, τ, and strain rate, $\dot{\gamma}$, is often sigmoidal (see Fig. 7). Under creep testing conditions, this sigmoidal relationship is manifested by the presence of three regions: region I (the low-stress region), region II (the intermediate-stress region), and region III (the high-stress region). In region II, the stress exponent, n, is about 2 and the activation energy for creep is equal to that for grain boundary diffusion, Q_{gb}. In regions I and III, both the stress exponent, n, and the activation energy for creep, Q_c, increase ($Q_c > Q_{gb}$). Finally, in region II, maximum ductility (>300 %) occurs. Because of this characteristic, region II is often referred to as the superplastic region.

From a practical point of view, it is very desirable to extend the superplastic region to high strain rates. As reported elsewhere [5], the superplastic region is in general observed at strain rates in the range of 10^{-5}–10^{-2} s^{-1}. These rates are too slow to be economically suitable for a variety of industrial applications. Nc-materials appear to offer an interesting possibility to address this issue. According to information on micrograin superplasticity, as the grain size decreases from micrometer to nanometer, it is expected that the superplastic region would be transposed to high strain rates or observed at low temperatures such as room temperature, that is, high strain rate and/or low temperature superplasticity is possible. Despite this attractive possibility and its implications in terms of the potential for industrial adaptation of superplastic forming, attempts made so far to explore the occurrence of superplasticity have been unsuccessful.

One possible reason for the difficulty of observing superplastic flow in nc-materials is the occurrence of grain growth: it is not possible to obtain low-temperature superplasticity in pure metals in which grain sizes are less than 100 nm, since the advantage of observing superplastic flow at low temperatures is neutralized by the onset of significant grain growth in this temperature range.

A second reason can be inferred from the rate controlling mechanism for deformation in nc-materials. Recently, a new model for

Mechanical Properties of Nanocrystalline Metals, Fig. 8 Schematic diagram for the model of dislocation accommodated boundary sliding, showing that as a result of boundary sliding, dislocations are generated at a triple junction and then traverse the grain to the opposite grain boundary where they climb and are annihilated

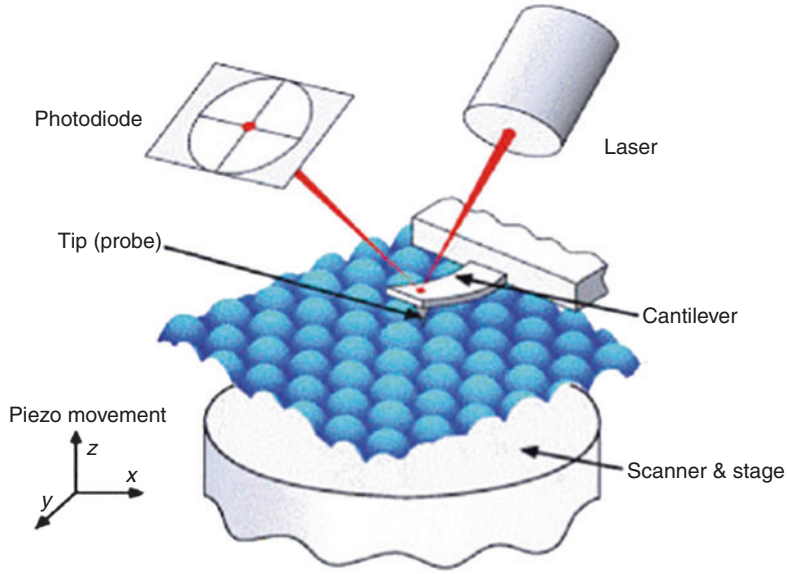
deformation in nanocrystalline (nc) materials has been developed [6]. The development of the model was based on the concept that plasticity in nc-materials is the result of grain boundary sliding accommodated by the generation and motion of dislocations under local stresses, which are higher than applied stresses due to the development of stress concentrations. Specifically, it has been assumed that as a result of sliding of a group of grains, the shear stress becomes concentrated at any grain, triple point, or protrusion that obstructs motion of this group; that this high local stress can then generate dislocations in the blocking grain (or initiate voids); and that the generated dislocations move one by one to the opposite boundary where they climb to their annihilation sites (no dislocation-ups). For illustration, see Fig. 8. By postulating that the creep rate, $\dot{\gamma}$, is governed by the time for the climb of a dislocation along the boundary until annihilation occurs, the following rate-controlling equation was derived [6]:

$$\dot{\gamma} = 9\left(\frac{b}{d}\right)^3\left(\frac{D_{gbo}}{b^2}\right)\exp\left(\frac{-Q_{gb}}{RT}\right) \times \left[\exp\left(\frac{\tau v}{kT}\right) - 1\right] \quad (9)$$

where b is the Burgers vector, D_{gbo} is the frequency factor for grain boundary diffusion, and Q_{gb} is the activation energy for grain boundary diffusion. The stress exponent for creep, n, as estimated from Eq. 9, exhibits high and variable values; for the applicable range of stresses, $n > 5$. Accordingly, it is expected that ductility in nc-materials would be much lower than those characterizing micrograined superplastic alloys for which $n = 2$, since ductility depends on $1/n$ ($n = 1/m$) as shown by the following (5):

$$e_f\% = [\exp(C/(n-1)) - 1] \times 100 \quad (10)$$

where $C = (n - (1/n))\ ln\ (400/n)$; $n = 1/m$. As shown in reference [6], combining Eqs. 9 and 10 leads to predicting that ductility not only is low and in the range 2–10 %. From a microstructural point of view, the low ductility can be explained in terms of the details of the concept of dislocation accommodated boundary sliding [5]. According to the concept, dislocations are generated under the local stresses and move in the blocking grains to boundaries where they are annihilated. This scheme results in the absence of dislocation accumulation and interactions, that is, nanograins are not able to sustain arrays of dislocations. This leads to loss of work hardening, which in turn results in low ductility.



Future Research

Creep

Nc-nickel has served as a model material to study the mechanical behavior of nc-materials. However, in order to establish the generality of the results, it is necessary to investigate the deformation behavior of other nc-materials using approaches similar to those adopted in studying the creep characteristics of nc-Ni. In addition, there is a need to study the creep behavior of nc-aluminum alloys to examine their thermal stability under temperature and stress.

Grain Boundary Sliding

Atomistic computer simulations on nc-materials have revealed the dominance of boundary sliding with decreasing grain size at room temperature. Despite this evidence and despite the need to establish the role of boundary sliding during

Mechanical Properties of Nanocrystalline Metals, Fig. 9 The illustration shows how the technique of atomic force microscopy works

deformation in nc-materials, the occurrence of this process has not been fully addressed in terms of experimental measurements. It is important to experimentally examine the hypothesis that strain measured during creep in nc-metals mostly arises from sliding.

Traditional techniques (surface marker and scanning electron microscopy) that were utilized in measuring sliding micrograined superplastic alloys do not have sufficient resolution. Recently, a solution for the above problem has become available: investigators have demonstrated that atomic force microscopy (AFM) provides a powerful technique for obtaining high-resolution images of the surface topography of bulk materials. AFM works by scanning a fine ceramic or semiconductor tip over a surface. The tip is positioned at the cantilever beam shaped much like a diving board. As the tip is repelled by or attracted to the surface, the cantilever beam deflects (see Fig. 9). The magnitude of the deflection is detected by a laser that reflects at an oblique angle from the very end of the cantilever. A plot of the laser deflection versus tip position on the sample surface provides the resolution of the hills and valleys that constitute the topography of the surface. On this basis, processes such as boundary sliding that are characterized by the occurrence of offsets at the surface of a flat specimen can be detected in ultrafine-grained and in nc-materials by AFM.

Evidence of Dislocations Activity During Deformation

Transmission electron microscopy (TEM) observations on deformed samples of nc-nickel have indicated the presence of few dislocations in grain interiors. However, *the absence of evidence regarding dislocations in deformed nc-Ni is not evidence of the absence of dislocation activity during deformation*. According to the model of dislocation accommodated boundary sliding [4], dislocations are generated under the local stresses and move in the blocking grains to boundaries where they are annihilated. Also, during unloading and/or subsequent specimen preparation for TEM examination, dislocations could disappear; dislocations only need to travel a very short distance of less than 100 b to be lost at nearby grain boundaries. The hypothesis to be tested is that dislocations are generated during deformation in nc-materials and that their absence in TEM micrographs are due to their annihilation at boundaries during deformation

or during unloading and subsequent sample preparation. In order to test the validity of this hypothesis, it is suggested that strong obstacles such as nanoscale particles be introduced in the grain interior to provide effective barriers to the movement of dislocations, leading to attachment of dislocations to particles and to dislocation tangles.

Synonyms

Elastic and plastic behavior of materials with nanometric dimensions; Properties related to applied stress or strain

Definition

In the context of materials science, the usual definition of a nanostructure implies that at least one of its dimension ranges from few nanometers to at most few hundreds. Then, according to the numbers of these dimensions, it could be (non-exhaustive list) a nanofilm, a membrane, a nanoplate, a multilayer (one dimension), a nanowire, a nanopillar, a nanobridge, a nanotube (two dimensions), or a nanoparticle, a nanograin (three dimensions). The response of these systems to an applied stress (or equivalently to a deformation) depends on their mechanical properties. Those include the elastic regime, for which changes induced in the material are reversible, and plastic regime, for which they are not.

Concepts

Nanostructures Versus Bulk Materials

The main difference between macroscale materials and nanostructures lies in the significant role of surfaces (or interfaces) for the latter. Atoms located at surfaces have typically fewer neighboring atoms than in bulk, leading to marked changes of the local

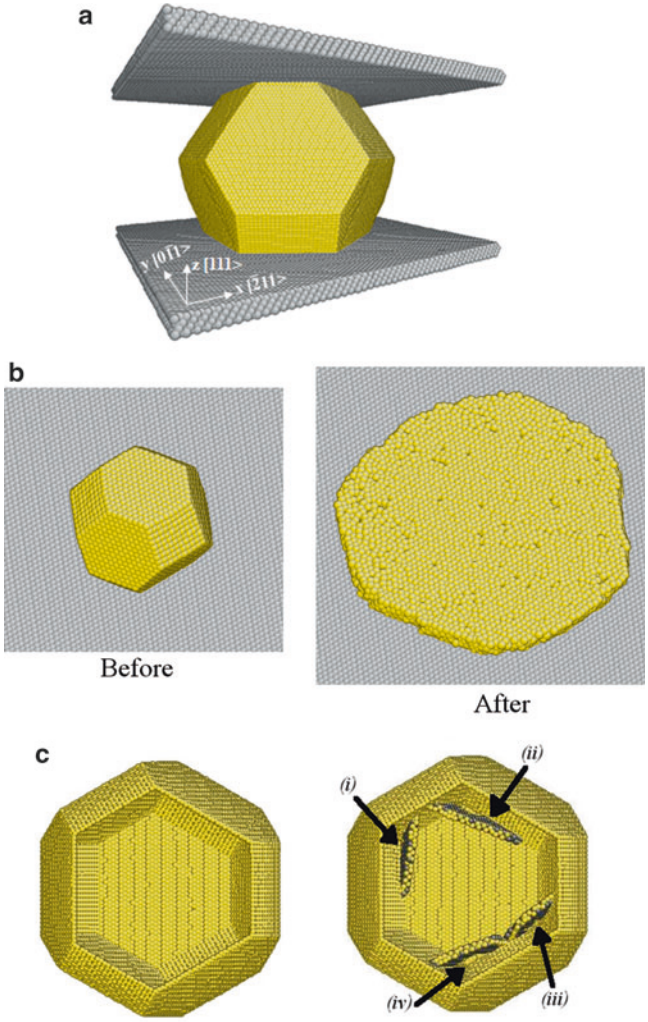
electronic structure. Structural modifications usually occur, thanks to surface relaxation or reconstruction, both mechanisms leading to surface energy minimization, but also adding an extra contribution to surface stress. Besides, surfaces are often reactive, and most of nanostructure surfaces are covered with passivants or oxide layers, except in a well-controlled environment.

Surfaces and interfaces can have a strong impact on mechanical properties of nanostructures. In the elastic regime, the moduli that link stress to strain can change compared to their bulk counterparts, due to the surface stress. The latter will either facilitate or hinder the deformation of the nanostructure, thus decreasing or increasing the elasticity coefficients. In the plastic regime, deformation mechanisms can be different in bulk and in nanostructures. For instance, the dislocation starvation process has been proposed to explain the first stages of plastic deformation in nanostructures [1]. Also, surfaces act as nucleation centers for dislocations [2]. This is also true for boundaries between nanograins, which can emit or absorb dislocations [3] or favor other deformation mechanisms like twinning for instance [4]. Furthermore surface diffusion may play an important role in the plastic deformation of thin nanowires.

In addition to surfaces/interfaces, the mechanical behavior of nanostructures is influenced by reduced dimensions. In fact, the number of preexisting defects which can act as sources for plastic deformation mechanisms scales with the volume of the nanostructure. This source exhaustion is often proposed as an explanation for the hardening in small nanostructures, as reported in many cases [5]. Reduced dimensions can also hinder common bulk mechanisms. At last, quantum confinement effects can become significant in nanostructures with a dimension of few nanometers. For instance they have been shown to influence elastic moduli [6].

Another phenomenon associated to nanostructures is phase transformation. In fact, in certain systems, phases metastable in bulk can be stabilized in nanostructures due to the large surface (or interface) to bulk ratio. This has obvious consequences on the mechanical properties. Finally, a special set of nanostructures includes systems which are characterized by a specific structure, as nanotubes or fullerenes, for example, inducing specific mechanical properties.

As a consequence of all the aforementioned points, the general response of nanomaterials to a mechanical solicitation can be much different than their bulk counterparts. This is spectacularly exemplified in the case of covalent materials like semiconductors. Although they are usually brittle at room temperature in bulk state, small systems can exhibit ductility instead [7, 8]. Overall, the mechanical behavior is greatly changed by the reduction of dimensions [9].



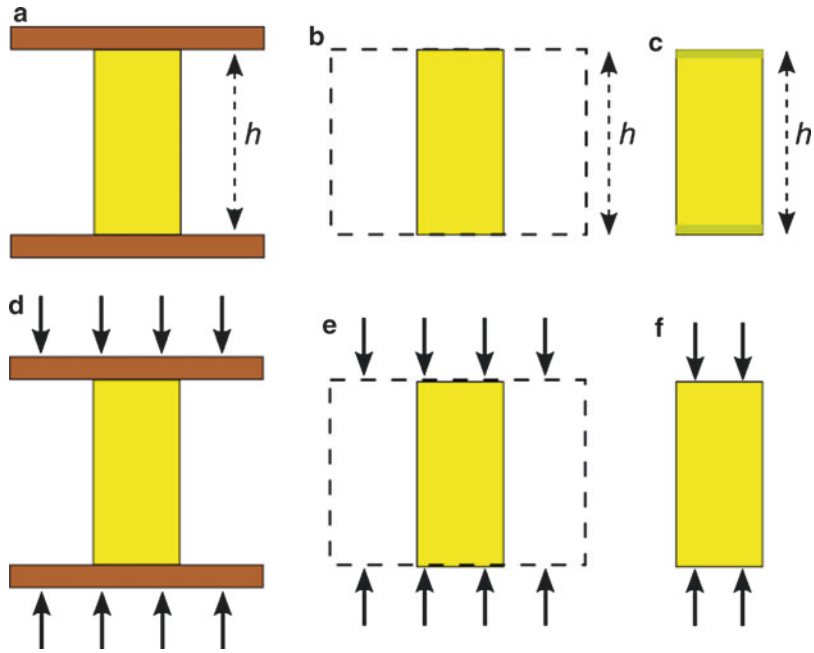
Molecular Modeling Versus Experiments

In molecular modeling, investigated system is described at an atomistic level, i.e., as a collection of atoms. Molecular modeling is complementary to experiments for several reasons. First, it allows to probe the mechanical properties of very small nanostructures, in a dimension range hardly attainable experimentally. Then, in the simulations, it is possible to follow the trajectories of all atoms in the system, which provides a wealth of information. Activated mechanisms can be thoroughly analyzed. Also, the time resolution is of the order of a femtosecond, much lower than in common mechanical testing experiments. This point is particularly important in the plastic regime, where plasticity mechanisms such as dislocation nucleation or fracture propagation can occur at very short timescale. Finally, molecular modeling allows a full control of the initial system and of the mechanical test. The effect of specific features or conditions, even beyond experimental realizations, can then be finely examined.

Methodologies

Different Theoretical Frameworks

There are two main classes of molecular modeling frameworks. In the first one, commonly called "classical," the electronic structure is not calculated and only the forces between atoms are considered. These are typically computed from empirical interatomic potentials, which are usually fitted on known bulk



Mechanical Properties of Nanostructures, Fig. 1 Atomistic simulations of the flat punch compression of gold nanoparticles (Courtesy of D. Mordehai [10]). (**a**) *Ball-and-stick* representation of the system setup (Au nanoparticle in *gold* and flat punch indenter atoms in *gray*) for a 4.9 nm high nanoparticle. (**b**) *Top view* of the nanoparticle, before and after complete load. (**c**) *Top view* of the nanoparticle, before and after the first dislocation nucleation events (*i*)–(*iv*) during compression (only atoms in free surfaces and in the defect cores are shown; atoms in stacking faults are shaded in *gray*)

materials properties. This is often the selected approach for modeling nanostructures, since it allows to describe systems whose dimensions are within the reach of experiments. With this approach, multicomponent systems can be more difficult to deal with, since appropriate potentials must be available to model all different atomic interactions.

In the second class of molecular modeling frameworks, the electronic structure is calculated and taken into account into the modeling. There are several ways to do it with different levels of approximation. In the case of nanostructure modeling, tight-binding and density functional theory are possible choices. However, although providing accurate and reliable results, only small nanostructures with dimensions of the order of several nanometers can be dealt with these approaches. As a consequence, to date most of the molecular modeling investigations have been performed using interatomic potentials.

Technical Setup

Prior to the numerical simulation step, one has to build the initial system by setting the positions in space of all needed atoms. This allows for a total control of the geometry and composition of the nanostructure. For instance, the Fig. 1a shows a typical setup for the compression of a nanoparticle. An important issue for the system setup concerns the boundary conditions used in the simulation. The most common choice is periodic boundary conditions (PBC). It can be required

Mechanical Properties of Nanostructures, Fig. 2 Possible ways to load a nanostructure (*yellow*) in a molecular modeling simulation. (**a**) and (**d**): the load is transmitted by an "indenter" (*brown*) made of atoms. (**b**) and (**e**): the load is transmitted by the simulation cell. (**c**) and (**f**): the load is directly applied on the nanostructure. In (**a**–**c**), the mechanical testing is strain controlled by changing the dimension h, eventually rescaling atoms positions, whereas it is stress controlled in (**d**–**f**). Simulations are usually performed in strain-controlled mode, easier to use than the stress-controlled mode

depending on the selected theoretical framework. For instance, PBC are enforced when plane-waves density functional theory simulations are made. This has obvious consequences on the modeling setup. PBC can be used to model a nanostructure with one or several infinite dimensions (as one of the examples will show in the following). When PBC are used, it is important to check possible artificial size effects due to the interaction of the system with its replicas. Note that these potential size effects can often be dealt with by including a sufficient amount of void around the system, which then exhibits surfaces, simply by increasing the size of the simulation cell.

The mechanical properties of a given system can be obtained as its response to a mechanical load. Three different classes of methods can be used to apply this load. In the first one (Fig. 2a, d), not only the nanostructure is modeled with atoms but also the devices that transmit the load in a real experiment (such as plates or an indenter). This method is probably the closest to experiments and allows for taking into account the additional mechanical response of the devices or possible adhesion effects. Besides, devices can also be modeled as non-attractive or infinitely rigid. The mechanical test can be strain or stress controlled, depending whether the position of devices is fixed, or an applied stress is used. The drawback of this approach is the extra computational cost associated with the atoms used for modeling the devices. A second option is to take advantage of PBC (Fig. 2b, e). In that case, strain- or stress-controlled testing is done by simply setting the computational cell dimensions or applying the appropriate stress on the cell faces. With this method, load-transmitting devices are not considered. This is best suited to determine intrinsic nanostructure properties such as elastic constants, except for nanoparticles for which void is necessary present around the whole system. Finally, in the third method, the load is transmitted to the nanostructure by either applying a force field on selected atoms (stress controlled) or by fixing the

positions of these atoms (strain controlled). The latter is also called fixed boundary conditions and can be useful in specific cases. For instance, it does not rely on the use of PBC (as the first method), and additional atoms are not required.

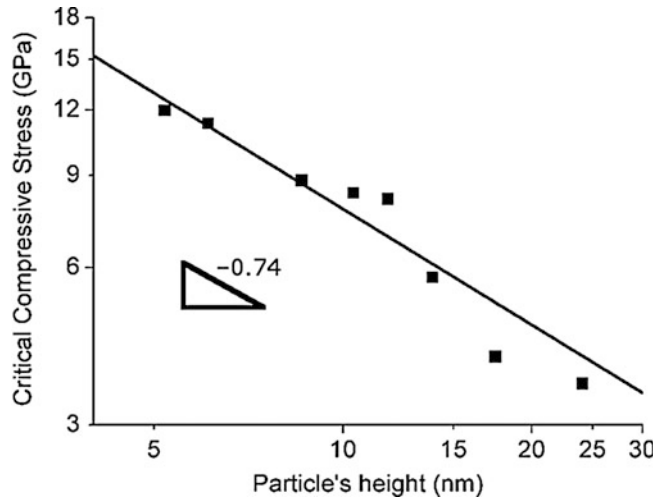
Molecular Dynamics or 0 K Force Relaxation

Simulations are often performed at finite temperature using molecular dynamics. In this framework, the dynamical evolution of all atoms in the system can be calculated by solving the Newton equations of motion, interatomic forces being obtained with one of the aforementioned formalisms. In order to compare with experiments, simulations are typically done in the canonical ensemble, using a thermostat to keep the temperature to the desired value. Generally, a simulation starts by a thermalization step, followed by an increasing applied strain (or stress) on the nanostructure. Important quantities such as the energy variation, the positions of atoms, or the local stress tensor can be monitored during the test for further analyses.

Besides, zero temperature simulations can also be performed (also known as molecular mechanics). For instance, this is done to compute elastic constants or to investigate the effect of stress on the plastic deformation without the stochastic influence of thermal activation. In that case, forces are simply relaxed at a given strain (or stress), leading to a configuration of minimum energy. To be complete, one can also mention that advanced simulation techniques such as chain of states methods have also been applied for determining the mechanical properties of nanostructures [11].

Examples

Molecular modeling has been used to investigate the mechanical properties of many nanostructures. Most of these were metallic systems or nanotubes, for which there are a lot of experimental data. But the literature also includes several studies of nanostructures made of covalent or ionic materials, such as semiconductors or oxides. Furthermore, although most of the studied systems are quite ideal, there is an effort to consider more realistic or complex nanostructures in molecular modeling simulations. Those could be core/shell systems, for instance, where the nanostructures are composed of two different phases or materials.



In this entry, three examples of recent works focusing on the molecular modeling of the plasticity properties of nanostructures are presented, in order to better illustrate the concepts developed in the previous sections.

Metallic Nanoparticles

The first example concerns the plastic deformation of facetted gold nanoparticles [10]. The latter can be experimentally obtained as stand-alone nanostructures on a sapphire substrate by using a solid-state dewetting process and are next compressed by a flat punch indenter. Equivalent computational systems have been built (Fig. 1a), the nanoparticle being located between two infinitely rigid gold plates, which are then brought closer during a molecular dynamics simulation, in a strain-controlled mode, with a constant rate of 1 m s^{-1}. An embedded atom model potential is used to model interatomic interactions. The procedure used here corresponds to the case (a) in Fig. 2.

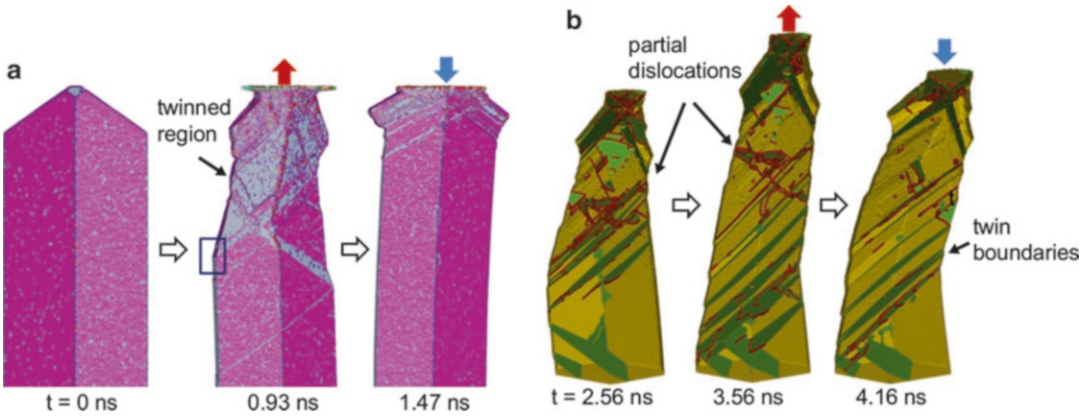
After complete compression of the nanoparticle, a flake-like structure is obtained (Fig. 1b), in excellent agreement with the combined experiments. Nevertheless, the true power of the simulations is revealed when focusing on the plasticity onset. Experimentally, one can only see the termination of the elastic regime due to a sudden and large strain burst. Instead, atomistic simulations allowed to fully characterize the very first stages of plasticity. Hence it is revealed that plastic deformation first occurred by the nucleation of leading Shockley partial dislocations from the upper vertices of the nanoparticles (Fig. 1c).

Experiments as well as simulations both showed that the yield stress associated with the onset of plasticity is size dependent and well reproduced by a power law (Fig. 3). The exponents are found to be -0.77 and -0.74 in experiments and simulations, then in excellent agreement. This proves the ability of molecular

Mechanical Properties of Nanostructures, Fig. 3 Compressive stress at the point of nucleation of the first dislocation versus particle height in the simulations (Adapted from Fig. 5 in Mordehai et al. [10], courtesy of D. Mordehai). A scaling effect can be clearly seen and is best fitted by a power law with an exponent of -0.74 ± 0.08

modeling to accurately describe a complex process such as the plastic deformation of a metallic nanostructure.

Metallic Nanowires



A second example concerns the plastic deformation of gold nanowires with a $\langle 110 \rangle$ orientation. Molecular dynamics simulations have been performed for nanowires of lengths 200 nm and diameters of at most 50 nm, including several millions of Au atoms, and compared to deformation experiments on slightly larger systems [12]. The flat punch indenter and the supporting surface ($SrTiO_3$ in experiments) are modeled by few infinitely rigid gold layers. The setup is then quite similar to the previous example, albeit the used EAM potentials are different and the deformation rate of 20 m s^{-1} is higher.

In both experiments and simulations, the nanowire is initially compressed until a significant amount of plastic deformation is obtained, first due to the nucleation of perfect dislocations in form of prismatic loops in both cases. This stage also allows to form a strong adhesive contact between the testing devices and the nanowire. In a second step, the nanowires are deformed in tension and yield by the formation of twins (Fig. 4). The simulation reveals that these twins result from the successive nucleation of leading partial dislocations in adjacent planes. Reversing again the deformation direction leads to a detwinning process in the nanowire in compression (Fig. 4), due to the successive nucleation of trailing partial dislocations in the twinned layers. This quite impressive result can be explained by the differences in resolved shear stresses for leading and trailing partial dislocations according to the deformation direction. As a result, it is demonstrated that these gold nanowires combine an ultrahigh strength together with a very high ductility (strains of at most 30 % were obtained).

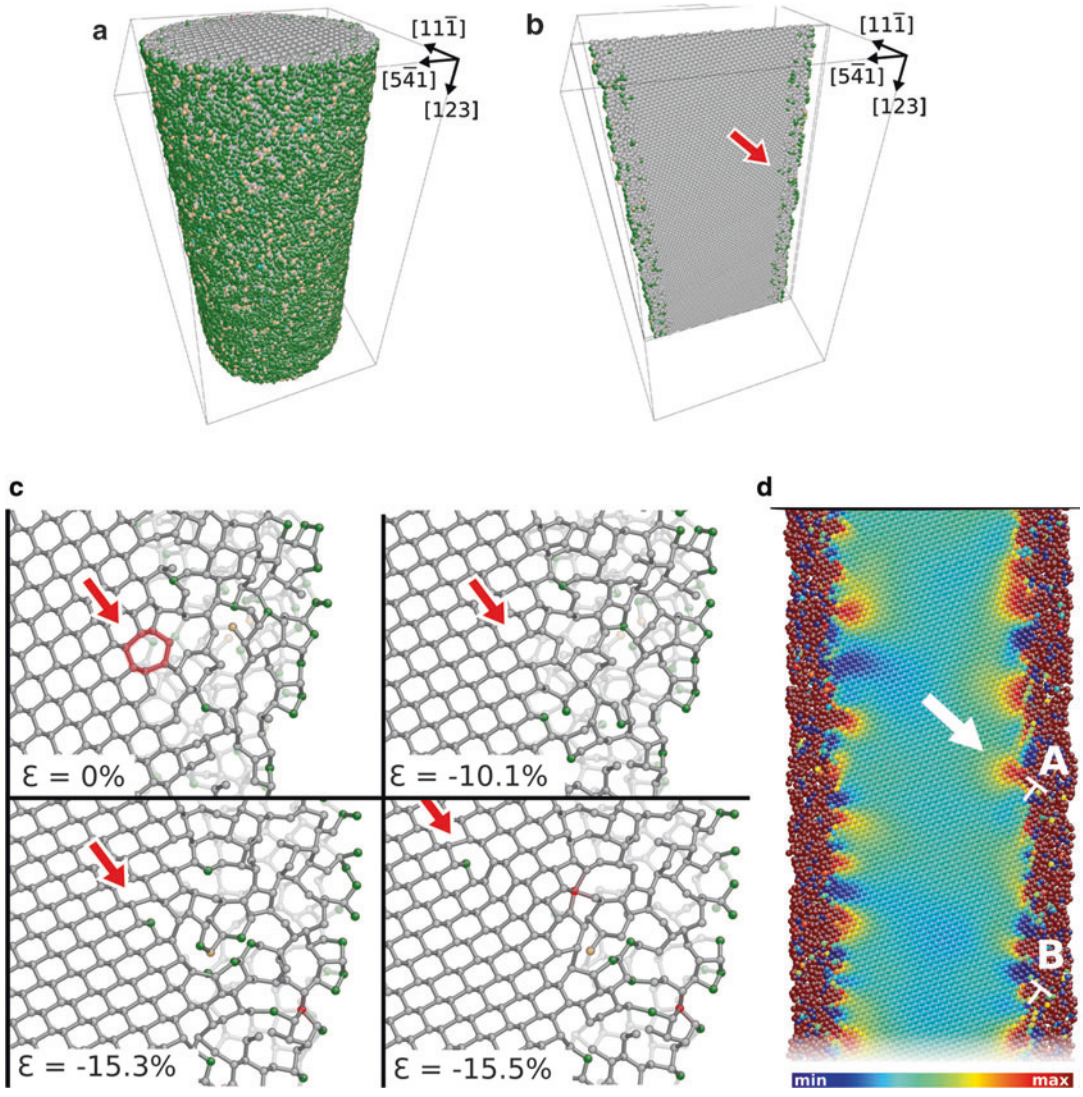
Overall, the virtual mechanical tests performed with these large-scale molecular dynamics simulations lead to structures in excellent agreement with in situ transmission electron microscopy observations. The activated plasticity mechanisms also appear to be similar in simulations and experiments. This confirms the reliability of these simulations for the investigation of mechanical properties of nanostructures. This study also emphasizes how molecular modeling can be helpful for a fine analysis of the plasticity mechanisms.

Silicon Nanowires

As a last example, the molecular modeling of the mechanical properties of a semiconductor nanostructure is presented. J. Guénolé and coworkers have recently investigated the behavior in

Mechanical Properties of Nanostructures, Fig. 4 Snapshots from 300 K molecular dynamics simulations of a gold nanowire, showing the size increase (decrease) of the twinned regions during tension (compression). The *left* representation shows atoms belonging to twins as *gray balls* and the other as *pink balls*. The *right* representation shows later stages, with the presence of partial dislocations as *red lines* and twin boundaries in *green* (Adapted from Fig. 6 in Lee et al. [12], courtesy of E. Bitzek, S. Lee, and S.H. Oh)

compression of silicon nanowires with a ⟨123⟩ orientation, using either conjugated gradient minimization or finite temperature molecular dynamics [13]. In this work, the systems are smaller than in previous examples, with characteristic dimensions of about several tens of nanometers, but several different surface states and nanowire shapes are considered. In particular, the effect of an amorphous coating of the surface is analyzed, in order to obtain insights about the influence of an oxidized nanowire surface, or amorphized following preparation by ion beam implantation for instance.



Conversely to the examples described above, no indenters are used in this study, and compression is obtained by scaling the simulation cell along the nanowire orientation (case (b) in Fig. 2). The chosen interatomic potential is specifically designed for modeling silicon in high pressure high shear conditions.

The simulations revealed that plasticity at 0 K occurred at large compressive strains, about 15–18 % depending on the surface state and nanowire shape. Dislocations are nucleated from the surface, with an increased probability in case of slightly disordered surfaces, and preferentially at edges in rhombic nanowires. However, these features all vanish when an amorphous Si coating is present. In this case, the activated plasticity mechanism remains dislocation nucleation, but it now always occurs at the interface between the a-Si layer and the c-Si core for a strain of about 15 %. Structural analysis reveals that the dislocation formation is initiated at interface sites characterized by a specific topology (Fig. 5c). Also, only those sites concentrating enough stress can be dislocation sources (Fig. 5d).

This work shows how simulations can be useful for obtaining information on nucleation sites, even when those are located deep below the surface, and to investigate many different configurations (shape, surface state). Besides, while simulations were used as complement to experiments in the previous cases, their predictive power is illustrated in the present case.

Limits and Issues

Atomistic simulations rely on several approximations and suffer from certain technical limitations. For instance, although an accurate description can be obtained using first-principles approaches, they are computationally too demanding to deal with nanostructure sizes usually found in experiments. This is why the vast majority of the available simulation works make use of classical interatomic potentials. The reliability of these potentials is an important issue. In fact, they are

Mechanical Properties of Nanostructures, Fig. 5 Atomistic simulation of the mechanical test of a Si nanowire at 0 K (Figure adapted from Guénolé et al. [13]). (**a**) 3D view of the nanowire for a compressive strain of −15.5 % strain, just before yielding (atoms colored according to the coordination number). (**b**) Same nanowire state, but only the slice including the site of plasticity onset is shown (marked by the *red arrow*). (**c**) Zoom on this plasticity mechanism for different deformation states. (**d**) Shear strain map just before yielding (the *white arrow* shows the site *A*, characterized by a stress concentration high enough to nucleate a dislocation, unlike the site *B*)

fitted on several properties of the materials and usually tested for low energy configurations, not far from stable states. Conversely, the atomistic modeling of nanostructures first requires a good description of surfaces, which include undercoordinated atoms. Moreover, mechanical testing of nanostructures in the plastic regime involves highly strained systems and distorted atomic configurations. For instance, the description of crack tip formation and propagation is one of the most difficult phenomena to reproduce with interatomic potentials, for it involves bonds that are highly stretched until the rupture. Without any references to compare with, it is not always possible to assess

the reliability of a given potential in a specific situation. Nevertheless, it seems that for fcc metals, an accurate and reliable description can be obtained using embedded atom method potentials, as shown in the aforementioned examples. For other materials such as bcc metals or covalent systems, no such consensus exists. Then, if an original mechanism is revealed by using a given interatomic potential, one may often question whether the mechanism is real or an artificial product of the use of this potential. One way to tackle this issue is to try to reproduce the same mechanism in a much smaller systems, using more accurate and reliable calculations [14]. Another approach is to employ different interatomic potentials for the same investigation. Obtaining the same outcome in all cases surely strengthen the conclusions.

Another issue is related to the size difference between systems investigated in experiments and simulations. It is possible to perform classical molecular dynamics simulations including tens and even hundreds of millions of atoms on nowadays computers (but at the expense of the timescale, see below). This corresponds to system dimensions in the range 50–100 nm at most, thus large enough for many of the experimentally investigated systems. Other systems in the submicronic scale remain hardly accessible with current atomistic simulations. However, the size issue is not very severe. In fact, on the one hand, atomistic modeling using interatomic potentials scales linearly as the number of considered atoms, and the continuous increase of available computational power should allow larger systems in the future. On the other hand, the comparison with experiments is increasingly possible because of impressive recent experimental developments. It is now more and more feasible to fabricate systems truly in the nanoscale, which can be mechanically tested (and sometimes monitored in situ). For instance it has been possible to measure the mechanical strength of nanowires with diameters of few nanometers [15].

At last, the timescale issue is probably the most critical one in dynamical molecular modeling simulations. A standard timestep in these simulations is about 1 femtosecond, because of physical arguments and numerical stability constraints. Then to reach a simulation duration of only 1 ns, 10^6 iterations are required. While this is not problematic for small systems, it severely conflicts with the above size issue when one wants to consider multimillion atom systems. Mechanical properties of materials are experimentally probed by deformation apparatus working at rates in the range $10^{-4} - 10^{-1}$ s^{-1}, typically. However, because of the timescale issue, molecular dynamics simulations of large systems are performed at best at deformation rates of 10^7 s^{-1}, thus many orders of magnitude higher. Such a huge difference is probably not an issue in the elastic regime but can be dramatic in the plastic regime. For instance the nucleation of the first dislocation, setting the onset of plasticity in the nanostructure and defining the yield point, is a rare event in the dynamical evolution of the system. Very high deformation rates mean less time for this unfrequent event to occur. As a consequence, yield strains (or stresses) are much higher in numerical simulations than in experiments. Fortunately it is possible to apply post-corrections to bring numbers in closer agreement [16]. Nevertheless, it cannot be stated with certainty that plasticity mechanisms activated in the simulations and in experiments at different stresses/strains are always the same, since counterexamples exist [17]. There have been several attempts to improve this timescale issue. For instance, few orders of magnitude can be gained by using specific techniques such as hyperdynamics, parallel replica dynamics, or temperature accelerated dynamics [18]. Another approach relies on the use of static saddle point searching methods such as ART, dimer, or nudged elastic band to investigate mechanisms [11, 19], but the comparison with experiments is much less straightforward than with molecular dynamics.

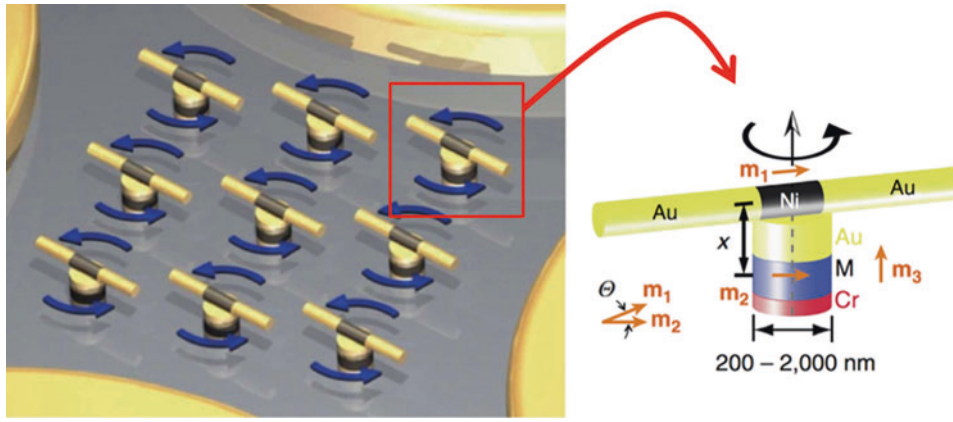
Rotary nanoelectromechanical systems (NEMS); Rotary nanomachines; Rotary nanomotors

Definition

Rotary nanoelectromechanical devices are miniaturized actuators that can generate rotational motion. They typically have a few microns to submicron feature sizes and are referred to as rotary nanomotors because of their size and function. Assembling arrays of rotary nanoelectromechanical system (NEMS) devices is a precise and efficient method to fabricate single or multiple rotary nanomotors in a desired location with

nanoentities, e.g., nanowires, nanotubes, and even biomolecules, as components or building blocks.

Miniaturization of Rotary Motors



Machines that convert various types of energy sources into rotational motion are widely used in our lives, from small electric motors for household appliances to combustion engines and even large-scale turbines. Since Richard Feynman's legendary talk titled "There's Plenty of Room at the Bottom" in the late 1950s, miniature motors that could work inside the human body has been imagined and inspired researchers. The advance in microelectronics and semiconductor device fabrication technology opened up the field of microelectromechanical systems (MEMS) including a variety of sensors and actuators from hundreds of microns to a millimeter in size. The first rotary micromotors have been developed in the late 1980s [1], and even smaller devices have been reported owing to the astonishing progress in micro-/nanofabrication for the last couple of decades. However, while many techniques have been developed for the fabrication of integrated circuit (IC) microchips even with tens of nanometer feature size, it is still challenging to further reduce the size of rotary motors down to a few microns or submicron range with micromachining and conventional semiconductor device fabrication technology. Only several rotary nanomotors have been successfully fabricated using those sophisticated fabrication processes [2, 3].

Recently, assembling miniaturized electromechanical devices with nanoentities as components, or building blocks, has attracted attention from researchers. Nanoentities have obvious advantages for use in building NEMS devices. Their small footprint and unique chemical, mechanical, electromagnetic properties can significantly downsize devices and effectively improve performance. Moreover, owing to the recent progress in nanotechnology and nanomaterial synthesis process, nanoentities with desired chemical, mechanical, and electromagnetic properties as well as dimensions and geometry can be readily synthesized at low cost [4].

Assembling Rotary NEMS Devices

In order to build a NEMS device from nanoentities, it is essential to precisely bring them to targeted positions, align them in a certain orientation, and securely connect each component forming functional joints. Previously, nanomotors can be assembled without positioning and aligning nanoentities, solely relying on biochemical interactions between nanoentities [5]. However, they have low device yield and could not be suitable for systematic device fabrication for practical use, which tells why precision nanomanipulation is important. While the fabrication processes of nanoentities were well established, e.g., vapor-liquid-solid (VLS) [6], hydrothermal synthesis [7], and template-assisted electrodeposition [8], precision nanomanipulation and assembling strategies were relatively less developed due to significant technical difficulties. Recently, the field has been vigorously explored, and a variety of mechanisms generating and controlling the motion of micro-/nanoparticles have been developed, including optical, plasmonic, magnetic, electric, and acoustic tweezers [9].

Once positioned and aligned, each component should be properly connected and assembled for a working device. Depending on the purpose, working principles, and materials, different types of joints and connections are required. One effective way to accomplish this is to use magnetic interaction between components that contain magnetic materials or are comprised of magnetic nanoentities. Approaches for nanoparticle synthesis with controlled magnetic properties have been well developed owing to the vigorous research in various fields from data storage to biomedical applications [10, 11]. Due to controlled magnetic interactions, magnetic nanostructures can be efficiently integrated with other components and form joints and movable structures. In an alternative approach, chemical bonding and bioconjugation have been widely used to link surface-modified nanoparticles. These only occur with selective pairs of chemicals or biomolecules, useful for site-specific assembling process.

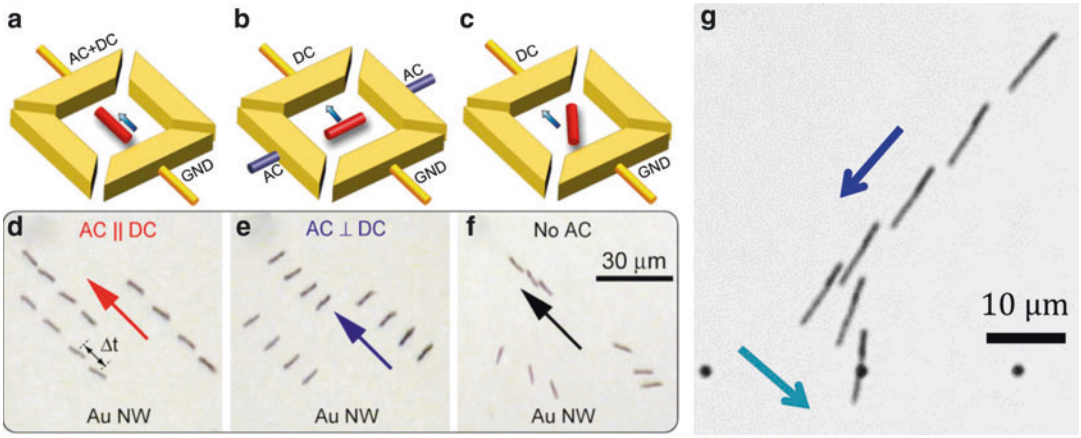
Examples of Rotary NEMS Devices Assembled from Nanoentities



Rotary Nanomotors

Recently, a rotary nanomotor has been assembled from a nanowire and a patterned micro-/nanomagnet working as a rotor and a bearing, respectively (Fig. 1) [12]. 800-nm- to 10-μm-long Au/Ni/Au nanowires are synthesized through template-assisted electrodeposition, and patterned magnets 200 nm to 2 μm in diameter are fabricated by depositing stacks of Cr/Ni/Au thin films on a substrate. Then, the nanowires suspended in deionized (DI) water are transported to patterned magnets with the electric tweezers [13, 14].

The electric tweezers are a nanomanipulation technique to precisely control the motion of nanoentities in a liquid medium using uniform DC and AC electric fields. Nanoparticles with a charge (q) are compelled to move by electrophoretic force ($F_{EP} = qE_{DC}$) in a DC electric field (E_{DC}), while dielectrophoretic torque ($\tau_{DEP} = p \times E_{AC}$) drives nanoparticles, which have the induced dipole moment p, to rotate under a uniform AC electric field (E_{AC}) where there is no electric field gradient [15]. Based on these electrophoresis (EP) and dielectrophoresis (DEP), the electric tweezers can not only convey and transport nanoentities but also rotate them and adjust their orientation by just applying DC and AC electric fields.

The electric tweezers have two orthogonal sets of parallel electrodes that steer the motion of nanoparticles in each direction (Fig. 2a–f). This enables two-dimensional motion control, and nanoentities can be delivered to anywhere in the region surrounded by the electrodes along an arbitrary route at a desired orientation with a precision of 300 nm and a maximum speed of ~80 μm/s. Besides high precision and speed, the electric tweezers are applicable to any nanoentities regardless of their dimensions, geometry, chemical, and electromagnetic properties and can manipulate wide selection of nanoentities.

Once the nanowires are delivered to the magnetic nanopatterns, each component should be properly assembled for a working device. Having a magnetic segment, i.e., nickel, embedded in its center, the nanowire located in the vicinity of the patterned magnet is quickly attracted, attached to the patterned magnet, and even aligned along the magnetization of the patterned magnet (Fig. 2g). This saves time and effort required for the position and posture control of the nanoentities, which not only expedite the whole assembling process but also enhance the quality of the assembly. The patterned magnet is covered with a nonmagnetic layer, i.e., gold, whose thickness determines the magnetic force holding the nanowire, as magnetic force is inversely proportional to the fourth power of the distance (x) between two magnets ($F \sim 1/x^4$).

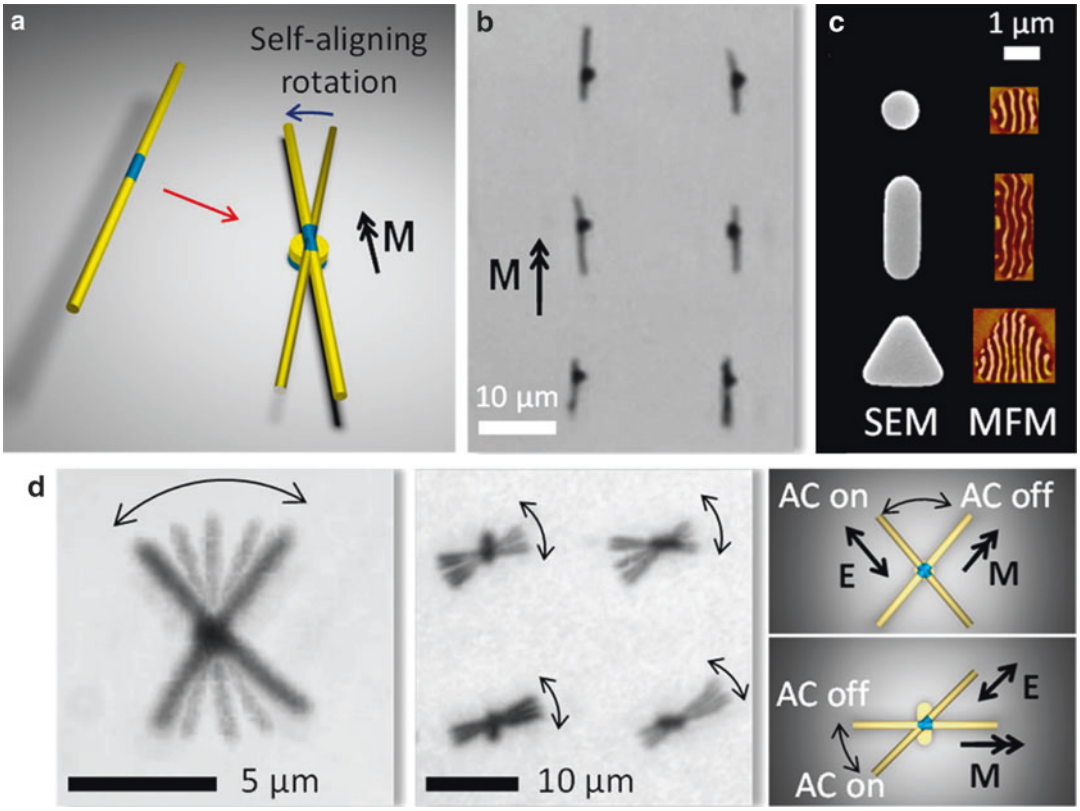
With properly designed dimensions, the nanowire rotor can be securely anchored but still can rotate so that the device readily works as a rotary NEMS actuator.



The assembled motor is driven by a rotating electric field generated by four AC voltages (V_{AC}) applied to the surrounding electrodes with 90° phase shift either clockwise or counterclockwise, and their rotation speed (ω) is easily controlled by the voltage ($\omega \sim {V_{AC}}^2$) [12, 16]. Multiple motors are assembled in ordered arrays, and their rotation can be initiated, stopped, and reversed simultaneously (Fig. 3). A motor can rotate over 18,000 rpm and continuously work for 15 h over 2.4×10^5 cycles. Based on the original device, the design including materials and magnetic configurations has been rationally modified for improved durability and controllability. As a result, the lifetime has been enhanced to 80 hours over 1.1 million cycles [17], and it has been even possible to fine control angular displacement and position of the nanomotors like step motors [18].

Rotational Nano-Oscillators

In a similar manner, nano-oscillators rotating between two different positions are assembled from a Au/Ni/Au nanowire, a patterned magnet in different shapes and geometry, e.g., disks, triangular and rectangular plates with feature size from 1 μm to 3 μm, and a set of quadruple microelectrodes [19]. Assembled nanowires in arrays are well aligned parallel to the striped magnetic domain structures uniquely remaining in the Ni magnets after the demagnetization and magnetization treatment (Fig. 4a). Their orientation can be readily altered at an arbitrary angle with the demagnetization and re-magnetization treatment in a different direction. When the nanowires are perturbed or rotated to a certain position, they return to their original position. This is caused by the magnetic interactions between the nanowires and the patterned magnets, more specifically magnetic torque exerted on the nanowires ($\boldsymbol{\tau_m} = \boldsymbol{m} \times \boldsymbol{B}$), where $\boldsymbol{m}$ and $\boldsymbol{B}$ are the magnetic moment of the nanowires and the magnetic field created by the patterned magnets, respectively. The assembled nanowires synchronously oscillate between distinct angular positions, e.g., 0° and 45°, when an AC electric field is switched on and off in a desired direction other than the initial orientation of the nanowires set by their magnetic interaction with the patterned magnets (Fig. 4b). Oscillation amplitude and

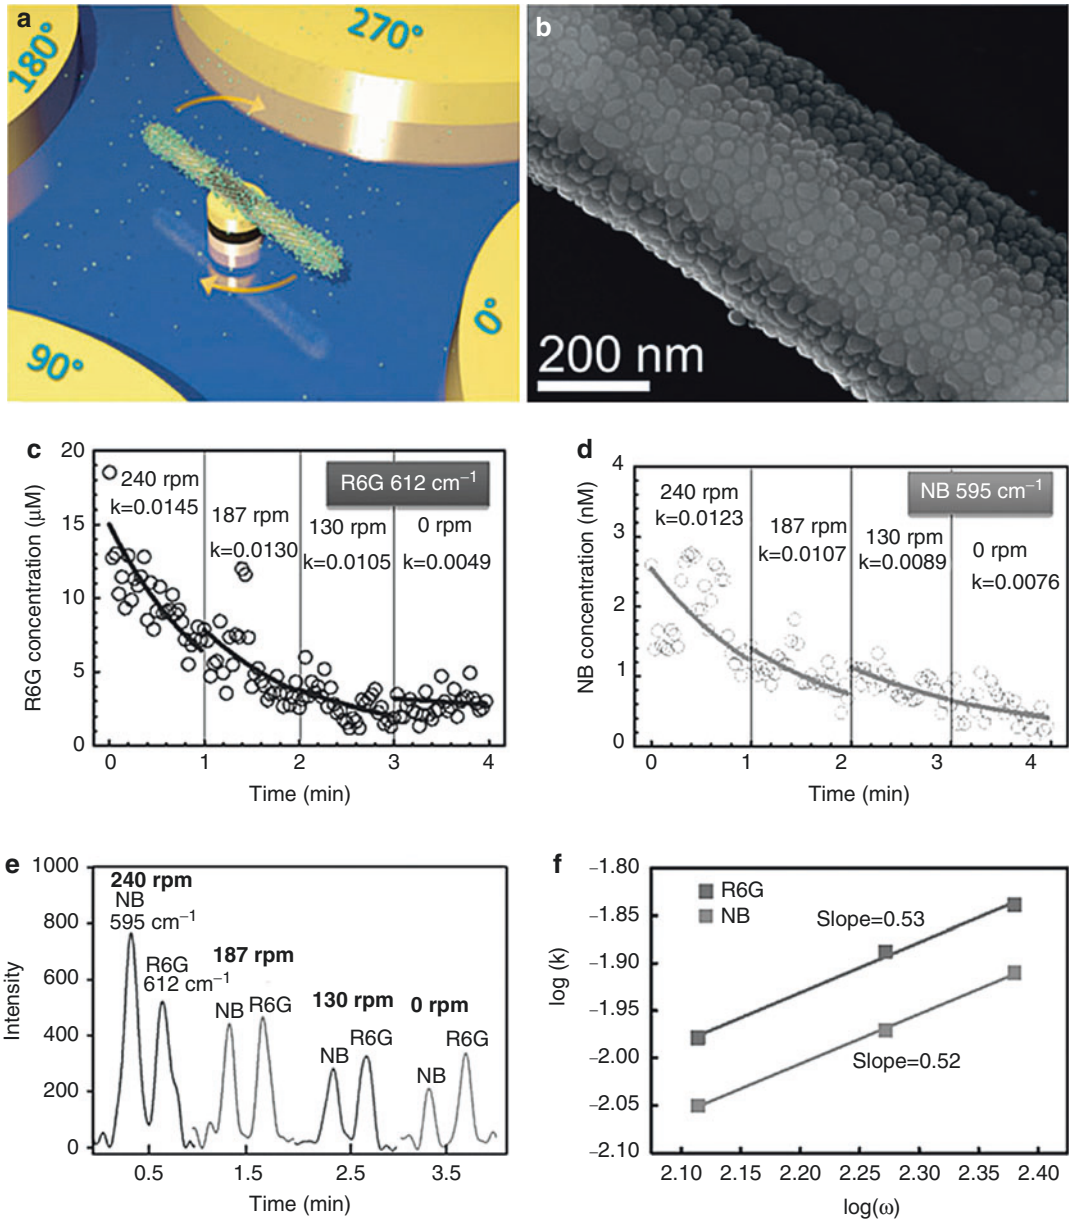
frequency are controlled with the direction, intensity, and switching frequency of the AC electric field. A nano-oscillator can toggle over 4,000 consecutive cycles and finally stopped by the increased friction at the interface of the nanowires and the pattern magnets. One thing interesting about this type of NEMS oscillators is that their oscillation is enabled by magnetic interaction between the components and traditional mechanical springs or flexures are not required.

Organic-Inorganic Hybrid Nanomotors

In nature and biological systems, miniaturized motors and actuators commonly exist and function for various purposes with great performance and efficiency [20]. With those biological molecular motors powered by the dissociation of hydrolyzing adenosine triphosphate (ATP) in a surrounding medium, nanoscale organic-inorganic hybrid actuators have been assembled and demonstrated their rotation at fixed positions [5]. A batch of 750–1400-nm-long Ni nanorods with 150 nm in diameter and Ni nanopillars of 50–120 nm in diameter are separately patterned on substrates. The Ni nanorods are released from the substrate and suspended in a liquid medium. After the preparation of the nanowires, nanopillars, and biomolecular motors, each component is introduced and assembled sequentially, i.e., biomolecular motors on nanopillars and then



Mechanism for Assembling Arrays of Rotary Nanoelectromechanical Devices, Fig. 5 Organic-inorganic hybrid nanomotors. From ref [5]. Reprinted with permission from AAAS. nanowire rotors to the tips of biomolecular motors. They are randomly attached to each other via bioconjugation and chemical bonding and form biomolecular motors with Ni nanorod rotors on Ni pillars (Fig. 5). With the introduction of ATP to the assembled devices, the biomolecular motors drive the Ni nanorod rotors at 0.74–8.3 revolutions per second. Relying on the complex bioconjugation and random positioning of nanoentities, it has a low device yield and difficult site-specific assembling. Besides, the rotation direction and speed of the nanomotors are arduous to control because of the nature of biomolecular motors. However, the hybrid nanomotors introduced innovative mechanisms for assembling and powering rotary nanomachines, and refined device fabrication processes and improved controllability of device behavior would make them more inspiring.

Applications

Rotary NEMS devices, assembled by the electric tweezers and magnetic interaction between nanoentities, have been used for precisely tunable biochemical release with their highly controllable assembling and actuation characteristics [12, 21]. The nanowire rotors are densely coated with surface-enhanced-Raman-scattering (SERS)-sensitive Ag nanoparticles, and then biochemicals, such as pure Nile blue (NB) and multiplex of NB and Rhodamine 6G (R6G) molecules, are loaded on the surface of the nanowires (Fig. 6a, b). While a nanomotor is releasing the loaded biochemicals to the surrounding medium, time-dependent release rate is determined via Raman spectroscopy on the nanomotor, showing the remaining amount of the molecules on the surface of the nanowire rotor. The release rate (k)

(**a**) Illustration of biochemical release from a nanomotor with a SERS-sensitive nanowire rotor. (**b**) SEM image of a nanowire rotor densely covered with Ag nanoparticles. (**c**–**f**) Characterization of biochemical release of R6G and NB controlled by the rotation. The release rate k linearly increases with the square root of the rotation speed ω

is linearly dependent on the square root of the rotation speed ($\sqrt{\omega}$) for both the single and multiplex molecule release (Fig. 6c–f). It could be explained by the fact that the thickness of the diffusion layer in the vicinity of the nanowire rotors decreases as a result of higher flow speed due to the rotation of nanomotors and this could expedite the whole biochemical release process

including their diffusion from the surface. This molecule release mechanism is applicable to any biochemical of interest in addition to the Raman-sensitive molecules, including drugs, cytokine, DNA, antigens, and antibodies.

Nanoparticles in Liquid Solution; Role of Cavitation Bubble Dynamics on Nanoparticle Generation; Role of Plasma Confinement on Nanoparticle Generation

Definition

There are various complex mechanisms present in laser ablation of metallic targets in a liquid medium (PLAL). Many of these mechanisms play a key role in nanoparticle synthesis namely, plasma confinement by the liquid medium and cavitation bubble dynamics. Laser interactions with nanoparticles in colloidal solutions, may also affect particle size and composition.

Nanoparticle Synthesis by Laser Ablation in Liquid

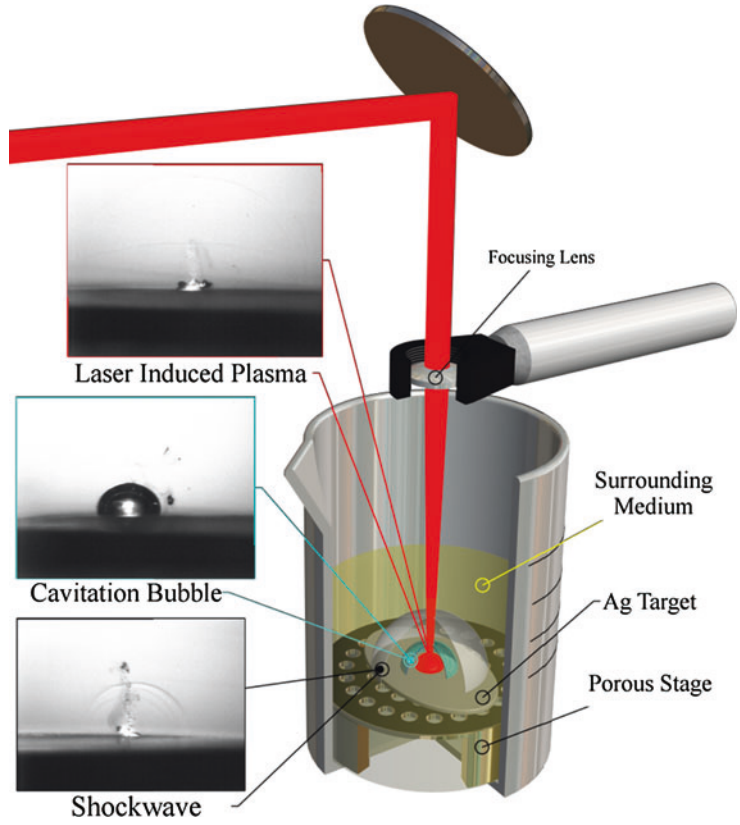
Laser ablation describes a process by which material is removed from a surface by the application of a high-intensity laser beam. Pulsed laser ablation in a liquid medium (PLAL) can be a method used to produce a clean, stable, and relatively homogeneous dispersion of nanoparticles in a liquid medium. This process has been carried out for metals [1], semiconductors [2], and even organic materials [3] to produce colloidal solutions. One remarkable feature of this process is the very different conditions under which these solutions are formed.

Several parameters can be tuned for the laser (pulse duration, wavelength, energy, beam waist, etc.) and for the liquid (depth, composition, temperature). One of the most important quantities that can be specified is the intensity of the incident laser beam. The intensity parameter is given by

$$I = \frac{E_p}{A \cdot \tau_p}, \tag{1}$$

where E_p is the energy contained in the laser pulse, A is the area of the laser beam on the target surface, and τ_p is the duration of the laser pulse. Although this field encompasses studies that utilize continuous wave (*CW*) to *attosecond* (10^{-18} s) lasers, we will focus our attention on the pulse regime between 10 *fs* and 10 *ns*, as it it most relevant to laser synthesis of nanoparticles. For many laser systems, pulse duration is the main determinant of the intensity output. For purposes of this article, we will define ultrashort laser pulses as $\tau_p < 1\ ps$ duration and long pulses as $\tau_p > 1\ ns$. Short-pulse lasers will be those for which $1\ ns > \tau_p > 1\ ps$.

A typical experimental setup for laser ablation involves a laser beam being focused onto a metal, oxide, polymer, or semiconductor surface with concomitant ejection of material as the result of strong explosive vaporization, spallation, or in some cases photoablation. Laser ablation is very challenging and computationally expensive to model; nonetheless, much insight has been gained in recent years from the application of the two-temperature model and molecular dynamics [4].



In the case of PLAL, all of the complexity of laser ablation is present, with the addition of hydrodynamic and thermodynamic processes in the liquid medium. Here the atoms and small clusters that are ejected from the surface undergo many more collisions than they would for laser ablation in air or vacuum as the result of the much smaller mean free path for the liquid. The liquid medium also induces both inertial and plasma confinement and strong cavitation near the surface. These processes strongly influence the observed particle size and distribution that is obtained.

Finally, PLAL process depicted in Fig. 1 can be modified to proceed without the solid target. In this case, the target is understood to be a colloidal liquid. This process of postproduction laser irradiation (PIR) is used to homogenize and sometimes reduce the size distribution of the nanoparticles. Typically, this is referred to as laser-induced size reduction, although this usage is not universal.

Confinement, Cavitation, and Nucleation

Plasma Confinement

Once the laser energy has been deposited in the target medium, the system relaxes from a highly nonequilibrium state. The particular relaxation mechanisms depend on the laser wavelength and

Mechanisms of Nanoparticle Generation by Laser Ablation in Liquids, Fig. 1 Schematic of laser ablation in liquids experiment

its relationship with the target's optical constants, as well as the presence of nonlinear effects at sufficient peak intensities of the incident beam. Shorter-wavelength lasers (i.e., UV and near-UV) possess enough energy to directly break bonds, and the mechanism of nanoparticle formation is dominated by photoablation. Near-IR lasers are more efficient at igniting plasma close to the target surface through inverse Bremsstrahlung (IB) absorption. The cross sections for ion-electron and atom-electron IB absorption are given as a function of laser frequency (v):

$$\text{Ion} - \text{electron: } \sigma_{IB}(v) = \frac{3.7 \times 10^{18}}{\frac{1}{T_e^2} v^3} Z^2 \left[e^{\frac{hv}{k_B T_e}} - 1 \right] n_e n_i \tag{2}$$

$$\text{Atom} - \text{electron: } \sigma_{IB}(v) = \frac{e^2}{\pi m_e c v^2} n_e n_0 \sigma_{\text{col}} \left(\frac{8 k_B T_e}{\pi m_e} \right) \tag{3}$$

where T_e is the electronic temperature, h is Planck's constant, Z is the ionic charge, c is the speed of light in vacuum, σ_{col} is the cross section for neutral-atom collisions, m_e is the electronic mass, and n_e, n_i, and n_0 are the number density of electrons, ions, and atoms, respectively. Lasers with relatively longer pulse durations allow for the ignited plasma and late photons to temporally overlap, thus enhancing IB absorption. The plasma will rapidly expand into the surrounding liquid medium and the quenching process produce spherical nanoparticles. A fraction of these nanoparticles will be at a sufficient temperature such that they sinter together into larger aggregates, giving rise to a polymodal size distribution. Previously produced nanoparticles may interact with subsequent pulses and undergo laser-induced melting and Coulomb explosion, which tends to reduce the size. This effect of postirradiation is more intense for larger particles. For example, the absorption coefficient per unit volume at the

plasmon peak of a 4 nm *Au* NP is one-fourth the absorption coefficient per unit volume at the plasmon peak of a 30 nm *Au* NP [5]. This selective absorption will tend to fragment larger particles, while smaller particles do not absorb enough energy to explode or melt, thus homogenizing the colloidal nanoparticle solution.

Cavitation Dynamics

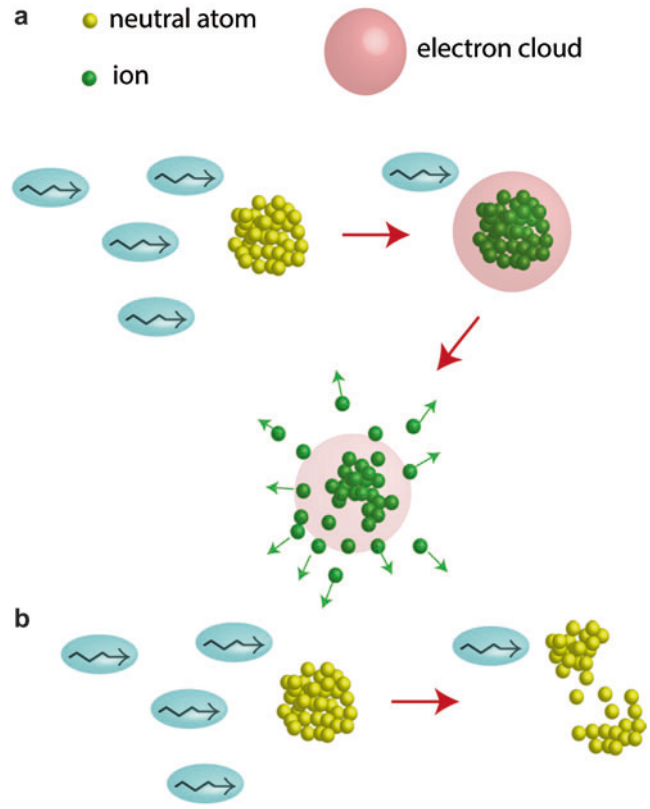
Approximately 100 ns -1 μ*s* after the arrival of the laser pulse, rapid heating of the target surface induces the growth of a cavitation bubble which undergoes rapid oscillation, typically for several hundred microseconds. Cavitation is typically modeled by the Rayleigh-Plesset equation, which is given as

$$\frac{P_B(t)-P(t)}{\rho_L}=R(t)\frac{d^2R(t)}{dt^2}+\frac{3}{2}\left[\frac{dR(t)}{dt}\right]^2+\frac{4v}{R(t)}+\frac{2S}{\rho_L R(t)}, \quad (4)$$

where $R(t)$ is the bubble radius as a function of time, t, after the arrival of the laser pulse, $P_B(t)$ and $P(t)$ are the pressures in the interior and exterior of the bubble, respectively, the surface tension of the bubble is S, and the kinematical viscosity is given by v. Finally, the density of the liquid medium is ρ_L.

The dynamics of this cavitation bubble on the surface of the target appear to be well described by the Rayleigh-Plesset equation for *ps* and faster pulses. For long-pulse ablation (i.e., *ns*), the thermodynamic parameters need to be modified to account for the presence of nanoparticles and ejected material [6]. The role that the bubble plays in the growth and nucleation of nanoparticles is less clear, although some reports indicate that the primary particles form during bubble expansion, while the aggregates form during collapse [7], although more recent work [8] has shown that the role of the bubble is still not completely understood. Nonetheless, cavitation plays a fundamental role in nanoparticle formation by laser ablation in liquids, whether it is through influencing the nucleation kinetics or inducing tertiary material ejection during the collapse phase.

Nucleation



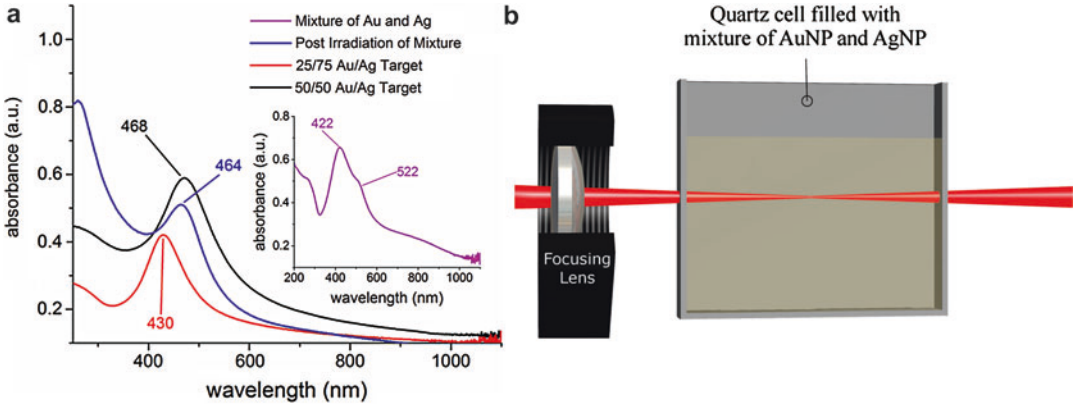
Classical nucleation theory is often invoked to explain the growth of nanoparticles in solution. So-called Lifshitz-Slyozov-Wagner (LSW) theory models this process as a diffusion-limited reaction with a rate constant given by $k=\alpha\frac{T}{\eta}$ where α is a proportionality constant, T is the solution temperature, and η is the dynamic viscosity. Then the particle radius is given as a function of time (t) as

$$R^3(t)=R_0^3+kt. \quad (5)$$

Of course, the application of any equilibrium theory to a dynamic process such as laser ablation in liquids is expected to be largely qualitative, and studies have shown that the dependence of particle volume on viscosity does not scale directly as $\frac{1}{\eta}$ [9]. Actually, for gold nanoparticles, it is found that the compressibility of the the water medium is more correlated with the hydrodynamic radius than the viscosity is. Nonetheless, LSW theory provides useful guidance for considering what occurs in solution for times long after the arrival of the laser pulse. As discussed in section "Plasma Confinement," the presence of a large number of particles in the solution can interact with subsequent laser pulses, thus leading to an increased reaction rate and larger particles.

Laser Interactions with Particles in Solution

As briefly discussed earlier, laser irradiation of nanoparticles may be performed purposefully as a means of size reduction and homogenization, or it can occur during the synthesis of nanoparticles in solution. In the latter case, this process is often viewed as a nuisance, or at least an interferent; however, in the former case such interactions can be beneficial under the right circumstances. Incident laser radiation may be absorbed by the nanoparticles through either the excitation of interband transitions or, in the case of metal and semiconductor nanoparticles, excitation of a surface plasmon resonance (SPR). With short and ultrashort laser pulses, multiphoton absorption



Mechanisms of Nanoparticle Generation by Laser Ablation in Liquids, Fig. 2 (**a**) Representation of Coulomb explosion: First, the neutral nanoparticle is irradiated with a high flux of photons that are capable of ionizing individual atoms. This produces ions and a delocalized electron cloud. The ions are forcefully ejected from the core due to Coulomb repulsion. Note that in the last step the electron cloud is more faint due to interactions with the surroundings and other nanoparticles (**b**) Laser melting: absorption of photons leads to the particle exceeding its melting temperature, and it subsequently fragments

can also occur at sufficient pulse energies. It is currently believed that fragmentation of nanoparticles can take place via either thermal evaporation or Coulomb explosion – see Fig. 2. Upon absorption of the laser light, the temperature of the nanoparticle can increase to above the boiling point, thus resulting in evaporation of the outer layers of the particle. In fact, the melting of *Au* nanoparticles during pulsed irradiation has been confirmed by X-ray scattering where the loss of long-range order occurred ~ 1 *ps* after the arrival of the laser pulse [10]. Additionally, gold nanorods were converted into nanospheres by pulsed irradiation that induced melting and a subsequent Rayleigh instability [11]. This melting and rise in temperature can be accompanied by strong thermionic emission which leads to a loss of stability in the highly charged particles. The strong repulsive forces lead to fragmentation of the particle by Coulomb explosion into smaller and more stable units. It is also possible to have direct photoionization of particles leading to Coulomb explosion when very high-intensity laser pulses are used.

Nanoalloys and Nanocomposites

Composite and alloy nanoparticles can be produced by laser ablation in liquids in a number of ways. First, two colloids may be mixed together (pink line in below spectra) and irradiated to alloy the colloids (blue line in below spectra). The diagram in Fig. 3b shows a typical experimental setup used to postirradiate a nanoparticle mixture. Second, an alloy target can be used in the PLAL setup depicted in Fig. 1, producing a colloidal alloy nanoparticle solution. When followed by postirradiation, the particles are simultaneously homogenized and further alloyed. Third, a metal target can be ablated in the presence of a colloidal NP solution of the desired alloy partner, again followed by postirradiation. These procedures can easily be performed with miscible systems such as $Ag - Au$, where it is fairly easy to tune the surface plasmon resonance (SPR) over the

Mechanisms of Nanoparticle Generation by Laser Ablation in Liquids, Fig. 3 (**a**) Extinction spectra for various alloying methods. When the target is composed of equal amounts of *Ag* and *Au* the SPR is located at $\lambda = 468$ nm; this SPR shifts to $\lambda = 430$ nm when the target is composed of mostly *Ag*. (**b**) The diagram to the right illustrates an experimental setup where a mixture of *Ag* and *Au* nanoparticles is postirradiated to induce alloying

range of $\lambda = 400$–520 nm. When the second procedure is used, it can be seen in Fig. 3a that a target with a higher *Ag* mol fraction will result in SPR closer to that of *Ag* ($\lambda = 400$ nm) (red line vs. black line).

Experimentally the former two methods discussed above produce the best alloying and are the most reproducible. Alloy nanoparticles are very desirable for nanoparticle plasmonics and surface-enhanced Raman spectroscopy (SERS) applications where one desires to tune the resulting SPR. Many other alloys and nanocomposites can be created with this technique, but it is not always trivial to characterize the particles, and high-resolution transmission electron microscopy might be necessary to adequately perform the analysis.

Conclusion

This entry focuses on the mechanism by which nanoparticles are generated during laser ablation of solid targets submersed in liquid. The role of plasma confinement and cavitation was discussed with a special emphasis on their influence on the nanoparticle size and polydispersity of the resulting colloids. The effect of laser interactions with nanoparticles was also reviewed in two contexts. First, the influence of temporal overlap between the incident laser pulse and nascent particles is argued to be a mechanism by which laser-generated nanoparticles become bi- or polymodal. Secondly, the irradiation of colloidal solutions is often performed to reduce the polydispersity within nanoparticle solutions, as well as reduce the primary particle size. The two most commonly cited mechanisms by which this size reduction and homogenization occurs are Coulomb explosion and laser-induced melting. Finally, the role of these irradiation mechanisms is discussed with respect to nanoalloying of the noble metals *Au* and *Ag*.

Definition

MEMS: Micro-electro-mechanical Systems

MEMS are small silicon-based mechanical devices that employ semiconductor fabrication techniques in their construction. MEMS devices may take various forms: from pressure, chemical, and vibration sensors, to optical switches and mirrors through to inkjet printer heads. MOEMS – Micro-Opto-Electromechanical Systems – are a subset of MEMS devices that in addition employ optical components; an example could be a photon detector mounted on a silicon chip.

Note: MEMS/MOEMS devices have structures that can be measured at the micrometer level, whereas nanotechnology deals with scales at the level of an individual molecule (generally taken to be in the 1–100 nm range).

Adaptive Optics

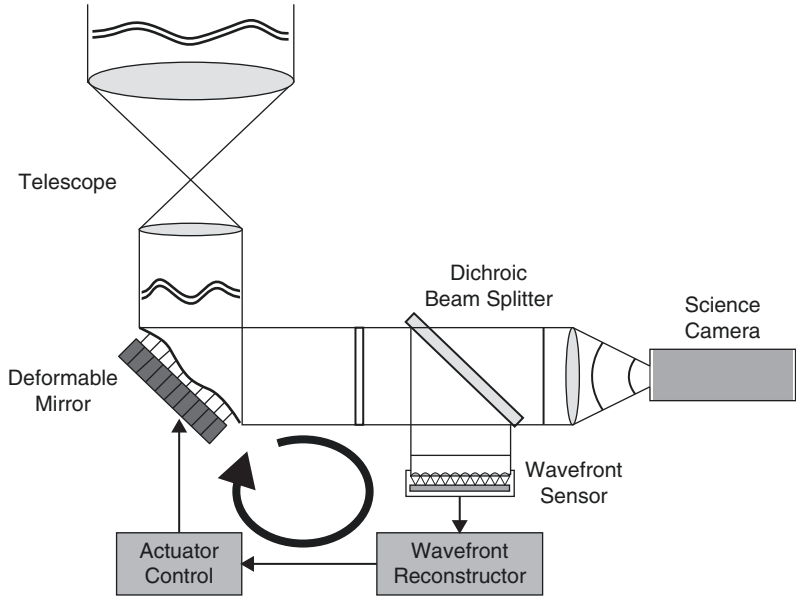
Adaptive Optics (AO) are optical systems that can both measure and correct optical wavefront aberrations in real time. Real time depends on the particular AO application: in astronomy closed loop bandwidths of several hundred Hertz are required to correct the rapidly changing atmospheric turbulence. For vision science, changes in the lens/cornea and head/eye movements require a slower correction speeds (a few Hertz). Typically, an AO system has three main system components: (1) a wavefront sensor (WFS) that measures the aberration (note: there are also wavefront sensor-less AO systems), (2) a wavefront corrector – typically a deformable mirror (DM), and (3) a control computer that controls the WFS and wavefront corrector.

MEMS Adaptive Optics

An AO system that employs MEMS technology in the wavefront corrector

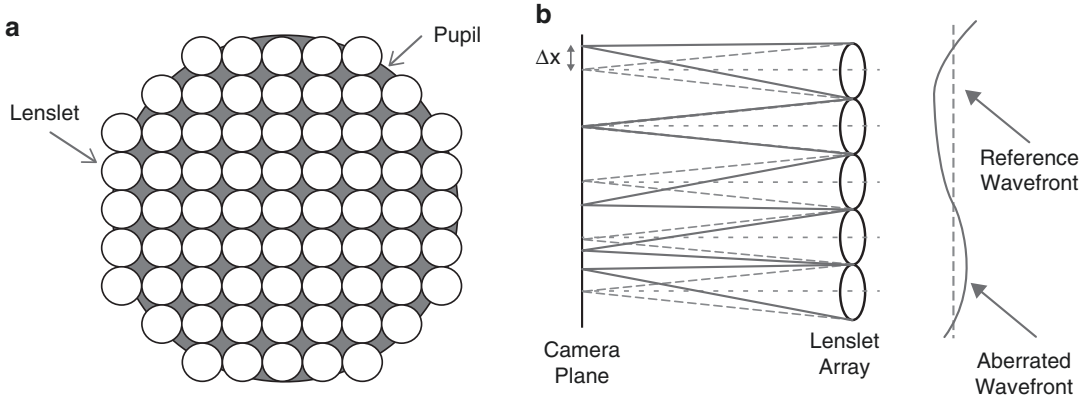
Introduction

Adaptive optics (AO) is a technique that measures and corrects wavefront distortions. These distortions may be due to effects of atmospheric turbulence (astronomy or free space communications); however, they may also be biological in nature (vision science or microscopy).



AO was first proposed by Babcock in 1953 for use in large, ground-based telescopes but implementation at that time was limited by the available technology. The initial development beginning in the 1970s was for military applications. Declassification in the early 1980s led to significant use in astronomy with all large terrestrial telescopes now using AO to enhance their image quality. Other scientific fields have benefited greatly from this work particularly in the fields of vision science and microscopy, both of which have leveraged the technology and know-how to provide AO corrected images with remarkable clarity.

This entry focuses on recent developments in AO that use micro-electro-mechanical systems (MEMS) technology. The technology itself and the results in a range of research fields are described. A detailed discussion of AO principles is, however, beyond the scope of this entry and the interested reader is referred to the reference texts [1–3].



Principle and Application of Adaptive Optics (AO)

A schematic AO layout is shown in Fig. 1 and generally requires the implementation of three main subsystems:

The Wavefront Sensor (*WFS*) – This measures the optical aberrations in the incoming distorted wavefront. There are two broad WFS classes [1, 2]: (1) *direct* – in which the phase or optical path difference is measured, e.g., Hartmann-Shack (Fig. 2), curvature, and pyramid sensing, (2) *indirect* – the wavefront properties are not explicitly measured, but rather the correction signals are deduced from whole-aperture intensity measurements made at or near the focal plane. These are generally iterative in nature with

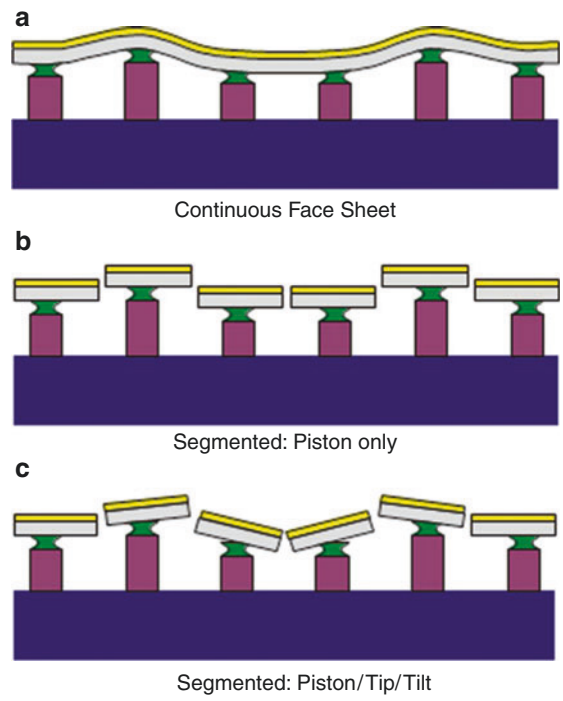
MEMS Adaptive Optics, Fig. 1 The basic AO operating principle. In this case, the distorted wavefront from a telescope is reflected off the deformable mirror (*DM*). A fraction of the reflected light is redirected to the wavefront sensor (*WFS*) where the aberrations are measured and the appropriate control signals are determined for the DM. This continual measurement and correction of the wavefront distortion is termed closed loop, the speed of which depends on the particular application. The majority of the light is used in forming the image at the science camera, the aim being to obtain planar wavefronts that focus down close to the limits imposed by diffraction. Note: there are wavefront sensor-less AO approaches that use a measure of the light intensity at the science camera to drive the AO loop and which do not require a separate WFS arm (Reproduced from Expert Review of Medical Devices, 2, 205–216 (2005) with permission of Expert Reviews Ltd)

MEMS Adaptive Optics, Fig. 2 Principle of the Hartmann–Shack WFS. (**a**) The incident pupil (*gray circle*) is sampled by a two-dimensional array of lenslets, the diameter and focal length of which are chosen to give the required measurement resolution and dynamic range. (**b**) For the reference wavefront (*gray hatched line*), a focal spot is formed by each lenslet on the camera plane and is exactly centered behind each lenslet. For an aberrated wavefront (*solid gray line*), variations in the slope between each lenslet will cause the focal spots to be shifted from the position of the reference. By determining both the Δx and Δy shifts for each lenslet, the aberrated wavefront may be reconstructed

examples being image sharpening and phase diversity.

The Control Computer – This takes the output of the WFS and converts it to voltage commands that are sent to the wavefront corrector.

The Wavefront Corrector – This device provides the conjugate correction to the measured optical distortions. The aim of any wavefront corrector is to equalize the optical path length (OPL) seen by all points on the incident wavefront, resulting in a flat wavefront after correction. The OPL is defined as the product of the refractive index, n, and the physical path length, d. Wavefront correctors can be divided into two main classes depending on how they impart the OPL change: (1) *deformable mirrors (DMs)* – these are by far the most common device used. As the name suggests these operate by locally deforming a mirrored surface, i.e., they change the physical path length, d, and (2) *liquid crystal spatial light modulators (LC-SLMs)* – these produce localized changes in their refractive index, n (d is fixed). The refractive index change is achieved through the application of a voltage that rotates the liquid crystal molecules.



Consider Fig. 1 and the example of aberrations entering a telescope; the incident distorted wavefront is reflected by the DM with a fraction of the reflected light being redirected into the WFS arm where the aberrations are measured and the appropriate control signals are determined for the DM. The DM surface profile is then updated to exactly cancel the aberrations in the wavefront. Both the DM and WFS are placed in optical planes that are conjugate to the source of the aberration, for example, in the human eye this plane is taken to be somewhere between the cornea and lens. The majority of the light is used in forming the image at the science camera, the aim being to obtain planar wavefronts that focus down close to the limits imposed by diffraction. This continual measurement and correction of the wavefront distortion is termed closed loop control.

Within AO, MEMS technology has been used extensively in the construction of DMs and the next section details their design. Particular emphasis on the use of MEMS AO is given over to vision science as it was in this field that such technology was first used. Recently, MEMS AO has increased its breadth and the newer applications and results are described.

MEMS Deformable Mirrors

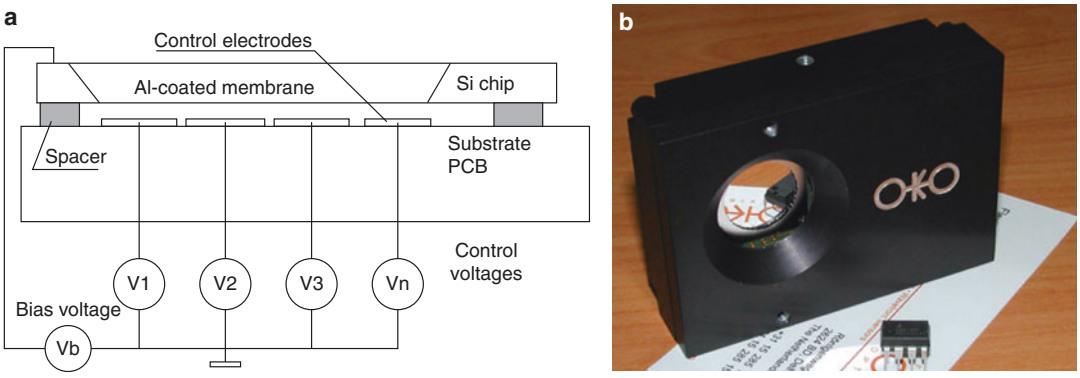
MEMS has seen considerable research interest in the development of DMs and is a field of active research and development. The basic principle of a DM is simple; however, fabricating them with the required operating parameters has proven to be extremely challenging. Figure 3 shows the three basic DM types in cross section – light would be incident from the top of the figure. Continuous face sheet (Fig. 3a) – a continuous reflective mirror surface is deformed by an underlying two-dimensional array of actuators. Piston-only DMs (Fig. 3b) are composed of a discrete array of segments, each of which may individually move in a pure piston (vertical) motion only. Figure 3c shows a piston/tip/tilt DM, an individual segment may now also move in tip and tilt in addition to piston. All the DM types in Fig. 3 show piston-like actuators under the mirror surface(s) and an example actuation mechanism could be piezoelectric. However, there are other forms of actuation, for example, electrostatic, magnetic, thermal, or voice coil. MEMS-based DMs generally use electrostatic attraction; however, other forms have been employed.

The first AO systems had physically large (>10 cm diameter), expensive (>$100 K), non-MEMS DMs that had been primarily designed for the military/astronomy communities. The DM was required to provide a modest amount of stroke (~5 μm) with quick response times (several kHz). In biomedical imaging the requirements are much different, (1) the DM diameter needs to be small (a few mm in diameter), hence minimizing the pupil magnification and allowing for the design of compact systems, (2) the DM must also be inexpensive particularly if AO is to transition into commercial products, and (3) these applications require slower response times (a few Hz), fewer actuators (or segments), but much more stroke (>50 μm) [4].

MEMS Adaptive Optics, Fig. 3 Deformable mirror (DM) types. (**a**) A continuous mirror surface is deformed by an underlying array of actuators. Many forms of actuation are possible, for example, piezoelectric, electrostatic, or magnetic. (**b**) The mirror surface is composed of a discrete array of segments each of which may move in a pure piston motion only. (**c**) Similar to (**b**) but each segment may now also move in tip and tilt in addition to piston

Structure of MEMS DMs

The first MEMS mirror was the Texas Instruments digital micro-mirror device (DMD) introduced in the late 1990s which comprises up to one million mirror segments. It is used extensively in high-quality projection systems with each mirror segment representing one pixel in the image. However, it is bistable in nature with a low fill factor and a surface profile which precludes its use in AO. Around the same time, MEMS-based DMs designed specifically for AO applications were being introduced and they can be divided into two broad classes: (1) bulk micromachined and (2) surface micromachined devices, the difference being in the way the mirrors are fabricated and assembled. The first MEMS DMs were bulk micromachined [5]; a few years later saw the introduction of the first surface micromachined devices [6].



Bulk Micromachined Membrane DMs (MMDM)

In these electrostatic devices, a flexible, reflective membrane lies between a transparent top electrode and a patterned array of bottom electrodes [5]. Application of a voltage to the bottom electrodes causes the mirror surface to deflect downward. The DM has two principal components:

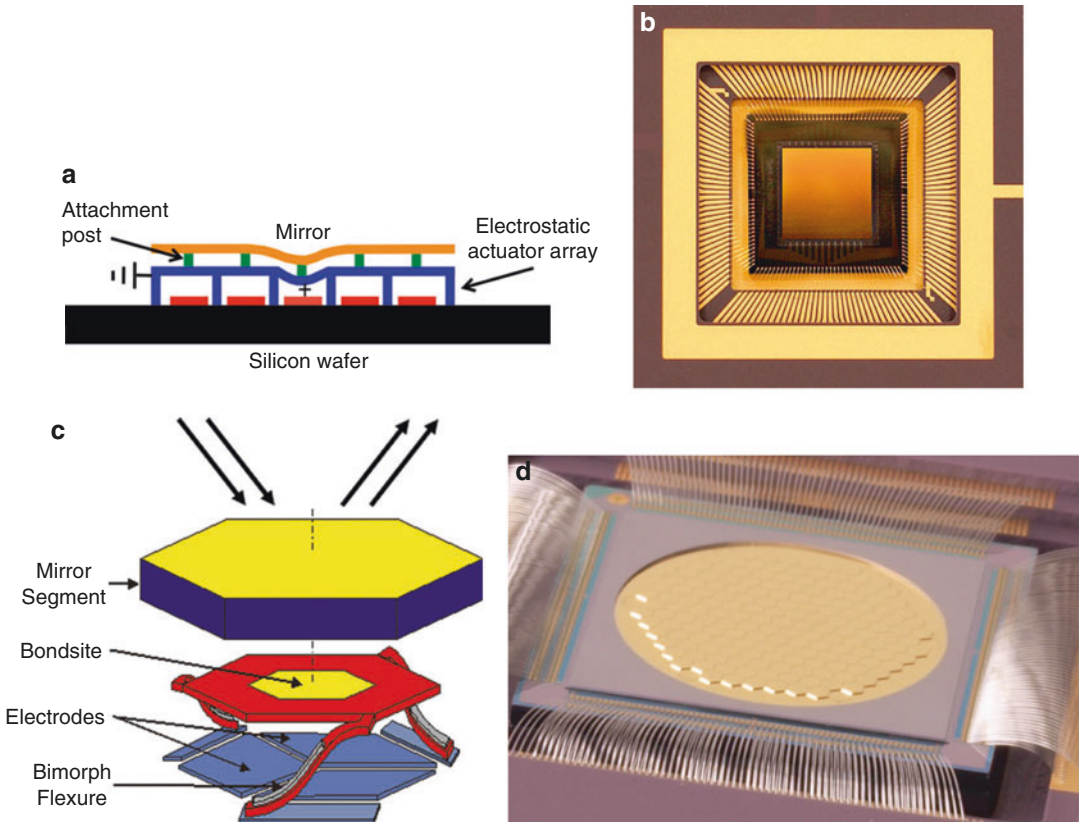
- *A reflective mirrored membrane*: This is made from silicon nitride and an evaporated layer of aluminum or sometimes gold to provide the reflective layer. The membrane stress can be controlled during the nitride deposition.
- *The electrode array*: The bottom set of electrodes are formed by patterning a layer of aluminum deposited onto a silicon wafer.

Wafer bonding is then used to join these two sections; this has a particular advantage as it allows fabrication of devices with a large actuator gap and hence large dynamic range. However, membrane DMs are generally used for applications which require the correction of large, low spatial frequency aberrations as it is difficult to make devices with high actuator packing densities.

A cross section through the OKO Technologies DM [5] is shown in Fig. 4. Up to 9 μm of mirror

MEMS Adaptive Optics, Fig. 4 Structure of the OKO Technologies' bulk micromachined membrane DM. (**a**) A reflective mirrored membrane is positioned above a patterned set of bottom electrodes (V_1,. . .,V_n). A voltage difference between these electrodes and the top transparent grounded electrode causes the DM surface to deflect. (**b**) The packaged DM – up to 9 μm of deflection is possible at the center of the 15 mm DM aperture. The DM has 37 electrodes with operating voltages between 0 and 260 V (DM schematic and photograph provided courtesy of OKO Technologies)

deflection is possible at the center of the 15 mm DM aperture. The DM has 37 electrodes with operating voltages between 0 and 260 V and has been used in a variety of AO applications.



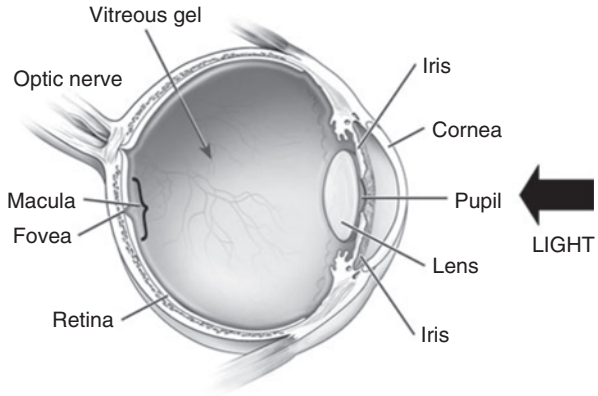
Surface Micromachined Continuous Surface MEMS Mirrors

Another class of MEMS DMs is formed by surface micromachining, in which devices are built up from a series of deposited layers. A layer is deposited, etched before the next is added, much like a layer cake. This construction technique allows for devices with broad functionality. The various layers can be (1) polysilicon – structural and conductive properties, (2) oxides – sacrificial and dielectric, (3) nitride – insulator and dielectric, and (4) various metals – good conductors and optically reflective. With surface micromachining it is more challenging to achieve the necessary dynamic range for some applications; however, devices with extremely high actuator counts are possible.

Instead of a continuous flexible membrane as in the MMDM case, these DMs allow for more localized deformations of the top mirrored surface. This permits the correction of higher order aberrations due to the ability to impart high spatial frequency patterns onto the DM. Figure 5a shows a cross section of a continuous surface MEMS DMs manufactured by Boston Micromachines Corporation (BMC). A top metal-coated mirror surface is attached by silicon posts to a locally anchored, grounded top membrane. Applying individual voltages to the bottom actuator array causes the top mirror surface to deflect. The amount of deflection is proportional to the applied drive voltage. Figure 5b shows a photograph of a gold-coated 140 actuator, 5.5 μm stroke BMC MEMS DM. Another surface micromachined MEMS DM manufactured by Iris AO Inc. [7] consists of a tiled array of hexagonal segments (Fig. 5c). Each segment is raised above a set of three diamond-shaped electrodes via the bimorph flexures. A high-quality mirror surface is bonded to the platform surface which also serves as the ground electrode. Application of voltages to the bottom three electrodes gives tip, tilt, and piston motion on a per segment basis. Figure 5d shows a fully assembled MEMS DM from Iris AO Inc. consisting of a gold-coated tiled array of 163 segments. The thin wires at the perimeter of the chip provide the voltage connections.

AO for Vision Science

A research area where the acceptance and implementation of MEMS devices has been extremely rapid is in vision science. The need for low cost



MEMS Adaptive Optics, Fig. 5 Examples of surface micromachined MEMS DMs manufactured by Boston Micromachines Corp. (BMC) and Iris AO Inc. (**a**) Cross section of a continuous surface MEMS DM from BMC. A top metal-coated mirror surface is attached by silicon posts to a locally anchored, grounded top membrane. and physically small devices has made MEMS particularly attractive.

Structure of the Eye

Vision is the primary human sense with over half of the cortex being used to process the signals coming from the visual pathways. Furthermore, the human eye is the only organ allowing a direct in vivo view of the human nervous system. The eye is therefore the subject of intense interest as a means to the early detection of a host of retinal and possibly systemic diseases.

The human eye is a complex optical structure (Fig. 6); incident light is focused by the lens and cornea onto the light-sensitive retinal surface. The primary sources of aberration are the cornea and lens, with the aberration magnitude increasing with larger pupil diameters. Upon reaching the retinal surface, the light traverses many layers before being incident on the light-sensitive photoreceptor cells (rods and cones) where the photons are absorbed. The macula or foveal region is where the cone photoreceptors have the smallest diameter (1.9–3.4 μm) and where one has the

MEMS Adaptive Optics, Fig. 6 The structure of the human eye. The primary sources of aberration are the cornea and lens, the aberration magnitude increases with larger pupil diameters. The incident light propagates to the retinal surface where it is sampled by the rod and cone photoreceptors. The photoreceptors are a few microns in diameter and are unresolvable without the application of AO (Credit: National Eye Institute, National Institutes of Health)

highest visual acuity. The signals from these photoreceptors are then processed by many intervening cell types before exiting the retina via the ganglion cells and the optic nerve. For detailed information of the physiology of the eye, the reader is referred to the references [8, 9].

The ability to visualize the individual retina layers and cells is particularly important as various retinal diseases manifest themselves in different retinal layers. Glaucoma, for example, attacks the retinal ganglion cells leading to a thinning of the nerve fiber layer. Other diseases such as retinitis pigmentosa (RP) and various cone/rod dystrophies manifest themselves in the photoreceptors. Age-related macular degeneration (AMD) first shows in the deeper retinal layers, with thickening of Bruch's membrane and/or drusen between the retinal pigment epithelium (RPE) and the underlying membrane.

Aberrations

Both the lens and cornea introduce low- and high-order spatial aberrations [3], which along with temporal instabilities (accommodation, eye and head movements) limit the ability to obtain high-resolution, in vivo images of retinal cells. These aberrations also limit an individual's visual perception of everyday scenes. Spectacles, contact lenses, or refractive surgery, for example, only provide a low-order, static correction of these aberrations, primarily focus and astigmatism. Theoretically, the lateral (transverse) resolution of the eye is given by Eq. 1:

$$r = 1.22 f\lambda / nD \tag{1}$$

where r is the distance from the center of the Airy disk to the first minima, f is the focal length of the reduced eye, λ is the imaging wavelength, n is the refractive index, and D is the pupil diameter. Hence, the highest resolution would be achieved using the shortest wavelength, λ and the largest possible aperture, D (f being fixed). For the human eye, with $D = 8$ mm, $f = 22.2$ mm, n ~1.33, and imaging at $\lambda = 550$ nm, one could theoretically achieve a resolution on the order of 1.4 μm, comparable to the size of the smallest photoreceptors. Foveal cones have center-to-center spacing ranging from 1.9 to 3.4 μm, whereas for rods, the range is 2.2–3.0 μm. However, uncorrected aberrations limit the lateral (transverse) resolution to approximately 10 μm and hence these small structures would be unresolvable.

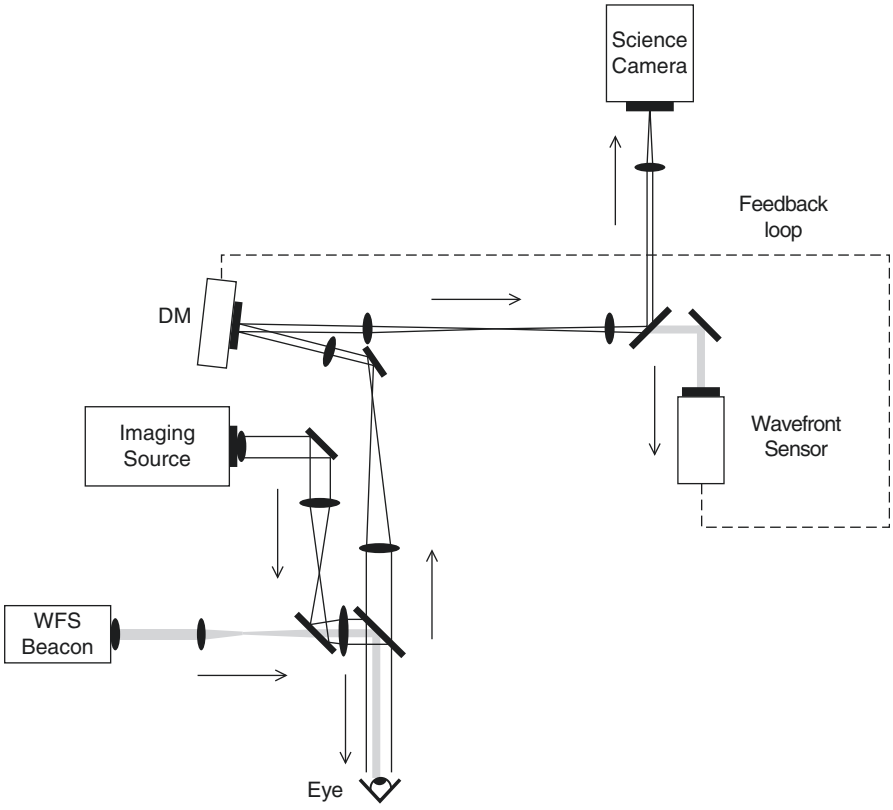
Moreover, the aberration magnitudes change with time and hence a static correction such as spectacles or contact lenses would not be optimal. Even with static correction of the higher order aberrations, the temporal changes can reduce the retinal image contrast by 33 % and the Strehl ratio

(SR) by a factor of 3 [3]. The SR is defined as the ratio of the peak intensity in the aberrated point spread function (PSF) to that of the unaberrated case, a SR greater than 0.8 being considered diffraction limited. AO corrects both the low- and high-order aberrations in real time and has been applied to various ophthalmic imaging modalities: flash (flood) fundus cameras, confocal laser scanning ophthalmoscopes (cSLOs), and optical coherence tomography (OCT). To date, AO imaging has provided imagery of several important cell types, namely, cone, rod, RPE, and leukocyte cells in the intact, living human eye – in all cases without the use of any contrast-enhancing agents.

Brief History of AO in the Human Eye

In 1989, Dreher et al. [10] used a 13 electrode membrane DM to provide a static correction of astigmatism for use in conjunction with a scanning laser ophthalmoscope. Several years later, Liang et al. [11] implemented the Hartmann-Shack wavefront sensor (HS-WFS) for measurement of the human wavefront aberration. The same author [12] was then the first to combine a HS-WFS and a DM into one system for the active correction of the higher order ocular aberrations. Today, these systems use a variety of DM technologies with MEMS being just one subset. The next section details the application of AO to these cameras, highlighting the use of MEMS technology where appropriate.

Retinal Imaging Modalities



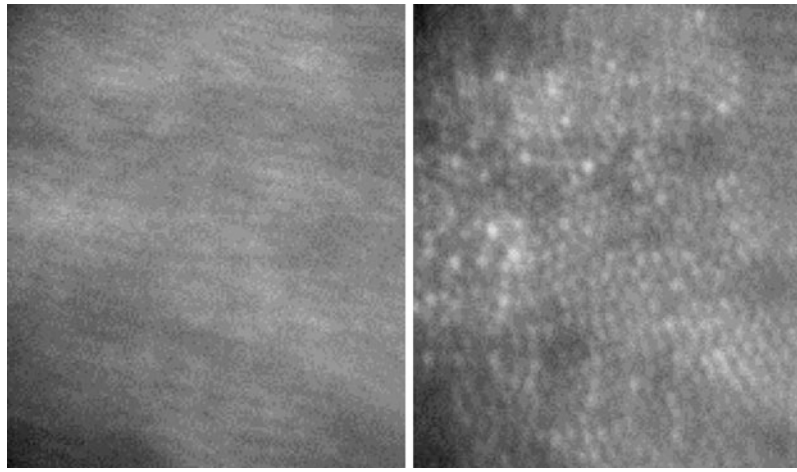
Flood-Illuminated (Flash) AO Fundus Cameras

Figure 7 shows the basic operation of a flood-illuminated (flash) AO fundus camera. Such systems take short exposure (4–6 ms) images of the retinal surface; longer exposures can introduce blurring due to eye movements. Two light sources are used: a superluminescent diode (SLD) in the near IR is used to measure the ocular aberration. A small (1 mm diameter) SLD beam (shown in gray) is incident on the cornea and focuses to a ~10 μm diameter spot on the retina. Small diameter beams are used to avoid blurring from the lens and cornea. The SLD light is scattered by the retina and the reflected light exits through the dilated pupil (typically 6–7 mm in diameter). This light is redirected by the DM and the dichroic beamsplitter into the WFS. The aberrations are measured and the DM commanded to take on the conjugate phase profile. Once the aberrations have been corrected to a suitable level (typically <0.1 μm RMS over a dilated 6–7 mm pupil), the imaging source (typically an arclamp) is triggered. The imaging wavelength (between 500 and 800 nm) is chosen through the use of an interference filter. The field of view (FOV) of the retinal images is 1–3° in diameter (~0.3–0.9 mm on the retina). Multiple images are acquired at one retinal location before post-processing to improve the signal to noise.

These systems were the first to use MEMS DM technology. In 2001, Fernandez et al. [13] used a 37-element MMDM from OKO Technologies to dynamically correct the human ocular aberration. Doble et al. [14] used a surface micromachined MEMS DM to obtain high-resolution images of the human cone photoreceptors in vivo. Figure 8 shows before and after AO images, visualization of individual photoreceptors corresponding to a transverse (lateral) resolution of approximately 3 μm at a horizontal eccentricity of 1° from the fovea are clearly visible [14]. Several other authors report high-resolution imaging of the human retina using an AO flood-illuminated fundus camera using other DM technologies [3].

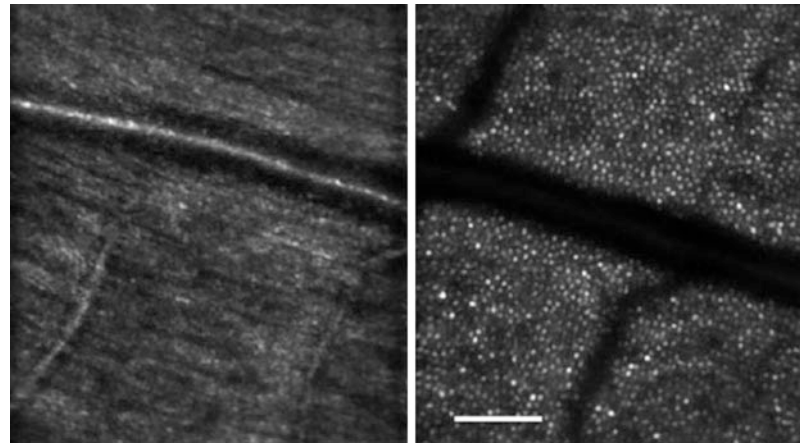
Adaptive Optics Confocal Scanning Laser Ophthalmoscopes (AOCSLO)

Instead of taking a two-dimensional snapshot retinal image like those obtained with flood-illuminated fundus cameras, a SLO rasters a point of light across the retina with the reflected and de-scanned light being measured by a point detector such as an avalanche photodiode or photomultiplier tube. The confocal nature of the cSLO is implemented using a pinhole in front of the detector that is placed optically conjugate to a particular layer of the retina. This confocal pinhole then acts to block any scattered light from layers in front or behind the layer of interest, greatly improving image contrast. The raster is achieved through scanning mirrors (or rotating polygons) with typical frames rates of 20–30 Hz,



MEMS Adaptive Optics, Fig. 7 Schematic of a flood-illuminated (flash) AO fundus camera. A superluminescent diode (SLD) in the near IR is to measure the ocular aberration. A small (1 mm diameter) SLD beam (shown in *gray*) is incident on the cornea and focuses to a ~10 μm diameter spot on the retina. This light is scattered by the retina and the reflected light exits through the dilated pupil (typically 6–7 mm in diameter). This light is redirected by the DM and the dichroic beamsplitter into the WFS. Once the aberrations are corrected, the imaging source (typically an arclamp) is triggered. This source delivers a 4–6 ms retinal exposure. The wavelength (between 500 and 800 nm) is chosen through the use of an interference filter. The reflected visible light is then directed onto the science camera. Retinal images with diameter of 1–3° (0.3–0.9 mm) are acquired and post-processed to improve the signal to noise

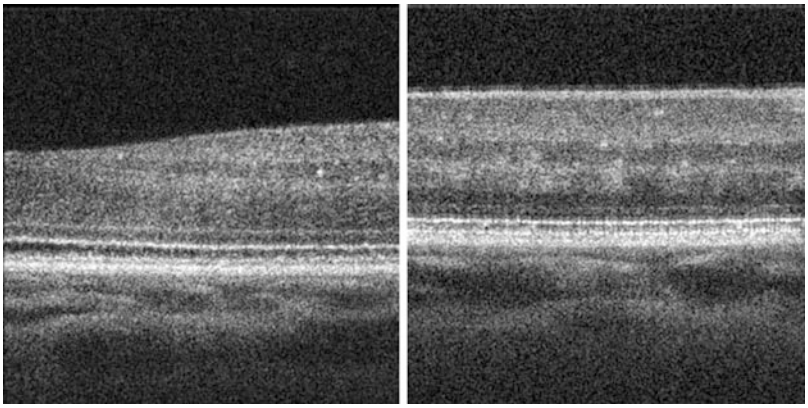
each 512 × 512 pixels in size. cSLOs typically have lateral and axial resolutions of 5 and 300 μm, respectively. By incorporating AO, these values are improved to 2.5 μm laterally and <100 μm axially.



Roorda et al. [15] was the first to detail a fully closed loop AOcSLO system using a 37 channel Xinetics DM and a Shack Hartmann WFS. They demonstrated the axial sectioning capability of the system and highlighted its ability for dynamic retinal imagery by visualizing single bold cells flowing through the retinal capillaries. Newer AOcSLOs are employing MEMS DMs in conjunction with a low-order wavefront corrector such as trial lenses/Badal optometers or even a second DM. Figure 9 shows an example of the axial sectioning capability of an AOcSLO [16]. Adding in a defocus changes the retinal plane that is conjugate to the confocal pinhole, allowing for clear imagery of the retinal nerve fiber layer followed by the cone photoreceptors [17].

Adaptive Optics Optical Coherence Tomography (AO-OCT)

The final retinal imaging modality that has successfully employed AO is optical coherence tomography (OCT) [3]. OCT does not image the



MEMS Adaptive Optics, Fig. 8 Before (*left*) and corrected (*right*) AO images of the human retina at an eccentricity of 1° using a surface micromachined MEMS DM in a flood-illuminated AO fundus camera. Cone photoreceptors are clearly visible in the corrected image; the *dark shadows* are anterior blood vessels. The horizontal field of view is 0.3° (75 μm on the retina), from Ref. [14] (Reproduced with permission of the Optical Society of America)

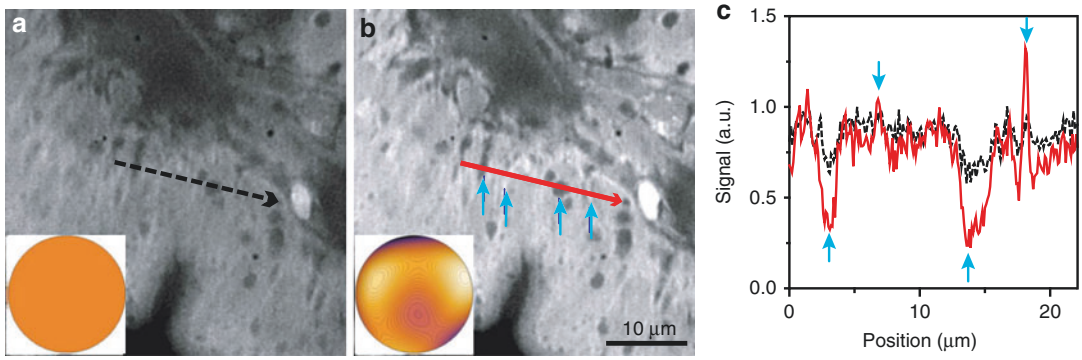
MEMS Adaptive Optics, Fig. 9 Images of the human retinal nerve fiber layer (*left*) and cone photoreceptors (*right*) [17] taken with the AOcSLO described by Burns et al. [16]. The scale bar is 100 μm. The ability for axial sectioning and video rate imaging of the retina is a major advantage of such systems

retina in the conventional sense but rather uses the coherence properties of light to form the image. It is an interferometric, noninvasive method that offers very high axial resolution. In OCT, the axial and lateral resolutions are decoupled. The axial resolution is a function of the source bandwidth, the wider the bandwidth the higher the resolution; however, the chromatic aberration of the eye can then become problematic. The lateral resolution of an OCT system is a function of the pupil size and hence is limited by optical aberrations. OCT systems are based on the Michelson interferometer using a broad bandwidth, low coherence light source. The light is split into and then recombined from a reference and a sample arm (which includes the eye). The first systems were operated in the time domain; today most systems work in the spectral domain whereby the recombined signal is passed through a spectrometer and the resulting spectra imaged onto a

MEMS Adaptive Optics, Fig. 10 AO-OCT images of the human retina [18] from the system described by Zawadzki et al. [19]. The high axial resolution (3.5 μm) coupled with the high lateral resolution (3 μm) afforded by AO enables exceptional 3D rendering of the living retina. *Left* −1.5° temporal retina, *right* −4.5° nasal retina. For both images the field of view is 3° with the system focused in the plane of the photoreceptors. Light would be incident from the *top* of the image

line scan camera – allowing for very rapid image acquisition.

To improve the lateral resolution, several research groups have incorporated AO into OCT systems [3]. The first systems employed large piezoelectric or bimorph DM technologies; today newer systems are employing MEMS DMs usually in conjunction with a second high stroke DM. Figure 10 shows AO-OCT images of the human retina [18] from the system described by Zawadzki et al. [19]. The high axial resolution (3.5 μm) coupled with the high lateral resolution (3 μm) afforded by AO enables exceptional 3D rendering of the living retina. Figure 10 (left) −1.5° temporal retina, right −4.5° nasal retina. For both images the field of view is 3° with the system focused in the plane of the photoreceptors. OCT images show clear stratification of the various retinal layers which are easily related to histological sections.



AO for Microscopy

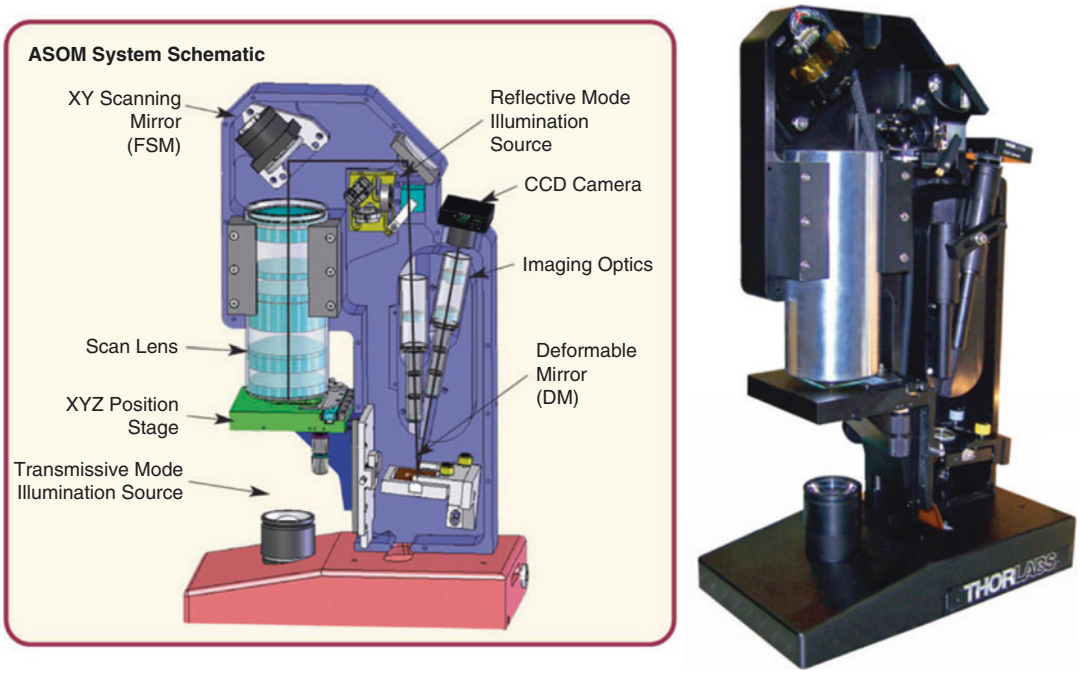
Another application that is particularly suited to MEMS technology is the realm of biological microscopy. Like vision science, the small size of MEMS devices and the fact that they are relatively inexpensive make them an attractive choice.

Both confocal and two-photon imaging modalities are widely used in the study of cellular-level process [20, 21]. The confocal microscope works in a very similar way to that of the SLO described previously. The lens and cornea are replaced by a specially designed objective and the retina by the sample under study. A point source is rapidly scanned across the sample of interest and the reflected light is imaged onto a point detector. The two-photon microscope relies on excitation fluorescence caused by the simultaneous absorption of two photons by a molecule in the sample. A major advantage of the two-photon microscope is the very high depth penetration (around 1 mm). The excited fluorescence is very strongly localized due to the efficiency of the excitation process being proportional to the square of the intensity resulting in excellent three-dimensional imaging.

Sources of Aberrations

There are two primary sources of aberration in microscopy: (1) The sample itself is inhomogeneous with refractive index changes within it's three-dimensional structure this can lead to significant aberrations particularly when focusing through thick specimens. (2) There is a further index mismatch between the sample and the immersion media (oil or water). These aberrations cause loss of resolution, contrast, and signal.

MEMS Adaptive Optics, Fig. 11 Before (**a**) and after (**b**) AO-corrected image of mouse intestine under structured light illumination microscopy [25]. The *insets* show the phase in the pupil plane of the objective. The AO correction allows for the visualization of detail previously not observed – denoted by the *arrows*. (**c**) Shows the improvement in the recorded signal for the small features. The imaging depth was approximately 10 µm (Reproduced with permission of the Optical Society of America)



Wavefront Sensing

However, a particular challenge with microscopy is optical scatter, particularly when trying to image within thick samples. The scattering profile makes conventional WFS techniques such as Shack–Hartmann challenging to implement, as multiple layers within the sample can reflect light. In many AO microscopy systems, indirect (wavefront sensor-less) control has been applied to overcome the scatter issue. Indirect methods do not explicitly measure the wavefront aberration but instead use an iterative search algorithm to converge to the best AO correction state. Generally, a stochastic or hill climbing algorithm is used with an image quality metric (IQM). The IQM is a single figure that the search algorithm tries to optimize, example IQMs could be the Strehl ratio or simply the energy through the pinhole in a confocal system. Several authors have built on the first indirect astronomical AO systems [1, 2] and have adapted them for microscopy [22, 23]. One issue with these approaches is the convergence speed as many iterations are required to find the best solution; however, modal-based approaches reduce the number of iterations improving the convergence speed [24, 25]. Figure 11 shows before (a) and after (b) AO-corrected images of mouse intestine under structured light illumination microscopy [25]. Small details (denoted by the arrows) previously unseen were observed after the AO correction.

Indirect AO approaches have several advantages over direct schemes. Firstly, all of the light is used to form the image as none is required for the separate WFS arm; this reduces the required light levels minimizing possible phototoxic effects to the sample. Secondly, it removes any non-common path errors: in many AO systems there may be optics that are not in the optical path of the WFS; any misalignment will not be measured and hence will be uncorrected.

Using AO to Improve Microscope Capabilities

The standard role of AO is to correct for aberrations due to some intervening optical media between the object and the detector. However, it is also possible to use AO to reduce the cost of complex optical system by reducing the design constraints of certain elements. An example is the adaptive scanning optical microscope (ASOM) designed by researchers at Rensselaer Polytechnic Institute [26] and subsequently commercialized by Thorlabs. In high-power microscopes, methods to obtain a large field of view either require moving the sample itself and stitching together the small FOV images or designing wide field objective which can become prohibitively expensive for some applications. The ASOM overcomes these limitations by using a fast steering mirror and a MEMS DM to firstly scan the sample and secondly correct for the

MEMS Adaptive Optics, Fig. 12 The adaptive scanning optical microscope (*ASOM*) designed by researchers at Rensselaer Polytechnic Institute [26] and subsequently commercialized by Thorlabs. In high-power microscopes, methods to obtain a large field of view either require moving the sample itself and stitching together the small FOV images or designing wide field objectives which can become prohibitively expensive for some applications. The ASOM overcomes these limitations by using a fast steering mirror and a MEMS DM to firstly scan the sample and secondly correct for the aberrations at the various scan angles. This provides diffraction-limited imaging over a wide FOV (ASOM schematic and photograph provided courtesy of Thorlabs)

aberrations at the varying field angles. This provides diffraction-limited imaging over a wide FOV; a schematic and photograph of the system is shown in Fig. 12.

MEMS AO for Astronomy

All of the world's large ground-based telescopes require AO to overcome the degrading effects of atmospheric turbulence [1, 2]. The improvement afforded by AO has aided in every field of optical astronomical imaging. Large aperture DMs have generally been used in part to limit the demagnification required in going from the large (3–10 m) diameter primary mirrors to the rest of the optical train. In recent years, however, the increasing size and actuator counts of MEMS devices have made them attractive for astronomy.

Extreme AO

Extreme AO is the use of very high order AO systems in conjunction with coronagraphs or spectroscopy to enable imaging and measurements of extrasolar planetary systems. The aim being to detect very faint objects (planets) close to very bright sources (stars) that would otherwise be unseen. An exoplanet can be over a million times fainter than the companion star. Extreme AO systems increase the peak intensity of point-source images and remove the scattered light due to the atmosphere and the telescope optics. Overcoming these two sources of image degradation dramatically improves the contrast of these very faint objects.

An example instrument is the Gemini Planet Imager (GPI) project [27] being led by Lawrence Livermore National Laboratory, designed to image planets that are one to ten million times fainter than the companion star. GPI will use

MEMS AO to deliver diffraction-limited images and spectroscopy between 0.9 and 2.4 μm and is due to be delivered to Gemini South telescope (Cerro Pachon, Chile) in 2011. A key element of this system is a 4096 (64 × 64) actuator continuous surface MEMS DM manufactured by BMC, which will be used for the wavefront correction.

A European consortium is building a similar instrument for the European Southern Observatory. The Spectro-Polarimetric High-contrast Exoplanet Research (SPHERE) instrument [28] is due for delivery in 2011 to the Very Large Telescope (VLT) at Paranal, Chile.

Other MEMS AO Applications

There are several other applications that benefit from the small form factor and the potential low cost of MEMS devices.

Free space laser communications – Changes in the refractive index of turbulent air cause optical aberrations; these are manifest as beam spreading and scintillation causing loss of signal. These are particularly strong at ground level and become extremely challenging for horizontal, line-of-sight applications, such as laser communication and range finding. Atmospheric beam spreading requires the use of large detectors which in turn limits the data rates; by using AO to improve the beam quality, smaller, higher frequency detectors can be used. This can increase data rates by a factor of 10–100 [29].

Laser beam shaping – Many applications require precise control of the beam profile, for example, in laser machining. Beam control may be required to overcome aberrations due to thermal effects for example, or manipulation of the beam profile may be required to increase the efficiency of the material processing. AO may be implemented in either an intracavity or extracavity mode. Intracavity AO directly controls the beam profile and may be used to modify the temporal shape of the laser pulse or the transverse profile of the beam. For example, the ability to produce supergaussian profiles (so-called top hat functions) over the typical TEM00 Gaussian profile has particular attraction. Extracavity control is used for focus control or the control of optical distortions outside of the laser cavity. For laser machining applications the challenge for the use of MEMS AO is the harsh environment and the extremely high intensities incident on the active DM surface.

Optical manipulation – The effectiveness of the optical trap is limited by the aberrations (mainly spherical aberration) due to the refractive index mismatch at the glass/water interface. Similar to high NA microscopy, MEMS AO can be used to overcome this source of aberration [30].

Conclusion

The range and applicability of MEMS AO is constantly growing and evolving. It has proven highly successful in improving the performance of optical instrumentation in a variety of fields. Perhaps the biggest challenge to widespread adoption will be the cost of adding MEMS AO to a particular system. MEMS promises the ability to mass produce many millions of identical devices at low cost but to date the high-volume application is unclear. There exist low-volume, high-unit-cost applications such as microscopy and ophthalmology that make current AO technologies a viable economic proposition.

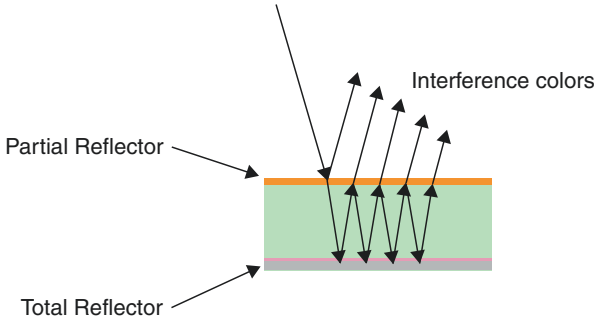
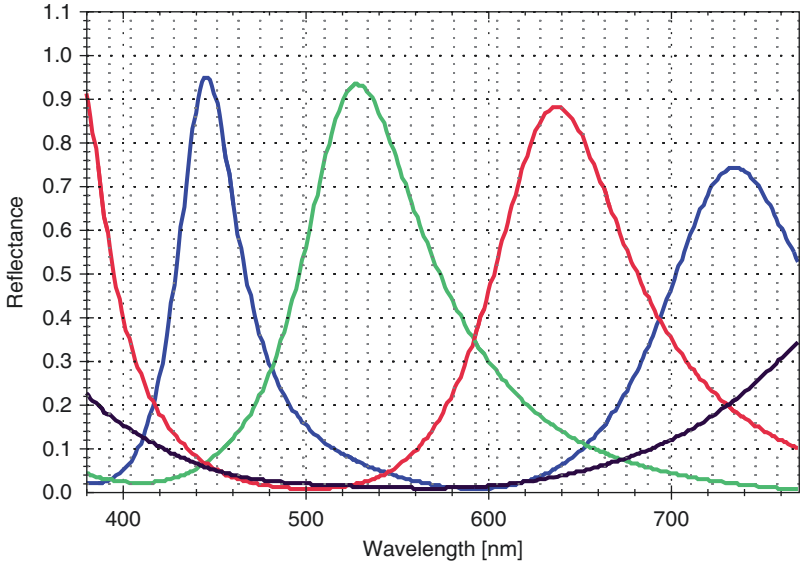
Interference Modulator (IMOD) technology; mirasol® displays

Definition



Happy "marriage" of micro/nanomachining (MEMS/NEMS) and thin-film optics brings about a new disruptive display technology, mirasol®, offering low-power operations and consistent viewing quality in various ambient lighting conditions including direct sunlight. Based on the principles of interferometric light and color modulation and microelectromechanical device operation and fabrication, the technology demonstrates unique attributes of low power consumption and reflective nature of display operations. Fast switching of the MEMS pixel elements enables video operation of mirasol displays at high refresh rates. mirasol displays can be manufactured using conventional tools and materials in standard glass TFT fabs balanced and modified for MEMS processing steps.

Introduction

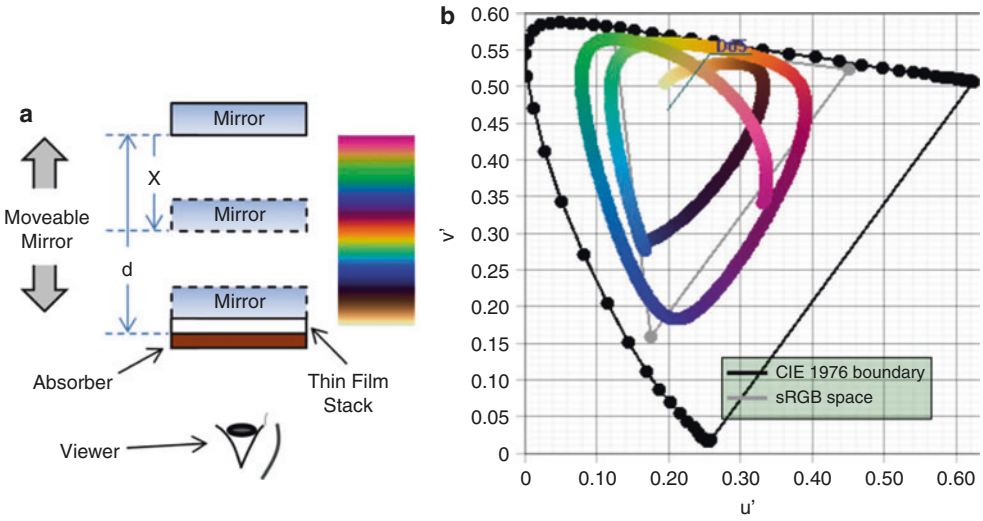


Coloration in nature is generally realized in two ways, through pigmentation or by means of controlling the flow of photons in thin optical films and/or 3D structures [1, 2]. Iridescence (originated from the Greek word *irides* – "rainbows") is an optical phenomenon caused by multiple reflections from multiple layers of optical films in which phase shift and interference of the reflections modulate the incident light by amplifying or attenuating certain wavelengths more than others. Some examples of this effect in living creatures include butterfly wings, feathers of some birds, and seashells [3].

Recent developments in micro- and nanofabrication and photonics allow one to fabricate structures that can mimic iridescence in nature by manipulating light in a controlled manner in MEMS/NEMS architectures, thus opening up a window for a variety of novel devices and applications [4–6]. The Qualcomm mirasol reflective display is a high-speed, electrostatically actuated, bi-stable MEMS device built on a transparent (e.g., glass) substrate and represents one of these emerging MEMS applications [7–10]. The basic device consists of a suspended conductive membrane serving as a mirror, over a partially reflective optical stack. There is a few hundred nanometers wide gap between the two that is filled with air. Interference between light reflected from the mirror and from the partially reflective optical stack generates vibrant color. Applying bias to this capacitive MEMS device color can cause change, for example, from color to black, thus enabling information display operation. The core of the technology, the mirasol display pixel, is designed on the principles of (1) thin-film interferometric modulation optics to produce color in the reflected spectrum of a (white) ambient light and (2) MEMS switching mechanism for changing the pixel state and, as a result, refreshing an image by applying low voltage. The same MEMS device achieves functions of color generation, fast light modulation, and memory, which are the three key elements required for making a video-capable color display. In contrast, the most commonly used display technology, liquid crystal display (LCD), uses color filters to generate colors, the liquid crystal layer with polarized light and an analyzer for light modulation, and generally thin-film transistor (TFT) circuits for memory.

Fundamentally, these principles offer significant power advantages because (1) reflected light (energy) is modulated from an ambient lighting

MEMS Display Based on Interferometric Modulation Technology, Fig. 1 "Folded" etalon



MEMS Display Based on Interferometric Modulation Technology, Fig. 2 Reflection spectra for four different air gaps corresponding to *red*, *green*, *blue*, and *black* colors respectively

source and (2) low-voltage MEMS pixel switching automatically means low power consumption during display array addressing. Therefore, this revolutionary interferometric modulator (IMOD) technology offers significant benefits in viewability, ruggedness, and power reduction, which make it attractive for a wide variety of consumer electronics applications. While LCDs in particular have also been used to make direct-view reflective displays, they have some inherent limitation especially due to the requirement of polarizer for light modulation because of which less than half of the light gets used to display images.

In this entry, basic electromechanical physics of the IMOD device and principles of color generation and modulation is described. Device fabrication and manufacturing utilizing mostly existing materials and tools available from TFT display industry will also be discussed as well as necessary modifications due to the MEMS nature of the technology. Other MEMS-based display technologies will be also reviewed.

Color Generation in IMODs

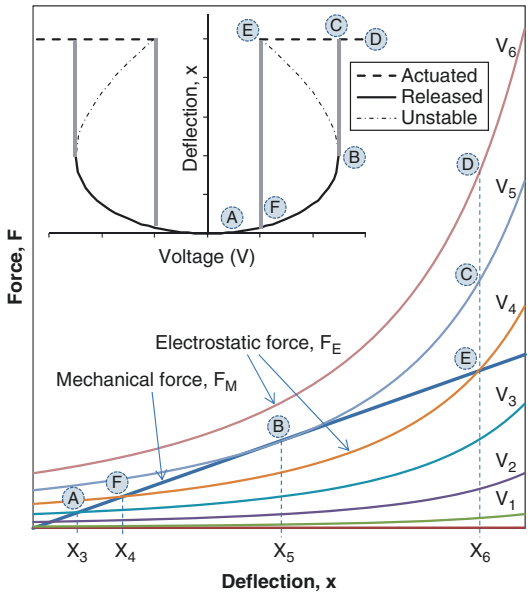
IMOD device is analogous to a Fabry Pérot interferometer [11, 12] operating in reflection mode (Figs. 1 and 3a). The air gap between the two reflectors shapes the spectrum of the reflected light as some wavelengths go though constructive interference while others through destructive interference. Figure 2 shows the example reflection spectra for IMODs for air gaps (on the order of 40–400 nm) corresponding to red, green, blue,

MEMS Display Based on Interferometric Modulation Technology, Fig. 3 IMOD colors for varied air gap. (**a**) IMOD device structure and color vs. gap. (**b**) IMOD color spiral on CIE u′-v′ chart

and black states respectively. The range of colors reached by the device as a function of the air gap can be computed using transfer-matrix method [11] and are shown on a standard CIE 1976 chromaticity diagram [13] in Fig. 3b for a given thin-film optical stack. A typical optical oxide stack has a thickness of several tens of nanometers.

Light Modulation and Electro-Mechanics

To change the color seen by the human observer, the air gap is changed by application of voltage on the two parallel plates of the IMOD device that results in electrostatic force of attraction between them given by:



$$F_E = \frac{1}{2}QE = \frac{1}{2}A\varepsilon_0\left(\frac{V}{d-x}\right)^2$$

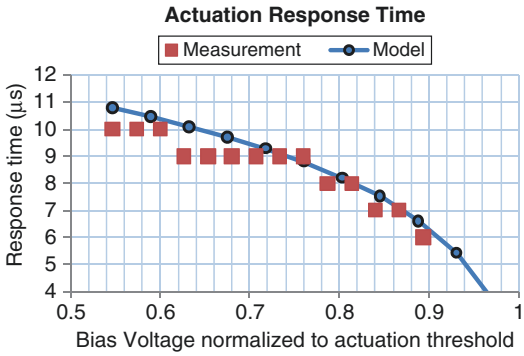
where F_E is the electrostatic force of attraction between the two plates, Q is the magnitude of charge on the plates, E is the electric field between them, A is the area of the plates, V is the applied voltage, d is the electrical gap in undeflected state, and x is the deflection.

Under equilibrium, this force is balanced by the mechanical restoring force F_M that follows Hooke's law:

$$F_M = K \cdot x$$

where K is the effective spring constant. This results in a cubic equation in x solving which results in the three solutions shown in Fig. 4 inset labeled actuated, released, and unstable respectively. Only two of the three solutions correspond to a stable equilibrium. With reference to Fig. 4, as the voltage is increased in magnitude starting from zero volts, IMOD starts in "released" state ('A') while the moveable plate gradually deflects toward the fixed plate. Once a threshold called pull-in or actuation voltage ('B') is crossed, the moveable plate collapses toward the fixed plate, reducing the air gap thickness to practically zero ('C') ("actuated" state). The transition to the actuated state is accompanied by a nonlinear increase of the electrostatic attraction, which increases rapidly as the air gap decreases. If the voltage now is decreased in magnitude, the electrostatic force needs to be reduced significantly before the moveable plate is able to snap back to the released state again. The threshold voltage level when the transition to the released state ('E' → 'F') happens is called release voltage. When a voltage between the actuation and release voltages called "bias voltage" is applied,

MEMS Display Based on Interferometric Modulation Technology, Fig. 4 Balance between electrical and mechanical forces leads to hysteresis



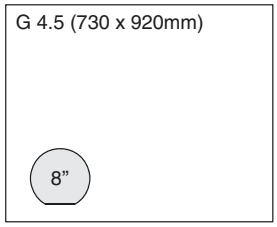
both actuated and released states are stable, akin to a memory effect where each pixel preserves the last state to which it was set.

The dynamical response time of the IMOD device can be modeled by including the terms for acceleration and squeezed-film damping into the force equation [14, 15]:

$$m\frac{d^2x}{dt^2} + \frac{\alpha\eta_0 A^2}{\left(1 + (9.638)K_n^{1.159}\right)(g-x)^3}\frac{dx}{dt} + Kx = \frac{A\varepsilon_0}{2}\left(\frac{V}{d-x}\right)^2,$$

where m is effective mass of the mirror, Kn is Knudsen number, η_0 is coefficient of viscosity of air, and α is a constant dependent on the geometry of the device [15]. Mechanical response times of a few microseconds are commonly achieved (compared to 2–40 ms for LCD), thus allowing for video capability. Figure 5 demonstrates a good match between model predictions for the response time and device measurements across a range of bias voltages.

Hysteresis behavior of the device is desirable for low-power operation as the content image



MEMS Display Based on Interferometric Modulation Technology, Fig. 5 Response time as a function of bias voltage; model vs. measurements

written on the panel does not need to be refreshed at a high frame rate as done by conventional LCD displays. It further allows passive matrix operation (thus saving panel manufacturing costs) without being subject to contrast ratio degradation as the vertical resolution of the display is increased [16].

To change the state of the IMOD device, a voltage pulse is applied to the device that takes it from the "hold" or bias voltage to either actuated or released state. Voltages much smaller in magnitude than the bias voltage are needed for this, allowing low-power image update operation.

Each mirasol pixel typically consists of three sub-pixels for red, green, and blue color channels, respectively, as traditionally used in other displays. The sub-pixels can be independently transitioned between the chosen primary color state and a black state. A common process sequence producing three separate air gaps is used to fabricate the individual sub-pixels. The color points for the sub-pixels are chosen from the IMOD color "spiral" shown in Fig. 3b considering white-balancing constraint and the trade-off between brightness and gamut pertinent to any reflective display technology. Given the bi-stable or 1-bit nature of the device, intermediate colors are generated for each sub-pixel by dividing it into multiple area-weighted IMODs and/or using spatial dithering techniques such as error diffusion commonly used by the print industry [17]. IMOD sizes used are optimized to avoid

MEMS Display Based on Interferometric Modulation Technology, Table 1 Examples of materials typically available for mirasol display manufacturing

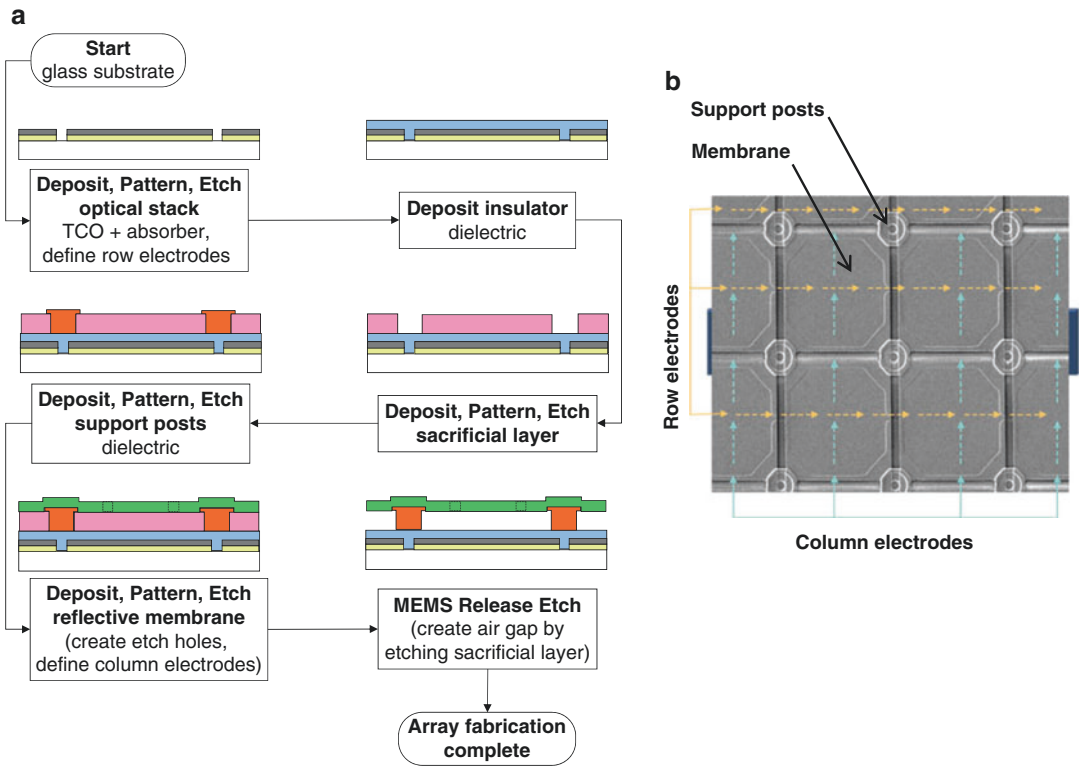
Material	Usage
Al alloys (AlNd, AlSi, AlCu, etc.)	Gate metal, gate bus line
Ta, MoW, MoCr, Mo	Gate metal
ITO	Transparent pixel electrode
SiO_2, SiN_X	Passivation, gate dielectric
a-Si, p-Si	TFT channel

dither artifacts while still maintaining a reasonably high fill factor. Device sizes ranging from 30 to 60 μm are typically used for high-resolution displays.

Future generations of the mirasol display technology may use multistate or analog control of the air gap. This allows each IMOD to reach a larger range of colors from the color spiral shown in Fig. 3b having varied color saturation and including a natively bright white state. The ability of generating all colors with a single IMOD device not only allows better color gamut, but also fundamental improvements to the overall brightness of the display [18, 19].

IMOD Device Materials Science and Processing Fundamentals

The development of direct-view display applications of the IMOD technology has been shaped by a defining decision to leverage the set of materials and processes available in flat panel display factories in order to enable a scalable and cost-effective manufacturing platform [20]. Currently in production on G4.5 (730 × 920 mm) glass substrates, mirasol displays represent a significant development in the MEMS industry that has been traditionally based on smaller size silicon wafers. As a result of this strategy, the production IMOD MEMS device architectures had to be adapted to fit the capabilities and constraints of TFT LCD type fabrication infrastructure (Fig. 6).



In this section, materials and processing aspects involved in fabricating the IMOD MEMS array glass panel are examined. The remaining steps toward producing finished mirasol displays are then described.

Basic Pixel Materials and Process Flow

The fabrication of the IMOD MEMS pixel is based on surface-micromachining of materials and process steps largely common to TFT array fabrication: large area deposition (Plasma-Enhanced Chemical Vapor Deposition (PECVD), sputter, etc.), photolithographic patterning, and etching (dry, wet) of dielectric and metallic layers [21]. In addition, MEMS-specific processes include forming the air gap below the moveable membrane, which is accomplished by depositing a sacrificial layer that is later etched out through appropriately designed openings in the membrane. Typical thickness of the films in the IMOD layers ranges from a several nanometers to submicron dimensions (Table 1).

A simplified process flow for IMOD pixel fabrication is shown in Fig. 7.

While there are significant similarities to standard processes used in TFT array manufacturing, a number of additional controls and optimizations are needed in order to ensure that the resulting MEMS device meets the desired operational and reliability specifications. Given the electro-opto-mechanical nature of the IMOD device, it is not surprising that additional attention is dedicated to engineering the combined optical, electrical, mechanical, and surface properties of the various layers forming the device. Some examples include the residual stress of the moveable membrane, the surface energy and topography of the surfaces on each side of the air gap [22], and the refractive index of each of the layers in the optical path [23].

M

Packaging

The next step in mirasol display module manufacturing is the display panel fabrication. mirasol display panels are made by encapsulating the array glass with a back glass in order to protect the MEMS structures against physical damage or environment contamination (Fig. 8).

As with the pixel array fabrication, the mirasol strategy for packaging is also based on leveraging the scalable, high volume solutions that have been developed for the FPD industry. IMOD pixel array glass encapsulation is done at G4.5 plate level by using a back glass substrate (item 2 in Fig. 8), followed by singulation of the glass bi-layer to yield the individual display panels. The characteristics of the environment inside the panel package need to be controlled in order to meet the device lifetime requirements for mobile display applications. Typically, the seal is formed by using thin curable polymeric layers, with the package being at near atmospheric pressure and

MEMS Display Based on Interferometric Modulation Technology, Fig. 8 Typical mirasol display panel structure: *1* IMOD pixel array substrate, *2* glass backplate, *3* seal layer, *4* routing, and pads for display driver attachment

including a desiccant designed to have a moisture capture capacity sufficient for the display lifetime. It should also be noted that vacuum encapsulation is not required as in other traditional MEMS devices, since the pixel response time is already

very fast for display applications as discussed in the previous section.

mirasol Display Fabrication

The fully finished mirasol display product is assembled from a number of components that complement the mirasol display panel. The intrinsic attributes of IMOD technology that eliminate the need for using traditional display components such as polarizers, color filters, etc., also reduce the complexity of basic mirasol display module architectures.

As described in Table 2, at minimum, the display panel needs to be integrated with the driver chip and connected to the display interface. In practice, depending on the particular requirements for the display product, additional components are integrated within the module – optical diffusion layers to manage reflective view angle, touch panels for enabling advanced user interactions, internal light sources (front light) to enable use of the display in dark ambient conditions, and a cover lens.

Comparison to Other MEMS Display Technologies

There are several other MEMS-based display technologies, some of them can already be found in products, others are still in the development phase. They can be grouped into two broad categories, projection type displays and direct-view displays. Most existing MEMS displays fall under the projection type. They typically utilize a single micromirror or an array of MEMS mirrors to modulate light from a powerful RGB light source and hence create an image.

Texas Instruments has pioneered digital micromirror device (or DMD) which forms a core element for their digital light processing (DLP) projection display technology [24, 25]. DMD is composed of an array of MEMS mirrors on the order of 10 μm each fabricated on top of CMOS SRAM cells. Each alloy mirror made of an aluminum alloy is mounted on a yoke which is connected to two support posts by hinges. SRAM controls mirror position from flat to tilted by about 10–15°. DMD is a binary device. In one state, light from the source is reflected into the lens making the pixel appear bright on the screen. In the other state, the light is directed onto a mask which also acts as a heat sink. As a result, the pixel and its screen image appear dark. RGB color wheel is used to generate color images. Current DMD devices demonstrate billions on cycles of MEMS operation and can reliably operate in a variety of consumer products (DLP projectors, large screen projection TVs, pico-projectors for portable devices) [25].

Projection type moving/scanning mirror devices are also developed by Microvision [26] and Fraunhofer Institute [27, 28]. Both technologies exploit laser sources. In the heart of Microvision's silicon MEMS device, there is a scanning mirror connected to flexures. The MEMS scanner oscillates in two directions in order to display an image on a projection screen, pixel-by-pixel. Fraunhofer Institute approach is based on a two degrees-of-freedom MEMS resonator which can be used for horizontal deflection of the laser beam in a projection display system. The device consists of a circularly shaped silicon plate suspended by beams in the center of an elastically suspended driving plate. The moving part of the device forms two mechanically coupled resonators. The inner resonator acts as a moving mirror and the outer resonator drives this mechanical system. In a 1D implementation, both devices can be used as scanners.

The grating light valve (GLV) technology originally proposed at Stanford University [29, 30] and then further developed by Silicon Light Machines start-up [31] is based on light diffraction optics. It is a projection-based technology which operates using dynamically adjustable diffraction gratings. The GLV technology is built using silicon surface micromachining. The core element of the device consists of parallel rows of

MEMS Display Based on Interferometric Modulation Technology, Fig. 9 Photograph of a 5.7″ diagonal color mirasol display (1024 × 768 pixel resolution)

highly reflective micro-ribbons suspended above an air gap. Alternate ribbons can be actuated by applying voltage. When all ribbons are undeflected, the device acts as a mirror. When the ribbons are deflected toward the substrate and the deflection is one quarter wavelength, diffraction effects occur and incident light is reflected at a different angle. It is worthwhile to note that GLV devices are very fast with a switching speed in the nanoseconds range. Another attractive feature is that it is a contactless MEMS device which, in turn, enables robust design for reliability.

Pixtronix's digital microshutter technology targets direct-view transmissive display applications [32]. It is based on several key components: (1) MEMS module, (2) TFT backplane (similar to TFT arrays used in LCD display manufacturing), (3) backlight (optical train) plane with RGB light sources, and (4) field sequential color generation. The MEMS module includes high-speed (less than 100 μs) shutters that operate in a binary (open or closed) fashion and hence module light transmitting from the backlight plane.

Compared to above optical MEMS, mirasol distinguishes itself as a direct-view reflective display technology based on low-voltage capacitive MEMS arrays and interferometric color generation. These basic device and design principles enable low-power operations and consistent viewing quality in a variety ambient light conditions including direct sunlight.

Summary

mirasol, a new technology that mimics the way nature generates bright color by interferometric modulation, enables a new type of low-power reflective displays for portable applications with a consistent viewing experience under a wide range of ambient lighting conditions including bright sunlight [7, 8]. Interferometric modulation, which can produce color by "recycling" light from the ambient, is used in a novel display pixel architecture based on microelectromechanical devices. This unique combination of color reflection, low-voltage switching MEMS, and bi-stable pixel architectures enables a low-power consumption superior to existing conventional display technologies. Qualcomm MEMS Technologies [7] develops and commercializes mirasol displays covering the whole technology and product development cycle from early phases of research all the way to module manufacturing, with the first product introduced to the marketplace in 2008. The technology is particularly attractive for mobile devices including e-reader applications (Fig. 9). Current research activities center around new pixel architectures and materials with enhanced

display performance, innovations in the array addressing, and low-cost component research, such as the front light technology.

Definition

In the semiconductor production process, probe card is an important tool that examines whether the IC components are functioning properly before package. The IC components that do not meet the specifications will be eliminated after wafer cuts into individual chips. Probing ICs while they are still on the wafer normally requires that contact be made between the automatic test equipment (ATE) and IC. This contact is usually made with some form of mechanical probe. A set of mechanical probes will often be arranged together on a probe card, which is attached to the wafer prober. The wafer is lifted by the wafer prober until metal pads on one or more ICs on the wafer make physical contact with the probes. A certain amount of overdrive is required after the first probe makes contact with the wafer, for two reasons:

1. To guarantee that all probes have made contact (to account for non-planarity of the wafer and the probe tips).
2. To break through the thin oxidized layer (if the metal pad is aluminum) on the pad.

There are numerous types of mechanical probes available commercially: Their shape can be in the form of a cantilever, spring, or membrane, and they can be bent into shape, stamped, or made by microelectromechanical systems (MEMS) processing. Historically, probe card has evolved from cantilever type (1960), vertical type (1970), membrane type (1980), and micro-spring type (1990) to present MEMS probe card (2000∼). The evolution indicates the traditional mechanical processing methods cannot cope with the amount of I/O pad for current semiconductor IC. Only the development of near-mature MEMS technology can produce high-density probe card and even ultra high-density probe card.

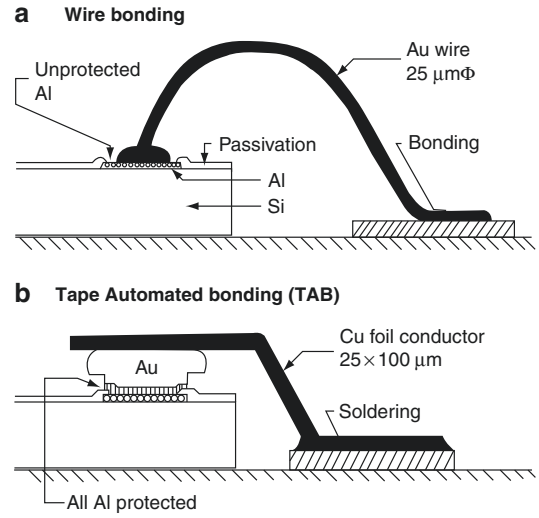
Introduction

Under the trend of VLSI (ULSI), the volume of semiconductor transistor become smaller, that enhances the density of the components of integrated circuit (IC). But the technology of producing semiconductor encounters many new challenges as the volume of integrated circuit shrinks. In addition, the rapid development of electronic products requires all types of electronic products to be small, light, multifunctional, and fast. Thus, the trend of the integrated circuit will continue to set goal in developing higher density integrated products.

In recent years, the technology of developing of high-density semiconductor has been from submicron (submicro) technology to nanometer

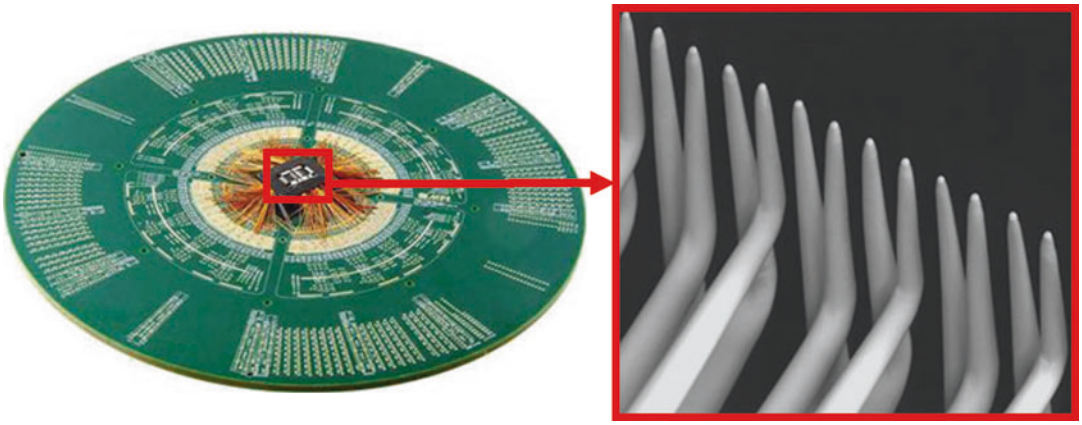
(nano) system regulation. The pin count for I/O for semiconductor of IC has become more and more, the density has become higher, and the speed has become faster; similarly, the pin count of package's components has increased accordingly. Under the area limit, high-density integrated circuit must cope with pin count of high-density I/O; thus, traditional chips are packed with plastic or ceramic material and wire bonding to lead frame package do not meet the requirements. The structure of IC's pad has changed from peripheral arrangement to matrix arrangement or even 3-D IC stacking arrangement. The matrix type of arrangement of package can be completed through the technology of flip chip of ball matrix type arrangement, which is characterized by I/O pad using preimplantation solder ball through reflow to directly bond with substrates. This can shorten the connection path but also enhance the electrical transmission speed, and the packaging technology can meet current and future demand for electronic products.

In early period, the lead frame or flip-chip packaging methods have been continuously used for a long time. Previously, the wafer must be cut to be individual, which is integrated circuit (or bare die). The function of the probe card is to examine the features of the chips, and to filter out defective products; therefore, it can avoid completing the package steps of defective products, which might lead to additional costs and waste. In addition, the I/O pad of integrated circuits has been switched from peripheral arrangement to matrix arrangement in order to achieve the objective of higher density. The higher density and quantity of the pads has substantially increased the difficulties in examining ICs.



Traditional cantilever probe card has not been able to meet the testing conditions; thus, the development has shifted to probe card with matrix arrangement or the so-called vertical probe card. However, the capacity of bumping is expanding more than 25 % of compound annual growth rate as the technology of flip chips have been used widely. It is expected that there will be rapid growth on demand of integrated high-frequency matrix probe card.

Probe Cards for Peripheral Pads



Conventional Packaging Technology

Wire bonding is the primary method of making interconnections between an integrated circuit (IC) die and a lead frame or a printed circuit board (PCB) during semiconductor device fabrication (Fig. 1a) [1]. Although less common, wire bonding can be used to connect an IC to other electronics or to connect from one PCB to another. Wire bonding is generally considered the most cost-effective and flexible interconnect technology, and is used to assemble the vast majority of semiconductor packages. Bond wires usually consist of one of the following materials: aluminum, gold, and copper. There are two main classes of wire bonding: ball bonding and wedge bonding.

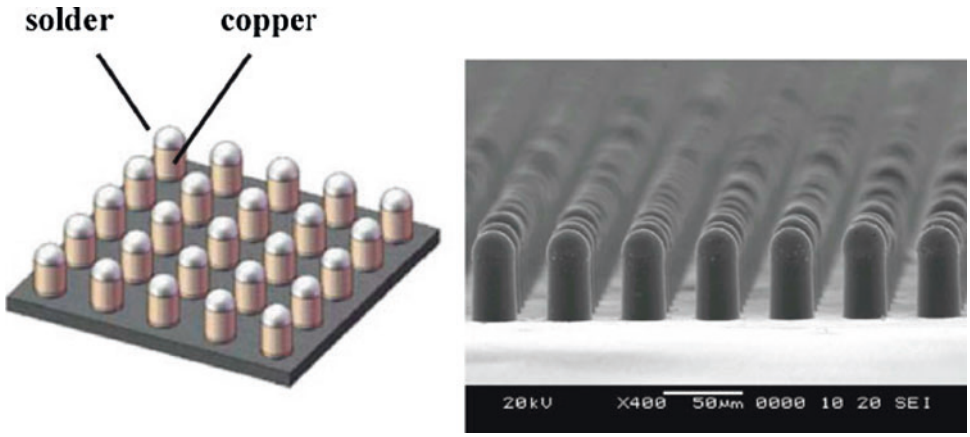
Tape-automated bonding (TAB) is a process that places bare integrated circuits onto a printed circuit board (PCB) by attaching them to a polyamide or polyimide film (Fig. 1b) [1]. The mounting is done such that the bonding sites of the die, usually in the form of bumps or balls made of gold or solder, are connected to fine conductors on the tape, which provide the means of connecting the die to the package or directly to external circuits. Historically, TAB was created as an alternative to

MEMS High-Density Probe Cards, Fig. 1 Schematic of wire bonding and tape-automated bonding. [1]

MEMS High-Density Probe Cards, Fig. 2 Schematic of epoxy ring probe card [2]

wire bonding and finds common use by manufacturers in LCD display driver circuits.

Testing Technology for Peripherial Probe Pads



The epoxy ring probe card, chronically the industry standard for probing silicon wafers which include memory, RF and logic devices with peripheral pads, continues to dominate as the principal interface between the wafer and the ATE (Automatic Testing Equipment). The epoxy ring probe card with cantilever needles has the merits of lower cost and easy maintenance. In the past year, probably the greatest concentration of effort has been focused upon the needle design and quality associated with achieving a tighter pitch. At present, the pad pitch achieves the level to 30–40 μm. Figure 2 shows the picture of an epoxy ring probe card [2].

As for the needle material, the addition of beryllium to copper increases its strength, resulting in tougher wire but maintaining conductivity close to copper. The corresponding force for the beryllium copper needle is 1.2–1.5 g per pin at 50 μm overdrive, achieving the object of an ultra-low-force probe card. A low resistance must be achieved by the contact area at the end of probe sliding.

Fabrication procedure of the epoxy ring probe card includes Mylar drilling, needle bending, components assembling, epoxy fastening, conducting wire welding, needle pin etching, and position adjustment. In the probe card functions test, in addition to the detection of electric characteristics, the contact force and the forward displacement of the needle tip are inspected, which are both important indices to maintain the probing quality. The length of scrub mark on the weld pad is decided by the forward displacement of the needle tip. Due to the structure of cantilever needle, the arrangement of multiple needle arrays is difficult to meet the requirement of IC with matrix pads without mutual interference or non-consistent geometrical and mechanical features for each needle.

Probe Cards for Matrix Pads

Wire bonding process only provides peripheral interconnect, making a finer pad size and higher I/O count impossible. Other limitations are lower throughput and higher parasitic components, which would result in high propagation delay [3]. In tape-automated bonding (TAB), copper (Cu) leads pattern on polymer tapes are used to connect bare chips and substrates. The advantage of TAB technique is that it could test and burn-in devices prior to assembly; that is, it permits to test for known good die (KGD), provides better electrical performance, and higher circuit density compared to wire bonding. The disadvantage of TAB is that it requires additional processes to bump devices or tapes and specially

MEMS High-Density Probe Cards, Fig. 3 Schematic of solder bump package

designed tapes for each die. Similar to wire bonding, TAB provides only peripheral interconnect [4]. As the demand for cheaper, smaller, faster, portable, and yet multi-featured electronic consumer devices or products increase, wide use of flip-chip bonding in high-density electronic packaging will become indispensable [4]. Accordingly probe cards for probing matrix pads of flip chips are necessary tools for guaranteeing known good die (KGD), especially further stack IC or 3-D IC package in the future.

Solder Bump Technology

Flip-chip bonding, in essence, utilizes an array of solder bumps varying in shapes, sizes, or materials, to serve as I/O count to connect with chips or substrates rather than employ traditional lead frames or gold wires as connecting devices. This innovative packaging process invented by IBM in the early 1960s is characterized by yielding smaller substrate size, larger number of I/O count, and less pitch size between each solder bump [7]. Figure 3 shows the high-density copper pillar bumps with pitch of 50 µm and diameter of 30 µm.

Other advantages provided by flip-chip bonding include better electrical performance, shorter interconnection length, lower inductance effect, better electromagnetic shielding effect, self-alignment ability, and lower cost [8–11].

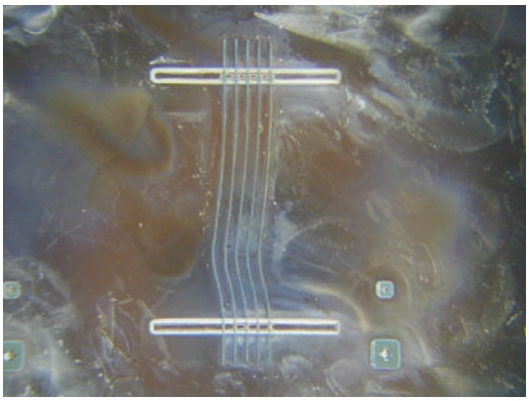
MEMS High-Density Probe Cards, Table 1 Comparison of three COB bonding processes

	Wire bonding	Tape-automated bonding	Flip-chip bonding
Area ratio	1	1.33	0.33
Weight ratio	1	0.25	0.2
Thickness ratio	1	0.67	0.52
Input/Output (Max)	300–500	500–700	>1,000
Rework	Superior	Inferior	Superior
Cost	×	>2×	0.8×

A detail comparison among wire bonding, tape-automated bonding, and flip-chip bonding is listed in Table 1.

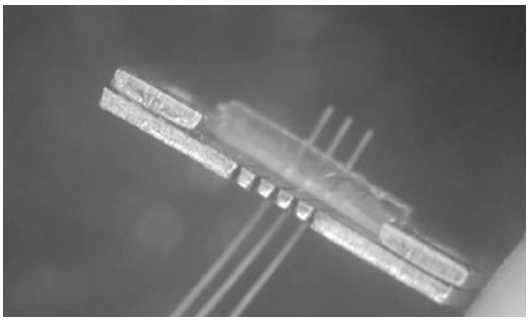
Vertical probe cards are indispensable for testing flip chip with matrix pads due to limited space of fine pitch among pads to accommodate too many horizontal cantilever probes. At present, FormFactor Company catches the largest market share in the probe card industry. In addition, a famous vertical probe, named as Cobra, invented by IBM was initiated in late 1970s for testing C4 (Controlled Collapse Chip Connection – which is also associated with flip-chip package) process base semiconductor devices.

MEMS Technology for Matrix Pads



Most of the traditional methods of vertical probe production are completed through punching or drawing; thus, it is not easy to control the radius of the curves of the probe. It is then followed up with assemble work which is particularly difficult to control its accuracy. The traditional probe card has the following disadvantages:

1. There is poor coplanarity of probes due to manual assembly, which causes defective contacts that lead to excessive contact resistance and even fail conduction.
2. It is not easy to adjust the accurate position of each probe; thus, it must go back to the factory for maintenance after every period of using time.



MEMS vertical probe card employs MEMS technology with electroforming alloy technology to produce spring-like probe, which enables the probe to have greater degree of compliance, and provides adequate vertical deformation (Fig. 4). For the purpose of convenience and alignment in the probe assembly process, a guide plate is indispensable (Fig. 5). The guide plate can be fabricated by using the lithography, electroforming, and DLC coating processes to complete the definition of perfect spacing between each guide hole. The insulated guide plate is then combined with the technology of packaging to produce high precision probe card. In this way, it can reduce complexity in the assembly process with accuracy at the same time.

Besides importing the technology of MEMS to produce probe card, it can also use the technology of CMOS-MEMS to design the probe's arrangement and force sensor. It can improve the issue of accuracy control for many traditional probe cards. The standard CMOS process, such as TSMC 0.35 um or 0.18 um process can provide flexibility of designing microstructure with diversification and low development cost. The main advantages are summarized in the following points:

1. The accuracy and the coplanarity can be improved by using the technology of multiple probe packaging [12, 13].

MEMS High-Density Probe Cards, Fig. 4 Schematic of packaged with the probe photoresist

MEMS High-Density Probe Cards, Fig. 5 Schematic of single row of the probe assembly to the guide

2. The FEA software used to analyze design can optimize overdrive and vertical press force to reduce contact resistance and horizontal force that scrub off oxide layer on the surface of the pad.
3. The planar or 2-D manufacturing process can produce long and thin probe with different width [12, 13].
4. Using lithography and the electroforming technology can enhance the capacity of batch production [14].
5. The multiple probe packaging with real-time detection of force sensor can decrease the recovering or repair time of probe, and reduce cost and labor [15–18].

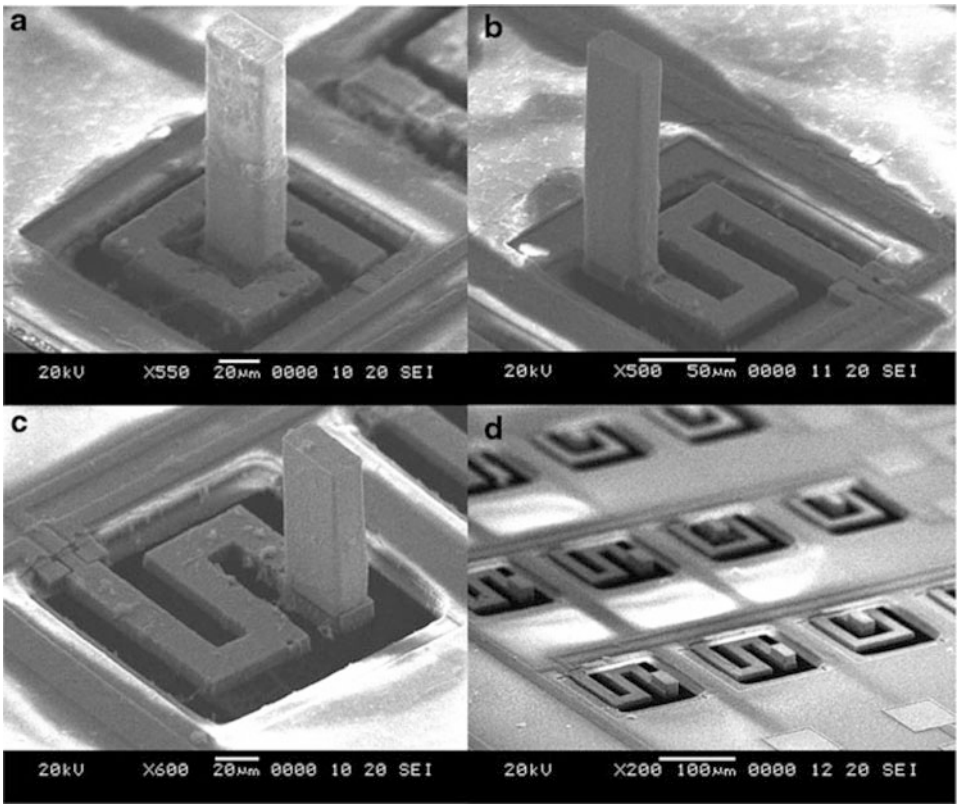
As the production of probe becomes smaller, it is very important to know the characteristic of the

probe to find out the maximum current and resistivity that a probe can withstand. Based on the study [12], the result after number of measurements was that the probe maximum current was between 700 and 850 mA and the resistance was 35 μΩ-cm or less. This probe composes of nickel cobalt alloy, and the result of EDX quantitative ratio analysis of components was Co 28 % and Ni 70 %. The nano-indentation system had evenly gathered ten testing points in the testing chip, which yielded Young's modulus of 180 GPa for nickel and cobalt alloys, and hardness of HV 450.

MEMS Probe Evolution

In 1995, Mark Beiley et al. have used thin film structure with importing gas as a way for the probe to apply force, in order to achieve the concept of reduction of contact resistance [19, 20]. In 1997 and 1999, Yanwei Zhang et al. have used technology of MEMS to produce circular form of bimetallic microprobe which is working as a thermal actuator [21, 22]. In 2000, Ito Takahiro et al. have used SOI wafer technology to produce probe with arch-shaped beam [23].

In 2000, Dong-Seok Lee et al. have also used SOI chip and bulk micromachining technology to produce microprobe structure that the probe tip could move up to 80 μm. In 2001, Robert B. Marcus et al. brought up a new technology, which was to utilize the residual stress of bimetallic (Cu, Cr) that worked with sacrificial layer etching, and then, after annealing treatment, it would produce a warping cantilever [24]. In 2002, Bong-Hwan Kim et al. used monocrystalline silicon (100) to produce structure of three-dimensional microprobes [25, 26]. In 2002, Kenichi Kataoka et al. used electroforming nickel process that worked with sacrificial layer etching and utilized residual stress to form a warping cantilever.



In 2003, Younghak Cho et al. used properties of anisotropic etching for KOH to etch an inverted triangle concave hole in the monocrystalline silicon, and then used deposition method to produce metal (Cr, W, Au) probe tip [27]. In 2004, K. Kataoka brought up electroformed multilayer film with three-dimensional S-shaped spring of microprobe arrangement [28]. In 2005, Si-Hyung Lee and Bruce C. Kim took advantages of two different residual stress relationships between BCB and Mo layers to produce a warp probe beam for wafer-level testing. [29]. In 2005, Young-Min Kim used KOH to etch silicon wafer and annealing process to produce microprobe [30].

In 2007, T. Namazu et al. used nickel titanium memory alloy to produce micro-actuator MEMS probe card [31]. In 2007, Seong-Hun Choe et al. used doping of P++ to silicon to make cantilever probe [32–34]. In 2008, Fei Wan et al. used wet etching and microelectroforming of nickel on a 4 in. wafer to provide 110,000 out-plane hoe-shaped probes for wafer-level IC testing [35–37]. Then all the probes were transferred onto the corresponding solder balls of the adaptor board. The contact force of the probe is 7.5 mN with deformation of 20 μm, the pitch of the probe is X-160 μm, Y-240 μm, and the contact resistance is 0.8 Ω.

In 2008, J. Liu et al. used the technology of CMOS process, MEMS etching, and microelectroforming of nickel to produce thermoelectric actuating cantilever probe [38]. The probe is to test the memory components, and has contact resistance of 10 Ω and the power consumption of 3.7 mW. In 2009, Fei Wang et al. used bulk micromachining technology as cantilever arm of the probe, while using the concept of TSV to produce tip of the probe [39–41]. It was used in wafer-level IC testing, of which the displacement was about 20–33 μm, the contacting force of 50–80 mN, contact resistance of 1 Ω. In 2009, Bong-Hwan Kim used bulk micromachining technology and electroformed nickel and cobalt alloy material to produce MEMS probe used in testing DRAM [42–45]. The probe had contacting force of 20 mN at deformation of 50 μm and resulted in contact resistance of 3.5 Ω.

Summary

The probe card produced by using CMOS process with MEMS process [46–49] has become indispensable testing components in the next generation of semiconductor (Fig. 6). It can be used in

MEMS High-Density Probe Cards, Fig. 6 SEM images of the CMOS-MEMS probe chip after ICP dry etching: (**a**) a 106-mm-tall probe tip with spiral cantilever, (**b**) a 106-mm-tall probe tip with meander cantilever, (**c**) a 42.4-mm-tall probe tip with spiral cantilever, and (**d**) the chip with a 14.8-mm-tall probe tip

the practice of high frequency, wafer-level testing, and batch of production, which can reduce the cost to meet the trend.

Regardless of how the semiconductor's technology evolve, the probe card produced by CMOS process with MEMS technology can work effectively with the IC pad size and space, especially the circuits are next to the back end of the probe, so it can reduce the transmission losses and noises. This is a technology to realize system integration on a chip (System On Chip), which cannot be reached with the traditional assembled probe.

Using CMOS technology not only significantly reduces the size of the probe, but it can also connect the external components with the circuit, which are integrated in the design of CMOS chip. Thus, it can increase the convenience of wiring that is the space transformer needed by the probe card, which can be achieved using the metallic layer in the CMOS process. The process is not only simple and without traditional assemble method, but also enhances yield rate; therefore, the cost can be significantly decreased. This will be a great support for the present and future generation of testing IC.

While the IC designer implements the IC's layout, he may also provide with the circuit layout that is required for testing IC based on the technology of the built-in testing circuits on the CMOS-MEMS probe card. These can be processes together to save cost and accelerate time for product launch at market in order to achieve ultimate technology in "Using IC to test IC." Especially when the pilot run is completed for mass production, the use of CMOS-MEMS probe card can accelerate time on product to be in the market.

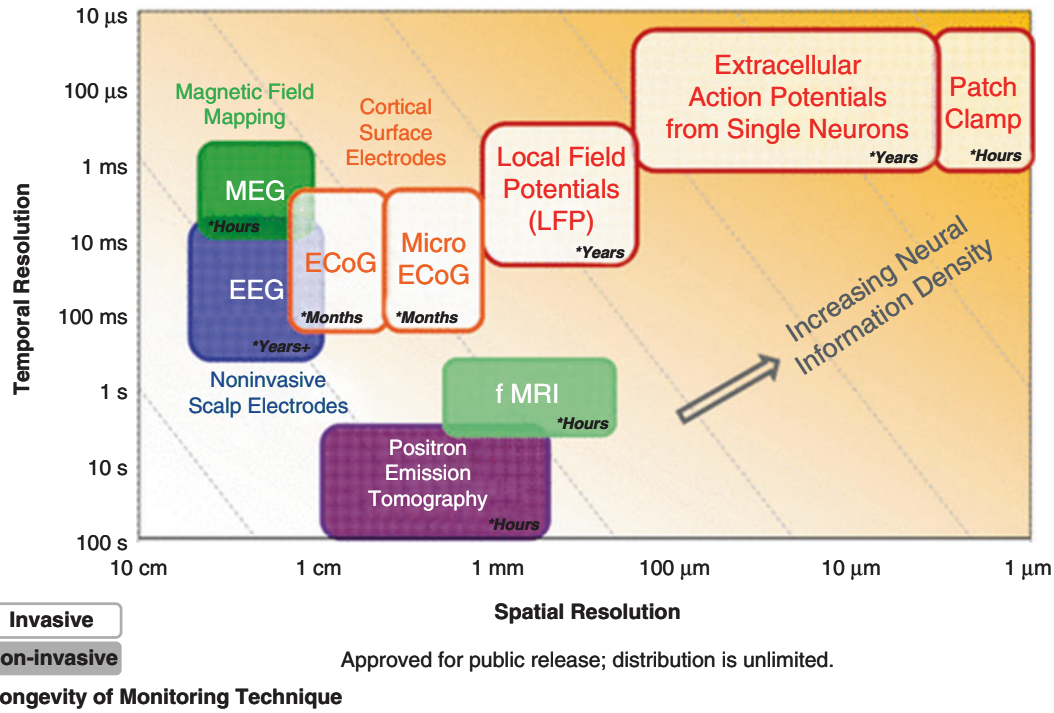
Definitions



MEMS neural probes are microscale implants for the brain or peripheral nervous system that use

micro-electromechanical systems to assess function or stimulate activity in specific regions of the brain, ensembles of neurons, or neuronal fibers.

Brain Monitoring Technologies

Hypotheses regarding brain function or dysfunction are generally verified and confirmed using accurate measurements of brain activity at different scales – from whole brain regions to single cells or neurons and subcellular structures such as synapses, ion channels, etc. Such measurements are made using a variety of different techniques each with their own spatial and temporal resolution. The technologies are generally invasive or noninvasive; the noninvasive technologies include a whole spectrum of imaging modalities as illustrated in Fig. 1, electroencephalograms (EEG) from the scalp, etc.

The invasive technologies typically involve electrodes placed either on the brain (such as in electrocorticogram or ECoG) or microelectrodes implanted in specific brain regions of interest for obtaining electrical activity from the brain. This may be in the form of field potentials from ensembles of neurons or from extracellular action potentials of single or a few neurons in the vicinity of the microelectrode. Generally, electrical activity from single neurons has been a preferred currency for testing hypotheses about brain function. Over the last 10 years, exciting applications such as cortical prostheses have also been developed using electrical activity from single neurons in motor and premotor cortices of the brain. Success in this effort will lead to wider application of this theme in other brain prosthetic applications such as memory and cognitive prostheses. Neural probes of different kinds have been developed for a variety of applications such as electrical stimulation of specific neurons in deep brain stimulation (DBS) therapy, monitoring neurotransmitters and other neurochemicals, and delivering drugs. However, currently

MEMS Neural Probes, Fig. 1 Illustration of the spatio-temporal resolution of current brain monitoring technologies (Courtesy: Jack Judy, program manager, DARPA (MTO), approved for public release; distribution is unlimited)

micro-electromechanical systems (MEMS)-based technologies are primarily used for monitoring electrical activity from single neurons in mainstream research and emerging prosthetic technologies. Therefore, this chapter here will focus on neural probes used for monitoring the electrical activity of single neurons.

Implantable technologies to monitor electrical activity from single neurons have existed for over six decades. The earliest single neuronal recordings consisted of manually fabricated glass micropipettes that tapered down to few microns at one end. These pipettes were backfilled with electrolytes and a conducting wire was inserted. The tapered end was stereotactically positioned in the brain after a craniotomy in the vicinity of neurons of interest. They were initially used to record intracellular membrane potential changes [1, 2]. Insulated tungsten or platinum microelectrodes were used for recording extracellular activity [3, 4]. One of the first attempts to use such cumbersome manual approaches to obtain long-term recordings from animals was Strumwasser's bold effort in 1958 [5] to record activity of specific neurons in hibernating California ground squirrels. This was followed by several decades during which bundles of metal microwires in different configurations were manually assembled along with interconnects to record from ensembles of single neurons in the brain. The microwires were insulated along the length and the insulation at the tip of the microelectrode was etched a few tens of microns to allow an electrical interface with single neurons. The length (and consequently the electrical impedance) of the uninsulated tip or the size of the recording site determined the number of neurons that would be recorded. Microelectrodes developed using MEMS-based approaches have been a relatively recent development and have significantly evolved in complexity over the last 25 years. The development of the first neural probe using microfabrication technologies in 1970 [6] demonstrated the promise of MEMS-based systems to make neural probes more usable for uninitiated researchers. Using a manufacturing process that readily allowed batch fabrication, they dramatically improved scalability in terms of number of neurons that could be recorded and allowed possibilities for integrating multiple functionalities. Previously interconnects were manually soldered or glued. MEMS technology improved interconnect reliability. It also significantly reduced the overall form factor, which allowed animals to behave naturally.

General Features of Neural Probes

An individual neural probe must be slender (tens to hundreds of micrometers in diameter or in cross-sectional dimensions) and several millimeters long. This will allow interrogation of neurons in the cortical and deep brain structures while minimizing trauma and displacement of brain tissue during penetration and eventual implantation. Multiple probes are often integrated to form arrays of neural probes. Some studies [7, 8] have suggested that slender probes with smaller cross-sectional areas significantly decrease the reactive response of the brain tissue to the foreign body implant. However, the lower limit for slenderness appears to be that which will allow for successful penetration without bending or buckling of the probe. In addition, a smooth tapered probe is generally preferred to minimize dimpling of the meningeal layers such as the dura mater during penetration. However, the likelihood of such tissue dimpling is also dependent on the velocity of penetration and on the number of probes constituting an array. Therefore, design of the mechanical structure of the neural probe is constrained by requirements such as minimal tissue response, adequate stiffness for penetration, minimal brain tissue dimpling during penetration, etc.

One of the features of a probe used for recording from single neurons is the presence of one or more recording sites along the length of a probe. To ensure recording from one neuron or a few selected neurons, the recording sites are of similar geometrical scale as the neuronal cell bodies, which are typically 10–20 μm in diameter in the mammalian brain. Ion exchange across the cell membrane during a neuronal action potential results in current flow. The current flow in a volume conductor results in lines of electrical field intensities and spatial potential gradients being

established in the extracellular space. Microelectrodes in the extracellular space therefore register the spatial potentials (typically less than 1 mV) at any given point. The interface between the recording site (typically made of metals like platinum, platinum/iridium, gold, and also sometimes doped polysilicon) and the surrounding ion-rich extracellular media usually determines the overall electrical impedance of the probe. This impedance is with respect to a reference electrode remotely placed on or in the brain, or on the neck muscles depending on the application and the type of recording desired. The interface impedance is largely capacitive due to the spontaneous formation of an ionic double layer on the probe recording site surface upon insertion. However, faradic reactions take place at the recording site and give rise to a parallel pathway for charge transfer. This can be modeled as a resistive pathway in parallel to the double-layer capacitance.

Given the above general mechanical and electrical features of neural probes, two broad classes of MEMS micromachining techniques have been used successfully to fabricate slender neural probes and arrays of neural probes out of silicon wafers. These are bulk micromachining and surface micromachining. Silicon has been a preferred substrate material for a variety of reasons: (a) well-established micromachining methods, tools, and recipes are readily available, (b) silicon lends itself readily to subsequent integration of circuitry and other functionalities, (c) silicon has been shown to be nonreactive or inert as an implant material [9], eliciting minimal foreign body response. Directional, material, and dopant-dependent selectivity of anisotropic etching is used in both of the above classes to machine microscale mechanical structures in the form of slender neural probes. Besides these classes, MEMS neural probes have also been fabricated out of nonconductive polymers spun-coat on micromachined silicon or from metal molds. A wide variety of MEMS neural probes have been developed and tested. A few representative technologies that are broadly distinct and have been tested in long-term animal experiments are described here.

Bulk Micromachining of MEMS Neural Probes

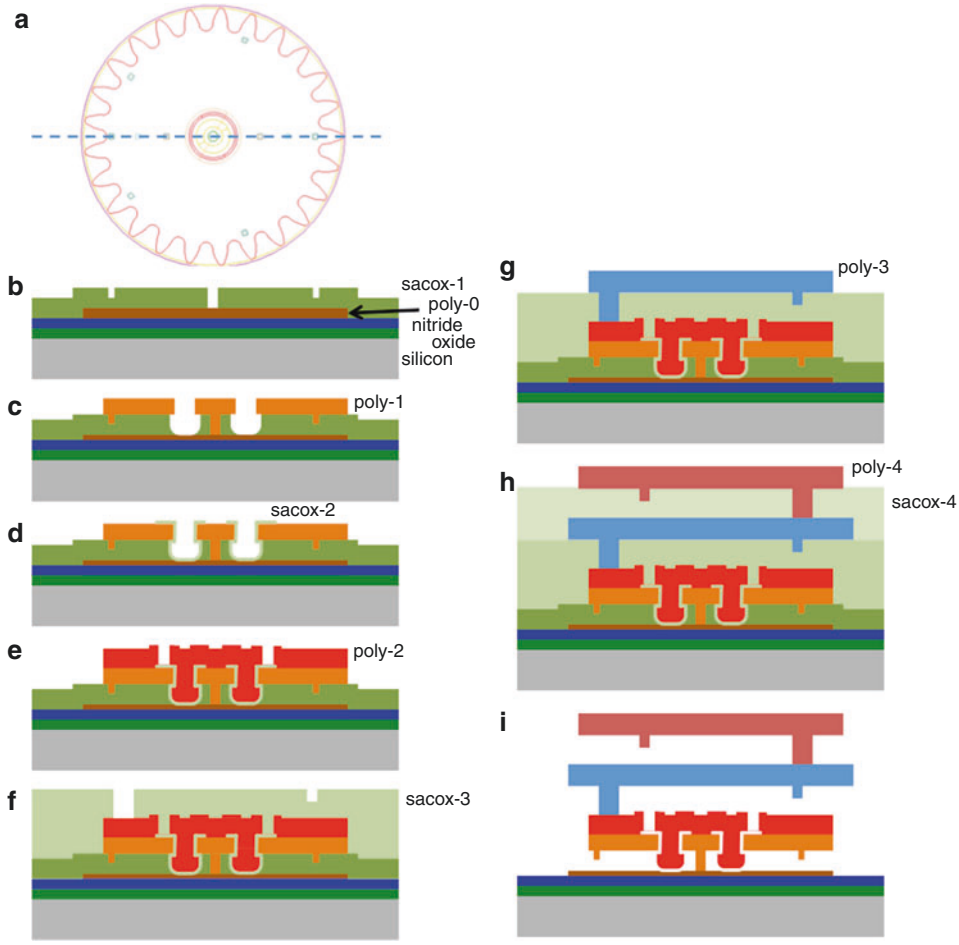
The first MEMS-based neural probes were microscale shanks of silicon with metal recording sites along the length [10]. They were fabricated by bulk micromachining of silicon using anisotropic etching techniques. A boron-doped silicon substrate acted as an etch-stop and shanks of silicon 8–15 μm in thickness, 75–100 μm in width at the base that narrowed down to 25 μm and 1.5–3 mm length were machined in the initial versions. Each shank was capable of hosting multiple recording sites of gold with polysilicon or tantalum conductors. Currently these probes are fabricated and distributed by Neuronexus Inc., Ann Arbor, MI.

Another widely used silicon MEMS technology using bulk micromachining is a 3-D array of 10×10 microelectrodes that was first reported in 1991 by the University of Utah [11]. Aluminum (5 μm thick) was deposited on the polished surface of silicon wafers (1.7 mm thick) and then patterned into squares (325 μm sides and 400 μm separation between the centers of adjacent squares). A temperature gradient between the two sides of the wafers created a thermal migration of the eutectic droplets of aluminum and silicon with silicon recrystallizing behind the eutectic droplet trail. The net result was the creation of highly conductive trails of doped (p+) silicon within the bulk silicon wafer. Chemical and mechanical polishing of the wafer resulted in pillars of p+ doped silicon (approximately 1.5 mm long) isolated from its immediate neighbors by back-to-back p-n junctions that provided the isolation. The pillar tips were finally coated with platinum and insulated with polyimide after establishing interconnects at the back end. Bulk micromachining approaches have also been used successfully with other materials such as ceramic and diamond.

Surface Micromachining of MEMS Neural Probes

Surface micromachining allows the fabrication of neural probes that are generally thinner (2–5 μm

thick) than typical bulk micromachined probes (>8–15 μm thick). There is no evidence yet that a reduction in one of the dimensions of the neural probes leads to an improvement in performance. However, a significant reduction in the cross-sectional area of the neural probe has been shown to significantly improve the inflammatory and foreign body reaction of the tissue immediately surrounding the neural probe [7, 8]. There are other significant and unique advantages of surface micromachining over bulk micromachining such as the ability to integrate (a) complex mechanical structures such as microactuators, gears, etc. on the same die and (b) signal conditioning and control circuitry to significantly enhance the functionality of neural probes.



Complex mechanical structures such as microactuators and gears can potentially enhance the reliability and functionality of the neural probe in the development of autonomous neural probes. These are capable of adapting their position in the brain to compensate for any change in the quality of neuronal signal being recorded [12]. Such movable neural probes enhance the ability (a) to obtain well-isolated and stable single neuronal activity with high signal-to-noise ratio over longer durations, (b) to carefully and unambiguously monitor changes in the underlying neurobiology, (c) to monitor neurons and neuronal tracts of specific functional interest, and (d) potentially to enhance the reliability of brain prosthetic devices that require reliable operation over a life of the patient.

Innovative approaches have been used to develop neural probes using surface micromachining process. One involved the fabrication of a 3D array of polyimide pillars (1.5 mm long) with metal (Titanium on Aluminum) traces for three recording sites on each pillar, as opposed to the single recording site that was found in the Utah microelectrode array [13]. Polyimide film (10 μm) was spun coat over a 5 μm-thick film of Nickel electrodeposited on silicon. Nickel acted as a backing metal for the polyimide film. After patterning the metal interconnects and recording sites on the polyimide film, a second layer of polyimide (also 10 μm) was spun coat on top. Finally, and most interestingly, an externally applied magnetic field was used to lift the nickel backing layer and along with it the polyimide films. Similar surface micromachining approaches have been used to fabricate slender neural probes from other polymers such as benzocyclobutene (BCB).

One of the key challenges in using surface micromachining approaches to fabricate neural probes is to ensure that there be no residual stress in the thin films that constitute the substrate of the neural probe. Simultaneously, the thin films will also need sufficient stiffness to penetrate the outer meningeal layers and the brain itself and travel through the brain tissue without significant bending, buckling, or breaking. The five-layer polysilicon SUMMiTV^{TM} (*S*andia's *u*ltraplanar *m*ultilayer *m*icromachining *t*echnology) process of Sandia National laboratories, Albuquerque, NM, has been extremely useful in fabricating complex, surface micromachined, movable neural probes, and have been tested successfully in long-term animal experiments. Details of this process are explained in the remaining sections of this essay.

SUMMiT^{TM} Surface Micromachining Process

A brief summary of the SUMMiT process flow is presented here; more detailed process description can be found elsewhere [14]. An example of a multilayer mechanical structure that can be formed in this process is shown in Fig. 2a, a gear with close-tolerance hub and four mechanical layers. SUMMiT surface micromachining process is carried out on 150 mm, (100), 2–20 Ω.cm, *n*-type silicon wafers. First steps are a thermal oxidation (0.6 μm) and low-stress silicon nitride deposition (low-pressure chemical vapor deposition – LPCVD, 0.8 μm), which form the insulating stack for the following process steps. An etch through the insulating stack allows electrical connection between polysilicon layers and the substrate. First polysilicon layer (poly-0) deposited by LPCVD is 0.3 μm thick; this layer usually serves as a ground plane, mechanical anchor, electrostatic shield, and part of the

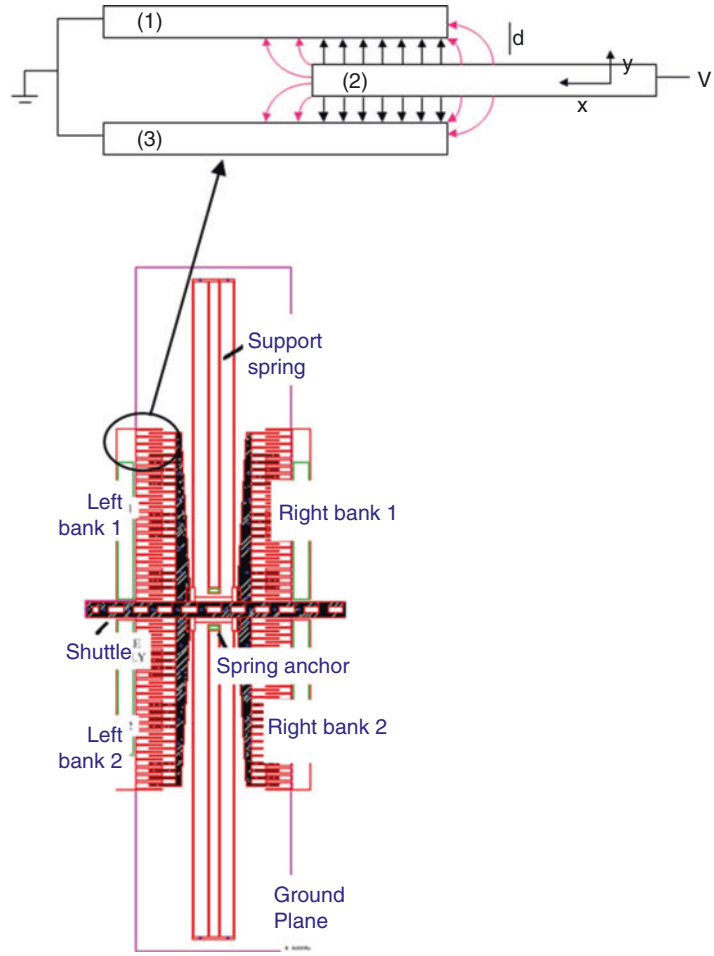
MEMS Neural Probes, Fig. 2 Plan view and cross section of multi-layer gear illustrating the process technology sequence for fabrication

electrical interconnect. All of the polysilicon layers in the process flow are heavily *n*-type doped, providing the required electrical conductivity.

Next layer is a 2 μm LPCVD sacrificial oxide layer (sacox-1). Two separate etch steps form the features for mechanical anchors, which are also electrical connections and dimples (Fig. 2b). The partial etch of oxide allows the dimples to be formed in the following polysilicon layer. This helps in preventing stiction by allowing relatively small areas to come into contact rather than the full surfaces that might be available in the structures. The following polysilicon layer (poly1) deposited by LPCVD is 1 μm thick. Mechanical features in this layer can be defined by lithography and etching at this step or also by a following etch after the next polysilicon layer, which generates features that are a laminate of the two layers. Close tolerances needed for forming hubs, captive mechanical features, sliding seals, and pressure/flow sections are formed by deposition and patterning of a conformal, thin (0.5 μm) silicon dioxide layer (sacox-2) after an isotropic oxide etch through lithographically defined and etched regions in poly-1 (Fig. 2c–d). Poly-2 layer (1.5 μm) is then deposited and patterned. In areas where sacox-2 was remaining, a close-fitting and mechanically free linkage is formed between poly-1 and poly-2 layers (Fig. 2e). Sacox-3 is then deposited and chemimechanically polished (CMP) which removes the topography that was a result of the

preceding etch and deposition steps. The final thickness of sacox-3 above poly-2 is 2 μm. The dimple and anchor etch steps prepare the dimples and mechanical connections between poly-3 and poly-2 (Fig. 2f). Poly-3 is then deposited (2.25 μm) and patterned (Fig. 2g). Following oxide layer (sacox-4) is deposited by LPCVD and planarized with a CMP step to a thickness of 2 μm above poly-3. After the dimple and anchor etch steps, final mechanical polysilicon layer (poly-4, 2.25 μm) is deposited and patterned (Fig. 2h). An aluminum metallization layer is the last layer that is deposited and patterned on poly-4 features to enable wire-bonding and low-resistance electrical connections. The release step is performed in an HF containing chemistry to remove all sacrificial oxide layers while preserving the polysilicon and metal features (Fig. 2i). In order to prevent stiction, a supercritical CO_2 drying step is used following the release etch to displace all liquids between layers without exposure to a gas-liquid interface. The release can be performed at die level or as full wafers, depending on the design and application requirements.

Further modifications of the SUMMiT process are also available, such as SwIFT [15, 16] and SFET [17, 18]. SwIFT process adds two silicon nitride layers (0.3 μm thick nitride-1 on poly-0 and 0.8 μm thick nitiride-2 below poly-3), a deep oxide cut (from poly-3 to poly-0, filled with nitride-2), and Bosch etch through the substrate to enable the creation of insulator-lined microfluidic channels, fluidic connections, and other novel features. SFET integrates NMOS transistors in the silicon substrate, which allows pre-amps and addressing circuitry to be fabricated for signal conditioning and dense-matrix addressing.

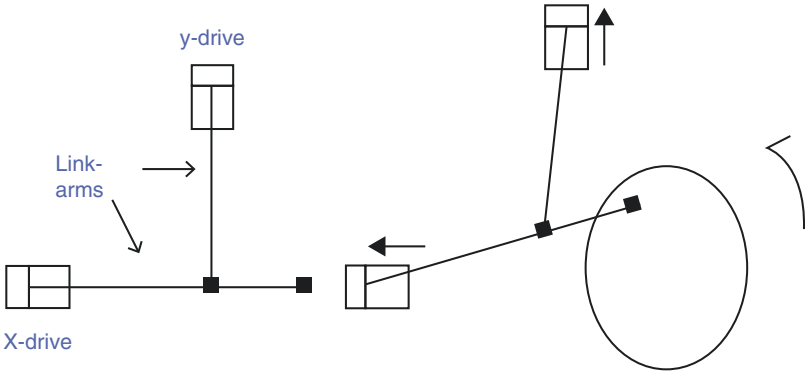


The neural probe in the form of a long, slender beam of doped ($10^{21}/cm^3$) polysilicon 7 mm long, 50 μm wide and approximately 5 μm thick is defined in the poly-1, poly-2, poly-3, and poly-4 layers of the SuMMITV™ process. Interestingly, the nonlinear I-V characteristics of doped polysilicon has an inflection point in the same range of voltages that typically separate noise signal amplitudes (10–30 μV peak-to-peak) from action-potential signal amplitudes (typically >100 μV) [14]. The above property, remarkably, results in selective suppression of noise when recording extracellular potentials from the brain [14]. The polysilicon neural probe has been demonstrated to produce significantly higher signal-to-noise ratios compared to commonly used tungsten neural probes.

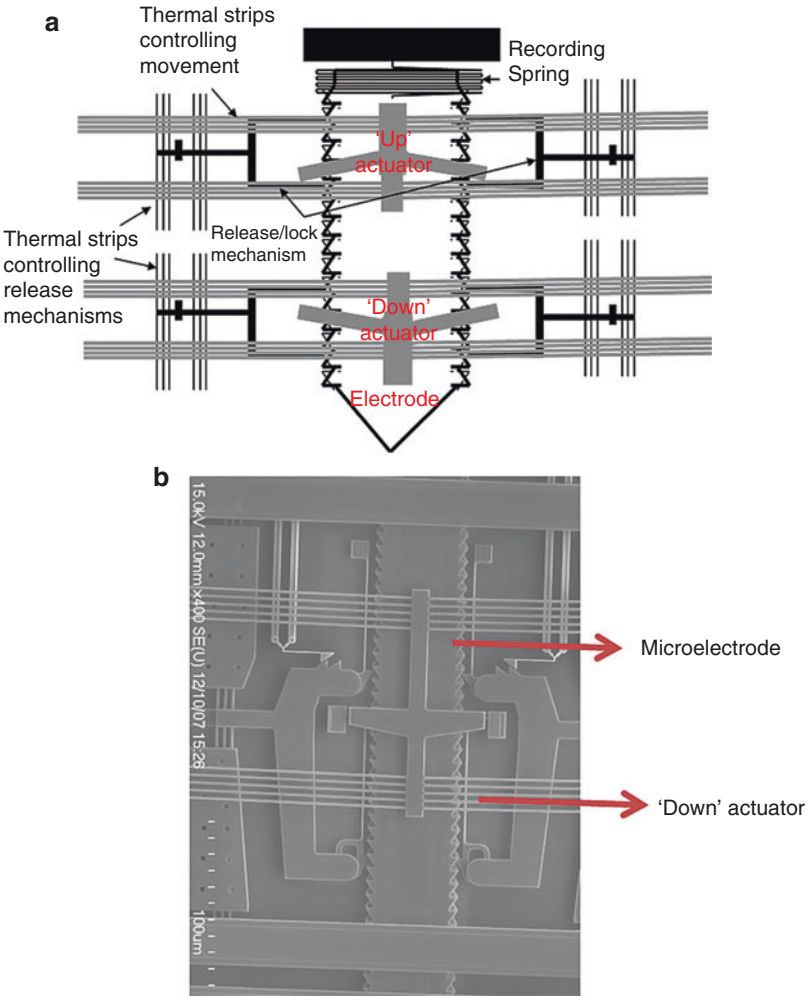
MEMS Neural Probes with Electrostatic Microactuators

Integrated electrostatic microactuators have been developed for moving neural probes in the brain using comb drives. Electrostatic forces due to a fringing electric field between a movable plate and stationary plate upon application of a voltage (90–110 V) between the two plates creates a movement in one of the plates. A bank of such parallel plates forming a comb drive is used to create translation (∼30–40 μm) in the x-direction as shown in Fig. 3.

A similar arrangement is used to create translation in the y-direction. The above two systems are driven by voltages that are 90° phase shifted and the translations are coupled to a pin joint that rotates a flywheel as shown in Fig. 4. The direction of rotation of the flywheel is determined by which of the two drives (x- or y-drive) is leading in phase. The flywheel is coupled to the microelectrode either directly or through gears to move the microelectrodes in steps of 1 μm over a distance of 5 mm. The above system of electrostatically actuated microelectrodes has been successfully tested in acute rodent experiments [15] but was found to be prone to mechanical failure. There were stiction issues between the parallel plates of the comb drive, alignment issues between the gears and the microelectrode that resulted in the microelectrode getting stuck particularly during intense behavioral routines of the rodent. Besides such serious mechanical robustness issue, the electrostatic microactuators also required high voltages (90–110 V) and optimally designed voltage waveform shapes.



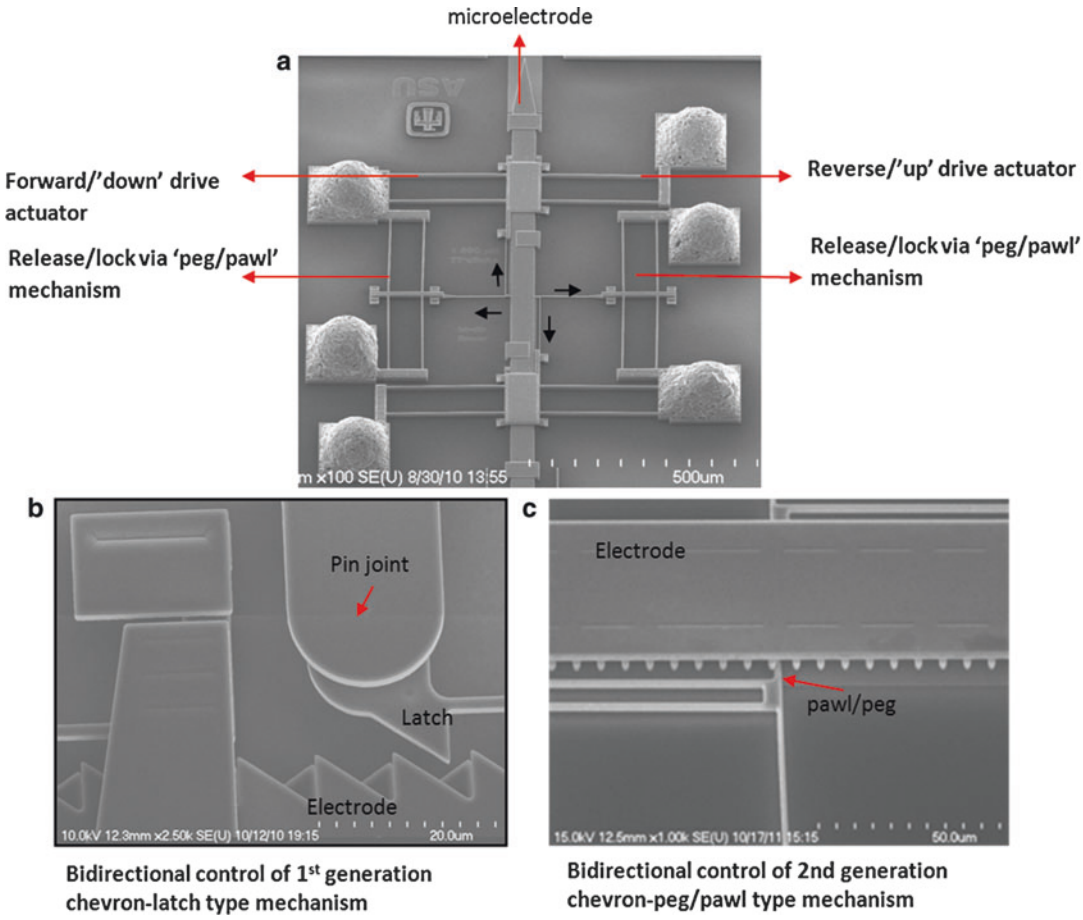
Electrothermal microactuators have, on the other hand, been demonstrated to be more robust and occupy smaller footprint on the die [16, 17]. In addition, the waveforms required to drive the electrothermal actuators are 6–10 V and standard rectangular pulses that can be



MEMS Neural Probes, Fig. 3 Schematic of the comb drive actuator and a close-up of one of the parallel plates and the associated fringe field intensity lines that make up the comb drive

readily generated. At the core of electrothermal microactuators are the electrothermal strips that consist of parallel beams of doped polysilicon that expand upon the application of voltage, displacing a shuttle in the middle of the electrothermal strips as illustrated in Fig. 5. Each microelectrode was designed with one set of actuators to move the microelectrode up, one set to move the microelectrode down, two sets of microactuators to release the lock that prevents the microelectrode from moving up, and finally two sets of microactuators to release the lock that prevents the microelectrode from moving down. The above neural probes had a displacement resolution of approximately 9 μm over a total displacement capability of over 5 mm. The electrothermal microactuators and the integrated neural probes have been successfully tested in long-term rodent experiments lasting over 13 weeks [16].

The electrothermal microactuators are operated on a bent-beam actuation design known as the chevron-type mechanism. The first generation of chevron-type MEMS actuators utilized a complex latch-based release mechanism for controlling the bidirectional movement of the electrode. Long-term in vivo rodent testing of these first-generation actuators revealed the need to improve the (a) reliability of bidirectional control of electrode movement due to out-of-plane errors in the latch mechanism and (b) force output for moving the microelectrode in a viscoelastic medium like brain tissue in the presence of inflammation and subsequent immune response. The second-generation chevron-type MEMS device address the above key issues (Fig. 6)



MEMS Neural Probes, Fig. 4 Schematic of the x- and y-drive connected to a pin joint and a fly-wheel. The x- and y-drives are activated at 90° phase difference to produce a net rotational motion of the fly-wheel that will eventually drive a gear or the microelectrode

MEMS Neural Probes, Fig. 5 (**a**) Schematic of a microelectrode and six electrothermal actuators associated with the microelectrode. The "Up" and "Down" actuators move the microelectrode in the center up or down respectively. (**b**) SEM of the one of the actuators showing the electrothermal heat strips and ratchets that move the microelectrode

[18]. The improved design simplified the actuation mechanism for the bidirectional movement by placing "upward" and "downward" movement actuators on either side of the electrode. To prevent movement in the opposite direction of desired direction, a "peg/pawl" was added on either of the electrodes. The new design improved the cross-sectional area upon which the MEMS

MEMS Neural Probes, Fig. 6 (**a**) SEM of the electrode actuated by the Chevron-peg/pawl type of mechanism with a pair of release/lock actuators and "up"/"down" actuators placed opposed to each other. The microelectrode has maximum displacement of 5 mm in steps of about 6.5 μm. (**b**) SEM of the 1st generation chevron-latch type mechanism controlling bidirectional movement. High precision is required as the distance between "up" and "down" teeth is 2–4 μm. (**c**) SEM of the 2nd generation chevron-peg/pawl type mechanism with contact between the pawl/peg and a single row of teeth on the microelectrode

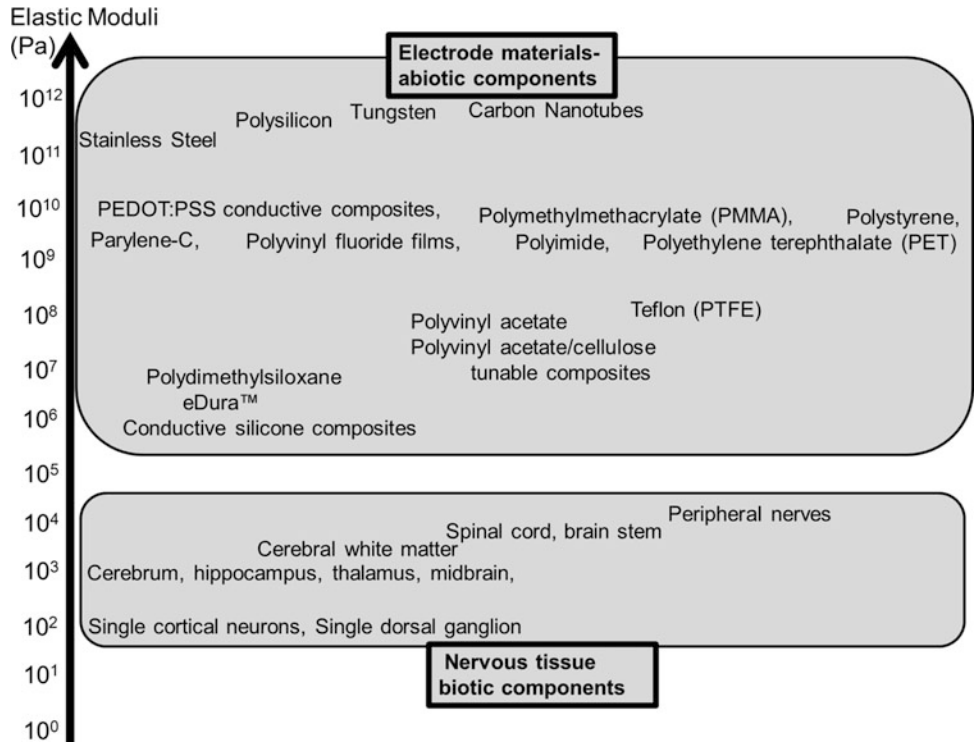
electrothermal actuator could impose its thrust, generating more force per stroke. The comparative advantages of the new design include (a) finer displacement resolution (6.5 μm), (b) increased force output (upto 1 mN per stroke), (c) upto 76 % less power consumption, and (d) increased movement reliability up to to four million cycles.

However, the key challenge in the application of MEMS neural probes in brain prosthetic technologies as well as technologies to monitor single neurons for neurobiological applications has been the unreliable interface between the implanted microelectrode and the neurons in the brain tissue surrounding the microelectrode. Current technologies do not have the stability, consistency, or reliability to record from targeted single neurons for long periods of time. The MEMS-based movable microelectrodes with their flexibility to be repositioned offer a very promising approach to overcome the above challenges.

MEMS with Soft Interfaces

As the next generation of MEMS for brain-machine interfaces evolve, several

MEMS Neural Probes, Table 1 Typical elastic moduli of nervous tissues



Type of nervous tissue	Elastic modulus	References
Single cortical neurons	0.2 kPa	[19]
Single dorsal root ganglion	0.9 kPa	[19]
Fresh peripheral nerves (Sciatic)	20–40 kPa	[20]
Acellular sciatic nerve	576 kPa	[21]
Spinal cord with meninges	8–36 kPa	[22]
Spinal dura mater	1.2 MPa	[23]
Cranial dura mater	420 kPa	[23]
Cerebral white matter	12–15 kPa	[24]
Cerebral gray matter	4–6 kPa	[24]
Cerebrum	1.6–11.4 kPa	[25]
Hippocampus	0.8–4.2 kPa	[25]
Caudate/ Putamen	0.51–3 kPa	[25]
Thalamus	2.8–3.0 kPa	[26]
Midbrain	2.9–3.1 kPa	[26]
Brain stem	2.9–20.52 kPa	[27] (assumed 80 % stiffer than cerebrum)

unconventional materials are currently being explored to enhance long-term reliability and performance. One such effort is directed toward the development of soft neural interfaces that match the stiffness of the surrounding brain tissue. Typical elastic moduli of nervous tissue from the periphery to the spinal cord and cortex are summarized in Table 1. The peripheral nerves tend to be slightly stiffer (20–40 kPa) compared to central nervous system tissues (1–20 kPa). The central nervous system also displays a wide range in elastic moduli in terms of regional variations (i.e., white matter – 12–15 kPa vs. gray matter – 4–6 kPa), in addition to differential anisotropy. Nevertheless, it is clear that the biotic component of the neural interface such as the brain tissue is approximately 2–3 orders of magnitude softer or less stiff compared to the abiotic component of the interface comprising of conventional materials used in neural devices (Fig. 7).

Abiotic components, such as conductive wires used in recording (i.e., tungsten, stainless steel, polysilicon) range 100–400 GPa in elastic modulus. In addition, brain tissue is typically viscoelastic in nature compared to stiffer electrode and insulation components. Therefore, there is a mechanical mismatch between the material properties of the brain and commonly used materials at the neural interface. It is widely hypothesized that this mechanical mismatch between the abiotic and biotic components of the neural interface aggravates inflammatory response and glial scarring that typically surround neural probes under chronic implantation conditions.

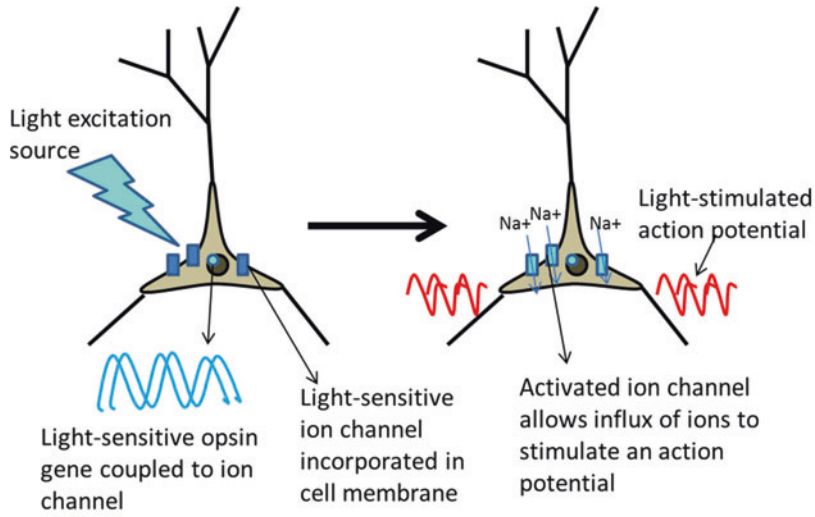
To make neural probes more mechanically biocompatible, several groups have designed softer materials for interfacing with the brain. A key design parameter is to increase the compliance by using elastomeric materials as a base for conductive thin films. This strategy has been successfully utilized for peripheral nerve, EEG, and ECoG applications [28–31]. Ultrathin, flexible materials with thin films of gold were used to conform to the unique surface topology of the ear [29]. Silicon nanomembrane "ribbons" were deposited on top of a highly flexible, elastomeric substrate to conform to the undulating gyri of the cortex [28].

Another common strategy has been to develop soft conductive composites using elastomeric materials. Using a composite of MED6607 silicone material and poly (3,4-ethylenedioxythiophene) (PEDOT)-based conductive polymer, a "soft" neural interface with an elastic modulus of 974 kPa was developed that showed higher neuronal attachment and reduced inflammation [32]. Elastomeric composites of poly-dimethyl siloxane (PDMS) (15–20 %) and platinum particles (with a composite elastic modulus of 10 MPa) have been tested for peripheral nerve interfaces [33, 34]. A PDMS-gold composite (2 MPa elastic modulus) has been developed that can be used as stretchable, elastomeric films for in vitro applications [35].

MEMS Neural Probes, Fig. 7 A diagram showing the elastic moduli of common materials used in neural interface applications (abiotic components) and nervous tissue (biotic components). Abiotic components such as electrodes, insulation, etc. are 2–4 orders higher in magnitude compared to biotic components, reflecting the mechanical mismatch found at the neural interface

A third, innovative strategy has been to utilize materials having tunable mechanical properties. An advantage of using materials with tunable properties is that stiffer materials have better penetration properties during insertion into the brain. Upon insertion into the brain, the material adjusts to a softer elastic modulus, leading to better biocompatibility with the nervous tissue. An example of a mechanically dynamic material is a polyvinyl acetate/cellulose-based nanocomposite inspired by the tunable stiffness properties of sea cucumbers [36]. Cellulose-based microwhiskers tune the softness of the composite material within 300 s in a hydrated environment from ~80GPa to ~12 MPa. When implanted in rodent brain models, these materials show reduced inflammation and increased biocompatibility [37, 38]. A conductive composite with Ti/Au micromachined in the cellulose-based material has been demonstrated as a potential neural probe [39]. Another example of a material with tunable mechanical properties is the thioacrylate-based shape memory alloy. These shape memory polymers modulate their material properties from 1 GPa to 18 MPa after insertion [40]. The thioacrylate-based material can be incorporated with conductive elements such as gold with platinum black or iridium for novel probes for the nervous system [40, 41]. In addition, the materials are conducive to photolithography techniques, leading to potentially innovative MEMS-based solutions for conformal and biocompatible neural devices.

Emerging High-Density Neural Probes



It is estimated that there are >100,000 neurons/mm^3 in the brain [42]. There is a significant need to map function in neural circuits in the human

brain across scales – from events at the molecular scale to microscale to macroscale. The idea of mapping the human brain "connectome" requires cutting-edge tools that have the capacity to record from the maximum neurons possible with high spatial and temporal resolution [43]. This ambitious goal remains one of the holy grails of neural interfaces alongside the goal of developing reliable, long-term interfaces. High-density neural probes are needed to monitor local populations across multiple anatomical regions for better understanding neuronal dysfunction and disease pathology. High-density EEG (up to 256 electrodes) and ECoG arrays (250–360 channels) are increasingly used for neural disease applications such as epilepsy and sleep disorders [28, 44, 45]. Current state-of-the-art intracortical technologies can monitor tens to hundreds of single neurons in parallel [46]. High-density Utah electrodes with the capacity of 25 electrodes/mm^2 have been reported [47]. Recent advances in CMOS and other silicon-based technologies have enabled massively parallel devices with upward of 10,000 electrodes [42]. In vitro CMOS-based systems can go up to 65,536 electrode sites (1536 electrode/mm^2), enabling highly precise subcellular to network-level resolution of neural signals [48–51]. Significant advantages using CMOS-based technologies includes monolithic integration of the (a) electrode recording readout, (b) signal processing, (c) in situ amplification, and (d) data transfer processes [52]. Key challenges in the fabrication of high-density neural probes include trade-offs with the number of electrode sites, device width and geometry, and scalability and reliability of interconnects. Innovative solutions such as double-sided fabrication of electrodes on either side of the planar substrate and using the e-beam technique to reduce lead width and separation to submicron dimensions (~290 nm) pave the way for high-density, high-resolution neural probes [53, 54]. Using hybrid e-beam lithography and conventional photolithography techniques, a highly dense electrode array (1000 electrodes) in an area of 10 × 10 μm has been fabricated and tested in animals [55]. Additional strategies for obtaining high resolution is via incorporation of silicon and other nanowires [56, 57]. These nanowire-based electrodes can serve a dual purpose of stimulation and obtaining "gold standard" intracellular recording via harmless penetration of cells.

Neural Interfaces with Integrated Optoelectronics

Neural interfaces with integrated optoelectronics are critical to serve the needs of the exciting, emerging discipline of optogenetics. Optogenetics utilizes genetic engineering techniques to genetically modify a neuron and render it light sensitive (Fig. 8) opening up the exciting possibility of stimulating the neuron using light. The light-sensitive gene typically encodes for either a cation (i.e., Na^+, H^+) or anion (Cl^-) ion channel coupled to a microbially derived, light-sensitive gene (i.e., rhodopsins). Light-sensitive genes that incorporate a biochemical modulation method (i.e., G-protein coupled receptors, cAMP modulation) for manipulating the excitatory or inhibitory response have also been demonstrated [58]. Upon excitation with an appropriate wavelength and light intensity, the ion channel pumps in the ion either hyperpolarizing or depolarizing the cell. This action leads to increased or decreased generation of action potentials and hence affects neural activity at the cellular level. Sodium (Na^+) and calcium (Ca^{2+}) ions typically have excitatory effects, while chloride (Cl^-) and proton (H^+) ions have inhibitory effects on the neural activity. There are numerous genetic constructs that have been developed and offer a wide spectrum of selectivity (350–1050 nm) [59, 60]. Typical light intensities required to stimulate a neuron are 1–5 mW/mm^2, though recent advances have increased the relativity sensitivity of the gene constructs to ~0.1 mW/mm^2 [46, 59]. Nevertheless, optogenetics offers a unique method to perturb a specific neural circuit in brain-mapping studies.

Key technological challenges in developing MEMS-based solutions for the above needs are in (a) developing scalable, low-power approaches for light source and (b) delivering light to localized neuronal populations. Typical light sources include high-intensity lasers and light-emitting

Light-sensitive gene family	Excitatory or Inhibitory	Ion channel sensitivity
Channelrhodopsin	Excitatory	Na+/ cations
Halorhodopsin	Inhibitory	Cl-
Bacteriorhodopsin	Inhibitory	H+

MEMS Neural Probes, Fig. 8 Illustration of the principle of optogenetic stimulation. A neuron is genetically modified by the addition of a light-sensitive gene. Upon excitation from a light source, the excited ion channel pumps ions into the cell. Depending on the type of ion pumped in, the cell then either hyperpolarizes or depolarizes. In the illustrated example, an excitatory response is depicted, leading to increased action potential generation. The ion channel typically comes from one of three classes of light-sensitive microbial genes: channelrhodopsin, halorhodopsin, bacteriorhodopsin

diodes (LEDs). Most systems utilize a laser coupled with optical fiber-based delivery method. However, LEDs have an advantage in that they utilize less power and can be integrated in neural interfaces readily. Recent advances in LEDs for optogenetics include utilizing multicolor diodes that were coupled to fiberoptics mounted on micromachined grooves on silicon shanks [61, 62]. This innovation allowed for multisite targeting and perturbation of neural circuits at different points. Another interesting innovation is the development of wirelessly powered, injectable GaN-based μLEDs (6.45 μm thick) that could potentially be placed inside deep brain structures of a rodent with relatively better biocompatibility compared to fiberoptics [63]. GaN μLEDs were fabricated using conventional epitaxial methods and microtransfer printed onto microneedles [64]. These μLEDs are highly versatile with independently addressable, inorganic LEDS with variable-wavelength emissions that implanted in the brain for precise, localized stimulation or used on stretchable, conformal substrates for ECoG applications [65]. Their modular nature allows for ready incorporation with multiple electronic sensors and MEMS devices. An example of a complete, injectable, multifunctional optoelectronic system is ~20 μm thick [63]. The other rapidly growing area of innovation is in developing novel optical fiber-based waveguide systems for precise and spatially selective delivery of light in a large-scale manner. Strategies for spatial targeting include glass-sharpened optrodes [61]. Another strategy is to etch the cladding at various points using a focus-ion beam for targeting neuronal populations along the length of the optrode [66, 67]. An alternative strategy is to use individual waveguides that were addressed by a matrix of micromirrors separately coupled to different light sources, allowing optical stimulation at each point with tunable wavelength and intensity [68]. Optrode arrays, such as the 3D optrode array, have also been fabricated using micromachined quartz and fused silica for optogenetic and IR application [69]. A completely microfabricated μLED coupled optrode array

(32 channel) with microneedle waveguides, a switched-capacitor stimulator, and wireless telemetry on a single platform [70] was demonstrated recently. Based on the rapid advances in optogenetic-related technologies, the development of scalable, high-throughput, flexible, and efficient optical stimulation-coupled recording electrodes is emerging as an innovative front in neural probe designs.

Future Directions

While MEMS-based neural probes have already made a significant impact on the field of neural monitoring, the immediate interface between the neural probe and the brain tissue is a key challenge that is poorly understood. So it is important to direct future efforts toward a better understanding of the events at the interface over the lifetime of the implant. On the device side, future efforts are likely to be focused on developing technologies that will allow us to scale up the number of probes (both movable and fixed). Such high-density probes are essential for monitoring large ensembles of neurons simultaneously. Integrating wireless telemetry to the above probes will also be critical to allow monitoring from the brains of awake, behaving subjects besides enhancing the long-term reliability of the probes. Finally, integrating multiple functionalities such as the ability to perform neurochemical monitoring, deliver drugs, stimulate the brain tissue electrically and/or optically will dramatically enhance our ability to assess brain function in a multimodal framework.

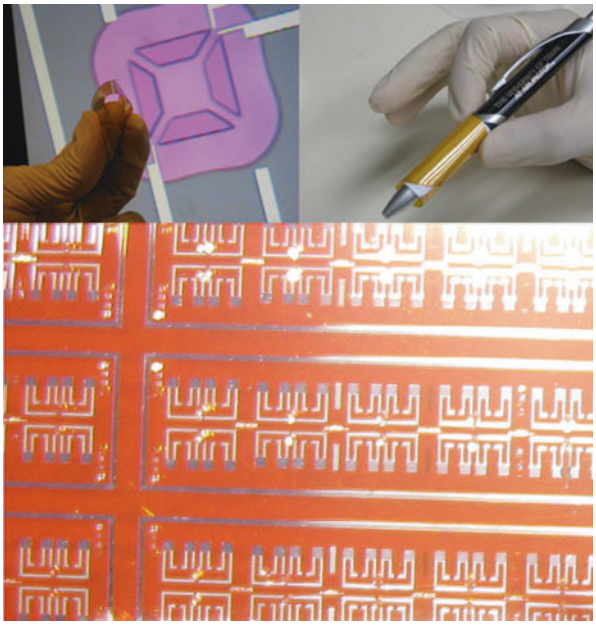
Synonyms

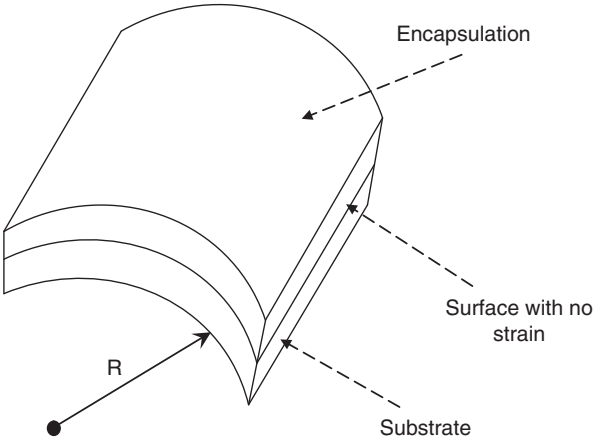
MEMS = microelectromechanical systems

Definition



MEMS in flexible substrates can be defined as microelectromechanical devices and systems embedded in a flexible polymer or plastic film such that the device is conformal to nonplanar surfaces and objects.

Introduction



Flexible electronics [1] is a rapidly emerging field that has resulted in flexible displays using organic light-emitting diodes being inserted into the marketplace in commercial products such as cell phones. Flexible circuit boards are also seeing widespread use in commercial electronics. These flexible electronic components have the advantage of being able to conform to nonplanar objects and surfaces. They can be bent or folded to some degree. They also provide decreased size and weight when compared to their rigid conventional electronic counterparts. The use of organic semiconductors to form transistors and diodes has so far limited the performance of the components due to the low intrinsic mobility of the materials developed so far. Current organic transistors are sufficient for the low speed switching requirement of a video display but do not possess the performance of Si or SiGe transistors that are utilized for computing, communication, and signal-processing applications. This has resulted in hybrid systems constructed of both rigid Si components for high-performance applications and flexible organic transistors and diodes for the display. The recent development of graphene-based transistors [2] with high mobility and the continued research on other polymer materials for electronic applications may change this scenario in the near future by allowing for low-cost, high-speed electronics to be placed on or in flexible substrates. The inherent paradigm of flexible electronics would have potential beyond displays including sensing and communication electronics.

Microelectromechanical (MEMS) devices exist as both sensors [3] and actuators [4]. Microelectromechanical devices were first developed by bulk micromachining where the substrate was etched to form the device structure. This process has rapidly given way to surface micromachining for many devices, where the device is formed by the subsequent deposition of layers on a substrate. Some of these layers are sacrificial layers which are removed to release parts of the device giving them the freedom to move and form the electromechanical device. Surface micromachining is independent of the choice of substrate material, hence can readily be adapted to flexible substrates made of polymers and plastics so long as low-temperature processing techniques are employed that do not exceed the glass transition temperature of the substrate. This has been a challenge in developing MEMS sensors on flexible substrates since many traditional sensor designs use polycrystalline piezoresistive materials that require high temperature processing. MEMS devices in flexible substrates have applications where the ability to conform to a nonplanar surface or the savings in size and weight are advantageous. Toward this end, MEMS sensors in flexible substrates have been developed for medical and structural health-monitoring applications (Fig. 1), and also in defense. This work has been focused on MEMS sensors that measure infrared radiation, pressure/force, acceleration, strain, and other physical parameters.

Traditional electronics utilize stiff and thick substrates where the films on top must conform to the substrate. Any stress that develops is mainly

concentrated in the films forming the device structure on the top surface of the substrate. In the case of flexible electronics, when the substrate is bent with the circle center closer to the *bottom* surface, the top surface goes into tension while the bottom surface goes into compression, as shown in Fig. 2. Under compression with the circle center closer to the *top* surface, a film or device may buckle and delaminate from the substrate. Under tension, a film or device may tear. At the neutral plane of the stack lies a low stress plane which experiences minimal strain. The devices are best suited to be located at this low stress plane where they are supported by a substrate layer below and a superstrate or encapsulation layer above. If the stiffness of the device layer in the middle is negligible, then the electronic layer can be made to lie on a plane of no strain as long as the following expression $Y_s d_s^2 = Y_e d_e^2$ is valid [5]. Here, the subscript e refers to the encapsulation while the subscript s refers to the substrate. Y is the Young's or tensile modulus and d is the thickness of the layer. By using an encapsulation, the electronic MEMS devices will not only lie at a low stress plane but they will be protected from the environment thus removing the need for

MEMS on Flexible Substrates, Fig. 3 (*Left*) An expanded view of a self-packaged microbolometer (not to scale: the *vertical* dimensions have been exaggerated and the bump bonds are placed next to the bolometer; the polyimide substrate and superstrate have been compressed for clarity). further packaging. Thus, the devices can be referred to as being self-packaged or device-level packaged [6–8] since the flexible substrate layer, encapsulation layer, and device layer are all fabricated using microfabrication techniques. This results in a MEMS device that is embedded in a flexible film or substrate. To produce a MEMS device layer in which parts of the device must be free to move, a local cavity is formed around the device by micromachining (Fig. 3). An alternative to device-level packaging the MEMS devices is to package the flexible encapsulation layer or superstrate to the substrate at the wafer level with a wafer bonder.

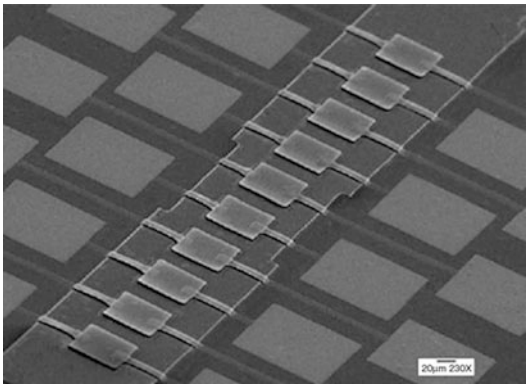
In this entry, the reader is introduced to the development of MEMS devices on flexible substrates and their packaging through the presentation of several examples including microbolometers, pressure sensors, and accelerometers. In addition, several other examples are discussed with their relationship to developing flexible electronics that include MEMS devices.

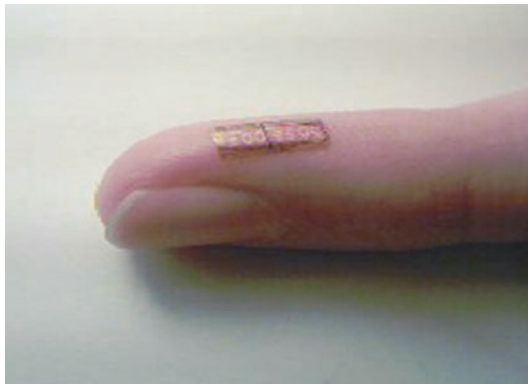


Microbolometers on Flexible Substrates

Microbolometers are thermal optical detectors whose electrical resistance changes as a result of the heating from the absorbed optical radiation. To minimize the heat lost by the microbolometer to the substrate, the resistive thermometer is suspended above the substrate through micromachining. The detectors are also placed in vacuum to eliminate the heat loss through the surrounding atmosphere. Suspending the thermometer above the substrate also allows for the formation of an optically resonant cavity to increase absorption of the detector. Microbolometers are typically used in night vision as infrared imagers operating in the 8–14 μm atmospheric transmission window.

The development of micromachined sensors on flexible substrates began with microbolometers [6, 9, 10]. There are advantages to producing curved imaging elements because the number of optical elements in the lens can be decreased, resulting in cameras that have reduced size and weight. Early work first investigated fabricating microbolometers on Kapton sheets bonded to Si carrier wafers so that conventional photolithography and semiconductor processing equipment could be used. This permitted the patterning of structures with micron precision. However thermal cycling that occurred during the microfabrication process caused distortion of the Kapton films that resulted in low device yield across the wafer [10]. The fabrication process was adapted to use polyimide (liquid Kapton, Dupont, now HD Microsystems, PI5878G) substrates that were formed by spin casting the

substrate onto a Si carrier wafer and curing the polyimide at the beginning of the microfabrication process [9]. In this case, the polyimide film did not undergo distortion during the microfabrication process, allowing for precise alignment of the device features across the wafer and a corresponding high yield. Polyimide and Kapton, for that matter, are attractive materials to use due to their flexibility and relatively high glass transition temperature, up to 400 °C. Polyimide is unattractive due to its moisture sensitivity, limiting its deployment in some applications. However, its material properties allowed for a good test bed to demonstrate the feasibility of the technology. New polymers are continually being developed for future application. Moreover, the evolution of high precision roll-to-roll processing equipment allows for high volume, large area fabrication of devices for commercial manufacturing [1]. The technique of utilizing a Si carrier wafer is more appropriate for the university research environment and small production lines.



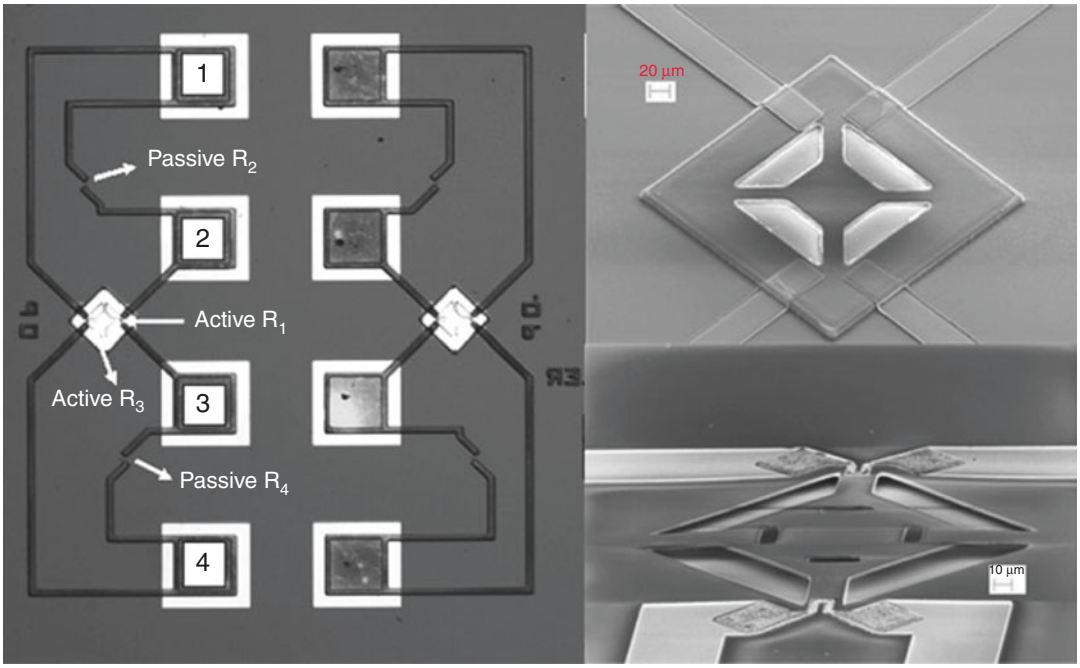
After spin casting and curing the polyimide substrate, a Si_3N_4 film was deposited to protect the substrate from future microfabrication processes and define the device plane [9]. The microbolometers were then fabricated on top of the Si_3N_4 film by using conventional photolithography and rf magnetron sputtering to deposit the metal electrodes and yttrium barium copper oxide (YBCO) thermometer. All sputter depositions were performed in a conventional turbo-pumped sputter system at room temperature. The highest temperature step was hard baking the photoresist at 105 °C. This ensured that the glass transition temperature of the polyimide substrate was not exceeded. The fabrication process involved the patterning and deposition of an Al mirror that would form an optically resonant cavity with the YBCO thermometer. A photodefinable polyimide sacrificial layer was then spin coated and cured on the wafer. The polyimide sacrificial layer was designed to be approximately 2-μm thick to maximize the infrared absorption at a wavelength of 10 μm and satisfy the approximately $\lambda/4$ relationship for maximum absorption in the suspended thermometer, where λ is the wavelength of the incident radiation. Subsequently, Ti electrode

MEMS on Flexible Substrates, Fig. 4 Micromachined YBCO microbolometer array fabricated on a spin-on polyimide substrate (liquid Kapton)

arms were patterned and deposited, followed by Au contacts on the bond pads and to the YBCO thermometer which was deposited next. The microbolometers were patterned into 1×10 arrays of 40×40 and 60×60 μm detectors. The polyimide sacrificial layer was then removed by ashing in an oxygen plasma to suspend the microbolometers above the substrate and form the optically resonant cavity with the Al mirror. The Si_3N_4 film deposited initially protected the polyimide substrate from being attacked by the oxygen plasma.

Some of the microbolometer die were gently peeled off the Si carrier wafer while others were left on the Si carrier wafer for characterization. An SEM micrograph of a section of a 1×10 array is shown in Fig. 4. Two microbolometer dies are applied to a fingertip in Fig. 5, demonstrating the conformal nature of the devices. The microbolometers were characterized by gluing the die, both attached to and removed from the Si carrier wafer, into a conventional integrated circuit package. The packaged microbolometers were placed into an evacuated cryostat with a ZnSe window. No significant difference in the responsivity and detectivity was observed between the microbolometers that were removed from the Si carrier wafer, those that remained on the Si carrier wafer, or to ones that were fabricated directly on a Si substrate. This indicated that MEMS microbolometers can be fabricated on both rigid or flexible substrates without

MEMS on Flexible Substrates, Fig. 5 Microbolometer arrays fabricated on flexible polyimide substrates applied to a finger



degradation of their performance. The infrared detectors showed broadband optical responsivity as high as 6.1×10^4 V/W and detectivity of 1.2×10^8 cm $Hz^{1/2}$/W at 1 μA of current bias [9].

This work also demonstrated that, in the general case, there is no need to fabricate sensors on flexible substrates if they are going to be placed in rigid, conventional integrated circuit packages. Such packaging defeats the ability of the devices to conform to nonplanar surfaces. Therefore, as a next step, device-level packaging of the microbolometers was developed [6]. The package for the microbolometer was now created during the microfabrication process, with a local vacuum cavity surrounding the microbolometer to minimize its thermal conductance with its surroundings. A schematic and optical micrograph (top view) of the device-level vacuum-packaged microbolometer is shown in Fig. 3. This device-level package flexible device would be compatible with direct integration or bonding to a flexible circuit board. In this case, the flexible die can be glued to the flexible circuit board with an appropriate adhesive with the electrical connections being made by bump bonding.

Here, the fabrication proceeded along the same lines as in the previous case up through the deposition of the YBCO thermometer. The precise details can be found in Ref. [6]. After the YBCO thermometer was deposited, a second polyimide sacrificial layer was spin coated and patterned on top of the thermometer. This was followed by an aluminum oxide, Al_2O_3, packaging layer. Al_2O_3 was chosen for its high mechanical strength and optical transparency, which extends into the infrared. The Al_2O_3 packaging layer had trench cuts or openings to facilitate the removal of the sacrificial layers above and below the thermometer by ashing in an oxygen plasma. After the sacrificial layers were removed, the trench cuts were sealed by sputtering more Al_2O_3 at 10 mTorr Ar pressure, thereby creating a vacuum cavity around the microbolometer. Once sealed, a polyimide encapsulation or superstrate could be applied to place the microbolometer at a low stress plane inside the polyimide film.

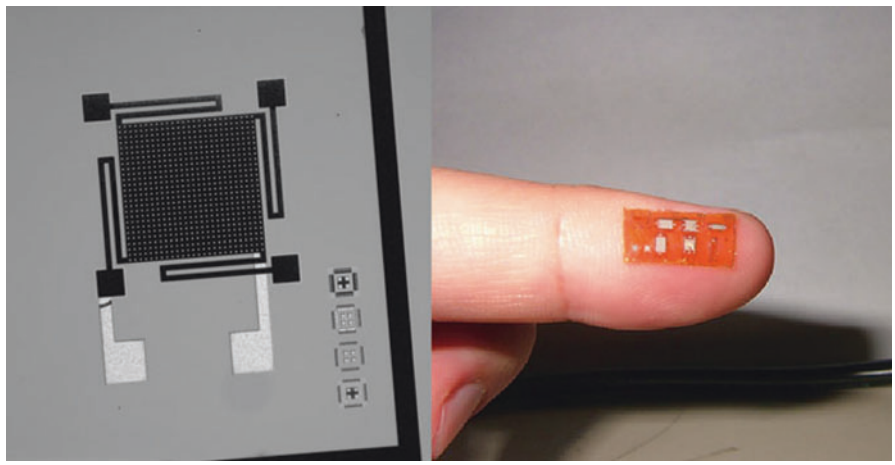
Pressure/Tactile Sensors on Flexible Substrates

Pressure/tactile sensors on flexible substrates have been developed for medical and structural health-monitoring applications. Two types of MEMS pressure sensors have been investigated: absolute pressure sensors and delta pressure sensors. Absolute pressure sensors measure the external pressure relative to a sealed reference cavity while delta pressure sensors respond to an external pressure of force relative to the ambient pressure. This entry will focus upon delta pressure sensors. MEMS delta pressure sensors operate by deflecting a suspended membrane with an external pressure or force. The deflection of the membrane can be sensed capacitively or by measuring the resulting strain induced in the membrane with piezoresistors. In the latter case, the piezoresistors can be configured into a Wheatstone bridge geometry with two active and two passive piezoresistors. This configuration provides zero output under a no load condition when the resistors are balanced and also provides temperature drift compensation by fabricating the piezoresistors from the same material with the same temperature coefficient of resistance. A confocal microscope picture of a piezoresistive delta pressure sensor is shown in Fig. 6. In the case of pressure sensors, since the sensor is designed to measure an external pressure, the

MEMS on Flexible Substrates, Fig. 6 (*Left*) A confocal microscope picture showing a piezoresistive delta pressure sensor in a Wheatstone bridge geometry. (*Top right*) A SEM micrograph of the piezoresistive delta pressure sensor in a mesa geometry. (*Bottom left*) A SEM micrograph of a delta pressure sensor showing the cavity underneath

sensor must have access to the environment through a hole in the superstrate or have a thin superstrate, less than 10-µm thick, so the external pressure is transferred to the sensor.

Two types of piezoresistors have been investigated, polycrystalline Si piezoresistors [11, 12] and nichrome piezoresistors [13]. In the case of polycrystalline Si piezoresistors, normally to achieve the polycrystalline lattice structure requires deposition or annealing temperatures that would be prohibitively high (>600 °C) for their use with flexible polymer substrates. By utilizing aluminum-induced crystallization, Si can be crystallized after its deposition by annealing at temperatures as low as 152 °C [14]. Piezoresistive Si with gauge factor ([ΔR/R]/average strain) in the range of 7–12 was obtained through this technique [15]. Alternatively, nichrome (nickel 80 %, chromium 20 %) thin films were employed as the piezoresistors [13]. The advantage of using metallic piezoresistors is their ability to be deposited at room temperature while one sacrifices the magnitude of the response due to their lower gauge factor, in the range of 1–3.



The fabrication of the delta pressure sensors on flexible substrates proceeded along lines similar to the fabrication of the microbolometers on flexible substrates described earlier. The basic fabrication began with spin coating the polyimide substrate onto a Si carrier wafer. After curing, a protective film of Si_3N_4 or Al_2O_3 was sputtered to protect the polyimide substrate during subsequent fabrication steps. Next, the polyimide sacrificial layer was spin coated and cured on the wafer. Then, the Si_3N_4 or Al_2O_3 membrane layer was deposited. The piezoresistors were then fabricated. Here, the process differed depending upon whether nichrome [13] or aluminum-induced crystallization polysilicon [12] was used as the piezoresistor. In the case of nichrome, the few tens of nanometer thick piezoresistor was deposited by rf magnetron sputtering and patterned by photolithographic liftoff to complete the piezoresistor fabrication.

For aluminum-induced crystallization of polysilicon, first a 0.5-μm-thick aluminum layer was deposited, followed by a 0.5-μm-thick amorphous Si layer. The two layers were patterned together by liftoff to define he piezoresistor geometry. Then, the wafer was annealed. During this process, the aluminum and silicon layers change positions through interdiffusion and a polycrystalline Si layer results at the bottom of the stack. The Al top layer is then removed by wet etching leaving behind an Al-doped poly-Si piezoresistor. The Al metallization layer was then deposited and patterned by liftoff to wire the active and passive piezoresistors into a Wheatstone bridge geometry. To prevent the piezoresistors from oxidizing during the removal of the polyimide sacrificial layer, a protective layer was deposited over the piezoresistor. In the case of the nichrome piezoresistors, a thin layer of Al_2O_3 was used. The polyimide sacrificial layer was ashed in an oxygen plasma to suspend the membrane above the substrate. In some devices, a thin polyimide layer was then bonded on top of the wafer to protect the pressure sensors. In other devices, a photo-patternable superstrate was spin coated on top of the pressure sensors and developed to open a small access hole to the sensor. At this point, the fabrication was complete and the sensor could be removed from the substrate.

The sensors can be designed to have various sensitivities by varying the membrane thickness and size of the suspended region. In this case, typical dimensions were 70–150 μm across. After completion of the sensor fabrication, the sensors were tested by deflecting the membrane with a probe tip in a probe station or applying a known load with a load cell [13] or atomic force microscope [16].

Accelerometers on Flexible Substrates

MEMS accelerometers on flexible substrates have applications in structural health monitoring of aircraft and aiding in the control of micro air vehicles [17]. The basic operating principle of a MEMS accelerometer is an under-damped to critically damped spring-mass system. The inertia of the mass causes a deflection when the mass is accelerated. By measuring the deflection, the acceleration can be determined [3]. The deflection can be measured by piezoresistive, piezoelectric, or capacitive transducers. Capacitive accelerometers, fabricated using a modified UV-LIGA process [18] with an electroplated Ni proof mass (Fig. 7), have been investigated. Both z-axis (perpendicular to substrate) and lateral axis (parallel to substrate) accelerometers have been

MEMS on Flexible Substrates, Fig. 7 (*Left*) An optical micrograph of a z-axis accelerometer fabricated on a polyimide substrate. (*Right*) A flexible polyimide die containing z-axis and lateral axis accelerometers conformally resting on a finger

designed to measure accelerations up to 20 *g* where *g* is the acceleration due to gravity. The details of the fabrication process are given elsewhere [17]. The fabrication will be described in brief here.

The basic fabrication process started with spin coating the polyimide substrate onto a Si carrier wafer followed by the sputter deposition of a Si_3N_4 protection layer. The accelerometers were constructed using a polyimide sacrificial layer that was patterned by photolithography and cured. An Au seed layer was utilized for electroplating the Ni proof mass. The mold for the proof mass was defined with a 6-μm-thick negative photoresist. The low stress Ni was electroplated in a nickel sulfamate solution. After electroplating, the mold resist was stripped and the Au seed layer was wet etched. Then, the polyimide sacrificial layer was ashed with an oxygen plasma to suspend the proof mass above the substrate with Ni springs defined by the photoresist mold. The dies were then packaged for testing. Some of the dies were taken off the substrate as shown in Fig. 7. Figure 7 also depicts an optical micrograph of a z-axis accelerometer.

The accelerometers were tested with a shaker that provided accelerations up to 8 g. The acceleration was calibrated through a commercially available accelerometer which was mounted beside the accelerometer under test. The z-axis accelerometers displayed a sensitivity exceeding 20 fF/g while the sensitivity of the lateral axis accelerometers was more than 10 fF/g [17]. The sensitivity was compared to identical accelerometers fabricated directly on Si substrates and found to be the same within the measurement and fabrication tolerances. The noise floors due to Brownian motion of the suspended sensor was calculated to be 2.25 μV/√Hz compared to the measured noise floor of the readout circuit of 0.13 mV/√Hz indicating that the measurement system dominated the measured noise [17].

Other MEMS on Flexible Substrates

At the University of Illinois at Urbana-Champaign (UIUC) work on incorporating electronic devices on flexible substrates [19] has also turned to micromachining in some cases [20, 21]. Using micromachining, ribbons of electronic devices [20] and interconnects [21] have been suspended above the substrate to enable both flexibility and stretchability of the electronic film. This work is separated from the work described earlier in that electronic devices such as diodes and transistors are incorporated on the flexible substrate. Micromachining is used to suspend the electronic ribbons or interconnects above the substrate with periodically spaced anchor points so that when the substrate is bent or stretched, there is room for the electronic ribbons and interconnects to deform without encountering a large strain that could damage the devices. Therefore, in this case, the devices are more traditional electronic devices rather than traditional MEMS devices described earlier. The research at UIUC may form a path for the integration of MEMS devices with electronic components such as transistors. One factor not addressed by this work is the packaging of the suspended components. Along similar lines, other investigators have also reported micromachined interconnects that are suspended above the substrate [22, 23].

Using MEMS cantilever rf switches, reconfigurable frequency-selective surfaces [24] and antennas [25, 26] have been demonstrated on flexible substrates. A surface micromachined hot-wire anemometer has also been shown [27]. In addition, a variety of MEMS biomedical devices have been developed on flexible substrates including implantable moveable electrodes for the brain [28] and a polymerase chain reaction (PCR) system for DNA amplification [29]. These devices validate the attractiveness of MEMS devices on flexible substrates for a variety of applications. Yet a common set of problems always exists and is sometimes neglected such as packaging of the MEMS devices so that they have the ability to function without losing their flexibility and can be freely handled without damage. This property is more easily achieved for small-area MEMS devices but becomes more difficult as the size increases. In addition, the design process to achieve flexibility is easier for small-area devices compared to large area devices since the

deflection and stress encountered by a small-area device is less than those experienced by a large area device for the same radius of curvature.

Future Directions and Conclusions

This work has demonstrated MEMS sensors can be fabricated on a variety of substrates from rigid Si to flexible polyimide without losing performance. The work on flexible substrates has thus far been focused on constructing MEMS using conventional electronic materials for the insulators and metals for the wiring. The key restriction has been the necessity to use low-temperature processing to maintain the polyimide below the glass transition temperature during the fabrication process. In future, the traditional electronic materials of Al_2O_3, Si_3N_4, Al, and nichrome will give way to polymer and plastic materials that can be used for the structural MEMS materials. Work has already been started on using polymer-carbon nanocomposites for the piezoresistive transducers employed in many MEMS sensors. The compatibility with organic semiconductors and graphene transistors will pave the way for the integration of transistor readout circuitry in the near future. MEMS sensors on flexible substrates provide the ability to conform to nonplanar surfaces that are attractive in medical, robotic, and aviation applications. The resulting devices have the potential to be fabricated at reduced cost, size, and weight. Flexible electronics appears to be growing in its attractiveness for a variety of applications.

MEMS encapsulation

Definition

A method of protecting microelectromechanical system (MEMS) devices from the environment by means of physical enclosures.

Introduction

Packaging is a challenging and critical step in the development of MEMS products. MEMS structures are generally very fragile, have moving structures, and must interface with the environment. The requirements for packaging are application specific and differ from each other, thus standard MEMS packaging protocols are difficult to establish, leading to an increase in product cost. For many MEMS products, the cost for packaging often dominates over the device fabrication cost. In this entry, general packaging requirements for typical MEMS devices will be discussed, followed by requirements for specific applications. Then, various state-of-the-art MEMS packaging approaches will be introduced with some examples.

General Requirements for MEMS Packaging

To ensure proper operation in environments that may be encountered, packaging is required for any semiconductor electronic device. Generally,

packaging is the final step of semiconductor device fabrication before final product testing. The packaging activity encompasses a wide spectrum of materials and technologies from the back-end-of-line (BEOL) of the semiconductor manufacturing process until the final product itself. The most basic function is to distribute the electrical connections from the semiconductor chip to a circuit board. This function is usually realized by wirebond or flip chip technology. Besides establishing electrical connections, other functions include: (1) mechanical protection from the environment of use or subsequent packaging process, (2) chemical protection from the environment, and (3) thermal management of the heat generated from the chip. Depending on the device and product requirement, the importance of packaging functionality listed above varies. For example, for modern central processing unit (CPU) devices, thermal management is the most critical, while mechanical protection and chemical protection are relatively less important.

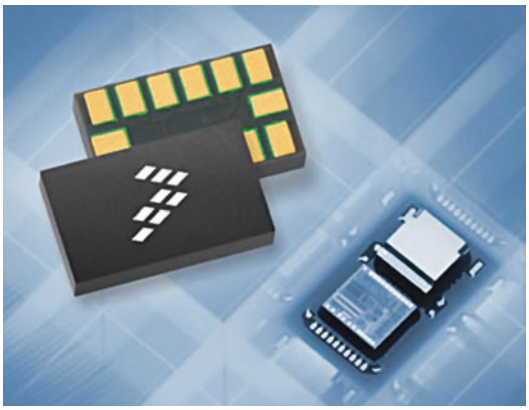
In the case of MEMS devices, thermal management is usually less problematic, since most applications draw relatively low current, and thus generate little heat. However, MEMS devices contain mechanical structures. Therefore, they tend to be more sensitive to mechanical perturbation from the environment. Also, as the size scales down, the surface-to-volume ratio increases, which makes MEMS devices more susceptible to surface forces that may develop.

Mechanical Protection

Usually, MEMS devices contain suspended microscale mechanical structures with micrometer-spaced gaps. Mechanical protection is the most obvious required functionality of MEMS packaging. Airborne particles must be kept away from structures to ensure proper function. Impact can potentially fracture fragile structures, or cause compliant structures to come into contact, leading to adhesion failure. Mechanical stress on the device structure can also jeopardize its reliability. For example, stress can lead to a change in the electrical signal in the devices using piezoresistive or piezoelectric transduction. Capacitively transduced devices can also generate unreliable output signal, if the relative positions between electrodes are shifted by stress. Therefore, one important requirement of MEMS packaging is preventing MEMS devices from exposure to direct mechanical impact or shock. For example, shock requirement becomes more important in some applications such as automotive airbag sensors (sensing range ~50 g), and consumer devices that are prone to be dropped by the user.

Chemical Protection

Chemical protection must also be provided by MEMS packaging technology. Water condensation on the micromechanical structure can create permanent failure to the MEMS device. Due to their large surface-to-volume ratio, chemical reactions on the surface can completely change the device performance. For example, surface oxidation can completely change the mechanical fatigue behavior of silicon-based MEMS devices. For such reasons, from the beginning of the MEMS device development, the Hermeticity of its packaging has been a significant issue. Early studies were focused on hermeticity against humidity or moisture [1]. Later, hermeticity against atmospheric gas species has become important for many vacuum applications such as IR sensors and RF resonators, or inertial sensors where certain level of damping has to be maintained during operation [2]. Recent research works have investigated the diffusion characteristics of different gas species and diffusion pathways in MEMS packagings [3].



Cost-Effectiveness

Although MEMS packages have many stringent requirements (electrical connections, mechanical and chemical protection), cost minimization is required to gain commercial success. With respect to the mass market, MEMS sensors first penetrated the automotive industry. Even though the cost of the packaging could be up to 90 % of the device cost, MEMS sensors were still much more economical choice compared to the few existing solutions. In order to provide isolation from the harsh environment of automobiles (e.g., high temperature and humidity), ceramic packages that closely matched the coefficient of

thermal expansion (CTE) of silicon were first used. They were later replaced by molded packages to reduce cost. Since molded packages have a different CTE from silicon, a soft and thick die-attach such as DOW RTV and gel dome coating have been used for stress isolation (i.e., to minimize the transfer of stress from the package to the device).

In the consumer electronics market, the requirement for cost reduction became even higher. To bring the cost of the overall sensor to less than $1, cost reduction is needed in all areas of product manufacturing, and packaging is no exception. Today the most prevalent standard packages used are quad flat no leads (QFN), dual flat no leads (DFN), or land grid array (LGA) packages (testing is done in arrays before package singulation). Another important requirement for consumer electronics applications is the size of the overall package. The packages need to have the smallest possible footprint, and thin profile. The accelerometers (STMicroelectronics LIS331series) used in Apple's Iphone 4 have dimensions of 3 mm × 3 mm × 1 mm. Because of this small size, the thick and soft die-attach or the gel dome coating cannot be used anymore. Although themomechanical stress or long-term reliability is not as stringent as in automotive products, stress isolation remains an issue with the thin die-attach and gel coating. Alternatively, more effort was directed toward the MEMS sensor design to compensate the stress. One example is a single anchor design, so that no thermomechancial stress is applied due to anchor movement.

Advances in consumer electronics applications will be applied back to automotive applications, leading to further cost reduction. This is important as passenger safety requirements are becoming even more strict for automobiles. For example, in the USA, the National Highway Traffic Safety Administration (NHTSA) has already implemented front-seat airbag regulation, tire pressure monitoring systems, and will implement vehicle stability program regulation in 2012 for all vehicles. All of these safety regulations require MEMS sensor-based systems, and must be affordable for cars in all classes.

Various MEMS Applications and Their Packaging Requirements

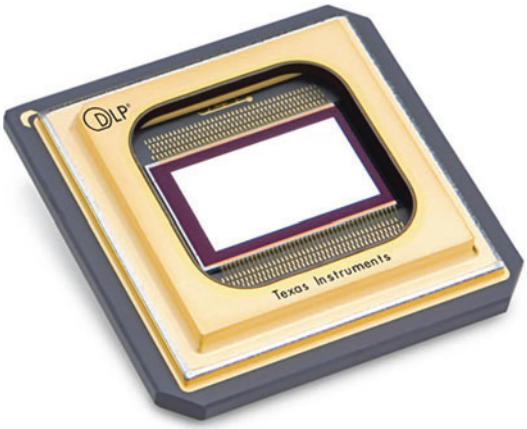
Inertial Sensors

Accelerometers, such as shown in Fig. 1, are one of the most successful MEMS devices. This success is due to MEMS technology advances and to the NHTSA airbag safety regulation (section 208) in the 1990s. Further success will be aided by recently announced side airbag regulations beginning in 2013. Accelerometers have contributed in saving millions of lives. For consumer electronics, accelerometers were used to detect "portrait-landscape" orientation for wide-screen phones. They are currently also widely used as motion control sensors in consumer electronics.

Accelerometer sensitivity can often be improved by increasing the size of released proof mass. Due to the need for a relatively large cavity, wafer bonding is preferred over other wafer-level encapsulation methods. In this approach, after device release, encapsulation is accomplished by sealing the device wafer with a separate "cap" wafer. Pre-etched wafers with cavities are bonded to the device wafer immediately after the release step (see the descriptions in the next section for more details). The gas environment during the bonding step must be controlled to establish the sensor dynamics. Nitrogen is used

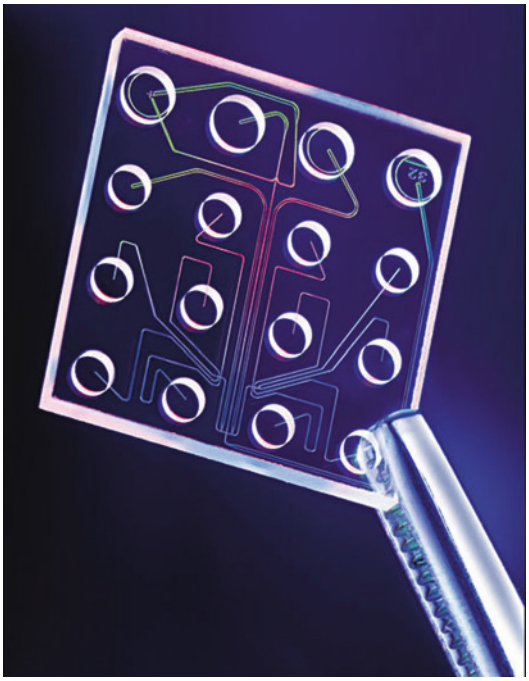
MEMS Packaging, Fig. 2 Freescale pressure sensor packaged with die-level packaging [4]

as the main filling gas, because it is inert and the molecules are relatively large (compared to hydrogen or helium), so diffusion is slow. Pressure is carefully set to critically damp the mass.



Gyroscopes have a more complex device structure than accelerometers. MEMS gyroscopes are usually designed as vibration-based structures, so high vacuum is required (<1 Torr). Because of this requirement, there are many considerations to be made. First, the bonding wafers and the bonding chamber need to be sufficiently outgassed before bonding. Outgassing from the surfaces of the wafer and chamber has high impact on the resulting vacuum level of the device. Second, the encapsulation volume must be tailored. Subsequent outgassing cannot be avoided completely and extreme outgassing steps are expensive and not manufacturable. Therefore, the encapsulation volume needs to be large enough to overcome the inevitable outgassing from the device surface. Finally, the encapsulation material needs to be hermetic. Polymer-based materials are not suitable since gas can easily penetrate the barrier over time. A getter material such as titanium or zirconium can also be used to ensure vacuum and will also help to maintain the long-term reliability of the device.

Pressure Sensors



Pressure sensors are different from inertial sensors since the movable structure, the membrane, needs to be exposed to the environment during use. Another difference is that the membrane can be cleaned during the packaging process if any debris settles on it. Therefore, encapsulation need not be done immediately after the membrane is formed. Manufacturers use a soft gel type polymer to encapsulate the membrane for packaging. The gel allows the transmission of pressure to the membrane while protecting it from debris. The gel is used for packages having the pressure port close to the membrane. An example of a pressure sensor package is shown in Fig. 2. For differential pressure sensing, another hole in the backside is needed. Although most pressure sensor packages are not molded (unlike accelerometers), model LPS001D from ST microelectronics use a "holed" cap wafer on top of the membrane to realize a molded package. This new method should reduce the packaging cost and provide a standard packaging method as the accelerometers.

Optical MEMS

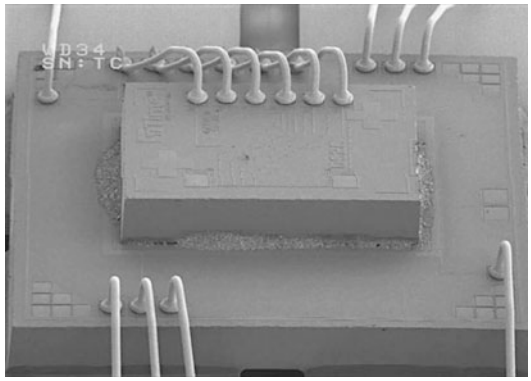
Packaging for many optical MEMS device must be optically accessible (transparent), which significantly limits the choice of materials. Typically,

MEMS Packaging, Fig. 3 MEMS mirror-based digital light processing (DLP™) product packaged with die-level packaging (Picture courtesy Texas Instruments)

MEMS Packaging, Fig. 4 Agilent Labchip™ packaged with a polymer bonding technology (Picture courtesy Agilent Technologies)

coating materials for AR (antireflection) surface or HR (high reflection surface) are not standard semiconductor materials, which makes the choice for packaging options even narrower. Epoxy is often used to hold optical components together; however, its use in the light pathways must be avoided because of long-term reliability and drift issues. Figure 3 shows an example of a packaged optical MEMS device, MEMS mirror-based digital light processing products from Texas Instruments.

Hermetic sealing is highly desirable since moisture can cause electrode erosion or degrade AR or HR surface coatings. Optical alignment of the packaging window with MEMS components can be critical. In addition, thermal management is important since optical MEMS systems can incorporate high laser power.



Fluidics/Bio Applications

Packaging for microfluidics requires good level of sealing to prevent leakage of the liquid in the device. In many applications, packaging materials have to be carefully selected considering their chemical compatibilities with the interfacing fluid. Also for the applications in this category, micro-to-macro interconnectors are often needed such as reservoirs and micropumps, which pose another challenge for packaging. Figure 4 shows an example of a packaged bio-MEMS product, Agilent Labchip™.

Especially for bio-related applications such as lab-on-a-chip or implantable devices, material biocompatibility is one of the most important criteria. Polymers have been widely used for the materials in such bio-related applications but usually polymers require joining processes that are different from those developed for silicon or glass-based devices. Polymer bonding particularly needs low-temperature processes that do not necessitate the use of high voltage, high pressure, or vacuum. Examples of sealing methods for polymer fluidic devices are adhesive joining, thermal welding, solvent welding, and plasma welding.

RF MEMS

RF MEMS is one of the most rapidly growing MEMS fields in market (Fig. 5). After Stanford University demonstrated long-term stability of silicon MEMS resonators [5], several silicon-based oscillator start-ups have been successfully

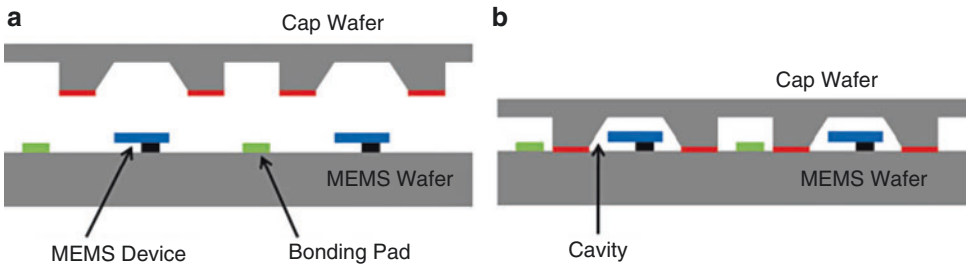
MEMS Packaging, Fig. 5 MEMS resonators packaged with an epitaxial silicon thin-film deposition as the cap layer. Packaged MEMS dies are bonded with CMOS circuit chips connected by wirebonds (Picture courtesy SiTime)

launched. Aluminum nitride-based MEMS filters appear to be next on the horizon. RF MEMS switches have also recently demonstrated good reliability [6], and are becoming commercialized.

The reliability of RF MEMS devices heavily rely on their packaging quality. For resonating devices for filters or oscillators, surface contamination plays a key role for their long-term frequency stabilities; therefore, hermetic packaging that can protect contaminant intrusion is essential for such applications. In addition, many resonator-based RF MEMS devices require high level of vacuum to minimize damping for high-Q, therefore hermetic vacuum packaging is needed for many RF MEMS applications. In the case of mechanical switches, the humidity has been observed to be the main cause of switch performance degradation [7].

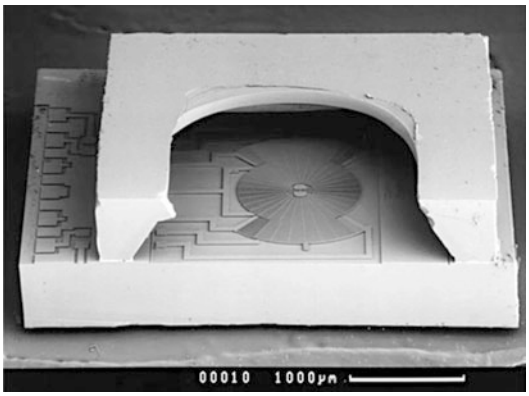
Discera utilizes glass frit packaging, which provides required vacuum hermeticity. Discera also uses a transparent cap to allow the use of laser trimming for the absolute frequency tuning of the resonator. SiTime utilizes epitaxially deposited silicon film encapsulation. The technique provides advantages not only on the cavity cleanliness due to extremely high sealing temperature, ~1,000 °C, but also on its capability to be integrated with transistor circuits. These factors may enable huge system-level benefits such as reduction in size, cost, and noise.

Examples of MEMS Packaging Approaches



Wafer-Level Packaging

In most cases, fabricated MEMS devices are singulated from the host wafer in order to be packaged. This singulation process generally involves mechanical dicing and wet processes, which can cause yield loss of MEMS devices. Wafer-level packaging (WLP) refers to the technology of packaging MEMS devices at the wafer level, avoiding difficulties in singulation. WLP can dramatically reduce the handling and increase the yield of MEMS devices, thereby significantly decreasing the manufacturing cost. Traditionally, two approaches have been widely researched and developed for wafer-level packaging methods for MEMS devices. One is wafer-bonding packaging while the other is thin-film packaging.



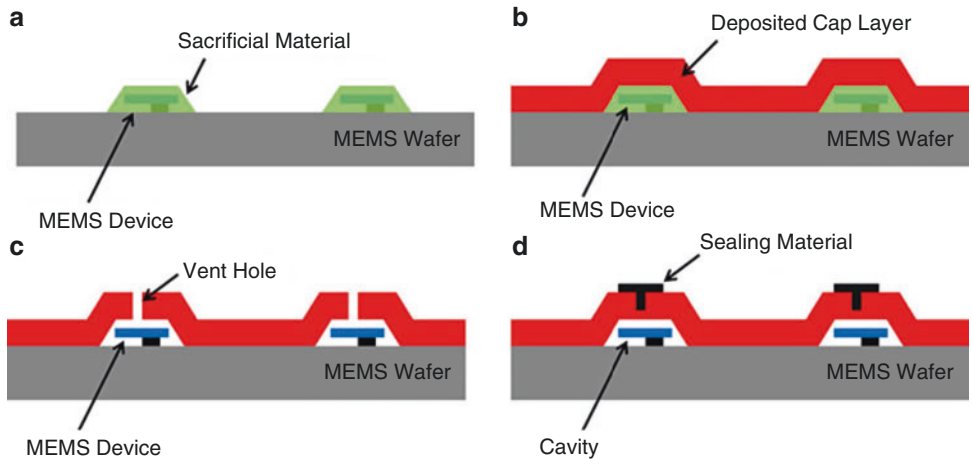
Wafer-Bonding Packaging

Wafer-bonding packaging involves fusing two separate wafers. A wafer containing MEMS devices is mechanically bonded with a separately prepared wafer having a cavity for MEMS devices, as shown in Fig. 6. A variety of bonding techniques have been introduced including silicon-silicon fusion bonding, silicon-glass bonding anodic bonding, glass frit bonding, and eutectic bonding. Silicon-silicon fusion bonding and silicon-glass anodic bonding both require high temperature, limiting the range of materials that can be present during bonding. Also, the prepared bonding surface needs to be ultra flat (<10 nm). This type of bonding is used to enclose pressure sensors and other MEMS devices before metallization is done. Recent developments, using plasma activation of the fusion bonding surfaces, are enabling low temperature or even room temperature bonding of ultra flat layers.

Glass frit bonding utilizes a glass frit that is screen printed to the wafer, fired to remove the solvents, and bonded at ~500 °C [8]. Due to the multiplicity of MEMS devices that can be packaged inside the cavity using this technique as well as the relatively cheap processing cost, this type of packaging (as shown in the example of (Fig. 7)) is the most widely used MEMS packaging method

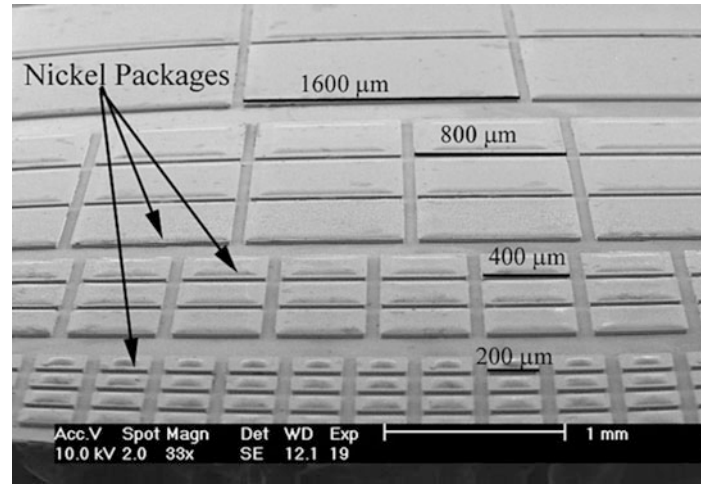
MEMS Packaging, Fig. 6 (**a**) A MEMS wafer and a cap wafer with cavities are prepared separately. (**b**) The two wafers are bonded mechanically, realizing MEMS devices in the packaged cavities

MEMS Packaging, Fig. 7 An SEM image of a MEMS accelerometer packaged by the wafer-bonding approach (Picture courtesy Bosch RTC)



in MEMS industry. One drawback of this approach is the efficiency of the area utilization. For secure bonding, significant area on the wafer is occupied by the surfaces to be bonded, and therefore fewer devices can be fabricated in a single wafer. This limitation can be overcome by improving the control of the frit flow and reducing the "safety zone" between the device and the frit. However, to ensure hermeticity, glass requires a thicker seal width than metal or silicon.

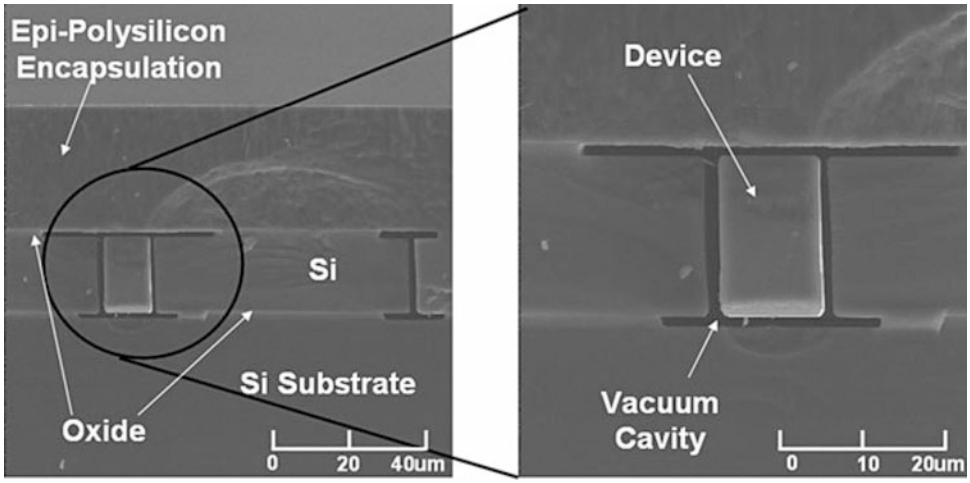
Eutectic bonding is a more recent development that addresses the limitation of glass frit bonding without sacrificing the bonding topography flexibility of glass frit bonding. Using metal also enables thinner sealing widths since metal has 100 times less permeability compared to glass [9]. Au–Sn bonding works well with most processing conditions, but since gold is not compatible with most fabrication environments, metal layers such as Al–Ge [10] or Cu–Sn [11] are the current focus in research and manufacturing focus. Since metal has much less diffusibility than glass, a finer sealing ring can be realized, enabling chip sizes to further reduce for higher profitability.



Thin-Film Packaging

Unlike the wafer-bonding approach, thin-film packaging techniques use deposited thin films as a cap layer. As shown in Fig. 8, MEMS structures are covered first by a sacrificial material, and then by a deposited cap material. Vent holes are patterned in the cap layer to remove the sacrificial material, followed by hole sealing. This approach can maximize the area utilization since the area needed for packaging is minimal; however, the choice of materials and processes becomes more problematic. For example, both MEMS device and sacrificial materials that can sustain the high temperature and the corrosive processing environment of the cap layer deposition must be selected. The current status of thin-film packaging methods is less mature relative to wafer-bonding approaches.

The University of Michigan has developed a thin-film packaging technology that utilizes nickel as the cap layer (see Fig. 9) [12]. Specifically, photoresist was used as a sacrificial layer followed by a nickel cap layer electroplating step. Solder bumping has been identified as the most effective sealing method among other approaches (localized welding and evaporated/sputtered/seals). A cavity pressure of ~1.5 Torr was measured at the time of the fabrication and a slight



MEMS Packaging, Fig. 8 (**a**) A sacrificial material covers released MEMS devices. (**b**) A cap layer covers the sacrificial material. (**c**) Vent holes are patterned in the cap layer and the sacrificial material is removed through the vent holes. (**d**) The vent holes are sealed to realize MEMS devices in the packaged cavities

MEMS Packaging, Fig. 9 An SEM image of multiple nickel packaged MEMS devices (Reprinted by permission [12])

increase was detected during the 30 days of monitoring. At a maximum of 250 °C, this packaging technology has an advantage with respect to process temperature. This low temperature allows the realization of MEMS packaging of wafers containing CMOS circuitry without compromising their functionality; i.e., MEMS and CMOS integration is possible with CMOS first.

Epi-seal encapsulation technology (see Fig. 10) was developed in collaboration between Stanford University and Bosch [5]. The packaging utilizes epitaxially deposited silicon as both a cap and a sealing layer. Silicon dioxide is used as the sacrificial layer. By the nature of the high temperature epitaxial deposition (∼1,000 °C), most of the contaminants and native oxide are eliminated, leaving an extremely clean surface and an encapsulated cavity. Long-term hermeticity of the package was investigated and the cavity pressure remained at less than 10 mTorr over a year while exposed to atmospheric pressure. This approach has also the advantage of potentially integrating with CMOS circuitry as a MEMS-first approach. However, the materials

MEMS Packaging, Fig. 10 An SEM image of a cross section view of a device fabricated by the epi-seal encapsulation process. The polysilicon cap layer creates a hermitically sealed enclosure (Reprinted by permission [5])

and processes that can be used for the MEMS structures are limited due to the high temperature of the sealing deposition (1,000 °C).

Die-Level Packaging

Die-level packaging was the first form of MEMS packaging, and is still used for many types of devices. Although wafer-level packaging options are often preferred in many MEMS applications, such methods cannot be applied to devices such as most pressure sensors, digital light processing (DLP) mirrors, thermo-accelerometers (which need sufficient gas volume), and some quartz-based piezoelectric gyroscopes.

After the devices are released, a special singulation process (dicing) is required. Temporary protective tape with cavities can be used to encapsulate the released die prior to the regular dicing, or stealth dicing using IR laser, can be used to dice without any debris or liquid involved. After singulation, careful assembly process in a clean room environment (at least class 1,000) is needed to avoid debris on the die.

Cavity packages are used for die-level packaging. These are packages with premade cavities. After the die is attached and electrically connected, the lid is sealed by soldering or by welding. Die-level packaging is more expensive than wafer-level packaging since it requires special treatment of the die, a clean room for assembly, and more expensive packages.

Definition

A microelectromechanical system (MEMS) resonant infrared (IR) sensor is a particular class of thermal detectors that relies on a transduction scheme based on the change in vibration frequency of a microelectromechanical resonator with a temperature dependent mechanical resonance frequency. The incident IR radiation heats the MEMS resonator changing its resonance frequency. By monitoring such resonance frequency shift, the incident IR power is detected. Unlike other IR sensors, MEMS resonant IR sensors do not require cooling and are suitable for the implementation of high performance, miniaturized, and power efficient thermal imagers and spectrometers.

Principle of Operation

The core of a MEMS resonant IR detector is a microelectromechanical resonator whose resonance frequency is highly sensitive to temperature. An IR absorbing material is typically integrated on the surface of the resonator. The freestanding micromechanical resonant structure can be simply modeled as a thermal mass (with thermal capacitance C_{th}) coupled to the heat sink at a constant temperature, T_0, via a thermal conductance, G_{th} (thermal resistance, $R_{th} = 1/G_{th}$). Upon exposure to IR radiation, the absorbed power causes a large and fast increase of the device temperature, ΔT, due to the excellent thermal isolation and extremely low thermal mass of the freestanding micromechanical structure (released from the substrate):

$$\Delta T = \frac{\eta Q_p}{\sqrt{{G_{th}}^2 + \omega^2 {C_{th}}^2}} \tag{1}$$

where Q_p is the incident IR power, η is the absorption coefficient of the material stack forming the resonator (typically set by the IR absorbing material), ω is the modulation frequency of the incident IR radiation, respectively. Such IR-induced temperature rise results in a shift in the mechanical

resonance frequency of the micromechanical resonator due to the large temperature dependence of the structure equivalent Young's modulus. Absolute values of temperature coefficient of frequency, $|TCF|$, in the 10–100 ppm/K range are typically achieved in MEMS resonators [1–4]. Therefore, for IR radiation slowly varying over time ($\omega \approx 0$), the overall responsivity of the MEMS resonant detector to IR radiation can be expressed according to Eq. 2:

$$R_s = \frac{\Delta f}{Q_p} = \eta \cdot R_{th} \cdot TCF \cdot f_0 \tag{2}$$

Taking advantage of the high quality factor, Q, resonant system (unique feature compared to conventional microbolometers), extremely small IR radiation-induced frequency variations can be detected by a compact and low power electronic readout (i.e., a single transistor oscillator circuit). In fact, higher resolution and stability, compared to static measurements, is typically achieved in the MEMS domain by exploiting the high Q resonant behavior of a micromechanical structure. Such MEMS resonant sensors use frequency as the output variable, which is one of the physical quantities that can be monitored with the highest accuracy and converted to digital form by measuring zero-crossings without the need of an analog-to-digital-converter to digitize the voltage or current readout.

A crucial parameter that ought to be considered for the design and optimization of a MEMS resonant IR sensor is the noise equivalent power, *NEP*, which represents the IR power that gives a signal-to-noise ratio equal to 1 in a 1 Hz measurement bandwidth (minimum detectable IR power) and it is defined as the noise-induced frequency fluctuation, f_n, divided by the responsivity of the detector, given by:

$$NEP = \frac{f_n}{R_s} = \frac{f_n}{\eta \cdot R_{th} \cdot TCF \cdot f_0} \tag{3}$$

Among different noise sources, the fundamental limit to the frequency stability of a MEMS resonant IR sensor is set by [5]: (1) the thermal fluctuation noise associated with the spontaneous temperature fluctuations of the detector element due to the finite heat conductance G_{th} to the surroundings, (2) the background fluctuation noise due to radiative heat exchange with the environment, and (3) the thermomechanical noise originated from thermally driven random motion of the mechanical structure. Therefore, the minimization of the *NEP* values associated with each of these three fundamental noise contributions (respectively NEP_{th}, NEP_{rad}, and NEP_{mec}) is typically used to drive the design of MEMS resonant IR sensors:

$$NEP_{th} = \frac{2T_0}{\eta}\sqrt{\frac{K_B}{R_{th}}} \tag{4}$$

$$NEP_{rad} = \frac{1}{\eta}\sqrt{16A\varepsilon\sigma k_B T_0^5} \tag{5}$$

$$NEP_{mec} = \sqrt{\frac{K_B T_0}{4P_c}}\frac{1}{\eta \cdot R_{th} \cdot TCF \cdot Q} \tag{6}$$

where K_B is the Boltzmann constant, T_0 is the temperature of the resonator, A is the area of the device, ε is the emissivity, σ is the Stefan-Boltzmann constant, P_c is the power used to drive the mechanical resonance in the structure, Q is the resonator's quality factor. The total *NEP* can be expressed as:

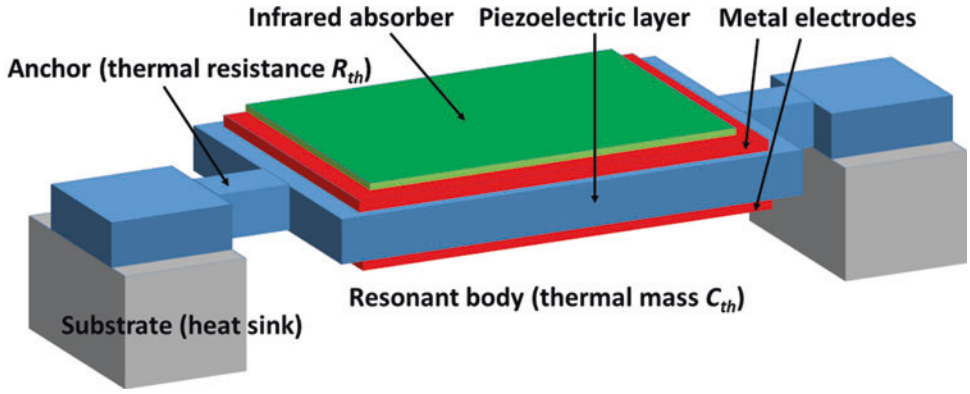
$$NEP_{tot} = \sqrt{NEP_{th}^2 + NEP_{rad}^2 + NEP_{mec}^2} \tag{7}$$

Equations 4, 5, and 6 indicate that minimum *NEP*, thus a high resolution resonant IR detector, can be achieved by maximizing the device thermal resistance R_{th}, absorption coefficient η, temperature coefficient of frequency, *TCF*, quality factor Q, and power handling P_c. The minimization of detector *NEP* also minimizes its noise equivalent temperature difference (*NETD*) which is a widely used figure of merit for IR detector arrays, especially IR imaging systems based on focal plane arrays (*FPA*), representing the minimum temperature change of the scene that induces a detector output signal equal to the noise level [6]:

$$NETD = NEP \frac{(4F^2+1)B^{1/2}}{\eta A \gamma} \left[\int_{\lambda_a}^{\lambda_b} \frac{\partial M(\lambda)}{\partial T} d\lambda \right]^{-1} \quad (8)$$

where F is the focal ratio of the optics, B is the measurement bandwidth and γ is the transmission of the optical path between the IR source to the IR detector, and the last term on the right-end side of the equation is the radiant exitance integrated over the wavelength range of interest [6]. It is worth noting that, beyond the minimization of the *NEP*, a small focal ratio of the optics and a large absorption coefficient are generally desirable for the implementation of high resolution infrared imagers.

Another crucial parameter to be considered for the design of a high performance MEMS IR resonant sensor is its response time which is characterized by the thermal time constant, τ, of the device, defined as the product between its thermal resistance, R_{th}, and capacitance, C_{th}:



$$\tau = R_{th} \cdot C_{th} \quad (9)$$

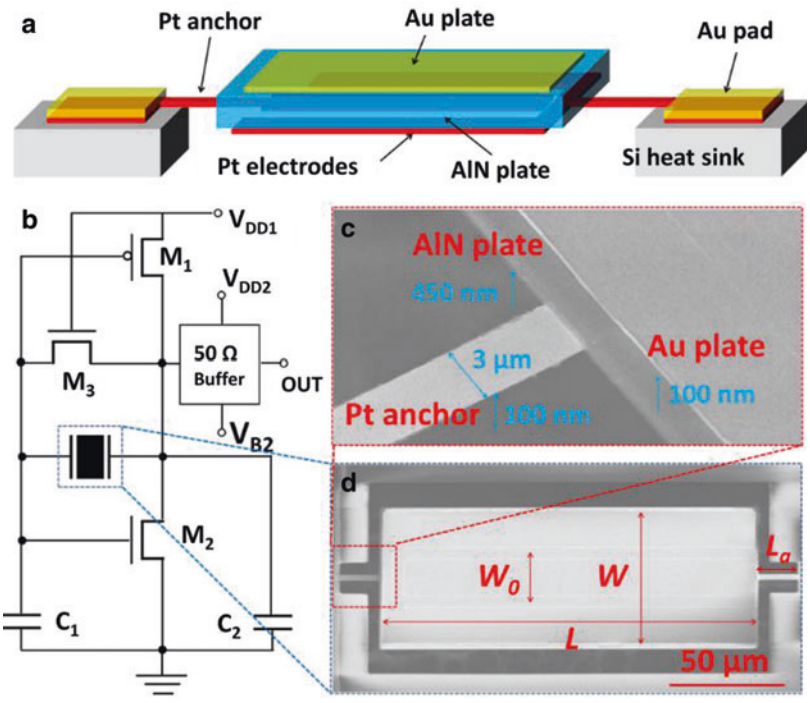
Equation 9 indicates that by improving the thermal isolation of the sensing element from the heat sink (hence increasing R_{th}), the *NEP* of the device is reduced but its response time is increased. Therefore, a trade-off between these two important performance metrics needs to be generally considered for the design of the detector. Nevertheless, for a given thermal resistance (guaranteeing a satisfactory *NEP*) the response time of the sensor can be reduced by minimizing its thermal capacitance which directly translates into reducing the volume of the micromechanical resonant structure.

Main Research Accomplishments

Different micro- and nanoelectromechanical system (MEMS/NEMS) resonator technologies have been explored for the implementation of resonant IR sensors [1–3, 5, 7–12]. Among them, thin-film piezoelectric MEMS resonators have shown a great potential, thanks to their intrinsic efficient on-chip piezoelectric transduction mechanics. In particular, the efficient on-chip piezoelectric actuation and sensing of high frequency bulk acoustic modes of vibration in micro-/nano-plate structures (Fig. 1), instead of conventional beams, have enabled the fabrication of high frequency and high power handling resonators that can be directly connected to compact and power efficient electronic readouts [9, 13] (without the need of off-chip bulky piezoceramic disks for actuation and complex and power inefficient optical readouts for displacement detection), which is a crucial requirement for the implementation of miniaturized thermal imagers and IR sensing systems.

The idea of using piezoelectric MEMS resonators for the implementation of high performance

MEMS Resonant Infrared Sensors, Fig. 1 Mock-up view of a typical thin-film piezoelectric MEMS resonant infrared sensor

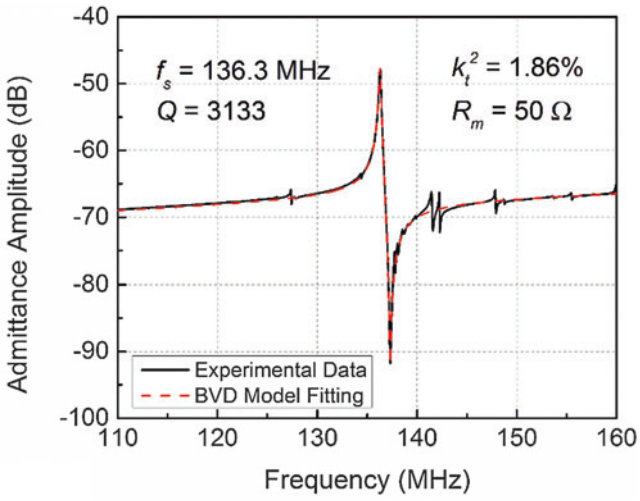


MEMS resonant infrared sensors was first introduced in 1996 [11]. Theoretical analysis predicted that an array of quartz microresonators working in the 200 MHz to 1 GHz range could be employed for the implementation of uncooled infrared imaging systems with *NETD* values lower than 10 mK. The first compelling experimental demonstration of a high performance MEMS resonant infrared sensor based on a micromachined Y-cut-quartz film (6.9 μm thick) resonator (working at 241 MHz with a quality factor, Q of 4200) was reported in 2011 [3]. Given the good IR absorbance of quartz in the 8–12 μm spectral range [3], no additional IR absorbing material was required. Thanks to the large temperature coefficient of frequency, $|TCF|$ of the Y-cut quartz microresonator (92 ppm/K) and its relatively large thermal isolation, a responsivity of 11.4 Hz/μW was demonstrated. The *NEP* of the device was extracted to be 3.9 nW/Hz$^{1/2}$, thanks to the low noise performance of the resonator (0.0445 Hz/Hz$^{1/2}$). The thermal time constant of the infrared sensor was also predicted by three-dimensional finite element method (FEM) time domain simulation and found to be 5.92 ms.

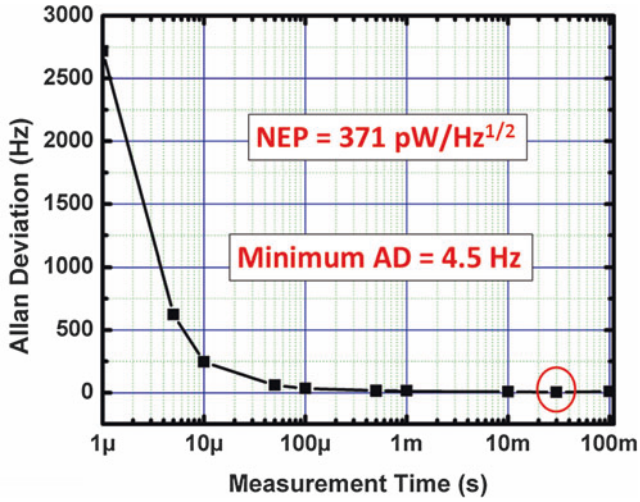
A fundamental limitation of quartz-based MEMS resonant IR detectors is the complexity associated with high density micromachining of quartz substrates (i.e., substantial thinning of the quartz substrate is required to produce a few microns thick quartz film), which poses some significant challenges in terms of yield and reproducibility of the device fabrication process, miniaturization, and dense integration of resonator arrays in a small footprint. In this context, the use of a thin-film piezoelectric material (such as aluminum nitride or gallium nitride) instead of a bulk piezoelectric material (such as quartz) can potentially reduce significantly the complexity of the microfabrication process (using conventional micromachining of thin-film materials) and enable the implementation of high performance, miniaturized, and highly integrated resonant sensors on a silicon substrate.

A MEMS resonant IR sensor based on a gallium nitride (GaN) thin-film piezoelectric resonator was recently demonstrated [2]. The core of the device consisted of a GaN (1.4 μm thick) on silicon (10 μm thick) micromechanical resonator, working at 101 MHz with a quality factor Q of 280 (the 10 μm thick silicon layer was necessary to reduce the relatively high stress of the epitaxially grown GaN thin-film). The $|TCF|$ of the GaN resonator was measured to be ~3 kHz/K (29.7 ppm/k) and the responsivity of the infrared sensor was extracted to be ~1.7 Hz/μW (1.68 %/W). The frequency stability of the device was characterized showing a ~8 Hz (~80 ppb) frequency fluctuation in a 1 Hz measurement bandwidth (~8 Hz/Hz$^{1/2}$) which translated in an estimated *NEP* of ~4.7 μW/Hz$^{1/2}$. The thermal time constant of the sensor was also experimentally measured and found to be ~556 μs.

Despite the demonstrated potential of quartz and GaN MEMS IR sensors, these technologies are fundamentally limited by the lack of cost-effective and low temperature deposition techniques capable of producing high quality piezoelectric quartz or GaN thin films on an arbitrary substrate. In this context, the aluminum nitride (AlN) MEMS technology offers some unique advantages compared with other piezoelectric resonant technologies: ultrathin (10s ~ 100 s nm) and high quality AlN film can be directly deposited on silicon substrates by low-temperature sputtering process [14], enabling the fabrication of ultralow volume resonators with excellent electromechanical performance. Furthermore, the post-CMOS compatibility of the microfabrication process used for the fabrication of AlN MEMS resonant devices [15] enables the monolithic integration of resonant sensors and the CMOS electronic readout on the same substrate which is an attractive feature for the implementation of ultraminiaturized, high performance, and low power sensing platforms.



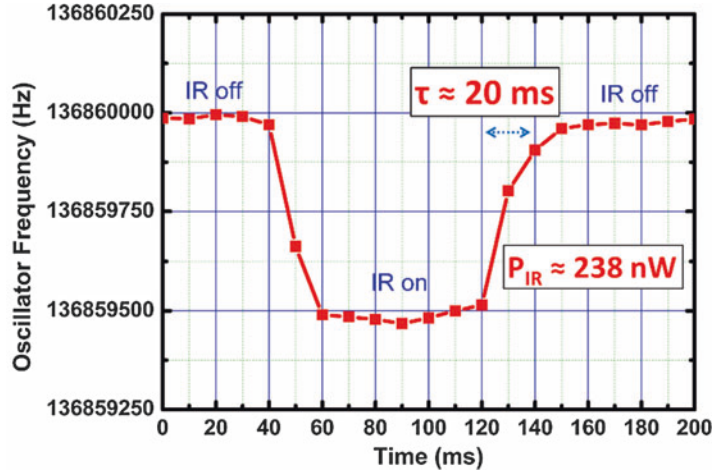
A step stone toward the development of MEMS resonant IR thermal detectors with high sensitivity, high resolution, fast response, and compact readout has been recently set with the introduction of a novel micromechanical resonant structure, based on the use of ultrathin (100 nm) fully metallic tethers to support the resonant body of an AlN piezoelectric nano-plate resonator (NPR) [9]. Such innovative device concept enables the implementation of uncooled IR



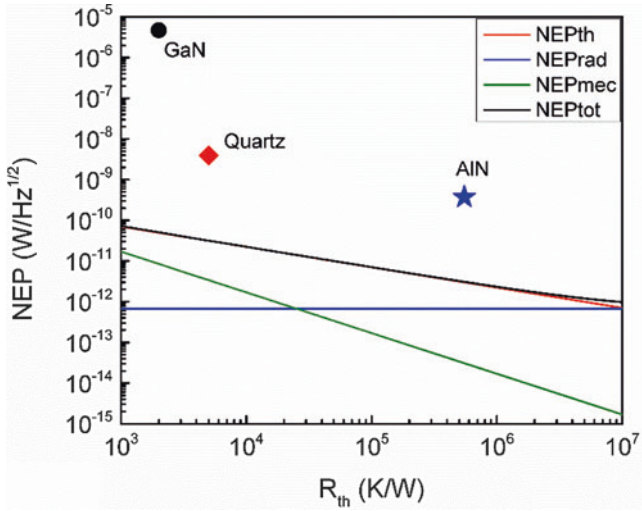
MEMS Resonant Infrared Sensors, Fig. 2 (**a**) Mock-up view of the AlN piezoelectric nano-plate resonator with nanoscale Pt anchors; (**b**) complementary metal-oxide-semiconductor readout circuit for the AlN MEMS resonant infrared sensor; (**c**–**d**) scanning electron microscopy image of the nanoscale metallic anchor and the AlN nano-plate resonator: $L =$ 200 μm, $W = 75$ μm, $W_0 = 25$ μm

detectors with a unique set of application enabling features. High $|TCF|$ (~ 30 *ppm/K*) is guaranteed by the large temperature coefficient of Young's modulus of the material stack forming the resonant nano-plate, and maximum thermal isolation of the device resonant body from the heat sink (maximum R_{th}) is readily achieved by completely removing the relatively thick piezoelectric material from the anchors, hence minimizing their thicknesses (ultimately limited by the need of a thin metal layer for low electrical resistance routing), which results in a resonant thermal detector with enhanced responsivity, R_s ($\sim Hz/nW$). At the same time, a low thermal time constant ($\sim ms$) is achieved by exploiting the unique capability of depositing high quality ultrathin AlN films ($< 1\ \mu m$) on a Si substrate by low temperature sputtering process which enables the implementation of low volume nano-plate resonant structures with a significantly reduced thermal mass (low C_{th}). Despite the resonator volume scaling, low noise performance is achieved thanks to the unique piezoelectric transduction properties of AlN ultrathin films which enable efficient on-chip piezoelectric actuation and sensing of a high quality factor ($Q > 2000$) and high frequency bulk acoustic mode of vibration (with associated high power handling, P_c) in a freestanding nano-plate, enabling the implementation of low *NEP* ($\sim pW/Hz^{1/2}$) resonant thermal detectors.

The electromechanical performance of such AlN nano-plate resonator with nanoscale Platinum (Pt) anchors was characterized by measuring its admittance amplitude versus frequency and performing Butterworth-Van Dyke (BVD) modeling fitting (Fig. 2) [16]. Despite the device volume reduction, high quality factor Q (3133) and electromechanical coupling coefficient k_t^2 (1.86 %) were attained. Such high electromechanical performance (Figure of Merit FOM $= k_t^2 \cdot Q_M \approx 58$) enabled direct wire bonding of the AlN nano-plate resonator to an oscillator circuit chip fabricated in the ON Semiconductor 0.5 μm CMOS process (Fig. 3) resulting in the first complete and compelling prototype of a high performance MEMS resonant thermal detector with a compact and power efficient Complementary Metal-Oxide-Semiconductor oscillator as direct frequency readout (Fig. 3).



MEMS Resonant Infrared Sensors, Fig. 3 Experimental and fitted (BVD model) admittance curves of the fabricated AlN nano-plate resonator with nanoscale Pt anchors



MEMS Resonant Infrared Sensors, Fig. 4 Measured Allan deviation (*AD*) of the AlN piezoelectric MEMS resonant infrared sensor

The $|TCF|$ of the AlN nano-plate resonator with nanoscale Pt anchors was measured using a temperature-controlled radio frequency probe station and found to be 3.8 kHz/K (28 ppm/K). The thermal resistance of the device was estimated by performing three-dimensional FEM simulation using COMSOL and found to be 5.5×10^5 K/W. The responsivity of the infrared sensor was calculated by multiplying the $|TCF|$ by the thermal resistance, and found to be 2.1 Hz/nW, which is one order of magnitude higher than the one achieved using conventional AlN nano-plate resonators with anchors made out of a thicker AlN/Pt material stack. The short-term frequency stability of the oscillator output signal was characterized by measuring its Allan deviation [17], which is a measurement of the noise-induced frequency fluctuation. A minimum Allan deviation was found to be 4.5 Hz for a measurement time of 30 ms (Fig. 4), translating into a noise-induced frequency fluctuation of ~33 ppb and a noise spectral density of ~0.78 Hz/Hz$^{1/2}$. The *NEP* of the infrared detector was extracted by dividing the measured noise spectral density by the responsivity and found to be ~371 pW/Hz$^{1/2}$. Such *NEP* is one order of magnitude lower than

MEMS Resonant Infrared Sensors, Fig. 5 Measured response of the AlN nanoplate MEMS-CMOS prototype to NIR radiation

MEMS Resonant Infrared Sensors, Fig. 6 Noise equivalent power (*NEP*) for different values of thermal resistance (R_{th}). The *solid lines* indicate the calculated NEP values associated with each of the three fundamental noise contributions (thermal fluctuation noise, NEP_{th}; background fluctuation noise due to radiative heat exchange with the environment, NEP_{rad}; thermomechanical noise, NEP_{mec}; and NEP_{tot} the total noise as expressed in Eq. 7), assuming: resonator area = 200 × 75 μm, $\varepsilon = 1$, $T_0 = 300$ K, $P_c = 0$ dBm, |TCF| = 30 ppm/K, $Q = 2000$. The individual data points indicate the demonstrated performance of the state-of-the-art MEMS resonant IR sensors based on quartz [3], GaN [2], and AlN [9] piezoelectric resonator technologies

the ones achieved with other piezoelectric MEMS resonant IR detector technologies [3].

The frequency response of the device prototype to near infrared (NIR) radiation was characterized using a Bruker Vertex 70 FTIR and Hyperion microscope. A broadband IR radiation from a tungsten halogen lamp (0.25–100 μm) was optically filtered (0.33–2.8 μm transmission) and chopped (6.25 Hz) before it was coupled into a Hyperion microscope used to focus the light onto the resonant body of the device. The frequency variation of the MEMS-CMOS oscillator was monitored using an Agilent 53230A frequency counter (Fig. 5). The measurement was performed in air. Despite the fact that no specific IR absorbing element was integrated with the AlN resonator, an absolute frequency shift of ~ 500 Hz was recorded when the device was exposed to NIR

radiation. Such frequency shift translates into an absorbed NIR power of ~238 nW (minimal IR absorption due to the intrinsic material loss), considering the device absolute responsivity of 2.1 Hz/nW. A thermal time constant of ~20 ms was also experimentally recorded (Fig. 5).

The demonstrated MEMS-CMOS resonant IR detector prototype, based on an AlN NPR with ultrathin Pt anchors, reduced the performance gap with the theoretical predicted limits (Fig. 6), setting a milestone toward the development of a new technology platform that, by taking advantage of the unique transduction properties and scaling capabilities of AlN nano-plate resonators, can potentially deliver fast (~ms) and high resolution ($NEP \sim 1$ pW/Hz$^{1/2}$, $NETD \sim 1$ mK) uncooled IR detectors suitable for the implementation of high performance, miniaturized, and power efficient IR imaging systems. Possible approaches to further improve the performance of these AlN MEMS resonant IR detectors include: optimization of the device thermal isolation (investigating optimal materials and geometries for the device anchors); further scaling of the device volume maintaining high electromechanical performance; proper engineering of the absorption properties of the ultrathin piezoelectric resonant structure; and investigation of strategies to reduce the effect of all the noise sources contributing to the generation of frequency fluctuations (such as the resonator flicker noise, random walk, and drifts).

Definition

Vacuum electronics is the area of research focused on the generation of coherent electromagnetic radiation, in which kinetic energy of the collisionless ballistic motion of electrons in vacuum is converted to electromagnetic (RF/microwave) energy [1–3]. At high frequencies (100 GHz and above), unconventional fabrication techniques for features with sizes 0.01–2 mm, tolerances <1 μm, and surface roughness 50–200 nm are employed with the various techniques generally called MEMS or micro-electro-mechanical systems.

The operating principle and constituent parts of a typical Microwave Vacuum Electron Device are shown in Fig. 1.

The heart of a Microwave Vacuum Electron Device (MVED) is a high current emission cathode. A thermionic cathode emits a high current density beam of electrons when heated. The electron beam is accelerated by the applied high voltage between the cathode and anode. This whole setup is commonly called an electron gun assembly. The first cavity of a typical Klystron is excited by a low power RF input signal using a coaxial line loop or a waveguide aperture. The electrons that lie on the crest of the RF get accelerated and the ones which lie on a trough get decelerated; this results in velocity modulation of the electron beam and subsequent bunching after appropriate drift. Due to this bunch formation, the first cavity is also called a "buncher" cavity. The electron beam passes through a "drift space" under magnetic focusing to maximize the ac current in the second cavity, called a "catcher" cavity. The ac current in the second cavity excites high intensity RF fields and amplification of the RF signal takes place. The high RF/microwave power is extracted through the output coupler attached to the output cavity. The spent electron beam goes to a copper block called collector. Klystrons typically have more than two cavities for higher gain. There are various kinds of MVEDs: Klystrons, Traveling-Wave Tube Amplifiers (TWTA), Backward Wave Oscillators, Crossed-Field Amplifiers and Oscillators, Electron Masers, and Free Electron Lasers. The scope of this entry is to give an overview of

MEMS Vacuum Electronics, Fig. 1 A typical microwave vacuum electron device (Klystron)

the recent efforts to scale MVEDs to near THz frequencies for substantial applications, where advanced fabrication methods like MEMS (micro-electro-mechanical system) are considered.

Overview

Vacuum Electron Devices

Vacuum electron devices (VEDs) have been widely employed as high-power radiation sources for communications, plasma heating, thermonuclear fusion diagnostics, and radar since the Second World War. However, vacuum electronics tended to fall behind solid-state electronics in the competition for the development of efficient low to moderate power microwave/millimeter wave sources due to the rapid advance of semiconductor technologies after 1970s. The merits of the solid-state devices, e.g., low voltage, small size, and light weight, surpassed the bulky VEDs for applications requiring low to moderate power (mW to W) in the lower frequency region ($\lesssim$30–100 GHz). Nonetheless, with the advent of a demand for powerful radiation sources in the millimeter and submillimeter wave region, the classical technologies have been again paid attention to together with advances in the so-called micro-electro-mechanical systems (MEMS) or microfabrication. Unlike the collisional conduction transport of electrons in a typical solid-state device, a large portion of electron energies can be transformed to the EM (electromagnetic) energies through collisionless convection transport in vacuum with a significant fraction of the spent beam energy available for electrostatic recovery; consequently, VEDs can provide very high radiation efficiency. Furthermore, the lower ohmic loss and the higher breakdown threshold compared to the solid-state devices make it possible to handle extremely high energy density in the high-frequency regime at room temperature.

Taken together, these advantages suggest the broad applicability of THz technology as long as some problems of miniaturizing VEDs down to millimeter and submillimeter wave scales are solved.

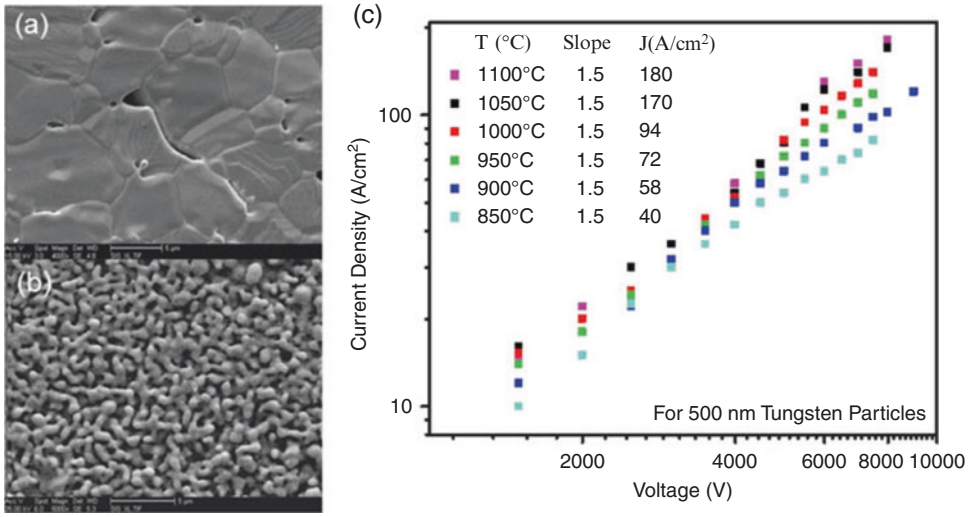
Terahertz (THz) Region of Electromagnetic Spectrum

Despite several potentially high impact commercial and security applications in the THz region (0.1–1 THz), the source technology is not available with reasonable power in a compact package. This so-called THz gap [4] occupies a large portion, 0.1–10 THz, of the electromagnetic (EM) spectrum that lies between the microwave and infrared region.

THz-rays (T-rays) have a number of advantages like: visible light creating a photograph, radio waves transmitting sound, and x-rays allowing us to observe inside of the human body, THz waves can create images and transmit information. The photon energies of T-rays are very low, so that they are not harmful to living organisms as opposed to x-rays. THz waves with

rotational, vibrational, and translational response modes to molecules, radicals, and ions can provide a range of unique information, which is difficult to obtain from optical, x-ray, and NMR (Nuclear Magnetic Resonance) images. The peculiarity of THz reactivity is very effective to fingerprint specific materials in the THz range. It provides conformational information closely related to the biological functions of molecules in tissues and cells and inaccessible by other technical means. While dielectrics are opaque to visible light and provide only low contrast to x-rays, T-rays can easily penetrate and image inside most dielectric materials. Furthermore, T-ray imaging can provide strongly enhanced contrast because of low scattering (Rayleigh scattering) due to their longer wavelengths, whereas large amounts of scattering in conventional optical transillumination, using near-infrared pulses, tends to blur images of objects.

Challenges in THz Devices



The expression μVEDs refers to high-power and high-frequency vacuum tubes based on advanced MEMS technologies. Recently, owing to high efficiency, robustness, and stability, this promising area is beginning to attract considerable attention from the THz community seeking a practical solution to advance imaging and sensing technologies. However, despite many advantages, some remaining technical issues [5] still hamper its practical applications. The most critical issues to the advancement of μVEDs are oscillation threshold and miniaturization, which severely affect device performance at increasing frequencies.

Enabling Technologies/High Current Density Electron Sources

μVEDs need high start-oscillation current density electron beams proportional to f_0^2, where f_0 is the frequency, in the millimeter and submillimeter wave region. Reduction of the electron beam cross section due to an increase of operational frequency dramatically increases the beam current density. For instance, a straightforward estimation of current density through scale-down indicates that 3 A/cm^2 at 10 GHz run corresponds to 3 × 10^4 A/cm^2 at 1 THz [6]. This is hardly achievable by conventional electron beam sources, particularly given the need to transport the electron beams with low interception. Recently, some electron emitters capable of producing a high emission current density have been challenged for THz μVED application and the electron gun issues have also been discussed [7–9]. The quality of these cathodes is usually evaluated by using scanning electron microscope images of the emitting surface (Fig. 2a, b) and by plotting testing data on logarithmically scaled I-V (Current–voltage) curves (Fig. 2c).

Scandia-Doped Tungsten Nano-composite Cathodes' Development at Beijing Vacuum Electronics Research Institute and Beijing University of Technology

Li and his colleagues at the Beijing Vacuum Electronics Research Institute (BVERI) have been investigating scandate cathodes since 1981 with a considerable portion of this work aimed at the development of impregnated scandate cathodes (I-Sc) for use in linear beam devices [10]. The work has focused on both an understanding of emission mechanisms and achieving high current density up to 100 A/cm^2 [11, 12]. Beginning in 2002, BVERI began collaborations with the materials science group at Beijing University of Technology (BJUT) with an emphasis on studies of scandia-doped dispenser (SDD) cathodes [11, 13]. In closely spaced diodes, pulsed emission in excess of 30 A/cm^2 at 850°C$_b$ and 2 A/cm^2 at 950°C$_b$ with DC loading for over 10,000 h has been obtained from SDD cathodes. In addition, the SDD cathode was tested at the Stanford Linear Accelerator Center in a cathode life test vehicle with a Pierce gun configuration, and 100 A/cm^2 for 500 h with a cathode operation temperature of 1,170°C$_b$ was achieved. Recently Liu et al. [14] at BJUT reported that SDD cathodes have reproducible high emission capability tested in open-structure Pierce electron guns. The SDD cathodes with planar emitting surfaces achieved 100 A/cm^2 SCL current densities at 950°C$_b$. For the SDD cathodes with concave emitting surfaces, 80 A/cm^2 pulsed emission has been reached at

MEMS Vacuum Electronics, Fig. 2 (**a**) Commercially available tungsten scandate cathode 311X made by SpectraMat, (**b**) scandia-doped tungsten nano-composite cathode made by UC Davis, (**c**) I-V emission curve for scandia-doped tungsten nano-composite cathode

1,025°C_b [14]. Such Sc-type cathodes offer the promise of the development of a new class of long lived and reliable microwave tubes as well as opening the way to the development of millimeter wave and THz sources. Current work is aimed at developing reliable and repeatable low-work-function scandate cathodes [8, 15]. The precise emission mechanism for scandate cathodes is still unclear. This limits the application of these cathodes. Continuing research is required to elucidate this mechanism and to establish the details of the structure and composition of the emission sites.

Scandia-Doped Tungsten Nano-composite Cathodes' Development at the University of California, Davis

Jinfeng Zhao et al. [8, 15] at UC Davis have been working on improving emission uniformity and increasing current density of porous nano-structured tungsten cathodes doped with nano-size scandium oxide and impregnated with $BaO–CaO–Al_2O_3$. Jinfeng Zhao uses sol–gel method to produce nano-size tungsten matrix doped with scandium oxide. Tungsten particle size can vary between 200 nm and 2 μm depending on desired cathode performance. The cathode matrix fabricated from the powders made by sol–gel method has high porosity, uniform grain size and scandia distribution, and open pore distribution. The uniform cathode matrix structure makes the emission surface acquire more uniform barium, oxygen, and scandium distribution, thereby improving the emission uniformity and lowering the work function of the emission surface. The UC Davis team was able to reproduce cathodes with 40 A/cm^2 current densities at 850 °C and 170 A/cm^2 current densities at 1,050 °C. Their life tests have shown that the cathode can produce 50 A/cm^2 at 1,050 °C for over 10,000 h.

Circuit Fabrication Methods/MEMS Fabrication

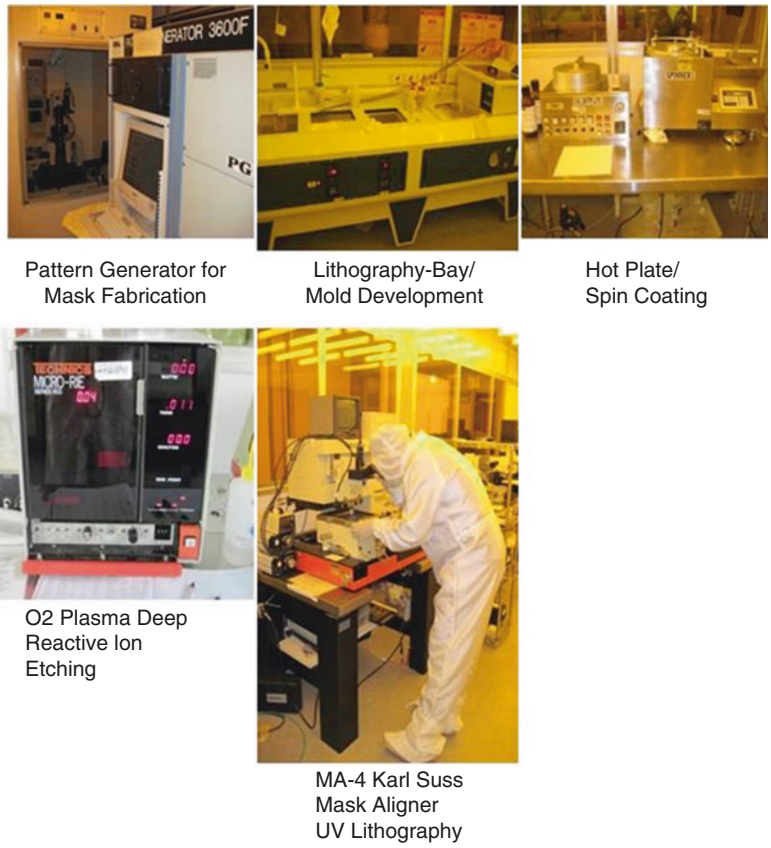
For the realization of a compact THz source, the lateral dimensions of the RF structure (slow wave structure or cavity) scale as ~0.1 λ_0 (~100 μm at 300 GHz) [5]. There are two fabrication constraints: (a) the fabrication tolerances for the metalized sub-mm structures should be kept typically <10 % (b) the surface roughness should be much less than the skin depth at the operating frequency. Hence, conventional machining technology is unable to meet the design specification.

MEMS Vacuum Electronics, Table 1 MEMS fabrication technologies and their typical machining capability range

Fabrication technique	Typical capability range
Conventional machining	>300 μm
EDM	80–1,000 μm
X-Ray LIGA	<1 mm
UV LIGA	10–1,000 μm
DRIE	10–500 μm
Nano wire EDM	>2 μm
Nano-CNC milling	>10 μm

MEMS fabrication has been extensively used by the semiconductor-based integrated circuit (IC) fabrication industry. More recently, vacuum electronics research has exploited the same techniques for precision fabrication of sub-mm scale, high aspect ratio micro-metallic structures. For an overview, a few techniques and their applicability range are described in Table 1. Nanoscale sinker EDM (electron discharge machining), ion beam milling, laser micro-machining, and ultrasonic machining are some of the available manufacturing techniques that could be applicable to miniaturizing of VEDs, but have not been explored extensively.

X-ray LIGA



LIGA is an abbreviation of *Lithographe, Galvonoformung, und Abfornung* and translates as lithography, electroplating, and micromolding. The process uses X-rays from a synchrotron to expose a resist material through a metallic mask containing an image of the structure to be produced. Poly-methylmethacrylate (PMMA) is deposited on a metal substrate up to a maximum thickness of approximately 1 mm. In some cases, a thin titanium coating is applied to the metal substrate before deposition to improve adhesion. Following deposition (casting) it is annealed at temperatures between 110 °C and 170 °C. An X-ray mask containing the image of the desired part is placed over the PMMA, and the structure is exposed to X-rays produced by a synchrotron. Only synchrotrons can provide the dose rates required, approximately 3,000–10,000 J/cm^3, and several hours of exposure are required. Following exposure, regions of the PMMA impacted by the X-rays are removed, leaving a positive image. The removed regions are replaced by electrodeposited metal, and the structure is lapped to the desired thickness. The remaining PMMA is removed to obtain the finished part. Some issues with X-ray LIGA include: Considerable care is necessary to create high-contrast and high accuracy exposure masks, adhesion of PMMA to wafers can be troublesome, and finally, the X-ray source used for exposure is an expensive investment causing X-ray LIGA to be the least economically viable choice for inexpensive circuit production.

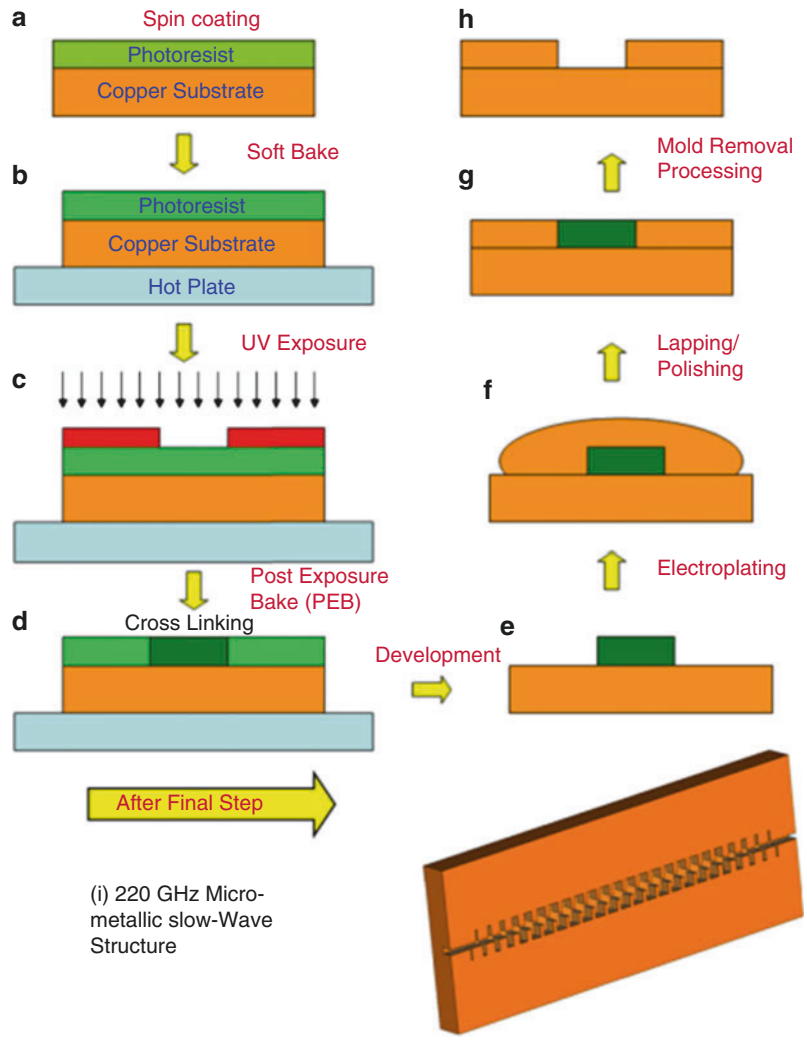
UV-LIGA

With the availability of improved photoresists namely SU-8 and KMPR, it became possible to use a UV (ultraviolet) source integrated into a mask aligner in a typical class-100 clean room facility that usually exists in many universities. Figure 3 shows the typical class-100 clean room equipment required for the UV-LIGA process. Figure 4 shows the LIGA process flowchart.

SU-8 LIGA

SU-8 LIGA is a lithographic process using a negative photoresist originally developed by IBM. It consists of a polymeric epoxy resin dissolved in an organic solvent together with a photo-acid generator. The SU-8 is placed on a silicon wafer to the desired thickness. It can be spun up to a thickness approaching 500 mm in a single step. Multistep applications can achieve thicknesses greater than 1 mm. Thickness nonuniformity will result in exposure nonuniformity in later processes as will any tilting of the substrate. The wafer is then baked at a low temperature to remove the solvent. SU-8 has low optical absorption in the ultraviolet (UV) range at 365-nm wavelength; consequently, the photoresist film can be used with thicknesses greater than 1 mm. When exposed to UV light, absorption of a photon reacts with the photo-acid generator to form a photo-acid acting as a catalyst. This photo-acid causes a cross-linking reaction, primarily during a postexposure bake (PEB). Cross-linking only occurs where the photo-acid is present, i.e., in regions exposed to UV radiation. The PEB

MEMS Vacuum Electronics, Fig. 3 Typical class-100 clean room equipment for UV-LIGA lithography



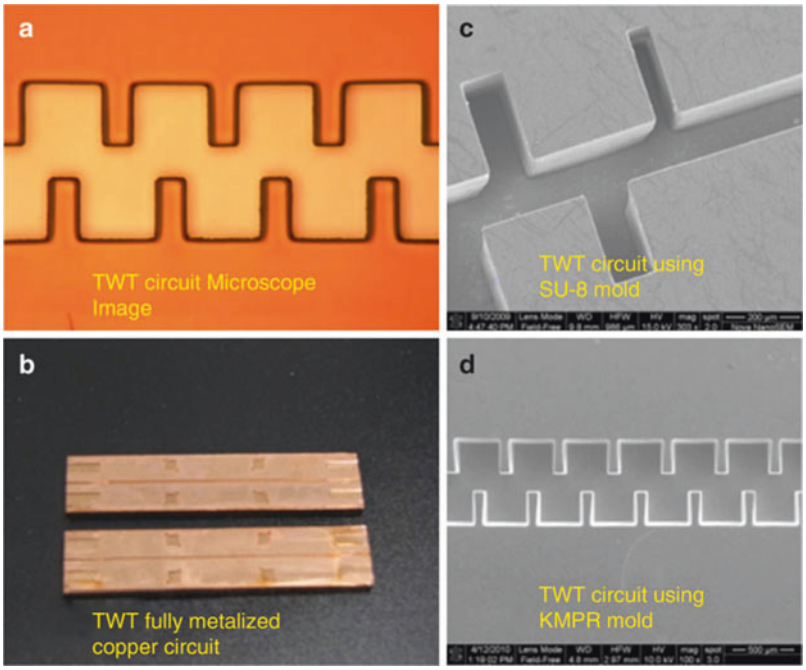
completes the cross-linking reaction. The degree of cross-linking depends on both the exposure dose and bake conditions. After PEB, the resist is developed with a two-stage process using a solvent, followed by an isopropanol wash and air dry. Impressive structures can be found in the literature; however, there are a number of significant problems with SU-8 removal. Performance is very sensitive to the process parameters. All parameters, including resist deposition, pre-exposure bake, exposure dose, post exposure bake, and final development, impact the performance. As an example, a UCD fabricated TWT circuit using an SU-8 mold is shown in Fig. 5c.

KMPR™ LIGA

KMPR is a negative tone photoresist. This chemically enhanced carboxylated epoxy resin consists of a photo-generated acid which requires a postexposure bake to fully activate the solidification process called cross-linking. For electroforming applications, this can withstand acidic solutions at relatively high temperatures compared to room temperature. UC Davis has worked on specially fabricated 4 in. Oxygen Free High Conductivity OFHC Cu wafers with highly flat (±0.5 μm) and polished surfaces. The process consists of spin coating, soft bake, UV exposure, postexposure bake, electroplating, lapping/polishing, and mold removal processing. The UC Davis team has successfully characterized the entire process to precisely fabricate 220 GHz Traveling-Wave Tube Amplifier TWTA copper circuits ~400-μm thick in a single layer process. Figure 5d shows the fully metalized half of the TWT circuit using a KMPR mold.

Si DRIE

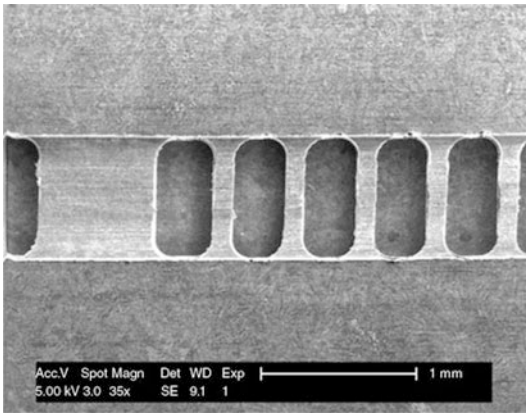
Deep reactive ion etching (DRIE) is a process whereby high aspect ratio structures are etched into silicon [16]. These structures can be used to generate molds or serve as a mold themselves for



MEMS Vacuum Electronics, Fig. 4 LIGA process flow chart

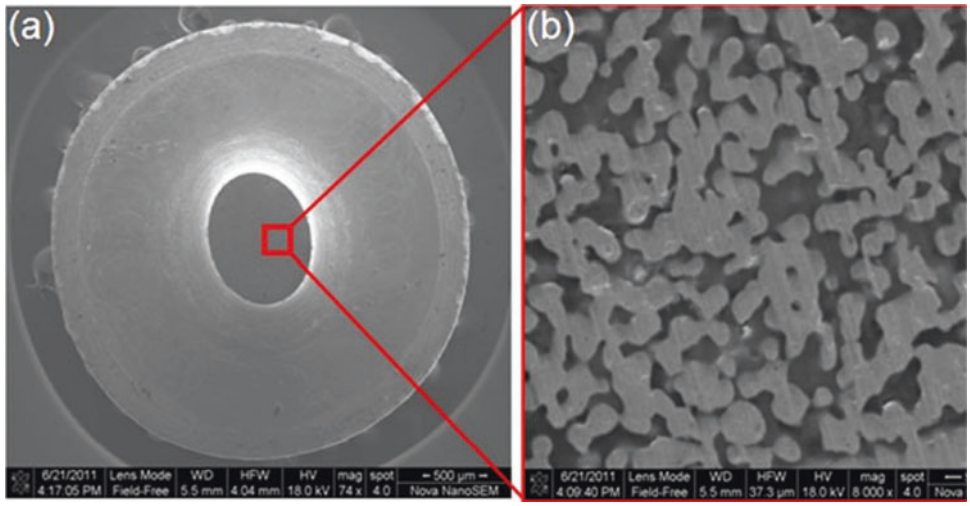
generating metallic structures. Silicon structures ranging from two to hundreds of micrometers can be created. Fluorine-based chemistry is typically used because of its high etch rate (10 mm/min) and selectivity (100:1). The silicon is etched with SF_6. Anisotropy is improved by ion impact assistance coupled with sidewall passivation using flourocarbon polymer deposition and/or O_2 plasma oxidation and redeposition at the silicon sidewall surface. The flourocarbon polymer consists of a chain of CF_2 molecules similar to Teflon with a film thickness of approximately 10–50 nm. It is derived from a 4–8 s application of C_4F_8 applied as a plasma source gas. The introduction of oxygen improves anisotropy by acting as a gettering agent for carbon. The following etch cycle consists of 4–12 s of SF_6, applied as a plasma source gas. The ion assisted SF_6 removes the polymer passivation on horizontal surfaces prior to etching the underlying silicon, leaving the polymer on the sidewalls relatively intact.

Nano-Computer Numerical Controlled (CNC) Milling



The common wisdom has been that direct machining cannot meet the sensitive tolerances of high-frequency vacuum electronic devices (dimensional tolerance <3 μm, surface finish

MEMS Vacuum Electronics, Fig. 5 UCD LIGA fabricated 220 GHz TWTA circuit in a single layer ~400 μm process (**a**) Microscope image (**b**) Fully metalized copper circuit (**c**) TWT circuit using SU-8 mold (**d**) TWT metalized circuit using KMPR mold



<100 nm R_a). However, since the invention of the *Mori Seiki* NN1000 "Nano-Mill" developed by Digital technology Laboratory in Davis, the UC Davis team has successfully fabricated broadband (~60 GHz), 0.22 THz traveling wave tube components using Nano CNC (computer numerical control) milling as their primary approach (Fig. 6) [17, 18]. The NN1000 Nano-Mill features air-bearing guideways, vibration isolation technology, and laser-scale position sensors that have a resolution of 34 pm, and work in concert with linear drive magnetic motors to allows position control resolution of 1 nm. The machine can use either an air spindle capable of 55,000 RPM or a fixed mandrel for linear scribing. The NN1000 is a smooth and steady platform designed for ultraprecision work with exceptionally fine surface finishes. The capabilities of this machine have yet to be fully incorporated into miniaturizing the vacuum electronics industry.

Also, the UC Davis team has used Nano CNC Milling for machining of tungsten high current density cathodes [15]. Since the particle size of the tungsten nano-composite cathodes is usually less than one micron, it is very difficult to achieve good quality emission surface using conventional cathode machining techniques (the surface becomes smudged and the pores are closed). UC Davis has shown that the NN1000 machine is also an excellent choice for creating an ideal cathode emission surface (Fig. 7).

Key Research Findings

Two-Step X-ray LIGA at Seoul National University

Shin et al. [19] at Seoul National University were able to build the first working LIGA fabricated vacuum electron device operating at 35 GHz. To further their achievement, the group was able to fabricate a circuit for a device that would operate at 100 GHz using two-step X-ray LIGA creating three-dimensional structures with two-dimensional techniques.

Northrop Grumman 650 GHz Folded Waveguide TWT

Northrop Grumman [20] fabricated and demonstrated a Folded Waveguide TWT amplifier with regenerative feedback at 650 GHz. The device maximum output power was 16 mW at a duty factor of 1 % in the frequency range 600–675 GHz. This is significantly higher than the power capability of existing sources operating at these frequencies.

Nano-Klystron at Jet Propulsion Laboratory, CA, USA

Siegel et al. [21] at Jet Propulsion Laboratory have reported on the designing and fabrication of Nano-Klystrons at 640 and 1,200 GHz. They were able to manufacture a cavity for a 640 GHz Nano-Klystron using precision metal machining on copper and they are working on developing a manufacturing method for 1,200 GHz cavity using silicon DRIE. To achieve the current densities required for Nano-Klystrons, they are planning to use cold cathodes that are capable of generating 1,000 A/cm^2. These cathodes are made of carbon nanotubes and they are well suited for low power high current density applications.

Diamond-Based Submillimeter Backward Wave Oscillator

Dayton et al. [22] at the GENVAC Aerospace Corporation, OH, were able to produce a 300 GHz circuit by forming chemical vapor deposited diamond around lithographically constructed silicon mold. They believe that similar techniques can be easily adapted to producing 600 GHz circuits. They are applying solid-state fabrication techniques to vacuum electronics: The gun is manufactured as an integral part of the slow wave structure. In addition, they were able to apply precision fabrication and assembly techniques used in fabrication of liquid crystals to bring vacuum electronics even closer to being truly nanoscale.

The Klystrino at the Stanford Linear Accelerator Center (SLAC)

Stanford Linear Accelerator Center (SLAC) reported on the development of a "klystrino" [23] – high-power RF source at W-band intended for tabletop accelerator, radar, and communications applications. An X-ray LIGA process was used to manufacture the circuit with deep features (<3 mm) and surface finish of about 50 nm. The klystrino was designed to operate at 110 kV, 2.4 A and produce 10 kW of peak power with 1 kW of average power at 1 % duty.

220 GHz TWT by UC Davis, CPI, and Teledyne

At UC Davis, a novel 0.22 THz Traveling Wave Tube Amplifier design was conceived [24] with potential application for high data rate communications and imaging. It consists of a staggered double-vane grating array operating in the TE mode. The device performance using the MAGIC PIC code showed a power bandwidth product of >1,000 W GHz with 3–5.5 % intrinsic electronic efficiency, and >25 % bandwidth at a center frequency of 220 GHz. The shortest dimension of this 220 GHz TWTA double-vane micrometallic structure is 75-μm wide and 385-μm deep, corresponding to an aspect ratio of ~4:1. The MEMS fabricated circuits are shown in Fig. 5. The RF measurements conducted at UCD demonstrated excellent RF transmission for KMPR LIGA fabricated circuits [25] and the Nano-CNC fabricated circuits [17, 26] with S_{21} ~ 5 dB in passband (~200–265 GHz) and S_{11} ~ −10 dB.

Definition

Metal nanoparticles are particles composed of metal elements (most frequently transition metals such as Ag, Au, Co, Cu, Fe, Ni, Pd, Pt, Re, Ru) with a size below ~200 nm and an aspect ratio close to 1 (as opposed to nanowires and nanosheets). Particles smaller than 3 nm (~500–1000 atoms) are also called *clusters*.

A first-principles approach aims at computing the properties of a system by directly solving the quantum-mechanical Schrodinger equation for atomic cores and electrons without the input of empirical parameters.

Introduction

Metal nanoparticles have been used since ancient times as famously exemplified by the fine Lycurgus Cup in the British Museum. This fourth-century Roman glass cup is green in reflected light and ruby red in transmitted light owing to the presence of gold colloids embedded in the glass, where the size of the colloids does not exceed 70 nm [1]. Interestingly, the manufacture of gold-ruby glass was subsequently lost and rediscovered in Europe only in the seventeenth century.

Nowadays, metal nanoparticles have become critically important and promising components in a large variety of fields such as biological imaging and sensing, drug delivery, catalysis, thin film technology, optoelectronics, optics, and magnetic recording. The use of nanoparticles may be primarily motivated by geometric constraints, as is the case for drug delivery to the central nervous system through the brain-blood barrier. Similarly, metal nanoparticles have been used in catalyst arrays as a way to maximize the active surface area for a given amount of material, and thus increase the efficiency or reduce the cost of the device. In most cases, however, downsizing the material to the nanoscopic scale will also modify or generate new properties that are either detrimental to the intended application or on the contrary specifically targeted. For instance, the surface activity of Pt nanoparticles used in proton exchange membrane fuel cells to catalyze the oxygen reduction reaction (ORR) has been shown to deteriorate with reducing size. Therefore the optimal diameter of the Pt nanoparticles is practically around 3–5 nm before this detrimental effect starts outweighing the benefit of size reduction on the specific activity (activity per unit volume). A counterexample is offered by gold. While bulk gold is noble and does not easily adsorb molecules, gold nanoparticles have been found to be good catalysts for some applications such as CO oxidation even at room temperature.

Thus, while a vast amount of experimental work is devoted to finding easy, robust, and cost-effective synthetic routes for particles of targeted composition, shape, and size, it is equally important to develop theoretical tools that can predict their properties at the nanoscale, and first-principles techniques have a long record in this field. This entry first explains why the simulation of metal nanoparticles requires the use of first-principles techniques and particularly density functional theory (DFT). Then, it describes a series of well-established DFT-based methodologies to obtain some of the main properties of metal

nanoparticles, namely, chemical and geometric stability, growth, segregation effects in the case of alloy particles, electrochemical stability, and catalytic properties.

First-Principles Calculations

The metallic bond is remarkable, first because it tends to favor high coordination numbers, up to 12 in close-packed atomic arrangements, second because it is moderately directional, which means that the bond energy has a small dependence on the bond angular variables. This has important implications when dealing, for instance, with small metal clusters (<50 atoms). First, the metallic bond in a small cluster is not saturated and thus not fully developed, and the empirical embedded-atom method (EAM), which is often a method of choice for predicting the energy of metallic systems, is then not applicable. Second, a small cluster with a given composition and number of atoms may adopt a large number of metastable configurations that are very close in energy. It is therefore necessary to be able to accurately compute the energy of each configuration at a small computational cost. The accurate treatment of atomistic systems is specifically the object of *first-principles methods*, whereby the energy of the system is determined by directly solving the quantum-mechanical Schrödinger equation without inputting empirical parameters. Given that the nuclei are much heavier than the electrons, it is in most cases reasonable to treat the former as classical particles moving in the field generated by the electron cloud, the latter being represented by the full electronic wave function $\Psi_{\mathrm{el}}(r_1, \ldots, r_{N_e})$ as a function of the coordinates r_i of the N_e electrons in the system. In this so-called Born-Oppenheimer approximation, one should then solve for Ψ_{el} in the Schrödinger equation written for any fixed position of the nuclei as [2]

$$\left(-\sum_{i=1}^{N_e}\frac{\hbar^2}{2m_e}\nabla_i^2 + V_{ext} + \sum_{i\neq j}^{N_e}\frac{q_e^2}{4\pi\epsilon_0 r_{ij}}\right)\Psi_{\mathrm{el}} = E_0\Psi_{\mathrm{el}}. \quad (1)$$

Here, the first term stands for the kinetic energy, where $\hbar$ is the reduced Planck constant and m_e is the electron mass. The second term stands for the external energy, where V_{ext} is the potential created by the nuclei and possibly by any other external source and acting on the electrons. The third term stands for the electron–electron interaction energy, where q_e is the electron absolute charge, ϵ_0 is the permittivity of free space, and $r_{ij} = |r_j - r_i|$. The total ground-state electronic energy of the system E_0 is obtained as the lowest eigen value of Eq. 1. However, in practice, the multibody character of Ψ_{el}, whereby the probability distributions of any two electrons i and j are correlated in this wave function, makes this general approach intractable even numerically, and thus calls for an approximate solution.

Hartree-Fock Approximation

In the Hartree-Fock approximation [2, 3], the electronic wave function is written as the Slater determinant of $N_e/2$ one-body wave functions, $\Psi_{\mathrm{el}} = |\Psi_1(r_1)\ldots\Psi_{N_e/2}(r_{N_e/2})|$, which satisfies the Pauli exclusion principle for a system of fermions (here, for simplicity, we assume that N_e is an even number and that the system is not spin polarized, in which case each wave function is occupied by two electrons of opposite spins). This allows separating the coordinates in Eq. 1 and to obtain the $\Psi_i(r_i)$ as the solutions of a system of $N_e/2$ coupled eigen equations, which can be solved through a self-consistent numerical scheme. This approach is also interesting because the Ψ_i can be chemically interpreted as orbitals occupied by the electrons, and an approximation of the total energy E_0 can be obtained from the orbital energies ϵ_i. One drawback of this approach, however, is that the Slater determinant form of Ψ_{el} is unable to capture all of the electronic correlation, notably leading to a poor description of the Coulomb hole at short range. As a consequence, it is known that for a metallic system, the bandwidth and the density of electronic states at the Fermi level are largely exaggerated at the Hartree-Fock level [2–4].

Density Functional Theory (DFT)

Metallic systems are better described in the framework of density functional theory [2, 3], where the ground-state electronic density $n(r)$ is taken as the primary unknown and determines the total energy of the system E_0 and the full electronic correlation. In the Kohn-Sham approach to DFT (KS-DFT), the electronic density can be in principle obtained exactly by solving the Kohn-Sham eigen equation

$$\mathcal{H}_{\mathrm{KS}}[n(r)]\Psi_i = \left(-\frac{\hbar^2}{2m_e}\nabla^2 + V_{ext} + V_{xc}[n(r)]\right)\Psi_i = \epsilon_i\Psi_i. \tag{2}$$

In the Kohn-Sham Hamiltonian $\mathcal{H}_{\mathrm{KS}}$, $n(r)$ determines the exchange-correlation potential V_{xc} and is itself determined by the Kohn-Sham orbitals Ψ_i, implying that Eq. 2 has to be solved self-consistently. Because the core electrons are usually not involved into bonding with surrounding atoms, the core electronic density may be taken within a good approximation as the sum of the core densities of isolated atoms stored in atomic pseudopotentials. The unknown is then only the valence electronic density, which drastically reduces the computational cost of the simulation. For heavy elements such as gold, the relativistic character of the core electrons modifies their interactions with the valence electrons and thus the chemical behavior of the latter, in which case a relativistic pseudopotential has to be used for the accuracy of the calculation. Also, in practice, the exact dependence of V_{xc} on $n(r)$ is unknown, and approximate functions have to be used. Most commonly, V_{xc} is expressed as a local function of $n(r)$ in the local density approximation (LDA), or as a local function of $n(r)$ and its gradient in the generalized gradient approximation (GGA). Moreover, some DFT functionals have also been developed to include the long-range van der Waals interactions, which are especially important for metal clusters.

Although the computational cost of a naively implemented KS-DFT scheme scales $\mathcal{O}(N_e^3)$, a number of approaches reduce this scaling to $\mathcal{O}(N_e^2)$ or even $\mathcal{O}(N_e)$, allowing for the treatment of systems that contain hundreds or thousands of atoms. Thus, in general DFT represents the best compromise between accuracy and computational effort for metal clusters. It is however important to note that contrary to the Hartree-Fock approach, the KS-DFT formalism is in principle affected by electronic self-interaction, whereby an electron interacts with the electronic density of its own orbital. While this has a minor impact on metallic systems where the wave functions are largely delocalized, this may be the source of substantial discrepancies for insulators and systems with a sizable HOMO-LUMO gap such as oxides and organic components. The energetics of these systems may be improved by introducing some of the Hartree-Fock correlation in the KS-DFT potential. Alternatively, in the DFT + U approach, an additional potential characterized by the U term may be selectively applied to some elements, e.g., oxygen atoms, to penalize the electronic overdelocalization induced by the self-interaction. Such hybrid approaches have been shown, for instance, to better describe the magnetic properties of transition metal complexes [2, 4].

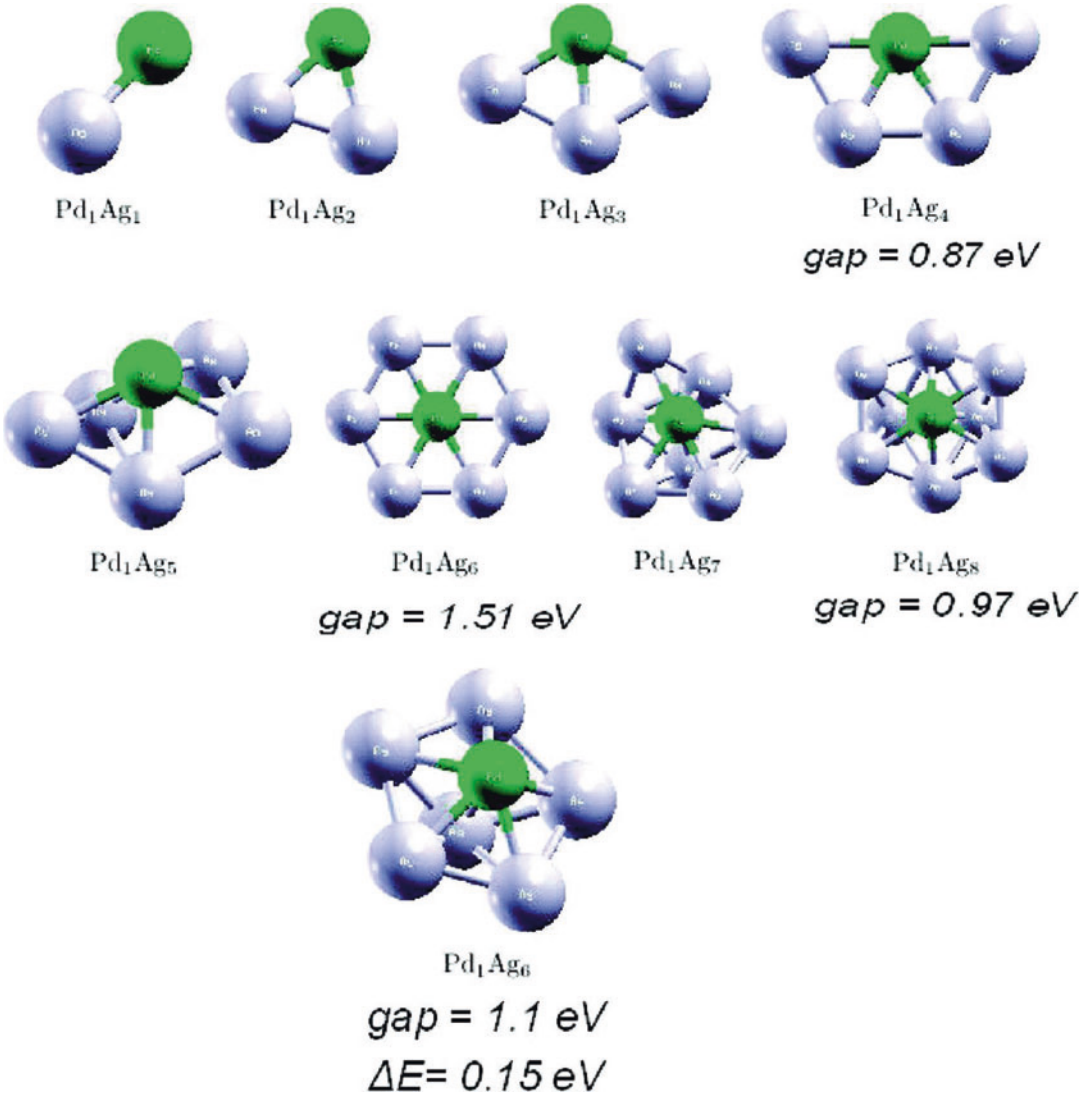
Chemical Stability of Metal Clusters

Small metal clusters have interesting properties related to their persistent molecular character. Particularly, they exhibit distinct electronic shells, and thus tend to favor atomic arrangements and numbers of atoms (kwown as *magic numbers*) ensuring electronic shell closure [4]. An example is provided by the synthesis of monodisperse, ultrastable silver clusters protected by a thiolate layer [5]. X-ray spectroscopy has revealed a core structure consisting of a Ag_{12} hollow icosahedron within a Ag_{20} dodecahedron enclosed in a sulfur rhombicuboctahedron, six faces of which are capped with Ag_2S units, resulting in an overall octahedral particle with 44 Ag atoms. By computing the electronic structure of this system with DFT, one shows that the delocalized electrons not involved in bonding with thiolates occupy

spherical orbitals around the Ag cluster playing the role of a superatom. The number of these electrons is 18, which corresponds to the Aufbau closed-shell filling $1S^2 \mid 1P^6 \mid 1D^{10}$ and thus explains the outstanding stability of this structure. This is further supported by the relatively large HOMO-LUMO gap (0.78 eV) obtained for this structure.

Structure Optimization of Metal Clusters (<500 atoms)

The purpose of structure optimization is to minimize the energy of a particle with a given composition and number of atoms. This can be achieved, for instance, by the basin-hopping (BH) algorithm, consisting in a series of random perturbations of the atom coordinates followed by local relaxations. The new coordinates are accepted or rejected based on the value of the relaxed energy, for instance, by using the Metropolis criterion of a standard Monte-Carlo simulation. The efficiency of this algorithm is sensitive to the coordinate perturbation step, which may consist in a simple kick on the atoms or in the exchange of two atoms of distinct species. The selection of new coordinates may also be enhanced or oriented through some pattern recognition functionalities, e.g., using a nearest-neighbor analysis. The stable patterns are either entered in advance or learned during the simulation as in genetic algorithms. The approach to compute and locally minimize the energy of intermediate configurations depends on the size of the system.

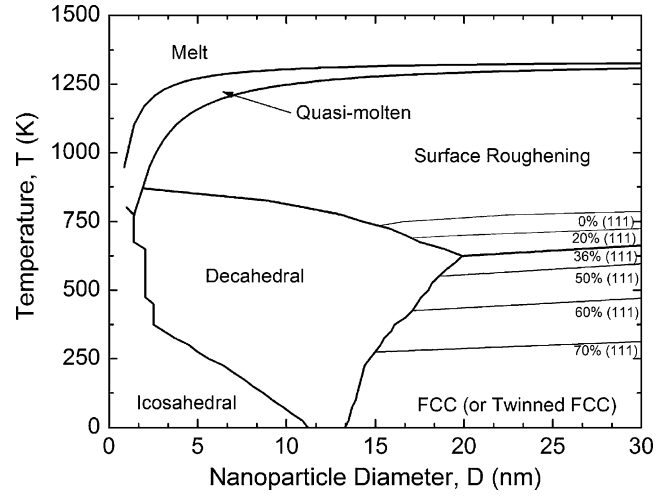


For small clusters (<50 atoms), it is necessary, and computationally affordable, to apply first-principles techniques (such as DFT) to accurately describe the specific chemistry of the system. The resulting BH-DFT algorithm has been used, for instance, to predict the stable structure of $PdAg_M$ nanoclusters as shown in Fig. 1. While in general for $M > 4$ the cluster favors a 3D structure to maximize the number of bonds, the PdAg6 exceptionally retains a planar geometry to achieve a closed-shell electronic structure in the 2D jellium model [4].

For large clusters (50–500 atoms), the computational cost implied by the large number of configurations starts precluding an all-DFT treatment. Fortunately, as the system size increases the electronic shells start to merge to build up the metallic character of the system. The vanishing of shell closure effects justifies developing and using empirical potentials (EP) to calculate the energies in the EP-BH algorithm. However, in this size range it is recommended to check a posteriori the energy ordering of the most stable configurations by DFT and possibly to refine the EP in case of a discrepancy.

DFT-Based Modeling of the Shape Stability of Metal Nanoparticles (>500 Atoms)

Beyond a few hundreds of atoms, it becomes too costly to perform first-principles calculations of the entire particle, implying the need for some modeling and multiscale approaches. Regarding the particle shape, one can use the fact that in most cases highly symmetrical shapes exposing highly packed facets such as (111) and (100) are energetically favorable. Typically, this can lead to multiply twinned particles such as icosahedra and decahedra or monocrystalline particles such as cubes, octahedra, and cuboctahedra. Thus, in the case of monoelemental particles, a general expression for the particle free energy can be obtained within this limited set of geometries as a function of the temperature T and external pressure P_{ext} through a simple thermodynamic model including the contributions of the bulk, surfaces, and twin boundaries [6]:



$$G(T,P_{\text{ext}}) = G_{\text{bulk}}(T) + v\left(1 - \frac{2\sum_i f_i\sigma_i(T)}{B_0 R} + \frac{P_{\text{ext}}}{B_0}\right) \times \left[q\sum_i f_i\gamma_i(T) + n\sum_\theta \left(a_\theta v_\theta(T) + \sum_\phi l_{\theta\phi}\eta_\phi(T)\right)\right], \quad (3)$$

Metal Nanoparticles from First Principles, Fig. 1 Optimal structures of $PdAg_M$ clusters as obtained from BH-DFT (Reprinted with permission from Ref. [17]. Copyright 2007 American Chemical Society)

where $G_{\text{bulk}}(T)$ is the bulk energy at normal pressure; v, the molar volume; q, the surface-to-volume ratio; f_i, the surface fraction of facet i; $\gamma_i(T)$ the surface energy of facet i; n, the density of planar defects; $v_\theta(T)$, the energy of the twin plane of area a_θ in orientation θ; and $\eta_\phi(T)$, the re-entrant line tension where the twin plane intersects with the free surface in the orientation ϕ with length $l_{\theta\phi}$. We note that by definition, $\sum f_i = 1$; This model also includes volume change effects induced by the surface stresses σ_i and external pressure P_{ext} through the Young-Laplace law, requiring the bulk modulus B_0 and the radius of the particle averaged to a sphere R. The quantities B_0, $\gamma_i(T)$, $\sigma_i(T)$, $v_\theta(T)$, and $\eta_\phi(T)$ are input parameters that need to be calculated in advance, and the optimal particle shape is then obtained by minimizing $G(T, P_{\text{ext}})$ over the f_i, a_θ, and $l_{\theta\phi}$. The surface energy of a facet γ_i may be determined at zero temperature as the quantity satisfying the relation

$$E^N_{\text{slab}} = 2\gamma_i + NE_{\text{bulk}}, \tag{4}$$

Metal Nanoparticles from First Principles, Fig. 2 Phase diagram of nanogold as obtained from relativistic DFT calculations (Reprinted with permission from Ref. [18]. Copyright 2009 American Chemical Society)

where E^N_{slab} and E_{bulk} are the total energy of an N-atom slab in the direction of the facet and the total energy of the bulk per atom, respectively, and are computed with DFT. The factor 2 accounts for the fact that the slab contains two facets. The temperature dependence of $\gamma_i(T)$ can then be extrapolated from $\gamma_i(0)$ through a semiempirical law [6]. The same kind of DFT approach may be used to determine B_0, $\nu_\theta(T)$, and $\eta_\phi(T)$, and the surface stress may be obtained through the common approximation $\sigma_i(T) \sim \gamma_i(T)$, With this approach, the phase diagram of nanogold has been obtained as a function of size and temperature based on relativistic DFT calculations, as shown in Fig. 2. At low temperature, a striking feature of this diagram is the change of the stable structure from the icosahedron, to the decahedron (>9 nm), and finally to the truncated octahedron for sizes larger than 12 nm. Below 9 nm (~20,000 atoms) the energetics are dominated by surface effects, and the icosahedron, with its 20 (111) facets, is the most stable structure. By contrast, above 12 nm the energetics are dominated by the bulk, which penalizes structures with internal twinning. Thus, the monocrystalline truncated octahedron becomes the most stable structure, in spite of the energy penalty associated with its six (100) facets [7].

The treatment of the surface tension in this approach can be refined by including the dependence of the facet energies on the lattice parameter a. The free energy of a monocrystalline structure is then written, with the temperature and pressure dependence being kept implicit,

$$G(a) = G_{\text{bulk}}(a) + vq\sum_i f_i\gamma_i(a), \qquad (5)$$

where $G_{\text{bulk}}(a)$ and $\gamma_i(a)$ have to be computed for different values of a. The particle shape is then obtained by minimizing $G(a)$ over the f_i and a. By comparing the predictions of this approach with explicit DFT calculations for small Pt particles, it has been shown that Eq. 5 is adequate to describe the surface tension effects on the relative stabilities of monocrystalline structures below ~3 nm [8], For larger particles, this differential effect becomes negligible, and it is then valid to use surface energies at the bulk lattice parameter $\gamma_i(a_{\text{bulk}})$ as in Eq. 3. As the particle size increases further, dilation effects too become progressively negligible, and thus for monocrystalline particles Eq. 3 simplifies into

$$G = G_{\text{bulk}} + vq\sum_i f_i\gamma_i. \qquad (6)$$

Wulff Construction (in the Presence of Adsorbates)

In the regime of validity of Eq. 6, the Wulff theorem states that the energy-minimizing polyhedron is such that the distance of each facet to the center of the nanoparticle is proportional to its surface energy. This approach can, for instance,

be used to predict the effect of the chemical environment on the particle shape stability. First, the facet energies in the presence of adsorbates $\gamma_i(\theta)$ are computed using the following formula:

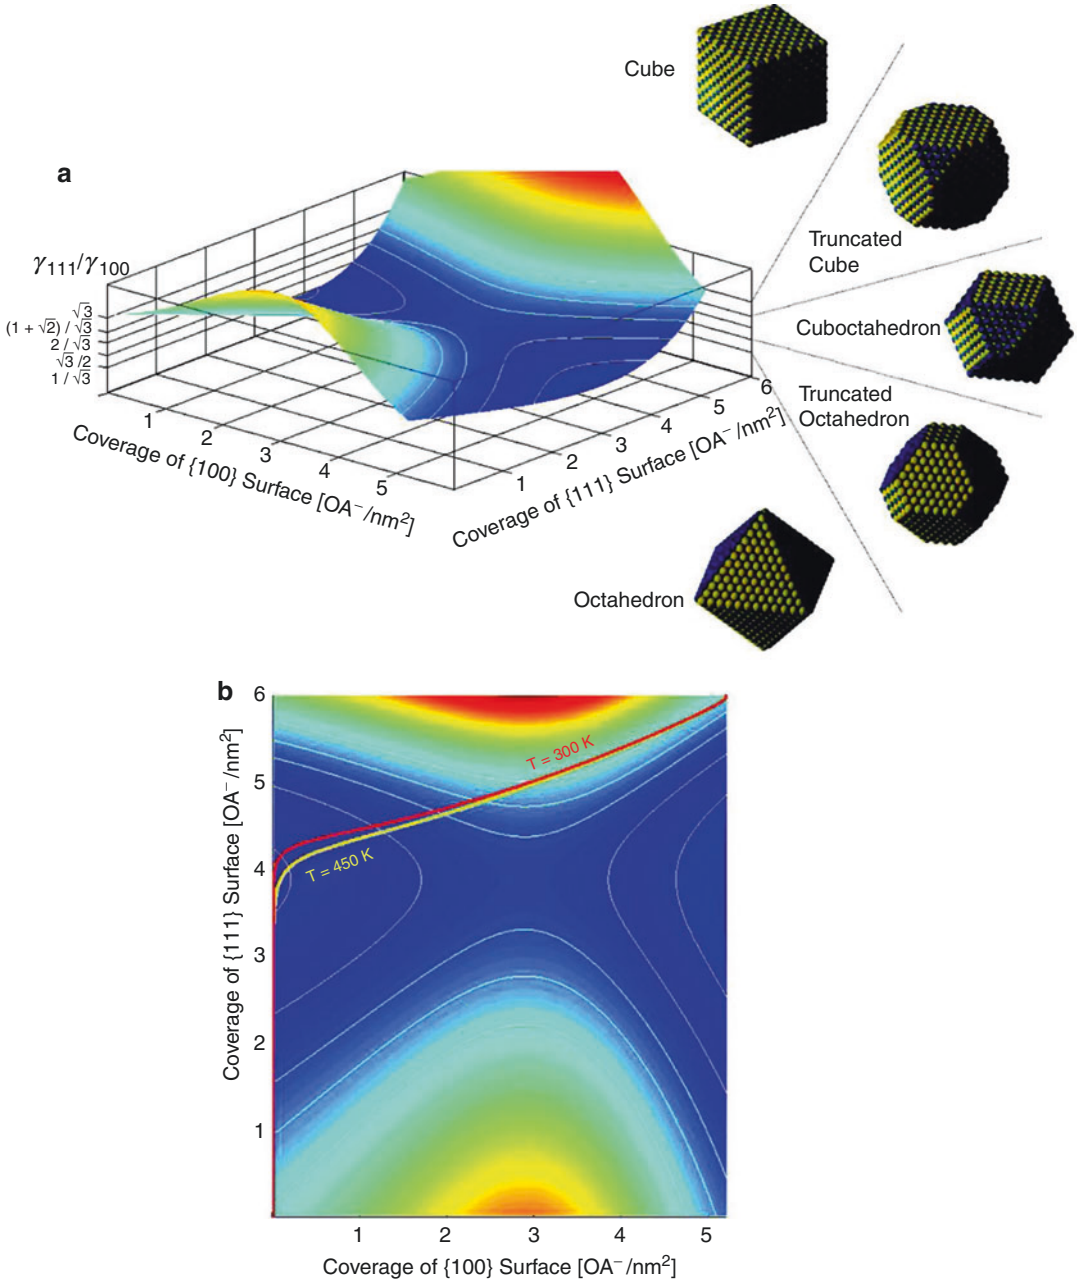
$$\gamma_i(\theta) = \gamma_i(0) + \Delta g_{\text{ads}}(\theta). \tag{7}$$

Here θ is the adsorbate coverage, which is a vector $\theta = (\theta_1, \ldots, \theta_j, \ldots)$ if molecules of different species j are adsorbed; $\gamma_i(0)$ is the surface energy of the bare surface as given by Eq. 4; and $\Delta g_{\text{ads}}(\theta)$ is the free energy of adsorption per unit surface area. This can be computed again with a slab approach,

$$\Delta g_{\text{ads}}(\theta) = \frac{1}{A}\left(G_{\text{slab}}(\theta) - G_{\text{slab}}(0) - \sum_j N_j g_j\right), \tag{8}$$

where $G_{\text{slab}}(\theta)$ is the free energy of the slab + adsorbates; $G_{\text{slab}}(0)$ is the free energy of the bare slab; g_j is the free energy of a molecule of species j in solution or in the gas phase; and N_j is the number of molecules of species j adsorbed on the slab of surface A, which implies $\theta_j = \frac{N_j}{A}$;. The electronic energies and zero-point energies (ZPEs) may be determined by DFT, while entropy contributions are often taken from experiment or estimated through simple statistical models of adsorption [9], The coverage at equilibrium is obtained by minimizing $\Delta g_{\text{ads}}(\theta)$. This approach has been applied, for instance, to study the effect of oleic acid (OA) adsorption on the shape stability of PbSe particles [10]. OA tends to bind more strongly to the (111) surface, such that at low OA concentrations Δg_{ads} is more negative on this surface and the octahedral particle shape is stabilized. However, as the OA concentration increases, the (100) facets become also covered and stabilized by OA, which can ultimately lead to the cubic shape as shown in Fig. 3.

Growth Morphology



In some cases, nevertheless, such as particle bottom-up synthesis, the particle shape is mainly controlled by kinetic effects and can thus substantially deviate from the ideal thermodynamic shape. The small clusters formed upon initial nucleation and their interactions with other species, e.g., the surfactant molecules used in colloidal synthetic methods, can be explicitly treated with DFT [11]. However, as the particle size increases, the growth morphology can be predicted through the kinetic version of the Wulff theorem, whereby the distance of a facet i to the particle center is proportional to its growth rate v_i. In the framework of transition state theory, the growth rate of a facet (in units of nm/s in a specific direction) can be expressed as

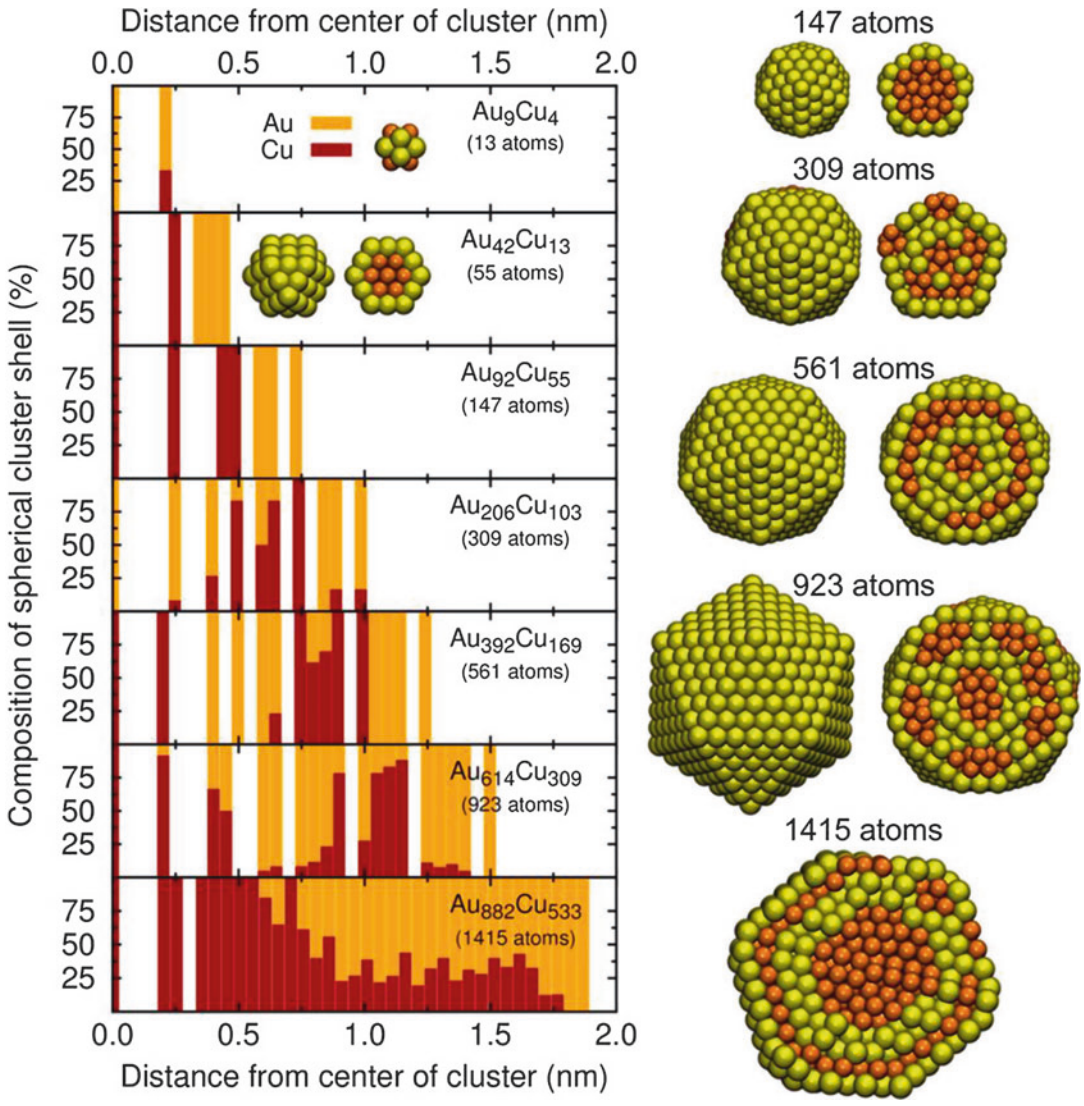
$$v_i = v_0 \exp\left(-\frac{\Delta G_i^*}{kT}\right), \tag{9}$$

where v_0 is the rate of an ideal barrierless growth process and ΔG_i^* is the effective activation barrier for the growth of a monolayer. As such, ΔG_i^* depends on the specific mechanisms of atom diffusion and adsorption on the surface and can be estimated through molecular-dynamics simulations. This general approach has been demonstrated in the case of urea particle growth [12], where the facet growth process and rate are found to be orientation dependent and may furthermore be modified by the addition of simple surfactant molecules such as biuret and acetone as a way to control the particle growth morphology. The simulation times required for unveiling these mechanistic features are of the order of tenths of μs, implying the need for classical force fields, either empirical or fitted on DFT calculations. There is much interest in applying this approach to the case of metal nanoparticle growth possibly in combination with more complex surfactant molecules, as exemplified by the recent development of DFT-based effective force fields for the interaction of polyvinylpyrrolidone chains on Ag surfaces [13].

DFT-Based Modeling of Elemental Distributions in Alloy Nanoparticles

The physical and chemical properties, particularly at the surface, of alloy nanoparticles depend critically on their elemental distribution. For instance,

Metal Nanoparticles from First Principles, Fig. 3 (**a**) Surface energies and thermodynamic shapes of the PbSe particle as a function of OA coverages on (100) and (111) facets as obtained from the Wulff construction. (**b**) Isotherms for OA adsorption on (100) and (111) facets at 300 K (*red line*) and 450 K (*yellow line*), illustrating how the equilibrium shape can be varied through ligand concentration (Reprinted with permission from Ref. [10]. Copyright 2012 American Chemical Society)



core-shell bimetallic nanoparticles, in which the constitutive elements tend to segregate from each other toward the center and surface of the particle, have been used in an increasing number of applications. The search for new stable structures can be aided by theoretical tools that, for a given chemical composition, minimize the particle energy over the large number of possible

elemental distributions. This can be achieved through a multiscale treatment consisting in the following two steps: first develop a model Hamiltonian that can provide the energy of any configuration at a reasonable trade-off between accuracy and computational cost; second minimize the value of that Hamiltonian over the configurational phase space through an optimization algorithm, such as simulated annealing. Typically, to develop the model Hamiltonian, one first builds an appropriate set of reference configurations and computes their energies from first principles; then the parameters of the Hamiltonian are fitted on this set of accurate energies. One of the most delicate aspects of this approach is the choice of the functional or structural form of the Hamiltonian. Three common forms are here briefly listed:

- **Analytical formula**: The energies are fitted on an explicit analytical expression as is the case, for instance, in the embedded-atom model (EAM), which has been extended, for instance, to the case of bialloys.
- **Cluster expansion (CE)**: The value of the energy is written as the Taylor-like expansion of two (three, four, etc.)-body interactions between first (second, third, etc.)-nearest-neighbor atoms around a set of fixed sites, where the fitting parameters are the weights in the expansion.
- **Artificial neural network (NN)**: A set of variables characterizing the system structure is fed into a neural network (NN) consisting of several layers of artificial neurons. Each neuron in a layer processes a linear combination of the outputs of the previous layer through a sigmoid function, and the predicted energy of the system is obtained as the output of the last layer consisting of a single neuron. The fitting parameters are the weights in the linear combinations between two layers.

Each form has its advantages and drawbacks. The CE approach allows a quick and easy analysis of the energy in terms of local atomic contributions, but it is constrained by its reliance on a set of fixed sites, which may not apply for systems with a large number of translational and rotational degrees of freedom. As a flexible and universal fitting scheme, NNs are useful, for instance, when the analytical approach cannot cover the entire phase space; however, the fitting error may converge slowly with the size of the NN. Thus, in some cases, it is found necessary to combine these approaches. The model Hamiltonian that is obtained must finally be cross-validated against a set of configurations not included in the original reference set, and the development workflow "reference set → model Hamiltonian → cross-validation" must be repeated self-consistently until the desired convergence is reached.

These principles have been illustrated by the prediction of the equilibrium composition of Au-Cu bimetallic nanoparticles in vacuum and water, and particularly their surface structure as a key to understand their catalytic activity for CO_2 reduction [14]. A NN is used to predict the energy of an individual atom in the particle. For transferability across all possible structures, the NN input variables representing the local environment around the atom are obtained by integrating the Cartesian coordinates of the neighbor atoms into a fixed number of radial and angular symmetry functions. The total energy of the particle is then simply obtained as the sum of the atom energies. Thus, an analytical approach (the symmetry functions) and a CE approach (summing over the atom energies) are embedded within the NN and are essential for the accuracy. The fitting parameters of the resulting model Hamiltonian are obtained by training the NN on a reference set of ~20,000 local environments including bulk and slab structures, atomic clusters, and molecules, where the reference energies are computed with DFT and include the van der Waals interactions. A NN consisting of two hidden layers of five neurons each is found to be sufficient to approximate the DFT energies within a mean absolute error of 6 meV per atom and allows computing the total energy of a 6-nm nanoparticle in less than a minute on a single core. Simulated annealing of the nanoparticle with this Hamiltonian shows that the equilibrium distribution differs whether the particle is placed in vacuum or in water. In vacuum, Au atoms tend to segregate toward the low-coordinated surface sites because gold is more noble than copper, as shown in Fig. 4. However, the presence of water lifts this

Metal Nanoparticles from First Principles, Fig. 4 Optimized compositions of Au-Cu nanoparticles in vacuum as obtained from simulated annealing using the NN potential. Au atoms tend to segregate to the surface (Reprinted with permission from Ref. [14]. Copyright 2014 American Chemical Society)

segregation effect by promoting mixed Au-Cu surface structures as a result of the stronger van der Waals interaction of water with Cu atoms.

Electrochemical Stability of Metal Nanoparticles

It is important to be able to predict the electrochemical stability of nanoparticles in aqueous environment. For instance, the dissolution of small Pt particles and coarsening into larger particles through Ostwald ripening is a phenomenon observed in practical catalyst arrays that is responsible for the performance degradation of fuel cell systems over time. While the Gibbs-Thomson effect in basic thermodynamics predicts a decreased stability with reduced particle size, there is a need to better characterize this effect at the atomic scale. The electrochemical stability of

metals as a function of solution pH and electrode potential U, also known as Pourbaix diagrams, can be determined through an established method combining first-principles techniques and a careful set of reference energies [9]. It is equally applicable to nanoparticles, and it is outlined in the following for Pt particles in aqueous solution. In the stability region, the particle may adsorb hydroxides and oxides generated by electrochemical water splitting:

$$\begin{aligned} \mathrm{Pt} + \mathrm{H_2O_{(l)}} &\rightarrow \mathrm{PtOH} + \mathrm{H^+_{aq}} + \mathrm{e^-} \\ \mathrm{PtOH} &\rightarrow \mathrm{PtO} + \mathrm{H^+_{aq}} + \mathrm{e^-}, \end{aligned} \tag{10}$$

where the adsorption of OH and O on the particle surface is thermodynamically driven by decreasing the electron chemical potential -eU and increasing the pH. Alternatively, in the instability region, the particle is subject to dissolution:

$$\mathrm{Pt} \rightarrow \mathrm{Pt^{2+}_{aq}} + 2\mathrm{e^-}, \tag{11}$$

which is also driven by increasing the electrode potential. In general, the equilibrium state of the particle at given pH and U may be determined by minimizing the total free energy over the different adsorption patterns and coverages of OH and O as well as the dissolution state. However, the free energy of liquid water and ionic species such as Pt^{2+} and H^+ is challenging to estimate from first principles. A solution then consists in assigning free energies to these species in a way that is consistent with well-known reaction energies. For water, one knows the experimental free energy of condensation $\mathrm{H_2O_{(g)}} \rightarrow \mathrm{H_2O_{(l)}}$. Thus, the chemical potential of water in the liquid phase $\mu_{\mathrm{H_2O_{(l)}}}$ can be related to that in the gas phase, which in turn is obtained as

$$\mu_{\mathrm{H_2O_{(g)}}} = E_{\mathrm{el}} + \mathrm{ZPE} - Ts_{\mathrm{H_2O_{(g)}}}, \tag{12}$$

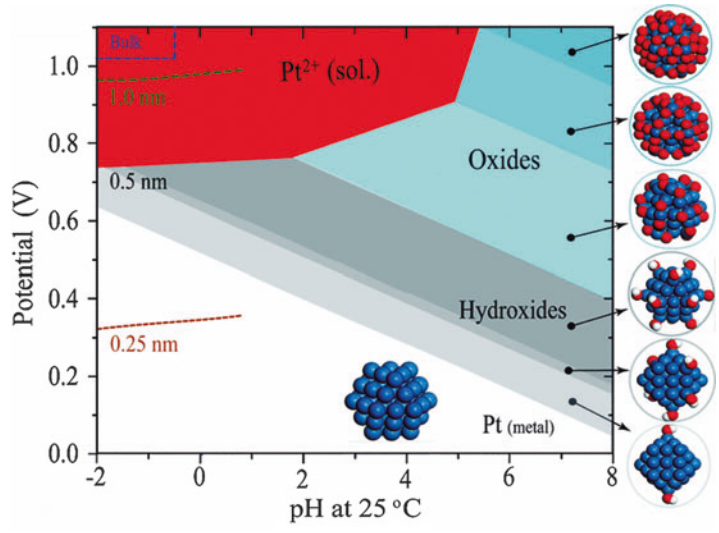
where E_{el} and ZPE are the electronic and zero-point energies as obtained from DFT, while $s_{\mathrm{H_2O_{(g)}}}$ is the entropy of the H_2O molecule in the gas phase as taken from experimental tables. For H^+, one can use the fact that at any temperature the free energy of the reaction

$$\frac{1}{2}\mathrm{H_2} \rightarrow \mathrm{H^+_{aq}} + \mathrm{e^-} \tag{13}$$

is by definition 0 in standard conditions of pressure and concentration and at the potential of the standard hydrogen electrode (SHE). Thus, at any pH and electrode potential U, the chemical potential of the proton + electron can be written

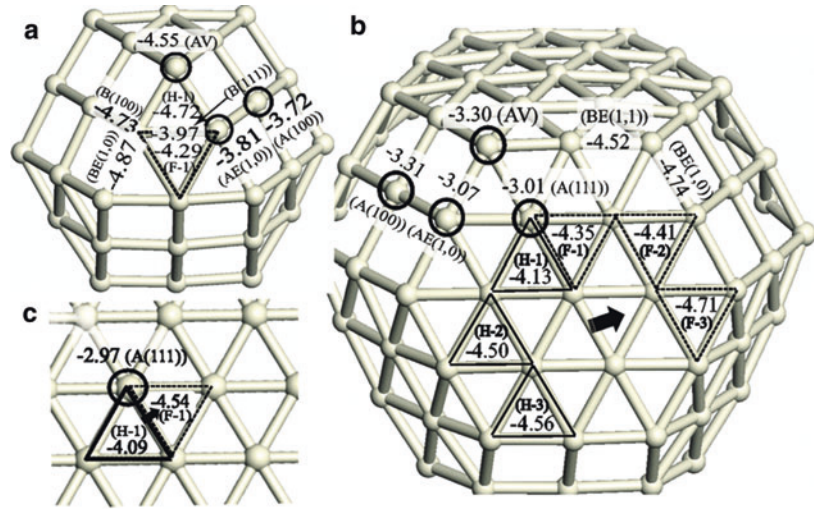
$$\mu_{\mathrm{H^+_{aq}+e^-}} = \frac{1}{2}\mu^{\mathrm{1atm.}}_{\mathrm{H_2}} - kT\log(10)\mathrm{pH} - eU, \tag{14}$$

where U is referenced to the SHE and $\mu^{\mathrm{1atm.}}_{\mathrm{H_2}}$ is the chemical potential of a H_2 molecule in the gas phase at one atmosphere and is obtained as in Eq. 12. Likewise, the free energy of the dissolution reaction



$$\mathrm{PtO} + 2\mathrm{H^+} \rightarrow \mathrm{Pt^{2+}_{aq}} + \mathrm{H_2O} \tag{15}$$

is well known experimentally at given concentrations of the ions. Consequently, the chemical potential of $\mathrm{Pt^{2+}_{aq}} + 2\mathrm{e^-}$ can be related to those of PtO, $H^+_{aq} + e^-$, and H_2O, where μ_{PtO} is dominated by the electronic energy and is obtained from DFT.



The aqueous chemical potentials obtained through this reference scheme can then be combined with the DFT energies of a set of Pt cuboctahedra with various adsorption patterns to determine the Pourbaix diagram for particle sizes between 0.25 and 1 nm, as shown in Fig. 5 [15]. Particularly, this approach allows quantifying the extension of the dissolution region at low pH and high electrode potential with respect to bulk platinum as a result of the dramatic decrease in the average cohesive energies for sizes smaller than 3 nm.

Catalytic Properties

Metal nanoparticles are commonly used in catalytic arrays as a way to maximize the active surface area per unit mass of the catalyst material.

Both the particle size and surface site effects can be evaluated (Reprinted figure with permission from Ref. [19]. Copyright (2008) by the American Physical Sciety (a))

However, reducing the particle size may also modify the intrinsic catalytic activity owing to the larger number of low-coordinated sites sitting on the vertices and edges of the particle, which tend to exhibit stronger chemical reactivities. The binding energy of a given adsorbate on the different sites of a particle may be computed by DFT, as illustrated in Fig. 6, and the resulting effect on the overall catalytic turnover depends in general on the specific application. For instance, a stronger binding of OH on the low-coordinated sites of the particle may accelerate the CO oxidation reaction by increasing the amount of oxidant on the catalyst surface. Inversely, this effect can be deleterious for the oxygen reduction reaction by reducing the number of active sites for oxygen adsorption. The DFT approach can be equally applied to determine activation barriers on different sites of the nanoparticle [16].

Nanostructured SERS-active metal oxides

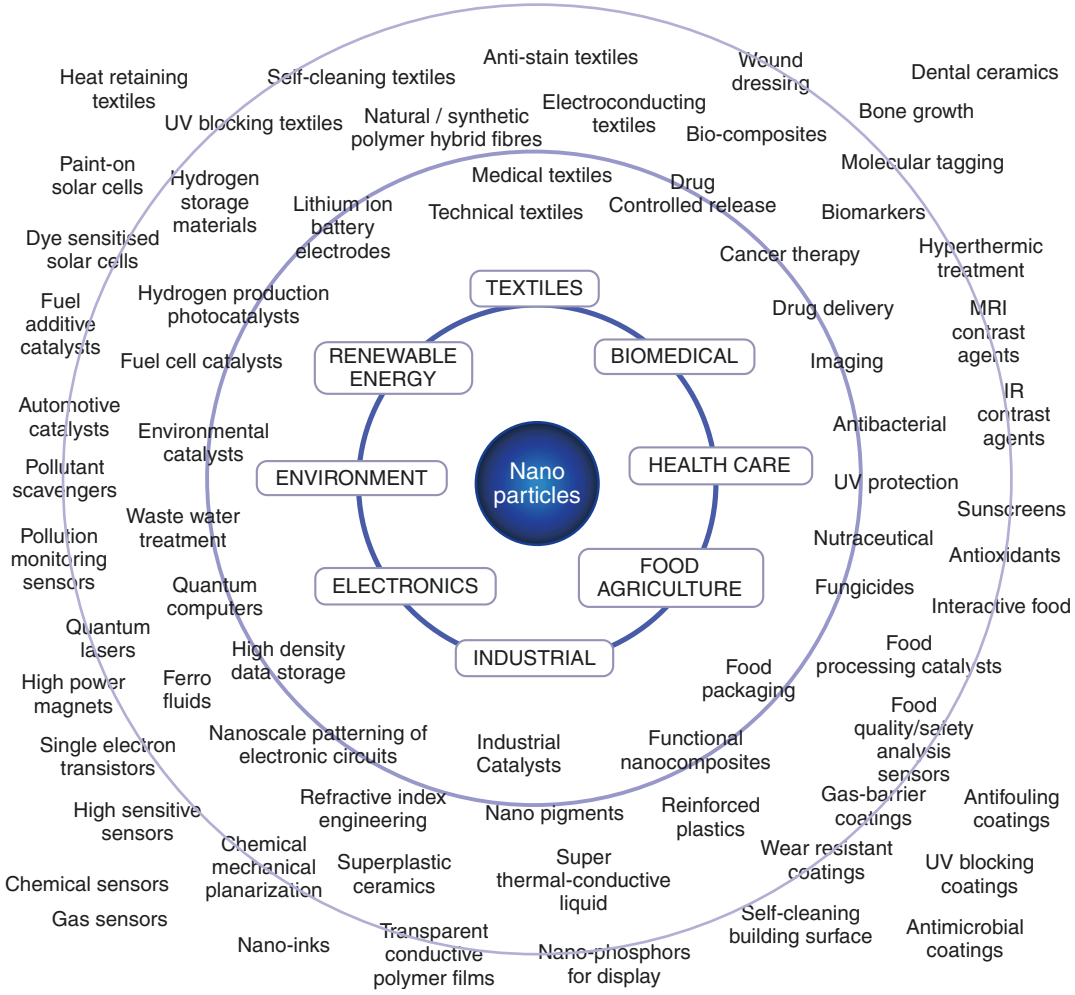
Definition

A metal oxide is a chemical compound that contains one metal element and at least one oxygen atom. If one of the characteristic dimensions of the material was at the nanoscale, thus, it was called metal oxide nanostructure. Thanks to their smart properties, metal oxide nanostructures, alone or decorated with noble metal nanoparticles, can enhance the Raman signal and are called SERS-active substrates.

Metal Oxide Nanostructure Applications

Nanomaterials are able to show completely different properties from their conventional bulk counterpart, and several applications are suitable to exploit the unique properties of these materials. Figure 1 collects the enormous variety of application of nanoparticles, but the same sectors take advantage also from different nanomaterial shapes. Among the inorganic semiconductor materials, nanostructured semiconductors have recently invaded the scientific activity related to devices for sensing, energy conversion, and energy storage. Indeed these materials can overcome the limitation imposed by the relatively poor properties of the standard electrodes, showing high surface area, superior carrier mobility, and significantly low charge recombination rates.

Metal oxide (MO) nanostructures are the focus of current research efforts in nanotechnology since they are the most common minerals on the Earth and thanks to their special shapes, compositions, and chemical and physical properties [2]. They have now been widely used in the design of energy saving and harvesting devices such as lithium-ion batteries, fuel cells, solar cells, and even transistors/FETs, light-emitting devices (LEDs), hydrogen production by water photolysis and its storage, water and air purification by degradation of organic/inorganic pollutants, bio-sensing devices, environmental monitoring by their applications in the fabrication of gas, humidity and temperature sensors, and photodetectors [3].



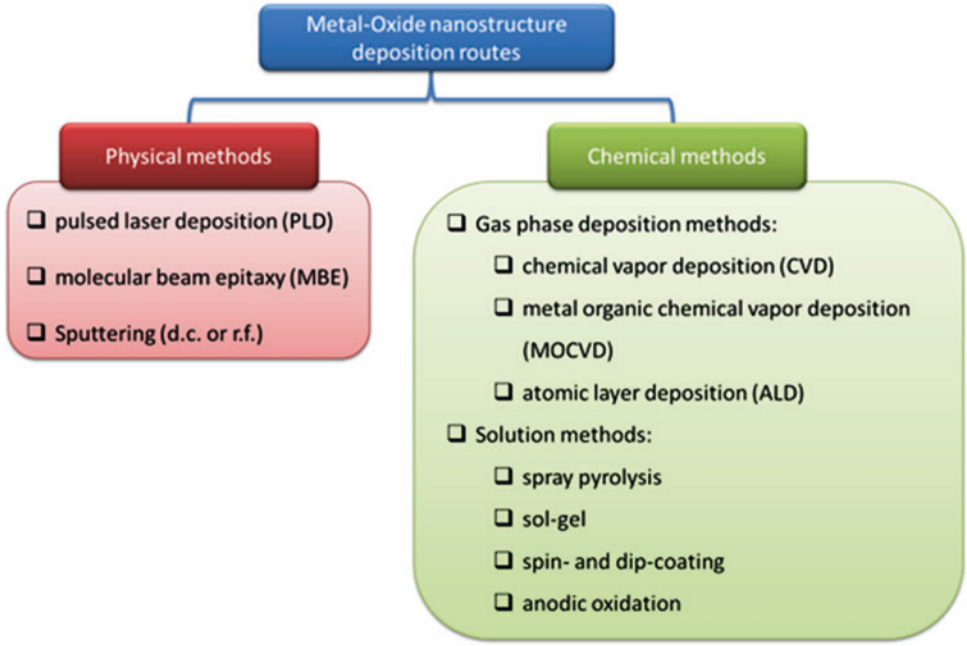
Besides the great application potential, oxide-based nanomaterials such as ZnO and TiO_2 have recently revolutionized the nanomaterial research because of the availability of soft-chemical synthesis.

Metal Oxide Nanostructure Synthesis and Deposition

Nanostructured metal oxide semiconductors can be deposited on any type of substrates such as metals, semiconductors, polymers, and flexible plastics unlike other III-V semiconductor and silicon, which requires specific and costly substrates.

All these metal oxide materials can be produced in different shapes (such as nanowires, nanobelts, nanorods, nanotubes, nanocombs, nanorings, nanohelixes/nanosprings, nanocages and nanosheets, and nanostars) depending on the synthesis routes, which can range over a wide variety of techniques [4].

The methods usually employed for metal oxide film deposition can be divided into two groups based on the nature of the deposition process, as depicted in Fig. 2. The physical methods include pulsed laser deposition (PLD), molecular beam epitaxy (MBE), and sputtering. The chemical methods comprise gas-phase deposition methods and solution techniques. The gas-phase methods are chemical vapor deposition (CVD), metal organic chemical vapor deposition (MOCVD), and atomic layer deposition (ALD), while spray



Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy, Fig. 1 Scheme illustrating all the fields of application of nanomaterials (Adapted from Ref. [1])

pyrolysis, sol–gel, and spin- and dip-coating methods employ precursor solutions.

Each method has certain advantages and disadvantages on issues ranging from ease of use to operating expense to time required for growth to quantity and quality of material produced.

Among them, the most employed to deposit metal oxide nanostructures for SERS application are:

– Sputter deposition, which involves bombardment of a target (metal or metal oxide) with a plasma (usually a noble gas, such as argon). The relatively low target temperature makes sputtering one of the most flexible deposition techniques. The sputtered atoms ejected into the gas phase are not in their thermodynamic equilibrium state, so they tend to condense back into the solid phase on the substrate surface. Film-grown rate is well controllable, allowing the reproducibility of the samples' thickness.
– Chemical vapor deposition (CVD), in which one or more precursors, usually activated by temperature, react at a substrate to form a film. The molecules must have a vapor pressure high enough to be transported to the reaction chamber, but yet they must have a high thermal

Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy, Fig. 2 Scheme collecting the metal oxide nanostructure deposition methods

stability to prevent particle formation in the gas phase. In this method, controllable film growth rate is attainable.

– Hydrothermal processing that can be defined as any heterogeneous reaction in an aqueous solvent (or nonaqueous solvent for solvothermal processing) under high pressure and temperature conditions, which induces the dissolution and recrystallization of materials that are relatively insoluble under ordinary conditions.
– Anodic oxidation, i.e., the process of forming an oxide on a metal surface by applying an electrical current or potential through a cell containing a suitable electrolyte. The metals that can be anodized to form oriented nanostructures belong to the so-called valve-metal group. The characteristics of a layer treated with anodic oxidation can vary according to the type and concentration of the electrolytes as well as the processing variables used during anodic oxidation. Compared with other synthesis approach, electrochemical anodization is a simple and convenient technique to fabricate uniform layer of vertically self-oriented nanostructures.

SERS-Active Substrates

Surface-enhanced Raman scattering (SERS) has been a growing area of interest in recent years due to its potential as label-free detection in materials science, biophysics, medical diagnostics, and molecular biology.

SERS technique is based on impressively enhanced Raman signal from Raman-active molecules that have been adsorbed onto certain metal surfaces (Au, Ag, Cu, etc.). These increases in the intensity of Raman signal have been commonly observed in the order of 10^4–10^6 and can be as high as 10^8 and 10^{14} for some particular systems [5].

There are two main mechanisms that contribute to the scattering enhancement observed in SERS: the electromagnetic and the chemical enhancement. The former is a moderate long-range effect and comes from the interaction of

free electrons on the metal surface with the excitation laser beam to yield surface plasmon resonance (SPR). The SPR is basically a collective oscillating electron wave on the metal surface. The SPR intensity on the metal surface is strictly related to the excitation light wavelength and the surface roughness of substrates and the dielectric constant of an eventual external medium at the interface of the metal structure. By acting on the shape, the size, and the spacing between metal surfaces (such as in the case of nanoparticles), it is possible to tune the SPR to obtain the optimized SERS signal from the metal nanostructures at a desired wavelength [5].

The chemical enhancement mechanism instead primarily originates from the charge-transfer (CT) mechanism involving changes to the molecule electronic states due to its chemisorption.

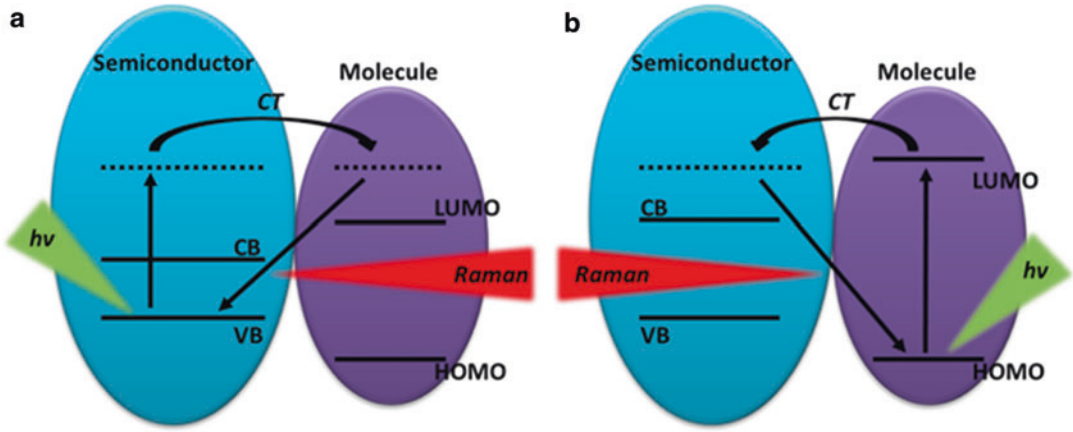
In noble metal nanoparticle (NP) interaction, the SPR mechanism is the main contribution. The most common types of SERS-active substrates exhibiting the largest enhancement effects are clusters of silver and gold NPs, generally used in colloidal solution.

Besides colloidal solutions, several lithographic techniques have been employed for the production of uniform and controllable SERS substrates with fully controlled shape and size. Despite the high efficiency of such substrates, the involved technology presents some drawbacks concerning cost and complexity.

Metal Oxide SERS Substrates

Recently, it has been observed that several metal oxides such as TiO_2, ZnO, α-Fe_2O_3, and CuO also exhibit SERS capability, although their enhancement effects are weaker than those of noble metal substrates. In all of these cases, CT at the semiconductor−analyte interface plays a major role in their SERS activity.

As described above, MO materials can be produced in different shapes (such as nanowires, nanorods, nanotubes, nanosheets, etc.) depending on the synthesis routes, which can range over a wide variety of techniques. The high specific surface area intrinsic in their nanostructuration allows a higher amount of metal particle loading with the consequent formation of 3D plasmon "hot spots" which could provide giant enhancement. Additionally, the 3D network can provide larger adsorbing area for analyte molecules than the standard planar substrates further increasing the Raman signal.



The first observation of Raman signal enhancement on metal oxide surface dates back to 1983, when Yamada and coworkers found SERS effect of pyridine molecules anchored on single crystal TiO_2 and NiO surfaces [6] attributing such improvement to the chemical enhancement mechanism. That work opened the way to the study of metal oxide surfaces as innovative SERS-active substrates, while the growth of nanoscience and nanotechnology has contributed to a rapid development of SERS-active nanostructured substrates.

Nanostructured TiO_2 indeed shows higher enhancement with respect to the single crystal counterpart: reducing the characteristic dimension and increasing the surface area, the charge transfer from TiO_2 nanocrystal to adsorbed molecule is strongly amplified.

As introduced before, the chemical enhancement mechanism implies that, when an analyte molecule was adsorbed on the surface of the SERS-active material, a chemical interaction between the molecules and the atoms of the substrate surface takes place. This interaction directly acts on the electron density distribution of the molecule in correlation with the vibrational energy states. Consequently the variation of the electron density distribution could enhance the Raman scattering cross section in respect to specific molecular vibrational modes.

According to recent literature [7], it is possible to distinguish different kinds of chemical enhancement mechanisms: the chemical-bonding enhancement, the surface complexes resonance enhancement, and the photon-induced charge-transfer (PICT) enhancement.

Among them, the PICT mechanism is the most suitable to explain the SERS from metal oxide semiconductor nanostructures. This photoactivated charge transfer can occur from the semiconductor to the molecule that is in the

Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy, Fig. 3 Scheme of the PICT process

opposite direction. To ensure its occurrence, it is necessary to actuate a thermodynamically favored condition under light excitation, i.e., the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the adsorbed molecule should energetically match the valence band (VB) and the conduction band (CB) of the semiconductor. This process mainly involves three electronic transitions as depicted in Fig. 3.

The PICT from the semiconductor surface to the adsorbed molecule can be summarized in the following steps (Fig. 3a):

1. An electron in the VB of the semiconductor is excited by the incident light to the CB.
2. The photogenerated electron can be rapidly transferred by resonant tunneling from the metal oxide CB to a matching energetic level above the LUMO of the molecule involving a vibrational level.
3. The as-transferred electron could turn back to the semiconductor VB (through an electron–hole recombination), thus, a vibrational quantum of energy can be involved, giving a Stokes Raman scattering process.

Likewise, the PICT from the molecule to the semiconductor involves the other following steps (Fig. 3b):

1. An electron in the HOMO of the adsorbed molecule is photoexcited to an energy level above the LUMO.
2. The photogenerated electron can be quickly transferred by resonant tunneling to a matching energetic level within the metal oxide CB.
3. The as-transferred electron could turn back to the HOMO of molecule, and a vibrational quantum of energy can be involved giving a Stokes Raman scattering process.

It should be underlined that, contrary to what happens in the other two chemical enhancement mechanisms, SERS activated by PICT does not need a molecule chemisorption on the metal oxide surface.

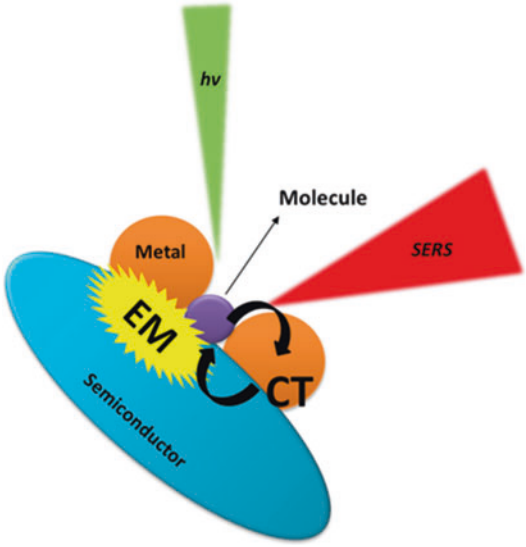
Several kinds of metal oxide nanostructures have been investigated in the last decades. Yang et al. [8] observed SERS signal from the 4-mercaptobenzoic acid molecules adsorbed on TiO_2 nanoparticles, thanks to the contribution of the TiO_2-to-molecule CT mechanism related to the surface state energy level of TiO_2 nanoparticles. Obviously such CT process is strongly related to the intrinsic nature of the adsorbed molecules and to the substrate surface properties.

Musumeci et al. [9] reported strong enhancement of selected Raman-active modes of biologically active molecules adsorbed on the surface of

TiO_2 NPs. In contrast with the previous example, they presented the evidence of the electronic mechanism involving molecule-to-TiO_2 charge transfer, which results in significantly larger enhancement factors.

Ivano Alessandri [10] demonstrates that a remarkable enhancement of Raman scattering can be achieved by TiO_2 shell-based spherical resonators ascribing the effect to the synergistic combination of high refractive index of the shell layer, multiple light scattering through the spheres, and related geometrical factors.

Differently from titania, SERS effect on zinc oxide was firstly observed in 1996 [11] increasing the interest of the SERS scientific community on this semiconductor.



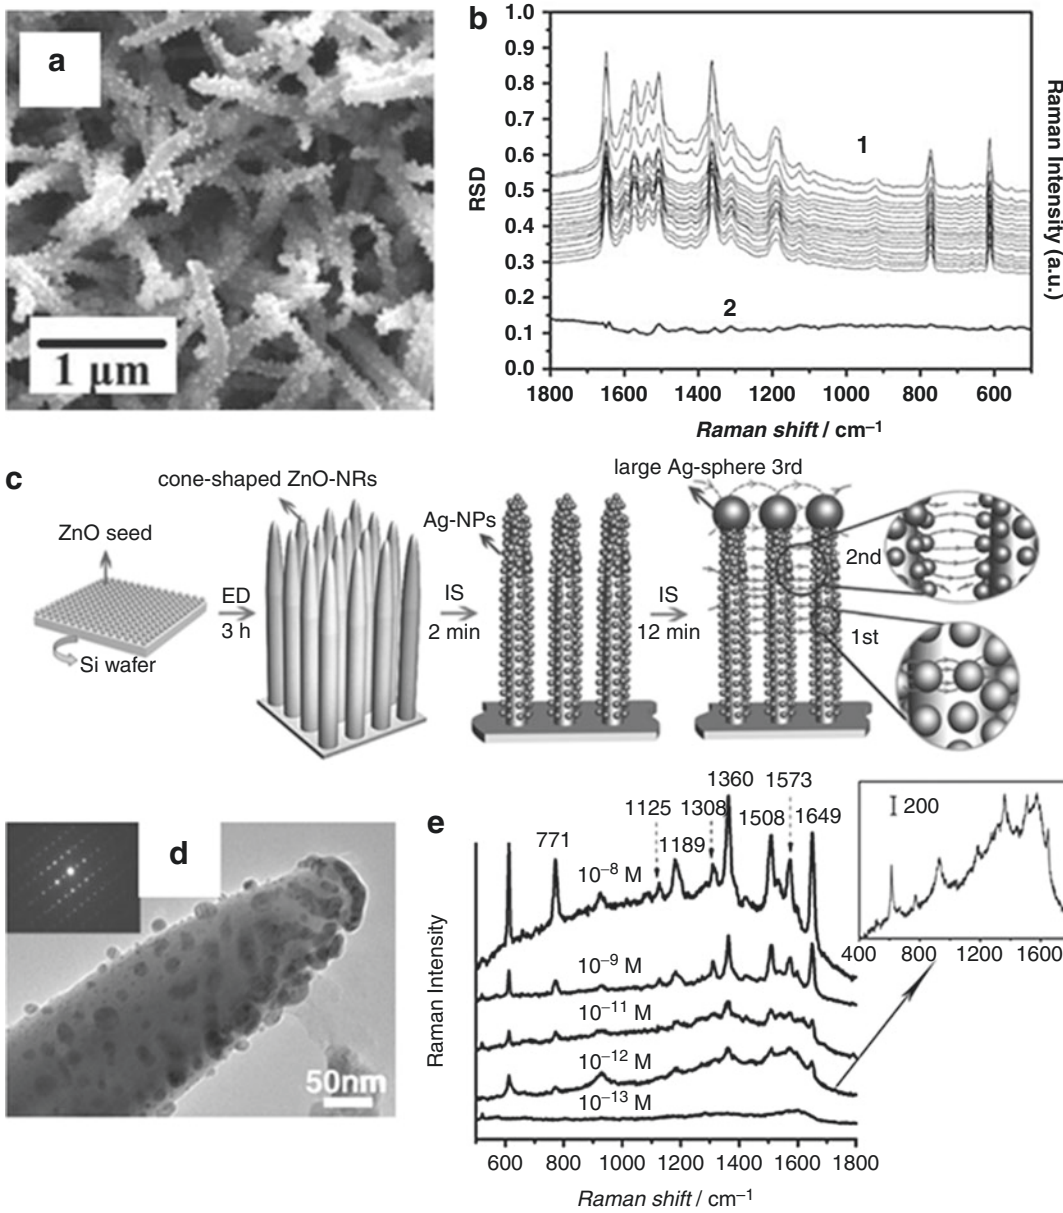
A strong CT process between ZnO nanocrystals and 4-mercaptopyridine electronic states was clearly demonstrated by Wang et al. [12] observing an excitation wavelength-dependent behavior.

SERS signal from 4-aminobenzenethiol on porous Cu_2O and Cu_2O/CuO nanowires was also demonstrated [13] showing a strong signal dependence to the Cu_2O/CuO ratio and particle size of the porous nanowires. The extraordinary enhancement of such SERS signals is attributed to numerous nanoparticles acting as hot spots on the surface of the porous nanowires.

More recently [14], surface-enhanced Raman signal of 4-mercaptobenzoic acid (4-MBA) has been detected on the surface of Cu_2O nanospheres. Simulations were employed to demonstrate the nature of the enhancement mechanisms operative between the molecules and the semiconductor. Density functional theory (DFT) calculations suggested a charge-transfer (CT) transition process between the molecules and the Cu_2O nanospheres.

Noble Metal Nanoparticle-Decorated SERS Substrates

More significant improvements can be obtained by using composites of nanostructured semiconductors and noble metals, which integrate the advantages of the electromagnetic coupling among metal nanoparticles with those of chemical enhancement arising from both noble metal and semiconductor charge transfer with adsorbed molecules (as schematically represented in Fig. 4).



Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy, Fig. 4 Scheme of the hybrid MO-noble metal nanostructure under excitation

Thanks to their nanostructuration, the specific surface area is usually high, thus allowing an increased loading of metal particles as well as the high possibility of forming 3D plasmon "hot spots" which provide giant enhancement. Moreover, the 3D substrates can also supply larger surface area for adsorbing probe molecules than the 2D substrates.

Recently, following this concept, several composites were investigated as SERS-active substrate. Li and coworkers [15] have investigated multifunctional Au-coated TiO_2 nanotube array made by synthesis of a TiO_2 nanotube array through a template, followed by deposition of Au particles onto the TiO_2 surface. In Fig. 5a, a FESEM micrograph of the obtained composite nanostructure is reported. Such substrate exhibits superior SERS detection ability with good signal reproducibility as shown in Fig. 5b.

Despite the greater chemical stability, biocompatibility, and easier surface chemistry of gold, silver is often used since it can provide the highest efficiency in enhancing the Raman scattering due to its optical absorption properties.

For this reason Tan et al. [17] have chosen to fabricate three-dimensional hybrid nanostructures made of TiO_2 nanorods decorated by silver nanoparticles. The hybrid substrate exhibits excellent SERS enhancement effect due to the formation of high-density hot spots among the Ag NPs able to detect malachite green (MG) down to of 1×10^{-12} M. The experimental

results show that this substrate has high activity, uniformity, and stability. Moreover the density and sizes of Ag NPs can be easily controlled by the deposition times, which induced the decrease of the distance between Ag NPs. Ag NPs aggregations with small gap distance produce giant Raman enhancement due to strong electromagnetic coupling. There are two kinds of hot spots that contribute to the huge enhancement effect of the substrate: few hot spots are from Ag NPs adsorbed on same rod, more hot spots are from two near-crossover rods because of the 3D configuration.

A possible alternative in terms of NP-supporting material leads in zinc oxide nanostructures. Au-coated ZnO nanorods have been fabricated by Sakano and coworkers [18]. ZnO nanorod arrays on silicon substrate were coated with Au by ion beam sputtering. High SERS enhancement was observed: the Raman spectra of rhodamine 6G (R6G) as low as 1 nM were measured and explained by the field enhancement effect induced by surface plasmon polaritons of Au nanoshells coating the nanorods. Moreover, the results indicate that the SERS properties depend strongly on the geometry and the size of the nanorods that can be easily tuned acting on the growth PLD parameters.

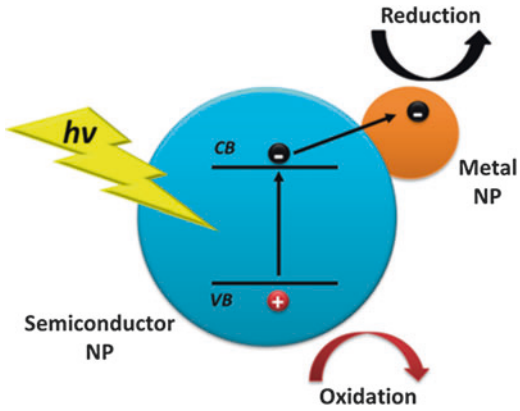
Obviously, also silver can be coupled to ZnO as shown by Tang et al. [16] via simultaneously assembling small Ag nanoparticles (Ag NPs) and large Ag spheres onto the side surface and the top ends of large-scale vertically aligned cone-shaped ZnO nanorods (ZnO NRs), respectively, by simple physical ion sputtering (Fig. 5c). Three kinds of inter-Ag-NP gaps in 3D geometry create a huge number of SERS "hot spots" as schematically shown in Fig. 5c: "1st" stands for the gaps between the Ag NPs located on the side surface of the same NR; "2nd" stands for the gaps between the two Ag NPs located on the side surface of two neighboring NRs; and "3rd" stands for the gaps between the two large Ag spheres located on the tops of two neighboring NRs. Figure 5d shows the TEM image of the ZnO NRs after an Ag sputtering. This 3D "hot spot" network mainly contributes to the high SERS sensitivity. Moreover, the supporting chemical enhancement effect of ZnO NRs and the large surface area of the substrate also help to achieve a low detection limit for rhodamine molecule down to 10^{-12} M, as observed in Fig. 5e.

Lastly, alternative metal oxide nanostructure has been proposed by Ji et al. [19]. In their work, highly ordered porous anodic aluminum oxide (AAO) templates were fabricated using a two-step anodization approach, and then an alternating-current (AC) electrochemical deposition was used to fill AAO templates with Ag nanoparticles. High-quality SERS spectra were observed using 4-mercaptopyridine (4-MPy) as the probing molecule. Good homogeneity and stability make these substrates good candidates for SERS spectroscopy.

Intrinsic Functionalities of Metal Oxide Nanostructures for SERS

Photocatalytic Cleaning for Recyclable SERS Substrates

The Raman substrates most commonly used (Au or Ag nanoparticles on silicon) cannot be easily reused. This could be an important drawback from the economical point of view, but also from the substrates reproducibility standpoint. Indeed one of the most serious problems in SERS technique is related to the poor reproducibility of the Raman signal among identical substrates as well as in different place within the sample itself.



For these reasons a lot of efforts have been addressed in the last years in studying recyclable SERS substrates. As discussed above, the intrinsic photocatalytic activity of metal oxide nanostructures could be exploited to degrade the analyte molecules after the SERS analysis allowing recyclability for a new detection run.

The general mechanism of photocatalysis on MO nanostructures is based on the electron–hole pairs photogeneration under UV light, inducing the reaction with both oxygen and water molecules to promote the oxidation of organic substance.

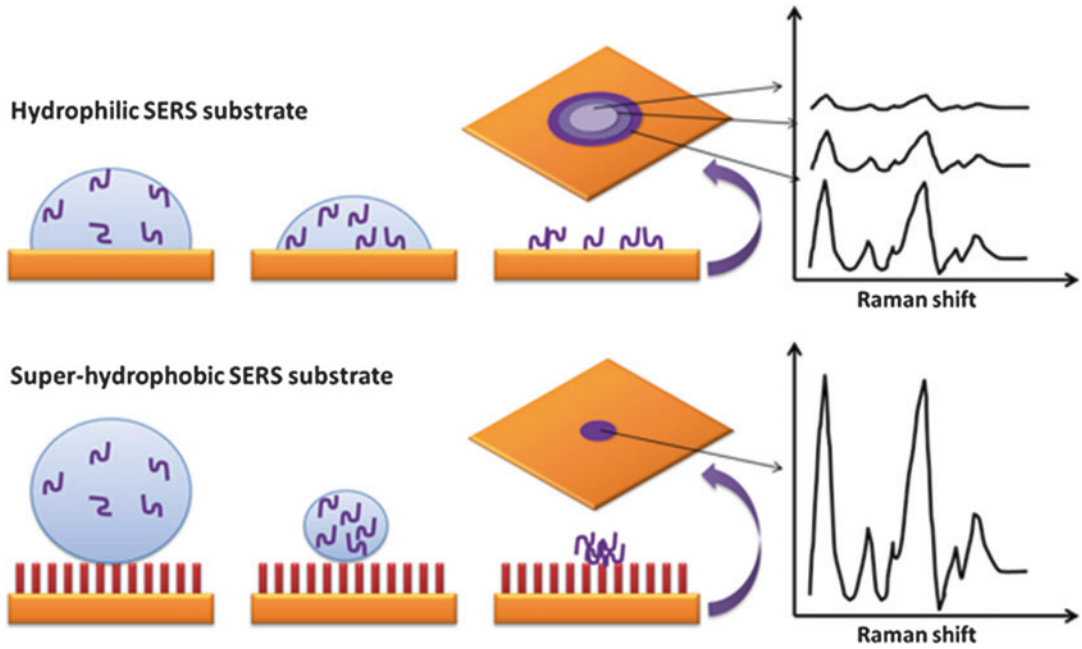
The photocatalytic process for the degradation of organic molecules (e.g., methylene blue – MB)

can be described following a well-known mechanism – efficient photons are absorbed by MO (e.g., TiO_2), and the following reactions associated with electron and hole pair occur:

$$TiO_2 + hv\ (UV) \rightarrow\ TiO_2^*\left(e_{CB}^- + h_{VB}^+\right) \quad (1)$$

Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy, Fig. 6 Scheme of the hybrid MO-noble metal nanostructure during photocatalytic cleaning of the substrate

$$H_2O + h_{VB}^+ \rightarrow\ OH^{\bullet} + H^+ \quad (2)$$



$$OH_{ad}^- + h_{VB}^+ \rightarrow\ OH_{ad}^{\bullet} \quad (3)$$

$$e_{CB}^- + O_2 \rightarrow\ O_2^{\bullet -} \quad (4)$$

$$MB + OH_{ad}^{\bullet} + OH^{\bullet} + O_2^{\bullet -} + h_{VB}^+ \rightarrow \text{Photodegraded products} \quad (5)$$

where TiO_2^* is the excited state of titania, OH_{ad}^- are adsorbed hydroxide ions, e_{CB}^- is a photoexcited electron in the conduction band and h_{VB}^+ the photogenerated hole in the valence band $OH^{\bullet}$, and $O_2^{\bullet -}$ obtained in reactions (2) and (4) are active species highly oxidative, and they can contribute significantly to photocatalytic decomposition.

Nevertheless the fast recombination of charge carriers in the semiconductor alone could reduce the resulting photocatalytic efficiency. To obtain effective molecule photodegradation, the electrons and the holes in semiconductor must be separated to suppress their recombination. The noble metal-decorated metal oxides are more efficient than their uncoated counterpart since for

Metal-Oxide Nanostructures for Surface Enhanced Raman Spectroscopy, Fig. 7 Scheme of the behavior of hydrophilic and superhydrophobic surfaces during analyte droplet evaporation

semiconductor/metal hybrid nanostructures with suitable energy level alignment, electrons can be quickly transferred to metal nanoparticles to achieve charge separation (see Fig. 6).

Superhydrophobic Condensation Effect

Another important property of some metal oxide nanostructures is the superhydrophobicity.

Indeed, thanks to their high surface area, the transition to Cassie–Baxter state could happen dramatically reducing the contact area between the droplet and the MO surface. This phenomenon can be exploited in SERS to achieve more sensitive detection [20].

A survey of SERS substrate literature shows that one of the major reasons for poor Raman signal reproducibility is the nonuniformity of molecule spot profile on the surface. As depicted in Fig. 7, when drop delivery was performed onto a hydrophilic surface, spots often exhibit ringlike structures (the most common are coffee stains).

Exploiting a superhydrophobic surface, the diluted analyte in the droplet could be highly concentrated after the droplet evaporation (Fig. 7). This effect is known as the superhydrophobic condensation and can lead to a further amplification of the SERS signal together with a higher signal reproducibility.

Obviously the signal amplification effect is dependent by the contact angle and the volume of water droplet delivered on the surface. Consequently, a higher contact angle and the suitable drop volume could be tuned to obtain stronger SERS signal.

Definition

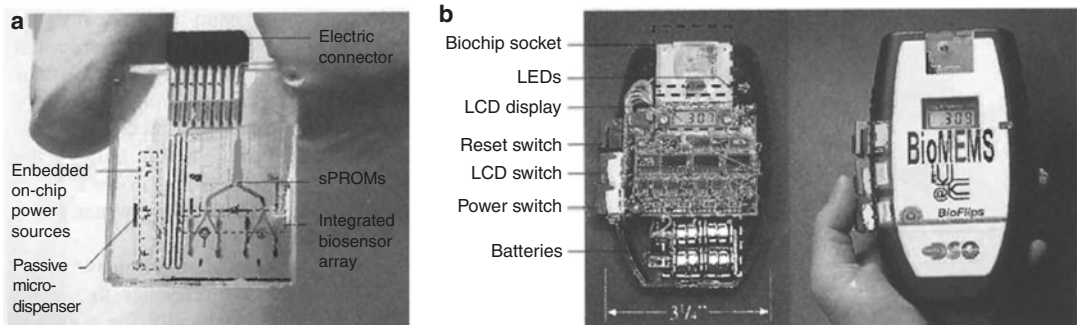
The use of fluid flow in micro- and nanochannels to perform diagnostics of a variety of diseases.

Overview of Micro- and Nanofluidics

Although the science of fluid mechanics at the microscale has been around for a long time, the technology of microfluidics finds its roots during the 1970s, when pioneering work in microfluidic systems was developed at IBM labs for an ink-jet printing device and at Stanford University for the development of a gas chromatograph [1]. Microfluidics is a technology that deals with the manipulation of fluids inside microstructures (usually microchannels) (1 μm = 10^{-6} m), whereas nanofluidics is a technology that deals with the manipulation of fluids in and around nanosized objects (1 nm = 10^{-9} m) [1, 2]. Manipulation of fluids encompasses a number of issues including mixing fluids, controlling their flow profile, and directing the flow to a desired location. Additional requirements might be necessary for specific applications such as medical diagnostics, where manipulation of cells or proteins could demand a number of tasks such as cell lyses, control over biochemical reactions, analyte or cell transport and separation, analyte or cell capturing, and the integration within a single system of miniaturized molecular biology tools such as PCR or electrophoresis. Although a promising technology, the realm of micro- and nanofluidics

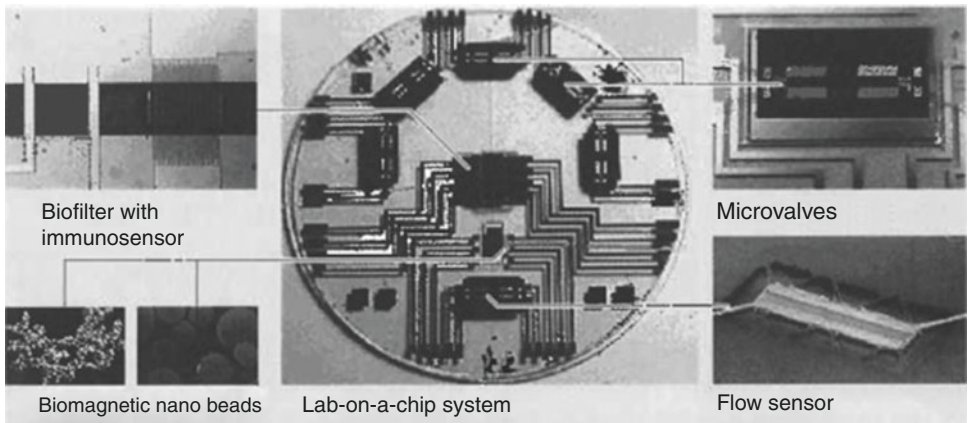
faces critical challenges. For example, many physical properties of fluids at the macroscale change radically at the micro- and nanoscale. Moreover, many of these physical phenomena still remain under study at the basic science level. Therefore, understanding fluid behavior at the micro- and nanoscale becomes mandatory in order to develop micro- and nanofluidic devices [1, 2].

Microfluid Mechanics: Harnessing New Physical Properties at the Microscale



The physics of fluids on microchannels is based on a number of physical effects that appear at the micro- and nanoscale. That is, these are not seen at the macroscopic scale. The Reynolds number has a critical role in this venue. The Reynolds number (Re) relates the viscosity forces with the inertial forces, which determines whether the flow profile behaves as laminar (parallel flow lines that do not mix) or turbulent (a chaotic flow without a specific profile that mix). The Reynolds number involves several fluid properties such as mean velocity of the object relative to the fluid, density of the fluid, traveled length of the fluid, and viscosity. In addition to that, and in order to better understand microfluidic mechanics, other properties such as diffusion, fluid resistance, surface to volume ratio, and surface tension should be taken into account. Diffusion indicates the motion of a particle in a fluid through a concentration gradient. Fluidic resistance is a parameter dependent on the channel geometry. Surface to volume ratio of microstructures such as microchannels increase orders of magnitude against its macro counterparts. Surface tension, the property of water molecules to remain together when exposed to an interface like a gas, increases at the microscale as the surface to volume ratio increases [2].

Nanofluidics: Mimicking Nature



"Nanofluidics" is a term that encompasses a variety of disciplines including biochemistry, biophysics, microengineering, bioengineering, and membrane science. Biology occupies a special place among nanofluidic disciplines since nature has been developing an astonishingly diverse array of nanofluidic systems during the course of evolution. Examples include biomolecular transport inside and across the cells, lateral flow of proteins along the cell membrane, traffic through nanoscale pores from the cytoplasm to the cellular nucleus, axon transport in neurons where nutrients and neurotransmitters flow from the neuron body to the axon terminal, transport of proteins through the complex endoplasmic reticulum, and many others [3].

Nanofluidics deals with several architecture and mechanisms that rely on forces that operate on fluids at the nanoscale. Among them we can mention van der Waals forces (attractive forces that appear when two objects are closer than 2 nm), electrostatic forces that operate at distances between 1 and 100 nm and are either attractive or repulsive, and to a much lesser extent gravitational and inertial forces. As a consequence of the aforementioned, a number of phenomena arising from these nanoscale forces have been described, such as a surface-energy-related phenomenon, a shear-related phenomena, a double electrical layer phenomenon, a size-dependent phenomena, and an entropy-related phenomena. A theoretical approach on the study of nanofluidics has also been developed through the so-called DVLO theory. DVLO theory was developed taking into account the interaction of two objects at the nanoscale by considering van der Waals and electrostatic forces. The DVLO theory accounts to explain the interaction of colloidal systems and has been very successful in this regard. In addition, molecular dynamics (MD) simulations have been developed to study biological nanofluidic systems such as the study of protein transport through nanopores or nanochannels embedded in cell membranes and other biomolecular-nanostructure interactions [2].

Finally, biomimetic approaches where biological nanostructures assist in the development of nanopores and nanochannels are becoming an alternative or complimentary to the above-described techniques. As it was mentioned previously, nature provides an amazing repertoire of nanostructures that provide to be useful for nanofluidic purposes. These structures could be

Micro- and Nanofluidic Devices for Medical Diagnostics, Fig. 1 (**a**) Microfluidic cartridge to be used in an equipment at the clinical laboratory setting and (**b**) handheld microfluidic device suitable for rapid sample analysis of the sample at the bedside of the patient avoiding the need of sample transport (Developed at University of Cincinnati with permission from Bhushan, from Ref. [5])

Micro- and Nanofluidic Devices for Medical Diagnostics, Fig. 2 Microfluidic device designed for an immunoassay test (With permission from Bhushan from Ref. [5])

used directly or as templates for constructing artificial nanochannels or nanopores. Some examples include the use of zeolites found in natural sources for the synthesis of nanopore membranes, or the assembling of protein monomers to create a nanochannel; such is the case of alpha-hemolysin monomers. Other examples include the use of biological motors such as ATPase or kinesins to impulse nanofluids inside nanochannels [3].

The Impact of Micro- and Nanofluidic Devices in Medical Diagnostics

In order to harness the properties of micro- and nanofluidics for medical diagnostics, it becomes necessary to build up a system where several structures such as microchannels, microchambers, and microvalves are integrated with functional parts such as microsensors and microactuators in a single platform or chip to create a device (see Figs. 1a, b and 2), where the fluid containing the patient sample will be injected, transported, and mixed with reagents such as fluorescent labels, or where the sample will be subjected to a variety of process commonly used in the molecular biology laboratory, such as PCR and electrophoresis or biochemical reactions, in order to obtain valuable information about the patient sample.

With that being said, it is now important to understand the implications of such microdevices in the medical diagnostic arena. In medicine,

micro- and nanofluidic devices have found an important niche in the diagnostic area. This is particularly true for mass screening test to detect the presence of absence of a disease at an early stage to allow a prompt therapeutic intervention. Mass screening has a significant role in public health as is shown by the early detection of several types of cancer at an early stage (i.e., breast cancer in women, prostate cancer in men, colorectal cancer), neurological disorders such as Alzheimer disease, and infectious diseases such as AIDS, among the general population, saving the life and improving the quality of life of millions of people worldwide.

From a technological standpoint, it is important to note how many of the current test available at the clinical laboratory setting using the molecular biology toolbox are now starting to harness all the possibilities that micro- and nanofluidics bring about. An example of the later is seen in immunoassays, a kind of test used for diagnosis of several disorders such as AIDS that are now being developed in microfluidic chips (see Fig. 2). It is also important to understand the impact of micro- and nanofluidics in diagnostics from a clinical standpoint. Clinical decision making requires appropriate data in a timely manner. The diagnosis of a disease may require a comprehensive interrogation and clinical examination of the patient. In addition, complimentary information could be obtained from a series of laboratory test and imaging techniques. Laboratory test could be performed in the clinical laboratory setting (in vitro), at the bedside taking a sample from the patient (ex vivo), or inside the body of the patient (in vivo). Laboratory test are standardized according to performance parameters including sensitivity, specificity, predictive value, and accuracy of the test. Sensitivity involves the capacity of a test to detect the presence of the disease (test positive, people with the disease). Specificity is the capacity of a test to detect the absence of the disease (test negative, healthy people). Predictive value is how believable the test result is, namely, if a test result is positive, how believable is that the patient has the disease (positive predictive value), and if the test result is negative, how believable is that the patient does not have the disease (negative predictive value). Finally, accuracy accounts for how the test performs overall, that is to say among all the population tested, which percentage was correctly diagnosed as positive (carrying the disease) or negative (healthy) [4].

Microfluidics and nanofluidics may have a positive impact on sensitivity on medical diagnostics in several ways. First, using small volumes of samples that react with the reporting element in an extremely confined space, such as microchannels, nanochannels, microchambers, and nanopores, the chances of detection of small amounts of the target biomolecule (that indicates the presence of disease, also called biomarker) increase. Microfluidic and nanofluidic devices may also achieve high specificity. A high level of specificity can be achieved when incorporating nanosensors or molecular recognition moieties like antibodies or DNA probes into the micro- or nanochannels that could interact with the biomolecule target (biomarker) with high spatial resolution and affinity, by controlling separation, mixing, and other flow conditions, thus avoiding false unspecific recognition events (if the target biomolecule is not present, the test will be negative since the system will not bind to any other biomolecule than the target) at the sensor–target interface. On the other hand, predictive values are more dependent on epidemiological parameters such as prevalence of the disease and do not depend solely on the technology being used for the test. However, in terms of device performance, as microfluidics and nanofluidics will improve sensitivity and specificity of the test which in turn determines accuracy, new diagnostic devices based on these technologies will outperform current technologies as more accuracy will be obtained.

Potential Applications of Microfluidics and Nanofluidics for Medical Diagnostics

Cancer

A microfluidic device that can capture circulating cancer cells, particularly those with high metastatic ability, has been developed (Cell Search™ Circulating Tumor Cell Kit). The detection of

metastasizing cancer cells could have a prognostic value and perhaps a therapeutic value if early detection can be done [6–8].

Infectious Diseases

Identifying the infectious agent and its response to treatment is of critical importance, particularly with the increasing number of resistant infectious strains. Furthermore, a broad-spectrum treatment is usually given when there is no immediate answer of what the infectious bacterial agent is and its response to treatment. Therefore, when administering broad-spectrum treatment that is not targeted specifically against a specific agent, a possibility of developing resistance to treatment against this potent and important treatment can occur. A portable microfluidic device with high accuracy and rapidity could provide the caregiver an immediate and reliable data output about the infection and its susceptibility to treatment, assisting in early and appropriate therapeutic decisions; furthermore, early and appropriate decisions can safeguard the important broad-spectrum treatment from encountering resistance strains in the future [9].

Neurological Diseases

Earlier detection of neurological disorders such as Alzheimer disease using biomarkers would allow an earlier intervention on the patient, improving his quality of life. In addition, and until an effective therapy becomes available, it could prepare the patient's family to afford the challenge of taking care of his relative more effectively. Future systems may be able to monitor new biomarkers and their clinical therapeutic justification for their early detection [9, 10].

Critical Care

Point of care (POC) devices are of great utility in a critical care unit setting if they can accurately provide important data relevant for the resuscitation, metabolic, and respiratory status of the patient. If they can provide it very rapidly and accurately, then immediate intervention may be warranted for a prompt intervention over critical conditions, improving survival rates. The same concept applies for POC devices in remote settings where healthcare facilities are scarce or in human and natural catastrophes when the healthcare infrastructure is overwhelmed [9, 11].

Neonatology

A point of care device for measuring bilirubin in neonates has been commercialized. The system called Bilichek™ could be used at the bedside and avoids the need for transporting the sample to the central laboratory, allowing a fast decision making. The device works by measuring the levels of bilirubin in a noninvasive manner using optical technology instead of a needle. The device has been developed for newborns wherein hyperbilirubinemia is suspected [12, 13].

Advantages of Microfluidic and Nanofluidic Technologies over Standard Technologies

Some of the advantages of micro- and nanofluidic devices over existing technologies include less reactant and sample consumption (the volume to perform the reaction is limited to a volume of nanoliters, an important requirement in pediatrics wherein the amount of sample could be significantly small), automatization (the technology is integrated with microelectronic circuits that are programmed to perform a sequence of steps), parallelization (several reactions are being run along parallel microchannels and chambers), and sequencing integration (miniaturization allows to add several techniques one after the other in the same device). Lower power consumption, portability, and low cost per unit, as developed through batch microfabrication technologies, are additional assets. As described earlier, different physical phenomena take place at the micro- and nanoscale in fluids limited to micro- and nanochannels. As the size of the channel shrinks, there is an increasing chance of two molecules to meet and react. In diagnostics, this means that a sample containing the analyte would interact with the recognition system such as antibody in less time and thus the result of the diagnostic test will be obtained faster. Moreover, for diagnostic kits employing reactants, a faster mass and heat

transfer along the microstructures means faster reaction kinetics, allowing faster results. Parallelization allows the use of a single patient sample to perform a battery of test such as a metabolic profile decreasing the time for diagnostic results significantly and avoiding the need to puncture the patient several times to obtain a blood sample. Automatization avoids the need of personnel during the running of the diagnostic test protocol, which decreases the human factor error and improves results reliability. Sequencing integration avoids sample transport from one machine to another, making the process less time consuming and decreasing the chance of sample contamination and human error [14].

To better understand how micro- and nanofluidics could outperform current standard diagnostic methods, a few examples will be given. The first example relates to infectious diseases. When suspecting an infectious disease, the physician has to test antimicrobial susceptibility of the pathogen in order to take clinical decisions to initiate an effective antimicrobial therapy. Current methods based on cell culture systems are time consuming, requiring sample transportation and culture of the pathogen, taking a few days to obtain the result. By taking advantage of microfluidic systems, this time will be reduced to only 2 h [15].

The second example refers to cancer diagnostics. Current procedures for performing cancer diagnostics include obtaining a piece of the patient tissue (a biopsy) and its evaluation through microscopic analysis (histopathology). Biopsies are pieces of tissue that are usually obtained invasively from the patient. In addition, histopathology could be a time-consuming process. Microfluidic devices capable of detecting circulating tumor cells in the blood as the one described above will use a blood sample analyzer, avoiding the need to perform biopsies. Moreover, these tests will operate much faster than current histopathology analysis since they will not require time-consuming sample preparation and they will be operator independent, which will make them devoid of human error as opposed to current histological examinations that require an interpretation of the microscopy images, since the microfluidic device will operate automatically detecting very specific markers at the cell surface.

The third example in how microfluidics will make a difference with conventional technologies is the detection of microsatellite regions of chromosomes in malignant tumors using electrophoresis on chip. Microsatellites are sites of DNA with higher rates of mutations, having a prognostic value in several types of cancer such as colorectal cancer. Currently, fluorochrome-based PCR with electrophoresis is one of the techniques used for assessing the presence of mutations in microsatellite regions of chromosomes. This technique requires the use of labels that make the test costly and time consuming. Using miniaturized electrophoresis on a microfluidic chip, it is possible to achieve high sensitivity, rapidity (sample preparation and running time between 30 and 45 min versus 4–6 h in conventional systems), and cost-effectiveness because it does not require using labels and the equipment associated with it [16].

Finally, in neurological disorders such as Alzheimer disease, current methods based on microarray technology require are time consuming and expensive. A microfluidic chip for detection of single DNA mutations (single nucleotide polymorphism or SNP) has been described as a promising tool for early detection of Alzheimer disease [17].

Regulation of Diagnostic Devices

Diagnostics represents a very significant portion of the biomedical market. In order to commercialize such products, it becomes mandatory to obtain regulatory clearance. Within the United States, the Center for Devices and Radiological Health (CDRH) at the Food and Drug Administration (FDA) oversees diagnostic medical devices, controlling their commercialization by ensuring they perform in a safe and reliable manner [18].

Diagnostic devices are classified as in vitro systems or ex vivo or in vivo devices. In vitro diagnostic devices are those located in the clinical laboratory where the sample is transported

and processed. Ex vivo devices or point of care (POC) devices are those used at the bedside of the patient. Finally, in vivo devices are those devices that perform the diagnosis inside the human body such as pressure sensors inside catheters. However, FDA classifies diagnostic devices according to the general category of "in vitro diagnostics." Within this category, it is possible to find home test devices like pregnancy test, laboratory devices used in the clinical laboratory setting by the physician to measure a clinical parameter, and point of care devices such as glucose monitoring systems (ex vivo point of care devices) that are used by the physician at the bedside. Regulation of in vitro systems is based on the intended use of the devices, indication of use of the devices, and, in a major extent, the risk that the device possesses to the patient. In vitro systems, as other medical devices, are classified as class I, class II, and class III. Class I in vitro systems are considered of lower risk. Class II in vitro systems are considered medium risk and are required to comply with standards along with additional data including analytical sensitivity and specificity. Finally, class III in vitro systems are high-risk devices and, in addition to analytical sensitivity and specificity, they must provide clinical validity including clinical sensitivity and specificity of the device when using a clinical sample [17].

To date, microfluidic technology has been developed mostly for point of care diagnostics (commercial examples include the iSTAT™ system and Bilicheck™) and as disposable cartridges for clinical laboratory apparatus systems. Commercial examples of the later include the Agilent 2100 Bioanalyzer™ and the Cepheid Xpert system™ [18].

Micro- and Nanomanipulation for Nanomanufacturing

Stefan Johansson
Department of Engineering Sciences, Uppsala University, Uppsala, Sweden

Synonyms

Dip-pen nanolithography; Microrobotics; Nanoprinting; Nanorobotics

Definition

Micro- and nanomanipulation for nanomanufacturing concern the manipulation of micrometer or nanometer sized objects to build nanostructures. In spite of the intuitive impression that the concept in this entry is limited to individual and physical handling of nanoscale objects, also parallel processing with a large degree of self-assembly is normally included in the definition. The manipulation can be made both by physical contact, e.g., electrostatic gripping, and by non-contact techniques, e.g., optical tweezers. The manipulation equipment could be any size while the tool(s) should have a manipulation resolution in the sub-micrometer range.

Essay Disposition

This essay is divided in seven main sections. After a very brief introduction to the "History" of this entry, the "Concepts" used in the text are explained to avoid misunderstandings. There are slight variations of concept definitions depending on the different authors' scientific background and the youth of the research field as well as political and societal factors. The possibilities with the entry "micro/nanomanipulation for nanomanufacturing" are given in the section "Examples of Micro/Nanomanipulation for Nanomanufacturing" while the basic equipment is presented in two different sections: "Micro- and Nanomanipulators" and "Manipulation Tools." The equipment defines and limits the present possibilities for nanomanufacturing. To give a brief understanding of differences between manipulation in the macroscopic and nanoworld, some important "Phenomena" are presented in a separate chapter. As concluding remarks some "Future Trends" are presented.

History

The interest in the atomic world dates back a long time while a first practical approach to enter the nanoworld was given by R. P. Feynman in his talk "There is plenty of room at the bottom" December 1959. He addressed a technological route to manipulate atoms and identified several of the phenomena that occur when we arrive at that size scale. He suggested scaling down, a quarter at a time, our engineering factories and in that way arrive at nanofactories. The possibility to scale down tolerances in parallel with the physical size of the objects/tools/machines is not that straightforward and most efforts towards the nanoworld have followed "shortcut" paths; the nanomanipulating instruments are themselves macroscopic, often decimeter-meter sized while the precision is in the nanometers range or even better.

Nanomanufacturing by manipulation in the broadest sense has occurred naturally in all biological systems since the dawn of biological life. Inorganic nanomanipulation dates back even further, as long as matter has existed, if we include physical and chemical processes with rearrangements at an atomic level in materials. Human beings have been able to manipulate at a nanolevel, even though not in a controlled fashion, since prehistoric times and one example is when one macroscopic object is put in friction contact with another. However, most of us consider nanomanipulation as an artificial and controlled process with spatial resolution in the nanometer range, which excludes these natural and random processes. The possibility to observe nanomanipulation has so far been the key point to get control and the "eyes" into the nanoworld are

the high resolution instruments, for instance Scanning Tunneling Microscopes (STMs) and electron microscopes. The evolution of manipulating techniques in the nanoworld has hence followed the development of the imaging techniques.

It is fair to say that the atomic manipulations began with the experiments at IBM where xenon atoms were manipulated on a Ni surface to form the word "IBM" [1]. These experiments were based on the development of the Scanning Tunneling Microscope (STM) by G. Binnig and H. Rohrer which awarded them the Nobel Prize in Physics 1986 [2]. Still, controlled manipulation at nanoscale has been possible as long as there has been means to obtain spatial resolution at that scale. With the development of scanning electron microscopes (SEMs) in the 1930s it was also possible to locally deposit materials at sub-micrometer scale even though this was rather an unwanted side effect of undesired molecules condensing/reacting on the specimen surface. Electron Beam Lithography in the nano-range by SEMs or similar instruments – making it possible to manipulate atomic bonding in the nano-range – was developed more or less in parallel with the atomic manipulations in the STM. There were also early mechanical "blind" approaches towards the nanoworld – nanomechanical testing with subsequent high resolution imaging – and one example is controlled scribing at the nanoscale during the 1980s.

During the 1990s manipulation experiments with instruments based on the STM gained momentum and also dedicated equipment for micro- and nanomanipulation were developed and presented. The aim with the dedicated nanomanipulators was more or less to provide "hands" in the nanoworld e.g., [3]. Typically these tools were more dexterous than those of the STM and the "eyes" were imaging by SEMs. During the following decade the main research within the controlled inorganic nanomanipulation was based on STM-based instruments and it was not until the launch of dedicated nanotechnology research programs in the beginning of the 2000s that the present bio/micro/nano- technology cross-disciplinary efforts started pacing up.

Concepts

Nanomanufacturing

Manufacturing of artificial structures where the final structure size in at least two dimensions is in the sub-micrometer range is commonly referred to as nanomanufacturing. Artificial is here a key word – biological processes at the nanoscale are not considered as nanomanufacturing. Biochemical synthesis with molecules in the sub-micrometer size range is the borderline of this concept, sometimes included, sometimes not. The final size of the manufactured component is not limiting. Also the fabrication of structures larger than micrometer sizes, by techniques that control sculpturing or assembly at nano-level with spatial definition in at least two dimensions, is considered nanomanufacturing.

MEMS, NEMS and MST

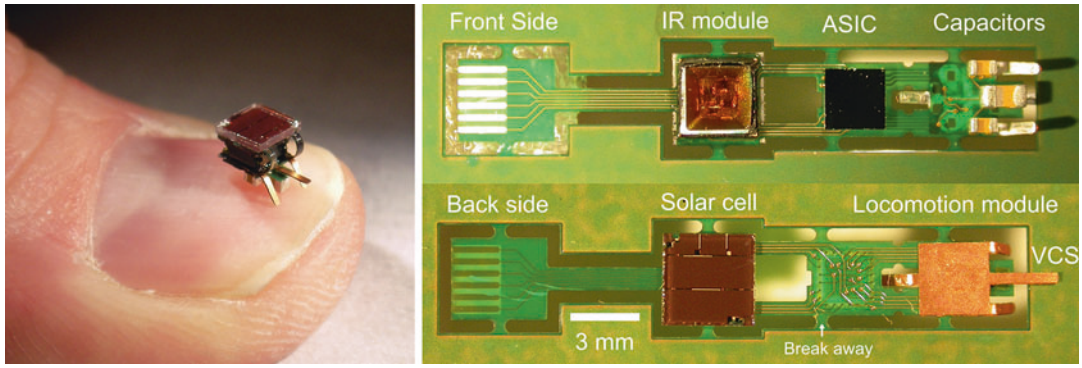
Microelectromechanical systems (MEMS), Nanoelectromechanical systems (NEMS) and Micro Systems Technology (MST) are based on the same concept – the use of processing technology that originates from the microelectronics industry. NEMS indicate that there are spatial dimensions in the sub-micrometer range. Often MEMS/NEMS is used for devices essentially produced with microelectronics processing equipment while processing with dedicated equipment is sometimes considered MST. Still, there is no real difference in technology behind these concepts and hence MEMS will be used synonymously for all three concepts in this essay.

Top-Down and Bottom-Up

The conventional fabrication technology used for Micro Electro Mechanical Systems (MEMS) is considered "top-down" processing since a larger workpiece, typically a silicon wafer, is sculptured by various etching techniques. Nanomanufacturing, on the other hand, is typically a "bottom-up" process since nanometer sized objects, ranging from atoms to sub-micrometer particles, are assembled to create the final product. Still, the concepts of "top-down" and "bottom-up" are not synonymous with MEMS and nanomanufacturing, respectively. Local

micro-deposition to build MEMS would be considered a "bottom-up" technique while parallel manipulation of nanoparticles by imprinting techniques is rather a "top-down" technique.

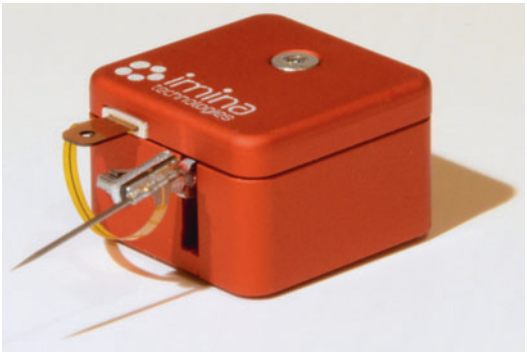
Micro and Nanorobots



Microrobots are usually defined as robots with a physical size in the micrometer size range, i.e., less than a millimeter. Such robots can be made by slightly modified MEMS technology and microelectronics processing techniques of today (2015). The level of autonomy is not strict; both fully autonomous robots and fully teleoperated robots are included in the concept. A nanorobot is a futuristic idea of a similar artificial unit with similar properties but in a sub-micrometer size range. A modified virus could in many respects be considered an autonomous nanorobot. To distinguish the biologically based molecular components from pure artificial machines the term bionanorobotics has been coined. If we consider present research efforts, the most probable nanorobot that will occur appears to be biologically based and hence these will be considered nanorobots here. Robotic equipment of centimeter or decimeter size with manipulating capacity in the micro- or nanometer size range is here consider as micro- or nanorobotic systems, i.e., robots for micro- or nanomanipulation.

Micro- and Nanomanipulators

Microrobots



In R. P. Feynmans talk "There is plenty of room at the bottom" 1959 he suggests scaling down our present manufacturing equipment step-by-step, one quarter at a time, to eventually create a factory for nanocomponents. While the interest in micro- and nanotechnology developed in the direction he envisioned the scaling down of equipment followed another route. Even though watchmaking industry has been able to produce mechanical details well below millimeter sizes for decades, the microelectronics processing technology made it possible to go some steps further. In comparison with discrete electronics, the introduction of integrated circuits (IC) made it possible to shrink inter-component distances with at least two orders of magnitude. The size reduction of the IC structures has continued with some 10 % each year since the 1970s. The miniaturization level attained by MEMS technology is rather impressive but the tolerances of the details manufactured have not scaled down in the same manner as the sizes have been reduced. There are about the same tolerances in MEMS devices as high quality fine-mechanics details. The possibility to make scaled down manufacturing plants by MEMS technology is therefore not easily accomplished in the manner presented in R.P. Feynmans talk. To describe it in simple terms – microrobots fabricated by present MST are still too clumsy to manage any sub-micrometer manipulation/processing and are, of course, not able to build any nanofactories.

What type of manipulation can be made with microrobots of today? Figure 1 is an example of a miniaturized robot built with MEMS technology [4]. The size is $4 \times 4 \times 3$ mm and it is made with techniques that would allow for mass-production. The robot is designed to be autonomous but with a possibility to communicate with a master system. There are essentially five different modules that are assembled on a flexible printed circuit board (FPC): a solar cell, an IR communication unit, an Application Specific Integrated Circuit (ASIC), capacitor(s) and a locomotion unit. The solar cell is multifunctional – it can provide the robot with power as well as communication and sensing capabilities. Two small areas are dedicated for position identification and communication. The capacitors are used as energy storage and to stabilize the electrical power. The IR communication consists of four photoemitters and photodiodes directed in four lateral directions. The ASIC is basically a microcontroller with some specific peripherals to manage the other modules. Finally the locomotion unit consists of three legs that create motion by vibrations, tapping the leg tips against the floor. The legs are made of polyimide with a multilayered piezoelectric Poly(Vinylidene DiFluoride-TriFluoroEthylene) P(VDF-TrFE) on top. The carrier is also made of polyimide and the idea was to demonstrate that microactuators can be integrated in the carrier directly (not made in the referred article).

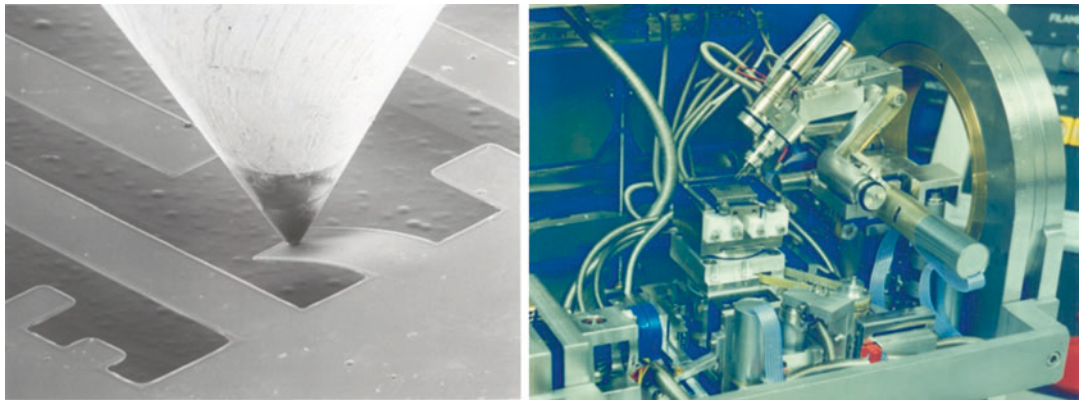
Returning to the question – what can be made with microrobots – we should maybe first address the possibility to make a sub-millimeter sized robot with present technology. The answer is yes, we can make them, if we accept the robot intelligence that can be achieved with an IC of sub-millimeter size. Most of the modules in Fig. 1 have substrates which are inactive and can be removed to a large extent. If we add the active thickness of all modules we will be well below 1 mm and there are possibilities to go even further with an ample budget for processing. The next part of the question is what manipulation such a microrobot can do. As part of the locomotion module there is actually a vibrating "tool" which was designed as a touch sensor, to detect when the tool gets in contact with some physical object. We could imagine using something similar to manipulate. Would we also be able to make one tiny hand on this type of robot? The microactuator technology used [5] would not allow for anything complex at a sub-millimeter size range but it is possible to make something more advanced with refined technology. Still, the dexterity of such hands would be extremely limited and we should rather be looking at "grasping" by, for instance, electrostatic forces and releasing by tilting or vibrations. Maybe more interesting is what a large number of microrobots can do together. The tools of each robot might be more or less a needle but the combined action of several robots makes it possible to perform various manipulating tasks. If we imagine some three-four needles that can be controlled arbitrarily in space then most basic manipulating tasks can be accomplished: grasping, moving, rotating, positioning, releasing etc. The crucial points are the precision in movement by the robots, the observation/sensing capacity, the ability of moving the tool in all three dimensions and also their capability to cooperate. Without too much speculation about these engineering challenges, all of them will by themselves limit the handling to the micron range, presently. At this robot size range – sub-millimeter size – there is however nothing in the physics that introduces insurmountable obstacles. It is merely a question of solving technical challenges and the demand for access to an extensive research budget. Considering the 55 years it has taken to reach this immature stage after R. P. Feynmans talk it appears to take another century before we will manipulate the nanoworld with tiny artificial microrobots, though. The cm-sized robot by Imina Technologies, Fig. 2, is the smallest commercial robot with nanometer resolution manipulating capacity that exists today. With its piezodriven motion system it is able to manipulated objects at the nano-level with 4 degrees of freedom (DOF). It is designed for operation in vacuum making it possible to observe the manipulation in situ in a scanning electron microscope (SEM).

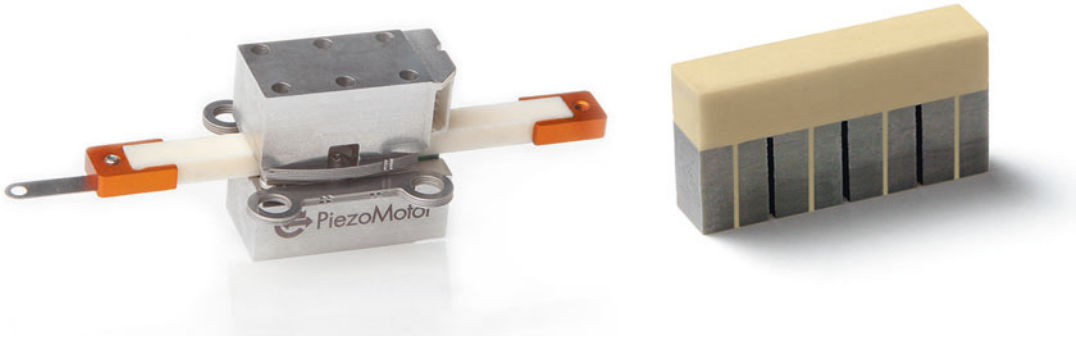


Micro- and Nanomanipulation for Nanomanufacturing, Fig. 2 A cm-sized nanorobotic manipulator from Imina Technologies. The robot has a tool holder allowing up-down movements of the tool and the robot itself can rotate and move in two orthogonal directions (Reprinted with kind permission from Imina Technologies SA)

Using biological molecules, e.g., DNA and proteins, as base elements to build nanorobots appears to be an efficient strategy solving crucial issues like propulsion. These molecules already have highly developed functionality and it would be difficult competing with artificial structures. Some ideas to build nanorobots from these base building blocks are based on nanoassembly. The present state of the art is summarized in [6] and it can be concluded that we are far from building any nanorobots and hence even further from using this type of nanorobots for nanomanufacturing. The question that arises is which path is most efficient for building nanorobots. There is already an extensive ongoing bio-chemical research regarding existing "bionanorobots," viruses, cells etc., and it might prove to be more efficient to (genetically) modify these than building artificial counterparts. A recent example of manipulating with bacteria has been shown in [7]. In the experiments the bacteria are randomly attached to microbeads with 10 μm diameter. The bacteria propulsion is controlled chemically in a digital fashion (on/off). The observed random motion of the microbeads appears to be due to both the arbitrary attachment and random propulsion. The possibility to manipulate microbjects in a controlled and efficient way is obviously far away and there are several critical issues to solve before this will occur.

The magnetically guided microsized object investigated for medical therapy [6] at nano level should maybe be classified as nanorobotic systems. These magnetic particles, without own propulsion, need to be rather large, $>$ 50 μm, to overcome the Brownian motion in a liquid (typically blood), see "Phenomena", with available magnetic field forces. An interesting approach is to synthesize magnetic crystals inside bacteria to guide these self-propelling 1–2 μm "micro/nanorobots" inside a biological body. These guided bacteria are developed to carry therapeutic drugs but we could as well imagine them carrying nanoscale base building blocks. The ability to control nanomanipulation is so far limited and the most obvious control will be by methods that resemble those of conventional (bio-) chemical processes.

Micro- and Nanomanipulators

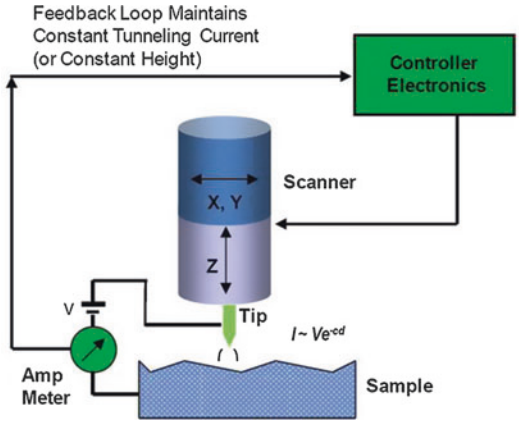


During the 1980s the field of MEMS became an important research field globally. At that time it was called micromechanics and the possibilities to build complex mechanical systems at micron level appeared endless. The two dimensional character of the structures as well as poor relative tolerances proved to be major obstacles. As part of the general characterization of the materials used in MEMS a simple micromanipulator operating in situ in a SEM was used for mechanical characterization of silicon cantilevers, Fig. 3 [8]. These tests were fairly straightforward – a simple spherical diamond tip was used to deflect the silicon elements until fracture, Fig. 3. The fascinating high fracture stress/strain of these close to perfect materials/components could be observed for the first time. The successful use of that equipment with barely μm precision can be attributed to the ability to observe the tool and device at high magnification with a large depth of focus. The SEM gave us eyes in the micro- and nanoworld and most of the mechanical errors as hysteresis, non-linearity and even back-lash can be compensated for with no or little prior knowledge. Most of us that have been working with objects in the sub-millimeter size range have noticed that it is possible to manipulate, possibly with some simple support/leverage, micro-object by the bare hand

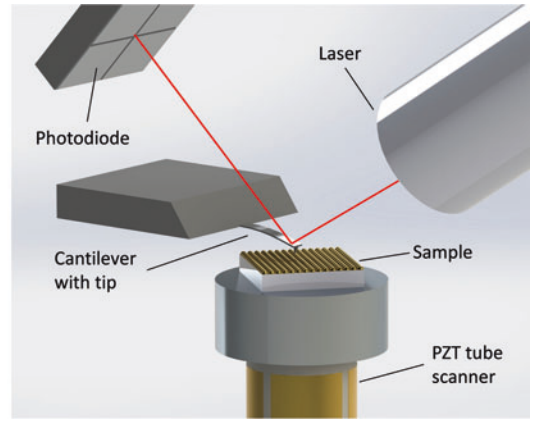
Micro- and Nanomanipulation for Nanomanufacturing, Fig. 3 Micromanipulation in a Scanning Electron Microscope (SEM). *Left*: Silicon cantilever microstructures are fracture tested in-situ. *Right*: A nanorobotic system for operation in a SEM with a 4 DOF specimen heating table and a 5 DOF manipulation station using micromachined tweezers as tool

as long as the tool and object can be observed at relevant magnifications, often sufficiently well with a stereo microscope. There were several different micro- and nanomanipulation projects running during the 1980s [9] with focus on different applications, typically medical, micro/nanorobotics and micro/nanomanufacturing. The parallel development of Scanning probe Microscopes (SPMs) for nanomanipulation did not appear to be the desired manipulation equipment since the available 2–3 degrees of freedom (DOF) – x, y and possibly z- movements – in that instrument does not give the flexibility desired for general manipulation tasks. Full flexibility demands at least 6 DOF at the point of observation and rather complex instruments were built to accomplish this. One example of a micro/nanomanipulating equipment with 6 DOF at the observation area in the SEM is given in Fig. 3. The specimen table and the two tool stations were designed for 14 DOF to become, in some sense, the "tiny hands" in R. P. Feynmans talk. The SEM has several advantages in comparison with e.g., SPMs and real-time imaging with large depth-of-focus at high resolution is very attractive. To utilize the highest resolution some contrasting means might be necessary but the main drawback is the need for operation in a vacuum environment. The use of environmental SEMs (E-SEMs) [10] solves this to a certain extent – the need for short distance between sample and lens at higher pressures limits the workspace. The resolution is also somewhat reduced.

The mechanical design in Fig. 3 is based on DC-motors, leadscrews, linear bearings and piezotranslators. The DC motors and mechanical devices are used for the rough positioning while the piezotranslators are used to compensate for back-lash etc. Since the piezomaterials deform smoothly with applied voltage it is possible to achieve nm resolution using a sufficient voltage resolution. The piezotranslators are used to "scan" within the steps of the rough positioning. Piezoactuators are key components in both the SPM manipulators and dedicated manipulating equipment. Present piezomotors, Fig. 4, are able to both make the rough positioning by a "walking" mechanism and nm-positioning by "scanning." The motor core is a unit with four legs, Fig. 4 Right, consisting of piezoelectric bimorphs that individually can make steps, very much like the movement of a four legged animal [11]. The legs are pressed with a fairly high normal force against the drive rod (white rod in Fig. 4) and the frictional contact makes it possible to generate large driving forces. The use of piezomotors has made it possible to build compact manipulating units with high stiffness and nm-resolution. Commercial nanomanipulators are optimized for



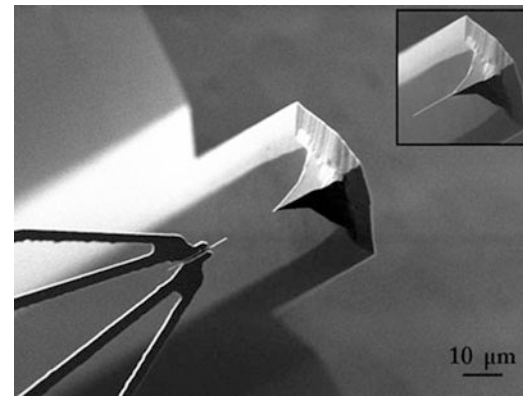
Micro- and Nanomanipulation for Nanomanufacturing, Fig. 4 *Left*: a piezoelectric "walking" motor from Piezomotor® able to drive the central rod (*white*) with sub-nanometer resolution continuously over the whole rod length. *Right*: the motor core is a four legged piezoelectric unit with bimorph legs that can both extend and bend. The legs are operating in pairs and can "walk" continuously while the in-step resolution is mainly limited by the voltage resolution of the drive electronics (Reprinted with kind permission from Piezomotor Uppsala AB)



various applications and imaging instruments used. Typically each axis is guided by linear roller bearings and piezomotors or piezotranslators are used to achieve nanometer – or better – movement precision. Optical scales are most often used to get positioning resolution in the nanometer range and feed-back for controlled motion and automatic operation ("► Robot-Based Automation on the Nanoscale"). One drawback is that the speed of a piezomotor is lower than that of an electromagnetic motor, typically by one-two orders of magnitude. While a Hard Disc Drive is able to "manipulate" magnetic particles within an area of 10 × 100 nm every ns the Piezomotor needs to manipulate atoms to keep the same pace. Still, the resolution and the outstanding high speed dynamics of the piezomotors makes it possible to reach the same manipulation frequency at the very bottom-up atomic spatial dimensions. The processing tools with this resolution and speed are yet to be developed.

Scanning Probe Microscopes

The scanning probe microscopes (SPMs) originate from the scanning tunneling microscope (STM) invented by G. Binnig and H. Rohrer in the late 1970s. Initially they wanted to characterize the tunneling behavior locally, at an area less than 100 Å, and later it turned out to be one of the most versatile and accessible high-resolution imaging techniques. The instrument developed was based on piezotranslators arranged to get sub-nanometer resolution in three orthogonal directions. Typically tripods or tubes are used to achieve controlled movements with minimized vibration sensitivity, Fig. 5. The piezoelectric material deforms linearly with supplied charge (more or less linearly with voltage) and the resolution of the voltage source will determine the positioning resolution. A sharp tip – it has to end with a single atom – is positioned by the piezoactuator at a few Ångströms distance from the substrate. In the STM there is no need for a position detector since the instrument uses the tunneling current to measure the surface topography, e.g., operate in constant tunneling current mode and calculate the z-movement (orthogonal to the investigated surface) from the voltage changes in the piezotranslator. This gives a map of the surface with atomic resolution at the correct experimental conditions.



If a position sensor with nanometer resolution of the tip is added to a STM then it can operate as an Atomic Force Microscope (AFM), Fig. 5. Typically a laser beam and split photodiode are used to detect deflection of a cantilever with the probe tip. Apart from being able to image non-conducting substrates several new modes and various detection methods can be used. The tip can be in constant contact or in non-contact with the surface. There is also a so-called tapping mode where the tip is intermittently in contact

Micro- and Nanomanipulation for Nanomanufacturing, Fig. 5 *Left*: scanning tunneling microscope with a piezoelectric tube scanner able to move in three orthogonal directions with sub-nanometer resolution (Reprinted with kind permission from Springer Science and business media [12]). The tunneling current is used for feed-back to keep the atomically sharp tip at a given distance from the surface. *Right*: in an atomic force microscope the tip is mounted on a cantilever beam. The atomic forces between sample and tip will deflect the cantilever and the deflection is detected with a laser beam and split diode

with the surface. Numerous interactions can be imaged, e.g., forces, chemical and optical, and such an instrument is often called Scanning Probe Microscope (SPM). These instruments are well suited for nanometer manipulations on a surface and many nanomanipulation tasks have been explored, see ("▶ Robot-Based Automation on the Nanoscale"). Assuming a layer-by-layer technique to build nanostructures we could also consider this an instrument also for three-dimensional 3D manufacturing. One common drawback is the speed of operation; the time to scan a full image takes some tens of seconds which does not allow for real time observation and manipulation. There has been a development towards video-rate scanning by particular scanner and cantilever solutions.

Manipulation Tools

Physical Probes

The SPMs typically have a probe tip on a cantilever. The conventional probes are made of Si and Si_3N_4 with a tip radius down to a few nm. The cone angle is typically down to some 10°. There are equally sharp tips made of Diamond Like Carbon (DLC) and more blunt polycrystalline diamond coated tips. The tips with highest aspect ratio have a Carbon Nano Tube (CNT) as tip with a radius of a few tens of nm and length of some hundreds of nm, Fig. 6.

There are several examples of miniaturized manipulation tools and the simplest is a sharp needle as in the case of SPMs. These types of tools become more versatile if several can be operated independently and close to each other.

The closeness is often limited by the fairly large manipulators, in comparison with the manipulation space, that are used so far. The nanoparticles/objects are held with electrostatic or interatomic forces and the main concern is often how to detach the particle/object from the tool. Micromachining techniques have been used to fabricate various microtweezers and one example is given in [13]. Tweezers are typically used for releasing/breaking nanostructures from carrier substrates without losing them after removal.

Nanodroplets can be ejected by both physical and non-contact means. Conventional printing techniques can be miniaturized and using nozzles of sub-micrometer size also droplets of sub-micrometer size have been printed on a substrate. Experiments with sub-micrometer capillaries have shown that it is possible to transfer some few hundred nanometer diameter droplets to a substrate by surface tension at physical contact. Using an AFM it is possible to transfer an ink by capillary forces to a substrate by e.g., heating the tip, the so called *dip-pen technology*. The printing line widths are typically 100 nm while enriched particles in the center could have a line width of 10 nm.

Non-contact Probes

Most high resolution probes can be used for non-contact manipulation of atoms or nanoparticles. Focused atom/ion- and electron beams are used both for removal and deposition of material locally with a spatial resolution in the nanometer range. Electromagnetic forces are used in many different ways. Needles are used to create local electric fields that result in manipulation of material and magnetic probes are e.g., used to manipulate the magnetization of nano-areas in present hard discs. Electromagnetic field manipulation is often based on fields close to or within the visible spectrum. Optical tweezers and two-photon processes are two particular techniques.

The technique to manipulate small particles by optical light is called optical-trapping or -tweezers ("► Optical Tweezers") and is based on the radiation pressure that forces particles towards the focused light center. This non-contact tool is particularly well suited for manipulation of biological molecules in aqueous solutions and the typical technique is to attach (biological) molecules to micrometer sized beads. The beads can be displaced with nanometer spatial resolution using e.g., piezotranslators to move the focused laser beam. The applied forces, typically in the range 0,1–100 pN, can be controlled by variations of the optical intensity or trap displacement using calibration constants for the measured displacement at given force. Using several lasers it is possible to make parallel manipulation and with super-resolution fluorescence imaging, single molecule microscopes, molecules can be observed with close to nanometer resolution.

Two-photon excitation microscopy uses a process where two photons of lower energy than needed for fluorescence, e.g., for observation of biological cells, together will cause the excitation of the atoms. One important improvement from a single photon excitation is that the spatial resolution is much better. The same technique is employed to manipulate bonds in photopolymers and both 3D-lithography and printing in the sub-micrometer range can be made. Nanoscribe GmbH has commercialized equipment with spatial resolution down to 200 nm.

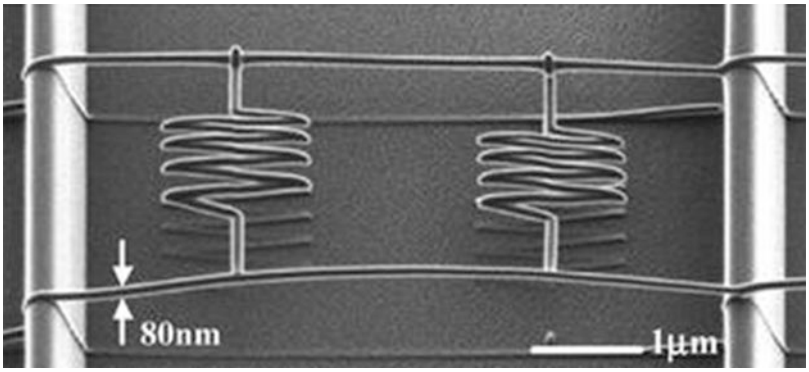
Dielectric particles can be manipulated by inhomogeneous electric fields and this method is called dielectrophoresis. The forces are due to polarization effects and gradients in the electric field (in analogy with optical trapping). Using a physical electrical probe in a nanorobotic system the particles can be manipulated with nanometer precision. Typical particles sizes that can be manipulated by this technique are in the range 1–1,000 μm.

Acoustic radiation forces can also be used to manipulate particles in the micrometer or sub-micrometer range. Typically the particles are handled in MEMS based microfluidic channels and the particles are suspended in the liquid. At frequencies above about 10 MHz it is possible to trap or force particles of sub-micrometer size. The need for standing waves, typically by integrated transducers, makes this technique most advantageous for dedicated manipulation tasks in liquids.

Phenomena

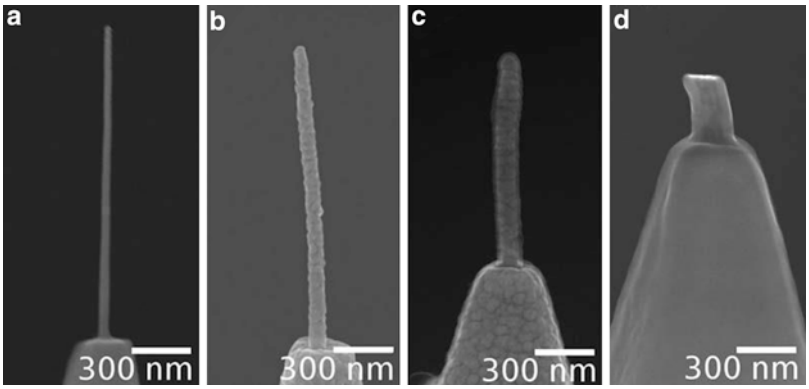
In the nanoworld, the nanoparticle mass is low and inertial forces as well as gravitational forces can be neglected. Manipulation of nanoparticles will therefore be rather different from handling of macroscopic objects. As the particles are essentially without inertia a constant manipulation force is needed to move them in a desired direction. The Brownian motion of surrounding molecules will result in random impacts and the necessary manipulating forces have to be relatively large to give a controlled movement. For instance the manipulation force from optical tweezers is too weak to "hold" sub-micrometer sized particles. Most manipulation difficulties might though result from the "stickiness" of the surrounding tools, surfaces and molecules.

Our intuitive macroscopic feeling is that the adhesive force between two objects getting in contact is in most case negligible. This is partly due to the extremely small real contact area with nanometer spacing between two macroscopic objects and partly due to protective surface adsorbates and inactivated surfaces (recombined bonds). If the objects become extremely flat and have nanometer roughness the objects will however stick to each other (assuming that no microscopic particles will be trapped in between), e.g., Johansson gauges, and it might be close to impossible to part them if the surfaces are ultraflat. The situation with microscopic objects is even more particular.



There are three main phenomena that will make small particles stick and an additional number of phenomena that will make them bond to another object. Bonding can be due to chemical reactions and formation of primary bonds between the particle(s) and object. This might be a desired process in a nanofabrication sequence but can normally be avoided for manipulation tasks in conventional environments. Typically an elevated temperature is needed to form primary bonds and this is one of the most straightforward methods to get controlled fixation. Energy supply by tools such as focused electron or ion beams can be used at the local nanoscale.

The sticking in dry environments by electrostatic and Van der Waals forces are essentially impossible to avoid with particles of micron and sub-micron sizes. The Brownian motion makes the particles constantly move and the probability that they will encounter each other – creating agglomerates – or some larger object, is high. Long-range electrostatic forces are not as strong as Van der Waals forces but will still result in strong bonds and become more important when the surface contact area is less. The third sticking phenomenon is wetting and can occur in e.g., humid environments. The adhesive forces by capillary action can be as strong as the two other sticking forces and it might be difficult to remove the particles held by capillary forces even at elevated temperatures.



The sticking effects make it difficult to manipulate nanoparticles and even rather large microparticles. The particles stick to the tools and it is normally not necessary to use tweezers to hold the particles but the concern is rather to remove them from the tool or carrier substrate. The techniques to manipulate and in particular to release particles/objects in the nanoworld reminds more about handling objects in the macro world with all fingers and tools covered with sticky glue. In general the contact surface has to be reduced in order to release something and the strategy presented in ▶ Robot-Based Automation on the Nanoscale is illustrative.

Examples of Micro-/Nanomanipulation for Nanomanufacturing

This entry covers processes and methods that still are in an immature state. In an engineering context the word "manipulation" leads our thoughts towards gripping, moving, orienting and assembling nanoparts. The nanoworld is however different from our macroscopic world (see "Phenomena"), and we therefore act accordingly. Nanoparticles should be *guided*, preferably in parallel, to the preferred sites. If we want to assemble, then we want to *arrange* for sufficiently strong interatomic forces, or even bonds, to keep them in place. The tools are typically not based on

M

mechanical contact; the physical shape is rather used for non-contact spatial control. Several of the manipulation experiments made here follow this strategy. The examples below present some of the possibilities with present technology.

With non-contact tools as ion- and electron beams, atoms and molecules can be manipulated during simultaneous observation. The focused ion beam (FIB) instrument is one of the more common nanolabratories. This instrument resembles a SEM but with an ion beam source. The ions, usually Ga, can be focused to a spot size of some few nanometers and this beam can be used for both imaging and manipulation of atoms. Impinging ions will remove (sputter) surface atoms and the sample can be sculptured with down to nanometer precision. Atoms can also be deposited locally by the focused ion beam and the process is local activation (Chemical Vapor Deposition) of adsorbed molecules on the surface, Fig. 7. As mentioned in the "History", electron beams have been used to manipulate atoms and molecules since 1930s but mainly in top-down approaches. One example of a bottom-up process is electron beam induced deposition (EBID) which is similar to the FIB deposition process. Adsorbed molecules are decomposed by electrons at the focused electron beam on the surface and subsequently reacting with the underlying surface. The electron beam can be focused to sub-nanometer size and nanometer sized features can be deposited. In the example shown in Fig. 8 the electron beam is used to deposit a needle some tens of nanometer in diameter and the FIB is used to cut and form the tip. The conventional optical lithographic techniques – producing integrated electronics and MEMS – should be mentioned for reference. The optical light manipulates the bonds (make chemical changes) in the photoresist which allows for selective removal of the exposed pattern in a developer (chemical solution). Diffraction limits the smallest feature size and with present deep

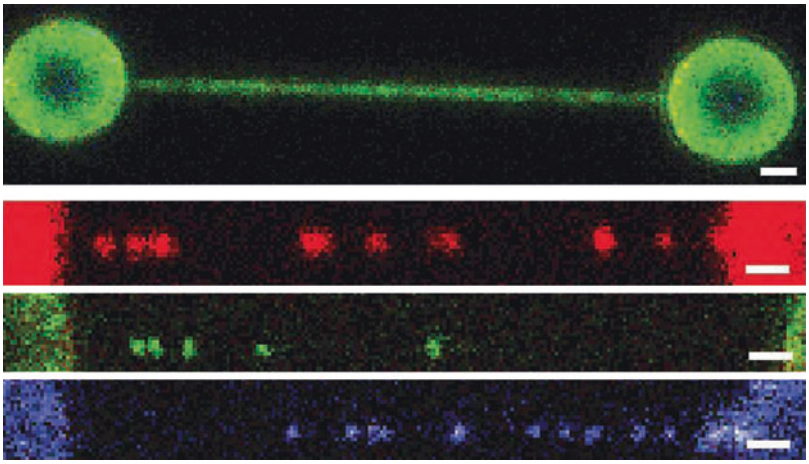
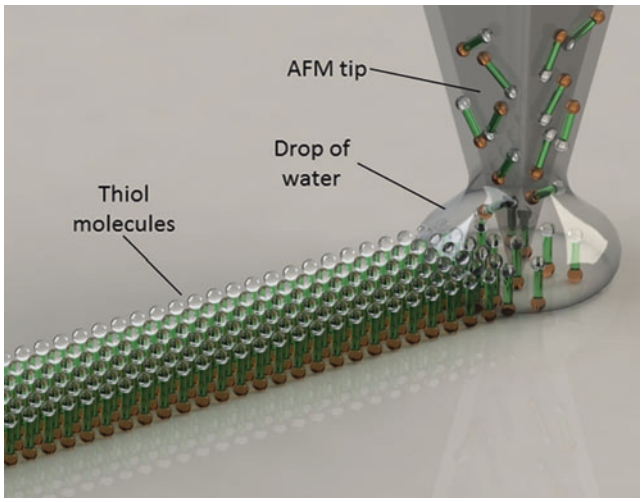
ultraviolet lasers the smallest details are of the order 50 nm, i.e., well into the nanoregion.



Carbon Nanotubes (CNTs), one atom thick tubes of Carbon atoms, are of great interest for scientific, as well as commercial and technical reasons. Single walled tubes can have diameters less than 10 nm and AFMs have been used to explore the possibility to manipulate these nanoobjects. The adhesive forces between the tubes and surface typically makes the tube bend when forced with the AFM probe. Apart from deforming the CNTs it is possible to translate and rotate the tubes as well as cut them – if they get pinned at two different positions. Figure 9 shows the formation of the letter θ by moving and bending the tubes.

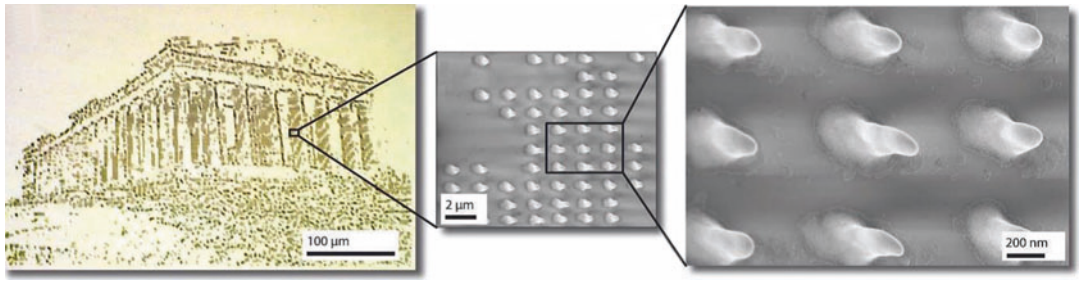
Nanorobotic systems have been used for the assembly of CNTs on AFM tips as illustrated in Fig. 6 [13]. The nanorobotic system consists of commercial units, a 4 DOF manipulator and a 3 DOF nanostage, mounted on the SEM specimen stage. A thermally actuated microgripper (made by MST) mounted on the manipulator is used to grip and release a CNT by sideways movement causing fracture close to the attachment site at the substrate surface (this technique is explained in detail in ▶ Robot-Based Automation on the Nanoscale) The CNT is moved to get in contact with the AFM tip and thereafter attached with electron beam induced deposition (EBID).



CNTs have also been manipulated by dielectrophoresis and large concentrations of CNTs can be handled in parallel in the fluid channel [17]. The technique is to create parallel electrodes in a fluidic channel and trapped tubes will align with the electric field. This allows for nanofabrication of single-layer arrays but does not allow for free manipulation of individual nanocomponents. Another parallel nanomanipulation technique that has good potential for multi-layered structures is soft- and imprinting lithography [18]. These techniques are normally not considered as manipulation but in practice multiple atoms can be manipulated, e.g., transferred or displaced, with nanometer control. These top-down processes need unique stamps/tools for each pattern, which rather categorizes them as high-volume production than scientific techniques.

Biological molecules are often studied by fluorescence imaging where fluorescent molecules are chemically linked to the molecules of interest, e.g., proteins, making it possible to image single molecules. These molecules can be manipulated by optical tweezers in their natural aqueous environment with real-time imaging. The technique is to attach the molecule to a polymer microbead and use this bead as a handle for holding and moving the molecule. Figure 10 is an example of a manipulation experiment. A DNA is attached to two microbeads and using two optical tweezers the DNA strand can be stretched. Using different fluorescence labels on three proteins the individual positions can be imaged. Improved resolution, down to the order of tens of nanometers, is achieved with superresolution techniques.

One of the techniques that might appear to be the most straightforward way to manufacture at nanoscale is dip-pen nanolithography. Nanoparticles are loaded on an AFM tip and by positioning the tip in proximity to the surface and using a wetting aqueous meniscus (humid environment) the nanoparticles can be deposited on a substrate with nanometer precision.



Micro- and Nanomanipulation for Nanomanufacturing, Fig. 10 Stretching of DNA attached to two microbeads (3.2 μm) by optical tweezer. Micro- and Nanomanipulation for Nanomanufacturing, Fig. 11 Dip-pen Nanolithography using an AFM to make a pattern with nanometer resolution. The aqueous meniscus defines the line width of the thiol molecules which form a self-assembling monolayer

The nanoparticles can also be dissolved in a polymer matrix and by heating the tip the liquid ink can be printed on the substrate. It is possible to deposit inks with line widths less than 100 nm and for particular conditions the nanoparticles can be enriched in the center of the ink. By removal of the polymer matrix line widths down to 10 nm has been presented [20]. One drawback with this method is the slow deposition speed. Typically polymer lines can be written at speeds of hundreds of μm/s while the speed for nanoparticles rather is in the order of μm/s. The speed could be increased by using tip arrays, a large number of pens operating in parallel. Arrays with 55,000 pens have been demonstrated and hence five orders of magnitude in speed improvement should be possible. It is possible to tailor the interfacial properties of the substrate within large ranges using inks of alkanethiols which form self-assembling monolayers, Fig. 11. These last two techniques are examples of nanoscale manufacturing in parallel with a large degree of self-assembly.

The last selected examples are nanoparticle printing which are techniques well suited for local and parallel manipulation of nanoparticles. There are several printing methods with sub-micron, or potential sub-micron resolution [21]. Figure 12 shows dielectrophoretic printing of Au nanoparticles using a sub-micrometer sized capillary. The Au particles suspended in a non-polar liquid is dispensed by the electric field gradient at the nozzle opening and are pinned at

the surface by Van der Waals forces. Both dots and pillars with diameters of 200 nm have been made. There are also commercial 3D printers with sub-micrometer resolution. Nanoscribe GmbH has developed an equipment for additive fabrication based on a two-photon process which gives a printing resolution of about 0,2 µm. The instrument can handle writing areas of 100 × 100 mm by stitching scanned areas of typically 300 × 300 × 300 µm.

Future Trends

The vision of entering the nanoworld and using nanofactories to create completely new materials, machines and therapeutic devices are receiving more and more attentions as the decades pass and particularly now during the 2010s since dedicated research funding for nanotechnology is available globally. The amount of published material is, as often, not in proportion to the real progress and we are still just touching the surface of this vast and fascinating field. Piezotechnology has been the key for the progress in nanomanipulation and even though there has existed commercial actuators and equipment for more than three decades there are still several improvements to come during the coming decade(s). For instance, sub-nanometer resolution actuators with continuous movements and stable speed over a large working range are still lacking.

Nanomanufacturing was made by biochemical techniques prior to the introduction of the nanotechnology concept and the artificial micro/nanomanipulating tools have so far made little impact. The fast growth of Artificial DNA nanofabrication appears to open up new possibilities. A more extensive cross-fertilization between biotechnology, MEMS/NEMS and other nano-engineering is expected and this will give us more effective "manipulation" means. Among the artificial nanomanipulating techniques both 3D microprinting and microcontact printing might become something that we could consider as generic nanofactories. While microcontact printing is a top-down technique, 3D nanoprinting has a potential to be the general, parallel, bottom-up "manipulation" method for nanomanufacturing. It can be concluded that nanotechnology will be very important since most of the coming challenges in the society, health, environment and energy supply could benefit from nanotechnology, one way or another. The development might possibly not follow the visionary directions, though. As always, the identification of a large value application will accelerate and focus the research efforts. If nanomanipulation will play a central role is yet to be discovered.

Department of Chemistry, University of Minnesota, Minneapolis, MN, USA

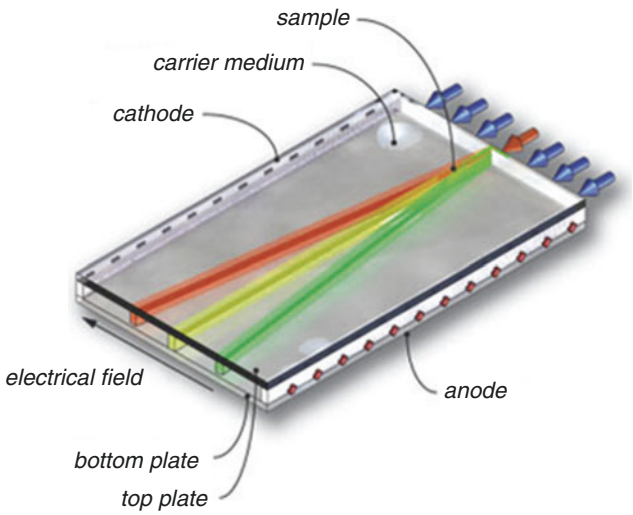
Synonyms

Carrier-free electrophoresis

Definition

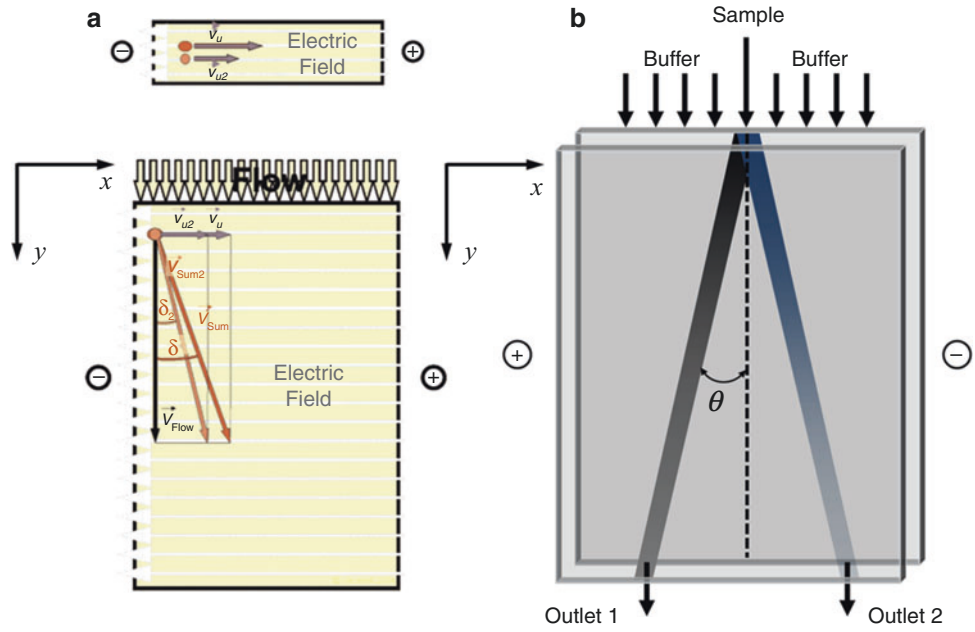
Micro free-flow electrophoresis (μFFE) is an electrokinetic technique that can continuously separate and focus charged analytes in the microflow of a carrier buffer where an electric field is applied. A thin sample curtain is introduced into a planar separation chamber with a flowing buffer stream. An external electric field is provided perpendicularly to the buffer flow in the separation chamber. Then the ionic components contained in the sample are laterally deflected along the applied electric field lines depending on their respective electrophoretic mobility and subsequently, collected through the outlets installed at downstream of the chamber.

Introduction



The rapid growth of biotechnology during the past 20 years has constantly emphasized the importance of efficient purification methods for screening and isolating specific constituents from a complex biological mixture. Until now, cell purification has been performed mostly for amino acids, peptides, proteins, nucleic acids, viruses, and bacteria. However the recent emergence of genetically engineered cells enhanced its significance further [1].

Various methods and techniques have been developed for cell separation and isolation [2]. Fluorescence-activated cell sorting (FACS) is the most common method of cell purification. The technique takes advantage of antibodies linked with fluorophores for the purification. The fluorescent antibodies combine with specific surface markers of target cells to be separated. The cells are separated according to the existence and nonexistence of the fluorescently labeled cell surface proteins in the application of an excitation laser and an external electric field. FACS received much attention from scientific communities because of its outstanding efficiency, accuracy, and reliability for cell purification. It led to the extensive applications of the method in the various research fields including tissue engineering and molecular biology. However FACS sometimes suffered from the availability of fluorescent antibodies to tag target cells, the ease of surface marker protein identification, and the viability of cells during FACS process. Most of proteins considered for cell separation are intracellular and hence, they are not easy to be labeled with fluorescent antibodies. If cells to be separated are in a developmental stage, finding their surface marker proteins also is very difficult. Further, since some cells are too sensitive to external stimulations, they may be damaged or killed during the FACS process. Magnetic cell sorting utilizes antibodies tagged with magnetic beads, unlike the FACS using fluorescent antibodies. Thus, the method can easily obtain targets of interest at cheap price. However, there are not many antibodies available for the magnetic cell sorting. Besides, only one kind of protein at a time can be processed by the method. And the accuracy and reliability of the cell purification is not as high as FACS. Cells can also be sorted based on their size (density purification). The introduction of centrifugation media predefined for the sorting into a cell sample rearranges target cells to be separated by forming successive liquid layers with density. It enables to separate a mixed cell population with their sizes through centrifugation at optimized rpm.



The density-based separation has the advantages of being fast, simple, and cheap. However, the method cannot be used to separate cell populations of similar size. Also it is relatively inefficient compared to other purification techniques. As introduced previously, each of the existing cell purification techniques has several limitations in screening and isolating interesting cells. Those disadvantages motivated the need of a novel separation technique or method that can perform cell purification in the simultaneous mode of ease, accuracy, high speed, and high throughput.

Since its first introduction about 50 years ago, free-flow electrophoresis (FFE) has steadily evolved to one of the most promising techniques for separation of cells, organelles, proteins, and peptides [3–5]. In FFE, analytes are introduced into the pressure-driven flow of a carrier buffer between two parallel plates and then laterally separated along their electrophoretic mobility by an electric field applied perpendicularly to the flow direction (Fig. 1). The separated ionic components are transported with the flowing buffer toward downstream of the FFE device for selective collection at outlets. The greatest advantage of FFE is that a continuous separation and collection of a sample is possible, unlike liquid chromatography and gel electrophoresis requiring repetitive sample loading. It significantly reduces the time and labor consumed for sample separation. The range of electric field intensity used for FFE operation dispels the concern about the electric breakdown of bioanalytes such as electroporation, membrane fusion, bleb formation, and cell lysis [2]. Generally electroporation and the related phenomena are induced by a high-intensity electric field of several kilovolts per centimeter, which is much stronger than the one for a FFE system. This ensures the viability of biomolecules processed by FFE. With the trend of miniaturization and the advancement of microfabrication technology, the FFE has been integrated on lab-on-a-chip (LOC) systems and which, in turn, allowed to find more benefits in some aspects [3, 4]. Compared to macroscale FFE, chip-based FFE can separate and focus analytes within a shorter time. Furthermore, the amount of a sample consumed for analysis also is small (several hundred microliter volumes). High surface area-to-volume ratio minimizes the Joule heat produced by an applied electric field. These advantages have caused wide applications of the micro-FFE (μFFE) for cell separation and isolation.

This manuscript provides a detailed theoretical and technical overview of μFFE so that readers can find more abundant μFFE-based approaches for cell purification through fundamental understanding of the technique. First, a basic principle and separation resolution of μFFE are discussed. It is followed by introducing the various operation modes of the technique and the application cases of each mode.

Principle of μFFE

Cell purification by μFFE takes advantage of the difference of electrophoretic mobilities of ionic components contained in a cell sample [3, 4]. The principle is similar to capillary electrophoresis (CE) (Fig. 2a) [2, 6]. Each of cell components has their unique charge-to-size ratio (i.e., electrophoretic mobility) and accordingly, migrates along a capillary at different velocity ($\vec{v}$) under the application of an external electric field ($\vec{E}$). The velocity is given in Eq. 1:

$$\vec{v}_i = \mu_i \vec{E} \tag{1}$$

where μ_i is the electrophoretic mobility of ionic species to be separated and is defined by the size (r_i) and the charge (q_i) of the species as shown in Eq. 2:

$$\mu_i = q_i / 6\pi\eta r_i \tag{2}$$

where η indicates the dynamic viscosity of the suspending medium. The velocity difference of the cell components produces the difference of deformation angles of each component stream in the continuous flow of a carrier buffer in a μFFE system (Fig. 2b). When a cell sample is introduced into a flowing buffer solution at one point through an inlet, it is transported along y-direction with the buffer. While passing across an applied electric field, the sample recedes linearly from the buffer flow direction in x-direction. The deformation angle (θ) is defined as a ratio of the electrophoretic velocity of the sample to the flow velocity of the buffer, like in Eq. 3:

$$\tan\theta = \mu_i I / \kappa A_c v_b \tag{3}$$

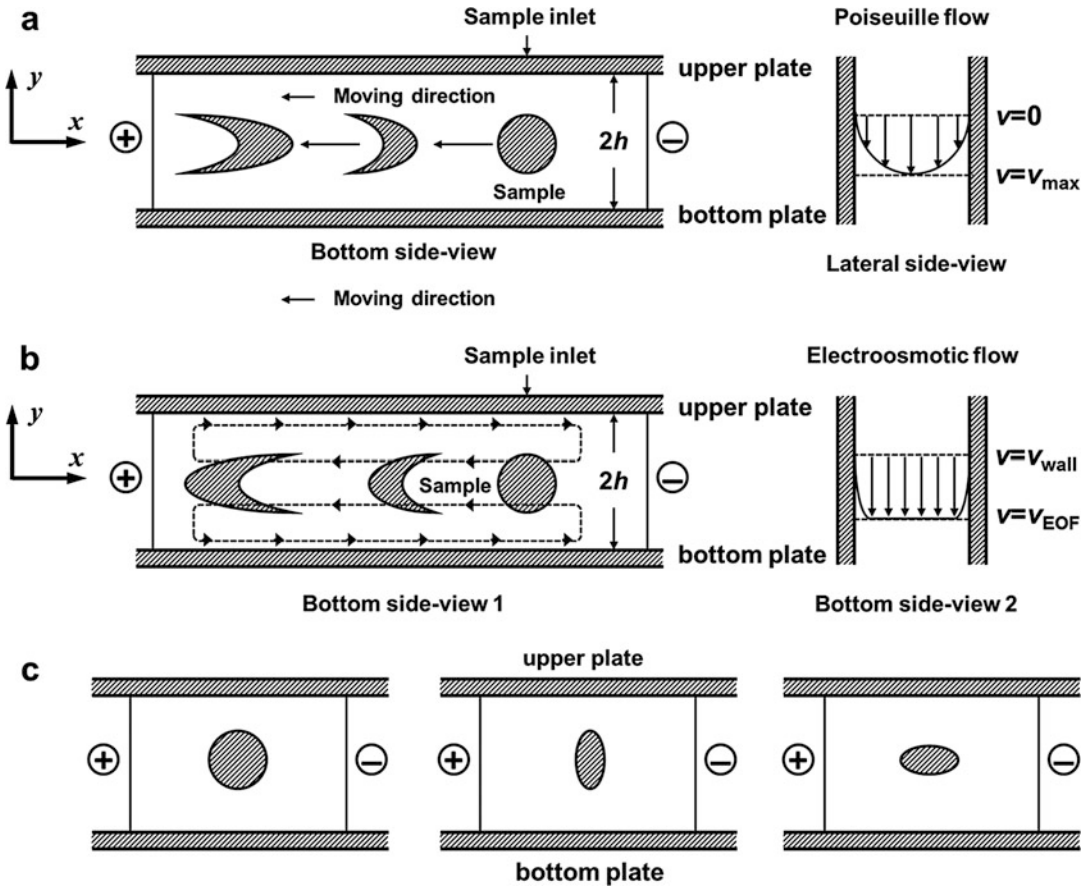
where I represents the applied electric current and κ the electrical conductivity of the buffer solution, A_c the cross-section area of the separation chamber in a μFFE device, and v_b indicates the linear velocity of the buffer solution. The electric current and the

electrical conductivity can be assumed to be constant as long as certain ionic materials are not added to the system during μFFE process. Therefore the deformation angle depends only on the electrophoretic mobility of each of cell components to be separated. It makes them move along different flow paths in the separation chamber for separation and selective collection of the components. This is the principle of μFFE-based cell purification.

Band Broadening and Resolution of μFFE System

The most important and ideal thing in cell purification is to obtain desirable target materials from a cell complex in the separation mode of high throughput and high resolution. μFFE system can separate a large amount of cell samples in real time. However the separation resolution is often limited by several physical phenomena which cause the band broadening of a sample introduced [3, 4, 7]. The broadening mechanisms can be understood by discussing those that occur in a macroscale FFE system. It includes the following things: (1) Poiseuille flow profile of a carrier buffer in two fixed parallel plates, (2) Joule heating produced by an applied electric field, (3) electroosmotic flow (EOF) near the walls of a separation chamber, and (4) the difference of electrical conductivity of a cell sample and a buffer solution.

Poiseuille Flow Profile of a Carrier Buffer



When a carrier buffer flows along a pressure gradient between two parallel plates in a FFE system, the buffer has a Poiseuille velocity profile given by Eq. 4 [5]:

$$v = -(\mathrm{d}p/\mathrm{d}x)\left(h^2/2\eta\right)\left(1 - y^2/h^2\right) \qquad (4)$$

where v represents the velocity of a carrier buffer at a distance y from the middle of the two parallel plates and η the dynamic viscosity of the buffer, $\mathrm{d}p/\mathrm{d}x$ the pressure gradient along the flow direction, and h denotes the half height between the two parallel plates. In the flow profile, the maximum velocity occurs at $y = 0$ which is the middle height of the buffer bed. At the plate surfaces ($y = \pm h$), the flow velocity is essentially zero by no-slip condition. This velocity gradient causes the ionic components in a cell sample to migrate at different velocities according to their location in the buffer. The cell components near $y = 0$ move fast toward downstream of the separation chamber, spending a short residence time in the applied electric field. The cell species around the channel walls move very slowly and accordingly, takes a long time until getting out of the electric field. The difference of the residence times results in the deformation of the sample stream in a FFE system (Fig. 3a). The sample band takes the form of a crescent while flowing downward with the buffer. The sample broadening caused by the Poiseuille velocity profile is referred as hydrodynamic distortion [3–5]. It can be minimized by reducing the diameter of the sample stream or increasing the height of the separation chamber. However those things should be addressed in the viewpoint of throughput and thermal stability of a FFE system. Reducing the sample diameter decreases the amount of a target sample collected by the FFE-based separation. Increasing the height of the separation chamber hinders the dissipation of the Joule heat produced by an applied electric field by increasing the volume of a carrier buffer occupying the chamber.

Electroosmosis (EOF)

Electroosmosis (EOF) occurring near the walls of the separation chamber also distorts the sample stream. EOF is defined as the movement of a fluid driven by an external electric field, which is relative to a stationary and charged solid surface [5]. Most substances acquire surface electric charges through electrostatic interaction when they are in contact with an electrolyte. The charged surface affects the distribution of ions in the electrolyte. While the co-ions of the surface charges are pushed from the surface, the counterions are attracted to the surface. This attraction and repulsion results in the formation of electric double layer (EDL) on the charged surface.

(**b**) Electrodynamic distortion of a sample due to electroosmosis (EOF) of a buffer near separation chamber walls. (**c**) Electrohydrodynamic distortion of a sample due to the electrical conductivity difference with a carrier buffer. Reprinted with permission from [5]. Copyright (1994) American Chemical Society

The mobile counter-ions in the EDL migrate toward the counter electrode in the application of an external electric field. Then they drag fluid elements at the same time with their movement due to low Reynolds number of a microflow. It leads to the generation of EOF with a plug-flow velocity profile. In a FFE system, the EOF induces the circulation flow of a carrier buffer. The flow distorts the streams of cell components to be separated (Fig. 3b). This phenomenon is termed electrodynamic distortion. The electrodynamic distortion can be suppressed by coating the surfaces of a separation chamber with non-ionic surfactants like polyethylene oxide [7].

Joule Heating

When an electric current passes through a buffer solution with electrical conductivity, the temperature of the buffer rises by Joule heating effect [8]. Generally the Joule heat can dissipate effectively in FFE systems where a shallow separation chamber is built [5, 7]. However, as the thickness of a buffer bed flowing in the chamber increases, the heat dissipation occurs slowly at the bed center

while it progresses quickly near the chamber walls due to the heat transfer to surrounding atmosphere. This temperature gradient results in natural convection that can distort or completely disturb the sample streams to be separated. The thermal instability of FFE-based cell purification caused by the Joule heat can be minimized by examining several points found in Eq. 5 [2]:

$$J = DAE^2\kappa t \tag{5}$$

where J represents the Joule heat and D the distance between two integrated electrodes, A the surface area of the electrodes, E the strength of an applied electric field, and t means the residence time of a carrier buffer in the separation chamber. The equation implies that the range of the applied electric field intensity can be set to reduce the Joule heat under given working conditions. The electric field strengths below the upper limit ensure thermally stabilized FFE-based cell purification. The stability is also supported by the use of a carrier buffer with low electrical conductivity because the Joule heat is produced proportional to the electrical conductivity of a buffer solution [8]. Short residence time of a buffer in the separation chamber decreases the amount of the Joule heat absorbed into the buffer. Therefore a high-buffer flow rate is advantageous to prevent the overheating of a FFE device.

Difference of Electrical Conductivity Between a Cell Sample and a Buffer Solution

The difference of electrical conductivity of a cell sample and a buffer solution also causes the deformation of sample streams (Fig. 3c) [3–5, 8]. The deformation is called electrohydrodynamic distortion. The electrical conductivity difference results in the gradient of local electric field intensity between the sample and the surrounding buffer. It produces a non-zero net electrical force on the interface of the two. When the sample is less conductive than the buffer, the local electric field strength in the sample is stronger than it in the buffer and accordingly, the net electrical force compresses the stream horizontally. On the contrary, when the sample is more conductive than the buffer, it lengthens the diameter of the sample stream along the width of a separation chamber. The electrohydrodynamic distortion can be eliminated by choosing a carrier buffer with similar electrical conductivity with a sample.

In addition to the above four distortions, the injection width and the diffusion of a cell sample also causes sample broadening. The total deformation of a sample band in a FFE system produced by these factors is mathematically described by the sum of variations of all the broadening sources (Eq. 6) [3, 4, 7]:

$$\sigma_T^2 = \sigma_{INJ}^2 + \sigma_D^2 + \sigma_{HD}^2 + \sigma_{ED}^2 + \sigma_{JH}^2 + \sigma_{EHD}^2 \tag{6}$$

σ_{INJ}^2, σ_D^2, σ_{HD}^2, σ_{ED}^2, σ_{JH}^2, and σ_{EHD}^2 represents the variations related to the injection width, diffusion, hydrodynamic broadening, electrodynamic broadening, Joule heating, and electrohydrodynamic broadening of a cell sample, respectively. However all of these factors need not to be considered for the prediction of sample broadening in a μFFE system. As mentioned previously, some can be eliminated or minimized by coating the separation chamber surfaces with non-ionic surfactants, increasing the buffer flow rate, or choosing the buffer solution with similar electrical conductivity with a sample. Consequently, Eq. 6 is simplified to Eq. 7:

$$\sigma_T^2 = \sigma_{INJ}^2 + \sigma_D^2 + \sigma_{HD}^2 \tag{7}$$

Equation 7 is re-expressed to Eq. 8 by taking the mathematical definitions of each variation into the equation [3, 4, 7]:

$$\sigma_T^2 = \frac{w^2}{12} + \frac{2DL}{v} + \frac{h^2 d^2 v}{105DL} \tag{8}$$

where w is the injection width of the cell sample at an inlet and D the diffusion coefficient, L the length of the separation chamber, v the linear

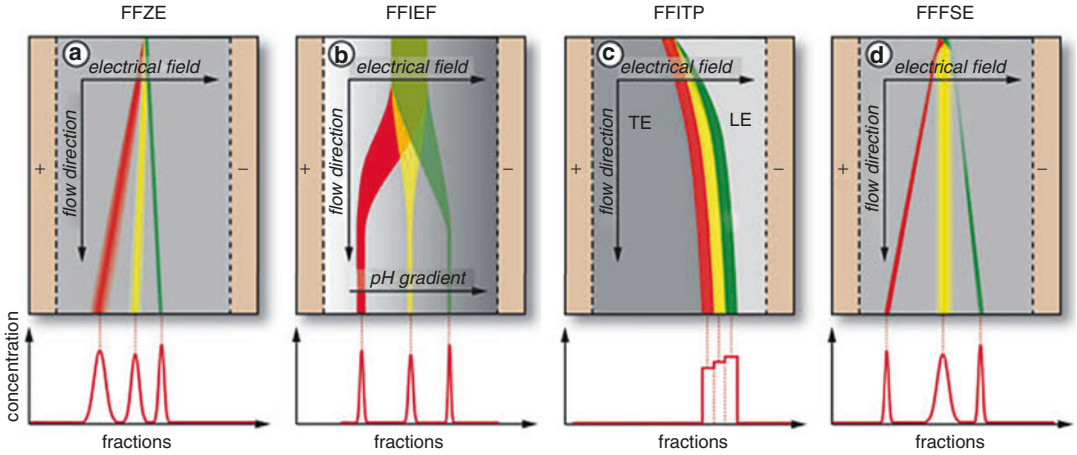
velocity of the carrier buffer, and h represents the height of the separation chamber. Fonslow et al. suggested the following equation for the separation resolution (R_s) in μFFE through several theoretical findings observed from Eq. 8 and their experimental demonstration [7]:

$$R_s = \frac{(d_1 - d_2)}{(w_1 + w_2)/2} = \frac{(\mu_{total,1} - \mu_{total,2})\mathrm{Et}}{2\left(\sqrt{w_{inj}^2/12 + 2D_1L/v + h^2d_1^2v/105D_1L} + \sqrt{w_{inj}^2/12 + 2D_2L/v + h^2d_2^2v/105D_2L}\right)} \quad (9)$$

For the case that the flow velocity of a carrier buffer is low, the separation resolution is determined by diffusion as in Eq. 10. When the diffusion dominates, the resolution increases with the applied electric field strength and decreases with the square root of the buffer velocity:

$$R_s = \Delta\mu E\sqrt{\frac{L}{32Dv}} \quad (10)$$

For high-buffer velocities, hydrodynamic broadening governs the separation resolution (Eq. 11). The resolution is inversely proportional to the height of the separation chamber and the square root of the buffer velocity:



$$R_s = \frac{\Delta\mu}{4h\mu}\sqrt{\frac{105L}{v}} \quad (11)$$

μFFE Modes and their Applications

μFFE has been extensively applied in various fields because of the enormous advantages like high-throughput collection of wanted cell components and online real-time monitoring of separation processes. The applications were made mostly in four operation modes [6, 7, 9–20]: micro free-flow zone electrophoresis (μFFZE), micro free-flow isoelectric focusing (μFFIEF), micro free-flow isotachophoresis (μFFITP), and micro free-flow field-step electrophoresis (μFFFSE).

μFFZE

μFFZE is a method that separates and purifies cell samples in the uniform pH and electrical conductivity distribution of a carrier buffer in a separation chamber (Fig. 4a) [11, 12, 14, 15, 18, 20]. The separation is performed based on the difference of ionic mobilities of the sample components. μFFZE has been often utilized for selective isolation of various biomolecules. Raymond et al. separated lysine, glutamine, and glutamic acid using their microfabricated silicon device for μFFZE (Fig. 5a) [18]. The separation was achieved in 73 s by the applied electric potential of 50 V (I = 7.5 mA). Also they showed experimentally that the μFFZE separation resolution can be improved by varying electrical conductivity of the buffer solution flowing in a side bed in the device. Sodium sulfate Na_2SO_4 was used for the control of the buffer electrical conductivity. The capability of μFFZE was also applied to separate large biomolecules like bradykinin, ribonuclease A, and FITC-labeled human serum albumin in their another study. They sorted the molecules successively within 62 s by increasing applied electric field strength from 25 to 100 V/cm. The peak capacity obtained from the separation was about 8 bands/cm, and it is similar to the peak capacity of commercial FFE systems. Fonslow et al. attempted the separation of fluorescein, rhodamine 110, and rhodamine 123 using an anodic-bonded glass microchip where a μFFE module is integrated (Fig. 5b) [12]. The fluorescent dyes were selectively isolated in 9.6 s by the electric field of 259 V/cm. The separation resolution increased along the strength of the applied electric field. However, electrolysis resulting from a high electric current hindered the continuous performance of the separation. To resolve this

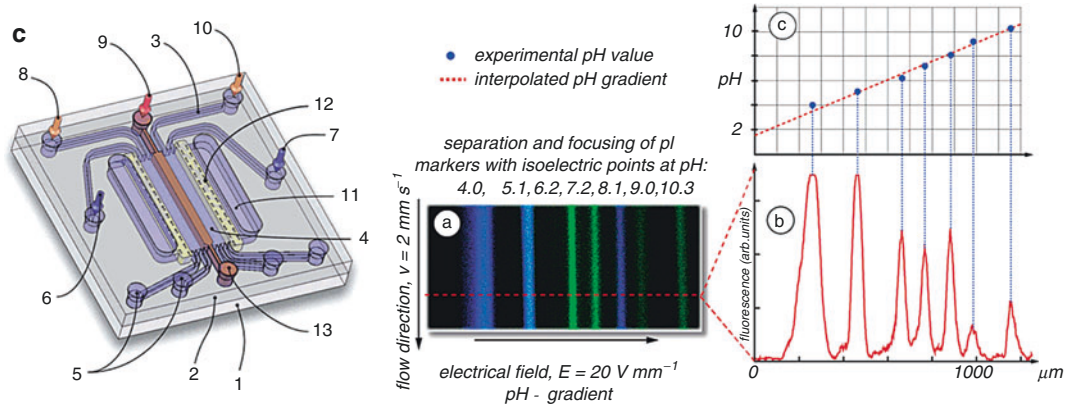
problem, they varied the depth of channels in the chip [11]. While the separation channel has 20 μm in depth, the electrode channel (i.e., side channel) has 78 μm in depth. Using these multiple-depth channels, they could eliminate the electrolysis effectively and consequently perform more stable separation compared to their previous device. Kobayasi et al. separated a mixture of horse heart cytochrome c and sperm myoglobin using the μFFZE mode [14]. The purity of the two proteins separated by 2 kV electric potential within 10 s was estimated in a HPLC system connected with the μFFZE device through a micromodule fraction separator (MFS). Zhang et al. developed a hybrid PDMS/glass-based high-speed μFFZE system where 31104 posts are built in the separation chamber (Fig. 5c) [20]. They isolated fluorescein and rhodamine 110, respectively, using the device. The isolation was completed in about 0.1 s under the electric field strength of 1.75 kV (I = 140 μA). The μFFZE system also was used to separate FITC-labeled amino acids, i.e., Arg-FITC and Gly-FITC. The electric potential of 3.5 kV was applied for the separation. Kohlheyer et al. separated a mixture of fluorescein and rhodamine B in a μFFZE glass chip with an ion-permeable membrane (Fig. 5d) [15]. Each of the separated fluorescent dye streams was continuously collected at the chip outlets by applying 180 V electric potential (I = 50 μA).

μFFIEF



μFFIEF takes advantage of a pH gradient in a carrier buffer for separation and focusing of a cell sample (Fig. 4b) [9, 10, 15–17, 19]. This pH gradient is obtained by adding a mixture of ampholytes to the buffer. The addictive produces a linear pH gradient between an anode and a cathode in an applied electric field. The gradient direction is perpendicular to the buffer flow. In the pH gradient, sample components to be separated migrate by an applied electric field till reaching the buffer region with the same pH with their own pI (isoelectric point). At the arrival points, the components are focused stopping the lateral movement. The broadening of the focused sample streams is constant because they are in an electrochemically stabilized equilibrium state after the separation and focusing. Even though some of the sample components get out of their streams, they immediately return to their initial locations acquiring electric charges again. Therefore, the band broadenings associated with an injection width and diffusion of a cell sample need not to be considered in a μFFIEF system. Xu et al. first introduced μFFIEF-based cell purification by applying the mode to the focusing of

[Asn1, Val5]-angiotensin II peptide labeled with 5-CR 6G (Fig. 6a) [19]. They concentrated the peptide sample 400 times through the application of 135 V/cm electric field strength and 10 μL/min flow rate. The concentration was achieved within 430 ms much faster than conventional FFIEF systems. Also they successfully separated and focused a mixture of angiotensin I and [Asn1, Val5]-angiotensin II under the same experimental conditions. Lu et al. attempted the continuous separation of subcellular organelles using μFFIEF (Fig. 6b) [17]. They focused and concentrated mitochondrial fraction purified from lysate of HT-29 cell in their IEF device consisting of electroplated electrodes and microchannels. It was completed in about 6 min by the low electric potential of 2 V. Analogous experiments were performed for not only the selective isolation and focusing of mitochondria from whole cells and nuclei but also the separation of two different mitochondrial subpopulations. Their studies were very successful in the aspect of minimizing Joule heating effect and electrolysis because low electric potential was used. However it took a long time to obtain a stable focusing of the samples. Kohlheyer et al. focused four IEF markers with pIs between pH 4 and 9 by means of the same FFE device which they had used in their previous study (μFFE glass chip with an ion-permeable membrane) [15]. The markers with their pIs at pH 4.5, 5.5, 7.6, and 8.7, respectively, were separated successively by increasing the applied electric potential from 0 to 20 V. The separation was achieved in about 3 s in the carrier ampholytes with a 500 μm width pH gradient (pH 3 ~ 10). In their another study, Kohlheyer et al. attempted to improve the separation efficiency of the μFFIEF system through the use of multiple sheath flows and pretreated ampholytes (Fig. 6c) [16]. As a result, the rapid linear pH gradient of the ampholytes buffer from pH 2.5 to 11.5 could be produced between 1.2 mm and 2 mm of the separation chamber width. In the gradient, seven IEF markers were successfully separated and focused within 2.5 s through the application of 20 V/mm electric field strength. The experiment demonstrated that their improved μFFIEF device can separate analytes with a minimum pI difference

of 0.4. However further theoretical investigation showed that the resolution can be lowered to 0.23. The value corresponds to the peak capacity of 29 peaks within 1.8 mm width. This is eight times larger than the peak capacities other researchers obtained. Albrecht and Jensen developed a μFFIEF device with a miniaturized thermoelectric cooler and porous conductive gel bridges in a focusing chamber [10]. The gel structures built by functionalized polyacrylamide not only allow ion exchange between the focusing chamber and the electrode buffer but also prevent gaseous bubbles produced by electrolysis from interrupting μFFIEF-based separation and focusing process. The thermal cooling system mitigates the Joule heating effect in the focusing chamber. The μFFIEF device was used to separate and focus a mixture of low molecular weighted pI markers and protein G-mouse IgG. Based on the results obtained from the experiment, Albrecht et al. developed a cascaded μFFIEF system with improved focusing speed and separation resolution [9]. The device performs the separation of analytes in two stages. The analytes are first processed by the steep pH gradient with low separation resolution in the first focusing chamber. The primarily separated components are processed once again by the shallow pH gradient enabling high-resolution separation in the second focusing chamber.

This device was used to separate and focus native model proteins, denatured proteins, and protein complexes.

μFFITP

μFFITP utilizes three buffer regions with distinct ion mobility difference for separation of analytes: leading buffer zone, terminating buffer zone, and sample zone (Fig. 4c) [3–6, 13]. While the leading zone is filled with electrolyte with higher ion mobility than analytes, the terminating buffer zone is composed of lower ion mobility electrolyte. When a sample is introduced between the two regions and an external electric field is applied to the μFFITP system, the streams of ionic components in the sample are aligned adjacent to each other along their ion mobilities and collected individually at the downstream outlets by a continuous flow of the buffers. Janasek et al. first applied μFFITP for separation of a sample mixture consisting of fluorescein, eosin G, and acetylsalicylic acid (Fig. 7a) [6]. The components were separated and concentrated within 1 min under the application of 210 V/cm electric field strength. Additionally they demonstrated the potential of μFFITP for online sample preparation through isotachophoretic separation of myoglobin and fluorescein isothiocyanate. However their device had several problems like electrolysis and low transfer efficiency of an applied electric potential into a separation chamber. To complement the defects, Janasek et al. integrated insulating barriers between the separation chamber and the electrode reservoirs (Fig. 7b) [13]. The improved μFFITP device focused a fluorescein sample successfully with the application of low electric field intensity of 18 V/mm.

μFFFSE

μFFFSE-based separation takes advantage of the difference of the local electric field intensities in a focusing chamber, which are determined by electrical conductivity of carrier buffers in the application of an external electric field (Fig. 4d) [3–5]. The focusing chamber is filled with a buffer with low electrical conductivity, being surrounded by a high electrical conductivity buffer. It produces a step gradient of local electric field intensity in the focusing chamber when applying an external electric field. Accordingly analytes introduced into the chamber exhibit sluggish movement, when they enter a weak local electric field region while migrating by the external electric field. This mechanism enables the concentration and focusing of a sample by μFFFSE. The application of μFFFSE is found in the review paper published by Kohlheyer et al. (Fig. 8) [3].

Conclusion

This manuscript was designed to introduce a theoretical and technical overview of μFFE and its applications. μFFE is a promising technique that can continuously separate and focus a target analyte and detect the components in real time. This capability has been steadily used for selective isolation of biomolecules such as amino acids, peptides, and proteins. From it, μFFE established its firm position as a powerful tool for high-speed and high-throughput cell purification. The development of the related theory and technology made until recently enhanced the ability and potential of μFFE further, resolving several primary problems

inherent in the technique. It will help to find abundant μFFE applications in disparate research and industrial fields as well as biotechnology fields.

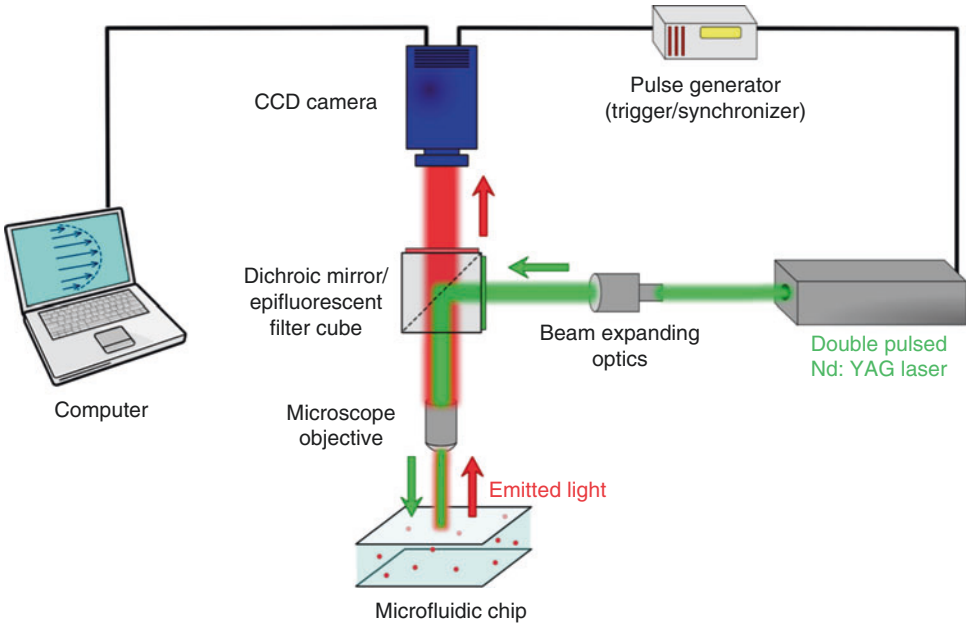
Definition

Micro/nano flow characterization techniques are methods used to measure fluid motion in a spatially resolved manner over short length scales, usually ranging from 1 mm to 10 μm. Typically the fluid motion is observed through the introduction of tracer particles, and multiple experimental images are acquired and analyzed with spatial correlation methods or particle tracking algorithms. These measurement techniques are distinguished from their macroscale counterparts by the various difficulties associated with imaging at these length scales and the methods used to overcome these difficulties.

Overview

Micro/nano flow characterization techniques are used to develop spatially resolved velocity measurements of micro- and nanofluidic devices. The need for these measurement techniques has continued to grow since the development of the first micro flow characterization technique, microparticle image velocimetry (μPIV), in 1998 [1]. Since then the number and variety of methods of manipulating micro- and nanofluidic flows has exploded. It is now common to find microfluidic devices with several different forces acting on the flow that are not typically significant at macroscales. Surface tension gradients, electrophoretic effects, and electrothermal forces are all common drivers of microfluidic flows.

As a result of the increasing complexity of micro- and nanofluidic devices and the flows within them, what started with μPIV has grown into a range of techniques capable of measuring flows of varying complexity and length scales. This entry will discuss the most prominent of these flow measurement methods covering the basics of each technique as well as their applications.



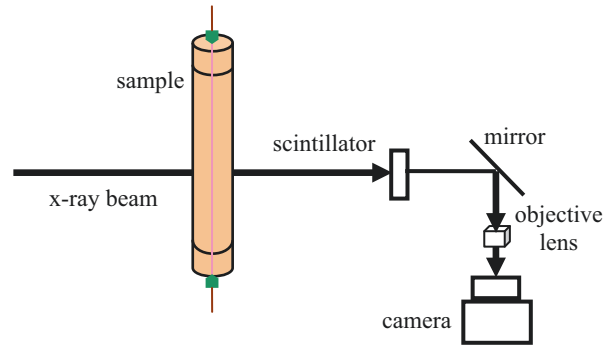
μPIV

Microparticle image velocimetry (μPIV) is the oldest of the micro/nanoscale flow characterization techniques and shares many features with its macroscale counterpart, PIV. Many thorough reviews of PIV techniques exist [2, 3], and because of the similarity between the two techniques the reader is encouraged to consider them. Here the focus will be on the unique constraints imposed on μPIV by viewing the test section through a microscope.

The first difference relates to the fact that both PIV and μPIV are two-dimensional two-coordinate measurement techniques. What this means is that the resulting velocity data is confined to single plane and each velocity vector has only in-plane components. In PIV the measurement is confined to a single plane by illuminating the sample with a laser sheet. In this way the only particles that are imaged are those in the plane of the laser. This is not practical in many micro/nanoscale applications due to the small dimensions of the fluidic channels. As a result the sample is usually volume illuminated using the microscope's built-in illumination light path. In order to restrict the field of view to as thin a measurement plane as possible, a high numerical aperture microscope objective is used [4]. The high numerical objective results in a relatively thin plane in which particles are in focus. Particles outside the focal plane of the microscope objective are defocused and contribute less to the resulting velocity field [5]. This can result in relatively large errors in the measurement if there are large velocity gradients perpendicular to the measurement plane. Choosing a microscope objective with a high numerical aperture and using small-diameter tracer particles (<1 μm) can minimize this effect.

Because the microfluidic test section is volume illuminated there is often a lot of background noise. Reflection of the illumination light off the walls of the test section can overwhelm the signal from the particles. Minimizing the background noise is typically accomplished using fluorescent tracer particles and an epifluorescence filter cube in the light path. A typical μPIV setup is shown in Fig. 1.

As in traditional PIV, a double-pulsed Nd:YAG laser is used to illuminate the sample. However, in μPIV this light is sent through an epifluorescence



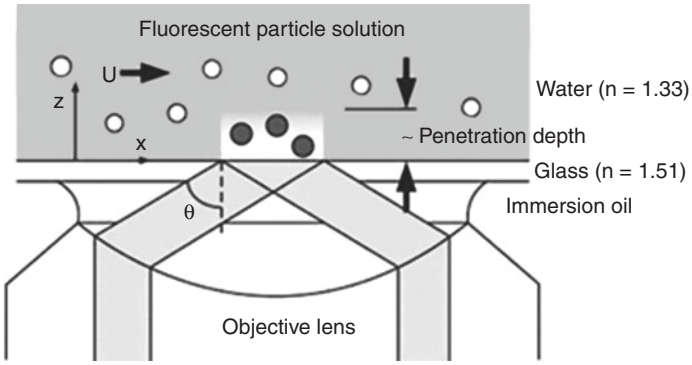
Micro/Nano Flow Characterization Techniques, Fig. 1 Schematic of conventional micro PIV system illustrating the essential components (From Williams et al. [6] with permission)

filter cube which has a dichroic mirror in it. The mirror reflects short wavelengths and passes long wavelengths. In this manner the excitation light from the laser of 532 nm is filtered from the light passing to the camera. The emitted light from the particles, usually around 630 nm, passes freely to the camera, greatly increasing the signal-to-noise ratio. Companies like Thermo Scientific, Polysciences Inc., and Sigma Aldrich offer a variety of microparticles available in a range of excitation and emission wavelengths.

As in PIV, the images in μPIV are evaluated with a conventional correlation-based algorithm. Like in PIV, a sufficient number of particle images are required in the interrogation window for reliable and accurate measurements. For practical reasons this high particle seeding can be difficult to achieve in microfluidic devices. For example, since defocused particles still contribute light to the image, increasing the number of particles in the measurement volume can have the effect of lowering the signal-to-noise ratio of the images. Additionally, both the seeding particles and the velocities being measured are small enough that the random walks of particles due to Brownian motion can contribute significantly to the uncertainty of the measurements. For both of these reasons the velocity field calculated from a single pair of images is likely to have an unacceptably high uncertainty.

This high uncertainty is easily addressed due to one of the advantages of studying microfluidic flows: The fluid mechanics can often be simplified as steady, quasisteady, or periodic due to the very low Reynolds numbers involved (usually less than one). This results in laminar Stokes flow. Due to the laminar and steady nature of many microfluidic flows, a large number of image pairs can be analyzed with a correlation technique termed ensemble averaging or correlation averaging [7]. This technique can compensate for suboptimal particle seeding and low-quality images by averaging the correlation over many image pairs, typically hundreds, thereby significantly increasing the signal-to-noise ratio. If the flow is not steady state or periodic, then the velocity analysis is restricted to only one pair of images at a time. In this instance, the measurements may contain erroneous vectors which deviate significantly in magnitude or direction from their neighbors.

Micro/Nano Flow Characterization Techniques, Fig. 2 Example application of X-ray μPIV measuring the velocities of inside flow (From Vlachos et al. [9] with pemission)



Traditional μPIV techniques have been applied successfully to a wide range of microfluidic flow field investigations. As a result of its popularity, several companies now offer turnkey μPIV systems: TSI (www.tsi.com), Dantec Dynamics (www.dantecdynamics.com), and LaVision (www.lavision.de) are some of the main suppliers of systems and related equipment. Despite its wide use, μPIV has several limitations. The first is that the calculated velocity fields are two dimensional two component, meaning that out-of-plane velocities are not measured. Second, the flow needs to be steady state or periodic such that a sufficient number of image pairs can be taken and averaged to minimize sources of measurement error. Finally, at least one surface of the system being investigated needs to be transparent in order for the tracer particles to be excited and viewed. Overcoming these limitations has been a recent area of development and will be discussed in the following sections.

X-Ray and IR μPIV

For several reasons it may be necessary to use a wavelength of light other than those in the visible spectrum. Usually this occurs when attempting to study microfluidic flows in vivo or in devices that cannot be fabricated in a clear material. For the first case it is possible to use a coherent synchrotron X-ray beam as a light source, much like medical X-rays are used to see inside the body. X-ray μPIV has been used to investigate blood flow in an opaque tube by analyzing the fringe patterns of red blood cells [8]. Even the thick hydrated collagen tissue has no effect on the quality of the phase-contact X-ray image, which can pave the way toward future experimental investigations of the vitro tissue vascular flow. A typical X-ray μPIVsketch is shown in Fig. 2 [9].

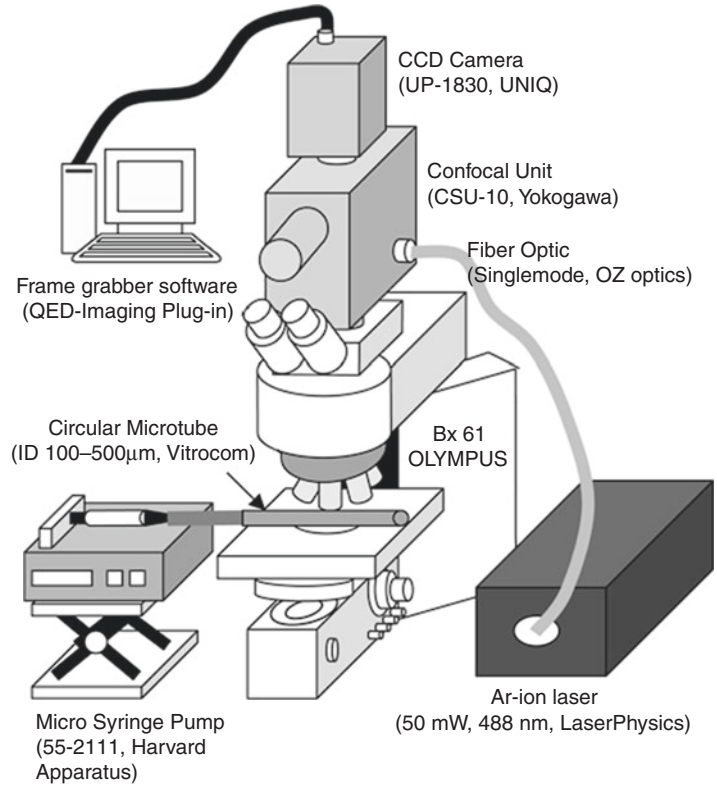
Visualizing the X-rays is achieved by passing them through a scintillating crystal and converting them to visible light capable of being imaged by a camera. One of the disadvantages of this technique is that the coherent X-rays are simply shown through the sample without focusing or conditioning. This means there is no way to restrict the measurements to a single plane; all particles in the flow are imaged with no way to determine their depth.

Moving to the other side of the visual spectrum is infrared (IR) radiation which has found use as a light source in silicon devices as a technique called infrared-μPIV (IR-μPIV). Silicon, which is transparent to infrared wavelengths, is often used in heat transfer experiments where the temperatures are too high for typical transparent microfabrication materials. Care must be taken when performing μPIV with infrared illumination. The particle size and material must be matched well to maximize scattering of light at these longer wavelengths since conventional tracers do not absorb or emit in the infrared. Additionally, silicon has a very high index of refraction ($n = 3.3$) which results in aberrations affecting the image quality. Finally, microscope objectives are designed to minimize aberrations in the visible spectrum, and so some optical aberrations are likely to be present when imaging in the infrared. For these reasons the resolution of IR-μPIV is not as good as that of conventional μPIV systems.

Micro/Nano Flow Characterization Techniques, Fig. 3 Example application of evenescent wave micro PIV demonstrating illuminating laser path and measurement region (From Jin et al. [12] with permission)

IR μPIV has been used to investigate flow around a heat sink, and the images were processed with an algorithm that was developed to improve the quality of IR recordings [10].

Evanescent Wave μPIV



For many applications it is the fluid flowing very near a wall (<1 μm) that is of interest. Since this is less than the practical spatial resolution of μPIV, it is necessary to confine the field of view to only those tracer particles immediately adjacent to the wall. This is accomplished by using evanescent waves generated by total internal reflection (TIR) [11]. Since the intensity of the evanescent wave decays exponentially away from the wall the measurement is confined to a region only 50–250 nm thick. This small penetration depth, which can be adjusted according to the incident angle, also reduces background noise from out-of-focus tracer particles [12, 13].

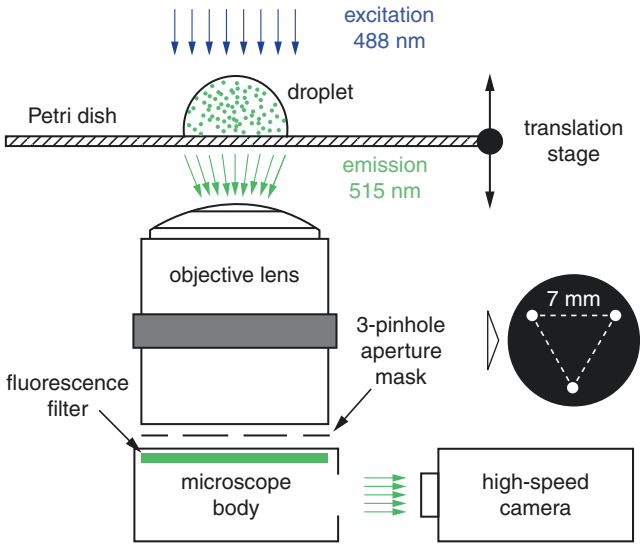
This technique has been used often to study near-wall velocity profiles [12]. Since the intensity of particles varies in a consistent way according to their distance from the wall, the height of the particles can be inferred from the brightness of the particle images. Using this technique with submicron particles, researchers were able to extract information about the apparent slip length for flow in a microchannel [14] (Fig. 3). Furthermore, this technique can also be applied to study not only fluid flows but also nanoparticle dynamics, a fundamental issue for designing novel devices in fields like nanochemistry [15].

Confocal and Scanning Confocal μPIV

Confocal μPIV takes advantage of the much thinner focal plane that is characteristic of a confocal microscope. The thinner focal plane leads to several advantages: the first is a significant reduction in light from defocused particles; the second is to minimize depth of correlation (DoC) errors inherent in flows with large velocity gradients. In practice, the DoC, which is adjusted by filter parameters, is able to recover the in-plane loss of correlation [16]. It also can be modeled by a weighting function. The DoC correction has been explicitly demonstrated for a stationary flow field in a rectangular channel [17]. Adapted a high-speed confocal scanner to μPIV applications, an illustration of which is shown in Fig. 4 [18]. Usually, a high-speed video camera is used to record data in order to adjust the DoC [19].

Despite recent advances in scanning speed, confocal μPIV is limited to steady flows as it takes a relatively long time to adequately scan the depth of the measurement volume. Although the thinner focal plane allows closer spacing of the measurement planes, and thus finer depth resolution, the technique still is only able to resolve the velocity components in the measurement plane. To get an estimate of the out-of-plane velocities, it is necessary to integrate the continuity equation over the volume of interest. If the image planes are closely spaced this technique has been shown to agree with numerical simulations to within 3 % [20]. To achieve reliable, time-resolved measurements, the robust phase correlation (RPC) method

Micro/Nano Flow Characterization Techniques, Fig. 4 Example application of high-speed scanning confocal microscopy to micro PIV (From Park et al. [18] with permission)



is used to increase the signal–noise ratio (SNR). RPC applies a PIV-optimized spectral filter to the cross-correlation planes resulting in correlation planes with sharper primary peaks and low background levels [21].

Stereo μPIV

Stereo particle image velocimetry allows one to measure all three velocity components but only in a single plane. Stereo PIV uses two viewpoints separated by an angle to infer the three-dimensional position of particles. This technique has been well developed and used successfully in macroscale PIV [22]. Stereo PIV hardware and software are also available commercially.

Applying this technique to microscale flows has proved considerably more challenging due to conflicts between the requirements for good spatial resolution and the accuracy of out-of-plane velocity components. Stereo μPIV gives reliable results in 2D2C (two dimension two components), but due to the unavoidable mismatch of focal planes, systematic errors will appear that cannot be compensated digitally [23]. In order to achieve high spatial resolution, it is necessary to have a large imaging aperture. However, a large imaging aperture imposes practical limits on the angle separating the two viewpoints. This is typically not a problem for macroscale applications as the cameras and optics can be placed sufficiently far away from the measurement plane such that the two viewpoints do not interfere. For microscale applications though there is simply not enough room to place two large aperture imaging optics, typically microscope objectives, separated by a small angle and close enough to view the same measurement plane.

Despite these drawbacks, the technique has been successfully developed, albeit with lower spatial resolution than typical μPIV. Bown et al. [24] reported a spatial resolution of $10 \times 10 \times 10\ \mu m^3$ when measuring the flow over a backward-facing step [24]. In practical

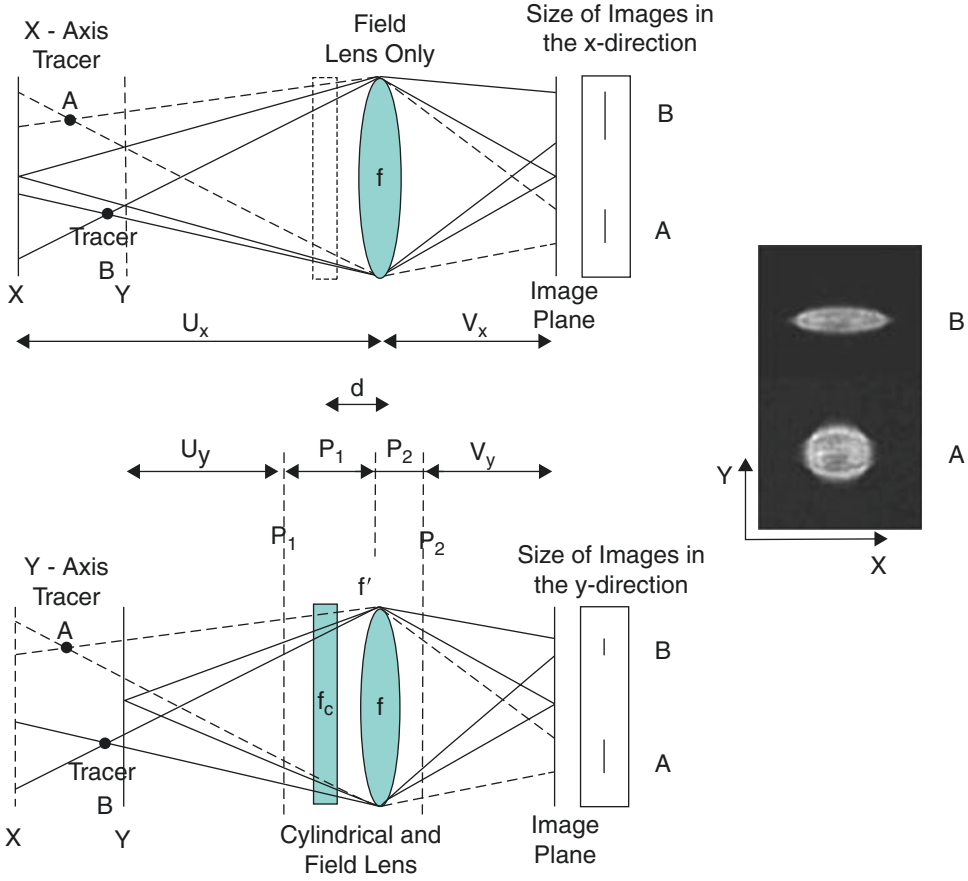
Micro/Nano Flow Characterization Techniques, Fig. 5 Schematic demonstrating a typical defocusing micro PIV setup (From Pereira et al. [29] with permission)

applications, stereo μPIV is used to investigate oscillatory flows, whose Reynolds number is 150 and 2.65 at inspiration and expiration, in the realistic human lung model [25]. Recently, this technique has also been used to investigate the tip leakage vortex and the flame propagation in a practically premixed flow [26, 27].

Particle Image Defocusing

Some of the complexity of stereo imaging optics can be avoided by employing a particle image defocusing technique. These techniques rely on a single light collection lens and camera and determine the three-dimensional location of the particle using the degree of defocusing of the particle image. Once the location of the particles is determined for two images, a particle tracking velocimetry (PTV) algorithm can be used to determine the velocity components. Furthermore, interference-PTV, which determines the depth of particle, is suited to situations with nonuniform illumination. It can be applied to any optical imaging system where a light source with high contrast must be located in three dimensions [28]. Since the positions of the particles are known in three dimensions, the resulting velocity vectors are also known for all three dimensions throughout the measurement volume. This is in contrast to the previously mentioned techniques for which many two-dimensional measurement slices have to be acquired in order to build up a measurement volume. One drawback though is that these techniques typically require a much lower particle seeding concentration so that the particle images do not interfere with each other. As a result, many image pairs must be acquired and combined in order to increase the spatial resolution to an acceptable level.

The first of these techniques to be applied to microscale flows was defocusing digital particle image velocimetry (DDPIV). The arrangement is shown in Fig. 5 [29]. DDPIV is employed to visualize the resist filling process, which helps to understand the resist filling behavior and mechanism [30].



This transforms the particle image into a set of dots, the relative spacing of which can be used to determine the depth of the particle. Yoon and Kim [31] applied this technique to a backward-facing step and by averaging over 2,000 image pairs were able to achieve an average spatial resolution of 5 μm in plane and 1 μm out of plane [31].

A similar technique does away with the mask and instead uses the ring structure from the diffracted defocused image of a particle. An example of this effect is shown in Fig. 6.

The diameter of the outermost ring of the diffraction pattern can be related to the depth of

Micro/Nano Flow Characterization Techniques, Fig. 6 Images of a fluorescent bead scanned at 10 μm intervals along the optical axis with a 20× objective (From Wu et al. [32] with permission)

Micro/Nano Flow Characterization Techniques, Fig. 7 Schematic of astigmatism micro PIV demonstrating the arrangement of optical elements and the resulting ellipsoidal particle image (From Chen et al. [34] with permission)

the particle through a calibration curve obtained prior to the experiment. Once this is done the three-dimensional position of the particle can be extracted and a particle tracking algorithm used to determine the velocity components [32].

This technique has the obvious advantage of requiring only common μPIV equipment. However, in order to get good particle images it is necessary to use larger particles (>2 μm) and high magnifications. This technique also requires images with a good signal-to-noise ratio in order to determine the radius of the outermost ring of the particle image which is often quite faint. Recent research has shown that the defocusing-based 3D particle tracking method by automatic calibration can be used to track particles less than 2 μm in diameter [33].

Rounding out this class of measurement techniques is astigmatism microparticle tracking velocimetry (A-μPTV). This technique also relates the diameter of a defocused particle to its depth but adds an asymmetry to the optical path. This asymmetry causes the perimeter of the defocused particle image to form an ellipse for which the aspect ratio is a function of particle depth. In A-μPTV this asymmetry takes the form of a cylindrical lens placed between the camera and the microscope as shown in Fig. 7 [34, 35].

This technique has recently been used to measure a three-dimensional micro vortex with an estimated resolution of 3 μm. This technique has proved more robust with respect to noise and image quality as the light from the particles is typically spread out over a smaller area as compared to the other defocusing techniques [35].

To date, mPIV has been applied to an ever growing list of practical microfluidics problems. Micro-PIV has been used to investigate a wide range of fluid properties beyond simple velocity, such as micro-volume viscosity [36], fluid mixing [37], and viscoelastic microfluidic hydrogels [38]. In the future μPIV will be used in many more fields.

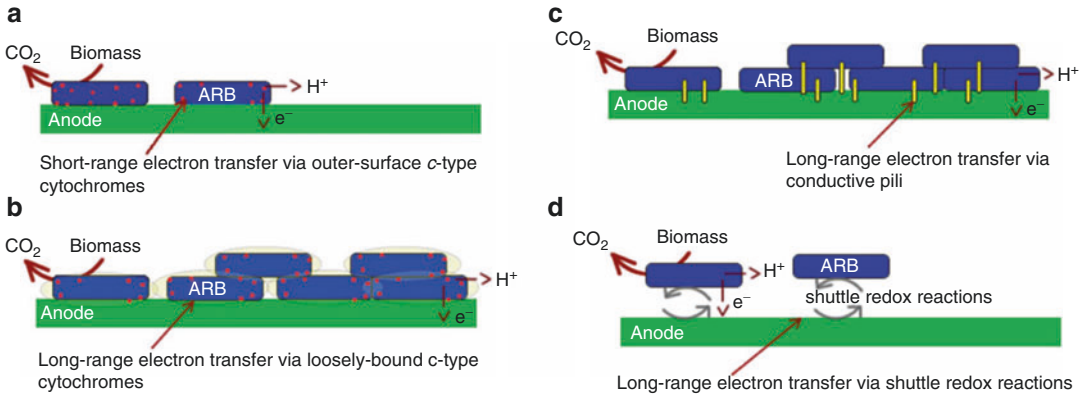
Definition

Prokaryotic cells under some conditions are capable of extracellular transport of electrons generated during their metabolic processes. When these cells donate electrons to a conductive surface (e.g., an electrode), they cause electron flow, which can be used for harvesting energy from organic substrates. Disparate multi-scale transport processes relevant to the energy generation scenario are elucidated in this entry.



Overview

Microbes are micro organisms which survive by utilizing energy from environmental nutrients (organic substrates) through the process of respiration. These organic substrates are essentially electron donors, which carry electrons at high energy levels that are ultimately transferred to a biomolecule (called the electron acceptor) through a set of complex biochemical reactions involving the electron transport chain (ETC) [1]. Microbial energy-harvesting techniques successfully capture the electrons at various stages of the ETC and deliver these electrons to an electrode, where they can flow through an external circuit thus performing electrochemical work. Needless to say, not all microbes are capable of successful extracellular electron transport. This energy transport from the substrate to the electrode involves complex multi-scale phenomena, which include, but are not limited to, mass transport of charged species through diffusion and convection, chemical transfer through mediator species, direct conduction through bacterial nanowires, microscale aggregation of bacteria into complex continua, and nucleation of heterogeneities through mutations.

A typical design of a microbial energy harvesting device is depicted in Fig. 1. It consists of an anaerobic anode chamber and a cathode chamber which are open to air and separated from each other by an ion exchange membrane. In the anode chamber, living microbial cells harvest high-energy electrons from an electron-rich substrate generating H^+ (proton) and CO_2 in the process. At the end of energy extraction, the now low-energy electrons combine with an ambient

Micro/Nano Transport in Microbial Energy Harvesting, Fig. 1 A schematic of a typical microbial energy-harvesting device

Micro/Nano Transport in Microbial Energy Harvesting, Fig. 2 Electron transfer from a microbe in the biofilm to the anode surface can occur via various mechanisms. (**a**–**c**) Schematics of conductive transport of electron; (**d**) advection-based transport through a biochemical mediator

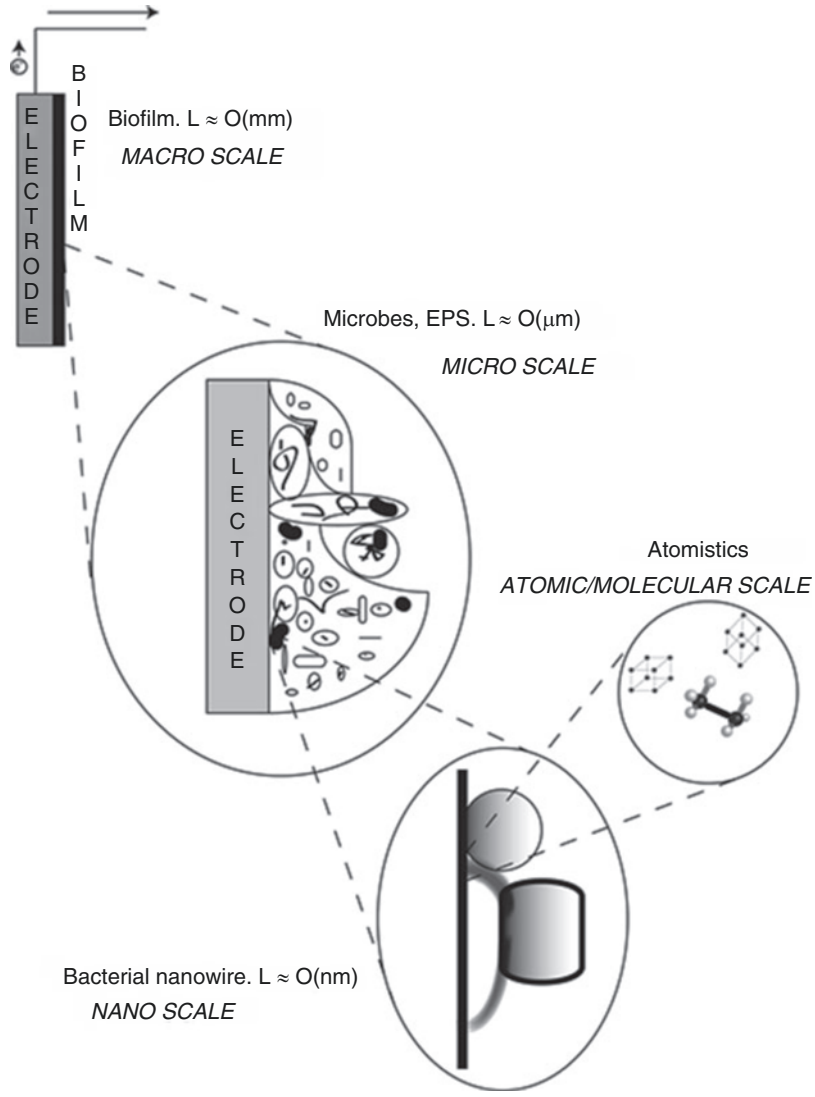
electron acceptor and are removed from the cell. In an aerobic respiration process, dissolved oxygen acts as the ultimate electron acceptor whereas in a usual microbial energy-harvesting device, the conducting electrode placed in the anaerobic anodic chamber acts as the ultimate electron acceptor. This entire process proceeds via a set of extremely complex chemical reactions as part of the ETC and occurs inside the mitochondria of a cell isolated from the external environment [2]. These transferred electrons can flow through an external circuit to the cathode chamber, where the H^+ is reduced to H_2O in the presence of oxygen. A device, which is capable of executing this energy-harvesting process, is schematically shown in Fig. 1. It can be noted that the design is very similar to a fuel cell and hence such a device is also known as a microbial energy-harvesting (MEH) device. The most important transport process involved in a device like the one shown in Fig. 1 is the transport of electrons to the anode surface.

Typically, microbes associate with an external electrode through a phase of aggregative living called a biofilm inside which the electron transfer takes place. The exact mechanism of this extracellular electron transport is still an active area of research [3] although two broad mechanisms exist – mediator-based and conduction-based electron transport. In the mediator-based mechanism, an intrinsically produced (or externally added) chemical called the mediator capable of freely moving into and out of the mitochondrial structure acts as an electron acceptor. It gets reduced by the electrons inside the mitochondria, diffuses out of the cell, and is finally oxidized by the electron-accepting electrode. Hence, at the end of the electron donation to the electrode, the mediator is once again free for further electron transport and the process continues. On the other hand, in the conduction-based mechanism, electrons are directly deposited onto the electrodes through extracellular electron transport like conducting pilli or other mechanisms [4, 5] obviating the need for mediators. However, at any given time it is highly likely that a combination of mechanisms described above is present. A schematic picture explaining the various mechanisms is shown in Fig. 2.

It is clear from the above discussion that efficiency of the microbial energy transport will depend critically on a number of complex biological, chemical, and physical factors, namely, species of microbes used, mechanism of electron transfer onto the electrode surface, ambient physical and chemical environment of the electrode chamber, as well as the materials used for electrodes. Each of the above-mentioned factors intimately affects the others creating coupled multiphysics operating conditions. For instance,

although the biological species being used in the electrode chamber can affect the electron transfer mechanism and thereby the chemical environment of the microbe colony, the chemical environment itself can affect the dynamics of metabolism and growth of the microbe colony. This also means that research carried out in a number of areas is relevant to understanding the science of microbial energy transport. It is appropriate therefore to classify the rapidly growing and variegated literature of microbial energy transport into the following broad areas of research:

- Microbiology and biochemistry research
- Device design
- Transport studies



In this entry, the transport modeling aspect of microbial fuel cell energy conversion would be dealt with. The next sections describe the methodology of modeling, key findings, and future directions for research.

Method

The overall principle of operation of an MEH device was described in the previous section. It is evident that modeling microbial-level energy transfer critically depends on our ability to understand and quantify the complexities described above.

As noted in the previous section, only some microbes can participate in extracellular energy transport. Two such microbes, which have been extensively investigated, are *Geobacter sulfurreducens* and *Shewanella oneidensis*. As depicted in Fig. 1, the appropriate microbe grows in the anode chamber over the anode surface. The microbes organize themselves in an elaborate thin structure bonded to the anode where they are embedded within a self-produced matrix of extracellular polymeric substance (EPS) [6]. EPS is generally composed of extracellular DNA, proteins, and polysaccharides. The colony thus formed grows because of continuous diffusion of the nutritious substrate. This diffusion of nutritious substrate is afforded by a constant flux of biomass into the anode chamber. This substrate is utilized by the microbes for respiration under a favorable biochemical environment, producing electrons which are then transferred to the electrode (Fig. 2) [7], with the simultaneous production of H^+ ions. The H^+ ions then migrate via a proton-exchange membrane to the cathode chamber (Fig. 1). Finally, in the cathode chamber, the H^+ ions are reduced by the electrons thus completing the cycle.

A complete modeling effort for an MEH device would naturally include multi-scale transport aspects. Figures 1, 2, and 3 capture various aspects of the multi-scale charge and mass transport processes. The overall MEH device and, consequently, the fluxes and transport of the bulk fluid are macroscale. Thus, the transport of H^+ ions from the anode to cathode is seemingly macroscale in nature. However, the H^+ ions themselves need to diffuse out of the biofilm which has a typical thickness of the order of hundreds of microns. Thus modeling of transport in the biofilm has to take into account this much smaller length scale that starts at the biofilm boundary. Looking more closely at the biofilm itself, one finds that the microbes, which reside in the biofilm, are of micron to submicron resolution. On the other hand, charge transport from individual microbes to the electrode surface may encompass an even smaller length scale defined by pilli and certain protein complexes (Fig. 2). Their characteristic lengths often lie in the nanometer scale. The complete illustration of the hierarchical length scales present in the system is shown in Fig. 3. It is usual for a model to deal with variables defined on a higher spatial scale which itself approximates (or homogenizes) information from a lower scale assuming fluctuations to be averaged out. For instance, nanoscale energy transfer through pilli (bacterial nanowires) can be taken into account through a micro-level conductivity variable rather than through molecular-level simulations. The choice of scale of model depends on the available computing power as well as resolution necessary to observe critical control variables. In addition to the spatial multi-scale described above, disparity on temporal scale also

Micro/Nano Transport in Microbial Energy Harvesting, Fig. 3 Multi-scale energy transport in a microbial fuel cell

exists during a typical MEH device operation. For instance, the diffusion and convection take place at much smaller timescale than the growth of biofilm which itself grows at a much smaller timescale than the entire operating life cycle of an MEH. In addition, the chemical kinetics of the rate-determining steps of various reactions also provide another timescale. Therefore it is important to note that steady state assumption of one model may be a transient for another. This interplay between the multiple length and timescales makes the operating dynamics of an MEH device both complex as well as rich.

Electrochemistry

In contrast to fuel cells, the voltage generation of an MEH device is intimately tied to the biological properties of the microbes in addition to the chemistry of the fuel (substrates). The microbes take time to colonize the electrode by synthesizing enzymes and biological structures necessary to transfer electrons outside their cellular structure. This possibility of electron transfer causes a voltage or an electro motive force (EMF) to appear at the electrode capable of charge transport through current flow if connected to an external circuit.

In this way one can estimate the net voltage of a cell made of two such electrodes (half cells) as follows:

$$E_{emf} = E_{Cathode} - E_{Anode} \tag{1}$$

where $E_{Cathode}$ is the cathode EMF and EA_{node} is the anode EMF.

In mixed cultures, different bacteria can grow, setting different potentials. Unfortunately, predicting these potentials even for pure cultures is impossible. However, limits to the maximum voltage generation can be calculated using thermodynamic properties of the electron donors (substrates) and acceptors (oxidizers). The maximum equilibrium electromotive force that can be generated for a given chemical reaction is governed by the laws of thermodynamics and depends on the concentration of the species involved, nature of the reaction and the ambient temperature. This equation known as the Nernst equation in electrochemistry is mathematically expressed for both electrodes (cathode and anode) as:

$$\begin{aligned} E_{Cathode} &= E^0_{Cathode} - \frac{RT}{nF}\ln(\Pi_{Cathode}), \\ E_{Anode} &= E^0_{Anode} - \frac{RT}{nF}\ln(\Pi_{Anode}), \end{aligned} \tag{2}$$

where $E_i(i = Cathode,\ Anode)$ is the maximum electromotive force (EMF) of the half cell, $E^0_i(i = Cathode, Anode)$ is the standard half cell potential standardized against a standard electrode such as the normal hydrogen electrode (NHE) [8], T is the ambient temperature, n is the number of electrons transferred in the reaction, $R = 8.314$ J mol^{-1} K^{-1} is the universal gas constant, and $F = 96{,}485$ C mol^{-1} is the Faraday's constant. The reaction quotient $\Pi i(i = Cathode,\ Anode)$ is defined as:

$$\Pi_i = \frac{[products]^P}{[reactants]^r}, \qquad (i = Cathode, Anode) \tag{3}$$

Substrates oxidized through a set of complex biochemical reactions by the microbes in the anode chamber produce a number of different electron carriers. It is these electron carriers that become the immediate electron donors during the ETC from which electrons are tapped out of the cell. For instance, if the substrate is oxidized using a citric acid cycle, an electron carrier compound called NADH becomes the immediate electron donor. In the absence of oxygen in the anode chamber, NADH donates its electrons to the anode and is oxidized into NAD^+. The electron-deficient NAD^+ is then free to accept electrons from the substrate and continue the process. This electron donation process can be represented by the following chemical reaction:

$$NAD^+ + 2H^+ + 2e^- \rightarrow NADH \tag{4}$$

Using the Nernst equation described above, a theoretical limit of the potential difference produced by this reaction can be obtained as follows:

$$E_{emf} = E^0 - \frac{RT}{2F}\ln\left(\frac{[NADH]}{[NAD^+][H^+]^2}\right) \tag{5}$$

Several conclusions can be drawn almost immediately from the above equation if it is rewritten as:

$$E_{emf} = E^0 - \frac{RT}{2F}\ln(\gamma) - \frac{2.303RT}{F}pH \tag{6}$$

where the ratio of [NADH] and $[NAD]^+$ is denoted by γ and $pH = -\log[H^+]$. Equation 6 clearly indicates that the voltage generated depends on the relative intracellular chemical pool of NADH/NAD^+ as well as the acidity of the ambient quantified by the pH. Since production of the NADH/NAD^+ couple is tied to the citric acid cycle, the microbial energy production is now physically linked to the chemistry of microbial respiration. It must be noted that NADH is not the only critical electron donor species generated. The respiration process is composed of many different steps, which can produce many such electron carrier chemical species.

The electrode potentials (EMFs) can also be used to predict the direction of a chemical reaction

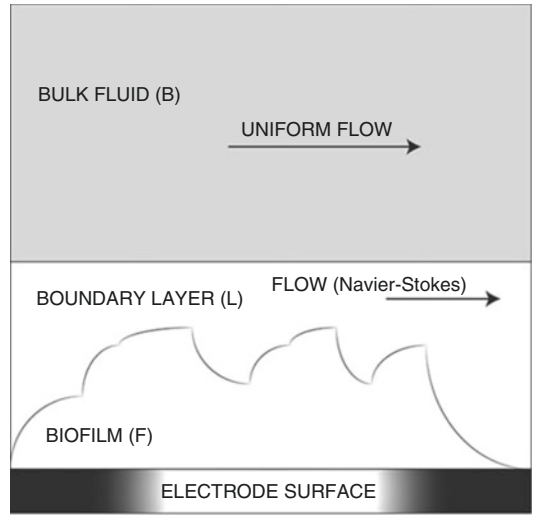
through their relationship with the Gibb's free energy. Thermodynamically, the electrode potential can be related to the Gibb's free energy (ΔG) as follows:

$$E^0 = -\frac{\Delta G}{nF} \tag{7}$$

Since the sign of free energy change indicates the direction of change of a system, it is evident that comparison of the EMF of half reactions enables the prediction of the direction of various chemical pathways depending on the sign of the net free energy change. Thus electrochemistry yields a powerful tool in investigating the intermediate complexities like interspecies electron transfer and the role of communities versus enzymes in setting anode potentials for certain strains of microbes [8]. This is still an active area of research with important implications in the production of bioenergy.

Charge Transport

In the previous section, the electrochemical analysis of the microbial energy transport was presented which yielded the theoretical open circuit potential (EMF) of a cell. As soon as the cell is connected to an external circuit, current flows due to the motion of electrons and power is obtained according to the following equation:



$$P = IE_{emf} \tag{8}$$

where P is the power, I is the current (often analyzed in terms of the current density j), and E_{emf} is the EMF of the cell. Flow of electrons (current flow) is related to the mechanism of charge transport as well as rate of production of electron carrier species like NADH. The production of such electron carrier species depends on the respiration process which itself depends on the diffusion of the substrates. The substrates act as the ultimate electron donors (EDs) for the entire process.

In the conduction-based mechanism, microbial nanowires play a significant role in the electron transport and hence their electrical properties are critical to charge transport processes [9]. The charge transport will be, in general, dependent on biofilm geometry, its electrical properties, as well as the electric field. Although conductivity can be treated as a biofilm material property, the geometry and potential difference depend both on the nature of electron-producing chemical reactions as well as the growth dynamics of the biofilm itself.

The amount of charge produced at any point in the biofilm depends on the concentration of the chemical species taking part in the electron-producing (and consuming) reactions. The concentration of chemical species in the biofilm is in turn governed by their mass transport dynamics. The concentration gradient of these species causes charge flow and a corresponding current determined by the electrical properties of the biofilm. The computational domain of the biofilm with boundaries is schematically shown in Fig. 4.

Mathematically, the concentration of a chemical species under an applied electric field can be expressed by the following Nernst-Planck equation [10]:

Micro/Nano Transport in Microbial Energy Harvesting, Fig. 4 Key aspects of anodic biofilm computational domain

$$\frac{\partial S_i}{\partial t} = \nabla \cdot \left(D_i \nabla S_i - \mathbf{u} S_i + \frac{D_i z_i e}{k_B T} S_i \nabla \Phi \right) + r_i \tag{9}$$

where the subscript i denotes the cardinal number of the species, S is the concentration of the dissolved substrate, D is the diffusivity, z is valence of the ionic species, $e = 1.602 \times 10^{-19}$ C is the elementary charge, $k_B = 1.38 \times 10^{-23}$ J K^{-1} is the Boltzmann constant, T is the temperature, $\mathbf{u}$ is the fluid velocity vector inside the biofilm, Φ is the potential difference corresponding to the electric field, and r_i is the species utilization rate which models the transformation processes. If the chemical species are individually electro-neutral and fluidic velocity is negligible, Eq. 9 reduces to the standard diffusion–reaction equation.

The physical interpretation of the quantity r_i is similar to the rate of a rate-limiting reaction and can have various empirical forms. If, for instance, first-order kinetics is followed, one can write:

$$r_i = k_i S_i \tag{10}$$

where k_i is the first-order rate constant and S_i is the instantaneous concentration of the ith rate-limiting species. Simple though the relation is, it suffers from runaway transformation rate with increasing concentration tending toward infinite transformation rate.

In actual systems, such infinite quantities are never encountered; instead, the reaction rates tend to a constant saturation value. The anomaly of infinite rates of first-order kinetics can be addressed by the following empirical Monod kinetics capable of showing the experimentally observed saturation-like behavior [11]:

$$r_i = r_{\max} \frac{S_i}{K_s + S_i} \tag{11}$$

where $r_{\max}$ is the maximum specific growth rate, S_i is the instantaneous concentration of the ith species, and K_s is the concentration with one half the maximum rate. It is to be noted that when species concentration is much farther away from saturation ($S_i \ll K_s$) Monod kinetics reduces to first-order kinetics as follows:

$$r_i = r_{\max} \frac{S_i}{K_s + S_i} \approx \bar{r}_{\max} S_i, \quad \bar{r}_{\max} = \frac{r_{\max}}{K_s} \text{ if } S_i \ll K_s \tag{12a, b}$$

On the other hand, the concentration gradient of the charged chemical species inside the biofilm results in a potential difference which can be written in terms of the following charge balance equation [12]:

$$\nabla \cdot \boldsymbol{j} = -\rho_{-E} \tag{13}$$

where $\boldsymbol{j}$ is the current density and $\dot{\rho}_E$ is a function denoting net time rate of charge density at a point in the biofilm implicitly dependent on the rate of reactions which produce charged species in the film. The fluidic velocity component can be solved using the incompressible Navier–Stokes equation:

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = \frac{1}{\rho_F} \nabla p + \nu \nabla^2 \mathbf{u} + \mathbf{g} \tag{14}$$

where $\mathbf{u}$ is the fluid velocity vector, $\boldsymbol{g}$ is the body force vector, ρ_F is the fluid mass density, ν is the kinematic viscosity, and p is the pressure. In addition, the incompressibility condition implies:

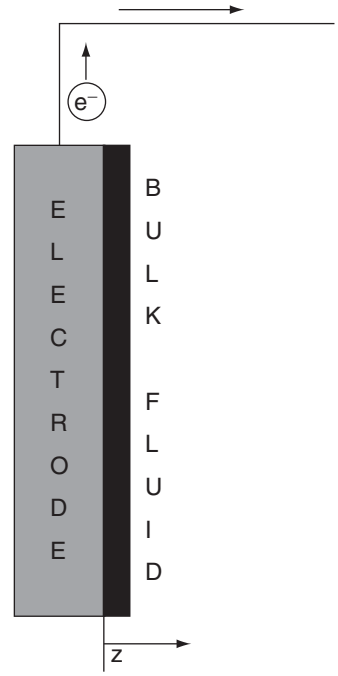
$$\nabla \cdot \mathbf{u} = 0 \tag{15}$$

The current density itself can be related to the potential difference in the biofilm through the Ohm's law:

$$\mathbf{j} = \kappa \nabla \Phi \tag{16}$$

where $\mathbf{j}$ is the current density vector and κ is the conductivity of the biofilm.

One can note that the mass and charge balance described above (Eqs. 9, 13, 14, 15 and 16) form a system of coupled partial differential equations (PDEs) which describe the physical processes occurring in the biofilm. In addition, the potential difference Φ inside of the biofilm is also linked to the chemistry of the respiration process through the Nernst-Planck equation described in Eq. 2.



Hence the complete set of physical PDEs coupled with the chemical processes yields the complete spatial distribution of the potential difference, current density, as well as chemical species concentrations. The general solution of such a system is analytically intractable and numerical algorithms are regularly employed [13]. The total current thus generated can be computed from the current density as:

$$I = \int\int \mathbf{j} \cdot d\mathbf{A} \tag{17}$$

where I is the total current expressed as the area integral of the current density over the electrode surface.

A simplified biochemistry has been postulated by Kato and Marcus [14] in their one-dimensional, conduction-based model. The authors assume that the substrate electron donor donates its electrons to an intermediate chemical species called the electron acceptor which then deposits the electrons directly onto a solid biofilm which transfers them directly to the anode through electrical conduction. A schematic description of their simplified model is given in Fig. 5.

Another model popularized by Picioreanu and his coworkers [15] describes the charge transport assuming a mediator-based mechanism. In their model, the authors utilize the electrodic Butler-Volmer (B-V) equation to obtain currents in the biofilm. However, a complication in the said model is brought about by the stoichiometric information of the mediator species needed to solve the B-V equations. Hence, in their model a detailed description of chemical reactions is important. In addition, rather than using a one-dimensional model for diffusion, Picioreanu et al. used a more general three-dimensional model inside the biofilm.

Micro/Nano Transport in Microbial Energy Harvesting, Fig. 5 Simple one-dimensional, conduction-based energy transport

Biofilm Growth and Species Transport

The previous section described the governing PDEs which can then be integrated over the domain of the biofilm. The biofilm itself is not a static structure but continuously grows due to the consumption of nutritious substrate from the bulk liquid. In a typical MEH device, the biofilm attached to the anode is the actual energy-producing region and its growth dynamics is crucial to performance characteristics of the device.

The modeling of biofilm growth commenced in the 1970s [13] when simple one-dimensional, homogeneous models were used. Since then, biofilm modeling has encompassed increasingly sophisticated models involving both geometrical as well a functional heterogeneities to take care of the spatiotemporal multi-scale phenomena described earlier. As a biofilm grows by taking nutrients from the environment, it becomes prone to detachment due to external mechanical loads. This implies that biomass growth is enhanced by nutrient diffusion into the biofilm and impeded by the detachment phenomena. In the absence of any net external biomass flow across the biofilm, a general mass balance equation can be written as follows:

$$\dot{m}_{biomass} = \dot{m}_{production} - \dot{m}_{detachement} \tag{18}$$

where $\dot{m}_{biomass}$ denotes the net rate of biomass accumulation in the biofilm, $\dot{m}_{production}$ denotes the rate of biomass production in the biofilm, and $\dot{m}_{detachement}$ denotes the rate of detachment of biofilm due to mechanical loads.

The rate of detachment is often assumed to be proportional to the current mass of biofilm:

$$\dot{m}_{detachement} = k_{det} m_{biomass} \tag{19}$$

where k_{det} is the constant of proportionality dependent on the physics of the detachment process. The biofilm production rate depends on the respiration process which is in turn dependent on the chemistry of substrate utilization. Various models exist incorporating the chemistry of respiration into the growth model [14, 15]. In general, the production term can be assumed to have a functional dependence on substrates and biomass concentration:

$$\dot{m}_{production} = f(S_i, X_{biomass}) \tag{20}$$

where f is an appropriate production function and $X_{biomass}$ is the biomass concentration. If the biomass concentration is assumed to be constant (e.g., constant mass density of microbes) the entire rate of biomass accumulation can be directly related to the volume change by:

$$\begin{aligned} m_{biomass} &= X_{biomass} V_f, \\ \dot{m}_{biomass} &= X_{biomass} \dot{V}_f \end{aligned} \tag{21}$$

where the overdot denotes time rate of change and V is the current volume of the biofilm. The mass balance equation can now be written as:

$$\begin{aligned} \dot{V}_f &= \overline{f}(S_i) - k_{det} V_f, \\ \overline{f}(S_i) &= f(S_i, X_{biomass}) / X_{biomass} \end{aligned} \tag{22}$$

It must be noted that $\overline{f}(S_i)$ implicitly depends on the spatial coordinates due to the dynamics of respiration processes which involves the spatial gradients of the chemical species. The simplified functional form of Eq. 22 indicates a general saturation-like behavior of the biofilm growth. In other words, biofilm thickness over the anode would approximately tend to a steady state asymptotic value given sufficient time.

The above analysis implies that the differential equations derived in the earlier sections must be solved on a domain which in general changes with time. The time evolution of the domain itself depends on the variables, which are being solved in the domain creating a highly coupled set of partial differential equations. Various numerical integration schemes have been provided over the years to accurately solve these equations.

Key Research Findings

One of the key issues at hand is the competitive transport of proton and electrons taking place inside the anode chamber. In chemical terms, this means current density is affected by the pH of the solution. The chemical basis of this phenomena stems from the fundamental nature of cellular respiration. As explained before, during the process of respiration, microbes gain energy by transferring electrons from a donor to an acceptor. The electron donor generates electrons in an oxidation half reaction, while the electron acceptor consumes the electrons in a reduction half reaction. Normally, the bacteria combine the two half reactions stoichiometrically to form an overall balanced reaction. For anaerobic process taking place in anode, however, only the donor half reaction occurs, and this makes the anode biofilm's performance dependent on the pH. Excess acidity (low pH) often results from poor transport of H^+ from the biofilm into the bulk liquid from where it must pass on to the cathode chamber. This effect is shown in the work of Torres et al. [16] where a phosphate buffer was employed for the bulk fluid. The authors, from their computational models showed that the effect of pH is extremely pronounced at higher current density. The authors showed that at high current densities a slight drop in pH (increased acidity) sharply reduced the current density thus adversely affecting the performance. The total movement of H^+ ions inside the biofilm is a sum of diffusion as well as migration. Diffusion is a concentration-determined process whereas migration is

governed by the electric field. Torres et al. [16] showed that the main effect of migration comes from the buffer concentration. They found that increase in ionic concentration by adding a salt like NaCl has very little effect on the current density. Therefore, the authors concluded that anodes for MEH device applications should be designed to increase the contact between the biofilm and the bulk liquid in addition to improving the hydrodynamic conditions at the biofilm-liquid interface for better mass transport of proton out of the biofilm. The chemical effect of buffer species was further investigated by Marcus et al. [17]. The authors showed a sharp improvement in current density depending on the particular species of buffer. The effect of buffer was also shown to affect the pH profile inside the biofilm and thus indirectly control the chemical ambience of the respiration reactions. Picioreanu et al. [18] incorporated the effects of electrode morphology and bulk fluid hydrodynamics in their mediator-based, two-dimensional microbial energy transport model. The authors also confirmed the adverse effect of acidity (low pH) on the current densities. In their model which was capable of capturing the spatial distribution of the pH, the authors pointed out that mass transport through diffusion is dominant near the biofilm surface whereas electromigration is important near the electrode surface. Interestingly, they also found that increased porosity of the biofilm complex which enhanced the specific surface area did not necessarily result in higher current densities.

Future Research Direction

Mathematical modeling frameworks have two essential roles to play in the area of MEH devices. On an application-driven outlook, mathematical modeling facilitates design and maintenance of MEH devices and is thus vital to commercial adoptions of this technology. On a fundamental-level, experimentally validated models are necessary ingredients in the understanding of the complex charge-transport processes that participate in an MEH device. Today, despite strides, a complete elucidation of the interdependencies of the various mass and charge transport mechanisms is yet to be fully described. One reason is due to lack of proper understanding of all the multi-scale and multiphysics aspects of the charge-transport processes which demand a concerted effort from researchers from a number of disciplines, whereas another reason is difficulty in obtaining model parameters which have various scale-dependent transient effects.

Definition

Icephobicity is the ability of a solid surface to repel ice or prevent ice formation due to a certain micro/nanotopographical structure of the surface and hydrophobic coating. Icephobic surfaces (i) prevent freezing of water condensing on the surface (ii) prevent freezing of incoming water, and, (iii) if ice formed, it should have weak adhesion strength with the solid so that it can be easily removed.

Occurrence and Key Findings

Although the term "icephobic" was coined in the early 1950s, only the progress in micro/nanopatterned superhydrophobic surfaces since the 2000s resulted in the emergence of micro/nanostructured icephobic surfaces which delay or suppress frost formation, bounce off incoming water droplets and, if ice still forms at the surface, reduce ice adhesion to solids [1].

Suppression of Frost Formation

Humid conditions can lead to water condensation and freezing on surfaces if the temperature is below the dew point. An important requirement for an icephobic surface is the ability to expel condensing water droplets and delay the process

of ice nucleation or frost formation on a surface. Condensation frosting occurs on a surface as a result of a formation of interdroplet frost bridges. However, so called "jumping-drop superhydrophobic surfaces" can eject condensed water droplets spontaneously using the energy released during droplet coalescence [2]. This can be achieved by designing a hierarchical superhydrophobic surface that can delay ice nucleation and suppress the interdroplet frost bridge formation.

Experiments with water droplets on superhydrophobic surfaces have shown that ice nucleation can be delayed up to 25 h for a droplet at −21 °C by carefully controlled nanoscale roughness of the surface. The coated Slippery Liquid-Infused Porous Surfaces (SLIPS) exhibited delayed ice nucleation compared to textured and hydrophobic surfaces. Water droplets condensing and coalescing on tilted SLIPS at −10 °C were seen to roll off before they could freeze [3].

Minimizing Contact Time for Incoming Droplets

Icephobic surfaces delay or prevent freezing of incoming water droplets (e.g., freezing rain) by bouncing off or breaking up the droplets. Minimizing the contact time of a droplet with a cold surface reduces the time for heat transfer and also reduces the chance of heterogeneous ice nucleation thus leading to bouncing off. Hydrophobic and superhydrophobic self-cleaning surfaces often repel incoming water droplets at room temperature. However, operation at temperatures below 0 °C poses a different challenge. As temperature decreases, the increase of the viscous force is much more significant than the increase of the surface tension forces. Therefore, a high contact angle and low contact angle hysteresis help minimizing contact time and maximizing droplet shedding.

Although the dynamic pressure of impacting droplets is small, the "water hammer-type" pressure on impact can cause the transition from the heterogeneous solid-water-air (Cassie-Baxter) to homogeneous solid-water (Wenzel) wetting regime on the surface. Droplet pinning, as a result of this wetting transition, increases the contact time as well as heat transfer through the contact area at the surface. Oblique and asymmetric impacts of droplets on hydrophobic and superhydrophobic surfaces can reduce chances of this wetting transition as well as droplet pinning [4]. Functionalized carbon nanotube superhydrophobic surfaces repel obliquely impacting water droplets at −8 °C. Nanostructured silicon superhydrophobic surface could repel low-velocity supercooled water droplets at −25 °C and thus remain ice free. Experimental studies showed that droplets freeze below −25 °C, however their removal was easy because the droplets did not undergo Cassie-Baxter to Wenzel wetting transition prior to freezing [5]. A study of hydrophobic fiber-reinforced concrete showed that it can repel obliquely impacting water droplets (Weber number ~55) at 20 °C and −5 °C [4].

Ice Adhesion to Solids

Adhesion of ice to surfaces is a result of the synergistic effect of chemical bonding, van der Wall's forces, and direct electrostatic interactions. Charges on the surface of the ice causes mirror charges in the metallic surface in contact with ice, thereby causing adhesion. Dielectrics can reduce these mirror charges, and in principle reduce ice adhesion strength. The effect of dielectric constant on ice adhesion is significant only for very low values of the dielectric constant. Polytetrafluoroethylene-coated superhydrophobic surfaces showed negligible ice adhesion. High contact angle alone does not always translate into low ice adhesion. The adhesion of ice to a superhydrophobic surface is related to the contact angle hysteresis and thus to the ice-solid interfacial area [6]. Theoretical considerations have suggested that ice adhesion is closely correlated to contact angle hysteresis, but experiments have shown this is not always the case [1]. High contact angle coupled with low contact angle hysteresis implies the presence of air pockets on the surface. These air pockets can act as stress concentrators at ice-solid interface. The size of microvoids/cracks at the ice-solid interface is critical for ice adhesion to a surface. If the cracks are not sufficiently large, the superhydrophobic surface may exhibit strong ice adhesion [7].

The latent heat released during freezing of a droplet on a surface can temporarily increase the vapor pressure in the vicinity of the solid-ice-vapor contact line. This may result in desublimation of supersaturated water vapor as a "frost halo" surrounding the three-phase contact line. The increase in ice-solid interfacial area manifests as an increase in ice adhesion to the surface [8].

Ice adhesion to a surface is quantified by the adhesion strength. A method of measuring adhesion strength of ice is by shear (or ice adhesion) test. A shear force (push or pull) is applied to the substrate-ice interface, and the ultimate shear strength at which the ice detaches is experimentally determined. Ice adhesion strength is often reduced on superhydrophobic surfaces. Ice adhesion strength to SLIPS-coated aluminum is one to two orders of magnitude less than to regular aluminum [3]. Low ice adhesion strength to lubricant-infused surfaces is due to the thick excess layer of lubricant atop the textured surface [9]. For a surface with a thermodynamically stable lubricant film (with no excess liquid completely covering the surface textures), the ice adhesion strength decreases as the surface texture density increases. A similar mechanism may be found in thermogenic icephobic plants [10].

Comparison of the Superhydrophobicity and Icephobicity

The hydrophobicity or the ability of a molecule to be repelled from a mass of water is a property that has a rigorous definition in thermodynamic terms. Thus, hydrophobicity is often compared with the lipophilicity (affinity to fats, oils, and organic liquids), and it is viewed as an "entropic" effect. In turn, the superhydrophobicity is an extreme degree of the hydrophobicity with (i) CA $>150^\circ$ and (ii) low CA hysteresis, whereas the ability to repel incoming water droplets is sometimes added as an additional independent feature of a superhydrophobic surface. Unlike the hydrophobicity, it is difficult to provide a thermodynamic definition of the icephobicity. However, most scientists agree that the property should involve (i) low ice-solid adhesion energy, (ii) a delay in freezing of supercooled droplets, and (iii) repellence of incoming water droplets by a cold surface [1].

The usual assumption is that mechanisms of ice and water adhesion are similar, and therefore, by designing a surface with low surface energy (large water contact angle), one can also achieve weak adhesion between the surface and the ice. However, ice detachment from a solid surface occurs through fracture, and therefore, it is different from the dewetting mechanism. Fracture can occur within the ice itself when the interface with the substrate is strong or at the substrate-ice interface if defects (e.g., cracks) are present. Fracture occurs in accordance with mode I (opening) or mode II (edge sliding) cracking scenarios, which correspond to normal and shear loading. The critical strength τ_{yy} above which the fracture occurs in mode I with the critical stress is related to the receding CA, θ_{rec}, as

$$\tau_{yy} = \sqrt{\frac{EG_{rec}}{\pi a}} = \sqrt{\frac{E\gamma(1 + \cos\theta_{rec})}{\pi a}} \quad (1)$$

where E is the Young modulus, G_{rec} is the surface energy of the crack during its opening, γ is the surface tension, and a is the crack length [7]. The analysis for mode II crack fracture is similar. From equation (1), we concluded that (i) shear strength correlates with the receding contact angle; (ii) the superhydrophobic surface has low shear strength because high CA, $\theta_{rec} \rightarrow 180^\circ$, corresponds to low values of $(1 + \cos\theta_{rec})$; and (iii) the effect of initial crack size is very significant. Therefore, it is important that the so-called Cassie state exists with air pockets trapped between the solid and the water droplet. When water freezes, the pockets become air voids and can serve as stress concentrators.

When a snow crystal grows, the direction of growth depends on the "roughening transition" which occurs at a certain critical temperature, so that entropy ΔS prevails over the enthalpy ΔH in the Gibbs energy ΔG formula $\Delta G = \Delta H - T\Delta S$. The combination of various directions of ice crystal growth provides the complexity of snowflake shapes and apparent "synchronization" of growth at different branches of a snowflake [1].

Micro-/Nanostructured Icephobic Materials, Table 1 The comparison of the hydrophobicity and icephobicity [1]

Property	Water	Ice
Definition of "phobicity"	Low surface energy/low adhesion	Low adhesion
	High contact angle	Low normal strength (maximum stress)
	Low CA hysteresis	Low shear strength
	Bouncing-off	Bouncing-off supercooled droplets
Interaction	Hydrophobic interaction	Crystallization of ice and snowflakes ("icephobic interactions")
Thermodynamic relationship	Minimization of $\Delta G=\Delta H-T\Delta S$	Surface-roughening transition $\Delta G=\Delta H-T\Delta S=0$ and similar
Typical manifestation of the interactions	Hydrocarbon molecules in water environment	Ice molecules in saturated vapor environment at negative temperatures
Effects	Protein folding (including fractal shape), self-organized criticality, long-range hydrophobic force, wetting transitions	Snowflakes (diverse but symmetric, fractal)

The parallelism of the superhydrophobicity and icephobicity is shown in Table 1. The three requirements for an icephobic surface (low ice normal and shear adhesion, bouncing-off droplets) are similar to the three properties for a superhydrophobic surface (high contact angle, low contact angle hysteresis, bouncing-off droplets). Both hydrophobic interactions and ice crystallization are governed by minimizing the Gibbs free energy, ΔG. Both hydrophobic and icephobic interactions are responsible for a wide range of entropic effects, from protein folding to snowflake formation.

Synonyms

Nucleic acid amplification; Oligonucleotide synthesis

Definition

Oligonucleotide synthesis: A process to construct a piece of desired oligonucleotide sequence using a chemical additive method. It is also called de novo oligonucleotide synthesis.

Microarray: It is also called a DNA microarray or DNA chip. It usually presents in the microchip format with a variety of DNA sequences on the chip. Each spot contains multiple strands with the same sequence and forms arrays on the substrate. Biologists use DNA microarrays to genotyping biological samples or test the level of expression of the specific gene.

Introduction

Synthetic biology is an emerging field that is being applied in a wide range of disciplines. The burgeoning ideas of its applications involve gene circuits and DNA computing, biomolecule nanosensors, genome or chromosome construction, and DNA nano-robots for medical and therapeutic applications [1–10]. To achieve these goals, techniques for oligonucleotides assembly are critical. Several bioengineering methods have been developed. Among them, ligation-based assembly and PCR-based assembly are the two most commonly used methods to construct the gene-sized DNA sequences using synthesized oligonucleotides fragments as building blocks. Although these techniques are mature and routine, the bottleneck still exists on synthesis of the oligonucleotide fragments with diverse sequences. The method to chemically de novo synthesize oligonucleotides was developed in the 1980s, and the method has been commercialized and automatic. However, the capacity to provide low-cost and high-throughput products is still far behind the demands.

Microelectromechanical system (MEMS) technology has been applied in building miniaturized devices for a long time. The devices made by this technology have several benefits including low cost, less sample or reagent consumption in chemical or biological applications, easy to control and flexible expansion as well as integration in hardware. These benefits provide a potential solution to reduce cost, increase throughput, device automation and integration to the conventional oligonucleotide synthesis as well as microarray fabrications. This entry will outline several MEMS technologies that have been used on oligonucleotide synthesis and explicate their major functions in the conventional oligonucleotide synthesis.

Chemical Oligodeoxynucleotides Synthesis

The phosphoramidite reaction is currently the most widely used technique in the chemical oligonucleotide synthesis. The method was developed in the early 1980s by Caruthers et al. and has been adopted by most commercial oligonucleotide synthesizers [11, 12]. The standard phosphoramidite method is a four-step cyclic process which elongates the synthesized nucleotide chain from the 3′ end to the 5′ end. The process is initiated by tethering the first protected nucleoside on a solid support via its 3′ hydroxyl group. The 5′ end of the nucleoside is blocked via a non-reacted dimethoxytrityl (DMT) ether molecule. The commonly used solid supports are polystyrene

(PS) beads and controlled pore glass (CPG). In a single cycle of the stepwise addition of nucleotide monomers, different reagents are sequentially applied to the elongating chain.

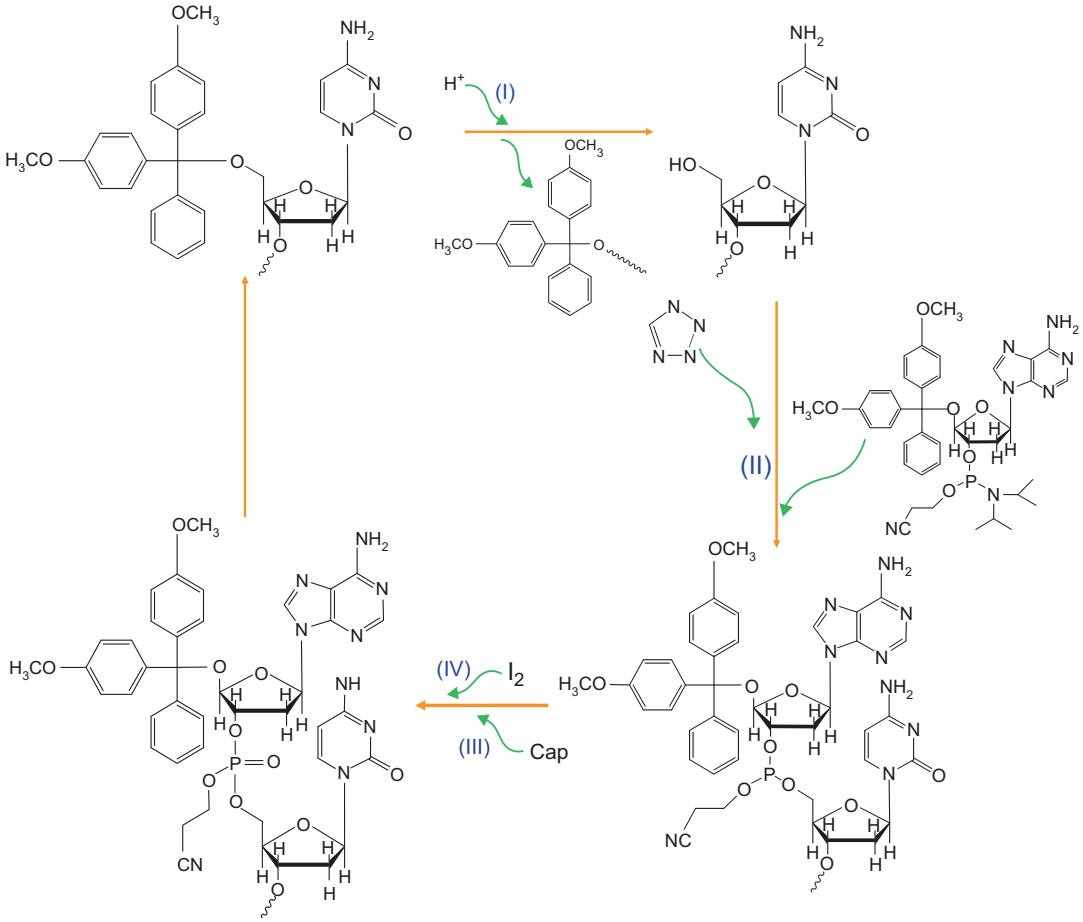
The reactions are carried out in four steps:

1. Deprotection: The capping molecule on the 5′ end of the previous nucleotide needs to be removed to form a reactive function group on the growing chain. A weak acid is normally used in this step to remove the dimethoxytrityl (DMT) ether capping group and leaves the 5′ end hydroxyl (5′-OH) group on the chain;
2. Coupling: The desired phosphoramidite monomer couples to the chain via the 5′-OH group generated in step (1). The desired phosphoramidite monomers are activated simultaneously in solution with an appropriate activator (i.e., tetrazole) to facilitate the coupling reaction;
3. Capping: The uncoupled 5′-OH groups need to be blocked to prevent further reactions that produce error sequences. The acylating molecules are normally used in this step;
4. Oxidation: The phosphite triester linkage between two coupled oligonucleotides formed in step (2) is not strong with chemicals in subsequent reactions. An oxidizer agent is used to produce a more stable phosphotriester bond in growing chains.

This four-step cycle process is repeated to add nucleotides until the desired sequence is completed. The illustration diagram of this four-step process is depicted in Fig. 1.

In the post-synthesis process, all protection groups on the oligonucleotide chains are removed by a concentrated ammonium hydroxide solution. For DNA or gene synthesis purposes, the synthesized oligonucleotide fragments are cleaved from the solid support in the same solution with a higher reaction temperature.

The solid-phase oligonucleotide synthesis procedure has been implemented in automatic machines, and different types of synthesizers with various synthesis capacities from 1 to 1536 sequences [13–16] have been developed. In most traditional synthesizers, the required reagents are pumped into the column where the solid supports reside, and all procedures are controlled by a programmable microcontroller.

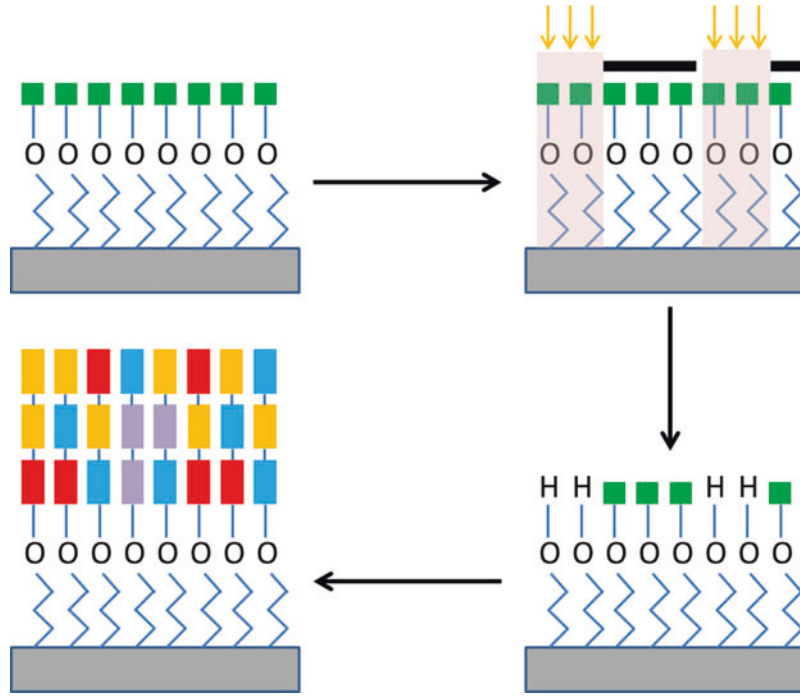


Rather than the four-step synthesis process, a two-step alternative method in oligonucleotide synthesis has been reported [17]. This two-step method simplifies the procedure by combining steps with one chemical reagent. For example, a peroxy anion agent has been used to remove 5′-end cap molecule and simultaneously transforms a phosphite triester to a more stable phosphotriester with the agent oxidation capability. This chemical reaction design has the potential for quicker and simpler automation procedures and will be a cost-efficient alternative for large-scale oligonucleotides synthesis in the future.

MEMS Technology for DNA Microarrays Fabrication

Unlike synthesizing oligonucleotides in columns, the fabrication of DNA microarrays grows oligonucleotide chains directly from the surface of substrates. Each spot contains multiple strands with the same sequence, and various sequences at different spots form the arrays. Silicon (Si) wafers, glass slides, or functionalized plastic slabs are widely used for the substrate. A conventional four-step synthesis process is also adopted yet through different mechanisms. Most of these mechanisms combine MEMS technologies to decrease the cost and further increase the throughput. Regarding the synthesis results, for microarray fabrication, oligonucleotides will remain on the substrate, but all strands can also be digested and collected from the substrate for further bioengineering applications.

Photolithography



Photolithography is one the most common microfabrication procedures in constructing micron or submicron devices. In this technique, the process is exclusively used on pattern transfers through a mask to the thin-film polymer on the

Microarray, Fig. 1 Cycle of standard "phosphoramidites" oligonucleotides synthesis

substrate via a suitable light source. The masks are used to generate light patterns that dictate exposure and non-exposure areas on the polymer and form desired patterns. The concept of this technique has been applied to oligonucleotide synthesis on the microarrays [18–20]. The technique employed masks and photolabile nucleoside monomers to grow oligonucleotides in arrays on a solid substrate. In an early system, physical masks were used to generate light patterns. The light exposure on the specific array area removes photolabile capping groups from oligonucleotide chains and results an active functional terminal (i.e., deblocking). Afterward, the desired phosphoramidite monomer is applied to all arrays on the entire substrate surface. The coupling of the oligonucleotide monomer only occurs in arrays which were light exposed in the previous step and add oligonucleotides to the elongation chains. The steps repeat until all desired sequences are synthesized (Fig. 2). To perform the synthesis on diverse oligonucleotide sequence, a stack of masks with various light exposure patterns needs to be pre-manufactured based on the desired oligonucleotide sequences. Affymetrix Inc. pioneered this technique and employed the technology to fabricate the high-density probe arrays product GeneChip™ for gene sequence analysis.

As mentioned, in the previous technique, a stack of physical masks needs to be fabricated. Therefore, the cost to use this technique to synthesize oligonucleotides dramatically increases when the

Microarray, Fig. 2 Schematic illustration of DNA synthesis using photolithography technique

sequence diversity increases. In addition, in order to increase the sequence diversity in one chip, the feature size of each array needs to be decreased to increase the array density. The cost for masks is also increased when the pattern feature size decreases. Therefore, the technique is only justifiable for large-scale, fixed-sequence and high-volume microarray manufacturing. Recently, a low-cost alternative method using virtual masks to perform light patterning in the deprotection step has been developed. The technique employed "Digital Light Processing" (DLP™) technology with "Digital Micromirror Device" (DMD™) developed by Texas Instruments. The device consists of a high-density micromirror array manufactured by MEMS technology that is used as a light-reflective display by electromechanically switching each micromirror between on and off positions. Thus, the device generates the specific light pattern digitally with a computer control. Compared with using the physical masks in photolithography, the use of this device avoids the tremendous cost in physical mask fabrications. In addition, the light patterns are easily programmed through software to match the desired sequences.

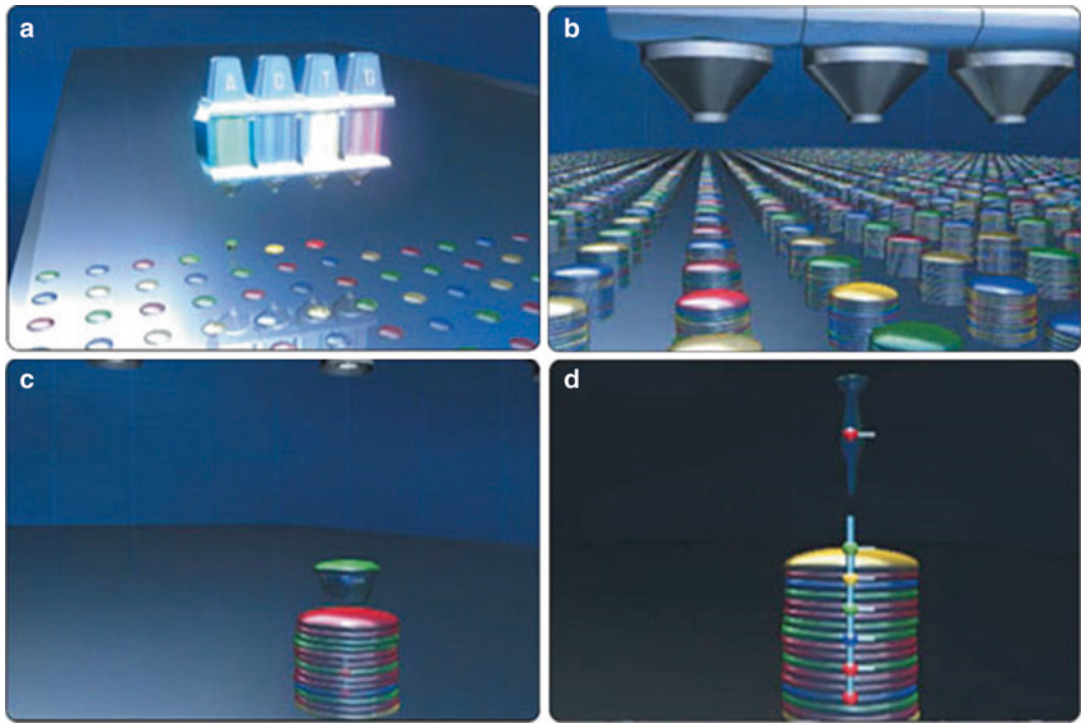
In regard to chemical developments, progress has been made in DNA microarray fabrication using the photolithography technique. Chemicals such as (R,S)-1-(3,4-(methylenedioxy)-6-nitrophenyl)-ethyl chloroformate (MeNPOC) or 2-(2-nitrophenyl)propoxycarbonyl (NPPOC) have been reported [21, 22]. In another report, an alternative technique used the photo acid generator (PAG) agent to produce acids in the reaction solution when exposed to light. The generated protons (i.e., H^+) are used to eliminate the protection group on the phosphoramidite monomer and generate an active 5′-OH terminal in the oligonucleotide chain as in the conventional phosphoramidite reactions. Gao et al. [23] have successfully demonstrated using such methods in oligonucleotide synthesis.

Electrochemical Array

Instead of using photo-generated acids for the deprotection step, Egeland et al. reported using a hydrolysis reaction in an electrolyte solution to generate acids [24]. In this technique, the authors

used thin-film iridium metal to fabricate arrays of microelectrodes and used hydroquinone and benzoquinone with tetrabutylammonium hexafluorophosphate in anhydrous acetonitrile as the reaction electrolyte. When a voltage was applied to the microelectodes, a corresponding current was applied to the electrolyte. An oxidation reaction occurred at the anodes and produced acids in the solution. The acids were confined to the anode region by the adjacent cathode electrodes and directly diffused to the area of the array where the deprotection reaction would be performed. In this technique, the electrode needs to be separated from the substrate at which the oligonucleotide synthesized to prevent an oxidation reaction on oligonucleotide chains. An alternative technique performed synthesis directly on the electrode surfaces and used a porous polymer layer to protect oligonucleotide chains from oxidation damages. In this technique, due to the slow diffusion of the acid molecules in the porous polymer, the overall time for the whole synthesis procedure is extended.

Microfluidics



Microfluidic devices have been widely used in various applications such as the chemistry, biology, and medical fields. Although microfluidic devices can be fabricated with various materials such as silicon, glass, or quartz, the technique to fabricate these devices using elastomeric materials is most popular. This is due to the characteristics of the material such as ease and flexible fabrication processes, low cost, and versatile material properties. From application aspects, due to the miniaturized size of device components (i.e., channels and wells), the amount of sample and reagents required for each application is dramatically reduced, and the throughput is increased. Recently, several groups reported adopting microfluidic devices in microscale oligonucleotide synthesis to reduce the total cost. In those studies, the microfluidic devices were used to transport reagents used for each synthesis step, and oligonucleotides were synthesized in the micro-wells, which were fabricated by etching on the substrate. Several technical challenges have been discussed including individual addressability to each synthesis array, processes robustness and reliability, and the chemical resistance of the elastic materials used in microfluidic fabrication. Most plastic devices lost sustainability upon contact with organic solvents or harsh chemicals which are all used in synthesis procedures. For example, devices made of poly(dimethylsiloxane) (PDMS), a popular polymer material used in most microfluidic device fabrication, became swollen and had their channels clogged during synthesis while the material was in contact with the organic solvents. Moorcroft et al. [25] first attempted to solve this dilemma by modifying the synthesis protocol. They changed the solvent used in the deprotection step and the reagent used in the oxidation step. In addition, in order to immobilize linkers on the PDMS substrate, a surface treatment technique was developed. First, the microchannel surface was oxidized via a UV-ozone system to introduce a functional silanol (Si-OH) group. A subsequent silanization step was performed on the oxidized surface using vapor phase 3-glycidoxypropyltrimethoxysilane (GPTMS). Finally, PEG was introduced to link to the silane as a spacer to connect the first oligonucleotide for whole synthesis. The author reported 21-mer oligonucleotides that were successfully synthesized with this microfluidic device.

Several other strategies have also been developed to avoid PDMS swelling when it is used as the material in microfluidic oligonucleotide synthesis. Hua et al. used parylene to coat on PDMS and form a highly chemical-resistant hybrid film in microfluidic devices for the oligonucleotide synthesis [26]. Quake et al. reported using perfluoropolyether (PFPE), a high chemical-resistant polymer material, to replace PDMS as the material for fabricating the microfluidic devices for oligonucleotide synthesis. In their method, porous silica beads were used as the solid support, and all the same synthesis reagents were used in the conventional phosphoramidite method [27]. This work also demonstrated that microfluidic device consumed 60-fold less reagents as compared with the conventional column apparatus.

Inkjet Printing

Another example using the MEMS technique in oligonucleotide synthesis is inkjet printing. In this technique, an inkjet printer is employed to deliver liquid droplets of reaction reagents to specific spots on a substrate to complete the four-step cycle in the conventional oligonucleotide synthesis procedure. A piezoelectric printer head, fabricated using MEMS techniques, consists of ink reservoirs and is controlled by a piezoelectric crystal. When a voltage is applied to the crystal, the lateral contraction force causes the attached diaphragm to deflect and ejects a drop of liquid from the reservoir. The printing head is controlled by motion controllers to precisely "print" the liquid at specific areas on the substrate. Blanchard et al. first demonstrated using this mechanism to synthesize oligonucleotides [28]. In their system design, the inkjet head consisted of six liquid reservoirs with four different phosphoramidite monomers, one for activators and one for modified base solution. Afterward, other groups also demonstrated using commercial piezoelectric inkjet printers to fabricate oligonucleotide microarrays [29, 30].

One of the major technical issues discovered in this technique is that the open environment caused fast evaporation of the pico-liter liquid on the substrate. Acentonitrile is the major solvent chosen in conventional oligonucleotide synthesis. However, when using it in printing synthesis mechanism, the printing head nozzle became clogged, and crystallized dry reactants on the substrate were discovered, which deteriorated the whole synthesis process. Therefore, the solvent selection is critical. Lausted et al. [29] developed a technique using propylene carbonate (PC) with a mixture of 2-methyl glutaronitrile (MGN) and 3-methoxypropionitrile (3-MP) as the solvents in the whole synthesis procedure. These solvents showed low volatility, high vapor pressure, and

Microarray, Fig. 3 Cartoon of DNA microarray synthesis with inkjet printing technology by Agilent Technologies Inc. [37]

full compatibility with all phosphoramidite chemicals which are suitable in all oligonucleotide synthesis. Agilent Technologies Inc. has commercialized the technique to fabricate microarray for gene-expression profiling applications (Fig. 3) [31–32].

Conclusion

Oligonucleotide synthesis is the foundation of many DNA technologies including biomolecular engineering, gene circuits, nano-devices and computing, synthetic biology, and genome synthesis [1–4, 33]. However, one of the biggest barriers to commercial applications of oligonucleotides synthesis still remains on making primers for PCR (i.e., polymerase chain reaction) and mutagenesis. The reasons are high cost in the units priced for each synthesized base and low-throughput techniques used in the market with conventional synthesis methods or machines.

With the benefits from microfabrication technology, many novel synthesis technologies have been developed. As we mentioned previously, those techniques have brought benefits in low-cost device manufacturing, fewer amounts of reagents used, fast and flexible sequence synthesis, and batch or high-throughput production to the oligonucleotide synthesis and further to all DNA technology. For example, in 2002, the de novo synthesis of a functional poliovirus genome was achieved. The size of it is around 7500 bp [34]. In 2003, a functional bacteriophage genome (5386 bp) was synthesized in 2 weeks [35]. The synthesis of a genome of equal size needed months with earlier technologies. In 2008, a breakthrough genome synthesis and cloning of the *Mycoplasma genitalium* (582970 bp) was completed [36] which demonstrated a milestone in the synthetic biology discipline. It is believed that with the continued evolution of microfabrication and material technology, full automation and platform integration, further decreases in unit price, and increases in throughput, de novo DNA synthesis will become a standard technique for all DNA engineering applications.

Microcantilever Chemical and Biological Sensors

Hashem Etayash and Thomas Thundat
University of Alberta, Edmonton, AB, Canada

Definition

Advanced sensing techniques are currently being developed so that quick and accurate detection of chemical and biological analytes can be obtained. Among those techniques, microcantilever Array sensors, have attracted considerable attention as a result of their potential as highly sensitive platforms for real-time, high-throughput, and multiplexed detection of a myriad of chemical and biological analytes. Microcantilevers are microscale beams which are anchored at one end. Molecular adsorption on a cantilever surface can generate bending as a result of adsorption-induced changes in surface stress. In addition, mass loading due to molecular adsorption results in changes in the resonance frequency of the cantilever. Chemical/biological selectivity can be achieved via immobilized receptors on the cantilever surface. The microcantilever array platform has the potential for application in many areas such as monitoring of water quality, chemical analysis, detection of food pathogens, and medical point-of-care diagnosis.

Introduction

A need currently exists for miniature devices to use in chemical and biological analysis, which can provide fast and accurate diagnoses in real time. The necessity for rapid and sensitive sensing with high selectivity in a multiplexed fashion is becoming urgent as multiple markers are required for accurate detection [1, 2]. The contamination of food, water, and plants by pathogenic bacteria, poisons, and toxic chemicals is causing concern across the world [3, 4]. Survival rates depend on early detection and treatment, both of which are

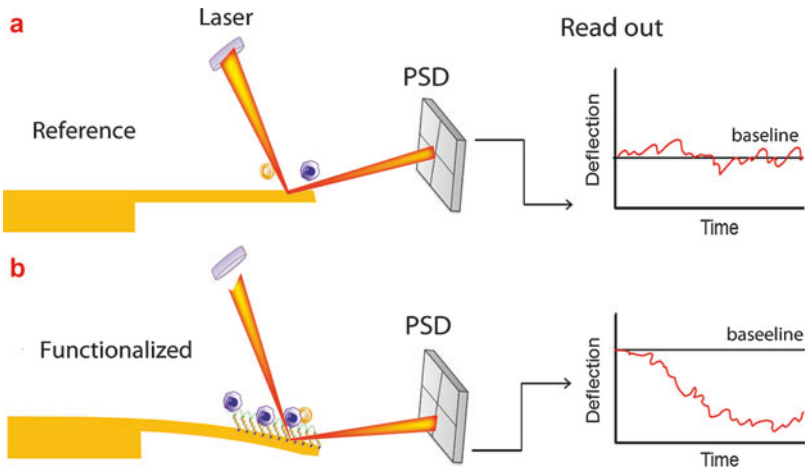
difficult to achieve when a diagnosis is based on slow, non-movable equipments. Therefore, the development of inexpensive handheld chemical/biological sensors with high selectivity and sensitivity and low power consumption is crucial for early detection in the field.

Conventional medical diagnostic tests [5], such as colony-based platforms (blood, biopsy, saliva culture, or food/product contaminated cultures), are efficient, sensitive, and accurate. However, they are time consuming, inconvenient, and cannot be miniaturized for use in field applications. High-throughput microarrays such as DNA and protein microarrays are prevalent and versatile tools in detection, but they require time- and expensive steps of labeling using fluorescent tags [6, 7]. In existing clinical diagnostic methods, results are not received quickly resulting in treatment delays, and this can have a negative impact on a patient's health and overall long-term treatment outcomes [8, 9]. Delays in the accurate detection of food contamination can affect public health while discovering and treating outbreaks. There is an urgent need for the development of cost-effective, and rapid diagnostic tools that can be mass deployed.

Miniature sensors for rapid detection are increasingly finding applications in fields such as chemical analysis, drug discovery, blood analysis, glucose monitoring [10], microbial detection, food/water analysis, and medical diagnostics [11, 12]. Chemical/biosensors are basically devices with engineered interfaces that respond to specific analytes in complex environments by measuring the variations in the physical properties of the sensing elements [13]. Generally, chemical and bio interfaces for molecular recognition are derived from receptor molecules which selectively interact with target molecules under specific conditions. Miniature sensor technologies that allow simultaneous sensing of multiple chemical and biological entities in a single experiment are, therefore, becoming essential tools in drug discovery, clinical detection, safety, and life science research. A typical sensor contains three main components: a bio-/chemical recognition element, a transduction component, and a response detector. Based on the transduction mechanisms, sensors can be classified into optical, electrochemical, electrical, and electromechanical [14]. The bio-recognition interfaces used in the biosensors are usually receptors, antibodies, proteins/enzymes, nucleotides, and other chemical recognition molecules. These elements are attached physically or chemically onto the surface of the physical sensor, and their interactions with the target analytes lead to specific sensor responses, which can be displayed using simple read-out methods.

The microcantilever, which resembles a miniature diving board, can be readily fabricated on silicon wafers and other materials using conventional microfabrication techniques. Originally, microcantilevers were introduced as displacement detection probes in atomic force microscopy (AFM) for acquiring surface topographies [15]. Soon afterwards, it was recognized that they could be used to sense changes in temperature and relative humidity [16]. The ability to fabricate arrays of extremely small structures using standard wafer-scale semiconductor processing techniques has allowed the development of practical micromechanical chemical sensors and biosensors. The microcantilevers are displacement sensors which respond to surface energy changes as a result of chemical or biomolecular interactions. Restricting adsorption of the molecules on one side of the cantilever surface results in a surface stress that can be observed as a deflection. In addition to bending, the mechanical resonance frequency of the cantilever can undergo variations due to molecular adsorption-induced mass loading. These two signals, cantilever bending and resonance frequency variation, can be monitored simultaneously using a variety of techniques.

In the mid-1990s, the ability to functionalize cantilevers with molecular probes for the generation of selective responses to targeted biochemical compounds opened a new field of biosensor technology based on electromechanical properties and surface structures [17, 18]. Despite it being relatively new, the microcantilever detection methodology has attracted significant attention as an approach for label-free sensing device. Microcantilever platform has the advantage as a



label-free detective method that is extremely sensitive, reliable, and scalable. Recent studies have shown that cantilevers are capable of sensing biomolecules in liquid sat concentrations of nano- to femtomolars [19]. Microcantilevers have been used for detection of numerous chemical and biological entities including nucleotides [20, 21], proteins [22], microbes [23, 24], as well as a wide range of toxic chemicals [25] and heavy metals [26]. Nanomechanical cantilevers have demonstrated mass resolution of a zeptogram mass when operated in a vacuum. However, the mass resolution is only in the nanogram range when operated in liquid media due to the liquid damping. The mass resolution depends on the frequency of the cantilever. The higher the resonance frequency of the cantilevers, the higher the mass resolution. The ultra-small size of the cantilevers allows the sensor to exhibit quick responses to the evolving biological and chemical deviations in timescales of micro- and milliseconds.

Cantilever Principle and Modes of Operation

Microcantilevers are beams fabricated from materials such as silicon using conventional microfabrication techniques [27]. Typical dimensions of silicon microcantilevers are 20–50 μm (width), 100–500 μm (length), and 0.3–2 μm (thickness). Nanoscale cantilevers, on the other hand, have dimensions of 600–950 nm (width), 300–650 μm (length), and 50–100 nm (thickness). For most biochemical applications, cantilevers are first vacuum deposited with a thin layer of gold (20–30 nm) on one side. The gold-coated side of the cantilever is functionalized with ligand molecules which are specific to the target analytes. Many different attachment techniques are used in functionalizing the cantilever, such as, the alkane thiol binding chemistry. During the detection process, the immobilized ligands selectively capture the target molecules from the surrounding medium, causing the cantilevers to bend, and/or change the resonance frequency, depending on the mode of operation. Since liquids heavily damp the resonance frequency, this approach is not routinely used in sensing. Adsorption-induced cantilever bending is largely independent of the medium; therefore, it is routinely used as a sensing method. The specificity of detection relies deeply on the molecular interaction between the predesigned detective agents (ligands) and the unknown sample molecules (targets). Figure 1 illustrates the basic principle of the cantilever sensor technique based on beam deflection.

Modes of Operation

- Static Mode of Operation (Surface Stress Mode)
Microcantilevers are routinely operated in a static deformation mode, where the cantilever beam

Microcantilever Chemical and Biological Sensors, Fig. 1 Basic principle of cantilever technique; (**a**) no deflection from a reference cantilever (no binding to the target analyte); (**b**) cantilever deflection as a result of the ligand-analyte binding

bends as a result of increasing or decreasing the surface stress generated by analyte-ligand interactions on the sensor. While an increase in the surface stress (compressive stress) leads to downward bending of the cantilever, a decrease in the surface stress (tensile stress) leads to upward bending of the cantilever. Since the cantilever bending reaches a steady state after attaining equilibrium during adsorption, this operational mode is called the static deformation mode. Specific adsorption of the molecules on one side of the cantilever results in a decrease in the surface free energy. The surface free energy per unit area is the surface stress and preferential molecular adsorption on one side of the cantilever which results in differential surface stress. The difference in surface stress between the functionalized surface and the passive (nonfunctionalized) surface leads to cantilever deflection (bending), the value of which can be estimated according to Stoney's formula:

$$\Delta\sigma = \left[\frac{Et^2}{3\,(1-\nu)}\,L2\right]\Delta \qquad (1)$$

where $\Delta\sigma$ is the change in surface stress (or surface energy) due to the molecular adsorption, E is the Young's modulus of the cantilever, ν is the Poisson ratio, and L and t are the length and thickness of the cantilever, respectively. From Eq. 1, it is clear that a longer cantilever generates larger bending.

- Dynamic Mode of Operation (Resonance Mode)
The dynamic mode of operation of the cantilever is based on resonance frequency of the cantilever. Adsorption of specific molecules on the cantilever surface leads to a change in the cantilever mass. The resonance parameters include resonance frequency, amplitude of vibration, quality factor (Q), and phase of vibration. The fundamental resonance frequency f_0 of a cantilever is expressed as

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{k}{nm}}$$

where k is the spring constant of the lever, n is a geometrical parameter for the fundamental vibration of the cantilever beam, and m is the effect of mass of the cantilever.

- Bi-material Mode of Operation (Thermal Mode)
When a microcantilever is deposited with a thin layer of metal on one of its sides, it exhibits bi-material (bimetallic) properties. In the bi-material mode, the cantilever undergoes a static deflection in response to changes in temperature. The bending of a bi-material cantilever is a result of the different coefficients of thermal expansion between the metallic thin film and the underlying cantilever. This mode of operation is also referred to as the heat mode of operation due to its dependence on changes in temperature. A bi-material cantilever is an extremely sensitive thermometer. This mode is widely used for temperature-related applications such as calorimetry and thermal actuators. The temperature changes on the surface of the cantilever can be driven by catalytic reactions. The thermal sensitivity of the cantilever heating mode is orders of magnitude higher than that of conventional calorimetric methods.

Cantilever Surface Functionalization

The selectivity of a microcantilever sensor originates from the selectivity of receptor-analyte binding. The receptors are immobilized on the cantilever surface using surface functionalization techniques. The attachment of chemical or biological receptor molecules (proteins, DNA, cells, and other semiselective biochemical elements) has drastically enhanced the selectivity of several biosensors, including microcantilevers in molecular recognition applications [28, 29]. One of the advantages of surface functionalization is its ability to detect specific targets in an unknown mixture.

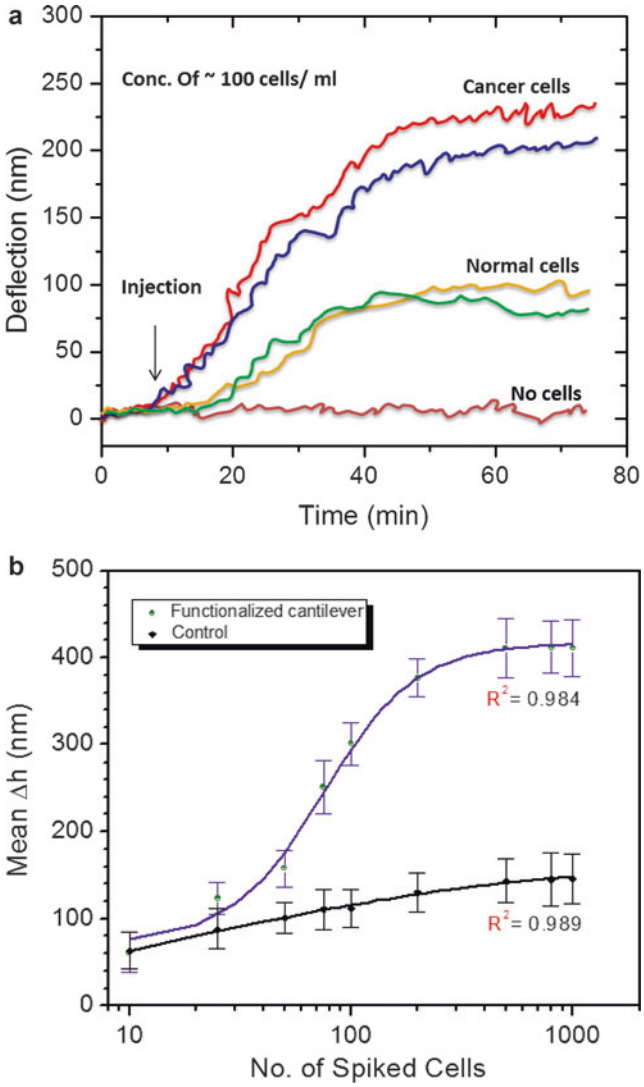
There are many approaches that can be used to functionalize the cantilever with specific recognition molecules depending on what the final applications of the sensor will be. On silicon cantilevers for instance, functionalization can be performed using so-called silicon chemistry [30], based on coating the cantilevers with polylysine, aminosilane, epoxysilane, or nitrocellulose.

On gold-coated cantilevers however, the functionalization can be easily implemented using thiol chemistry [31],which takes advantages of the strong covalent interaction between Au and the thiol group of the ligand molecules. The challenge of these approaches is developing a healthy reaction chemistry which can ensure the required chemical selectivity, stability, and complete bioactivity of the attached molecules. The immobilization mechanism is determined both by the chemical nature of the molecular probes and their reactive functional groups. In the case of the surface stress-based operating mode, the functionalization must be carried out only on one of the sides of the cantilever, not both. Failure to do so can result in minimal differential surface stress and insignificant cantilever deflection. To prevent that from happening, the inactive surface of the cantilever should be made passive by coating it with a material that does not interact with the analyte or other solution components. Typically in microcantilevers, one surface is made passive by salinization or grafting with inert polymer substances such as polyethylene glycol.

Functionalizing individual cantilevers is an array with different receptors for multiplexed detection is a challenge. For a single cantilever, the process of immobilization is performed simply by dipping the cantilever in a solution contains the receptor molecules. Although the procedure is simple and easy, it is not applicable to individually functionalize a cantilever in an array. Cantilever arrays are useful in multiplexed detection where a specifically functionalized individual cantilever detects a specific analyte molecule in a mixture. In general, cantilevers are operated in a differential mode where a chemically or biologically inert cantilever serves as a reference. Reference cantilevers are important since a typical cantilever is sensitive to many environmental factors, such as flow rate, mechanical vibrations, temperature, pH, etc. Many methods are currently under development to functionalize individual cantilevers in an array without affecting the neighboring ones. One of these techniques includes cantilever insertion into dimensionally matched capillary arrays containing specific receptors. Techniques based on inkjet printing are also under development. Other approaches that have been used recently include photolithographic approach, liquid drop dispensing tools, and microcontact printing.

Microcantilever as Chemical and Biological Sensors

Microcantilever sensors continue to find applications in the fields of chemistry and biomedical sciences. In recent years, cantilever biosensors have broadened their applications to include diagnostics. They have been used to detect chemical agents, volatile compounds, heavy metals, and toxic industrial gases [32]. However, specificity in detection has been a challenge. To obtain high selectivity, the cantilever has to be coated with a thin layer of materials that can interact specifically to the target analytes. Coating the cantilever with a thin layer of certain metals allows a semiselective sensing of certain toxic gases. A gold-coating layer, for instance, is used to detect mercury and thiol impurities [32]. Likewise, a palladium thin layer coating allows a semiselective detection of hydrogen [32]. Water vapor can also be sensed using a layer of hydrophilic polymers such as polyvinyl alcohol, carboxymethyl cellulose, or polyvinylpyrrolidone [32].



Functionalized microcantilevers have also been used to detect several toxic organic compounds such as organophosphorus compounds, dichlorodiphenyltrichloroethane (DDT), endocrine-disrupting chemicals (EDCs), hydrofluoric acid (HF), and others [32]. Microcantilevers have also been demonstrated to detect toxic heavy metals generated in water from polluted soil and ground water. Ion-specific, self-assembled monolayers (SAMs) immobilized on the cantilever surface provide selectivity. Microcantilevers are also used as an electrode in an electrochemical cell for use in the detection of metal ions. Many exciting applications of microcantilever chemical sensors with high sensitivity and selectivity are currently being demonstrated. However, simultaneous detection of multiple analytes is still in its infancy. Cantilever arrays functionalized with unique selective layers provide a real possibility of achieving this goal.

The microcantilever deflection-based sensing technique has drawn substantial attention as a biosensor platform due to its simplicity, sensitivity, and label-free detection, as well as its ability for real-time, in situ monitoring. Unlike the resonance frequency-based approach, cantilever bending is not significantly affected by the liquid medium. As biological sensing devices, microcantilever applications have included studying antigen–antibody interactions [33]; DNA hybridizations [20]; detection of superbugs such as pathogenic bacteria, fungus, and viruses; and, most recently, the monitoring and detection of cancer biomarkers and gene transmutations [2, 12]. Observations that multiple DNA hybridizations and antigen–antibody interactions can collectively produce a nanomechanical motion in a cantilever make the platform suitable for developing sensors based on DNA [34]. Several studies have shown the applicability of using cantilever sensors to detect DNA hybridizations and mismatching [21, 35, 36]. The detection is simply based on the interaction of immobilized DNA probes (oligonucleotides) with complementary DNA strands in solutions. The process also requires reference cantilevers functionalized with negative oligonucleotides that do not match the target DNA strands. It has been demonstrated that the cantilever biosensors offer interesting possibilities for label-free detection of biomolecules such as proteins and enzymes and carbohydrates based on nanomechanical motion [37]. Recent advances in cantilever technology developments have shown the ability of microcantilevers to detect a number of pathogenic microorganisms and cancer biomarkers. A large number of published works show the capability of cantilever technologies to detect bacterial cells at very low concentrations in different samples. For example, a report by *Mutharasan et al*. showed the capability of a piezoelectric-excited millimeter cantilever (PEMC) functionalized with a virulent gene stx2 to detect *E. coli O157:H7 (EC)* in both buffer and proteinous sample at very low concentrations of the bacteria ($\sim$700 cell mL^{-1}) and without any sample pretreatment steps [38]. Recently *Huber F et al.* showed a gold standard assay for detecting the BRAF gene mutation using an array of microcantilever sensors [2]. The BRAF gene mutation is a characteristic indication of malignant melanoma, the deadliest form of skin cancer. This study indicated the applicability of cantilever assays to distinguish between mutated cell lines and wild-type cell lines and gives hope for the system to be used for real-time cancer detection. Furthermore, in our unpublished results, a microcantilever sensor array functionalized with cancer-specific peptides was found to bend specifically to cancer cells over a wide range of concentrations as a result of a peptide–receptor interaction. As shown in Fig. 2, the bending response due to cancer cell adsorption was higher than that due to normal cells.

An ideal sensing device should meet a number of specific criteria such as exceptional sensitivity, specificity, and time-independent functionality for real-time monitoring. Microcantilever sensors offer the possibility of highly sensitive, real-time detection, and cost-effective analysis assays that can be used for multiplexed detection with no need for extrinsic labels. Thus far, the microcantilever array platform has shown significant progress toward becoming an advanced sensing tool for chemical and biological detection. The cantilever platform has proven to be very effective, ultrasensitive, and a time-saving tool which can potentially be used as a diagnostic device in the near future.

Challenges

Despite enormous advances over the past decade in the development of cantilever sensors, the transition from laboratory sensing to the outside world has been slow. There are many potential reasons behind this slow transition. Chemical sensing of small molecules has been limited by the challenge of selectivity. Even in array-based cantilever sensing, achieving selectivity in detection has been a challenge. Efforts are underway to develop selective interfaces in order to enhance selectivity. For microcantilever-based biosensors, the main challenge has been reproducibility. Reproducibility is affected by several factors

Microcantilever Chemical and Biological Sensors, Fig. 2 (**a**) Real-time detection of breast cancer cell lines using microcantilever functionalized with a cancer-specific peptide. Significant deflection of the cantilever as a result of interaction of the immobilized peptide with a specific receptor over expressed on the outer membrane of cancer cells. (**b**) Microcantilever bends as a function of time for different concentrations of breast cancer cell line. Microcantilever bending increases as the concentration of the cells increases, indicating a linear scaled relationship. The control experiment, where normal cells are spiked, indicates specificity of peptide binding to the cancer cell membrane receptor

which need to be resolved. Finding the ideal recognition molecule or binding receptor which can selectively and specifically capture the target analyte is still missing. Despite the fact that coating cantilevers with semiselective receptors such as antibodies, nucleic acid probes, or targeting peptides have significantly enhanced cantilever detection sensitivity and selectivity, the challenges remain in the sense that the ideal selective ligand is not available yet. Though selectivity can be achieved to some extent by coating the cantilevers with semiselective receptors, the issue of immobilizing the receptors without hampering its specificity and sensitivity is still under development. Reliable receptor immobilization techniques on an individual cantilever in an array in a reproducible manner still need to be developed. Furthermore, cantilevers can be affected by the variation of the environmental parameters such as temperature, humidity, and flow rate. In general, although a common-mode rejection approach using reference cantilevers may provide sufficient protection from changes in the environmental factors, more work is required. Systematic investigations are also needed to understand the side effects of the fluid delivery systems to enhance reproducibility.

Conclusion

Although a number of obstacles remain to be resolved, the microcantilever sensor platform offers a viable approach with high-sensitivity, high-throughput, and multiplexed detection capabilities. Development of sensors capable of determining several analytes simultaneously with proper sensitivity, accuracy, and real-time detection would lead to an ideal sensing tool in product analysis, environmental monitoring, clinical diagnostics, and biomedical point of care. So far, the instantaneous determination of multiple analytes in real time has been a great challenge in clinical diagnosis. However, recent developments in microcantilever technologies are paving the way toward real-time monitoring in complex samples with high sensitivity and selectivity using miniature handheld devices.

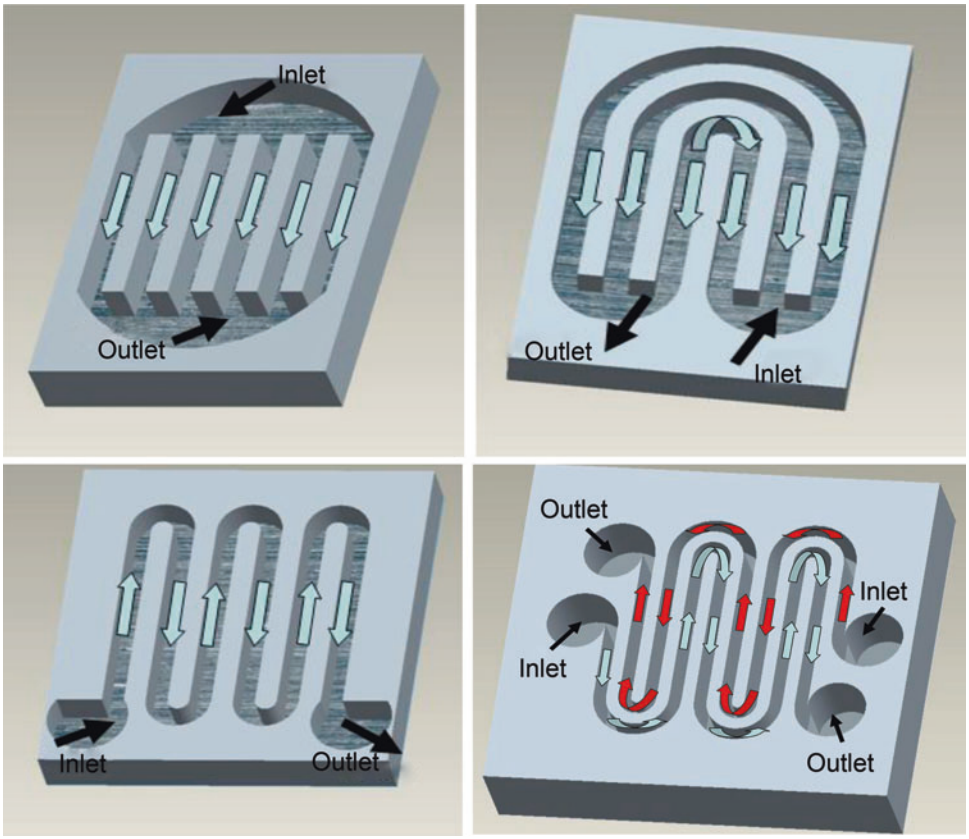
Definitions

Microchannel, heat sink, thermal management, slip flow, pressure head, viscous dissipation, heat transfer rate, heat transfer coefficient, Pareto frontier.

Introduction

The cooling of electronic components is one of the main barriers to developing faster, smaller, and more reliable systems. Heat removal, or *thermal management*, is critical to achieving higher data processing speeds, particularly for large-scale computers such as data centers. Because of the growing trend of assembling increasing numbers of electronic chips on a single module and multiple modules on a single board, higher power densities are encountered at both the chip and module levels. Similarly, the number of devices at chip level has increased from thousands to several millions, while the average chip size has reduced from a few millimeters to a few microns, making the thermal management problem even more challenging [1–3]. Emphasis has been placed on improving the reliability and performance of electronic devices by means of appropriate cooling techniques. As a consequence, several cooling arrangements are currently being used in the industry, of particular interest being air and



liquid cooling. The heat transfer modes associated with air cooling are largely natural, forced, and mixed convection [4]. Liquid cooling can be direct or indirect, the former being the result of physical contact between the coolant and the heat sources [5]. Convection and boiling are the most commonly used heat transfer modes in both types of liquid cooling. Though air cooling is still widely used due to availability, low cost, easy maintenance, and simple design, high heat flux inputs require liquid cooling, which has thus been increasing in popularity, particularly for high-performance and rapid response electronic systems. The system design is largely dominated by the temperature constraints, which are generally quite severe. For this purpose, it is desirable to remove the energy dissipated by the electronic components efficiently and at minimum cost.

Over the last few decades, substantial work has been done on the thermal management of electronics systems, considering new systems and devices, with increasing diversity, complexity, performance, and reliability. The challenges posed by continued reduction in physical size, while the number of processors over a given area has continued to increase, have been met by a wide variety of solutions based on air and liquid cooling. This has resulted in a phenomenal increase in our capacity to achieve a wide range of operations in computation, monitoring, and control, with fairly compact systems [6, 7]. However, as the power densities have increased, reaching into hundreds of W/cm^2 and placing stringent demands on the *heat removal* systems, the use of *microchannel* flows for heat removal has become important to remove excessive heat and control the temperature for every component to ensure reliable performance and prevent any failure or malfunction. Microchannels are generally in the range of 10–200 μm, with respect to the diameter or width, with larger channels, in the range 1–5 mm, often being termed as minichannels.

A *heat sink* is typically a finned structure in contact with the heat source and is applied as an effective arrangement to remove the heat dissipated by electronic chips and other devices. It is cooled largely by forced convection with forced air cooling the most commonly used approach for heat removal. The power dissipated by the electronic chips is conducted through the substrate of the heat sink to the fins and to the coolant. However, these are typically at lower heat flux inputs, up to a maximum of around 0.2 W/cm^2 for air and around 1 W/cm^2 for liquids.

For higher heat fluxes, ranging from 1 to 10^2 W/cm^2 and beyond, air or liquid flow without phase change in microchannel heat sinks provides a promising thermal management arrangement. Heat fluxes as high as 10^3 W/cm^2 can also be addressed by single-phase liquid flow, though the pressures generally become unacceptably high due to the small microchannel diameters needed [8, 9]. Two-phase flow with boiling can then be employed for still higher heat fluxes, without the large pressures encountered in single-phase flow, though the complexity of the system further increases due to the different flow regimes, instability, and complex nature of the basic phenomena [10]. Compared with two-phase flow, single-phase cooling systems have less complicated physical phenomena, and the system is easier to control.

Electronic cooling problems are generally considered for steady-state conditions. Assuming the power to the electronic chip is constant, and after the electronic system is turned on and kept running for a long period of time, the temperatures of the electronic chips and cooling devices are expected to reach steady state. When the thermal equilibrium condition is met, the rates of heat being transferred by conduction, convection, and radiation all remain constant. For a large electronic system, it may take a very long operation time before the system becomes steady. It may only need several minutes for a cooling system of a small electronic chip to become thermally developed. However, the maximum heat load usually appears at the start or the shutdown. In order to control the temperature and prevent the electronics from overheating, it is important to study the transient heat transfer behavior for electronic cooling as well [11]. Thus the thermal management problems involve both steady and time-dependent situations.

Microchannel Flows as Heat Sinks, Fig. 1 Different configurations of microchannels in heat sinks

The thermal performance of the heat sink can be changed by varying the configuration of the microchannels. Several configurations are sketched in Fig. 1, indicating straight, U-shaped, and serpentine microchannels with different inlets and outlets [12]. Similarly, the flow may be split into different channels, such as a tree-shaped structure or fork-shaped flow structure, in order to improve the heat removal effectiveness. This breaks up the generally developed flow in the microchannel and increases the heat transfer coefficient. Multiple microchannel heat sinks with a bifurcation along the flow direction may also be considered, so that the bifurcation can augment the heat transfer coefficient due to flow separation, secondary flow, and restarting of the boundary layer, if the system is designed properly. The aim of the design in all these cases is to enhance the heat transfer without unacceptably high pressures. Modeling and experiments have been used to provide the basic information and characteristics that may be used to design and optimize the heat removal system so that the energy dissipated is removed without exceeding the temperature constraints at any point within the electronic components. Such points, where excessive temperature may arise, are known as hot spots, and the cooling system must ensure that unacceptable localized temperature levels do not arise.

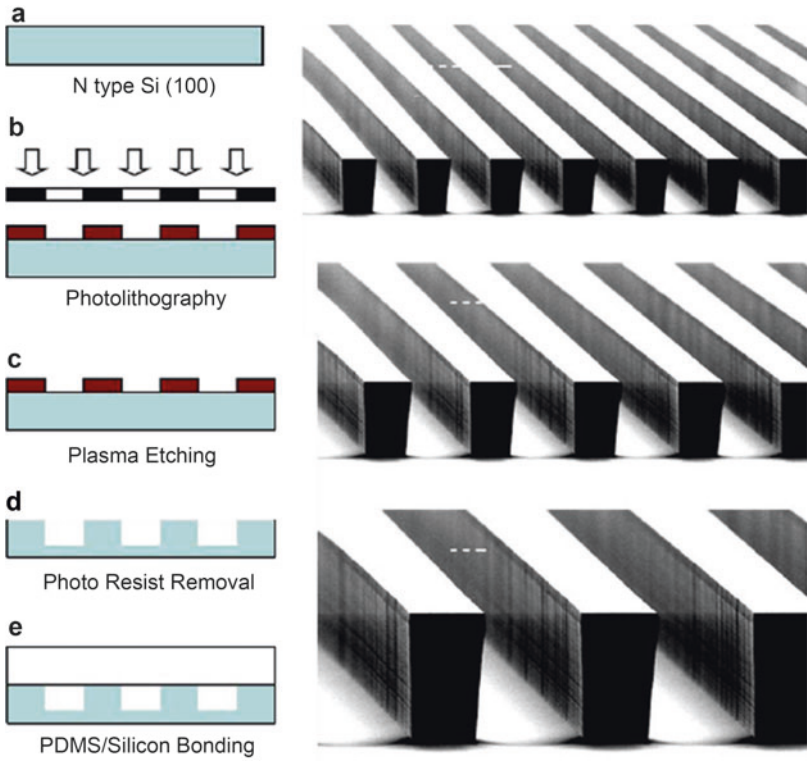
Basic Considerations

As mentioned in the preceding, many important basic and practical considerations arise and must be addressed for a satisfactory deployment of microchannel heat sinks. Some of the most important ones are

1. Heat transfer rates achieved by the microchannel flow
2. Pressure head needed for the flow to achieve desired heat transfer characteristics
3. Predictability, reliability, control, and stability of the flow
4. Required characteristics of the coolant
5. Fabrication and cost of the microchannel heat sink
6. Space and weight constraints

The focus is often placed on the heat transfer rates, or heat transfer coefficients, attained by the use of microchannels. The heat transfer enhancement, over traditional heat sinks, can be substantial, making this an attractive heat removal approach. However, as the flow rate increases to obtain higher heat transfer rates, the pressure head needed to maintain the flow also increases and can, in many cases, make the use of microchannel heat sinks difficult, if not impossible. Also, if the channel dimensions are reduced for heat transfer enhancement, the pressures increase as D^{-4}, where D is the diameter, limiting this approach for increased heat transfer rates. Similarly, fabrication costs, flow instabilities, particularly in phase change systems, and coolant leakage at high pressures can limit the advantages offered by microchannel heat sinks in terms of higher heat transfer rates.

There are several methods for fabricating microchannels. Among these are wet etching and plasma etching. In wet etching, a potassium hydroxide solution can be used as etchant for the silicon-based microchannels. Since KOH is an orientation-dependent etchant, which means it attacks {111} much more slowly than other planes, P type {110} oriented single-crystal silicon can be masked with nitride and oxide together. A magnetic stirrer is used to agitate the solution to eliminate the difference in rate of etching from the top to the bottom of the solution. Isopropanol is added to the KOH solution to improve the uniformity, though it also reduces the etch rate.



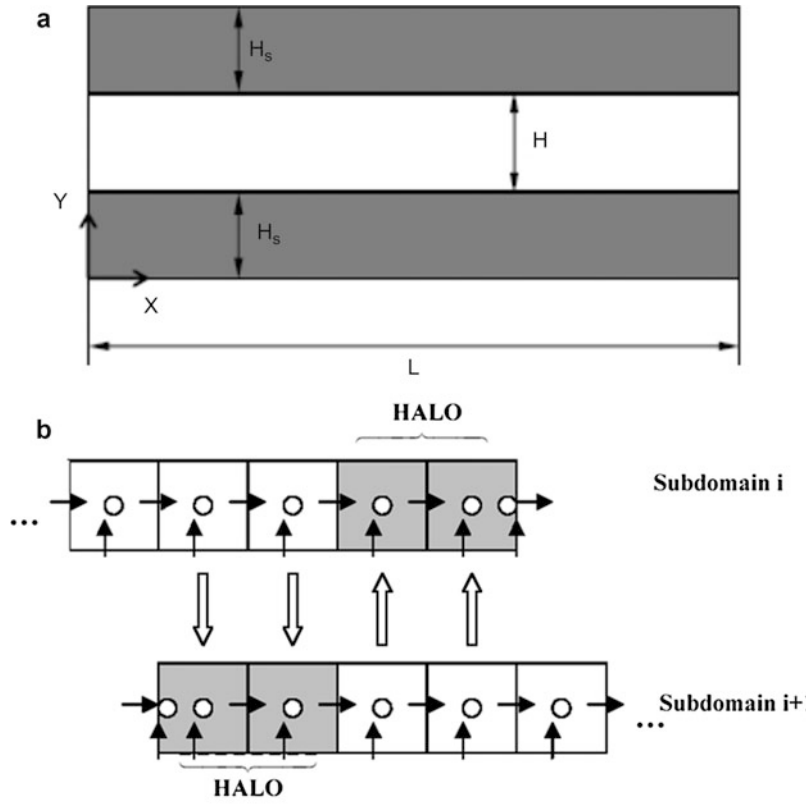
Plasma, or dry, etching yields better microchannel uniformity compared to that obtained with wet etching. The wafer preparation for this technique is easier since it involves fewer steps compared with wet etching. The basic approach and the resulting microchannels are shown in Fig. 2. Typically, the heat sinks are fabricated on a silicon wafer and are integral with the heat-dissipating electronic chip. Bare silicon is cleaned to remove organic contamination, followed by a HF dip to remove native oxide on the silicon in order to reduce undercutting of the photoresist mask. After conventional ultraviolet (UV) photolithography defines the microchannel pattern on the photoresist, the silicon wafer is etched to create microchannels by a state-of-the-art inductively coupled plasma etcher. It is optimized for deep Si etching using Bosch process. This is a high–aspect ratio etching technology, which employs a protection film deposition after the isotropic etching. A Polydimethylsiloxane (PDMS) layer may be bonded on top of the silicon microchannels to create fluid passages, as shown in Fig. 1. Openings can then be made for fluid connections [12].

Heat transfer and fluid flow in a single microchannel tube or a channel for use in a heat sink have been studied by several researchers experimentally and numerically, particularly for liquids without phase change as the coolant for chip cooling. As mentioned earlier, the heat transfer rate, or heat transfer coefficient, with the microchannel flow and the pressures needed for the flow are of particular interest. In addition, the thermal response is of interest in time-dependent problems. The overall size and weight are also of practical interest.

Modeling and Simulation

The modeling of microchannel sinks involves several important aspects because of the relative small size of the channels, generally being between a few microns to about 200 μm in diameter or width, and typically macro, or engineering, scale of the electronic components and systems. Thus, the modeling must consider

1. Flow and heat transfer at the microscale level
2. Conjugate heat transfer in the solid material surrounding the microchannels



Microchannel Flows as Heat Sinks,
Fig. 2 Fabrication and packaging process for microchannel heat sinks, using plasma etching

3. Multiscale modeling, considering widely different length scales of interest
4. Time-dependent and steady-state situations

Many mathematical and numerical models have been developed to study microchannel flow and heat transfer systems. The majority of these use the Navier–Stokes equations to analyze the microscale fluid flow, as also in other microchannel flows such as those in *microfluidics*. However, unlike the macroscale channels, the ratio of fin width to channel width, as well as the ratio of the silicon substrate thickness to the channel depth, are not negligible as in microscale systems. Because of changes in temperature and pressure, the influence of the variable thermal properties on heat transfer and flow in microchannel heat sinks can not generally be neglected. Combined conduction and convection, or conjugate heat transfer, needs to be considered for numerical analysis in this case.

Let us first consider the modeling at microscale length dimensions. As an example, consider the numerical simulation of pressure-driven nitrogen slip flow in long microchannels, with conjugate heat transfer at the walls of the heat removal system under a uniform heat flux wall boundary condition, as sketched in Fig. 3. For the gas phase, the two-dimensional momentum and energy equations are solved, considering variable properties, rarefaction, which could give rise to velocity slip at the walls, thermal creep and temperature jump, compressibility, and viscous dissipation. Slip conditions generally do not arise for liquid flow. However, the basic concerns with pressure, viscous dissipation, variable properties, and fine grids to capture the flow and heat transfer characteristics have to be considered at these length scales. For conduction in the solid region, which forms the bounding materials around the channel and which are much larger in dimensions, the energy equation is solved with variable properties [13]. Thus, the two regions need to be treated with different approaches, resulting in multiscale modeling and simulation. In many practical systems, transport processes in

Microchannel Flows as Heat Sinks, Fig. 3 Nitrogen flow in a microchannel, with conjugate transport at the walls. (**a**) Sketch of the microchannel; (**b**) domain decomposition for parallel computation of the microchannel flow, as well as of heat transfer

various components or subsystems are at different length or time scales. Then the governing equations for different components are different. Figure 3b shows a domain decomposition approach that may be used for parallelization of the computation process, as well as for different components or subsystems. This allows an efficient approach to the modeling of microchannel heat sinks.

Due to rarefaction, discontinuous boundary conditions are applied at the wall, particularly for gases, depending on the Knudsen number, $Kn = \lambda/H$, where λ is the mean free path of the gas molecules and H is the channel height for two-dimensional rectangular channels or diameter for circular channels, as shown in Fig. 3. Continuum flow is assumed if the Knudsen number $Kn \leq 10^{-3}$; slip flow occurs when $10^{-3} \leq Kn \leq 10^{-1}$; transition flow arises $10^{-1} \leq Kn \leq 10$; and free molecular flow arises for $Kn > 10$. These aspects have been considered in detail in the literature [9]. For isothermal walls, the wall boundary conditions are at $y = 0$ and $y = H$, $u = \frac{2-\sigma_v}{\sigma_v}\lambda\left(\frac{\partial u}{\partial n}\right)_w + \frac{3}{4}\frac{\mu}{\rho T}\left(\frac{\partial T}{\partial x}\right)_w$, $v = 0$,

$$T_g - T_w = \frac{2-\sigma_T}{\sigma_T}\left[\frac{2\gamma}{\gamma+1}\right]\frac{\lambda}{\mathrm{Pr}}\left(\frac{\partial T}{\partial n}\right)_w$$

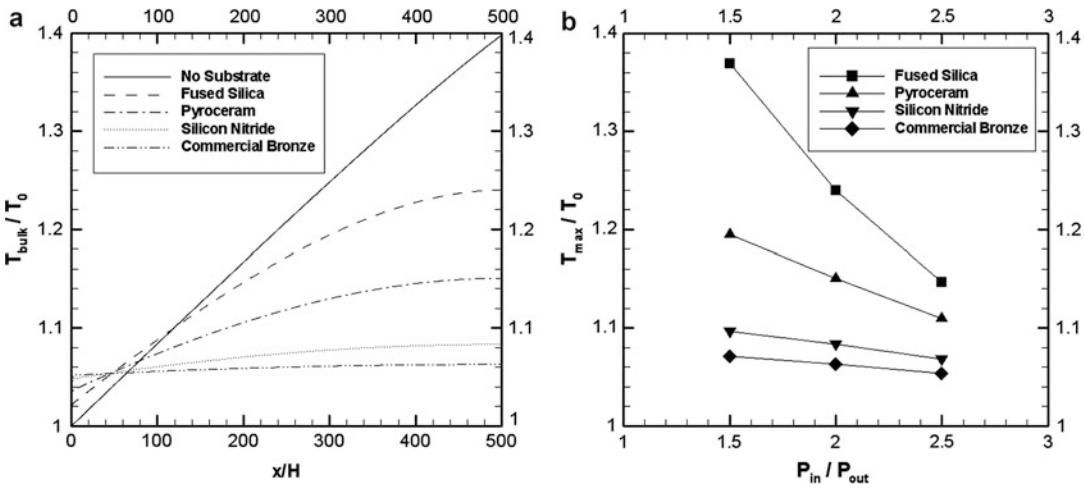
The coefficients σ_v and σ_T depend on properties of the gas and on the surface characteristics. They represent the fraction of the molecule's tangential momentum and energy loss through the interactions with the solid wall, respectively. The substrates, or solid regions, are governed by the energy equation,

$$c_p\left[\frac{\partial \rho T}{\partial t} + \frac{\partial \rho u T}{\partial x} + \frac{\partial \rho v T}{\partial y}\right] = \left[\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)\right]$$

The boundary conditions in the y-direction, i.e., at $y = 0$ and $y = 2H_s + H$, are given by $q = q_w$,

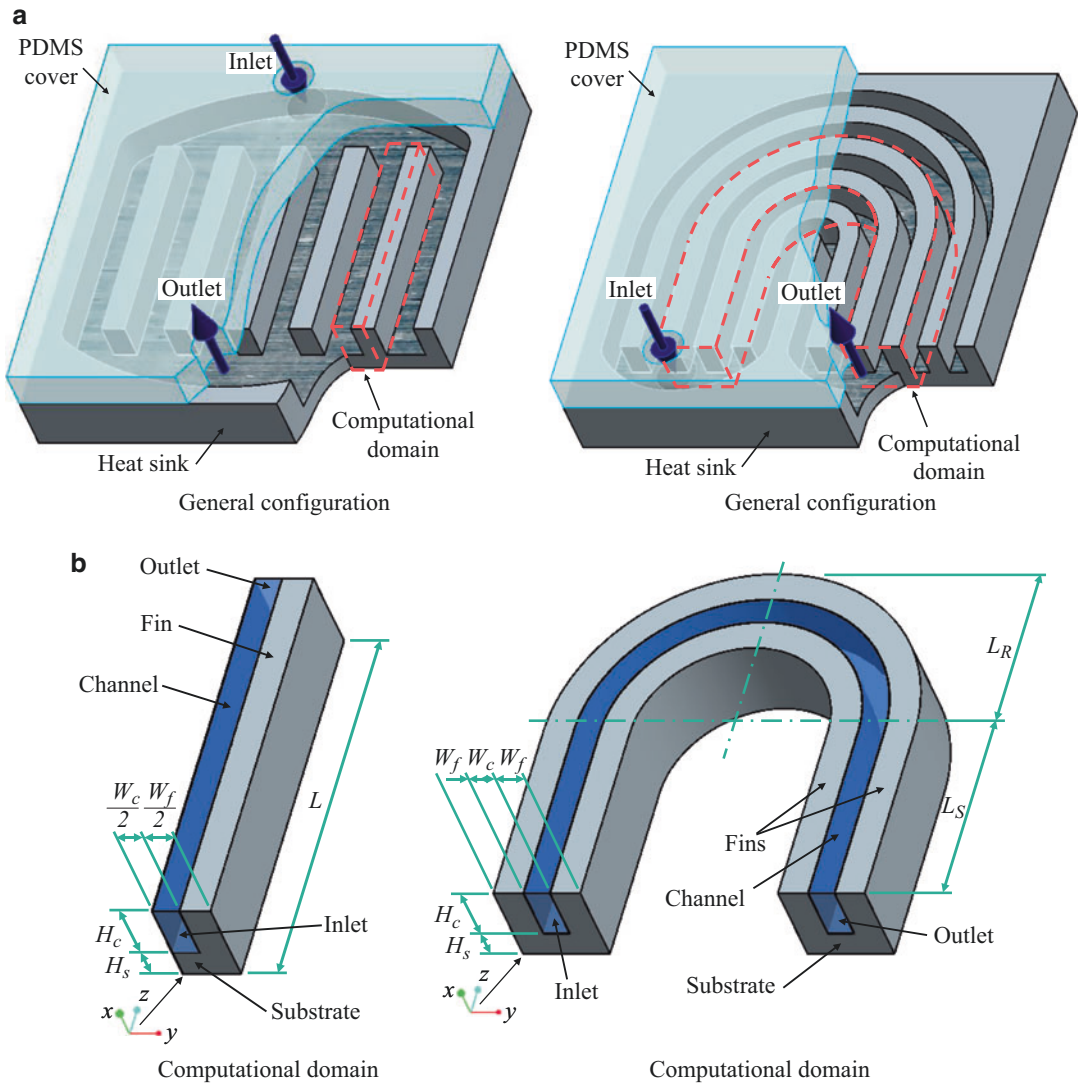
q being the heat flux and subscript w referring to the wall. The temperature at the fluid–solid interface is obtained by solving the two equations

$$T_g - T_w = \frac{2-\sigma_T}{\sigma_T}\left[\frac{2\gamma}{\gamma+1}\right]\frac{\lambda}{\mathrm{Pr}}\left(\frac{\partial T}{\partial n}\right)_w$$



$$q_g = q_s$$

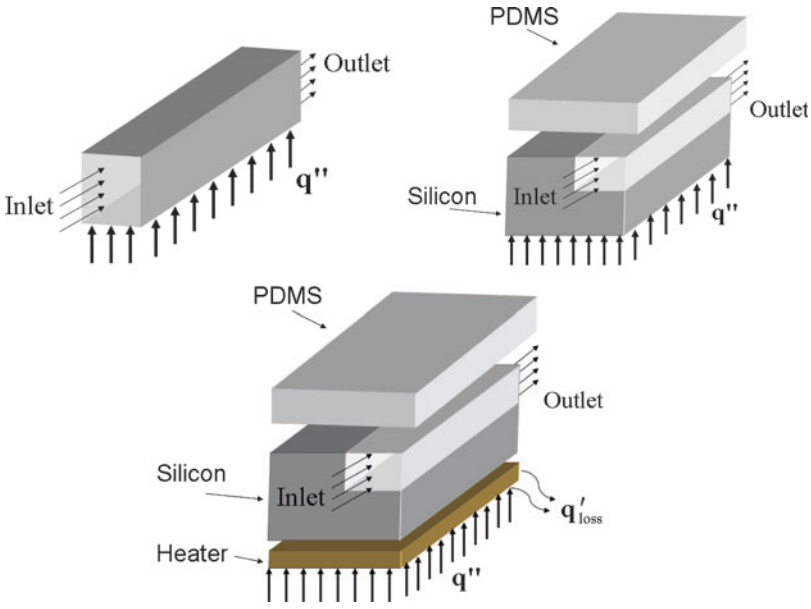
where the first equation is due to the temperature jump at the gas-solid interface and the second one arises from the fact that energy cannot be stored in the interface. Here, u, v are the velocity components along x and y coordinates, T is the temperature, subscripts g and w refer to the gas and wall, respectively, Pr is the Prandtl number, c_p is the specific heat at constant pressure, k is thermal conductivity, γ is the ratio of the two specific heats, and t is time.



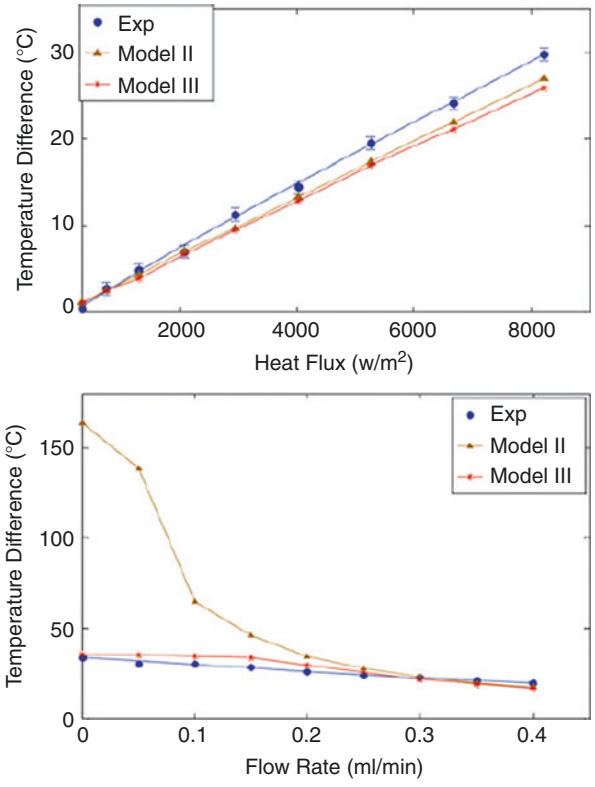
Typical results for different substrate materials including commercial bronze, silicon nitride, pyroceram, and fused silica are shown in Fig. 4. The effects of axial conduction in the substrate, material thermal conductivity, and substrate thickness are clearly seen. The substrate axial conduction leads to a flatter bulk temperature profile along the channel, lower maximum temperature, and lower Nusselt number. The effect of substrate thickness on the conjugate heat transfer is very similar to that of the substrate thermal conductivity. Thus, in terms of axial thermal resistance, the increase in substrate thickness has the same effect as that caused by an increase in its thermal conductivity [14].

The same concepts may be used for typical heat sinks using microchannel flows. Figure 5 shows close-up sketches of straight and U-shaped microchannels. The substrate is shown along with the microchannels. Thus, two different configurations are considered. Microchannel heat sinks with bent, or curved, regions can be compared with straight channels with the same surface area. Numerical models need to be validated by experimental data. For each configuration, the influence of geometry and flow rate on the heat transfer and fluid flow characteristics of the system are determined. The validated numerical models can then be used for the system design and optimization. The objective is to minimize the thermal resistance and maintain the chip temperature below a given limit of about 90 °C with an acceptable pumping power.

It is computationally intensive to model the whole microchannel heat sink with multiple microchannels. Therefore, simplified domains are used in the model, as shown. For the straight



Microchannel Flows as Heat Sinks, Fig. 4 Conjugate transport in microchannels. (**a**) Bulk temperature distribution for different wall materials; (**b**) maximum temperature as a function of the imposed pressure difference for different wall materials



Microchannel Flows as Heat Sinks, Fig. 5 Sketch of straight and U-shaped microchannel heat sinks, along with their computational domains

microchannel heat sink, because the entire heat sink is geometrical symmetric, only half of the fin and the microchannel need to be considered. It is noted that for the U-shaped channels, the length of each channel is different. The channels located at the center of the heat sink are chosen for study as the computational domain because there is relatively little heat transfer to the sides at the center. It was shown that the channel at the center and one on either side are adequate to model the entire sink consisting of 40 microchannels or more.

Figure 6 shows straight channels embedded in a solid substrate and in contact with a heat source. Three different models are shown, from the simplest focusing on the microchannel to a complete model that considers the heater and the substrate along with the microchannel. The validity of any given model is based on comparisons with experimental data. Figure 7 shows such comparisons, indicating that an accurate modeling demands that the entire region consisting of the heater, microchannel, and substrate be considered, rather

Microchannel Flows as Heat Sinks, Fig. 6 Different mathematical and computational models for a straight microchannel heat sink

Microchannel Flows as Heat Sinks, Fig. 7 Comparison between numerical results and experimental data for the systems shown in Fig. 6

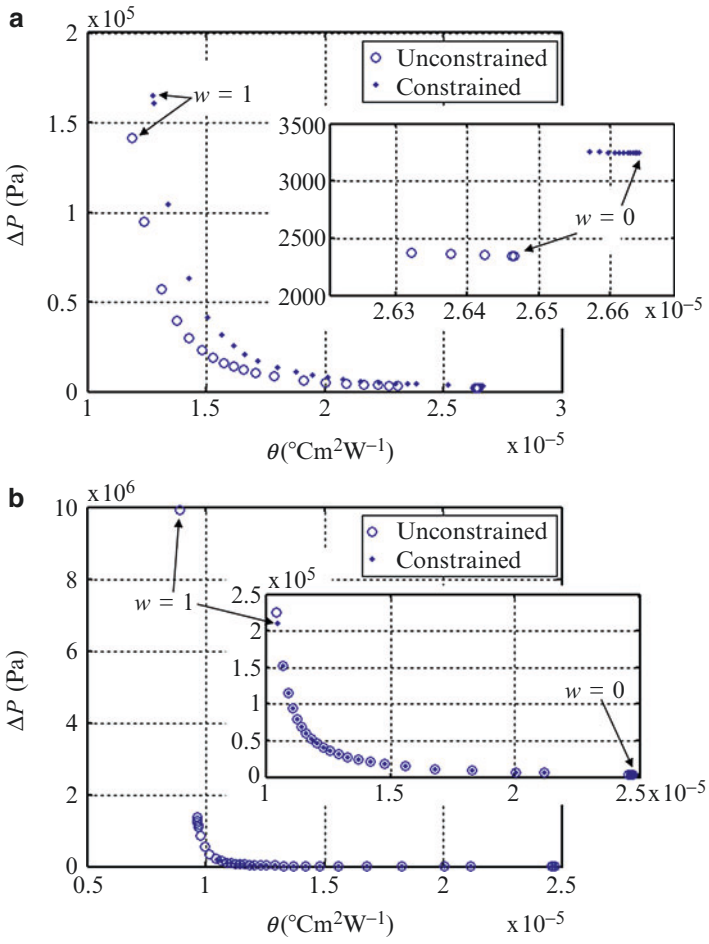
than using approximations for the boundary conditions. This simple example illustrates the simulation of different components with different length scales, followed by coupling of the results to obtain the model for the entire system. These comparisons are shown for steady operation, and similar conclusions are obtained from time-dependent investigations. This is particularly

valuable in electronic thermal management systems.

Many studies have focused on heat transfer enhancement in microchannel flows. The effects of increased flow rate and reduced diameter, or width, on enhancing the heat transfer coefficient have been mentioned earlier. The effect of the flow configuration on both transient and steady operation was discussed. Other techniques considered include enhancement features, such as pin fins, surface roughness, flow disruption, and cross mixing, in the microchannels [15]. Many such techniques disrupt the developed flow in the channel and thus lead to higher heat transfer coefficients. Appropriate fabrication techniques have also been developed for such enhancement features.

Thermal Management and Optimization

A wide range of microchannel heat sinks have been considered in the literature [16, 17] from both fundamental and applied viewpoints. Even though considerable information exists on the flow and heat transfer in microchannels for single- as well as multiphase flow, arising from boiling [18, 19], the implementation of these results into practical systems for heat removal, or thermal management, involves several other important considerations, as mentioned earlier. Certainly, among the most important is the pressure needed for the flow and the consequent concerns with pressure supply, leakage, dimensions, and cost. These must be addressed for a feasible or optimal design. In addition, cost for fabrication and maintenance of the sink, as well as the weight and volume, are important considerations. The coolant, particularly its cost, availability, dielectric and thermal properties, and interaction with materials being used is also an important consideration. Air is generally the most convenient and inexpensive coolant, though obviously the heat transfer rates are much lower than those for liquids. Liquids such as water, refrigerants R123 and R134a, fluorocarbons, and Ethylene or Propylene Glycol/water mixtures are commonly used in cooling systems for electronics. Phase change results in very high heat transfer coefficients, but the stability, control, and maintenance of the system poses its own challenges.



Increase in heat transfer rates for single-phase coolants can thus be achieved in many ways, as mentioned earlier. Some of these are

Reducing diameter of the microchannels
Higher flow rates of the coolant
Varying the flow configuration of the channels
Building heat transfer enhancement structures in the microchannels
Adding nanoparticles in the fluid, i.e., use of nanofluids
Increasing the roughness of the surface in the channel

There are several other approaches for heat transfer enhancement that have been considered in the literature. However, in most cases the price paid for the increase in heat removal is in terms of the increased pressure head needed for the flow.

Therefore, it is critical to optimize the microchannel heat sink with respect to these two main objectives – heat transfer rate, or heat transfer coefficient, and the pressure head. Using both numerical simulation and experiments, as outlined earlier, a large database can be built up to characterize the behavior of microchannel heat sinks. From these results, an optimization of the system, with respect to the heat transfer rate and the pressure, can be undertaken. Even though this is clearly a critical consideration in the design and use of heat sinks, it has not received as much attention as is necessary. Much of the focus has been on raising the heat transfer rates and thus removing the heat generated by the electronic components at very high heat flux levels [20].

The data obtained from experiments and numerical simulation can be used to generate response curves and simplified models that can form the basis for optimization. Since there are two parameters to be minimized or maximized, namely, the heat transfer coefficient h and the pressure Δp, it is a multiobjective optimization problem. For isothermal surfaces, we can consider the heat transfer coefficient h, and for uniform heat flux surfaces, we may consider the temperature θ. Thus, the response surfaces focus on h, or θ, and Δp, with

Microchannel Flows as Heat Sinks, Fig. 8 Pareto frontiers for multiobjective optimization of straight microchannel heat sinks for (**a**) a given number of microchannels, $N = 56$, and (**b**) varying number of microchannels

the above variables, such as channel diameter and flow rate, as the independent variables. It is possible to combine θ and Δp into a composite objective function, with different weights, and thus optimize a single objective function. But this is arbitrary and does not represent the actual problem. However, by following well-established multiobjective techniques, one could generate *Pareto frontiers* that represent the dominant solutions for the two objective functions.

Figure 8 presents some of such multiobjective optimization results in terms of Pareto frontiers. Different weights may be assigned to the two objective functions, depending on the particular system under consideration. Each point on the frontier is the result of substantial calculation to obtain the dominant solutions. Then the designer can choose a point on the curve as the desired solution. As one lowers the temperature θ in a uniform heat flux situation, or increases h in an isothermal case, the pressure needed increases. Thus, the price paid in terms of pressure for increasing the heat transfer rate is clearly seen, and the choice is made in terms of acceptable pressure and the associated components needed to supply this pressure. There may be constraints on the design, or it may be unconstrained in terms of size, weight, etc. Cost can also be built into the deliberations for an optimum.

Summary

Considerable challenges arise for heat removal from high-performance and large electronic systems due to increased energy dissipated

per unit area. Microchannel heat sinks provide a valuable means to remove these high inputs without exceeding the stringent temperature limitations generally placed on electronic components. Consequently, recent years have seen an explosion of research and development in this area, starting with air cooling and then moving on to single-phase liquid cooling and to liquids with phase change for very high heat flux levels. By using a variety of heat transfer enhancement techniques, it has been clearly demonstrated that heat flux levels as high as 1000 W/cm^2 and beyond can be handled by using liquid flow in microchannels with and without phase change. The focus has been largely on high heat transfer rates under steady conditions. However, a major problem is the increase in pressure needed for the flow and the associated concerns with delivering this pressure, leakage, and space and weight limitations. The stability, predictability, control, and maintenance of the heat removal system, particularly for phase-change methods, are also of concern. Finally, time-dependent problems are also of considerable interest for changing load and operating conditions, as well as for start-up and shutdown. Many of these aspects have been considered in the literature. Appropriate systems have been designed, optimized, and implemented, particularly for air and single-phase liquid flow. This is an active an important area of research and development with respect to electronic systems, which continue to grow in performance and versatility while reducing in the physical size. Thus the challenges posed to the heat removal systems are expected to increase and microchannel heat sinks suitably modified, designed, and optimized to meet challenges in years to come.

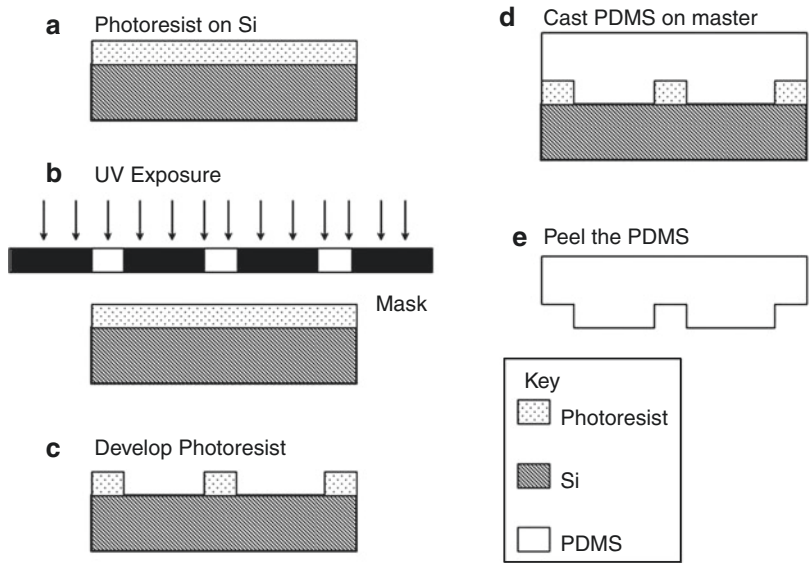
Definition

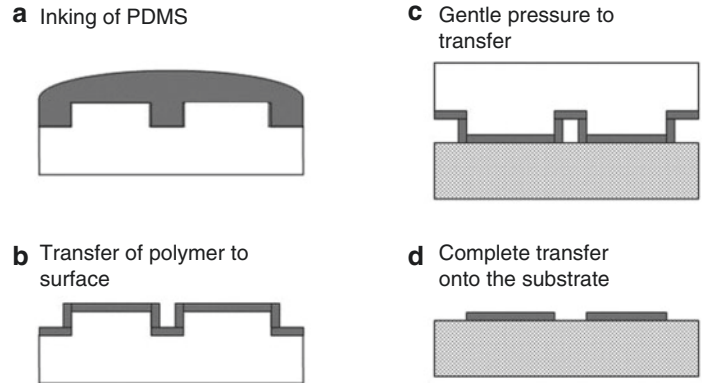
Microcontact printing is a method of transferring patterns of various materials such as polymers, proteins, nanoparticles, etc., onto another surface. Typically a polydimethylsiloxane (PDMS) stamp is dipped in a solution of a material that has to be patterned and is brought into contact with the surface. Transfer of micrometer (μm)/nanometer (nm)-size patterns is possible by this technique.

Overview of Microcontact Printing



Optical lithography is a fundamental step in microfabrication technology. Almost all integrated circuits are fabricated using a standard lithography process to achieve scalable manufacturing at low cost. However, this method has some shortcomings of compatibility issues, and it cannot be used for substrates that are not flat. Furthermore, the top-down lithography process cannot be easily integrated with labile biological systems because removal of photoresist from the polymers or proteins or quantum dot layer without damaging them would be challenging. Microcontact printing overcomes most of these shortcomings and can be used as a cost-effective alternative. The term soft lithography is coined from the fact that it is a method, which uses patterned elastomer or polymer as a stamp or a mold [1]. There are a number of elastomers that can be used for patterning surfaces. PDMS is a common elastomer used for soft lithography [1]. A number of stamps can be generated from one master mold, and each stamp can be used more than one time for a particular application.

Mold Preparation



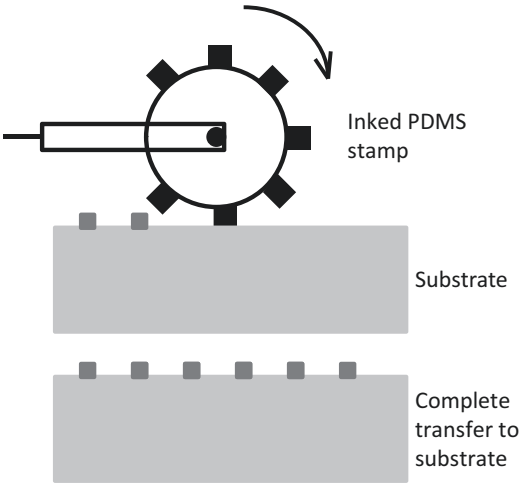
Elastomer molds are usually made with templates from silicon (Si) wafer called "master." First, a silicon master is patterned with high-aspect-ratio photoresist (SU8 or AZ 4562 or AZ 9260) or using deep reactive-ion etching (DRIE) of trenches on silicon substrate using standard semiconductor processing techniques [2]. A thin layer of photoresist is spin coated on a Si wafer. The resist is patterned by ultraviolet (UV) lithography via a mask. The resist is then developed to obtain the pattern onto the master. Polydimethylsiloxane (PDMS, Sylgard 184) is mixed with curing agent (10:1 ratio), degassed, poured onto the master, and degassed again. It is then allowed to cure at 70 °C for 30 min. The PDMS "stamp" is then removed from the master and cut into desired shape and size (Fig. 1). Patterned stamps should have the following properties: they should (a) be peeled off their mold without being damaged, (b) have the accurate replica pattern of their mold, (c) be soft enough to provide conformal contact with substrates, and (d) have patterns that are mechanically stable during inking and printing. To prevent the PDMS from sticking onto substrates, its surface is typically coated with Sigmacote (Sigma Aldrich) or exposed to CHF_3 gas. This would avoid the bonding of PDMS onto the substrate.

Printing Process

The polymer film to be patterned is picked using the PDMS stamp. During the stamping process, only the raised part of the stamp transfers the ink onto the substrate. The inked stamp is then inverted onto a substrate. A gentle pressure is applied for about 30 s such that the polymer transfers completely onto the substrate (Fig. 2). Pompe et al. [3] developed a typical inking method of PDMS stamps. A stamp-pad method was

Microcontact Printing, Fig. 1 Fabricating a PDMS mold (Adapted from Madou [2])

Microcontact Printing, Fig. 2 Microcontact printing of polymer onto a substrate (Adapted from Madou [2])

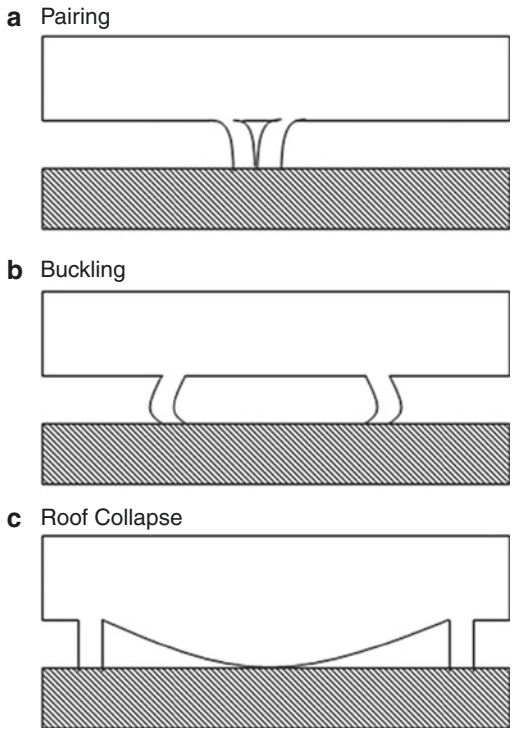


developed where the PDMS stamp was placed in contact with the ink and then the ink is transferred from the stamp to the substrate on the area of contact. This method reduces the swelling of the stamp and minimal absorption of the molecules on the surface after patterning [4]. Inking of the substrates with alkylthiols was also demonstrated by Pompe et al. [3]. The inked areas are self-passivating and have low interfacial tension that repels additional monolayers such that uniform self-assembled monolayers (SAM) are formed on the substrate. The SAM patterns act as localized barrier to wet etching. Sometimes certain conditions require microcontact printing of hydrophobic ink onto the substrate. Typically PDMS is hydrophobic in nature. To overcome this drawback, the PDMS was oxygen plasma treated or alternate polymer based on poly(ether-ether) was used. These inked stamps are patterned on flat substrates or functionalized substrates.

Microcontact printing is a stamping-based method for the transfer of molecules or polymers onto a surface [2]. The stamp is inked with the material or polymer to be transferred by inking techniques. These patterns when pressed against the substrate would selectively transfer the pattern onto the substrate. These elastomers have the capability to pattern on different topographies flat or curved [2]. Deformation of the polymer elastomer allows it to accommodate rough surface. This method is also used to make arrays of multiple units on a large area

simultaneously [5]. The capability of transferring patterns on to curved surfaces such as lens structures has been successfully demonstrated [6]. For surfaces with large radii of curvature, the deformation of the stamp allows for contact with the non-flat surface. For very small radii of curvature, the substrate can be rolled on top a flat elastomeric stamp. Another method which is especially suited to microcontact printing on large areas is "roller imprinting." A cylindrical rolling stamp [7] was inked, dried, and mounted on a roller. This setup was used for patterning surfaces up to 3 in. in diameter.

Recent developments in microcontact printing have focused on patterning with precise alignment. The basic printing process has been modified in various ways to achieve specific patterning goals. One such demonstrated method is vacuum-assisted microcontact printing. This method was demonstrated for patterning of functional materials with precise alignment. The elastomeric stamp was fabricated using double-exposure process to obtain different-height protrusions on the stamp. Printing pressure was applied using a pressure difference between the inside and outside of the stamp. Various materials like proteins and nanomaterials could be successively patterned on a large scale using this printing process [8].



Numerous elastomers have been developed for soft-lithography process. Some of them include polydimethylsiloxane, polyurethanes, polyamides, and phenol formaldehyde polymer. The most commonly used elastomer for soft lithography is PDMS. PDMS is a silicon-based organic polymer. It is flexible, inert, transparent, durable, nontoxic, and not flammable, has modifiable interfacial properties, and allows gas to pass through. PDMS is a liquid at room temperature but can be cured into solid by cross-linking. It is commercially available from Dow Corning, known as Sylgard 184. The master for microcontact printing is typically prepared by photolithography on silicon. The PDMS stamp is peeled from the master. Adhesion of PDMS onto the master substrate is observed in certain cases after peeling. These cause unnecessary contamination to the substrates. A number of methods have been developed to avoid the adhesion of PDMS. Passivation of silicon masters with hydrogen fluoride or treatment with sodium dodecyl sulfate [9] could overcome this issue.

Microcontact Printing, Fig. 3 Microcontact printing of polymer onto a substrate with a rolling stamp (Adapted from Qin et al. [7])

If an elastomeric stamp is too soft, it loses definition to replicate microstructures. Deformation of the stamp causes distorted patterns on the substrate. Stamp deformation can occur during the removal from the template and during contact of the stamp with the substrate. This limits the resolution of patterning. Deformations of the PDMS stamp occur when the aspect ratio is high, and buckling and lateral collapse of the PDMS features can occur. When the aspect ratio is low, roof collapse is possible for the PDMS. Typical deformations that have been observed are due to pairing, buckling, or roof collapse of the structure during contact with the surface. The phenomenon is attributed to the elastomeric nature of the stamp [2]. Figure 3 shows the deformation of such stamps. Thermal expansion of PDMS makes it difficult to get high accuracy across a large area. This limits the application of soft lithography in nanofabrication. Several methods have been proposed to overcome these problems such as developing new stamp materials, adjusting the aspect ratio of the features, and the use of composite stamps [10] (Fig. 4).

There are developments of harder polymers to achieve smaller sizes by increasing the stiffness of a stamp. Thermoplastic elastomers were

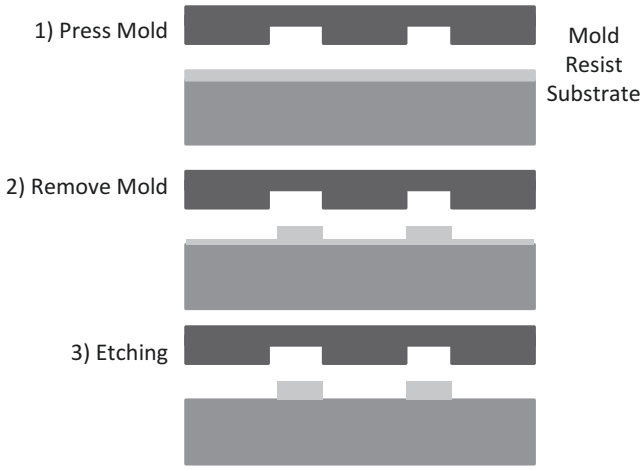
Microcontact Printing, Fig. 4 Deformation of the stamps (Adapted from Madou [2])

developed for printing thiols. They are typically polymers such as poly(styrene-b-butadiene-b-styrene) and poly(styrene-b-(ethylene-co-butylene)-b-styrene) that have been used as elastomers for printing. These new materials typically have better mechanical properties, and these materials have low chance to transfer of uncured polymer impurities. These elastomer stamps are produced in minutes, using hot embossing method. They have overcome the problem of residual monomers in the stamp material like PDMS.

Poly(ether-ester) elastomers were used as stamp materials to pattern proteins on surface using lower ink concentrations. The time for inking in these elastomers also is lower compared to PDMS elastomers [11]. PDMS has a tendency to expand on exposure to organic solvents. They tend to lose their conformal shape. UV curable stamps are based on functionalized prepolymer with acrylate groups for cross-linking and different monomeric modulators [12]. These have been used for printing 100-nm hexadecanethiol patterns on gold. These elastomers do not deform on exposure to organic solvents. By varying the modulator, the mechanical properties of the polyurethane acrylate stamp can be varied.

Composite stamps consist of two layers, a stiff layer supported by a flexible layer. Stamps used a thick, flexible 184 PDMS slab to support a thin, stiff *h*-PDMS underlayer. This was used to perform soft lithography to sub-100-nm features. The preparation of these stamps was developed by Schmid et al. for microcontact printing [13].

Key Research Findings



Microcontact printing method was first described in 1993 by Kumar and Whitesides [14]. The authors reported using a patterned stamp with hexadecanethiol as ink brought into contact with gold (Au)-coated surface. The hexadecanethiol molecules form a monolayer in the area of contact between the elastomeric stamp and an Au surface area.

This method was extended to numerous biomedical applications such as patterned cell culture and fabrication of microarrays for biosensor purposes. The range of inking molecules can be extended from alkylsilanes and alkylthiols to various higher molecular weight organic molecules. Printing has been performed for proteins DNA and using Langmuir-Blodgett films [15].

Patterning in Semiconductor Processing

Lithography Masks

Microcontact printing has been used to imprint self-assembled monolayers (SAM) as masks for gold etching in Si semiconductor processes. PDMS stamp was inked with an SAM solution consisting of ethanol or diethyl ether and dried with nitrogen flow [14]. The inked stamp was brought in soft contact with the substrate typically consisting of a thin Au layer. The SAM layers transferred on to the Au surface upon removal of the stamps were used as a mask layer for the gold. These masks could then be used in two ways: (i) patterning of gold using wet etching and [16]

Microcontact Printing, Fig. 5 Nanoimprint lithography demonstrated in Ref. [18]

(ii) as a mask for selective deposition of metals by CVD and electroplating [17].

Nanoimprint Lithography

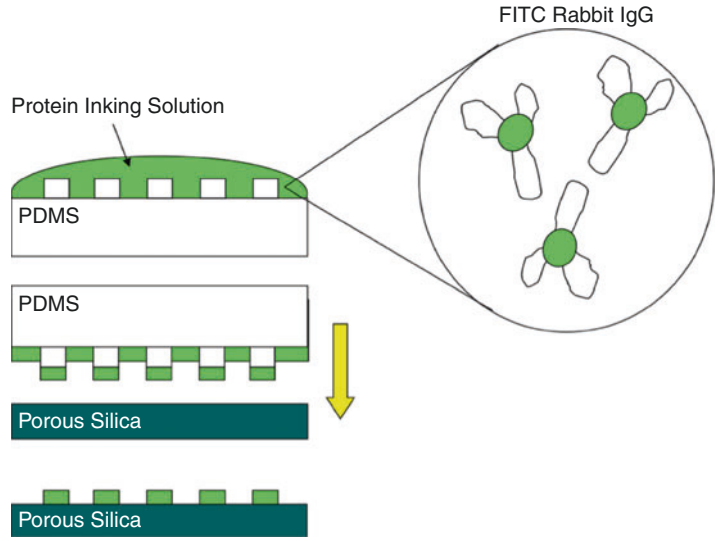
In this technique, a mold with nanostructures on its surface was pressed into a thin resist cast on a substrate. Upon removal of the mold, the nanostructures on the mold were duplicated on the resist film. This was followed by an anisotropic etching process to remove the residual film. This simple two-step process is shown in Fig. 5 [18].

Gratings and Integrated Optics

Wang et al. showed the use of nanoimprint lithography in the fabrication of a double-layer metal grating as a broadband waveguide polarizer. A transverse magnetic (TM)-pass waveguide polarizer was fabricated with SiN as top layer, SiO_2, and silicon. Nanoimprint lithography, lift-off, and dry etching were used to fabricate the waveguide stripes [19]. Seekamp et al. also investigated the printing of polymer films in polymer waveguides and demonstrated the feasibility of printing a polymer waveguide with micrometer features combined with photonic crystals [20].

Lithographic Molding

Lithographic molding technique has been demonstrated to achieve patterns for use in basic microcontact printing technique. In this technique a normal microcontact printing step was followed by an anisotropic etch into the Si substrate with patterned Au as a mask. The resulting grooves and pyramids were molded again into three-dimensional PDMS stamps used for microcontact printing of smaller patterns. Applied pressure was also finely tuned to control the pattern sizes [21].



Patterning of Biomaterials

Patterning of Self-Assembled Monolayers

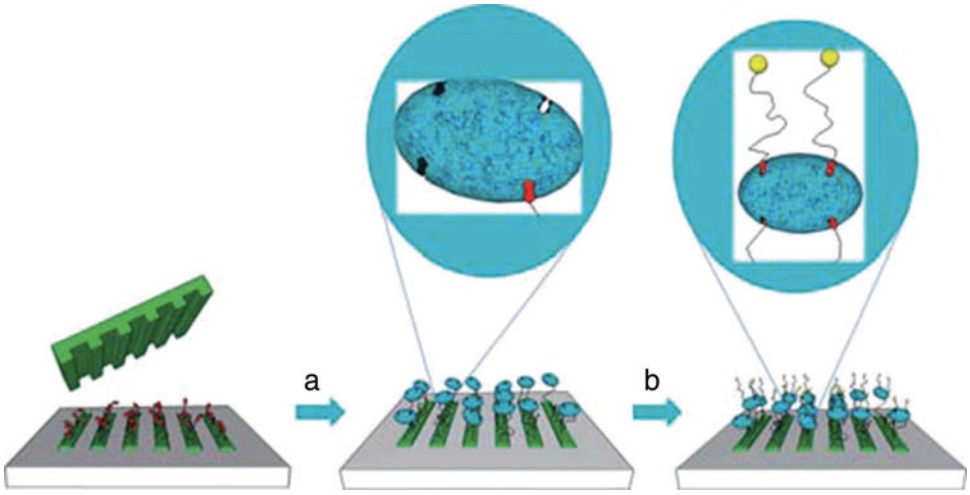
Microcontact printing provides the patterning of self-assembled monolayers (SAM). Many studies involving the patterning of proteins and cells using microcontact printing have used self-assembled monolayers of alkanethiols on gold. This technique is useful to pattern surfaces with multiple SAMs on a single substrate. After a SAM of an alkanethiol is patterned on a gold-coated surface by microcontact printing, the substrate is again dipped into a solution of a second alkanethiol to form a different SAM pattern. This technique has been used to make multiple islands of SAMs that adsorb proteins and cells and which are surrounded by SAMs that resist the adsorption of biomaterial. Patterns of SAMs have been used to study the adhesion of mammalian cells on surfaces [22].

Patterning of Proteins

For applications in biomedical engineering, microcontact printing has been a developed method for printing patterns of biomolecules

Microcontact Printing, Fig. 6 Microcontact printing of proteins onto porous silica substrate demonstrated in Ref. [25]

onto flat surfaces with high resolution (100 nm) [15]. Microcontact printing method was extended to the transfer of protein molecules by Bernard et al. in 2000 [23]. Microcontact printing can be used to pattern multiple proteins on the same substrate, thus allowing for biological assays with greater diagnostic power.



A number of possible applications would be enabled if the same surface could be patterned with proteins of different types [15]. The large-scale (>50 μm) patterning of therapeutic proteins is key to the efficient design, characterization, and production of biologics for cost-effective, high-throughput, and point-of-care detection and analysis system. The hydrophobic nature of PDMS causes the denaturation and irreversible adsorption of the proteins. This can be overcome by surface treatment of the PDMS stamps (chemical modification or oxygen plasma) or by selecting a polar polymer to prepare the stamp.

Bernard et al. used microcontact printing to pattern proteins with a resolution of 1 μm [23]. They found that a monolayer of immunoglobulin antibody (IgG) adsorbed to the PDMS stamp during the inking process and that it was transferred fully after only a few seconds of contact with glass or polystyrene. The stamped immunoglobulins were recognized by secondary antibodies that were attached to them. Kwak et al. demonstrated the patterning of protein cytochrome c using microcontact printing onto gold substrates [24].

Blinka et al. demonstrated an efficient method for protein deposition and adsorption on porous silica substrates in specific patterns using microcontact printing [25]. Relative to the chemically modified and untreated substrates, the porous silica-coated substrates provided for thicker and more uniform protein layers. Protein layers observed on the chemically treated substrates that were thinner than the smallest dimension of the stamped protein were observed, indicating denaturation (Fig. 6).

Indirect Patterning of Proteins

A simple method to place multiple proteins on a surface is to print one that binds another in solution. This has been done to pattern proteins by using biotin-avidin interaction. The avidin is first printed onto the polymeric substrate containing biotin. Avidin binds to biotin moiety with great affinity. Addition of a solution of biotin-conjugated protein leads to the capture of that protein by the available biotin-binding sites on avidin and consequently the patterning of that protein. This can be used to pattern cells [26]. A variation of this method was performed by patterning the biotinylated substrate with avidin molecules. A carboxylic acid group was coated on the polymer surface and activated using

Microcontact Printing, Fig. 7 Printing biotin ligands onto a substrate and subsequent binding of streptavidin or avidin which can be used to direct the immobilization of further biotinylated molecules (Reprinted with copyright permission from Polymer Chemistry [26])

pentafluorophenol. A stamp with the biotin amine group was brought into contact with the surface (Fig. 7).

Patterning of DNA Molecules

Patterning of biomolecules onto solid substrates is needed to provide controlled biocompatible surfaces [15]. Microcontact printing techniques have been used to deposit DNA molecules with chemically modified PDMS surface. Chemical modification enabled the DNA molecules to stick to the PDMS surface. Bernard and his coworkers demonstrated the microcontact printing of DNA on APTES-modified substrates. They demonstrated that microcontact printing has advantages compared to microspotting of DNA solutions. This method has an advantage of reduction in time and DNA material. Spotted stamps can be used to print multiple arrays as well as homogeneous sensitive dots. An alternate method for developing arrays of DNA was developed with different fragments of loading flat stamps with a multichannel microfluidic network. Binding of complementary nucleotides was observed [27].

Indirect Patterning of Cells

Patterning methods have been translated to better understanding on how cells interact with substrates. Islands of printed SAMs promote the adsorption of extracellular matrix protein. Singhvi et al. observed the cells preferentially bound to printed islands and spread to conform their size and shape [28]. Microcontact printing has helped to study the effect of the cell shape on cell division on cell axis orientation. The cell division axis orientation was determined by the adhesion pattern rather than the shape of the cell. Stamping was used to study growth in endothelial and epithelial monolayers. In this study, it was observed that the proliferation was highest in cells at the monolayer edges. These studies demonstrate that the patterning of cells can lead to new findings not possible with traditional cell culture techniques.

Microcontact Printing for Patterning of Nanoparticles, Nanorods, and Nanotubes

Nanoparticles

Patterning colloidal nanoparticle films enables patterning of desired conformations and good quality deposition of quantum dots on substrates. Quantum dot films cannot be patterned using standard process. They are inhomogeneous in nature that contains a semiconductor material and organic capping. Lithography processes are unsuitable because removal of photoresist from

the quantum dot layer would be an issue. Conventional shadow mask technique to deposit particles is undesirable. The quality of quantum dot in solution would degrade using this method. Typically deposition of uniform quantum dots on substrates is critical for creating quantum dot-based light-emitting diode systems.

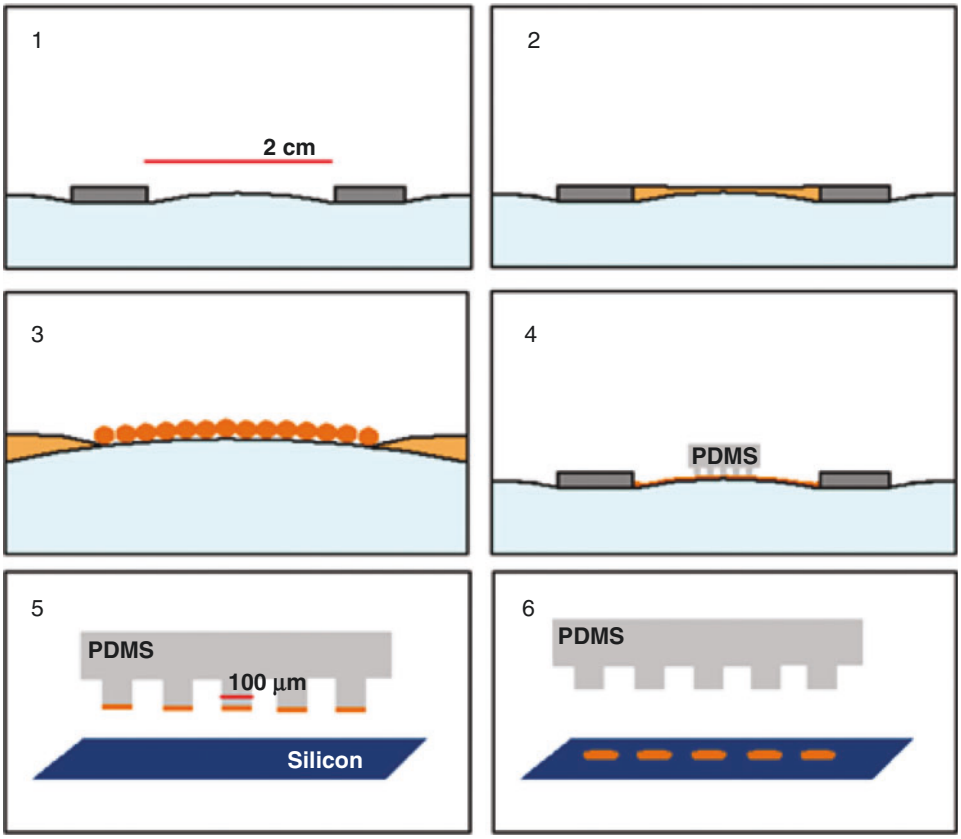
Microcontact printing has also been developed as an alternate method for depositing nanoparticles by a number of research groups. This method has been used to deposit close packed monolayer of alkanethiol Au nanoparticles [29]. Microcontact printing has also been used for deposition of $(Cd_xZn_{1-x}Se)$ $Cd_yZn_{1-y}S$ core: shell on 4,40-N,N0-diphenylcarbazole (CBP) for fabrication of green diodes [30]. Typically in microcontact, a polydimethylsiloxane (PDMS) stamp is inked with the polymer and is then transferred onto a solid substrate. PDMS substrates can make conformal contact with surfaces over large areas, enabling patterning in nanometer- or micrometer-size features.

As mentioned previously, PDMS stamps have a drawback that it swells on absorption of organic solvents. This changes the shape and dimensions of the protrusions that have to be patterned. Ethanol has minimal swelling effect on the polymer compared to other organic solvents like pentanes or xylenes. They have adverse effect of swelling of the elastomer. PDMS can easily melt in contact with nonpolar solvents such as toluene and chloroform solutions. Microcontact printing is limited to polar inks that are soluble in ethanol.

In this case, conformal deposition becomes difficult. A number of methods have been developed to overcome this problem. Coe-Sullivan et al. have a modified surface of PDMS stamp by coating chemical vapor-deposited parylene-C layer [31]. The particles are then spin coated onto the PDMS surface that is microcontact printed onto the hard substrate. This enables uniform deposition of multilayer of quantum dots onto the substrates. The process has a drawback such that spin coating consumes a large amount of particles; thereby, significant amount of the material is wasted.

Gopal et al. have developed a modified microcontact printing method, where the nanoparticles resuspended in hexane are used in a modified Langmuir-Schaffer technique to create thin films of particles which are picked up by PDMS stamps and microcontact printed on silicon substrates [32]. The quantum dot thin film is self-assembled onto water surface by dispensing a hydrophobic suspension of CdSe/ZnS quantum dots in a solvent mixture of 1,2-dichloroethane and hexane. The uniform film is picked up by the PDMS stamps with nano-/micro-features and deposited onto silicon substrate (Fig. 8).

Hoshino et al. have demonstrated the deposition of quantum dots onto three-dimensional substrates with great accuracy. This method enables accurate control on the deposition of the number of particles of quantum dots onto a substrate [33].



Nanorods and Nanotubes

Murphy et al. developed a method for patterning the growth of Au nanorods. This was achieved by microcontact printing gold nanoparticle seeds on a hard surface. The nanorods then have grown from the seed via seed-mediated growth process [34]. Jen et al. developed a method to deposit 1-D n-type hexaazatrinaphthylene (HATNA) via microcontact printing. The nanostructures were spin coated onto the PDMS stamp; this was allowed to form conformal contact with SiO_2/Si substrate for about 30 s. The nanostructures were transferred onto the surface without additional surface modifications.

A similar method was described for patterning ZnO nanostructures [35]: selective growth of ordered single-crystal ZnO nanostructures based on the microcontact printing of nanocrystal seeding films. The pattern transfer quality is dependent on the concentration of the inking solution. Subsequently, the growth of the ZnO nanowires was carried out with different chemical components.

Future Research Directions

Microcontact printing has the advantage that it can be carried out outside a clean room

Microcontact Printing, Fig. 8 Principle of quantum dot film self-assembly and microcontact printing. These steps illustrate total film self-assembly and microcontact printing process: 1. Convex water surface is created. 2. Colloidal suspension is poured – first, hydrophobic solvent holding the nanoparticles begins to evaporate. Because of the convex water surface, the layer in the center of the surface is the thinnest, exposing the nanoparticles and forming solvent menisci between individual exposed nanoparticles. 3. Film is self-assembled – as the solvent evaporates in the thinnest region, an attractive capillary immersion force collects the nanoparticles into densely packed hexagonal arrays called the nucleus. 4. Hydrophobic PDMS stamp is lowered to pick up the nanoparticle film. 5. PDMS stamp is lowered onto flat substrate. 6. Film is stamped onto the flat substrate [32]

environment conveniently, rapidly, and inexpensively for large features (>50 µm) for cell biology. Through various techniques, it can be scaled down to the nano-regime where it can pattern delicate inorganic nanostructures and biological molecules on a number of materials [36].

This technique is extremely flexible in terms of shapes of the patterns obtained. It enables to control the chemistry at a molecular level. Studies have been developed at reducing some of the drawbacks of microcontact printing such as stamp deformation and ink-transfer issues. Advances allow the technique to be applicable in many fields and enhance the capability of patterning nanometer-scale structures with high precision. The characteristics of microcontact printing can enable new techniques for micro-nanoscale patterning and for new generation of microdevices for biology.

Probe technology of scanning probe microscopy (SPM) and its fabrication technology

Definition

Microfabricated microprobes play important roles in SPM. In order to develop functional and high sensitive microprobes, microfabrication technology is employed.

Overview

Scanning Probe Microscopy

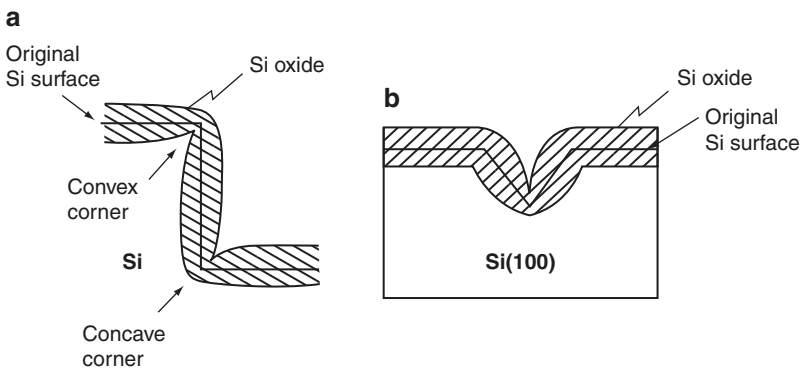
Scanning probe microscopy (SPM) families have been widely used as an essential tool in nanoscience, with applications in an increasing range of fields such as nanomaterials, bioscience, and nanoengineering [1]. Also the environment, in which dynamic SPM is required, is broadening, allowing applications such as nanolithography [2, 3], nano-oxidation [4, 5], controlled deposition of molecules [6, 7], fabrication of nanotransistors [8, 9], and molecular modification [10, 11].

Among them, operating SPM in a liquid now became a powerful measurement instrument to investigate the morphology of biological samples with a high resolution in their native solutions [12]. Also near-field scanning optical microscopy (NSOM) has been extensively studied owing to the capabilities for optical imaging with a spatial resolution beyond the diffraction limit of the light [1]. NSOM is also used as an essential tool for observing biological samples, including cells and viruses. In addition, NSOM can be applied to fluorescence imaging and spectroscopy. In these technologies, microfabricated probes play an important role. In this chapter, microprobe technology based on microfabrication will be presented.

Overview

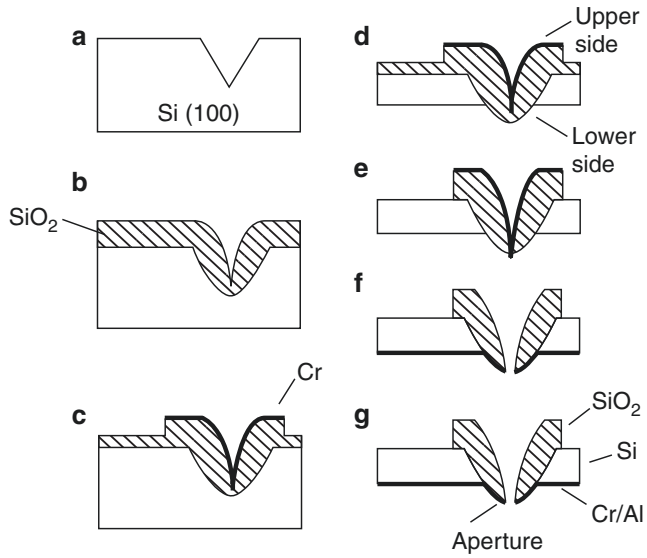
Microfabrication of Near-Field Probe

Together with scanning tunneling microscopy (STM) and atomic force microscopy (AFM), the near-field scanning optical microscopy (NSOM) has been extensively studied owing to the capabilities for optical imaging with a spatial resolution beyond the diffraction limit of the light [13], for subwavelength photolithography [14], and for next generation optical data storage [15] using the near-field light. The most crucial part of the NSOM probe is a subwavelength size aperture at the apex of the tip. Tapered optical fiber probes are most widely used for the NSOM. However, the shape of the tip and the size of the metallic aperture of the fiber tip are not reproducible. The opening angle of the fiber tip is small. Therefore, most of the light is absorbed at the metal wall, which leads to a low optical transmission efficiency. Moreover, it is very difficult to fabricate the fiber NSOM probe in a mass production.



Contrarily, Si based NSOM probe can be easily fabricated in a batch process. It is very easy to combine the microfabricated NSOM probe with a well-developed AFM as an AFM/NSOM probelight [16–20]. In order to create the aperture at the apex of the tip, several technological approaches have been developed such as coating and selective etching metal at the apex of a Si_3N_4 tip [17], metal molding with an aperture at the pyramidal etched pit on Si cantilever [18], or creating the metallic aperture at the apex of a metal-coated SiO_2 tip on Si cantilever by field evaporation [19], etc. However, until recently, a simple method to fabricate the aperture for the NSOM probe with a high reproducibility for mass production has not yet been achieved. Here, a simple method using a low temperature oxidation and selective etching technique to fabricate the aperture for the NSOM probe is presented [21].

Basic Methodology

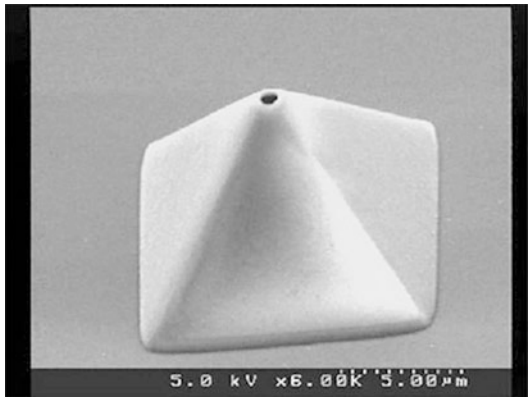


Fabrication and Evaluation of Apertured Probe for NSOM

It is known that the thickness of the oxide grown at a low temperature at convex and concave corners is thinner than that at a flat surface of Si due to the compressive stress at the corner structures (see Fig. 1) [22]. The nonuniform Si oxidation effect at the convex corner has been used for fabrication of Si conical sharp tips for the AFM or field emitter [23]. The anomaly of the thermal oxidation at the concave corner has been used to produce a mold for fabrication of a Si_3N_4 pyramidal sharp tip for the AFM [24].

On the other approach, the nonuniform Si oxidation effect at the pyramidal etched pit is useful to fabricate the aperture for the NSOM probe using the LOSE technique. The process flow of the LOSE technique is schematically shown in Fig. 2. First, a Si(100) wafer is thermally oxidized. Next, photolithography is done to define the mask patterns for etching SiO_2. In order to make a perfect pyramidal etched pit (i.e., four (111) surfaces should intersect at a point), electron beam lithography is used to define square patterns on a resist as a mask for SiO_2 opening. Consecutively, pyramidal etched pits and structure of cantilevers are formed by anisotropic etching of Si in a tetramethyl ammonium hydroxide (TMAH) (step a). Next, a SiO_2 film is thermally grown by wet oxidation at 950 °C with a thickness of about 1 μm (step b). Subsequently, a chromium (Cr) film of about 100 nm in thickness is sputtered and lifted

Microfabricated Probe Technology,
Fig. 1 Schematic of Si thermal oxidation at the convex and concave corner (**a**) and at the pyramidal etched pit formed on Si (100) (**b**)



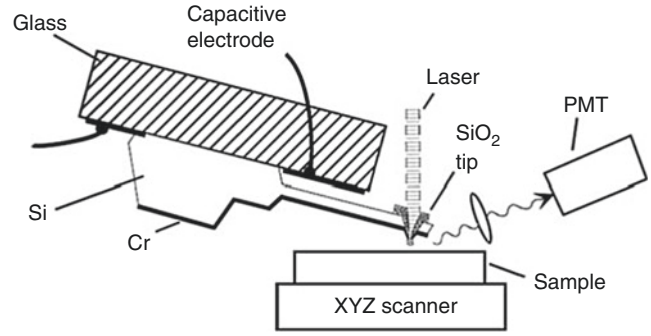
Microfabricated Probe Technology,
Fig. 2 Process flow for making aperture at the apex of the SiO_2 tip on Si cantilever for NSOM probe using the LOSE technique

off to form a protective pattern on the upper side of the oxidized pit (step c). Using this Cr pattern as a mask, the SiO_2 of about 0.6 μm in thickness is partly etched as shown in step c. The remaining oxide of about 0.4 μm in thickness is needed for following steps. Next, the Si wafer is anisotropically etched from the back side in the TMAH solution until forming Si cantilever with the SiO_2 tip at the end of the cantilever (step d). The wafer is then dipped into the buffered-HF (50 % HF:40 % NH_4F, 9 cm^3:100 cm^3) (BHF) solution for selective etching SiO_2 until the Cr protrusion comes in sight (step e). At this step, only exterior wall of the SiO_2 tip is etched in the BHF while the interior wall is protected by the Cr pattern. Finally, a metal film (Cr, or Cr-Al) is entirely deposited onto the back side of the cantilever to form an opaque layer (step g).

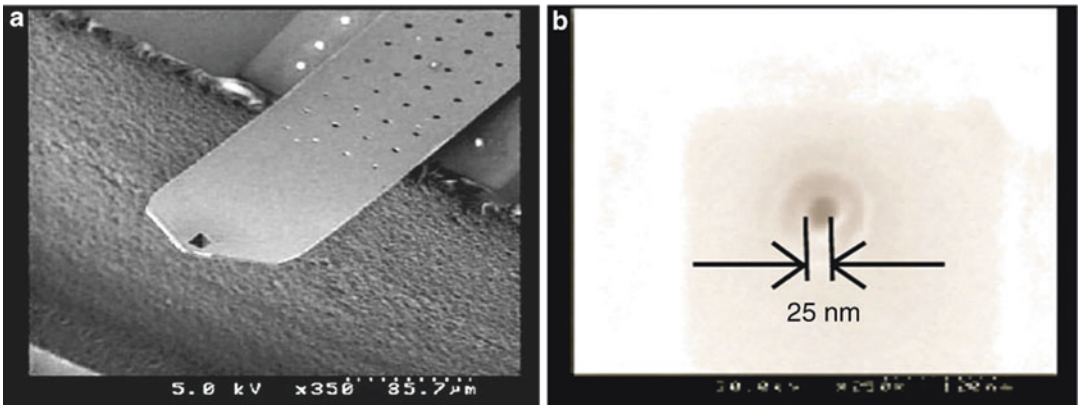
SEM image of a typical Cr-coated SiO_2 tip with an aperture of about 500 nm diameter fabricated using this technique is shown in Fig. 3. It can be seen that the aperture is exactly situated at the apex of the tip. Pinholes were not found on the sidewall of the tip. The aperture sizes ranging from 10 to 500 nm are experimentally achieved, corresponding to etching time ranging from 3 to 6 min in BHF at 36 °C. In the case of the patterning window for the etched pit in step a, Fig. 2 is not very square or round, double apertures can be formed. The distance between the centers of two apertures is as same as the discrepancy of the opening window of the etch pit. Normally, the size of the two apertures in the double one is identical. In order to fabricate only one small aperture, the patterning window for the etch pit

should be done by electron beam lithography. The fabricated silicon probe is bonded with a glass substrate on which an electrode is formed. A three-dimensional view of the probe is shown in Fig. 4. The probe consists of the Si cantilever with the tiny aperture at the apex of the tip and the opposed parallel electrode with a narrow gap for capacitance detection or electrostatic actuation. SEM images of the fabricated probe and a close-up view of the aperture with about 25 nm diameter are shown in Fig. 5a, b.

The throughput of several apertures is evaluated and plotted, as shown in Fig. 6. It can be seen that the throughput of the probe is several orders of magnitude higher than that of the conventional optical fibers [25, 26] and is also higher than other published throughput on the micromachined tips [27, 28]. The reason for that is the opaque layer is formed on the outer curvature of the SiO_2 tip. The outer curvature angle of the thermal SiO_2 tip grown at low temperature at the apex area is very large (almost flat in the area of about $0.5 \times 0.5\ \mu m^2$ at the apex or nearly equal to the curvature of a sphere with about 1 μm diameter). Therefore, the cut-off effect (if the incident light passes through a narrow wave-guide of which diameter is less than the wavelength, absorption of light by the coated metal results in decrease the throughput) is minimized. The laser light beam is come to the aperture without any strong losses inside the tip. Furthermore, the aperture is empty, i.e., there is no glass core as in the optical fiber tip; therefore, many modes of the light can reach to the aperture and transmit through the aperture as same as transmitting through a small aperture in a perfectly conducting plane [29]. However, for the aperture smaller than 100 nm, the throughput is still drastically decreased.



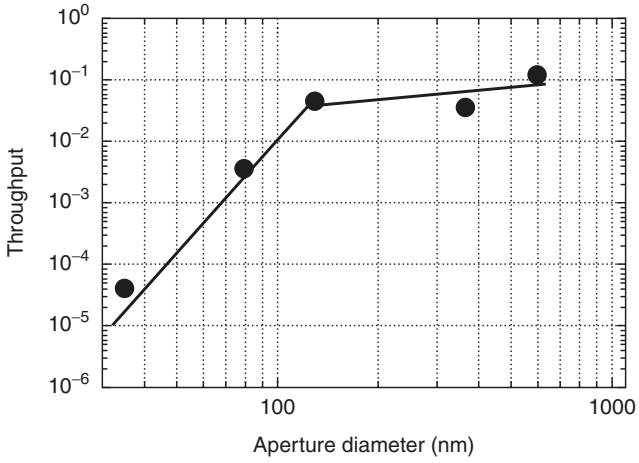
Microfabricated Probe Technology, Fig. 3 SEM image of a typical NSOM tip with an aperture of about 500 nm



Key Research Findings

Imaging Using the Apertured Probe

Imaging with fabricated aperture probe is demonstrated. A simple characterization setup for the fabricated NSOM/AFM probe in contact and tapping modes is used. The fabricated NSOM/AFM probe is mounted on the AFM stage. The tip-sample distance is kept constant by utilizing the well-developed AFM technique. The light beam from the laser diode of 780 nm wavelength, 2 mW power is directly focused on the tip area using an objective lens. A part of the incident light is reflected by the tip's walls and is monitored by a deflection detector. The near-field light passing



Microfabricated Probe Technology, Fig. 4 Schematic view of the NSOM/AFM probe

Microfabricated Probe Technology, Fig. 6 Throughput of the fabricated aperture NSOM probes as a function of the aperture diameter

through the aperture is reflected by the surface of the sample, is collected by a long distance working lens, and is detected by a photomultiplier tube (PMT). The signal from the output of the PMT is amplified and acquired by the AFM controller as an optical signal. Using the described measurement setup and the fabricated probe with the aperture of about 120 nm, NSOM and corresponding AFM images in contact mode of 200 nm Cr grating on glass substrate are simultaneously observed as shown in Fig. 7a, b. It should be noted, however, that even with 120 nm aperture size, very small Cr particles (about 20 nm diameter) can be observed. The system presented here is specialized for illumination mode; however, it is possible to use the fabricated aperture tip as a receiver for collection mode NSOM. It is also expected to develop this setup for optical near-field and Raman near-field spectroscopy as well. The setup can also be used for NSOM/AFM in non-contact or tapping modes. The probe is mounted on an AFM non-contact stage on which the cantilever can be vibrated by a piezo element. The near-field signal modulated by the vibration signal is lock-in amplified using the vibration signal applied to the piezo element as a reference and acquired by the AFM controller.

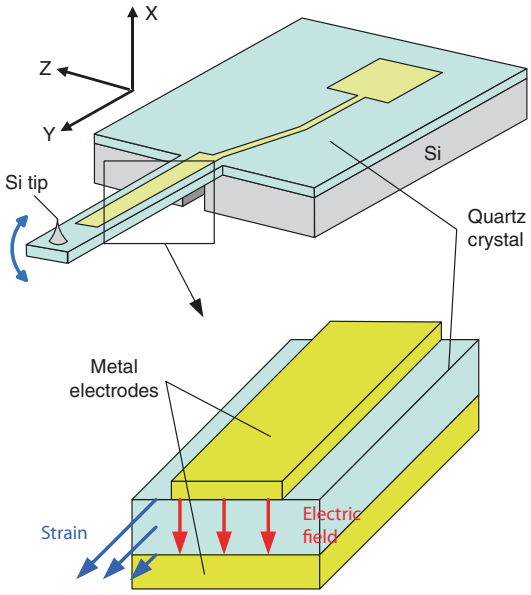
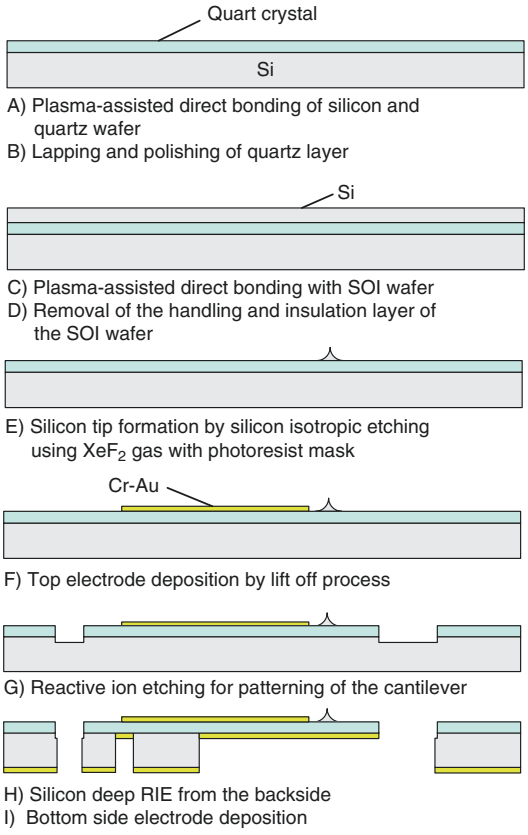
Overview

Quartz-Crystal SPM Probe



SPM can be used for imaging of a biological sample in liquid. There are several difficulties in liquid operation of dynamic-mode SPM (DM-SPM). The quality factor (Q factor) severely drops due to the viscous damping in a liquid, and that leads to low spatial resolution [30]. In addition, when the cantilever is driven indirectly with acoustic excitation, several spurious resonance peaks are observed around the resonance peak of the cantilever [31]. Thus, it is difficult to identify the "true" resonance peak of the cantilever, and in a worst case, one cannot operate DM-SPM in the liquid solution. One of the solutions for these problems is to use quartz-crystal tuning fork (QC-TF) as a force sensor of DM-AFM. QC-TF has higher Q factor than that of conventional silicon cantilevers [32–39], and one of quartz sensor [36] with both actuation and sensing performances has been available on the market from Nanosensor™ [40]. QC-TF SPM sensors with attached tip can be applied to atomic resolution imaging in high vacuum [35] also in ambient atmosphere [41], high-speed imaging [42], and can be operated even at low temperatures [43]. QC-TF are also used for other applications such as resonant biosensors operated in liquid [44], and mass sensors [45].

QC-TF can vibrate by itself by applying an AC voltage near the resonant frequency, so it expected to causes no spurious resonances. In addition, the vibration signal can be detected electrically; thus, no optics is needed. This self-sensing property is advantageous to the simplicity of the SPM system and the ability of utilizing in an opaque liquid. However, the spring constant of conventional QC-TF is on the order of a few thousands of N/m [34], which is much larger than that of a conventional silicon probe and results in reducing the force sensitivity and the injury of the soft biological sample. For SPM in liquid with high resolution and usability, self-sensing and self-actuation are desirable. Although QC-TF has both properties in these points, lower spring constant and more convenient method of the probe tip formation are needed. Additionally, the preparation of the tip requires great care, i.e., the tip has to be mounted on one of the prongs of the QC-TF piece by piece. Recently various quartz-crystal sensors (QC-S) have been developed for advanced performances, and some of them have been commercialized. Needle-type QC resonator with a high frequency ~1 MHz can improve the scan speed [33]. Cantilevered QC sensors have been developed for decreasing the spring constant [38], also cantilevered sensors with ability of self-sensing and self-actuation using three electrodes have been reported [39]. Using advanced microfabrication technology, a silicon microresonator is combined with QC-TF sensors [36]. Here, the design, the fabrication, and characterization of new quartz-crystal force sensor with a low spring constant are presented.

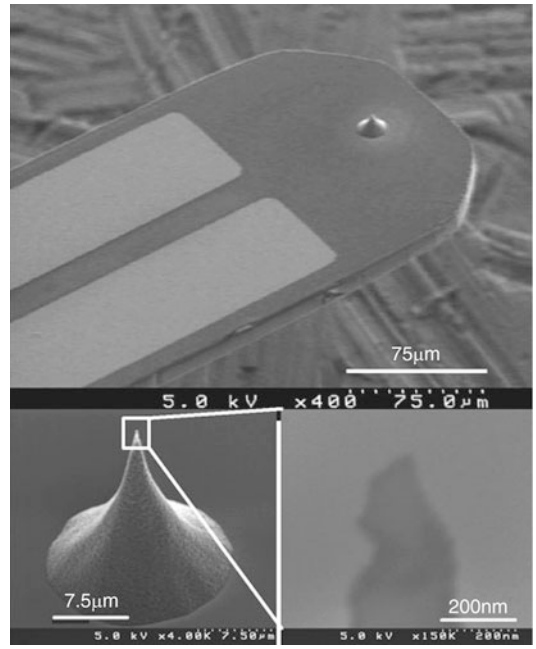


Basic Methodology

Design and Fabrication of Quartz Cantilever Sensors

Schematic view of the quartz cantilever is shown in Fig. 8 [46]. The quartz-crystal cantilever is

Microfabricated Probe Technology, Fig. 8 Schematic of the quartz-crystal cantilever (*up*) and the excitation principle of the flexural mode vibration (*bottom*)



Microfabricated Probe Technology, Fig. 9 Process flow of the quartz-crystal cantilever with an integrated silicon tip

made from X-cut quartz plate that is bonded with silicon substrate. Y axis of the quartz-crystal is designed to be parallel to the longitudinal direction of the cantilever. On the both sides of the cantilever, metal electrodes are formed. The top electrode pattern size is designed to be narrower than that of bottom electrode. By applying a voltage between two electrodes, strain is generated in y direction due to inverse piezoelectric effect. The generated strain in y direction is distributed in thickness direction because of the asymmetric pattern sizes of the top and bottom electrodes; therefore, the applied AC voltage near the resonant frequency generates the flexural vibration of the cantilever (self-actuation). By measuring the generated charge using a current amplifier, vibration signal can be detected with no optics (self-sensing). A sharp silicon tip is integrated on the free end of the cantilever.

Fabrication process flow is shown in Fig. 9. Starting materials are a 100-µm-thick, both side mirror-polished X-cut quartz-crystal wafer and both side mirror-polished 200 µm-thick (100)-oriented silicon wafer. Before the bonding process, each wafer was cleaned by a megasonic cleaner using deionized water in order to remove contaminants such as particles, organic matters, and metals contaminants. Subsequently, plasma treatment for surface activation was performed on the quartz wafer using N_2 plasma with gas pressure of 0.8 mbar, RF power of 150 W, and activation time of 30 s. In similar way, the surface of the silicon wafer is activated by N_2 plasma (0.4 mbar, 100 W, 30 s). After this surface activation treatment, only silicon wafer was rinsed with deionized water. Both wafers were contacted together in ambient atmosphere at room temperature. Then, this pre-bonded wafer was annealed at 180 °C, which increases the bonding strength. Surface roughness and morphology of the bonding surfaces are critical parameters for bonding. If wafer's surface is too rough, bonding will fail despite using surface activation. A surface

roughness of less than 1 nm in Ra was needed to obtain enough strength in our experiments. The bonded quartz layer was thinned down to the designed thickness (2 ~ 10 μm) by conventional lapping and polishing techniques. Then a SOI wafer (20/1/400 μm) is bonded with the polished quartz layer, and handling layer and insulating layer are removed. Next, silicon sharp tips are formed by XeF_2 anisotropic etching using photoresist as a mask. After depositing Cr-Au with thicknesses of 20 and 100 nm, respectively, an electrode pattern was formed by lift-off process. The cantilever shape is defined by reactive ion etching (RIE) using a mixture gas of SF_6 and Xe gases with a ratio of 1/1 at process pressure of 0.27 Pa. As a masking material for RIE process, we used a thick photoresist (approximately100-μm thick). Then, cantilevers are released by silicon deep RIE from the bottom side. Then, Cr-Au with thicknesses of 20 and 100 nm, respectively, as an electrode was deposited on the entire area of the bottom side. Finally, using catalytic chemical vapor deposition, a thin SiCN film was deposited on the electrodes to prevent current leakage to a sample. Typical SEM image of the fabricated quartz-crystal cantilever is shown in Fig. 10. In this cantilever, two metal electrodes are formed on the top side for detection and excitation. The tip is electrically separated from the excitation electrode; therefore, electric field effect to a biological sample can be minimized. It can be seen that the silicon tip is very sharp and the curvature radius of the tip is below 50 nm. Sensitivity for external force depends on the spring constant of the cantilever. By using bonding and thinning technique, the thickness of the cantilever can be tuned. The smallest spring constant is 0.1 N/m (length, width and thickness of the cantilever are $l = 800$ μm, $w = 200$ μm, $t = 2$ μm, respectively). This value is approximately 10^4 times smaller than that of conventional quartz tuning fork.

Key Research Findings

Evaluation of Quartz-Crystal Sensor

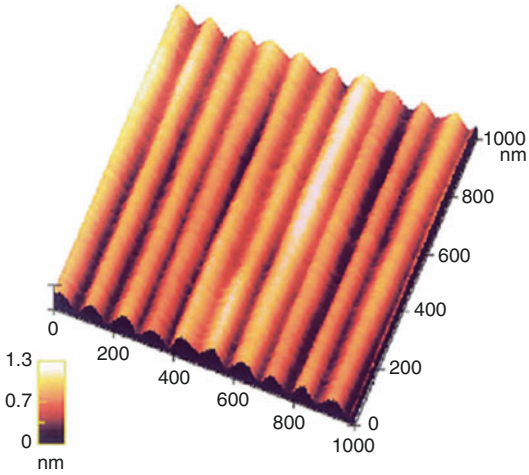
The vibration characteristics are measured in atmosphere and in water. Also mechanical response spectra actuated by the self-actuation and the acoustic actuation using piezoceramics are compared. In order to evaluate the difference between conventional excitation method and self-actuation, the quartz cantilever is excited using piezoceramics placed near the cantilever or excited by self-actuation.

The amplitude of the quartz cantilever is measured by a laser Doppler vibrometer and lock-in amplifier. In liquid, the resonant frequency and quality factor decline due to the viscosity of the liquid, as shown in Fig. 11a. The measured resonant frequencies in atmosphere and water are 11.67 and 4.7 kHz, respectively, and the quality factors are 270 and 7, respectively.

As shown in Fig. 11b, the self-actuation of the quartz cantilever using the inverse piezoelectric effects is very effective to remove spurious resonances in liquids. No spurious resonances are observed in the self-actuation, while many spurious resonances can be seen in the case of the acoustic excitation in water using the

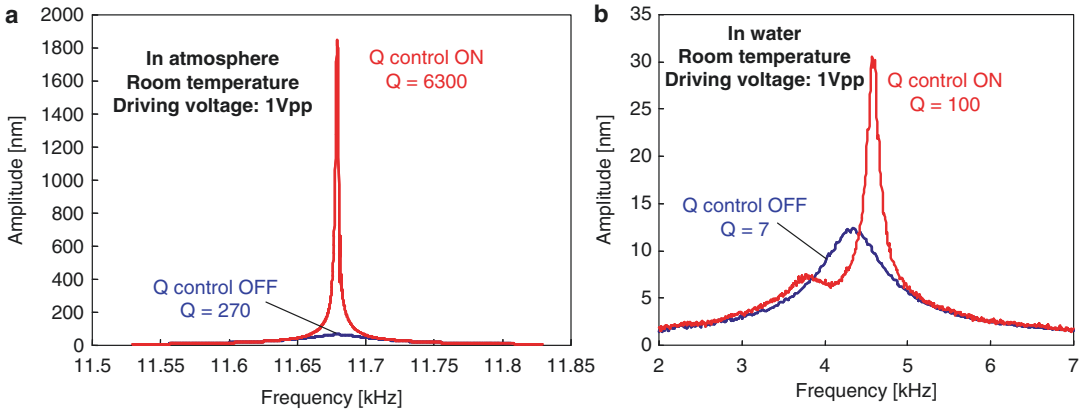
Microfabricated Probe Technology, Fig. 11 Vibration characteristics of the X-cut quartz-crystal cantilever: (**a**) Mechanical vibration spectra in water and atmosphere; (**b**) comparison of mechanical response spectra between self-actuation and acoustic excitation using piezoceramics in water near the first resonance frequency

piezoceramics. This is advantageous for SPM operation in liquids.



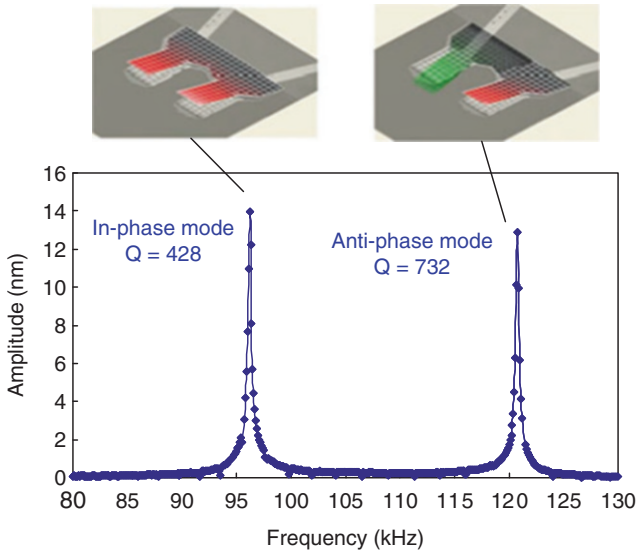
SPM imaging using a fabricated quartz cantilever was demonstrated at the amplitude-modulation SPM mode. A commercial SPM (Olympus, NV2000) was used in this experiment. A quartz cantilever (*length*: $l = 800$ μm, *width*: $w = 200$ μm, thickness: $t = 8$ μm) was actuated by applying 2 Vp-p of AC voltage, and the vibration was detected using a laser displacement sensor of the SPM. Flexural first mode with a fundamental resonant frequency of 10.7 kHz was employed for the measurement. The nominal spring constant is 4 N/m, amplitude of the cantilever is 30 nm, and the measured Q factor is 300. Figure 12 shows the demonstrated SPM image of the silicon grid pattern.

In a liquid, the Q factor of the sensor decreases due to viscous damping, which declines the sensor sensitivity. In order to increase the Q factor of the quartz-crystal cantilever, electrical Q-enhancement was tested. This method is so-called active Q control. Figure 13 shows the results of active Q control. Displacement signal of the cantilever from the laser Doppler vibrometer is added to the oscillation AC signal through an amplifier and phase shifter. The Q factors could be increased up to 6,300 from 270 in atmosphere, and up to 100 from 7 in water. Thus, it is found that the quartz-crystal cantilever is very effective



to enhance the Q factor using the self-oscillation function.

Self-sensing property was examined with coupled quartz-crystal cantilevers. Two cantilever structures are mechanically coupled via thin quartz plate formed at the cantilever support. In this coupled quartz resonator, the detection electrode and excitation electrode are electrically isolated by each other. Therefore, electrical cross talk between excitation signal and detection signal can be minimized, and from observation using an oscilloscope, no cross talk was recognized at off-resonance frequency. In addition, in this coupled resonator, the self-oscillation based on self-sensing becomes easy in comparison with the sensor with two electrodes. The dimensions of the rectangle beam are $l = 200$ μm, $w = 150$ μm, $t = 5$ μm. The calculated spring constant of the beam is approximately 50 N/m. Frequency response of the quartz resonator measured by laser Doppler vibrometer is shown in Fig. 14. This is actuated with driving AC voltage of 1Vp-p. This quartz resonator has two flexural vibration modes, i.e., 97.3 kHz of in-phase mode and 120.7 kHz of anti-phase mode. The anti-phase mode vibration exhibits higher Q factor ($Q = 732$) than that of in-phase mode ($Q = 428$), due to the suppression of the support energy loss.



For self-sensing, AC voltage was applied to one cantilever, and the generated current from the other cantilever was detected using a current-to-voltage converter with a feedback resistance of 10 MHz. The bottom side electrode was grounded. The parallel capacitance of the quartz resonator was canceled by active bridge circuit. The output current of the current-to-voltage converter was successfully measured using a lock-in amplifier. It is expected that this quartz resonator can be applied to the SPM imaging with abilities of self-actuation and self-sensing.

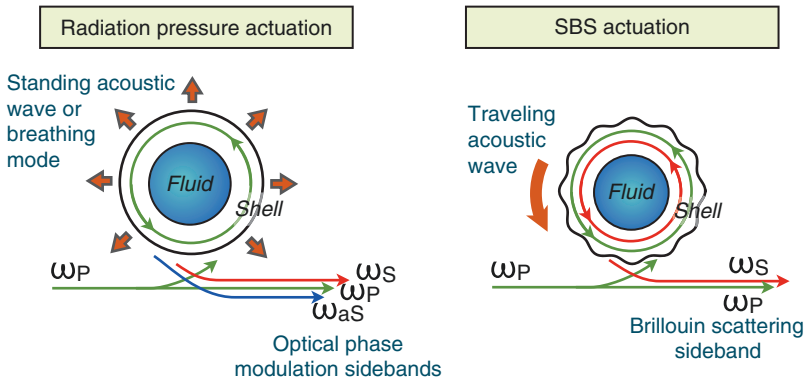
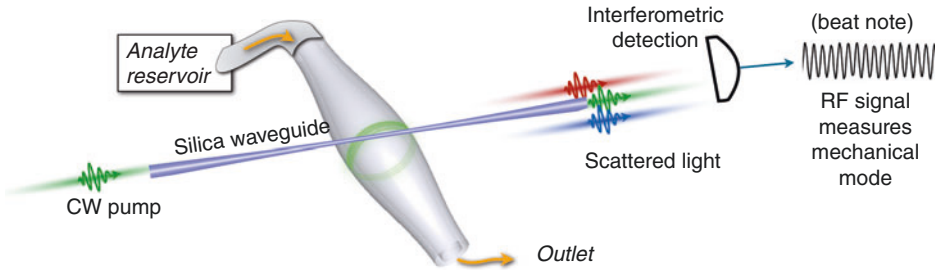
Definition

Microfluidic optomechanical resonators (opto-mechano-fluidic resonators or OMFRs) enable coupling between light, solids, and fluids by means of optical forces and opto-acoustic scattering. This is achieved through solid–fluid hybrid modes that span vibrational frequencies in the MHz–GHz range. Using these interactions, microfluidic optomechanical devices can be used to perform acoustic rheological measurements on fluids using only light.

Principle of Operation

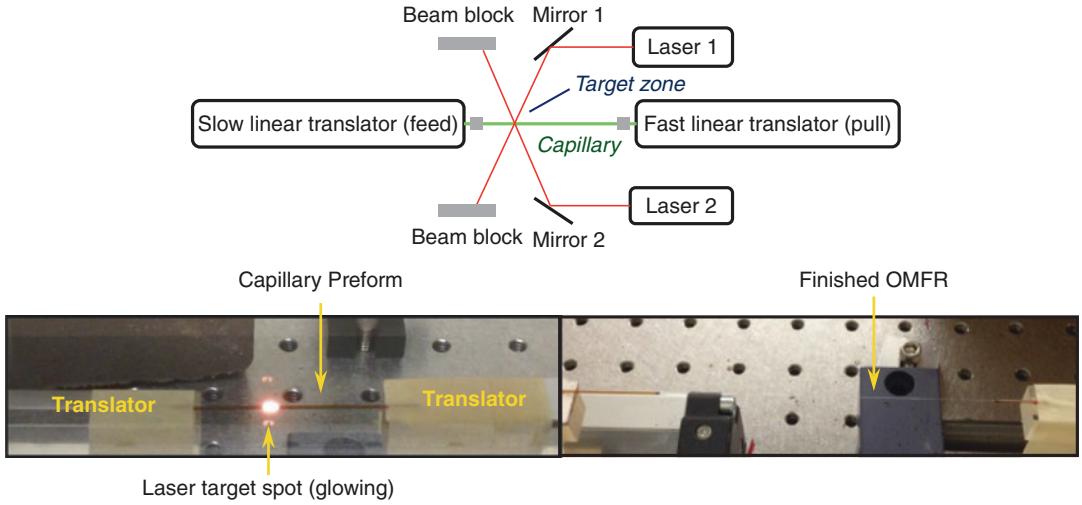


OMFRs are hollow silica microcapillary devices of diameter typically around 50–300 um, with diameter modulation along their length. These regions of larger diameter simultaneously host ultrahigh-Q optical resonant modes and high-Q acoustic resonant modes in the solid shell (see Fig. 1). Fluids infused into the hollow core of OMFRs do not directly interact with light in the shell (see *optofluidics*), provided the shell is made sufficiently thick. As a result, high optical Q can be maintained. Vibration of the solid shell, however, entrains the fluid and results in hybrid solid–fluid acoustic resonances that are influenced by the properties (speed of sound, bulk modulus, damping) of the fluid. These hybrid modes can be optically sensed by modulation of the input laser



Microfluidic Optomechanics, Fig. 1 (*Left*) Electron microscope image of a microfluidic optomechanical resonator. These devices confine fluid inside while being exposed to air on the outer surface. (*Right*) The device can host both mechanical and optical resonances (Graphics adapted from [1])

Microfluidic Optomechanics, Fig. 2 (*Left*) Actuation of stationary resonant acoustic modes of the OMFR by means of optical radiation pressure. (*Right*) Actuation of traveling acoustic waves in the OMFR by means of stimulated Brillouin scattering (*SBS*)

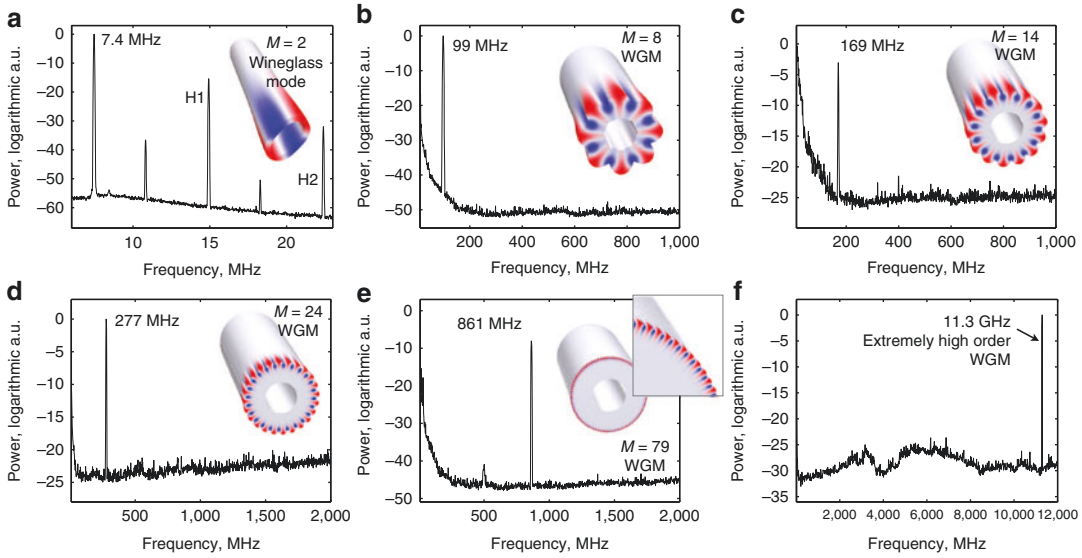


Microfluidic Optomechanics, Fig. 3 Arbitrary analytes can be flowed through an OMFR. A continuous-wave (*CW*) pump laser passing through an adjacent optical waveguide is modulated by the stochastic thermal–mechanical fluctuations and by the optically induced vibrations of the OMFR. The scattered light can be retrieved by the same waveguide, and the radio frequency (*RF*) spectrum can be monitored experimentally to measure the vibration

light by the vibration (see Figs. 2 and 3). This coupling permits all-optical measurement of fluid acoustic properties and even extends to flowing particles within the fluid. The optical sensing mechanism is sufficiently sensitive for the detection of stochastic thermal fluctuations of the vibrational modes.

In addition to sensing-only operation, light is also able to directly actuate mechanical vibrations within the device through optical radiation pressure [2] and through stimulated Brillouin scattering [3]. These modes of actuation are illustrated in Fig. 2. The optical radiation pressure actuation mechanism operates because photons carry linear

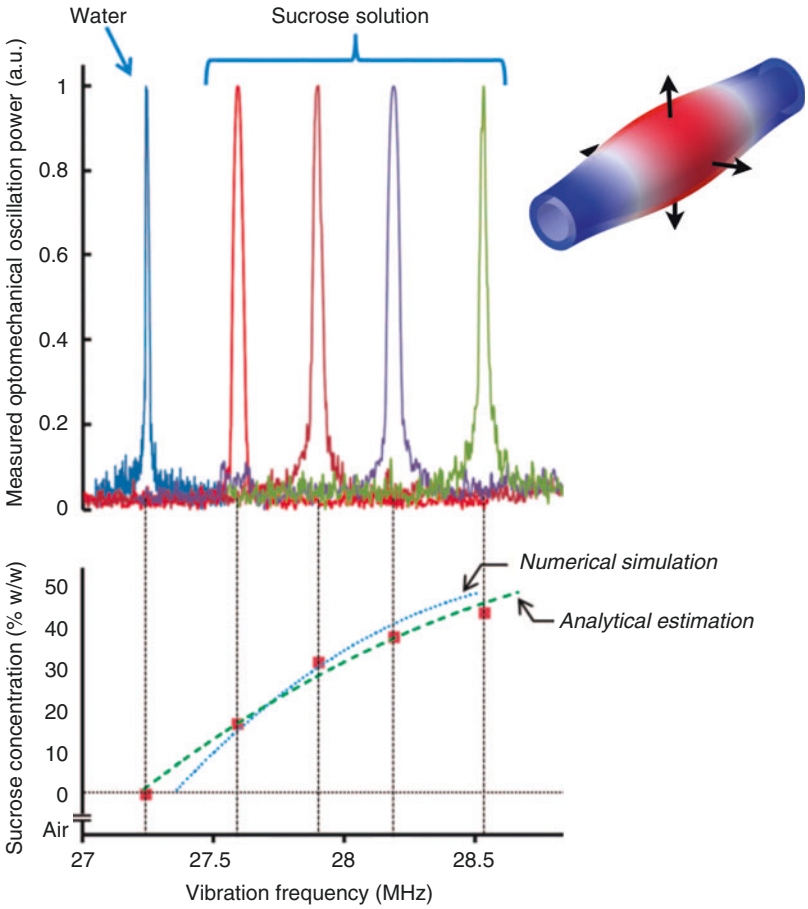
Microfluidic Optomechanics, Fig. 4 OMFRs are fabricated from silica capillary preforms by linear drawing under high-power laser heating (Graphics adapted from [5])



momentum that must be conserved, and when they are guided around a circular path, a centrifugal force must be generated. The simulated Brillouin scattering mechanism is a self-feedback lasing process [4] in which traveling sound waves are spontaneously generated and amplified by light.

Methods of Fabrication

OMFRs are fabricated from commercially purchased fused silica capillaries as described in [5] (see Fig. 4). The capillary is heated using CO_2 laser illumination (10.6 μm wavelength is absorbed by silica). When the glass heats up to the softening point, two linear pulling stages can draw the capillary into a thinned-down OMFR. Modulation of the CO_2 lasers permits rapid spatial variation of the local OMFR diameter, where the optical and acoustic modes can be simultaneously confined. The fabrication method is derived from existing techniques employed in optofluidics [6]. Alternative heating methods include hydrogen flame, arc discharge [7], laser glassblowing [8, 9], and even coil heaters, each having limitations on temperature ramp-up/ramp-down time constants with consequent limitation on the bubbled region geometry.



Main Research Accomplishment

The presence of fluids in the medium around an optomechanical device leads to both mechanical damping [10] and water-induced optical absorption, making optically induced oscillations challenging to actuate and observe. The development of *microfluidic* optomechanical devices has permitted, for the first time, testing of fluid-phase or fluid-suspended analytes and gases through high-frequency and high-fidelity optomechanics techniques. By placing the fluid within the device, OMFRs circumvent high mechanical damping in a similar manner to suspended microchannel resonators [11, 12]. Additionally, since the fluid is confined inside, the optical mode that remains at the exterior surface of the device remains largely unperturbed. As a result of the above characteristics, mechanical Q of several thousand and optical Q of 100 million can be readily achieved for high-sensitivity measurement of thermal fluctuations. The low optical and mechanical damping have permitted the actuation and sensing of vibrational modes in the 10's of MHz–10 GHz range (see Fig. 5).

Microfluidic Optomechanics, Fig. 5 Experimental results of the excitation of MHz–GHz vibrational modes of an OMFR with water infused within the device (Figure from [3])

Microfluidic Optomechanics, Fig. 6 Example of sucrose solution sensing through an OMFR. While the infused sucrose concentration is changed, the vibrational frequency of the OMFR breathing mode (visualized *top right*) changes monotonically (Graphics adapted from [2])

Examples of Application

OMFRs were first reported in 2013 in the work of Bahl and Kim [2, 3, 13], in which a sensitivity to fluid density properties was noted using sucrose solutions of varied sucrose weight fraction (Fig. 6). Han et al. later employed OMFRs to demonstrate pressure sensing [14] and fluid viscometry [15]. Kim and Fan experimentally have evaluated the surface sensitivity of OMFRs for potential biomolecule sensing applications [16].

Microfluidic Whole-Cell Biosensor

Soichiro Tsuda
School of Chemistry, University of Glasgow, Glasgow, UK

Synonyms

Lab-on-a-chip whole-cell biosensor

Definition

Microfluidic whole-cell biosensors incorporate living cells, such as bacteria, inside lab-on-a-chip sensing devices for a conversion of initial inputs (e.g., environmental samples) into cellular response as primary transducer.

Overview

Whole-cell biosensors are a type of biosensor that incorporates living cells as a biorecognition element [1].

Conventionally, chemical or physical sensors, such as high-performance liquid chromatography (HPLC) or gas chromatography coupled with mass spectrometry (GC-MS), have been used for analyzing samples of interest (e.g., the composition and concentration of chemicals). Although they are highly accurate and results are reliable, such instrumentation is expensive and often requires special skills and facilities for analysis. An alternative approach in sensor technologies is sensors using biological components, such as enzymes and living cells. They are simpler and often single-purpose devices, but can be easily produced (hence inexpensive).

There are two different objectives in biosensor research: One objective is to develop biological counterparts of conventional chemical or physical sensors. Biological molecules (enzymes, antibodies, and nucleic acid fragments) are commonly used to develop such biosensors due to their substrate specificities [2]. Another objective is the toxicity assessment. While biomolecule-based biosensors are more accurate and give more detailed information about analytes, it is difficult to know the effect of the analyte on living organisms. Thus, a main application domain of biosensor using living cells or tissues is to obtain information about functional consequences of substrates being analyzed or the measurement of the total "bioavailability." The bioavailable (or bioaccessible) compound is defined as "(a molecule that) is freely available to cross an organism's cellular membrane from the medium the organism inhabits at a given time" [3], which would be useful for the understanding of, for example, the environmental effect of the compound. Potential applications of whole-cell biosensors could be the assessment of physiological effect of a pharmaceutical compound, checking if a substance is an agonist or an antagonist for a receptor, the cellular toxicity test, and the environmental pollution test [4]. As these types of information involve vital reactions inside biological cells, whole-cell biosensors are considered to be the most suitable sensor in order to investigate these questions.

Living cells employed for whole-cell biosensor development are quite diverse: bacteria, oocytes, cultured fish cells, fibroblasts, neurons, cardiac myocytes, etc. Among others, bacterial cells are commonly used due to the ease of use. For extensive lists of bacteria used for biosensor and target compounds, see [5].

In microbiologist's term, it is often assumed that "biosensor" refers to biological cells themselves. However, biosensor cells need to be actually integrated into hardware devices that allow readout of the output response of cells, when practical applications are in focus. Microfluidic or lab-on-a-chip technologies would contribute in this regard and will help further integration and miniaturization of biohybrid sensor devices.

This entry first gives an overview of whole-cell biosensors and then describes possible interfaces between cells and readout devices. Lastly, examples of actual whole-cell biosensor implementations using microfluidic techniques are given.

Types of Whole-Cell Biosensor

Whole-cell biosensors can be categorized into three groups based on the specificity to external stimuli to be analyzed [4]: specific, semi-specific, and nonspecific biosensors.

The specific whole-cell biosensor reacts only to a certain compound, and thus it is a biosensor counterpart of standard analytical chemical techniques. So far various types of specific whole-cell biosensors have been developed. They mostly rely on genetic engineering of reporter genes

with inducing promoters. Hansen and Sørensen categorized specific whole-cell biosensors into two subgroups [5]: activator-type and repressor-type. The important elements of those biosensors are DNA sequences of a cell: DNA sequences of activator-type biosensor cells contain an activator gene, promoter, and reporter genes. The activator gene constantly produces activator proteins, but they can bind to the promoter region only when a target compound to be detected is present. Binding of the activator protein to the promoter allows the reporter genes to be read and produce reporter signals (e.g., fluorescent proteins), which are picked up by detection devices (fluorescent microscopes). On the other hand, cells of the repressor-type biosensor have a repressor gene instead of activator gene. The repressor gene constantly produces repressor proteins that bind to the promoter region which prevent reporter genes to be transcribed unless a target compound is present. The target compound binds to the repressor proteins and releases them from the promoter region. This triggers the transcription of reporter genes and production of reporter signals. However, due to the genetic engineering of biosensor cells, these types of specific whole-cell biosensor can be constructed only after the gene regulation mechanisms related to target compounds are discovered.

Another type of whole-cell biosensor is the semi-specific or group-specific biosensor. This biosensor also employs gene regulation mechanisms for the detection of substance classes. A typical genetic circuit of the biosensor consists of an activator gene, promoter, and reporter gene. While only one target compound could trigger the reporter protein production in specific whole-cell biosensor, different stresses can induce the activator gene in semi-specific biosensor cells. The activator gene subsequently induces transcription of the reporter gene and production of reporter signals. Examples of stresses demonstrated to detect are antibiotics, gamma irradiation, genotoxins, oxidative stress, and UV radiation (cf. [3, 5]).

Nonspecific or general whole-cell biosensors are developed to obtain general information about the presence of toxic compounds. Cells of nonspecific biosensors constantly produce detection signals, such as bioluminescent proteins. Any condition that affects the activity of nonspecific biosensor cells, such as pH, salinity, metals, and xenobiotics, will cause degradations of the released signal, which are used as a measure to estimate toxicity. Although it is not possible to detect a specific compound with this biosensor, it gives information about, for example, the effect of a compound or environmental sample to biological cells by employing complex cascades of intracellular reactions. Such biosensor can be used to prescreen environmental samples, which will be further analyzed using specific chemical or physical sensors to track down the chemical identity of toxic substances. Nonspecific biosensors have been more commonly used for commercial environmental toxicity test, for example, the Microtox test.

Detection Methods

A primary role of biological cells employed for detection is a conversion of initial inputs (e.g., environmental samples) into cellular response as primary transducer. The next required step is to develop secondary transducer that converts the cellular response into detectable signals, as secondary transducer.

A most commonly used interface is optical detection using bacterial luciferase (Lux), firefly luciferase (Luc), aequorin, and green fluorescent protein (GFP) [6]. Among others, bacterial luciferase and GFP are commonly adopted for whole-cell biosensor use. A bacterial bioluminescence reaction involves the bacterial luciferase enzyme, oxygen, reduced riboflavin phosphate ($FMNH_2$), and a long chain fatty aldehyde. When the luciferase enzyme catalyzes the oxidation of the aliphatic aldehyde, a high-energy intermediate of $FMNH_2$, oxygen, and the aldehyde emits light primarily at a wavelength of 490 nm. A chief advantage of this bioluminescent system as bioreporter is an autonomous nature of *lux* operon. When genes required for aldehyde biosynthesis are integrated in biosensor cells, they can function to produce light completely autonomously without any additional inputs. This nature

makes the Lux bioluminescent system suitable for nonspecific whole-cell biosensor in which reporter signals (in this case, bioluminescence) are constantly produced. When the cells are exposed to toxic compounds, the bioluminescent signal will decrease depending on the viability of cells. Another widely used bioreporter, GFP, is an autofluorescent protein, first discovered in 1962 together with aequorin [7]. It has two absorption peaks at 397 nm (major) and 475 nm (minor) and emits light at 504 nm. While bacterial luciferase (*lux*) genes can be expressed only in prokaryotes without any gene sequence alterations, GFP can function in both prokaryotic and eukaryotic cells [8]. It also has been shown that GFP can be used for all three types of biosensor described above (cf. [9–11]).

So far several types of devices are developed for detection of these optical signals. Fiber-optic cable is one of the most common interfaces. Bioluminescent light can be detected by attaching bioreporter cells and photomultiplier tube (PMT) on each end of the cable. In the case of GFP detection, however, an additional cable is required for interfacing an excitation light source (e.g., tungsten lamp) and cells because GFP is a fluorescent protein. Fiber-optic cables can be used for various types of samples (liquid, solid, gaseous), but is not a suitable interface for miniaturization of the device because of size and power constraints. Toward the on-chip integration of whole-cell biosensor device, complementary metal-oxide-semiconductor (CMOS) [12], MOEMS (Micro-Opto-Electro-Mechanical System) [13], and avalanche photodiode (APD) [14] devices have been developed for the detection of bioluminescent signal.

Apart from the optical interface, electrochemical and electrical interfaces are developed. Electrochemical whole-cell biosensors monitor cellular redox events due to metabolic activity of cells by amperometric, potentiometric, and conductometric techniques. Analytes detected at working electrodes are normally natural chemical species, such as oxygen, or an introduced chemical which can exist in both the oxidized and reduced forms. In the case of amperometry, measured current is linearly dependent on the concentration of chemical species. Electrical interfaces are mainly for neuronal biosensors. Single neurons are grown on a microelectrode array, and their electrical activities are monitored by the microelectrodes [15]. A main advantage of the electrical interface is real-time detection. Neurons react to external stimuli within a second, whereas other (typically microbial) whole-cell biosensors take over minutes.

Lab-on-a-Chip Device Integration

Although biological cells are employed as sensors for detection of chemicals, cell-based biosensor research often experiences problems with reproducibility and stability of the biosensors. This is mainly because of the lack of control over the (micro)environment of cells used for detection. Microfluidic and lab-on-a-chip technologies are expected to fill the gap, and thus microfluidic-based biosensors would have a large potential to improve these problems. This section introduces examples of microfluidic biosensors using biological cells to illustrate various types of ongoing research in this field.

One of the first developments of microfluidic whole-cell biosensors is by Derek DeBusschere and Kovacs [16]. They have developed a cell cartridge consisting of polydimethylsiloxane (PDMS) fluidic chambers and integrated CMOS circuits. The cell cartridge provides temperature control system, microelectrode sensors, analog signal buffering, and digital interface for a portable handheld measurement device. Cardiomyocytes are cultured in the cartridge, and the electrophysiological activity (cell contraction) is monitored by the integrated electrodes attached to the cells. As their implementation represents, a typical usage of microfluidic devices is for compartmentalization and immobilization of sensor bacteria in microchambers. Rabner and coworkers developed a PDMS-based integrated whole-cell biosensor for water toxicity analysis [17]. This is basically a kind of semi-specific biosensor using genetically modified *E. coli* cells harboring bacterial luciferase (*lux*) genes. When cells are exposed to genotoxic chemicals in

cylindrical reaction chambers of the microfluidic device, they start to produce bioluminescent proteins as described above. Light emissions from the cells are picked up by PMT integrated in the sensor. A motorized XY stage controls the position of PMT to go through the reaction chambers one by one. Tani and coworkers developed a bacterial biosensor chip for genotoxic bioassay [18]. The chip comprised of two layers of PDMS microfluidic channels sandwiching a silicon substrate layer with 25 well arrays. A mixture of *E. coli* as sensor strains and agarose is introduced from one side of the microfluidic layer and immobilized in the 25 wells. Samples of interest with different concentrations are applied from separate lines of fluidic channels in another PDMS layer to stimulate the cells. Reactions of cells are detected as bioluminescent light emission. This whole-cell biosensor has been demonstrated to assay the genotoxicity of mitomycin C and can be used for high-throughput multiple assays of drugs or physiological substances.

Ben-Yoav and coworkers developed an on-chip electrochemical biosensor using *E. coli* and *Salmonella typhimurium* [19]. Three gold electrodes (working, counter, and reference electrodes) are patterned on a single crystal silicon substrate, and a PDMS microfluidic chamber for cell culture was mounted on the chip. This device detects a genotoxin, nalidixic acid (NA), by means of catalytic reactions in the culture solution. For example, in the presence of NA, the genetically engineered bacteria produce the reporter enzyme β-galactosidase which catalyzes the conversion of para-aminophenylphosphate (pAPP) into the electroactive species pAP. This reaction is picked up as increasing electrochemical current by the electrodes.

Integration of nerve cell culture and electrical measurement device is also one of the active areas in this field. Prasad and coworkers patterned single neurons on individual microelectrodes integrated in a microfluidic device [15], and the electrophysiological activities are monitored by the electrodes. Although a broad spectrum of chemical agents does stimulate the patterned neurons, reaction patterns of neurons to each chemical (called "signature patterns") can be identified using fast Fourier transformation and wavelet transformation analyses. Takeunchi and coworkers developed a microfluidic odorant sensor using oocytes of African clawed frog *Xenopus laevis* [20]. Oocytes are modified to express insect membrane proteins (pheromone and odorant receptors). Cells are trapped in a microfluidic channel, and the receptor activities are monitored by microelectrodes integrated in the device. If a ligand (e.g., bombykal) attaches to a receptor on the oocyte membrane, the cation channel opens up, and influx of cations changes the current across electrodes inserted in the cell. It has been shown that this biosensor qualitatively detects several chemicals with high reproducibility and high specificity with the working range of 10 nM to 1 μM.

Daunert and coworkers developed a spore-based lab-on-a-compact disk (CD) biosensor. Microfluidic channels are fabricated by micromachining on a 12 cm poly(methyl methacrylate) (PMMA). The fluidic part consists of reagent reservoirs and detection chamber connected by mixing channels. Samples and cells (in this case, spores of *B. subtilis* strain) are loaded in the reagent reservoirs and microcentrifugally move toward the detection chamber through mixing channels. When exposed to a target chemical (e.g., arsenite), genetically modified spores start to express GFP proteins which are detected by a fluorescence spectrophotometer equipped with a fiber-optic system at the detection chamber. Although detection of chemicals takes time (over 150 min) due to the germination of spores in the CD, this spore-based biosensor showed sensitive detection (1×10^{-7} M for arsenite) and excellent storage life (more than 2 years at room temperature).

Microinjection Molding

Fred Chiou
Department of Engineering Technology, Weber State University, Ogden, UT, USA

Definition

Microinjection molding is defined as a particular injection molding process that requires a specialized molding machine that is capable of delivering

high injection speed, high injection pressure, precise shot control, uniform melt temperature, and ultrafine resolution using servo-electric drives and sophisticated controls geared specially to mold micro-miniature components [1]. In other words, as cited by Attia et al. [2], microinjection molding is the process of transferring a thermoplastic material in the form of granules from a hopper into a heated barrel so that it becomes molten and soft. The material is then forced under pressure inside a mold cavity where it is subjected to holding pressure for a specific time to compensate for material shrinkage. The material solidifies as the mold temperature is below the glass transition temperature of the polymer. After sufficient time, the material freezes into the mold shape and gets ejected, and the cycle is repeated. A typical cycle lasts between few seconds and few minutes.

Introduction

Microinjection modeling is a very specialized precision injection molding technique. The technique can be used in microfluidic devices for various applications such as chemistry, medicine, and biotechnology. Some articles, capillary electrophoresis (CE) platforms [3–7], miniaturized heat exchangers [8], and nanofilters [3] reported that microinjection molding was also used for microfluidic applications. It is also used to mold micro-miniature components for the applications of micro-optical (gratings, waveguides, and lenses – [5, 6, 8–11]), micro connectors (ceramic ferrule holder, capacitor housing, etc.), automotive (axle for cockpit instruments, etc.), Microdrive system and controls (potentiometer gear, acetal stepper motor axle for watches, micro gears, etc.), medical and surgical (blade holder, dental prosthetic, etc.), micromechanics (micro-springs, gears and miniaturized switches, catch wheels, etc. – [6, 8–10]), hearing aid (sensor holder, etc.), catheter components, clot removal catheter, communications (for devices that require connectors, gaskets, rollers, lenses, switches, etc.), watch industry, computer, electronics, sensors, and actuators [5, 6]. Surace et al. [12] summarized some examples of microinjection molding in various application fields. These examples can be categorized as shown below.

Micromechanical Parts

- Locking lever for micromechanical industry or micro switch
- Latch for the watch industry
- Catch wheel for micro switch
- Operating pin
- Gear plate for motive power engineering

Micro Gear Wheel

- Dented wheel for watch industry
- Rotor with gear wheel for watch industry
- Gear wheel for micro gear
- Spur wheel in the field of electrical technology
- Spiral gear in the field of electrical technology/metrology
- Spline in the field of electrical technology/metrology

Medical Industry

- Microfilter for acoustics, hearing aid
- Implantable clip
- Bearing shell/bearing cap
- Sensor housing implantable
- Aseptic expendable precision blade

Optical and Electronic Industries

- Coax plug/switch MID for mobile phone
- SIM card connector for mobile phone
- Pin connector for mobile phone
- Single mode and multimode ferrules

The definition of a micro-molded part can be classified by some factors such as weight and dimension. Generally speaking, if a part with the weight from 0.1 to 0.001 g and the part size is in the range of 0.1 in. in diameter, it can be categorized as a micro-molded part [2]. Kukla et al. [13], Angelov and Coulter [10], Whiteside et al. [14], Martyn et al. [15], Bibber [16], and Tom et al. [17] presented a set of criteria to classify the micro-molding parts [1]. They mentioned that a

micro-molding part has one or more of the following specifications: (1) It weighs less than 1 mg, or it is a fraction of a polymer pellet, where a pellet can be approximated to be spherical in shape with an average diameter of approximately 3 mm. (2) It is a part with microstructured regions, or more specifically, with wall thicknesses less than 100 μm. Microfluidic devices usually fall in this category. (3) It is a micro-precision part, which is a part that can have any dimensions, but has tolerances in the micrometer range, or more specifically, between 2 and 5 μm.

Michaeli et al. [18] investigated the use of microinjection molding for the assembly of hybrid structures. This process is called micro-assembly injection molding (μAIM). It is derived from the rather common processes two-component injection molding and over-molding. It is the combination of the positioned joining of inlay parts with the generation of functional microstructures. Some applications of using micro-assembly injection molding (μAIM) are movable structures, hard/soft combinations, hollow structures, optical systems, and electrically functional structures [18].

The advantages of using microinjection molding include the following features:

1. Cost-effectiveness for mass production process, especially for disposable products [3, 5, 19–21].
2. Available wide range of thermoplastics and the potential for full automation with short cycle times [3, 19, 22].
3. Good dimension control and accurate shape replication [19, 20, 22].
4. Relative low-maintenance costs of capital equipment compared to lithographic methods, for example [22].
5. Large amount of know-how knowledge and industrial information are available from conventional injection molding.

Aspect Ratio (AR)

The aspect ratio is defined as the ratio of the longer and the shorter dimensions of a micro-miniature component. For the three-dimensional components, the aspect ratio will be the longest and the shortest axis [12]. When replicating microfeatures using microinjection molding, the aspect ratio becomes an important issue, and the constraint – what is the maximum achievable aspect ratio or how small the micro-miniature component – can be replicated. Heckele et al. [23] discovered that achievable aspect ratio is a function of geometry of microfeatures, their position on the sample, the polymer type, and the process parameters. They suggested that the aspect ratio is the main factor of determining the critical minimum dimensions that can be successfully replicated using injection molding.

Hesitation Effect

The hesitation effect [12] is a phenomenon that can occur during the filling of polymers, and it is common when an injection-molded part contains different thicknesses [19]. It may also take place when microstructures with high aspect ratio (HAR), usually larger than 2, are placed on a relatively thick substrate such as the microfluidic devices [2]. The polymer melt tends to flow easier into cavities with relatively low resistance in the areas of greater cross section, while the flow stagnates at the entrance of microstructures. The causes that the melt frozen in this area is because the filling time of the substrate is usually greater than the freezing time of the microfeature. Rötting et al. [24] recommended in their literature that injection-molded parts with HAR microstructures should have a thickness in which a quick filling of the substrate can allow for filling of the micro-cavities before solidification starts.

Tools for Microinjection Molding

As discussed above, microinjection molding has been widely used for manufacturing micro-miniature components for consumer products. For example, low-cost mass production of polymer microfluidic components can be achieved using either injection molding. The technique

requires a tool to transfer the microstructures to the polymer material. The manufacturing of the tool becomes essential. There are many ways to manufacture the tools or tool inserts. The combination of photolithography, etching, and electrodeposition is commonly used for this process. The basic fabrication schemes can be summarized and listed as shown in schemes 1–4B below from Bissacco et al. [25]. Silicon, polymers, or metals can be used as the substrates. The micromachining can be subtractive (reactive-ion etching, mechanical micromachining, or laser micromachining) or additive (such as UV lithography combined with electroforming).

1. Fabrication scheme 1 – tool insert based on a metal substrate, lithography, and electroforming

Step	Process
1	Machining and cleaning of metal wafer
2	Spin coating, exposure, and development of photoresist
3	Electroforming of Ni
4	Removal of photoresist

2. Fabrication scheme 2A – silicon substrates, lithography, and electroforming

Step	Process
1	Sputtering of 50/500 Å Ti/Au on SiO_2
2	Spin coating, exposure, and development of photoresist
3	Electroforming of Ni
4	Sputtering of 50/500 Å Cr/Cu
5	Electroforming of Ni
6	Selective etching of Si, Au, and photoresist

3. Fabrication scheme 2B – silicon substrates, lithography, and electroforming

Step	Process
1	Sputtering of 50/500 Å Ti/Au on SiO_2
2	Spin coating, exposure, and development of photoresist
3	Electroforming of nickel
4	Machining of tool back
5	Selective etching of Si, Au, and photoresist

4. Fabrication 3A – utilize reactive-ion etching of silicon directly

Step	Process
1	Deposition of mask on Si
2	Spin coating, exposure, and development of photoresist
3	Selective etching of mask and removal of photoresist
4	Reactive-ion etching of Si
5	Mask removal and sputtering of 50/500 Å Ti/Au
6	Electroforming of Ni
7	Machining of tool back
8	Selective etching of Si

Microinjection Molding, Table 1 Commonly used polymers for microinjection molding, maximum aspect ratios (AR), minimum structural thickness, and applications [1]

Polymer	Abbrev.	Maximum aspect ratios (AR)	Minimum structural thickness (μ lm)	Example of application	References
Polymethyl methacrylate	PMMA	20	20	Optical fiber connector	Piotter et al. [26]
Polycarbonate	PC	7	350	Cell container	Piotter et al. [26]
		4–8	0.2–0.5	Optical element	Wimberger-Friedl [20]
Polyamide	PA	10	50	Micro gear wheels	Piotter et al. [26]
Polyoxymethylene	POM	5	50	Filter with defined pore diameters	Piotter et al. [26]
		10	80	Microrods	Ong et al. [27]
Polysulfone	PSU	5	270	Housings for microfluidic devices	Piotter et al. [26]
Polyetheretherketone	PEEK	5	270	Housing for micropumps	Piotter et al. [26]
Liquid crystal polymers	LCP	5	270	Microelectronic devices	Piotter et al. [26]
Polyethylene (high density)	HDPE	8	125	High aspect ratio squares	Despa et al. [28]
		10	225	Microwells	Yao and Kim [19]
Cyclic olefin copolymer	COC	0.02–2	0.1–0.9	Microfluidic patterns	Mönkkönen et al. [29]
Conductively filled polyamide	PA 12-C	10	50	Housing for electrostatic microvalves	Piotter et al. [26]

Bissacco et al. [25] also presented a classification of the available process sequence alternatives and proposed a solution based on generation of the pattern by mechanical or thermal material removal operation. Their viable alternative is constituted by the introduction of mechanical and thermal processes based on material removal in the process chain for insert fabrication. They reported that the solution allows manufacturing of complex three-dimensional shapes with high aspect ratios.

Polymeric Microstructure Replication by Microinjection Molding

Among the materials that have been used for microstructured parts (such as glass, polymer, silicon, acetal, polyester, and polycarbonate), polymers show superior properties that become promising materials for microinjection molding [1]. Microstructures can be easily replicated in medium and large production by using polymer in microinjection molding. Commonly used polymers for microinjection molding, maximum aspect ratios (AR), minimum structural thickness, and applications are shown in Table 1. Several authors [3, 22, 23, 30–36] discovered that polymers have a wide variety of characteristic material properties, such as mechanical strength, optical transparency, chemical stability, and biocompatibility.

Because the costs are not greatly affected by the complexity of the design and the design complexity mostly impacts on mold design rather than

on the molding process itself [3, 23, 31, 37, 38], the cost of polymers is relatively low, especially for high-production disposable devices [30, 39].

Another advantage of polymers is their excellent replication fidelity. A typical polymer can completely fill and accurately replicate small features down to tens of nanometers if the optimum processing conditions are applied [1]. The polymer, due to its viscoelasticity, would fill the smallest mold details with a low viscosity if the shear rate is increased and polymer temperature above its T_g is maintained during the filling stage.

De Mello [22] reported that the quality of the molded surface features is almost completely dependent on the quality and precision of the mold. Some reports from the experiments have demonstrated the successful replication using injection molding, for example, submicron test features [29, 40], submicron grating optical elements [20, 41, 42], and surfaces with nanostructured patterns [43, 44] or nanoscale topography [45].

Polymers show good electrical insulation compared to silicon [7, 22]. However, polymers have some limitations such as temperature range, higher autofluorescence, and limited well-established surface modification techniques compared to glass due to their properties [1].

Material Selection for Polymeric Microfluidic Devices

Material requirements for polymeric microfluidic devices have been investigated by several authors in the literature [3, 6, 7, 22, 35]. It is suggested that the material should possess appropriate mechanical properties, thermal properties (especially when the microfluidic device is subject to elevated temperatures while in service), appropriate glass transition temperature Tg, melt temperature Tm and thermal expansion coefficient (in order to avoid softening of the device and subsequent deformation in features), good heat dissipation ability (in order to avoid local high temperatures in the device when it is subject to high temperatures while in service), chemical resistance (to certain solvents or strong acids), properties of dimensional stability and accuracy (including reproducibility, tendency to shrinkage, and warpage), good electrical insulating properties, biocompatibility and permeability (for biological applications), high mechanical strength, low viscosity, and good flow properties. Generally speaking, all standard thermoplastic materials suitable for conventional injection molding can be used for microinjection molding [9], provided that some manufacturability conditions are met [11, 32, 46, 47].

Part Shrinkage and Shape Distortions

Part shrinkage and shape distortions are common problems during the molding process. Part shrinkage causes volume changes while shape distortions result in warpage. Shrinkage happens with the decrease in part volume due to the temperature change between the demolding temperature and the ambient temperature. Geometrical changes and controlling the processing parameters can improve demolding and part shrinkage [23].

Heckele and Schomburg [23] investigated the orientation of the polymer being injected that affects the direction at which shrinkage is mostly observed. They suggested that the path of polymer injection inside the mold should be considered. In addition to demolding and feature replication, shrinkage affects shape stability in the form of induced warpage. Warpage is produced due to the nonuniformity of the shrinkage because of the residual stresses induced by the complex thermal variation inside the mold [48].

In injection molding, the position of the cooling channel is dependent on part geometry, cavity configuration, and location of ejection mechanism. So it is not always possible to design an ideal cooling system. Greener and Wimberger-Friedl [48] discovered that the variation in temperature across the molded part should be expected depending on the geometry. Cooling the mold is not always required, especially when it is desired to keep the mold temperature above the Tg of the polymer to ensure complete filling of the mold cavity.

Giboz et al. [49] suggested the method of increasing the amount of holding pressure to decrease the effect of shrinkage. This method, on the other hand, will also increase stresses inside the part. Another technique is to allow the part to thermally equilibrate inside the mold cavity, i.e., have a long cooling time. The temperature is to be approximately uniform in this condition. The part is likely to distort because of lack of homogeneity in shrinkage in precision molding, which is likely to occur if the cycle is terminated before the thermal equilibrium is reached, i.e., the part is ejected before its temperature is reduced to the ambient temperature [48]. The cost of this technique is a longer cycle time.

Besides the consideration of decreasing shrinkage, Heckele and Schomburg [23] discovered that the molded parts that need to be assembled in subsequent stages should be placed on the same mold because the degree of shrinkage will vary over time.

Micrometal Injection Molding

Microinjection molding can also be used to produce micrometal parts [50]. The process is called micrometal injection molding or μ-MIM. Authors have studied miniaturization of metal parts by using metal injection molding (MIM) and developed the advanced process of μ-MIM to fabricate ultrafine structures and realized mass production of μ-MIM products [51–53]. In metal injection molding (MIM) process, metal powder is mixed with organic binder and kneaded and pelletized [54]. The injection machine works in the same manner as with plastics: the compound pellet is plasticized and injection-molded into high-precision near-net-shaped products [55]. The process of MIM shows the advantage of high productivity of complicated three-dimensional parts.

The molding conditions such as injection speed, mold temperature, and holding pressure have the impacts on dimensional accuracy of micro-sized parts. The holding pressure can be accurately measured. The measuring device is normally equipped to the injection machine for operational control. Therefore, with the stable material, mixing, and sintering conditions, the dimensional accuracy of μ-MIM products may be improved by monitoring the cavity pressure and controlling the injected volume during injection molding.

Micro-Miniature Component Quality

Studies with different experimental conditions and test parts have been conducted to investigate the process parameters that affect the quality of

Microinjection Molding, Table 2 Some microinjection molding machines

Manufacturer	Machine model
Single-step system	
Standard technology – downscaled technology	
Standard injection molding machines for small pieces	
Arburg GmbH & Co. KG	Allrounder 170 U
Battenfeld Kunststoffmaschinen GmbH	HM 250 Micromelt
Dr. Boy GmbH & Co. KG	Boy 12 A
Demag Ergotech GmbH	IntElect 50
Engel Austria GmbH	E-Motion (X-Melt)
Krauss Maffei-Kunststofftechnik GmbH	KM 35-55 CX
Mitsui Machine Tool – Fanuc	Roboshot S-2000i 5A
Sumitomo Plastics-Machinery	SE18D
Toshiba Machine Co.	EC20P-0.4
Two-step system	
Semi microtechnology – split plasticizing and injecting screw-piston-machines for micro parts	
Cronoplast, sl bzw. ICH-Christmann	Babyplast 6/10
Ettlinger Kunststoffmaschinen GmbH	D-I-M
Ferromatik Milacron GmbH	K-TEC

Battenfeld Kunststoffmaschinen GmbH	Microsystem 50

the micro-miniature components and their optimization in addition to part geometry. Surace et al. [12] reported these main process parameters:

Mold temperature	Melt temperature
Injection speed	Injection pressure
Holding time	Holding pressure
Cooling time	

Microinjection Molding Machines

Some microinjection molding machine manufacturers and their products are listed in Table 2 [56].

Conclusion

Microinjection molding is the process of transferring a thermoplastic material in the form of granules from a hopper into a heated barrel so that it becomes molten and soft. The material is then forced under pressure inside a mold cavity where it is subjected to holding pressure for a specific time to compensate for material shrinkage. The material solidifies as the mold temperature is decreased below the glass transition temperature of the polymer. After a sufficient time, the material freezes into the mold shape and gets ejected, and the cycle is repeated. Microinjection modeling is a very specialized precision injection molding technique. The technique can be used in microfluidic devices for various applications such as micromechanical parts, micro gear wheel, and medical, optical, and electronic industries.

The advantages of using microinjection molding include cost-effectiveness for mass production process, its availability for a wide range of thermoplastics, its potential for full automation with short cycle times and good dimension control and accurate shape replication, etc. Among several materials, polymers show superior properties that become promising materials for microinjection molding. The material should possess appropriate mechanical properties, thermal properties, appropriate glass transition temperature Tg, melt temperature Tm and thermal expansion coefficient, good heat dissipation ability, chemical resistance, properties of dimensional stability and accuracy, good electrical insulating properties, biocompatibility and permeability, high mechanical strength, low viscosity, and good flow properties.

Many studies discovered that the process parameters such as mold temperature, melt temperature, injection speed, injection pressure, holding time, and holding pressure will influence the quality of the micro-miniature parts. Several microinjection molding machine manufacturers and their products are listed in this article.

Micromachined 3-D Force Sensors

Ryan M. Pocratsky and Maarten P. De Boer
Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

Force measurement; Micromachining; Transduction

Definition

Micromachined three-dimensional (3-D) force sensors measure forces from 10 Newtons (N) to less than 1 nN. This large range depends on the details of the processing technique and the application. Loads are applied to a probe or stylus that extends from the moving body. The input signal can be transduced by various methods including optical, piezoelectric, piezoresistive, and capacitive. The latter two transduction methods are the focus of this entry. The force sensor design typically has a moving body connected by flexible members to a stationary structure. Displacement or strain is measured in the flexible members and correlated to the applied force.

Introduction

This entry provides an overview of a 3-D force sensor design and a summary of recently

published work. First, the various applications for 3-D force sensors are described. Then, design considerations such as sensing methods, cross-sensitivity, flexure design, probe or stylus design, and fabrication methods are discussed. A table that summarizes published results on 3-D force sensors is included. Finally, a section on current and future work is presented.

Force Sensor Applications

Micromachined 3-D force sensors are used in a consumer application known as the Smartpen™ and in disciplines such as biomedicine, robotics, and metrology. Micromachining is a process used to produce microstructures by depositing and selectively etching thin layers. The small-scale features of this process allow precise sensor dimensions to be achieved, which is needed to obtain high force resolution. Additionally, this process allows high volume production of identical devices with integrated mechanical and electrical components. Applications of 3-D force sensors will be described in this section.

In the Smartpen™ [1], the force sensor was developed to measure microscale forces and torques. Although not micromachined, it works according to principles that are used in micromachined 3-D force sensors. The pen utilizes the force sensor to record the motion of the pen on paper and in air [1]. The pen positions can be calculated and an electronic representation generated to store handwritten notes or sketches in a computer [1]. The force range for this sensor is ±5 N with an accuracy of ±0.015 N.

The information obtained from a 3-D micro-force sensor has been used for biomedical research including force feedback in surgical instruments [2] and cell injection studies [3] and for the evaluation of a prosthesis fitting [4]. The force feedback improves the performance of the operator by improving alignment. The surgical instrument utilized a sensor with a force range of ±1 N with a resolution of 5 mN [2]. This sensor was fabricated by wire-cut electrical discharge machining (EDM). The cell injection sensor has a ±300 mN force range in the out-of-plane direction and ±50 mN range in-plane [3]. The larger force range is required for the out-of-plane direction because it is the primary needle insertion direction. The prosthesis of interest was for an above-knee amputee. The user comfort is highly conditioned by the normal and shear forces between the socket surface and the stump [4]. This application required a sensor with a force range of 7 N [4]. A short probe length (200 μm) allows a sensor array to measure the shear and normal force distribution during locomotion, thus reducing skin damage without significantly affecting the dimensions of the prosthetic. To summarize, force feedback information from 3-D force sensors has improved the performance of surgeries [2], biological studies [3], and prosthetic fittings [4].

Another major area of use for 3-D force sensors is tactile sensing for robotic grasping. Arrays of force sensors detect the normal and shear forces developed during a tactile sensing or surface texture qualification operation in robotics [5]. Previous tactile sensors utilized polymer-based techniques, in which it is difficult to control material properties in all directions [6]. Therefore, a micromachined silicon force sensor was proposed by Chu et al. [6] because of its excellent mechanical properties. From Table 1 in the comparison section, the force range for tactile sensors varies from 10 mN (1 g) to about 2 N, depending on the grasping application.

A mesoscale 3-D force sensor has been designed for a surface forces apparatus (SFA) and can be scaled for use in an atomic force microscopy (AFM) application [14]. The fabricated sensor has a force range of 2.7 N out-of-plane and 1 N in-plane with resolutions of 0.23 and 0.16 mN, respectively [14]. Common sensing techniques for currently available AFM tips include optical and piezoresistive methods. However, such sensors work only in two directions, have different sensitivities in each direction, and there is cross-sensitivity between directions [14]. The sensor developed by Kristiansen et al. [14] has little to no cross-sensitivity and similar sensitivities in each direction. The additional dimensional information from the sensor in AFM or SFA applications allows frictional forces,

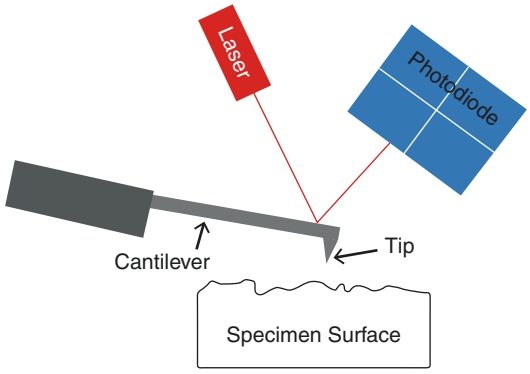
normal forces, and surface roughness to be distinguished. Additionally, greater topographical image resolution can be achieved because the actual position of the tip can be measured.

The measurement of tip position has driven the use of 3-D force sensors in coordinate measurement machines for micro- and nanocomponents [9–12]. Typically, optical methods are used for metrology for devices because of the excellent out-of-plane resolution. However, the moderate lateral resolution of optical sensors prevents them from being useful for structures with steep sidewalls or undercuts [10]. Sensor configurations that utilize multiple 1-D sensors have been used to obtain highly accurate measurements in multiple directions, but they require a complicated setup [11]. The designed 3-D force sensors for this application [9–12] have given measurement resolutions in the range of nanometers, which is similar to the resolution of a scanning electron microscope.



Design Considerations

There are three main components to the design of a 3-D force sensor: sensors, flexural members, and a probe or stylus. The fabrication process has significant impact on the design, performance, and production cost of the sensor. The number and thickness of fabrication layers as well as the etching process limits the possible dimensions of the flexible members. Additionally, the feature resolution through the masking process limits the performance and repeatability of the sensor.

The typical transduction methods used for micro-force sensors are optical, piezoelectric, piezoresistive, and capacitive. These methods are described next, but the optical and piezoelectric methods are used mainly in 1-D and 2-D force sensing. The other design considerations discussed in this section are cross-sensitivity, circuitry, flexure design, probe orientation, fabrication processes, and calibration.

Optical and Piezoelectric Transduction Methods

Optical and piezoelectric methods are mostly used for one- or two-dimensional force sensors. The optical method typically uses a laser reflected from the free end of the cantilever beam to a four-quadrant photodiode, which is the common method used for AFM. Figure 1 shows the typical setup for the optical method. The deflection of the cantilever changes the position at which the light is received on the photodiode. Micromachined

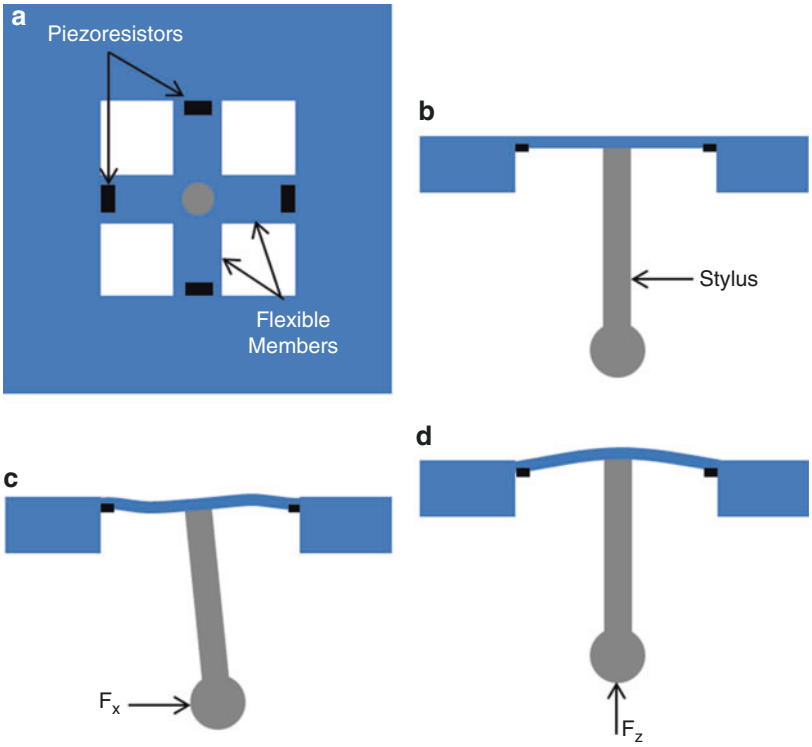
Micromachined 3-D Force Sensors, Fig. 1 Optical sensing method shown in a typical AFM application

cantilevers with a wide range of stiffness and tips are currently available for AFM applications. Based on the deflection and the known stiffness of the cantilever, the applied force can be calculated. The complicated and relatively large spatial setup of the optical systems prevents its extension to 3-D force sensors [18]. The piezoelectric method has also not been extended to 3-D because it can only measure dynamic loads, has a large sensitivity to temperature, and is difficult to set up for multiaxis measurements [18].

Piezoresistive and Capacitive Methods

The piezoresistive and capacitive methods are the primary transduction methods for 3-D micro-force sensors and will be described in this section.

Piezoresistive Method



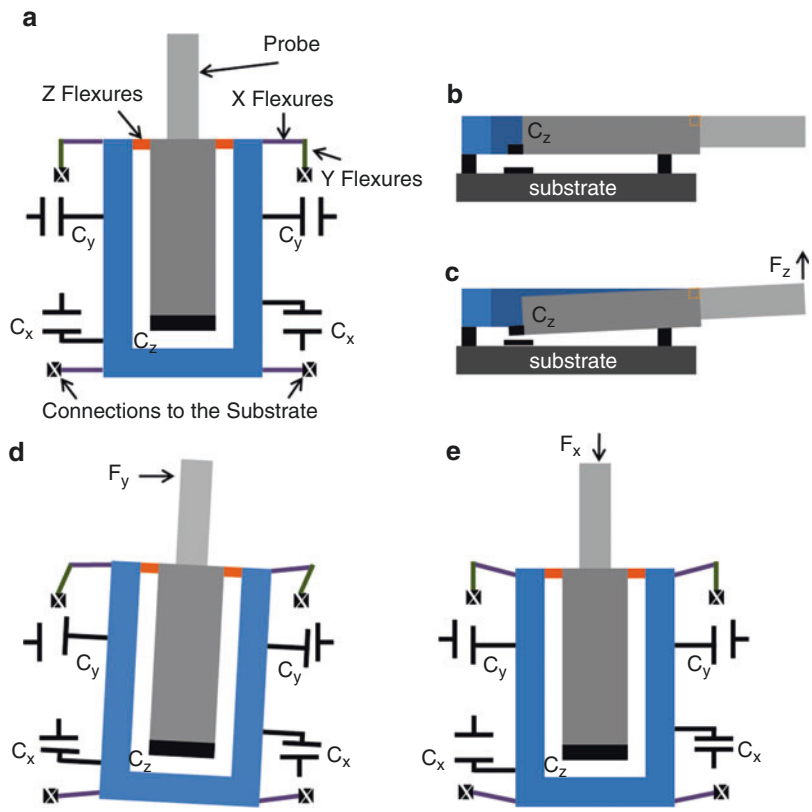
The piezoresistive method relies on strain in the flexible members to create a change in resistance. In piezoresistors, strain affects electron mobility, causing the resistance change. Piezoresistors are placed or fabricated in locations on the flexible members that experience the maximum strain to achieve the greatest sensitivity. Additionally, the flexible member design and piezoresistor locations should be optimized to reduce cross-sensitivity. Piezoresistor placement can be performed during the fabrication process or as a post-processing step. Generally, applying piezoresistors in a postprocessing step increases the variability, cross-sensitivity, and cost of the sensors. The fabrication process will be discussed briefly in the fabrication processes section below.

A common piezoresistive micro-force sensor is shown in Fig. 2. The top view, shown in Fig. 2a, shows a cross-bar flexure design with the typical location of the piezoresistors. Extending from the center of the device is the stylus, shown in Fig. 2b. Loads applied to the stylus tip cause deflections in the flexure members, which create strain in the piezoresistors. The flexure response due to in-plane loads and out-of-plane loads is shown in Fig. 2c, d, respectively. In this design, an out-of-plane load causes an equal amount of strain in all four sensors. An in-plane load applied along a flexible member direction causes equal and opposite strain in two of the four sensors. A simple algorithm can be applied to determine the amount of each.

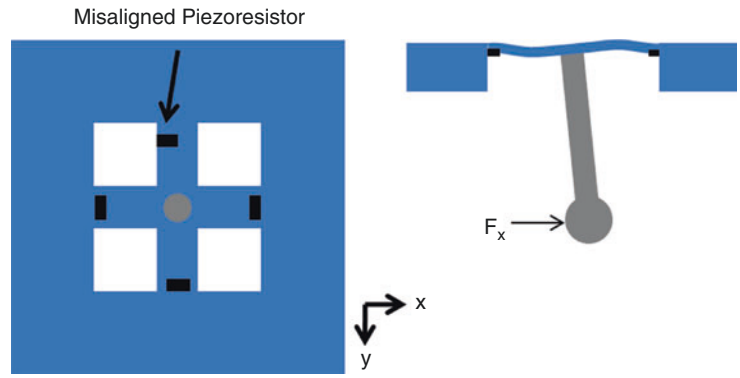
Capacitive Method

The capacitive method relies on displacement changes, which affect parallel-plate capacitor gaps. A generic capacitive force sensor is shown in Fig. 3. Figure 3a shows the various components used in capacitive force sensor design. Flexure members and capacitors are in place for sensing in each direction. A cross section is shown in Fig. 3b to indicate the setup of the out-of-plane capacitor, C_z. If an out-of-plane force is applied to the probe tip, as shown in Fig. 3c, the inner body of the sensor rotates causing a change in capacitance C_z. Similarly, in-plane force responses are shown in Fig. 3d, e. The in-plane capacitors are shown in a differential configuration, which is explained in the circuitry section.

Capacitive force sensing is relatively insensitive to changes in light, temperature, and humidity and exhibits low drift [17]. In-plane capacitors are typically set up in a comb-finger arrangement to increase the overlap area when the device thickness is small. Out-of-plane capacitance is typically set up by a parallel-plate configuration. However, Muntwyler et al. [17] have developed a sensor that uses differential overlap area of two isolated layers for out-of-plane capacitance. The capacitors are typically placed in a location that has the greatest displacement to maximize sensitivity while isolating motion along each axis.



Micromachined 3-D Force Sensors, Fig. 2 Common piezoresistive micro-force sensor with cross-bar flexure design: (**a**) *top view*, (**b**) *side view*, (**c**) in-plane loading response, (**d**) out-of-plane loading response



A drawback to this method is that the application of a sensing voltage to the capacitors creates an electrostatic force on the moving body. This electrostatic force generated from the input voltage signal could cause pull-in issues. Pull-in is an instability that occurs when the electrostatic force overwhelms mechanical spring stiffness. It causes a sudden displacement of the body that closes the capacitor gap, and short-circuiting will occur unless precautions are taken in the design.

Cross-Sensitivity

Cross-sensitivity occurs when a force applied in one direction causes a response in one or two perpendicular directions. It has also been referred to as cross talk or cross-coupling. It is minimized by designing a balanced force sensor with similar stiffness and sensitivity in each direction. Additionally, the location of each sensing element should be optimized to minimize cross-sensitivity. For example, Fig. 2c shows the response of flexures along the x-direction to an x-force. The response of the flexures along the y-direction is a twisting motion. The location of the y-piezoresistors is close to the device base, and therefore they experience minimal strain due to an x-force. Common contributions to cross-sensitivity include variations in material properties along the device, in flexure dimensions due to processing, in the location and fabrication of piezoresistors, and in the dimensions or motions of the parallel plates in capacitive sensors. Returning to the example described above from Fig. 2, the importance of precise positioning of piezoresistors can be seen. If the alignment of a y-piezoresistor were shifted from the center of the y-flexures, the cross-sensitivity between the x and y directions will increase. This misalignment is shown in Fig. 4. If a load is applied along the x-direction, the twisting motion in the y-flexures causes more strain in one of the y-piezoresistors than the other, which generates an output indicating a force along the y-direction. Cross-sensitivity contributes to the output noise from the sensor and reduces the reliable resolution of the sensor. Cross-sensitivity in capacitive sensors is described jointly in the Circuitry section below.

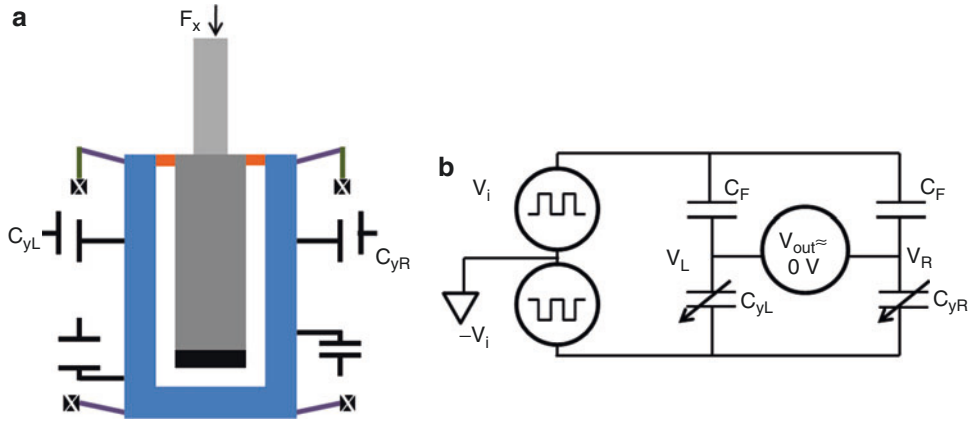
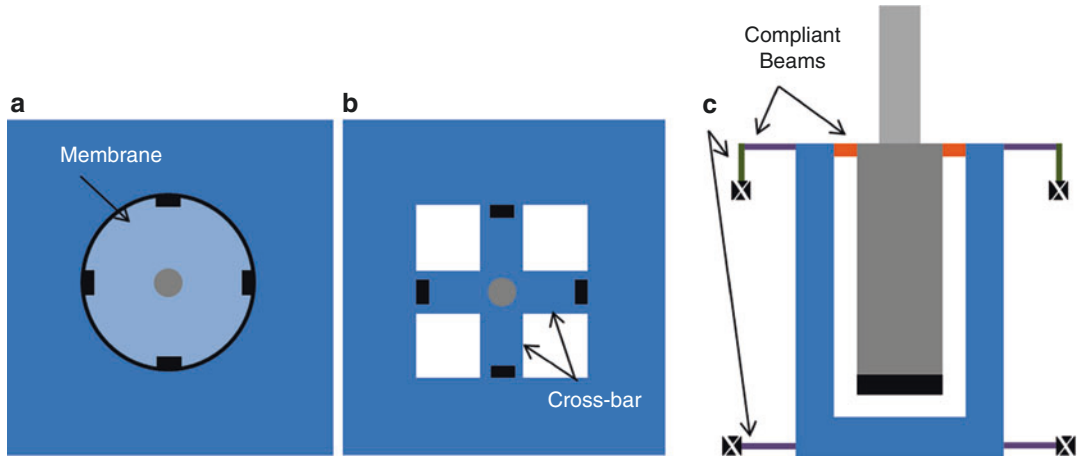
Circuitry

Both piezoresistive and capacitive 3-D force sensors typically utilize a differential sensing configuration with a Wheatstone bridge. An example of the Wheatstone bridge circuitry for the capacitive method with differential capacitor setup is shown in Fig. 5. Figure 5a shows the capacitive device with the circuitry for the x-direction included. The Wheatstone bridge schematic is shown in Fig. 5b. The differential setup of the capacitors allows the gap of one capacitor to increase while the other decreases under the loading in the x-direction, as shown in Fig. 5c. This generates an output voltage that is correlated to the applied force. The circuit schematic shown in Fig. 5d shows the effect of the applied x-force. The left capacitance decreases, the right capacitance increases, and the output signal goes to a negative value. If displacement



Micromachined 3-D Force Sensors, Fig. 5 Wheatstone bridge circuitry for a capacitive force sensor: (**a**) sensor circuit schematic, (**b**) Wheatstone bridge circuit, (**c**) capacitive response to in-plane loading, (**d**) Wheatstone bridge circuit response to in-plane loading

occurs in the opposite direction, the same voltage is output with the opposite sign. The differential resistive Wheatstone bridge behaves in the same way where the compression of one piezoresistor and extension of another creates the differential resistance legs of the circuit.



The differential sensing configuration and Wheatstone bridge circuitry can reduce cross-sensitivity, compared to measuring the output from individual sensing elements. Consider the capacitive force sensor shown in Fig. 3 with an applied load in the x-direction. Figure 6a shows the resulting displacement and effect on the y-capacitors. The overlap area of the y-capacitor plates decreases, which could result in an erroneous signal in the y-direction. However, both capacitors in the differential pair decrease by the same amount. The overall change in capacitance does not affect the output voltage for the y-direction because the same capacitance change is experienced on each side of the Wheatstone bridge, as shown in Fig. 6b.

Flexure Member Design

The design of the flexure members, or flexible members, controls the force range, displacement range, and sensitivity of the device. Three common designs are thin membrane, cross-bar, and compliant beams as shown in Fig. 7. Thin membrane, cross-bar, and combinations of these

Micromachined 3-D Force Sensors, Fig. 6 Differential capacitor configuration with applied x-load and net effect on the y-direction Wheatstone bridge circuit: (**a**) sensor response to in-plane loading, (**b**) circuit response for y-capacitors

Micromachined 3-D Force Sensors, Fig. 7 Common flexure designs: (**a**) thin membrane, (**b**) cross-bar flexures, (**c**) compliant beams

designs are typically used with the piezoresistance method, which can be seen from Table 1 in the comparison section. Compliant beams are typically used with the capacitive method. Analytical considerations determine the approximate stiffness and position of flexures. Then, finite element modeling (FEM) is used to optimize the design to achieve the desired stiffness for the target force range. The results from FEM are also used to determine the optimum placement of the piezoresistors. The flexure design is also affected by the length of the probe or stylus. A long probe tends to amplify the effect of applied loads because of the greater leverage. Therefore, the flexure members must have greater stiffness for longer probes for the same force range.

Probe Orientation

There are two probe, or stylus, orientations: in-plane and out-of-plane. Out-of-plane probes are common for piezoresistive sensors. The probe can be attached to the moving body as a postprocess operation or fabricated with the body. Attaching the probe allows for greater probe lengths than available from fabrication but introduces greater variability in position and increases cost.

Additionally, an off-center probe contributes to the cross-sensitivity of the sensor. In-plane probes are common for capacitive sensors. Since it is cofabricated, its length and position are easily controlled. However, additional processing could be required for applications that require the probe to extend beyond the edge of the substrate.

Fabrication Processes

The fabrication processes used to create the sensors in Table 1 include photolithography, multiple masks, reactive ion etching, and a wet release etch. Typically, bulk micromachining processes are used, but the piezoresistive sensors require additional processing to become functional. Piezoresistive sensors require the piezoresistors to be attached in postprocessing by epoxy or can be integrated in the fabrication process by ion implanting or diffusion. The doping of silicon with ions like boron can create a p-type piezoresistor directly on the flexure members of the device.

Calibration

Calibration of a force sensor requires a known load to be applied and correlated to the output signals. The increased importance of measuring small-scale forces has driven the need to verify these measurements. The small force metrology section of the mass and force group of the National Institute of Standards and Technology (NIST) has developed an electrostatic force balance that can be used to measure nanoscale forces and calibrate other force sensors. Their work has focused on achieving International System of Units (SI) traceability for forces below 1 mN to verify forces measured by indentation equipment and atomic force microscopes (AFMs).

For 3-D sensors, the orientation of the force vector also needs to be known to decompose it into the sensing directions. A matrix can be created to convert a vector of electrical signals to a vector of forces. Ideally, the relationship between force input and the output from the sensor would be linear. Nonlinearities in the response of the device cause additional error in the conversion matrix. For micro-force sensors, applying a known load in a known direction is a difficult task because the resolution of some sensors is smaller than that of the calibration method. However, standards for small force metrology are currently being developed. The sensors presented in Table 1 in the comparison section used the following methods for calibration.

Jin and Mote [16] used Lorentz forces generated from an aluminum cross-beam structure over the force sensor. The aluminum cross-beam is suspended over the force sensor and connected to its center where the probe would be located. This calibration structure is micromachined along with the sensor. Deposition of an aluminum layer on a patterned sacrificial area is used to create the cross-beams and connections to the sensor. Based on the applied current direction to the aluminum beams and magnetic field, forces in each direction can be generated. The analytical model of the generated force is used to calibrate the output signals from the force sensor.

Wang et al. [13] used a precision positioning micro-stage and an analytical balance to calibrate their sensor. The micro-stage has a resolution in the nanometer scale, and the balance has a resolution of 0.01 mg (0.098 μN). The stage is used to move the sensor tip into the balance. The output signals are calibrated to the measurement from the analytical balance. Butefish et al. [9] used the same method with a commercial compensation balance. Valdastri et al. [19] and Tibrewala et al. [11] used a similar method with a commercial load cell rather than a balance.

Dai et al. [12] used a method that requires a micromachined cantilever. Standards have been developed to calibrate the stiffness of micro-cantilevers. The calibrated micro-cantilever is then used to determine the stiffness of the micro-force sensor. The cantilever is moved into the force sensor probe tip along one direction. The deflection of the cantilever and the force sensor probe are measured. The known stiffness of the cantilever and these displacements are used to determine the spring constant of the force sensor. Currently, only one direction was calibrated with this method. Future work on a 3-D micro-force calibration standard will allow the other directions to be calibrated.

Comparisons

A table comparing various designs and sensing methods is shown in Table 1. The published sensors measure forces that range from less than 20 μN to 7 N with resolutions in the nanoNewton scale. The majority of 3-D force sensors utilize the piezoresistive method with a cross-bar and out-of-plane probe design.

Current Status and Future Work

Experiments that require monitoring multiple force components can be set up to use multiple single axis sensors or can be repeated multiple times to gather the necessary information. A 3-D micro-force sensor will reduce this complicated and time-consuming setup. Therefore, there is a growing need for the additional information from higher-dimensional force sensors that has created an active area of research. The sensors presented above were produced for specific research applications. Recently, Muntwyler et al. [17] have developed a sensor with an adjustable force range to allow it to be used for different applications. Future work includes SI-traceable calibration of 3-D force sensors and further improvements in resolution and force range to meet desired research study requirements.

Micropreconcentrators for Micro Gas Chromatography System; Microfabricated Preconcentrator-Focuser in Micro Gas Analyzers

Definition

A micro-preconcentrator is one of the key components in micro gas chromatography system and increasing the concentration of an analyte before detection by using high surface-area adsorbents and rapid thermal desorption of the trapped analytes.

Preconcentration refers to a process of concentrating an analyte (a substance to be identified) before analysis. It is often used by analytical chemists when a concentration of the target

analyte is too low and below the detection limit of a detector. Preconcentration is one of the sample treatment procedures, and many preconcentration methods utilize the isolation and separation techniques such as extraction, sorption, precipitation, distillation, filtration, and centrifugation. For instance, the concentration of solid or low-boiling-point analytes can be increased simply by evaporating or filtrating solvents. In this contribution, a gas-phase preconcentrator, a device that increases the net concentration of gaseous analytes, will be discussed with a particular emphasis on design and manufacturing aspects for small-scale portable applications.

A **gas preconcentrator (GPC)** is installed at the front end of an analytical system [1] to significantly improve the overall performance of the system. Examples of the analytical instruments that can benefit from GPC include gas chromatography (GC), mass spectrometry (MS), ion-mobility spectrometry (IMS), and electrochemical sensors. Concentration enhancement and subsequent improvement of the detection limit are not the only role of GPC [2]. In some cases, GPCs can purify a sample stream and reduce interferents by selective preconcentration. The use of the standard gas source in conjunction with GPC substantially facilitates calibration. Another important role of GPCs is sampling, and sample injection as a focused injected sample eluted into a column can significantly improve a chromatographic resolution.

Preconcentration Method for Gas Phase

Three main methods for gas preconcentration are cryogenic trapping, solvent extraction, and sorption trapping [3]:

(i) Cryogenic trapping typically utilizes a cooled tube filled with high surface-area glass beads through which an air with analytes flows. Cryogenic fluids such as liquid nitrogen or liquid CO_2 are used to achieve trapping temperature between $-150°C$ and $-170°C$. Trapped analytes are released from the cryotrap by direct heating, creating a concentrated band of analytes. The instrumentation involved in cryogenic cooling is however cumbersome and not suitable for portable and miniaturized system. Recently, pseudo-cryogenic trapping using micromachined Peltier coolers was implemented to generate sub-ambient temperature (+10 °C to −30 °C) but had to be combined with sorbents for efficient cryogenic preconcentration.

(ii) Solvent extraction is another popular gas sampling technique – dissolving airborne analytes in an appropriate liquid solvent for preconcentration. Dissolution of the analytes into a solvent is conducted either by bubbling an analyte-containing gas through a dispersion device (called an impinger) or by flowing a film of absorbing liquid along the inner wall of a cylindrical tube, while the gas sample passes through in a counter-flow manner (called a denuder). This solvent loaded with analytes is typically analyzed using liquid-phase detectors such as liquid chromatography and fluorescent spectroscopy, and therefore miniaturization of the solvent extraction method for portable applications appears to be impractical. Moreover, dissolution of analyte into a solvent is thermodynamically limited, and sometimes chromatographic peaks from analytes overlapping with the extract solvent peaks can be a concern.

(iii) Sorption trapping collects analytes onto solid sorbents based on sorption phenomena, including adsorption and absorption. Either active or passive sampling is used – for active sampling, pumping an air with analytes through a bed of sorbents in the order of minutes while, for passive sampling, a gas transport relying on pure diffusion taking in the order of days. Sorbents enriched with the analytes are typically desorbed by thermal desorption. The desorbed analytes form an injection plug in a carrier stream, subsequently eluted into a separation column. In comparison to cryogenic trapping or solid phase microextraction, the main disadvantages of the sorbent-based

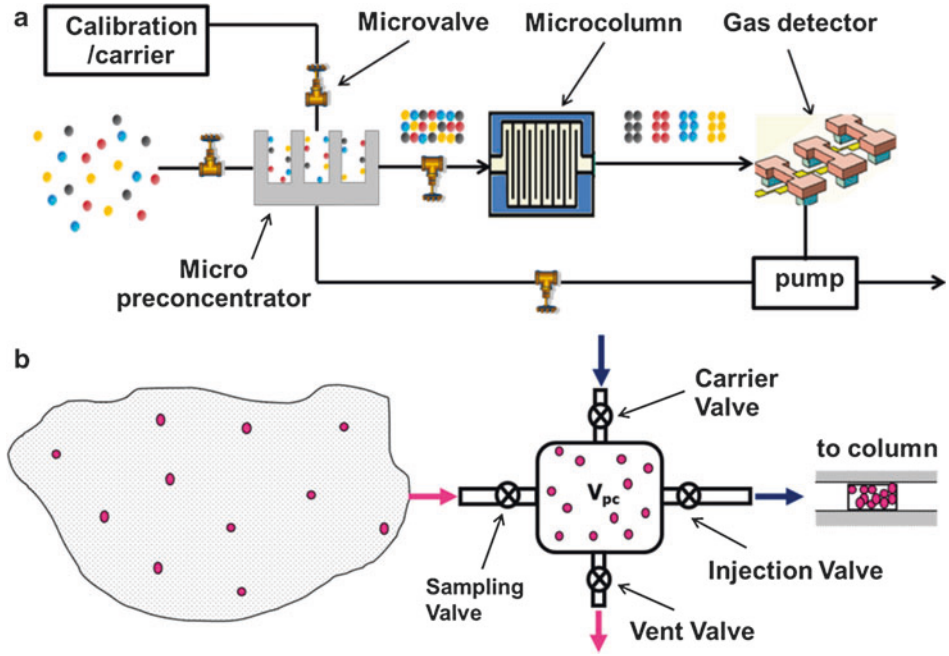
preconcentration using conventional thermal desorption are significant thermal resistance between heating elements and sorbents and long diffusion paths, resulting in a slow analysis and high power consumption. Refocusing of analytes is often required for high-resolution chromatographic separation. Unlike the other sample trapping techniques, GPCs using solid sorbents can greatly benefit from miniaturization for the reasons to be discussed later and are relatively easier to be realized for portable applications.

Preconcentration Factor

The performance of the preconcentrator can be characterized by the preconcentration factor (or preconcentrator gain), G_{PC}, the ratio of the outlet concentration to the inlet concentration of an analyte. Various definitions of preconcentration factor have been introduced in literature, but the most straightforward concept is to take the ratio of the peak height obtained in a detector with preconcentration to the peak height obtained without preconcentration [4]. The other common definition, often used in conjunction with the injection system, is a ratio of the sampling volume, V_{sample}, to the desorption volume, $V_{desorbed}$, (which is the same as the preconcentration volume plus the dead volume).

$$G_{PC} = \frac{V_{sample}}{V_{desorbed}} = \frac{V_{sample}}{W_a \cdot \dot{Q}}$$

The desorption volume can be estimated as a product of the width of the injection peak, W_a, and the desorption flow rate, $\dot{Q}$. The column efficiency is measured by a number of theoretical plate, N_p, and the larger the plate number, the more efficient the chromatographic separation.



$$N_P = 5.545\left(\frac{t_R}{W_a}\right)^2$$

where t_R is the retention time. Therefore, the main role of the preconcentrator is to decrease W_a, i.e., a narrow bandwidth, for a higher number of available theoretical plate.

Micro Gas Preconcentrator (μGPC)

Many environmentally toxic chemicals and other harmful airborne substances are hazardous to human at concentration below 1 ppb, but many portable gas detectors have difficulties in detecting such a trace concentration of toxic vapors. In line with developing a microscale/portable detector with the highest possible sensitivity for a high performance miniature GC system, μGPCs can provide an alternative means to improve the detection limit of the detection system. The role of the μGPC is to capture the vapors of low concentration (<1 ppb) from ambient and thermally desorb them to a much smaller volume eluted in a separation column, thereby increasing the effective concentration to facilitate detection as well as providing a sharp injection plug to promote high-speed chromatographic separations.

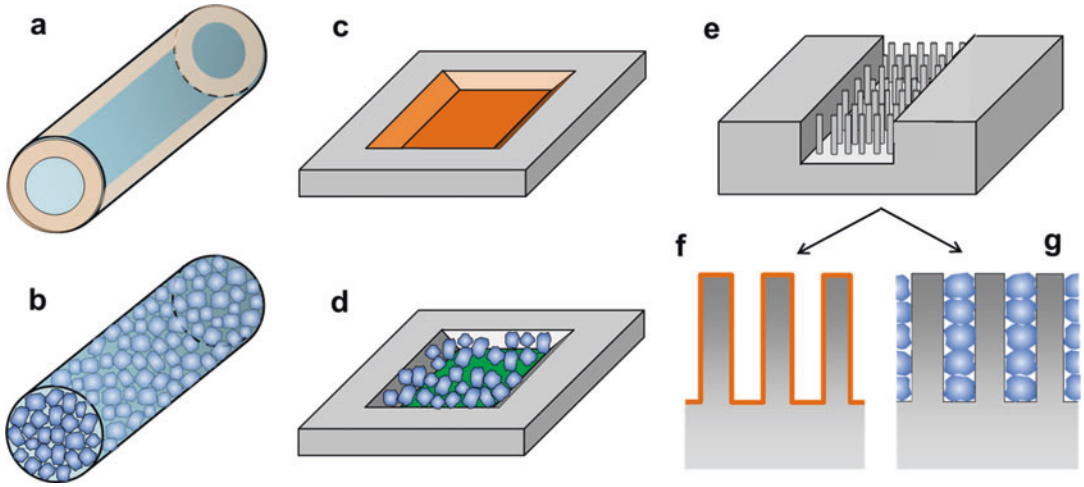
Almost all μGPCs rely on sorption trapping preconcentration. There are two types of preconcentration mode with regard to sorption trapping: exhaustive versus equilibrium preconcentration [5]. In exhaustive preconcentration, all the analytes in a given sample volume are captured for analysis. A typical embodiment of exhaustive preconcentration is a tube packed with a granular adsorbent material, depleting all the sample gases and letting only a carrier gas pass through. While a quantitative trapping can be obtained using this method, it is important not to exceed the predetermined maximum sample volume, *aka* breakthrough volume. In equilibrium preconcentration, the analytes are absorbed into absorbent films until the analytes in stationary and mobile phases reach equilibrium. Because the analytes are not completely trapped by the sorbent system, the captured analyte mass is independent of the sampled volume but rather directly related to the concentration of analytes. The fact that the sample volume does not need to be measured is a key advantage of equilibrium preconcentration approach.

Micropreconcentrator Technology for Portable Gas Chromatography System, Fig. 1 (**a**) A simplified diagram of a micro gas chromatography system including the key components such as a micro-preconcentrator, microvalves, a microcolumn, and a gas detector(s) and (**b**) a diagram of the micro-preconcentrator with the four microvalves (sampling, carrier, vent, and injection) – sampling a trace concentration of target analyte into a small volume reactor packed with adsorbents and later thermally desorbing the analyte into a column

Figure 1a shows how the key components (μGPC, microvalves, microcolumn, sensor array, micropump, and carrier source) are connected in the microGC with a detailed view of the μGPC in Fig. 1b. First, a low concentration of the analyte is pumped into the μGPC chamber and preferentially adsorbed/absorbed onto/into sorbents from a gas stream. In this sampling stage, sampling and vent valves are open, while the other two valves are closed. Once sufficient mass of analytes is gained in the sorbents, the adsorbed/absorbed analytes are thermally desorbed into a smaller volume (corresponding to the chamber volume of the μGPC) and swept into a microcolumn with a carrier gas. In this injection stage, carrier and injection valves are open, while the sampling and vent valves are closed. In the end, the eluted peaks would become sharp and tall with the μGPC, increasing overall sensitivity and detection limit of the system.

Thermal Desorption The trapped analytes need to be recovered for the analysis, and for a microsystem, thermal desorption is considered to be the only viable method due to its simplicity and compatibility with miniaturization. Thermal desorption is carried out by a rapid heating of the sorbents to release the trapped analytes, and this thermally desorbed plug is often coupled to a GC column for efficient separation. The factors that influence the desorption efficiency and the narrowness of the desorption peak are the preconcentrator geometry, sorbent materials, and the operation parameters. These factors need to be considered when designing the μGPC. Especially the geometry of μGPC and sorbent type are the most important design consideration. Some of the operation conditions such as a heating rate, final desorption temperature, desorption duration, and a flow rate will also have an effect on the μGPC design. Desorption performance can be measured by the width and height of desorbed band (*aka* injected plug) – the narrower and taller the desorbed peak, the better the preconcentration device. In general, a fast heating rate and a higher

flow rate produce an arrow bandwidth in the peak. The operation parameters for desorption cannot be however arbitrarily chosen, and a care must be taken such that the desorption temperature is not too high to cause the decomposition of the analytes or sorbent degradation.



Absorbent/Adsorbent Materials A great deal of absorbent or adsorbent materials has been developed and commercially available for gas preconcentration and sampling applications. While absorbent refers to a process by which a material absorbs analytes into its volume, adsorbent is a process by which analytes are accumulated on the surface of the sorbent material. Therefore, whether absorbent or adsorbent materials are used and what characteristics sorbent materials should have are determined based on the type of target analytes. Some common criteria of the sorbent materials include (i) the specific surface area and the porous structure to trap the target analyte, (ii) ability to completely and quickly desorb the analytes, (iii) reversible absorption (or adsorption) and desorption, (iv) chemical stability especially with humidity, (v) thermal stability, and (vi) durability or reusability. Supelco (subsidiary of Sigma Aldrich) is one of the leading manufacturers/distributors for sorbents and has retention and desorption data available for a wide range of sorbents, facilitating the selection of the appropriate sorbents.

The types of absorbent/adsorbent materials are carbon-based or inorganic granular adsorbents and porous polymers. Porous polymers are typically applied as a thin film onto the structure within the μGPC and have smaller surface area and breakthrough volume in comparison to granular-type sorbents. Instead, the low partition coefficient of the porous polymers allows equilibrium in the analyte concentration between the stationary phase (polymer coating) and the mobile phase (carrier gas) to be reached relatively quickly. One of the main disadvantages of porous polymer-based sorbents is its low thermal stability, making it difficult to use them for high-boiling-point compounds that require higher thermal desorption temperatures. Popular trade names for porous polymer sorbents are Tenex®, Porapak™, Chromosorb®, and HayeSep®.

Conversely, granular adsorbents, in general, possess higher breakthrough/retention volumes than porous polymers, leading to higher adsorption capacity and preconcentration factor. Some of the granular adsorbents (e.g., carbon-based adsorbents) are stable at higher temperatures suitable for analysis of high-boiling-point compounds. But it requires a longer time to reach an equilibrium, and a high adsorption capacity typically results in poor desorption efficiency, meaning that it takes more time and energy to completely desorb the trapped analytes. Common granular adsorbents for the μGPCs include inorganic molecular sieves (silica or alumina zeolite), carbon-based molecular sieves (Carboxen® or Carbosieve®), and graphitized carbon black (Carbopack™ series and Carbotrap®). Note that porous polymer adsorbents can be also available in a granular form.

Design of μGPC Portable air sampling and preconcentration have been conducted using a tube preconcentrator, typically consisting of a stainless steel or glass tube packed with one or multiple adsorbent materials. Camsco Inc. is one of the leading manufacturers to produce thermal desorption preconcentrator tubes, and each tube costs around $100. A personal air sampling pump draws a known volume of air at a set flow rate (e.g., 100 ∼ 500 mL/min) through the tube preconcentrator. After completion of sampling in the field, desorption of analytes from the preconcentrator is performed using the desorption apparatus in the laboratory for further analysis. The size and cost of this desorption instrument are similar to the benchtop GC system, and therefore the miniaturization of the desorption instrument along with the preconcentrator unit has been pursued for the past two decades so that both air sampling and analysis can be done on site.

Like the conventional preconcentrators, μGPCs need to be equipped with three key components – adsorbent materials, a heating element for desorption, and fluidic interconnects. In order to promote miniaturization of the device, the preconcentration chamber which holds adsorbents

Micropreconcentrator Technology for Portable Gas Chromatography System, Fig. 2 Schematic diagrams of various μGPC designs: (**a**) wall-coated open tube, (**b**) a packed-bed tube, (**c**) a microheater membrane coated with a thin adsorbent layer, (**d**) a microheater surface packed with granular adsorbents, and (**e**) a preconcentrator chamber filled with an array of microposts; two possible ways to incorporate adsorbents are the surface of the microposts is coated with a thin adsorbent layer (see **f**) and the empty space packed with granular adsorbents (see **g**)

is generally made of a thermally conducting material and directly integrated with a heating element. Figure 2 shows schematic diagrams of the common μGPC designs that have been explored by various research groups. Capillary preconcentrators coated with a thin layer of the adsorbent layer on the inner wall or packed with granular adsorbents are shown in Fig. 2a, b, respectively. The configuration and operation of the capillary preconcentrators are similar to those of the separation column: porous layer open tubular column for Fig. 2a and packed-bed column for Fig. 2b. While capillary preconcentrators offer an effective test platform to characterize the adsorbents in light of preconcentrator operation, the fabrication process is not compatible with the other components of the micro gas chromatography system. A micromachined chamber atop the membrane heater in Fig. 2c and d coated with a thin layer of the adsorbent layer or packed with granular adsorbents is a popular design. One example of the membrane microheater μGPC is the μChemLab® at Sandia National Laboratories, employing a freestanding silicon nitride microhotplate onto which the porous polymer adsorbents were spray-coated [6]. Higher adsorption capacity and a resultant increase in a preconcentration factor can be achieved by incorporating three-dimensional microstructures into the preconcentration chamber (see Fig. 2e–g). An array of slats or posts is commonly utilized to distribute heat more uniformly.

These μGPC designs can be categorized into either equilibrium-type or exhaustive-type preconcentrators. The definition of each preconcentration mode was discussed in the previous section, and Table 1 summarizes the characteristics of each mode. In essence, the equilibrium-mode preconcentrators employ a thin-layer adsorbent layer, which becomes quickly saturated with the analyte concentration and facilitates fast desorption. The designs shown in Fig. 2a, c, f are considered to be equilibrium-mode preconcentrators. A thin adsorbent layer on the heater surface implicates their very low thermal mass and proximity of the thin adsorbents to the heater surface, permitting fast desorption kinetics and low power consumption for operation. But the main disadvantage is their inherently low adsorption capacity and thus low preconcentration factor. On the other hand, the exhaustive-type preconcentrators are supposed to trap all analytes from the sample stream for a larger preconcentrator factor, and therefore the

Micropreconcentrator Technology for Portable Gas Chromatography System, Table 1 Summary of the two different preconcentration modes

	Equilibrium preconcentration	Exhaustive preconcentration
Adsorption capacity (breakthrough volume)	Low	High
Adsorbent design	Thin layer	Packed-bed
Desorption efficiency	High	Low
Desorption time	Short (<100 ms)	Long (>1 s)
Power consumption	Low (<0.2 W)	High (>1 W)
Eluted peak width	Narrower	Broader

packed-bed designs with the granular adsorbents are widely used as shown in Fig. 2b, d, g. Closeness in the packed-bed adsorbents forces a sample gas to flow by poro-diffusion and induces a higher pressure drop (meaning more pumping power). Moreover, the high surface-area granular adsorbents are a poor thermal conductor, leading to a non-uniform heat distribution in the μGPC. Some adsorbents away from the heater surface in the packed-bed require a longer time for a complete desorption.

Whether or not the equilibrium-type or exhaustive-type preconcentrators should be used for μGPCs is related to two engineering trade-offs:

1. Miniaturization versus sample capacity – reduction in device size results in limited surface sites for adsorption and subsequent decrease in a preconcentration factor.
2. High density versus low density packing of adsorbents – solid granular adsorbents packed in the μGPC increase the surface area and adsorption capacity, which comes at a price of a large pressure drop for a fluid flow, large thermal contact resistance, and poor heat and mass transfer during sampling and desorption.

From Fig. 2, each type of the μGPCs can have a range of geometrical configurations and adsorbent/absorbent materials, and therefore a choice of the type, design, and materials of the μGPCs depends on the desired performance characteristics such as adsorption capacity and desorption efficiency (typically lumped as a preconcentration factor) and operation constraints (flow conductance or power consumption).

Fabrication of μGPCs Most of the μGPCs have been built on the silicon substrate because (i) silicon has a relatively high thermal conductivity (~150 W/m · K) for uniform unit conduction; (ii) doped silicon itself can be used as a microheater; (iii) a wide range of micromachining techniques are available for silicon, facilitating the fabrication of intricate geometries; and (iv) other micro gas chromatography components are also based on silicon – ease of integration. A few examples of silicon-based μGPCs will be discussed to delineate the fabrication sequences. The membrane heater-based μGPC like one from Sandia National Laboratories (Fig. 2c, d) consists of a low-pressure chemical vapor deposition (LPCVD) silicon nitride membrane on which a platinum microheater is photolithographically patterned and a silicon cavity created by KOH anisotropic etching followed by deposition of porous polymer adsorbents. The μGPCs with the 3D Si microstructures have been adopted by more research groups – the Wireless Integrated MicroSensing and Systems team from University of Michigan [7, 8], Shannon's group from University of Illinois [9, 10], and Agah's group from Virginia Tech [11, 12]. Arrays of microslats and posts with various cross-sectional geometries have been proposed to better trap analytes and at the same time reduce a pressure drop across the μGPC. These 3D microstructures often serve as microheaters and have been created using photolithography and deep reactive ion etching (DRIE). The porous polymer adsorbents are coated on the surfaces of microstructures (Fig. 2f) by spray-coating or flowing the polymer solution through the microchannels created after bonding with a cover plate. The granular adsorbents can be integrated into the voids of the 3D microstructures (Fig. 2g) by manual insertion with an aid of a shaking table or sonication.

The micromachining techniques such as photolithography, metal deposition, etching, and bonding are scalable (high throughput and large area) and can be used to build the μGPC structures in a manufacturable fashion. However, a method to integrate adsorbent materials is not scalable and incompatible with the micromachining techniques regardless of the type and design of the μGPC. These fabrication challenges associated with integrating heterogeneous materials into μGPCs are as follows:

1. μGPC packed with adsorbent particles: Packing adsorbent particles whose size is comparable to the channel dimension of the device is not trivial. A good packing density entails the application of high pressure, shaking, or ultrasonication, which can damage the microstructures of μGPC. Thus, far adsorbent packing has been carried out for one device at a time with a low success rate.
2. μGPC coated with a thin polymer absorbent: It is difficult to achieve uniform coating. Significantly thicker films are obtained in the corners or turns of the microchannel walls due to higher surface tension. Nonuniform thicknesses may cause slow or incomplete desorption.

Another common design/fabrication issue is the harsh operation condition (due to large temperature difference between adsorption and desorption states). Cyclic thermal stresses exerted to fluidic and electrical connections in μGPCs may cause the premature device failure [10].

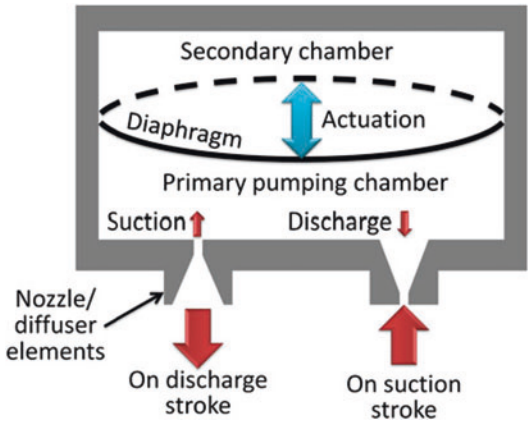
Micropumps

Shawn Litster
Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

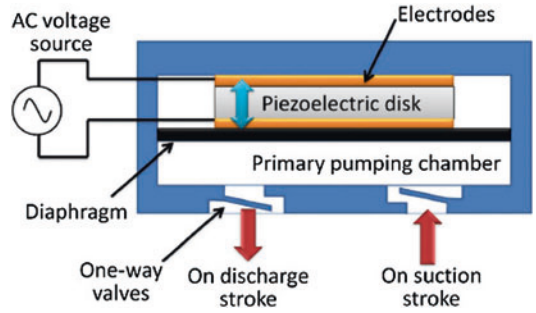
MEMs pumps; Microfluidic pumps; Mini pumps

Definition



A micropump is a miniature fluid delivery device capable of generating flow at finite pressure loads. Micropumps are smaller than the conventional pumps, which use rotary or sliding motion to generate flow, and are usually made by microscale fabrication methods such as micromachining or microinjection molding. Because of their small size, micropumps are capable of using novel actuation mechanisms that are only effective with small length scales, such as piezoelectric strain and electrokinetic effects.

Overview



The demand for micropumps arises from a broad spectrum of applications, including drug delivery, coolant pumping for thermal management, fuel delivery for miniature energy conversion devices like micro-fuel cells, and fluid handling for miniature chemical analysis systems. The following is an introductory review of micropump technology that outlines the various classifications of micropumps and pumping mechanisms. The term "micropump" often refers to pumps with length scales below those of conventional fluid pumping devices that rely on rotary or piston-cylinder mechanisms. Thus, the size of micropumps ranges from lengths of several centimeters to tens of micrometers and less. Furthermore, micropumps typically do not feature the sliding contacts and gaps for the clearance of components, such as the vanes in conventional rotary vane pumps, due to fabrication tolerance limits and the dominance of surfaces, high viscous stresses, and low inertia at smaller scales. A common feature of micropumps is fluid conduits that are sufficiently small that viscous forces dominate over inertia and viscosity rapidly diffuses momentum (i.e., inertia). These conditions are characterized by a low Reynolds number, a nondimensional measure of the ratio of inertial forces to viscous forces.

Micropumps can also be identified by the use of micro-fabrication methods for constructing the pumps, often following microelectromechanical systems (MEMS) fabrication techniques. Often this entails micromachining of silicon and glass substrates, but also microinjection molding of polymers, polymer hot pressing, stereolithography, and printed circuit board methods. As advanced micro- and nanoscale fabrication technologies proliferate and become more affordable, the need for compact devices for pumping small volumes will become more pronounced.

Micropumps are often divided into two main groups: mechanical pumps that displace a diaphragm to generate flow and nonmechanical pumps that have no moving parts. Alternatively, micropumps can be classified by the temporal characteristics of their flow, including whether the flow is periodic as in the case of pumps with oscillating diaphragms, continuous as in the case of many dynamic nonmechanical pumps, or aperiodic as in the case of one-time, single-displacement pneumatic pumps. In the following section, the primary mechanical and nonmechanical types of micropumps are reviewed. These descriptions are intended as brief overviews of the more common micropump architectures and actuation mechanisms and this is certainly not an exhaustive review. For detailed reviews of micropump technology, the reader is referred to the more comprehensive reviews by Laser and Santiago [1], Woias [2], and Nisar et al. [3]. These reviews include comparative benchmarking of various micropumps, which is valuable in selecting a micropump for a given application.

Micropumps, Fig. 1 Schematic of mechanical displacement micropump. The pumped fluid is displaced within the primary pumping chamber and the actuation mechanism is located in the secondary chamber. This schematic is shown with nozzle/diffuser elements for directing the flow in preferential direction

Micropumps, Fig. 2 Schematic of a piezoelectric micropump that uses axial strain in a piezoelectric disk to displace the diaphragm. This pump is shown with one-way valves for setting the flow direction

Mechanical Pumps

As Fig. 1 shows, mechanical pumps use the displacement of a diaphragm to pump fluids. The fluid being pumped passes through the primary pumping chamber and the actuation component is typically the secondary chamber on the other side of the diaphragm. The pump operation consists of two strokes; the discharge stroke when the diaphragm pressurize the primary pumping and the suction stroke when fluid is drawn into the chamber as the diaphragm retracts. These pumps can be devised to deliver a one-time, finite volume fluid or to deliver a continuous, albeit pulsatile, flow. To achieve continual flow, mechanical micropump designs need to include valves or nozzles and diffusers for directing the flow in a preferential direction. Figure 1 illustrates a mechanical pump with nozzle/diffuser elements, whereas Fig. 2 shows a pump with a pair of one-way valves. The nozzle/diffuser approach requires a flow of sufficient inertia such that geometry imposes a preferential direction. Within the family of mechanical micropumps, different pumps technologies are distinguished by the origins of the actuation force that displaces the membrane. The various micropumps include those that have piezoelectric, electrostatic, electromagnetic, thermal, and chemical actuation of membrane displacement.

As depicted in Fig. 1, the actuated diaphragm pressurizes and displaces the fluid in the pump chamber. The valve or nozzle/diffuser arrangement directs the flow in the forward pumping direction. Mechanical pumps can also be arranged in series within elongated pump chamber to mimic a peristaltic pump using a traveling wave of actuation that continually pushes the fluids along in a forward direction. Thus, in those cases, the membranes also serve as the valves that direct the forward flow. A benefit of that arrangement is that the flow can be reversed. One useful design specification for mechanical pump is the compression ratio, which is the ratio of the pumps chamber volume without membrane actuation to the maximum value of the displaced volume with actuation. Another useful metric is the stroke length, which represents the maximum displacement of the diaphragm. The following subsections outline the specific methods for membrane actuation.

Piezoelectric Actuation

Flow in piezoelectric micropumps is actuated by the strain of a piezoelectric substrate upon the application of an electric field and the resulting diaphragm deflection. The use of piezoelectrics in micropumps can be traced to piezoelectric inkjet printer heads first developed by IBM in the 1970s. Although many variations exist, a common arrangement, shown in Fig. 2, is the placement

of a piezoelectric disk, with electrodes on each face, between a deformable diaphragm and the rigid housing of the pump. The pumped fluid is located in a chamber on the other side of the diaphragm. In this case, the axial strain in the piezoelectric disk is used for actuation. In another arrangement, the piezoelectric disk is affixed to the diaphragm and the radial strain induces the deflection of the diaphragm. The primary chamber is connected to the inlet and outlet by valves or a nozzle/diffuser pair. Periodic flow is generated by applying an axial AC electric field to the piezoelectric substrate, which generates a cycle of suction and discharge strokes similar to piston-cylinder pumps. These pumps benefit from being operated at high frequencies, often several kHz. For sufficient stroke length of the diaphragm, piezoelectric pumps are typically operated with high voltages, ranging from 50 to 300 V, which can be considered a disadvantage of piezoelectric pumps. Several commercial pumps feature embedded voltage step-up circuits and have a much lower device-level voltage input. Another challenge of piezoelectric pumps is the small stroke length due to strain limitations of the piezoelectric materials.

Electrostatic Actuation

Mechanical electrostatic micropumps use the electrostatic attraction between polarized parallel electrodes to deflect a diaphragm and produce flow. In this case, one of the electrodes is mounted on the diaphragm and the other on the rigid pump housing (top of the secondary chamber). When the voltage is applied, the electrodes experience a mutual attractive electrostatic force, generating the suction stroke. When the voltage is removed, the elastic deflection of the diaphragm is reversed and the diaphragm returns to its original position, generating the discharge stroke. Thus, an AC electric field or voltage pulses can be used to generate periodic flow. Two advantages of electrostatic pumps are their low power consumption and their fast response time. However, they are challenged by small stroke lengths (<5 μm). This small stroke arises because the induced electrostatic force on the diaphragm scales as one over the electrode spacing squared ($1/x^2$). Thus, the electrodes must be closely spaced, limiting the maximum displacement.

Electromagnetic Actuation

In contrast to electrostatic forces, strong electromagnetic forces can be induced over large length scales. In typical arrangements, a permanent magnet is mounted to the surface of the diaphragm and coils are attached to the housing to generate magnetic fields when electrical currents are applied. A benefit of electromagnetic actuation is the large forces with low applied voltages. Moreover, large diaphragm displacements have been reported with electromagnetic actuation, as much as 200 μm [3]. However, electromagnetic actuation is challenged by unfavorable scaling with miniaturization as well as the greater difficulties in fabricating micro-magnetic devices. In addition, these electromagnetic micropumps tend to be very inefficient, requiring large amounts of power and generating significant heat.

Thermal Actuation

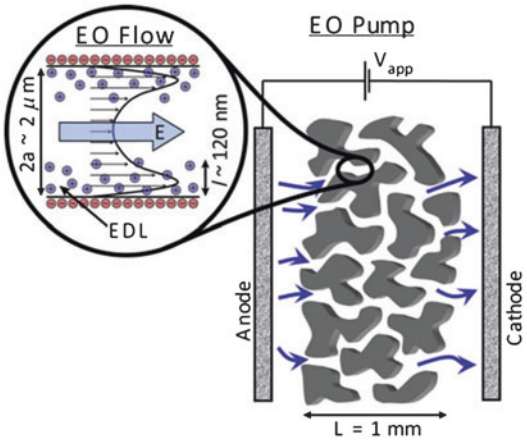
Thermal actuation refers to mechanical micropumps that use heat to actuate the flow. There are two main categories of such pumps: (1) thermopneumatic and (2) phase-change. Thermopneumatic micropumps use the expansion of gases upon heating to generate the diaphragm displacement. The heat is generated by resistance heating (Joule heating) in thin-film heaters, such as aluminum traces. During heating, the expansion of the gas in the secondary chamber drives the diaphragm deflection and the discharge stroke. The temporal response of thermopneumatic pumps is slowed by the heat capacitance of the device, which slows the return of the diaphragm during the suction stroke when heat is removed. Some thermopneumatic micropumps vent the gas upon the beginning of the suction stroke to accelerate the diaphragm. Benefits of thermopneumatic pumps include the ability to generate high displacements. The high displacement is partially enabled by the use of low modulus diaphragms, unlike the more rigid diaphragms of the piezoelectric and electrostatic membranes. This difference is allowed because no components are mounted to the diaphragm in thermopneumatic pumps and

thus large strain is permissible. Unfortunately, thermopneumatic pumps consume a large amount of power and are rather inefficient.

Phase-change actuation for micropumps uses heat to generate displacements by the evaporation/condensation or melting/solidification of a secondary pumping fluid. The evaporation/condensation pumps are also sometimes referred to as "bubble" pumps. Ideally, the melting point or boiling point of the secondary fluid is not significantly far from the temperature of device's surroundings in order to reduce parasitic sensible heating. For evaporation/condensation pumps, the secondary fluids used include isopropyl alcohol. Paraffin has been previously used for melting/solidification pumps.

Bimetallic, Shape Memory Alloy, and Chemical Actuation

Other actuation methods for mechanical pumps include bimetallic, shape memory alloy, and chemical types. In general, these mechanisms share the feature of a bending displacement which actuates the flow. These actuators also share the feature that they can be used to form the diaphragm. Bimetallic and shape memory alloy actuation types use the response of these components to heat to actuate the diaphragm. Bimetallic actuation employs differences in the thermal expansion coefficients between layered materials to generate a bending displacement. Shape memory alloys use the change in these metal's properties caused by the transitions from the malleable martensite phase to the more rigid austenite phase with the application of heat. With these materials, the shape memory alloy can be the actuation component as well as the diaphragm [4].



Chemical actuation can be achieved with ion conductive films, which are often a hydrated polymer electrolyte film with surface adhered electrodes. Examples of these films are perfluorosulfonic acid membranes, which are a Teflon-like polymer backbone with sulfonic acid groups attached to the backbone by side chains. When an electric field is applied across this film, sometimes referred to as an ionic polymer–metal composite (IPMC), the mobile ions migrate towards the electrode with opposite polarity. The ions exert a drag force on the surrounding water, which causes swelling on one side of the film and generates a bending moment similar to that in a bimetallic strip. A benefit of IPMCs is the large displacement at low voltages. However, they require humid environments [5].

Nonmechanical Pumps

Nonmechanical pumps, sometimes referred to as continuous or dynamic pumps, rely on applied electric and magnetic fields as well as chemical reactions to drive the flow. Variations of these pumps include electroosmotic (EO), electrohydrodynamic (EHD), magnetohydrodynamic (MHD), and electrolysis pumps. A common characteristic of these pumps is their continuous flow in comparison to the periodic or aperiodic flows of the mechanical pumps with reciprocating diaphragms described in the previous section. Another feature of many nonmechanical pumps is the generation of flow due to body forces generated within the fluid rather than surface forces due to displacements. A benefit of nonmechanical, continuous pumps is that the lack of moving parts can simplify fabrication and enable smaller devices.

Electroosmotic (EO) Micropumps

EO pumps use the electric double layer (EDL) that naturally forms between solid surfaces and liquids to generate flow. EO pumps can be prepared in a number of arrangements, including a single microchannel, arrays of microchannels, and a porous substrate. In the case of pumping aqueous solutions with a porous glass substrate, silanol groups on the surface of the glass spontaneously deprotonate, creating a negative surface charge and a net-positive layer of mobile ions with a generated potential of roughly -60 to -100 mV. The EDL thickness is characterized by the Debye length, λ. The Debye length physically represents the distance from the charged wall where the electric potential energy balances the thermal energy, with lengths ranging between 1 and 100 nm depending on the ionic strength of the fluid being pumped.

Micropumps, Fig. 3 Schematic of EO flow in a porous glass EO micropump. The EO pump is formed by placing electrodes on either side of a porous glass substrate. When saturated with water, the walls of the porous glass generate a negative charge according to the deprotonation of silanol groups on the surface. A diffuse layer of positive charge in the liquid shields the negative wall charge and completes the EDL. When an electric field, *E*, is applied, the diffuse charges experience a columbic force and bulk flow is generated by viscous interaction

As depicted in Fig. 3 (inset), applying an electric field tangential to a porous glass substrate induces a Columbic force on this mobile ion layer. The viscous interaction between ions and water generates a bulk flow. EO pumps with porous substrates can be fabricated from glass-particle-packed fused silica capillaries, porous borosilicate glass, in situ polymerized porous monoliths, and both planar and porous silicon. Ideally, the porous substrate has high porosity for high flow rates and small pores sizes (<2 μm) to achieve reasonable pressure capacities. A thin substrate is desirable so that high electric fields can be generated with low voltages. The maximum flow rate of EO pumps is linearly proportional to the electric field across the substrate, and the maximum pressure is linearly proportional to the applied voltage.

A benefit of EO pumps is their lack of moving parts, high pressure and flow rate capabilities, and low power consumption. Two issues with the common form of EO pumps are the sensitivity of the EO mechanism on the properties of the fluid and the bubbles generated by the electrolysis at the electrodes for applying the electric field. To avoid the issue with the sensitivity to the pumped fluid, pumps have been developed to use the EO flow of a secondary fluid to displace a diaphragm that drives the primary fluid [6]. Other classes of EO pump use high frequency AC electric fields and asymmetric electrodes to induced charge and generate flow [7]. Another form of induced charge EO pumps are those that employ electroosmosis of the second kind (EO-2) arising from ion-permselective porous media [8, 9]. A benefit of EO-2 pumps is that the flow scales quadratically rather than linearly with applied voltage.

Electrolysis Pumps

Electrolysis pumps are a promising class of micropumps because they have a low voltage requirement and high pressure capacity. In these pumps, the flow is actuated by the generation of gas bubbles by electrochemical reactions. These reactions include the hydrogen and oxygen evolution reactions. These pumps typically operate with an applied voltage of 1.5–3 V. The voltage of 1.5 V is a lower bound because it is the thermal neutral voltage for the decomposition of liquid water. Relative to EO pumps, which also employ electrochemical reactions, electrolysis pumps have a lower flow rate per unit of current. The maximum theoretical flow rate per unit of current, which occurs when the hydrogen and oxygen evolution reactions simultaneously generate displacement, is 11 nl/min/μA. Li et al. [10] demonstrated an implantable electrolysis drug delivery pump with a flow rate per current of 6 nl/min/μA. However, electrolysis pumps are less sensitive to changes in the properties of the aqueous solution and the flow rate can be accurately controlled by the current, which dictates the reaction rate and molar gas generation rate.

Electrohydrodynamic (EHD) Pumps

EHD pumps use an electric field to generate charge and then use that applied charge to induce the flow of a dielectric fluid. Several mechanisms exist for generating charge with an electric field. Two reported types of EHD pumps are the induction and injection types. An induction EHD pump generates charge at the interface of immiscible

fluids with different properties, such as different permittivities. Injection EHD pumps use the charge generated electrochemically at the electrode interfaces. Many of the EHD micropumps developed require very high applied voltages (>200 V). A considerable challenge of EHD pumps in practical applications is the need to have liquids with quite low conductivities, restricting them to certain applications.

Magnetohydrodynamic (MHD) Pumps

MHD pumps use the magnetic component of the Lorentz force to generate flow. This Lorentz force is mathematically described as the cross product of the ionic current with the magnetic field. Thus, axial flow can be generated in a rectangular channel by driving ionic current between electrodes on two opposing channel walls while using permanent magnets to generate a magnetic field between the other two opposing walls. Problematic bubbles due to electrolysis of aqueous solutions can arise with DC ionic currents and this has led to the use of alternating currents that suppress gas evolution. Since the force is proportional to current, these pumps perform best with high conductivity fluids, which restricts their application.

Characterizing Micropump Performance

There are several important figures of merit (FOMs) by which to evaluate micropump performance and suitability to a given application. These FOMs are often either related to pumping hydrodynamic capabilities, the pump power consumption, or the dependence of the pump on certain fluid properties (e.g., high conductivity for MHD pumps). The reviews by Laser and Santiago [1] and Nisar et al. [3] provide useful tabulated comparisons of the many FOMs. Here, the FOMs that generally apply to all of the pumps described are reviewed.

The key FOMs for hydrodynamic micropump performance are the device's maximum flow rate and maximum pressure. The maximum flow rate, Q_{max}, is the flow rate measured where there is zero pressure load. In contrast, the maximum pressure, p_{max}, is evaluated when flow is completely prevented and the total flow rate is zero. Such a condition can be achieved by plugging a pump outlet with a pressure transducer. It is important to note that the required maximum flow rate and pressure depend on the application. For example, an important benchmark for the maximum pressure of micropumps is the central vein pressure of approximately 1.4 kPa, which may serve as a minimum pressure for drug delivery pumps.

A metric related to the maximum flow rate, is the self-pumping frequency, which is the ratio of the maximum flow rate to the volume of the pump. This is important when considering the miniaturization of pump technologies, where it is preferred that the pump's flow rate scales proportionally with its size. This scaling depends on the physics of the flow generation and the fabrication technology. High self-pumping frequencies have been reported for piezoelectric pumps, with the highest values being greater than 10 min^{-1}.

Although the maximum pressure and maximum flow rate serve as first as indication of whether a micropump is sufficient for a given application, the pump's performance curve should be evaluated to determine if a pump is truly viable for a given flow rate and pressure load requirement. Micropump performance curves are often presented on a chart of flow rate versus the pressure load. This curve can usually be approximated as linear line between the maximum flow rate and the maximum pressure, entailing that the flow rate is half its maximum value when the pressure load is half its maximum value. These charts usually contain a family of curves that differ by the constant value of voltage, current, or power that is input to the pump. Thus, the required power, voltage, or current can be determined for a given operating condition.

The pump's required power ($P = VI$) and voltage can be equally important when considering the viability of a micropump. For example, with micropumps for implantable drug delivery devices, it is crucial the power is low such that battery replacement is either rarely required

(>10 year) or not necessary. Similar requirements are required for micropumps in portable devices, such as pumps for fluid handling in distributed chemical sensors.

Another important FOM for evaluating pump performance is efficiency, which is a function of flow rate, pressure load, and power; $\eta = Qp = V_{app}I$. Thus, the efficiency value depends on the operating point within the pump performance curve. To avoid ambiguity, Laser and Santiago [1] used an efficiency metric based on linear pump performance curves to compare micropumps, which estimates the maximum efficiency when the pressure load and the flow rate are half of their maximum values. This efficiency metric is defined by the equation $\eta = 0.25Q_{max}p_{max} = V_{app}I$. Due to many of the actuation methods for micropumps being very inefficient, often including thermal actuation by Joule heating, micropumps tend to have very low efficiencies. For example, for most EO pumps, their efficiency is <1 %. However, in many applications, the efficiency is an irrelevant FOM because the power consumption is negligible relative to the power of the total system that includes the micropump. An example is the negligible power draw of an EO pump that used to regulate liquid water within a polymer electrolyte fuel cell [11].

Definition

Semiconductor-based optoelectronic quantum devices are new-generation nanosystems in which the carrier dynamics shows purely quantum-mechanical or phase-coherence phenomena. The latter result from a proper combination of quantum confinement effects and ultrafast intra- and/or interband optical excitations. A cohesive theoretical treatment of transport versus optical properties is both the key tool for the microscopic investigation of such nanosystems and the essential prerequisite for the modeling and optimization of customized device designs. Diverse simulation strategies, ranging from semiclassical to fully quantum-mechanical approaches, may be devised each with its own validity limits. More specifically, one has to distinguish between ultrafast and steady-state properties of the system, in the linear as well as in the nonlinear response regime, thus identifying the corresponding levels of description. The most severe problem in quantum-device modeling is the microscopic treatment of a quantum system with spatial open boundaries. Any solid state electronic nanodevice is an intrinsically open quantum system, exchanging both energy with the host material and carriers with connected reservoirs. Its out-of-equilibrium behavior is determined by a complex interplay between electronic dissipation and decoherence induced by inelastic processes within the device, as well as by the coupling of the latter to metallic electrodes.

Introduction

Following the path paved by the early proposal by Esaki and Tsu [1], artificially tailored semiconducting heterostructures at the nanoscale now form the leading edge of device technology. The design of modern optoelectronic devices, in fact, heavily exploits the principles of band-gap engineering [2] achieved by confining charge carriers in spatial regions comparable to their de Broglie wavelengths. A proper combination of quantum confinement effects and ultrafast intra- and/or interband optical excitations may give rise to purely quantum-mechanical or phase-coherence phenomena in the carrier dynamics of new-generation optoelectronic devices, and for this reason the latter are often referred to as semiconductor quantum devices [3]. Indeed, present micro/nanoelectronics technology together with modern ultrafast optical spectroscopy push device dimensions and external electrooptical excitations toward space- and timescales where the traditional semiclassical picture mentioned above can no longer be applied and genuine quantum approaches are imperative [3, 4]. However, in spite of the quantum-mechanical nature of electron and photon dynamics in the core region of typical solid-state nanodevices – e.g., superlattices [5] and quantum-dot structures [6] – the overall behavior of such quantum systems is often governed by a highly nontrivial interplay between phase coherence and energy dissipation/decoherence [7, 8], the latter being also strongly influenced by the presence of spatial boundaries [9].

This entry aims to present a cohesive theoretical treatment of transport versus optical properties of semiconductor nanomaterials, essential prerequisite for the microscopic modeling of new-generation optoelectronic quantum devices. We shall discuss different simulation strategies,

ranging from semiclassical to fully quantum-mechanical approaches, together with their validity limits. More specifically, we shall distinguish between ultrafast and steady-state properties of the system, in the linear as well as in the nonlinear response regime, thus identifying the corresponding levels of description. In particular, we shall address the most severe problem in quantum-device modeling: the microscopic treatment of a quantum system with spatial open boundaries. In this context, (i) we shall point out and explain intrinsic limitations of the conventional quantum-device modeling based on the well-known Wigner-function paradigm [9] (providing a definite answer to open questions related to the applicability of the semiclassical spatial-boundary-condition scheme [10]), and (ii) we shall discuss how to overcome such limitations by adopting a nonlocal density-matrix based treatment, in terms of a recently proposed Lindblad-like system-reservoir scattering superoperator [11].

The present essay is organized as follows: In section "Microscopic Modeling of Semiconductor Nanostructures" we shall provide a thorough (intra versus interband) theoretical framework for the microscopic modeling of semiconductor nanostructures based on the density-matrix formalism. In section "From Nanomaterials to Nanodevices" we shall extend such framework to semiconductor nanodevices; in particular, we shall address the most critical task in quantum-device modeling, i.e., the microscopic description of a finite-size quantum nanodevice with open spatial boundaries, corresponding, e.g., to the case of a "small" semiconductor nanodevice embedded into an electric circuit.

Microscopic Modeling of Semiconductor Nanostructures

Physical System

In order to provide a global (intra versus interband) description of the electro-optical properties of semiconductor nanomaterials and nanodevices, we consider a generic carrier gas within a semiconductor nanostructure in the presence of electromagnetic fields. The corresponding Hamiltonian can be schematically written as

$$\hat{H} = \hat{H}^{\circ} + \hat{H}' + \hat{H}_{\mathrm{ern}}. \tag{1}$$

Here, the noninteracting term

$$\hat{H}^{\circ} = \hat{H}_{\mathrm{c}} + \hat{H}_{\mathrm{p}} \tag{2}$$

is the sum of the noninteracting carrier and phonon Hamiltonians, the many-body term

$$\hat{H}' = \sum_{s} \hat{H}'_{s} \tag{3}$$

may include all relevant interaction mechanisms s, namely various carrier-carrier as well as carrier-phonon contributions, and the Hamiltonian $\hat{H}_{\mathrm{em}}$ describes the interaction of the carrier system with the electromagnetic (em) radiation.

More specifically, the noninteracting-carrier Hamiltonian $\hat{H}_{\mathrm{c}}$ describes the scattering-free carrier system within the effective three-dimensional confinement potential of the nanomaterial. By denoting with α the generic noninteracting carrier state and with ϵ_{α} the corresponding energy, the noninteracting-carrier Hamiltonian can be written as

$$\hat{H}_{\mathrm{c}} = \sum_{\alpha} \epsilon_{\alpha} \hat{c}^{\dagger}_{\alpha} \hat{c}_{\alpha}, \tag{4}$$

where the usual second-quantization picture in terms of creation ($\hat{c}^{\dagger}_{\alpha}$) and annihilation ($\hat{c}_{\alpha}$) operators has been employed.

The explicit form of the various many-body contributions $\hat{H}'_{s}$ in Eq. 3 as well as of the electromagnetic-coupling term $\hat{H}_{\mathrm{em}}$ can be found in Rossi and Kuhn [7]; the latter depend on the specific interaction mechanism considered, and typically involve additional degrees of freedom, like phonons, photons, etc. From the point of view of the carrier subsystem, such contributions can be divided into two different classes: single-particle terms – including carrier-phonon and carrier-light interactions – and two-body Coulomb interactions.

Single-particle Description

In order to investigate the electro-optical response of a nanomaterial, it is crucial to study the time evolution of single-particle quantities, such as the total carrier density, mean kinetic energy, charge current, and so on. In general, such quantities are given by a suitable (quantum-plus-statistical) average of a corresponding single-particle operator $\hat{a}$, usually expressed in terms of the global density-matrix operator $\hat{\varrho}$ as [3, 12]

$$\langle a \rangle = \mathrm{tr}\{\hat{a}\hat{\varrho}\}. \tag{5}$$

Recalling that any single-particle electronic operator is of the form

$$\hat{a} = \sum_{\alpha_1 \alpha_2} a_{\alpha_2 \alpha_1} \hat{c}^{\dagger}_{\alpha_2} \hat{c}_{\alpha_1}, \tag{6}$$

the average value in Eq. 5 can simply be written as

$$\langle a \rangle = \sum_{\alpha_1 \alpha_2} a_{\alpha_2 \alpha_1} \rho_{\alpha_1 \alpha_2}, \tag{7}$$

where

$$\rho_{\alpha_1 \alpha_2} = \mathrm{tr}\left\{\hat{c}^{\dagger}_{\alpha_2} \hat{c}_{\alpha_1} \hat{\varrho}\right\} \tag{8}$$

is the single-particle density matrix [7]. Its diagonal elements ($\alpha_1 = \alpha_2$) correspond to the single-particle carrier distribution of the semiclassical Boltzmann theory (see section "Semiclassical Limit") while the off-diagonal contributions ($\alpha_1 \neq \alpha_2$), also referred to as interstate polarizations [7], describe quantum-mechanical phase coherence between the single-particle states α_1 and α_2.

Before continuing, it is worth mentioning that an alternative approach, equivalent to the density-matrix formalism considered here, is given by the nonequilibrium Green's-function technique. An introduction to the theory of nonequilibrium Green's functions with applications to many problems in transport and optics of semiconductors can be found in the book by Hartmut Haug and Antti-Pekka Jauho [13]; by employing – and further developing and extending – such nonequilibrium Green's function formalism, a number of groups have proposed efficient quantum-transport treatments for the study of various meso- and nanoscale structures as well as of corresponding micro- and optoelectronic devices [14].

As discussed below, in addition to this basic subdivision between diagonal (classical) and off-diagonal (quantum) density-matrix elements, the latter are also classified according to their intra- versus interband nature. It is thus clear that the actual set of density-matrix elements $\rho_{\alpha_1 \alpha_2}$ to be considered depends strongly on the particular problem under examination, e.g., ultrafast versus steady-state conditions as well as intra- versus interband carrier dynamics.

In the Schrödinger picture, the time evolution of the average value in Eq. 7 is fully dictated by the time evolution of the single-particle density matrix Eq. 8. Starting from the Heisenberg equations of motion for the creation and destruction operators, it is possible to derive a set of equations of motion for the density-matrix elements $\rho_{\alpha_1 \alpha_2}$ – often referred to as generalized semiconductor Bloch equations [3, 7] – whose general structure is given by:

$$\frac{\mathrm{d}\rho_{\alpha_1 \alpha_2}}{\mathrm{d}t} = \left.\frac{\mathrm{d}\rho_{\alpha_1 \alpha_2}}{\mathrm{d}t}\right|_{\hat{H}^{\circ}} + \left.\frac{\mathrm{d}\rho_{\alpha_1 \alpha_2}}{\mathrm{d}t}\right|_{\hat{H}'} + \left.\frac{\mathrm{d}\rho_{\alpha_1 \alpha_2}}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}}. \tag{9}$$

The time evolution induced by the noninteracting Hamiltonian $\hat{H}^{\circ}$ in Eq. 1 can be evaluated exactly, yielding

$$\left.\frac{\mathrm{d}\rho_{\alpha_1 \alpha_2}}{\mathrm{d}t}\right|_{\hat{H}^{\circ}} = \frac{\epsilon_{\alpha_1} - \epsilon_{\alpha_2}}{\mathrm{i}\hbar} \rho_{\alpha_1 \alpha_2}. \tag{10}$$

The resulting dynamics is thus diagonal within the $\alpha_1 \alpha_2$ representation, i.e., each density-matrix element evolves independently according to

$$\rho_{\alpha_1 \alpha_2}(t)\big|_{\hat{H}^{\circ}} = \mathrm{e}^{-\mathrm{i}\omega_{\alpha_1 \alpha_2}(t - t_{\mathrm{o}})} \rho_{\alpha_1 \alpha_2}(t_{\mathrm{o}}) \tag{11}$$

with $\hbar\omega_{\alpha_1 \alpha_2} = \epsilon_{\alpha_1} - \epsilon_{\alpha_2}$. In particular, while the diagonal elements are not affected by the free dynamics, the off-diagonal elements (describing

interstate electronic polarization) rotate with a frequency proportional to the energy difference between states α_1 and α_2. As we shall discuss below, this off-diagonal dynamics – absent in the semiclassical (diagonal) limit – gives rise to a variety of phase-coherence phenomena in quantum optoelectronic devices [3, 6].

The time evolution induced by the many-body Hamiltonian in Eq. 3 involves, in general, phonon-assisted as well as higher-order density matrices. Thus, in order to "close" the set of equations of motion (with respect to the single-particle density matrix in Eq. 8) approximations are needed. A detailed discussion of the various approximation schemes – based on a dynamical expansion in powers of the various interaction Hamiltonians $\hat{H}'_s$ – can be found in Rossi and Kuhn [7]. In particular, the "mean-field" approximation together with the Markov limit allows one to derive a set of closed equations of motion still local in time. For a number of interaction mechanisms, including carrier-phonon as well as carrier-carrier scattering, their second-order contributions to the time evolution can be cast into the general form:

$$\left.\frac{\mathrm{d}\rho_{\alpha_1\alpha_2}}{\mathrm{d}t}\right|_{\hat{H}'} = \Gamma(\rho)_{\alpha_1\alpha_2}. \tag{12}$$

Although $\Gamma(\rho)$ is, in general, a nonlinear function of ρ, in the low-carrier-density limit (i.e., $|\rho_{\alpha_1\alpha_2}| \ll 1$), carrier-carrier scattering as well as Pauli-blocking phenomena play a minor role, and the many-body contribution in Eq. 12 can be written as

$$\left.\frac{\mathrm{d}\rho_{\alpha_1\alpha_2}}{\mathrm{d}t}\right|_{\hat{H}'} = \sum_{\alpha'_1\alpha'_2} \Gamma_{\alpha_1\alpha_2,\alpha'_1\alpha'_2}\rho_{\alpha'_1\alpha'_2}, \tag{13}$$

where $\Gamma_{\alpha_1\alpha_2,\alpha'_1\alpha'_2}$ are the matrix elements of the so-called scattering superoperator Γ [3]: their real parts describe incoherent phenomena, like energy-dissipation and decoherence processes, while their imaginary parts lead to modifications of the free coherent evolution in Eq. 11 through nontrivial energy-renormalisation effects.

The explicit form of the time evolution induced by the electromagnetic-radiation coupling Hamiltonian $\hat{H}_{\mathrm{em}}$ heavily depends on the adopted level of description, which, in turn, is dictated by the problem under examination: in order to investigate high-field phenomena and/or ultrafast nonlinear optical excitations, this interaction can be treated exactly in terms of purely classical electromagnetic fields; in contrast, in order to investigate quantum-optics phenomena – like photoluminescence experiments – additional approximation schemes are needed [7].

By combining Eqs. 9, 10 and 13, the explicit form of the generalized semiconductor Bloch equations turns out to be

$$\frac{\mathrm{d}\rho_{\alpha_1\alpha_2}}{\mathrm{d}t} = \sum_{\alpha'_1\alpha'_2} L_{\alpha_1\alpha_2,\alpha'_1\alpha'_2}\rho_{\alpha'_1\alpha'_2} + \left.\frac{\mathrm{d}\rho_{\alpha_1\alpha_2}}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}}, \tag{14}$$

where the effective Liouville superoperator

$$L_{\alpha_1\alpha_2,\alpha'_1\alpha'_2} = \frac{\epsilon_{\alpha_1} - \epsilon_{\alpha_2}}{\mathrm{i}\hbar}\delta_{\alpha_1\alpha_2,\alpha'_1\alpha'_2} + \Gamma_{\alpha_1\alpha_2,\alpha'_1\alpha'_2} \tag{15}$$

is the sum of two terms: free single-particle evolution plus scattering-induced energy-dissipation/decoherence dynamics.

The above single-particle quantum equation applies to a variety of physical problems [3], ranging from quantum-transport phenomena to ultrafast electro-optical processes. However, it is worth emphasizing that the degree of accuracy of such density-matrix formalism is intimately related to the choice of the scattering superoperator Γ. Indeed, oversimplified phenomenological treatments can lead, for instance, to a violation of the positive-definite character of the density matrix [15], a crucial prerequisite of any quantum-mechanical time evolution. This issue is particularly important for solid-state devices, which are characterized by a complex many-electron quantum evolution. A general prescription ensuring the positive-definite character of the density matrix consists in expressing dissipation versus decoherence phenomena in terms of suitable Lindblad-type superoperators, containing a few crucial system-environment coupling parameters. This problem has been discussed in Taj

et al. [16], where a novel Markov procedure leading to positive-definite superoperators has been proposed. More specifically, thanks to a proper reformulation of the Markov limit, for each single-particle interaction mechanism in the low-density limit one is able to perform a fully microscopic derivation of a corresponding Lindblad scattering superoperator, thereby preserving the positivity of the single-particle density matrix. The Lindblad-type approach in Taj et al. [16] has been recently extended to the high-density regime [17].

Global Versus Partial Treatments

The above-discussed general or global density-matrix formalism does not distinguish between intra- and interband excitations, i.e., it is not grounded on an explicit separation between valence and conduction bands. Indeed, such a formulation applies to bulk as well as to nanostructured materials: for the case of bulk crystals one has $\alpha \equiv \mathbf{k}v$, where $\mathbf{k}$ denotes the three-dimensional carrier wavevector and v is the crystal band index; for the case of a semiconductor nanostructure, by employing the conventional envelope-function picture [3], the generic label α of the noninteracting electronic states is given again by the band index v, whereas the three-dimensional wavevector $\mathbf{k}$ is replaced by a low-dimensional wavevector $\mathbf{k}_{\|}$ plus a subband index n, i.e., $\alpha \equiv \mathbf{k}_{\|}nv$.

Recalling that for a semiconductor nanostructure an optical excitation – according to its spectral range – may induce transitions between different electronic bands (interband transitions) or within the same band (intraband transitions), it follows that the relevant set of density-matrix elements $\rho_{\alpha\alpha'}$ to be considered depends crucially on the excitation spectral region. More specifically, in addition to the state populations corresponding to the diagonal density-matrix elements $\left(\rho_{\mathbf{k}_{\|}nv,\mathbf{k}_{\|}nv}\right)$, for intraband ($v = v'$) excitations the only relevant quantities are given by intraband polarizations corresponding to the off-diagonal density-matrix elements $\rho_{\mathbf{k}_{\|}nv,\mathbf{k}_{\|}n'v}$; the latter are also referred to as intersubband ($n \to n'$) polarizations. In contrast, for interband ($v \neq v'$) excitations the only relevant quantities are given by interband polarizations corresponding to the off-diagonal density-matrix elements $\rho_{\mathbf{k}_{\|}nv,\mathbf{k}_{\|}n'v'}$; the latter describe interband optical transitions connecting the generic subband n in band v to the generic subband n' in band v'. As observed above, moving from bulk to nanostructures the three-dimensional wavevector $\mathbf{k}$ is replaced by the so-called parallel-subspace wavevector $\mathbf{k}_{\|}$, while – in addition to the band index v – the subband index n should be considered as well.

The intra- versus interband classification scheme just introduced suggests to separate the global set of states α according to the well-established electron–hole picture [3, 7]. To this end, we shall denote by $i \equiv \mathbf{k}_{\|}n_e v_e$ and $j = -\mathbf{k}_{\|}n_h v_h$, respectively, electron and hole states, and with $\hat{c}_i^{\dagger}$ $(\hat{c}_i)$ and $\hat{d}_j^{\dagger}$ $(\hat{d}_j)$ the corresponding creation (destruction) operators. Within such electron–hole picture, the original/global single-particle density matrix in Eq. 8 is replaced by the following electron and hole density matrices,

$$\mathrm{f}^{e}_{i_1 i_2} = \mathrm{tr}\left\{\hat{c}^{\dagger}_{i_2}\hat{c}_{i_1}\hat{\varrho}\right\}, \quad \mathrm{f}^{h}_{j_1 j_2} = \mathrm{tr}\left\{\hat{d}^{\dagger}_{j_2}\hat{d}_{j_1}\hat{\varrho}\right\}, \quad (16)$$

together with the following interband-polarization matrix

$$p_{i_1 j_1} = \mathrm{tr}\left\{\hat{d}_{j_1}\hat{c}_{i_1}\hat{\varrho}\right\} \quad (17)$$

and the density-matrix equation in 14 is transformed into the following set of coupled kinetic equations:

$$\begin{aligned}
\frac{\mathrm{d}\mathrm{f}^{e}_{i_1 i_2}}{\mathrm{d}t} &= \sum_{i'_1 i'_2} L^{e}_{i_1 i_2, i'_1 i'_2}\mathrm{f}^{e}_{i'_1 i'_2} + \left.\frac{\mathrm{d}\mathrm{f}^{e}_{i_1 i_2}}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}} \\
\frac{\mathrm{d}\mathrm{f}^{h}_{j_1 j_2}}{\mathrm{d}t} &= \sum_{j'_1 j'_2} L^{h}_{j_1 j_2, j'_1 j'_2}\mathrm{f}^{h}_{j'_1 j'_2} + \left.\frac{\mathrm{d}\mathrm{f}^{h}_{j'_1 j'_2}}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}} \\
\frac{\mathrm{d}p_{i_1 j_1}}{\mathrm{d}t} &= \sum_{i'_1 j'_1} L^{p}_{i_1 j_1, i'_1 j'_1} p_{i'_1 j'_1} + \left.\frac{\mathrm{d}p_{i'_1 j'_1}}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}},
\end{aligned} \quad (18)$$

where L^e, L^h, and L^p are again effective Liouville superoperators acting separately on electrons, holes, and interband polarizations; similar to the general structure in Eq. 15, each of these superoperators is again the sum of two

terms: free single-particle rotation plus scattering-induced energy-dissipation/decoherence dynamics.

As anticipated, in order to describe the ultrafast nonlinear response of bulk as well as nanostructured materials, the nontrivial coupling between electron/hole density matrices and corresponding interband polarizations is expected to play a major role, and for this reason a solution of the above coupled set of kinetic equations (equivalent to the global density-matrix equation (14)) is imperative [3, 7]. In contrast, for the case of an interband optical excitation that varies slowly compared to the typical carrier free-dynamics as well as decoherence time-scales, the interband polarization fields $p_{i_1 j_i}$ may be adiabatically eliminated [7], and the original set in Eq. 18 reduces to:

$$\begin{aligned} \frac{\mathrm{d}f^{e}_{i_1 i_2}}{\mathrm{d}t} &= \sum_{i'_1 i'_2} L^{e}_{i_1 i_2, i'_1 i'_2} f^{e}_{i'_1 i'_2} + G^{e}_{i_1 i_2} \\ \frac{\mathrm{d}f^{h}_{j_1 j_2}}{\mathrm{d}t} &= \sum_{j'_1 j'_2} L^{h}_{j_1 j_2, j'_1 j'_2} f^{h}_{j'_1 j'_2} + G^{h}_{j_1 j_2}. \end{aligned} \tag{19}$$

Equation 19 thus express the effect of the external electromagnetic excitation simply via generalized generation/recombination rates $G^{e/h}$, describing the effect on the electron–hole system of both intra- and interband optical excitations. It follows that within such approximation scheme these generation/recombination rates act as input parameters determined by the shape of the external electromagnetic excitation, and electron and hole subsystems are not coupled anymore. In particular, in the presence of an intraband (i.e., infrared) excitation only, the two density-matrix equations in 19 can be solved independently.

The main conclusion of the analysis presented so far is that the level of description used to simulate the electro-optical response of a semiconductor nanostructure depends strongly on the nature of the external electromagnetic excitation: for the case of ultrafast nonlinear interband excitations one deals with a highly nontrivial coupling between carrier populations and interband polarizations, often dominated by excitonic effects [3, 7]. In contrast, for slowly-varying interband illumination or for intraband excitations only, the electron and hole subsystems can be simulated independently. Moreover, for specific operation conditions of the nanodevice, phase-coherence phenomena – described by off-diagonal density-matrix elements – can be safely neglected, and the semiclassical or Boltzmann picture is recovered (see below).

Semiclassical Limit

For various optoelectronic devices operating in steady-state or quasi-steady-state conditions, electronic phase coherence is expected to play a minor role, and for this reason one is allowed to employ the standard semiclassical picture. A relevant example of such a semiclassical modeling is the microscopic simulation of infrared quantum-cascade lasers [8] and photodetectors.

In any semiclassical treatment the off-diagonal elements of the density matrix are neglected, i.e., the density-matrix elements acquire the form

$$\rho_{\alpha_1 \alpha_2} = f_{\alpha_1} \delta_{\alpha_1 \alpha_2}. \tag{20}$$

In this limit (i) the coherent free evolution in Eq. 10 vanishes, and (ii) the many-body contribution in Eq. 13 reduces to

$$\left.\frac{\mathrm{d}f_\alpha}{\mathrm{d}t}\right|_{\hat{H}'} = \sum_{\alpha'} [P_{\alpha\alpha'} f_{\alpha'} - P_{\alpha'\alpha} f_\alpha], \tag{21}$$

where $P_{\alpha\alpha'}$ is the total (i.e., summed over all relevant interaction mechanisms) scattering rate from state α' to state α. It follows that the semiclassical limit of the density-matrix equation (14) is given by the following Boltzmann-like equation

$$\frac{\mathrm{d}f_\alpha}{\mathrm{d}t} = \sum_{\alpha'} [P_{\alpha\alpha'} f_{\alpha'} - P_{\alpha'\alpha} f_\alpha] + \left.\frac{\mathrm{d}f_\alpha}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}}. \tag{22}$$

Let us finally reformulate the semiclassical limit in terms of the electron–hole picture previously introduced (see Eqs. 16 and 17). By inserting into the effective set of density-matrix equations (19) the corresponding semiclassical-limit prescription, i.e.,

$$\mathrm{f}^{e}_{i_1 i_2} = f^{e}_{i_1}\delta_{i_1 i_2},\ \mathrm{f}^{h}_{j_1 j_2} = f^{h}_{j_1}\delta_{j_1 j_2}, \tag{23}$$

one obtains the following set of Boltzmann-like equations for electron and hole carrier distributions:

$$\begin{aligned}\frac{\mathrm{d}f^{e}_{i}}{\mathrm{d}t} &= \sum_{i'}\left[P^{e}_{ii'}f^{e}_{i'} - P^{e}_{i'i}f^{e}_{i}\right] + G^{e}_{ii}\\ \frac{\mathrm{d}f^{h}_{j}}{\mathrm{d}t} &= \sum_{j'}\left[P^{h}_{jj'}f^{h}_{j'} - P^{h}_{j'j}f^{h}_{j}\right] + G^{h}_{jj}.\end{aligned} \tag{24}$$

Compared to the quantum-mechanical equation in 19, here the effect of the external electromagnetic excitation is expressed via conventional carrier generation/recombination rates, given by the diagonal elements of the generalized (i.e., off-diagonal) generation/recombination rates $G^{e/h}$ in Eq. 19.

From Nanomaterials to Nanodevices

The density-matrix treatment discussed so far applies to "extended systems," i.e., systems extending over the whole coordinate space; in contrast, a semiconductor device [3, 8] is typically a "localized system," i.e., a portion of material characterized by a well precise volume and spatial boundaries acting as electric contacts.

The impact of such spatially open boundaries depends crucially on the actual size/length of the nanodevice under examination. As we shall see, for periodically repeated nanostructures, finite-size effects can be safely neglected, and one can still employ the density-matrix description of section "Single-particle Description" as well as its semiclassical version in section "Semiclassical Limit". In contrast, when the effective size of the nanodevice is comparable to the relevant system space scales, e.g., scattering free path and/or coherence length, the microscopic modeling of such quantum devices constitutes a formidable task. Indeed, while in the semiclassical limit – typically applicable to steady-state operation regimes in the presence of a strong dissipation/decoherence dynamics – such finite-size effects can be properly incorporated via effective injection/loss models [3], the investigation of genuine quantum phenomena in finite-size nanodevices is still an open problem.

Modeling of Periodically-repeated Nanodevices

State-of-the-art semiconductor-based optoelectronic devices at the nanoscale are often based on periodically repeated core regions, for which spatial-boundary effects may be safely neglected. This strategy is exploited, for example, to increase either the photocurrent in infrared detectors or the emitted power in coherent-light sources like quantum-cascade lasers [2]. This feature turns out to be crucial also in the proper modeling of these optoelectronic devices [8], since it allows one to consistently "close the circuit" without the need for any phenomenological parameter accounting for the coupling of the device with its electric contacts. While for small/moderate applied fields it is possible to exploit the fully three-dimensional superlattice periodicity of the nanostructure under examination, in the presence of a significant applied bias the latter cannot be treated via the conventional drift term of the Boltzmann equation [18]. In this regime, the applied field needs to be added to the nanostructure potential profile; as a result, the total potential acting on the carriers is not periodic anymore, i.e., the usual superlattice periodicity is lost. Nevertheless, by assuming a uniform bias drop, the effective field profile across the nanostructure is still periodic, which implies that also in the presence of a strong homogeneous external field all relevant physical properties (e.g., the semiclassical distribution function f_α) should display the periodicity of the nanostructure under investigation.

More specifically, by neglecting finite-size effects, the theoretical description of the whole (periodically repeated) nanodevice under examination can still be grounded on the global density-matrix equation in 14 as well as on its semiclassical version in Eq. 22, where the generic carrier state is specified again by its low-dimensional wavevector plus its subband and band indices, i.e., $\alpha \equiv \mathbf{k}_{\|}nv$. Since such nanostructures are obtained as periodic repetition of a given building block usually referred to as "device stage," it

follows that in the presence of an applied uniform electric field the Wannier-Stark-like states localized in the different stages are physically equivalent. Based on such translational symmetry, the global subband index n – running over the whole nanostructure – may be conveniently replaced by a stage index ℓ plus an intrastage subband index $\overline{n}$, i.e., $n \equiv \overline{n}\ell$.

Employing the compact notation $\alpha = \overline{\alpha}\ell$ (with $\overline{\alpha} \equiv \mathbf{k}_{||}\overline{n}v$) and recalling that the carrier distribution function is stage-independent, the global Boltzmann-like equation (22) can be transformed into the following single-stage version

$$\frac{df_{\overline{\alpha}}}{dt} = \sum_{\overline{\alpha}'} \left[\overline{P}_{\overline{\alpha}\overline{\alpha}'} f_{\overline{\alpha}'} - \overline{P}_{\overline{\alpha}'\overline{\alpha}} f_{\overline{\alpha}}\right] + \left.\frac{df_{\overline{\alpha}}}{dt}\right|_{\hat{H}_{\mathrm{em}}} \tag{25}$$

with

$$\overline{P}_{\overline{\alpha}\overline{\alpha}'} = \sum_{\ell'} P_{\overline{\alpha}\ell,\overline{\alpha}'\ell'}. \tag{26}$$

This represents a strong simplification of the problem, since within the present single-stage scheme the kinetic description of the device is limited, e.g., to the $\ell = 0$ stage only, and thus to a limited number of subbands $\overline{n}$ (typically of the order of ten [8]); moreover, in view of the spatial periodicity, all inter-stage scattering rates depend on the stage difference $\ell' - \ell$ only, and for this reason the single-stage rates in Eq. 26 are ℓ-independent as well.

Within such single-stage picture each device stage actually behaves as an injector/collector of carriers for the following/previous one; this suggests an alternative rearrangement of the global Boltzmann-like equation (22) by splitting the scattering term into intra-stage ($\ell = \ell'$) and inter-stage ($\ell \neq \ell'$) contributions; as a result one obtains

$$\frac{df_{\overline{\alpha}}}{dt} = \left.\frac{df_{\overline{\alpha}}}{dt}\right|_{\mathrm{intra}} + \left.\frac{df_{\overline{\alpha}}}{dt}\right|_{\mathrm{inter}} \tag{27}$$

with

$$\left.\frac{df_{\overline{\alpha}}}{dt}\right|_{\mathrm{inter}} = \overline{S}_{\overline{\alpha}} - \overline{\Gamma}_{\overline{\alpha}} f_{\overline{\alpha}}. \tag{28}$$

Here, the first term describes intra-stage scattering processes only, while the second contribution has been intentionally expressed in terms of a source/injection term

$$\overline{S}_{\overline{\alpha}} = \sum_{\ell \neq 0} \sum_{\overline{\alpha}'} P_{\overline{\alpha}0,\overline{\alpha}'\ell} f_{\overline{\alpha}'} \tag{29}$$

and of a loss/escape rate

$$\overline{\Gamma}_{\overline{\alpha}} = \sum_{\ell \neq 0} \sum_{\overline{\alpha}'} P_{\overline{\alpha}'\ell,\overline{\alpha}0}. \tag{30}$$

This result may be regarded as a formal derivation/justification of the partially phenomenological injection/escape loss model [3] usually employed in the semiclassical simulation of finite-size quantum devices (see below).

Such single-stage picture – introduced above for the case of the Boltzmann-like Eq. 22 – applies to the density-matrix equation 14 as well. More specifically, by neglecting any inter-stage ($\ell \neq \ell'$) phase coherence (i.e., the electron coherence length is significantly shorter than the period of the nanostructure), the global quantum equation (14) can be cast into the following single-stage version:

$$\frac{\mathrm{d}\rho_{\overline{\alpha}_1\overline{\alpha}_2}}{\mathrm{d}t} = \sum_{\overline{\alpha}_1'\overline{\alpha}_2'} \overline{L}_{\overline{\alpha}_1\overline{\alpha}_2,\overline{\alpha}_1'\overline{\alpha}_2'} \rho_{\overline{\alpha}_1'\overline{\alpha}_2'} + \left.\frac{\mathrm{d}\rho_{\overline{\alpha}_1\overline{\alpha}_2}}{\mathrm{d}t}\right|_{\hat{H}_{\mathrm{em}}}, \tag{31}$$

with

$$\overline{L}_{\overline{\alpha}_1\overline{\alpha}_2,\overline{\alpha}_1'\overline{\alpha}_2'} = \frac{\epsilon_{\overline{\alpha}_1} - \epsilon_{\overline{\alpha}_2}}{\mathrm{i}\hbar} \delta_{\overline{\alpha}_1\overline{\alpha}_2,\overline{\alpha}_1'\overline{\alpha}_2'} + \overline{\Gamma}_{\overline{\alpha}_1\overline{\alpha}_2,\overline{\alpha}_1'\overline{\alpha}_2'}, \tag{32}$$

where

$$\overline{\Gamma}_{\overline{\alpha}_1\overline{\alpha}_2,\overline{\alpha}_1'\overline{\alpha}_2'} = \sum_{\ell} \Gamma_{\overline{\alpha}_1 0,\overline{\alpha}_2 0;\overline{\alpha}_1'\ell,\overline{\alpha}_2'\ell} \tag{33}$$

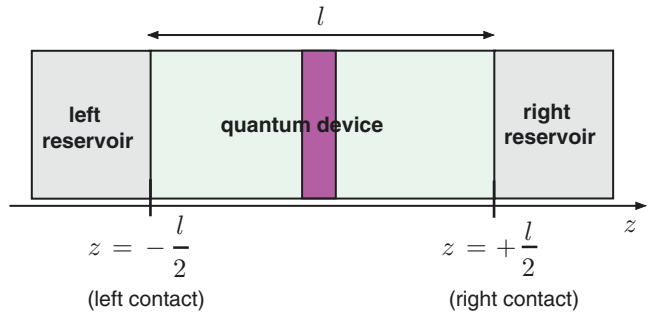
is the reduced or single-stage version of the scattering superoperator in Eq. 13. The above single-stage density-matrix equation has been successfully employed for the investigation of ultrafast phase-coherence versus energy-dissipation/decoherence in quantum-cascade lasers [8].

Modeling of Finite-size Quantum Nanodevices

The theoretical modeling of finite-size nanodevices is by far the most difficult task. Indeed, in sharp contrast to the case of the periodically repeated nanostructures considered in the above subsection, the description of finite-size electronic and optoelectronic devices cannot be grounded on the extended-system formalism presented in section "Microscopic Modeling of Semiconductor Nanostructures".

Once again, for the case of nanodevices operating in steady-state or quasi-steady-state conditions and in the presence of significant dissipation/decoherence phenomena, a semiclassical treatment of the problem is fully satisfactory. To this end, based on the rigorous injection/escape equation Eq. 28, the effect of the external charge reservoirs on the device active region (see Fig. 1) is usually described via a partially phenomenological injection/escape model of the form:

$$\left.\frac{\mathrm{d}f_\alpha}{\mathrm{d}t}\right|_{\mathrm{res}} = S_\alpha - \Gamma_\alpha f_\alpha = -\Gamma_\alpha\left(f_\alpha - f_\alpha^\circ\right). \qquad (34)$$



Such effective spatial-boundary term may be regarded again as a source/injection contribution $S_\alpha = \Gamma_\alpha f_\alpha^\circ$ describing a sort of quasithermal injection rate into state α (dictated by the reservoir carrier distribution f_α°) minus a loss term $\Gamma_\alpha f_\alpha$ describing the escape of carriers from state α according to the escape rate Γ_α.

For genuine semiconductor quantum devices such a semiclassical picture is not applicable, and a fully quantum-mechanical treatment is imperative. A finite-size nanodevice is a "localized system," i.e., a portion of material characterized by a well defined volume and by spatial boundaries acting as electric contacts to external charge reservoirs, as sketched in Fig. 1; here, z denotes the transport direction, l is the longitudinal length of the device, and the electric contacts are located at $z = -l/2$ and $z = +l/2$. The modeling of such a nanostructured device thus represents an intrinsically space-dependent problem, so that a real-space quantum treatment accounting for the presence of quite different spatial regions becomes mandatory.

To this purpose, the Wigner-function formalism [9] is a widely adopted framework. Within this formalism, the statistical quantum state of the electronic subsystem is fully described in terms of the Wigner function; for the case of a one-dimensional electronic system (with real-space coordinate z and wavevector k) the latter is defined over the conventional phase-space z, k as the Weyl-Wigner transform of the single-particle density-matrix [3, 12]:

$$f_W(z,k) = \sum_{\alpha_1\alpha_2} W_{\alpha_2\alpha_1}(z,k)\rho_{\alpha_1\alpha_2} \qquad (35)$$

with

Microscopic Modeling of Solid-State Quantum Devices, Fig. 1 Schematic representation of a typical semiconductor-based quantum device as an open system connected to two external charge reservoirs. Here, the distance between the interfaces is l, and z is the longitudinal transport direction

$$W_{\alpha_2\alpha_1}(z,k)=\int dz'\phi_{\alpha_1}\left(z+\frac{z'}{2}\right)e^{-ikz'}\phi^*_{\alpha_2}\left(z-\frac{z'}{2}\right), \tag{36}$$

where $\phi_\alpha(z) = \langle z|\alpha\rangle$ denotes the real-space wavefunction corresponding to the noninteracting carrier state α.

By neglecting all many-body interactions in Eq. 3 as well as the electromagnetic-radiation coupling in Eq. 1, it is possible to derive a closed equation of motion for the Wigner function in Eq. 35. More specifically, describing the electronic band structure via the conventional envelope-function theory [3] in terms of a single effective mass m^* and denoting by $V(z)$ the effective potential profile of the semiconductor nanostructure, the resulting equation of motion – obtained applying the Weyl-Wigner transform Eq. 35 to the noninteracting evolution in Eq. 10 – is given by

$$\begin{aligned}&\frac{\partial f_W(z,k)}{\partial t}+\upsilon(k)\frac{\partial f_W(z,k)}{\partial z}\\&+\int dk'\mathcal{V}(z,k-k')f_W(z,k')\\&=0,\end{aligned} \tag{37}$$

where

$$\mathcal{V}(z,k'')=\frac{i}{\hbar}\int dz'\frac{e^{-ik''z'}}{2\pi}\left[V\left(z+\frac{z'}{2}\right)-V\left(z-\frac{z'}{2}\right)\right] \tag{38}$$

is a nonlocal potential superoperator corresponding to the device profile $V(z)$.

Equation 37, also referred to as the Wigner transport equation, describes the time evolution of the Wigner function in the coherent limit, i.e., in the absence of energy-dissipation/decoherence processes. In steady-state conditions ($\partial f_W(z, k)/\partial t = 0$) the latter reduces to

$$\upsilon(k)\frac{\partial f_W(z,k)}{\partial z}=-\int dk'\mathcal{V}(z,k-k')f_W(z,k'). \tag{39}$$

In order to account for many-body dissipation versus decoherence processes, the simplest model is the well-known relaxation-time approximation; the latter amounts to replace the general scattering-superoperator dynamics in Eq. 13 with a relaxation-time term of the form:

$$\left.\frac{d\rho_{\alpha_1\alpha_2}}{dt}\right|_{\hat{H}'}=-\overline{\Gamma}\left(\rho_{\alpha_1\alpha_2}-\rho^\circ_{\alpha_1\alpha_2}\right), \tag{40}$$

where $\rho^\circ_{\alpha_1\alpha_2}$ are the matrix elements of the equilibrium density-matrix operator

$$\hat{\rho}^\circ=\sum_k|k\rangle f^\circ(\epsilon_k)\langle k| \tag{41}$$

(expressed via the corresponding Fermi-Dirac distribution f°) and $\overline{\Gamma}$ is the relaxation rate. By applying to the relaxation term Eq. 40 the Weyl-Wigner transform in Eq. 35, it is easy to get

$$\begin{aligned}\upsilon(k)\frac{\partial f_W(z,k)}{\partial z}=&\int dk'\mathcal{V}(z,k-k')f_W(z,k')\\&-\overline{\Gamma}\left(f_W(z,k)-f^\circ_W(k)\right),\end{aligned} \tag{42}$$

where the equilibrium Wigner function coincides with the Fermi-Dirac distribution f°, i.e., $f^\circ_w(z,k) = f^\circ(\epsilon_k)$. The relaxation rate $\overline{\Gamma}$ can be regarded as a sort of effective or average inverse coherence time, and is mainly determined by carrier-phonon as well as carrier-carrier scattering.

The inclusion of incoherent processes via the above relaxation-time framework implies the appearance of an additional contribution to the steady-state Wigner equation (39), leading to the generalized Wigner equation

$$\begin{aligned}\upsilon(k)\frac{\partial f_W(z,k)}{\partial z}=&-\int dk'\mathcal{V}(z,k-k')f_W(z,k')\\&-\overline{\Gamma}\left(f_W(z,k)-f^\circ_W(k)\right),\end{aligned} \tag{43}$$

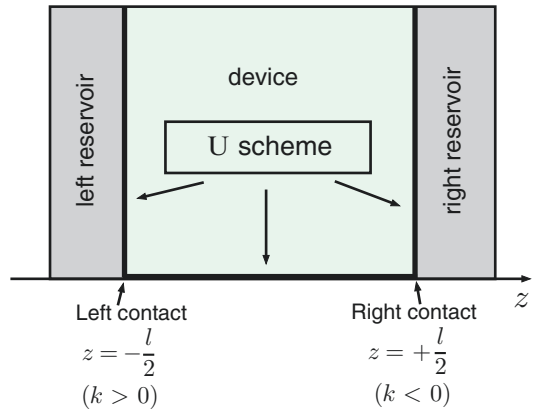
where $f^\circ_w(k) \equiv f^\circ(\epsilon_k)$ denotes the equilibrium Fermi-Dirac distribution induced by the host material.

By applying the Weyl-Wigner transform (35) to the general average-value prescription in Eq. 5, one obtains

$$\langle a \rangle = \frac{1}{2\pi} \int dz \int dk a_W(z,k) f_W(z,k) \tag{44}$$

with

$$a_W(z,k) = \sum_{\alpha_1 \alpha_2} W_{\alpha_1 \alpha_2}(z,k) a_{\alpha_1 \alpha_2}. \tag{45}$$



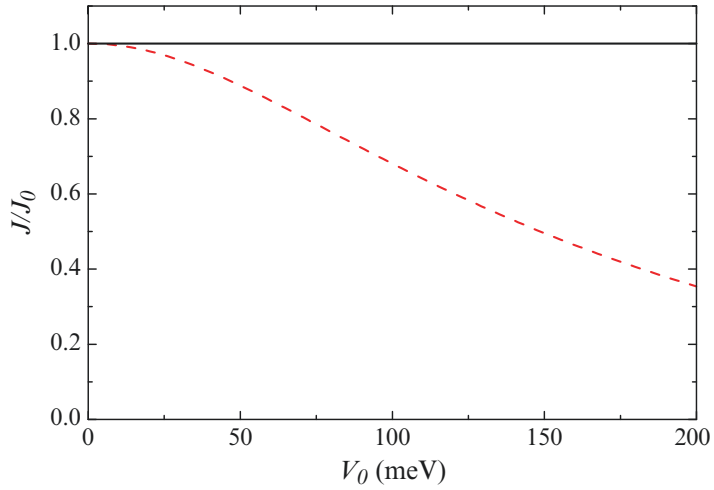
In particular, the average charge and current densities may be expressed via the Wigner function as:

$$n(z) = \frac{1}{2\pi} \int dk f_W(z,k), \tag{46}$$

$$J(z) = \frac{1}{2\pi} \int dk v(k) f_W(z,k). \tag{47}$$

Based on the steady-state Wigner equation (39) as well as on its generalized version in Eq. 43, various approaches for the study of quantum-transport phenomena in semiconductor nanomaterials and nanodevices have been proposed In particular, starting from the pioneering work by Frensley [9], quantum-transport simulations based on a direct numerical solution of the Wigner equation have been performed via finite-difference approaches, by imposing on the Wigner function the standard U boundary-condition scheme (see Fig. 2) of the semiclassical device modeling.

Motivated by a few unphysical results obtained via the generalized semiconductor Bloch equations mentioned above, a more recent study [19] has however shown that the application of the conventional space boundary condition scheme to the Wigner transport equation may lead to negative spatial charge densities, unambiguous proof of the failure of such classical-like Wigner-function treatment. Indeed, the conventional boundary-condition scheme adopted for the solution of the Wigner equation exhibits intrinsic limitations, whose impact may lead to totally unphysical results, especially in the coherent-transport regime. In the following, we shall first review and discuss such limitations [10] and then present a sounder approach based on a nonlocal density-matrix framework [11].



Microscopic Modeling of Solid-State Quantum Devices, Fig. 2 The U boundary condition scheme adopted in semiclassical device modeling [3] for a one-dimensional problem. The value of the Wigner function $f_W(z, k)$ is specified at the boundaries of the active region, i.e., $f_W(-l/2, k > 0)$ and $f_W(+l/2, k < 0)$ are fixed by the incoming carrier distribution function

Failure of the Conventional Boundary-Condition Scheme

In order to point out the most severe limitations of the conventional, i.e., classical-like, boundary-condition scheme applied to the Wigner transport equation, it is worth summarizing its main features.

In terms of the variable z, the Wigner transport equation (39) [as well as its generalized version in Eq. 43] is a first-order differential equation. In this respect, it is thus similar to the steady-state version of the Boltzmann equation [3]. Based on this analogy, outlined in the pioneering work by Frensley [9], in the last decades several quantum-transport problems have been treated by following a semiclassical approach, i.e. by applying to the Wigner transport equation the simulation strategies commonly adopted for the Boltzmann equation. Indeed most of these studies [9] are based on a numerical solution of Eq. 43, where one imposes on $f_W(z,k)$ the inflow or U spatial boundary-condition scheme of the semiclassical device modeling. The latter, depicted in Fig. 2, consists in requiring that the inflowing Wigner function acquires some fixed values at the two contacts $z = \pm l/2$, and that these values are determined by classical-like quasi-thermal distributions of carriers incoming from the two

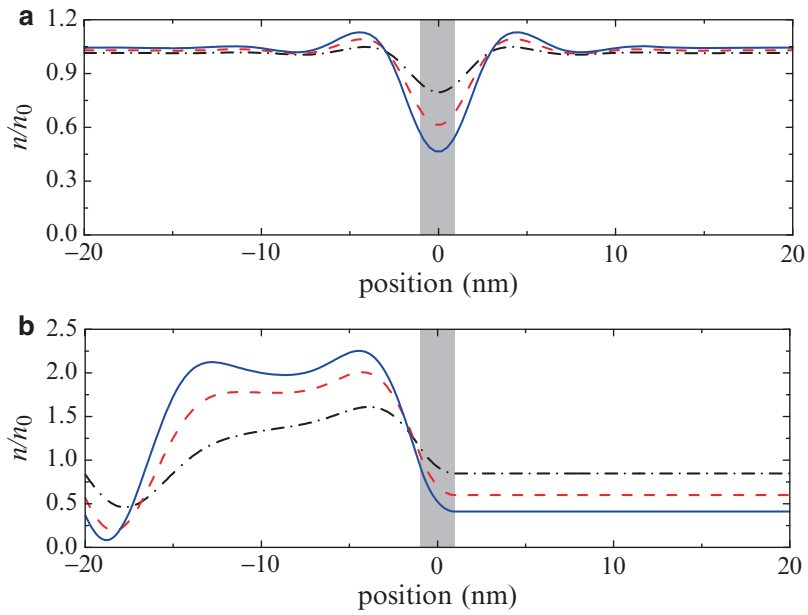
Microscopic Modeling of Solid-State Quantum Devices, Fig. 3 Steady-state current density J across the rectangular barrier Eq. 50 (device length $l = 40$ nm and barrier width $a = 2$ nm) as a function of the barrier height V_0 (in units of the barrier-free ($V_0 = 0$) value J_0) in the coherent limit $\left(\overline{\Gamma} \to 0\right)$ and in the presence of a room-temperature carrier injection only from the left (chemical potential $\mu = 4k_BT$). The result of the Wigner-function calculation (*solid curve*) is independent of the barrier height V_0. This unphysical behavior is compared with the analytical current density predicted by the Landauer-Büttiker theory (*dashed curve*), which decreases as a function of V_0. Here, the Wigner-function result has been obtained as a numerical solution of the integral Wigner equation in (49) via a standard phase-space discretization scheme (in terms of a 120 × 120 uniform grid) (see text)

reservoirs. Explicitly, the values $f_W(-l/2, k)$ are specified for carriers incoming from the left reservoir ($k > 0$) and the values $f_W(+l/2, k)$ are specified for electrons incoming from the right reservoir ($k < 0$). In a compact notation, introducing $z^b(k) = \text{sign}(k)l/2$ (where sign is the sign function), the Wigner transport equation (39) is thus equipped with the k-dependent boundary condition

$$f^b(k) \equiv f_W\left(z^b(k), k\right). \tag{48}$$

It is thus useful to rewrite the Wigner problem Eqs. 43, 44, 45, 46, 47, and 48 in an equivalent integral form [19]:

$$\upsilon(k) f_W(z,k) = \upsilon(k) f^b(k) - \int_{z^b(k)}^{z} dz' \int dk' \mathcal{V}(z', k-k') f_W(z', k') - \overline{\Gamma} \int_{z^b(k)}^{z} dz' \left(f_W(z', k) - f_W^{\circ}(k)\right). \tag{49}$$



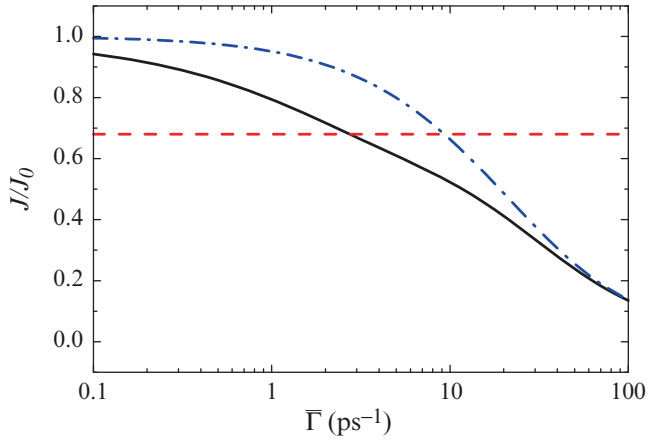
In order to show the intrinsic limitations of such classical-like boundary-condition treatment, let us consider, as prototypical device, a potential profile given by a rectangular barrier of width a and height V_0, i.e.,

$$V(z) = V_0 \theta\left(\frac{a}{2} - |z|\right), \tag{50}$$

where θ denotes the usual Heaviside step function. For this particular device potential profile, the explicit form of the corresponding potential superoperator in Eq. 38 turns out to be

$$\mathcal{V}(z, k'') = -\frac{4}{2\pi\hbar} V_0 \sin\left(2k''z\right) \frac{\sin\left(k''a\right)}{k''}. \tag{51}$$

As a first step, we shall investigate steady-state charge transport across the potential barrier in Eq. 50. In particular, in the coherent-limit regime $\left(\overline{\Gamma} \to 0\right)$ the results of the Wigner-function calculation may be directly compared to those of the well-known Landauer-Büttiker theory [14] based on elementary scattering-state calculations. Such comparison is reported in Fig. 3, where the steady-state current density corresponding to a room-temperature carrier injection from the left contact



Microscopic Modeling of Solid-State Quantum Devices, Fig. 4 Spatial carrier density n (in units of its barrier-free ($V_0 = 0$) value n_0) in the presence of a rectangular barrier (Eq. 50) for the same device parameters and operation conditions employed in Fig. 3: comparison between the Wigner-function (panel (**a**)) and the Landauer-Büttiker results (panel (**b**)), for three different values of the barrier height: $V_0 = 50$ meV (*dash-dotted curves*), $V_0 = 100$ meV (*dashed curves*), and $V_0 = 150$ meV (*solid curves*) (see text)

only is plotted as a function of the barrier height V_0. The result of the Landauer-Büttiker formalism (dashed curve) describes a well-established behavior, i.e. for increasing values of the barrier height the tunneling process across the barrier is progressively reduced. In contrast, the result of the Wigner-function calculation (solid curve) appears to be unphysical: the value of the current turns out to be *independent* of the barrier height, and coincides with the barrier-free case.

In order to better understand such highly nonphysical behavior, it is useful to analyze the shape of the spatial charge density within the device active region. Figure 4 shows a comparison between the spatial charge density provided by the numerical solution of the Wigner equation (a) and the Landauer-Büttiker theory (b) for three different values of the barrier height: $V_0 = 50$ meV (dash-dotted curves), $V_0 = 100$ meV (dashed curves), and $V_0 = 150$ meV (solid curves). The charge-density profile given by the Landauer-Büttiker approach (b) well reproduces the physically expected scenario mentioned above: for increasing values of the barrier height, an increasing fraction of the injected carriers are reflected, and only a small fraction of them is transmitted into the right part of the device, inducing an asymmetry in the carrier density across the barrier. In contrast, the Wigner-function scenario reported in (a) clearly shows that an increase of the barrier height only results into a more pronounced minimum in the charge density due to the presence of the barrier itself. However, for any value of the barrier height the charge profile is always symmetric, implying that reflection is not accounted for. Indeed in this case all the injected carriers are able to reach the right contact of the device. This result shows that, in the coherent limit $\overline{\Gamma} \to 0$, the conventional Wigner-equation approach is definitely unable to account for key phenomena in mesoscopic transport theory, like quantum-mechanical reflection versus transmission.

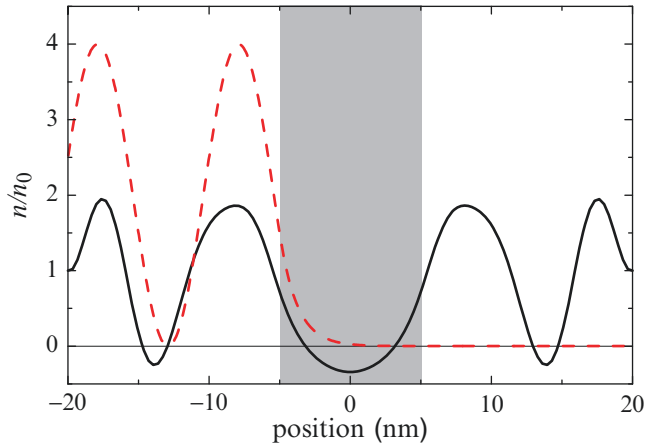
In the presence of energy-dissipation/decoherence processes, the anomalous behavior reported in Figs. 3 and 4 is expected to be partially mitigated. Figure 5 shows the steady-state current density as a function of the relaxation rate $\overline{\Gamma}$ obtained from a numerical solution of the Wigner equation 43 for a fixed value of the barrier height ($V_0 = 100$ meV, solid curve) as well as for the barrier-free case ($V_0 = 0$, dash-dotted curve), compared to the (dissipation-free) result of the Landauer-Büttiker theory (dashed curve). As one can see, for a relaxation time $\left(\overline{\Gamma}^{-1}\right)$ of about 400 fs the current provided by the

Microscopic Modeling of Solid-State Quantum Devices, Fig. 5 Steady-state current density J (in units of its barrier-free and coherent-limit value J_0) as a function of the relaxation rate $\overline{\Gamma}$. The result is obtained from a numerical solution of the integral Wigner equation (49) for a fixed value of the barrier height ($V_0 = 100$ meV, *solid curve*) as well as for the barrier-free case ($V_0 = 0$, *dash-dotted curve*), compared to the (dissipation-free) result of the Landauer-Büttiker theory (*dashed curve*). Here, all the device parameters and operation conditions are the same employed in Figs. 3 and 4 (see text)

Wigner-function calculation (solid curve) well reproduces the Landauer-Büttiker one (dashed curve). However, it is crucial to point out the quite different physical origin of such current suppression. Within the Landauer-Büttiker approach this is due to quantum-mechanical reflection versus transmission in a fully coherent system, whereas within the Wigner-function approach this suppression is essentially driven by the presence of dissipation, via the relaxation-time term. The presence of the barrier has nevertheless some influence, as shown by the fact that the barrier-free current (dash-dotted curve) differs, in general, from the potential-barrier one (solid curve). Such difference vanishes in the coherent limit $\left(\overline{\Gamma} \to 0\right)$ as well as in the fully incoherent one $\left(\overline{\Gamma} \to \infty\right)$.

The numerical analysis presented so far clearly shows intrinsic limitations of the conventional Wigner-function treatment. In order to identify the origin of such anomalies, a few remarks are now in order.

Given an electron in the noninteracting state α, the corresponding pure-state density matrix is



$$\rho_{\alpha_1\alpha_2} = \delta_{\alpha\alpha_1}\delta_{\alpha\alpha_2}, \tag{52}$$

and the corresponding pure-state Wigner function – obtained via the standard Weyl-Wigner transform (35) – is simply given by the diagonal elements $W_{\alpha\alpha}(z, k)$ in Eq. 36:

$$f_W^{\alpha}(z,k) = \int dz' \phi_{\alpha}\left(z + \frac{z'}{2}\right) e^{-ikz'} \phi_{\alpha}^{*}\left(z - \frac{z'}{2}\right). \tag{53}$$

In the coherent limit $\left(\overline{\Gamma} = 0\right)$ it is possible to show that (i) the Wigner function (53) is always a solution of the Wigner equation (39); (ii) by employing as inflow boundary values $f^b(k)$ (see Eq. 48) those given by the Wigner solution itself, the pure-state Wigner function (53) is a solution of the integral equation (49).

This implies that, if one is able to compute the Wigner function from the density matrix (like in Eq. 53 or any thermal average of it), such Wigner function will properly describe all the quantum-mechanical features of the problem – including reflection versus transmission phenomena – and will produce the very same results provided by the Landauer-Büttiker formalism. However, in the conventional Wigner-function approach, the Wigner function is initially unknown, and the spatial boundary condition $f^b(k)$ is treated as an arbitrary

Microscopic Modeling of Solid-State Quantum Devices, Fig. 6 Spatial carrier density n (in units of its barrier-free value n_0) corresponding to the rectangular-barrier profile in Eq. 50 (device length $l = 40$ nm, barrier width $a = 10$ nm, and barrier height $V_0 = 150$ meV): comparison between the Wigner-function result obtained in the coherent limit $\left(\overline{\Gamma} \to 0\right)$ assuming a monoenergetic injection $\left(\overline{\epsilon} = \hbar^2\overline{k}^2/(2m^*) = 50\,\text{meV}\right)$ from the left (*solid curve*) and the analytical result corresponding to its scattering-state calculation (*dashed curve*) (see text)

input function, usually expressed in terms of equilibrium or quasi equilibrium inflowing semiclassical carrier distributions (see Fig. 2). As recently pointed out in Savio and Poncet [20], such a semiclassical treatment/description of the boundary function $f^b(k)$ seems to be not necessarily compatible with the quantum-mechanical nature of a genuine Wigner function.

The above remarks about quantum-versus-classical boundary values lead to a crucial question: for a given semiclassical-like (i.e., positive-definite) boundary condition $f^b(k)$, under which condition is the corresponding solution $f_W(z, k)$ of the Wigner transport equation (39) physically acceptable?

To concretely address this important issue, we have performed a numerical solution of the integral Wigner equation (49) in the coherent limit $\left(\overline{\Gamma} \to 0\right)$ for the case of the rectangular-barrier potential in Eq. 50. In order to definitely point out nonphysical features of the Wigner-function treatment, we have replaced the thermal carrier injection employed so far by a simple monoenergetic carrier injection from left, i.e.,

$$f^b(k) \propto \delta\left(k - \overline{k}\right). \tag{54}$$

The result of such calculation (solid curve), together with the corresponding quantum-mechanical (i.e., scattering-state) one (dashed curve), is reported in Fig. 6. As one can see, in addition to the presence of an anomalous amount of charge on the right-hand side of the device with respect to the scattering-state result (dashed curve), the carrier-density profile corresponding to the mono energetic injection (solid curve) also displays a significant negative-value region and thus comes out to be definitely nonphysical, i.e., no more positive-definite. This result also agrees with the one reported in Taj et al. [19], thereby confirming the strong physical limitations of the conventional Wigner-function modeling. From the numerical analysis performed so far, one is forced to conclude that the set of mathematical solutions $f_W(z, k)$ corresponding to the set of all possible semiclassical (i.e., positive-definite) boundary conditions $f^b(k)$ contains also nonphysical solutions, i.e., solutions not corresponding to the Weyl-Wigner transform of a density matrix. Indeed, this important conclusion is fully supported by the detailed discussion about physical versus nonphysical solutions of the Wigner transport equation recently proposed in Rosati et al. [10], thus confirming the serious limitations of the conventional device modeling based on the Wigner-function formalism originally pointed out in Taj et al. [19].

Density-Matrix Based Treatment

In order to overcome the intrinsic limitations of the conventional Wigner-function modeling just recalled, the crucial step is to replace the local (i.e., classical-like) boundary condition-scheme treatment of the device-reservoir interaction with a fully nonlocal approach; to this end, in order to ensure/maintain the positive-definite character of the electronic density matrix, a possible strategy, recently proposed in Dolcini et al. [11], is to describe the system/device-environment/reservoir interaction via a Lindblad-like coupling term.

As discussed in detail in Dolcini et al. [11] and Rosati et al. [17], the explicit form of the desired device-reservoir coupling superoperator should fulfill the following three basic requirements: (i) it should preserve the positivity of the single-particle density matrix $\rho_{\alpha_1\alpha_2}$; (ii) due to the thermal (i.e., fully incoherent) nature of the external reservoirs, it should not induce phase coherence on the device electronic subsystem; (iii) in the semi-classical limit it should reduce to the standard injection/escape model in Eq. 34.

More specifically, in Dolcini et al. [11] the density-matrix treatment of section "Single-particle Description" is extended to quantum systems with spatially open boundaries, namely to the case of a quantum device electrically connected to one or more external carrier reservoirs; this is performed adding to the density-matrix equation (9) the device-reservoir scattering superoperator

$$\left.\frac{\mathrm{d}\rho_{\alpha_1\alpha_2}}{\mathrm{d}t}\right|_{\mathrm{res}} = -\frac{\Gamma_{\alpha_1}+\Gamma_{\alpha_2}}{2}\left(\rho_{\alpha_1\alpha_2}-\rho^{\mathrm{res}}_{\alpha_1\alpha_2}\right), \quad (55)$$

where

$$\rho^{\mathrm{res}}_{\alpha_1\alpha_2} = f^{\circ}_{\alpha_1}\delta_{\alpha_1\alpha_2} \quad (56)$$

denotes the quasiequilibrium density matrix of the external carrier reservoirs (injected over our single-particle states α) [11].

The above scattering superoperator can be regarded as the quantum-mechanical generalization of the injection/escape model in Eq. 34. Opposite to the genuine Lindblad form usually employed for the description of various carrier-environment coupling mechanisms [16, 17], the device-reservoir superoperator in Eq. 55 involves the reservoir density matrix $\rho^{\mathrm{res}}_{\alpha_1\alpha_2}$ in Eq. 56. This feature makes our density-matrix equation inhomogeneous, implying that the trace of the density matrix is not conserved, as expected in a system where the number of particles may change with time. Nevertheless, as discussed in Dolcini et al. [11]) the positive-definite character of the single-particle density matrix is ensured by the Lindblad-like form of the proposed coupling term in Eq. 55. It is also worth noticing that in this approach the local (i.e., classical-like) boundary-condition treatment of the system-reservoir interaction employed in the Wigner formulation [9] is replaced by a nonlocal quantum-mechanical coupling.

In order to point out the main features of the device-reservoir coupling in Eq. 55, it is useful to analyze the so-called mesoscopic regime, i.e., the case where inelastic scattering mechanism are negligible. In this regime the steady-state (ss) density matrix is given by

$$\rho^{\mathrm{ss}}_{\alpha_1\alpha_2} = \rho^{\mathrm{res}}_{\alpha_1\alpha_2} = f^{\circ}_{\alpha_1}\delta_{\alpha_1\alpha_2}, \quad (57)$$

and the standard Landauer-Büttiker result [14] is recovered: the steady-state single-particle density matrix $\rho^{\mathrm{ss}}_{\alpha_1\alpha_2}$ of the device is diagonal, thus preventing any phase-coherence transfer between reservoirs and device. Its diagonal values coincide with the distribution f°_{α} of the carriers injected from the reservoirs. Notice that such steady-state solution $\rho^{\mathrm{ss}}_{\alpha_1\alpha_2}$ is independent of the value of the device-reservoir coupling constants Γ_{α}.

It is however worth stressing that this density-matrix approach goes far beyond the steady-state regime just recalled, and enables one to address ultrafast-dynamics phenomena, nowadays accessible via time-resolved optical experiments. In particular, if at time $t = 0$ one "prepares" a device electron in a coherent superposition of single-particle states α, characterized by a device density matrix $\overline{\rho}_{\alpha_1\alpha_2}$, in the mesoscopic regime its subsequent time evolution is given by:

$$\rho_{\alpha_1\alpha_2}(t) = \rho^{ss}_{\alpha_1\alpha_2} + \left(\overline{\rho}_{\alpha_1\alpha_2} - \rho^{ss}_{\alpha_1\alpha_2}\right) e^{\frac{\left(\Sigma^*_{\alpha_1} - \Sigma_{\alpha_2}\right)t}{i\hbar}}, \tag{58}$$

where

$$\Sigma_\alpha = \epsilon_\alpha + i\hbar\Gamma_\alpha/2 \tag{59}$$

can be regarded to as the device single-particle self-energy ϵ_α "dressed" by an imaginary life-time contribution induced by the device-reservoir interaction. Thus Eq. 58 enables one to interpret the coupling Γ_α as the inverse time-scale over which the diagonal density-matrix element $\rho_{\alpha\alpha}$ reaches the steady state value $\rho^{ss}_{\alpha\alpha}$; furthermore, the time evolution in Eq. 58 shows the interplay between phase coherence and reservoir-induced dissipation versus decoherence processes. Indeed in Eq. 58 the diagonal contributions ($\alpha_1 = \alpha_2$) describe the population transfer and therefore energy dissipation, whereas the off-diagonal contributions ($\alpha_1 \neq \alpha_2$) exhibit a temporal decay of the inter-state polarizations, leading to decoherence.

In addition to the reservoir-induced dissipation/decoherence just described, in the presence of nonelastic scattering processes one deals with a complex interplay between carrier-reservoir and carrier-environment coupling; as anticipated, the latter may be described adding to the density-matrix equation (9) the device-reservoir superoperator in Eq. 55. The power and flexibility of such microscopic modeling has been recently demonstrated in Dolcini et al. [11] by investigating the highly nontrivial interplay between ultrafast optical-excitation and transport phenomena in a semiconductor-based triple-barrier nanodevice.

Thermal management materials

Definition

Carbon nanostructure composites consist of carbon nanostructures, like carbon nanotubes, diamond nanorods, graphene ribbons, etc., dispersed in a polymer matrix. The thermal properties of interest for carbon nanostructure composites are the thermal conductivity of the matrix, the thermal conductivity of the nanostructure, and the interfacial thermal conductivity between the matrix and the nanostructure. The interfacial

thermal conductivity is the limiting factor on the overall thermal performance of these materials.

Overview

Carbon nanostructures have a relatively high thermal conductivity, which should make them ideal for use as heat sinks, particularly in electronics. At 300 K, isolated single- and multiwalled carbon nanotubes (CNTs) have thermal conductivities that range from 300 to 6,600 $Wm^{-1}\ K^{-1}$ [1], for diamond nanorods (DNRs) the thermal conductivity is near 50 $Wm^{-1}\ K^{-1}$ [2], and vapor grown carbon fibers have a thermal conductivity of 1,950 $Wm^{-1}\ K^{-1}$ [3]. At 300 K, most polymers have a relatively low thermal conductivity, approximately 0.10 $Wm^{-1}\ K^{-1}$ [1, 4, 5]. It has been proposed that combining carbon nanostructures with a polymer matrix will result in an advanced material with improved thermal characteristics compared to the polymer alone, while maintaining or improving other desired properties needed for the application, such as being electrically insulating, having high strength, and being moldable [1, 4, 6, 7]. These carbon nanostructure composites typically consist of single- or multiwall carbon nanotubes (CNTs) or other nanostructures of carbon well dispersed into a polymer matrix at low weight percent concentrations.

The percolation threshold, the minimum concentration where well-dispersed carbon nanotubes become fully interconnected, has been experimentally determined by many researchers [2, 6]. This concentration varies from 0.023 to 11 wt%, depending on the carbon nanostructure, the polymer matrix, and the dispersion method [2, 6]. Once above the percolation threshold, the thermal conductivity of the composite, κ_{comp}, can be estimated from the following equation, assuming the thermal resistance at the nanotube interfaces is negligible [4]:

$$\kappa_{comp} = \left\langle \cos^2\theta \right\rangle \kappa_{nano} V_{nano} \qquad (1)$$

where κ_{nano} is the thermal conductivity of the nanomaterial, V_{nano} is the volume fraction (percent composition/volume concentration) of the nanomaterial, and θ is the angle between a given direction and the nanomaterial axis. The brackets indicate an average over all nanomaterials in thecomposite; for well-aligned nanomaterials, $<\cos^2\theta> = 1$ and for completely random orientation $<\cos^2\theta> = 1/3$. Using this expression, an estimate of the thermal conductivity for a composite consisting of randomly dispersed CNTs with a thermal conductivity of 3,000 $Wm^{-1}\ K^{-1}$, at a volume fraction of 0.01, is 10 $Wm^{-1}\ K^{-1}$. Although experimental studies on composites with CNT concentrations well above the percolation threshold show an increase in thermal conductivity, this increase is limited to less than 1 $Wm^{-1}\ K^{-1}$ at 300 K [5, 6]. It is thought that these lower than expected results are due to limited interfacial thermal conductivity between the CNT and the polymer matrix [5, 7]. The failure of the material to perform as expected has sparked many computational studies. Some have attempted to elucidate the mechanism behind this limited interfacial thermal conductivity while others have worked to find alternative nanostructures with improved performance.

Basic Methodology

Atomic-scale modeling is used to characterize the thermal properties of carbon nanostructure composites. These properties include the thermal conductivity of pristine and functionalized nanostructures and the interfacial thermal conductivity between the carbon nanostructure and the polymer matrix [1, 4–6]. The study of these systems provides insight into the atomic-level physical and chemical interactions that contribute to the thermomechanical properties of carbon nanostructure composites. They also provide important data not readily available from experimental measurements. The results of these studies are being used to develop a complete analytical model of thermal conductivity in nanostructure composites and a more complete theory of how functionalization affects interfacial thermal conductivity.

In a typical study of the thermal conductivity of a carbon nanostructure composite, the isolated

nanostructure is built using standard techniques. This structure is equilibrated at a specified temperature with potential energy functions chosen to describe the bonding and nonbonding interactions on and between the atoms. Commonly used potential energy functions are REBO, ReaxFF, and PCFF; these can be found in the LAMMPS software package [8]. After equilibrating the carbon nanostructure, it is solvated with the matrix material used to create the composite. This is usually done using an optimization program, such as the Packing Optimization for Molecular Dynamics Simulations (Packmol) [9]. The optimization program places the matrix molecules in a defined region of space, ensuring short-range repulsive interactions do not overwhelm the simulation. Once the complete composite has been created, the system is again equilibrated to ensure it begins in a stable state. The thermal conductivity is typically measured using one of the following methods. These methods are Fourier's law, the Müller-Plathe reverse nonequilibrium molecular dynamics, and the Green–Kubo formula.

Fourier's law describes how heat energy moves in a diffuse manner across a temperature gradient

$$J = -\kappa \nabla(T) \tag{2}$$

where the heat energy, J, is related to the spatial gradient of the temperature, $\nabla(T)$ by the thermal conductivity, κ. In this method, the energy added to the hot region equals the energy subtracted from the cold region and is proportional to the heat flux moving between the regions [8].

Another method to determine the thermal conductivity is through the reverse nonequilibrium molecular dynamics method described by Müller-Plathe [8, 10]. In this method, the velocities (kinetic energy) of the hottest atoms in the cold region are switched with the coldest atoms in the hot region. This results in a known quantity of heat flux, J, being transferred against the thermal gradient between the two regions:

$$J = \frac{\sum_{i=1}^{n} \frac{1}{2} m_i \left({v_{hi}}^2 - {v_{ci}}^2 \right)}{2\mathrm{At}} \tag{3}$$

where m is the mass of the atoms, t is the time in the simulation, A is the cross-sectional area, v_h and v_c are the velocities chosen from the cold and hot regions, respectively, and n is the number of transfers. After the system has reached equilibrium the thermal conductivity κ is obtained as:

$$\kappa = -\frac{\langle J(t) \rangle}{\langle \delta T / \delta z \rangle} \tag{4}$$

where $J(t)$ is the total heat flux, $\delta T/\delta z$ is the temperature gradient between the two regions, and the brackets denote the statistical time average.

The third method to determine thermal conductivity is derived from the Green − Kubo formula which relates the ensemble average of the autocorrelation of the heat flux to the thermal conductivity

$$\kappa = \frac{1}{V k_B T^2} \int_0^\infty \langle J(0) J(t) \rangle dt \tag{5}$$

where V is the volume, k_B is the Boltzmann constant, and T is the temperature. The heat flux vector, J, is calculated as

$$J(t) = \sum_i \varepsilon_i v_i + \frac{1}{2} \sum_{ij, i \neq j} r_{ij} \left(f_{ij} \cdot v_i \right) \tag{6}$$

where the fluctuations of the per-atom (i) energy (ε) are added to the per-atom stress tensor in a steady-state equilibrated simulation, v_i is the velocity of the ith atom, r_{ij} is the distantace between atoms i and j, and f_{ij} is the force between atoms i and j [1, 8, 11].

Key Research Findings

The thermal conductivity of a carbon nanotube is influenced by its diameter, chirality, length, temperature, and functionalization. As described above, the thermal conductivity is calculated based on the volume or cross-sectional area of the nanostructure, both of which require the cross-sectional area. There is no standard

definition for measuring the cross-sectional area: one definition uses an annulus centered on the carbon atoms, each with a thickness of 0.34 nm, the van der Walls radius of carbon; another uses the inter-atom separation distance between layers of graphite as the thickness of the annulus; other definitions calculate the area as a circle with a circumference defined by the centers of atoms around the nanotube [1, 10, 11]. Simulations reveal that, for CNTs in a vacuum, the thermal conductivity is minimally affected by the overall diameter or by changes in the chirality [10]. Some simulations indicate for composites, the larger the diameter of the CNT the lower the thermal transfer; this is due to a decrease in the vibrational bending modes in the nanotube [12]. As the length of a carbon nanotube increases, in a vacuum or a composite structure, the thermal conductivity also increases, in a power–law relationship between nanotube length and thermal conductivity, with an exponent value less than one [2, 9, 10]. Simulations indicate that as the temperature of a single carbon nanotube in vacuum increases, the thermal conductivity increases, to a maximum near 100 K, and then decreases exponentially [1, 11]. In carbon nanostructure composite materials, the thermal conductivity of the composite follows the same trend as the isolated carbon nanotube, but with the maximum value found near 300 K [5].

Above 300 K, isolated carbon nanotubes and graphene monolayers have similar thermal conductivities; however, below 300 K, graphene's thermal conductivity is much greater [11]. When simulations of graphene and bulk graphite are compared, it has been shown that the interlayer interactions in the graphite quench the thermal conductivity of this system by an order of magnitude [11]. A similar reduction is seen when two carbon nanotubes come into contact with each other, as in a multiwall carbon nanotube or when a "bundle" or "mat" of single-walled carbon nanotubes are formed [11].

As increasing numbers of functional groups are added to a carbon nanotube, the thermal conductivity of the carbon nanotube decreases [2]. Also, as the carbon nanotube length increases, but the percent functionalization remains constant, the thermal conductivity of the carbon nanotube reaches a maximum with respect to length [2]. Additionally, this maximum occurs at shorter lengths as the percent functionalization increases, implying a short scattering length for phonons in the carbon nanotube. Comparing the phonon power spectra of functionalized carbon nanotubes shows a decrease in spectral density at the high frequency carbon–carbon optical mode, while the low frequency acoustic modes remain nearly constant [2]. These results support the idea that the reduction in thermal conductivity of carbon nanotubes is caused by a reduction in phonon scattering length rather than changes in the vibrational modes caused by functionalization [2].

The thermal conductivity of several carbon nanostructure composite materials has been examined. Composite structures with single-wall carbon nanotubes require only 0.1–0.2 wt% before the onset of percolation, whereas structures composed of vapor grown carbon fibers require a mixture of 1.0–2.0 wt% [5]. In these experiments, the thermal conductivity of the composite structure reached a maximum of approximately 0.5 $Wm^{-1}\ K^{-1}$ while mixing theory predicts a value of 10–20 $Wm^{-1}\ K^{-1}$ [5]. Other studies have shown that aligning the fibers has a dramatic increase in the thermal conductivity; one study showed a composite of aligned vapor grown carbon fiber at 56 vol.% in epoxy had a thermal conductivity of 291 $Wm^{-1}\ K^{-1}$ [3].

Another possible reason for the lower than expected thermal conductivity of composites is the interactions between nanotubes and composite scatter phonons traveling along the tube. In addition, due to the chemical inertness of nanotube walls, only weak dispersion forces exist between the tube and matrix. Atomistic simulations demonstrate that similar dispersion forces acting between graphite planes or between single-wall carbon nanotubes lead to a reduced conductivity but only by a factor of 2 or 3, not by the observed factor of 10 [12]. According to these results, the thermal properties of the composite or nanostructure alone are not enough to explain the experimental observations [12]. Other studies suggest that the low thermal conductivity of composites may be caused by the interfacial thermal resistance [4]. A measure of the relative importance

of the interfacial resistance to the overall heat flow in a composite is obtained from the "equivalent matrix thickness," h. For the planar interface geometry, h is equal to the matrix thickness over which the temperature drop is the same as at the interface, this is given by the ratio of bulk thermal conductivity (κ) to the interfacial conductance (Λ):

$$h = \frac{\kappa}{\Lambda} \tag{7}$$

h has been measured for nanotubes in composite materials [4] and is found to be approximately 5 nm [12]–20 nm [4]. This means that even when touching, two nanotubes appear to be 10–40 nm apart, coupled only by weak dispersion forces and a small contact area [4]. Continuing the discussion of interfacial thermal resistance, Shenogin et al. [12] mention Λ is affected by nanotube length, which is apparent only at small lengths (1–10 nm) because Carlborg et al. [7] show that interfacial conductance (Λ) remains nearly constant for nanotubes at lengths from 1 to 50 nm. For CNTs, this value is approximately 1.6 $MWm^{-2}\,K^{-1}$ in liquid argon [7].

In a single-walled carbon nanotube composite, the interaction between the nanotube and matrix material is weak, and thus requires low frequency vibrational modes to be activated for the transfer of thermal energy between the two materials. When the carbon nanotube is heated, the high-frequency vibrational modes become activated [4, 7]. Energy is transferred between vibrational modes through phonon–phonon coupling. In carbon nanotubes, this intermode transfer is slow, limiting the amount of energy transferred from the high- to low-frequency vibrational modes and then exchanged into the matrix [4]. If the matrix is not bound to the CNT, where the phonon modes become coupled, the matrix material does not greatly effect the Λ [4].

Functionalization of CNT surface before embedding in matrix increases the interfacial thermal conductance by increasing the interfacial adhesion [6]; however, functionalization decreases the intrinsic thermal conductivity of the CNT [2]. Functionalization of the CNT surface at various percent functionalization (0–0.11 %) with hydrocarbon chains of various lengths (8, 12, 18, 50) in a composite has been examined [9]. It was found that as grafting density increases, the interfacial thermal conductivity increases, as the chain length increases, the interfacial thermal conductivity increases to close to 50 $Wm^{-1}\,K^{-1}$, approaching the theoretical limit. Also, the interfacial thermal conductivity is the same if the chains are covalently bound to the nanotube (sp^3 bond) or if there is a defect and then the chain is bound (sp^2 bond) [9].

Future Directions for Research

The current models and results clearly show the potential of carbon nanostructure composite systems for use as thermal management materials. Before their full potential can be realized experimentalists will need to create functionalized carbon nanostructure composites based on the above results and determine their thermal conductivity. Molecular modelers will need to refine their simulations to guide the development of an analytical model that uses the various physical dimensions of the carbon nanostructure, combined with the size of the functional groups and the number of surface atoms functionalized on the carbon nanostructure and the surrounding environment to predict the thermal conductivity of that particular composite.

While an initial model has been developed, as described in reference [5], it does not account for the functionalization effect on the intrinsic thermal conductivity of the carbon nanostructure. With an improved model in hand, and the relationship between functionalization effect and functionalization group determined, modelers can begin to examine the interfacial thermal conductivity of different functional groups in various polymers (i.e., phenyl groups for CNTs embedded in styrene vs. hydrocarbon chains in octane).

In the long term, once the results for functionalized hydrocarbon systems are understood, additional modeling potentials, which can handle halogens or metals, may be used to

develop a more complete theory of more complex composite systems.

Cancer modeling

Definition

Procedure to transfer biological processes related to tumor growth to a system of equations describing the state and the evolution of the biological system through suitable numerical simulation tools.

Introduction and Historical Landmarks

Cancer is one of the most complex diseases and this by itself represented a strong stimulus for the development of many different models, each one focusing on a specific aspect of its complexity. In fact, in addition to the multiplicity of known tumors, in general one can observe that even focusing on a single type of tumor, there can be several causes of carcinogenesis and several different evolutionary trends. One can then say that tumors are multifactorial and multipath, and mathematical models typically consider only one of the possible starting points and one of the possible evolutions (see [1]). Tumors are also heterogeneous and multicomponent with the presence of several other host cells playing relevant roles in tumor growth and of complex interactions with the environment. Even within the population of tumor cells, multiple clones with different abilities and characteristics can be identified. Every single aspect categorized above can be the object of a mathematical model.

The classification of the type of models to describe tumor evolution is then rather difficult and several criteria can be used. One way is to follow the different phases of growth distinguishing during the evolution of tumors:

- An avascular phase, in which the tumor is not yet surrounded by a capillary network and the nutrients necessary for cell survival reach the cells via a diffusion process
- A crucial phase, called angiogenesis, consisting in the stimulus and the formation of a vascular network surrounding the tumor, which represents the transition from a benign to a malignant growth
- The subsequent vascular growth, when the tumor mass, surrounded by a capillary network, coopts existing and newly formed vessels and grows around them
- The invading phase characterized by a strong tumor–tissue interaction involving both mechanical and chemical processes causing, for instance, the rupture of basement membranes and the degradation of the extracellular matrix
- The diffusion of metastases, including the processes of intravasation and extravasation via the blood or the lymphatic system and the formation of secondary tumors
- The therapeutic phase with the optimization of chemotherapies and radiotherapies, drug delivery, use of nanotechnologies, thermotherapies, and so on

Another way of classifying the mathematical models is related to the scale of interest, in the sense that the model can focus on what happens inside the single cell, on the behavior of the single tumor cell, on the interaction between cells and between tumor and healthy cells, or on the massive growth of the tumor. As a first approximation one can state that in general

- Macroscopic models, aimed at describing the tumor at the tissue level, write as systems of partial differential equations.
- Mesoscopic models, aimed at describing the tumor at the cellular level, develop in the framework of kinetic theories, individual-based models, cellular automata, and similar.
- Microscopic models, aimed at describing the tumor at the subcellular level, are mainly based on systems of ordinary differential equations, or network methods.

The history of mathematical modeling of tumor growth started in the 1950s with the first works by Thomlinson and Gray (1955), Burton (1966), and Greenspan (1972) (see [2] for references), who had mainly the merit of bringing the topic to the attention of the scientific community. The models were mainly based on diffusion equations and mass balance laws. The interest grew considerably in the 1990s with the development of many models which were, however, based on the work just mentioned. The history was then characterized by a burst of attention at the beginning of this century. This was due to several reasons:

- The improved knowledge on the behavior of tumors, both at the tissue and at the cellular level, pushed for the development of more detailed frameworks, such as multiphase models and kinetic models.
- The improvement of computational capacities gave a strong stimulus to the development of individual-based models, cellular automata, cellular Potts models, that could handle an acceptable number of cells.
- The decoding of the human genome and the development of proteomics, with the study of the signaling cascades and of the protein networks governing the behavior of cells, opened up to the burst of subcellular models, to the birth of system biology and to its application in cancer modeling.
- The use of nanotechnologies allowed new experimental measurements performed at the cellular and subcellular level and to the device of possible new therapies to be virtually tested.

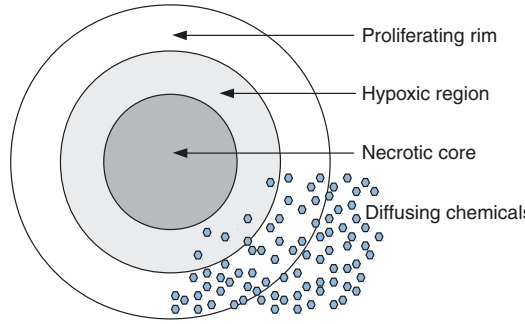
Modeling Avascular Tumors

Referring to [2–4] for recent reviews or to the volumes [5–7], the first models dealing with avascular tumor growth worked under the hypotheses that the tumor is made by only one type of cells occupying a time-dependent region of space $\Omega(t)$ keeping a constant density $\overline{\rho}$. In this approach, the tumor cells fill the space as a bunch of rigid spheres in a close-packing configuration, so that the mass balance equation simplifies to

$$\overline{\rho}\nabla \cdot \mathrm{v}_T = \Gamma_T,$$

where Γ_T is a function of the concentration of nutrients and of many fundamental chemical cues, e.g., growth promoting factors and growth inhibitory factors, that are diluted in the extracellular liquid surrounding the cells and that influence all vital functions of the tumor.

Enforcing a symmetry condition, usually spherical symmetry, allows to reduce the number of space variables to one and the velocity vector to a scalar, so that one can directly integrate the equation above to have the velocity in any point and, in particular, the evolution of the free border of the tumor



$$\begin{aligned}\frac{dR}{dt}(t) &= v_T(R(t),t)\\ &= \frac{1}{R^2(t)\overline{\rho}}\int_0^{R(t)} \Gamma_T(C_i(r,t))r^2 dr\end{aligned}$$

This equation is equivalent to writing an integral mass balance over the entire tumor volume.

The core of these types of models consisted then in describing how the growth term Γ_T depends on the chemical factors and nutrients c_i diffusing in the environment according to reaction–diffusion equations

$$\frac{\partial c_i}{\partial t} = D_i\nabla^2 c_i + \gamma_i - \partial_i c_i,$$

where D_i is the diffusion coefficient, γ_i is the production term, and δ_i is the absorption/decay term. The problem is then a free boundary problem, being the equation above valid for $r < R(t)$.

Models for Tumor Growth, Fig. 1 Structure of an avascular tumor

In particular, nutrient-limited radius can possibly be obtained if the equation

$$\int_0^{R\infty} \Gamma_T(c_i(r,t))r^2 dr = 0$$

has a solution that can be interpreted as a global balance between proliferation in the outer rim and death mainly occurring in the core (see Fig. 1).

Later on, in order to describe tumors with greater accuracy, it became necessary to consider the fact that, as most tissues, tumors were made of cells (possibily of different types), extracellular liquid, and extracellular matrix. The first multiphase models to appear were, of course, biphasic models mainly deduced with the aim of describing the behavior of (avascular) multicellular spheroids in vitro and to overcome some difficulties encountered in generalizing the constant density models described above either to three-dimensional problems or to problems involving more populations. The tumor mass was then treated as an ensemble of cells wet by an extracellular liquid full of chemicals, such as nutrients and growth factors. Since the size of the proteins dissolved in the extracellular liquid, absorbed or produced by the cells is very small compared to the size of the cells, their evolution can still be described by suitable reaction–-diffusion equations. The ensemble of tumor cells instead needs to be described using mass and momentum balance equations.

The inclusion of the capillary network and the extracellular matrix was a natural step that allowed to consider, still in the multiphase framework, fundamental interactions with the environment and to describe vascular growth, tumor–tissue interaction, and invasion of the surrounding tissue. Though many models consider three phases (cell population, liquid and extracellular matrix), more general multiphase models were also developed to describe the interaction of tumors with external tissues, to include different cell populations, e.g., fibroblasts or possibly engineered macrophages, to consider polyclonality of tumor masses, to distinguish the different constituents making up the extracellular matrix, e.g., collagen and elastin.

Referring to [8], chapter 9 of [6], or chapter 7 of [7] for more details, in addition to the reaction–diffusion equations for the molecules considered essential for the description of the evolution of the system, the structure of the model consists in a set of mass and momentum balance equations for the constituents. Denoting by α the generic constituent, one can then write

$$\frac{\partial \phi_\alpha}{\partial t} + \nabla \cdot (\phi_\alpha \mathbf{v}_\alpha) = \Gamma_\alpha,$$

(where ϕ_α is the volume ratio of the constituent, $\mathbf{v}_\alpha$ its velocity, and Γ_α its growth/death term) and, considering that inertia is negligible in the description of growth phenomena,

$$-\phi_\alpha \nabla p + \nabla \cdot \left(\phi_\alpha \mathbf{T}'_\alpha\right) + \mathbf{m}_\alpha = \mathbf{0}$$

where p is the interstitial pressure of the extracellular fluid, $\mathbf{T}'_\alpha$ is the so-called excess stress tensor, and $\mathbf{m}_\alpha$ is the interaction force accounting for the forces acting on the constituent α due to the interactions with the other components of the mixture.

The model then specializes according to the constituents considered. For instance, in many cases, the tumor mass can be modeled as a porous material, or the mechanical interaction with the liquid can be neglected. In addition, recent nanotechnologies allow to experimentally evaluate the strength of single adhesion bonds between cells and between cells and extracellular matrix and the mechanical properties of the cells. Such techniques include the use of optical tweezers, of AFM cantilevers with suitably functionalized tips to compress the cell body or to stretch the adhesion bonds, of functionalized nanobeads attached to the cell membrane or that, internalized by the cell and dispersed in the cytosol, are then suitably stimulated. This information can then be upscaled to estimate the parameter appearing in the partial differential equations [9].

To be specific as an example it is here reported a tri-phasic model deduced under the assumption that the interactions with the liquid are negligible and that the extracellular matrix is a deformable porous medium in which the cellular population moves and grows like a sticky granular material.

$$\begin{cases} \dfrac{\partial \phi_c}{\partial t} + \nabla \cdot (\phi_c \mathrm{v}_c) = \Gamma_c, \\ \dfrac{\partial \phi_m}{\partial t} + \nabla \cdot (\phi_m \mathrm{v}_m) = \Gamma_m, \\ \mathrm{v}_c - \mathbf{v}_m = K\left(1 - \dfrac{\sigma}{\left|\nabla \cdot (\phi_c \mathrm{T}'_c\right|}\right)_+ \nabla \cdot \left(\phi_c \mathbf{T}'_c\right), \\ \nabla \cdot \left(\phi_c \mathbf{T}'_c + \phi_m \mathbf{T}'_m\right) = \mathbf{0} \end{cases}$$

where c refers to the cellular population, m to the extracellular matrix, $(\cdot)_+$ stands for the positive part of the parenthesis, K is the motility coefficient, and σ measures the adhesive properties of the cell to the extracellular matrix. Of course, the equations above need to be accompanied by the constitutive equations for the excess stress tensors $\mathbf{T}'_c$ and $\mathbf{T}'_m$, describing the response of both cells and ECM to deformation.

Recently, also Lowengrub and coworkers [3] focused their attention on the adhesion properties of cellular populations introducing it as an adhesion energy. Still working in a multiphase framework, the final model consists of a fourth-order nonlinear advection-reaction–diffusion equation of Cahn–Hilliard type characterized by the presence of a term regularizing the backward heat equation term related to adhesion phenomena.

Modeling Angiogenesis

When the tumor grows too much getting larger than few hundreds microns, the amount of nutrients reaching the center of the tumor is not sufficient to feed all cells, so that its central region becomes hypoxic (see Fig. 1). In this situation most cells die, but some tumor cell might have acquired the ability of producing a class of protein generally called tumor angiogenic factors that stimulate the existing capillaries to produce new capillary networks reaching the tumor. This process, called angiogenesis, is a fundamental step in tumor growth because it distinguishes the avascular phase from the vascular phase. The difference between the two phases of growth is dramatic because in the avascular phase the tumor is very small (with a radius that is smaller than a millimeter and limited by the diffusion of nutrients), stationary, and therefore harmless, while in the vascular phase the tumor has all the nutrients to grow in an unlimited way and has a highway to spread metastases throughout the body.

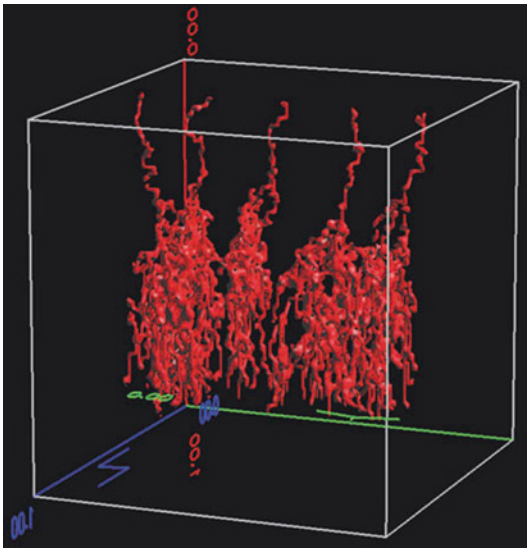
One of the most celebrated model is the one due to Chaplain and Anderson (1998) (see [10] for a review on the topic, and the volume [11]) who had the main merit to relate a continuous model with its discrete version allowing a better visualization of the process of formation of capillary trees starting from existing vessels.

In their model Chaplain and Anderson omit any birth and death process for the cells forming the capillaries focusing on the trajectories formed by the tip cells of the newborn capillaries, assuming that the endothelial cells forming the capillary walls will follow. Other key ingredients are chemotaxis toward higher densities of tumor angiogenic factors produced by the tumor, and haptotaxis toward higher concentration of extracellular matrix that is degraded by the tip cells. The model then writes as

$$\begin{cases} \dfrac{\partial n}{\partial t} + \nabla \cdot \left[\left(w_c \nabla c + w_f \nabla f \right) n \right] = k_n \nabla^2 n, \\ \dfrac{\partial c}{\partial t} = -\delta_c n c, \\ \dfrac{\partial f}{\partial t} = \gamma n - \delta_f n f, \end{cases}$$

where n is the density of tip cells, c is the density of tumor angiogenic factor, and f is the density of fibronectin. In addition, w_c and w_f are motility coefficients referring respectively to chemotaxis and haptotaxis sensitivity, k_n refers to random motility, δ_c and δ_f are the uptake coefficients from the tip cells, and γ is the production rate of fibronectin by the cells.

The aim of the discrete technique then introduced develops in the framework of reinforced random walk. It consists in using the resulting coefficients of the five-point stencil of the standard central finite-different scheme to generate the probabilities of movement of an individual cell in response to the chemoattractant gradients and to diffusion.



The extraction of a random number will decide whether the tip cell will stay still in the node or will move to a particular neighboring node rather than another. However, with respect to the standard random walk algorithm, in presence of chemotaxis or haptotaxis the motion becomes biased, because the cell has higher probabilities to move up the gradients of chemical factors.

In addition to that, the discretized setup allows to include some phenomena difficult to describe using a model based on partial differential equations, e.g., capillary branching and anastomosis, i.e., the formation of capillary loops.

In fact, when during their motion a capillary tip meets another capillary, then they merge to form a loop. If two sprout tips meet, then only one of the original sprouts continues to grow.

As shown in Fig. 2, the capillary network built in this way looks very realistic and compares well with what is observed experimentally. A three-dimensional animation of the angiogenic process is available at the web site www.maths.dundee.ac.uk/sanderso/3d/index.html.

Historically speaking, the interest in modeling angiogenesis was due to the interest in developing anti-angiogenic therapies aimed at destroying the disordered and leaky tumor-induced vessel network. Unfortunately, at present antiangiogenic therapies don't look so successful as expected. However, there is now a renewed interest due to the concept of vessel remormalization proposed in order to optimize drug delivery [12].

Models for Tumor Growth, Fig. 2 Tumor-induced capillary trees as simulated by Chaplain and Anderson (1998)

Modeling Vascularized Tumors and Invasion

Compared with the models focusing on the avascular phase, relatively fewer models were developed dealing with tumor invasion and vascular growth.

Most of them have a structure similar to the ones mentioned above. For instance, some vascular growth models develop assuming a constant density of tumor cells duplicating along a blood vessel and forming what is called a tumor cord possibly surrounded by a necrotic region farther away from the blood vessel (see chapter 3 of [13] or chapter 7 of [6]). Others develop in the multiphase framework looking more closely at the change in metabolism occurring in some tumor cells that in hypoxic conditions acquire the ability to survive and extract energy also in absence of oxygen. This makes the environment more acidic and unsuitable for the host tissue that dies leaving room for tumor growth (see chapter 4 of [13]). Other models focus on the mechanical interaction with the capillary walls, and on the fact that newborn vessels are immature and therefore subject to mechanical collapse due, for instance, to the pressure exerted by the tumor growing around them. This will cause hypoxia and the generation and remodeling of blood vessels. Others again use the discrete angiogenesis model described above to focus on the perfusion of drugs or on vessel remodeling (see chapter 15 of [6] or [11]).

Another key aspect in tumor invasion is the ability acquired by the tumor cells to produce and secrete certain factors known as matrix degrading enzymes that chop the extracellular matrix and then modify the local tissue environment making it easier for the cells to invade the surrounding tissue finding easier paths to move. This process, called metallo-proteinases, is also used by tumor cells to break through basal membranes, which otherwise would compartimentalize the tumor.

A simple example of models including the action of matrix degrading enzymes is, for instance, the following (see chapter 10 of [5] for more details):

$$\left\{ \frac{\partial n}{\partial t} + \nabla \cdot \left[(\chi(n,f) n \nabla f) = D_n \nabla^2 n + \Gamma, \frac{\partial f}{\partial t} = -\delta m f, \frac{\partial m}{\partial t} = D_m, \nabla^2 m + \mu n - \lambda m, \right. \right.$$

where the first equation describes the diffusion of tumor cells under the action of haptotaxis (second term on the left-hand side) and growth/death (second term on the right-hand side), the second equation describes the degradation of the extracellular matrix, and the third equation the diffusion of matrix degrading enzymes produced by tumor cells.

Models at the Cellular Scale

Looking at the population of tumor cells at the cellular scale, it is possible to realize that the behavior of the cells is not always the same. Their evolution is characterized by the presence of switches and acquired ability that allow them to resist to particularly unfavorable conditions or by

the birth of daughter cells that have a clonal advantage on their mother cells. For instance, in the initial stages of tumor development a corruption in the mechanotransduction pathway leads to the existence of cells that are not so sensitive to the mechanism of contact inhibition of growth, so that they continue activating their duplication program even when they should stop proliferating. This misperception of the compression state by the abnormal cells, called cadherin switch, can generate by itself a clonal advantage on the surrounding cells, leading ultimately to the replacement and the invasion of the healthy tissue by the tumor (see chapter 7 of [7]). After that, other landmarks characterize tumor evolution as the angiogenic switch stimulating the formation of tumor-induced capillary plexus, or the just mentioned metabolic switch from aerobic to anaerobic production of ATP, or the epithelial-mesenchymal transition, that triggers the formation of metastases.

Also from the morphological viewpoint tumor cells present differences that are usually identified by histopathologists to classify tumor malignancy, e.g., presence of particular receptors or organelles, or loss of cell polarity. The mathematical models focusing on the inclusion of the inner evolution of the tumor population briefly described above needs to incorporate a new independent variable which is able to describe the state (or the states) characterizing the cells and how such a state influences their behavior. This state might refer to the aggressiveness, the activity, the maturation state, and so on (see chapter 3 of [6], and [14, 15]).

The key steps in the modeling process are then the selection of the cell populations of interest for the evolution and the identification of their specific activity/ies, their mechanisms of progression, of proliferation, and of interaction.

The structure of the model then develops in the framework of kinetic theories and may be written as follows:

$$\begin{aligned}&\frac{\partial}{\partial t}f_i(t,u)+\frac{\partial}{\partial u}\left[c_i(t,u)f_i(t,u)\right]\\&=S_i+f_i(t,u)\sum_{j=1}^{n}\int_{-1}^{1}p_{ij}(u,w)f_i(t,w)dw\\&\quad+\sum_{j=1}^{n}\left[\int_{-1}^{1}\eta_{ij}(v,w)\Psi_{ij}(v,w;u)\right.\\&\quad\times f_i(t,v)f_j(t,w)dv\,dw-f_i(t,u)\\&\quad\left.\times\int_{-1}^{1}\eta_{ij}(u,w)f_i(t,w)dw\right],\end{aligned}$$

where the second term on the left-hand side represents the intrinsic evolution operator which takes into account of the progression of the cells even in absence of interactions and proliferation/death. The second term on the right-hand side represents the net proliferation operator, i.e., stimulated mitosis minus killing due to interaction with other cells. In it $\eta_{ij}(v, w)$ denotes the number of encounters per unit volume and unit time between cell pairs of the (i, j)-th populations with states v and w, respectively, and $\psi_{ij}(v, w; u)$ denotes the probability of transition of the i-th cell to the state u, given its initial state v and the state w of the encountering cells belonging to the j-th population. The last two terms are related to interactions which only change state in the interacting cells, while the second one refers to proliferative/destructive interactions. Finally S_i is the source/sink term which may be external (e.g., effect of chemotherapy and radiotherapy) or internal, like the net proliferation term (mitosis-apoptosis) $\gamma_i(t, u)\, f_i(t, u)$.

Other popular models focusing on the cellular scale, in general without considering the inner evolution of cells, are based on cellular automata, cellular Potts models, and individual cell-based models [16].

In individual cell-based models, a cell is schematized by its center, then surrounded by a deformable spherical shell or by a Voronoi tessellation (see Part III of [16] for more details). If a spherical cell gets in contact with other cells, it adheres to them and as a result of the contact, the

shape of the cell changes by flattening at the contact area. A similar thing occurs for the interaction with the substrate that is typically a rigid impermeable plane or with other elements of the environment, e.g., bones and vessel walls.

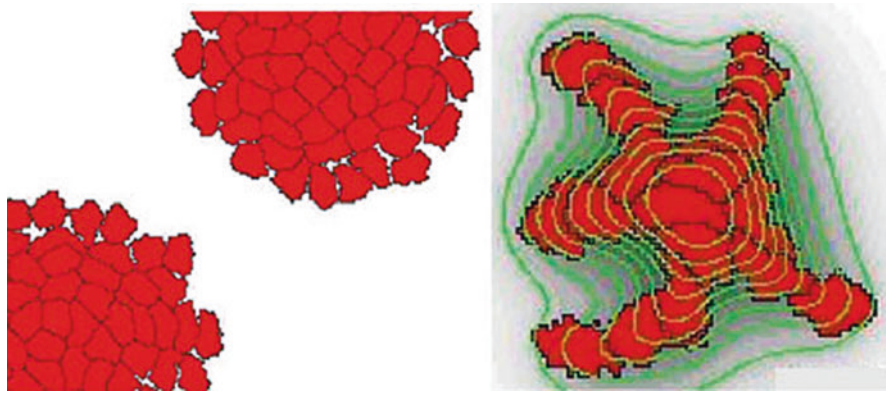
The dynamics of each individual cell is then modeled by Langevin equations in a friction-dominated regime. Thus, in the absence of an external stimulus the cells perform a random movement. For instance, the motion of the i-th cell is modeled by

$$\sum_j \mathrm{C}_{ij}\left(\mathrm{w}_i - \mathrm{w}_j\right) + \mathrm{C}_{is}\mathrm{w}_i = \mathbf{F}_i^{\mathrm{det}} + \mathbf{F}_i^{st},$$

where $\mathbf{w}_i$ are the cell velocities and $C_{i\alpha}$ are related to the friction coefficients, respectively, with between cells ($\alpha = j$) and between cells and the substrate ($\alpha = s$). On the right-hand side, $\mathbf{F}_i^{\mathrm{det}}$ summarizes the deterministic forces related to the total interaction energy between the cell pair (i, j) defined by the sum over all individual energy contributions, that depend on the distance between the cells and the radius of both cells. Thus, cell–cell contacts can equilibrate via cell displacements or changes in the cell radius R. The total interaction energy between a cell and the substrate is defined analogously. The term $\mathbf{F}_i^{st}$ denotes the stochastic force with zero mean and delta-correlated autocorrelation function that models the random component of cell movement.

The cellular Potts model is another modeling framework that has been used to describe several tumor growth problems, such as avascular and vascular tumor growth, angiogenesis, and cell invasion problems (see Part II of [16]). The cellular Potts model is a grid-based, stochastic Monte Carlo method in which each cell is described as an ensemble of nodes. The core driving the evolution of the system is an energy minimization philosophy. Depending on the problem, the energy functionals to be minimized may include adhesion energies between cells or with the substrate, terms mimicking energies, for instance, the energetical response of a cell to a chemical gradient, or persistence of cell motion, and possible constraints, such as on the volume or the surface area of the cells.

The energy functional



$$H = H_{\mathrm{adhesion}} + H_{\mathrm{shape}} + H_{\mathrm{chemotaxis}} + H_{\mathrm{persistence}} + \ldots\ldots,$$

then describes the state of the system and drives all lattice rearrangements with an algorithm of stochastic minimization (a modified Metropolis procedure).

In this way, it is possible to mimic the natural behavior of migrating cells, via thermal-like membrane fluctuations and extension of pseudopodia to explore the surrounding environment. Procedurally, a lattice site is selected at random and assigned the state of one of its unlike neighbors, which has also been randomly selected. The Hamiltonian of the system is computed before and after the proposed update: If it is reduced as the result of the copy, the change is accepted, otherwise it is accepted with a probability that decreases exponentially with the energy increase that such an unfavorable choice would give. Figure 3 gives an example of a CPM describing the motion of a single cell or of a cell cluster through the mesothelial layer.

Therapy and Multiscale Models

Many models based on systems of ordinary differential equations have been deduced to describe the pharmacokinetics, the pharmacodynamics, or the response of the body, possibly divided in compartments, to cancer treatments. Generally, the aim of these models is the optimization and personalization of therapeutic protocols, identifying optimal doses and optimal schedules. This is usually done using optimal control theory. Similar problems are encountered in testing immunotherapies or combined therapies and in describing the action and the use of radiotherapies [17].

Models for Tumor Growth, Fig. 3 Growing tumor masses (*left*) and invading aggregate of a liver tumor cell line (*right*) as simulated with a cellular Potts model

Focusing here on the recent trends, nowadays there is a big interest in understanding and modeling the action of radiation and drugs at the subcellular level, which means not only how genetic changes or the expression of particular genes or gene networks determine cell behavior, how radiotherapy can induce fatal genetic damages, but also understanding and describing how the protein networks inside the tumor cells work, how the activation of specific signaling cascades govern cell motion, duplication, and death, and therefore what are the main crossroads of the networks to attack or stimulate from the therapeutical viewpoint. Eventually, from the pharmaceutical viewpoint what kind of drug should be developed because it is more likely to be successful.

From the modeling viewpoint, once such networks are understood, the following step consists in inserting them into the macroscopic or the mesoscopic models building what can be called multiscale models, because they take into account of phenomena occurring at different spatial and temporal scales [18, 19]. They, in fact, nest into the macroscopic or mesoscopic representation one or more modules accounting for processes at the microscopic scale. Because of the most recent discoveries in the field of genomics, proteomics, and system biology, these descriptions are now expanding considerably. In this respect, models at the cellular scale, such as individual cell-based models or cellular Potts models, seem more flexible and suited to include subcellular mechanisms, though it is possible to nest protein networks in macroscopic models, so that they influence the coefficients of the partial differential equations.

Coming back to modeling drug delivery, many of the mathematical models dealing with vascular growth were actually developed with the aim of describing the transport of chemotherapeutic drugs, their perfusion through the vessel walls, their effectiveness in killing tumor cells, or as antiangiogenic therapies [11]. This approach has been recently used also to describe the infiltration of engineered macrophages. In fact, it is known that macrophages migrate specifically toward, and localize within, hypoxic tumor regions, that are the hardest region to cure via radiotherapy. So they can be in principle used as vehicles to deliver drugs and perform antitumor activities such as inducing cell lysis or inhibiting angiogenesis. The mathematical models are generally based on advection–diffusion equations with chemotactic terms to describe the directed motion of macrophages toward hypoxic regions.

Very similar models are deduced to describe and optimize drug delivery using other macromolecular carriers like liposomes or suitable nanodevices and nanoparticles. In fact, such macromolecules might more easily reach the tumor sites with respect to other parts of the body exploiting the fact that, because of the action of

tumor angiogenesis factors, tumor-induced capillaries are fenestrated and therefore highly permeable. Moreover, for instance, it is possible to attach an antibody to the liposomes, so that the drug is specifically targeted to the tumor cell. The transport, extravasation, and diffusion of nanoparticle in tumors is also modeled to optimize related therapeutical actions, e.g., magnetic nanoparticles are used so that they can be trapped either to occlude capillaries or to be heated up; gold nanoshells are used to enhance laser thermal therapy [20].

As it might be easily guessed, there is not a single model to approach the same biological phenomenon. Of course, each approach has its advantages and disadvantages. For instance, models based on systems of partial differential equations are more suited and computationally cheaper to describe the behavior of tumor tissues from the macroscopic point of view, but, as discussed above, it is more difficult to account for subcellular mechanisms such as signal transduction, expression, or internalization of receptors, and so on. Conversely, individual cell-based models can focus more closely on the cellular level, but they might become computationally expensive when using a large number of cells, and inefficient in providing a general outlook on the system as a whole. Luckily, it is often not necessary to keep the same level of detail throughout the tissue. The idea behind building what can be called interfacing hybrid models is to use the modeling tools like a microscope, focusing on the cellular or subcellular level where and when needed and blurring when such a detailed description is not needed. For instance, the spatial domain can be partitioned in few time-dependent domains, and in each piece of this moving puzzle a different modeling framework can be used, so that it is possible to take advantage of the positive aspects of both frameworks. Of course, in order to do that one should compare, for the same biological phenomenon, the results obtained via different models and transfer information from one modeling framework to another. Allowing the models to properly cross talk needs the development of suitable mathematical procedures which nowadays represents a challenging research field.

Definition

Molecular computing is a novel approach to develop computing systems and devices alternative to conventional silicon-based computing using (biological) molecules.

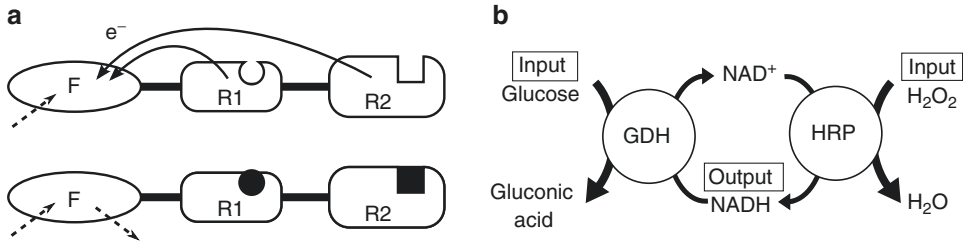
Overview

Molecular computing research aims at developing computing systems and devices that are fully or partly composed of molecular materials. It typically refers to molecular devices or systems consisting of molecular substrates (mostly biomolecules, such as protein and DNA) for information processing.

Ultimate goals of molecular computing research are not to replace well-established semiconductor materials used for today's computer systems. Molecular computer devices are generally slow, unstable, and hard to connect up together, compared to conventional semiconductor devices. It is less likely that they could be much improved in the future. Instead, a main application domain of molecular computing is the integration with biological systems, such as

biological cells. Molecular computing devices can be directly interfaced with biochemical processes of living cells such as gene regulation network and intracellular signal transduction, whereas semiconductor devices are incompatible with them in terms of size and material. Ultimately, the molecular computing devices would offer more countability to the engineering of biological systems, for example, the controlled release of a therapeutic agent in the cell [1].

In addition to biocompatibility, molecular devices have several other advantages, such as massive parallelism and self-assembly. The former concerns the order in which molecules typically operate. Because molecules in general work in the order of Avogadro number, it has been suggested that theoretically molecular devices which contain a massive amount of molecules can carry out computing in truly parallel fashion, even though each molecule has a little computing power. The latter mainly concerns the free energy minimization process of molecular recognition. If two molecules are complementary, they self-assemble into a supramolecular complex. These advantages lead to DNA computing devices described below, whereas the biocompatibility of molecules bloomed into molecular logic gates, which are also covered here.



Molecular Logic Gates

In living cells, there are numerous protein "logic gates" operating in order to process external and internal information. An external physical or chemical signal arriving at the cell's surface "turns on" a receptor on the membrane, and the activated receptor releases signals to downstream messenger proteins in a cascade to activate another protein and so forth. In this sense, a living cell can be seen as a system with a vast network of simple switches and logic gates made from molecular materials. Motivated by this view of living cells, research on molecular switch and logic gate aims at designing and developing such molecular computing elements that are controllable from the outside.

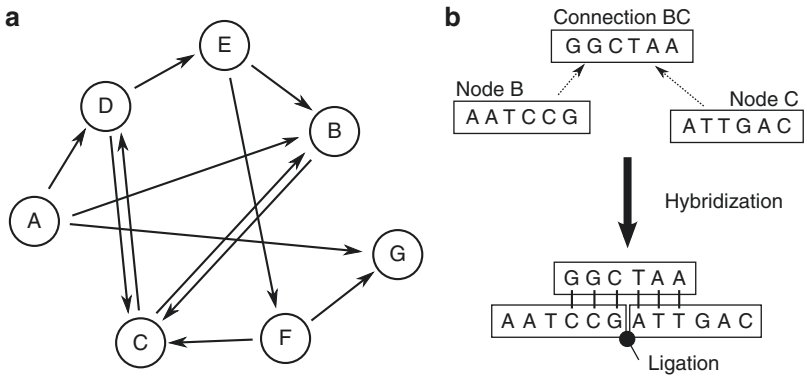
A simpler but essential computational element in the electronic devices is the switching device. Tyagi and Kramer implemented a molecular switch in single-stranded DNA using fluorescence resonance energy transfer (FRET). A fluorophore is attached on one end of a single-stranded DNA and a quencher on the other end. The strand folds into a hairpin structure because of complementary sequences in both ends, and the fluorophore and quencher come close together. If a complement single-stranded DNA string is present, they form a double-stranded DNA, which keeps the fluorophore and quencher apart. As a result, the fluorescence is activated. If the fluorescence is considered as output signals, the switch works as a one-input one-output logic gate, NOT gate, which inverts a binary input signal.

Two-input one-output logic gates are also implemented with molecules. De Silva and coworkers developed a molecular AND gate based on photoinduced electron transfer (PET) [2]. The molecule consists of a fluorophore and two receptors (amine and benzocrown ether) connected by spacers (Fig. 1a). Amine binds a proton, and benzocrown ether targets Na^+ as inputs, respectively. If both receptor sites are empty, an electron is transferred to the fluorophore from one of the receptors, and the fluorophore does not emit light. Even when one of the receptor sites is occupied by an input (H^+ or Na^+), an electron is transferred to the fluorophore. Light emission will be observed only when both receptor sites are occupied because electrons are used to bind input H^+ and Na^+ ions. Thus, the AND operation, which outputs "1" only when both inputs are "1," is realized.

Katz and coworkers employed enzyme-catalytic reactions to construct various Boolean logic gates, such as AND, OR, NOR, XOR, YES, and NOT [3]. For instance, the enzymatic XOR gate consists of two enzymes, glucose dehydrogenase (GDH) and horseradish peroxidase (HRP). GDH and HRP take glucose and hydrogen peroxide (H_2O_2) as inputs, respectively, and interact via nicotinamide adenine dinucleotide (NAD), which absorbance changes are used as output (Fig. 1b). A XOR gate outputs "1" when only one input is "1" (i.e., inputs are "0, 1" or "1, 0").

Molecular Computing, Fig. 1 (**a**) A molecular AND gate based on photoinduced electron transfer. F, R1, and R2 represent fluorophore, amine, and benzocrown ether, respectively. *Dotted arrows* indicate excitation and emitted lights. It uses H^+ and Na^+ ions as inputs and fluorescence as outputs (After Ref. [4]). (**b**) An enzymatic XOR gate. If both inputs (glucose and hydrogen peroxide) are either present or absent, the UV absorbance of the system will remain the same as that of before input signal application. Otherwise, it decreases or increases, which is read as output "1" (After Ref. [3])

When inputs are both present or both absent ("0, 0" or "1, 1" case), the small enzyme network keeps balance of NAD, and the ratio of NAD^+ and NADH concentrations remains the same. On the other hand, if the levels of two inputs are not equal, "0, 1" or "1, 0", it loses the balance, and the NADH concentration will decrease or increase. When the optical absorbance of the system with "0, 1" or "1, 0" input is compared to that of a control case (before input signals are applied), the absolute value of absorbance change, particularly in the ultraviolet (UV) range, is quite large, whereas that of "0, 0" or "1, 1" case is almost zero.



Molecular logic gates can be implemented on various materials (cf. [3, 4]) as well as supermolecules and proteins described above. Those computing elements can be built from supermolecules, macromolecules (e.g., proteins), DNA, and RNA. In some cases, whole cells are also used. Various options are available for inputs and outputs of the systems. As to inputs, molecular logic devices have been developed using light, atomic/molecular ions, magnetic field, redox changes, chelating reactions, oligonucleotides and oligopeptides additions, etc. Output signals can be read by absorbance, fluorescence, electric current, etc. Based on those molecular systems, molecular analogues of digital computing devices can be realized: Boolean logic operations, comparator, flip-flop, arithmetic operations, half adder, full adder, multiplexer, keypad lock, memory unit, and automaton were developed so far.

DNA Computing

DNA computing has become a vast research field which encompasses from formal language theory to practical implementations [5]. This article gives an overview of the first experimental demonstration by Adleman in 1994 [6], which well represents the core ideas of DNA computing.

In the seminal paper, Adleman showed that DNA can be used to solve a type of combinatorial problem called "directed Hamiltonian path problem (directed HPP)." This problem is defined as follows: Given a finite number of nodes and directed connections, determine if there is a path which visits all the nodes only once (Hamiltonian path) in polynomial time. This is known as one of the NP-complete problems, a class of decision problems that can be solved in polynomial time on a nondeterministic Turing machine [7]. In other words, the computational time for solving this type of problems increases exponentially as the size of the problem.

Figure 2a shows a graph Adleman used for DNA computing to solve directed HPP. It has seven nodes labeled as A to G and connections between the nodes. For example, consider if there is a Hamiltonian path starting from node A (in principle, any node can be start of a Hamiltonian path). From A, possible connections are *AB*, *AD*, and *AG*. However, *AG* has no outgoing connections, and it cannot be a Hamiltonian path. Any paths after *AD* are not Hamiltonian paths because they form a loop at some point

Molecular Computing, Fig. 2 (**a**) A Hamiltonian path problem solved by Adleman's DNA computer. (**b**) Encoding of nodes and connections into DNA strands

in the path. By repeating this search process till it finds a path that connects all the nodes without any loop in the path, the path *ABCDEFG* can be determined as only one Hamiltonian path in the graph. The directed HPP can be solved by the brute-force search as above, but with the algorithm, the computational time exponentially increases even when the number of nodes increases linearly.

Adleman tackled this problem by employing the massive parallelism and complementarity of DNA molecules. DNA (deoxyribonucleic acid) consists of nucleotides in polymer form, and each nucleotide consists of a nitrogen-containing base, sugar, and phosphate base. Four types of nucleotides occurring in the DNA are adenine (A), guanine (G), cytosine (C), and thymine (T). Adenine and thymine (A-T) and guanine and cytosine (G-C) can form a base pair with hydrogen bonds, and those pairs are said to be complementary. If a sequence of oligonucleotides (short strand of nucleotides) is complementary with another oligonucleotide, they can form a stable double-stranded DNA.

Path finding of the graph by Adleman's DNA computer was carried out as follows:

1. Encode the graph into the DNA

   Each node and connection was encoded as a single-stranded DNA oligonucleotide. First, each node is represented as a specific length of DNA sequence. In Fig. 2b, nodes B and C are represented as AATCCG and ATTGAC, respectively. Then, if there is a connection between two nodes, for example, connection *BC*, a DNA sequence representing the connection is designed as half of the sequence is complementary to half of the sequence representing node B and another half is to that of the node C sequence (in Fig. 2b, *BC* is encoded as GGCTAA).
2. Generate Random Paths

   Mix all the DNA sequences encoding nodes and connections in a test tube together with DNA ligases. Single-stranded DNA strings self-assemble into double-stranded DNA due to the base pair complementarity. This process is called DNA hybridization. DNA ligases repair breaks in complementary strands of DNA (ligation). At this point, the computation of Hamiltonian path finding has effectively completed. The following steps are required to verify the answer of computation.
3. Extract DNA Sequences Starting with Node a and Ending with Node G

   This step is done using polymerase chain reaction (PCR). Using complementary sequences of node A and node G as primers, PCR amplifies DNA sequences that start with node A and end with G only for easier detection of Hamiltonian path sequences.
4. Extract Sequences with the Length of Exactly Seven Nodes

   Gel electrophoresis separates mixture of DNA fragments with different lengths by their sizes. By comparing with molecular weight markers, an area in the gel which contains DNA sequences with the length of exactly seven nodes can be spotted.
5. Extract Sequences Containing All the Nodes

The last verification process is done by magnetic beads. DNA fragments are first heated and denatured into single-stranded DNA sequences. Then, complementary sequences of a node with magnetic beads attached bind to the single-stranded DNA and picked up by magnets. Repeat this process for each node.

6. Check the Test Tube

   Check if there is any DNA sequence left in the test tube. If yes, it corresponds to a Hamiltonian path of the graph. If not, the graph does not have any Hamiltonian paths starting from node A and ending with node G.

The directed HPP is considered to be a computationally hard problem because a conventional computing system, or conceptually a Turing machine, performs at most one action at a time step, i.e., such a system has only one single processor to process inputs. Thus, if a graph has n nodes and start-end nodes are fixed, potentially it requires $(n-2)!$ computational steps to determine the presence or absence of a Hamiltonian path in the graph. DNA computing, on the other hand, involves a massive amount of simple processors. If a DNA computer has $(n-2)!$ processors, then the computation can be accomplished in a step. It has been suggested that a DNA computer could potentially execute approximately 1.2×10^{18} computations in a second, the energy efficiency could be up to 2×10^{19} computations per joule, and the memory density would be 1 nm^3 per bit, all of which outperform any present-day conventional computing systems.

However, several downsides of DNA computing were also pointed out [1, 8] Error rate. Computations by DNA involve a relatively large amount of errors which inherently come with the use of biological materials. They significantly reduce the reliability of computation, in particular when a number of computations are combined together [2]. Scalability. Provided that Adleman's protocol is employed for problems with larger nodes, the amount of DNA molecules required for encoding exponentially increases, which could be over hundreds of kilograms [3]. Diffusion speed. Even if such a large amount of DNA can be put into place, the computation relies on diffusion of DNA fragments, which does not scale up with the size of DNA. Hence, the reaction speed takes longer for a large-scale problem, but mixing is difficult because DNA molecules are fragile.

Other Molecular Computing Devices

As another approach to exploit computational capabilities of DNA, Winfree proposed an experimentally implementable low-error cellular automata model that can perform Turing-universal computation using the self-assembly capability of DNA tile [9]. When carefully designed DNA strands are mixed in a solution, they self-assemble into two-dimensional shapes according to the designed sequence called DNA tiles. A single-stranded DNA at the edge of a tile ("sticky end") allows the tile to connect only to other tiles which have a complementary sticky end. This "programmability" of DNA tiles allows to self-organize a larger pattern similar to one-dimensional cellular automata (1D-CA), which development is controllable by choosing an initial pattern seed. 1D-CA is proved to have Turing universality, and in this sense, the DNA-based cellular automata system also has the computational power equivalent to a universal Turing machine. Based on this, he and his coworkers have developed tile-based DNA computing devices, such as logic gates [9], automata, gain amplifier, and neural network.

A chemistry-based approach has been pursued by Adamatzky and De Lacy Costello [10]. The main focus in their approach is massively parallel nature of chemical reaction, in particular, Belousov-Zhabotinsky (BZ) reaction. This reaction is known to show excitability: If a BZ solution is stimulated (e.g., by a silver wire), the color of the solution oscillates, and propagating wave patterns are observed. Using the reaction (particularly the propagation waves and their collisions), it has been shown that Boolean logic gates, calculating Voronoi diagram, shortest path planning, robot control can be achieved.

Perspectives

Although there has been a lot of research conducted on molecular computing, this field is still at an early stage of development and is unlikely that this technology would be commonly available in the near future. One of the key issues for molecular computing is the application domain of the technology. It has been claimed that it could be used for life science applications, such as controlled gene regulation. However, there will be many hurdles to develop molecular computing components that work in the complex in vivo environment of living cells. Thus, numerous challenges in the molecular computing research will need to be overcome so that the molecular computing technology will come into wide use.

Another issue for molecular computing devices is the development of computing concepts that make the most of molecular dynamics. Conventional computing concepts are based on the theory of Turing computability, and hence, they are irrelevant to the dynamics of materials on which computing devices are implemented. On the other hand, living organisms arguably employ radically different computing concepts that leverage the physics of biological materials. For example, self-organization, self-repair, and self-reproduction are commonly found in biological systems but are difficult to achieve with conventional computing systems. New computing paradigms, such as cellular automata, neural networks, and evolutionary computing, may provide clues to utilize the complexity of molecular dynamics for information processing.

Molecular computing devices are not likely to compete with and replace conventional computing technology. Rather, they are complementary approaches to silicon-based systems, and a hybrid system which incorporates molecular devices into artificial systems would find potential application domains in, for example, medical and environmental applications. It is, thus, expected that molecular computing will be one of the important technologies, together with other technologies such as synthetic biology, in the age of biomolecular nanotechnology.

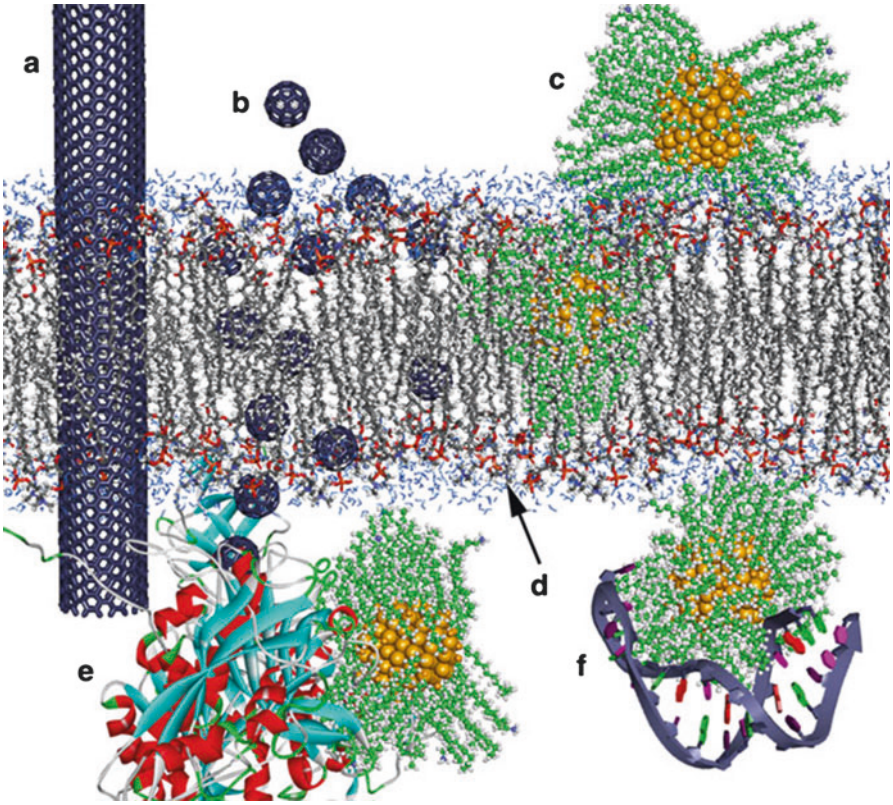
Molecular dynamics simulations of interactions between biological molecules and nanomaterials

Definitions

Nano-bio materials are materials that are composed of biomolecules (protein, DNA, RNA, lipids) and nanoscale materials (nanoparticles, nanotubes, nanocrystals).

Molecular dynamics simulation is a computer simulation technique that is based on integration of Newton's equations of motion and reflects physical movements of atoms and molecules.



Overview

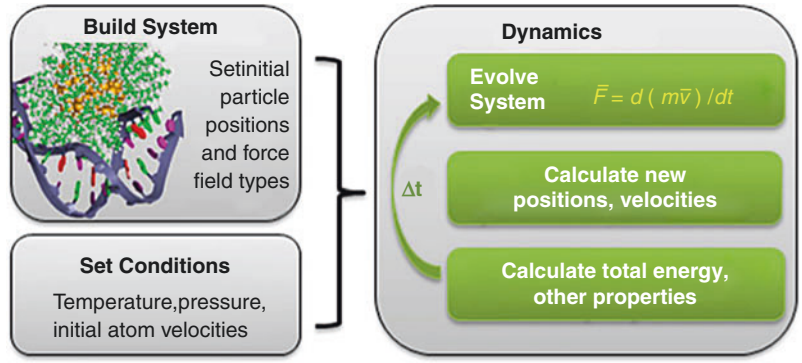
Introduction

Nanotechnology has received increasing public attention as more and more practical applications of nanoparticles and nanomaterials are emerging, especially in the biomedical field. For example, inorganic nanoparticles (NPs) functionalized with synthetic or biological molecules have been used in a broad range of biomedical applications, including imaging, diagnostics, and drug delivery. The advantage of using NPs in biomedical applications is that a single nanoparticle can simultaneously carry imaging probes, drug molecules, receptor-binding molecules, and antibodies on the surface, which promise the most efficient drug delivery platform and detection scheme. However, interactions of NPs with biological molecules may lead to structural and functional changes, which in turn may result in unexpected biological reactions and toxicity. For example, it has been shown that metallic NPs, quantum dots, and carbon nanotubes can translocate to the brain from different entry points, such as skin, blood, and respiratory pathways.

Moreover, the properties of NPs, such as size, shape, hydrophobicity, charge density, and chemical composition, can directly influence the ability of NPs to enter the cellular environment, bind to proteins, activate receptors, and translocate and accumulate in target tissues, as depicted in Fig. 1. Biological molecules can also be used as scaffolds for precise deposition of NPs for electronic and optical devices. However, the effect of nanomaterials on the biomolecular structure and function is not yet elucidated, which limits advancements within the potential applications and the development of new ones. A better understanding of the biological effects of NPs requires knowledge of the mechanisms of interactions between NPs and biomolecules.

Computer simulations can yield a wealth of insights on interfacial dynamics, structures of ligands, electrostatics, and binding of biomolecules. One of the most promising and rigorous methods for simulating complex and large-scale processes in various materials and biosystems is molecular dynamics (MD) simulations. MD simulations have been used for gaining comprehensive information on "nano-bio" systems, including ligand dynamics

Molecular Dynamics Simulations of Nano-biomaterials, Fig. 1 Atomistic view of the interactions of different types of nanoparticles, (*a*) carbon nanotubes, (*b*) buckyballs (fullerenes), and (*c*) gold nanoparticles, with biological molecules, (*d*) a lipid membrane, (*e*) a protein, and (*f*) nucleic acids



on NPs, conformational transitions of biomolecules, protein and ligand binding, enzymatic catalysis, and the dynamic, thermodynamic, and mechanical properties at different spatial and temporal resolutions [1]. Thus, MD simulations are a natural complement to experimental techniques at the nanoscale to yield insight on molecular interactions involved in nanoparticle–biomolecule binding and mechanisms of molecular recognition.

Overview of Molecular Dynamics Simulations

The steps of an MD simulation are given in Fig. 2. First, the initial system is built; coordinates of some specific biological molecules can be obtained from databases such as the Protein Data Bank [2], while others must be developed using in-house scripts. The initial velocities are assigned from a Boltzmann distribution at the desired temperature. The force field parameters for all of the components are assigned. The system is then evolved with Newton's equations of motion for each Δt, which provides new positions and velocities for each atom.

The potential energy of the system is calculated from force field parameters, which are comprised of both the bonded and nonbonded interactions. The bonded interactions include bond lengths, angles, and dihedrals, whereas the nonbonded terms are mainly electrostatics and van der Waals. The total potential energy can then be defined by the following equation:

$$U = \sum_{\text{bonds}} k1\left(r - r_{eq}\right)^2 + \sum_{\text{angles}} k2\left(\phi - \phi_{eq}\right)^2 + \sum_{\text{dihedrals}} \frac{Vn}{2}\left(1 + \cos\left(n\varphi - \gamma\right)\right) + \sum_{\text{nonbonded}} \left[4\varepsilon_{ij}\left(\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} + \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right) + \frac{q_i q_j}{\varepsilon r_{ij}}\right],$$

Molecular Dynamics Simulations of Nano-biomaterials, Fig. 2 The main components of an MD simulation

where r_{eq} and ϕ_{eq} are equilibration structural parameters, *k1*, *k2*, and *Vn* are force constants, n is dihedral multiplicity, and γ is phase angle for torsional angle parameters.

The choice of a force field is dependent on the chemical composition of the system and the molecules under study, and thus dictate the reliability of the results. A recent review outlines the comparison between most widely used protein force fields [3]. For example, the CHARMM27 [4] force field can be used to simulate DNA, RNA, and lipids, while for CHARMM22 [5] force field is parameterized to simulate proteins. The AMBER program contains force field parameters for DNA, RNA, and proteins (Cornell force field [6]); small molecular ligands (GAFF force field [7]); and carbohydrates (GLYCAM force field [8]). Other all-atom force fields include OPLS [9], which contains parameters for proteins, carbohydrates, and nucleic acids. United atom models such as GROMOS [10] are also available that treat nonpolar hydrogens implicitly, which is commonly done for lipid membranes. The challenge, however, for bio-nano systems is that there is no generalized force field for metallic, carbon, and complex NPs and coarse-grained representations of the molecules, and thus the parameters are calculated on a case-by-case basis. In addition, all-atom MD simulations are not possible for some systems of interest and thus some level of coarse-graining is required, which necessitates a whole new set of force field parameters. An example of a commonly used coarse-grained force field for bio-nano systems is MARTINI [11].

Solvent molecules are often included in the simulation. The most complex solvent is water, and a variety of water models have been developed; the most commonly used models are SPC, TIP3P, and TIP4P. Explicit solvent simulations are the most accurate and can provide information on specific solvent–nanoparticle or solvent–biomolecule interactions; however, they are more computationally extensive since significantly more atoms are being included in the simulations. MD simulations can be significantly accelerated by treating the solvent with continuum dielectric methods. In this case, only the intrasolute electrostatics need to be evaluated. Even though implicit MD simulations are less accurate than simulations with explicit solvent, they permit not only much longer simulations and larger molecules but also provide a variety of sampled conformations.

The time length of simulations is typically based on the type of processes under study and must ensure that a sufficient amount of phase space is sampled. Typically, to observe any significant conformational change of biological molecules, the simulations time needs to be on the order of hundreds of nanoseconds. A useful measure of the accuracy of a simulation is the total energy of the system, which means that typically throughout the simulations, the total energy should not increase. The size of deviations of the total energy gives the measure of precision of the integration. The accuracy of the integration procedure depends on the value of the time step. For the simulations to be as long as possible, the time step needs to be chosen as large as possible. However, the maximum time step is limited by the

Advantages and Limitations

The challenges in using an MD description of complex nano-biosystems are the severe limitations of time and length scales, limited to several hundreds of nanoseconds, and moderately sized biomolecules and NPs. However, as computer speed and memory increase, so do the simulation time and size limits. For example, for all-atom simulations the reasonable simulation time 10 years ago was on the order of 1 ns, but now about100 ns time length can be obtained for the same size of a system. The main advantage of an MD simulation is that only details of the microscopic interactions need to be specified and no assumptions are made about the character of the processes under investigation. Moreover, the MD simulation method is capable of providing a complete microscopic description of the dynamical processes involved.

Most importantly, the reliability of MD simulations depends on accurate force fields for all system components. The classical MD simulation method also prevents study of processes like proton transfer, tunneling effects, zero-point motions, behavior of electrons and atomic nuclei, and making/breaking chemical bonds. Problems like these require modeling that applies the laws of quantum mechanics, the fundamental physics equations that describe electrons. However, because of the complex nature of the equations, these models can handle only a few atoms at a time. Some efforts are underway to create force fields that overcome these barriers. Considerable improvements in force fields have also been achieved, making simulations more reliable and accurate.

Application of MD Simulations to Study Nano-Biosystems

In the subsequent sections, an overview of utilizing MD simulations for investigations of a variety of properties of nano-biosystems is provided. Figure 1 summarizes the types of systems that are included in this entry and specific simulation conditions for five simulations highlighted here are summarized in Table 1. The overview begins

with carbon nanoparticles, which are the most actively and successfully used systems for simulations of nanomaterials. Then, the application of MD technique to other nano-biosystems, such as functionalized gold nanoparticles, will be addressed. The focus is on the interactions of these nanoparticles with lipids, proteins, and nucleic acids that have been investigated with MD simulations are then summarized.

Interactions of Carbon NPs with Biological Molecules

The most common type of carbon NPs are fullerenes or buckyballs (Fig. 1b) and carbon nanotubes (Fig. 1a). Both of these carbon NPs are important in many technologically relevant areas due to their unique properties. Buckyballs have potential as drug delivery mechanisms and medical diagnostic devices because of their size, spherical shape, stability, and the ability to be functionalized with other atoms; however, their hydrophobic character is a drawback to some medical applications.

Carbon nanotubes (CNTs) have unique mechanical and electrical properties, as well as strong chemical reactivity due to their high surface area. Their large diameter-to-length ratio provides unique applications, such as microcatheter reinforcements for tissue engineering scaffolds. CNTs can have an impact on biomolecules by enhancing their electrochemical reactivity and promoting protein electron transfer. They are very attractive materials for the design of electrochemical biosensors ranging from an amperometric enzyme electrode to DNA hybridization biosensors. For example, a CNT-based sensor has been developed for detection of hepatitis B virus (HBV), which enables a diagnostic application for nontreated human blood.

A significant amount of MD simulations at various levels of detail have been employed to explore the interactions of CNTs and buckyballs with lipids, proteins, and nucleic acids [17–19]. These simulations have revealed the physicochemical details for a variety of applications. Such focus areas include potential mechanisms for toxicity of carbon nanoparticles and the design of engineering devices such as sensors, drug delivery vehicles, and actuators. Factors for the carbon NPs that were studied include diameter size, structural alignments, aromaticity, nanoparticle curvature, degree of hydrophobicity, and the local environment. Two recent exemplary articles are summarized next.

MD Simulations of a Carbon NP Nanobiosensor

A nanobiosensor has been shown experimentally to be a feasible device for detecting adenovirus proteins, particularly the Knob proteins. This nanodevice is comprised of a single-walled CNT that is functionalized with the coxsackie-adenovirus receptor (CAR) protein. However, many questions remain about the system, including how structural rearrangements and dynamics may impact its efficiency, as well as the specificity of CAR when bound to the CNT outside its native environment. Johnson and coworkers [12] recently performed MD simulations on this nanobiosensor system to provide some molecular insights into these questions. They investigated three different types of systems in its physiological aqueous conditions CAR with a bound Knob protein, and then both systems attached to a CNT. The physiological conditions were created by adding a 100 mM concentration of Na^+ and Cl^- ions to the aqueous system comprised of TIP3P water molecules; an additional three Na^+ ions were added to also neutralize the slightly negative charge on CAR. The CNT was covalently attached to residue Asn98 on CAR through a carboxylic acid defect on the CNT surface, which replicates the experimental conditions that are done via diimide-activated amidation.

The systems were built from a crystal structure of the CAR-Knob complex from the Protein Data Bank. Since CAR is known to only undergo minor structural rearrangements upon binding Knob, this crystal structure was claimed by the authors to be sufficient for both the bound and unbound configurations, after the structural properties were equilibrated from an MD run; structural equilibrium was defined as when the root-mean-square-deviation of the C_α atoms no longer varied with time. The CNT was built the same length as the MD box, connecting terminal atoms across that box boundary, thus creating an infinite tube with the use of periodic boundary conditions.

In addition, the positions of the CNT atoms were constrained with a harmonic potential, which reduces the computational cost of the simulations with minimal effect on the results. The atomistic MD simulations were run with a 1.5 fs time step, for around 11 ns, and with the NPT ensemble at 1 atm and constant temperature of 300 K.

The use of the Amber99 force field was first validated by comparing the simulations on the systems without the CNT in the physiological aqueous environment to known experimental information, such as NMR observations of the structural and dynamical properties of CAR. For the MD simulations of the systems with the CNT present, some interesting observations were made. First, for the systems with the CNT, physisorption of the proteins onto the CNT surface was observed, which still preserved most of the structural features of the unbound CAR and unbound CAR-Knob; the most significant changes occurred in the loop regions and C-terminus since the CNT can restrict the configurational space of the bound proteins. In addition, for the CAR-Knob-CNT complex, a salt bridge and some hydrogen bonds were lost between the proteins, but not enough to impact its overall stability. Therefore, it was concluded that the CNT does not significantly perturb CAR, except for reducing the available configurational space due to confinement. These results indicate that comprised of protein receptors that rely on large conformational changes as part of their mechanisms could be significant.

MD Simulations of C60 Embedded in Potassium Channels

Potassium (K^+) channels are ion channels that span the cell membrane and are selective for K^+. They control a wide variety of cell functions that are involved in biological processes such as nerve impulses, or smooth muscle contraction. The selectivity is due to the so-called selectivity filter, which is a highly conserved sequence. K^+ channels are also targets for a variety of pore-blocking toxins that (1) bind to the extracellular pore entrance and prevent ion conduction; or (2) permeate the pore channel and disrupt binding sites within the pore. Since studies have indicated that fullerenes can cross the lipid membranes of cells, it is expected that they could also impact K^+ channels.

Kraszewski and coworkers [13] recently performed extensive MD simulations to investigate molecular aspects of how K^+ channels are impacted by the presence of the C60 buckyball. They investigated three different types of channels, specifically those comprised of the proteins KcsA, MthK, and Kv1.2 embedded into a fully hydrated DOPC lipid bilayer, which included water molecules and counter ions to neutralize the overall system charge. The total system sizes ranged from 90,300 (KcsA) to about 173,000 atoms (Kv1.2). Up to six C60 molecules were put near the pore region. As a comparison, systems were built of the C60 molecules in a water box and with a fully hydrated DOPC layer without the proteins. The atomistic MD simulations were run with the NAMD software program, using the CHARMM27 force field, where united atoms were used to represent the lipid molecules and chemical bonds between hydrogen and heavy atoms were constrained to their equilibrium values elsewhere.

The C_{60} molecules were first put near the pore on the extracellular region. The MD simulations revealed that no C_{60} molecules anchor or block the selectivity filter of the K^+ channels. In addition, for the voltage-gated K^+ channel, Kv1.2, the C_{60} molecules bound to residues within the voltage sensor domain, which triggered a large conformational movement. When the C_{60} molecules were put near the pore on the intracellular region, a different behavior was observed. Quick binding of the C_{60} molecules was observed, which resulted in conformational changes that plugged the ionic conduction pathway. Finally, when the C_{60} molecules were placed within the membrane core, the C_{60} molecules were observed to migrate laterally toward the membrane proteins, and eventually bind to interhelical domains, which can alter their function. Therefore, these simulations revealed a variety of potential molecular mechanisms for binding of C_{60} nanoparticles, depending on the structure and properties of the channel as well as the initial locations of the nanoparticles.

Interactions of Functionalized Nanoparticles with Biological Molecules

Ligand-protected nanoparticles (Fig. 1c) consists of metallic nanocrystals coated by a monolayer of thiolated molecules. The ligands control the specific properties of the nanoparticle, such as solubility, electro-optical and catalytic behavior. Such nanoparticles can be dispersed in various solvents without irreversible aggregation. Functionalized NPs are a much more challenging case for simulations and modeling than carbon NPs due to their complexity, overall size, and features at multiple length and timescales. In addition, not only are functionalized NPs composed of various organic and inorganic components, but the nanoparticle corona of functionalized ligands is also a dynamic entity by itself. However, MD simulations have been performed to elucidate details about the structure and dynamics of these complex NPs. Recent atomistic MD simulations of NPs functionalized with alkanethiol ligands provided atomistic data on the ligand shell organization and indicated that the ligand's tilt angle is affected by solvent, temperature, nanoparticle size, and the ligand tail length [1, 20].

The complexity of ligand behavior, recognition, dynamic interactions, and assembly between ligand functionalized NPs and biomolecules is not trivial to simulate and challenges the current limits of the MD simulation techniques. To date, most of the simulations that address the interactions between functionalized NP and biological molecules (proteins, ligands, and nucleic acids) have a simplified representation of the nanoparticle and a few simulations have explicit ligands represented via a united-atom approximation, which have provided insights into their biorecognition properties.

A few such studies are summarized next.

Functionalized NPs with Lipids

Properties of functionalized NPs, such as size and type of ligands, can directly control the ability of a NP to enter the cell. The properties that control the NP uptake in cells can cause cellular response and undesirable toxic effects and can also control the performance of NPs in imaging, biosensing, and drug delivery. An understanding of the processes controlling the uptake and accumulations of the NPs by the cell is important for NP design, assessment of nanoparticle toxicity, and improvement of the NP properties for use in imaging and drug delivery applications. However, the rules of uptake kinetics have not yet been determined. In order to gain a deep understanding of NP translocation through a membrane, a complete picture of the processes at the molecular level is needed, which can be delivered through MD simulations. To the best of our knowledge, only coarse-grained MD simulations of NP interactions with the membrane have been used. The advantage of the coarse-grained representation of lipids and NPs is the ability to use larger time and size scales at the expense of observing the intricate behavior of H-bonding network formation and the atomic interactions.

Lin and coworkers [14] recently performed coarse-grained MD simulations of penetration of lipid membrane by gold nanoparticles. They investigated two kinds of lipids, DPPC and DPPG, and NPs with alkyl thiol chains that can contain two different functional group, ammonium and carboxylate, using GROMACS 3.3.2 package [10]. The coarse-grained representation of NPs and lipids was compatible with the MARTINI force field [11]. The gold NP was 2.2 nm in diameter functionalized with 104 alkyl thiol ligands. The NPs were charged with 70 % cationic or anionic coverage represented by the charge on the end functional ligand group and both electronegative and electroneutral bilayers were examined. The coarse-grained force field for the NP was parameterized to represent experimental values of the radius of gyration, the diffusion coefficient, and the average carbon distance. The membrane bilayer was composed of 1,152 coarse-grained lipids in a periodic box filled with explicit water and ions. The initial placement of NPs was chosen to be 7 nm above the bilayer center. The system was carefully equilibrated for a cumulative time of 20 ns before the production run of 40 ns was performed with a 20 fs time step.

The simulations revealed that NP charge and surface change density (electrostatic interactions) control the ability of the NP to penetrate, adhere, or repel from the lipid bilayer. Interestingly, NP penetration into the lipid bilayer causes lipid

disarrangement and formation of a hydrophilic pore that can transport water molecules. The extent of membrane disruption was determined to depend on the NP charge density. Thus, the simulations indicate that control over the NP cellular uptake can be achieved through charge density of the functional groups.

Functionalized NPs with Proteins

The effect of protein interactions with various NPs and nanomaterials can shed light on their possible toxicity and aggregation behavior linked to some neurological disorders. The interface, which is composed of covalent or secondary bonding interactions between NPs and proteins, is highly complex. The properties of this interface may largely affect the protein structure and function. Only a few MD studies were devoted to study protein–NP interactions.

Simulations by Aubin-Tam and coworkers [15] were performed on nanoparticle–protein conjugates comprised of Cyt c from *Saccharomyces cerevisiae* to understand the effect of the NP ligand on protein structure. The NP was modeled as a dummy atom that is 1.5 nm in diameter with Lennard Jones parameters. A total of 21 bathophenanthroline disulfonate (BPS) ligands were uniformly distributed on its surface. The coordinates for the Cyt c protein structure was obtained from the PDB databank (PDB id 2BCN), mutated and covalently linked to the NP surface. MD simulations were performed for 8 ns at 300 and 450 K using CHARMM and param22 all-atom force-fields and the generalized Born implicit solvent. Simulations were also performed in explicit solvent to verify the results in implicit solvent.

MD simulations of Au nanoparticle/Cyt C conjugates indicated that NP labeling induces site-specific, local-to-global structural perturbations to the protein [15]. Protein conformations obtained at 300 and 450 K showed that side chains of positively charged residues interact with BPS ligands, and that perturbation of the secondary structures depends on the NP attachment site, which agrees well with the experimental observations. MD simulations of the semirigid, coarse-grained protein/nanoparticle model revealed the importance of lysine and arginine amino acids on the interactions of Cyt C and nanostructured surfaces, which suggest the design rules for peptides with enhanced surface adsorption [21, 22]. Thus, MD simulations can be successfully employed for identifying mechanisms responsible for fine tuning of the biorecognition properties of the nanocomplex, and more detailed investigations are needed in this area.

Functionalized NPs with Nucleic Acids

MD studies have been successful at corroborating and elucidating experimental findings, or exploring fundamental aspects of DNA dynamics and structure [23]. For example, MD simulations were applied to a 12-base-pair DNA duplex tethered on a neutral silica surface to assess its structural and orientation changes [24]. MD simulations were used to study the conformation of seven DNA strands attached to the (111) gold surface via a six-carbon alkylthiolate linker [25]. These simulations indicated that while the overall structure is disordered, both base stacking and non-Watson-Crick base pairing can be formed between short single-stranded regions of adjacent DNAs. Moreover, the separation distance between DNAs is similar to one calculated by theory and estimated from experiments.

MD simulations of a 2-nm gold nanoparticle functionalized with four single-stranded DNA molecules were used to determine the structure and dynamics of DNA thiolates on a gold surface [16]. The 10-mer of ssDNA polythymines and poly adenines were symmetrically distributed on four (111) gold surfaces of an NP. The interactions between gold atoms were represented by Lennard Jones parameters, and the CHARMM force field was used for the ssDNAs. The resultant DNA-functionalized NP structure was placed in a box with water and 0.5 M NaCl. After equilibration, the NVT Langevin production simulations were carried out using NAMD at 300 K for 8 ns. The results indicated that base–base stacking is better for poly adenines than for poly thymines and the effective radius of DNA-NPs agrees well with experiment. Thus, the MD simulations provided an insight onto the dynamics of DNA strands on the gold NP surface.

In addition, atomistic MD was used to study the behavior of the DNA strands during the assembly of layer-by-layer DNA capsules, which produced a prediction of the optimal length for the NP assembly [26]. Thus, MD simulations were able to provide important information on the behavior of DNA strands on the surface of the NPs; however, the DNA-driven assembly is outside of the reach for atomistic MD simulations. A recent coarse-grained model [27] of DNA-driven NP assembly indicated the possibility to explain the DNA-induced crystallization of NPs and established a general phase diagram.

Summary and Future Directions

The future development of many biomedical devices and the optimization of current systems are dependent on the fundamental knowledge of properties of the interface between NPs and biomolecules. MD simulations are capable of producing such fundamental knowledge, but on limited time and length scales. While the interactions of carbon-nanostructures are significantly explored by MD simulation techniques, the use of MD simulations for other systems such as colloidal gold and magnetic and inorganic nanoparticles is not covered as much. With the increase in computational power and improvements of algorithms, as well as the development of new hardware systems such as GPU systems, it is expected that more MD simulations will be used for detailed studies of interactions between biomolecules and NPs.

Further work is needed on the understanding of interactions between nanomaterials and biomolecules, such as on the surface of inorganic and organic nanoparticles and nanofilms. The investigations at the atomistic and molecular levels will provide information on collective biomolecular behavior and change in properties and will ultimately enable access to new and valuable future applications.

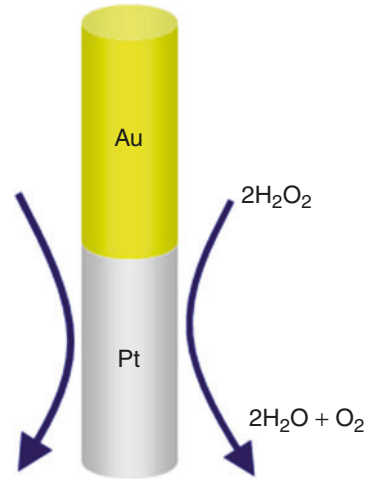
Definition

Molecular motors are nanoscale objects capable of converting a certain energy source (chemical energy, photons, etc.) to mechanical work.

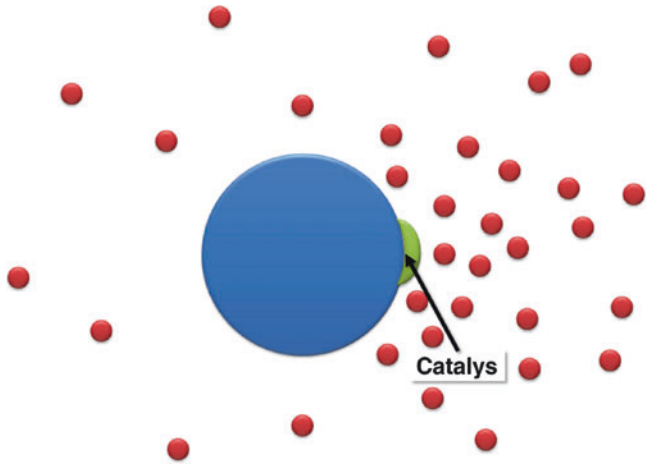


Background

One universal driving force for nanotechnology is miniaturization. The realization of nanometer scaled machineries needs nanometer scaled motors to provide mechanical power for nanofluidic and nanorobotic devices. Another underlying theme for nanotechnology is biomimetic. The fascinating biological world, as optimized by billions of years of evolution, provides answers of science and engineering challenges. In this regard, biomolecular motors play important roles in almost all important physiological processes in a cell, including transportation, actuation, nanostructure assembly, and disassembly. All the aforementioned functionalities are performed at the nanometer scale, thus molecular motors are important enablers in nanotechnologies inspired by biology.

Molecular motors can be classified as active nanostructures (capable of energy conversion or structural transformation upon a local stimuli), as opposed to passive nanostructures (usually operate within a bulk and are not designed to function upon local stimuli). According to Roco's classification, molecular motors belong to the second generation of nanotechnology applications and will play an important role in the third generation (nanosystems) [1].

Survey of Experiments



Artificial molecular motors have been fabricated with supramolecules [2], metal nanocrystal, [3] or magnetic colloidal chains [4]. The operation of these motors is mostly powered by an external agitation such as light, an electric/magnetic field, or oscillating chemical concentration. Therefore, unlike biomolecular motors, the motions of the above artificial motors are not strictly autonomous. Recently, it has been shown that catalytic bimetallic nanorods (illustrated in Fig. 1) exhibit interesting self-propelled motion in hydrogen peroxide solutions [5, 6]. Interestingly, these nanorods have comparable size, speed, and energy source (catalytic chemical reactions) to bacteria.

Molecular Modeling on Artificial Molecular Motors, Fig. 1 Illustration of a bimetallic nanorod which relies on decomposition of hydrogen peroxide

Various propulsion mechanisms have been proposed, including bubble recoil [5], interfacial tension [6], self-electrophoresis [7], and self-diffusiophoresis [8]. The driving force for different molecular motors is thought to be system-dependent, and multiple propulsion mechanisms might operate at the same time. For instance, self-electrophoresis seems to be responsible for propulsion in bimetallic nanorod systems, while self-diffusiophoresis is likely to play an important role for systems without electrochemical reactions. An apparent universal feature is to achieve asymmetric reactions by placing the catalysts on one side of the motor or partially blocking the release routes of the products.

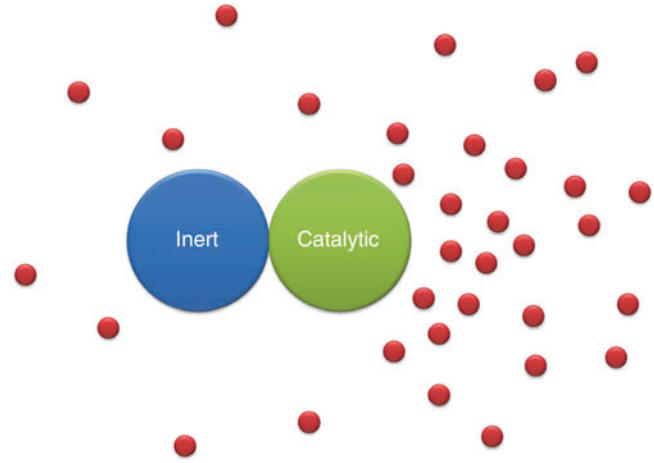
The smallest dimension of the catalytic molecular motors investigated in the above studies is about one third of a micron. This is largely due to the technical difficulty in discerning directional motion for objects at submicron sizes [9]. Therefore, it is unclear whether this type of catalytic system can operate when being scaled down to the tens of nanometers (or less) scale. In addition, the thermodynamic efficiency of catalytic molecular motors has not been directly measured. By considering the viscous drag force instead of coupling external loads, Paxton et al. [10] estimated the efficiency of bimetallic nanorods to be on the order of 10^{-9}. The fact that multiple (sometimes

Molecular Modeling on Artificial Molecular Motors, Fig. 2 Illustration of asymmetric product distribution caused by the catalytic patch

competing) propulsion mechanisms operate simultaneously makes it difficult to rationally optimize these nanomotors.

Roles of Simulations

Molecular-level simulations are ideal tool to gain mechanistic details in complex systems, such as the energy conversion process in a molecular motor. In the spirit of taking simulations as "controlled numerical experiments," the goal of molecular simulation is to simplify, instead of reproduce the exact experimental condition, so as to distil the precise mechanism at work. Specific objectives include enhancing the overall energy conversion efficiency and exploring the feasibility of molecular motors that are at least one to two orders of magnitude smaller than current experimental motors. On what follows, three main simulation approaches to model artificial molecular motors based on asymmetric chemistry are described.



Constitutive Simulation Approach

The first modeling strategy stems from existing treatment of interfacial forces at the continuum level. Although not strictly at the molecular level, this method considers molecular-level events such as reaction and diffusion. Generally, the initial step is to solve the diffusion–reaction equation written below, subjected to the proper boundary conditions such as the motor dimension, catalytic site locations.

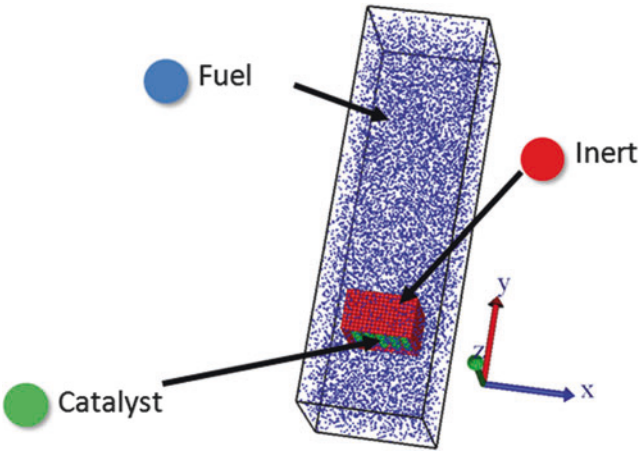
$$\partial_t \rho\left(\vec{r},t\right) - D\nabla^2\rho\left(\vec{r},t\right) = \frac{dN_p(t)}{dt}\delta^3\left(\vec{r}-\vec{r}_s\right) \quad (1)$$

ρ is the density of the products, D is the diffusivity, and $\frac{dN_p(t)}{dt}$ is the catalytic reaction rate at site $\vec{r}_s$. As illustrated in Fig. 2, a concentration gradient is established due to the chemical reactions localized near the catalytic site. Thus, products diffuse from high concentration region to low concentration region. Moreover, solvent flow can also occur driven by osmotic forces. Both processes can deform the interfacial layer between the motor–fluid interface and lead to motion of the motor itself.

From the interfacial theory [11], the drift velocity of the motor is proportional to first momentum of the product concentration distribution. In other words, if the product distribution is symmetric, the drift velocity of the motor is zero, and vice versa. As the catalytic site is decorated on the motor, a concentration gradient will be quickly established even though the motor is moving around. Thus, the molecular motor is self-propelled without any external intervention.

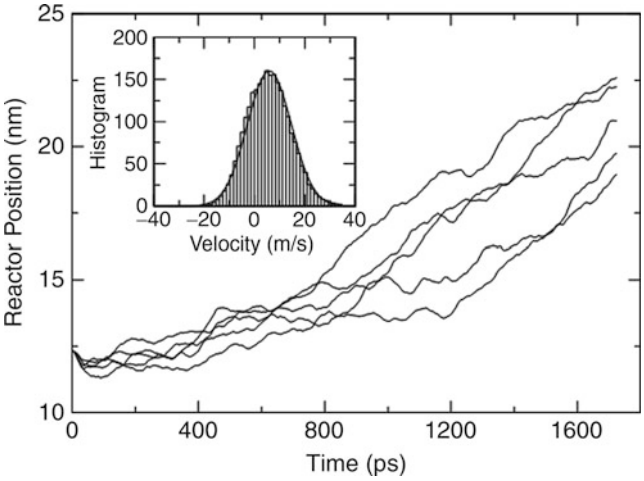
Molecular Modeling on Artificial Molecular Motors, Fig. 3 Illustration of a nanodimer consisting of an inert particle and a catalytic particle

Monte Carlo Simulation Approach



The second approach to treat catalytic chemical reaction is through Monte Carlo (MC) operations, which can be coupled to molecular dynamics (MD) simulations [12]. As illustrated in Fig. 3, a nanodimer consists of a catalytic sphere and a noncatalytic sphere. A collision between the reactant particle and the catalytic sphere will trigger a Monte Carlo operation that will convert it to a product particle at a probability determined by reaction kinetics and temperature. However, neither a collision between the product particle with the catalytic sphere nor collisions between any particles with the noncatalytic spheres will lead to chemical reaction. Thus, the irreversible catalytic chemical reaction can be accomplished.

This method has been used in conjunction with multiparticle collision (MPC) to study the self-motile behavior of nanodimers. MPC is a mesoscopic particle-based simulation method, which is capable of capturing the essential features of MD simulations. As shown in Fig. 3, the product concentration is again distributed asymmetrically around the nanodimer which is a result of the catalytic chemical reaction. By controlling the interparticle interaction, dimer separation, and temperature, the directed motion of the nanodimer can be controlled. The orientational relaxation time for this simulated nanodimer is very long so that the directed motion of the nanodimer is not overwhelmed by the random Brownian motion.



The main disadvantages of this method are the crude representation of chemistry. Particularly, the exothermicity of the chemical reaction is not described in this approach. Moreover, chemical reaction is only possible at the catalytic site. Thus noncatalytic chemical reactions, which are nonetheless present, are not described here.

Reactive Molecular Dynamics Simulation Approach

The third approach is to utilize reactive molecular dynamics simulations to describe the full dynamics of molecular motors. The most important component of this approach is a reactive force field to describe catalytic chemical reaction. Many reactive force fields (REBO [13], ReaxFF [14], etc.) based on the chemistry of bonding have been used to successfully describe hydrocarbon systems, among other systems. However, little work has been done to model catalytic reactions, for instance, the decomposition of hydrogen peroxide with platinum as catalysts. An alternative approach is the recently proposed reactive state summation (RSS) scheme, which does not aim for accuracy but for efficiency and tunability [15]. RSS scheme has been used to describe phase transformations in silica and boron oxide, detonation of nitrogen cubane, growth of nanoporous carbon, and catalytic chemistry in a model fuel-catalyst system [16].

Molecular Modeling on Artificial Molecular Motors, Fig. 4 Illustration of a molecular motor asymmetrically decorated with catalyst

Molecular Modeling on Artificial Molecular Motors, Fig. 5 Displacement of the molecular motor simulated by reactive molecular dynamics. The inset shows the instantaneous velocity distribution which is a shifted Gaussian curve (Adapted from reference [16])

A chemical reaction is accomplished by a transition from one reactive state to another. The reactive state can be characterized conveniently by partial coordination. For instance, oxygen next to just another oxygen is in diatomic oxygen, while oxygen next to just two hydrogen is in a water molecule. The essence of the RSS scheme is to use nonreactive two-body force field to describe individual reactive states, which will be switched on or off by the partial coordination numbers. This switching function can be written as:

$$W_i\left(CN_j\right) = e^{-A_i \sum_{j=1}^{N} \left(CN_j - \overline{CN_j}\right)^2} \qquad (2)$$

Weight function W_i is designed for reactive state i, which is characterized by partial coordination. $\overline{CN_j}$. CN_j is the current partial coordination which can be another reactive state or a transition state in-between. W_i approaches unity if the current reactive state matches reactive state i, while diminishes to zero if it is far away. Thus, the total potential energy of the system can be written as a combination of all nonreactive pair interactions weighted by the above switching function:

$$PE = \sum_{p<q} \sum_{i} W_i\left(CN_j\right) \cdot E\left(r_{p,q}\right) \qquad (3)$$

The first summation loops over all pairs of atoms, while the second summation sums up all reactive state.

Figure 4 shows the model molecular motor inside a fuel environment. This motion can be characterized by a dominant Brownian motion plus a directional motion due to chemical propulsion (Fig. 5). Furthermore, an external force can be coupled to the molecular motor. It was shown that the maximum thermodynamic efficiency of this molecular motor is on the order of 0.0002, which is significantly higher than the experimental bimetallic nanorods [10].

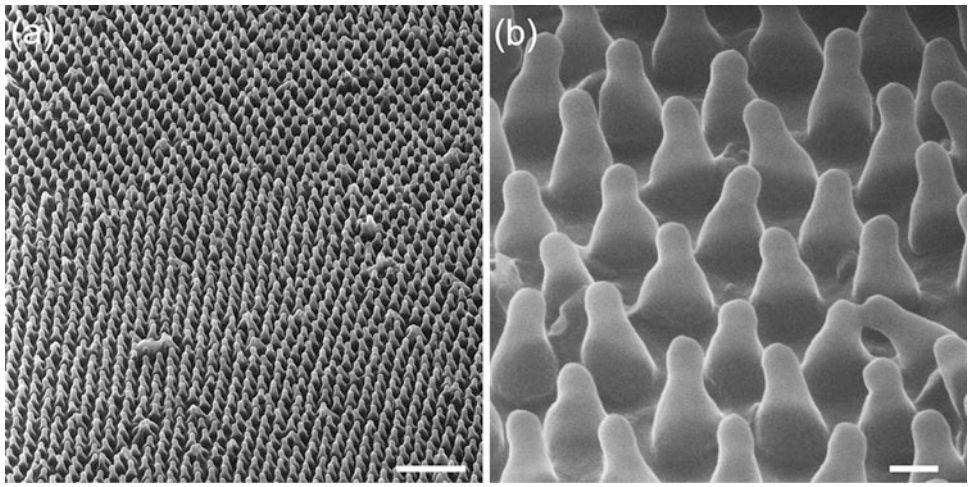
Definition

Moth-eye antireflective (AR) structures are arrays of protuberances, with dimensions smaller than the wavelength of the light incident upon them. They form a region of graded refractive index at the interface between two media, substantially reducing the amount of light reflected by the interface.



Such protuberance arrays are found on the eyes of some species of moth, butterfly, and fly, where the reduction in reflectance is thought to increase visual system sensitivity, and on transparent sections of insect wing where they have a camouflaging effect. Biomimetic, artificial moth-eye AR structures have been fabricated on a range of materials such as polymers, glass, silicon, and GaAs for applications including photovoltaics and display technologies.

Natural Moth-Eye Structures

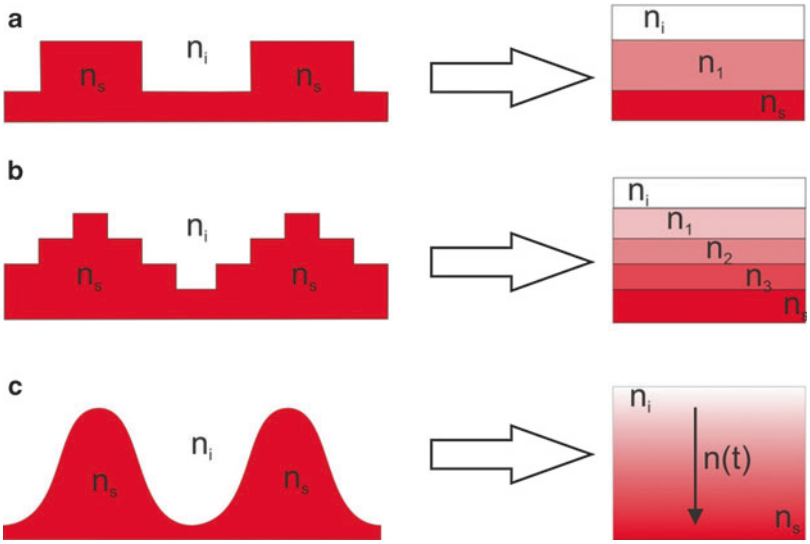
From a nanotechnology viewpoint, moth-eye antireflective structures generally refer to artificial structures fabricated to increase the amount of light coupled through the surfaces of optical devices. However, the term originates from the natural world where such structured arrays were first discovered on the corneal surfaces of some species of moth and termed "corneal nipple arrays" [1]. Since then, nipple arrays have also been found on transparent wings of moths and the corneal surfaces of butterflies [2, 3]. Similar antireflective structures have also been identified on the eyes of some species of fly and mosquito [4, 5]. Natural moth-eye structures consist of arrays of protuberances with heights up to 250 nm and spacings of 200–250 nm arranged in domains where, within each domain, the features are arranged in a highly ordered hexagonal array (Fig. 1). The structures reduce the reflectance of the lens surface on which they are formed from approximately 4 % to less than 1 % [3].

Development of nipple arrays on the corneal surfaces of moths for antireflection is thought to serve two purposes:

1. The reduction in reflection is accompanied by an increase in transmission of light into the eye, enhancing the sensitivity of the visual system of the moth.
2. Reflection of sunlight from the eyes could expose the location of the moth to passing

Moth-Eye Antireflective Structures, Fig. 1 Scanning helium ion microscope images of natural moth-eye structures found on the transparent wing of *Cephonodes hylas* (scale bars: (**a**) 1 μm and (**b**) 100 nm)

predators. By reducing the reflectance of light, the moth-eye structures reduce the visibility of the moth, making it less vulnerable to predation.



For nipple arrays found on winged surfaces, only the camouflage hypothesis applies. Some species of moth, for example, *Cryptotympana aquila* and *Cephonodes hylas* (Fig. 1), employ nipple arrays on both dorsal and ventral surfaces of transparent sections of the wing, increasing optical transmission to above 90 % over a broadband of wavelengths, with a peak of ~98 % [6], making the creature practically invisible to any passing predators. The protuberance arrays have also been shown to confer superhydrophobicity to a surface, which leads to antifogging, anti-adhesive, and self-cleaning properties, exhibited by a range of species [5, 7].

Inspired by the effectiveness of natural moth-eye structures for reducing surface reflection, researchers have created biomimetic, artificial moth-eye structures in technologically important materials such as silicon and glass, in attempts to lower the amount of light reflected at the surfaces of these materials to a greater extent than is possible with traditional thin-film antireflection coatings (ARCs).

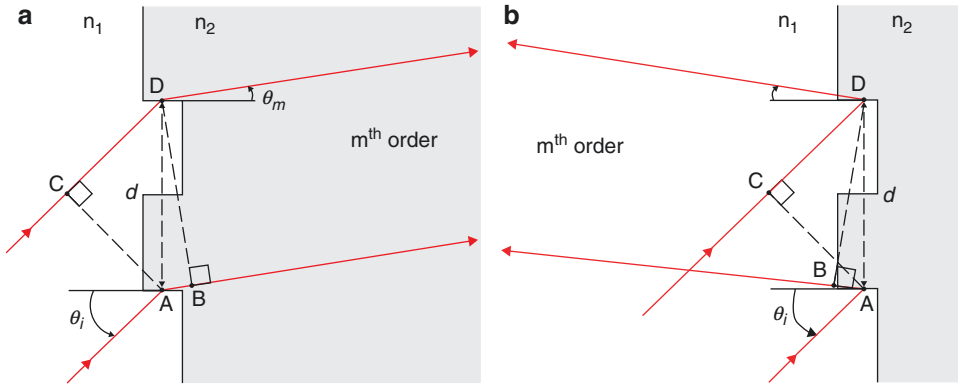
Optical Mechanism

The mechanism through which moth-eye structures reduce reflection relies on their dimensions being less than the wavelength range of incident light. A large proportion of the solar spectrum lies within the visible range (0.4–0.7 μm). When light interacts with structures of dimensions much below this range, it behaves as if it were encountering a homogeneous medium whose optical properties are a weighted spatial average of the profile's optical properties. If the subwavelength features are regular in size and arrangement, the array is known as a zero-order diffraction grating because all the higher orders are evanescent and only the zero-order propagates. Consequently, a surface textured with ridges smaller than the wavelength of light will interact with the light as if it had a single-layer ARC of refractive index governed by the ratio between the ridges and channels (Fig. 2a). Likewise, a stepped profile will act as a multilayer ARC (Fig. 2b), and a tapered profile will behave as an infinite stack of infinitesimally thin layers, introducing a gradual change in refractive index from one medium to the other (Fig. 2c).

The moth-eye array effectively acts as an impedance-matching device smoothing the transition between one medium and another, ensuring

Moth-Eye Antireflective Structures,
Fig. 2 Subwavelength structures and their analogous refractive index profiles, as experienced by incident light: (**a**) ridged profile, (**b**) stepped profile, and (**c**) tapered profile (Adapted from Ref. [8])

that incident light does not encounter a sudden change in refractive index which would cause a proportion to be reflected. Another way to understand this is to imagine that the subwavelength-structured surface is a stack of thin layers, and so the destructive interference between reflections from each layer cancels out all reflected light, maximizing the proportion of light transmitted.



Theoretical Work

The qualitative description given above of the graded refractive index mechanism through which moth-eye structures reduce reflection from a surface suggests that such structures can be modeled by replacing the subwavelength-structured interface region with a stack of many layers, each with an effective refractive index in between those of the media either side of the interface. This is the basis of an approach known as effective medium theory (EMT) or homogenization [9]. The effective refractive index depends on the relative amounts of each medium in each layer which is determined from the profile of the graded index region. Studies of how the reflectance varies with the height-to-wavelength ratio show that if the graded index region is thicker than approximately half the wavelength, reflectance is reduced to below 0.5 % [10]. One way to proceed with this is to establish an optimum refractive index profile of a graded index ARC for minimum reflection over the broadest bandwidth. In one such optimization, this was demonstrated to be a quintic function for all coatings with thicknesses, t, greater than approximately half the wavelength of incident light [11]:

$$n = n_i + (n_s - n_i)\left(10t^3 - 15t^4 + 6t^5\right) \qquad (1)$$

where n_i is the refractive index of the incident medium and n_s is that of the substrate. EMT was then applied to determine the profile of features needed to produce this ideal gradient in various materials.

For EMT to apply however, the features at the interface must be sufficiently small so that they cannot be resolved by the incident light. In other words, the features should not be large enough to scatter light appreciably, either incoherently, as with randomly arranged features, or coherently, as with regular arrays of features such as those found on moth-eye surfaces. To analyze coherent scattering from a 2D moth-eye type array, it is useful to treat it as a diffraction grating with a period small enough so that all diffraction orders other than the zeroth are suppressed. To determine how small the period, d, must be for a zero-order grating, the well-known grating equation for an arbitrary angle of incidence can be used. This is

Moth-Eye Antireflective Structures, Fig. 3 Diagrams for the derivation of the arbitrary-angle grating equation describing diffraction from a grating at the interface between two media of refractive indices n_1 and n_2 (**a**) in transmission and (**b**) in reflection

derived by equating the path-length difference of two rays incident on adjacent features with an integer number of wavelengths so that they constructively interfere. In transmission, this is given by (see Fig. 3a)

$$n_2 AB - n_1 CD = m\lambda \tag{2}$$

$$n_2 \sin\theta_m - n_1 \sin\theta_i = \frac{m\lambda}{d} \tag{3}$$

where m is the order number (an integer), λ is the wavelength, θ_i is the angle of incidence, and θ_m is the outgoing propagation angle for order m. In reflection (Fig. 3b), light is only traveling in one medium so the grating equation becomes

$$\sin\theta_m - \sin\theta_i = \frac{m\lambda}{n_1 d} \tag{4}$$

If the incident medium is air, then $n_1 = 1$. As d is decreased, θ_m increases, with diffraction orders becoming evanescent when $\theta_m = 90°$ for the last remaining order. For all values of d below this, only the zero-order propagates. At normal incidence, $\theta_i = 0°$, and the last order to disappear is the first order, $m = 1$ (or $m = -1$). The zero-order grating condition is then given (for the transmission grating) by

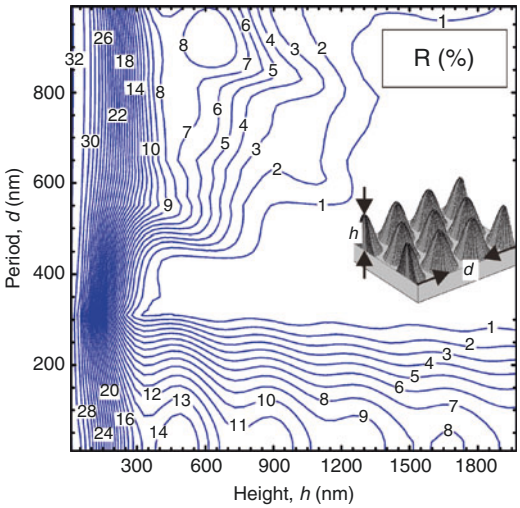
$$d < \frac{\lambda}{n_2} \tag{5}$$

and for the reflection case, it is given by

$$d < \lambda \tag{6}$$

For oblique incidence, if the angle of incidence is positive, the -1 order may still propagate even when d is sufficiently small to suppress the $+1$ order. Therefore, d has to be decreased further to suppress the -1 order. So for non-normal incidence, the zero-order grating condition for reflected orders becomes

$$d < \frac{\lambda}{2} \tag{7}$$

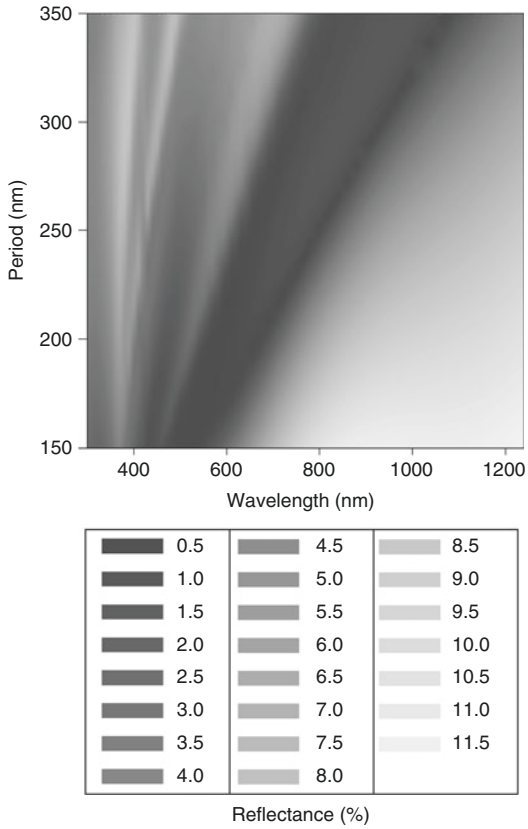


To also suppress *transmitted* orders other than the zeroth, the condition to be satisfied is

$$d < \frac{\lambda}{n_2 + 1} \tag{8}$$

When working in the infrared region, it is relatively easy to fabricate sufficiently small features to satisfy these conditions and produce antireflective, zero-order gratings which can be analyzed using EMT [12]. Fabricating a zero-order grating with $d << \lambda$ to operate in the visible range however is more difficult, and so subwavelength AR schemes for visible wavelength applications tend to have periods closer to the operating wavelengths. EMT breaks down

as the resonance regime is approached (i.e., as $d \rightarrow \lambda$). This, coupled with the increase in computational power available to researchers, led to the rise in popularity of rigorous methods of modeling such structures. Finite-difference time-domain (FDTD) and finite element methods (FEM) have been used, but the most commonly employed modeling method for moth-eye structures is known as rigorous coupled-wave analysis (RCWA) [13]. Developed in the early 1980s, RCWA is a differential-based method to calculate the efficiencies of orders in diffraction gratings. Differential solutions to Maxwell's equations applied to diffraction gratings involve expressing the field in the grating region due to the periodicity present as a Fourier series representation, from which a set of differential equations are developed. RCWA uses an eigenvalue numerical technique to solve these for rectangular grooves. More complicated profiles can be analyzed using a staircase approximation, representing the shape as a series of blocks. By defining the period to be less than the wavelength and representing the feature profile with a staircase approximation, RCWA can be used to model regular subwavelength arrays such as moth-eye structures.



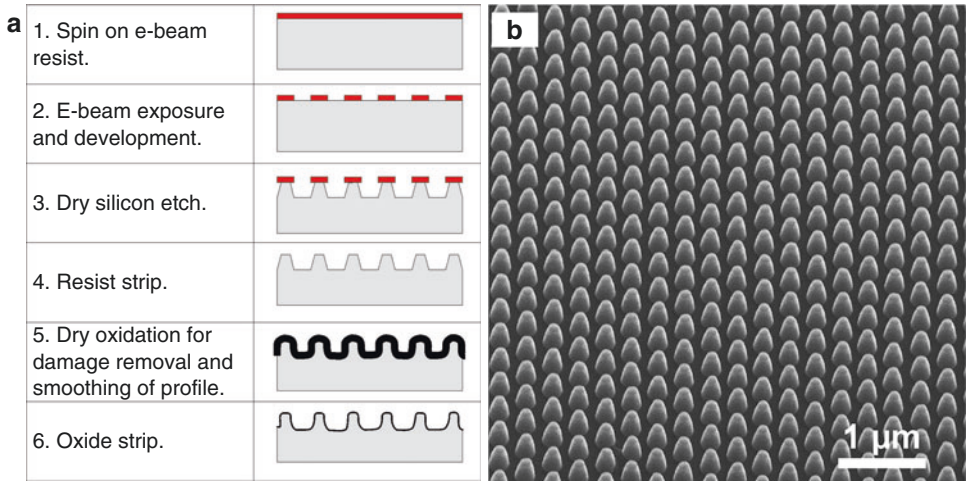
RCWA is widely used to model artificial subwavelength AR structures with good agreement between theory and experiment [14]. The successful experimental verification of RCWA simulation results has meant that the technique can be used to explore the parameter space for artificial moth-eye structure design. It has been shown that pillar height, period (spacing), and shape are all key factors for the AR performance of the moth-eye structure. Parameter maps can be generated of array period versus height or aspect ratio for a single wavelength (Fig. 4) [15, 16]. This type of analysis reveals that for small periods ($d << \lambda$), the structures behave collectively as an effective medium creating a refractive index gradient: Increasing the height in this region initially leads to a sharp drop in reflectance which then remains low but with low-amplitude interference fringes due to discontinuities at the boundaries of the structure, as predicted by EMT. For periods approaching the wavelength, more complicated resonance behavior is observed. Between

Moth-Eye Antireflective Structures, Fig. 4 Parameter map from RCWA simulations of a silicon moth-eye structure showing reflectance (R) versus height and period at a wavelength of 1000 nm [15]

these two regimes exists a low reflectance band at relatively modest feature heights, representing a "sweet spot" for artificial moth-eye designs. In general, for all periods, increasing the height decreases the reflectance, but this comes at the expense of difficulties in the experimental realization of high aspect ratio features. It is a case of diminishing returns for feature heights above approximately half of the wavelength which explains why natural examples of AR nipple arrays generally have heights <250 nm. Although AR with moth-eye structures is a broadband effect, there are local maxima and minima in the reflectance spectra of such arrays, and the position of these can be tuned by varying the period of the array (Fig. 5). In addition, RCWA simulations of moth-eye arrays with different feature profiles indicate that the biomimetic, smoothly tapered design is closer to optimum than arrays comprising sharper or flat-topped features.

Efforts have been made to use RCWA to optimize the design of moth-eye arrays for specific applications, for example, AR for solar cells. One such study showed that a biomimetic moth-eye structure fabricated on a monocrystalline silicon solar cell with a period of 312 nm would be optimal for reducing reflection of the AM 1.5

Moth-Eye Antireflective Structures, Fig. 5 Contour plot, generated by RCWA simulations, of reflectance spectra as the period of the silicon moth-eye array is varied for a feature height of 400 nm [17]



solar spectrum at the silicon-EVA interface (EVA is a typical solar cell encapsulant material) [17]. Calculations on the proposed structure predicted a daily average short-circuit current that was only 0.6 % less than that of a cell with an ideal AR surface (0 % reflectance). This represents around a 3 % improvement over the best double-layer thin-film antireflective coating and demonstrates the potential of moth-eye AR structures for solar cell applications.

Practical Realization

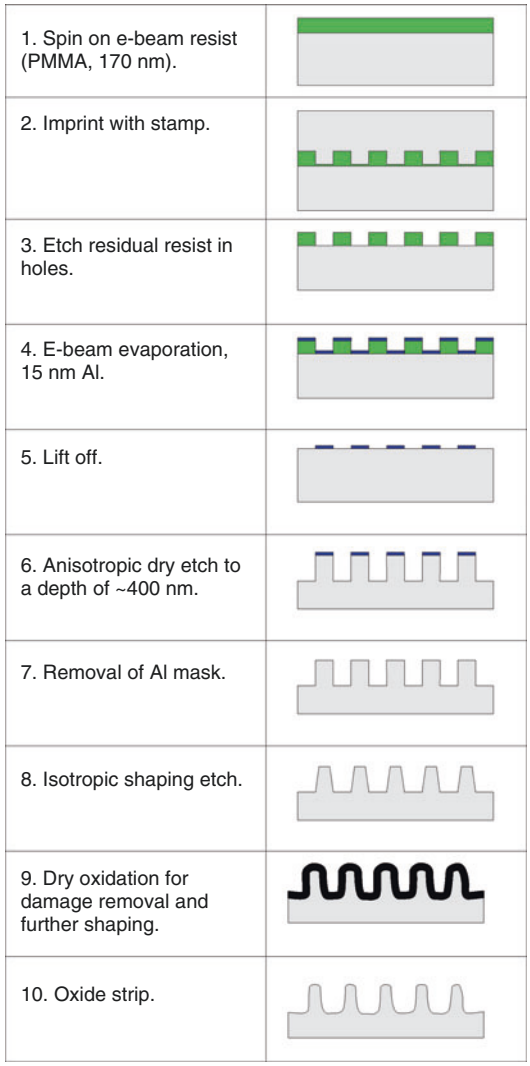
The effectiveness of nature's solution to unwanted reflection in the form of moth-eye structures led to efforts to reproduce such structures for technological applications. As described previously, moth-eye structures designed for visible wavelengths have spacings on the scale of several 100 nm, too small for a suitable mask to be fabricated using standard photolithography techniques. A range of other nanoscale fabrication techniques have been employed to create artificial moth-eye AR structures in a variety of materials. In general, this involves using electron-beam lithography or interference lithography to define a pattern in a polymer film on top of a hard substrate. Etching is then performed to transfer the pattern into the hard substrate. This could be the device itself or could be used as a master to form moth-eye structures in a polymer film by nanoimprinting. Polymer moth-eye structures are often used as an AR surface for glass by careful choice of the polymer so its refractive index matches closely with that of the substrate. However, for other materials such as silicon and GaAs, the lack of polymers with a sufficiently high refractive index means that a further etching step is required to transfer the structure into the underlying substrate to form an effective AR surface.

Electron-Beam Lithography

Although the wavelength of light prevents standard photolithography from being used to form moth-eye arrays for visible operation, sub-100 nm patterning with electron-beam systems is routine. A focused beam of electrons is scanned over a layer of polymeric resist in the pattern required. The resist is developed, leaving behind the exposed resist in the form of arrays of dots. Dry etching is then used to transfer the pattern into the underlying substrate (see Fig. 6). Etch resistance of polymers is relatively low; therefore, in order to achieve sufficient feature height, e-beam sensitive flowable oxides are sometimes used or an intermediate oxide or metal mask is employed. In the latter case, this can be deposited on the substrate before resist spinning and then etched through the resist mask, or alternatively a negative pattern can be formed in the resist and used in a subsequent lift-off procedure to leave a metal mask of the required pattern. Etch chemistries are chosen for the particular material needing to be structured,

Moth-Eye Antireflective Structures, Fig. 6 (**a**) Schematic of silicon moth-eye fabrication process using electron-beam lithography and dry etching and (**b**) scanning helium ion micrograph of silicon moth-eye structure fabricated using electron-beam lithography and dry etching

with a level of anisotropy and selectivity often required in order to achieve sufficient feature height. For patterning silicon, SF_6, HBr, and Cl_2/BCl_2 are often used, followed by an isotropic etch or an oxidation and oxide strip to further shape the features into the required moth-eye profile. In other examples, CHF_3 and $C_4F_8/CH_2/O_2$ mixtures have been used for silica moth-eye structures and $SiCl_4/Cl_2$ for GaAs.



Electron-beam lithography allows precise control over feature size, spacing, and arrangement, but the electron beam has to trace out each individual feature in series. This, combined with the required density of the patterns, means that it is a time-consuming and so expensive fabrication method. Patterning times vary considerably with pattern density and resist sensitivity but are of the order of 1 mm^2 per hour, making this technique unsuitable for commercial, large area moth-eye fabrication.

Interference/Holographic Lithography

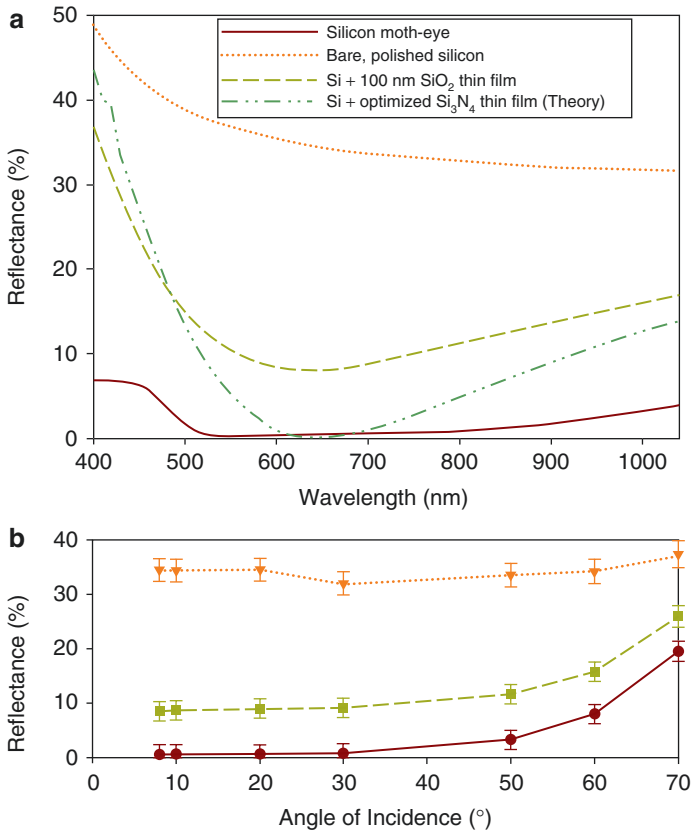
The interference pattern formed between two or more laser beams consists of a periodic series of fringes with a spacing less than the wavelength of the laser and so at a scale suitable for moth-eye array fabrication [18]. This interference pattern can be used to expose a layer of photoresist deposited on the surface of a material which is then developed leaving a mask for a subsequent dry etch process. Systems employing a combination of three or four beams can be used to create the two-dimensional patterns required for moth-eye fabrication, but more often, a simpler arrangement of multiple exposures with two beams is used with sample rotation between exposures. Heat treatments can be used between photoresist development and etching to reflow the resist and improve the uniformity and symmetry of the pattern. Careful control of exposure dose and development time is necessary to produce patterns sufficiently dense to form effective AR structures [19]. Interference lithography is a fast and relatively cheap method of fabricating subwavelength structures over large areas and has been successfully implemented to form artificial moth-eye arrays in a range of materials including polymers, glass, silicon, and GaAs.

Nanoimprinting/Nanoimprint Lithography

A more scalable nanopatterning technique for moth-eye structure fabrication has emerged in recent years in the form of nanoimprint technologies [8]. A stamp, fabricated by conventional nanopatterning techniques (e-beam or interference lithography), is pressed into a polymer film

Moth-Eye Antireflective Structures, Fig. 7 Schematic of silicon moth-eye fabrication process using nanoimprint lithography [8]

on a heated substrate. After cooling, the stamp is removed, leaving an imprint of the stamp in the polymer film. For patterning of hard materials, a dry etch can then be performed, using the imprinted polymer film as an etch mask, to transfer the pattern into the substrate. Alternatively, metal is deposited and the imprinted polymer film is used as a lift-off mask, leaving a metal etch mask (Fig. 7). A related technique known as step-and-flash imprint lithography involves the use of a transparent stamp through which UV light is directed to cure the polymer before the stamp is released. The stamp can be reused many times; a protective anti-stiction layer is applied to ensure the easy release of the stamp from the polymer and to reduce wear of the stamp. The scalability of the technique is further enhanced when flexible stamps are used. For example, moth-eye structure fabrication over the entire surface of a silicon wafer has been achieved using nanoimprint lithography with a soft roller-type stamp, followed by a dry etch [20]. With the development of large-scale roll-to-roll processes, this technique has the potential to provide commercially viable moth-eye structures covering large areas required for, for example, solar cells.



Nanosphere Lithography

An example of a bottom-up, self-assembly approach to artificial moth-eye structure fabrication on the wafer scale involves the formation of a mask with submicron-sized silica spheres deposited from a colloidal suspension. In one example, 360 nm diameter silica spheres dispersed in a polymer were spin coated onto a 4 in. wafer. The polymer was etched away leaving an ordered array of spheres which could then be employed as a mask for an SF_6 etch to form moth-eye structures in the underlying silicon substrate [21]. A similar technique has been used to create moth-eye structures in GaSb, an important material for thermophotovoltaic applications.

Other techniques have been developed that employ the same graded index AR mechanism of moth-eye arrays but with less regular subwavelength structure (and so are not strictly artificial moth eyes). These include the various AR coatings made through sol–gel processes [22], nanophase-separated polymer films [23], and acid etching to obtain nanoscale texturing of a surface [24]. These techniques, which are more accurately described as bio-inspired rather than biomimetic, potentially offer cheaper routes to highly effective AR on a range of materials.

Applications

Applications for moth-eye structures exist wherever suppression of reflection is desired. The

Moth-Eye Antireflective Structures,
Fig. 8 Reflectance versus (**a**) wavelength and (**b**) angle of incidence from measurements on moth-eye structures formed in silicon, compared to bare silicon and thin-film ARCs [26]

broadband and wide-angle nature of their AR properties make moth-eye structures superior to more traditional thin-film AR schemes (Fig. 8). Such applications include reducing reflection from the top surfaces of photovoltaic and thermal solar cells, window panes, lenses, instrument panels, and displays [2, 25]. Moth-eye structures have also been applied to improve the light extraction in light-emitting diodes (LEDs) by reducing the number of photons trapped in the device due to total internal reflection [25]. Thin-film coatings can suffer from cracking and delamination, especially when used in applications involving large changes in temperature because thermal expansion coefficients of the film and substrate may differ. Moth-eye arrays can be formed in the substrate material itself and so do not suffer from these problems, making them particularly suitable for applications involving high light intensities and large thermal ranges such as in laser devices.

The main drawback with the technology is the requirement of dense arrays of submicron scale features, often over large areas, but these issues are being successfully tackled with the development of scalable fabrication techniques such as nanoimprint and interference lithography. There is also concern over the robustness of moth-eye structures and whether they can withstand harsh outdoor conditions. Self-cleaning through the natural superhydrophobicity exhibited by the structures helps reduce contamination buildup, but susceptibility to damage by abrasion remains an issue. The mechanical properties of the substrate material into which the moth-eye structures are formed are therefore important factors in the design of artificial moth eyes for practical purposes. Furthermore, moth-eye arrays may be more suited to application on inner surfaces or at the interfaces between two solids rather than on outer, exposed surfaces.

Most commercial applications of moth-eye structures to date involve the reduction of reflection from a glass or polymer surface because in these cases, an etch step is avoided and interference lithography or nanoimprinting can replicate the design into a soft plastic layer. Molds made by electron-beam or interference lithography for nanoimprinting of moth-eye structures into polymers on the scale of tens of centimeters are available commercially. Nanoimprinting can be used to produce moth-eye AR polymer films that can be applied to displays for mobile telephones, PDAs, e-readers, SatNav devices, etc., and to glass covers of solar cells. By reducing internal reflection, the structures can enhance the perceived brightness of LED/LCD screens and so reduce their power consumption. A combination of moth-eye structures to reduce reflection and larger-scale texturing to reduce the proportion of specularly reflected light creates surfaces with antiglare properties, in addition to low reflectances, for display applications.

The application of moth-eye structures in hard materials (except for when used as a nanoimprint stamp/mold) has seen more limited success, mainly due to the extra cost of etching required to transfer the pattern into the underlying substrate. The main application for moth eyes in semiconductors would be for solar cells, but the cost requirements of patterning large areas with regular arrays of subwavelength scale features mean that thin-film coatings are often used instead. The main trend in this area is a move away from regular, biomimetic arrays and toward more random subwavelength texturing using cheaper, mask less techniques [22–24], which, although employing the same graded index mechanism, no longer resemble the structures found in nature and therefore cannot be classified as artificial moth eyes. Nevertheless, moth-eye structures in semiconductors may still find applications where cheap, large area coverage is not so important, for example, in optical sensors, LEDs, and concentrator solar cells. Furthermore, recent developments in self-assembly techniques may provide a path to continued progress in this area.

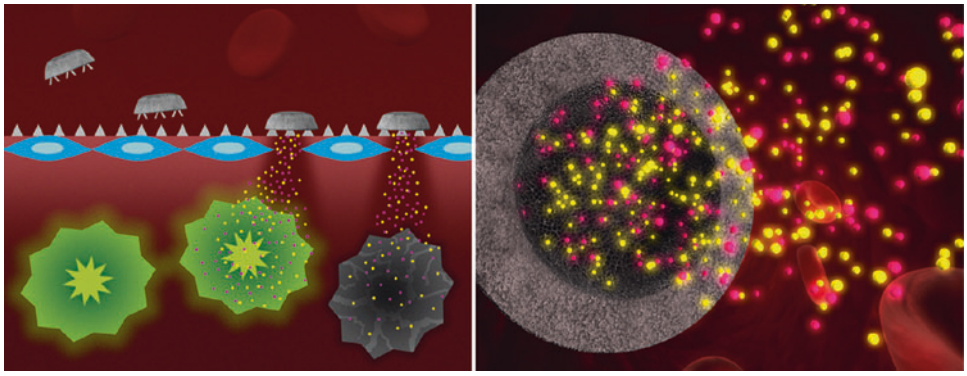
Definition

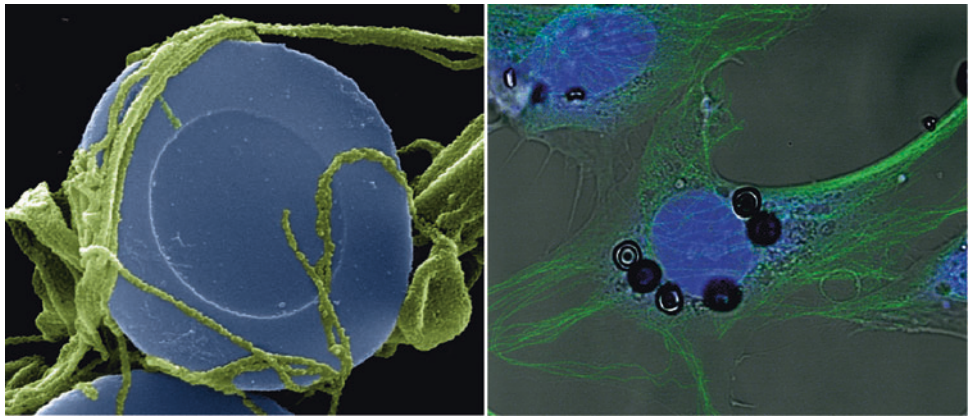


Multistage vectors are multiparticle, multifunctional vectors strategically envisioned to overcome abundant obstacles encountered by drug delivery vectors as they journey from the site of administration to the target site. These vectors are comprised of layers of particles, with secondary nanoparticles and active agents nested into first-stage porous silicon microparticles. The ability to achieve sequential targeting through particle optimization enhances the probability of reaching the appropriate cellular or subcellular target within a lesion with the appropriate drug. Multistage vectors are a subset of Logic-Embedded Vectors (LEVs) [1]. By definition, LEVs are vectors with the ability to perform a time sequence of functions through the use of multiple nano-based components that synergistically provide distinct functionalities.

Porous Silicon Particles as First-Stage Vectors

Well-established semiconductor microfabrication lithography and electrochemical etching techniques are used to fabricate porous silicon microparticles in well-defined, tunable sizes, shapes, and porosities [2]. Photolithographic masks are used to define particle shape, with porosity defined by the silicon-etch protocol. Both the size and shape of the particle affect physiological transport. To date, resulting particles have been in the micrometer size range, with shapes including tubular, discoidal, and hemispherical (Fig. 1). Particle porosities range from approximately 45–80 % [2], with the degree of porosity directly correlated with the rate of particle degradation. Greater particle porosities support faster rates of degradation. Thus, pore size permits controlled release of secondary agents and optimization of the matrix for specific cargo. In addition, chemical modification and the addition of functional groups to the particle surface have been shown to impact particle transport, stability and cargo release kinetics. Particles degrade to orthosilicic acid, a bioavailable form of silicon, when suspended in saline or serum [3].

Multistage Vectors, Fig. 1 Quasihemispherical (*left*; bar 400 nm) and discoidal (*right*, bar 500 nm) porous silicon microparticles. Images were taken using Hitachi S-5500 (*left*) and the Zeiss Neon 40 (*right*) scanning electron microscopes (Images courtesy of Rita Serda (*left*) and Xuewu Liu (*right*))



Multistage Vectors, Fig. 2 Schematic illustrating the multistage particle concept, with first-stage porous silicon particles adherent to tumor neovascular endothelia (*left*) or free in blood (*right*) with sustained or triggered release of second-stage nanoparticles. The released nanoparticles enter the tumor interstitial space by mechanisms that include the EPR effect. Molecular recognition of nanoparticles by tumor cells is followed by cellular internalization and trafficking of drugs to the appropriate subcellular organelle or cytosolic complex (Images created by Matthew Landry)

Biobarriers arise as a result of biological compartmentalization and the body's robust defense system. Multiple barriers decrease the probability of reaching the therapeutic target such that only 1 in 10,000 to 1 in 100,000 molecules reach the intended site of action [4]. Sequentially, with respect to intravascular injection site, these barriers include enzymatic degradation; sequestration by phagocytes of the reticuloendothelial system (RES); vascular endothelia; adverse oncotic and interstitial pressure in the tumor; cellular membranes, subcellular organelles such as the nucleus and endosomes; and molecular efflux pumps [5]. Without an effective strategy to negotiate these barriers, new or current therapeutic agents based on enhanced biomolecular selectivity may yield suboptimal therapeutic efficacy. Transport through different compartments and across biological barriers can be enhanced by the presentation of agents, such as permeation enhancers, and nanoparticles that present appropriate molecular moieties to influence biological associations. Sequential presentation of agents housed in multistage vectors is one means of achieving this goal.

When injected intravascularly, multistage vectors travel within the bloodstream, periodically interacting with the vascular endothelium. To enhance accumulation of vectors in the tumor neovasculature, particle parameters and surface chemistry of porous silicon particles are optimally designed with four primary objectives: (1) margination dynamics, (2) firm adhesion at the target site, (3) controlled rate of silicon degradation and/or release of secondary nanoparticles and agents, and (4) transport of particles across the endothelial barrier. The multistage vision is illustrated in Fig. 2. Similar to leukocyte extravasation, first-stage porous silicon particles bounce, roll, and adhere to the vascular wall at sites of molecular recognition.

The final step of extravasation, endothelial transmigration, is accomplished by a variety of mechanisms. With respect to tumors, transmigration may be achieved via sustained release of second-stage nanoparticles and accumulation in the tumor through mechanisms including Enhanced Permeability and Retention (EPR). EPR is based on abnormal blood vessel formation during cancer angiogenesis, leading to poorly aligned endothelial cells with wide fenestrations, as well as ineffective lymphatic drainage. Other mechanisms of transmigration include transcytosis and particle exocytosis.

Rational design is used to guide particle fabrication and produce vectors that can spontaneously move preferentially in close proximity to the blood vessel endothelium. The objective is to

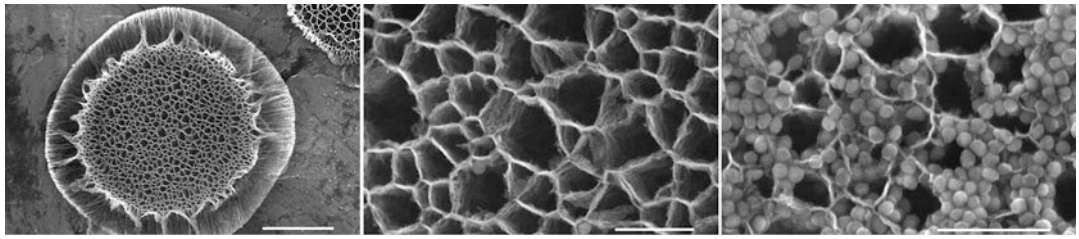
Multistage Vectors, Fig. 3 Cellular associations with porous silicon microparticles. *Left*: a scanning electron micrograph showing endothelial filopodia extending around a silicon microparticle. *Right*: a confocal micrograph showing endothelial cells that have internalized multiple silicon microparticles. Cellular tubulin was labeled with fluorescein isothiocyanate-conjugated antibody and 4′, 6-diamidino-2-phenylindole was used for nuclear labeling (Ref. [10] and [11])

create vectors that exhibit lateral drift from the center of the blood vessel toward the endothelial wall [6, 7]. Unlike spherical particles, nonspherical particles exhibit more complex motions that include tumbling and rolling, with a greater tendency to approach the vessel wall and periodically interact with the endothelial surface.

Targeting the tumor neovasculature is achieved by decorating the porous silicon particle with surface ligands that specifically bind to cell surface receptors over- or uniquely expressed on tumor-associated endothelia. The probability of cellular adhesion increases as the surface density of ligand molecules on the particle surface and receptor molecules on the cell membrane increase. In addition, for all particle shapes, a characteristic size can be identified for which the probability of adhesion has a maximum [8].

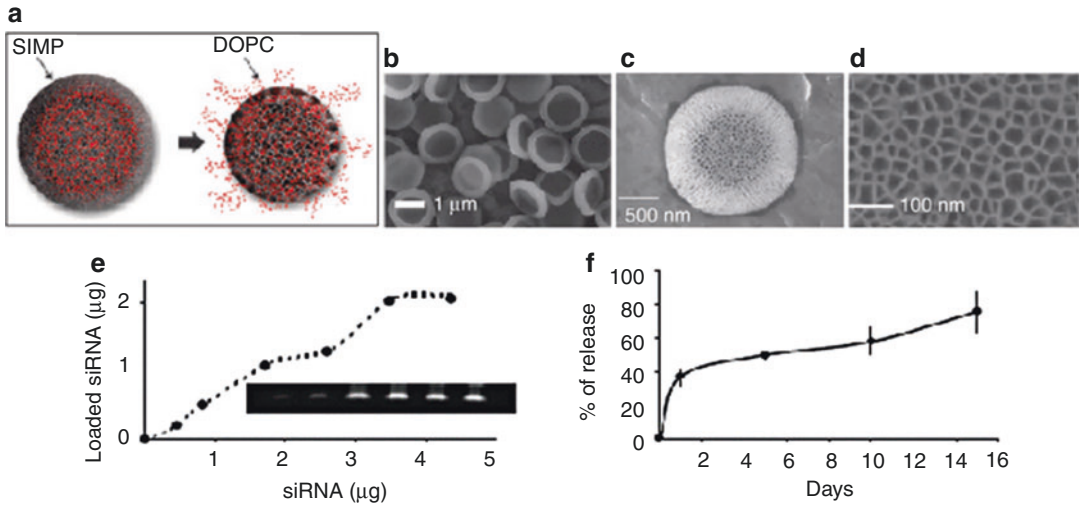
Cellular internalization of stage one porous silicon microparticles has been demonstrated in Human Umbilical Vein Endothelial Cells (HUVEC) and Human Microvascular Endothelial Cells (HMVEC) [9]. The process of internalization is actin dependent and includes both phagocytosis and macropinocytosis. Following cellular adhesion, and "cupping" of the particle (i.e., actin cup formation), the plasma membrane extends outward to surround the particle via formation of psuedopodia (Fig. 3, left). Internalized microparticles migrate along microtubules to the perinuclear region of the cell (Fig. 3, right). Macropinocytosis is also involved in particle internalization and is supported by formation of membrane ruffles.

Ligands for targeting specific cell populations include antibodies, peptides, oligonucleotides, small molecules, lipids, and carbohydrates. Optimal ligands include Fab (Fragment antigen binding) fragments, peptides, and aptamers (single-strand oligonucleotides) based on their small size, reduced antigenicity, and low levels of RES recognition. Inflammatory cytokine-driven expression of selectins, adhesion molecules, and integrins on endothelia function as targets for delivery vehicles at sites of pathology which include cancer, atherosclerosis, and rheumatoid arthritis. As an example, E-selectin-specific thioaptamers, which are thiophosphate ester-modified nucleic acids, have been shown to enhance tumor vasculature targeting in a breast cancer xenograft model [12]. Another example of enhanced targeting includes the use of the peptide "RGD" (arginine-glycine-aspartic acid), which is frequently used for integrin-mediated targeting of endothelial cells.



To achieve optimal targeting, a phenomenon known as biological fouling should be minimized through appropriate selection of surface polymers and targeting ligands for modification of each

particle population. Fouling is the process of serum components binding to the particle surface, with particle surface chemistry dictating the array of plasma components that bind to the outer particle creating a corona. Serum components are referred to as either opsonins or dysopsonins, depending on their impact, which either favor or disfavor cellular binding and uptake. Particles with a negative surface potential, including oxidized silicon microparticles and negatively charged polystyrene microparticles, bind to serum dysopsonins with respect to cellular uptake by endothelial cells, preventing adhesion and internalization [9]. Conversely, silicon particles with neutral or positive surface potential dictate adhesion by unique proteins that do not alter cellular uptake by endothelia. One method used to reduce serum protein binding and altered trafficking is functionalization of the particle surface with neutral polymers that reduce cellular uptake, such as poly(ethylene glycol) (PEG) [13–15]. Interactions between the aqueous environment and hydrophilic polymers include extension and mobility of the polymeric chains, such that protein binding is thermodynamically unfavorable [16]. An alternative strategy used to influence cellular interactions is modification of the particle surface to direct intentional binding of specific serum components to dictate cellular interactions. A final strategy to avoid binding of serum components to nanoparticles is to load them into larger carrier particles. Porous silicon particles provide protected transport of secondary and higher-level particles, negating the need for surface PEGylation. As an example, has been demonstrated that transportation of nanoparticles in the silicon matrix stabilizes chitosan-coated nanoparticles, enhancing chitosan-driven endosomal escape of internalized nanoparticles [17]. A potential benefit of cell uptake of carrier microparticles includes transcellular transport of nanoparticles across the endothelial barrier into the targeted tissue.



Candidates for Stage Two Vectors

Candidates for stage two vectors include liposomes, polymeric micelles, iron oxide, and gold nanoparticles. Liposomes (e.g., PEGylated liposomal doxorucicin; Doxil) and iron oxide nanoparticles [e.g., AMI-121 (siloxane), OMP (polystyrene-coated), and AMI-25] are two US Food and Drug Administration (FDA)-approved nanoparticles in clinical trials as therapeutic and magnetic resonance imaging agents, respectively. Liposomes are vesicular nanostructures, formed from phospholipid and cholesterol molecules. The inner hydrophilic compartment can encapsulate water-soluble drugs, as well as therapeutic proteins and oligonucleotides. Iron oxide nanoparticles have unpaired electron spins, which makes them superparamagnetic and influences the relaxation properties of protons in surrounding water molecules. This change in relaxation properties creates regions of dark contrast in tissues and cells where the nanoparticles accumulate. Figure 4 contains scanning electron micrographs illustrating the impact of particle surface chemistry on nanoparticle loading in to discoidal porous silicon microparticles [17].

Systemic delivery of therapeutic RNA for RNA interference (RNAi) therapy is challenged by short half-life, lack of plasma membrane penetration, and potential toxicity [18]. Nanoparticle-based delivery has achieved some success, but rapid clearance and instability present limitations. Multistage technology has been used to achieve sustained delivery of siRNA, long-term gene silencing, and reduced toxicity due to lower dose requirements. Neutral liposomes composed of dioleoyl phosphatidylcholine (DOPC) and associated siRNA, loaded into porous silicon microparticles (Fig. 5), exhibited sustained in vivo gene silencing for 3 weeks, significant antitumor effects in two orthotopic mouse models of human ovarian cancer (SKOV3ip1 and HeyA8), and no observable toxicity after a single intravenous injection. A single injection of multistage liposomal EphA2 siRNA resulted in greater than 80 % reduction of EphA2 expression, which lasted for 3 weeks, compared to a 6-day reduction for a single dose of liposomal siRNA. In addition, sustained EphA2 silencing reduced angiogenesis and cell proliferation compared to the control siRNA. Release of 35 % of Alexa555-siRNA-DOPC from porous silicon particles occurred in

[18])

the first 3 h, followed by sustained release of the remaining amount over 14 days (Fig. 5F). Tumor siRNA was evident in mice treated with a single injection of multistage vectors for longer time periods as compared to a single injection of the same dose of free siRNA. Together these data support improved long-term gene silencing and tumor reduction with multistage vectors as compared to free liposomal siRNA.

Multistage vectors singly or simultaneously loaded with quantum dots (Q-dots) and single-walled carbon nanotubes (SWCNTs) have been demonstrated [3]. 3′-aminopropyltriethoxysilane (APTES)-modified porous silicon particles were loaded with either polyethylene glycol (PEG)-fluorescein isothiocyanate SWCNTs or carboxylated Q-dots. Loading in large-pore silicon particles (20–30 nm) was rapid and abundant; however, loading of small-pore particles (5–10 nm) was minimal (6 and 25 %). The chemical properties of the particle surfaces affected loading, with electrostatic attractions enhancing loading and stability. Release of the nanoparticles at physiological temperature and pH in

Tris-buffered saline was sustained for 6 h. However, Q-dot release kinetics were significantly faster than that observed for SWCNTs, with 80 % of the Q-dots being released in the first 1.5 h, compared to 50 % of the SWCNTs. When the Q-dots and SWCNTs were loaded simultaneously, maximal load was achieved after 60 min, compared to 15 min for single cargo loading. However, release kinetics were unaltered. While SWCNTs were associated with the entire silicon particle, Q-dots were predominantly in the central region of the particle, owing to the presence of larger pores. These early studies have paved the way for current research focusing on codelivery of multiple therapeutic and/or imaging agents.

The biological impact of porous silicon vectors has been evaluated in cell lines representing the immune system (i.e., macrophages) and physiological targets (endothelial cells). Cellular morphology, cell viability, impact on cell cycle, mitotic potential, and proinflammatory responses following cellular engulfment of silicon microparticles have been evaluated [19]. Both cell types internalize microparticles via phagocytosis, with subsequent intracellular transport of vesicles to the perinuclear region of the cell (Fig. 3). During cellular division there is equal partitioning of microparticles between the two daughter cells owing to predominately single particle loading into endosomes during the internalization process. Equal partitioning of endosomes during mitosis, in cells containing microparticles supports undisturbed, healthy cellular function. Normal endothelial and macrophage proliferation and lack of cytotoxicity following internalization of silicon microparticles also support cellular biocompatibility of the first-stage vectors. In vitro studies support that endothelial cells are unaffected by the presence of porous silicon microparticles based on analysis of cell morphology, viability, cell cycle, apoptosis, mitosis, and lack of cytokine release.

Intracellular trafficking of particles is crucial to achieving the desired biological outcome. Intracellular targets include the mitochondria, nucleus, lysosomes, endoplasmic reticulum, golgi apparatus, and cytosolic complexes such as the RNA-induced silencing complex (RISC). Following cellular internalization of multistage vectors, the endosomal-entrapped assembly dissociates, and particles are sorted based on particle properties [17]. The larger silicon particles remain in endosomes, which undergo normal maturation to late endosomes and lysosomes. Released nanoparticles, for example, iron oxide nanoparticles, dissoicate from the silicon carrier and traffic to new destinations driven by the properties of the nanoparticle. For example, as stated previously, chitosan coating of the nanoparticles favors endosomal escape, while a PEGylated amine surface favors continued vesicular enclosure. Membrane-bound vesicles containing iron oxide nanoparticles have been reported to be secreted from both macrophages and endothelial cells. These membrane-enclosed vesicles typically have a diameter near 1 μm. The biological role of these biovesicles includes both proximal and distal communication between cells.

Recent findings challenge the dogma of particles functioning as static depots once they reach their destination. Endothelial cells shuttle particles between cells through cellular connections, known as tunneling nanotube (TNT), and via cellular shuttles [20]. TNTs are channels between cells that allow for the exchange of cellular constituents, including organelles [21, 22]. Cellular shuttles are relay cells. As documented using monolayer cell cultures, endothelial cells are capable of picking up particles from donor cells and transporting them to acceptor cells. Cell-to-cell transport of drug carriers may be one mechanism that can be manipulated to spread drug across specific cell populations.

Conclusions and Future Directions

Multistage vectors have the potential to bypass multiple, sequential barriers, targeting at multiple levels in order to achieve selective accumulation in tumors or pathogenic tissues. The ability to reproducibly and precisely tailor particle size, shape, and porosity creates an abundant pool of first-stage vectors that can be optimized for cargo loading and release, vascular margination, cellular targeting, adhesion, and internalization. The ability to load diverse cargo in the first-stage vector exponentially increases the possible cellular or

structural targets and therapeutic objectives. Therefore, multistage vectors exemplify a new paradigm in therapy that moves away from single-agent therapy toward combinatorial therapy with potential for personalization and real-time monitoring of therapeutic progress.

Definition

The term "nanoalloy" is employed in recent scientific literature to design materials consisting of metal structures with at least one nanoscale dimension and composed by two or more different metals. Often, the term is restricted to nanoscale alloy particles, i.e., multicomponent metallic aggregates with diameters ranging between 1 and 100 nm [1]. With respect to pure systems, nanoalloys present additional degrees of freedom of composition and chemical ordering, that is, the ratio among the elemental components can be varied as well as how these species are distributed within the nanostructure. By combining these variables with nanoscale confinement effects, it is possible to confer these nanomaterials' unique properties. They are therefore of great interest in basic science as well as in current nanotechnology and find applications in a variety of fields: from chemical sensing to heterogeneous catalysis and from magnetic recording to optoelectronic devices, thermal treatment of cancer, and "cell imaging," i.e., colorimetric probes for DNA detection [2]. Such interest at the experimental and industrial level has stimulated corresponding theoretical efforts, and a field of modern computational materials science is devoted to the prediction of the structure and properties of nanoalloys via simulations. While many theoretical methods here employed are borrowed from or shared with other fields, some are specific. For example, in nanoalloys the chemical ordering or

DOI 10.1007/978-94-017-9780-1

compositional structure, i.e., the way in which the different chemical elements are positioned within a fixed structural framework, gives rise to a huge number of isomers called "homotops" [3]. The computational approaches used to deal with this issue by efficiently sampling the chemical ordering phase space are thus specific to the nanoalloy field.

Introduction

Nanostructured alloy materials, such as alloy particles with nanoscale diameter, extended alloy materials with nanoscale structure, etc., represent an important field of current nanotechnology. Due to the increased freedom associated with composition and chemical ordering, new physical phenomena appear in metal multicomponent nanosystems with respect to their pure counterparts and novel or profoundly modified properties. There are several reasons why a gain can be achieved by employing a multicomponent nanostructured system with respect to pure and/or extended one which justify the importance of nanostructured alloys. First, new structural motifs with respect to pure systems can be created by alloying, thus generating novel structure-property relationships. Second, the chemical and physical properties of, e.g., a nanoparticle can be tuned by varying not only its size and shape but also its composition (i.e., the ratio between the different chemical species within the particle) and the degree of atomic mixing or chemical ordering or compositional structure (i.e., the distribution of the different atomic species in the structural framework). For example, the surface chemistry of a metal particle and its interaction with the environment can be modified by coating with an overlayer of a different metal, or additional functionalities can be added to change its recognition capabilities. The mechanical strength, the plasmonic and nonlinear optical, as well as magnetic response also exhibit features in multicomponent nanostructured systems which are different from their pure counterparts. This allows one to finely modulate the physics of the metal-metal interactions and consequently to tune the properties of these systems nearly at will. The fundamental reasons of this varied behavior ultimately lie in the peculiar features of confined metallic bond [4]. In metallic nanomaterials, in fact, the conduction band electrons, whose mobility enhances transport and response properties, are confined within a finite space, thus producing finite-size effects. Moreover, in transition metals in addition to conduction band electrons, one also finds localized electrons in partially filled d-shells, which assure simultaneously easy formation and breaking of chemical bonds (and thus a rich and varied chemistry) and large magnetic moments. Finally, the sensitivity of all these appealing properties to size, shape, composition, and external fields make that metal nanoparticles and nanoalloys are really unique materials, an ideal topic of research and investigation in many fields of science and technology.

From the point of view of simulating this diverse behavior, aiming at a rational design and a full exploitation of nanoalloy properties, significant challenges must be faced.

For example, chemical ordering can be crucial in determining the system properties. Alloy nanoparticles exhibit a different optical response depending on whether they are core-shell or random solutions; mechanical properties are equally affected by surface segregation, and the precise arrangement of the species in the particle is important in catalysis, dominated by processes occurring at surface or subsurface shells [2]. Describing and predicting the static and dynamical elemental distribution within a nanoalloy system is an extremely difficult task due to the huge number of possible configurations.

As another example, the need of accurately describing the mobility and polarizability of the metallic conduction band electrons entails that sophisticated electronic structure methods must often be employed to describe these systems, methods which are computationally demanding, and are thus unfeasible for the larger nanoalloy systems.

Finally, it should be recalled that metal nanostructures are intrinsically metastable phases, tending toward the thermodynamically stable bulk phases if not hindered by protective layers

which act as a stabilizing barrier or other forms of stabilization, and the interplay between thermodynamic and kinetic effects creates additional complexity to nanoalloy simulations.

These issues will be briefly expounded in this essay.

Simulation Methods

In this section, we briefly present some of the theoretical and computational methods that are employed in the field of nanostructured alloys.

First-Principles Methods

The first observation concerns the fact that – given the relatively small size of nanoalloys in at least one dimension – the description is often atomistic, i.e., the coordinates of each atom constituting the nanostructure are specified. To investigate structural properties, what is then needed is an expression for the energy of the system as a function of coordinates: $E(\mathbf{X})$, where E is the energy and $\mathbf{X}$ is the atomic coordinates. Such an energy expression can be derived using different methods.

At the most fundamental level, one can use first-principles methods (i.e., methods not introducing parameters other than the basic physical constants) in which the energy $E(\mathbf{X})$ is obtained by solving the time-independent many-body Schrödinger equation [5]:

$$H\Psi(\mathbf{r},\mathbf{X}) = E\Psi(\mathbf{r},\mathbf{X}) \tag{1}$$

where H is the Hamiltonian operator and E and Ψ are its lowest eigenvalue (energy) and corresponding eigenvector (ground state wave function), respectively: Ψ depends on both electronic ($\mathbf{r}$) and nuclear ($\mathbf{X}$) coordinates. In practice, it is computationally unfeasible to solve this equation rigorously except for systems composed of few electrons and ions, and approximate approaches have to be used to deal with realistic systems. Among the available approaches, the most widely employed in the nanoalloy field is density-functional theory (DFT), as it realizes the best compromise between chemical accuracy and computational effort. DFT in its most common form implies solving the single-particle Kohn-Sham equations [6]:

$$\left(-\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{r},\mathbf{X}) + \int\frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}d\mathbf{r}' + V_{xc}[(\mathbf{r})](\mathbf{r})\right)\varphi_i(\mathbf{r}) = \lambda_i\,\varphi_i(\mathbf{r}) \tag{2}$$

where the Kohn-Sham Hamiltonian operator (in parenthesis) is expressed as a functional of the electronic density $\rho(\mathbf{r})$ of the system, while $\varphi_i(\mathbf{r})$ and λ_i are the corresponding single-particle wave functions and energies, respectively. The Kohn-Sham Hamiltonian contains contributions of kinetic energy, external potential, coulombic repulsion, and exchange-correlation potential. Despite being less computationally demanding than the complete Schrödinger equation, DFT is still a first-principles method with an explicit description of the electronic wave function and can only be used in practice when the size of the system is relatively small – say, between subnanometer and 3 nm as typical dimensions, even though advances in software and hardware are continuously extending the scope of systems amenable to accurate DFT modelling.

Analytic Potentials

For larger systems – say, between 2 and 10 nm in size – a common approximation relies on the use of analytic potentials. In these approaches, the energy function $E(\mathbf{X})$ is expressed in terms of analytic expressions of the atomic coordinates. As the number of such coordinates is huge, further simplifications must be sought. A common practice is then first to define $E(\mathbf{X})$ as a sum of site atomic energies $E^{i,atomic}(\mathbf{X})$:

$$E = \sum\nolimits_i E^{i,\ atomic}(\mathbf{X}) \tag{3}$$

where the sum runs over all *i*-atoms, and then to express the dependence of $E^{i,\ atomic}(\mathbf{X})$ upon $\mathbf{X}$ through generalized collective variables (GCV), i.e., a limited number of functions which describe the distribution of neighbors around the given atom and depend in an analytically compact form upon their number, distance, and orientation.

What distinguishes the various analytic potentials is then the choice of the GCV and the analytic form by which $E^{i,\ atomic}$ depends on the GCV. In this respect, it has been shown that, to be accurate, an analytic potential for nanoalloys must satisfy two requirements and reproduce two salient features of the metallic bond:

(i) Its incremental character, i.e., the possibility of spanning a wide interval of coordination numbers (number of close neighbors), which in metallic systems typically range from 1 to 12 (or 13–14 in some cases)
(ii) Its many-body or nonlinear character, that is, the fact that atomic energies are not simply linear or additive, but go to saturation as the number of neighbors increases

These features can be illustrated by considering one of the simplest analytic potentials for metal systems: the second-moment-approximation (SMA) tight-binding potential, in which each atomic energy is written as a sum of a pair repulsive ($E^{i,rep}$) and a many-body attractive ($E^{i,\ att}$) component:

$$E = \sum_{i=1}^{N} \left\{ E^{i,\,rep}(i) + E^{i,\,att}(i) \right\} \tag{4}$$

where

$$E^{i,\,rep}(i) = \sum_{j \neq i}^{N} A \exp\left\{ -p\left(\frac{r_{ij}}{r_0} - 1 \right) \right\} \tag{5}$$

$$E^{i,\,att}(i) = \left[\sum_{j \neq i}^{N} \xi^2 \exp\left\{ -2q\left(\frac{r_{ij}}{r_0} \right) - 1 \right\} \right]^{1/2} \tag{6}$$

and the sums in Eqs. 5 and 6 run over all *j*-atoms different from the *i*-th. The parameters A, r_0, ξ, p, and q are characteristic of the given metal element and are usually fitted to the experimental quantities such as the cohesive energy, the equilibrium lattice parameter, and independent elastic constants for the reference crystal structure. It can be noted that in the SMA analytic potential, the repulsive term in $E^{i,atomic}(\mathbf{X})$ is of the Born-Maier form [7] and is linear, whereas the attractive term describes the many-body character of the metallic bond and is nonlinear as it is proportional to the square root of a sum over neighbors, thus satisfying requirement (ii) above. When working with nanoalloys, the Eqs. 4, 5, and 6 are generalized by defining three types of pair interactions – A-A, B-B, and A-B – and the corresponding A, r_0, ξ, p, and q parameters for each pair. Usually the parameters corresponding to the pure A and B elements are employed for the homo-interactions (A-A and B-B types), while the A-B hetero-interactions are described by a different set that can be derived by averaging the parameters of the pure elements or by fitting to (experimental or computational) data corresponding to bulk alloys. The analytic forms (4, 5, and 6) can be further refined by taking into account directionality effects in the choice of the GCV [8]: these effects are important when dealing with third-row transition metals where, due the relativistic contraction of the *s*-orbitals, *d*-orbitals (which are not isotropically distributed around the nucleus) play a role in metallic binding. As an example, the dipolar contribution of the neighbor distribution around the *i*-th atom is given by the following expression:

$$E^{dip,\,i} = \sum_{\sigma = x,\,y,\,z} \left(\sum_{j \neq i} \rho^{dip}\left(r_{ij}\right) \frac{r_{ij}^{\sigma}}{r_{ij}} \right)^2 \tag{7}$$

where $\rho^{dip}(r_{ij})$ is a function of the distance and r_{ij}^{σ} is the σ-Cartesian component of the interatomic distance r_{ij}.

Effective Hamiltonians

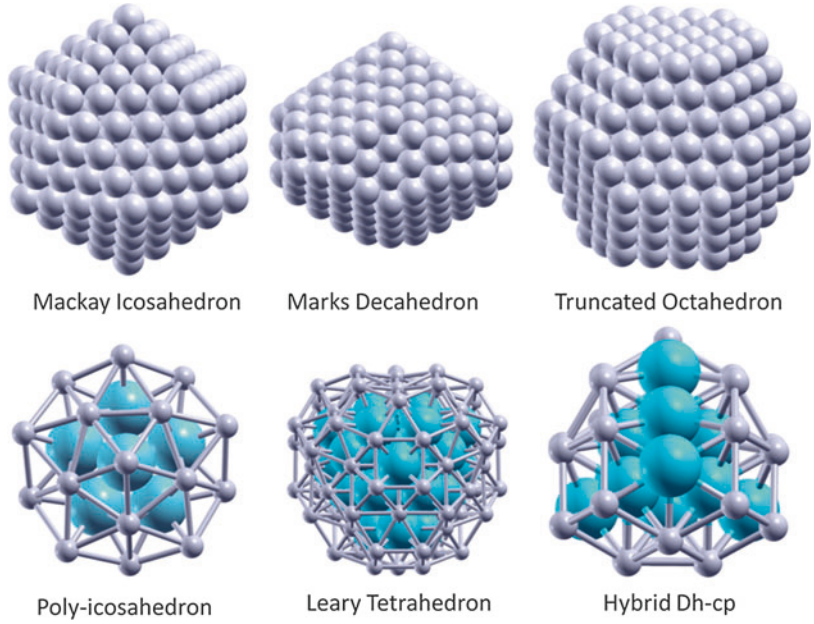
For even larger systems – say, between 5 and 50 nm in size – a third class of methods are often used, named effective Hamiltonian or pair-interaction methods [9]. In these approaches, the energy expression $E(\mathbf{X})$ is further simplified by ignoring the dependence of the atomic site energies upon the atomic coordinates and assuming that they only depend on the number of first neighbors, defined as atoms lying at a distance

smaller than a given threshold from the given *i*-th one. According to such scheme, each atom in the bulk gives the same contribution, whereas the surface energy of the particle can be written in the following way:

$$E_s = \sum_{i=1}^{N} \frac{1}{2}\left\{ \sum_{j \neq i}^{N} \left(\delta w_{ij} - \Delta Z_i w_b \right) \right\} \qquad (8)$$

where w_b is the bulk energy, ΔZ_i is the number of broken bonds of atom *i*, and δw_{ij} is a polynomial function also depending on the number of broken bonds. The functions w_b and δw_{ij} can be fitted to first-principles calculations or experimental values of, e.g., surface energies. These approaches can be applied to larger alloy nanoparticles. In such methods, in fact, an energy evaluation scale linearly with the number of atoms with a small prefactor related to the average number of first neighbors and is thus feasible for systems containing billions of atoms in a cpu time of the order of a second on a current standard processor. A given structural framework for the nanostructure is considered, and the main underlying assumption is that the structural relaxation around each atom only depends upon its coordination number, an assumption which is usually reasonable when the dimensions of the nanostructure exceed 4–5 nm.

As anticipated at the beginning of this section, only atomistic approaches have been discussed so far, which are appropriate due to the limited size of the systems. However, for the larger nanoalloys with sizes in the range of several tens of nanometers, continuum models and associated finite element solvers can in principle be employed [10], although this possibility has been rarely considered until now.



To conclude this section, two points can be highlighted.

First, in nanoalloys a complication exists connected with the *match* among the energy scales of the different elements composing the alloy. The presence of multiple length and energy scales is common to any composite system and must be dealt with care in order to achieve reliable predictions. Let us clarify this point via a specific example. If a given theoretical approach is not capable of predicting the surface energies of a pure element accurately, but it does predict the *ratios* between surface energies correctly, this is sufficient to predict the shape of a pure nanoparticle accurately. The shape of a nanoparticle is determined in fact only by the ratios of the surface energies, not by their absolute values, and multiplying all energies by a common scaling factor does not affect these ratios. However, if the scaling factors for the different elements in a mixed system are different, this will spoil the accuracy of the prediction. In nanoalloys an *absolute accuracy* in the description of the properties of each element (rather than a *relative accuracy*) must therefore be achieved, and this is a much more stringent demand on the theoretical approach.

Second, a problem in the field of nanoalloy simulation is how to compare the stability of nanoalloys with different chemical composition. In this respect, a very useful quantity is the mixing energy. Suppose to consider alloy nanoparticles of a given size (i.e., the same number of atoms) but different chemical composition, and suppose to know the energy of each one of them. The mixing energy is then defined as

$$\Delta[N_A, N_B] = E_{alloy}[N_A, N_B] - N_A E_A[N] / N - N_B E_B[N] / N \qquad (9)$$

where $E_{alloy}[N_A, N_B]$ is the energy of a nanoalloy composed of N_A atoms of the species A and N_B atoms of the species B, $N = N_A + N_B$ is the total number of atoms in the nanoalloy, E_A [N] is the energy of a pure structure of N atoms, and E_B [N] is the corresponding quantity for the B species (it is assumed that these are global minimum energies, i.e., the lowest energies among all possible isomers). $\Delta[N_A, N_B]$ is the mixing energy of a nanoalloy of the given size at the given composition, i.e., the energy released by mixing N_A A-type clusters and N_B B-type clusters all of size N to produce N alloyed clusters of size N with composition (N_A, N_B), divided by N. The quantity $\Delta[N_A, N_B]$ provides a measure of how

Nanoalloy Simulation, Fig. 1 Classical structural motifs (first row), together with structural motifs peculiar to nanoalloyed systems (second row). In particular, in the second row, a poly-icosahedron of 34 atoms (a 27-7 according to the definition given in Ref. [11]), a 98-atom Leary tetrahedron, and a 38-atom hybrid decahedral (Dh)/close-packed (cp) are shown

thermodynamically favorable is mixing the two elements at the given size and composition. Its definition represents the natural generalization of the corresponding quantity used for bulk alloys [2].

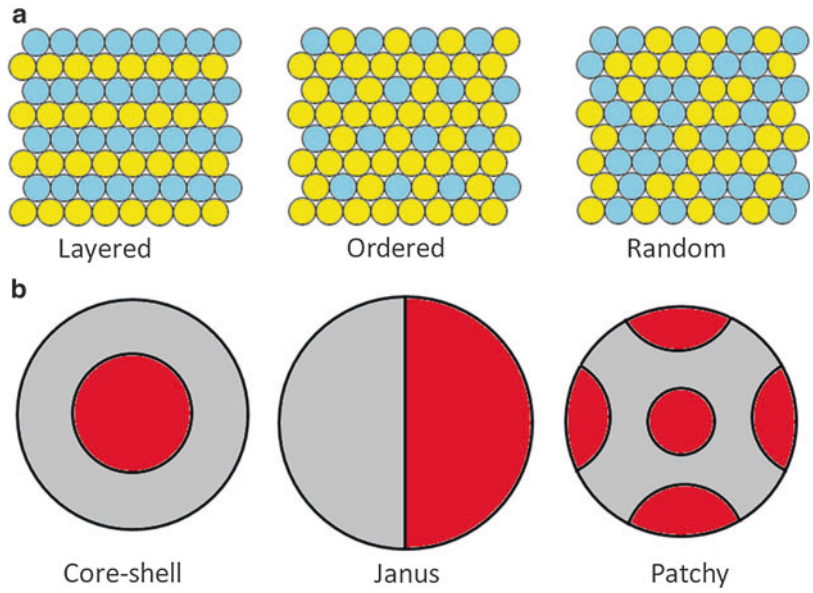
Structural Properties

Surfaces and interfaces play a crucial role in nanostructured systems, due to the large ratio between the number of atoms at the surface with respect to those in the bulk or core of the nanostructure. In such systems, the energy associated with surfaces or interfaces thus represents a sizeable component of the total energy. Moreover, some properties, such as catalytic ones, are entirely dominated by local chemical binding at the surface. The particle shape, determining the type of surfaces of the particle, is usually described in terms of model polyhedra from classical geometry, such as octahedra and truncated octahedra (crystalline motifs) or icosahedra and decahedra (noncrystalline motifs); see the first row of Fig. 1. Noncrystalline motifs cannot give rise to periodic patterns because they contain fivefold symmetry axes which are incompatible with translational symmetry, but they can exist in finite systems such as nanoparticles. The Mackay icosahedron is probably the most common one; see Fig. 1: this structure is limited by (111) close-packed facets only, which are usually the surfaces with the lowest energy, thus minimizing the cluster surface energy. However, in icosahedral structure, an internal strain is present due to the fact that radial inter-shell bonds are compressed, whereas intra-shell bonds are expanded. Mackay icosahedra are therefore highly stressed structures and are expected to be the favorable only at small sizes, in which the low surface energy overcomes the internal stress contribution. Another noncrystalline motif is represented by the decahedron: this structure is formed by two pentagonal pyramids sharing a base; its surface has only (111) close-packed facets, but its shape is very far from being spherical. A truncation of the five edges limiting the common basis of the pyramids to expose (100)-like facets is advantageous and produces the so-called Ino decahedron. Other cuts with reentrances exposing further (111) close-packed facets separating neighboring (100)-like facets can also be advantageous and produce

Marks decahedra; see Fig. 1. Decahedra are also strained structures, but the strain is much smaller than for icosahedra, making them favorable in an intermediate range of sizes [12].

In the family of crystalline motifs, the atoms of the clusters are positioned in the positions characterizing the metal in its bulk form (e.g., face-centered cubic, fcc). These motifs optimize volume energy contributions at the expense of a higher surface energy with respect to other motifs, so that they are thus preferred for large particles in which the volume contribution dominates. Other more exotic motifs can be encountered especially in the nanoalloy field, in which the mixture of different elements greatly increases structural degrees of freedom. Among these, a notable class is that of poly-icosahedra (pIh), which are built by packing elementary icosahedra (Ih) of 13 atoms in such a way that interior atoms in the structure are surrounded by a complete Ih_{13} shell (see second row of Fig. 1). Another common occurrence is represented by hybrid motifs, such as hybrid decahedral/close-packed structures, in which a close-packed core in the form of a trigonal pyramid or bipyramid is surrounded by atoms growing on the core faces in hcp(111) stacking plus further atoms arranged along edges between two faces thus creating a local decahedral arrangement [2]. The occurrence of these more exotic (such as hybrid) motifs in alloyed nanoparticles can be rationalized. Suppose, for example, to mix two species with different bulk cohesive energies. If the size mismatch between the two species is small or such that the more cohesive element also presents the smaller size and the two elements do not have a great tendency to mix, it is reasonable to expect a core-shell arrangement with a core segregation of the smaller species. Moreover, as this species achieves a complete coordination shell in the core, it will tend to arrange in a close-packed (cp) configuration. The less cohesive species, instead, being surface segregated and thus low coordinated, will tend to adopt noncrystalline, fivefold arrangements. Hybrid structures which combine a close-packed core with a decahedral or icosahedral surface can therefore be favorable.

Chemical Ordering



As recalled above, in addition to shape, specific to nanoalloys are the issues related with chemical ordering or compositional structure, i.e., the way in which elements are distributed within the nanostructure.

Let us focus for simplicity on a binary nanoalloy.

In the case of homogeneous systems, when the chemical ordering is uniform throughout the nanostructure, we can distinguish three variants of mixing patterns, depicted in Fig. 2a: (a1) layered, in which atomic planes composed of each component alternate regularly; (a2) ordered mixing, with a regular arrangement and a thorough intermingling of the two species; and (a3) random, i.e., mixing in which no long-range order can be recognized. These variants closely correspond to chemical orderings found in extended multicomponent systems (bulk alloys).

In the case of inhomogeneous or segregated systems, in which the nanostructure can be partitioned into disconnected, individually homogeneous pieces, three main segregation patterns can be defined, illustrated in Fig. 2b: (b1) core-shell, in which one piece (the inner core) is surrounded by a crown (or shell) of a different composition; (b2) Janus, in which the dividing interface corresponds to a plane bisecting the structure; and (b3) patchy, in which the surface of the nanostructure is a patchwork of islands of atoms of the two elements. Of course, there are intermediate cases in between these limiting ones, with variants such as multi-shell, in which the particle can be partitioned in more than one concentric shell, or off-centered core-shell structures, in which the core is asymmetrically centered and in the extreme can give rise to quasi-Janus arrangements, in which the core is so close to the surface that is covered only by a very thin layer with a different composition.

Clearly, each segregated piece depicted in Fig. 2b can be associated with one of the different mixing patterns depicted in Fig. 2a, thus giving rise to a multitude of different chemical ordering

Nanoalloy Simulation, Fig. 2 (**a**) Short-range mixing patterns in homogeneous systems and (**b**) possible realizations of segregated systems. It should be noted that the figures on the left and in the middle of part (**b**) represent a cross-section of the particle, whereas the figure on the right shows a surface view

possibilities. An important topic in nanoalloy simulation is therefore how to single out which chemical ordering is realized in a given nanoalloy (i.e., structural recognition). Order parameters can be defined to achieve this. An order parameter is an analytic function of the system coordinates that describes the structural features of the system. Commonly used order parameters are those describing the coordination environment of the atoms, such as those derived from a common neighbor analysis [13]. Other order parameters associated with chemical order or compositional structure can be defined to distinguish the ordered phases of bulk alloys and nanoalloys [14]. For example, an order parameter useful to characterize the short-range intermixing of two species is the following. Suppose that x_A and x_B are the relative quantities of the two components within an A-B nanoalloy and n_{AA} and n_{AB} the average number of homo- and hetero-bonds, respectively, around the species A. By defining $n_{AM} = n_{AA} + n_{AB}$, the α parameter

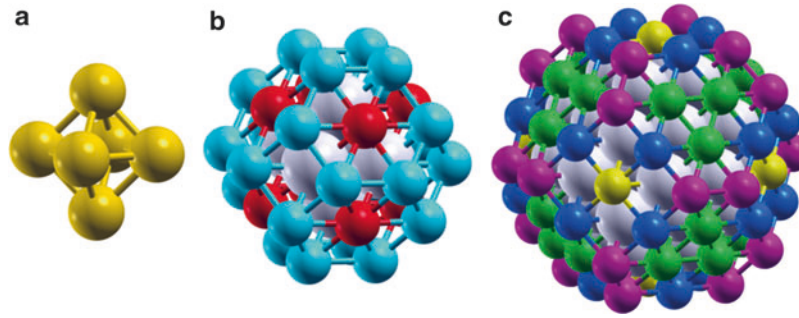
$$\alpha = 1 - \frac{n_{AB}/n_{AM}}{x_B} \tag{10}$$

becomes an indication of the tendency of the nanoalloy to segregate (positive values of α) or to mix (negative values of α). More sophisticated order parameters take into account not only the number of nearest neighbors of each species but also their relative orientation: for example, one useful order parameter is the dipolar contribution coming from the distribution of first neighbors around each atom; see its form in (7) [8]. Many other possible order parameters can of course be defined, tailored to the specific system under consideration. The order parameters can be used as averages over the whole nanoalloy or locally for each individual atom. In the case of homogeneous nanoalloys, the order parameters relative to chemical ordering will be independent of the position, whereas in the case of inhomogeneous or segregated systems, the value of such order parameters will vary within the structure.

Given the huge variety of possible structural families and compositional structures, one of the main issues in the theoretical research and simulation on nanoalloys is the accurate prediction of their favorable shape and degree of atomic mixing. As in other field of computational nanoscience, the problem is finding effective ways to systematically explore the potential energy surface (i.e., the $E(\mathbf{X})$ function) of the system [15]. This computational problem can be daunting, given the incremental and scarcely directional character of the metallic bond and the additional complication that chemical ordering

greatly increases the degrees of freedom of the system. In terms of structural framework, it is believed that the number of local minima increases exponentially with the size of the nanoparticle [15]. These different local minima give rise to structural isomers, such as icosahedra, decahedra, etc., as shown in Fig. 1, with all their numerous nonsymmetric variants. Chemical ordering also increases the complexity of the problem in a non-polynomial (exponential) way. In detail, the number of different possible realizations of a nanoalloy of a given size, structural framework, and composition increases in a combinatorial way due to the set of possible chemical orderings. In fact, neglecting the reduction due to point-group symmetry, for a cluster with a given structure and made of N atoms of which N_A of species A and N_B of species B, one has $(N_{tot})!/((N_A)!(N_B)!)$ possible different "homotops," i.e., isomers sharing the same skeletal structure and composition but differing in the mixing pattern. This number increases exponentially with the size of the system, rapidly becoming impossible to thoroughly sample or explore even using computationally inexpensive theoretical approaches such as effective Hamiltonians. In the following, the methods employed to predict the preferred (energetically most favorable) geometric and compositional structures of nanoalloys are briefly discussed.

Global optimization (GO) approaches: a viable procedure to search for the equilibrium configurations of a pure or alloy system is to start from a random arrangement and to consider moves eventually leading to lower-energy configurations, as realized in the basin-hopping (BH) algorithm [15]. The BH algorithm to explore the structural degrees of freedom of the system is realized as follows:



1. An initial random configuration of the system is chosen, a local geometry optimization is performed, and the final energy (the fitness parameter) is registered as E_1.
2. Starting from the relaxed configuration, the atoms of the system are subjected to a random move, a new local geometry optimization is performed, and the final energy is registered as E_2.
3. A random number (rndm) between 0 and 1 is generated, and the movement of step 2 is accepted only if $\exp[(E_1 - E_2)/k_B T] > \text{rndm}$ (Metropolis criterion).
4. Steps 2 and 3 – the Monte Carlo steps – are repeated a given number of times.

Depending on the k_BT parameter, which plays the role of a fictitious temperature, some high-energy configurations are accepted, and the search is able to explore different structural motifs (belonging to different funnels of the PES) of the metal cluster.

A crucial point in the implementation of the BH search is choice of the random move. This can be simply a spatial "kick," realized by randomly displacing the Cartesian coordinates of all atoms up to a certain amount, or more sophisticated choices, such as short runs of unstable molecular dynamics especially effective for larger clusters. The BH approach can be also used to explore the space of chemical ordering. In this context, the BH random move is usually taken as an exchange of the coordinates of two atomic species, as realized in the exchange-only basin-hopping (BH) algorithm.

The thoroughness of the BH search is much increased when the BH protocol is coupled with *structural recognition* algorithms, i.e., algorithms which classify geometrical configurations as belonging to a given structural motif (or structural family). Structural recognition makes use of the order parameters discussed above by distinguishing different structural families on the basis of the corresponding values of a chosen order parameter.

An alternative possibility is to consider structurally magic clusters, i.e., configurations exhibiting structural shell closure and thus as a norm a high point-group symmetry. This high symmetry is exploited to partition the atoms into symmetry "orbits," i.e., group of atoms equivalent by symmetry (transformed into one another by the operation of the symmetry group); see Fig. 3. As a consequence, the degrees of freedom of the system are reduced from the number of atoms N to the number of symmetry-nonequivalent orbits, N_{orb}, and correspondingly the number of distinct

Nanoalloy Simulation, Fig. 3 Orbit structure of selected truncated octahedral (TO) clusters: (**a**) 6-atom TO; (**b**) 38-atom TO, obtained adding 32 atoms to (**a**); (**c**) 116-atom TO, obtained adding 78 atoms to (**b**). Atoms belonging to different symmetry orbits are singled out by different colors

homotops is exponentially decreased, making theoretical simulations feasible even at the first-principles level for medium-sized particles. The use of magic clusters is also very useful for studying properties, both to reduce the computational effort associated with a single computation and to reduce the number of homotops to be considered.

Another efficient tool to drastically reduce the computational effort and to enlarge the scope of systems amenable to simulations is based on the use of periodic models. Instead of studying a 0D system, in fact, one can consider a 1D or "wire" model in which the section of the cluster is replicated ad infinitum and the number of nonequivalent atoms (in this case, those contained in the unit cell) is strongly reduced.

Catalytic Properties

So far static structural properties have been discussed, connected with the energetically most favorable configurations. One of the most important applications of nanoalloys and therefore of the corresponding simulation methods is however in the field of chemical reactions and in particular of catalysis, which involves *dynamic* in addition to *static* structural properties. Nanoalloy systems are indeed very relevant in catalysis and can be very efficient catalysts. A catalyst is a specific agent which is (i) able to increase the rate of a chemical reaction and (ii) which is not consumed by the transformation process. The important catalytic properties of nanoalloys are associated with the following features: (a) the incremental character of metallic bond, spanning a wide interval of coordination numbers (as recalled above), and the great polarizability of metallic electrons make that metal surfaces in general can promote chemical reactions by adsorbing/transforming/desorbing ligand species; (b) the multifunctional nature of nanoalloys as mixtures of different metals greatly expands catalytic degrees of freedom by creating geometrically or electronically novel adsorption sites; and (c) the high surface/volume ratio of nanoalloys as nanoscale systems makes them particularly efficient in catalysis with respect to extended crystals. The much higher selectivity of Cu-Ru particles with respect to pure Ru ones in orienting the dehydrogenation of cyclohexane into benzene rather than its hydrogenolysis into methane [16] and the greater efficiency of Ni_3Fe with respect to pure Ni systems as methanation catalyst [17] are examples of the important of nanoalloys in the catalysis field.

To simulate chemical reactivity, theoretical methods are required to be able to predict not only the minimum energy of a system but also the *minimum energy path* connecting an initial configuration (the reactants) with a final configuration (the products). One can distinguish two cases, according to whether one has a knowledge of the initial and final configurations or local minima to be connected or not. In the former case, the

nudged elastic band (NEB) method [18] is one of the most popular algorithms to find the reaction path between the two configurations and is implemented in many simulation codes. If instead knowledge on the final configuration is lacking, then the search for the local minima connected to the starting structure must use other methods, such as the intrinsic reaction coordinate (IRC) algorithm [18].

Another form of structural dynamics which is specific to nanoalloys is the kinetics of chemical ordering, i.e., the rate at which the different atoms interdiffuse within the alloy nanostructure. Information on interdiffusion kinetics is important to ascertain whether the thermodynamic predictions obtained via global optimization simulations and the favorable arrangements of the elemental species at the surface are then realized in practice. It often happens in fact that after a synthesis process, the as-prepared alloy nanoparticles are in a metastable phase or configuration, for example, with a distribution of the two elements which does not correspond to the lowest-energy or thermodynamically favorable arrangement. In such cases, their chemical ordering will evolve in time according to the kinetics of atomic interdiffusion. This phenomenon from a simulation point of view is akin to catalysis and can be treated using similar theoretical approaches [2].

Even assuming that the potential energy surface of a given system can be explored in an efficient way, a basic issue remains in modelling catalysis by nanoalloys that screening possible nanoalloy catalysts to find the optimal combination and composition via a trial-and-error approach is an extremely demanding task. This is true both at the experimental and theoretical level, even when combinatorial screening can be applied [19]. The number of possible binary pairs of an alloyed catalyst and of the possible different compositions is in fact huge, and some guiding principles are needed to orient the search. In this context, the concept of descriptors of the catalytic activity is commonly used.

The starting point is a basic principle in catalysis, the Sabatier principle [20], which states that, when trying to optimize the performance of any given catalyst, one faces as a norm conflicting requirements. For example, if the adsorption energy of the reactants on the catalyst is too strong (or they dissociate too easily), then the successive reaction energy barriers or desorption energies will also be large, whereas vice versa if the adsorption energy is too low, then the dissociation step necessary for the catalytic activity will be difficult. The Sabatier principle then states that the best compromise lies in between strong and weak energetics, and the performance of a catalyst as a function of any quantity correlated with the reaction energetics will go through a maximum, leading to a "volcano" relationship between catalytic efficiency and this quantity.

Another crucial point is the finding that linear correlations usually exist between different quantities such as adsorption energies and energy barriers, also called Brønsted-Evans-Polanyi (BEP) relations. The presence of such correlations effectively reduces the number of independent variables for a given catalytic process.

The strategy that results from combining the Sabatier principle and the existence of BEP relations is therefore to select a limited number of "descriptors," i.e., energy quantities that monitor the catalytic activity or selectivity of a catalyst [17], and plot catalytic efficiency as a function of such descriptors. These descriptors can be the adsorption energies of intermediates, reactants, and products or the activation energies of the rate-determining elementary steps, decided on the basis of experimental and/or theoretical results. In plotting the catalytic efficiency as a function of descriptors, one then expects to find a volcano curve, i.e., a curve with a maximum. In the search of new catalysts, one can then focus on the vicinity of the maximum of the volcano curve, which is the most interesting region, thus drastically reducing the effort of the simulation screening.

Conclusions

In conclusion, simulations can now be conducted and used as an effective tool to characterize and

predict the structure and properties of nanoalloys, i.e., metal alloy materials consisting of structures with at least one dimension at the nanoscale. The palettes of methods used in this field are mostly atomistic and range from sophisticated first-principles approaches to simpler analytic potentials to effective Hamiltonians. Given the striking structural, catalytic, mechanical, optical, and magnetic properties of these materials and their consequent use in fuel cells, energy storage, nanomedicine, magnetic nanostructures, plasmonics, and therapeutic and diagnostic applications [2], simulation methods are rapidly evolving, trying to keep the pace of experimental and technological developments. In the present essay, attention has been devoted to the simulation of structural behavior of nanoalloy systems, both static (i.e., favored arrangements and configurations) and dynamic (i.e., transformation kinetics, chemical reaction, and catalysis), whereas information on a wider set of properties and corresponding theoretical approaches can be found in the cross-reference essays.

Definition

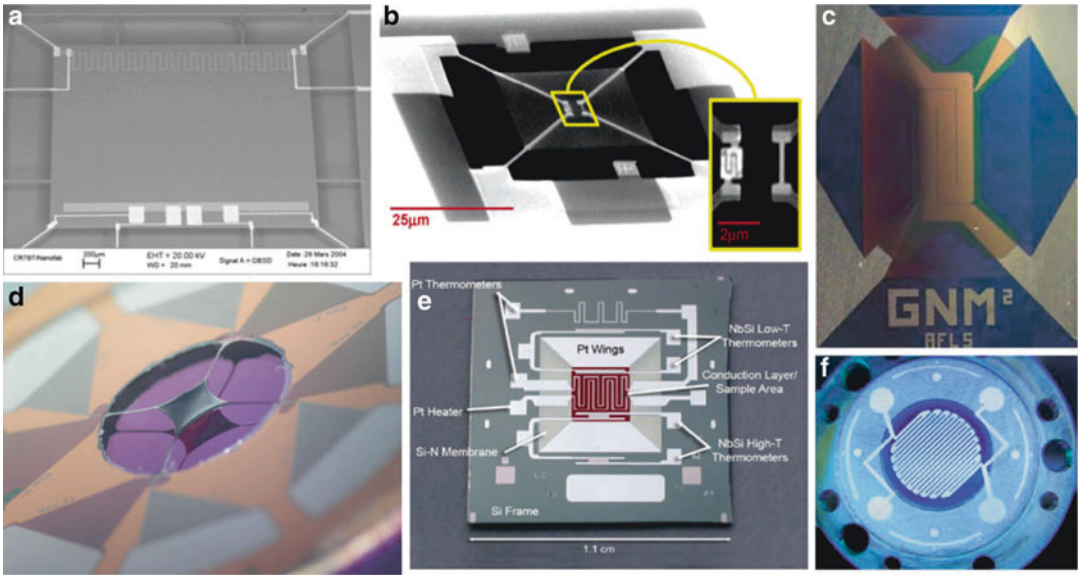
Calorimetry is the part of thermodynamics which aims to measure any quantity of heat (enthalpy, specific heat, heat release) stored, released or brought into play in any state of matter, in a reaction, or in phase transitions [1].

More precisely, the terminology of "Nanocalorimetry" may cover different concepts depending on the area of science where it is used. It concerns any calorimetric method in which either the samples to be studied have a size in the range of the nanometer scale or the measured energies involved are of the order of the nanojoule or below.

Although these two types of definitions are very different, they both have something in common. They are indeed concerned with the development of miniaturized sensors and more generally with ultrasensitive experiments imposed when small systems are involved. Indeed, most of the modern sensors are built to carry out measurements at the ultimate limit of

Nanocalorimetry, Fig. 1 Thermal schemes for calorimetric experiments (**a**) a quantity of heat ΔQ is released in the sample, an increase of temperature will appear. This system is assumed to be infinitely isolated from the heat bath. (**b**) An external heat is supplied to the sample also infinitely isolated from the heat bath. By measuring the increase of temperature we will get access to the heat capacity of the sample (adiabatic calorimetry). (**c**) The sample is linked to the heat bath through a thermal conductance K; a thermometer and a heater allow the measurement of the thermal properties (C and K)

what can be detected by calorimetry on thin films or very small volume samples.

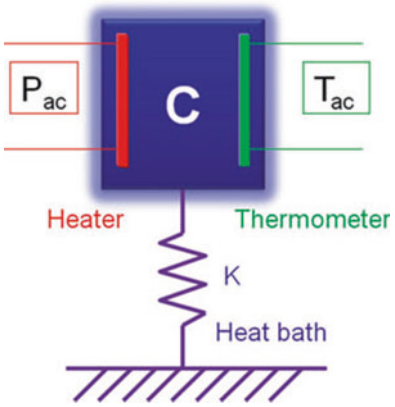


In this entry, the key issues governing an experiment of nanocalorimetry are discussed. In particular, for each point, recent experiments conducted in this area over the world are presented. This will provide a non-exhaustive overview of what is currently done in nanocalorimetry. Particular attention will be given to micro- and nanofabrication technologies as well as highly sensitive thermal technique necessary to achieve an experiment of nanocalorimetry. Here, bolometry is not discussed; despite its thematic proximity; the measurement of radiation and possible refrigeration at the mesoscopic scale has been described extensively in other works [2].

Nanocalorimetry

Introduction

In calorimetry, thermal isolation is the major issue. The heat capacity of a sample under study, or the measurement of exchanges of energy between the sample and its environment, is properly measured only if the sample is correctly isolated from its environment (adiabatic conditions). In practice, the thermal isolation is not perfect, and one overcomes this problem by calibrating correctly the thermal link between the sample and its surroundings. As discussed later in this entry, the thermal relaxation rate, τ, which determines the condition of adiabaticity, is a crucial parameter for the selection of measurement methods adapted to the physics to be studied (see the section "Experimental Techniques"). This problem of thermal isolation is more problematic in nanocalorimetry because the samples are very small in size and therefore have small masses and thus very small heat capacities. Therefore, to fulfill the requirement of adiabaticity, the experimentalist makes thin suspended membranes micrometer thick that will support small objects to be studied (see Fig. 1).



One of the advantage of working with membrane sensor is the reduction of addenda (the sample holder and the sensitive measuring elements are called "addenda"); this is especially important when working with very small systems. The small thickness of the membrane reduces also the thermal coupling to the outside providing then thermal isolation. Some membranes are structured to further limit the exchange of heat between the measurement area and the thermal bath. In this case, they look like micro-trampolines suspended by arms that allow the passage of current leads (see Fig. 2).

Nanocalorimetry, Fig. 2 Various sensors made in silicon, silicon nitride, or polymer. (**a**) Silicon membrane for very low temperature heat capacity measurement by ac calorimetry [3]. (**b**) Silicon nitride sensor made by e-beam lithography used for relaxation calorimetry [4]. (**c**) Silicon nitride sensor used for fast scanning calorimetry [5]. (**d**) Polyparaxylylene membrane for phase transition detection in thin magnetic films around 100 K [6]. (**e**) Silicon nitride sensor used for relaxation calorimetry over a wide range of temperature (Cooke 2010). (**f**) Polyimide membrane for heat capacity measurement of thin polymer films at ambient temperature [7]

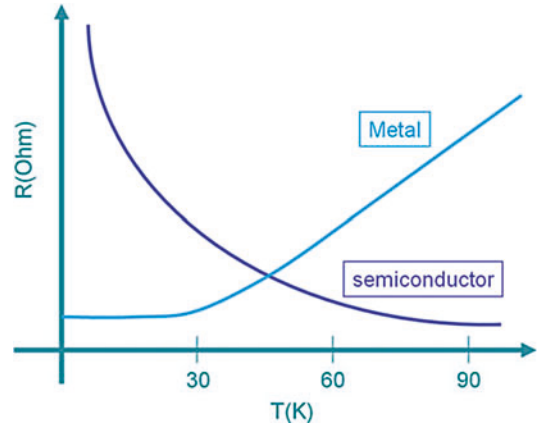
Another point is that, since in the case of nanocalorimetry the amount of energy to be measured is small, the resolution of the calorimetric measurement must be sufficiently high to access the expected thermal properties. A first means to increase the signal-to-noise ratio (SNR) of the measurement is to reduce the noise of the detected signals. In other words, one must develop a low noise electronic chain adapted to the chosen experimental technique and also adapted to the sensor converting temperature changes in measurable signals (usually voltage). This aspect, which concerns the sensitive measurements and thermometry, is discussed later on (see the section "Thermometry"). A second way is to reduce significantly the heat capacity of sample holder and measuring devices (thermometers and heaters).

In this case, the use of nanotechnology and microfabrication is indispensable for the realization of sample holder for which the heat capacity is at least equivalent (or smaller) than the sample heat capacity being studied. The use of these technologies is crucial for measuring heat capacities of objects of very small size or for the

Nanocalorimetry, Fig. 3 Scheme of the principle of a nanocalorimetric measurement on membrane

detection of low energy in relevant thermodynamic transformations. Therefore, micro- and nanotechnologies are essential keys to nanocalorimetry. This justifies the use of thin microfabricated membranes for thermal isolation (see Fig. 3). Each membrane contains the sensitive elements. These elements are micromachined in thin layers of sub-micrometer

thicknesses deposited by vacuum evaporation technique or by magnetron sputtering. Microphotolithography techniques are used to shape the geometry of the sensitive elements and define their impedances, and therefore define the sensitivity of the calorimetric measurement.



Another major issue in calorimetry is the temperature homogeneity of the sample and the addenda. Indeed, the low thermal diffusivity of some samples limits the dynamic of temperature variations during the measurement. The relaxation time of thermal diffusion in the sample and addenda, τ_{diff}, also depends on the geometry of nanocalorimeters. In general, a thin layer of gold, or highly diffusive material, is deposited by vacuum evaporation technique or sputtering on the measurement area so that the temperature is as uniform as possible in the sample. Finally, the thin thickness of the membranes reduces the thermal coupling to the outside providing then thermal isolation, while the isothermal layer ensures thermal homogeneity of the sensitive area. The experimental timescale Δt_{exp}, the timescale over which the thermal measurement occurs has to be slower than the diffusion time (to ensure a homogeneous temperature) and faster than the thermalization time of the sensing part to the heat bath. This last point can be mathematically summarized by the two following inequalities:

$$\tau_{\text{diff}} << \Delta t_{\text{exp}} << \tau$$

where τ_{diff} is the thermal diffusion time and τ is the thermal relaxation time.

Thermometry

The basis of the measurement of heat is essentially based on the ability of the experimentalist to accurately measure temperature. To obtain a sensitive measurement of temperature, it requires access to a physical quantity X, which varies greatly with temperature. This large variation with temperature is characterized by what is called the temperature coefficient $\frac{1}{X}\frac{dX}{dT}$. A highly sensitive measurement of temperature variation will allow a direct access to very small energy, which is the case generally when nanosystems are involved. The physical quantity X will be anything that can be accurately measured: a volume, a pressure, or an electrical quantity (capacitance, resistance, etc. . .).

Nanocalorimetry, Fig. 4 Variation of resistance versus temperature in the cases of metals and semiconductors

Some of the most used technique to measure temperature in nanocalorimetric experiments are detailed below.

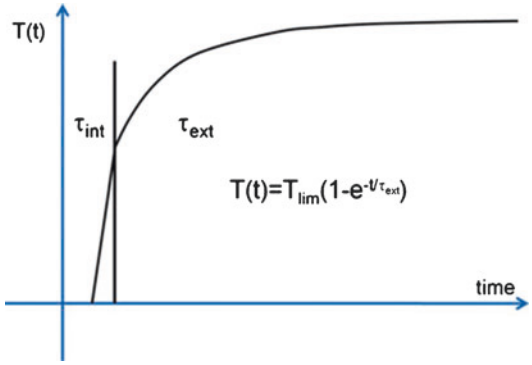
Resistive thermometry: One of the most commonly used physical quantities to measure a temperature is the resistance. The resistivity of pure metals is changing a lot with temperature from very high temperature down to 30 K. Then, these metals will be perfect thermometers in this temperature range. The most common thermometer is platinum; this metal when elaborated in thin films geometry has a positive temperature coefficient of resistance of about $\frac{1}{R}\frac{dR}{dT} = 3 \times 10^{-3}\text{K}^{-1}$; the resistance is decreasing when the temperature is decreased (Fig. 4). Other materials have also a strong change of resistance with temperature like semiconductor or like Anderson or Mott insulator. These materials have a huge increase of resistance as the temperature is lowered because the electron transport is more and more limited as the thermal activation is diminished. These materials (germanium, carbon, niobium silicon, niobium nitride) are widely used as thermometer at low temperature. They are much more efficient than metals below 40 K with temperature coefficient that can be above 1 K^{-1}! Temperatures as low as few millikelvin, close to the absolute zero, may be measured using this type of thermometry. The limitation comes from the applied current

necessary to measure the resistance; the Joule heating creates parasitic power. This dissipated power may induce temperature gradients and then induces error when estimating the real temperature of a nanosystem.

Noise thermometry: Any electrons in a regular resistance are subject to Brownian motion. This Brownian motion takes its origin in the temperature activation. This movement of electrons gives birth to a varying voltage across the resistor which is called the Johnson–Nyquist noise. Due to its origin this noise is a function of the temperature through $V = \sqrt{k_B T R \Delta f}$, where k_B is the Boltzmann constant, T the temperature, R the resistance, and Δf the frequency window where this noise is measured. By measuring the voltage versus time, knowing the resistance, one can deduce the temperature of the resistor R. This thermometry is not very sensitive but it has the major advantage of not dissipating any spurious power because its measurement does not require any electrical current.

Thermocouple thermometry: A thermocouple is composed of a junction between two different materials. A temperature difference between a "hot" and a "cold" junction will be converted into a voltage (Seebeck effect). The measurement of this voltage is a widespread way of measuring a temperature. However, the amplitude in volt per Kelvin produced by a usual thermocouple is small (of the order of magnitude of several hundreds of microvolts per degree), it needs at least a few hundred couples in a system called thermopile to obtain sensitivities equivalent to those of resistive thermometers.

A thermopile is a device composed of plenty of thermocouples connected electrically in series and thermally in parallel. Each couple participates in the total impedance of the sensor and therefore increases the thermal noise of electrons in conductors (Johnson–Nyquist noise). The fact that it is not necessary to polarize and thus generate thermal power in the sample to obtain a measuring signal is a major advantage of this technique.



When working close to room temperature, most calorimeters and differential nanocalorimeters use thermopile to measure directly the temperature difference between the sample cell and a reference neutral cell (see DSC). In this case, the "hot" and "cold" junctions are perfectly thermally coupled to the sample and reference, respectively (or vice versa). For zero signal detection devices, two thermopiles connecting sample/thermal bath and reference/thermal bath, respectively, are mounted in opposition in order that same temperature elevations of the sample and references with respect to thermal bath gives approximately zero signal. Knowing the thermal link (thermal exchange coefficient) between the sample and the reference with respect to the surrounding, the voltage from the thermopile is proportional to the difference of heat flows (W) exchanged between the sample and the reference with respect to thermal bath, respectively. One prefers to present the converted signals collected by thermopiles in watts rather than in Kelvin because their direct integration along time gives the heat absorbed or released by the sample during the experiment of calorimetry. In conclusion, the thermopile is the ideal element to detect differential temperature or differential heat flow between two objects without direct generation of power in one or (and) the other of these objects.

N

Experimental Techniques

Principle of Measurement

Calorimetry is the measurement of heat exchanges between a system for which the thermal properties have to be studied and its environment (thermal bath). There are two types of calorimetric measurements. The first is the measurement of the specific heat. In this case, the experimentalist provides a given heat flux to the sample and measures the resulting temperature rise (Fig. 1c). The second concerns the measures of energy released or absorbed by a sample during any transformations or physicochemical interaction at constant temperature; one speaks in this case about isothermal calorimetry. In all cases, the experiment of calorimetry consists in measuring a change in temperature. Thermometry and the measurement electronics are therefore two essential elements for nanocalorimetry. The temperature sensor is then chosen as a function of the particular

Nanocalorimetry, Fig. 5 Illustration of the two significant timescales in a nanocalorimetric experiment

experimental methods used; the latter being in fact adapted to the physical phenomena that the experimentalist wishes to study.

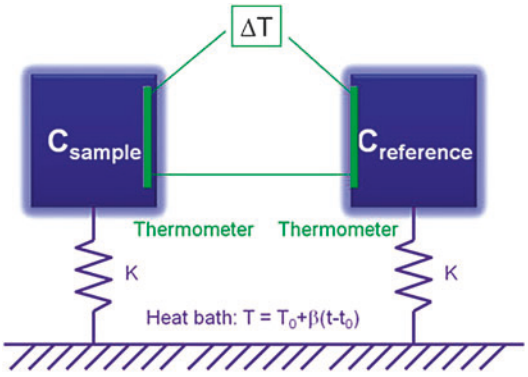
Let us introduce two characteristic times which will be very useful in the rest of this entry. First the internal thermalization time noted τ_{int} is defined; this time is related to the diffusion of heat inside the sample to be studied. Secondly, the external thermalization time noted τ_{ext} is defined. This time is given by the ratio C/K where C is the heat capacity of the system and K the thermal conductance of the link to the bath (see Fig. 1). If a heat power is supplied to the sample at a rate faster than the internal thermal time, then the temperature of the sample is not homogeneous (see Fig. 5). On the other hand, if a power is supplied to a sample over a very long time, then the external thermal time will be dominant. A gradient of temperature will be established following an exponential law between the sample and the heat bath as shown in the Fig. 5.

Experimental Methods

Adiabatic Calorimetry

Regarding the specific heat, various experimental methods allow its measurement. The most traditional is the adiabatic calorimetry in which the sample and its addenda are isolated as much as possible from their environment. A thermal power of known value is sent at a timescale much smaller than the thermal relaxation time τ_{ext}. The measured temperature rise is inversely proportional to the heat capacity of the sample (plus addenda)

$$\Delta T = \frac{\int_0^{\Delta t} P dt}{C}$$



Then, it remains simply to change the temperature of the thermal bath and carry out a new measurement in order to have a final C (T) curve. In practice, adiabaticity is not perfect, and the heat exchange coefficient has to be taken into account, and therefore energy losses between the sample and the thermal bath. This is especially true in nanocalorimetry because objects to be studied are small and therefore their heat capacity is small to. It is therefore very difficult to thermally isolate them, and the adiabatic nanocalorimetry method cannot be implemented. Scientists have developed calorimetric techniques better suited to the measurement of small samples to overcome the problem of heat loss. They are presented in the following sections.

Differential Scanning Calorimetry

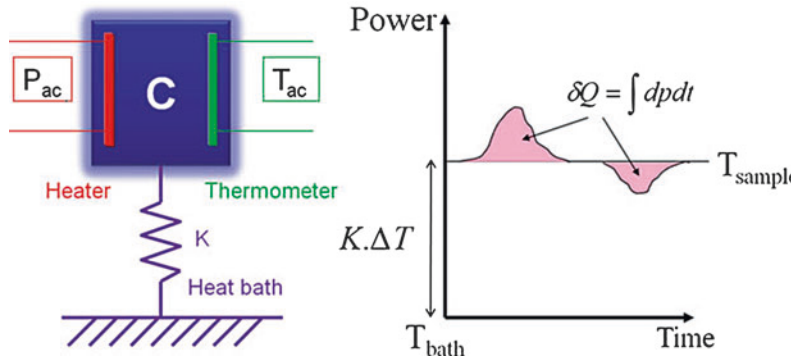
A second widespread calorimetric experimental technique is called differential scanning calorimetry (DSC) [8, 9]. It is a continuous method in which the sample temperature follows a temperature ramp imposed by the experimentalist (Fig. 6). The fact that it is differential indicates that what is measured is directly the temperature difference between the sample and a neutral reference. However, one must keep in mind that any calorimetric method can be conceived in differential mode. In the case of DSC, differential heat capacity ΔC and differential heat flux ΔP (between sample and reference) measured during the ramp temperature obey the following equation:

$$\Delta C = \frac{\Delta P + \tau \frac{d(\Delta P)}{dt}}{\beta}$$

where β is the scanning temperature rate and τ the thermal relaxation time. This differential heat flux (or thermal power) is related to the differential

Nanocalorimetry, Fig. 6 Thermal scheme for DSC experiment. One cell contains the sample and the other cell contains a neutral reference. During the scanning temperature rate the temperature difference (or heat flux difference) is recorded as a function of time

temperature by means of the heat exchange coefficient K:



$$\Delta P = K\Delta T$$

Compared with the adiabatic calorimetry, here the heat exchange coefficient K also plays a role at the same level than the heat capacity C. The former is measured by means of a prior calibration in quasi-static mode where the above equation is valid. In DSC, the scanning rate $\beta = dT/dt$, is an important factor since it determines the signal intensity. Indeed, the first equation above shows that for a given differential heat capacity, the differential signal ΔP is for a part proportional to this scanning rate. However, in this case, the power of resolution of the measurement is reduced due to the presence of the second term revealing the dynamic of the DSC. Again, the thermal time constant plays a key role at high scanning rates. It should be noted that the above equations are only valid for a large thermal diffusivity in the sample and the sample holder, so that the time constant of heat diffusion (τ_{int}) does not become the limiting factor. They are also valid under the assumption of perfect thermal symmetry of the calorimetric head (second-order terms are not shown) [8, 9]. Classical DSC based micro- and nanotechnologies are rare. Let us mention SiN membrane DSC for heat capacity detection of nl-range liquid droplets [10] and MEMS-DSC device where protein folding processes are analyzed via the measurement of differential heat capacity [11].

Fast speed DSC: In nanocalorimetry, the samples to be studied are so small that the internal thermalization time is not limiting. In this case, scientists have circumvent the problem of isolation of small samples in using scanning rates with values going from about 10^4 to 10^6 K/s. This new experimental technique, called "Fast Speed DSC," has grown significantly in recent years. They use microsensors, typically SiN thin membranes, produced through micro- and nanotechnology [12–14]). These very high speeds yield to high sensitivities and allow measurements of very thin films from 100 to 1,000 K [5, 15]. A last feature of these rapid calorimetric measurements is that, at such high temperature rates, kinetics of studied thermal event can be observed. This is also true for high-frequency nanocalorimetric methods as seen in the following.

Isothermal Calorimetry

A third widely used measurement method is called Isothermal Calorimetry [16]. It consists of measuring absorption (or removals) of energy in a sample over time at constant temperature (Fig. 7). Titration nanocalorimetry is an experimental method issued from Isothermal Calorimetry in which a compound A in solution (titrant) interacts with compound B in solution (titrate), producing or absorbing energy at constant temperature. If an aliquot (few percent in volume) of the titrant solution containing the molecule A interacts with the solution containing the molecule B, then the experiment can be carried out N times to achieve complete disappearance of B. In this way, through this type of experience, not only the enthalpy of reaction between molecules A and B can be obtained (during the firsts interactions), but also, thanks to the saturation curve $\Delta H = f(N)$, the constant of reaction between A and B is obtainable, like for acid-base chemical titrations. The constant of reaction allows access to the Gibbs free energy at a certain temperature. With calorimetric titration, the thermodynamic parameters ΔH, ΔG, and ΔS *could be accessed* for the

Nanocalorimetry, Fig. 7 Thermal scheme for isothermal calorimetry experiment. The power necessary to maintain the temperature of the sample at a constant value is represented versus time. The integration of this power provides the energy absorbed or dissipated by the sample at such temperature

reaction A/B which provide complete thermodynamic data at determined temperatures. This technique is mainly used in chemistry, biochemistry, and biology [17]. Since in this field, firstly biochemical and biophysical reactions generally have relatively low energy values, and secondly available volumes of biological samples are generally reduced (simply because they are expensive due to the cost of the synthesis) the use of nanocalorimetry is a natural choice. In the past decades, the development of isothermal titration nanocalorimeters has been increasing a lot [18, 19]. Another approach to induce interaction of A with B is to mix the two solutions in the sensitive area via two differentiated liquid inputs. The mixture produces or absorbs energy in the sensitive area which is detected by the sensor and then flows through a third flow output path. One speaks about flow nanocalorimeters [20–24]. An original way of binding has been obtained by means of electrostatic mixing [25].

A major technical difficulty in the development of isothermal titration or flow nanocalorimeters is the need for a coupling of microfluidic techniques with that of the microfabrication of nanosensors. Indeed, one needs to bring the various liquid reactants on the measurement area while maintaining the highest thermal insulation of the same area. Certain isothermal nanocalorimeter measures only the power or heat released or absorbed by a small biological object already positioned (e.g., living cells) along time [26–28]. In the field of biocalorimetry, volumes of analyzed samples comprise between few nanoliter and few microliter, and minimum detectable powers are between few nanoWatt and few hundredth of nanoWatt depending on the nanocalorimeters designs. Integration of power measured versus time yields to minimum recorded energies from few tenth of nanoJoule to few microJoule (see tables showing performances of various isothermal calorimeters in Refs. [29, 21]).

Low Temperature Calorimetry

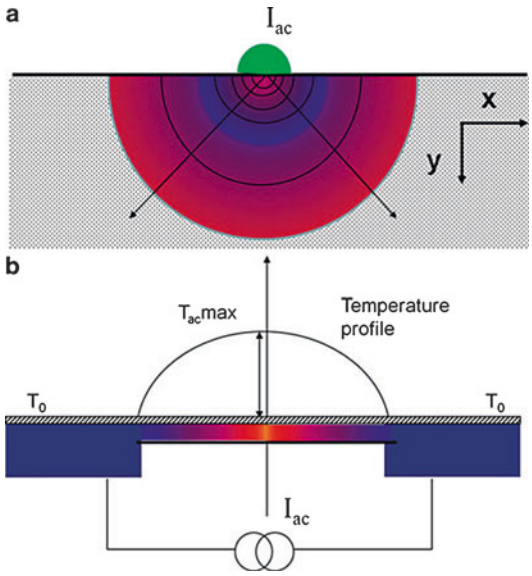
Traditionally, at very low temperatures, the most used calorimetric method is the adiabatic calorimetry. However, as the adiabatic nanocalorimetry is difficult to carry out at low dimension, scientists have developed new techniques known as dynamic calorimetry techniques, which overcome the problem of heat loss. There are two main different methods: the relaxation calorimetry and ac-calorimetry [30]. Relaxation calorimetry overcomes poor insulation in directly measuring the exponential decay of the temperature of the sample compared to the thermal bath after a pulse of power. Measuring the thermal conductance K is necessary to have the heat capacity. On contrary, ac-calorimetry depends only on the frequency of temperature oscillations to be placed in adiabatic condition or quasi-adiabatic conditions. The sample temperature oscillates at a frequency such that no heat loss holds over one period of oscillation. In this case, it is not necessary to measure K. These different experimental techniques suitable for nanocalorimetry are described below.

Relaxation calorimetry: Relaxation calorimetry is to apply a heat pulse on the sensitive area of a sensor. An increase in the temperature of the

sample appears; this increase will be faster than heat leak because the internal diffusion time is very short. The technique involves recording the decrease of the temperature sensor over time:

$$T = T_{bath} + \frac{P_0}{K}\exp\left(-\frac{t}{\tau}\right)$$

This decay is exponential and depends on the ratio between the heat capacity of the sensor with the sample and the thermal conductance to the bath. The thermal conductance can be estimated by other means, hence from the exponential decay the heat capacity can be deduced. This measurement is usually performed on a membrane where the thermometer and heater are lithographed. It is a sensitive method which may cover a large temperature range [31, 32]. One weak point of this technique is that the measure is not based on an oscillating method, and therefore the SNR is degraded by the presence of thermal drift. This technique has been applied in some recent cases of specific heat measurement on very small sensors at low temperature [4, 33].



AC-calorimetry: In ac calorimetry, an input thermal power $P(t) = P_{dc} + P_{ac}$ constituted by a dc and a ac term is supplied to a system connected to a thermal bath by means of a thermal conductance of known value [34–37]. In focusing on the ac term only, the corresponding oscillating temperature T_{ac} is measured. At low frequencies the measurement is not adiabatic or quasi-adiabatic, and at high frequencies the temperature of the sample is not homogeneous anymore. This means that the thermal relaxation time and the thermal diffusion time have to be carefully taken into account. However, in choosing the appropriate frequency range, it is possible to circumvent the problem of thermal insulation of small objects to be measured by nanocalorimetry. It remains to design a calorimetric device with an appropriate working frequency range. The frequency of the temperature oscillation has to be faster than the relaxation time to the heat bath τ_{ext} (adiabatic condition) and slower than the diffusion time in the sensor τ_{int}. Under these circumstances, the heat capacity of the sample is simply obtained by the ratio of the ac power on the ac temperature:

$$C = \frac{P_{ac}}{i\omega T_{ac}}$$

The measured heat capacity is actually a complex number with real and imaginary components of different physical meaning. These are obtained by means of the measure of either the amplitude or the phase of the oscillating temperature. This method is particularly sensitive because locking-amplifiers with narrow bandwidth filter can be used for oscillating temperature recording but also because dc or low frequency thermal drifts are less important. Heat capacity resolutions $\Delta C/C$ of the order of 10^{-5} to 10^{-4} are currently obtained while in relaxation calorimetry or other methods resolutions lay between 10^{-3} and 10^{-2}. Thus, ac-calorimetry is a technique particularly adapted to nanocalorimetry because, on one side it allows measures on small objects, and on another side it allows measurement in the nanoJoule/Kelvin or nanoJoule/picoJoule ranges [6, 38]. Although ac calorimetry has been developed in the field of low temperature physics [39]), for few decades it has been adapted to different temperature ranges in several domains of research (magnetic films, biological objects, polymers, etc. . .) where the detection of fine phase transitions or phase transformations were researched [7, 40, 41]. More precisely, the record in sensitivity was obtained in attojoule calorimetry (10^{-18} J) which allowed access to complete new physics [3]. The principal inconvenient of ac-calorimetry is the useable frequency range limited to no more than one or two decades when measurement of the dynamic of the studied system via $C(\omega)$ is wanted. This disadvantage is avoided in another dynamic calorimetric method called 3ω method (Fig. 8).

Other Methods

3ω-method. In the 3ω method, the thermal power that generates temperature oscillations in the sample is provided by the thermometer itself. A current of frequency f passes through the thermometer-like heater resistance (called the transducer), which produces a thermal power oscillating at frequency $2f$ due to Joule effect. As the transducer temperature varies at that

Nanocalorimetry, Fig. 8 Schemes of the 3ω method with the thermal wave in the plane (perpendicular to the transducer) (**a**) or along the sample (parallel to the transducer) (**b**)

frequency, this results in a $3f$ term which contains all the thermal information of the sample [42, 43]:

$$\delta T_{ac} = \frac{P_0}{K\sqrt{1+(\omega\tau)^2}} \text{ or } \delta T_{ac} = \frac{P_0}{\sqrt{2\omega CK}}$$

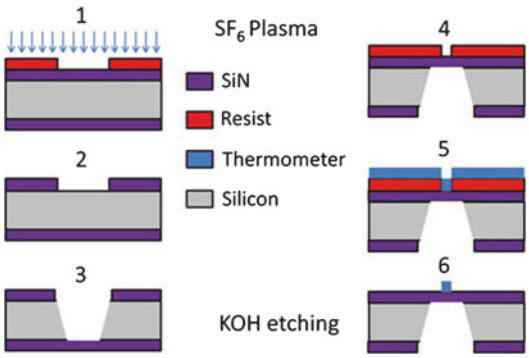
The two above equations apply depending on the geometrical design of the sensor. ω is the pulsation, related to the frequency through $\omega = 2\pi f$. At very low frequency, the amplitude of the temperature oscillation is only related to the thermal conductance. If the measurement is made as a function of the frequency, the heat capacity can be extracted through the estimation of the thermalization time $\tau = \frac{C}{K}$.

The purely electrical term oscillating at frequency f, which is much larger than the $3f$ component, has generally to be removed using a Wheatstone bridge circuit, otherwise the quality of the measurement will suffer. This method, non-adiabatic by principle, was used to measure the thermal properties of material of very small thermal diffusivity for which a frequency dependence of the specific heat was expected. It has, for example, been successfully used to study the frequency-dependent specific heat at the glass transition of some glass formers over several decades of frequency [42]. Depending on the geometry of the couple transducer with sample, the thermal effusivity $c \times k$ (product of specific heat by thermal conductivity) is measured or, upon particular geometrical conditions, the thermal conductivity k is directly measured at low frequency (see equations above) [44]. In nanocalorimetry, this method has been successfully applied to the measurement of the thermal conductivity of crystalline silicon wires of nanometric sizes for which phonon-blocking effects were observed at very low temperatures [45, 46]. Recent experiments use the 3ω method for thermal properties measurement of nl liquid-like samples [47, 48].

Unconventional methods: measurement of caloric curve. In this technique developed for the in-flight measurement of clusters (hundred of atom), one uses the photofragmentation of the clusters by a laser beam to estimate the internal energy U as a function of temperature. The clusters ions are selected using a mass spectrometer and thermalized in helium gas. Then they are irradiated by a laser, the fragments produced are analyzed by a second mass spectrometer. Their number depends directly on the inner energy of each clusters, hence its measurement gives the internal energy of the cluster. Its derivative $\left(C = \frac{\partial U}{\partial T}\right)$ will give the heat capacity of the clusters ions (see Refs. [49, 50]). Melting point and heat capacity of cluster of 140 atoms or less could be measured using this technique, a performance never equaled with other techniques. Others unconventional methods of nano- and microcalorimetry exist but are not described in this brief entry.

Micro- and Nanosensors

It is the need to do thermodynamic measurements on specific physical or chemical nanosystem that will determine what type of sensor that must be developed for nanocalorimetry. Secondly, the choice of the experimental technique (as detailed

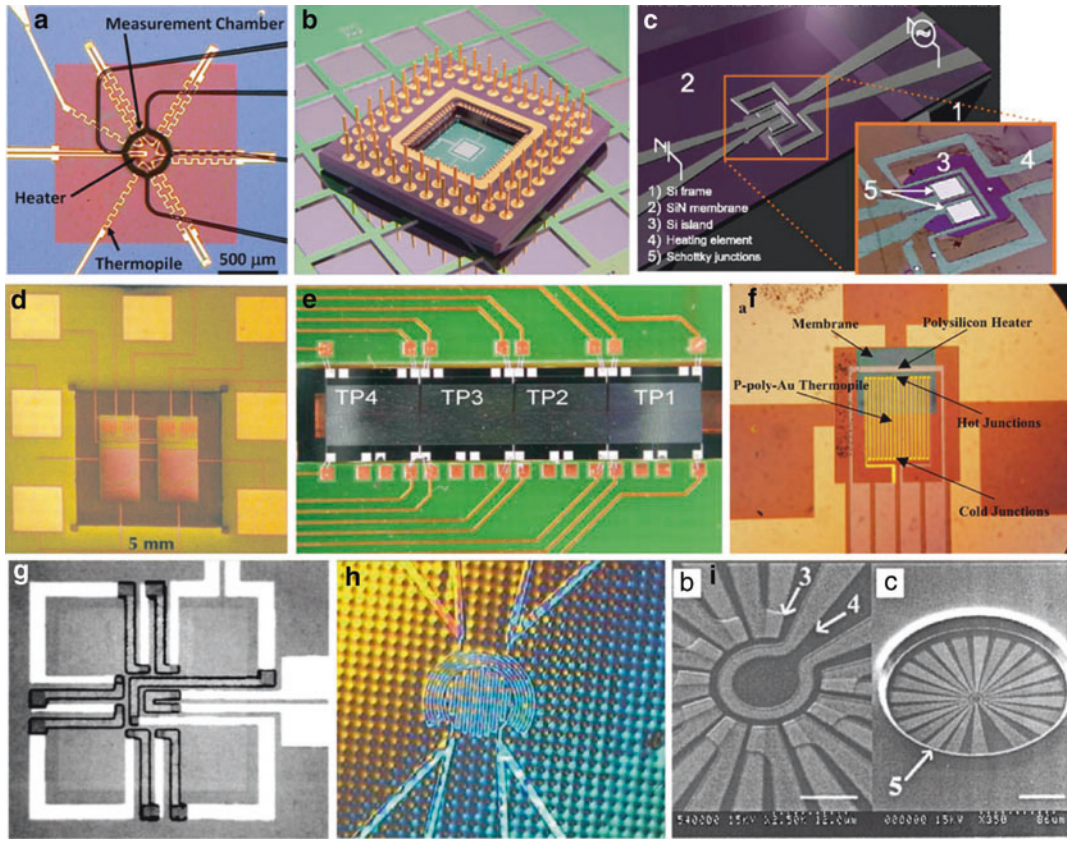


in the previous section) will also influence the conception of the sensing part. Several examples of nanocalorimeter based on micro- or nanofabrication are shown below where the best results have been obtained in terms of sensitivity and/or resolution. Great care must be taken in the choice of materials along with the geometry of the system (thermometry and heater); it will fully determine the thermal performance of the sensor. Two main parameters should orient the choice of materials for the sample holder: small heat capacity and a complete absence of phase change in the working temperature area to avoid spurious signal coming from the holder. The geometry will be chosen to reduce the leak to the heat bath or to control it through a dedicated thermal link. Thermal data of the main materials used for manufacturing sensors are summarized in Table 1. This table will be fruitfully used during the design of a new sensor depending of its future working temperature range or its particular specifications (materials compatibility).

The first attempt to measure the heat capacity of thin films was done by G.D. Zally et al. [51]. He built a calorimeter based on a very thin pyrex membrane where thermometer and heater were attached. Since this attempt, numerous different sensors have been built in various materials from silicon, silicon nitride, glass to polymer. Some of them are detailed below.

Silicon, Silicon Nitride, or Diamond Membranes

As mentioned above, the choice of the materials is given by the specification of the experiment to be performed. The best material for application in a wide temperature range (from 40 K to 1,000 K) is, for sure, silicon nitride (SiN). This amorphous material is totally inert in that temperature window and can be easily manipulated. Fabrication of membrane out of SiN is masterized in all cleanrooms in the world using chemical etching of silicon by KOH (see the sketch in Fig. 9). Thermometer and heater can be lithographed on top, which permits the measurement of thermal properties. The design of the heat link and the choice of materials for the transducers will set the performance of the calorimeter.



If one wants to apply nanocalorimetry technique at low or very low temperature, SiN is not the best choice. As it can be seen in the Table 1, the heat capacity is high as compared to single crystal silicon. Then the fabrication of silicon membrane is more appropriate and should be preferred. Moreover, the structuring of the membrane

Nanocalorimetry, Fig. 10 Various sensors for isothermal or biological liquid-sample nanocalorimetric experiments. (**a**) Parylene membrane for isothermal chemical and biological interactions [21], (**b**) silicon sensor for isothermal chemical and biological interactions (Photograph courtesy www.xensor.nl, [14]), (**c**) silicon nitride sensor for small-volume-liquid calorimetric detection [18], (**d**) polyimide membrane for electrostatic-liquid-mixing calorimetric detection [25], (**e**) silicon microfluidic chamber for flow-through isothermal calorimetry [52], (**f**) glass microfluidic reaction chamber for flow-through calorimetry [24], (**g**) silicon nitride membrane for small-volume-liquid calorimetric detection [26], (**h**) micro-posts sustained polyimide membrane for small-volume-liquid calorimetric detection [7], (**i**) silicon nitride suspended sensor for isothermal detection of living cells [27]

will be absolutely necessary to create a well-defined isotherm. Indeed, the thermal conductance of silicon (or SiN) is still high below 10 K, and then a proper thermal isolation lies in suspending a membrane through isolated arms (see Fig. 2a or b). In Fig. 10, examples (c), (g), and (i) are silicon membrane for isothermal flow-through or small-volume-liquid nanocalorimetric measurements.

Polymer Membranes

In nanocalorimetry, thin polymer membranes are also used to insure good thermal insulation of the measurement area. This type of membrane is mostly used for medium to high temperatures because of the low thermal conductivity of polymers (see Table 1). At very low temperatures, they are less attractive because their heat capacity is very high (see Table 1). To ensure uniformity of temperature in these sensors, the low thermal diffusivity of these materials is generally eliminated through the deposition of a thin layer of metal diffusing heat over the entire surface of the sensitive area (e.g., gold, aluminum, silver). Figures 2d, f and 10a, d, h are examples of polymer membranes for experiments of ac-nanocalorimetry or isothermal nanocalorimetry on thin magnetic films, thin polymer films, and low volumes

chemical or biological objects or reactions. The thickness of these membranes can range from a few hundreds of nanometers to several tens of micrometers. The use of micro- and nanotechnologies is obviously necessary to deposit and lithographically machined sensing elements on the membrane, as well as a possible step of membrane design through dry etching techniques (e.g., reactive ion etching or oxygen plasma).

Conclusion

In that not complete review, various experimental methods named "nanocalorimetry" have been presented. It has been shown that it concerns all calorimetric method for which the dimensions of the objects studied are in the order of magnitude of nanometer, or measured energy or power are in the range of nanojoule or nanowatt. The review has been based on numerous examples of nanocalorimeters existing in the literature from low temperature to room temperature with application in condensed matter, chemistry, biophysics, or biology in general. The aspect of micro- and nanofabrication, essential for the achievement of nanocalorimetric devices, has been emphasized as well as the importance of sensitive instrumentation, electronic conditioning, and the choice of materials for the thermal detectors.

Calorimetry is by essence a universal method of measurement, covering by this way a wide spectrum of different researches. The emergence of nanocalorimetry in recent decades has allowed the exploration of new and original fields of research. With the evolution of modern micro- and nanofabrication technologies, many new developments will appear especially toward more sensitive sensor especially in biophysics. Significant room for improvement still exists in many areas of nanoscience, which makes nanocalorimetry quite an open subject of research.
